Abstract: While considerable evidence suggests that bilateral cochlear implant (CI) users' sound localization abilities rely primarily on interaural level difference (ILD) cues, and only secondarily, if at all, on interaural time difference (ITD) cues, this evidence has largely been indirect. This study used head-related transfer functions (HRTFs) to independently manipulate ITD and ILD cues and directly measure their contribution to bilateral CI users' localization abilities. The results revealed a strong reliance on ILD cues, but some CI users also made use of ITD cues. The results also suggest a complex interaction between ITD and ILD cues.

1. Introduction

Bilateral cochlear implant (CI) users demonstrate a significant bilateral benefit for localization (e.g., van Hoesel, 2004). Although considerable evidence suggests that this localization benefit is dominated by interaural level difference (ILD) cues, as opposed to interaural time difference (ITD) cues (van Hoesel and Tyler, 2003; Schoen *et al.*, 2005; Grantham *et al.*, 2007; Poon *et al.*, 2009), this evidence has largely been indirect. Some studies have only minimized either the ITD or the ILD cues rather than completely eliminating them (Schoen *et al.*, 2005; Grantham *et al.*, 2007). Other studies have measured ITD sensitivity in μs and ILD sensitivity in dB (van Hoesel, 2004; Schoen *et al.*, 2005; Poon *et al.*, 2009) rather than using a secondary measure, such as spatial resolution, that would allow for a direct comparison between the two.

Recently, direct measurements of the relative contribution of ITD and ILD cues were performed by Seeber and Fastl (2008). They used a single participant's own head-related transfer function (HRTF), allowing them to create stimuli that contained the ITD cues for one location and the ILD cues for a separate location. Consequently, they were able to measure the

[a]These participants only participated in the SF and DC ITD+ILD conditions.
[b]This participant originally was implanted on the right side 3 years before testing, but electrodes started turning on and off unpredictably within 3 months, and the device was replaced approximately 1 year before testing.

availability of each cue using a single measure of performance, the perceived location. Their results demonstrated that ILD cues had a primary role in localization, with no evidence of a secondary role for ITD cues.

One limitation of the Seeber and Fastl (2008) study is that they used stimuli with the ITD cues for one location and the ILD cues for another rather than presenting each cue in isolation. Given that many studies have indicated a strong dominance for ILD cues (van Hoesel and Tyler, 2003; Schoen *et al.*, 2005; Grantham *et al.*, 2007; Poon *et al.*, 2009), any effect the ITD cues might have had on the perceived location in the Seeber and Fastl (2008) study may have been masked by the more dominant ILD cues. Another limitation of the Seeber and Fastl (2008) study is that only a single subject was tested, making it difficult to generalize their findings, especially since other studies have shown considerable variability in ITD sensitivity across CI users (e.g., van Hoesel, 2004; Poon *et al.*, 2009).

The purpose of the present study was to measure bilateral CI users' ability to use ITD cues and determine how this compared and related to their ability to use ILD cues for sound localization. Because HRTFs were used to independently manipulate ITD and ILD cues, the first goal was to verify that the HRTFs appropriately simulated the soundfield (SF). Given that other researchers have demonstrated considerable variability across bilateral CI users in terms of ITD sensitivity (e.g., Poon *et al.*, 2009), the second goal was to determine if the primary role of ILD cues in localization, reported in Seeber and Fastl (2008) based on one subject, extends to a larger population of bilateral CI users. The third goal was to determine if ITD cues played a secondary role in localization.

2. Methods

Six bilateral CI users participated in a localization task both in the SF and with a process that simulates the microphone input by sending HRTF-processed signals through a cable directly connected to the CI processor's auxiliary input port (Chan *et al.*, 2008), referred to as direct connect (DC) testing. For DC testing, there were three conditions: (1) both ITD and ILD cues present (ITD+ILD), (2) only ITD cues present (ITD-only), and (3) only ILD cues present (ILD-only). Four additional bilateral CI users completed only the ITD+ILD condition as well as SF testing (see Table 1 for listener details). Participants were assigned identifiers using the following con-

vention: [Left processor] [Right processor] [sequential number], where the processors were coded as F = Cochlear's Freedom, O = Med-El's Opus 2, and T = Med-El's Tempo+ (e.g., the subject identifier FF2 represents the second bilateral Freedom processor user tested).

Generic HRTFs were created from recordings from each processor's microphone with the processor positioned on a Knowles Electronics Manikin for Acoustic Research (KEMAR). Each HRTF was represented as the impulse response of a 100-tap finite impulse response (FIR) filter at a sampling rate of 24 kHz. Separate filters were created for the left and right ears at each azimuth. Anatomical symmetry was assumed, so the right ear HRTF for azimuth A° was identical to the left ear HRTF for azimuth 360 A°. Details of the process by which the HRTFs were created are given in Chan *et al.* (2008).

The ILD-only HRTFs for each ear had the magnitude responses of the original HRTFs, with the ITD cues eliminated by using the identical phase responses for both ears, derived from the right ear HRTF for a source at 180° (i.e., back center). The ITD-only HRTFs for each ear had the phase response of the original HRTFs, with the ILD cues eliminated by using the identical magnitude response for both ears, derived from the right ear HRTF for a source at 180°.

The testing procedure was similar to that in Chan *et al.* (2008). Participants were asked to locate the stimulus (a broadband impulsive gunshot sound) presented from 1 of 12 locations, ranging from 97.5° to 262.5° (i.e., always located behind the participant) and spaced 15° apart. The locations were numbered from 1–12, with 1 located at 97.5° and 12 located at 262.5°. The participant's task was to identify the location that the stimulus originated from. Prior to testing in each condition, participants were familiarized with the real (SF) or virtual (DC) space by listening to the stimulus presented at each location once in ascending and once in descending order. For DC testing, familiarization also included a reference stimulus presented immediately prior to each stimulus, located at 90° and at 270° when familiarizing in the ascending and descending orders, respectively. After familiarization, participants were presented with a practice block followed by the test. Neither the practice block nor the test contained reference stimuli. For practice and test (but not for familiarization), roving was applied to assure that the task was testing participant's use of ITD and ILD cues rather than their ability to discriminate loudness. For SF testing, the presentation level for each stimulus was roved by a randomly selected offset in the range of ±5 dB. For DC testing, the presentation level was roved by using the overall magnitude of a randomly selected location while maintaining the ILD of the target location. To achieve comparable performance between SF and DC testing, the target was presented once at each location for SF testing and twice for DC testing prior to the participant identifying the location (Chan *et al.*, 2008). The number of stimuli presented during the test varied based on the participant's localization performance (Chan, *et al.*, 2008). All participants completed one block of 24 stimuli. Participants who, at minimum, were able to distinguish adjacent groups of three locations with an accuracy of at least 75% for the first block were presented with another block of 24 stimuli.

3. Results

The first goal was to verify that the HRTFs accurately simulated the SF. To compare localization performance between SF and DC testing, root-mean-square (RMS) error scores were calculated for each participant in each condition (Fig. 1). RMS error scores were used because, in addition to being sensitive to information across all locations, this type of analysis is also sensitive to a wide range of changes in the target-response relationship. A paired *t*-test indicated no significant difference between SF and DC testing ($t(9) = -0.8571$, $p = 0.4$), with the two testing modes resulting in very similar mean performance (SF = 26.6°, DC = 24.9°).

The second goal was to determine if the reduced availability of ITD cues for the CI user reported by Seeber and Fastl (2008) was also found for this larger set of participants. Figure 2 shows RMS error scores per listener in the three DC conditions: ITD+ILD (left panel), ITD-only (middle panel), and ILD-only (right panel). A one-way repeated measures analysis of variance revealed a significant main effect of condition [$F(2, 10) = 24.7$, $p < 0.001$]. Paired *t*-tests indicated that performance was significantly worse in the ITD-only condition (mean = 57.7°) than in either of

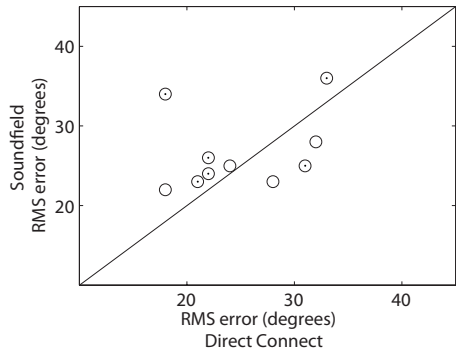

Fig. 1. Scatter plot of RMS error scores obtained when testing in the soundfield and with the ITD+ILD condition of the direct connect testing. Lower scores indicate better performance. Each circle represents one participant. The diagonal line indicates equivalence between the two testing conditions. Dotted circles demarcate participants who also completed the ITD-only and ILD-only conditions.

the other conditions (ITD+ILD mean=24.5° [$t(5)=-5.0$, $p<0.01$]; ILD-only mean=24.5° [$t(5)=-5.4$, $p<0.01$]). Every participant demonstrated this pattern. There was no significant difference in performance between the ITD+ILD and the ILD-only conditions [$t(5)=0$, $p=1$], both having the same mean RMS error. These results indicated that ILD cues played a primary role in the participants' localization performance.

The third goal was to determine whether bilateral CI users can make use of ITD cues, albeit to a lesser degree than ILD cues. Grantham *et al.* (2007) evaluated whether CI users were performing better than chance by using a computer simulation approach, whereby target lists were randomly generated and paired with randomly generated response sets. This process was repeated to derive a 95% confidence interval for chance performance.

The method of Grantham *et al.* (2007) does not take into account the effects of response bias, e.g., that a given subject might use only a subset of all possible responses. When random guessing is combined with a response bias, the obtained scores can deviate significantly from those resulting from unbiased random guessing. Consequently, confidence intervals were calculated for random guessing that corrected for the response bias for each participant and condition. This was done by randomly sampling with replacement from a given participant's response set for a particular condition to create a generated response set that incorporated the participant's response bias. That generated response set was combined with a randomly generated target list. Ten thousand target-response sets were created per participant and condition following this procedure, and RMS error was calculated for each of these target-response sets.

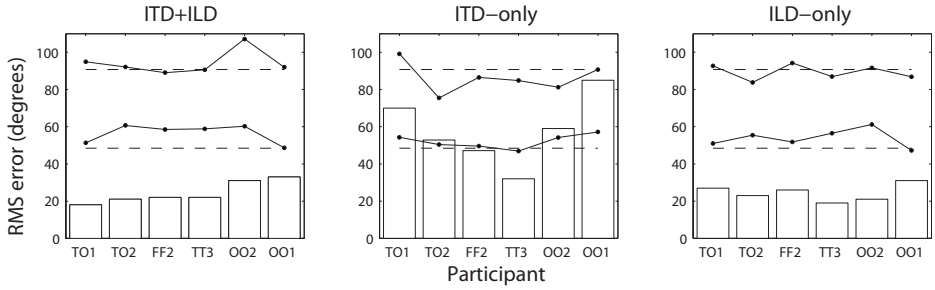

Fig. 2. Bar graphs of the RMS error scores for each participant for the three direct connect testing conditions. Lower scores indicate better performance. The dots connected with solid lines indicate the upper and lower bounds for the 99.2% confidence interval (α corrected for multiple comparisons) for random guessing corrected for the response bias of each participant. For reference, the upper and lower bounds for the 99.2% confidence interval for unbiased chance is shown as dashed lines, calculated as in Grantham *et al.* (2007).

To control for familywise error, a Bonferroni correction was used, setting α to 0.0083. The resulting confidence interval was defined as the range that encompassed 99.2% of the RMS error scores resulting from this simulation (marked by dots connected with solid lines in Fig. 2). Any participant whose RMS error score fell below the lower line of the confidence interval shown in Fig. 2 demonstrated a significant ability to use ITD cues. For comparison, chance, defined using the method of Grantham *et al.* (2007) but with α=0.0083, is also presented (confidence interval based on 10,000 randomly generated target-response sets: 48.4° and 90.7°; dashed lines in Fig. 2).

Comparison of the ITD-only scores to the biased random guessing confidence intervals (Fig. 2, middle panel) revealed that two participants performed significantly better than chance when response biases were taken into account (FF2 and TT3), indicating that some of the CI users had a significant ability to localize using interaural temporal cues only.

4. Discussion

This study examined the relative contribution of ITD and ILD cues for bilateral CI users' sound localization. The effects of these cues were independently measured using generic HRTFs designed for each type of CI processor. These HRTFs were verified by comparing each participant's RMS error scores for DC (using the HRTFs) and SF testing. These comparisons revealed similar means and no significant difference between DC and SF testing (Fig. 1).

Comparison of the RMS error scores across the three DC conditions revealed identical mean performance in the ITD+ILD and the ILD-only conditions, and significantly poorer performance in the ITD-only condition (Fig. 2). This pattern of poorer performance in the ITD-only condition was found for every participant and is consistent with the findings using indirect measures (e.g., van Hoesel and Tyler, 2003; Schoen *et al.*, 2005; Grantham *et al.*, 2007; Poon *et al.*, 2009). Despite ILD cues having a primary role, two participants were able to localize significantly better than chance in the ITD-only condition, even when response biases were taken into account (Fig. 2, middle panel).

A closer examination of Fig. 2 suggests that there was a complex interaction between ITD and ILD cues. For example, participants TO1 and OO1 were the two worst performers in both the ITD-only and the ILD-only conditions, yet TO1 was the best performer and OO1 was the worst performer for the ITD+ILD condition.

In summary, this study directly compared the contributions of ITD and ILD cues for bilateral CI users' localization, using the same measure, localization in terms of RMS error, to directly compare the two. The results demonstrated a strong reliance on ILD cues, although the interaction between ITD and ILD cues was complex. The results also indicated significant localization abilities when only using ITD cues for two participants, indicating that some bilateral CI users are sensitive to ITD cues, although further studies are needed to determine how widespread such sensitivity is across CI users. This pattern of results is quite different than that seen with individuals with unimpaired acoustic hearing, for whom ITD cues play a larger role than ILD cues for broadband sounds (e.g., Macpherson and Middlebrooks, 2002).

The results also suggest that improved temporal information may help some CI users. In current clinical practice, a variety of factors reduce the availability of temporal cues including the use of processing strategies that reduce temporal information, poor place pitch matching across interaural electrode pairs, and a lack of synchronization between the two processors. Given the evidence provided above that at least some CI users are sensitive to ITD cues, modifications to current practices that result in a more faithful transmission of temporal information may significantly improve bilateral performance.

Acknowledgments

We thank our participants for their time and effort. This work was supported by the NIH under Grant No. R44DC005759.

Retrieving the exact Green's function by wavefield crosscorrelation

Yingcai Zheng
Department of Earth and Planetary Sciences, University of California, Santa Cruz, California 95064
yzheng@pmc.ucsc.edu

Abstract: Recent development on the Green's function retrieval by wavefield crosscorrelation has substantially advanced the physical research in a multidisciplinary and unprecedented fashion. However, the underlying assumption of the theory that the sources are in the far-field limits the technology to extracting only the high-frequency part of the Green's function in an open system. This critical approximation can be eliminated using the exact boundary integral equation method. A scheme involving the crosscorrelation kernel is proposed to recover the exact Green's function including all-frequency content. Symmetric difference kernels are analytically constructed for sources on a plane or on a circle and can be reduced to the known Dirac delta kernel under the far-field approximation.

Date Received: October 19, 2009 **Date Accepted:** December 17, 2009

Crosscorrelating the diffuse wavefield recordings generated by random noise sources at two locations reproduces the Green's function that would be observed at one location as if a source were at the other location (e.g., Lobkis and Weaver, 2001; Weaver and Lobkis, 2001). No technology has been comparable to the Green's function retrieval in recent times that has produced far-reaching consequences across so many physical disciplines such as in ultrasonics (Lobkis and Weaver, 2001), acoustics (Derode *et al.*, 2003), ocean acoustics (Roux and Fink, 2003), terrestrial seismology (Aki, 1957; Claerbout, 1968; Campillo and Paul, 2003; Calvert *et al.*, 2004; Schuster *et al.*, 2004; Bakulin and Calvert, 2006; Schuster and Zhou, 2006), helioseismology (Duvall *et al.*, 1993; Rickett and Claerbout, 1999), and medical diagnostics (Sabra *et al.*, 2007). The emergence of the Green's function by wavefield crosscorrelation has been theorized using the normal modes based on the energy equipartition principle in which the wavefield is diffuse and waves propagate in all directions for both closed (Lobkis and Weaver, 2001; Tanimoto, 2008) and open media (Weaver and Lobkis, 2004). When the inhomogeneous medium is not illuminated by random noise sources and the diffusivity of the wavefield is not achieved, theoretical approaches including the stationary phase method (e.g., Schubert, 2001; Snieder, 2004) and the representation theorem (Wapenaar, 2004) were used to demonstrate the applicability of the technology. However, the theories, in particular, for the open system, invoked an assumption that the illuminating sources are in the far-field regime may be violated in important applications. The consequence of this critical approximation is that the retrieved Green's function contains incorrect amplitude and it consists of only high-frequency propagating waves and no evanescent waves which are crucial in applications such as the super-resolution diffraction tomography in medical imaging or mining activity (Lehman, 2002). In this letter, we show that the far-field approximation can be removed by the exact boundary integral equation method and the exact Green's function with full-frequency bandwidth can be retrieved, including all types of scattering effects. Our exact method leads to construction of a crosscorrelation kernel and because this kernel is same for both deterministic and noise sources, we consider the former case in the sequel.

The Green's function retrieval can be understood by a surface integral (Fig. 1) in the frequency ω domain using the Rayleigh's reciprocity of the correlational type (e.g., Wapenaar and Fokkema, 2006; Shuster, 2009):

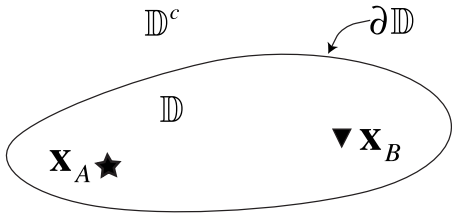

Fig. 1. Heterogeneous medium bounded by a surface $\partial\mathbb{D}$.

$$2i\ \mathrm{Im}\ G(\mathbf{x}_B|\mathbf{x}_A;\omega) = \oiint_{\partial\mathbb{D}} \left[G(\mathbf{x}'|\mathbf{x}_A;\omega)\frac{\partial\bar{G}(\mathbf{x}'|\mathbf{x}_B;\omega)}{\partial n'} - \bar{G}(\mathbf{x}'|\mathbf{x}_B;\omega)\frac{\partial G(\mathbf{x}'|\mathbf{x}_A;\omega)}{\partial n'} \right] d^2\mathbf{x}' \tag{1}$$

in which $G(\mathbf{x}'|\mathbf{x}_A;\omega)$ and $G(\mathbf{x}'|\mathbf{x}_B;\omega)$ are the Green's functions for the heterogeneous medium in $\mathbb{D}$ which satisfy differential equations

$$\nabla^2 G(\mathbf{x}'|\mathbf{x}_{A,B};\omega) + k^2(\mathbf{x}')G(\mathbf{x}'|\mathbf{x}_{A,B};\omega) = -\delta(\mathbf{x}'-\mathbf{x}_{A,B}), \quad \mathbf{x}',\mathbf{x}_{A,B} \in \mathbb{D}\cup\partial\mathbb{D},$$

and the overbar denotes the complex conjugate and $\partial/\partial n'$ is the directional derivative along the outward normal of the boundary $\partial\mathbb{D}$ with respect to position $\mathbf{x}' \in \partial\mathbb{D}$. For simplicity, we neglect the source time function in the formulation. The right hand side of Eq. (1) can be interpreted as focusing/backpropagating the wavefield on $\partial\mathbb{D}$ generated by a source at $\mathbf{x}_A$ to the observation point $\mathbf{x}_B$. Based on a physical argument using the time reversal acoustics (Derode *et al.*, 2003), the left hand side of Eq. (1) corresponds to $G(\mathbf{x}_B|\mathbf{x}_A;t)-G(\mathbf{x}_B|\mathbf{x}_A;-t)$ in the time t domain, which consists of the causal and the anticausal Green's functions. Let $p_A(\mathbf{x}')=G(\mathbf{x}'|\mathbf{x}_A;\omega)$ and $q_A(\mathbf{x}')=\partial G(\mathbf{x}'|\mathbf{x}_A;\omega)/\partial n'$ be the wavefields on $\partial\mathbb{D}$ produced by a source at $\mathbf{x}_A$. Likewise, $p_B(\mathbf{x}')=G(\mathbf{x}'|\mathbf{x}_B;\omega)$ and $q_B(\mathbf{x}')=\partial G(\mathbf{x}'|\mathbf{x}_B;\omega)/\partial n'$ are due to the source at $\mathbf{x}_B$. Equation (1) can be written in a compact form

$$2i\ \mathrm{Im}\ G(\mathbf{x}_B|\mathbf{x}_A;\omega) = \langle p_A, q_B\rangle - \langle q_A, p_B\rangle \tag{2}$$

in which $\langle f,g\rangle=\int_{\partial\mathbb{D}} f(\mathbf{x}')\bar{g}(\mathbf{x}')d^2\mathbf{x}'$ is the inner product defined on the boundary. In previous studies (e.g., Wapenaar *et al.*, 2005; Wapenaar and Fokkema, 2006; Snieder *et al.*, 2007), the integral was simplified in an open system using the far-field approximation for a spherical $\partial\mathbb{D}$ with a large radius such that $q_{A,B}(\mathbf{x}')\approx i\omega c^{-1}(\mathbf{x}')p_{A,B}(\mathbf{x}')$, $\mathbf{x}' \in \partial\mathbb{D}$. If the wave propagation speed $c(\mathbf{x}')$ is constant, we obtain

$$2i\ \mathrm{Im}\ G(\mathbf{x}_B|\mathbf{x}_A;\omega) \approx -2ik\langle p_A, p_B\rangle, \quad k=\omega/c, \tag{3}$$

which is referred to as Green's function retrieval from far-field correlations. By the source-receiver reciprocity in the Green's function, $p_A(\mathbf{x}')$ and $p_B(\mathbf{x}')$ can be interpreted as the wavefields recorded at $\mathbf{x}_A$ and $\mathbf{x}_B$, respectively, produced by a source at $\mathbf{x}' \in \partial\mathbb{D}$. Each source contributes equally to the Green's function retrieval on the left hand side. Next, we show that one can still relate the integral (1) to the crosscorrelation of the wavefield as in Eq. (3) even when $\partial\mathbb{D}$ is not in the far-field regime.

It is well known in the studies of the Huygens principle using single-layer and double-layer potential representations that the surface values p_A and q_A (or p_B and q_B) are generally not independent (e.g., Baker and Copson, 1950; Kupradze, 1963; Colton and Kress, 1983). To see this, we consider the scattering problem due to a source at $\mathbf{x}_A \in \mathbb{D}$ (Fig. 1). In the exterior domain $\mathbb{D}^c$, we apply the boundary integral equation method (e.g., Kleinman and Roach, 1974; Sanchez-Sesma and Campillo, 1991; Rjasanow and Steinbach, 2007):

$$\sigma(\mathbf{x}'')p_A(\mathbf{x}'') = \oint\!\!\!\!\!\!\int_{\partial\mathbb{D}} \left[p_A(\mathbf{x}')\frac{\partial G(\mathbf{x}'|\mathbf{x}'';\omega)}{\partial n'} - q_A(\mathbf{x}')G(\mathbf{x}'|\mathbf{x}'';\omega) \right] d^2\mathbf{x}', \quad \mathbf{x}',\mathbf{x}'' \in \partial\mathbb{D} \tag{4}$$

in which the continuity of p_A and q_A across the boundary is imposed and the integral is in the sense of Cauchy principal value. If the boundary is not smooth at $\mathbf{x}'' \in \partial\mathbb{D}$ (e.g., a vertex), $\sigma(\mathbf{x}'')$ is related to the solid angle spanned by the vertex locally and $\sigma(\mathbf{x}'')=0.5$ for a smooth boundary point at $\mathbf{x}''$. Equation (4) can be written in the integral operator form

$$Sq_A(\mathbf{x}'') = \left(K - \frac{1}{2}I \right) p_A(\mathbf{x}''), \quad \mathbf{x}'' \in \partial\mathbb{D} \tag{5}$$

(e.g., Martin, 2006). The exterior Green's function satisfies the differential equation in the exterior domain

$$\nabla'^2 G(\mathbf{x}';\mathbf{x}'') + k^2(\mathbf{x}')G(\mathbf{x}';\mathbf{x}'') = -\delta(\mathbf{x}' - \mathbf{x}''), \quad \mathbf{x}',\mathbf{x}'' \in \mathbb{D}^c \cup \partial\mathbb{D}$$

and the Sommerfeld radiation condition at the infinity

$$\lim_{r\to\infty} r\left(\frac{\partial}{\partial r} - ik \right) G(\mathbf{x}';\mathbf{x}'') = 0, \quad r = |\mathbf{x}' - \mathbf{x}''|$$

if the exterior medium is unbounded. The null space of the operator S is not empty if ω is one of the eigenfrequencies $\{\omega_k, k \in \mathbb{N}\}$ of the interior problem with the homogeneous Dirichlet boundary condition (Colton and Kress, 1983). Under this case, the inverse S^{-1} of S does not exist and q_A cannot be determined uniquely from p_A. Because the backpropagation integral is a general expression for all ω, we can restrict our discussion to the case $\omega \neq \omega_k$. However, if the exterior domain is unbounded and the Sommerfeld radiation condition is ensured at the infinity, the boundary value q_A is uniquely determined by p_A (Baker and Copson, 1950). Once the inverse S^{-1} of S exists, we have

$$q_A = S^{-1}\left(K - \frac{1}{2}I \right) p_A = Cp_A \tag{6}$$

in which I is the identity operator. The same reasoning can be applied to a source at $\mathbf{x}_B$:

$$q_B = Cp_B. \tag{7}$$

Substituting Eqs. (6) and (7) into Eq. (2), we obtain

$$2i \text{ Im } G(\mathbf{x}_B|\mathbf{x}_A;\omega) = \langle p_A, Cp_B\rangle - \langle Cp_A, p_B\rangle = \langle p_A, (C - C^*)p_B\rangle = \langle p_A, Wp_B\rangle \tag{8}$$

in which C^* is the adjoint of C. If we discretize the boundary, C will be a square matrix and C^* is the Hermitian transpose of C. The invertibility of the matrix S can be studied readily from its eigenvalues. We take the interpretation that $p_A(\mathbf{x}')$ and $p_B(\mathbf{x}')$ are wavefields at $\mathbf{x}_A$ and $\mathbf{x}_B$, respectively, due to a boundary source at $\mathbf{x}'$. Clearly, if $W=\{w_{ij}\}$ is a diagonal matrix, then the backpropagation is a weighted correlation, $\Sigma_i w_{ii} p_A^i \bar{q}_B^i$ in which i is the index of the source. However, if W is a full matrix, the backpropagation integral becomes $\Sigma_i \Sigma_j w_{ij} p_A^i \bar{q}_B^j$ and i and j are the source indices. In this case, the wavefield p_A^i at $\mathbf{x}_A$ due to the ith source on the boundary is crosscorrelated with the wavefield p_B^j at $\mathbf{x}_B$ due to the jth source, which is in sharp contrast with the previous thought that only wavefields at two locations from the same source are crosscorrelated. In general, the matrix W depends on the exterior medium and the boundary geometry. Note that if the exterior medium is unbounded and homogeneous, W only depends on the geometry of the boundary ∂D and the wavenumber k in the exterior medium.

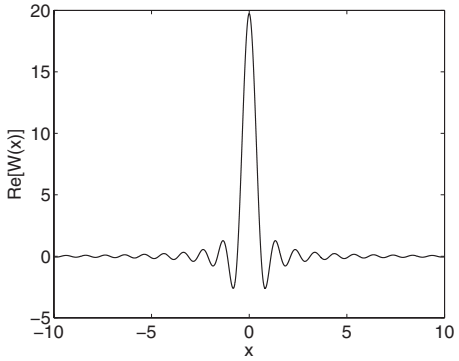

Fig. 2. Crosscorrelation kernel for the plane surface case. The wavelength $\lambda = 1$.

We derive the crosscorrelation kernels for two important boundaries frequently appearing in applications: an infinite plane boundary and a cylindrical boundary. Both problems are formulated in the two-dimensional space and both kernels are symmetric difference kernels whose actions on a function represent convolution operations.

Example 1. In the two-dimensional space, let the boundary $\partial\mathbb{D}$ be an infinitely large plane. In this case, $K=0$. The integral operator kernel is

$$S = \frac{i}{4} H_0(k|x|) \tag{9}$$

in which H_0 is the Green's function in the two-dimensional space. Because the kernel S is a symmetric difference kernel whose action on a function is a convolution, the Fourier transform in the distributional sense can be applied to compute its inverse and the crosscorrelation kernel reads

$$W(x) = ikJ_1(k|x|)/|x|, \tag{10}$$

where J_1 is the first order Bessel function of the first kind. Figure 2 plots one such a kernel.

Example 2. If the surface is a cylinder with radius R and the exterior medium is unbounded and homogeneous and has a wavenumber k, the integral equation in the exterior domain reads

$$\frac{1}{2}u(\theta) = -\frac{i}{4}\int_0^{2\pi} q(\theta')H_0\left(2kR\left|\sin\frac{\theta-\theta'}{2}\right|\right)Rd\theta' - \frac{ik}{4}\int_0^{2\pi} u(\theta')H_1\left(2kR\left|\sin\frac{\theta-\theta'}{2}\right|\right) \times \left|\sin\left(\frac{\theta-\theta'}{2}\right)\right| Rd\theta' \tag{11}$$

in which polar angles θ and θ' denote positions on the boundary. All the functions in the above integral are 2π-periodic. Therefore, we can use the Fourier series to obtain the crosscorrelation kernel in the discrete angular wavenumber domain

$$W_n = \frac{4i}{\pi R}|H_n(kR)|^{-2}, \quad n = 0, \pm 1, \pm 2, \ldots \tag{12}$$

in which W_n is the coefficient of the Fourier series for the expansion function $e^{in\theta}$ and H_n the first-kind Hankel function of order n. For the far-field case, $kR \gg 1$, our crosscorrelation kernel reduces to the known result, $W(\theta) = 2ik\delta(\theta)$, where $\delta(\theta)$ is the Dirac delta function. Hence we have rigorously justified the validity of using the far-field approximation in the Green's function retrieval in Eq. (3). Let $R=1$ and we compute the crosscorrelation kernels for several wavenumbers (Fig. 3). At the high frequency, the crosscorrelation kernel for the cylindrical boundary resembles that of the plane boundary case [Figs. 3(c) and 2], which indicates that if the radius of curvature is large compared to the wavelength, the kernel of the plane boundary may be applied

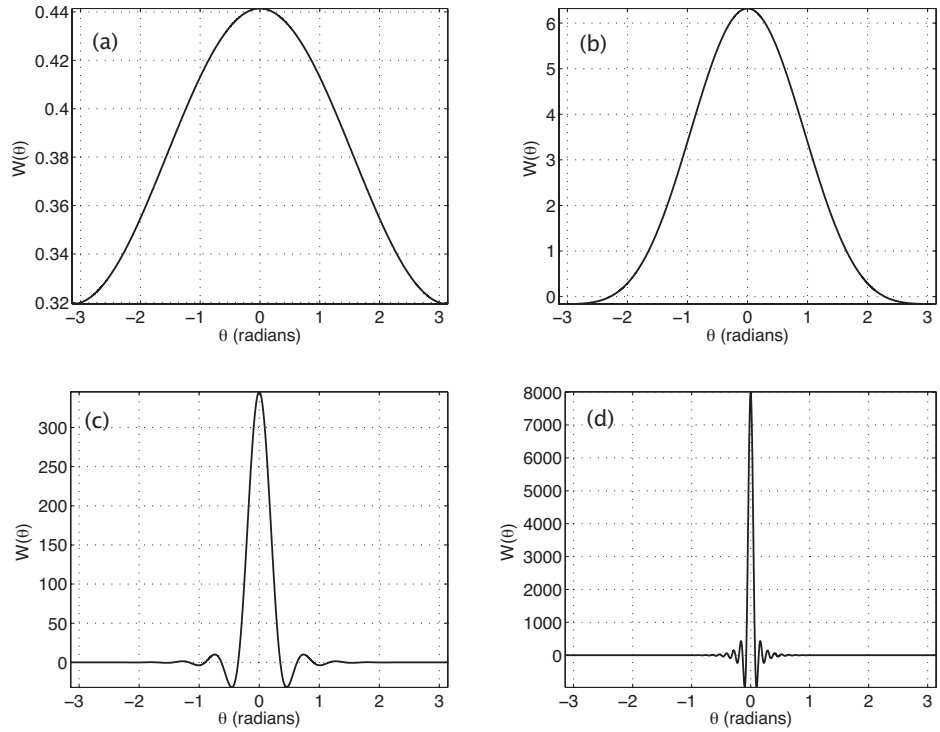

Fig. 3. Crosscorrelation kernels for a cylinder boundary with radius $R=1$ for different wavenumbers (a) $k=0.1$, (b) $k=1$, (c) $k=10$, and (d) $k=50$. The kernels are obtained by inverse Fourier transform of Im W_n.

locally. For both the plane and the cylindrical boundaries, the kernels approach the Dirac delta distribution if we increase the frequency ω. Numerical examples for the cylindrical boundary corroborated our theoretical prediction that the accuracy of the retrieved Green's function increases for large kR if we use the delta kernel (Wapenaar *et al.*, 2005).

In this letter, we have pointed out that the previous theory with the far-field approximation on the Green's function retrieval yielded incorrect amplitude and prevented its use from extracting the low-frequency content of the Green's function in an open system. We proposed a method based on the integral equation method to reconstruct the exact full Green's function including all wave phenomena if source locations are known such as in the seismic interferometry using controlled sources. If deterministic sources were used, we have shown that in order to exactly retrieve the Green's function we need to correlate wavefields not only between receivers for the same source but also between different sources. Finally, we remark that for a great number of applications, the Green's function retrieval technique is being applied to diffuse wavefields generated by noise sources and as such the crosscorrelation kernel should still be used if the source locations can be estimated. For a boundary with general geometric shape on which the sources are excited, the boundary element method can be used to solve for the crosscorrelation kernel.

I am grateful to Associate Editor Professor Andrew Norris and an anonymous reviewer for their constructive comments. I also thank Ru-shan Wu, Xiao-bi Xie, Yaofeng He, Rui Yan, and Qiaoer Zhou for verifying the idea and checking the derivation. The discussion with Professor Haruo Sato on the far-field approximation was illuminating. I thank Professor Harold Widom for the help on the integral equation with Hankel kernel and its inverse. I thank Dr. Brian Schlottmann and Dr. Heather Savage for reading the manuscript and their useful comments. This work is supported by the NSF Grant No. EAR-0838359 and by the Wavelet Transform on Propagation and Imaging (WTOPI) Consortium/UCSC. Facility support from the W. Keck Foundation is appreciated.

On the subtraction method for *in-situ* reflection and diffusion coefficient measurements

Abstract: The subtraction method is a technique critical to several important acoustic measurements. It involves subtracting a reference measurement including only direct sound from one with direct sound and a reflection, to isolate the reflection. The process is very sensitive to environmental conditions, such as changes in temperature, air movement, and microphone positioning. These variations cause small time differences between the reference and reflection measurements, which prevent complete subtraction of the direct sound; the residual direct sound then pollutes analysis of the isolated reflection. This work evaluates methods to compensate for differences to achieve minimal interference from the residual direct sound.

1. Introduction

The subtraction method is an important step in several acoustic measurements that are important to acoustic practitioners in the field. The first is the *in-situ* absorption/reflection coefficient measurement. This method was suggested by Yuzawa[1] as early as 1975 and further developed by Mommertz.[2] Nocke[3] and Garai[4] also utilized this technique. ISO Standard 13472 (Ref. 5) for the measurement of the absorption of roadway surfaces incorporates the subtraction technique and has been applied to other surfaces such as grass and turf.[6] The measurement involves taking an impulse response in the free field, and another with the microphone close to the surface under test. The free field measurement is subtracted from the test measurement to isolate the reflection, which is then compared to the free field direct sound to deduce the reflection coefficient from the surface. This measurement technique is of high practical significance because it allows testing of installed materials without the need to remove material to a laboratory for reverberation chamber[7] or impudence tube[8] measurements.

The second measurement that requires this technique is the measurement of diffusion coefficients.[9] Diffusion coefficients are measured by placing a semicircular or hemispherical array of microphones around the sample to be measured, a source outside of the microphone array, and taking impulse responses for each microphone. The polar response of the panel is then distilled into a diffusion coefficient using an auto-correlation function as in Eq. (2). In attaining the polar response from an architectural wall panel for many source incidences, it is often necessary to place the source at grazing incidence to the panel with the microphone opposite. Figure 1 (right) illustrates this condition. This results in the direct sound and panel reflection arriving at the microphone in close succession. Since only the reflection is of interest, a second measurement is taken without the panel present to attain a reference that can be subtracted from the measurement to isolate the panel reflection. This measurement is a simple and practical method to measure surfaces such as those described by Olson and Bradley,[10] Dadiotis *et al.*,[11] and D'Antonio,[12] among others. Both of these measurements require taking either two measurements with the same microphone or taking one measurement with two different microphones. In either case, there will be slight differences between the measurements. These differences arise from differences in the response of the microphones, no matter how closely matched

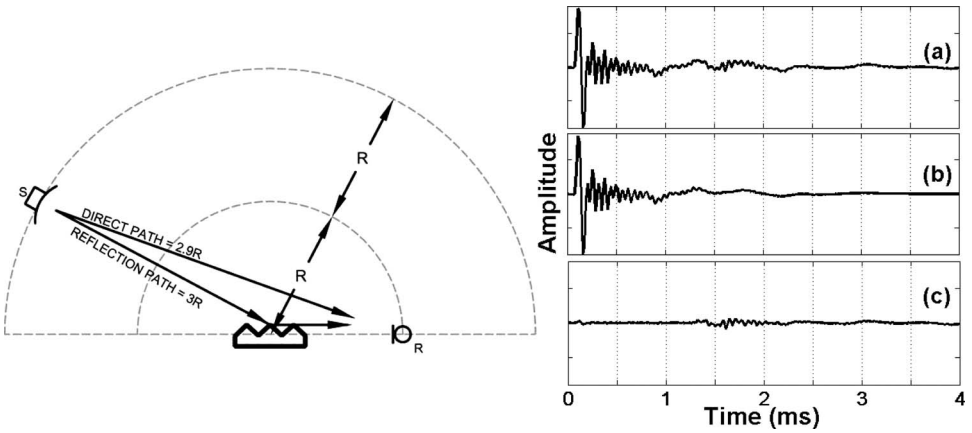

Fig. 1. Diffusion coefficient measurement setup that requires the subtraction method to isolate the reflection and the resulting impulse responses: (a) Impulse response of reflections including the direct sound impulse. (b) Reference impulse response. (c) Subtraction results.

they are, temperature changes and air movement between measurements, and variations in the response of the measurement equipment due to temperature or electrical deviations. This work examines methods to compensate for these small changes.

2. Experiment description

This experiment uses impulse responses obtained from diffusion coefficient measurements. A measurement as shown in Fig. 1 (left) without the diffuser panel present yields the reference measurement; one with the panel present provides the reflection measurement. Subtracting the former from the latter eliminates the direct sound and leaves only the reflection. This paper examines a variety of methods to correct for minor time misalignments between the two signals to attain the optimal result. The subtraction results from each method are then used to calculate the diffusion coefficient,[13] and variations are analyzed. Figure 1 illustrates the measured impulse responses and subtraction results.

3. Subtraction methods

The first scheme examined is the direct subtraction method. This method assumes that environmental conditions are constant between measurements and measurements can be repeated exactly. If this assumption is correct, direct subtraction should produce complete elimination of the direct sound and leave only the isolated reflection. If this is not effective, which is often the case, further processing is necessary.

Several steps may be taken to improve the results. All of these steps require comparing different features of the two measurements. To make this comparison more accurate it is desirable to oversample both signals so corrections of less than one sampling point can be made; after subtraction the signals are downsampled to their original sampling frequency.

The simplest correction is to calibrate the signals so that the amplitudes of the direct sound peaks are the same. This ensures that differences in magnitude do not skew the results and do not account for time misalignments. Aligning the signals in time further improves the subtraction results. This can be done in several ways. Utilizing the peaks of the direct sounds as a reference point and aligning them in time can help correct for overall shifts, but a small shift in the peak may not accurately represent the shift of the whole signal. To incorporate a larger portion of the signal into consideration, cross-correlation of a few milliseconds of the signals, centered on the direct sound peaks, may be effective. The location of the peak of the cross-correlation function will indicate how much to shift one signal in relation to the other to attain

the best alignment of the direct sounds. However, the cross-correlation function is often skewed by the presence of the reflection within the direct sound component. This is often the case when measuring the reflection coefficient of a rigid surface when the microphone is close to the surface.

4. Subtraction optimization

The optimized approach to achieve the best alignment includes all of the previous schemes, then shifts the signals across each other several points to either side of the shift indicated by the cross-correlation function. By subtracting the reference from the reflection measurement at each of these locations, the most effective result can be found. This is performed at a wide range of oversampling rates in order to have the ability to shift the signals by any fraction of a sampling point. So, for an oversampling rate of 2, the signals are shifted four points in either direction; for 3, six points in either direction; etc. This is repeated up to an oversampling rate of 20 or more, so that every fraction of shift within the four points around the peak correlation is investigated. There is some redundancy since, for example, 10/20 is the same as 1/2, but the advantage is that a step of, say, 1/19 of a point is investigated. At each shift the signals are subtracted and the residual direct sound is compared. More thorough organization of the oversampling rates could improve calculation time by removing the redundant steps. For a limited number of oversampling rates and shifts, a gridded search to find the most effective subtraction is sufficient to obtain optimized results; in more detailed investigations a genetic algorithm can be exploited to improve computation time.

5. Measuring subtraction effectiveness

The process above provides many varying subtraction results; in order to choose the best result, a metric of success is required. As the goal of the operation is to remove the direct sound, subtraction effectiveness can be measured by the percent reduction, or decibel level reduction in the direct sound from the measurement to the result. Specifically, the sum of the energy within 0.5 ms of either side of the direct sound can be compared before and after subtraction to find the effective reduction. Equation (1) defines the reduction factor R. A reduction factor equal to the peak to noise ratio of the measurement can be considered a complete subtraction, since this would leave nothing in the area of the direct sound except the background noise.

$$R = 10\ \log_{10}\left(\frac{\sum_{ds-0.5\ \mathrm{ms}}^{ds+0.5\ \mathrm{ms}} (S_{\mathrm{ref}})^2}{\sum_{ds-0.5\ \mathrm{ms}}^{ds+0.5\ \mathrm{ms}} (S_{\mathrm{result}})^2}\right), \tag{1}$$

where ds is the time of the direct sound peak, S_{ref} is the reference measurement, and S_{result} is the subtraction result.

Certainly, if direct subtraction provides suitable reduction in the direct sound component, no further processing is necessary. The level of the residual direct sound in relation to the level of the reflection should also be considered. The smaller the reflection component, the greater influence a given residual direct sound will have. This is particularly important in the *in-situ* measurement of absorptive materials and grazing source incidence diffusion coefficient measurements. In both cases the reflection is small and also within close proximity to the direct sound.

6. Results

Seventy-two sets of measurements were processed with five different subtraction schemes. The schemes, as described above, are direct subtraction, peak amplitude matching (PAM), peak amplitude and time matching (PATM), peak amplitude matching with cross-correlation alignment (PACA), and the optimized method (OM). An example of the results from two different methods is shown in Fig. 2 (left). Calculating the reduction factor R per Eq. (1) for each mea-

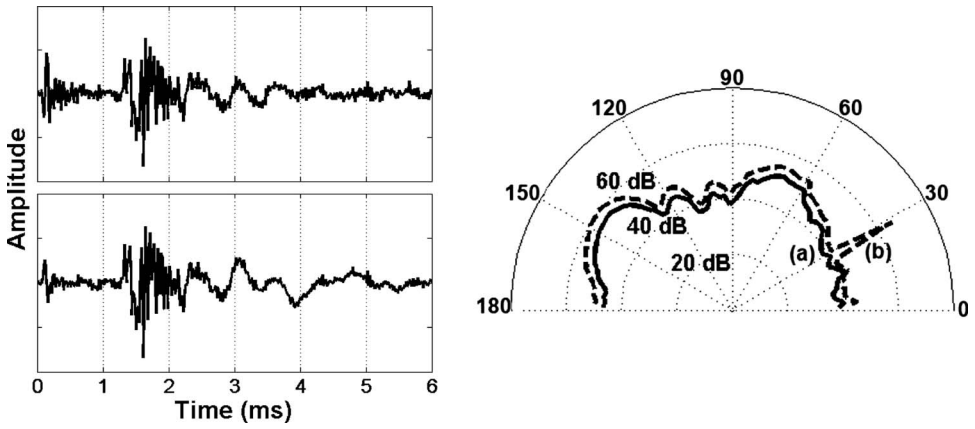

Fig. 2. (Left) A comparison of the direct subtraction result (a) and the optimized result (b). In this case, there was a 5 dB improvement in the reduction in the direct sound. (Right) A polar response with an anomalous spike from failed subtraction (b) and the corrected response (a). The diffusion coefficients are 0.19 and 0.35, respectively.

surement and subtracting the direct method reduction factor yield the improvement offered by each method. Table 1 lists the improvement results for the 72 measurement sets processed. Negative values indicate results that are worse than direct subtraction.

Peak amplitude matching provides some improvement, and since this scheme is so simple to implement, it should be used on all subtraction measurements. Note that aligning the peaks of the direct sound provides no additional improvement. This indicates that the exact alignment of the peaks does not correlate to the best time alignment of the entire direct sound. Cross-correlation, used blindly, provides generally worse results than if the signals had been subtracted directly. This is possibly due to the influence of the reflection in the correlation, which could skew the correlation peak due to the mismatch between the reflection and background noise after the direct sound. Finally, the optimization method shows a marked improvement over direct subtraction, sometimes as much as 12 dB. Where the optimization method failed, as indicated by the −1 dB improvement, was on the rare measurement where direct subtraction was extremely accurate; these measurements showed direct method R factors above all others.

7. Effect on the diffusion coefficient

Since the diffusion coefficient uses auto-correlation of many channels, per Eq. (2), it is susceptible to being skewed by one faulty channel.

Table 1. A comparison of the improvement ($R_{\text{method}}-R_{\text{direct}}$) provided by each subtraction scheme: PAM, PATM, PACA, and OM.

Method	Minimum (dB)	Mean (dB)	Maximum (dB)
PAM	−1.6	0.4	4.5
PATM	−1.6	0.4	4.5
PACA	−29.3	−2.5	4.5
OM	−1	2.6	12.1

Table 2. A comparison of the diffusion coefficients calculated from different subtraction schemes.

2500	0.03	0.03	0.03	0.04	0.45

$$D_\Theta = \frac{\left(\sum_{i=1}^{n} 10^{L_i/10}\right)^2 - \sum_{i=1}^{n} (10^{L_i/10})^2}{(n-1)\sum_{i=1}^{n} (10^{L_i/10})^2}, \quad (2)$$

where i is the microphone position, L_i is the level at i microphone, n is number of microphones in the array, and Θ is the source incidence.

In a semicircular array of 72 microphones, if the subtraction method fails on one or two channels, a spike can occur in the polar response. This spike is interpreted as highly directional reflection, and the diffusion coefficient will be artificially low. Figure 2 (right) shows a polar response that has a spike from failed subtraction and the corrected response calculated from optimized subtractions. The effect on the diffusion coefficient is pronounced.

Table 2 lists diffusion coefficients of a quadratic residue diffuser designed for 600–1600 Hz with the source at 60° incidence for each subtraction method. The effect of failed subtraction becomes most evident above 400 Hz where all of the non-optimized methods yield erroneous results. Even below this threshold, the optimized method, which eliminates the spikes, shows a higher diffusion coefficient indicating a more uniform polar response. The consistency of the optimized results also indicates that the method is less subject to variations in the quality of the measurement from each channel of the semicircular array.

8. Concluding remarks

The subtraction method is particularly sensitive to variations in environmental conditions between the reference measurement and the reflection measurement. Aligning the signals from these measurements in amplitude and time can eliminate the differences to provide clean subtraction results. This is a critical step in both *in-situ* reflection measurements and diffusion coefficient measurements; if the subtraction is not effective, the results from both measurements will be skewed if not entirely erroneous. This complication is amplified in diffusion coefficient measurements because the measurement gauges consistency across many channels. Shifting the signals across one another at various oversampling rates to attain the highest reduction factor is an effective method to determine the optimal subtraction result.

Abstract: Simple reaction times (RTs) were used to measure differences in processing time between natural animal sounds and artificial sounds. When the artificial stimuli were sequences of short tone pulses, the animal sounds were detected faster than the artificial sounds. The animal sounds were then compared with acoustically modified versions (white noise modulated by the temporal envelope of the animal sounds). No differences in RTs were observed between the animal sounds and their modified counterparts. These results show that the fast detection observed for natural sounds, in the present task, could be explained by their acoustic properties.

1. Introduction

The purpose of an auditory warning is to alert the user of a given system (car, plane, and hospital equipment) to a potentially dangerous situation and/or to the arrival of information on visual displays (Patterson, 1982). Several acoustical parameters have been shown to be good candidates to modulate the perceived urgency of an auditory warning: e.g., the higher the pitch and the faster the speed (in case of a multiple-burst sound), the higher the perceived urgency (Edworthy *et al.*, 1991). By contrast with these artificial auditory warnings, some authors have proposed the use of everyday sounds as warnings. For example, Graham (1999) observed shorter response times for everyday sounds (car horn and tire skid) than for conventional warnings (tone) and argued that everyday sounds are understood more quickly and easily than abstract sounds. However, simple acoustic differences, rather than semantic or cognitive differences, might be sufficient to explain the reaction-time advantage for everyday sounds.

More than an increase in the *perceived* urgency, a warning signal is efficient when it induces faster detection and increases the probability of an appropriate reaction under urgent conditions. In a companion study (Suied *et al.*, 2008), we have shown the advantages of an objective measurement [reaction time (RT)] to assess correctly the level of urgency of a sound.

In this study, we present a pair of experiments performed to investigate whether natural sounds are detected faster than artificial sounds by human listeners. First, we show that natural sounds are detected faster than simple artificial sounds (experiment 1). Then, we demonstrate that simple acoustic considerations, rather than very early recognition of the sound, can explain this behavioral advantage (experiment 2).

2. Experiment 1: Artificial sounds versus animal sounds

2.1 Methods

Twelve volunteers (7 women and 5 men; mean age 36 ± 10 years) participated in this experiment. All were naïve with respect to its purpose. None of them reported having hearing problems. The study was carried out in accordance with the Declaration of Helsinki. All participants provided informed consent to participate in the study.

Two categories of sounds were compared: classical warning sounds and animal sounds. Four sounds were tested in each category. For the classical warning sounds, we used the same template for the stimuli as in our companion paper (Suied *et al.*, 2008). The template for the different stimuli was an isochronous sequence of short pulses. Each pulse of the burst was a 1-kHz pure tone, 20 ms in duration, and included 5-ms linear onset and offset ramps. Stimuli varied along a single dimension, the interonset interval (IOI), defined as the time elapsed between the onsets of two pulses. The four IOIs tested were 100, 50, 33, and 25 ms (these four sounds are referred to hereafter as IOI100, IOI50, IOI33, and IOI25, respectively). The total duration of each burst was 220 ms. The natural sounds were animal sounds obtained from the SoundIdeas database (Sound Ideas General Series 6000, www.sound-ideas.com): a lion sound, two different leopard sounds, and one jaguar sound, referred to hereafter as Lion, Leo1, Leo2, and Jag, respectively. They were modified to be 220 ms in duration, with a linear ramp of 10 ms at the end of the sound (see Fig. 2 for the waveforms of the animal sounds).

Loudness equalization was performed on the eight stimuli to avoid any RT differences due to loudness differences (see Chocholle, 1940; Suied *et al.*, 2008). A group of nine other listeners participated in this preliminary experiment. Loudness matches were obtained with an adjustment procedure. The listener was asked to adjust the comparison stimulus until it seemed equal in loudness to the standard stimulus. IOI100 was used as the standard stimulus. The level of the standard stimulus was fixed at 76 dB sound pressure level (SPL). The mean level differences at which the comparison and the standard stimuli were judged to be equal in loudness were between 0.5 and 6 dB. IOI50 was presented at 75.5 dB SPL, IOI33 at 75.5 dB SPL, IOI25 at 75.2 dB SPL, Lion at 73.6 dB SPL, Leo1 at 75 dB SPL, Leo2 at 73.7 dB SPL, and Jag at 70 dB SPL.

The sound samples were presented at a 44.1-kHz sampling rate. They were amplified by a Yamaha P2075 stereo amplifier and presented binaurally over Sennheiser HD 250 linear II headphones. The experimental sessions were run using a Max/MSP interface on an Apple computer. Participants responded by using the space bar of the computer keyboard placed on a table in front of them. The responses were recorded by Max/MSP with a temporal precision for stimulus presentation and response collection of around 1 ms. The experiments took place in a double-walled Industrial Acoustics Co. (IAC) sound booth.

One exemplar of each of the eight stimuli was presented in random order for each trial. Following a standard simple-RT procedure, participants had to respond as soon as they detected the sound by pressing the space bar as quickly as possible. They were asked to keep the finger of their dominant hand in contact with the space bar between trials. The inter-trial interval was randomly fixed between 1 and 7 s. These stimuli were presented in six separate blocks of trials. Each block consisted of 96 stimuli. The stimuli of different IOIs were randomly intermixed. The number of stimuli of different IOIs was equal in each block (12 each), thus leading to 72 repetitions for each stimulus and each participant. Participants performed practice trials until they were comfortable with the task.

Responses were first analyzed to remove error trials, i.e., anticipations (RTs less than 100 ms) and RTs greater than 1000 ms. Each RT value was transformed to its natural logarithm

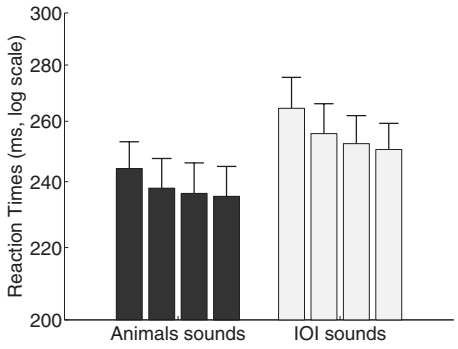

Fig. 1. RTs of the animal sounds and IOI sounds are presented (from left to right: Lion, Leo1, Leo2, Jag, IOI100, IOI50, IOI33, and IOI25; see text for details). RTs were first transformed to a log scale and then averaged across all participants. The log scale was converted back to linear ms for display purposes. The error bars represent one standard error of the mean. RTs to the animal sounds were shorter than those to the IOI sounds.

(see Ulrich and Miller, 1993; Luce, 1986), before averaging ln(RT) for each condition (see Suied *et al.*, 2009 for similar analyses on RTs). To identify between-condition differences in mean ln(RT), a repeated-measures analysis of variance (ANOVA) was conducted with sound as a within-subject factor (IOI100, IOI50, IOI33, IOI25, Lion, Leo1, Leo2, and Jag). A Kolmogorov–Smirnov test was performed to check for the normality of the distribution of residuals of the ANOVA. For this analysis, we pooled together the results for all conditions in order to increase the power of the statistical test. In addition, to account for violations of the sphericity assumption, p-values were adjusted using the Huynh–Feldt correction, and $p<0.05$ was considered to be statistically significant. Finally, we performed orthogonal contrasts to explain the main effect of the ANOVA. For the computation of the contrast in the case of repeated-measures ANOVA, the error term is based on the data on which the contrast is performed, instead of using the global error term of the ANOVA factor.

2.2 Results

There were no anticipations, only 0.2% misses and 0.2% of RTs greater than 1000 ms. These outlier data were discarded. The Kolmogorov–Smirnov test revealed that the distribution of the residuals of the ANOVA was not different from a normal distribution ($d=0.07$; $N=96$; $p>0.1$). This result validates the log transformation and shows that the original distribution of RTs was indeed log-normal.

The repeated-measures ANOVA of ln(RT) revealed a significant main effect of sound [$F(7,77)=27.25$; $\varepsilon=0.5$; $p<0.0001$]. These data are represented in Fig. 1. We then performed four mutually orthogonal contrasts [$F(4,44)=30.09$; $p<0.00001$] that show that: (1) RT was significantly shorter for the animal sounds than for the IOI sounds [Lion, Leo1, Leo2, and Jag compared to IOI100, IOI50, IOI33, and IOI25, $t(11)=6.7$; $p<0.00001$]; (2) RT was significantly longer for the Lion sound than for the three other animal sounds [$t(11)=3.5$; $p<0.005$]; (3) RT to the IOI100 sound was significantly longer than for the three other IOIs sounds [$t(11)=4.6$; $p<0.005$]; (4) RT tended to be shorter for IOI33 and IOI25 than for IOI50 [marginal significance: $t(11)=1.8$; $p=0.09$].

2.3 Discussion

Animal sounds led to a shorter RT than artificial sounds. This could be due to a very early recognition of the animal sounds. We could also hypothesize that because of some fundamental acoustical characteristic, these animal sounds induced a brainstem reflex by signaling an important and urgent event (for a review, see Juslin and Västfjäll, 2008), and this might be responsible for the shorter RT. It could also simply reflect acoustical differences, for example, in spectral

content, between the two categories of sounds: By statistical facilitation only, the greater the number of frequency channels activated, the shorter the detection process. Experiment 2 was designed to distinguish between these two possibilities.

For the IOI sounds, the shortest RTs were to IOI33. These data are consistent, at least qualitatively, with a multiple-look model for temporal integration (Viemeister and Wakefield, 1991). The IOI50 sound contains more pulses than the IOI100 sound (and similarly for the IOI33 and IOI50 sounds), so it may lead to more "looks," which might, in turn, induce shorter RTs. The threshold at 33 ms could, however, reflect another process: The lower limit of melodic pitch is around 30 Hz (Pressnitzer *et al.*, 2001). Interestingly, Russo and Jones (2007) recently found that the urgency of pulse trains is closely related to the perception of pitch: The pulse repetition rate corresponding to the transition between a pitch percept and independent pulses was judged as the most urgent and led to very short RT. For the animal sounds, the longest RT was observed for the Lion sound. This "Lion effect" will be discussed together with the results from experiment 2 below (see 3.3).

3. Experiment 2: Animal sounds versus modulated noises

In this experiment, we compared animal sounds to modified versions of the same sounds (white noise modulated with the temporal envelope of the animal sounds) in order to control for differences in spectral and temporal complexities between natural and artificial sounds in experiment 1.

3.1 Methods

Twelve new volunteers (5 women and 7 men; mean age 31 ± 7 years) participated in this experiment. All were naïve with respect to its purpose. None of them reported having hearing problems. The study was carried out in accordance with the Declaration of Helsinki. All participants provided informed consent to participate in the study.

The four animal sounds used previously in experiment 1 were tested again in experiment 2. The temporal envelopes of these sounds were applied to white noise to provide the "modulated noise" versions, denoted hereafter by the prefix "MN_." The temporal envelope was extracted using a half-wave rectifier followed by a low-pass filter (sixth-order Butterworth filter with a cut-off frequency of 5 kHz). As in experiment 1, the eight stimuli were equalized in loudness. The MN_Lion sound (used as the reference sound) was presented at 76 dB SPL, Lion at 78 dB SPL, Leo1 at 77.9 dB SPL, Leo2 at 78 dB SPL, Jag at 74.1 dB SPL, MN_Leo1 at 76 dB SPL, MN_Leo2 at 76.2 dB SPL, and MN_Jag at 75.5 dB SPL.

In addition, at the end of this second experiment, we verified that the participants could categorize the original animal sounds and their modulated noise versions correctly into "animal" and "non-animal" categories. They all performed this task very easily.

The apparatus, procedure, and statistical analyses were the same as in experiment 1.

3.2 Results

There were no anticipations, only 0.3% misses and 0.3% of RTs greater than 1000 ms. These outlier data were discarded. A Kolmogorov–Smirnov test revealed that the distribution of the residuals of the ANOVA was not different from a normal distribution ($d=0.11$; $N=96$; $p>0.1$). This result validates the log-transformation and shows that the original distribution of RTs was indeed log-normal.

The repeated-measures ANOVA on ln(RT) revealed a significant main effect of sound [$F(7,77)=6.72$; $\varepsilon=1$; $p<0.0001$]. These data are represented in Fig. 2. Three mutually orthogonal contrasts [$F(3,33)=11.62$; $p<0.00001$] showed the following: (1) There was no clear difference between RTs for the animal sounds compared to those for the MN versions [Lion, Leo1, Leo2, and Jag compared to MN_Lion, MN_Leo1, MN_Leo2, and MN_Jag, $t(11)=2.1$; $p=0.06$], and the MN sounds tended to be detected faster than the natural sounds (see Fig. 2); (2) as in experiment 1, RTs

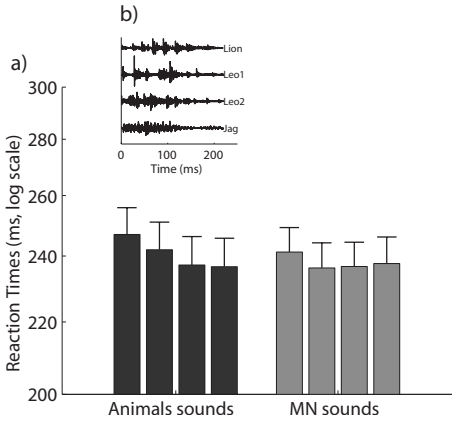

Fig. 2. (a) RTs of the animal sounds and MN sounds are presented (from left to right: Lion, Leo1, Leo2, Jag, MN_Lion, MN_Leo1, MN_Leo2, and MN_Jag; see Fig. 1 for details). RTs to the animal sounds were similar to RTs for the MN sounds that preserved the temporal envelope of the sound. (b) Temporal waveforms of the four animal sounds.

were significantly longer for the Lion sound than for the three other animal sounds [$t(11)=5.5$; $p<0.0002$]; (3) RTs were significantly longer for the MN_Lion sound than for the three other MN sounds [$t(11)=2.9$; $p<0.02$].

3.3 Discussion

We observed similar RTs for real animal sounds and their MN versions. This result validates the "acoustic" hypothesis, suggesting that the RT difference between the animal and the artificial IOI sounds in experiment 1 was indeed due to their difference in acoustic properties. Temporal and spectral differences can be responsible for the RT difference observed between the IOI sounds and the animal sounds (experiment 1). In experiment 2, similar RTs were obtained for sounds with the same temporal envelope; this suggests that differences in the temporal envelope between animal and IOI sounds could explain the faster RTs to animal sounds in experiment 1. The large difference in spectral content between repeated pure tones (IOI sounds) and animal sounds could also be responsible for the faster RTs to animal sounds. In experiment 2, we compared two categories of sounds with less obvious differences in the spectral content. If anything, there was a trend for faster RT for the MN sounds, which could be due to the higher number of channels activated for the MN sounds than for the animal sounds.

The possibility that shorter RTs for animal sounds (experiment 1) were due to cognitive factors (learned associations between feline sounds and danger, for example) is ruled out by experiment 2: RTs for animal sounds were not shorter than for the artificial MN sounds, although participants were still able to recognize animals vs non-animals sounds. Although we do not deny a plausible and potential specificity in the encoding and recognition of natural sounds, these findings suggest that, at least for simple detection tasks, the behavioral advantage for natural sounds can be easily explained by simple acoustic differences. The relationships between the acoustic characteristics of different types of animals (predators or non-predators) and RTs might be an interesting generalization of the current study.

The Lion effect observed in experiment 1 (that is, a longer RT for the Lion sound compared to the other animal sounds) was reproduced in experiment 2. Interestingly, this Lion effect held for the MN sounds, which preserved only the temporal envelope of the sounds. We computed the attack time (defined as the time it took for the temporal envelope to reach the maximum from 40 dB down) on the animal sounds; there was no obvious relationship between the attack times and the RTs that could explain the Lion effect (attack times for Lion: 96.1 ms, Leo1: 107.2 ms, Leo2: 67.7 ms, and Jag: 57.4 ms). The waveforms of the animal sounds are presented in Fig. 2. The importance of the temporal envelope for speech recognition has already

been evidenced (Shannon *et al.*, 1995). From the current data, it also seems that the temporal envelope has an impact on the speed of detection. This requires further investigation.

The behavioral audiogram of whitetail deer (*Odocoileus virginianus*)

Henry Heffner, Jr. and Henry E. Heffner[a)]
Whitetail Deer Research LLC, P.O. Box 412, Swanton, Ohio 43558
hheff@adelphia.net, heff270@yahoo.com

Abstract: The behavioral audiograms of two female white-tailed deer (*Odocoileus virginianus*) were determined using a conditioned-suppression avoidance procedure. At a level of 60 dB sound pressure level, their hearing range extends from 115 Hz to 54 kHz with a best sensitivity of −3 dB at 8 kHz; increasing the intensity of the sound extends their hearing range from 32 Hz (at 96.5 dB) to 64 kHz (at 93 dB). Compared with humans, white-tailed deer have better high-frequency but poorer low-frequency hearing.

1. Introduction

White-tailed deer have perhaps the largest economic impact of any wild animal in North America. On the one hand, billions of dollars are spent each year on equipment and travel related to deer hunting (e.g., Conover, 1997). On the other hand, deer spread Lyme disease, causing millions of dollars of damage to both the agriculture and timber industries, and over a billion dollars of damage to vehicles that collide with them each year (Conover, 1997; Schwabe and Schuhmann, 2002). Indeed, more than 100 people are killed each year in deer-vehicle collisions, with many more seriously injured, making deer the most deadly wild animals in North America (Bailey, 2001). As a result, there is much interest in the behavior of white-tailed deer, particularly in their sensory abilities (e.g., Gerlach *et al.*, 1994).

Because deer are naturally afraid of humans and do not readily tolerate our presence, it is difficult to conduct behavioral tests on them. As a result, the only measure of their hearing currently available is their auditory brainstem response (D'Angelo *et al.*, 2007). This measurement indicates that the hearing range of deer extends from 250 Hz to 30 kHz, with a best sensitivity of only 42 dB at 4 and 8 kHz. However, the auditory brainstem response does not give an accurate measure of an animal's absolute sensitivity nor does it necessarily indicate the relative sensitivity of an animal to different frequencies (Heffner and Heffner, 2003). Such information can only be obtained from a behavioral audiogram.

We present here the absolute pure-tone thresholds obtained for two domestically raised whitetail deer using standard animal psychophysical procedures. These results will be of interest to those who wish to attract, repel, or conceal their presence from deer.

2. Method

The animals used in this experiment were two whitetail does (*Odocoileus virginianus*) 1–2 years of age that had been born and raised domestically. The animals were weighed daily during testing to help monitor their health.

The deer were tested using a conditioned-suppression avoidance procedure in which a thirsty animal was trained to maintain mouth contact with a small stainless steel water bowl in order to receive a steady trickle of water. The bowl, which was mounted on a post 0.5 m above the floor, was carefully positioned so that the animals made little or no drinking noise. Pure tones were then presented at random intervals followed by a mild electric shock delivered between the

[a)]Author to whom correspondence should be addressed.

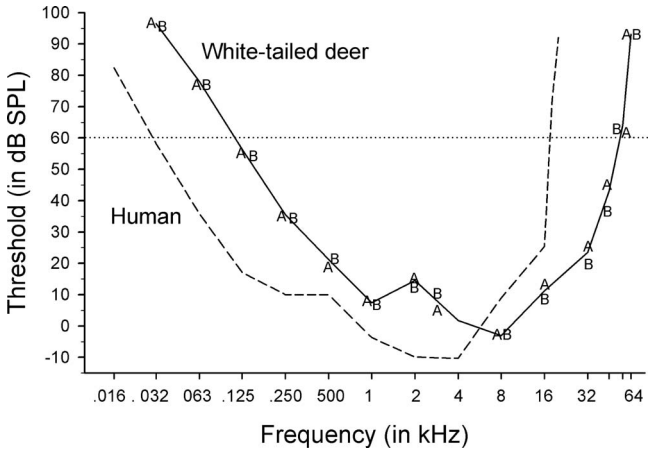

Fig. 1. Absolute thresholds of two white-tailed deer (A and B). The solid line indicates the average thresholds of the deer. The dashed line is a human audiogram obtained in comparable free-field conditions (Jackson *et al.*, 1999). The horizontal dotted line indicates the 60 dB sound pressure level, which is the level commonly used when comparing the hearing ranges of different species.

bowl and the floor. An animal avoided the shock by breaking contact with the bowl whenever it heard a tone, thereby also indicating that it had detected the tone. Thus, the task resembles the natural situation in which an animal at a water hole pauses when it senses danger. That the shock level used was "mild" was indicated by the fact that the deer never developed a fear of the water bowl and returned to it as soon as the sound was turned off (for details of this procedure, see Heffner and Heffner, 1995).

Thresholds were determined by reducing the intensity of a tone in 5 dB steps until an animal could no longer detect it above chance level. Threshold was defined as the intensity at which an animal could detect a sound 50% of the time (corrected for false positives), which was usually calculated by interpolation (Heffner and Heffner, 1995).

To produce the tones, sine waves were generated with an oscillator or a digital signal generator, gated with a rise-fall gate set to at least 10 ms to eliminate onset and offset artifacts, pulsed (400 ms on, 100 ms off), filtered ($\pm 1/3$ octave settings), monitored with an oscilloscope, amplified, and sent to a loudspeaker: either a subwoofer (32–63 Hz), woofer (125–4 kHz), piezoelectric tweeter (8–32 kHz), or leaf tweeter (45, 56, and 64 kHz). Most testing was conducted with the speaker placed in front of the animal at a distance of 1 m. However, because the animals sometimes did not point their pinnae forward, a second speaker was placed off to one side or behind an animal at a distance of 1.5 m or more with the exact location depending on the direction in which an animal tended to point its pinna. The procedure for calibrating the sound has been described elsewhere (Jackson *et al.*, 1997) and the sound pressure level (SPL) used was referenced to 20 $\mu N/m^2$. Testing was conducted in a single-wall sound-proof chamber, the walls and ceiling of which were lined with acoustic foam.

3. Results

The deer learned to enter the sound chamber, drink from the water bowl, and break contact with the bowl whenever a suprathreshold stimulus was presented. Although the animals usually pointed their pinnae straight ahead at the loudspeaker located in front of them, they sometimes rotated their pinnae to the side or back as though they were checking for sounds coming from those directions. When this occurred, the tone trials were delayed until their pinnae were again directed toward the loudspeaker. However, for frequencies of 8 kHz and higher, a second loudspeaker was placed in the location toward which they oriented their pinna. This procedure resulted in stable thresholds that represent the animals' optimal sensitivity.

The audiograms of the two deer, shown in Fig. 1, have the characteristic shape of

mammalian audiograms. Beginning at the low frequencies, the deer were able to hear 32 Hz at an average threshold of 96.5 dB with sensitivity improving as frequency was increased. The animals showed a broad range of good sensitivity extending from 500 Hz to 32 kHz with a best threshold of −3 dB at 8 kHz. Above 32 kHz, sensitivity decreased rapidly to an average threshold of 93 dB at 64 kHz. Overall, at an intensity of 60 dB SPL, the deer were able to hear from 115 Hz to 54 kHz.

4. Discussion

There are two points to note about this deer audiogram. First, because sounds were only presented when at least one, if not both, of an animal's pinnae were pointed toward a loudspeaker, they represent the animals' optimal sensitivity. As has been demonstrated in reindeer, the pinnae of deer are directional for high frequencies and sensitivity may be reduced by 20 dB or more when the pinnae are pointed away from the sound source (Flydal *et al.*, 2001). Second, although we only tested females, these results are expected to apply to male deer as well, as the auditory sensitivity of mammals has not been observed to differ between the sexes (Heffner and Heffner, 2003).

Because of the extensive interactions between humans and white-tailed deer, it is of interest to compare their audiogram with that of humans. As can be seen in Fig. 1, the deer audiogram is similar in shape to that of humans and, indeed, looks like the human audiogram shifted approximately two octaves toward the higher frequencies. Some of the differences between the human and deer audiogram are well understood. In particular, the better high-frequency hearing of deer is explained by the observation that mammals rely on high-frequency cues to localize sound, high frequencies being particularly important for localization in the vertical plane and for preventing front-back confusions (Heffner and Heffner, 2008). However, because the directionality of high frequencies depends on the size of an animal's head and pinnae, the smaller the animal, the higher it must hear in order to use the high-frequency locus cues. Thus, deer hear higher than humans because they are smaller. However, less is known about the variation in mammalian low-frequency hearing and there is currently no explanation for the difference in the low-frequency sensitivity of humans and deer (Heffner and Heffner, 2003). (The audiograms of other mammals are available at http://psychology.utoledo.edu/showpage.asp?name=mammal_hearing for comparison with deer.)

Finally, the audiogram provided here can be used to obtain a preliminary estimate of the audibility of a sound to deer. That is, sounds whose spectra fall within the bounds of the audiogram will be audible to deer if they reach a deer's ear at a sufficient sound pressure level. Sounds that fall above or below the frequency range of deer will not be audible to them regardless of the intensity. However, care must be taken in using these data to estimate the relative loudness of sound to deer. This is because the audiogram measures the sensitivity to pure tones, whereas most sounds of interest are complex sounds containing multiple frequencies, and it has been shown that the perceived loudness of such sounds is not easily estimated from measures of pure-tone sensitivity (e.g., Hellman and Zwicker, 1987).

Dispersion of sound in dilute suspensions with nonlinear particle relaxation

Max Kandula
ASRC Aerospace, NASA Kennedy Space Center, Florida 32899
max.kandula-1@ksc.nasa.gov

Abstract: The theory accounting for nonlinear particle relaxation (viscous and thermal) has been applied to the prediction of dispersion of sound in dilute suspensions. The results suggest that significant deviations exist for sound dispersion between the linear and nonlinear theories at large values of $\omega\tau_d$, where ω is the circular frequency and τ_d is the Stokesian particle relaxation time. It is revealed that the nonlinear effect on the dispersion coefficient due to viscous contribution is larger relative to that of thermal conduction.

1. Introduction

Sound attenuation in fluids, representing the dissipation of acoustic energy from a sound wave, occurs through a number of physical processes involving molecular viscosity, thermal conductivity, and other dissipative or relaxation processes.[1–7] When a fluid contains inhomogeneities such as suspended particles (solid particles, drops, and bubbles), additional viscous and heat conduction losses occur in the immediate neighborhood of the suspended particles.[1–3,8] Particle relaxation in a dilute suspension is the process by which particles adjust to fluctuations (velocity and temperature) of the surrounding fluid, leading to attenuation and dispersion of a sound wave. A comprehensive review of the physics and scientific history of acoustic interactions with particulate mixtures is provided by Challis *et al.*[9] The acoustic intensity I of a plane wave propagating through an absorbing medium is expressed by

$$I = I_0 e^{-\alpha_i x}, \tag{1}$$

where x is the distance traversed, I_0 is the intensity at $x=0$, and α_i is the intensity attenuation coefficient for the medium. The quantity α_i depends on viscosity, thermal conductivity, and other factors such as molecular relaxation.

Sound propagation in aerosols and fog has been studied experimentally and theoretically by several investigators since the pioneering work of Sewell,[10] with the aid of a scattering formulation on the assumption of immovable particles. Epstein[11] extended this theory for particles in motion, and Epstein and Carhart[12] additionally considered heat conduction effects. Allegra and Hawley[13] provided further extensions by including liquid-liquid as well as liquid-solid systems.

Temkin and Dobbins,[14] in their classical work involving a coupled-phase formulation, theoretically considered particle attenuation and dispersion of sound in a manner which illustrates explicitly the relaxation character of the problem. Basset history and added mass terms were included in an elegant coupled-phase formulation by Harker and Temple.[15] Coupled phase effects were also treated by Evans and Attenborough[16,17] in an extension to the work of Harker and Temple[15] to incorporate thermal conduction.

The absorption of sound in suspensions of irregular (nonspherical) particles was considered by Urick.[18] Experimental and theoretical studies (extension of Urick's model) on sound absorption involving irregular particles were also considered by Richards *et al.*[19,20]

The particulate relaxation models for the sound attenuation are all based on Stokes drag (linear drag law) and pure conduction limit (linear heat transfer). Recently the author[21] investigated sound attenuation in dilute suspensions and extended the theory of Temkin and

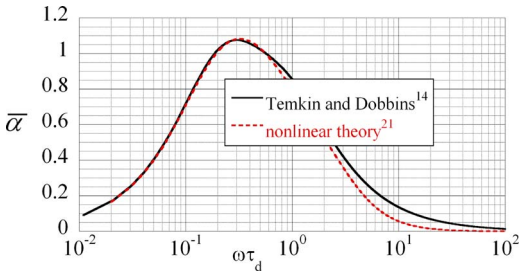

Fig. 1. (Color online) Predicted absorption coefficient with nonlinear particle relaxation processes.

Dobbins[14] by considering nonlinear drag and heat transfer laws applicable to relatively large-sized droplets. The absorption coefficient per unit frequency predicted by the nonlinear theory is compared with that indicated by the theory of Temkin and Dobbins[14] in Fig. 1. In Fig. 1,

$$\bar{\alpha} = c_0\alpha/(C_m\omega) = f(\omega\tau_d, \mathrm{Pr}, c_{pp}/c_{pg}, \gamma), \tag{2a}$$

where

$$\tau_d = d_p^2\rho_p/(18\mu_g) \tag{2b}$$

and

$$C_m = n_0 m_p/\rho_g. \tag{2c}$$

In the above, $\bar{\alpha}$ is the attenuation per unit frequency per unit mass fraction, α is the amplitude attenuation coefficient, c_0 is the speed of sound in the gas phase, ω is the circular frequency, C_m is the mass concentration, τ_d is the dynamic relaxation time of the particle (relating to particle-fluid velocity lag), n_0 is the mean number of particles per unit volume of mixture, m_p is the mass of one particle, ρ_p is the mean particle density, ρ_g is the mean density of gas, μ_g is the mean dynamic viscosity of gas, and d_p is the particle diameter. Also the quantity Pr refers to Prandtl number of the gas, c_{pg} is the specific heat of gas, c_{pp} is the specific heat of the particle, and γ is the isentropic exponent (specific-heat ratio). Note that $\alpha = \alpha_i/2$. The results shown in Fig. 1 correspond to $c_{pp}/c_{pg} = 4.17$, $\mathrm{Pr} = 0.71$, and $\gamma = 1.4$ (representative of water droplets in air[14]). With the aid of this nonlinear model, the existence of the spectral peak in the linear absorption coefficient α has been demonstrated.[21]

Based on this extension, good agreement was achieved with the recent data of Norum[22] for sound attenuation in perfectly expanded supersonic jets containing suspended water droplets, which reveal that the linear absorption coefficient displays a spectral peak (Fig. 2, adapted from Ref. 21). The data correspond to hot supersonic jet of air from a convergent-divergent nozzle operation at a jet total temperature $T_t = 867$ K and a jet exit Mach number M_j

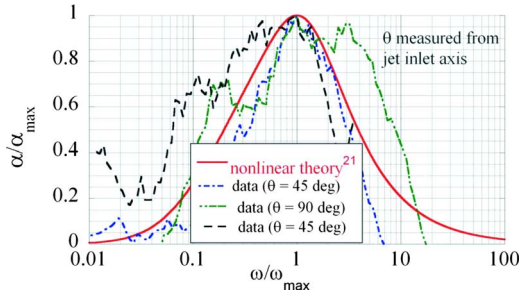

Fig. 2. (Color online) Comparison of the predictions for the linear absorption coefficient with test data of Norum (Ref. 22).

=1.45. The jet Mach number is defined as $M_j = u_j / c_j$, where the subscript j refers to the nozzle exit conditions. The mass flow rate (maximum considered) of water to that of the jet is about 0.85. The angle θ is measured from the jet inlet axis. In the data, water is injected at 45°.

Similar spectral peaks in the attenuation coefficient have been observed in the measurements by Krothapalli *et al.*[23] for microjet injection of water into high speed exhaust jets. Spectral peaks in the linear absorption coefficient in dilute suspensions were also noticed in the experimental data of Richards *et al.*[19,20] covering a frequency range 50–150 kHz.

In the preceding work by the author,[21] results were presented only for sound attenuation with nonlinear particle relaxation, and the effect of nonlinearity on the dispersion effects was not considered. In practical applications such as combustion chamber instability (related to liquid propellants or metallized solid propellants) and exhaust jets with injected water droplets, in addition to sound attenuation (damping of pressure oscillations) the dispersion effects (phase velocity changes) are also important from the standpoint of sound propagation. The present work applies the nonlinear theory for the dispersion of sound in dilute suspensions and compares the linear and nonlinear theories for sound dispersion.

2. Sound dispersion

The present analysis for sound dispersion is similar to that proposed by the author[21] for sound attenuation and will be briefly presented as below. Without any loss of generality, the dispersion of sound for large particle Reynolds numbers with nonlinear particle relaxation may be expressed with the aid of Temkin and Dobbins[14] results as follows:

$$\bar{\beta} = \left[\left(\frac{c_0}{c} \right)^2 - 1 \right] \Big/ \; C_m = \frac{1}{1 + \omega \tau_{d1}^2} + (\gamma - 1) \left(\frac{c_{pp}}{c_{pg}} \right) \frac{1}{1 + \omega^2 \tau_{t1}^2}. \tag{3}$$

In the above the quantity, $\bar{\beta}$ is the dimensionless dispersion coefficient, c_p is the specific heat, c is the actual speed of sound in two-phase medium (phase velocity), and γ is the isentropic exponent (specific-heat ratio). The subscripts g and p, respectively, denote the gas and the particle.

The relaxation times τ_{d1} and τ_{t1} correspond to those under nonlinear drag conditions (generally representative of large-sized particles). Physically the dynamic relaxation time τ_{d1} is a measure of the time scale in which the particles follow (respond to) the fluctuations in the fluid motion.[3] Likewise, the thermal relaxation time τ_{t1} is a measure of the thermal response time of the particles to follow the fluctuations in the temperature of the fluid. They are related to the relaxation times τ_d and τ_t by the relations[21]

$$\tau_{d1} = \tau_d \psi_1(\mathrm{Re}_p), \quad \tau_{t1} = \tau_t \psi_2(\mathrm{Re}_p, \mathrm{Pr}), \tag{4a}$$

where

$$\psi_1(\mathrm{Re}_p) = C_{D1}/C_D, \quad \psi_2(\mathrm{Re}_p, \mathrm{Pr}) = \mathrm{Nu}_1/\mathrm{Nu}, \tag{4b}$$

with C_{D1} standing for the nonlinear drag coefficient and Nu_1 for the nonlinear heat transfer (Nusselt number). In the above, the quantity τ_d is given by Eq. (2b), and

$$\tau_t = \frac{m_p c_{pp}}{2\pi d_p k_g} = \frac{\mathrm{Pr}\, c_{pp} d_p^2 \rho_p}{12 \mu_g c_{pg}} = \left(\frac{3}{2} \right) \left(\frac{c_{pp}}{c_{pg}} \right) \mathrm{Pr}\ \tau_d. \tag{4c}$$

Also the particle Reynolds number Re_p is defined by

$$\mathrm{Re}_p = \rho_g |u_g - u_p| d_p / \mu_g, \tag{4d}$$

where u_g and u_p denote the velocity of the gas and the particle, respectively. Also the quantity $\mathrm{Pr} = c_{pg} \mu_g / k_g$ stands for the Prandtl number of gas, where k_g stands for the thermal conductivity of the gas.

The drag coefficient and the Nusselt number in Eq. (4b) are defined by

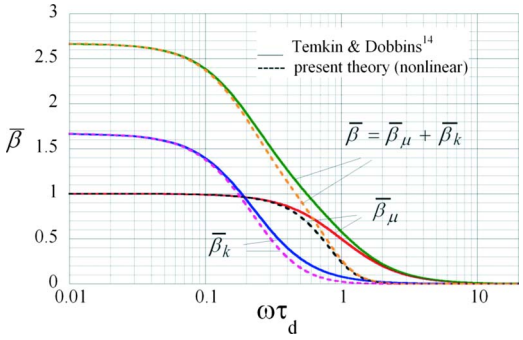

Fig. 3. (Color online) Comparison of the predictions for the dispersion coefficient between the linear and nonlinear theories for particle relaxation.

$$C_D = 2F_p \Big/ \left(\rho_g \frac{\pi}{4} d_p^2 u_g^2\right), \quad \mathrm{Nu} = h_g d_p / k_g, \tag{5}$$

where F_p is the particle drag force, and h_g is the gas-droplet convective heat transfer coefficient. For rigid particles, the linear droplet drag and heat transfer are, respectively, obtained from

$$F_p = 6\pi\mu_g(u_p - u_g), \tag{6a}$$

$$Q_p = 2\pi d_p k_g (T_p - T_g), \tag{6b}$$

which correspond to the zero droplet Reynolds number limit ($\mathrm{Re}_p \to 0$). According to Temkin and Dobbins,[14] Stokes linear drag law can be justified for $0 \le \omega\tau_d \approx 1$, provided that $\rho_g/\rho_p \ll 1$ and $(\omega d_p^2/8\nu_g)^{1/2} \ll 1$.

The expressions for ψ_1 and ψ_2 have been taken as[21]

$$\psi_1(\mathrm{Re}_p) = 1 + \frac{\mathrm{Re}_p}{24}\left(\frac{6}{1+\sqrt{\mathrm{Re}_p}} + 0.4\right), \tag{7}$$

$$\psi_2(\mathrm{Re}_p, \mathrm{Pr}) = \mathrm{Nu}_1/\mathrm{Nu} = 1 + 0.3\ \mathrm{Re}_p^{0.5}\ \mathrm{Pr}^{0.33}. \tag{8}$$

Equation (7) is obtained from Ref. 24, and Eq. (8) is based on Ref. 25.

The determination of particle Reynolds number required in the evaluation of the functions ψ_1 and ψ_2 in Eqs. (7) and (8), respectively, is exceedingly complex. There exists relatively little information on the dependence of particle Reynolds number on the particle characteristics in two-phase flows. In this connection the author[21] postulated that the particle Reynolds number depends only on the particle relaxation time and is independent of the particle to fluid density ratio for large particle to fluid density ratio, and the following power law relation is proposed based on the work of Ref. 26:

$$\mathrm{Re}_p = f(\omega\tau_d) = c(\omega\tau_d)^3. \tag{9}$$

The adjustable constant c is determined from a correlation of the theory with the test data. A value of $c = 10$ was found to be satisfactory based on the data of Norum[21] for water droplets in a supersonic air jet (Fig. 2).

3. Results and comparison

Figure 3 illustrates a comparison of the predictions for the dispersion coefficient between the linear and nonlinear theories for particle relaxation. The results are shown for $c_{pp}/c_{pg} = 4.17$, $\mathrm{Pr} = 0.71$, and $\gamma = 1.4$ (representative of water droplets in air[14]). The contributions of viscosity and the thermal conductivity along with their combined effect on the dispersion coefficient are shown for

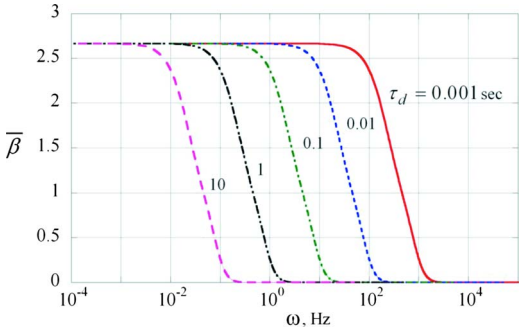

Fig. 4. (Color online) Variation in dispersion coefficient with frequency for various values of particle relaxation time.

both linear and nonlinear relaxations. It is seen that the nonlinear effects become important for $\omega\tau_d > 0.2$ (where heat conduction effects become important). With regard to the viscous contribution, nonlinearities are manifested for somewhat higher values of $\omega\tau_d$ in excess of about 0.4. The results also suggest that the nonlinear effect is more significant in the viscous contribution relative to that of thermal conduction. With nonlinear particle relaxation, the total dispersion coefficient approaches zero for smaller values of $\omega\tau_d$ than those in the case of linear relaxation.

The predictions for the dependence of the dispersion coefficient (yielding the phase velocity c) on the frequency for various values of the dynamic relaxation time τ_d is presented in Fig. 4. For example, the dynamic relaxation time τ_d for silica particles in air is about 10^{-3} s for a 5 μm particle and about 10^{-1} s for a 50 μm particle.[8] On the other hand, the thermal relaxation times for particles in air are about 5×10^{-4} s for a 5 μm particle and about 5×10^{-2} s for a 50 μm particle. For comparison purposes, the molecular and thermal relaxation time scales are of the order of 10^{-10} s for gases. The results suggest that as the particle relaxation time increases, the dispersion curve is shifted to lower frequencies, as is to be expected.

It is believed the nonlinear particle relaxation effects on sound attenuation and dispersion will be of interest in the prediction of jet noise reduction by water injection.[27–29]

4. Conclusion

The theory of nonlinear particle relaxation proposed previously for sound attenuation in dilute suspensions has been extended to investigate the effect of nonlinearity on sound dispersion. The results reveal that significant nonlinear effects are noticed at relatively large particle relaxation times. It is also observed that the nonlinear effect on dispersion due to viscous contribution is larger relative to that of thermal conduction.

LETTERS TO THE EDITOR

This Letters section is for publishing (a) brief acoustical research or applied acoustical reports, (b) comments on articles or letters previously published in this Journal, and (c) a reply by the article author to criticism by the Letter author in (b). Extensive reports should be submitted as articles, not in a letter series. Letters are peer-reviewed on the same basis as articles, but usually require less review time before acceptance. Letters cannot exceed four printed pages (approximately 3000–4000 words) including figures, tables, references, and a required abstract of about 100 words.

Causal analysis of the viscoelastic Lamb problem (L)

André Moura[a)]
Institute of Physical Chemistry, University of Heidelberg, Im Neuenheimer Feld 253, 69120 Heidelberg, Germany

(Received 25 April 2009; revised 26 October 2009; accepted 11 December 2009)

A mathematical development is given for the generation of viscoelastic waves by an impulsive line source acting on the interface of a viscoelastic half space, where the viscoelasticity is characterized by two relaxation processes. The considered idealized viscoelastic medium is isotropic and characterized by two Lamé constants appropriate for low frequencies, by their increments associated with the shift from low to high frequencies, and by separate relation times associated with each of the Lamé constants. A causal solution is developed using integral transforms and an extension of Cagniard's method [DOI: 10.1121/1.3290981]

PACS number(s): 43.35.Mr, 43.20.Bi, 43.20.Px [WMC] Pages: 1185–1188

I. INTRODUCTION

The viscoelastic Lamb problem is solved by means of a natural extension of the method we used to solve one-wave propagation problem,[1] which is based on the works of Ludvig and Levin[2] and the approach initiated by Strick.[3]

Lamb originally solved the homogeneous isotropic elastic half space problem for an impulse normal load acting on the free surface in order to analyze the Rayleigh wave contribution to the displacement field, i.e., the famous well-known surface wave in seismology theoretically predicted by Rayleigh in the framework of elastodynamics. Lamb's problem now refers to general source/medium geometries with a single interface and the main interest is the exact calculation in the time domain of waves emanating from an impulsive line or point source.

For ultrasonic or seismic waves, "friction" refers to the overall sum of all mechanisms responsible for the lost of elastic potential energy. We restrain our self to the losses due to viscosity because of the existence of a well-known mathematical procedure that conserves the causal aspect from the elastic to the viscoelastic problem, i.e., the so-called viscoelastic correspondence principle. Thus, consider the medium of propagation as a viscoelastic homogeneous continuum, and the problem is formulated in the framework of linear continuum mechanics in Eulerian representation. For the sake of simplicity and without lost of generality, we consider a two-dimensional problem instead of a three-dimensional one, i.e., the homogeneous isotropic viscoelastic half space problem for an infinite impulse normal line load acting on the free surface.

[a)]Electronic mail: moura@uni-heidelberg.de

II. PROBLEM FORMULATION

Let us consider a viscoelastic homogeneous half space V to the sense of the continuum mechanics. The outer of the half space is supposed to be occupied by vacuum. Hence waves can only propagate in the half space. In order to write the boundary conditions, the points of the space are represented in a Cartesian coordinate system $(Oxyz)$ with the Oxy-plane defining the free surface S and the Oz-axis oriented toward the interior of V. Application of an infinite spatially uniform line load over the free surface renders the problem two dimensional, and for the sake of simplicity and without lost of generality, one will orient it along the Oy-axis. Moreover, because of the problem symmetry with respect to the Oz-axis, only positive values of x are considered.

The elastic properties are defined by the Lamé constants λ_0 and μ_0, and the related relaxation functions for the special case of linear viscoelastic solid write, respectively,[4]

$$\lambda(t) = \frac{\lambda_0}{\lambda_0 + \lambda_1}(\lambda_1 + \lambda_0 \exp(-t/\tau_0)) \quad \text{and}$$

$$\mu(t) = \frac{\mu_0}{\mu_0 + \mu_1}(\mu_1 + \mu_0 \exp(-t/\omega_0)), \tag{1}$$

where λ_o (μ_o), λ_1 (μ_1), and τ_o (ω_o) are constants, with the first corresponding to the Lamé elastic constant and the last to the relaxation time with t, the time. The dilatational and shear elastic wave velocities then become

$$c_d = \sqrt{(\lambda_0 + 2\mu_0)/\rho} \quad \text{and} \quad c_s = \sqrt{\mu_0/\rho}, \tag{2}$$

respectively, with ρ, the mass density, from which the velocities are deduced from the two following wave equations in the elastic case:

$$\partial_{xx}^2\varphi+\partial_{zz}^2\varphi=\frac{1}{c_d^2}\partial_{tt}^2\varphi \quad \text{and} \quad \partial_{xx}^2\psi+\partial_{zz}^2\psi=\frac{1}{c_s^2}\partial_{tt}^2\psi, \tag{3}$$

where φ and ψ are the scalar potential and the nonvanishing component of the vector potential, respectively, and the operator ∂ denotes the derivative. For instance, ∂_{xx}^2 means the second-order spatial derivative with respect to x.

Because we restrain our self to the sake of the Green's function, one considers an impulsive load, and writes both the source and the boundary-initial conditions on S together as follows:

$$\partial_t(\lambda(t)(\partial_{xx}^2\varphi+\partial_{zz}^2\varphi)+2\mu(t)(\partial_{zz}^2\varphi+\partial_{xz}^2\psi))=-F\delta(t)\delta(x), \tag{4}$$

$$2\partial_{xz}^2\varphi+\partial_{zz}^2\psi-\partial_{xx}^2\psi=0, \tag{5}$$

where δ denotes the Dirac delta function, the asterisk represents the time convolution, and the constant F represents a force per unit length. Additionally, we impose the following radiation conditions in order to work only with bounded physical functions:

$$\lim_{z\to+\infty}\varphi(x,z,t)=\lim_{z\to+\infty}\psi(x,z,t)=0. \tag{6}$$

III. APPLICATION OF SPECIAL INTEGRAL TRANSFORMS

The method we used to solve the one-wave propagation problem is totally transposable, and the only main originality here is to apply two different two-sided spatial Laplace transforms on the variable x whether φ or ψ is considered. The overbar and the tilde refer to φ and ψ, respectively. Hence, to be concise, many intermediary calculations and mathematical aspects of the presentation will be omitted. Thus, let us define the one-sided Laplace transforms with respect to time as

$$\bar{\varphi}(x,z,s)=\int_0^{+\infty}\varphi(x,z,t)\exp(-st)dt,$$

$$\bar{\psi}(x,z,s)=\int_0^{+\infty}\psi(x,z,t)\exp(-st)dt, \tag{7}$$

the double-sided Laplace transforms

$$\tilde{\bar{\varphi}}(p,z,s)=\int_{-\infty}^{+\infty}\bar{\varphi}(x,z,s)\exp(f(s)px)dx,$$

$$\hat{\bar{\psi}}(p,z,s)=\int_{-\infty}^{+\infty}\bar{\psi}(x,z,s)\exp(g(s)px)dx, \tag{8}$$

and use the following viscoelastic correspondences:

$$\mu_o\leftrightarrow s\bar{\lambda}(s), \quad \mu_o\leftrightarrow s\bar{\mu}(s), \tag{9}$$

where

$$\bar{\lambda}(s)=\frac{\lambda_o}{\lambda_o+\lambda_1}\left(\frac{\lambda_1}{s}+\frac{\lambda_o}{s+1/\tau_o}\right),$$

$$\bar{\mu}(s)=\frac{\mu_o}{\mu_o+\mu_1}\left(\frac{\mu_1}{s}+\frac{\mu_o}{s+1/\omega_o}\right), \tag{10}$$

are the time Laplace transforms of the relaxation functions, with

$$f(s)=\sqrt{s\frac{\lambda_o+2\mu_o}{\bar{\lambda}(s)+2\bar{\mu}(s)}}=c_d\sqrt{\frac{s\rho}{\bar{\lambda}(s)+2\bar{\mu}(s)}},$$

$$g(s)=c_s\sqrt{\frac{s\rho}{\bar{\mu}(s)}}, \tag{11}$$

then we seek for two unknown functions $\tilde{\bar{A}}(p,s)$ and $\tilde{\bar{B}}(p,s)$ such that

$$\tilde{\bar{\varphi}}(p,z,s)=\tilde{\bar{A}}(p,s)\exp(-f(s)\eta_d z),$$

$$\hat{\bar{\psi}}(p,z,s)=\hat{\bar{B}}(p,s)\exp(-g(s)\eta_s z), \tag{12}$$

$$\eta_d=\sqrt{1/c_d^2-p^2}, \quad \eta_s=\sqrt{1/c_s^2-p^2}. \tag{13}$$

Note that although at this step the dual variables s and p can be considered as real numbers, the functions f, g, η_d, and η_s can be complex valued; thus, in order to both verify Eq. (6) and uniquely define the square root function, we choose the branch cut along the negative real axis of the complex plane, for instance, $]-\infty,-1/c_d]$ and $]-\infty,-1/c_s]$ for η_d and η_s, respectively, in the complex p-plane. The real and imaginary parts of complex number will be noted Im and Re, respectively.

Now, because $\tilde{\bar{A}}(p,s)$ and $\hat{\bar{B}}(p,s)$ must verify the boundary-initial conditions (4) and (5), we obtain the following system:

$$\begin{pmatrix}\left(\frac{\bar{\lambda}(s)+2\bar{\mu}(s)}{c_d^2\bar{\mu}(s)}-2p^2\right)f(s) & 2p\eta_s g(s)\\ -2p\eta_d f(s) & \left(\frac{1}{c_s^2}-2p^2\right)g(s)\end{pmatrix}\begin{pmatrix}\tilde{\bar{A}}(p,s)\\ \hat{\bar{B}}(p,s)\end{pmatrix}=\begin{pmatrix}-\frac{F}{\bar{\mu}(s)}\\ 0\end{pmatrix}, \tag{14}$$

where the Dirac delta function is defined either from the first or the second following double equality:

$$\delta(x)=\frac{f(s)}{2i\pi}\int_{-i\infty+a}^{+i\infty+a}\exp(-f(s)px)dx=\frac{g(s)}{2i\pi}\int_{-i\infty+a}^{+i\infty+a}\exp(-g(s)px)dx, \tag{15}$$

depending on whether we extract $\tilde{\bar{A}}(p,s)$ or $\hat{\bar{B}}(p,s)$, respectively, in Eq. (14), where a is a positive real number, and i

denotes the unit complex number. The potentials can be written as

$$\varphi(x,z,t) = -\frac{F}{2i\pi}\int_{-i\infty+a}^{+i\infty+a}\frac{1}{\bar{\mu}(s)}\exp(st)ds\frac{1}{2i\pi}\int_{-i\infty+b}^{+i\infty+b}\frac{1/c_s^2-2p^2}{R(p,s)} \times\exp(-f(s)(\eta_d z+px))dp, \tag{16}$$

$$\psi(x,z,t) = -\frac{F}{2i\pi}\int_{-i\infty+a}^{+i\infty+a}\frac{1}{\bar{\mu}(s)}\exp(st)ds\frac{1}{2i\pi}\int_{-i\infty+b}^{+i\infty+b}\frac{2p\eta_d}{R(p,s)} \times\exp(-g(s)(\eta_s z+px))dp, \tag{17}$$

where b is a real number belonging to the strip of convergence defined by $-1/c_d<\mathrm{Re}(s)<1/c_d$, whereas κ and the Rayleigh function R write

$$\kappa(s) = \frac{\bar{\lambda}(s)+2\bar{\mu}(s)}{\bar{\mu}(s)} \quad \text{and} \quad R(p,s) = \left(\frac{\kappa(s)}{c_d^2}-2p^2\right)\left(\frac{1}{c_s^2}-2p^2\right) + 4\eta_d\eta_s p^2, \tag{18}$$

respectively. First, given that s is initially considered to be a positive real number, the inner integrals in Eqs. (16) and (17) are performed via the well-known Cagniard change in variable. Second, the outer integrals on s are performed in the complex s-plane along appropriate Bromwich's path by analytical continuation.[5] These two integrations are thoroughly described in our previous publication on one-wave propagation problem,[1] and the calculations are not repeated here. Particularly, it is expedient to show that the branch points,

$$s_0 = 0, \quad s_{a_1} = -\frac{1}{\tau_o}, \quad s_{a_2}, s_{a_3}, s_{b_1} = -\frac{1}{\omega_o}, \quad s_{b_2} = -\frac{\mu_o}{\mu_o+\mu_1}\frac{1}{\omega_o}, \tag{19}$$

are not essential singularities, which verify with, for instance, $\omega_o>\tau_o$,

$$s_{a_1}<s_{a_2}<s_{b_1}<s_{a_3}<s_{b_2}<s_0, \tag{20}$$

where s_{a_2} and s_{a_3} are the two negative real solutions of the following quadratic equation:

$$\bar{\lambda}(s)+2\bar{\mu}(s)=0. \tag{21}$$

Moreover the Rayleigh pole location on the complex p-plane depends on the function $\kappa(s)$ but is still located on the positive real axis as s is initially assumed to be a positive real number. In order to shorter the presentation, the displacement on the free surface for which the Rayleigh pole contribution is involved is not discussed here. We will deal only with an arbitrary point in the interior of the half space.

IV. PROBLEM SOLUTION

After the Cagniard changes in variables,[6]

$$\eta_d z+px=\tau \quad \text{and} \quad \eta_s z+px=\tau, \tag{22}$$

the inner integrals in Eqs. (16) and (17) are integrated along the Cagniard contours $p(\tau)$ parametrized with the positive real variable τ. This procedure is now well known for solving the corresponding elastic solution.[7,8] The outer integrals in Eqs. (16) and (17) are performed by analytical continuation around the branch cuts located on the real axis of the complex s-plane $[s_{a_1},s_{a_2}]\cup[s_{b_1},s_{a_3}]$ and $[s_{b_1},s_{b_2}]$, respectively. The final result for the interior points, $z>0$, repaired in polar coordinates (r,θ), is concisely summarized as follows:

$$\varphi(x,z,t) = H(t-t_d)\frac{F}{\pi^2}\int_{s\in I}\frac{1}{\bar{\mu}(s)}ds\int_{t_d}^{t}\mathrm{Im}\left[\alpha(p_d(\tau))\frac{dp_d(\tau)}{d\tau}\right] \times\cos(f(s)(t-\tau))d\tau, \tag{23}$$

$$\psi(x,z,t) = H(t-t_s)\frac{F}{\pi^2}\int_{s\in J}\frac{1}{\bar{\mu}(s)}ds\int_{t_s}^{t}\mathrm{Im}\left[\beta(p_s(\tau))\frac{dp_s(\tau)}{d\tau}\right] \times\cos(g(s)(t-\tau))d\tau + H(t-t_{ds})H(\theta-\theta_c)\frac{F}{\pi^2}\int_{s\in J}\frac{1}{\bar{\mu}(s)}ds\int_{t_{ds}}^{t}\mathrm{Im}\left[\beta(p_{ds}(\tau))\frac{dp_{ds}(\tau)}{d\tau}\right] \times\cos(g(s)(t-\tau))d\tau, \tag{24}$$

where

$$I=[s_{a_1}+i\varepsilon,s_{a_2}+i\varepsilon]\cup[s_{b_1}+i\varepsilon,s_{a_3}+i\varepsilon],$$

$$J=[s_{b_1}+i\varepsilon,s_{b_2}+i\varepsilon], \quad (\varepsilon\to 0^+), \tag{25}$$

$$\alpha(p)=\frac{1/c_s^2-2p^2}{R(p,s)}, \quad \beta(p)=\frac{2p\eta_d}{R(p,s)}, \tag{26}$$

$$p_d(\tau)=c_d\tau/r\,\sin\theta+i[(c_d\tau/r)^2-1]^{1/2}\cos\theta, \tag{27}$$

$$p_s(\tau)=c_d\tau/r\,\sin\theta+ik[(c_s\tau/r)^2-1]^{1/2}\cos\theta, \tag{28}$$

$$p_{ds}(\tau)=c_d\tau/r\,\sin\theta+ik[1-(c_s\tau/r)^2]^{1/2}\cos\theta, \quad (k=c_d/c_s), \tag{29}$$

$$r=\sqrt{x^2+z^2}, \quad \theta=\arctan(x/z), \quad \theta\in[0,\pi/2], \tag{30}$$

$$t_d=r/c_d, \quad t_s=r/c_s, \quad t_{ds}=r/c_d[\sin\theta+\sqrt{k^2-1}\cos\theta], \quad \theta_c=\arcsin(1/k), \tag{31}$$

where H denotes the unit step function, t_d, t_s, and t_{sd} denote the travel times of the dilatational, shear, and head waves, respectively. Note briefly that the second term in Eq. (24) identifies the head wave, as the contour $p_s(\tau)$ intercepts the branch cut on the real p-axis, $[1/c_d,+\infty$ (, for $\theta>\theta_c$.

V. CONCLUSION

A full resolution of the viscoelastic half space Lamb problem was proposed from an extension of Cagniard's method. More generally, the developed method of resolution can be the basis for natural extension from elastodynamics to viscoelastodynamics of numerous existing analytical problem solutions. This extension can help the acoustician to a

better understanding of the wave conversion at an interface in presence of dispersion via the generation of the head wave.

(Received 31 August 2009; revised 15 December 2009; accepted 18 December 2009)

Nonlinear excitation of periodic shock waves in high-amplitude standing waves was studied from measurements of the acoustic intensity. A gas column of atmospheric air in a cylindrical resonator was driven sinusoidally by an oscillating piston at the fundamental resonance frequency. Acoustic pressure and axial acoustic particle velocity were simultaneously measured and decomposed into the Fourier components, from which the intensity associated with each of the oscillating modes in the resonator was determined. This letter reports the energy cascade from the driven mode to the second harmonic in the periodic shock waves in the resonator.

When a gas column in an acoustic resonator of finite Q value is periodically perturbed by a piston oscillating at frequencies away from the resonance frequencies, the gas oscillations are continuous. But as the driving frequency approaches the fundamental resonance frequency, nonlinear effects in gas dynamics give rise to periodic shock waves.[1–5] Notably in the long history of the study of this problem,[6] a great contribution has been made by Chester.[1] He derived a nonlinear differential-integral equation to solve the problem to second order from basic equations of hydrodynamics and succeeded in obtaining either continuous or discontinuous solutions depending on the frequency. The temporal waveform predicted by his solution was experimentally verified by Cruikshank[2] through measurements of the acoustic pressure at the rigid end of the resonator.

Wave distortion in the time domain is thought of as generation of harmonic oscillations in the frequency domain. The idea of energy cascade presented by Coppens and Sanders[7] explains the successive energy transfer from the driven mode to the higher harmonics in finite-amplitude standing waves, which led to development of the novel methods for suppressing shock waves. Lawrenson *et al.*[8] achieved a very high-amplitude shock-free oscillation using a *dissonant* resonator in which the overtones are not integer multiples of the fundamental frequency.[9] Sugimoto *et al.*[10,11] made use of wave dispersion caused by an array of Helmholtz resonators and successfully created a solitary sound wave instead of the shock wave. These methods play important roles in upgrading the performance of acoustic compressors and thermoacoustic heat engines since excitation of the harmonics limits the attainable acoustic pressure to about 10% of the filling pressure.[12] Although techniques have been found for inhibiting shock formation, little experimental attention has been directed to the question of how the acoustic energy is pumped up from the fundamental mode to the harmonics.

In order to answer this question, we focus on the acoustic intensity I of the gas column. Measurements of I have become possible recently through the simultaneous measurements of acoustic pressure P and axial acoustic particle velocity U (Ref. 13) and have been applied to the study of spontaneous gas oscillations in thermoacoustic systems.[14,15] The observation of the positive *work source* gave clear experimental insight into the generation of sound by heat.[16–19] We apply this method to the problem of nonlinear acoustic gas oscillation and observe how harmonics are generated. This paper documents the energy cascade which creates the shock wave in the resonator.

Acoustic intensity I represents the time-averaged acoustic power flux per unit cross-sectional area and is given by

$$I = \langle PV \rangle, \tag{1}$$

where V is the cross-sectional average of U, and angular brackets represent the time average. The *work source*

$$w = \mathrm{div}\, I \tag{2}$$

is equivalent to the time-averaged acoustic power production per unit volume. For a resonator closed at one end and driven by an acoustic driver at the other end, I flows down the resonator and its magnitude monotonically decreases to zero at the closed end. The negative w in this case means the rate of acoustic power dissipation, whereas a positive w represents acoustic power production.[16–19] Within the framework of linear acoustic theory, w is accounted for by surface attenuations at the tube wall due to viscosity and thermal conductivity of the gas and can be evaluated if the acoustic amplitude is given, as we will show later. We confirmed that the experimental w agreed with the theoretical one within the experimental error when the acoustic pressure was below 1% of the mean pressure.[20] Thus, a theoretical w given from the acoustic amplitude can serve as a good measure of acoustic power dissipation caused through a linear damping mechanism.

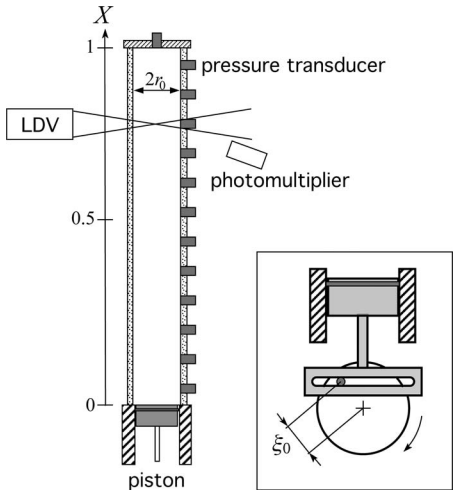

FIG. 1. Experimental setup. The oscillating piston at the bottom of the resonator was driven by a scotch yoke mechanism shown in the inset. Axial coordinate X was normalized with respect to the resonator length L. Pressure and velocity were measured at evenly spaced positions along X.

A schematic illustration of the experimental setup is shown in Fig. 1. Air at atmospheric pressure was confined in a cylindrical glass tube of length $L=1.15$ m and internal radius $r_0=10.5$ mm. One end of the tube was closed by a rigid plate, while the other was connected to a piston unit having a constant displacement amplitude $\xi_0=0.7$ mm. The unit employs a scotch yoke mechanism which ensures the piston's pure sinusoidal motion, as noted by Merkli and Thomann.[21] Thus, our acoustic driver excites only the fundamental oscillation and has no direct connection to the generation of harmonic oscillations. Before measurements of the acoustic intensity I, the shock region was confirmed from observation of the acoustic pressure at the closed end when the operating frequency of the piston was changed. It was found that the shock appeared in the region from 142 to 147 Hz, which coincided with the fundamental resonance frequency of the tube.

Simultaneous measurements of P and U were conducted at the frequency $f=144.4$ Hz. The corresponding piston's Mach number $M_P=\omega\xi_0/a$ is 1.8×10^{-3}, where ω $(=2\pi f)$ is the angular frequency of the piston, and a is the speed of sound in air (=344 m/s). The pressure $P(X,t)$ along the tube axis was measured by small pressure transducers (Kulite XT-190, natural frequency 350 kHz). The transducers were flush mounted on the tube wall and were arranged at an equidistant spacing from each other. The axial velocity $U(X,t)$ on the central axis of the tube was measured at the same axial positions as the pressure measurements using a laser Doppler velocimeter. Signal voltages of the pressure and velocity were sampled at high and low sampling frequencies of 102.4 and 2.56 kHz using a 24-bit spectrum analyzer (Onosokki Graduo).

Figure 2 shows the spatial and temporal evolutions of the periodic shock wave induced in the resonator. The time series of $P(X,t)$ and $U(X,t)$ sampled at the higher sampling frequency (102.4 kHz) is plotted with vertical offsets proportional to the measurement positions. It is seen that the shock front travels back and forth in the resonator at the speed of sound, bouncing off the solid end once per acoustic period $(=1/f)$. The pressure and velocity measured at the same axial position show the discontinuity at the same time, but their waveforms are significantly different. The pressure tends to form a sawtooth wave, whereas the velocity tends to form a rectangular wave with the highest peak to peak velocity at

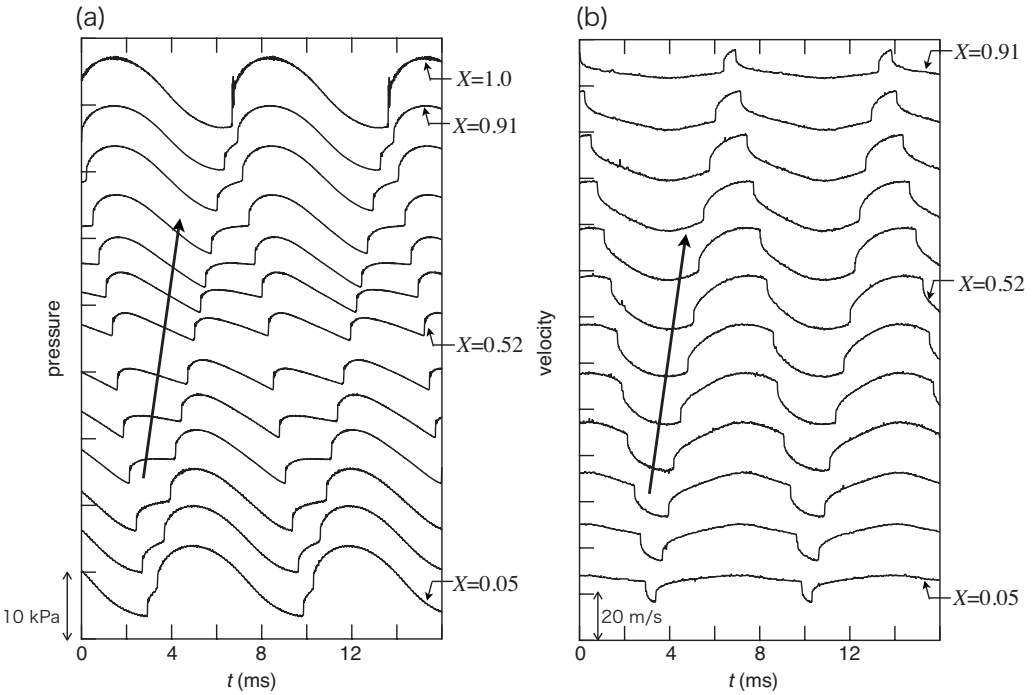

FIG. 2. Spatial and temporal variations in the periodic shock wave in the resonator. Pressure (a) and central velocity (b) are shown with vertical offsets according to their axial positions. Data with the largest X near the closed end are plotted at the top, whereas those near the driver end are plotted at the bottom. Arrows represent the propagation of the shock front.

the middle of the resonator corresponding to the pressure node.

Several experimental studies report the stability diagram of the oscillatory flow in tubes in terms of the Reynolds number $\mathrm{Re}_{\mathrm{OS}}$ based on the velocity amplitude defined as $\mathrm{Re}_{\mathrm{OS}} \equiv 2r_0 V/\nu$, and the square root of the non-dimensional frequency $\sqrt{\omega'}$ given by $\sqrt{\omega'} = \sqrt{2} r_0/\delta$, where δ is the viscous penetration depth ($\delta = \sqrt{2\nu/\omega}$, where ν is the kinematic viscosity of the gas). Acoustic turbulence takes place in the region satisfying both $2 \times 10^3 < \mathrm{Re}_{\mathrm{OS}}$ and $780\sqrt{\omega'} < \mathrm{Re}_{\mathrm{OS}}$.[21–23] The largest $\mathrm{Re}_{\mathrm{OS}}(=1.7 \times 10^4)$ in the present experiment ($\sqrt{\omega'} = 81$) was far below the critical Reynolds number $\mathrm{Re}_{\mathrm{OS}} \sim 6.3 \times 10^4$. Furthermore, we did not observe turbulent bursts which should appear as the manifestation of turbulent flow. These facts permit us to treat the present experimental data as laminar flow.

In order to determine I associated with each oscillating mode, we decompose the pressure and velocity sampled at the lower sampling frequency into Fourier components as

$$P = \sum_n p_n e^{in\omega t} \tag{3}$$

and

$$U = \sum_n u_n e^{in\omega t} \tag{4}$$

via the fast-Fourier-transform algorithm, where p_n and u_n are the complex amplitudes of the nth component of pressure and velocity. The fundamental and the second harmonic mode correspond to $n=1$ and $n=2$, respectively. The acoustic intensity I is rewritten as

$$I = \sum_n I_{2n}, \tag{5}$$

where

$$I_{2n} = \tfrac{1}{2}|p_n||v_n|\cos\,\phi_n. \tag{6}$$

Here, v_n represents the nth component of the cross-sectional mean velocity V, and $\phi_n(=\arg(p_n/v_n))$ is the phase lead of v_n to p_n. The velocity component v_n was determined from the measured central velocity u_n on the basis of the laminar oscillating flow theory.[20]

Figure 3(a) shows the experimental acoustic intensity I_2 determined using Eq. (6). The sign of I_2 was positive everywhere in the resonator, showing that the acoustic power flux consistently flowed in the direction from the driver end ($X=0$) to the closed end ($X=1$). This means that the solid piston supplies the acoustic power necessary to sustain the gas oscillation. The negative work source $w_2 = dI_2/dx$ ($x=LX$) observed throughout the resonator represents the dissipative power per unit volume and time, the average of which is found to be -1430 W/m^3. This is significantly larger than that expected in a linear standing wave with the same acoustic amplitude, as we show below.

Linear acoustic theory states that the total dissipation $\dot{E}$ is given by[12]

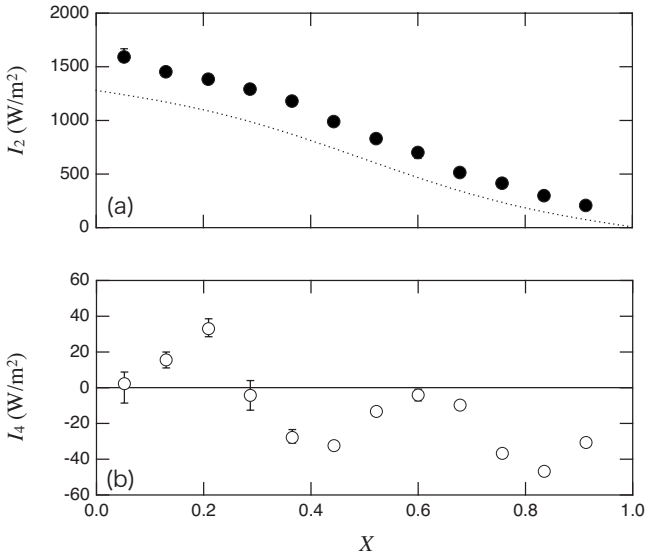

FIG. 3. Axial distribution of the acoustic intensity I_2 (a). The dotted curve represents the theoretical intensity estimated using the measured $p_{\max}$ through the linear acoustic theory. The intensity I_4 is shown in (b).

$$\dot{E} = \omega\pi r_0^2 L \frac{p_{\max} v_{\max}}{4a} \frac{\delta}{r_0}\left(1 + \frac{\gamma - 1}{\sqrt{\sigma}}\right), \tag{7}$$

where $p_{\max}$ and $v_{\max}$ are the maximum amplitudes of the pressure and velocity, and γ and σ are the ratio of isobaric to isochoric specific heats and Prandtl number of the gas. The average rate of the energy dissipation per unit volume, which we call the theoretical work source, is simply given by $\dot{E}$ divided by the internal volume $\pi r_0^2 L$. Using observed $p_{\max}$ (=5170 Pa) and $v_{\max}$ (=12.4 m/s), we obtain a theoretical work source of -1120 W/m^3 for the present acoustic oscillation. Therefore, the experimental work source w_2 exceeds the theoretical one by 28%. The theoretical work source should account for the surface attenuation due to the viscosity and the thermal conductivity of the gas. Thus, we attribute the extra damping given by the difference $\Delta w_2 = -310$ W/m^3 of the experimental work source w_2 from the theoretical one to the acoustic power consumed for the excitation of the higher harmonics.

Figure 3(b) shows the acoustic intensity I_4 associated with the second harmonic. Even though a positive work source is not found in the fundamental mode, it is clearly observed that I_4 increases in regions $0 < X < 0.2$, $0.4 < X < 0.6$, and $0.8 < X < 1.0$, demonstrating the acoustic power production. This positive w_4, reaching 170 W/m^3 at $X = 0.13$, represents the energy pumping from the driven mode to the second harmonic. Disappearance of I_4 at the driver end is reasonable because of the pure sinusoidal motion of the piston. Therefore, the second harmonic is produced by the gas column through nonlinear interaction between the oscillating modes. A very steep negative slope (-140 W/m^3) is observed near the sink of I_4 at $X=0.3$ that I_4 flows into from both sides, and the flow direction of I_4 becomes opposite when $X > 0.3$. The theoretical work source caused by the linear damping mechanism is estimated to be -91 W/m^3 using Eq. (7) based on the axial distribution of the Fourier components p_2 and v_2. The rest of Δw_2 should have a close

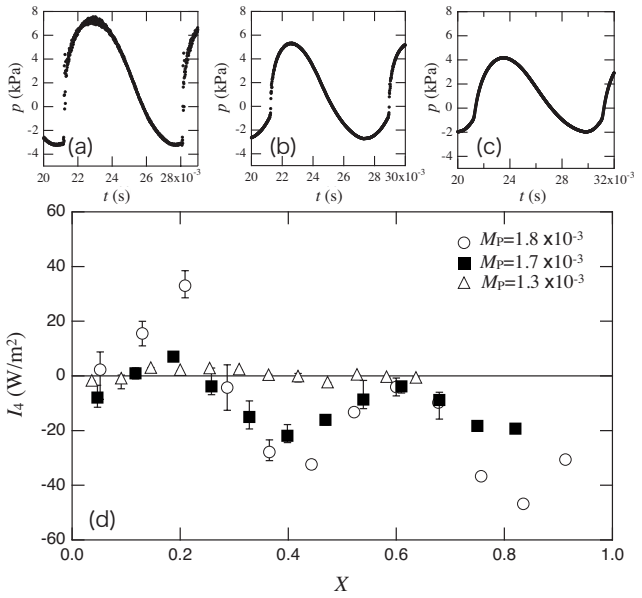

FIG. 4. Temporal variation in the pressure observed at the rigid end of the resonator when $M_P=1.8\times10^{-3}$ (a), 1.7×10^{-3} (b), and 1.3×10^{-3} (c). Axial distribution of the acoustic intensity I_4 is plotted in (d). Symbols correspond to the data with $M_P=1.8\times10^{-3}$ (○), 1.7×10^{3} (■), and 1.3×10^{-3} (△), respectively.

relation to the energy cascade process to the higher harmonics with $n>3$.

In order to see how the characteristic behavior of I_4 is related to the generation of the shock waves, we conducted the same measurements with the piston's Mach numbers $M_P=1.7\times10^{-3}$ and 1.3×10^{-3}. Smaller values of M_P were achieved by using longer glass cylinders, which reduces the fundamental resonance frequency. The piston displacement was kept at $\xi_0=0.7$ mm. Figures 4(a)–4(c) show the temporal pressure waveforms observed at the closed end, and Fig. 4(d) shows the corresponding axial distribution of I_4. We can verify that the energy cascade is executed in the same axial positions, but it becomes gradually weaker with the lower M_P. In response to such changes, the shock disappears when M_P is the lowest, as shown in Fig. 4(c). Hence, it is concluded that the energy pumping from the second harmonic leads to the formation of the shock wave in the resonator. If we can suppress the positive w_4 distributed in the resonator, a new method would be found to annihilate shock waves in the resonator.

Although we have focused on the intensities I_2 and I_4 in the present study, the higher order intensities would be of importance in shock waves that have shock fronts reaching 80% of the mean pressure.[5] Intensity measurements may also give some insight into the fascinating nonlinear processes in high-amplitude acoustics such as the acoustic soliton[11] and acoustic chaos.[24]

Active control of one-dimension impulsive reflection based on a prediction method (L)

Ning Han,[a] Shengzhen Feng, and Xiaojun Qiu
Key Laboratory of Modern Acoustics and Institute of Acoustics, Nanjing University, Nanjing 210093, China

(Received 6 March 2009; revised 19 July 2009; accepted 31 December 2009)

An approach for predicting the reflected sound pressure is proposed in one-dimensional sound field. For a duct ended with a rigid reflective surface, only one microphone is required to measure the total sound pressure on the surface, which is further used as the error sensing strategy in an active noise control (ANC) system to reduce the in-duct reflection. Experiments are carried out to validate the prediction method, and a broadband feedforward ANC system is implemented to suppress the impulsive reflection. It is found that the ANC system based on the reflected sound prediction is effective, and 12.2 dB attenuation of the one-dimension impulsive reflection is obtained after the active control. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3295691]

I. INTRODUCTION

Active noise control (ANC) usually aims at reducing the total sound pressure radiated by a noise source; it may also be applied to reduce the reflected sound from a reflective body, which is useful for extending the low frequency range of wedges for building anechoic rooms or making an object invisible to incident detecting waves. Bao *et al.*[1–3] proposed a piezocomposite actuator for absorbing both the reflection and the transmission of normally incident waves. Experiments were presented for one-dimensional incident plane waves. Lafleur *et al.*[4,5] used the piezoelectric material to form active surfaces. Measurements in a tube indicated that the single layer can eliminate either the reflection or transmission, while the double layers eliminated both of them.

Guicking and Karcher[6] investigated the active impedance control for one-dimensional sound. The reflection coefficient was smaller than 0.05 from 100 to 1000 Hz. Orduña-Bustamante and Nelson[7] made a secondary source to be an active sound absorber in a duct, which can work with periodic, random, and transient input signals. Smith *et al.*[8] implemented a broadband hybrid absorption system in an impedance tube and found that the impedance matching method can provide better absorption than that achieved in the pressure-release method. Finneran and Hastings[9] adjusted the acoustic pressure/particle velocity ratio to match that of a plane wave in an active control system. Recently, Cobo and Cuesta[10,11] confirmed that releasing the sound pressure at the rear face of materials can provide active absorption at normal and oblique incidences. The direct and reflected events were picked up by time windowing.

For the direct control of the in-duct reflection, the wave separation algorithm[12] was used to separate the reflected and the incident waves, where the reflected sound pressure at the midpoint of two microphones is calculated through the measured signals. The two microphones cannot be positioned practically too close for the low frequency limitation or too far for the high frequency limitation. Friot and Bordier[13] introduced a method to distinguish the three-dimension scattered sound pressure from the total sound field and then suppressed it by ANC system. Preliminary result was given for one-dimension cases with more than 10 dB reflected noise reduction below 800 Hz. But the method for distinguishing the reflection is complex to implement, and the experimental control effect can only be obtained by comparing the noise without and with the rigid reflective surface. In the present paper, the impulsive wave will be chosen as the primary sound; thus the control effect can be obtained directly by comparing the amplitudes of the impulsive reflections before and after the active control.

Virtual sensing is a novel active control technique, and microphone arrays were used to predict the information at the virtual error sensor.[14–16] The concept of the virtual error sensing will be employed in this paper differently since the reflected sound pressure, which needs to be controlled, cannot be obtained directly by locating a physical sensor there. In the present research, a method is proposed for predicting the in-duct reflected sound pressure, and it is further used in the error sensing strategy of an ANC system to reduce the reflected sound. Different from the pressure-release or the impedance matching method in the previous reflection control, where the attentions were paid on the sound pressure or the particle velocity in the total sound field, the proposed ANC system attenuates the in-duct reflected wave directly by predicting it, and for a rigid reflective surface, only one microphone is required. The simple and compact structure of the ANC system can be further extended into three-dimension cases and applied to create cost effective anechoic tiles.

II. BASIC THEORY

A. Prediction of the reflected sound in a one-dimension duct

For simplicity, the origin of the coordinate system is positioned on the reflective surface, shown in Fig. 1. The

[a]Author to whom correspondence should be addressed. Electronic mail: hanning@nju.edu.cn

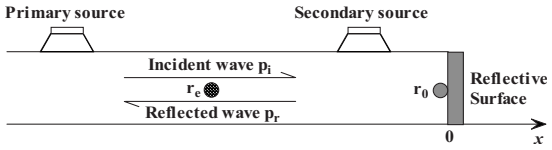

FIG. 1. ANC setup for the in-duct reflection. p_i the incident sound, p_r the reflected sound, r_e the location of the virtual error sensor, and r_0 a point on the reflective surface.

incident plane wave p_i with amplitude p_{ai} and the reflected plane wave p_r with amplitude p_{ar} are written as

$$p_i = p_{ai}e^{j(\omega t-kx)}, \quad p_r = p_{ar}e^{j(\omega t+kx)}, \tag{1}$$

where ω is the angle frequency, k is the wave number, and x indicates the position of the interested point on x-axis. Thus the total sound pressure and particle velocity are

$$p = (p_{ai}e^{-jkx} + p_{ar}e^{jkx})e^{j\omega t},$$

$$v = \left(\frac{p_{ai}}{\rho_0 c_0}e^{-jkx} - \frac{p_{ar}}{\rho_0 c_0}e^{jkx}\right)e^{j\omega t}, \tag{2}$$

where ρ_0 is the air density and c_0 is the sound velocity. On the reflective surface $x=0$, the sound pressure and the particle velocity are

$$p_0 = (p_{ai} + p_{ar})e^{j\omega t}, \quad v_0 = \left(\frac{p_{ai}}{\rho_0 c_0} - \frac{p_{ar}}{\rho_0 c_0}\right)e^{j\omega t}. \tag{3}$$

So p_{ai} and p_{ar} can be expressed as

$$p_{ai} = \tfrac{1}{2}(p_0 + \rho_0 c_0 v_0)e^{-j\omega t}, \quad p_{ar} = \tfrac{1}{2}(p_0 - \rho_0 c_0 v_0)e^{-j\omega t}. \tag{4}$$

In that way, the reflected sound pressure p_r can be predicted through the measured sound pressure and particle velocity on the reflective surface, i.e., $p_r=(p_0-\rho_0 c_0 v_0)e^{jkx}/2$, where e^{jkx} is regarded as the time delay $\tau=-x/c_0$. If the acoustic impedance ratio Z_s at $x=0$ is known, v_0 can be calculated by $v_0=p_0/Z_s$. For situations where the sound pressure is attenuated along with the propagation path, the wave attenuation should be added into the prediction equation $p_r=(p_0-\rho_0 c_0 v_0)e^{-\eta|x|}e^{jkx}/2$, and η is a positive number denoting the attenuation coefficient. For a rigid reflective surface, the particle velocity $v_0=0$, so the reflected sound pressure is predicted as $p_r=p_0 e^{-\eta|x|}e^{jkx}/2$.

B. ANC system for the reflected sound

In a duct ended with a rigid reflective surface, the ANC setup for the reflected sound is shown in Fig. 1. A microphone is positioned on the reflective surface r_0 for measuring the total sound pressure there, which is used to predict the reflected sound pressure at the virtual error sensor r_e. The secondary source is located between r_0 and r_e. The error signal in the ANC system for the in-duct reflection is comprised of the reflected sound pressure p_{pr} from the primary source and the total sound pressure $p_{cr}+p_{ci}$ from the secondary source

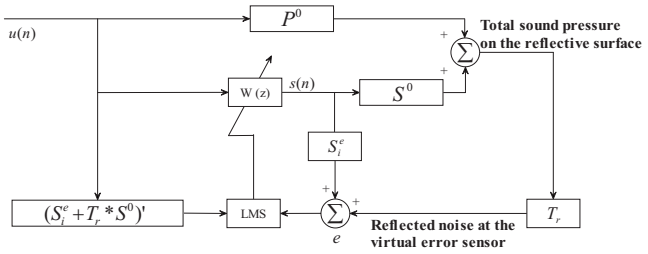

FIG. 2. Block diagram of the feedforward ANC system for the reflected sound. $W(z)$ the adaptive filter, $s(n)$ the input signal to the secondary source, and $'$ denotes the estimated FIR filter.

$$e = p_{pr} + p_{cr} + p_{ci}, \tag{5}$$

where $p_{pr}+p_{cr}=p_r=T_r*p_0$, p_0 is the measured sound pressure at r_0, $*$ is the time convolution, T_r denotes $e^{-\eta|x|}\delta(t-\tau)/2$ which is only applied for a rigid reflective surface, and $\delta(t)=1$ when $t=0$, otherwise $\delta(t)=0$. Defining S_i^e to be the impulse response from the secondary source input q_c to the direct secondary sound pressure at r_e, thus $p_{ci}=S_i^e*q_c$. The error signal e can be expressed by the sound pressure on the reflective surface p_0 and the secondary source input q_c,

$$e = T_r * p_0 + S_i^e * q_c. \tag{6}$$

Let S^0 be the impulse response from the secondary source input q_c to the total secondary sound pressure at r_0, and P^0 be the impulse response from the primary source input q_p to the total primary sound pressure at r_0. The ANC system for the reflected sound is shown in Fig. 2. Compared with the conventional feedforward ANC system with Filter-x LMS (FXLMS) algorithm, T_r*P^0 is regarded as the impulse response of the primary path, and $S_i^e+T_r*S^0$ is the impulse response of the secondary path. The measured total sound pressure p_0 on the reflective surface is used to predict the reflected sound pressure at the virtual error sensor r_e through the prediction filter T_r. With the identified S_i^e before control, the error signal can be obtained without using physical transducers at r_e.

III. EXPERIMENTS

Shown in Fig. 3, a 3.8 m long duct with cross-section dimensions of 0.165×0.166 m^2 (the cut-off frequency 1030 Hz) is employed in the experiment. An ADSP-21161N EZKIT digital signal processor (DSP) board is used as the signal generator for the loudspeaker input and the receiver of the microphone output, and further used as the controller in the ANC system with the sampling rate $f_s=4.8$ kHz.

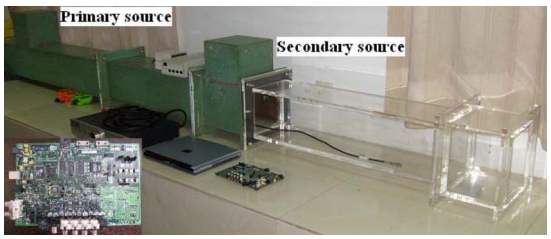

FIG. 3. (Color online) The experimental duct and the DSP board.

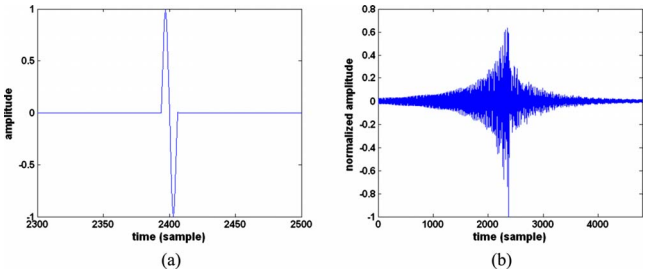

(a) (b)

FIG. 4. (Color online) (a) The desired observed signals and (b) the compensated input signals to the loudspeaker.

For clear observation in the experiments, the desired shape of the observed signals is shown in Fig. 4(a), where the impulsive part is a period of a sinusoidal wave at 400 Hz. The duration of the impulsive signal is 1 s, and the impulsive part is 0.0025 s. Its sound energy is mainly concentrated below 800 Hz, lower than the duct cut-off frequency; thus most of the sound waves are plane waves. In order to obtain the required waveform at the microphone, compensations are made for the loudspeaker input signal. The method is described as follows.

(1) Measuring the transfer function from the loudspeaker to the microphone

$$C(f) = \mathrm{FFT}\{c(n)\}, \tag{7}$$

where f denotes the frequency, $c(n)$ is the impulse response from the loudspeaker to the microphone, and n is the discrete time.

(2) Calculating the inverse transfer function from the loudspeaker to the microphone. Since zeros might be existent in the transfer function, a constant l is added to avoid the singular point in the inverse transfer function[17]

$$H(f) = \frac{C^*(f)}{C(f)C^*(f) + l}. \tag{8}$$

(3) Compensating the loudspeaker input signal. The needed output signal $y(n)$ is transferred into $Y(f)$ by fast Fourier transformation (FFT); thus the loudspeaker input is $Y_c(f) = Y(f)H(f)$. The driving signal to the loudspeaker is finally obtained by using the inverse FFT transformation

$$y_c(n) = \mathrm{IFFT}\{Y_c(f)\}. \tag{9}$$

The compensated input signals are shown in Fig. 4(b). By inputting the signals to the loudspeaker, a pulse in Fig. 4(a) can be observed at the microphone.

A. Validation of the prediction method for the reflected sound

The signals in Fig. 4(b) are input to the secondary source in Fig. 5(a). The signals measured at positions A and B are shown in the upper figure of Fig. 6(a). The ratio of the impulsive amplitudes at A and B is 0.9370, which is mainly due to the viscous losses at the surface of the walls as well as the structural acoustic coupling. The attenuation coefficient η is

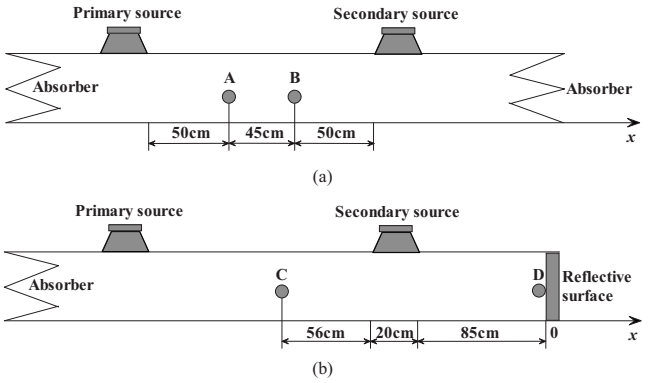

FIG. 5. The setup for obtaining (a) the attenuation coefficient in the duct and (b) the prediction equation of the reflected sound pressure directly.

calculated to be 0.1446; thus in the duct ended with a rigid reflective surface, the prediction equation for the reflected sound pressure at position C in Fig. 5(b) is

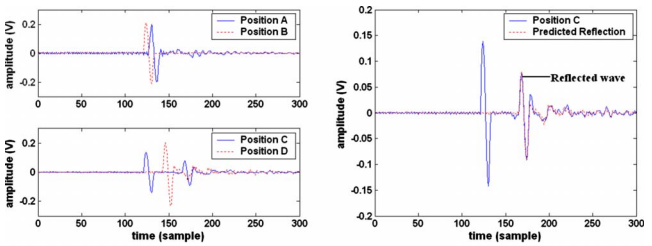
$$p_r = 0.3962 p_0 e^{jkx}. \tag{10}$$

The signals in Fig. 4(b) are input to the primary source in Fig. 5(b). The signals measured at positions C and D are shown in the lower figure of Fig. 6(a), and Fig. 6(b) shows the comparison between the reflected waves measured at C and predicted by Eq. (10). The predicted reflection is almost superposed on the measured one, expected for a little amplitude difference.

Comparing the amplitudes of the reflected sound measured at C and the total sound measured at D, the prediction equation for the reflected sound pressure at position C can be adjusted to be

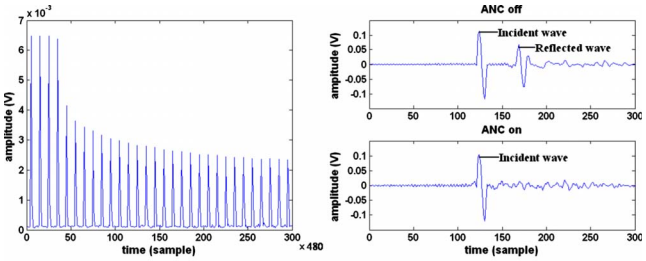
$$p_r = 0.3814 p_0 e^{jkx}, \tag{11}$$

whose amplitude is smaller than Eq. (10). This is mainly due to the un-uniform sound attenuation in the duct. For the experimental duct in Fig. 3, the sound attenuation in the first segment made of Perspex is different from that in the following wooden part; the secondary source is fixed on the duct by a wooden box, which might attenuate much sound and induce oscillations in the reflected wave. Also, the sound attenuation model $e^{-\eta|x|}$ may have deflections from the actual situation, which will induce errors in Eq. (10). In practice, special treatments should be implemented on the part of the secondary source in order to reduce its effect on the in-duct sound field. For the un-uniform inner surface, the duct attenuation $e^{-\eta|x|}$ should be obtained directly by comparing the



(a) (b)

FIG. 6. (Color online) (a) The measured signals in Fig. 5 and (b) the predicted reflection by Eq. (10) is compared with the measured reflection at C.



(a) (b)

FIG. 7. (Color online) (a) The attenuation process of the impulsive reflection; (b) the impulsive reflections in the duct before and after control.

measured amplitudes of the reflected sound at C and the total sound on the reflective surface D. Thus in the ANC experiment below, Eq. (11) is chosen as the prediction equation for the reflected sound pressure.

B. Suppressing the reflected sound by ANC system

In the experimental setup in Fig. 1, the duct is ended with a rigid reflective surface, and the virtual error sensor is located at position C in Fig. 5(b). According to the proposed ANC system in Fig. 2(a), where finite impulse response (FIR) filters with 256 taps are applied in the controller, the impulse response S_i^e from the secondary source input to the direct secondary sound pressure at C is measured when the reflective surface is absent, and the impulse response S^0 from the secondary source input to the total secondary sound pressure at the reflective surface is measured when the reflective surface is existent. In the active control for the in-duct reflection, a microphone is placed at C for observation. With the FXLMS algorithm in the ANC system, the error signal $e=T_r*p_0+S_i^e*q_c$ in Fig. 2(a) is reduced gradually to a steady level, and the reduction process is shown in Fig. 7(a), which indicates the curve of the root mean square for every 480 samples. The observed impulsive reflections without and with control are shown in Fig. 7(b), where 12.2 dB reduction is obtained after the active control.

For the non-rigid reflective surface, the particle velocity on the reflective surface should also be measured or calculated to predict the reflection for more general control conditions. Moreover, in the ANC system, the impulse response S_i^e from the secondary source to the direct secondary noise at the virtual error sensor is measured when the reflective surface is absent, which is not feasible in special situations where the reflective surface is not movable. This problem can be solved by measuring the impulse responses S^e and S^0 from the secondary source to the total secondary sound pressure at r_e and r_0 when the reflective surface is existent, and then the impulse response S_i^e is obtained approximately by $S_i^e=S^e-T_r*S^0$.

IV. CONCLUSIONS

Based on the sound field analysis in one-dimension duct, an approach is proposed for predicting the reflected sound pressure. For a rigid reflective surface, only one microphone is employed in the ANC system to form the error sensing strategy. The ANC system with the prediction method is validated to be effective, and 12.2 dB attenuation of the impulsive reflected sound is obtained after the active control. The introduced ANC system for the reflected sound is simple and compact and can be extended to the three-dimension cases, which will be more practical for building anechoic rooms with low cut-off frequency or making a reflective body invisible to the incident detecting waves.

The future work will mainly aim at the reflection control for the duct ended with a non-rigid reflective surface. Furthermore, the prediction method for the sound pressure scattered by three-dimension objects should be proposed in order to produce a compact ANC multi-channel system to control the scattered noise.

(Received 3 December 2008; revised 25 September 2009; accepted 22 December 2009)

In this work a continuum model for high frequency poroelastic longitudinal waves in hydrogels is presented. A viscoelastic force describing the interaction between the polymer network and the bounded water present in such materials is introduced. The model is tested by means of ultrasound wave speed and attenuation measurements in polyvinylalcohol hydrogel samples. The theory and experiments show that ultrasound attenuation decreases linearly with the increase in the water volume fraction β of the hydrogel. The introduction of the viscoelastic force between the bounded water and the polymer network leads to a bi-phasic theory, showing an ultrasonic fast wave attenuation that can vary as a function of the frequency with a non-integer exponent in agreement with the experimental data in literature. When β tends to 1 (100% of interstitial water) due to the presence of bounded water in the hydrogel, the ultrasound phase velocity acquires higher value than that of pure water. The ultrasound speed gap at $\beta=1$ is confirmed by the experimental results, showing that it increases in less cross-linked gel samples which own a higher concentration of bounded water. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3293000]

I. INTRODUCTION

The present work is motivated in defining a reliable model for ultrasound (US) wave propagation both in hydrogels[1–5] and in extra-cellular matrices of natural soft tissues.[6–8]

In fact, even if the structure of a synthetic hydrogel is somehow different from that one of extra-cellular matrices with proteoglycans exists a strong analogy between the macroscopic response of charged hydrogels and that one of natural matrices, such as that one of derma,[9] in the diffusional wave limit.

On this basis, the US model for hydrogels can be a theoretical tool for the study and the characterization of tissue-mimicking phantom for US thermal therapy and for the development of non-invasive assessment method of soft tissue stiffness.[10–12]

This possibility is confirmed by the current research investigations that clearly show how the knowledge of the link between the poroelastic characteristics of a biological tissue and its acoustical behavior is a source of information that can be used for non-invasive investigation techniques.[13,14]

On the other hand, the US propagation in natural hydrogels, mostly composed of water, is usually modeled by means of the wave equation that holds for liquids.[5] Even if this approach is sufficiently satisfying, it does not completely explain the experimental behavior of US.

There are many discrepancies between US propagation in water and in natural hydrogels of soft tissues both for transverse and longitudinal acoustic waves.[6–8]

As far as longitudinal waves in biological gels are concerned, in the US absorption frequency law $\nu^{(1+\delta)}$ (where ν is the US frequency) δ ranges between $\frac{1}{4}$ and $\frac{1}{2}$, while it holds that $\delta=1$ for water.[15]

The fractional value of δ cannot also be explained by means of the established bi-phasic theories that lead to a frequency dependence equal to that of water with $\delta=1$.[16,17]

The bi-phasic models of the acoustic wave propagation were born in geology and engineering sciences[18–22] from where they received a clear imprinting. All proposed theories[16–24] do not abandon the scheme of a solid matrix permeated by a well distinguishable fluid.

Actually, it is quite evident that gels constitute a possible exception where the solid phase and the liquid one are chemically interacting and the boundary is not simply defined. As a matter of fact, the presence of the bounded water around the polymer chains creates a bearing whose thickness and viscous force do not follow the fluid dynamics laws.[19,20]

In order to solve this theoretical leak, in the present paper, a viscoelastic matrix-fluid interaction specific for hydrogels is introduced.

The hydrogel structure is somewhere between a solid and a liquid. It consists of polymers, or long chain molecules, which are cross-linked to create an entangled network immersed in a liquid medium that fills the intra-molecular interstices.

The properties of gels are strongly influenced by the interaction of these two components.

First, gels were conceptualized as porous media consisting of two interpenetrating macroscopic substances (an elas-

tic and porous solid matrix and a fluid). An elegant and satisfying theory based on this approach is the poroelastic model developed by Biot.[16,17,23,24]

One of the main characteristics of the Biot theory is that the dissipative relaxation is mainly ascribed to the relative motion of fluid against solid, while dissipations within fluid and solid are neglected.

At low frequencies, the friction of the fluid that moves against the solid network leads to a "diffusional" wave, giving theoretical forecasts that well agree with many experimental results.[9,25–29] Instead, this solid-fluid interaction scheme becomes inadequate at high frequencies.

In order to obtain a more satisfying model to describe how ultrasounds propagate in hydrogels, we propose a new mechanism of interaction between the fluid (water) and the solid matrix (polymer network).

The main mathematical statement, introduced here, takes into account the presence of the bounded water attached to the polymeric network of the hydrogel. The fluid-matrix interaction is modeled by ascribing a viscoelastic force between the polymer matrix and the bounded water around it, while a viscous force between the "polymer-bounded water aggregate" and the interstitial free water is assumed.

This assumption leads to relevant outcomes concerning the US propagation in gels. As confirmed by the experiments, the effect of the bounded water in hydrogels on the US speed is quite relevant as well as the frequency dependence of their attenuation. The model of the US propagation in hydrogels can lead to the understanding of their behavior and how it takes origin from the poroelastic structure. The possibility to describe the US propagation in terms of the poroelastic characteristics of both cells and extra-cellular matrix may lead to US non-invasive technique for the evaluation of the tissue physiology since the permeability and elasticity of the cell structures are directly related to their state and functionality.

In the following we derive the phase velocity of longitudinal US plane waves and their attenuation in hydrogels (Sec. II) by using the proposed fluid-matrix interaction.

Then, in Sec. III, we compare the theoretical forecasts with the outcomes of experimental measurements.

II. POROELASTIC WAVES IN HYDROGELS

Biot's[16,17] theory is carried out by assuming that the fluid motion in the pores follows the Poiseuille flow. In this case, the characteristic boundary, where the velocity attains a certain percentage of its maximum, is known as the viscous skin depth[19,20] $(\eta_d/\pi\nu\rho_f)^{1/2}$, where ρ_f and η_d are the fluid mass density and its dynamic viscosity, respectively. In the low frequency limit, this layer becomes larger than the pore diameter and the velocity profile can be assumed parabolic. At higher frequencies, when the viscous skin depth is smaller than the pore size, Biot[17] added a compensating factor $F_{(\nu)}$ to the fluid-solid friction coefficient f to take into account for the divergence by the Poiseuille flow. He stated that $F_{(\nu)}$ increases according to the law $\lim_{\nu/\nu c\to\infty} F_{(\nu)} \propto (\nu/\nu_c)^{1/2}$, where $\nu_c = f/\rho_f$ and f is the zero frequency friction coefficient[23] (i.e., the inverse of the hydraulic permeability of the medium).

Given that pore dimensions are very small in gels, the crossover frequency ν_c is very high [for instance, polyvinylalcohol (PVA)-polyacrylic acid hydrogels[30] show $\nu_c \approx 10^{13}$ Hz, close to the maximum frequency allowed in material media]. Therefore, for usual US frequencies the factor $F_{(\nu)}$ in hydrogels should be always used in the low frequency limit (i.e., $F_{(\nu)}=1$). This fact gives the US attenuation[17] proportional to ν^2 while the experimental results follow the law[15] $\propto \nu^n$ with n ranging between 1,25 and 1,50.

In the frame of the bi-phasic approach one possible way out is to consider a different fluid-network interaction for hydrogels.

If we look at the hydrogel structure, it shows water molecules that are bounded to the matrix polymer chains by means of chemical interactions. The local polymer field organizes the water molecules around itself in a way that they can be assumed radially bounded to its chains, while relatively free to move along the perpendicular direction in a viscous manner. Due to the fact that in an isotropic gel the polymer chains are oriented in all directions, under the elastic wave action, the bounded water molecules will respond in an elastic and viscous manner as a mean. Thence, a more appropriate matrix-fluid interaction scheme is assumed:

(i) a viscoelastic interaction between the bounded water and the polymer matrix (with an elastic constant k and a friction coefficient η) and
(ii) a pure viscous interaction between the bounded water molecules (surrounding the polymer network) and the free water.

A. Compressional waves for dilute poroelastic media

Since the percentile content of water in gels is often very high (up to 99%), in the low frequency limit the poroelastic theories for hydrogels make historically use of the dilute matrix approximation[30–33] [i.e., $\beta \approx 1$, where $\beta = V_w/(V_w + V_p)$, where V_w and V_p are the volumes of water and polymer, respectively]. Such an approximation works very well even for gels with a remarkable polymer content (owing β down to 0.50).

For the high frequency limit, the dilute matrix approximation does not work so well especially for the US wave speed that shows to be sensibly dependent on the polymer content for values of β up to 0.7. Nevertheless, the dilute matrix approximation is still physically meaningful for β bigger than 0.8 where it clearly defines the behavior of the US wave speed.

Before introducing the specific hydrogel fluid-matrix interaction, we derive the poroelastic longitudinal wave equations in the limit of very dilute matrix with incompressible solid and liquid constituents.

In this case the compressional elastic moduli of the fluid and the solid matrix can be assumed to be greater than all the other elastic moduli in the poroelastic longitudinal wave equations[16,17,23,24] that read

$$\nabla^2(P\varepsilon_{\alpha\alpha}+Qe_{\alpha\alpha})=\partial^2(\rho_{11}\varepsilon_{\alpha\alpha}+\rho_{12}e_{\alpha\alpha})/\partial t^2 + \beta f F_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{1}$$

$$\nabla^2(Q\varepsilon_{\alpha\alpha}+Re_{\alpha\alpha})=\partial^2(\rho_{12}\varepsilon_{\alpha\alpha}+\rho_{22}e_{\alpha\alpha})/\partial t^2 - \beta f F_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{2}$$

where ε_{ij} is the solid strain tensor, $e_{\alpha\alpha}$ is the trace of the liquid strain tensor, β is the pore volume fraction (equating the fluid volume fraction), and ρ_{11}, ρ_{12}, and ρ_{22} are the mass density parameters for the hydrogel that are related to the solid and fluid mass densities ρ_s and ρ_f, respectively, by the identities

$$\rho_{11}+\rho_{12}=(1-\beta)\rho_s,$$

$$\rho_{12}+\rho_{22}=\beta\rho_f,$$

$$\rho_{12}=(1-\alpha)\beta\rho_f,$$

where $\alpha>1$ is a molecular shape factor which is independent of the solid or fluid mass densities. For a matrix built up by spherical particles, Berryman[34] showed to be $\alpha=\frac{1}{2}(\beta^{-1}+1)$.

Furthermore, ρ_{11} is the inertial mass density of the solid matrix when it accelerates while the fluid is contemporarily prevented to move, and ρ_{12} is the mass density parameter for the force that the fluid exerts on the solid as the latter is accelerated relative to the former.[23] This happens since the fluid and the solid in the poroelastic media are coupled to each other. If fluid and solid would be independent of each other (i.e., $\rho_{12}=0$) the inertial mass density of solid and fluid in the bi-phasic medium would result just equal to their specific ones (ρ_s and ρ_f) multiplied by their volume fractions $(1-\beta)$ and β, respectively.

Moreover, P, Q, and R are the poroelastic coefficients of the medium that can be measured by means of jacketed and unjacketed experiments.[24] In the jacketed rheological measurements, the solid matrix is subject to compressional tests carried out maintaining the pore fluid at constant pressure, while in the unjacketed ones, the specimen dilatation is measured as a function of the fluid pressure in the pores, leaving the solid matrix free from external forces.[24]

In the limit of high liquid phase content ($\beta\approx1$) and incompressible constituents, the following conditions over the poroelastic coefficients and mass density parameters hold:[16,17,23]

$$R\gg Q\gg P, \tag{3}$$

$$Q/R\cong(1-\beta)/\beta\cong(1-\beta), \tag{4}$$

$$\rho_{12}=-\rho_{11}\ll\rho_{22} \tag{5}$$

By introducing the above approximations into the longitudinal wave equations we obtain

$$\nabla^2 Qe_{\alpha\alpha}=\partial^2\rho_{11}(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t^2+\beta f F_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{6}$$

$$\nabla^2(Q\varepsilon_{\alpha\alpha}+Re_{\alpha\alpha})=\partial^2(\rho_{12}\varepsilon_{\alpha\alpha}+\rho_{22}e_{\alpha\alpha})/\partial t^2 - \beta f F_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t. \tag{7}$$

Given that the friction coefficient f is very high[25,27,30–33] it follows that the displacement $|\varepsilon_{\alpha\alpha}-e_{\alpha\alpha}|$ of the "slow" wave (liquid and solid in counter-phase) is very small compared to that of the fast wave $|e_{\alpha\alpha}|$ so that it is possible to pose $|\varepsilon_{\alpha\alpha}|\approx|e_{\alpha\alpha}|$ and, hence

$$(\rho_{12}\varepsilon_{\alpha\alpha}+\rho_{22}e_{\alpha\alpha})\cong(\rho_{22}+\rho_{12})e_{\alpha\alpha}=\beta\rho_f e_{\alpha\alpha}, \tag{8}$$

$$(Q\varepsilon_{\alpha\alpha}+Re_{\alpha\alpha})\cong(R/\beta)e_{\alpha\alpha} \tag{9}$$

that introduced in Eq. (7) leads to

$$\nabla^2\frac{R}{\beta}e_{\alpha\alpha}\cong\partial^2(\beta\rho_f e_{\alpha\alpha})/\partial t^2-\beta f F_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t. \tag{10}$$

Assuming for dilute matrices Berryman's[34] formula (that calculates ρ_{11} for coil-like polymer molecules as those ones of the PVA hydrogel), ρ_{11} reads

$$\rho_{11}=(1-\beta)\rho_s-\tfrac{1}{2}(1-\beta^{-1})\beta\rho_f$$

from where for $\beta\cong1$ it follows that $\rho_{11}\cong0$. Hence, Eqs. (6) and (10) approximately read as

$$\nabla^2 Qe_{\alpha\alpha}\cong\beta f F_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{11}$$

$$\nabla^2\frac{R}{\beta}e_{\alpha\alpha}\cong\partial^2(\beta\rho_f e_{\alpha\alpha})/\partial t^2. \tag{12}$$

Moreover, by introducing Eq. (12) into Eq. (11), the following relation between the "slow wave" and the fast wave displacements,

$$F(\nu)\frac{\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})}{\partial t}\cong\frac{1}{f}\frac{Q}{R}\frac{\partial^2(\beta\rho_f e_{\alpha\alpha})}{\partial t^2}, \tag{13}$$

is obtained.

Finally, by introducing Eq. (13) into Eq. (10), at first order in $(1-\beta)$, we obtain

$$\nabla^2\frac{R}{\beta}e_{\alpha\alpha}\cong\beta\partial^2(\beta\rho_f e_{\alpha\alpha})/\partial t^2 \tag{14}$$

that, under the hypothesis of β constant, reads

$$\nabla^2 Re_{\alpha\alpha}\cong\beta^3\partial^2(\rho_f e_{\alpha\alpha})/\partial t^2. \tag{15}$$

Equation (15) represents a purely elastic wave of the first type that propagates in a medium with a speed c according to the law

$$c^2=R/(\rho_f\beta^3)\approx c_f^2/\beta^3, \tag{16}$$

where c_f is the wave velocity in the fluid phase. Since β is smaller than but close to 1 in Eq. (16) we can observe that, in dilute poroelastic media, the compressional wave has a velocity that is close but always higher than that one in the pure fluid phase.

Since Eq. (14) is a completely elastic wave equation, to take into account for the US energy dissipation, the highest

order of approximation must be considered. In order to do that, we put Eq. (6) into Eq. (10) and, with the help of Eq. (4), we obtain the wave equation

$$\nabla^2 \frac{R}{\beta} e_{\alpha\alpha} \cong \beta \partial^2(\beta \rho_f e_{\alpha\alpha})/\partial t^2 + (1-\beta) \times (\rho_{11}/\beta f F_{(\nu)}) \partial^3(\rho_f e_{\alpha\alpha})\, \partial t^3. \quad (17)$$

1. Phase velocity and attenuation of "fast" plane wave

Equation (17) for plane waves $e_{aa} \propto e^{-\alpha x} e^{i(kx-\omega t)}$ gives the characteristic equation

$$(k+i\alpha)^2 = \omega^2 \rho_f (\beta^3/R)[1 - i\omega(Q/R)(\rho_{11}/fF_{(\nu)})]. \quad (18)$$

By solving k and α and by using the purely elastic phase velocity $c_0^2 = R/\rho_f \beta^2$, the speed and the attenuation per cycle are obtained, respectively, to be

$$c^2 = c_0^2(1 + \alpha^2/k^2), \quad (19)$$

$$2\pi\alpha/k = -\pi(c/c_0)^2 \omega(1-\beta)(\rho_{11}/\beta f F_{(\omega)}). \quad (20)$$

B. Compressional fast wave in hydrogels

Introducing a new constituent such as the bounded water, we must pay attention to the definition of the fluid volume fraction of the hydrogel.

Since the bounded water phase is not a fluid phase, it must be subtracted from the water volume fraction β that is the total volume fraction of the water.

The effective free water volume fraction β_e can be obtained on the hypothesis that the number of bounded water molecules is proportional to the polymer-water contacts.

Since the probability of a polymer-polymer contact at very low polymer concentration [near $\beta \approx 1$, let us say for $(1-\Delta) \ll \beta < 1$] is practically null, the bounded water volume fraction β_{bw} is proportional to the polymer volume fraction $(1-\beta)$ in that range.

When the polymer concentration is high [let us say for $0 < \beta \ll (1-\Delta)$], where Δ represents the parameter that marks the boundary between the two regimes, due to the high probability of polymer-polymer contacts, the increase in polymer content does not cause a proportional increase in bounded water so that β_{bw} must approach a constant value ϕ as β goes to zero.

If we approximate the approaching of the bounded water volume fraction to this constant value ϕ by means of an exponential law, we can write

$$\beta_{\mathrm{bw}} = \phi(1 - \exp[-(1-\beta)/\Delta]), \quad (21)$$

where $0 < \Delta < 1$ and $0 < \phi < 1$ are empirical parameters to be deduced from the experimental data.

Therefore, the free water volume fraction reads as

$$\beta_e = \beta - \phi(1 - \exp[-(1-\beta)/\Delta]). \quad (22)$$

By introducing the free water volume fraction β_e, the pure elastic acoustic fast wave (15) and its speed, respectively, read as

$$\nabla^2 R e_{\alpha\alpha} \cong \beta_e^3 \partial^2(\rho_f e_{\alpha\alpha})/\partial t^2, \quad (23)$$

$$c_0^2 \cong \frac{c_f^2}{(\beta - \phi(1 - \exp[-(1-\beta)/\Delta]))^3}, \quad (24)$$

where $c_0 = (R/\rho_f \beta_e^3)^{1/2}$ is the pure elastic longitudinal wave velocity, $c_f = (R/\rho_f)^{1/2}$ its velocity in the intermolecular fluid (free water), R is Biot's compressional modulus of the fluid,[16,21] and $e_{\alpha\alpha}$ is the trace of the free water stress tensor.

It is worth noting that for vanishing Δ and for $\beta \leq (1-\varepsilon)$, where $\varepsilon \gg \Delta$ is a positive number (smaller than 1), it holds that $\beta_{\mathrm{bw}} \cong \phi$, $\beta_e \cong (\beta - \phi)$, and Eq. (24) leads to the relation

$$c_{0(\beta)}^2 \cong \frac{c_f^2}{(\beta - \phi)^3}. \quad (25)$$

Therefore, the amount of bounded water ϕ can be evaluated by means of the best-fitted value $\lim_{\beta \to 1} c_{0(\beta)}$ of the experimental data $c_{0(\beta_{(i)})}$ for $\beta_{(i)} \leq (1-\varepsilon)$ following the equation

$$\phi = 1 - \left(\frac{c_f}{\lim\limits_{\beta \to 1} c_{0(\beta)}} \right)^{2/3}. \quad (26)$$

It is noteworthy to note that the presence of the bounded water generates a velocity gap between the US velocity in pure water and that one extrapolated for hydrogels at $\beta = 1$ (a hydrogel made up by 100% of water).

1. Bounded water-polymer network viscoelastic interaction

The bounded water-polymer network viscoelastic interaction can be introduced in the poroelastic equations by adding to Biot's viscous force (with $F_{(\nu)} = 1$)

$$\beta_e f\, \partial(e^*_{\alpha\alpha} - e_{\alpha\alpha})/\partial t, \quad (27)$$

the viscoelastic one due to the bounded water

$$\eta_{(\nu)}\, \partial(\varepsilon_{\alpha\alpha} - e^*_{\alpha\alpha})/\partial t + \kappa(\varepsilon_{\alpha\alpha} - e^*_{\alpha\alpha}), \quad (28)$$

where $e^*_{\alpha\alpha}$ is the trace of the bounded water stress tensor.

Actually, introducing the bounded water stress tensor variable, the bi-phasic approach disembogues into a three-phasic one that is out of the purpose of this work. Nevertheless, the bi-phasic model can be retained since the bounded water mass density is not much different from that one of the polymer. It is much like the bounded water "inflates" the polymer chains, creating a bearing around them. In this case, the bi-phasic medium can be conceived composed of the "polymer-bounded water aggregate," as matrix, plus the interstitial free water. Thence it is possible to introduce the following approximations.

(i) The mass density of the solid aggregate approximates that one of the polymer.
(ii) The trace of the strain tensor of the polymer $\varepsilon_{\alpha\alpha}$ approximates that one of the solid aggregate.
(iii) P, Q, and R are the poroelastic coefficients of the new bi-phasic medium. Moreover, since not the whole bounded water is involved in the fluid-solid shear process.

(iv) The inertial effect of bounded water involved in the fluid-solid shear process can be disregarded.

By means of the fourth hypothesis, the force between the free water and the bounded water can be equated to that one between the bounded water and the polymer matrix, leading to the additional equation needed to solve the three stresses that reads

$$\beta_e f F_{(\nu)}\,\partial(e^*_{\alpha\alpha}-e_{\alpha\alpha})/\partial t=\eta_{(\nu)}\,\partial(\varepsilon_{\alpha\alpha}-e^*_{\alpha\alpha})/\partial t+\kappa(\varepsilon_{\alpha\alpha}-e^*_{\alpha\alpha}). \tag{29}$$

Moreover, under hypotheses (i)–(iii) the system of poroelastic equations (1) and (2) reads as

$$\nabla^2(P\varepsilon_{\alpha\alpha}+Qe_{\alpha\alpha})=\partial^2(\rho_{11}\varepsilon_{\alpha\alpha}+\rho_{12}e_{\alpha\alpha})/\partial t^2+\beta f\,\partial(e^*_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{30}$$

$$\nabla^2(Q\varepsilon_{\alpha\alpha}+Re_{\alpha\alpha})=\partial^2(\rho_{12}\varepsilon_{\alpha\alpha}+\rho_{22}e_{\alpha\alpha})/\partial t^2-\beta f\,\partial(e^*_{\alpha\alpha}-e_{\alpha\alpha})/\partial t. \tag{31}$$

In dilute bi-phasic media the compressional plane wave of interstitial fluid, $e_{\alpha\alpha}\propto e^{-\alpha x}e^{i(kx-\omega t)}$, induces a planar slow wave, as shown in Eq. (13), that leads to

$$(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})=-(i\omega Q\beta_e{}^2/Rf)e_{\alpha\alpha},$$

where $\omega=2\pi\nu$.

In this case Eq. (29) reads as

$$\beta_e f\,\partial(e^*_{\alpha\alpha}-e_{\alpha\alpha})/\partial t=(\eta_{(\nu)}+j(\kappa/\omega))\,\partial(\varepsilon_{\alpha\alpha}-e^*_{\alpha\alpha})/\partial t, \tag{32}$$

leading after simple manipulation to the relation

$$\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t=\{(\beta_e f+\eta_{(\nu)}+j(\kappa/\omega))/(\eta_{(\nu)}+j(\kappa/\omega))\}\,\partial(e^*_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{33}$$

where that can be recast as

$$\beta_e f\,\partial(e^*_{\alpha\alpha}-e_{\alpha\alpha})/\partial t=F^*_{(\omega)}\,\partial(\varepsilon_{\alpha\alpha}-e_{\alpha\alpha})/\partial t, \tag{34}$$

where the complex "friction" coefficient $F^*_{(\omega)}$ reads as

$$F^*_{(\omega)}=[(\beta_e f)^{-1}+(\eta_{(\nu)}+j(\kappa/\omega))^{-1}]^{-1}. \tag{35}$$

Hence, by introducing Eq. (34) into Eqs. (30) and (31) for plane waves, the dilute matrix equation (17) reads as

$$\nabla^2\frac{R}{\beta}e_{\alpha\alpha}\cong\beta\partial^2(\beta\rho_f e_{\alpha\alpha})/\partial t^2+(1-\beta)\times(\rho_{11}/F^*_{(\omega)})\partial^3(\rho_f e_{\alpha\alpha})/\partial t^3 \tag{36}$$

so that for the fast plane wave $e_{\alpha\alpha}\propto e^{-\alpha x}e^{i(kx-\omega t)}$ it leads to the characteristic equation

$$(k+i\alpha)^2=\omega^2\rho_f(\beta_e{}^3/R)[1-i\omega(1-\beta_e)(\rho_{11}/F^*_{(\omega)})] \tag{37}$$

that solved in α and c gives

$$c^2=c_0^2\left(1+\alpha^2/k^2\right)\Big/\left[1+(1-\beta_e)\omega\rho_{11}\,\mathrm{Im}\{F^{*-1}_{(\omega)}\}/\beta_e{}^2\right], \tag{38}$$

$$\alpha/k=-1/2(c/c_0)^2\omega(1-\beta_e)\rho_{11}\,\mathrm{Re}\{F^{*-1}_{(\omega)}\}, \tag{39}$$

where

$$\mathrm{Re}\{F^{*-1}_{(\omega)}\}=[\eta_{(\omega)}(1+\eta_{(\nu)}/\beta_e f)+(\kappa^2/\beta_e f\omega^2)]/(\eta_{(\nu)}{}^2+(\kappa/\omega)^2), \tag{40}$$

$$\mathrm{Im}\{F^{*-1}_{(\omega)}\}=-(\kappa/\omega)/(\eta_{(\nu)}{}^2+(\kappa/\omega)^2). \tag{41}$$

In the following we consider the case when the bounded water-network interaction is prevalently viscous such as

$$\eta>(\kappa\rho_{\mathrm{bw}})^{1/2}, \tag{42}$$

where ρ_{bw} is the mass density of the bounded water that we assume close to that of free water ρ_f.

At high frequencies such $\omega>\omega_g=(2\pi\eta/\rho_f)>(\kappa/\rho_{\mathrm{bw}})^{1/2}$ (far away from bounded water resonance) hence, it holds that

$$\kappa/\omega\eta\ll\kappa/\omega_g\eta<1. \tag{43}$$

Moreover, in order that the crossover frequency $\nu_g=\eta/\rho_f$ is much smaller than the unattainable Biot's one $\nu_c=f/\rho_{f'}$ in the high frequency limit, it must hold

$$\lim_{\nu\to\infty}\eta_{(\nu)}\ll f. \tag{44}$$

If the high frequency behavior of the bounded water viscosity $\eta_{(\nu)}$ is modeled by a dimensionless coefficient as

$$\eta_{(\nu)}=\eta_0(\omega_g/\omega)^{\delta}, \tag{45}$$

it follows that $\omega_g=2\pi\nu_g=2\pi\eta_{(\nu=\nu_g)}/\rho_f=2\pi\eta_0/\rho_{f'}$ and that conditions (43) and (44) hold contemporarily by requiring $0<\delta\leq 1$. In such a case, by introducing them into Eqs. (40) and (41) it follows that

$$\lim_{\omega/\omega_g\gg 1}\mathrm{Re}\{F^{*-1}_{(\omega)}\}\cong(\kappa/\omega\eta)^2+[(1+\eta_{(\nu)}/\beta_e f)/\eta_{(\nu)}]\cong 1/\eta_{(\nu)}, \tag{46}$$

$$\lim_{\omega/\omega_g\gg 1}\mathrm{Im}\{F^{*-1}_{(\omega)}\}\cong 0, \tag{47}$$

where $\nu=2\pi/\omega$. Equations (46) and (47) introduced into Eq. (38), in a dilute polymer hydrogel ($\beta\approx 1$ and $\rho_{11}\ll 1$), lead to

$$c^2=c_0^2(1+\alpha^2/k^2)\cong c_0^2, \tag{48}$$

being typically $(\alpha/\kappa)^2$ very small (of order of 10^{-3} in our experiments) and to the specific US attenuation per cycle

$$2\pi\alpha/k\approx-\pi(c/c_0)^2(\omega/\omega_g)^{1+\delta}(1-\beta+\phi(1-\exp[-(1-\beta)/\Delta])\sigma_{pf}, \tag{49}$$

where $\sigma_{pf}=\rho_{11}/\rho_f$.

For hydrogels with small Δ, and for $(1-\beta)/\Delta\gg 1$, finally, Eq. (49) leads to

$$2\pi\alpha/k\approx-\pi(c/c_0)^2(\omega/\omega_g)^{1+\delta}(1-\beta+\phi)\sigma_{pf}. \tag{50}$$

From Fig. 1, that shows the acoustic US fast wave absorption, it can be observed that the bounded water raises the linear behavior, while Δ smooths the curve in the interval $1-\Delta>\beta>1$.

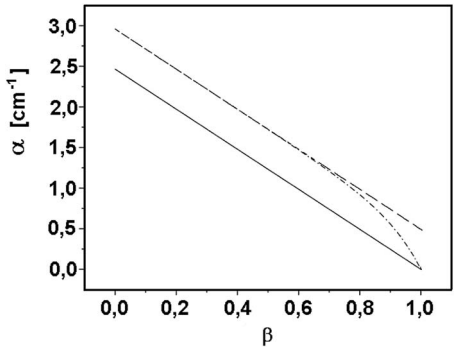

FIG. 1. Theoretical behavior of acoustic US fast wave absorption in a hydrogel given by Eq. (52) as a function of the water volume fraction for various values of the parameters: $\phi=0$ and $\Delta=0$ (full line), $\phi=0.2$ and $\Delta=0.0006$ (dashed line), and $\phi=0.2$ and $\Delta=0.1$ (dashed-dotted line).

From Fig. 2, depicting the theoretical behavior of the acoustic speed of US fast wave, it can be seen that

(i) the bounded water leads to an upward shift in the wave speed,
(ii) that Δ smooths the curve upward in the region $1-\Delta<\beta<1$, and
(iii) when $\Delta \ll 1$ there is a speed jump at $\beta \cong 1$.

C. High polymer concentration

The characteristic equation for slow and fast plane waves stemming from Eqs. (30) and (31) turns out to be formally the same as that one given by Biot[17] where the friction term $\beta f F_{(\nu)}$ is substituted by $F^*_{(\omega)}$ [see Eq. (34)] that at high frequency is given by Eqs. (46) and (47).

Nevertheless, it must be observed that Biot's[17] model assumes that the poroelastic coefficients are constants (or at least very smoothly varying) while in hydrogels they actually may change very much when they are partially dried up.[33]

Moreover, since we wish both to build up a model that can be applied to biological tissues, where the solid concentration as well as that one of the bounded water can be very high (up to 60%), and to improve the experimental fitting of data beyond the range of validity of the dilute matrix approximation at intermediate water volume fraction values (but not to validate the model), we opt for a more direct semi-empirical approach.

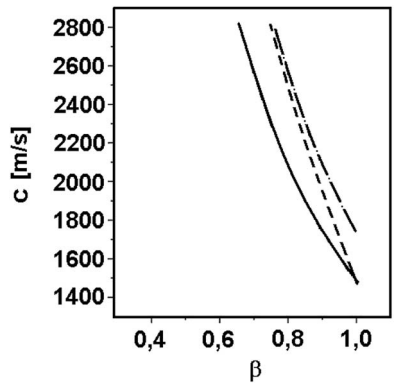

FIG. 2. Theoretical behavior of the acoustic speed of propagation of US fast wave in a hydrogel given by Eq. (24) as a function of the water volume fraction for various values of the parameters: $\phi=0$ and $\Delta=0$ (full line), $\phi=0.1$ and $\Delta=0$ (dashed line), and $\phi=0.1$ and $\Delta=0.1$ (dashed-dotted line).

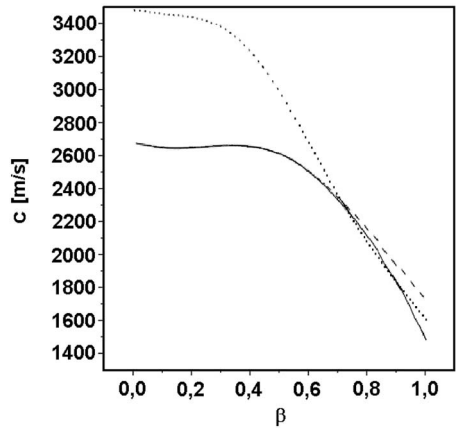

FIG. 3. Theoretical behavior of the acoustic speed of propagation of US fast wave in a hydrogel given by Eq. (52) as a function of the water volume fraction for various values of the parameters: $\phi=0.1$, $\Delta=0$, $\gamma=0.7$, and $\chi=-0.4$ (dashed line); $\phi=0.1$, $\Delta=0.1$, $\gamma=0.7$, and $\chi=-0.4$ (full line); $\phi=0.031$, $\Delta=0$, $\gamma=0.44$, and $\chi=-0.25$ (dotted line).

In order to do that, we observe that for vanishing $\beta=0$ values, the speed of propagation of the US is finite and equal to that of polymeric solid c_s, while the law (24) diverges to infinity at $\beta=\phi$ and gives negative values for $\beta=0$.

The contribution that cancels the divergence of the denominator of Eq. (24) (let us call it $G_{(\beta)}$ in the dilute matrix approximation) can be put in the form

$$c^2 = \frac{c_f^2}{(\beta - \phi(1-\exp[-(1-\beta)/\Delta]))^3 + G_{(\beta)}}, \tag{51}$$

where the conditions required to $G_{(\beta)}$ are

$$\lim_{\beta\to 1} G_{(\beta)} = 0,$$

$$\lim_{\beta\to 0} G_{(\beta)} > 0.$$

For this reason it is appropriate to use the series approximation

$$G(\beta) = \gamma(1-\beta) + \chi(1-\beta)^2 \quad \text{with} \quad \gamma+\chi>0$$

that in Eq. (29) leads to

$$c^2 = \frac{c_f^2}{(\beta - \phi(1-\exp[-(1-\beta)/\Delta]))^3 + \gamma(1-\beta) + \chi(1-\beta)^2} \tag{52}$$

and that for $(1-\beta)/\Delta \gg 1$ gives

$$c^2 = \frac{c_f^2}{(\beta-\phi)^3 + \gamma(1-\beta) + \chi(1-\beta)^2}. \tag{53}$$

From Fig. 3 we can see the change in the US wave speed following the introduction of the polynomial expression $G_{(\beta)}$: the polymer network cancels the divergence of US speed at $(\beta-\phi)=0$ and lowers it at the intermediate values of β in a progressive manner.

Finally, for β close to 1 we observe that the increase in the bounded water in Eq. (53) increments the US speed through the term $(\beta-\phi)^3$ while the elasticity of the polymer network lowers it mainly through the vanishing term $\gamma(1-\beta)$ (if $\gamma>0$).

III. EXPERIMENTAL

A. Materials and methods

Gel samples were prepared in parallelepipeds of $2\times2\times1$ cm^3 using PVA with a degree of hydrolysis of 99+% and an average molecular weight of 115.000 ± 30.000 (Aldrich, Milan, Italy) dissolved into de-ionized water in a concentration of 10% by weight. The homogeneous solution was refrigerated at −80 °C starting from room temperature 23 ± 1 °C. The freezing-thawing procedure was repeated two, three, four, and six times. The samples were left to equilibrate in de-ionized water for 72 h.

The experimental tests were carried out at different hydration conditions down to a minimum of about 50%, taking care that the drying was gradual and homogeneous.

The reversibility of the de-hydration treatment was checked at the end after the drying steps.

The ultrasonic pulses were generated by a Panametrics® Pulser model 5052PR (Waltham, MA) coupled with a polyvinylidene fluoride piezoelectric transducer assembled in our laboratory following the procedure of Naganishi *et al.*[35]

A cylindrical chamber immersed in a water bath constitutes the experimental cell. The US transducer/receiver is fixed on a planar side-wall. An inner flat counter-wall, free to translate inside the cylinder and put in contact with the back surface of the samples, is used as reflecting surface.

The ultrasonic disk-like transducer used in the experiment has an aperture size of 1.5 cm. The measurements are carried out in the near field condition with the front surface of the gel samples in contact with the transducer surface. All the volume in front of the transducer is occupied by the sample (so that there is no problem about US focalization) and US echoes are very well detected up to 10 cm far apart from the transducer.

The Pulser voltage spike of −270 V induces an ultrasonic pulse of 250 kHz of frequency through the transducer.

The distance between the transducer and the reflecting stainless steel layer behind the samples was measured with an accuracy of ±0.01 cm and maintained constant through the whole experiment.

Echo signal registration and conditioning data were collected with a routine and carried out with the LABVIEW™ software on a computer through a National Instruments® data acquisition device.

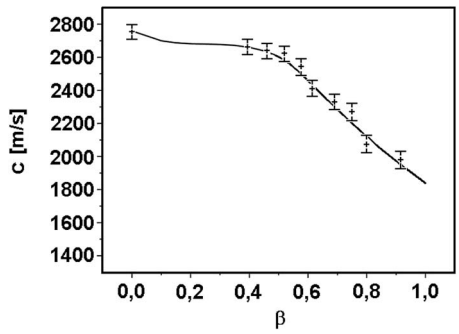

FIG. 4. Experimental acoustic US speed of propagation of fast wave in PVA hydrogels, with best fit (full line), as a function of the water volume fraction $(0<\beta<1)$ for a hydrogel sample obtained by means of 2 cycles of cross-linking.

Finally, the samples were totally dehydrated in an oven at 40 °C with desiccant silica gels to measure their polymer content and the US speed in the dry solid.

The US absorption coefficient α was deduced by using the mathematical relation $\alpha=(1/2d)\ln(A_0/A_{(2d)})$, where A_0 and $A_{(2d)}$ represent both the initial and final wave amplitudes, respectively, and where d is the sample thickness.

The water volume fraction of the hydrogel samples β was obtained by means of the respective weight fractions P_w and P_p such as $\beta\approx P_w/(P_w+P_p)$ since the water and PVA specific densities are very close to each other.

After the samples were left to fully hydrate themselves in distilled water, the fractional water volume was measured to be $\beta=0.917\pm0.001$ for all the samples.

The fitting of the experimental results was carried out by means of a multiple parameter best fit utilizing an appropriate routine in MATLAB® 7.0.

The error bars are obtained both from theoretical calculation (taking into account all the experimental errors in space, time, and temperature) and from experimental evaluation. The mean square root deviation of data resulted much smaller than the theoretical errors.

B. Ultrasound phase velocity

Experimental data of US wave speed with the best-fitted curve are shown in Fig. 4 for the hydrogel sample submitted to 2 cycles of cross-linking. The most probable values of the model parameters for all samples are given in Table I.

TABLE I. Most probable values of the model parameters ϕ, Δ, γ, χ, and $\gamma+\chi$ obtained from the best fit of the experimental data by means of expression (31) as a function of the number of cross-linking cycles (first column).

Number of cross-linking cycles	ϕ	Δ	γ	χ	$\gamma+\chi$	$\lim_{\beta\to1} c$ (m s^{-1})	c_s (m s^{-1})
2	0.131	0.0006	0.742	−0.453	0.289	1830	2755

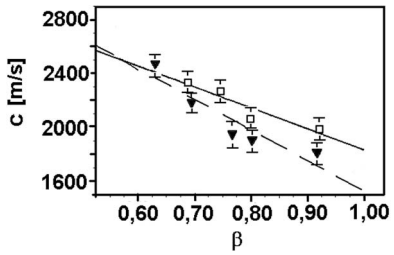

FIG. 5. Experimental acoustic US speed of propagation of fast wave in PVA hydrogels as a function of the water volume fraction at various degrees of polymer matrix cross-linking: 2 cycles (⊡) and 6 cycles (▽) of cross-linking, with the best fit (dashed line and full line, respectively). In this case, the detail of the US speed behavior for high water volume fraction values ($0.6<\beta<1$) is shown.

From Fig. 4 we can see that at intermediate values of β, the US wave speed progressively departs from the model dependence $(\beta-\phi)^{-3/2}$ toward the value of the dry solid polymer in agreement with the theoretical behavior (52) shown in Fig. 3. The measurements show that the effect of the polymer matrix starts to influence the US speed of propagation for values of β as high as 0.8.

For β close to zero, the US speed of propagation converges to the speed of the dry polymer which rises when the number of cross-linking cycles increases because of the greater polymer stiffness, as shown in Table I.

For β equal to 1, the US speed is extrapolated by means of a best-fit procedure and reported in Table I. The data referring to the samples with 2 and 6 cycles of cross-linking have been reported in Fig. 5. The data show that the US phase velocity is sensibly higher than that of pure water (that in our experimental condition has been measured to be 1483 m/s). In Fig. 6 the bounded water volume fraction ϕ is shown as a function of the number of cross-linking cycles of the sample. The evaluation of ϕ is obtained by introducing into Eq. (26), being $\Delta\cong 0$, the limiting velocity values of Table I. The bounded water volume fraction ϕ ranges from 2% in the PVA samples with six cross-linking cycles to 13% for the PVA samples with two cross-linking cycles.

As shown in Table I, we can observe that the lower the gap speed at $\beta=1$, the bigger the number of the cross-linking cycles and the lower the measured bounded water fraction ϕ present in the hydrogel. This agrees with the characteristics of PVA hydrogel synthesized by means of freezing-thawing

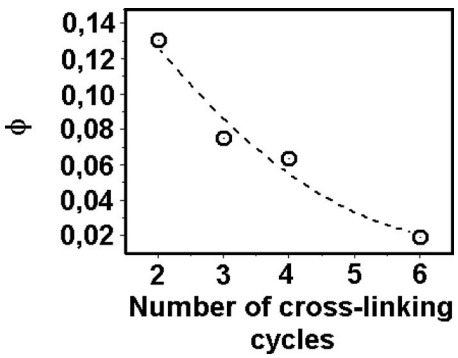

FIG. 6. Estimated bounded water fraction in PVA hydrogel as a function of the number of cross-linking cycles.

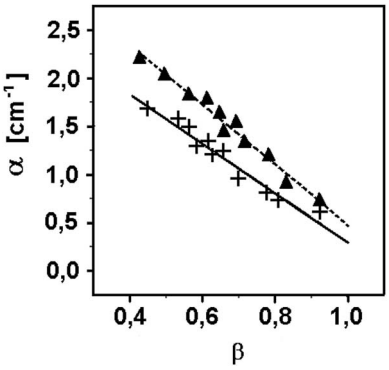

FIG. 7. Experimental acoustic US fast wave attenuation in PVA hydrogels as a function of the water volume fraction at various degrees of polymer matrix cross-linking: 4 cycles (▲) and 6 cycles (+) of cross-linking with best fit (dashed-dotted line and dotted line, respectively).

cycles where the number of polymer-polymer contacts (cross-links) grows as the number of freezing-thawing cycles increases.[36] Moreover, since lower values of ϕ in samples with higher cross-linking correspond to lower values of the US speed, this behavior cannot be ascribed to the elasticity of the polymer network that leads to a variation in opposite sign.

In fact, as shown in Table I, both γ and $(\gamma+\chi)$ (that account for the effect of the polymer network elasticity on the US speed [γ contributes prevailing in the region of high $\beta\approx 1$, while $(\gamma+\chi)$ in the region of small $\beta\approx 0$]) decrease as the network cross-linking increases so that by looking at Eq. (53) it comes clearly out that in such a case they would cause an increase in the US speed.

Moreover, since both γ and $(\gamma+\chi)$ are positive for the intermediate values of β, the effect of the polymer network is to decrease the US speed and to eliminate the US speed divergence due to the dilute matrix approximation for small values of β.

From experimental data we can also see that the value of the parameter Δ obtained from the last square fit procedure is equal to 0.0006 (practically null) for all PVA gel samples so that ϕ effectively represents the bounded water concentration and $(\beta-\phi)$ the free water concentration. This fact says that the bounded water concentration remains practically unchanged inside the PVA gel samples (as a function of β) so that primarily free water is subtracted when they are (mildly) dried.

C. Ultrasound wave attenuation

Some of the experimental data as well as the fits of the theoretical expression (49) are shown in Fig. 7. For the attenuation measurements as well as for the velocity ones, the value of the fitted parameter Δ resulted practically null.

A linear decrease in the US wave attenuation α is measured as a function of β for all samples with a mean value $\partial\alpha/\partial\beta=-2.4\pm 0.4$ cm^{-1}.

The pure water attenuation has also been measured to be 0.022 cm^{-1} and found to be much smaller than that one of the gel in the order of 1 cm^{-1}.

IV. DISCUSSION

The US propagation in natural hydrogels and soft tissues is currently described by a single-phase wave equation[37,38] where the medium is conceived as a fluid "solution" in which dissolved molecules can introduce processes of both dissipation and resonance. Even if this scheme completely ignores the liquid-solid arrangement, it gives appreciable results that are able to explain many aspects of tissue acoustical behavior. This probably happens because of the high built-in flexibility of such an equation that is able to comprehend a wide class of acoustical media thanks to a number of parameters that can be empirically adjusted to describe the propagation of acoustic waves.

Yang and Cleveland[39] showed that it is possible to reproduce the frequency dependence of the absorption with an exponent equal to 1.1 by supposing two juxtaposed relaxing processes that may or may not be real. In this way some information about the material medium (e.g., a natural gel or a tissue) is lost from the US behavior.

The model presented here discloses how the behavior of the US propagation is linked to the arrangement of the solid and liquid phases of the medium.

More recently Kowalski[40] developed a theory for the propagation of US in a dilute suspension. Even if conceptually different from a polymeric gel, a fluid suspension can be assimilated to a bi-phasic medium with a solid matrix (with its own elasticity and permeability) and a fluid that permeates the interstices. Obviously, the Kowalski model is expressed in terms of the viscoelastic parameters of the suspension that do not correspond *tout court* to those of the bi-phasic approach, except for the fluid fraction volume β.

The theoretical dependence of the US velocity as a function of the water volume fraction found by Kowalski is of the same type obtained in the present paper with the same good experimental agreement. The main difference is that the suspension does not have bounded water (i.e., $\phi=0$) so that at $\beta=1$ the US speed converges to that of the pure fluid.

Hence, the following features of the US propagation in hydrogels can be ascribed to their state of aggregation.

(i) The speed of propagation of US in highly hydrated gels is always a little bit higher than that of water (1480 m/s) since in Eq. (26) $\beta<1$ and $\phi>0$.

(ii) The US specific attenuation $2\pi\alpha/\kappa$ in natural hydrogels can follow a non-integer frequency law $\nu^{(1+\delta)}$ with $0<\delta\leq 1$, where δ is the exponent of the polymer-bounded water viscous interaction.

This outcome well agrees with the attenuation data of US in natural gels where δ is typically about 0.25–0.50 while the value for pure water is 1.

As far as it concerns the applicability of the diluted matrix approximation, we observe that the polymer content sensibly influences the US wave speed up to values of β as high as 0.7. For β higher than 0.70 the polymer effect on the US speed becomes smaller and smaller and the behavior approaches that one of dilute gels depicted in Fig. 1. By using Eq. (53) for $\beta=0.917$, the variation in the US speed due to the polymer network can be evaluated to be about 3.5% (for the PVA samples submitted to four cross-linking cycles) with a maximum value of 5.2% for the samples submitted to two cross-linking cycles.

It must also be noted that the development of tissue-mimicking US phantoms can take advantage by a model that discloses the relation between the medium organization and the US behavior.

In principle, even though living tissues, or organs, have their own complex morphology and anisotropy, a simplified bi-phasic model of soft (isotropic) natural tissue can be conceived by modeling biological cells as poroelastic spheres, endowed by internal and superficial elasticity and permeability, dispersed in a hydrogel environment.

Although the polymer and the bounded water contents of living tissues can reach much higher concentrations than in PVA gels, the present model can be used to describe the behavior of each type of biological hydrogel of a soft tissue (e.g., extra-cellular matrix, internal body of the cell, and so on). In this case, the "free water fractional content" is given by the effective β [given by Eq. (22) with $\Delta=0$] while the polymer-bounded water aggregate constitutes the solid part of the hydrogel matrix.

Even considering this simplest case, there are some limitations derived from the increased complexity of the architecture of the medium. First of all, in order to maintain the continuum approach, the US wave must not resolve the structure of the single cell. As a consequence of this, the theory is limited to US frequencies whose wavelength is much bigger than the cell dimensions. For instance, for cells of order of 30 μm and wave speed of order of 2×10^3 m/s, the upper frequency limit for the theory is smaller than 66 MHz.

It must also be pointed out that the number of material parameters of the model increases. In addition to β and f of the extra-cellular medium, the model would require β and f of the inner volume of the cells, the superficial elasticity as well as permeability of their membrane, and the percentage of the cellular volume. Such a relatively large number of material parameters will give rise to many possible tissue configurations. In this case, the major problem is to identify the appropriate set of values of those coefficients for each real tissue and how experimentally to measure them. Although the complexity of the model increases, it can definitely describe the US propagation in terms of collective cells and extra-cellular matrix poroelastic characteristics.

This opens up the way to US non-invasive tissue physiology evaluation since the permeability and elasticity of the cell structures depend on their state and functionality.

Once the model is validated, then it could be refined by introducing capillaries and blood vessels in the tissue as tubes filled by fluid (with their own internal β and wall elasticity and permeability).

V. CONCLUSIONS

In the present work a continuum model for US acoustic longitudinal waves in hydrogels has been presented. The model shows that a speed gap, at the hydrogel water volume fraction $\beta=1$, is generated by the presence of the bounded

water around the hydrogel polymer matrix: the bigger the bounded water concentration, the higher the US speed gap at $\beta=1$.

The poroelastic model also shows that in natural hydrogels the US attenuation follows a non-integer frequency law $\nu^{(1+\delta)}$ with $0<\delta\leq 1$ depending on the exponent δ describing the polymer-bounded water viscous interaction.

The experimental measurements confirm the gap between the US speed of propagation in the gel samples and that one of pure water at β close to 1 (100% water). Furthermore, the gel samples with a lower degree of cross-linking (and hence, with higher bounded water volume fraction) show a higher US speed gap at $\beta=1$. The evaluated bounded water fraction ranges from 2% in the PVA samples with six cross-linking cycles to 13% for the PVA samples with two cross-linking cycles.

In the range of experimental conditions ($\beta>0.4$), the bounded water volume fraction ϕ inside each type of PVA hydrogel does not depend on the free water amount. Moreover, as the gel water fraction β is lowered toward zero, the US propagation speed is more and more influenced by the matrix elasticity and increases in samples with higher network cross-linking in agreement with the classical rheological law.

The experimental data also show that the US attenuation in hydrogels decreases with the increase in the water volume fraction β in a linear way in agreement with the theoretical forecast.

All these results have been obtained by introducing into the bi-phasic theory the interaction of the bounded water around the polymer network that is peculiar of hydrogels. As a consequence of that, the proposed bi-phasic model has the capability to describe more appropriately the US propagation both in artificial hydrogels and in soft biological tissues, resulting in a promising tool in the biomedical field either for the development of non-invasive tissue-typing techniques or for the realization of phantoms for experimental tests such as those regarding the thermal therapy.

Self-demodulation of high-frequency ultrasound

Hendrik J. Vos, David E. Goertz,[a] and Nico de Jong[b]

(Received 29 December 2008; revised 16 December 2009; accepted 1 January 2010)

High-frequency (>10 MHz) ultrasound is used in, e.g., small animal imaging or intravascular applications. Currently available ultrasound contrast agents (UCAs) have a suboptimal response for high frequencies. This study therefore investigates the nonlinear propagation effects in a high-frequency ultrasound field (25 MHz) and its use for standard UCA and diagnostic frequencies (1–3 MHz). Nonlinear mixing of two high-frequency carrier waves produces a low-frequency wave, known as the self-demodulation or parametric array effect. Hydrophone experiments showed that the self-demodulated field of a focused 25 MHz transducer (850 kPa source pressure) has an amplitude of 45 kPa at 1.5 MHz in water. Such pressure level is sufficient for UCA excitation. Experimental values are confirmed by numerical simulations using the Khokhlov–Zabolotskaya–Kuznetsov equation on a spatially convergent grid.

I. INTRODUCTION

Over the past 20 years, high-frequency diagnostic ultrasound (>10 MHz) has found wide interest in areas such as intravascular ultrasound (IVUS),[1] small animal imaging,[2] and ocular diagnostics.[3,4] The improved spatial resolution at higher frequencies allows for imaging smaller anatomic or pathologic structures, such as atherosclerotic plaques. The implementation of flow imaging at higher frequencies has improved both sensitivity and resolution to permit microvascular imaging.[4,5] There remain, however, limitations in sensitivity due to issues of noise and tissue motion, such as in the context of vasa vasorum imaging in coronary arteries. This has led to investigating the use of ultrasound contrast agents[6] (UCAs) that enhance echo signals from the cardiovascular system, thus increasing the contrast to the surrounding tissue. The majority of ultrasound contrast imaging techniques are most efficient if the imaging frequency of the diagnostic system is approximately equal to the resonance frequency of the bubbles.[7,8] Commercial UCAs have therefore been developed to be primarily resonant within a limited frequency range, which is usually lower than the frequencies used in the aforementioned applications. For example, while contrast-enhanced IVUS and small imaging systems employ imaging frequencies of 15–50 MHz, the major resonance frequency of most conventional UCA bubbles is generally around 1–5 MHz.[9–11] The exception to this is Definity (Lantheus Medical Imaging, North Billerica, MA), which exhibits a dual frequency resonant peak, with a substantial subpopulation of bubbles resonant at higher ultrasound frequencies.[12] As a result, nonlinear (second and subharmonic) imaging approaches at higher frequencies have been shown to be feasible with Definity, either in native or population modified form, or with experimental bubble formulations that have been fabricated to be comprised primarily of bubbles below approximately 2 μm in diameter.[13] Despite the potential of second and subharmonic imaging of small bubble populations, it has yet to be established that these approaches are optimal for higher frequencies, which motivates the investigation of other approaches.

Often it is suggested in the literature that the detection of UCAs can be improved by using two-frequency approaches such as radial modulation[14–17] and nonlinear mixing.[18–21] Due to a nonlinear response of bubbles, the two frequencies would produce sum-and-difference components, which can be detected. For example, two studies exploited the beat frequency f_b of two carrier waves f_1 and f_2, where $f_b \ll f_1, f_2$.[20–22] The beat frequency was scattered by a population of bubbles and detected by a separate low-frequency transducer. Wu *et al.*[19] earlier used a similar technique, where the low-frequency was generated as a cross-product of all frequency contents of a short pulse. Using this method, Wu *et al.* reported a contrast-to-tissue ratio of ±15 dB (concentration was not reported) that the authors addressed fully to the nonlinear properties of bubbles.

However, in the rationale for such dual frequency UCA bubble detection techniques, it is neglected that sufficiently high pressure levels (on the order of 200 kPa and more), such as those used in the experiments, could introduce significant distortion of the pulse due to nonlinear propagation in the medium. More generally, clinical diagnostic ultrasound is regularly applied at pressure levels that introduce nonlinear distortion of the imaging pulse, not only leading to higher harmonics of the fundamental frequency[23,24] but also to low-frequency contents due to the so-called self-demodulation effect.[25–27] Self-demodulation is an effect in which a low-frequency pressure wave develops in a nonlinear medium as a function of the envelope of a high-frequency pulse. The low-frequency wave propagates as if it was generated by a planar low-frequency source and has di-

[b]Author to whom correspondence should be addressed. Electronic mail: n.dejong@erasmusmc.nl

rectivity about equal to the high-frequency carrier wave. Hence, the term "parametric array" has often been used in the past to describe such wave generation, particularly in marine applications.[25,28] Furthermore, self-demodulation has been experimentally shown to be able to excite uncoated gas bubbles.[29] The self-demodulation of short pulses was experimentally confirmed using carrier frequencies of 3.5 (Ref. 26) and 10 MHz.[30]

In an accompanying study, for which preliminary results are reported in Ref. 31, the current writers have found that a short (~2 cycles) ultrasound pulse with a carrier frequency of 10 MHz can excite bubbles having a resonance frequency of about 1 MHz by repeating the pulse at a repetition frequency of 1 MHz. In Ref. 31 it was suggested that the self-demodulation effect is the most significant mechanism to convert energy from the 10 MHz carrier wave into the lower bubble resonance frequency. However, no previous reports were found to address this effect in relevant settings for UCAs and high-frequency diagnostic ultrasound. This manuscript therefore characterizes the self-demodulation effect using both numerical simulations and acoustical experiments at frequencies and pressure levels suitable for high-frequency contrast-enhanced ultrasound imaging.

II. METHODS

A. Nonlinear ultrasound propagation

1. Transition pressure level for shock waves

The propagation of ultrasound can be described in three different regimes.[23,32,33] The first is the acoustical limit, which applies for very small amplitudes of the acoustic wave. The propagation is linear in such case. The second is a weakly nonlinear regime, in which waves can interact with other waves and itself; nonlinear distortion gives rise to second and higher harmonics of the fundamental frequency and also to lower frequencies due to the self-demodulation effect of non-continuous waves. The third approximation is the shock-front regime, in which nonlinear response of the medium has deformed an initially sinusoidal wave into sawtooth-like waves including a spatial discontinuity of the pressure. Such spatial discontinuity leads to high nonlinear dissipation of the acoustic energy.[27,32,34,35]

The current study addresses both the weakly nonlinear and shock-wave regimes. The transition pressure level between the two regimes can be estimated by considering the ultrasound field and medium properties. Bacon[34] theoretically derived the pressure in the focal region of a focused transducer for which the shock-front is fully developed. Equation (6) in Ref. 34 is rewritten as

$$p_f = \frac{\sigma_d \rho c^3 \sqrt{G^2-1}}{\omega \beta d \ln(G+\sqrt{G^2-1})}, \tag{1}$$

where p_f is the peak rarefaction pressure in the focus, σ_d is a dimensionless parameter related to the amount of distortion of the pulse[23,36] and the shock-front is fully developed for $\sigma_d = \pi/2$,[34] ρ is the density of the medium (998 kg/m^3 for water), c is the speed of sound (1482 m/s), ω is the driving frequency (rad/s), β is the nonlinear parameter [3.5 (Ref. 23)], and d is the geometrical curvature of the surface approximately equal to the focal distance if G is $\gg 1$. The acoustical gain G describes the focusing strength of a transducer defined by the ratio of the pressure level in the focus to the pressure level at the transducer surface, neglecting attenuation. The gain can be calculated by $G = \omega a^2/2cd$, with a as the aperture radius of the transducer.

Equation (1) assumes a Gaussian axial beam profile and neglects attenuation. Nevertheless it will serve as an estimator for the transition pressure from weakly nonlinear distortion to the full-shock theory throughout this paper.

2. Weakly nonlinear approximation of self-demodulation

As was derived by Berktay[25] in 1965 based on Westervelt's equation, the self-demodulation wave can be described as a function of the pulse envelope $E(t)$ only, i.e., independent of the carrier wave frequency and phase, as long as the time-scale of the envelope is far lower than the carrier frequency. Then, the self-demodulation pressure wave $p_{sd}(t)$ can be approximated by[25]

$$p_{sd}(t) \propto \frac{d^2}{dt^2}|E(t)|^2. \tag{2}$$

The current study exploits a transmitted ultrasound field $p_t(t)$ composed of a carrier wave having sine-wave envelope

$$p_t(t) = A \sin\left(\frac{\omega_{sd}}{2}t\right)\sin(\omega_c t), \tag{3}$$

which when employing Eq. (2) becomes

$$p_{sd}(t) \propto A^2 \omega_{sd}^2 \sin(\omega_{sd} t), \tag{4}$$

where A is the wave amplitude, ω is the angular frequency, "sd" denotes self-demodulation, and c is the carrier wave ($\omega_{sd} \ll \omega_c$). Since $E(t)$ is a sine-wave envelope in Eq. (3), $|E|^2$ has a frequency two times the frequency of $E(t)$. Furthermore, the second time derivative has a magnitude that depends linearly on $\omega_{sd}^2 E^2$. Hence the amplitude of the low-frequency component $p_{sd}(t)$ in Eq. (4) relates quadratically to the envelope frequency.

The transmitted pulse $p_t(t)$ in Eq. (3) is described likely by

$$p_t(t) = \frac{A}{2}\sin(\omega_1 t) + \frac{A}{2}\sin(\omega_2 t), \tag{5}$$

where $\omega_1 = \omega_c - \omega_{sd}/2$ and $\omega_1 = \omega_c + \omega_{sd}/2$. Hence, the frequency spectrum of $p_t(t)$ shows two separated peaks centered around the carrier frequency ω_c, with a difference frequency equal to ω_{sd}, the self-demodulation frequency.

A more thorough analysis of such bi-frequency source signal is found in the Fenlon solution,[32,37] which also addresses the nonlinear interaction between secondary frequency components, i.e., from all sum-and-difference combinations of $q\omega_1 + r\omega_2$, where q and r are integers. However, Eq. (2) provides an easy concept with the limitation that the approximation is only valid for low-level source pressures when secondary effects such as multiple harmonics of the

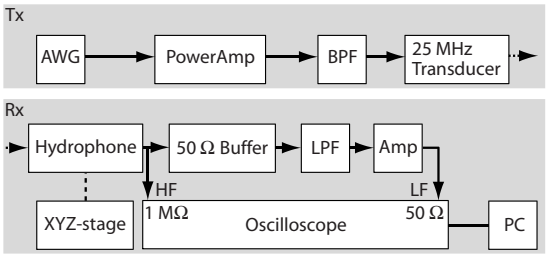

FIG. 1. Block diagram of the experimental setup. AWG is the arbitrary waveform generator, BPF is band-pass filter (8–28 MHz), and LPF is low-pass filter (10.7 MHz).

difference frequency are negligible. At the pressure levels reported in the current study, the secondary effects including shock-fronts will be shown to be significant, motivating the use of a numerical simulation model.

3. Numerical ultrasound propagation model

Simulation models of nonlinear propagation of ultrasound have found wide interest in the past.[23,35,38–42] One common approach for calculating the ultrasound field is the implementation of a parabolic wave-equation, as developed by Khokhlov, Zabolotskaya, and Kuznetsov (KZK).[32] The KZK-equation incorporates diffraction, absorption, and nonlinear propagation. As described by Lee and Hamilton,[38] the equations can be solved in the time-space-domain using a finite difference algorithm. Such approach has been shown to be able to predict the self-demodulation of a short pulse[26,38,43,44] and shock-fronts.[24,35]

In the experiments described in this paper, a strongly focused transducer was used, having an acoustical gain of 19. While the implementation of Lee and Hamilton is strictly limited to gains lower than 10, Hart and Hamilton[39] proposed a simulation grid that is suitable for strongly focused transducers. In Ref. 39 the KZK-equation is solved in frequency domain, while the current authors have chosen to adapt the time-domain numerical algorithm of Lee and Hamilton to work on the converging grid proposed by Hart and Hamilton. Details of the implementation are found in the Appendix. In the simulations the attenuation in water was taken as 25×10^{-3} Np/m MHz^2,[45] i.e., a sound diffusivity of 4×10^{-6} m^2/s (Ref. 32) and a converging-grid parameter δ of 7.[39] The grid resolution close to the transducer surface in the lateral direction was 16 μm (relative resolution of 0.005 of the aperture radius) and the axial stepsize was 38 μm. In focus these were 14 and 29 μm, respectively, showing the convergence of the grid. The temporal resolution was 0.66 ns.

B. Experimental setup

In order to verify the numerical results, an experimental setup was used to measure the actual ultrasound field of a 25 MHz single element transducer (V324, 1 in. focus, Olympus NDT, Waltham, MA). This transducer has an effective diameter of 6.3 mm and 27 mm focal distance, giving an acoustical gain of 19 at 25 MHz. With reference to Fig. 1, an arbitrary waveform generator (AWG520, Tektronix, Beaverton, OR) was connected through a −4 dB precision attenuator (VAT-4+, Mini-Circuits, Brooklyn, NY) to a linear power amplifier (1000 W, 10–86 MHz LPI-10, ENI, Rochester, NY). The output of the power amplifier was band-pass filtered using a custom high-power, 8–28 MHz, fifth-order Butterworth filter to reduce any residual low-frequency content and fed to the transducer. The transducer is characterized to generate a surface pressure of ~1.7 MPa peak-peak when driven by a 234 V peak-peak signal at 25 MHz. The acoustic pressure was measured by a calibrated needle hydrophone (0.075 mm diameter PVDF, Precision Acoustics Ltd., Dorchester, Dorset, UK) immersed in a large water tank. The tank contained tap-water left overnight to obtain room-temperature gas saturated water. The hydrophone was mounted on a computer-controlled precision XYZ stage. Although significant low-frequency content was present in the electric signal at the output of the high-power amplifier due to nonlinear amplification, this was strongly reduced by the band-pass filter at the output (reduction of >40 dB at 1.5 and 3 MHz) and by the reduced efficiency of the transducer at 1.5 and 3 MHz (additional reduction of >20 dB).

The expected low-frequency pressure levels are in the order of −30 to −50 dB below the high-frequency levels, and the receiving electronic circuit had to be extremely linear in order to avoid any nonlinear mixing. Therefore, the signal was split into low-frequency (LF) and high-frequency (HF) tracks. Again with reference to Fig. 1, the hydrophone signal was fed to a first channel of a 1 Gsample/s digital oscilloscope (Tektronix TDS3014B) set to 1 MΩ impedance and 256-averaging mode (HF track). The hydrophone signal was in parallel fed to a custom-built 50 Ω buffer amplifier (buf 602-opamp on a TI DEM-BUF-SO-1A demonstration fixture, Texas Instruments, Dallas, TX), a low-pass filter (10.7 MHz, Mini-Circuits, Brooklyn, NY), and amplified with a 36 dB low-noise amplifier (MiTEQ AU-1189, Hauppauge, NY) (LF track). This signal was averaged on a second channel of the oscilloscope.

The signal levels were carefully checked to be within the linearity-limits of the internal hydrophone amplifier, buffer amplifier, and low-noise amplifier. Also the amplification and attenuation of the components have been carefully characterized over the full range of frequencies employed (1–50 MHz). Final signal to noise ratio values were at least 17 dB at the low-frequency range (1–10 MHz) and 52 dB at the high-frequency range (20–60 MHz).

III. RESULTS

A. General principle

In the numerical simulation a pulse is constructed by summation of sinusoidal signals of 23.5 MHz (f_1) and 26.5 MHz (f_2) (see Fig. 2, left panel). The amplitude of the source pressure is set to 85 kPa, which results in focal pressures in the weakly nonlinear regime. The bottom panel shows the normalized frequency spectrum of the transmitted pulse obtained by the Fourier transform. The propagated pulse (Fig. 2, top middle) shows a rarefaction pressure level (0.7 MPa) smaller than the compression pressure level (1.6 MPa), demonstrating the distortion of the originally symmetric pulse. The spectrum in the bottom-middle panel contains the fun-

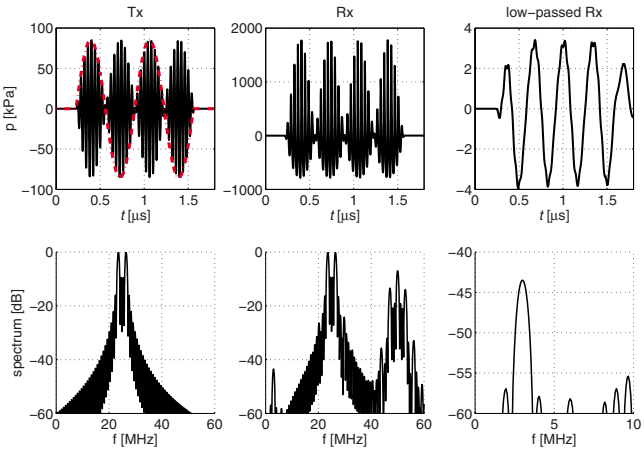

FIG. 2. (Color online) Simulation result of transmitting an ultrasound pulse constructed by the summation of 23.5 and 26.5 MHz waves, with 85 kPa amplitude (upper left), its frequency contents (lower left), and the resulting pulse (middle) and low-pass filtered pulse (right) in focus. The conversion of energy to lower frequency is caused by the self-demodulation effect.

damental frequencies f_1 and f_2, their second harmonic frequencies $2f_1$ and $2f_2$, and the sum-and-difference components of 50 and 3.0 MHz.

The pulse in focus is low-pass filtered (sixth-order Butterworth, −6 dB cut-off point at 6 MHz) and shown in Fig. 2 (top right panel). The amplitude of the low-frequency content is about 3 kPa. The corresponding spectral densities at the low-frequency are shown in the bottom panel. Note that the filtering operation is linear, and the low-frequency content is a "physical" wave that can autonomously interact with a bubble, even if the high-frequency carrier wave is attenuated in the focus.

Similarly, Fig. 3 shows the spectra of focal pulses with respective envelopes of 0 (i.e., no modulation), 1.5, and 3

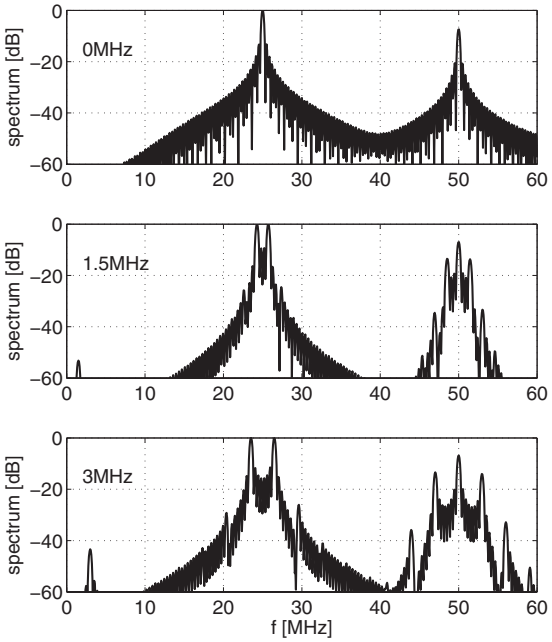

FIG. 3. Fourier spectra of weakly nonlinearly propagated pulses having center frequency of 25 MHz and source pressure amplitude of 85 kPa. The envelope frequencies are 0, 1.5, and 3 MHz.

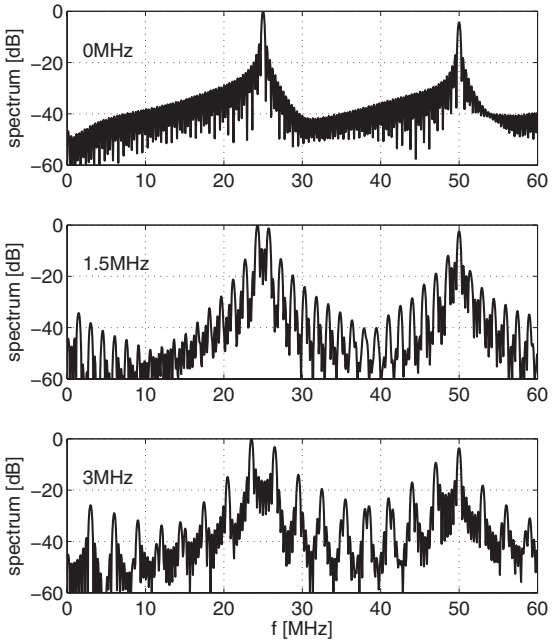

FIG. 4. Same parameter values as in Fig. 3, here with 850 kPa source pressure.

MHz. The increase in difference frequency f_1-f_2 leads to higher level of the self-demodulation frequency, as expected from application of Eq. (4). The time-domain pulses showed amplitudes of 1.1 kPa for the 1.5 MHz-envelope pulse and 5.7 kPa for the 3 MHz-envelope pulse. Such increase with a factor of 5 with double envelope frequency is roughly predicted by Eq. (4). With respect to the tone burst, a self-demodulation signal will appear, depending on the second derivative of the envelope squared [see Eq. (2)], but the level of this signal is outside the displayed dynamic range.

When setting the source pressure amplitude to 850 kPa, the threshold of 1.7 MPa of focal pressure predicted by Eq. (1) is exceeded. The pulse in focus has formed a full- shock-front, with a peak-negative value of 1.7 MPa and peak-positive value of up to 7 MPa. The spectra in Fig. 4 show many more sum-and-difference components, originating from interactions of both primary and secondary waves. The pulse contains strong second and higher harmonic contents of the low-frequency wave; for example, with the 3 MHz-envelope frequency, low-frequency waves with a frequency of 6 and 9 MHz are visible. Furthermore, the high-frequency contents show many side-bands with interspacing frequencies equal to the envelope frequency. Also, cross-products between f_1, f_2, and f_{sd} show up, at, e.g., 20.5 and 29.5 MHz, for a 3 MHz-envelope. Low-pass filtered waves had time-domain amplitudes of 45 and 130 kPa for the 1.5 and 3.0 MHz envelopes respectively, indicating a pressure increase by roughly a factor of 3 when the envelope frequency is doubled. In comparing this to the weakly nonlinear example, this shows that the formation of the shock-front reduces the squared dependency of the self-demodulation amplitude on the envelope frequency.

B. Transmit pressure dependency

Figure 5 shows the influence of the source pressure amplitude on the frequency content of the pulse at focus. For

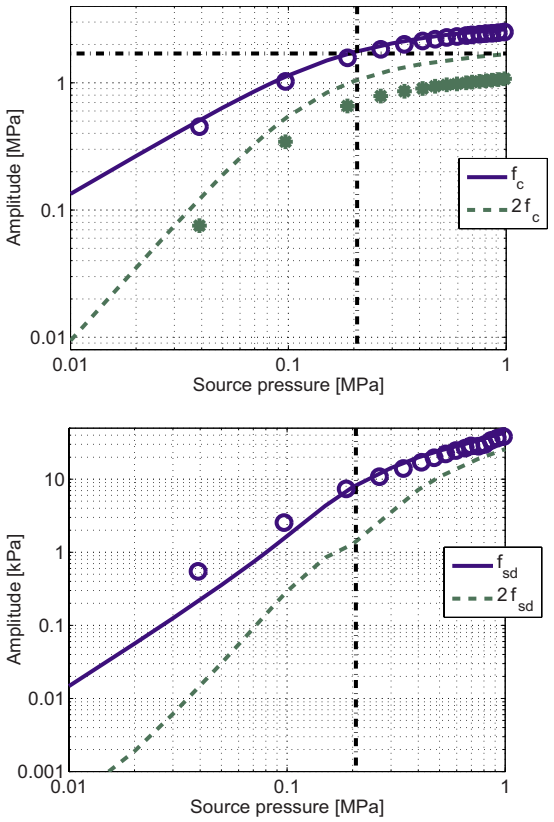

FIG. 5. (Color online) High-frequency (top) and low-frequency (bottom) pressure levels in the focus as a function of the source pressure. Circles denote experimental values. Carrier frequency f_c was 25 MHz and self-demodulation frequency f_{sd} was 1.5 MHz. The vertical line marks the full-shock pressure threshold of 1.7 MPa, as predicted by Eq. (1) for this transducer.

amplitudes lower than approximately 200 kPa, corresponding to a full-shock threshold of 1.7 MPa pressure in focus [Eq. (1), dashed-dotted lines in Fig. 5], the high-frequency f_c component has a linear relationship with source amplitude, whereas the low-frequency amplitude f_{sd} depends quadratically on the transmit pressure, as expected in the weakly nonlinear regime. The second harmonic of the low-frequency content ($2f_{sd}$) depends approximately cubically on the source level. This is unexpected since the bi-frequency solution of Fenlon predicts a power-of-4 dependency.[37] The difference will be further addressed in Sec. IV.

Above 200 kPa source pressure, the fundamental f_c component in the focus starts to deviate from a linear dependency, showing a flattening toward the acoustic saturation limit.[32,41] This is consistent with the expectation of nonlinear increase in dissipation associated with the presence of a shock-front.[41] Furthermore, the low-frequency (f_{sd}) amplitude starts to deviate from squared dependency to an almost linear relation, which is different from propagation in the weakly nonlinear regime.

Note that although the theoretical acoustical gain of this transducer at 25 MHz is 19, the actual ratio between source pressure and focal pressure for low amplitudes is only 12.5 [see Fig. 5(a), e.g., source pressure: 10 kPa, focal pressure: 125 kPa]. The difference of 52% (3.6 dB) can be fully attributed to the attenuation in water, which is about 2.2

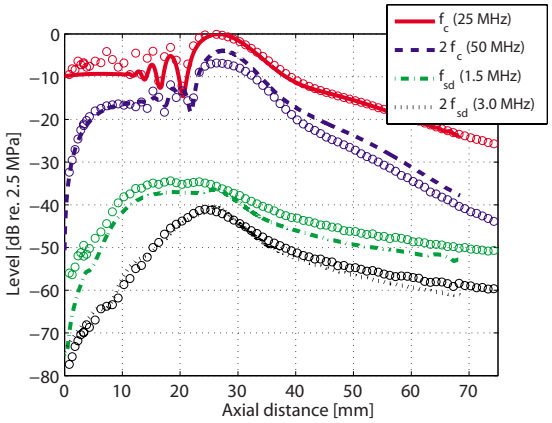

FIG. 6. (Color online) Simulated (lines) and experimental (circles) axial beam profiles at the fundamental frequency (25 MHz), second harmonic (50 MHz), self-demodulation frequency (1.5 MHz), and double self-demodulation frequency (3 MHz) as a function of distance from the transducer. Source amplitude is 850 kPa.

$\times 10^{-3}$ dB cm^{-1} MHz^{-2}.[45] At 25 MHz and a focal distance of 27 mm, the ultrasound is expected to be attenuated by 3.7 dB.

Experimentally obtained values are shown by dots in Fig. 5. The measured values of f_c and f_{sd} agree within 10% of the numerical predictions. The second harmonic amplitude at $2f_c$ is about 40% (3 dB) lower than the predicted amplitudes throughout the full range.

C. Beam profiles

Figure 6 shows the predicted axial beam profile of the transducer in the full-shock regime. The envelope frequency is set to generate 1.5 MHz self-demodulation waves and the pressure at the transducer surface is 850 kPa in amplitude, similar to the experimental value. Pulses obtained along the beam axis are digitally band-pass filtered at the carrier wave frequency (20–30 MHz, −6 dB bandwidth, Butterworth fourth-order) at the second harmonic frequency (40–60 MHz), at the self-demodulation frequency (0.75–2.25 MHz), and at twice the self-demodulation frequency (2.25–3.75 MHz). The plotted amplitudes are obtained in the time-domain after Hilbert transforming the filtered pulses.

At the carrier frequency f_c and its second harmonic, the highest amplitudes appear at 27 mm, which is the focal region. The self-demodulation wave begins to plateau at a 15 mm distance from the transducer, reaching a peak amplitude of −35 dB before decreasing after 25 mm. The amplitude of the 3 MHz wave, twice the self-demodulation frequency, is up to −40 dB in focus. Since 0 dB corresponds to 2.5 MPa in this figure, the amplitudes of the waves at 1.5 and 3 MHz are 45 and 25 kPa, respectively.

Figure 6 also shows the experimentally obtained amplitudes. The hydrophone was positioned along the beam axis at incremental distances from the transducer of 1–75 mm, in steps of 1 mm. The amplitude levels are obtained from the recorded pulses with the same filter characteristics as in the simulation and compensated for the hydrophone sensitivity. At 1 mm from the transducer, the amplitude of the self-demodulation pulse is over 50 dB smaller than the funda-

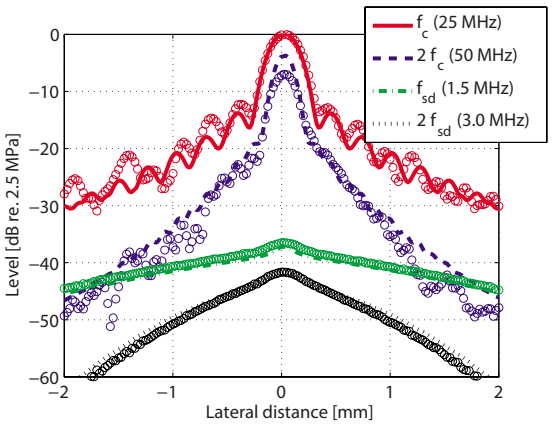

FIG. 7. (Color online) Simulated (lines) and experimental (circles) lateral beam profiles in focus (27 mm from transducer).

mental level, but achieves a maximum of −35 dB in the region before the focus. The normalization value was equal to that of the simulation. Note that the level at the second harmonic frequency matches the predicted values except for the focal region, where a difference of 3 dB is observed (cf. Fig. 5).

The lateral beam profile in the focal region (27 mm from the transducer) is plotted in Fig. 7. The −6 dB width of the fundamental frequency beam is 0.4 mm, while the self-demodulation beam measures approximately 3 mm. The high-frequency second harmonic beam at 50 MHz has about 0.3 mm width, and the low-frequency second harmonic beam at 3 MHz has 1.4 mm width.

The experimental lateral beam shown in Fig. 7 is very similar in shape and amplitude to the predicted beam. The fundamental-frequency side lobes show a slightly different spatial frequency, which could be attributed to a slight error in the estimation of the transducer geometry used for the simulation. Furthermore, the second harmonic levels are well predicted except for within the focal region and for $z \geq 0.7$ mm.

D. Influence of focusing and medium

Based on the simulation model, some additional comments can be made regarding the application of the self-demodulation technique.

First, focusing generally increases the pressure levels and therefore the self-demodulation pressure. For example, when modeling a focal distance of 13.5 mm (acoustic gain of 40) instead of 27 mm, with source pressure of 850 kPa, the self-demodulation pressure increases from 45 to 170 kPa. The change in focal distance also increases the primary wave amplitude in focus, and for comparison, reducing the source pressure in the latter configuration to 425 kPa gives a 92 kPa self-demodulation wave. Note that in such comparison the self-demodulation wave depends almost linearly on the source pressure, and not quadratic, as expected from Eq. (4), since nonlinear shock-wave dissipation is significant. As another example, taking a flat surface (i.e., unfocused) instead of curved one, the self-demodulation level is 4 kPa. Compared to the focused geometry the conversion is much lower.

TABLE I. Simulation results with two transducers models, in water and tissue. Carrier frequency is 25 MHz and envelope frequency is 1.5 MHz.

Aperture diameter (mm)	Focal distance (mm)	Acoustical gain	Source pressure (MPa)	Amplitude of self-demodulation wave (kPa)	
				Water	Tissue
6	12.7	36	0.5	100	4
			5	800	250
0.9	Flat	2	1.5	7	3
			5	60	30

This can be attributed to the lower acoustical gain and high attenuation in water at 25 MHz, giving lower fundamental-frequency pressure levels.

Second, the application of the self-demodulation technique *in vivo* implies a different propagation medium. Tissue generally has a higher nonlinearity value than water, but also higher attenuation. For example, liver tissue has a nonlinearity β of 4.4 compared to 3.5 of water.[45] The attenuation is about 20 dB/cm at 25 MHz, while water has attenuation of about 1.4 dB/cm at 25 MHz.[45] Combining tissue values with the focused transducer model gives a maximum self-demodulation pressure level of 6 kPa (peak rarefaction amplitude of 1.1 MPa at the 25 MHz primary field), which is low for contrast excitation applications.[46] In clinical applications it would be better to use strongly focused transducers. For example, a 25 MHz probe of the commercially available high-frequency scanner Vevo-770 (RMV 707B, VisualSonics, Toronto, Canada) has a diameter of 6 mm and focal length of 12.7 mm (gain of 36). The acoustic pressure close to the transducer was 0.5 MPa measured with the hydrophone setup. Inserting such model in the simulation with liver tissue, the self-demodulation pressure is 4 kPa. By artificially increasing the source pressure to 5 MPa, which might be achieved in future using more efficient transducers,[47] a self-demodulation value of 250 kPa can be obtained (see Table I). The peak rarefaction pressure value of 25 MHz wave is 4.5 MPa. Note that the high attenuation has resisted the formation of shock waves, giving an almost squared relation of the self-demodulation with source pressure in tissue; this relation could help evaluate the applicability of high-frequency systems for self-demodulation techniques.

Third, the combination of the self-demodulation technique with IVUS transducers[1] might be beneficial for contrast agent excitation. Such catheter based transducers are limited in size to about 0.9 mm in diameter, and the source pressure can reach higher values, currently up to at least 1.5 MPa. For this application, the simulated self-demodulation pressures will not exceed 3 kPa in tissue. We estimate that it would be necessary to increase IVUS source pressures by a factor of 3 in order to generate a self-demodulation signal sufficiently strong to excite contrast agents (see Table I).

IV. DISCUSSION AND CONCLUSIONS

A. General principle

Figures 2–5 show the general results of the self-demodulation technique. The full-shock threshold level is

well predicted by Eq. (1), even in the case of strong attenuation at such high carrier frequencies (Fig. 5). A focal pressure far below this threshold shows self-demodulation tendency described by Berktay[25] [cf. Eq. (2)], but a pressure close to the threshold resulted in significant spectral content at many distinct frequencies. In particular, the second and higher harmonic frequencies of the low-frequency wave are clearly visible in Fig. 4. The origin of these signals is the interaction of primary and/or secondary frequency components. For example, a 3 MHz wave could originate from the interaction of 22.75 (f_1-f_{sd}) and 25.75 MHz (f_2), or secondary frequencies only, for example, 48.5 ($2f_1$) and 51.5 MHz ($2f_2$). One way to look at the higher difference frequency is based on Berktay's approximation [Eq. (2)]. Because the envelope shown in Fig. 2 (middle panel) is not a sine-wave anymore, but rather a sum of sine-waves having multiple-integer frequencies of the fundamental, Eq. (2) will also predict multiple-integers of the self-demodulation frequency.

The third-power relation between the amplitude of the second difference frequency ($2f_{sd}$) and the amplitude of the source pressure is not predicted by nonlinear plane-wave propagation theory. Fenlon's solution[32,37] predicts that the amplitude of the second difference frequency should increase with the source pressure to the fourth-power, rather than the third-power increase found in the current simulations. Furthermore, we employed additional calculations in which the diffraction step was removed from the KZK simulations. This basically yields a numerical implementation of the plane-wave Burgers equation in time-domain.[32] When the other simulation parameters were kept equal to those described in the current paper, a fourth-power increase was found, like predicted by the Fenlon solution. Variation in the attenuation values in this plane-wave simulation did not change the result either. Hence, the deviation from the fourth-power dependency is not caused by the attenuation or numerical implementation. It can therefore be suggested that the focusing of the current sound field is responsible for the observed third-power dependency.

Another striking feature is seen in the lateral beam profiles at 1.5 and 3 MHz (Fig. 7). The −6 dB beam width of the low-frequency wave is 3 mm, which equals 3λ (wavelength $\lambda \approx 1$ mm at 1.5 MHz). The 3 MHz wave has −6 dB beam of 1.4 mm, again equal to about 3λ ($\lambda \approx 0.5$ mm at 3 MHz). The absolute beam width decreases with the harmonic number, as was earlier reported,[27] and the equality of the relative beam widths implies equal sources of the secondary waves, as long as the phenomenon is diffraction limited. Also note that the carrier beam width in focus is only 0.4 mm, much smaller than that of the self-demodulation wave, but is much wider in the pre-focal region where the self-demodulation wave is building up.

The −6 dB beam width of 3 mm (Fig. 7) could be somewhat disappointing for imaging applications since the parametric approach has been used in the past to generate narrow low-frequency beams with relatively small transducers. However, conventionally producing such beam width at 27 mm distance from a 6.3 mm transducer is impossible at 1.5 MHz (from KZK simulation: 6 mm beam width at 27 mm distance).[25] Also, the second harmonic beam width of such transducer transmitting a 0.75MHz ultrasound field still produces larger beam width (4 mm). Therefore, the self-demodulation technique provides narrowest beam. Apart from the lateral beam width, the axial focal region is smaller and more pronounced than with conventional 1.5 MHz ultrasound field generation.[48]

When comparing the simulation results of the beam profiles to the experimental ones (Figs. 6 and 7), in general, very similar levels occur for all four frequency components (except for the focal region; see below). This finding has two major implications. First, it implies that the simulations using the KZK-equation predicts correct attenuation and diffraction for the given transducer model. Second, it also correctly predicts the nonlinear distortion of the pulse. These are not trivial results since the parabolic assumption in the wave propagation is challenged by the geometries employed in this study. However, Naze Tjøtta *et al.*[48] derived that the parabolic approximation is valid as long as the ratio of focal distance d and aperture radius a are larger than 3.5, which is the case in the current study ($d/a \sim 8$).

The $2f_c$ level in focus is predicted by the model to be −4 dB compared to fundamental level, while the measured value is at −7 dB; this difference is also seen in Fig. 5. A −4 dB second harmonic level is perhaps surprising since nonlinear propagation theory predicts an absolute maximum of −6 dB.[23] The current writers can only hypothesize that the error originates from an underestimation of the shock-wave dissipation since the shock-wave is most prominent in the focal region.

B. Implications

The role of attenuation is twofold in the self-demodulation process. In general terms the self-demodulation process merits a highly absorptive medium to isolate the low-frequency components from the high-frequency primary waves. However, attenuation also reduces the pressure level, which, in turn, could affect the nonlinear conversion. Focusing of the beam produces a 40-fold increase in the self-demodulation amplitude in water, as shown with the additional simulations, because of the higher gain but also because of less attenuation since the distance to the focal region is reduced. Note that Naze Tjøtta *et al.*[48] earlier stated that focusing has only limited effect on the self-demodulation amplitude, but their finding was based on zero-absorption calculations.

The self-demodulation technique allows for engineering pulses, e.g., without any transient head or tail (cf. Fig. 2), or for generating very wide-band low-frequency signals.[25,29,40] This can be advantageous over conventional linear generation of pulses in an experimental setup with a possibly limited bandwidth. To produce low-frequency wide-band signals, a high-frequency carrier wave with Gaussian envelope suffices.[25,29,40] In fact, by carefully applying Berktay's approximation on a Gaussian-enveloped pulse, it can be shown that the center frequency of the self-demodulated wave is equal to the −3 dB absolute bandwidth of the transmission pulse.[25] This rule of thumb could help in analyzing the frequency spectrum of a nonlinearly propagating acoustic pulse.

Furthermore, the technique provides acoustic amplitudes suitable for contrast microbubble excitation. This has two major implications. First, the effect can, for example, be used in spectroscopy measurements, as shown by the current authors.[31] The high pressure amplitudes of the primary field in water could give rise to microbubble destruction that should be avoided. An acoustic filter[40] or absorptive medium such as tissue could reduce the level of the primary waves. A pressure value of 1.1 MPa in tissue at 25 MHz, as reported in Sec. III, is close to the microbubble destruction level at 20 MHz (Ref. 49) but below that of 30 MHz.[13] However, the approach is most suitable for imaging larger bubbles (i.e., resonant at the low frequencies), and these will be far less susceptible to being destroyed by high-frequency ultrasound than smaller bubbles that are closer to resonance. Second, the finding might be important for the works by, e.g., Wu *et al.*[19] and Chen *et al.*,[20] who used a semi-dual frequency technique to increase the detection signals of contrast bubbles. In the rationale all low-frequency contents in the echoes are suggested to be generated by nonlinear behavior of microbubbles. The current study, however, shows that nonlinear propagation cannot be *a priori* neglected. In contrast detection applications where the main low-frequency generation mechanism is nonlinear propagation, the low-frequency content will also be present in tissue-scattered signals, and the agents merely increase contrast by linear scattering. Hydrophone experiments or numerical propagation simulations showing the exact frequency content of the acoustic excitation pulse could elucidate the relative significance of nonlinear propagation compared to nonlinear scattering of bubbles.

C. Concluding remarks

This paper presents numerical and experimental results of the self-demodulation effect, using ultrasound conditions that are relevant for high-frequency medical imaging. The mechanism provides sufficient acoustic pressure in water, 45 kPa, to excite an UCA microbubble.[46,50] Although the self-demodulation technique has been previously used to investigate uncoated gas bubbles in water, see, e.g, Refs. 29 and 40, no reports have been found to address the possibility of its use in combination with UCAs.

The poor efficiency of the self-demodulation mechanism is a disadvantage. In the reported experiments, the source pressure is 850 kPa, giving 45 kPa low-frequency amplitude. Tissue attenuation decreases the self-demodulation pressure dramatically (Table I), which can be overcome by focusing and/or increased transmit amplitudes. Another solution is a reduction in carrier frequency to the range 10–20 MHz. Such range is currently used for small animal imaging and carotid artery scanning and might therefore be easily implemented in current clinical systems.

The authors wish to thank Dr. V. F. Humphrey and Dr. J. Huijssen for the very helpful discussions on the self-demodulation technique.

APPENDIX: KZK ON A CONVERGING/DIVERGING GRID

Hart and Hamilton described a numerical implementation of the KZK-equation for strongly focused spherical transducers accounting for absorption, diffraction, and nonlinear propagation.[39,48] The spatial numerical grid converges from the transducer to the focal region and diverges afterward, thus having highest resolution in the focal region where high spatial variations in the pressure are expected. The equations developed in Ref. 39 solve the KZK-equation in the frequency domain, while the current writers have opted for an implementation in the time-domain, analogous to the derivation by Lee and Hamilton.[38] Such an implementation in the time-domain is computationally more effective when acoustic shock-fronts are expected compared to the frequency-domain solution.[51] However, the numerical calculation scheme in Ref. 51 has to be adapted to suit the converging/diverging grid.

The reader is referred to Ref. 51 for a full description of the numerical implementation, and Refs. 39 and 48 for the theory on the converging/diverging grid. The KZK-equation in reduced units for the converging/diverging grid reads[39] as

$$\left((\sigma \pm \delta)^2 \frac{\partial^2}{\partial \bar{\tau}\, \partial \sigma} - \frac{1}{4G}\bar{\nabla}_{\perp}^2 - (\sigma \pm \delta)^2 A \frac{\partial^3}{\partial \bar{\tau}^3}\right)\bar{P} = (\sigma \pm \delta)\frac{B}{2}\frac{\partial^2 \bar{P}^2}{\partial \bar{\tau}^2}, \tag{A1}$$

with σ (≥ -1) the axial distance to the transducer, δ (>1) the parameter that governs the convergence of the grid, $\bar{\tau}$ the retarded time (≥ 0), G the acoustic gain, and $\bar{\nabla}_{\perp}^2$ the two-dimensional Laplace operator with respect to $\bar{u}$ (≥ 0), which is the lateral distance to the beam axis. The parameters A and B characterize the absorption and source amplitude, respectively.[39] The pressure signal is denoted by $\bar{P}$. The value of σ equals -1 at the transducer surface and 0 in the geometrical focus of the transducer. The $-$ sign in the denominator is chosen if σ is negative and + elsewhere.[39]

Compared to the time-domain code description in Ref. 51, diffraction and nonlinear propagation have to be adapted for the current grid; attenuation is unchanged. In Ref. 51, Eqs. (3.30)–(3.32) and (3.40–3.42) express the numerical implementation of the diffraction term. These are unchanged. However, the value of R defined in Eqs. (3.33) and (3.43) becomes

$$R = \frac{\Delta\bar{\tau}(\Delta\sigma)_k}{(\sigma_{k+1} \pm \delta)^2 (\Delta\bar{u})^2}, \tag{A2}$$

with k the index associated with finite steps of σ.

Calculation of the nonlinear propagation term is less straightforward due to the change in sign before δ at $\sigma=0$. Equation (3.56) in Ref. 51 is replaced by

$$\frac{\partial \bar{P}}{\partial \sigma} = \frac{N\bar{P}}{(\sigma \pm \delta)}\frac{\partial \bar{P}}{\partial \bar{\tau}}, \tag{A3}$$

with N the parameter of nonlinearity. Equation (A3) is solved using a stretched coordinate ζ,[51]

$$\frac{d\varsigma}{d\sigma}\frac{\partial \bar{P}}{\partial \varsigma} = \frac{N\bar{P}}{(\sigma \pm \delta)}\frac{\partial \bar{P}}{\partial \bar{\tau}}. \tag{A4}$$

With a definition of

$$\frac{d\varsigma}{d\sigma} = \frac{1}{(\sigma \pm \delta)}, \tag{A5}$$

Equation (A4) is reduced to

$$\frac{\partial \bar{P}}{\partial \varsigma} = N\bar{P}\frac{\partial \bar{P}}{\partial \bar{\tau}}, \tag{A6}$$

and Eq. (A5) is rewritten as

$$\varsigma = \int_{-1}^{\sigma} \frac{d\sigma'}{(\sigma' \pm \delta)}, \tag{A7}$$

where the integration limits are dictated by the boundary condition $\zeta=0$ when $\sigma=-1$, and the $-$ sign should be chosen when σ', the integration variable, is negative.

Tedious but straightforward evaluation of Eq. (A7) for all $\sigma<0$ and $\sigma\geq 0$ results in

$$\varsigma = \int_{-1}^{\sigma} \frac{d\sigma'}{(\sigma' \pm \delta)} = \ln\left(\frac{|\sigma| + \delta}{\delta + 1}\right). \tag{A8}$$

Following Lee, an exact implicit solution of Eq. (A6) is of the format

$$\bar{P}(\sigma, \bar{\tau}) = F(\bar{\tau} + N\bar{P}\varsigma), \tag{A9}$$

and at the subsequent spatial step, combining Eqs. (A9) and (A8),

$$\bar{P}(\sigma + \Delta\sigma, \bar{\tau}) = F\left(\bar{\tau} + N\bar{P}\ln\left[\frac{|\sigma| + \Delta\sigma + \delta}{\delta + 1}\right]\right). \tag{A10}$$

Rewriting the argument of the natural logarithm in Eq. (A10) and combining with Eq. (A9) yield the forward stepping algorithm

$$\bar{P}(\sigma + \Delta\sigma, \bar{\tau}) = \bar{P}\left(\sigma, \bar{\tau} + N\bar{P}\ln\left[1 + \frac{\Delta\sigma}{|\sigma| + \delta}\right]\right). \tag{A11}$$

The numerical implementation of the nonlinear differential equation is thus [compared with Eq. (3.71) in Ref. 51]

$$P_{i,j}^{k+1} = \frac{P_{i,j}^{k}}{1 - N[(P_{i+1,j}^{k} - P_{i,j}^{k})/\Delta\bar{\tau}]\ln\left[\dfrac{1 + (\Delta\sigma)_k}{(|\sigma_k| + \delta)}\right]} \quad \text{for } P_{i,j}^{k} \geq 0. \tag{A12}$$

For $P_{i,j}^{k}<0$ the pressure difference takes the form of $(P_{i,j}^{k} - P_{i-1,j}^{k})$, analogous to Lee's implementation.

Acoustic microstreaming around an encapsulated particle

Alexander A. Doinikov[a] and Ayache Bouakaz
INSERM U930 CNRS ERL 3106, Université François Rabelais, CHU Bretonneau, 2 Boulevard Tonnellé, 37044 Tours Cedex 9, France

(Received 10 December 2009; accepted 15 December 2009)

A theory is suggested to calculate acoustic microstreaming that develops around an encapsulated particle in an ultrasound field. It is assumed that the particle is suspended in an unbounded fluid and can have a gas core or a liquid core. Fluids outside and inside the particle are assumed to be viscous and compressible. No restrictions are imposed on the size of the particle relative to the sound and viscous wavelengths in the outer and inner fluids, and all modes of the particle's motion, including the surface ones, are taken into account. The shell of the particle is assumed to be an elastic viscous compressible medium. Solutions for the sound field within the shell are also valid for any ratio between the particle size and the sound and viscous wavelengths in the shell material. Numerical examples for the cases of an encapsulated gas bubble and an encapsulated particle with a liquid core are presented. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3290997]

I. INTRODUCTION

Acoustic streaming produced by bubbles oscillating in a sound field has been a topic of research for many years (Nyborg, 1958, 1965; Elder, 1959; Davidson and Riley, 1971; Lee and Wang, 1990; Wu and Du, 1997; Longuet-Higgins, 1998). This attention is related to a diversity of technological and biomedical applications where this phenomenon plays a role. In recent years, in connection with clinical applications of contrast agent microbubbles, interest to acoustic microstreaming generated by encapsulated bubbles has arisen. Liu and Wu (2009) developed a theory to calculate the microstreaming velocity for an encapsulated bubble, taking account of two modes of the bubble's motion: a monopole (volume pulsation) and a dipole (translational harmonic vibration). Their theory also assumes that the wavelength of the incident sound field is much greater than the radius of the bubble, and the thickness of the viscous boundary layer surrounding the bubble is much smaller than the radius of the bubble. Liu and Wu (2009) used a theoretical approach that was suggested previously by Wu and Du (1997) for a free bubble. This approach is based on the assumption that viscous effects are essential only within a thin boundary layer while beyond this layer the fluid motion can be considered to be inviscid. However, Doinikov and Bouakaz (2010) showed that the approach suggested by Wu and Du (1997) may be applied only to very low-viscosity fluids, whose viscosity is far less than that of water. Under normal conditions, their solutions lead to a severe underestimation of the strength of acoustic streaming because dominant viscous terms in the first-order velocity field are determined incorrectly. The work of Liu and Wu (2009) encounters the same problem.

In this paper, a theory void of the restrictions of Liu and Wu's (2009) approach is developed. It is assumed that fluids outside and inside an encapsulated particle are viscous and compressible. Solutions which are derived for the scattered sound fields outside and inside the particle are valid for the entire volume of the outer and inner fluids. No restrictions are imposed on the size of the particle relative to the sound and viscous wavelengths in the outer and inner fluids, and all modes of the particle's motion, including the surface ones, are taken into account. The shell of the particle is assumed to be an elastic viscous compressible medium. Solutions for the sound field within the shell are also valid for any ratio between the particle size and the sound and viscous wavelengths in the shell material.

II. THEORY

In the process of the derivation of acoustic radiation force acting on a spherical particle of arbitrary internal structure in a sound wave field, Doinikov (1994, 1997) obtained solutions to the equations of acoustic streaming developing around the particle. These solutions impose no restrictions on the size of the particle with respect to the sound and viscous wavelengths in the ambient fluid and take into account all modes of the particle's motion: volume pulsation, translation, and shape oscillations. The velocity field of acoustic streaming is expressed in terms of linear scattering coefficients which are determined by the particle's internal structure. To apply Doinikov's (1994, 1997) theory to an encapsulated particle, linear scattering coefficients for this particle should be calculated. In Secs. II A–II E, we carry out this calculation. Section II F provides the equations of acoustic streaming in which the calculated scattering coefficients are used.

A. Acoustic field in the ambient liquid

The first-order velocity in the ambient liquid is represented as

$$\boldsymbol{v}_l = \nabla\varphi_I + \nabla\varphi_l + \nabla\times\boldsymbol{\psi}_l, \tag{1}$$

where φ_I is the scalar velocity potential of the incident acoustic field, and φ_l and $\boldsymbol{\psi}_l$ are the scalar and the vorticity

 0001-4966/2010/127(3)/1218/10/$25.00

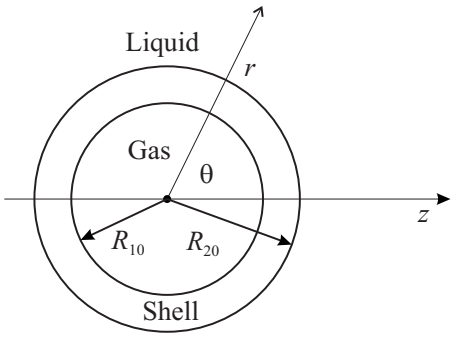

FIG. 1. Schematic sketch of an encapsulated particle.

velocity potentials of the scattered wave field. The potential φ_I is given by

$$\varphi_I = \exp(-i\omega t)\sum_{n=0}^{\infty} A_n j_n(k_l r) P_n(\cos\theta), \tag{2}$$

where j_n is the spherical Bessel function of order n, P_n is the Legendre polynomial of degree n, k_l is the wave number in the ambient liquid, and r and θ are the coordinates of the spherical coordinate system (r,θ,ε) whose origin is at the equilibrium center of the particle and the z axis (θ=0) lies in the direction of wave propagation, see Fig. 1. It should be emphasized that Eq. (2) describes an axially symmetric wave, and the particle is assumed to be located on the axis of the wave. The coefficients A_n specify the type of incident wave. For a plane traveling wave with the potential

$$\varphi_I = A\,\exp(i\boldsymbol{k}_l\cdot\boldsymbol{r} - i\omega t), \tag{3}$$

the coefficients A_n are given by

$$A_n = A(2n+1)i^n. \tag{4}$$

The wave number k_l is defined by

$$k_l = \frac{\omega}{c_l}\left[1 - \frac{i\omega}{\rho_l c_l^2}\left(\xi_l + \frac{4}{3}\eta_l\right)\right]^{-1/2}, \tag{5}$$

where c_l is the sound speed in the liquid, ρ_l is the equilibrium liquid density, η_l is the liquid shear viscosity, and ξ_l is the liquid bulk viscosity.

The velocity potentials of the scattered field are written as

$$\varphi_l = \exp(-i\omega t)\sum_{n=0}^{\infty} \alpha_n^{(l)} A_n h_n^{(1)}(k_l r) P_n(\cos\theta), \tag{6}$$

$$\boldsymbol{\psi}_l = \exp(-i\omega t)\boldsymbol{e}_\varepsilon \sum_{n=1}^{\infty} \beta_n^{(l)} A_n h_n^{(1)}(k_{lv} r) P_n^1(\cos\theta). \tag{7}$$

Here, $\alpha_n^{(l)}$ and $\beta_n^{(l)}$ are the linear scattering coefficients to be determined by the boundary conditions at the surface of the particle, $h_n^{(1)}$ is the spherical Hankel function of the first kind, $\boldsymbol{e}_\varepsilon$ is the unit azimuth vector of the spherical coordinate system introduced above, k_{lv} is the viscous wave number, and P_n^1 is the associated Legendre polynomial of the first order and degree n. Note that P_n^1 is defined here as

$$P_n^1(x) = (1-x^2)^{1/2} dP_n(x)/dx. \tag{8}$$

The viscous wave number k_{lv} is given by

$$k_{lv} = (1+i)/\delta_{lv}, \tag{9}$$

where $\delta_{lv} = \sqrt{2\nu_l/\omega}$ is the viscous penetration depth in the ambient liquid and $\nu_l = \eta_l/\rho_l$ is the liquid kinematic viscosity.

From Eqs. (1), (2), (6), and (7), the r and θ components of the liquid velocity are found to be

$$v_r^{(l)} = \exp(-i\omega t)\frac{1}{r}\sum_{n=0}^{\infty} A_n P_n(\cos\theta)[k_l r j_n'(k_l r) + \alpha_n^{(l)} k_l r h_n^{(1)\prime}(k_l r) + \beta_n^{(l)} n(n+1) h_n^{(1)}(k_{lv} r)], \tag{10}$$

$$v_\theta^{(l)} = -\exp(-i\omega t)\frac{1}{r}\sum_{n=1}^{\infty} A_n P_n^1(\cos\theta)[j_n(k_l r) + \alpha_n^{(l)} h_n^{(1)}(k_l r) + \beta_n^{(l)}(h_n^{(1)}(k_{lv} r) + k_{lv} r h_n^{(1)\prime}(k_{lv} r))], \tag{11}$$

where the prime denotes the differentiation with respect to the argument in parentheses.

The calculation of acoustic streaming also requires the expression for the first-order perturbation of the liquid density. Using the continuity equation, the liquid density perturbation can be written as

$$\tilde{\rho}_l = -\frac{i\rho_l}{\omega}\boldsymbol{\nabla}\cdot\boldsymbol{v}_l = \exp(-i\omega t)\frac{i\rho_l k_l^2}{\omega}\sum_{n=0}^{\infty} A_n P_n(\cos\theta) \times[j_n(k_l r) + \alpha_n^{(l)} h_n^{(1)}(k_l r)]. \tag{12}$$

If the particle is absent, the liquid density perturbation caused by the incident field is given by

$$\tilde{\rho}_I = i\rho_l k_l^2 \varphi_I/\omega. \tag{13}$$

B. Acoustic field in the encapsulating shell

The motion of the shell is described by the following equation (Landau and Lifshitz, 1986):

$$\rho_s \frac{\partial^2 u_i}{\partial t^2} = \frac{\partial \sigma_{ij}^{(s)}}{\partial x_j}, \tag{14}$$

where ρ_s is the equilibrium density of the shell, $\boldsymbol{u}$ is the displacement vector, $\sigma_{ij}^{(s)}$ is the shell stress tensor, and summation over double indices is implied. Assuming that the shell material possesses elasticity and viscosity, the shell stress tensor can be written as $\sigma_{ij}^{(s)} = \sigma_{ij}^{(\mathrm{el})} + \sigma_{ij}^{(\mathrm{vis})}$, where the elastic and the viscous parts are specified by Hooke's elastic law and Newton's viscous law,

$$\sigma_{ij}^{(\mathrm{el})} = \mu_s\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) + \left(K_s - \frac{2}{3}\mu_s\right)\delta_{ij}\frac{\partial u_k}{\partial x_k}, \tag{15}$$

$$\sigma_{ij}^{(\mathrm{vis})} = \eta_s\left(\frac{\partial v_i^{(s)}}{\partial x_j} + \frac{\partial v_j^{(s)}}{\partial x_i}\right) + \left(\xi_s - \frac{2}{3}\eta_s\right)\delta_{ij}\frac{\partial v_k^{(s)}}{\partial x_k}. \tag{16}$$

Here μ_s is the shell shear modulus, K_s is the shell bulk modulus, δ_{ij} is the Kronecker delta, η_s is the shell shear viscosity, ξ_s is the shell bulk viscosity, and $\boldsymbol{v}^{(s)}$ is the velocity within the shell material.

Substituting Eqs. (15) and (16) into Eq. (14) and taking into account that $\boldsymbol{v}^{(s)}=\partial \boldsymbol{u}/\partial t$ and the incident field depends on time as $\exp(-i\omega t)$, one obtains

$$\rho_s\omega^2\boldsymbol{u} + (\mu_s - i\omega\eta_s)\Delta\boldsymbol{u} + [K_s + \mu_s/3 - i\omega(\xi_s + \eta_s/3)]\nabla(\nabla\cdot\boldsymbol{u}) = 0. \tag{17}$$

The displacement vector can be represented as

$$\boldsymbol{u} = \nabla\varphi_s + \nabla\times\boldsymbol{\psi}_s. \tag{18}$$

Substitution of Eq. (18) into Eq. (17) yields

$$\Delta\varphi_s + k_s^2\varphi_s = 0, \tag{19}$$

$$\Delta\boldsymbol{\psi}_s + k_{sv}^2\boldsymbol{\psi}_s = 0, \tag{20}$$

where the wave numbers are given by

$$k_s = \left(\frac{\rho_s\omega^2}{K_s + 4\mu_s/3 - i\omega(\xi_s + 4\eta_s/3)}\right)^{1/2}, \tag{21}$$

$$k_{sv} = \left(\frac{\rho_s\omega^2}{\mu_s - i\omega\eta_s}\right)^{1/2}. \tag{22}$$

The axisymmetric solutions to Eqs. (19) and (20) are written as

$$\varphi_s = \exp(-i\omega t)\sum_{n=0}^{\infty} A_n[\alpha_{1n}^{(s)}h_n^{(1)}(k_s r) + \alpha_{2n}^{(s)}h_n^{(2)}(k_s r)]P_n(\cos\theta), \tag{23}$$

$$\boldsymbol{\psi}_s = \exp(-i\omega t)\boldsymbol{e}_\varepsilon\sum_{n=1}^{\infty} A_n[\beta_{1n}^{(s)}h_n^{(1)}(k_{sv}r) + \beta_{2n}^{(s)}h_n^{(2)}(k_{sv}r)] \times P_n^1(\cos\theta), \tag{24}$$

where $h_n^{(2)}$ is the spherical Hankel function of the second kind, and the coefficients $\alpha_{1n}^{(s)}$, $\alpha_{2n}^{(s)}$, $\beta_{1n}^{(s)}$, and $\beta_{2n}^{(s)}$ are determined by the boundary conditions at the outer and the inner surfaces of the shell.

Substituting Eqs. (23) and (24) into Eq. (18), one finds the r and θ components of the displacement vector to be

$$u_r = \exp(-i\omega t)\frac{1}{r}\sum_{n=0}^{\infty} A_n P_n(\cos\theta)\{\alpha_{1n}^{(s)}k_s r h_n^{(1)\prime}(k_s r) + \alpha_{2n}^{(s)}k_s r h_n^{(2)\prime}(k_s r) + n(n+1)[\beta_{1n}^{(s)}h_n^{(1)}(k_{sv}r) + \beta_{2n}^{(s)}h_n^{(2)}(k_{sv}r)]\}, \tag{25}$$

$$u_\theta = -\exp(-i\omega t)\frac{1}{r}\sum_{n=1}^{\infty} A_n P_n^1(\cos\theta)\{\alpha_{1n}^{(s)}h_n^{(1)}(k_s r) + \alpha_{2n}^{(s)}h_n^{(2)} \times (k_s r) + \beta_{1n}^{(s)}[h_n^{(1)}(k_{sv}r) + k_{sv}r h_n^{(1)\prime}(k_{sv}r)] + \beta_{2n}^{(s)}[h_n^{(2)}(k_{sv}r) + k_{sv}r h_n^{(2)\prime}(k_{sv}r)]\}. \tag{26}$$

C. Acoustic field in the inner medium

The inner medium of the particle is assumed to be a compressible viscous fluid. That can be a gas or a liquid. Although all equations obtained below can be also applied to a particle with a liquid core, the inner fluid will be referred to as a gas hereafter since the case of an encapsulated gas bubble is of primary interest to us.

The first-order velocity in the inner medium (gas) is represented as

$$\boldsymbol{v}_g = \nabla\varphi_g + \nabla\times\boldsymbol{\psi}_g. \tag{27}$$

For the velocity potentials, which should be finite at $r=0$, one has

$$\varphi_g = \exp(-i\omega t)\sum_{n=0}^{\infty}\alpha_n^{(g)}A_n j_n(k_g r)P_n(\cos\theta), \tag{28}$$

$$\boldsymbol{\psi}_g = \exp(-i\omega t)\boldsymbol{e}_\varepsilon\sum_{n=1}^{\infty}\beta_n^{(g)}A_n j_n(k_{gv}r)P_n^1(\cos\theta), \tag{29}$$

where the coefficients $\alpha_n^{(g)}$ and $\beta_n^{(g)}$ are determined by the boundary conditions at the inner surface of the shell, and the wave numbers are given by

$$k_g = \frac{\omega}{c_g}\left[1 - \frac{i\omega}{\rho_g c_g^2}\left(\xi_g + \frac{4}{3}\eta_g\right)\right]^{-1/2}, \tag{30}$$

$$k_{gv} = (1+i)/\delta_{gv}. \tag{31}$$

Here c_g is the sound speed in the gas, ρ_g is the equilibrium gas density, η_g is the gas shear viscosity, ξ_g is the gas bulk viscosity, $\delta_{gv}=\sqrt{2\nu_g/\omega}$ is the viscous penetration depth in the gas, and $\nu_g=\eta_g/\rho_g$ is the gas kinematic viscosity.

Substituting Eqs. (28) and (29) into Eq. (27), one finds the r and θ components of the gas velocity to be

$$v_r^{(g)} = \exp(-i\omega t)\frac{1}{r}\sum_{n=0}^{\infty}A_n P_n(\cos\theta)[\alpha_n^{(g)}k_g r j_n'(k_g r) + \beta_n^{(g)}n(n+1)j_n(k_{gv}r)], \tag{32}$$

$$v_\theta^{(g)} = -\exp(-i\omega t)\frac{1}{r}\sum_{n=1}^{\infty}A_n P_n^1(\cos\theta)[\alpha_n^{(g)}j_n(k_g r) + \beta_n^{(g)}(j_n(k_{gv}r) + k_{gv}r j_n'(k_{gv}r))]. \tag{33}$$

D. Boundary conditions

The boundary conditions at the outer and the inner surfaces of the shell are written as

$$v_r^{(l)} = v_r^{(s)}, \quad v_\theta^{(l)} = v_\theta^{(s)} \quad \text{at} \quad r = R_{20}, \tag{34}$$

$$v_r^{(s)} = v_r^{(g)}, \quad v_\theta^{(s)} = v_\theta^{(g)} \quad \text{at} \quad r = R_{10}, \tag{35}$$

$$\sigma_{rr}^{(l)} - \bar{p}_{\text{st}}^{(l)} = \sigma_{rr}^{(s)}, \quad \sigma_{r\theta}^{(l)} = \sigma_{r\theta}^{(s)} \quad \text{at} \quad r = R_{20}, \tag{36}$$

$$\sigma_{rr}^{(s)} = \sigma_{rr}^{(g)} - \tilde{p}_{\mathrm{st}}^{(g)}, \quad \sigma_{r\theta}^{(s)} = \sigma_{r\theta}^{(g)} \quad \text{at } r = R_{10}. \tag{37}$$

Here R_{10} and R_{20} are, respectively, the inner and the outer radii of the shell at rest, σ_{rr} and $\sigma_{r\theta}$ are the normal and the tangential components of the respective stress tensors, and $\tilde{p}_{\mathrm{st}}^{(l)}$ and $\tilde{p}_{\mathrm{st}}^{(g)}$ are the surface tension pressures at the liquid-shell and the shell-gas interfaces, respectively.

The r and θ components of the velocities are given by the equations derived in Secs. II A–II C. The quantity $\sigma_{rr}^{(l)}$ is calculated by (Landau and Lifshitz, 1987)

$$\sigma_{rr}^{(l)} = -p_l + 2\eta_l \frac{\partial v_r^{(l)}}{\partial r} + \left(\xi_l - \frac{2}{3}\eta_l\right) \boldsymbol{\nabla} \cdot \boldsymbol{v}_l, \tag{38}$$

where p_l is the first-order perturbed pressure in the ambient liquid. Using the continuity equation and the fact that $\boldsymbol{\nabla} \cdot \boldsymbol{v}_l = -k_l^2(\varphi_I + \varphi_l)$, p_l can be written as

$$p_l = -ic_l^2 \rho_l \boldsymbol{\nabla} \cdot \boldsymbol{v}_l / \omega = ik_l^2 c_l^2 \rho_l (\varphi_I + \varphi_l)/\omega. \tag{39}$$

Accordingly, Eq. (38) takes the final form

$$\sigma_{rr}^{(l)} = 2\eta_l \frac{\partial v_r^{(l)}}{\partial r} - \left(\frac{ic_l^2 \rho_l}{\omega} + \xi_l - \frac{2}{3}\eta_l\right) k_l^2 (\varphi_I + \varphi_l). \tag{40}$$

To calculate $\tilde{p}_{\mathrm{st}}^{(l)}$, the perturbed outer surface of the particle is represented as

$$R_2(\theta, t) = R_{20} + \exp(-i\omega t) \sum_{n=0}^{\infty} s_n^{(l)} P_n(\cos\theta). \tag{41}$$

Then the surface tension pressure on this surface can be written as (Jackson *et al.*, 1988)

$$p_{\mathrm{st}}^{(l)} = \frac{2\sigma_l}{R_{20}} + \exp(-i\omega t) \frac{\sigma_l}{R_{20}^2} \sum_{n=0}^{\infty} (n-1)(n+2) s_n^{(l)} P_n(\cos\theta), \tag{42}$$

where σ_l is the surface tension coefficient at the liquid-shell interface. The coefficients $s_n^{(l)}$ are found by using the following equality:

$$v_r^{(l)}(r = R_{20}) = \frac{\partial R_2(\theta, t)}{\partial t} = -i\omega \exp(-i\omega t) \sum_{n=0}^{\infty} s_n^{(l)} P_n(\cos\theta). \tag{43}$$

Substituting Eq. (10) into Eq. (43), one obtains

$$s_n^{(l)} = \frac{iA_n}{\omega R_{20}} [k_l R_{20} j_n'(k_l R_{20}) + \alpha_n^{(l)} k_l R_{20} h_n^{(1)\prime}(k_l R_{20}) + \beta_n^{(l)} n(n+1) h_n^{(1)}(k_{lv} R_{20})]. \tag{44}$$

In Eq. (36), the time-dependent part of $p_{\mathrm{st}}^{(l)}$ is required, which is indicated by the tilde. This part is given by

$$\tilde{p}_{\mathrm{st}}^{(l)} = \exp(-i\omega t) \frac{\sigma_l}{R_{20}^2} \sum_{n=0}^{\infty} (n-1)(n+2) s_n^{(l)} P_n(\cos\theta). \tag{45}$$

The quantity $\sigma_{r\theta}^{(l)}$ is calculated by (Landau and Lifshitz, 1987)

$$\sigma_{r\theta}^{(l)} = \eta_l \left(\frac{1}{r}\frac{\partial v_r^{(l)}}{\partial \theta} + \frac{\partial v_\theta^{(l)}}{\partial r} - \frac{v_\theta^{(l)}}{r}\right). \tag{46}$$

The expressions for the shell stress components are found from Eqs. (15) and (16) to be

$$\sigma_{rr}^{(s)} = 2(\mu_s - i\omega\eta_s)\frac{\partial u_r}{\partial r} - \left[K_s - \frac{2}{3}\mu_s - i\omega\left(\xi_s - \frac{2}{3}\eta_s\right)\right] k_s^2 \varphi_s, \tag{47}$$

$$\sigma_{r\theta}^{(s)} = (\mu_s - i\omega\eta_s)\left(\frac{1}{r}\frac{\partial u_r}{\partial \theta} + \frac{\partial u_\theta}{\partial r} - \frac{u_\theta}{r}\right). \tag{48}$$

By analogy with those for the ambient liquid, the expressions for the stress components in the gas can be written as

$$\sigma_{rr}^{(g)} = 2\eta_g \frac{\partial v_r^{(g)}}{\partial r} - \left(\frac{ic_g^2 \rho_g}{\omega} + \xi_g - \frac{2}{3}\eta_g\right) k_g^2 \varphi_g, \tag{49}$$

$$\tilde{p}_{\mathrm{st}}^{(g)} = \exp(-i\omega t) \frac{\sigma_g}{R_{10}^2} \sum_{n=0}^{\infty} (n-1)(n+2) s_n^{(g)} P_n(\cos\theta), \tag{50}$$

$$s_n^{(g)} = \frac{iA_n}{\omega R_{10}} [\alpha_n^{(g)} k_g R_{10} j_n'(k_g R_{10}) + \beta_n^{(g)} n(n+1) j_n(k_{gv} R_{10})], \tag{51}$$

$$\sigma_{r\theta}^{(g)} = \eta_g \left(\frac{1}{r}\frac{\partial v_r^{(g)}}{\partial \theta} + \frac{\partial v_\theta^{(g)}}{\partial r} - \frac{v_\theta^{(g)}}{r}\right). \tag{52}$$

Substituting the expressions for the velocity and stress components into the boundary conditions, one can calculate the unknown scattering coefficients.

E. Calculation of the scattering coefficients

The boundary conditions, Eqs. (34)–(37), give a system of eight algebraic equations in the unknowns $\alpha_n^{(l)}$, $\beta_n^{(l)}$, $\alpha_{1n}^{(s)}$, $\alpha_{2n}^{(s)}$, $\beta_{1n}^{(s)}$, $\beta_{2n}^{(s)}$, $\alpha_n^{(g)}$, and $\beta_n^{(g)}$. The system can be written in matrix form as

$$\boldsymbol{A} \cdot \boldsymbol{X} = \boldsymbol{B}, \tag{53}$$

where the elements of the matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are given in the Appendix, and the matrix $\boldsymbol{X}$ consists of the scattering coefficients which are arranged in the same order as indicated above. Note that the coefficients $\beta_0^{(l)}$, $\beta_{10}^{(s)}$, $\beta_{20}^{(s)}$, and $\beta_0^{(g)}$ are identically zero. Therefore for $n=0$ system (53) reduces to four equations in the unknowns $\alpha_0^{(l)}$, $\alpha_{10}^{(s)}$, $\alpha_{20}^{(s)}$, and $\alpha_0^{(g)}$,

$$\boldsymbol{A}_0 \cdot \boldsymbol{X}_0 = \boldsymbol{B}_0. \tag{54}$$

The elements of the matrices $\boldsymbol{A}_0$ and $\boldsymbol{B}_0$ are also given in the Appendix, and the matrix $\boldsymbol{X}_0$ is formed by the four coefficients pointed out above.

For the calculation of acoustic streaming, only $\alpha_n^{(l)}$ and $\beta_n^{(l)}$ are needed. They are calculated by

$$\alpha_0^{(l)} = \det(\boldsymbol{A}_0^{(1)})/\det(\boldsymbol{A}_0), \quad \alpha_n^{(l)} = \det(\boldsymbol{A}^{(1)})/\det(\boldsymbol{A}),$$

$$\beta_n^{(l)} = \det(\boldsymbol{A}^{(2)})/\det(\boldsymbol{A}), \tag{55}$$

where $\boldsymbol{A}^{(m)}$ denotes the matrix $\boldsymbol{A}$ in which the mth column is replaced with the elements of the matrix $\boldsymbol{B}$.

F. Acoustic streaming

According to the results of Doinikov (1994, 1997), the velocity of acoustic streaming can be written as

$$\boldsymbol{V} = \boldsymbol{\nabla}\Phi + \boldsymbol{\nabla} \times \boldsymbol{\Psi}, \tag{56}$$

where the scalar and vorticity potentials are given by

$$\Phi = \sum_{n=0}^{\infty} \Phi_n(r/R_{20}) P_n(\cos\,\theta), \tag{57}$$

$$\boldsymbol{\Psi} = \boldsymbol{e}_{\varepsilon} \sum_{n=1}^{\infty} \Psi_n(r/R_{20}) P_n^1(\cos\,\theta). \tag{58}$$

Substituting Eqs. (57) and (58) into Eq. (56), one finds the r and θ components of the acoustic streaming velocity to be

$$V_r = \frac{1}{R_{20}} \sum_{n=0}^{\infty} \left[\Phi_n'(x) + \frac{n(n+1)}{x} \Psi_n(x) \right] P_n(\cos\,\theta), \tag{59}$$

$$V_\theta = -\frac{1}{R_{20}} \sum_{n=1}^{\infty} \left[\frac{1}{x}\Phi_n(x) + \frac{1}{x}\Psi_n(x) + \Psi_n'(x) \right] P_n^1(\cos\,\theta), \tag{60}$$

where $x = r/R_{20}$ and the prime denotes the differentiation with respect to the argument in parentheses.

The functions $\Phi_n(x)$ and $\Psi_n(x)$ are calculated by

$$\Phi_n(x) = \frac{1}{x^{n+1}}[K_n(x,n+2) - C_{\varphi n}] - x^n[K_n(x,1-n) - K_n(\infty,1-n)], \tag{61}$$

$$\Psi_n(x) = \frac{1}{2(2n+3)} \left\{ \frac{1}{x^{n+1}} N_n(x,n+3) - x^{n+2}[N_n(x,-n) - N_n(\infty,-n)] \right\} + \frac{1}{2(2n-1)} \{x^n[N_n(x,2-n) - N_n(\infty,2-n)] - x^{1-n}[N_n(x,n+1) - C_{\psi n}]\}, \tag{62}$$

where

$$K_n(x,m) = \int_1^x y^m \mu_n(y)\,dy, \tag{63}$$

$$\mu_n(r/R_{20}) = \frac{R_{20}^2}{4\rho_l} \int_0^{\pi} \mathrm{Re}\{\boldsymbol{\nabla} \cdot (\tilde{\rho}_l^* \boldsymbol{v}_l - \tilde{\rho}_I^* \boldsymbol{v}_I)\} P_n(\cos\,\theta) \sin\,\theta\,d\theta, \tag{64}$$

$$N_n(x,m) = \int_1^x y^m [\chi_{rn}(y) + m\chi_{\theta n}(y)]\,dy, \tag{65}$$

$$\chi_{rn}(r/R_{20}) = \int_0^{\pi} W_r(r/R_{20},\theta) P_n(\cos\,\theta) \sin\,\theta\,d\theta, \tag{66}$$

$$\chi_{\theta n}(r/R_{20}) = -\frac{1}{n(n+1)} \int_0^{\pi} W_\theta(r/R_{20},\theta) P_n^1(\cos\,\theta) \sin\,\theta\,d\theta, \tag{67}$$

$$W(r/R_{20},\theta) = \frac{R_{20}^3}{4\nu_l} \mathrm{Re}\{\boldsymbol{v}_l^*(\boldsymbol{\nabla}\cdot\boldsymbol{v}_l) + (\boldsymbol{v}_l^* \cdot \boldsymbol{\nabla})\boldsymbol{v}_l - \boldsymbol{v}_I^*(\boldsymbol{\nabla}\cdot\boldsymbol{v}_I) - (\boldsymbol{v}_I^* \cdot \boldsymbol{\nabla})\boldsymbol{v}_I\}, \tag{68}$$

$$C_{\varphi n} = \frac{n(2n-1)}{2(n+1)} K_n(\infty,1-n) + \frac{n(2n+1)}{4(2n+3)} N_n(\infty,-n) - \frac{n}{4} N_n(\infty,2-n) + \frac{(2n+1)(n-2)}{2(n+1)} a_n + \frac{n(2n+1)}{2} b_n, \tag{69}$$

$$C_{\psi n} = (4n^2-1) \left[\frac{N_n(\infty,2-n)}{2(2n-1)} - \frac{N_n(\infty,-n)}{2(2n+1)} - \frac{K_n(\infty,1-n) + a_n}{n+1} - b_n \right], \tag{70}$$

$$a_n = \int_0^{\pi} U_r(R_{20},\theta) P_n(\cos\,\theta) \sin\,\theta\,d\theta, \tag{71}$$

$$b_n = -\frac{1}{n(n+1)} \int_0^{\pi} U_\theta(R_{20},\theta) P_n^1(\cos\,\theta) \sin\,\theta\,d\theta, \tag{72}$$

$$\boldsymbol{U}(r,\theta) = \frac{R_{20}}{2}\boldsymbol{V}_I - \frac{R_{20}}{4\omega^2} \mathrm{Re}\left\{ \left(\frac{\partial v_r^{(l)}}{\partial t} \right)^* \frac{\partial \boldsymbol{v}_l}{\partial r} \right\}. \tag{73}$$

Here, the asterisk denotes the complex conjugate, Re means "the real part of," and $\boldsymbol{V}_I$ is the velocity produced by the incident sound field in the ambient liquid when the particle is absent. This velocity results from the space attenuation of the incident sound wave. For a plane traveling wave, $\boldsymbol{V}_I$ is given by

$$\boldsymbol{V}_I = -\frac{|k_l A|^2}{2\omega} \mathrm{Re}\{\boldsymbol{k}_l\} \exp(i\boldsymbol{k}_l \cdot \boldsymbol{r} - i\boldsymbol{k}_l^* \cdot \boldsymbol{r}). \tag{74}$$

According to Eq. (60) in Doinikov (1997), the radial stress produced by acoustic streaming can be calculated by

$$S_r = -\frac{1}{2\rho_l} \left(\xi_l + \frac{4\eta_l}{3} \right) \mathrm{Re}\{\boldsymbol{\nabla} \cdot (\tilde{\rho}_l^* \boldsymbol{v}_l - \tilde{\rho}_I^* \boldsymbol{v}_I)\} - \frac{\eta_l}{R_{20}^2} \sum_{n=0}^{\infty} Q_{rn}(r/R_{20}) P_n(\cos\,\theta), \tag{75}$$

where

$$Q_{rn}(x) = \frac{n}{x^{n+1}}[N_n(x,n+1) - C_{\psi n}] + (n+1)x^n[N_n(x,-n) - N_n(\infty,-n)]. \tag{76}$$

Substituting Eqs. (59) and (60) into the formula

$$S_\theta = \eta_l \left(\frac{1}{r} \frac{\partial V_r}{\partial \theta} + \frac{\partial V_\theta}{\partial r} - \frac{V_\theta}{r} \right), \tag{77}$$

one finds the tangential stress produced by acoustic streaming to be

$$S_\theta = \frac{\eta_l}{R_{20}^2} \sum_{n=1}^{\infty} Q_{\theta n}(r/R_{20}) P_n^1(\cos\theta), \tag{78}$$

where

$$Q_{\theta n}(x) = \frac{2}{x^2}\Phi_n(x) - \frac{2}{x}\Phi_n'(x) + \frac{2-2n(n+1)}{x^2}\Psi_n(x) + \frac{2}{x}\Psi_n'(x) + x^n[N_n(x,-n) - N_n(\infty,-n)] - \frac{1}{x^{n+1}}[N_n(x,n+1) - C_{\psi m}]. \tag{79}$$

It should be noted that although the equations for acoustic streaming look cumbersome, their numerical calculation is straightforward.

III. NUMERICAL EXAMPLES

As a first example, let us consider an encapsulated gas bubble with $R_{20}=2$ μm and the shell thickness $R_s=10$ nm driven at $f=1$ MHz. The values of the other parameters used in this calculation are the following: $\rho_l=1000$ kg/m^3, $\eta_l=0.001$ Pa s, $\xi_l=0.0026$ Pa s, $\sigma_l=0.005$ N/m, $c_l=1500$ m/s, $\rho_s=1100$ kg/m^3, $\mu_s=15$ MPa, $\eta_s=0.05$ Pa s, $\xi_s=0$, $\eta_g=1.8\times10^{-5}$ Pa s, $\xi_g=1.6\times10^{-5}$ Pa s, and $\sigma_g=0.04$ N/m. These data correspond to the case considered by Liu and Wu (2009). The values of the shell parameters were adopted by Liu and Wu (2009) from Church's (1995) work. The equilibrium gas pressure inside the bubble is calculated by $P_g=P_0+2\sigma_l/R_{20}+2\sigma_g/R_{10}$, where $P_0=101.3$ kPa is the hydrostatic pressure in the liquid. The equilibrium gas density is then calculated as $\rho_g=\rho_{gA}P_g/P_A$, where $\rho_{gA}=1.2$ kg/m^3 is the gas density at the atmospheric pressure $P_A=101.3$ kPa. Finally, the sound speed in the gas is defined by the equation $c_g=\sqrt{\gamma_g P_g/\rho_g}$ which results from the adiabatic law, γ_g denoting the special heat ratio. Liu and Wu (2009) did not indicate the value of the acoustic pressure amplitude which was used in their simulation. Supposedly, they used 100 kPa. In our simulations, the same value is used. To make a comparison with Liu and Wu's (2009) results, one more point should be taken into consideration. Our theory allows the shell material to be compressible, which means that the shell bulk modulus K_s is finite. Liu and Wu (2009) assumed the shell material to be incompressible, which means that $K_s\to\infty$. To simulate this situation, however, it is sufficient to set K_s to be much greater than the shell shear modulus μ_s. We have used $K_s=10^{10}$ Pa.

Figure 2 shows the radial and the tangential acoustic streaming velocities versus θ, and Fig. 3 provides plots of the radial and tangential stresses produced by the acoustic streaming. The values of the velocities and the stresses are calculated at $r=R_{20}+0.5\delta_{lv}$ as in Liu and Wu's (2009) paper. In both figures, the solid lines correspond to an encapsulated bubble, and the dashed lines show the results for a free bubble of the same size. One can see that the acoustic streaming produced by the encapsulated bubble is weaker than that produced by the free bubble. Liu and Wu (2009) reported an opposite result. They stated that, in spite of the fact that the oscillation amplitude of the encapsulated bubble was smaller than that of the free bubble, the streaming velocity and the stress induced by the encapsulated bubble were considerably greater than those for the free bubble. They suggested that this enhancement is caused by the difference in the boundary conditions for the free and encapsulated bubbles. However, this argument does not look con-

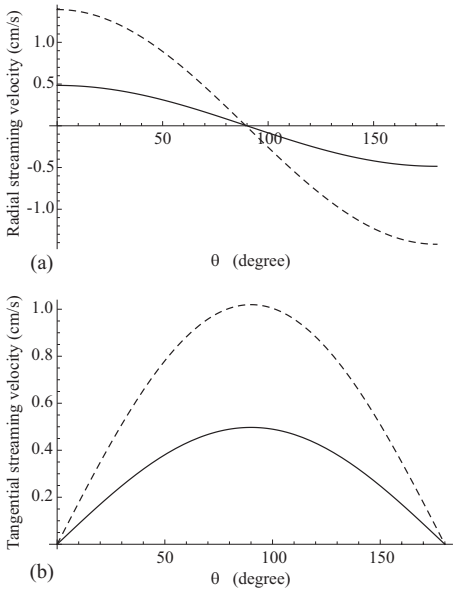

FIG. 2. Acoustic streaming velocity versus θ for an encapsulated gas bubble with $R_{20}=2$ μm and the shell thickness 10 nm. Excitation is a plane traveling wave with the frequency 1 MHz and the pressure amplitude 100 kPa. The dashed line corresponds to a free bubble of the same radius.

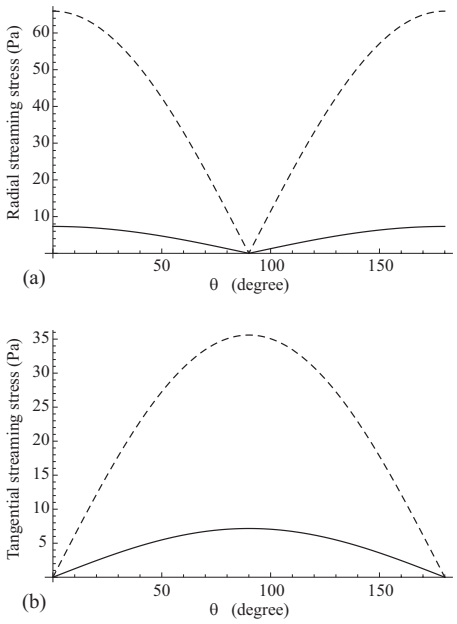

FIG. 3. Acoustic streaming stresses versus θ for the bubbles in Fig. 2. The dashed line corresponds to the free bubble.

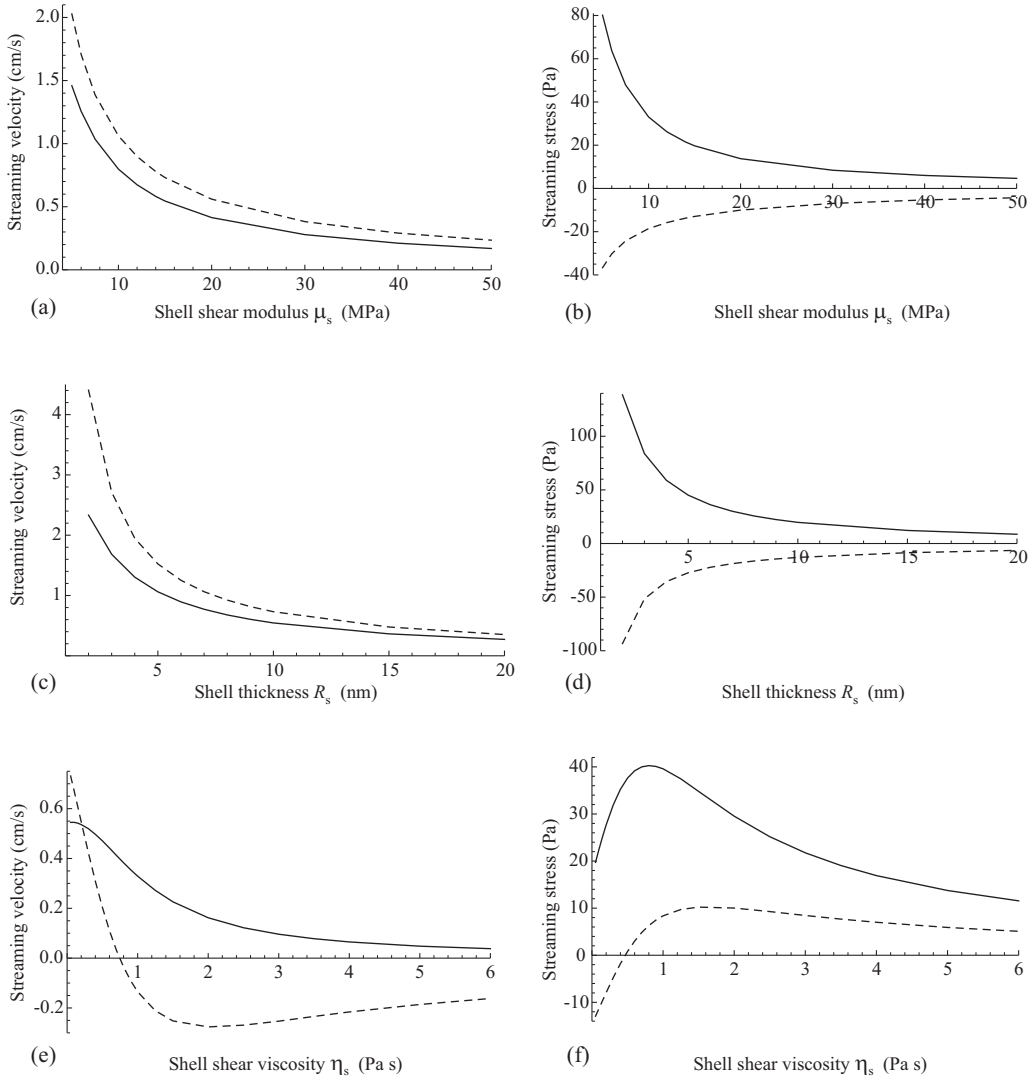

FIG. 4. Dependence of the maximum values of the streaming velocity and the streaming stress on the shell parameters. A bubble with $R_{20}=1.5$ μm is driven at 2.5 MHz and 100 kPa. The solid lines correspond to the radial velocity and stress components, and the dashed lines, to the tangential components. In (a) and (b), $R_s=10$ nm, $\eta_s=0.05$ Pa s; in (c) and (d), $\mu_s=15$ MPa, $\eta_s=0.05$ Pa s; and in (e) and (f), $\mu_s=15$ MPa, $R_s=10$ nm.

vincing as the increase in the acoustic streaming for the encapsulated bubble is extremely great. For example, according to Fig. 3(b) of Liu and Wu's (2009) paper, the radial streaming velocity for the encapsulated bubble is approximately 47 000 times greater than that for the free bubble, and Fig. 8(b) of their paper shows that the tangential stress for the encapsulated bubble is approximately 2400 times that for the free bubble. This erroneous finding is a consequence of the incorrect approximate approach which was used to calculate the first-order velocity field; see Doinikov and Bouakaz (2010). Figures 2 and 3 demonstrate that the correct calculation gives a quite expected result, namely, stronger oscillations produce a stronger acoustic streaming.

The effect of the shell parameters on acoustic streaming has been investigated. As could be expected, it is found that a stronger bubble oscillation leads to a stronger acoustic streaming. Thus a stronger acoustic streaming arises when a change in the shell parameters increases the bubble oscillation. For example, the oscillation increases when the resonance frequency of a bubble approaches the driving frequency. It is known that the resonance frequency increases with the shell shear modulus μ_s. Therefore, if a bubble is driven below resonance, a decrease in μ_s will enhance acoustic streaming and vice versa. This situation is illustrated in Figs. 4(a) and 4(b) which show the maximum values of the streaming velocity and the streaming stress as a function of the shell shear modulus μ_s. The simulations were carried out for a bubble with $R_{20}=1.5$ μm and $R_s=10$ nm driven at 2.5 MHz and 100 kPa. The other parameters are as indicated above. The values of the velocities and the stresses are calculated at $r=R_{20}+0.5\delta_{lv}$. The solid lines correspond to the radial components of the streaming velocity and the streaming stress, and the dashed lines, to the tangential components. Figures 4(c) and 4(d) show the effect of the shell thickness on acoustic streaming. It is known that the thicker the shell, the higher the resonance frequency. Therefore increasing the shell thickness gives the same effect as increasing the shell shear modulus. The effect of the shell viscosity is more complicated as the shell viscosity affects not only the resonance frequency of a bubble but also the damping and

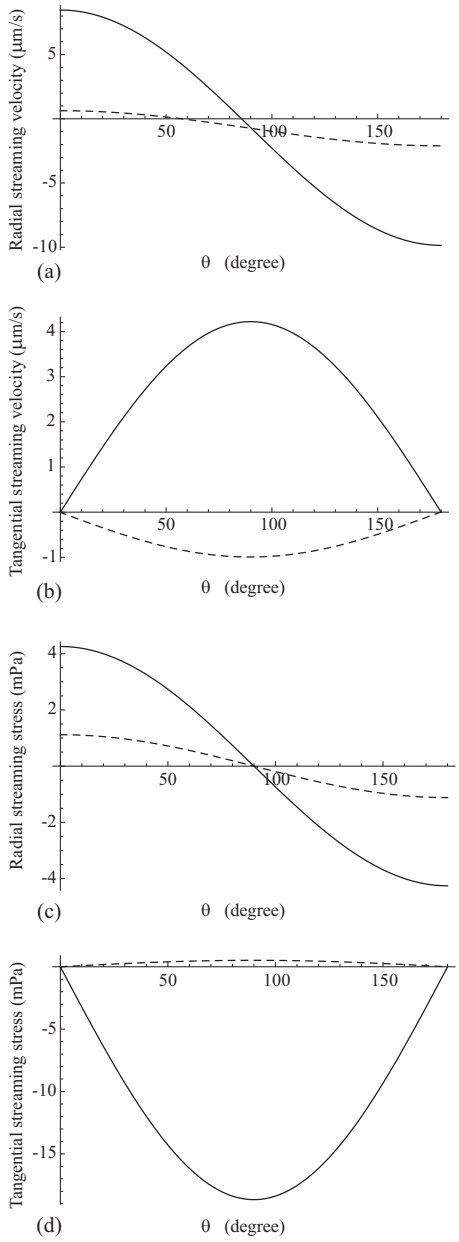

FIG. 5. Acoustic streaming velocities and stresses versus θ for an encapsulated particle with a liquid core. The dashed lines show the result of the calculation when the surface quadrupole mode is ignored.

the phase of the bubble oscillation. As a result, a change in the shell viscosity can even reverse the direction of acoustic streaming, as is seen in Fig. 4(e).

In the case of an encapsulated gas bubble, the radial oscillation mode is dominant. In combination with the translational mode, they make the main contribution to acoustic streaming. For example, for the bubble in Fig. 4, with the shell parameters $R_s=10$ nm, $\mu_s=15$ MPa, and $\eta_s=0.05$ Pa s, the ratio of the amplitude of the radial mode to R_{20} is 0.074, the same ratio for the translational mode is 0.0047, and that for the quadrupole mode is 3.4×10^{-5}. These figures show that the contribution of the surface modes is negligible. However, in the case of an encapsulated particle with a liquid core, the situation is different. As an example, let us consider a particle with $R_{20}=1.5$ μm and $R_s=10$ nm driven at 2.5 MHz and 100 kPa. The parameters of the ambient liquid and the shell are the same as indicated at the beginning of this section. Thus the only distinction from the bubble in Fig. 4 is that the particle under consideration has a liquid core. The data for the inner liquid are $\rho_g=880$ kg/m^3, $\eta_g=6.5\times10^{-4}$ Pa s, $\xi_g=0$, $\sigma_g=0.04$ N/m, $c_g=1321$ m/s, and $\gamma_g=1.1$. These parameters correspond to benzene. The subscript g is used here just as a sign of the inner medium. Under these conditions, the ratio of the amplitude of the radial mode to R_{20} is 2.1×10^{-5}, the ratio for the translational mode is 3.0×10^{-3}, for the quadrupole mode, 2.8×10^{-4}, and for the next surface mode, 4.5×10^{-8}. It follows that the main contribution to acoustic streaming comes from the interaction between the translational and the quadrupole modes. The velocity and stress fields of acoustic streaming that arises around the particle are shown in Fig. 5. The values of the velocities and the stresses are calculated at $r=R_{20}+0.5\delta_{lv}$. For comparison, the dashed lines show the result of calculation in the case that the quadrupole mode is dropped and only the radial and the translational modes are taken into account.

IV. CONCLUSIONS

A theory has been developed to calculate acoustic microstreaming that arises around an encapsulated particle in an ultrasound field. The particle was assumed to be suspended in an unbounded fluid. The surrounding fluid and a fluid inside the particle were assumed to be viscous and compressible. The shell of the particle was assumed to be an elastic viscous compressible medium. No restrictions were imposed on the size of the particle relative to the lengths of the sound and viscous waves that propagate in the surrounding fluid, the inner fluid, and the material of the shell. All modes of the particle's motion (volume pulsation, translation, and shape oscillations) were taken into account. The developed theory can be applied to an encapsulated gas bubble and an encapsulated particle with a liquid core. Numerical examples for both cases were presented.

Dynamic radiation force has been used in several types of applications, and is performed by modulating ultrasound with different methods. By modulating ultrasound, energy can be transmitted to tissue, in this case a dynamic force to elicit a low frequency cyclic displacement to inspect the material properties of the tissue. In this paper, different types of modulation are explored including amplitude modulation (AM), double sideband suppressed carrier amplitude modulation AM, linear frequency modulation, and frequency-shift keying. Generalized theory is presented for computing the radiation force through the short-term time average of the energy density for these various types of modulation. Examples of modulation with different types of signals including sine waves, square waves, and triangle waves are shown. Using different modulating signals, multifrequency radiation force with different numbers of frequency components can be created, and can be used to characterize tissue mimicking materials and soft tissue. Results for characterization of gelatin phantoms using a method of vibrating an embedded sphere are presented. Different degrees of accuracy were achieved using different modulation techniques and modulating signals. Modulating ultrasound is a very flexible technique to produce radiation force with multiple frequency components that can be used for various applications.

I. INTRODUCTION

Ultrasound radiation force is the phenomenon of acoustic waves transferring their momentum upon striking or interacting with an object thus creating a force and imparting motion to the object.[1,2] Investigation of ultrasound radiation force and its applications has been an area of research for almost 8 decades. Theoretical studies on radiation pressure were undertaken in Refs. 1–7. Within the last 15 years applications of radiation force in the medical imaging field have grown considerably making it an active area of research.

Ultrasound radiation force has been used to calibrate the output of transducers using the radiation force balance method.[8–10] The manipulation of spheres, drops, bubbles, and other objects using radiation force has also been explored.[11–16] Methods based on radiation force have been developed to characterize different materials such as soft gelatin phantoms and soft tissue.[17–19]

One of the emerging uses of ultrasound radiation force is its use in ultrasound-based elasticity imaging. Focused ultrasound is used to exert a force on soft tissue and the mechanical response is measured with ultrasound-based or other methods.[19–25]

Radiation force can be classified as either static or dynamic.[26,27] Static radiation force is produced using continuous wave ultrasound to exert a constant force. Dynamic radiation force is created using ultrasound that has some sort of amplitude modulation through time.[22,27] The force changes with time based on the modulating function.

Dynamic ultrasound radiation force can be subdivided further into three categories: quasi-static, amplitude modulated, and frequency modulated. The quasi-static case results from using a finite duration toneburst of ultrasound, which exerts a transient force while the ultrasound is transmitted. This type of radiation force is used in acoustic radiation force impulse (ARFI) imaging where short tonebursts of ultrasound are used to impulsively excite tissue and the response is measured with ultrasound.[19]

Amplitude modulated ultrasound can be used to create a harmonic or multifrequency radiation force. This type of radiation force has been used in vibro-acoustography and shear wave elasticity imaging to displace tissue with a known harmonic function.[20,22,28,29] The use of amplitude modulation will be the main subject of this study and general cases will be described in more detail.

Lastly, frequency modulation (FM) of the ultrasound signal can be used to create a radiation force that changes frequency with time. Typically, the frequency shifts linearly through time and a "chirp" results. Chirped ultrasound has been used in radiation force applications in vibro-acoustography and in applications using contrast microbubbles to reduce standing wave artifacts.[30–32]

Modulation is used in communications to transmit information in one frequency band using a carrier signal that can be transmitted over large distances. In our case, we use ul-

trasound at megahertz frequencies as a carrier signal to transfer energy, or a vibration force, at low frequencies, by modulating the ultrasound to elicit the desired stimulation force. We gain the advantage of beamforming at ultrasound frequencies for localizing the radiation force energy to create vibration motion at low frequencies such that the displacements are large enough to be measured with ultrasound or other techniques.

In this paper, we will present general theory that describes the formation of ultrasound radiation force using full amplitude modulation (AM) as well as double sideband suppressed carrier amplitude modulation (DSB-SC AM). The generation of radiation force with different modulating functions will be explored. Validation of the time- and frequency-domain relationships will be demonstrated with experimental data. Also, an example of material characterization using different modulation techniques and functions will be shown.

II. METHODS

The acoustic radiation force on an object can be defined as follows:

$$F(t) = d_r S \langle E(t) \rangle_T, \tag{1}$$

where $F(t)$ is the radiation force, d_r is the drag coefficient, S is the surface over which the ultrasound energy acts, and $\langle E(t) \rangle_T$ is the short-term time average of the energy density. The short-term time average is computed such that T, the averaging period, is longer than the period of the ultrasound wave but much shorter than the modulation period, $2\pi/\omega_c \ll T \ll 2\pi/\omega_m$ where ω_c and ω_m are the carrier (ultrasound) frequency and the modulation frequency, respectively.[22] If we have an absorbing medium we can write $F(t) = 2\alpha \langle I(t) \rangle_T / c = \alpha \langle E(t) \rangle_T$, where α is the ultrasound attenuation coefficient and $I(t)$ is the ultrasound intensity.[19] Assuming plane wave propagation, the energy density is defined as

$$E(t) = \frac{p^2(t)}{\rho c^2}. \tag{2}$$

Three types of modulation will be explored in this paper: amplitude modulation, double sideband suppressed carrier amplitude modulation, and frequency modulation. In this paper, we will ignore the spatial dependence of the focused ultrasound fields as that adds another dimension of complexity that is beyond the scope of this work.

A. AM

We start with amplitude modulation by defining $A(t)$ as the modulation function as follows, including a dc offset:[33]

$$A(t) = A_c[1 + \mu x_m(t)], \tag{3}$$

where A_c is the amplitude, μ is the modulation index that can vary from $0 \le \mu \le 1$, and $x_m(t)$, where $|x_m(t)| \le 1$, is the baseband or modulation function. The pressure for an AM ultrasound beam is given as

$$p(t) = A(t)\cos(\omega_c t) = A_c[1 + \mu x_m(t)]\cos(\omega_c t), \tag{4}$$

where ω_c is the carrier frequency, or in this case the ultrasound frequency. Equation (4) can be expanded as

$$p(t) = A_c \cos(\omega_c t) + A_c \mu x_m(t) \cos(\omega_c t). \tag{5}$$

To find the radiation force we need to square the pressure and take the short-term time average. We start by squaring the relationship in Eq. (5) and expand using the trigonometric identity $\cos^2(\omega t) = (1 + \cos(2\omega t))/2$.

$$p^2(t) = A_c^2 \cos^2(\omega_c t) + A_c^2 \mu^2 x_m^2(t) \cos^2(\omega_c t) + 2A_c^2 \mu x_m(t) \cos^2(\omega_c t), \tag{6}$$

$$p^2(t) = A_c^2 \left(\frac{1 + \cos(2\omega_c t)}{2} \right) + A_c^2 \mu^2 x_m^2(t) \left(\frac{1 + \cos(2\omega_c t)}{2} \right) + 2A_c^2 \mu x_m(t) \left(\frac{1 + \cos(2\omega_c t)}{2} \right). \tag{7}$$

After collecting terms, we arrive at the following expression for the square of the pressure function:

$$p^2(t) = \frac{A_c^2}{2}[\mu^2 x_m^2(t) + 2\mu x_m(t) + 1] + \frac{A_c^2}{2} \cos(2\omega_c t)[\mu^2 x_m^2(t) + 2\mu x_m(t) + 1]. \tag{8}$$

Applying the short-term time average eliminates the terms at $2\omega_c$ and the energy density is then computed in Eq. (10).

$$\langle p^2(t) \rangle_T = \frac{A_c^2}{2}[\mu^2 x_m^2(t) + 2\mu x_m(t) + 1], \tag{9}$$

$$\langle E(t) \rangle_T = \frac{A_c^2}{2\rho c^2}[\mu^2 x_m^2(t) + 2\mu x_m(t) + 1]. \tag{10}$$

For the case in which $x_m(t) = \cos(\omega_m t)$, we can substitute and rewrite Eq. (10) as

$$\langle E(t) \rangle_T = \frac{A_c^2}{2\rho c^2}[\mu^2 \cos^2(\omega_m t) + 2\mu \cos(\omega_m t) + 1]. \tag{11}$$

Applying the same trigonometric identity as above and simplifying give

$$\langle E(t) \rangle_T = \frac{A_c^2}{2\rho c^2}\left[\frac{\mu^2}{2}(1 + \cos(2\omega_m t)) + 2\mu \cos(\omega_m t) + 1 \right], \tag{12}$$

$$\langle E(t) \rangle_T = \frac{A_c^2}{4\rho c^2}[\mu^2 \cos(2\omega_m t) + 4\mu \cos(\omega_m t) + 2 + \mu^2]. \tag{13}$$

The result in Eq. (13) is interesting because the energy density has a dc term, a term at ω_m and at $2\omega_m$. In most cases $\mu = 1$, which represents 100% modulation, but if μ approaches 0, then the first term at $2\omega_m$ decreases.

B. DSB-SC AM

Now we will consider the case where the modulating function is defined without a dc offset[33]

$$A(t) = A_c \mu x_m(t). \tag{14}$$

We again consider the pressure signal

$$p(t) = A(t)\cos(\omega_c t) = A_c \mu x_m(t)\cos(\omega_c t). \tag{15}$$

Squaring the pressure gives

$$p^2(t) = A_c^2 \mu^2 x_m^2(t)\cos^2(\omega_c t), \tag{16}$$

and expanding and collecting terms give

$$p^2(t) = \frac{A_c^2 \mu^2}{2} x_m^2(t) + \frac{A_c^2 \mu^2}{2} x_m^2(t)\cos(2\omega_c t). \tag{17}$$

The short-term time average once again eliminates the term at $2\omega_c$ and the energy density is given in Eq. (19).

$$\langle p^2(t)\rangle_T = \frac{A_c^2 \mu^2}{2} x_m^2(t), \tag{18}$$

$$\langle E(t)\rangle_T = \frac{A_c^2 \mu^2}{2\rho c^2} x_m^2(t). \tag{19}$$

For the case in which $x_m(t)=\cos(\omega_m t)$, we can substitute and rewrite Eq. (19) as

$$\langle E(t)\rangle_T = \frac{A_c^2 \mu^2}{2\rho c^2}\cos^2(\omega_m t), \tag{20}$$

and then expanding we obtain

$$\langle E(t)\rangle_T = \frac{A_c^2 \mu^2}{4\rho c^2}(1 + \cos(2\omega_m t)). \tag{21}$$

This type of modulation provides a dc term and a component at $2\omega_m$, and in most cases $\mu=1$, which causes $\mu^2=1$.

As another more complex case, we can define $\mu=1$ and $x_m(t)$ as a square wave signal as has been previously explored,[34] but will be summarized here for emphasis.

$$x_m(t) = a\Pi\left(\frac{t - T_b/2}{T_b}\right) \otimes \frac{1}{T_r}\mathrm{III}\left(\frac{t}{T_r}\right). \tag{22}$$

Using Bracewell's notation and conventions, the radiation force can be written as a temporal convolution of an impulse train $\mathrm{III}(t)$, with a time-shifted rectangular function $\Pi(t)$.[35] The time-shifted rectangular function has width T_b, amplitude a, and the time shift is $T_b/2$. A repetition period of T_r, or a rate $f_r=1/T_r$, is used for the impulse train and $1/T_r$ is used to maintain unit height. The duty cycle can be written as $D = T_b/T_r = T_b f_r$.

Squaring $x_m(t)$ yields the same function assuming unit amplitude. We can examine the frequency components by evaluating the Fourier transform, where $X_m(f)$ is the Fourier transform of $x_m(t)$.

$$X_m(f) = \frac{aT_b}{T_r}\sum_{n=-\infty}^{\infty} e^{-i\pi T_b n/T_r}\,\mathrm{sinc}\left(n\frac{T_b}{T_r}\right)\delta\left(f - \frac{n}{T_r}\right). \tag{23}$$

We can substitute the repetition frequency f_r for the $1/T_r$ terms as follows:

$$X_m(f) = af_r T_b \sum_{n=-\infty}^{\infty} e^{-i\pi T_b n f_r}\,\mathrm{sinc}(T_b n f_r)\,\delta(f - nf_r). \tag{24}$$

We can further simplify by writing in terms of the duty factor.

$$X_m(f) = aD \sum_{n=-\infty}^{\infty} e^{-i\pi nD}\,\mathrm{sinc}(nD)\,\delta(f - nf_r). \tag{25}$$

The square wave radiation force has components at harmonics of the toneburst repetition frequency f_r, and the amplitude of those components will be governed by a sinc function that has the duty factor in its argument. The frequency-domain representation will be a set of impulses located at integral multiples of f_r and modulated by $af_r T_b e^{-i\pi T_b n f_r}\,\mathrm{sinc}(T_b n f_r)$.

C. FM

If we consider frequency modulation we can write the modulating function as[33]

$$A(t) = A_c(1 + \cos(\phi(t))). \tag{26}$$

In this paper, we will consider $\phi(t)$ to be a quadratic function with respect to time defined as $\phi(t)=((\omega_2-\omega_1)/(t_2-t_1))t^2 = (\Delta\omega/\Delta t)t^2$. The instantaneous frequency, which is the derivative of $\phi(t)$, is then a linear function $d\phi(t)/dt = 2(\Delta\omega/\Delta t)t$. The pressure is defined as

$$p(t) = A(t)\cos(\omega_c t) = A_c\left(1 + \cos\left(\frac{\Delta\omega}{\Delta t}t^2\right)\right)\cos(\omega_c t). \tag{27}$$

We then square the pressure and take the short-term time average and then arrive at the energy density.

$$\begin{aligned} p^2(t) &= A_c^2\left(1 + \cos\left(\frac{\Delta\omega}{\Delta t}t^2\right)\right)^2\cos^2(\omega_c t) \\ &= A_c^2\left[1 + 2\cos\left(\frac{\Delta\omega}{\Delta t}t^2\right) + \left(1 + \cos\left(2\frac{\Delta\omega}{\Delta t}t^2\right)\right)/2\right] \\ &\quad \times\left[\frac{(1 + \cos(2\omega_c t))}{2}\right], \end{aligned} \tag{28}$$

$$\langle p^2(t)\rangle_T = \frac{3A_c^2}{4} + A_c^2\cos\left(\frac{\Delta\omega}{\Delta t}t^2\right) + \frac{A_c^2}{4}\cos\left(2\frac{\Delta\omega}{\Delta t}t^2\right), \tag{29}$$

$$\langle E(t)\rangle_T = \frac{3A_c^2}{4\rho c^2} + \frac{A_c^2}{\rho c^2}\cos\left(\frac{\Delta\omega}{\Delta t}t^2\right) + \frac{A_c^2}{4\rho c^2}\cos\left(2\frac{\Delta\omega}{\Delta t}t^2\right). \tag{30}$$

If DSB-SC AM is used, $A(t)=A_c\cos(\phi(t))$, and $\langle E(t)\rangle_t$ is defined as

$$\langle E(t)\rangle_T = \frac{3A_c^2}{4\rho c^2} + \frac{A_c^2}{4\rho c^2}\cos\left(2\frac{\Delta\omega}{\Delta t}t^2\right). \tag{31}$$

D. Frequency-shift keying (FSK)

As an example of encoding the radiation force we present an example using FSK. The principle of this modulation technique is that the frequency of the carrier or the

modulating signal is adjusted to binary bits, 0 and 1.[33] In this study, we change the frequency of the modulating signal. To accomplish this, traditional AM or DSB-SC AM could be used and the modulating signal would change based whether the bit in a code $s[n]$ was 0 or 1. The energy density could be defined as in the following equation using AM where $x_{m,0}(t)$ is used to encode $s[n]$ as 0 and $x_{m,1}(t)$ is used to encode $s[n]$ as 1.

$$\langle E(t)\rangle_T = \begin{cases} \frac{A_c^2}{2\rho c^2}[x_{m,0}^2(t) + 2x_{m,0}(t) + 1], & s[n] = 0 \\ \frac{A_c^2}{2\rho c^2}[x_{m,1}^2(t) + 2x_{m,1}(t) + 1], & s[n] = 1. \end{cases} \quad (32)$$

III. EXPERIMENTS

We will present experiments designed to validate the theory that has been presented above and give an example of an application using multifrequency radiation force similar to that presented in Ref. 28. We modulated an ultrasound signal with different functions and derived the radiation force with the pressure from the needle hydrophone measurements. Because the force is a quadratic function of the pressure, we could not directly validate the force. We approached this validation in an indirect fashion.

To validate the theory presented in this study and exhibit an application of this general technique we measured the motion of a steel sphere in a gelatin phantom as we changed the modulating signal used. This is a variation of the method introduced by Chen *et al.*[17] to measure the viscoelastic material properties of the gelatin by finding the frequency response of the sphere induced by radiation force. First, we will use the method described by Chen *et al.*[17] to characterize the viscoelastic material properties of the gelatin. We will then use the theory presented below to compute the sphere displacement from the force derived from the needle hydrophone measurements, and the theory that was presented above. We will compare that displacement signal with the displacement we measure.

There is also another more indirect way of validating the theory that was presented above. If we use the same phantom and change the modulating signal, we will induce different motion. Using the derived force from needle hydrophone measurements and the motion measurements, we can find the material properties of the gelatin. If the developed theory is correct, then we should obtain the same values for the material properties regardless of the modulation technique.

These measurements with modulated ultrasound signals will provide an application of this general method for the characterization of the viscoelastic material properties in one measurement as opposed to the original method put forth by Chen *et al.*,[17] where multiple single frequency measurements are performed.

A. Needle hydrophone measurements

Needle hydrophone measurements were performed to measure the ultrasound radiofrequency (rf) signal in a water tank. This signal was used to derive the radiation force time- and frequency-domain representations to compare with results from the analytic expressions detailed above. These measurements will be used as a forcing function input for later measurements made in a gelatin sphere phantom to evaluate the transfer function of the phantom material. A 0.5 mm diameter needle hydrophone (NTR Systems, Seattle, WA) was positioned in a large water tank at the focus of a 3.0 MHz transducer with a diameter of 45 mm and a spherical focus of 70 mm, which was assembled in-house using a focused piezoelectric crystal (Boston Piezo-Optics, Inc., Bellingham, MA).

Different waveforms and types of modulation were used for validation of the theory presented above. A sine wave of frequency 100 Hz was used for $x_m(t)$ for AM, and a sine wave of frequency 50 Hz was used for $x_m(t)$ for DSB-SC AM. A square wave with a 50% duty cycle, T_b=5 ms and T_r=10 ms, was used with amplitude modulation. A triangle wave was used with AM. An AM implementation with a linear FM signal was used with a bandwidth of 1 μHz–5000 Hz, and the frequency sweep was performed in 50 ms. Lastly, a FSK signal was formed by defining a digital zero as 8 cycles of a square wave with 50% duty cycle with T_r of 5 ms (f_r=200 Hz) and a digital one as 4 cycles of a square wave with 50% duty cycle with T_r=10 ms (f_r =100 Hz).

B. Steel sphere phantom study

From the ultrasound rf signals, the radiation force can be calculated, within a constant multiplier, by squaring the pressure and applying a low-pass filter for each modulation waveform. We used the same waveforms as were characterized in the needle hydrophone measurements for vibrating a 440C stainless steel sphere with diameter of 1.59 mm embedded in three types of gelatin phantoms. Phantoms 1, 2, and 3 were made from 300 Bloom gelatin powder (Sigma-Aldrich, St. Louis, MO) with concentrations of 10%, 10%, and 12% by volume, respectively, and glycerol (Sigma-Aldrich, St. Louis, MO) with concentrations of 0%, 10%, and 10% by volume, respectively. A preservative of potassium sorbate (Sigma-Aldrich, St. Louis, MO) was also added with a concentration of 10 g/L to all three phantoms. Unless otherwise noted, the results shown are from phantom 1. A Doppler laser vibrometer (Polytec, Waldbronn, Germany) was used to measure the velocity of the sphere. We measure the velocity because it is proportional to the force imparted on the sphere.

The velocity can be used to characterize the system if the force is known. We can apply linear systems modeling where $v(t)$ is the velocity, $f(t)$ is the force, and $z(t)$ is the mechanical impedance function for the sphere/gelatin phantom. The force is equal to the convolution of the velocity and the impedance function.

$$f(t) = v(t) \otimes z(t). \quad (33)$$

In the frequency domain the force denoted as $F(\omega)$ is the product of the frequency-domain representations of the velocity $V(\omega)$ and the impedance $Z(\omega)$.[17,36]

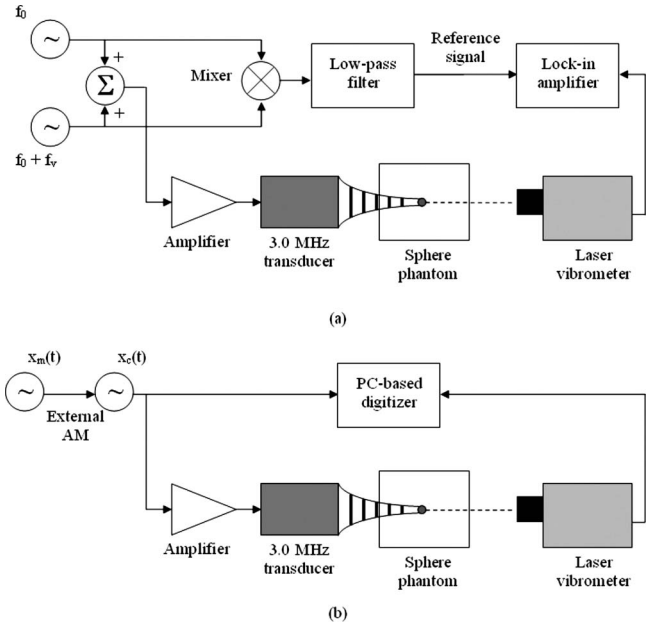

FIG. 1. Experimental setups. (a) Experimental setup with DSB-SC AM modulation, sphere velocity was measured with the laser vibrometer and lock-in filter. (b) Experimental setup with modulated ultrasound, sphere velocity was measured with the laser vibrometer and recorded with PC-based digitizer.

$$F(\omega) = V(\omega)Z(\omega). \tag{34}$$

We can estimate the impedance function $\tilde{Z}(\omega)$ by dividing the force function derived from the transmitted ultrasound measured before amplification by the measured velocity

$$\tilde{Z}(\omega) = \frac{F(\omega)}{V(\omega)}. \tag{35}$$

Using a model defined by Ostreicher and utilized by Chen *et al.*, we can find the shear elasticity μ_1 and shear viscosity μ_2, assuming a value of 1000 kg/m^3 for the density of the gelatin.[17,37] We consider this method to be our gold standard, or reference, measurement for μ_1 and μ_2.

To obtain a reference measurement for characterization of the gelatin, a DSB-SC AM signal with $x_m(t)=\cos(2\pi f_m t)$ where f_m was varied from 25 to 1000 Hz to yield vibration frequencies of 50–2000 Hz. The output of the laser vibrometer was processed by a lock-in amplifier (Signal Recovery, Oak Ridge, TN) to obtain the measurements of the magnitude of the velocity. The advantage of using the modulated ultrasound waveforms is that they produce multiple frequencies so that the impedance function can be estimated in one measurement compared to making a set of discrete measurements at single frequencies with the lock-in filter. However, when using modulation, each frequency component has a different magnitude and so we must take that into account when trying to characterize the mechanical system as indicated in Eq. (35). We normalize for the magnitude variation of the force when we use the DSB-SC AM method, varying the frequency to one value at a time, because we ensure that the same force magnitude is used for each measurement. A figure of the experimental setup with the lock-in filter is shown in Fig. 1(a) and with the digitizer in Fig. 1(b).

For the experiment with the lock-in filter we use two signal generators (33250A, Agilent, Santa Clara, CA) to generate signals at f_0 and f_0+f_v where f_0 is 3.0 MHz and f_v is the desired vibration frequency, and the carrier frequency is $f_c=(f_0+f_v)/2$. Those signals are added using a hybrid junction (M/A COM, Inc., Lowell, MA) and used as input to the amplifier. The amplified output was applied to the 3.0 MHz transducer. The ultrasound signals were also used as inputs for a mixer. The output of the mixer was low-pass filtered to get a reference signal at f_v for the lock-in amplifier (Signal Recovery, Oak Ridge, TN). The laser vibrometer output was also input to the lock-in amplifier.

For the experiment with the PC-based digitizer (Alazartech, Montreal, QC, Canada), the modulating signal $x_m(t)$ was created using one signal generator (33250A, Agilent, Santa Clara, CA) and that signal was applied to the external AM input of another signal generator set at 100% modulation index that was generating the 3.0 MHz ultrasound carrier frequency $x_c(t)$. The modulated signal was sent to one channel of the digitizer and also amplified and applied to the transducer. The laser vibrometer signal was sent directly to the digitizer. The sampling frequency for both signals was 50 MHz.

We fit the velocity data from the laser vibrometer to the model first presented by Ostreicher and subsequently used by Chen *et al.*, to characterize tissue mimicking gelatin[17,37] to find the viscoelastic parameters μ_1 and μ_2.

$$V(\omega) = \frac{F(\omega)}{Z(\omega)} = \frac{F(\omega)}{Z_r(\omega) + Z_m(\omega)}. \tag{36}$$

The impedance terms, derived under plane wave conditions, are given as

$$Z_r(\omega) = -i\frac{4\pi a^3}{3}\rho\omega \times \frac{\left(1-\frac{3i}{ah}-\frac{3}{a^2h^2}\right)-2\left(\frac{i}{ah}+\frac{1}{a^2h^2}\right)\left(3-\frac{a^2k^2}{aki+1}\right)}{\left(\frac{i}{ah}+\frac{1}{a^2h^2}\right)\frac{a^2k^2}{aki+1}+\left(2-\frac{a^2k^2}{aki+1}\right)}, \tag{37}$$

$$Z_m(\omega) = -i\frac{4\pi a^3}{3}\rho_s\omega, \tag{38}$$

where $k=\sqrt{\rho\omega^2/(2\mu+\lambda)}$, $h=\sqrt{\rho\omega^2/\mu}$, $\mu=\mu_1+i\omega\mu_2$, $\lambda=\lambda_1+i\omega\lambda_2$, a is the radius of the sphere, ρ is the mass density of the medium, μ_1 and μ_2 are the shear elasticity and viscosity of the medium, λ_1 and λ_2 are the bulk elasticity and viscosity, and ρ_s is the mass density of the sphere. The values used for this model implementation were $\rho=1000$ kg/m^3, $a=0.794$ mm, $\rho_s=7849$ kg/m^3, $\lambda_1=2.48$ GPa, and $\lambda_2=0$. The curve fits to the model were performed using the nlinfit.m function in MATLAB (The Mathworks, Natick, MA).

To validate the theory on modulating ultrasound with the measurements, we examine the displacement of the sphere from theoretical and experimental bases. For the sphere in the gelatin phantom we can derive the displacement by inte-

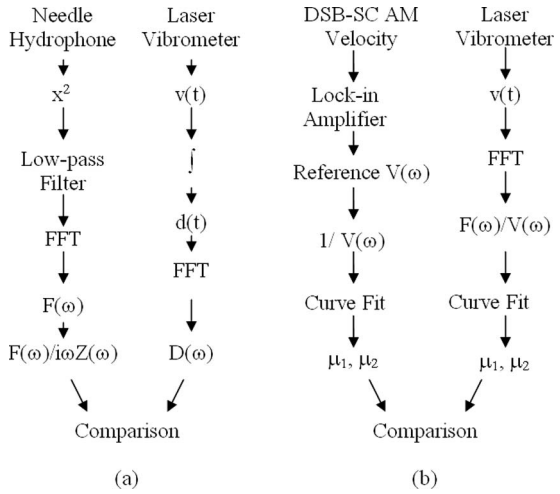

FIG. 2. Validation methods for the multifrequency radiation force theory. (a) The force is derived from the pressure measured by the needle hydrophone. The pressure is squared and low-pass filtered and the spectrum is computed. The force spectrum is divided by $i\omega Z(\omega)$. The velocity measured by the laser vibrometer was integrated to get displacement. The displacement spectrum was computed and compared to the signal derived from the needle hydrophone. (b) The DSB-SC AM measurements made with the lock-in amplifier provide a reference measurement of impedance $Z(\omega)$, and a curve fitting was performed to get μ_1 and μ_2. The laser vibrometer velocity signal is measured and the reference force signal is divided by $V(\omega)$. The curve fit is performed and μ_1 and μ_2 values are compared.

grating Eq. (36). In the frequency domain, this is accomplished by dividing both sides of the equation by $i\omega$, yielding

$$D(\omega) = \frac{V(\omega)}{i\omega} = \frac{F(\omega)}{i\omega(Z_r(\omega) + Z_m(\omega))}. \tag{39}$$

We can take the force that we derive from the pressure measurements using the needle hydrophone and divide by the product $i\omega Z(\omega)$ that is computed from the results of the reference measurement using single modulation frequencies and the lock-in amplifier. We then will compare this with the measured displacement. If the theory is correct, the results should match. A flow diagram of this process is shown in Fig. 2(a).

We also used a large set of modulating waveforms to estimate the impedance function for the gelatin phantom including AM with square waves of duty cycles ranging from 25% to 80%, a triangle wave, a sawtooth wave, a linear FM signal, and FSK performed with the square waves of duty cycles ranging from 25% to 75%, a triangle wave, and a sawtooth wave. Using DSB-SC AM we used a triangle wave, a linear FM signal, and a FSK with a triangle wave. These modulating signals yielded a multifrequency radiation force and we evaluated how these types of signals could be used to measure the mechanical properties of the gelatin phantom in one measurement. The reference measurements and the measurements with different modulating waveforms were performed on all three phantoms that were made for this study. A flow diagram for this process with the modulation functions is shown in Fig. 2(b).

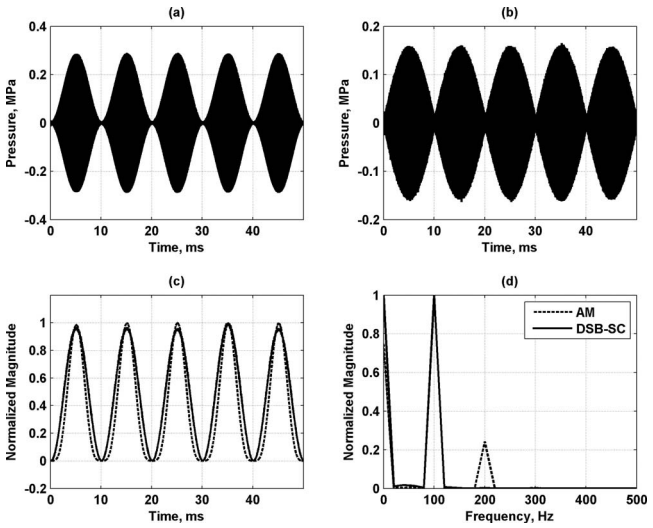

FIG. 3. Modulation with sinusoidal functions. (a) Ultrasound pressure for AM with sinusoidal function with frequency 100 Hz. (b) Ultrasound pressure for DSB-SC AM with sinusoidal function with frequency 50 Hz. (c) Calculated radiation force for modulation in (a) and (b). (d) Spectra for radiation force in (c). The legend in (d) applies to (c) and (d).

IV. RESULTS

A. Needle hydrophone measurements

Figure 3(a) shows the ultrasound pressure for AM performed with a sine wave with frequency of 100 Hz, and Fig. 3(b) shows the ultrasound pressure for DSB-SC AM performed with a sine wave with frequency of 50 Hz. The waveforms appear filled because of the many ultrasound cycles within the 50 ms timeframe of the transmission. Figure 3(c) shows the calculated radiation force produced by the two types of modulated ultrasound in Figs. 3(a) and 3(b). Figure 3(d) shows the frequency-domain representations of the signals in Fig. 3(c). The frequency components are in agreement in proportion and frequency as the analytic expressions in Eqs. (13) and (21) for the AM and DSB-SC AM cases, respectively.

Figure 4(a) shows the ultrasound pressure for AM with a square wave with 50% duty cycle. Figures 4(b) and 4(c) show the time- and frequency-domain representations of the intensity, which is proportional to the radiation force. The square wave has components at odd harmonics of the fundamental, 100 Hz. The components at the even harmonics are low compared to adjacent odd harmonics and are probably introduced because of the ultrasound overshoot at the beginning of a toneburst, and the extra transmission or standing wave at the end of the toneburst observed in the needle hydrophone measurements.

Figure 5(a) shows a triangle wave used for modulation. Figures 5(b) shows the intensity when the triangle wave is used in AM, respectively. The frequency-domain representations of the intensity are shown in Fig. 5(c). The triangle wave modulation signal provides components at harmonics of the fundamental frequency, 100 Hz. The use of different modulating functions changes the amplitude of the components that they produce in the radiation force.

Figure 6(a) shows a linear FM signal, and Fig. 6(b) shows the intensity. The frequency-domain representations

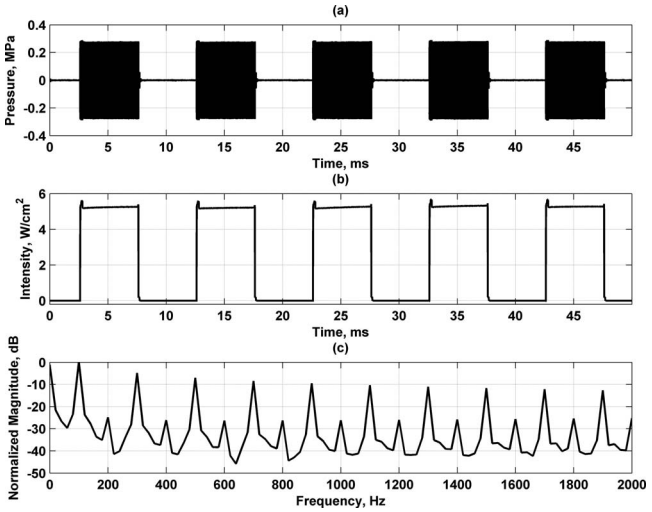

FIG. 4. Modulation with AM square wave with 50% duty cycle and frequency of 100 Hz. (a) Modulated ultrasound, (b) Intensity for modulated ultrasound in (a), and (c) spectrum for intensity in (b).

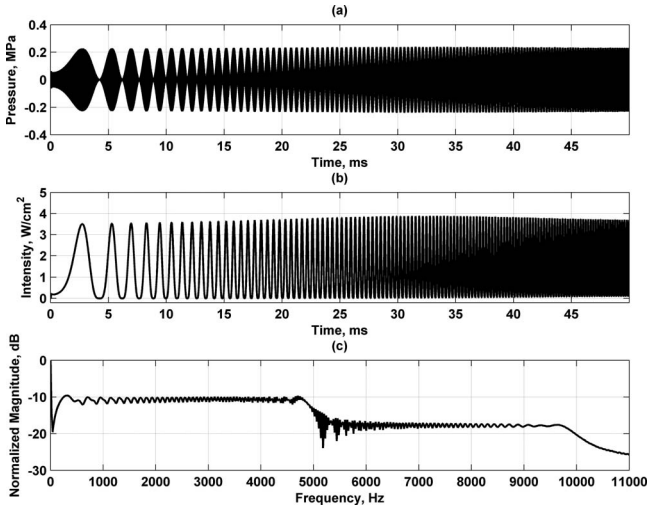

FIG. 6. Modulation with AM with linear FM signal that sweeps from 1 μHz to 5000 Hz in 50 ms. (a) Modulated ultrasound, (b) intensity for modulated ultrasound in (a), and (c) spectrum for intensity in (b).

of the FM function and the intensity are shown in Fig. 6(c). The use of frequency modulation provides a near constant bilevel radiation force from 0 to 5 kHz and from 5 to 10 kHz, which is separated by about 6 dB. However, the force is not constant at the extremes of the bandwidth used, particularly at the lower frequencies from 0 to 300 Hz and at the transition around 5 kHz.

For the case of the FSK with a square wave with two different fundamental frequencies, Fig. 7(a) shows the modulated ultrasound pressure signal. The intensity is shown in Fig. 7(b), and the frequency-domain representation of the intensity is shown in Fig. 7(c). The FSK square wave yields components at the odd harmonics of the fundamental frequencies of the modulating signals used to encode the different bits, 200 and 100 Hz, respectively. From the first segment (0–50 ms), components at 200, 600, 1000, 1400, and 1800 Hz result, and from the second segment (50–100 ms), components at 100, 300, 500, 700, 900, 1100, 1300, 1500, 1700, and 1900 result. In total, using this 2 bit code yields 15 unique components.

B. Sphere phantom characterization

We measured the velocity of a sphere induced by the multifrequency radiation force for different modulating functions directly with the laser vibrometer and derived the displacement by integrating the velocity signal. Figures 8(a) and 8(b) show the sphere displacement and velocity for the AM square wave excitation. Figures 8(c) and 8(d) show the sphere displacement and velocity for the AM triangle waveform. Figures 8(e) and 8(f) show the sphere displacement and velocity for the FSK square wave signal. The displacements look very similar to the force depicted in Figs. 4(b), 5(b), and 7(b) for the square, triangle, and FSK modulation functions. There is some very low frequency drift that is

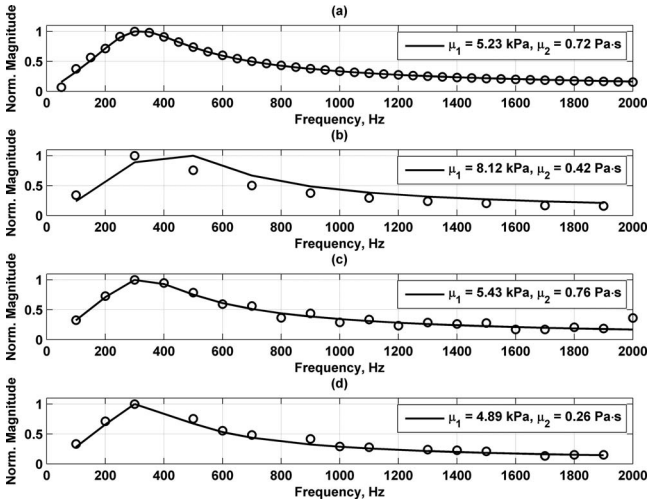

FIG. 10. Sphere phantom impedance functions and model fits for different modulation functions. (a) Data, denoted by the open circles, and model fit, denoted as the solid line, for DSB-SC AM with sinusoidal modulating function. The legends contain the material properties from the model fit in each respective panel, (b) Data and model fit for AM with square wave with 50% duty cycle as modulating function. (c) Data and model fit for AM with triangle wave as modulating function. (d) Data and model fit for AM with FSK square wave with 50% duty cycle as modulating function.

most prevalent in the AM triangle wave results. These qualitative similarities are an indication that the theory used to derive the force is correct.

The reference measurement with single frequencies was carried out and yielded $\mu_1=5.23$ kPa and $\mu_2=0.72$ Pa s for phantom 1. These values were used for computing the displacement using Eq. (39) and the velocity using Eq. (36) assuming a constant force for all frequencies. The normalized magnitude spectra for the displacement and velocity are shown in Fig. 9(a). If we look at these spectra from a linear systems perspective, the displacement has a low-pass filter characteristic and the velocity has a bandpass filter characteristic. The low-pass filter nature of the displacement response agrees with the qualitative assessment of the measured displacement previously mentioned and displayed in Fig. 8. We then took the derived force for square wave modulation from Fig. 4(b) and divided it by the computed product $i\omega Z(\omega)$ and compared that with the measurement from square wave modulation shown in Fig. 8(a). The normalized theoretical and measured results are shown in Fig. 9(b). The agreement is very good. This result serves as verification of the modulation theory.

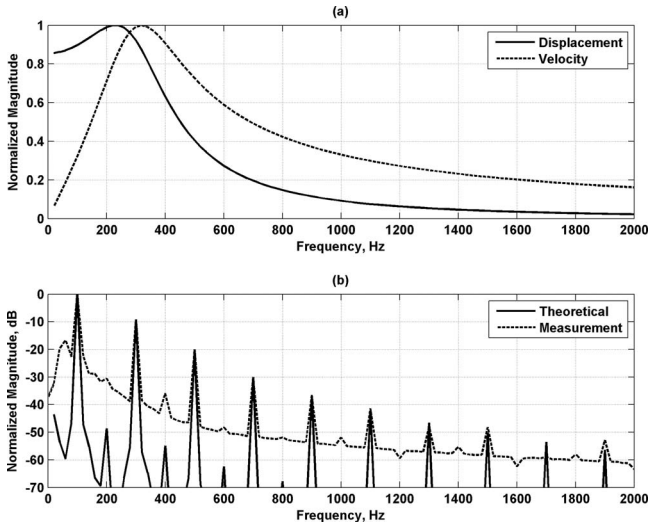

FIG. 9. Validation results using measured and calculated displacements. (a) Calculated displacement and velocity responses assuming a constant force at all frequencies. (b) Theoretical and measured displacement magnitude spectra results. The theoretical magnitude spectrum was calculated using the force derived from pressure measurements made with a needle hydrophone [Fig. 4(b)] divided by the calculated product $i\omega Z(\omega)$. The measured magnitude spectrum is from the displacement in Fig. 8(a).

Figure 10(a) shows the reference measurement made with the DSB-SC AM measurements and the estimated impedance function. Figure 10(b) shows the magnitude spectrum of the sphere phantom impedance function derived from the transmitted ultrasound and the velocity measured by the laser for the AM square waveform. Figures 10(c) and 10(d) show the magnitude spectra for the impedance function obtained using the AM triangle modulating signal and the FSK square wave signal, respectively. The number of frequency components with high signal-to-noise ratio (SNR) varies based on the modulating signal. The solid lines in the plots in Fig. 10 are the curve fits to the model for the embedded sphere in a viscoelastic medium. We performed this for the different waveforms used in this study and tabulated the results in Table I.

Noting that each modulating signal produces different components with significant SNR in the radiation force, we attempted to account for this fact by performing linear interpolation and extrapolation over the frequency bandwidth that was used for the reference measurement, 50–2000 Hz. We performed the linear interpolation and fit the results to the model as was explained above, and those results are also

TABLE I. Model fitting results for viscoelastic properties of gelatin with different modulation signals.

Modulation signal	μ_1 (kPa)	μ_1 (kPa) (interpolation)	μ_2 (Pa S)	μ_2 (Pa S) (interpolation)
DSB-SC sine (reference)	5.23	5.23	0.72	0.72
AM square 25%	5.15	5.32	0.62	0.88
AM square 30%	4.94	5.19	0.51	0.76
AM square 50%	4.57	5.60	0.19	0.77
AM square 75%	5.77	5.37	0.37	0.83
AM square 80%	5.89	6.00	0.53	0.57
AM triangle	5.27	5.55	0.67	0.59
AM sawtooth	5.22	5.30	0.58	0.63
AM chirp 5 kHz	7.24	6.85	−0.08	0.40
AM FSK square 25%	5.17	5.29	0.54	0.63
AM FSK square 50%	5.45	5.18	0.45	0.80
AM FSK square 75%	5.04	5.18	0.82	0.85
AM FSK triangle	5.47	5.56	0.86	0.90
AM FSK sawtooth	5.36	5.62	0.69	0.66
DSB-SC triangle	5.46	5.57	0.80	0.85
DSB-SC chirp 5 kHz	9.35	9.28	0.57	0.32
DSB-SC FSK triangle	5.33	5.44	0.79	0.87

summarized in Table I. Using the same modulation signals as shown Fig. 10, linear interpolation was performed and the model fits are shown in Fig. 11.

The reference measurement with single frequencies was carried out on phantoms 2 and 3 and yielded μ_1=7.21 kPa and μ_2=0.52 Pa s, and μ_1=8.92 kPa and μ_2=0.67 Pa s, respectively. The phantoms had increased shear elasticity, but did not have increased shear viscosity. We compared the material property estimates made from measurements using different modulation waveforms such as AM with square wave with 50% duty cycle, AM with a sawtooth wave, AM FSK

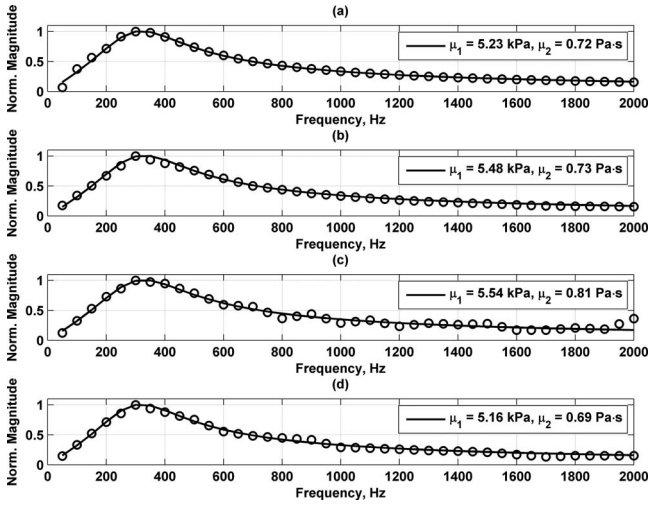

FIG. 11. Sphere phantom impedance functions and model fits for different modulation functions. (a) Data, denoted by the open circles, and model fit, denoted as the solid line, for DSB-SC AM with sinusoidal modulating function. The legends contain the material properties from the model fit in each respective panel. (b) Interpolated data and model fit for AM with square wave with 50% duty cycle as modulating function. (c) Interpolated data and model fit for AM with triangle wave as modulating function. (d) Interpolated data and model fit for AM with FSK square wave with 50% duty cycle as modulating function.

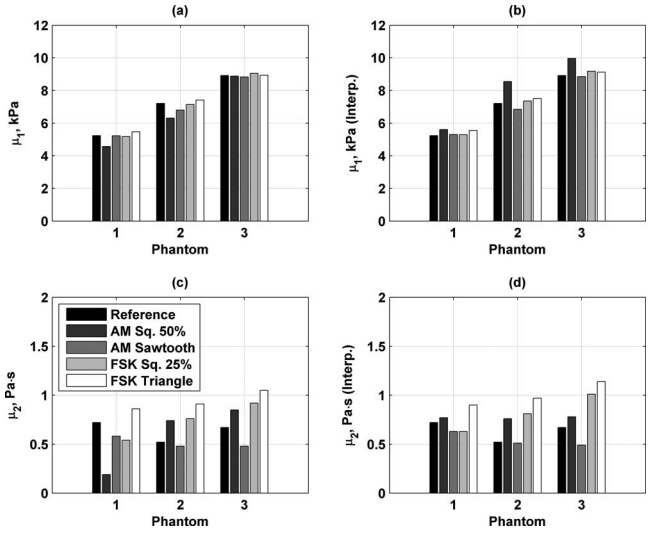

FIG. 12. Comparison of material property estimation for three gelatin phantoms for different modulation waveforms. The reference measurement is the DSB-SC AM measurements made with single frequencies. (a) Estimation of μ_1, (b) estimation of μ_1 with interpolation, (c) estimation of μ_2, and (d) estimation of μ_2 with interpolation.

with square wave with 25% duty cycle, and AM FSK with a triangle wave. Figure 12 summarizes those estimation results for all three phantoms for μ_1 and μ_2 without and with interpolation. In general, the estimates for μ_1 were similar to the reference measurement, but the estimates for μ_2 were more varied.

V. DISCUSSION

Using different types of modulation and modulating signals yields radiation force with different shapes and spectra. Using a sinusoidal modulation signal with either AM or DSB-SC AM yields spectra with different components and weighting of those components as predicted by the theory. When more complex modulating signals are used such as a square wave, a triangle wave, or a FM signal, the radiation force contains multiple frequency components. The magnitude of those components also changes and so different modulating signals could be used for different experiments based on the desired excitation.

We measured the cyclic velocity of a sphere induced by the multifrequency radiation force for different modulating functions. Using the velocity signals, we were able to estimate the viscoelastic properties of the gelatin in which the sphere was embedded. Figure 10 shows the fits using different modulation functions along with the reference measurement that was made using DSB-SC AM with a single sinusoid and varying the frequency. Using the triangle and FSK square waves seemed to produce results closest to the reference measurement, and the match was aided by the inclusion of more frequency components.

When linear interpolation was performed to achieve data with the same frequency resolution as the reference measurement, the fits matched better. The linear interpolation helped to compensate for frequency components that lacked significant SNR for certain modulating waveforms. For example, when using the square wave with 50% duty cycle [Fig.

10(b)], we only obtained components at 100, 300, 500,…, 1900 Hz, but the interpolation filled components at 200, 400, 600,…, 2000 Hz and improved the fitting. This was quantitatively evaluated and summarized in Table I. In a majority of cases, interpolation helped to improve the fits to obtain values of μ_1 and μ_2 that were closer to those of the reference measurement made at single frequencies. In general the values for μ_1 were in good agreement. The value of μ_2 was more difficult to estimate consistently, probably because the shear viscosity was fairly low. The worst results were given with the AM chirp signal and that may be due to low SNR at any given frequency during the course of the chirp as opposed to the other waveforms used. A slower chirp could be used and may improve the results because more time would be taken at a given frequency.

We compared the measured sphere displacement and that derived from the theoretical development, and the agreement was very good. We take this result as a validation of the theory. We also observed that different modulation signals yielded similar estimates of μ_1 and μ_2. Using the data in Table I, the median absolute percent errors in μ_1 were 4.12% and 3.94% without and with interpolation, respectively, and the median absolute percent errors in μ_2 were 21.54% and 16.56% without and with interpolation, respectively. The higher percent errors for μ_2 result because of the low value of μ_2. This agreement among material property estimates using different modulation signals would not be possible if the general theoretical basis was flawed. These results serve as an indirect validation as well as application of this multifrequency radiation force theory and method.

Modulating the ultrasound produces vibration with high SNR for a selected group of frequencies depending on the modulation function. The accuracy of the characterization of the viscoelastic properties of the gelatin material is dependent on the number of frequency components present and their respective weighting. Depending on the suspected material properties, one could choose one modulating signal versus another to optimize the ability to characterize the material. Either weighting at certain frequencies or desired bandwidth could be considered.

AM is probably the most versatile modulation technique while DSB-SC AM is also useful in creating modulated signals. FSK could be used for introducing codes into the radiation force if there was an application that necessitated this technique. FM could be used to distribute energy to a wide bandwidth. The modulation technique used for a given application depends on the way that the energy needs to be distributed in the forcing function.

One of the advantages of using modulation to produce a multifrequency radiation force is that one can obtain the same data in one measurement that the reference method took multiple measurements to obtain. The information gain can be quite high and the signal strength can be concentrated into known frequency components in the desired bandwidth through proper selection of the modulation function.

Two applications have arisen that utilize multifrequency radiation force to take advantage of obtaining information at multiple frequencies in one measurement. Vibro-acoustography has taken advantage of this multifrequency radiation force using DSB-SC AM waveforms to create multiple images from one scan.[28] Another method called shear wave dispersion ultrasound vibrometry (SDUV) uses square wave modulation to transmit multiple tonebursts of ultrasound at the frequency of the square wave f_r, and then elicits shear waves with components at harmonics of f_r.[25] The shear wave velocity is estimated at f_r and several of its harmonics to estimate the shear wave velocity dispersion and characterize the viscoelastic material properties of the tissue or medium.

One could also design modulating functions to emphasize certain frequency components with specific weightings. That signal could be entered as an arbitrary waveform in hardware to be used for the analog modulation function.

VI. CONCLUSION

In this paper we presented general theory for modulating ultrasound to produce multifrequency radiation force. We showed that using different modulation functions can create multifrequency radiation force with components at different frequencies and different relative weighting. As an example of the utility of using modulated ultrasound, we showed that this method could be used to characterize the viscoelastic properties of a tissue mimicking phantom material with differing degrees of accuracy based on the modulation function using *one* multifrequency measurement. Techniques such as SDUV and vibro-acoustography use these modulation techniques to perform noncontact, noninvasive characterization and imaging of materials and biological tissues.

(Received 2 September 2009; revised 14 December 2009; accepted 29 December 2009)

The stiffness of a consolidated granular medium experiences a drop immediately after a moderate mechanical solicitation. Then the stiffness rises back toward its initial value, following a logarithmic time evolution called *slow dynamics*. In the literature, slow dynamics has been probed by macroscopic quantities averaged over the sample volume, for instance, by the resonant frequency of vibrational eigenmodes. This article presents a different approach based on diffuse acoustic wave spectroscopy, a technique that is directly sensitive to the details of the sample structure. The parameters of the dynamics are found to depend on the damage of the medium. Results confirm that slow dynamics is, at least in part, due to tiny structural rearrangements at the microscopic scale, such as inter-grain contacts. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3294553]

I. INTRODUCTION: WHAT IS SLOW DYNAMICS?

Depending on the magnitude of the solicitation applied to it, a consolidated granular medium, such as sedimentary rocks or concrete, can asymptotically react either in the elastic (reversible) regime, or in the brittle regime, where irreversible fractures develop. A few years ago, several articles from Guyer and co-workers and Ten Cate and co-workers (Ten Cate and Shankland, 1996; Guyer *et al.*, 1998; Guyer and Johnson, 1999; Ten Cate *et al.*, 2000) reported on an intermediate regime, where they observed non-linear elasticity. This regime is observed after imposing a strain of moderate amplitude (10^{-6}) that does not generate any macroscopic damage. They called its time evolution as slow dynamics: it starts with a drop of the elastic modulus, followed by a logarithmic recovery of the sample stiffness toward its initial value after the strain is released. The $\log(t)$ recovery was found to be universal in granular solids of various composition (Ten Cate *et al.*, 2000; Lacouture *et al.*, 2003; Johnson and Sutin, 2005), humidity (Vakhnenko *et al.*, 2004), or level of damage (Van Den Abeele *et al.*, 2001). Most of the time, the evolution of the sample stiffness is monitored through the frequency of vibrational eigenmodes, using a technique named as non-linear elastic wave spectroscopy (Guyer and Johnson, 1999). More recently, Lobkis and Weaver (2009) proposed to monitor the stiffness of the material using the Larsen effect between two piezo-eletric transducers. The resonant frequency f_L observed with a feedback loop was measured with a relative precision of the order $\delta f_L/f_L \approx 10^{-6}$, and was found to satisfyingly monitor the rigidity of the material. This latter technique offers simultaneously an increased sensitivity and a temporal resolution of a few ms, thus allowing to study slow dynamics over very short time-scales.

In this article, we develop an alternative method based on broadband diffuse ultrasound. We take advantage of coda waves that can be observed in multicomposite materials, where multiple scattering effects (characterized by the scattering mean free time $t^\star$) dominate absorption effects (characteristic time τ_{abs}). Denoted by T, the central period of the ultrasound, and with Δd as the time between two ultrasonic records, the time-scales in our experiment follow the hierarchy

$$T < t^\star < \tau_{\mathrm{abs}} < \Delta d. \tag{1}$$

Similar to coda wave interferometry (CWI) (Poupinet *et al.*, 1984; Roberts *et al.*, 1992; Snieder *et al.*, 2002) and to diffuse acoustic wave spectroscopy (DAWS) (Pine *et al.*, 1988; Cowan *et al.*, 2002), we study weak changes in the diffuse waveforms in amplitude and phase. We compare waveforms recorded after a moderate solicitation to those recorded before it. The solicitation consists in the impact of a small steel ball falling onto the sample from a controlled height (1 m in general). The composition of the samples is displayed in Table I.

II. EXPERIMENTAL SETUP

In the first experiment, we use a cylindrical sample of 16 cm in diameter and 30 cm in height (sample 1). Two ultrasonic transducers are used: one as a source and one as a receiver (labeled as S and R, respectively, in Fig. 1); they are 10 cm apart. Note that the lateral part of the transducer is inactive and rigid, so that surface (Rayleigh) waves are neither excited nor recorded. In this sample, the scattering mean

TABLE I. Sample composition.

Composition (in weight)	Weight	Density
Cement: 17% Fine sand: 31% Gravel: 43% Water: 9%	12.5 kg	2.2 kg/l

free time is of the order of 12 μs, the transit time is of the order of 60 μs, and the absorption time is about 200 μs.

The lateral size of the active part of the transducers (0.7 mm) is much smaller than the wavelength (λ =5 mm–5 cm at working frequencies), which makes them very sensitive to multiply scattered waves. The transducers are glued onto the sample using a hot chemical glue (phenylsalicylic acid) that solidifies with cooling (below 43 °C). The ultrasonic experiment was performed several months after casting the samples. We send a 80 V broadband ultrasonic impulse with frequencies ranging from 50 to 500 kHz. The signal measured by the receiver is amplified, digitized, and stored in memory. A typical record $h_d(t)$ is shown in Fig. 2. The impulse response contains a hardly visible direct arrival, followed by a long lasting coda due to multiple scattered waves. The acquisition is repeated at various dates d (d=0 starts the experiment), over about 1 h. At date d_I, we drop a small metallic ball (m=30 g) from a height h=1.38 m onto the top face of the sample. The impact is about 15 cm from the source and receiver. The elastic energy released to the sample is $E_{\text{kin}}=mgh\approx 0.4$ J. Note that we observe no visible damage caused by this moderate impact.

III. DATA PROCESSING

From the set of ultrasonic data obtained during an experiment, we derive two quantities that depend on d. First, we measure the relative velocity change $\delta V_d/V$ within the material (Poupinet *et al.*, 1984; Snieder *et al.*, 2002; Lobkis and Weaver, 2003). Second, we measure the remnant decorrelation K_d of the waveforms after correcting for the effect of the relative velocity change (Lobkis and Weaver, 2003).

A. Relative velocity change $\delta V/V$ (CWI)

Let us describe the two steps of our data processing in details. To measure the relative velocity change, we compare the phase of the waveforms acquired at the date d to the phase of the initial record (d=0). Following Sens-Schönfelder and Wegler (2006), we interpolate and resample

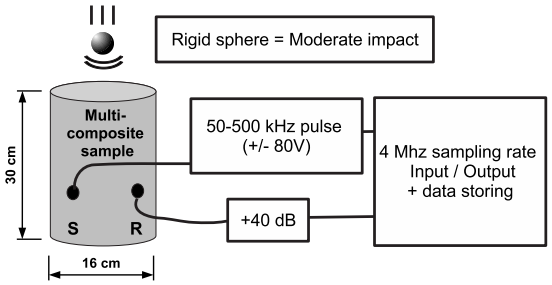

FIG. 1. Schematic view of the experimental setup for sample 1.

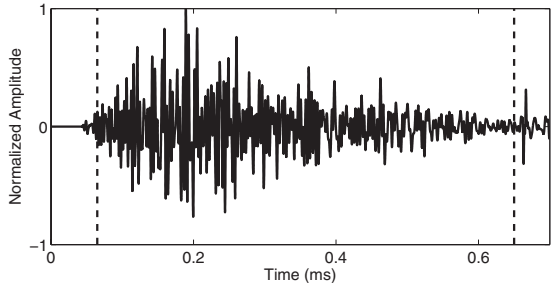

FIG. 2. Typical record collected through a concrete sample. The integration time-window is marked by the two dashed vertical lines at 0.05 and 0.65 ms. The initial impulse duration is about 10 μs.

$h_d(t)$ at times $[1+\epsilon]t$; this corresponds to stretching the time axis of the record by a factor of $1+\epsilon$. Then we evaluate the correlation coefficient between h_0 and h_d

$$X_d(\epsilon)=\frac{\int h_0(t)h_d([1+\epsilon]t)dt}{\sqrt{\int h_0^2(t)dt}\sqrt{\int h_d^2([1+\epsilon]t)dt}}, \tag{2}$$

where the integration is performed over a time-window larger than the period T. This time-window is marked by two vertical broken lines in Fig. 2. This calculation is repeated for various values of the parameter ϵ. The parameter ϵ maximizing X_d corresponds to the actual relative velocity change

$$\epsilon_{\max}=-\delta V_d/V. \tag{3}$$

The evolution of $\delta V_d/V$ as a function of d is displayed in Fig. 3 (top). Note that the ball impact occurs at date d_I =270 s after starting the experiment. Before the impact, there is no relative velocity change, indicating that the medium is at rest. Immediately after the impact, the velocity is noticeably decreased. Since the density of the material is not changed, and since diffuse waves are mainly in the trans-

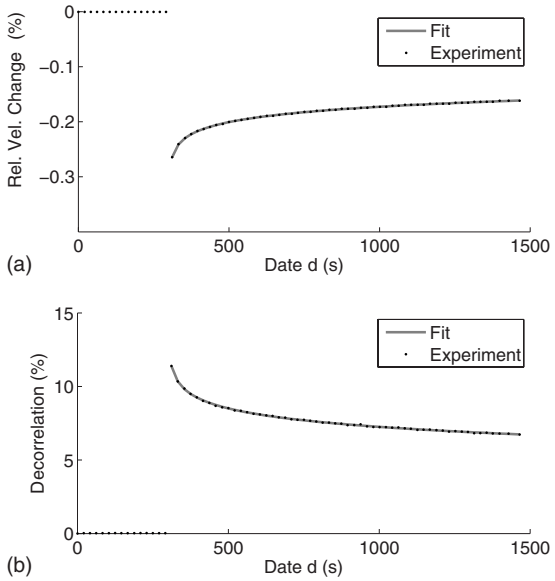

FIG. 3. Relative velocity change $\delta V/V$ (top) and decorrelation (bottom) versus the date d of the measurement. Impact is at d_I=270 s. Thermal effects are negligible. A logarithmic fit is added to each experimental curve.

verse (shear) polarization, this velocity drop is principally due to a drop of rigidity of the material. Then, the material stiffness rises back toward its initial value.

B. Remnant decorrelation *K* (DAWS)

In a second step, we use the dilated records to evaluate the remnant decorrelation coefficient K_d between the waveforms, which simply reads (Pine *et al.*, 1988; Cowan *et al.*, 2002)

$$K_d = 1 - X_d(\epsilon_{\max}). \tag{4}$$

The time evolution of K as a function of d is plotted in Fig. 3 (bottom). Again, the record is very stable (no change) before the impact. After the impact, the ultrasonic waveform differs significantly from the reference, then the decorrelation from the reference waveform decreases over several hundreds of seconds. The decorrelation K defined in Eq. (4) cannot be solely associated to a difference of relative velocity changes for different waves (for instance, between compressional and shear waves), contrary to the decorrelation studied by Lobkis and Weaver (2003). Also, the decorrelation cannot be attributed to changes in the bulk of the grains, which would require much more energy than the one released by the ball. Here, it corresponds to a feeble change in the scattering properties of the concrete sample, for instance, a small rearrangement of contacts between grains.

It is important to note that thermal changes are also well known to affect the average velocity within the sample (Lobkis and Weaver, 2003; Snieder *et al.*, 2002; Larose *et al.*, 2006), and consequently, the decorrelation. Relative velocity changes due to temperature variations are found to be negligible in our experiment, as can be noticed by the flat curve in Fig. 3, from $t=0$ to $t=270$ s. The decorrelation of the waveforms before the impact is actually near 0.1%, and is attributed to the noise generated by the electronic devices. We neglect it in the following. Note also that the changes in intensity of the diffuse waveforms (say, the quality factor of the coda) was observed to show some recovery (Ten Cate *et al.*, 2000), but this effect is not studied here and is beyond the scope of the present paper.

IV. THE PHYSICAL PARAMETERS OF SLOW DYNAMICS

The time evolutions of both $\delta V/V$ and K fit logarithmic laws (with d and d_I in seconds)

$$\delta V_d/V = A' - m' \log_{10}(d - d_I), \tag{5}$$

$$K_d = A - m \log_{10}(d - d_I). \tag{6}$$

Such a logarithmic evolution, valid if $d \ll 10^{A/m}$, is referred to as slow dynamics. A and m are the fit parameters, where A is the extrapolated decorrelation 1 s after the impact, and m is the slope of the logarithmic decay. $10^{A/m}$ represents the recovery time (in seconds), which is the time the system needs to recover its initial state. In general, this recovery time is of the order of 10^4–10^5 s. Parameters A and m were found to depend on the experimental apparatus, but Eq. (6) was found to describe the dynamics in all cases. Ten Cate *et al.* (2000) mentioned a break away from the log recovery after 1000 s. In our experiments, we should certainly expect an erosion of the log dynamics at some time. In particular, we must consider the possibility that part of the change in our experiments might be irreversible, and that the recovery might saturate. This could be ascribed to irreversible (but invisible) damages caused by the impact. As we could not monitor the sample longer than 1000 s, we cannot address this issue properly.

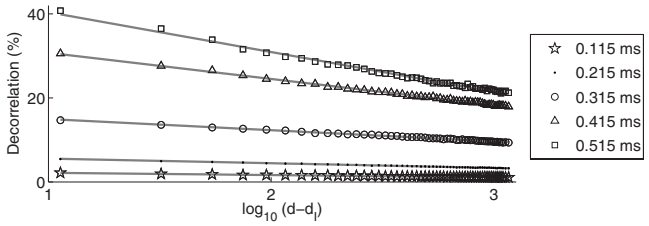

FIG. 4. Decorrelation versus the date of the measurement (in log scale) for various time-windows in the coda. The central time of each window is displayed in the box. The recovery time $10^{A/m}$ is found to be constant in the whole record.

A. Slow dynamics versus time in the coda

Let us now study the parameters A and m in more detail. As a first test, we evaluate these parameters at different times t in the coda. To that end, we split the initial time window (see Fig. 2) into five consecutive time-windows with length of 0.12 ms. The decorrelation K_d for these five windows is displayed in Fig. 4. A and m were found to increase with the time in the coda, confirming that late diffuse waves are much more sensitive to weak perturbation than early arrivals. Interestingly enough, the recovery time $10^{A/m}$ is constant within the whole record, which confirms that all time-windows (thus all wave paths) undergo the same slow dynamics phenomenon.

B. Slow dynamics versus frequency

To study the frequency dependence of slow dynamics, we filter the whole record into different frequency bands; we observe that A/m is constant in the 50–500 kHz frequency range. That the same dynamics was observed at different wavelength might suggest that there is no characteristic length in the rearrangement of the material structure. This confirms the assumption commonly made by previous authors (Ten Cate *et al.*, 2000) that the changes occur at various scales, following the probable continuous distribution of energy barriers.

C. Spatial dependence of slow dynamics

In the initial works on slow dynamics (Ten Cate and Shankland, 1996; Guyer *et al.*, 1998), the medium was subject to a global excitation, and resulted in a global change in the sample stiffness. The excitation presented here is a local impact (as in (Lobkis and Weaver, 2009). Determining whether the change induced by the ball impact is global (induced by the shock wave), or local is of some importance. To that end, we deploy a linear array of four sensors 10 cm

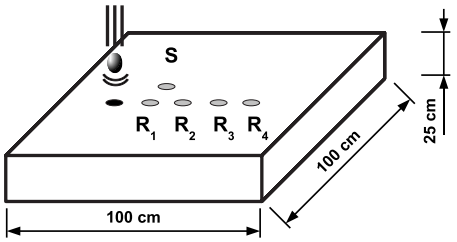

FIG. 5. Experimental setup for sample 2. Four receivers (R_{1-4}) are aligned with the impact location. The source S is 10 cm off the impact-receiver axis.

away from the impact location and from the source transducer. Because the initial sample is not large enough, we use a different sample (2) of similar composition but whose dimensions are now $1\times1\times0.25$ m^3 (see Fig. 5). The array has a spatial pitch of about 10 cm. The decorrelation K is found to strongly depend on the impact-receiver distance (Fig. 6). We therefore confirm the assumption issued by Lobkis and Weaver (2009) that the changes induced by the ball impact are located in the vicinity of the impact, and the seismic (shock) wave emitted by the impact has negligible effect on the material stiffness at large distances.

V. TENTATIVE APPLICATION TO ON-SITE DAMAGE ESTIMATION

Last, we address the issue of damage estimation through DAWS. Consider two blocks of concrete of similar constitution (see Table I) and of the same geometry (see sample 1); the first one is intact and the other one is damaged after undergoing a 30 MPa load. Both samples are tested using the same experimental protocol, and data are processed in the same time window and frequency range. Resulting decorrelations K_d are plotted in Fig. 7. Similar to Van Den Abeele *et al.* (2001), we observe that damage increases considerably the amplitude of change in the material, and thus, the absolute decorrelation A together with the speed of recovery m. Provided that the experimental protocol is rigorously similar from one site to another, this latter result suggests a possible route for on-site concrete damage assessment.

VI. CONCLUSION

In this article, we studied the slow dynamics behavior of concrete after a ball impact of moderate energy. We observed

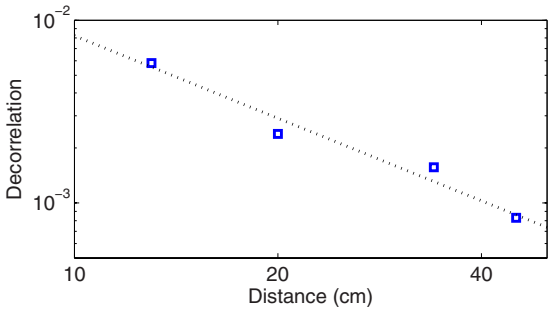

FIG. 6. (Color online) Decorrelation of ultrasonic waveforms obtained a few ms right after the impact in log-log scale, at different distances from the impact. Squares represent the experimental data, while dots represent a power law with the exponent −1.5.

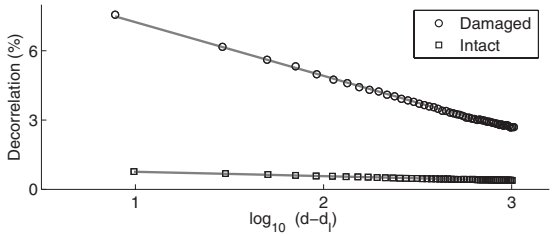

FIG. 7. Slow dynamics observed in undamaged and damaged concretes.

a drop of the acoustic velocity (probed by CWI, Poupinet *et al.*, 1984) and a decorrelation of the diffuse waveforms (probed by DAWS). Then the material recovers over characteristic times ranging from 100 to several 1000 s. In our experiments, the $\log(t)$ recovery was observed at all time in the coda, and at different frequencies; this does not allow to exhibit any characteristic length, time, or energy. This feature is in agreement with a fractal structure of concrete. Slow dynamics is thus interpreted as a series of jumps of energy barriers having a continuous distribution. In principle, slow dynamics could be either due to a homogeneous change in mechanical characteristics of all constituents, or to local rearrangements of inter-grain contacts. As we observe a noticeable decorrelation of the diffuse waveforms that cannot be solely ascribed to a homogeneous change in the material stiffness, we defend the second interpretation; slow dynamics is due to a collection of local changes in inter-grain contacts, which simultaneously result in changes in scattering properties and in a decrease in the effective wave velocity. The rearrangements of inter-grain contacts in our experiments are somehow analogous to those observed in solid friction (Lomnitz, 1962; Pandit and Savage, 1973; Karner and Marone, 1998). As concrete is an example of consolidated multicomposite granular material, we also believe that our laboratory experiment shares analogy with the time evolution of shallow sedimentary geomaterials after an earthquake (Sawazaki *et al.*, 2006; Brenguier *et al.*, 2008). In our experiments, slow dynamics parameters A and m where found to be very sensitive to experimental apparatus, particularly to the impact energy and position. While keeping these features perfectly constant and the experiment perfectly reproducible, we observed that the slow dynamics parameters were also found to strongly depend on damage, which suggest that they could characterize the aging of concrete structures. Since the experimental apparatus is light and easy to handle, it could have some practical interest in structural health monitoring, especially in civil engineering, or to perform down hole geomaterial characterization, provided that a reproducible and controlled impact could be delivered to the medium at depth.

Current efforts seek to monitor and investigate such naturally occurring events as volcanic eruptions, hurricanes, bolides entering the atmosphere, earthquakes, and tsunamis by the infrasound they generate. Often, detection of the infrasound signal is limited by the masking effect of wind noise. This paper describes the use of a distributed array to detect infrasound signals from four atmospheric detonations at White Sands Missile Range in New Mexico, USA in 2006. Three of the blasts occurred during times of low wind noise and were easily observed with array processing techniques. One blast was obscured by high wind conditions. The results of signal processing are presented that allowed localization of the blast-induced signals in the presence of wind noise in the array response. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3291683]

I. INTRODUCTION

Infrasound signals are classified as acoustic waves with frequencies below 20 Hz. These low frequency waves can propagate hundreds to thousands of kilometers depending on atmospheric conditions. This facet of long-range propagation makes infrasound useful in remotely detecting different levels of naturally occurring and man made events. A snapshot of some current infrasound research fields includes volcanic eruptions,[1–3] conventional and nuclear blast monitoring,[4,5] earthquake,[6,7] tsunamis[6,8] surf-shore interactions,[9–12] atmospheric phenomena,[13,14] and bolide/meteor entry into Earth's atmosphere.[15–17]

Applications for infrasound in each of these research fields suffer from a common problem; the background acoustic noise floor is a function of the wind velocity.[18,19] Winds of only a few m/s can raise the noise floor significantly, decreasing the signal-to-noise ratio, masking infrasound signals from events of interest. A technique commonly employed to separate infrasonic signals from wind noise involves spatially averaging the atmospheric pressure variations. While infrasonic signals are coherent over hundreds of meters,[20] pressure variations due to the wind are coherent over a few meters; thus, spatial averaging reduces the wind noise but not the coherent infrasound. The averaging is usually accomplished mechanically through the use of pipe or hose arrays.

Typical International Monitoring System (IMS) pipe arrays consist of multiple ports open to the atmosphere deployed in a rosette design with an array diameter usually between 30 and 70 m.[21] The pressure measured at a highly sensitive microbarometer has passed through a central manifold equidistant from all of the ports. Thus, the measured pressure is a spatial average of the pressure at the ports. Because the coherent length of wind is small with respect to the array aperture, local pressure variations due to wind advection are summed incoherently. Acoustic signals with wavelengths that are long relative to the array aperture constructively add at the summing manifold. Spatial averaging provides an amplitude signal-to-noise gain of the square root of the number of openings to the atmosphere. This type of array is currently deployed at Piñon Flat, CA.

Portable infrasound arrays and the IMS array employed at Manoa, HI are examples of the porous hose array. Here, multiple hoses are connected to a summing manifold which leads to a centrally located microbarometer. Spatial averaging with porous hose arrays is accomplished along the length of the porous hoses[22] instead of at the discreet ports of pipe arrays. It has been suggested that these arrays may provide better wind noise reduction than pipe arrays.[23] Mobile arrays of this type are deployed in the southeastern United States to investigate hurricanes in the Gulf of Mexico. Although porous hose arrays are easily deployed and mobile, their performance depends on their manufacture and can be compromised by degradation of the porous hose material by solar radiation.

An alternate method of spatial averaging is accomplished through the use of a distributed array.[20] Here, multiple microphone elements are deployed over an area. This type of array provides multiple pressure measurements over the array aperture compared to a single measurement from the pipe and hose arrays. The performance of this type of array is dependent on multiple factors: microphone sensitiv-

ity, number of sensors, sensor spacing, and array aperture. When the sensor spacing is such that the wind noise is incoherent between sensors, averaging the data from all the sensors at each recorded time step decreases the pressure amplitude of the wind noise by a factor of the square root of the number of sensors. As well as being mobile, an advantage of distributed arrays is that their data are amenable to various signal processing techniques.

II. DATA ANALYSIS: F-STATISTIC AND THE COEFFICIENT OF VARIATION

There is a need to scan large quantities of digitized data to identify events of interest. Therefore, an active area of interest is the development of detectors to locate events of interest. This enables the analyst to look at a small subset of the data when events of interest may have occurred. In the infrasound community the analysis of variance and Fisher's F-statistic are often used to indicate the presence of a coherent infrasound signal occurring on multiple sensors.[24] This test is a hypothesis test to determine if samples can be viewed as resulting from the same process. An event is deemed statistically important if the value of the F-statistic is larger than the associated critical value, calculated from the F cumulative distribution function.

Calculations of the F-statistic are found in the literature;[25–27] thus only a brief review will be provided here. Assume a data set from multiple sensors in tabular form. Further assume that each row represents the pressure recorded by all sensors at each time step so that the data from a singular sensor as a function of time are contained within a column. For T time steps and S sensors this data table would represent a $T \times S$ matrix. The value of the grand mean of all the samples is

$$\bar{X} = \frac{1}{TS} \sum_{j=1}^{T} \sum_{k=1}^{S} X_{jk}, \tag{1}$$

while the mean of each row would be

$$\bar{X}_j = \frac{1}{S} \sum_{k=1}^{S} X_{jk}. \tag{2}$$

This quantity is the mean pressure value over all sensors at the jth instant in time. The total variation is the sum of the squares of the deviations of each measurement from the grand mean,

$$V = \sum_{j=1}^{T} \sum_{k=1}^{S} (X_{jk} - \bar{X})^2. \tag{3}$$

After some algebraic manipulation, the total variation can be broken up into the sum of V_w and V_B, where

$$V_W = \sum_{j=1}^{T} \sum_{k=1}^{S} (X_{jk} - \bar{X}_j)^2 \tag{4}$$

and

$$V_B = S \sum_{j=1}^{T} (\bar{X}_j - \bar{X})^2. \tag{5}$$

The F-statistic, calculated from these quantities, is given by

$$F = \frac{V_B/(T-1)}{V_W/(T(S-1))}. \tag{6}$$

If the hypothesis that these data result from the same process is true, then the calculated F-value will be unity. This value will increase as the difference between the pressures at the sensors increases.

A second detector is based on the reciprocal of the coefficient of variation[28] (RCOV) ratio. Again assuming data from sensors in tabular form with the output from a single sensor being contained within a column, the mean value of the pressure over the array at the jth time instant is

$$\bar{X}_j = \frac{1}{S} \sum_{k=1}^{S} X_{jk}. \tag{7}$$

The standard deviation σ about the mean array pressure at each time step is

$$\sigma = \left[\frac{1}{S} \sum_{k=1}^{S} (X_{jk} - \bar{X}_j)^2 \right]^{1/2}. \tag{8}$$

The magnitude of the RCOV, calculated as the ratio of the mean to the standard deviation, is

$$\mathrm{RCOV} = \frac{|\bar{X}_j|}{\sigma}. \tag{9}$$

If the separation of the sensors in the array is larger than the coherent length of the wind, then spatially averaging the output from the elements reduces the wind noise amplitude by a factor of $\sqrt{S}$. It is thought that the RCOV will be most effective when the wavelength of the signal is much longer than the aperture of the array. For such acoustic signals, the associated pressure signal varies little over the distributed array elements. Thus, the standard deviation of the sensor signals is small and RCOV is large. For signals with wavelengths comparable to or shorter than the array aperture, the standard deviation resulting from the pressure signal would be large and the magnitude of the RCOV would be small. These two detectors were utilized in examining data from atmospheric explosions.

III. EXPERIMENTAL SETUP

A. Field setup and data collection

The data reported here were collected during two experiments conducted near the White Sands Missile Range (WSMR) in March (WSMR2) and July (WSMR3) of 2006.[29] For each experiment two rockets were launched, one occurring around 2 a.m. and the next around 6 a.m. Explosive charges for each launch were approximately 30 kg trinitrotoluene (TNT) equivalent. These charges were detonated near altitudes of 35 km (WSMR2) and 49 km (WSMR3).

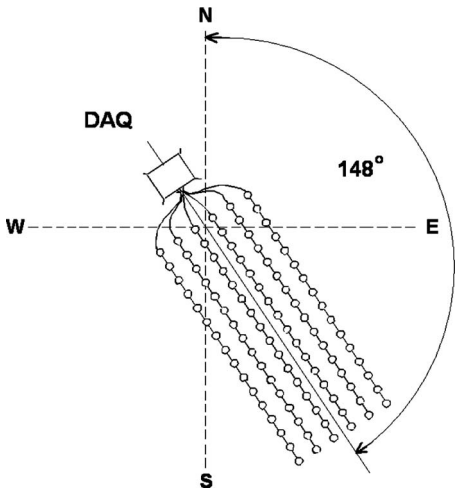

FIG. 1. Schematic of the distributed array layout and orientation for WSMR3.

The along the ground distance from the source to the distributed array was approximately 117 km (WSMR2) and 110 km (WSMR3).

Data for both experiments were collected at a site near Socorro, NM. For these tests a 93-sensor distributed array was deployed. Each array element was composed of piezounimorph elements housed in an engineered polyvinyl chloride (PVC) capsule.[20] These sensors exhibit a flat frequency response between 0.1 and 100 Hz relative to a 1/2 in. Brüel & Kjær 4193L-004 microphone. Signals output from each of the 93 sensors were digitized at 200 Hz by three National Instruments 6031E analog to digital converters. To reduce cross talk, a channel shorted to ground was read between each sensor signal reading.

The array setup for the two experiments was similar. For both tests the sensors were laid out in a rectangular aperture, as shown in Fig. 1. The array consisted of six rows with 16 sensors in each row. Spacing between rows was 2 m and sensors in each row were separated by 2 m, giving an array aperture of 30 m $\times$ 10 m. Shorted channels were substituted for sensors 1, 33, and 65. For the WSMR2 experiment, the rows were oriented along $144 \pm 1°$, relative to local magnetic North (0°). During the WSMR3 experiment the rows were oriented along $148 \pm 1°$, relative to magnetic local North. These orientations pointed the long arm of the array in the approximate direction of the explosion at detonation.

Wind speeds during the two WSMR2 tests were measured with a tri-axial Campbell Instrument Co. CSAT3 ultrasonic anemometer located near sensor 1. This anemometer, deployed 10 ft above the ground, provided simultaneous wind velocity data during the pressure measurements. Average wind speeds during the 2 a.m. and 6 a.m. detonations were 0.45 and 0.65 m/s, respectively. For the WSMR3 experiments, wind speeds were measured at 10 Hz by a tri-axial Vaisala ultrasonic anemometer located about 640 m away from the array. Figure 2 shows the measured wind speed for 15 min windows encompassing the 2 a.m. and 6 a.m. events. During the 2 a.m. event, the average wind speed was 5.0 m/s with gusts of almost 8.8 m/s while wind speeds for the 6 a.m. shot averaged 1.5 m/s with gusts of up to 2.7 m/s. Thus, the 2 a.m. wind speeds are three to four times greater than wind speeds from the 6 a.m. shot.

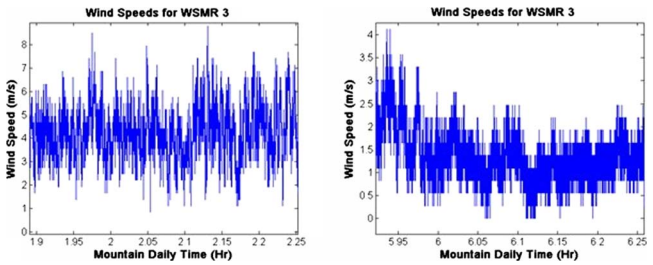

FIG. 2. (Color online) Measured wind speeds during the WSMR3 2 a.m. (left) and 6 a.m. (right) detonations.

B. Data processing

Data from each of the WSMR experiments were digitally filtered between 0.1 and 99 Hz with a fourth order Butterworth bandpass filter. The Butterworth filter was chosen as it has a maximally flat response and does not introduce ripple into the passband.[27] The mean pressure of the 93 sensors at each instant of recorded time was calculated. Data input to the RCOV and F-statistic calculations was further bandpass filtered between 1 and 10 Hz with the same fourth order digital Butterworth filter. The RCOV was calculated at each instant of recorded time over the entire file. A second program was employed to calculate the F-statistic value and associated critical value. This calculation was performed over 200 point bins, yielding a value of the F-statistic for each bin. The lag times between sensors, calculated via the cross correlation, were used to time shift the data before calculation of the F-statistic.

IV. EXPERIMENTAL DATA

A. WSMR2: Filtered and processed 2 a.m. shot

The digitally filtered (0.1–99 Hz) pressure data from sensor 39, located near the center of the array, are shown in the top graph of Fig. 3. For this shot the mean wind speed was 0.45 m/s. Several possible detonation arrivals are observed in the pressure versus time graph from the single sensor. A single infrasonic arrival is clearly indicated by the mean pressure from all 93 sensors at each recorded time (the bottom graph of Fig. 3). The insets in the top and bottom graphs of Fig. 3 show the pressure data for a 5 s window which included the blast arrival. Spatial averaging, without any time shifting to align the data from the sensors, reduced the wind noise pressure fluctuations observed with the single sensor response. This facilitated identification of the infrasonic arrival about 761 s into the WSMR2 2 a.m. data file. The mean peak-to-peak acoustic pressure over the array associated with the blast was about 0.6 Pa.

The raw pressure data from each sensor were then filtered between 1 and 10 Hz with a fourth order Butterworth filter. These filtered data served as input to programs that calculated the RCOV magnitude and the F-statistic value. In this analysis, the F-statistic value was computed over every 200 points (1 s). The pressure signal associated with the blast arrival is readily observed in both the RCOV magnitude (top

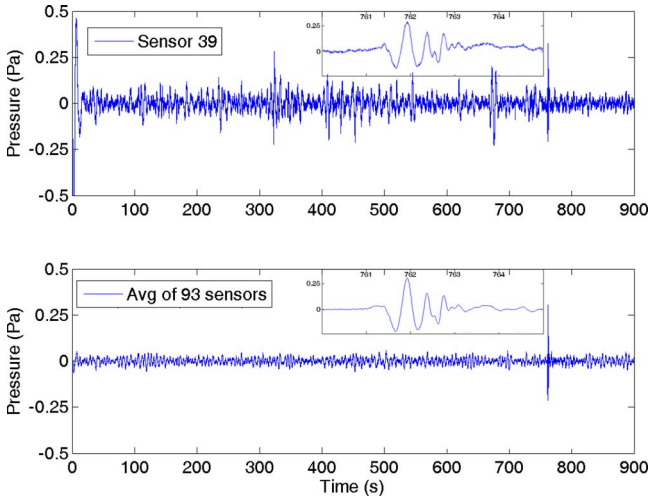

FIG. 3. (Color online) (Top) Pressure data from a single sensor near the middle of the array. (Bottom) The average pressure over the entire array during the 2 a.m. WSMR2 shot. The insets show the pressure data for the respective graphs over a 5 s window starting at 760 s.

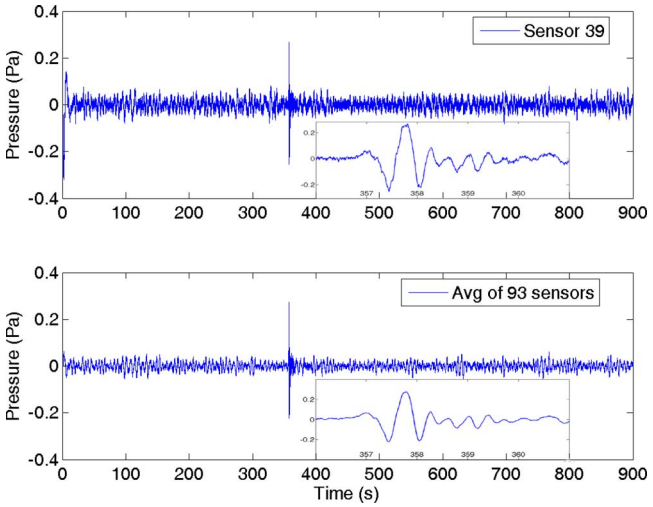

FIG. 5. (Color online) (Top) Pressure data from a single sensor near the middle of the array. (Bottom) The average pressure over the entire array during the 6 a.m. WSMR2 shot. The insets show the pressure data for the respective graphs over a 5 s window starting at 356 s.

graph Fig. 4) and F-statistic (bottom graph Fig. 4). The temporal location of the peak in both the RCOV and F-statistic graphs agrees with the arrival as observed in the average of the pressure data (bottom graph Fig. 3). Both the RCOV and F-statistic metrics indicate good agreement in localizing in time the blast event. The critical value for the 99.9% confidence level is 1.5201.

B. WSMR2: Filtered and processed 6 a.m. data

The 0.1–99 Hz digitally filtered WSMR2 6 a.m. pressure data are shown in Fig. 5 for both sensor 39 and the array mean. During this shot the mean wind speed was 0.65 m/s. In this figure the wind noise at sensor 39 does not mask the pressure associated with the blast arrival in the pressure versus time curve. The insets in the top and bottom graphs of Fig. 5 show the pressure data for a 5 s window which included the blast arrival. Calculation of the spatial average of the pressure further decreases the incoherent wind noise and indicates the arrival of the blast signal. For both the 2 a.m. and 6 a.m. WSMR2 measurements, the mean acoustic pressure over the array was about 0.6 Pa peak to peak.

After filtering the raw pressure data from each sensor between 1 and 10 Hz, the RCOV and F-statistic from these data were calculated. These results are observed in Fig. 6. The pressure data and temporal location of the peak in the RCOV and F-statistic graphs both indicate the blast arrival at 358 s in the recorded data. These both agree with the mean array response shown in the pressure curves of Fig. 5. Here also, the RCOV and F-statistic results indicate good agreement for detecting the blast event in low wind conditions.

C. WSMR3: Filtered and processed 6 a.m. shot

Pressure data collected from sensor 39, located near array center, and the mean of all 93 sensors for the 6 a.m. launch are shown in the top and bottom graphs of Fig. 7. These data have been bandpass filtered between 0.1 and 99 Hz. As seen from the top graph, the data from sensor 39 show instances of relatively low and high pressures. Some of these pressure events are comparable to the expected 0.6 Pa peak-to-peak amplitudes observed in both the WMSR2 tests. Comparison of the pressure data from sensor 39 to the wind

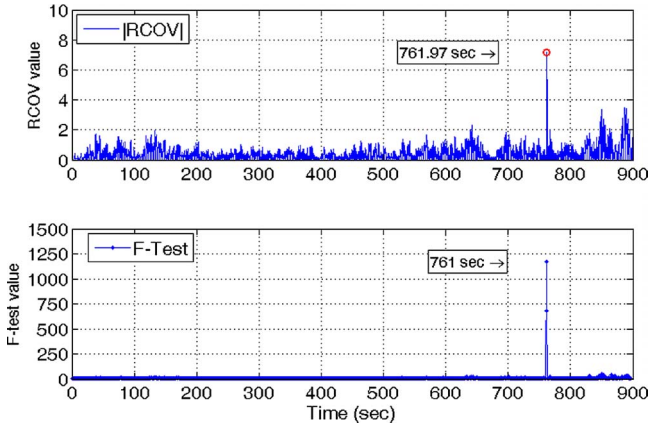

FIG. 4. (Color online) Results of the RCOV (top) and F-test (bottom) analyses on the 2 a.m. WSMR2 data.

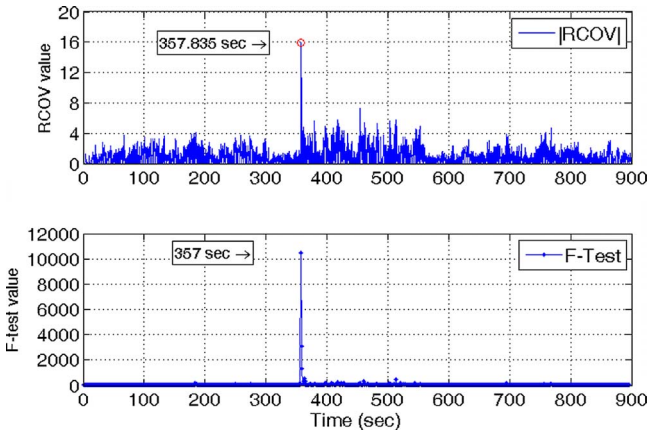

FIG. 6. (Color online) Results of the RCOV (top) and F-test (bottom) analyses on the 6 a.m. WSMR2 data.

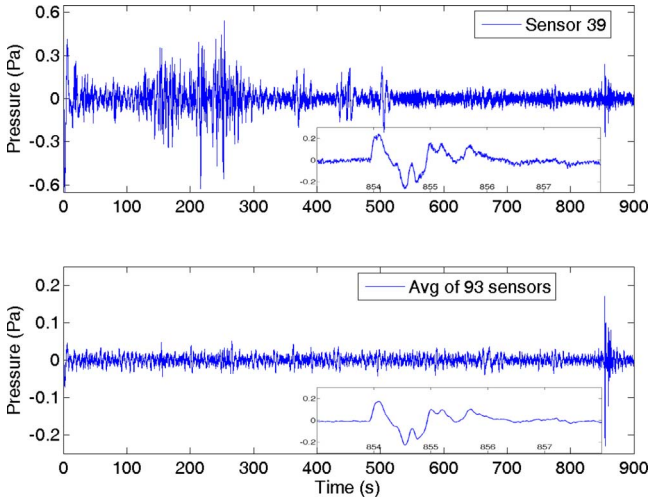

FIG. 7. (Color online) (Top) Pressure data from a single sensor near the middle of the array. (Bottom) The average pressure over the entire array during the 6 a.m. WSMR3 shot. The insets show the pressure data for the respective graphs over a 5 s window starting at 853 s.

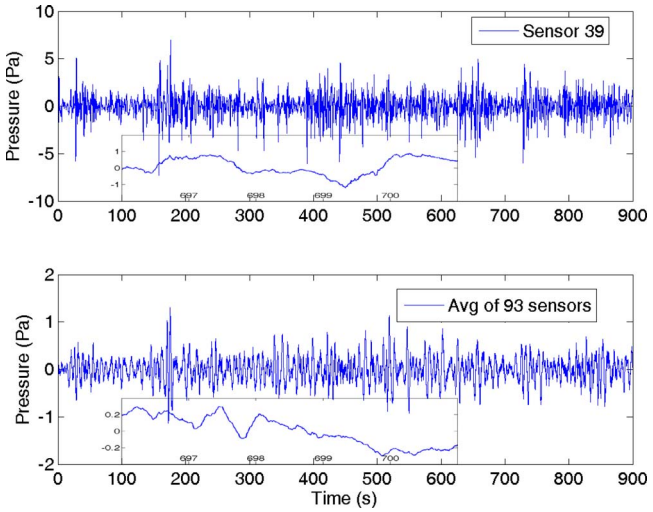

FIG. 9. (Color online) (Top) Pressure data from a single sensor near the middle of the array. (Bottom) The average pressure over the entire array during the 2 a.m. WSMR3 shot. The insets show the pressure data for the respective graphs over a 5 s window starting at 696 s.

speed data for this test (right graph, Fig. 2) indicates that larger pressure fluctuations result from higher wind speeds. The bottom graph shows the pressure calculated from averaging the data from all 93 sensors at each recorded time step. In this bottom graph, the incoherent wind noise reduced by the averaging process reveals the arrival of the infrasound signal around 855 s into the file. Although this arrival is also observed in the data from the single sensor, identifying this event in the pressure signal is problematic since the pressure amplitude resulting from the wind noise is comparable to the infrasound signal. The pressure associated with the blast is about a 0.5 Pa peak-to-peak signal in these pressure curves. This agrees with the data from the two WSMR2 tests. The insets in the top and bottom graphs of Fig. 7 show a close-up view of the pressure data for a 5 s window inclusive of the blast arrival.

The raw pressure data from each sensor were further digitally filtered between 1 and 10 Hz. Calculations of the RCOV magnitude and F-statistic values, shown in Fig. 8, provide confirmation that the signal observed around 855 s is indeed the blast-induced infrasonic signal of interest. Comparison between the data from the single sensor (top graph of Fig. 7) and the RCOV magnitude (top graph of Fig. 8) indicates that this measure shows low values during high wind conditions (right graph of Fig. 2) and higher values during low wind noise/coherent signal events.

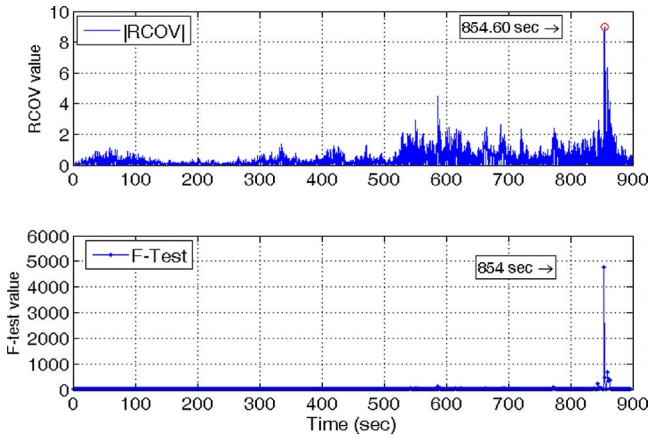

FIG. 8. (Color online) Results of the RCOV (top) and F-test (bottom) analyses on the 6 a.m. WSMR3 data.

D. WSMR3: Filtered and processed 2 a.m. data

The filtered data from sensor 39 and the average of all 93 sensors for the 2 a.m. shot are shown in Fig. 9. Pressure data from sensor 39 are nearly an order of magnitude larger than the data from the same sensor taken 4 h later. This is a result of the higher wind velocities during this test compared to any of the previous tests. In the pressure response from sensor 39, an infrasound signal of about 0.5 Pa, similar to that observed in the 6 a.m. data, would be masked by the wind noise. Computing the spatial average of the data from all 93 sensors (bottom graph of Fig. 9) does not identify the blast signal. Although the averaging reduced the incoherent wind noise, the pressure fluctuations in the spatial average are comparable or larger than the expected 0.5 Pa peak-to-peak signal. The blast arrival is also not readily observed in the expanded pressure inset plots in the top and bottom graphs of Fig. 9. Multiple bandpass filter values were employed to determine if better delineation of the signal arrival in the time-pressure plots could be achieved. None of these investigations proved fruitful in localizing the signal arrival in time.

For these high wind noise data, calculating the RCOV magnitude proved especially beneficial. After filtering the data between 1 and 10 Hz, the RCOV magnitude and F-statistic values were calculated. Results of this analysis are shown in Fig. 10. An event at about 698 s into the RCOV calculation stands out. Further investigation of this event shows it to be consistent with the arrival of the blast infrasound. Calculation of the F-statistic with a 200 point (1 s) window did not provide identification of the infrasonic blast event.

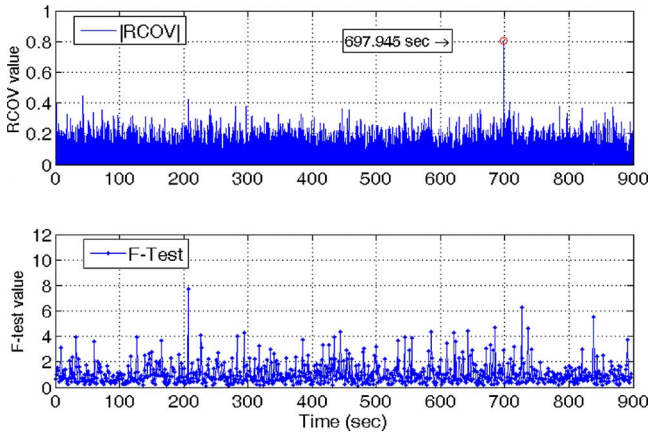

FIG. 10. (Color online) Results of the RCOV (top) and F-test (bottom) analyses on the 2 a.m. WSMR3 data.

V. DISCUSSION AND CONCLUSION

Both the F-statistic and magnitude of the RCOV provided clear indication of coherent sound propagation across the array in low wind conditions. Analysis of data taken when the mean wind speed about 5 m/s indicates that the RCOV technique presented above permits better temporal localization of the infrasound event. This agrees with the comment[24] that the F-statistic does not perform well for low signal-to-noise ratio events or when multiple signals are present in the data.

Smaller bin sizes were investigated to ascertain if newly calculated F-statistic values for the WSMR3 2 a.m. data would indicate the infrasonic arrival. Altering the F-statistic algorithm to calculate the F-value over a 20 point (0.1 s) window did provide indication of the blast event. This result is shown in Fig. 11. The value of the F-statistic corresponding to the infrasound arrival is greater than the 99.9% critical value obtained from Fisher's F probability function.

A significant percentage of the calculated F-statistic values is larger than the associated 99.9% F-critical values. Decreasing the size of the bins for analysis of the F-statistic did not show any appreciable difference in the percentage of calculations above the F-critical value threshold, except for the WSMR3 2 a.m. data. As an example, the F-statistic values for the WSMR2 2 a.m. data were greater than the critical value in 99%, 93%, and 62% of the bins when the bin sizes were 1000, 200, and 20 points, respectively.

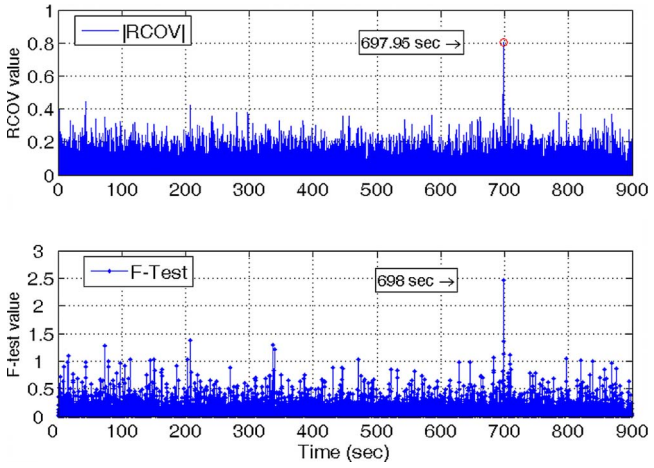

FIG. 11. (Color online) Results of the RCOV (top) and F-test (bottom) analyses on the 6 a.m. WSMR3 data with a 0.1 s (20 point) data window.

Pressure fluctuations due to wind noise present problems in the collection and interpretation of infrasound signals. A distributed array has been used to mitigate the influence of wind noise on infrasound signals of interest. Signals from four high altitude explosions in markedly different wind conditions have been collected. In each case the peak-to-peak pressure amplitude of the signals was between 0.5 and 0.6 Pa. In the cases of low wind velocity it was not always possible to clearly identify the arrival time of the blast-induced infrasound signal from pressure data from a single sensor. The spatial average of the pressure field from the multiple array elements reduced the wind noise and revealed the infrasound signal for winds below about 2 m/s. During the test in high wind conditions, the resultant wind noise at the sensors masked the arrival of the blast-induced infrasonic signal on both the single sensor and spatial average of the array. For all four tests, calculating the magnitude of the signal-to-noise ratio for each time step identified the arrival of the infrasonic signal during both low and high noise conditions. These results compared favorably to F-statistic calculations for successfully identifying the blast-induced infrasound events from all four tests.

A multi-mode screech frequency prediction formula for circular supersonic jets

J. H. Gao and X. D. Li[a)]
School of Jet Propulsion, Beihang University, Beijing 100191, People's Republic of China

(Received 13 July 2009; revised 16 December 2009; accepted 17 December 2009)

A time evolution analysis is presented for the interaction between the instability waves, shock cells, and screech tones based on the authors' previous numerical simulation database. An attachment and reinforcement process of the upstream propagating screech waves with the downstream hydrodynamic waves is identified and recognized as part of the screech loop. The first five shock cells are recognized as the effective sound source region. Through an analysis of the phase variation in the dominant pressure fluctuations for several typical Mach number screeching jets, it is found that the total number of the instability waves and the upstream feedback sound waves in the effective source region can be identified as 5 for the A1, B, and D modes and 6 for A2 and C modes, respectively. A screech tone frequency prediction formula is thus proposed based on this relation. The predicted screech wavelengths or Strouhal numbers of cold and hot jets all agree well with the experimental data by other researchers, except for a small discrepancy for the B mode. It is also noticed that the measured two A0 modes by Ponton *et al.* [NASA Technical Memorandum No. 113137, Langley Research Center (1997)] can be classified to A1 and A2 modes, respectively, according to the proposed formula.

I. INTRODUCTION

Jet screech has long been a fascinating subject of aeroacoustic research since Powell's[1] first observation in 1951. A large number of investigations on jet screech have been conducted from various aspects, and great advances have been achieved for the understanding of the sound generation mechanism which can be found in the reviews by Raman.[2,3] Among various investigations, the accurate prediction of the frequency and amplitude of jet screech tones has been one of the most important topics. The pioneering experimental observation of Powell elucidated jet screech as a nonlinear feedback mechanism. This provided a basis for his phased monopole model,[1] which explained the highly directional nature of screech. Tam *et al.*[4] also proposed a formula for screech frequency prediction. This formula can predict the screech frequencies of circular jet well at high Mach numbers, but there is a deviation for those modes at low supersonic Mach number. Panda[5] investigated the screech generation processes and provided detailed information on the time evolution of near-field pressure fluctuations. Based on the observation of a standing wave pattern in his experiment, Panda[5] established the relationship between the standing wave, the hydrodynamic wave, and the screech tone with the assumption of free acoustic reflections and proposed a screech tone frequency prediction formula. The standing wave pattern is a resultant of the upstream propagating screech waves with the downstream propagating hydrodynamic waves, and there is no explicit way to calculate the wavelength of standing wave by any theoretical method unless the screech sound wavelength is known. Thus it is not straightforward to apply Panda's formula for screech frequency prediction.

With the rapid development of the computational aeroacoustics (CAA), many researchers used CAA method to study the screech tones.[6–11] Remarkable progress has been made by these researchers in prediction and understanding the screech tones. Recently, Li and Gao[9,10] simulated the axisymmetric and three dimensional (3D) round supersonic jet screech tones by a CAA method. Their calculated screech tone wavelengths and amplitudes over a wide range of Mach numbers agree well with the experimental data of Ponton *et al.*[12] The advantage of numerical simulation over experiment is that it can provide very detailed flow and acoustic field. As such, it is possible to provide very insightful information on screech generation mechanism.

The objective of this paper is to propose a more accurate frequency prediction method based on a detailed analysis of the large database provided in our previous numerical simulations.[9,10]

In Sec. II, detailed analysis of the screech generation and propagation process are presented and the generation mechanism is discussed. In Sec. III, a frequency prediction method based on the screech generation mechanism analysis is proposed and the predicted results are compared with the experimental data by other researchers. Section IV gives the conclusions of this work.

II. FLOW AND SOUND NEAR FIELD ANALYSIS

A. Time evolution of the screech generation

The axisymmetric and full 3D supersonic round jet screech tones were simulated by the present authors in their

a)Author to whom correspondence should be addressed. Electronic mail: lixd@buaa.edu.cn

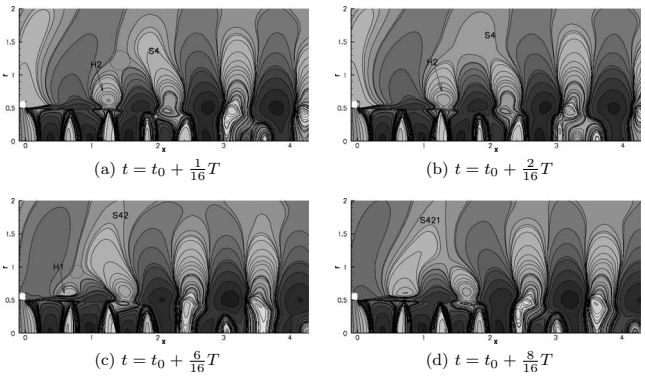

FIG. 1. Instantaneous pressure field of M_j=1.10 screeching jet at different times showing the interaction of screech with hydrodynamics waves.

previous work[9,10] by a CAA method. In those simulations, a fourth order dispersion-relation-preserving (DRP) scheme[13] was used for space discretization. A 5/6-stage low-dissipation and low-dispersion Runge–Kutta scheme[14] in the 2*N* storage form was employed for time integration. The detailed flow and near sound field of jets in a large Mach number range was obtained. Based on the database an analysis of the screech generation process is presented below.

A time evolution of the screech generation, propagation, and interaction with the hydrodynamic waves in the near sound field for the M_j=1.10 screeching jet is shown in Fig. 1. As shown in Fig. 1(a), the crest of a screech wave, labeled as S4, generated between the third and fourth shock cells, begins to attach to the crest of the downstream convecting hydrodynamic wave (labeled as H2) near the second shock cell. The S4 wave is then successively reinforced by H2 until it is detached from H2, as shown in Fig. 1(b). The reinforced screech wave, labeled as S42, and the hydrodynamic waves H2 continue to move upstream and downstream, respectively. The wave S42 propagating upstream begins to attach to and be reinforced by the hydrodynamic wave H1, which can be observed clearly in Fig. 1(c). In Fig. 1(d), when S42 attached completely to H1, the crest of the reinforced screech wave, labeled as S421, propagates upstream, reaches the nozzle exit, and excites a new instability wave in the near nozzle region due to receptivity.

A similar process can be found for the troughs of the screech waves and the troughs of the hydrodynamic waves, which are not presented here. It can also be observed in these figures that the strongest screech sound waves are generated between the second and fourth shock cells. Only weak sound waves are emitted in the regions in front of the first shock and beyond the fourth shock. The above analysis shows that the first five shock-cell spacing can be recognized as the effective source region. Similar but more complicated process can also be observed for the flapping and helical screeching jets, which cannot be presented here for brevity. The phenomenon described above is very similar to that observed in a lot of experiments by Davies and Oldfield,[15] Westley and Woolley,[16] Chan,[17] Panda,[5] and so on.

B. Phase variation

Panda[5] and Umeda and Ishii[18] studied the phase variation of the screech sound waves in their experiments, but

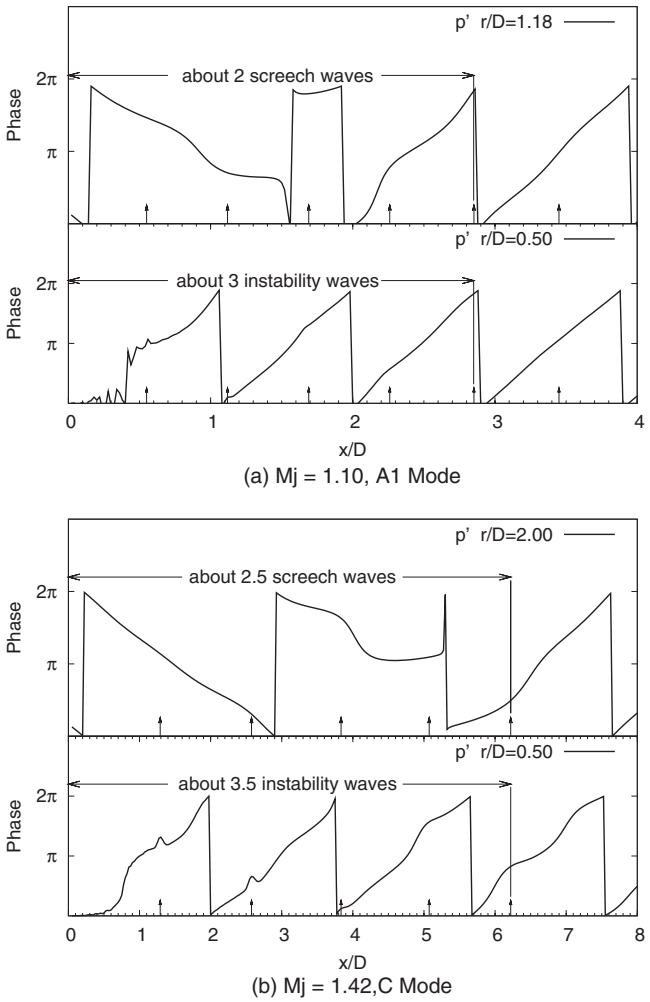

FIG. 2. Phase variation of the dominant mode pressure fluctuations in the shear layer for the M_j=1.10 and 1.42 screeching jets. The vertical arrows at the bottom of the figures represent shock locations.

they did not associate it with the screech frequency prediction. In this paper, a phase variation analysis similar to Panda[5] is applied to our numerical database. To obtain the phase of the pressure fluctuations in the shear layer and the near field outside the jet, cross-correlation functions between the signal at point near the nozzle lip (reference point) and the signals at other points are first calculated. Through a Fourier transformation of the cross-correlation functions, the relative phase (ϕ) of the dominant mode ($f=f_s$) in the shear layer and outside the jet is determined. The phase variations of pressure fluctuations in dominant mode along the x direction at fixed radial positions for several typical screeching jets are analyzed. Only the results of jets with Mach numbers 1.10 and 1.42 are plotted in Figs. 2(a) and 2(c), respectively, for limited space. In each figure the black vertical arrows at the bottom represent the shock locations. For the axisymmetric M_j=1.10 screeching jet, the number of waves along r/D=0.5 line in the first five shock-cell spacing is roughly 3, as shown in Fig. 2(a). Since the relative phase along r/D =0.5 increases with the axial positions, and the hydrodynamic waves dominate others along r/D=0.5, it can be considered that the phase along r/D=0.5 represents the phase of the hydrodynamic waves. In the upper part of Fig. 2(a), the

relative phase along $r/D=1.18$ decreases first and then increases. The decreasing part represents the phase of the upstream propagating sound waves, and the increasing part represents the phase of the hydrodynamic waves. With the help of the numerical predicted screech wavelength by CAA, the number of sound waves in the first five shock-cell spacing can be calculated and it is roughly 2. The total number of the instability waves and screech sound waves in the effective source region for the axisymmetric $M_j=1.10$ jet is 5. In this way, the total number of waves can be determined as 5 for the jets in flapping mode and 6 for jets in helical mode, which is shown in Fig. 2(c) for the $M_j=1.42$ jet.

It is known that the travel time associated with the convection of the downstream traveling hydrodynamic disturbances plus the time taken by the upstream traveling acoustic disturbance sum up to an integral number of periods of the screech cycle.[19] If the time delay in the receptivity and sound generation is not accounted for, the following equation can be established:

$$\frac{nL}{u_c}+\frac{nL}{c}=mT, \tag{1}$$

where T is the period of the screech cycle, m is an integral number and represents the number of screech cycles, u_c is the instability convective velocity, c is the ambient sound speed, L is the averaged shock-cell spacing, nL is the length of the effective source region, and $n=5$ according to observation.

Equation (1) can be rewritten as

$$\frac{nL}{u_cT}+\frac{nL}{cT}=m,$$

$$\frac{nL}{\lambda_h}+\frac{nL}{\lambda_s}=m, \tag{2}$$

where λ_h is the instability wavelength and λ_s is the screech sound wavelength. This equation means that the total number of the instability wave and the screech sound wave in the effective source region is equal to an integer. From the above wave number analysis it is known that for the axisymmetric $M_j=1.10$ screeching jet, $m=5$, for the $M_j=1.30$ flapping screeching jet, $m=5$, but for the $M_j=1.42$ helical screeching jet, $m=6$. Associated the value variation of m with the mode staggering from A1 to D mode, it is straightforward to assume that for the A1, B, and D modes, the value of m is 5 and for the A0, A2, and C modes, it is 6. This can be summarized as

$$\begin{cases} m=5 & \text{for A1, B, D mode} \\ m=6 & \text{for A0, A2, C mode.} \end{cases} \tag{3}$$

This assumption will be verified by the prediction results in the latter part of this paper. This equation relates the screech mode to the total number of instability waves and the screech feedback waves in a screech cycle. If the total number of waves in a whole cycle changes, the screech mode would change. This may be the reason of the mode switching for the round supersonic jet screech tones.

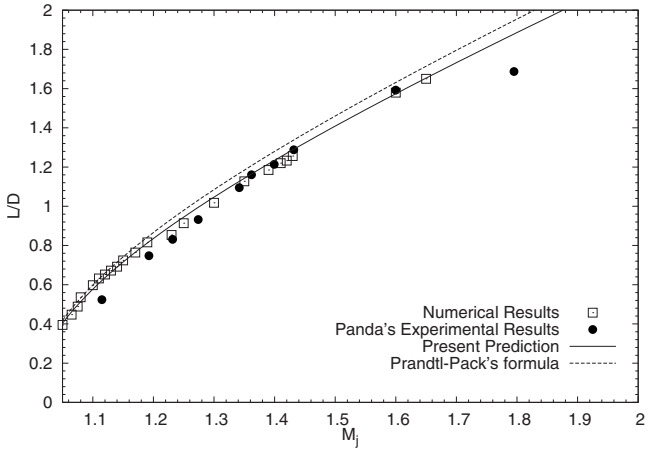

FIG. 3. Predicted shock-cell spacing with Prandtl–Pack formula compared with the experimental data of Panda *et al.* (Ref. 24) and the CAA results (Refs. 9 and 10).

III. FREQUENCY PREDICTION

Based on Eq. (2) and the relationship of $\lambda_h=\lambda_s M_c$, a formula for screech tone wavelength prediction can be obtained as

$$\lambda_s=\frac{nL}{m}\frac{1+M_c}{M_c}, \tag{4}$$

where M_c is the convective Mach number of the instability waves. Coupled with the assumption [Eq. (3)] of the total wave number in the effective source region for each mode, this new formula can be used to predict the screech wavelength if the averaged shock-cell spacing and the convective Mach number are known.

A. Shock spacing

Shock spacing is important in predicting jet screech tones. Several researchers studied the shock-cell spacing.[20–23] The Prandtl–Pack[20] formula provides a simple relationship between the shock spacing and the jet Mach number M_j based on a non-dissipative analysis:

$$L/D=1.306\sqrt{M_j^2-1}, \tag{5}$$

where D is the jet diameter. According to the study of Harper-Bourne and Fisher,[23] the Prandtl–Pack formula can predict well the first shock-cell length from the nozzle. But it cannot account for the shock-cell length reduction along the jet due to viscous dissipation. Therefore, the average shock spacing predicted by Prandtl–Pack formula would be greater than the experimental data[24] and the CAA results.[9,10] This is shown clearly in Fig. 3. Based on our previous numerical simulation results[9,10] and the experimental data of Panda *et al.*,[24] the coefficient in Prandtl–Pack formula is modified and calibrated. The formula with the modified coefficient is

$$L/D=1.26\sqrt{M_j^2-1}. \tag{6}$$

As shown in Fig. 3, the predicted shock spacing using the formula with modified coefficient agrees much better with the experimental data of Panda *et al.*[24] than that with the original coefficient.

TABLE I. Convective Mach number (or velocity) coefficient provided by other researchers [where data are u_c/u_j value].

	A mode	B mode	C mode	D mode
Powell *et al.*[a]	0.64	0.68	0.8	0.75
Panda *et al.*[b]	0.67	0.58	0.66	0.69
Tam *et al.*[c]			All 0.7	

[a]Reference 26.
[b]Reference 24.
[c]Reference 4.

B. Convective Mach number

Based on the assumption that the ratio of the convective velocity to the axial velocity is a fixed value, Tam *et al.*[4] proposed a formula to calculate the convective Mach number:

$$M_c = u_c/c = Cu_j/c = CM_j\left(1+\frac{\gamma-1}{2}M_j^2\right)^{-1/2}\sqrt{\frac{T_r}{T_a}}, \quad (7)$$

where C is a constant coefficient, M_j is the jet fully expanded Mach number, T_r/T_a is the ratio of the jet reservoir temperature T_r to the ambient air temperature T_a, and γ is the specific heat ratio. Several researchers have provided the convective Mach number (or velocity) data, as shown in Table I. In this table, the convective Mach number coefficient (C) data by different researchers are not consistent. This indicates that it is difficult to predict the convective Mach number accurately, especially when it varies with the screech modes. Panda[5] suggested a formula to calculate the convective Mach number with the phase derivative of instability waves along the shear layer:

$$M_c = \frac{u_c}{c} = \frac{2\pi f_s}{cd\phi/dx}. \quad (8)$$

Because the phase derivative in the axial direction is very large at some points (e.g., near the shocks), the calculated convective Mach number varies wildly. It is hard to calculate an averaged convective Mach number accurately by this method. Since an averaged convective Mach number in the effective source region is adequate for the screech wavelength prediction, the averaged form of Panda's method is applied here:

$$\bar{M}_c = \frac{\Delta x}{c\Delta t} = \frac{\Delta x}{c\Delta\phi/(2\pi f_s)} = 2\pi\frac{\Delta x}{\lambda_s\Delta\phi}, \quad (9)$$

where f_s is the screech tone frequency and $\Delta\phi$ is the phase variation in the distance of Δx. The relative phase variations of the dominated pressure fluctuations in the shear layer are calculated for M_j=1.10, 1.30, and 1.42 screeching jets, and only the results of M_j=1.30 screeching jet are plotted in Fig. 4. In this figure, a distance of two hydrodynamic wavelengths for Δx is used for the convenience of measuring the corresponding phase variation. Only the latter part of the phase variations in the effective source region is considered when calculating the averaged convective Mach number. In the region near the nozzle lip wall, the acoustic waves are dominant and a standing wave is formed by the upstream propagating sound wave and the reflected sound wave on the wall; thus it is difficult to determine the phase variation of the instability waves accurately. According to the measured distances and the corresponding relative phase variations, the calculated averaged convective Mach numbers are 0.572, 0.69, and 0.737 for Mach numbers 1.10, 1.30, and 1.42 screeching jets, respectively. According to Eq. (7), the coefficient C in the convective Mach number prediction formula can be determined as 0.58, 0.614, and 0.615 for the three cases, respectively. Therefore, the following coefficients will be used for the following screech prediction:

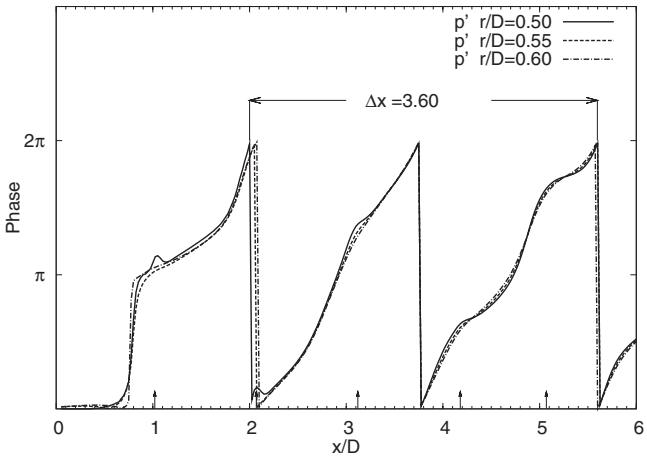

FIG. 4. Phase variation of the dominant mode pressure fluctuations in the shear layer for the M_j=1.30 screeching jet. The vertical arrows at the bottom of the figures represent shock locations.

$$C = \begin{cases} 0.580 & \text{for axisymmetric mode} \\ 0.615 & \text{for flapping and helical mode.} \end{cases} \quad (10)$$

It should be noted that a value of 0.615 is also used for jets with Mach number greater than 1.2 by Massey[25] to predict the screech frequency using Tam *et al.*'s formula.

C. Screech wavelength prediction

Based on Eqs. (4), (6), and (7) and the coefficients (3) and (10), the supersonic circular jet screech tone wavelength can be predicted.

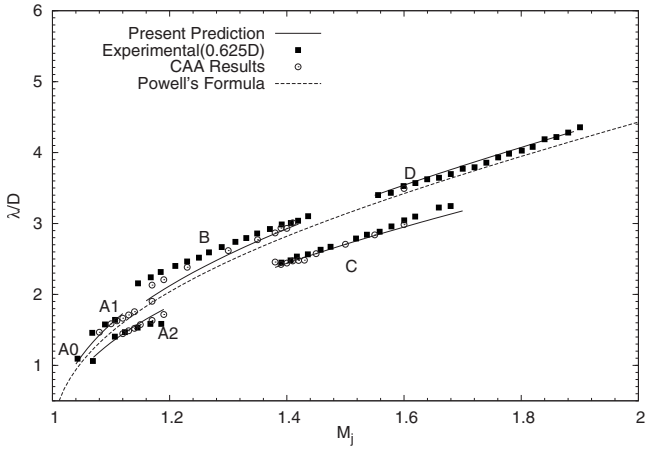

FIG. 5. Predicted screech tone wavelength with the present formula compared with the experimental data of Ponton *et al.* (Ref. 12) and that with Powell's formula.

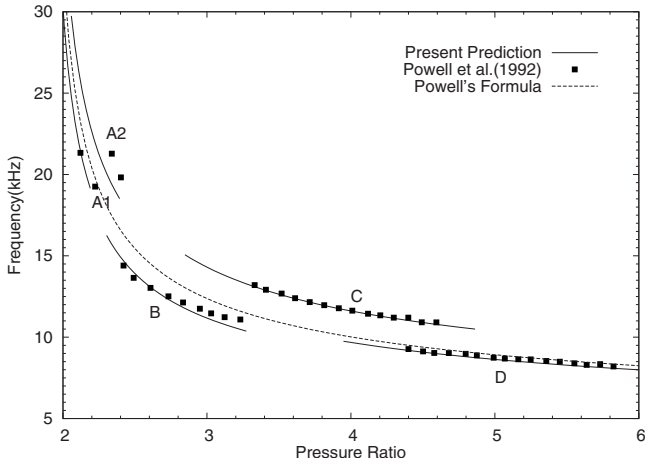

FIG. 6. Predicted screech frequencies versus measurements of Powell *et al.* (Refs. 18 and 26).

The predicted wavelengths for the supersonic cold jets in a large Mach number range are shown in Fig. 5. The predicted results are compared with the experimental data of Ponton *et al.*[12] and that with Powell's[19] formula. It is shown that the present predicted results agree well with the experimental data for A1, A2, C, and D modes, except for a small deviation for B mode. However, the predicted results with Powell's[19] formula only agree well with the experimental data for the A1 and D modes. It is interesting to find that the measured two A0 modes in the experiment of Ponton *et al.*[12] can be classified into A1 and A2 modes, respectively, according to the predicted results. In Fig. 6, the predicted dominant screech frequencies are presented and compared with the experimental data of Powell *et al.*[18,26] and that with Powell's[19] formula. It is shown that the predicted frequencies with the present formula agree well with the experimental data except for a small discrepancy for the A2 mode. However, the predicted results with Powell's formula only agree well with the experimental data for the A1 and D modes. In Fig. 7, the present predicted results are also compared with the experimental data of Chen *et al.*[27] and Yu[28] (quoted in the paper of Chen *et al.*[27]) and that with Tam *et al.*'s formula. The results with the present formula agree well with the experimental

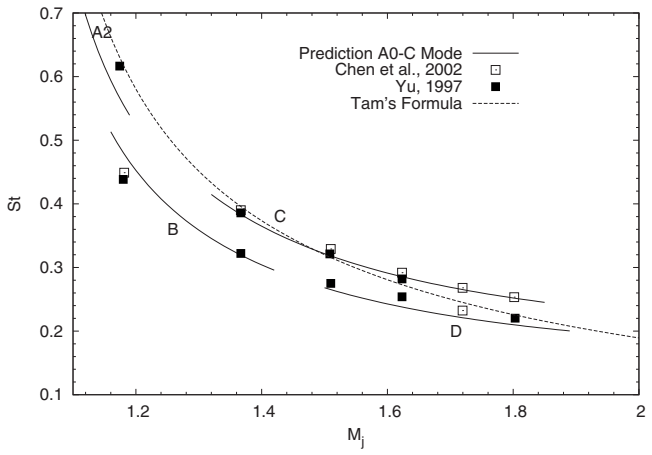

FIG. 7. Predicted screech Strouhal numbers versus measurements of Chen *et al.* (Ref. 27) and Yu (Ref. 28).

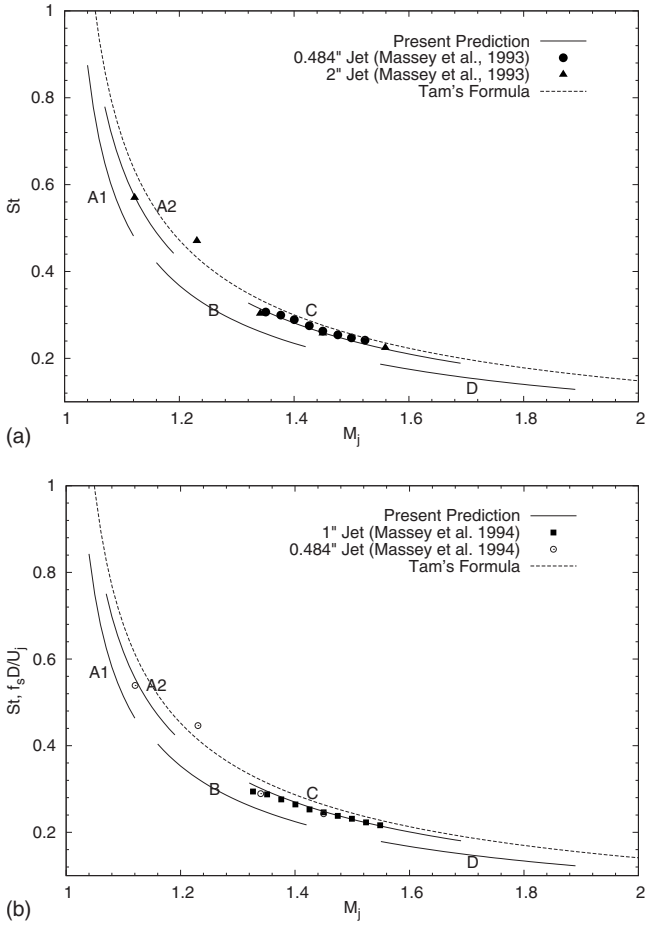

FIG. 8. Predicted screech Strouhal number versus measurements (Ref. 29) for jet with temperature ratios 2.37 and 2.78.

data except for a deviation for the point in A2 mode. Also, Tam *et al.*'s formula can only predict well for a limited Mach number range. In Fig. 8 the predicted Strouhal numbers for the hot jets are compared with the experimental data of Massey *et al.*[29] and that with Tam *et al.*'s[4] formula. The Strouhal number is calculated by the following equation:

$$\mathrm{St} = \frac{f_s D}{u_j} = \frac{m}{nL}\frac{CD}{1+M_c}. \tag{11}$$

It is shown that for the jets with temperature ratios of 2.37 and 2.78, the predicted Strouhal numbers agree better with the experimental data than the prediction results with Tam *et al.*'s formula. In Fig. 9, the predicted Strouhal numbers for the jet with different temperature ratios and Mach numbers are compared with the experimental data by Krothapalli *et al.*[30] and the predicted results with Tam *et al.*'s[4] formula. Here the Strouhal number is defined with the fully expanded jet diameter D_j instead of the jet diameter D.

$$\frac{D_j}{D} = \left\{\frac{1+[(\gamma-1)/2]M_j^2}{1+[(\gamma-1)/2]M_d^2}\right\}^{(\gamma+1)/4(\gamma-1)}\left(\frac{M_d}{M_j}\right)^{1/2}, \tag{12}$$

where M_d is the nozzle design Mach number. For the convergent circular nozzle, M_d=1. It should also be noted that for the results predicted with Tam *et al.*'s formula, the value of 0.615 for the coefficient C is used in calculation of the convective Mach number M_c. Since Tam *et al.*'s[4] formula

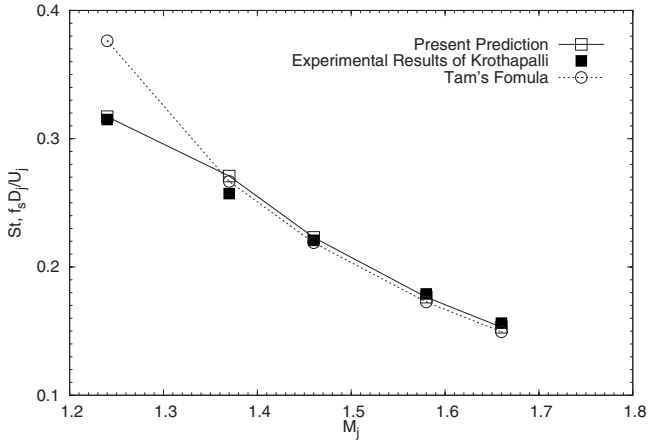

FIG. 9. Predicted screech Strouhal number compared with measurements (Ref. 30) and Tam *et al.*'s (Ref. 4) formula for jets with temperature ratios 2.5–3.5 and Mach numbers 1.24–1.66

considers all screech tones as a single mode, there is a large deviation for the first point. Actually, the mode of the first point should be B and the others should be C mode. The good agreement between the predicted results and the experimental data demonstrates that the assumption [Eq. (3)] of the total wave number in the effective source region for each mode is viable.

IV. CONCLUSIONS

Based on our previous numerical simulation database, the time evolution of the interaction between the instability waves, shock cells, and screech tones is analyzed and presented. The attachment and reinforcement process of the upstream propagating screech waves with the hydrodynamic waves is identified and recognized as part of the screech cycle. The first five shock cells are recognized as the effective source region, and the strongest screech waves are generated between the second and fourth shock cells. Through an analysis of the phase variation of the dominant pressure fluctuations for several typical Mach number screeching jets, it is found that the total number of instability waves and the feedback screech sound waves in the effective source region can be identified as 5 for the A1, B, and D modes and 6 for A2 and C modes, respectively. A new screech tone wavelength prediction formula is proposed based on this relation. A thorough comparison is done for the prediction results by this formula with the experimental data by Ponton *et al.*,[12] Powell *et al.*,[18,26] Chen *et al.*,[27] Yu,[28] Massey *et al.*,[29] and Krothapalli *et al.*,[30] respectively. The predicted results agree well with all the presented experimental data except for a small discrepancy for minority points. It is also found that the measured two A0 modes in the experiment by Ponton *et al.*[12] can be classified to A1 and A2 modes, respectively, according to the proposed prediction formula. This implies that there is no A0 mode for the round supersonic jet screech tones in reality.

For acoustic propagation through a shallow ocean channel or waveguide, the coherence between different transmissions is controlled primarily by the roughness of the ocean surface and to a lesser degree by fluctuations in the volume. In this study, the coherent-to-incoherent intensity ratio (CTIR) is defined as a way to quantify the coherence between multipath transmissions and ocean surface rms wave height and wind speed. A theory that connects the CTIR and the coherent surface reflection coefficient is developed using both Kirchhoff and small-slope approximations as rough surface scattering models. The CTIRs have been evaluated over a period of several days using broad-band experimental results from shallow-water deployment of source and receiver arrays that span most of the water column. Estimates of wind speed and rms wave height obtained using these CTIR calculations are compared with environmental measurements to demonstrate the validity of the theory. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3294493]

I. INTRODUCTION

This study examines the relationships between the condition of the sea surface and the coherent average of multipath acoustic signals that have propagated through a shallow-water channel. Acoustic signal coherence is quantified via the *coherent-to-incoherent intensity ratio* (CTIR), a processing approach that has been used successfully recently to measure scattering by small objects in motion in reverberant cavities (de Rosny and Roux, 2001; de Rosny *et al.*, 2005). The present study derives a theory that relates the CTIR to the ocean surface conditions for propagation through a shallow ocean channel.

It is well known that reflection and scattering by a time-varying, rough surface, such as the surface of the ocean, decreases the coherent average of the acoustic field. When acoustic signals are forward scattered by a dynamic, stochastic, rough surface, the resulting field (after ensemble averaging) is composed of a coherent component that is due to a near-specular reflection process and an incoherent component that is due to surface scattering. Here *coherent* loosely refers to the acoustic wave component that is not changed from one realization to another, while *incoherent* refers to the randomly scattered wavefield for each realization. As surface roughness increases, the forward-scattered field becomes less coherent and more incoherent. In a shallow ocean water channel, numerous interactions of the acoustic signals with the sea surface reduce the coherent field proportionally to the number of surface reflections.

It was shown many years ago that acoustic scattering at a time-varying ocean surface causes ping-to-ping changes in total path length and thus the time of arrival of the received signal. For example, Lynch *et al.*, (1987) showed that surface-interacting acoustic paths in shallow water have "very prominent" travel-time fluctuations. Miller *et al.* (1989, 1993) used fluctuations in the travel times of surface-interacting paths to estimate the ocean surface-wave height spectrum. More recently, Lewis *et al.* (2005) used acoustic travel-time variations in a double-surface bounce path to obtain information about the sound speed in the ocean volume, to update an ocean circulation model; however, they found that the travel-time variations due to surface motion were dominant.

In the present study, temporal fluctuations of the received signal are quantified using the CTIR, where from Ishimaru, 1978 and Sheng, 1995, the coherent intensity is defined as the intensity of the ensemble-averaged received signal, and the incoherent intensity is defined as the ensemble average of the received intensity. Our experimental results show that the CTIR decreases exponentially with time to the 3/2 power after direct arrival and varies with the sea state in a predictable manner. The goal of this study is to determine whether the physics of the surface interaction together with CTIR processing can explain the observed time-dependent relationship.

From a theoretical and numerical point of view, a series of studies in the late 1980s provided useful descriptors of sea

 0001-4966/2010/127(3)/1258/9/$25.00

surface scattering using Kirchhoff and perturbation approximations (Ogilvy, 1987; Thorsos, 1988; Thorsos and Jackson, 1989). More recently, the small-slope approximation (SSA) reflection coefficient was shown to be the most accurate model for surface forward-scattering of acoustic waves (Broschat, 1993). Meanwhile, the Pierson–Moskowitz sea surface-wave height spectrum had been used successfully as a fully developed sea model (Pierson and Moskowitz, 1964, Thorsos, 1990). The SSA coherent surface reflection coefficient (CSRC) was then used to model the coherent pressure field scattered by the rough ocean surface (Williams *et al.*, 2004). Of note also, the spatial coherence of a sound field scattered once from the sea surface has been investigated in the time domain through the van Cittert–Zernike theorem (Dahl, 2004). Finally, the scintillation index was introduced from optics, as a way to characterize surface roughness in a bistatic configuration (Yang *et al.*, 1991).

Although the scattering of an acoustic wave on a rough sea surface has been extensively studied, most of the above-mentioned analyses are either (1) frequency-domain methods performed with continuous waves (at one or several discrete frequencies) in shallow waters or (2) time-domain approaches with only one bounce on the ocean surface. From this perspective, our definition of the CTIR serves as a complement to these methods, in that it combines an ensemble average of multireverberated broad-band acoustic arrivals in the time domain between a set of sources and a set of receivers that applies to the case of many boundary interactions. It appears intuitive that temporal shifts in the received signals will reduce the coherent intensity more than the incoherent intensity, and that travel-time fluctuations should increase with an increasing number of surface interactions.

This study is organized as follows: after this introduction, Sec. II deals with the measurement of the CTIR and with a description of the experimental configuration used in an at-sea measurement north of Elba Island, Italy, in April 2003. In Sec. III, the CTIR is used with both the Kirchhoff and the small-slope approximations to estimate rms wave height and wind speed. These estimates are then seen to compare favorably with wave-rider-buoy data and wind speed measurements in Sec. IV.

II. EXPERIMENTAL CONFIGURATION AND CTIR MEASUREMENT

We performed an at-sea experiment in April 2003 [Julian days (JDs) 101–106], north of Elba Island, Italy, using the equipment, location, and basic setup discussed by Roux *et al.* (2004). As shown in Fig. 1(a), 29 equally spaced source transducers spanned 78 m, and 32 equally spaced receiver hydrophones spanned 90 m, in water that was 120 m deep. The distance between the two arrays was 8.67 km. The bottom was composed of sand, and the sound speed profile varied by only 2 m/s over the water depth [Fig. 1(b)]. The data from each receiver hydrophone were transmitted to the support ship via radio frequency telemetry. Transmitted pulses were 100-ms, 1-kHz-bandwidth chirps, centered at F_c =3.5 kHz. The received signals were match filtered using

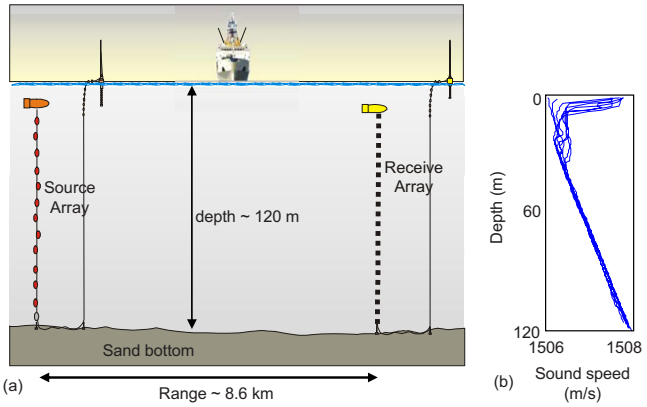

FIG. 1. (Color online) Experimental setup at sea. (a) The bottom-moored source array consisted of 29 transducers centered at 3.5 kHz that spanned 78 m of the water column. The bottom-moored receiver array consisted of 32 hydrophones with 90 m apertures. Both arrays were connected to surface buoys that contained batteries and radiofrequency telemetry hardware for data transfer and communication with the ship. The water depth was 118 m and the distance between the source and receiver arrays was 8.67 km. (b) Collection of sound speed profiles recorded in the area the same day that the acoustic experiment was performed. The average temperature profile is nearly uniform, leaving the sound speed profile with a constant pressure-related gradient.

the transmitted pulse to obtain an estimation of the channel impulse response with high signal-to-noise ratio and low transmission power.

The transmission setup used one acoustic projector transmitting at a time, while the received signal was recorded at all of the hydrophones (Fig. 2). The delay, T, between each transmission was chosen to be long enough for the signal to die out at all of the receiver hydrophones. The entire transmission sequence required 10 s, and it was repeated every 20 s over several long intervals (from 20 min to a few hours).

Figure 3 shows the matched filter output for the signals received on all of the hydrophones for a single transmission from the acoustic source at 58 m depth. As expected in a waveguide, the received signals are seen to be temporally dispersed, i.e., there is a direct path followed by arrivals that were reflected (or scattered) one or more times by the ocean surface and bottom. Time-delay beamforming was applied to the received pressure field in Fig. 3 to produce Fig. 4, which shows that the arrival angles increase with time after the first (direct path) arrival [Fig. 4(a)]. Distinct arrivals can be seen for up to 8° above and below the horizontal. There is good agreement with a ray-based acoustic prediction [Fig. 4(b)]. The ray paths plotted in Fig. 4(c) show that nearly all of the rays hit the ocean surface, a result that is due to the nearly uniform sound speed profile.

Figure 5 shows the signal arrival structure for a single source-receiver pair over a 7000 s (~2 h) period on JD 103. It is clear that the channel does not change significantly during this interval. However, it can be seen in Fig. 5 that late (multireverberated) signals lose coherence compared to (direct) early arrivals. Note also that the noise level after the direct path arrival is 5–10 dB higher than the noise level just prior to the direct path arrival. This is due to conversion of coherent acoustic energy to incoherent energy by sea surface scattering.

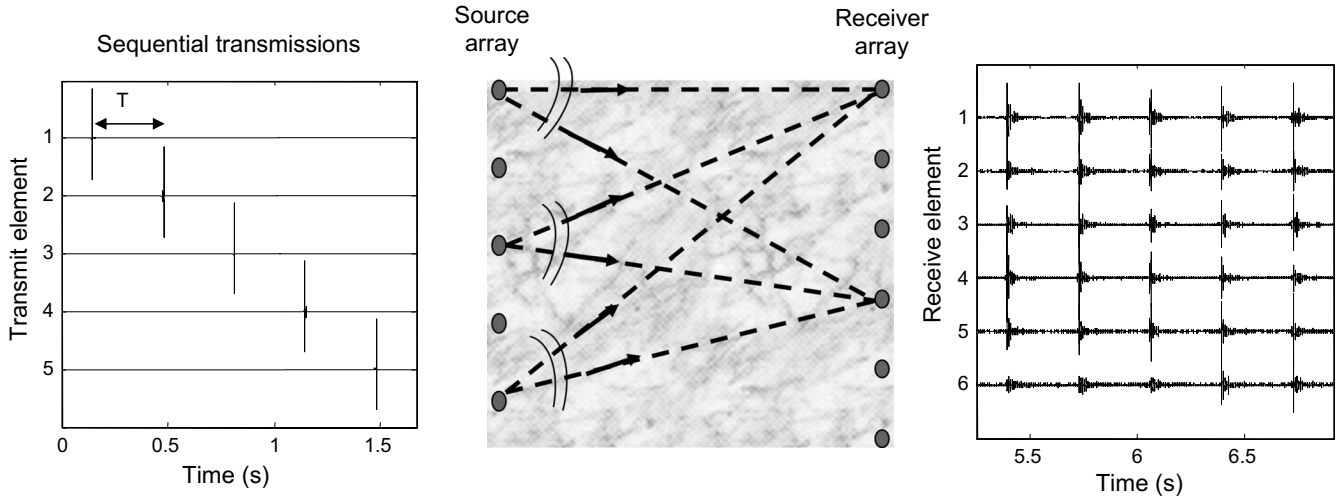

FIG. 2. Schematic of transfer matrix acquisition between the source and receiver arrays. The propagation medium between the two arrays can be any complex reverberating/scattering medium. (Left) The source array sequentially emits pulsed signals from each of its elements, separated by a time-window T that is larger than the expected acoustic dispersion in the propagation medium. (Right) After propagation, each receiver array element records dispersed signals from which the source array-receiver array transfer matrix is reconstructed.

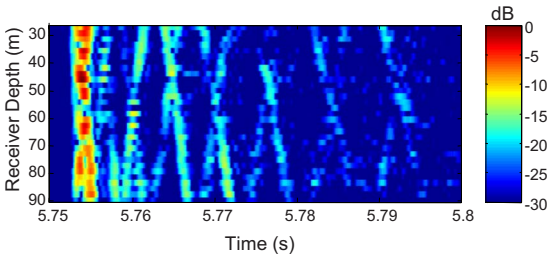

FIG. 3. (Color online) Spatiotemporal representation of the normalized acoustic intensity received at the receiver array for a pulsed signal emitted at a source array depth of 58 m. The data are from JD 105. The signal-to-noise ratio is on the order of 35 dB. The color bar is in dB.

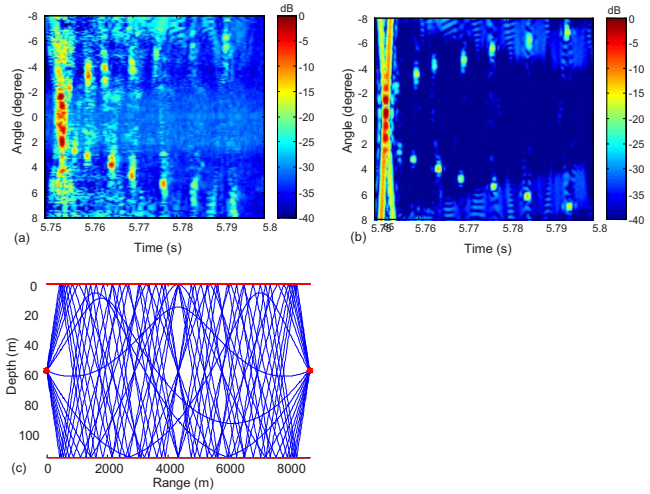

FIG. 4. (Color online) (a) Normalized intensity of the time-delay beamformer applied to the experimental pressure field recorded on the receiver array and shown in Fig. 3. (b) Normalized intensity of the time-delay beamformer performed on simulated data computed with a ray code for the same experimental configuration. (c) Eigenray paths between the source at 58 m depth and the receiver hydrophone at 60 m depth. Most of the rays are reflected by the ocean surface at least once.

Our goal was to evaluate the ratio between the coherent and incoherent intensities over multiply reflected echoes, as a way to characterize surface-height motion. The coherent and incoherent intensities are defined as

$$I_{\mathrm{coh}}(t) = \left[\frac{1}{P_{\mathrm{tot}}} \sum_{p=1}^{P_{\mathrm{tot}}} h_p(t) \right]^2, \tag{1}$$

$$I_{\mathrm{inc}}(t) = \frac{1}{P_{\mathrm{tot}}} \sum_{p=1}^{P_{\mathrm{tot}}} h_p^2(t), \tag{2}$$

where $h_p(t)$ is the signal received at a single hydrophone due to the pth transmission. Here P_{tot} is the total number of transmissions over which the average is performed. Note that some authors refer to the incoherent intensity in Eq. (2) as the total intensity (Ishimaru, 1978; Sheng, 1995). The coherent and incoherent definitions used here correspond to the type of averaging that is performed, i.e., the coherent intensity is defined as the intensity of the received signal coher-

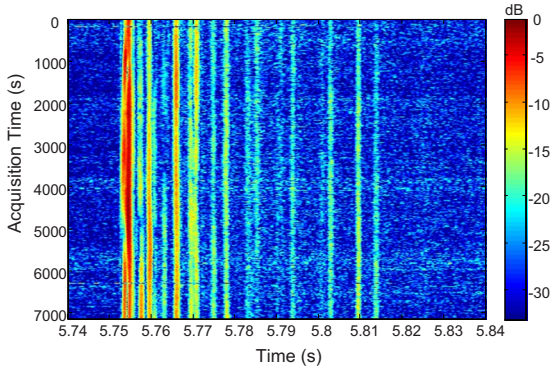

FIG. 5. (Color online) Normalized intensity of the impulse response for the signal transmitted by the 58-m-deep source and received by the 60-m-deep hydrophone during a nearly 2-h interval on JD 103. The pulse repetition rate was $1/30$ s^{-1}. Acquisition time corresponding to each transmission is along the y-axis. The horizontal axis is time after transmission. The color bar is in dB.

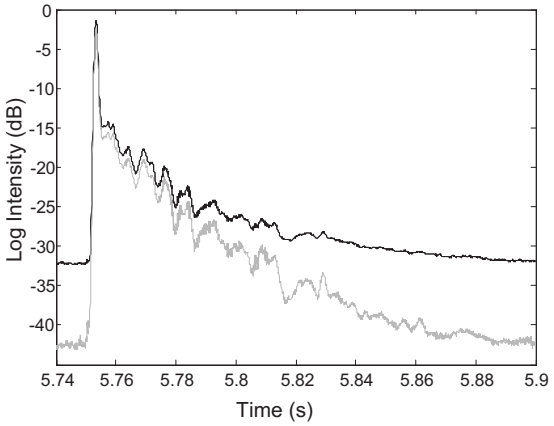

FIG. 6. Incoherent (black) and coherent (gray) intensities (in log scale) averaged over $M=29\times32=928$ source-receiver pairs. Here $P_{\text{tot}}=60$, which corresponds to a period of about 20 min on JD 103. Before coherent/incoherent averaging, each impulse response was normalized according to its maximum. Note that the coherent intensity falls off much faster than the incoherent intensity.

ently averaged over multiple pings, while the incoherent intensity corresponds to the average of the intensity. For the case of fast random perturbation of the ocean surface combined with a slowly varying medium such as the ocean volume (caused by internal waves, for example), a measurement of the coherent intensity associated with the ocean surface fluctuation only is (de Rosny and Roux, 2001)

$$I_{\text{coh}}(t)=\frac{1}{P_{\text{tot}}}\sum_{p=1}^{P_{\text{tot}}}h_p(t)h_{p+1}(t). \tag{3}$$

The CTIR is defined as

$$\text{CTIR}(t)=\left\langle\frac{I_{\text{coh}}(t)}{I_{\text{inc}}(t)}\right\rangle_M. \tag{4}$$

Here, the subscript M indicates the number of source–receiver pairs over which $I_{\text{coh}}(t)/I_{\text{inc}}(t)$ is averaged to obtain the CTIR. The coherent and incoherent intensities, calculated for $P_{\text{tot}}=60$, which corresponds to an integration of the wave height fluctuations over 20 min, and averaged over $M=928$ source-receiver pairs, are shown in Fig. 6. It is clear that $I_{\text{coh}}(t)$ falls off more quickly than $I_{\text{inc}}(t)$ which puts in evidence the effect of surface scattering on the coherent field.

The CTIR has been used over the last few years in diffusive reverberant acoustic wave spectroscopy (DRAWS) to measure the scattering cross section of small objects in motion in reverberant cavities (de Rosny and Roux, 2001; de Rosny *et al.*, 2005). In a reverberant cavity, the coherent intensity is due to reflections from the cavity boundaries, which do not change from transmission to transmission. When scatterers are present, the signal is different from one transmission to the next, and the CTIR quantifies the amount of coherent intensity that becomes incoherent because of the motion of the scatterer. DRAWS has been applied successfully at scales ranging from room acoustics at 1 kHz to ultrasonic cavities at 1 MHz (Conti *et al.*, 2004, 2006a).

For an infinite number of transmissions ($P_{\text{tot}}\to\infty$), the asymptotic expression for the CTIR classically decreases exponentially as $\text{CTIR}(t)=\exp(-t/\tau)$ (Ishimaru, 1978), where τ is defined as a scattering mean free time, from which the total scattering cross section of the scatterer can be determined. For a finite number of transmissions, it was shown in Appendix A of de Rosny and Roux, 2001 that the CTIR must include a second term that corresponds to the variance of P_{tot} random variables:

$$\widetilde{\text{CTIR}}(t)=\exp(-t/\tau)+\frac{1}{P_{\text{tot}}}(1-\exp(-t/\tau)). \tag{5}$$

The first exponential in Eq. (5) corresponds to the scattering effect of the scatterers, while the second term represents the residual variance of the scattered field. Indeed, for times much greater than the mean free time, i.e., $t\gg\tau$, the signal $h_p(t)$ is dominated by incoherent scattering from the moving objects rather than the coherent echoes from the cavity interfaces. In the following, we will alternatively use the *asymptotic* and *finite* notations $\text{CTIR}(t)$ and $\widetilde{\text{CTIR}}(t)$, respectively, for infinite and finite numbers of transmissions, respectively.

When there are no scatterers in the cavity, it has been demonstrated experimentally that the CTIR is affected, for example, by random motion of the cavity walls. As long as the ratio of volume to surface area of the cavity is large with respect to the acoustic wavelength, Eq. (5) remains valid and the CTIR still decreases exponentially (Conti *et al.*, 2006b; Conti, 2005). In this case, the mean free time τ is related to the rms displacement of the cavity walls.

However, the physical properties of an acoustic waveguide and a cavity are very different. In a cavity, reflections by the boundaries randomize the pressure field very quickly, in the sense that after a short transition time, a receiver at any location in the cavity will record a nearly continuous sequence of coherent acoustic echoes that have investigated the whole cavity volume. We classically describe this property of nontrivial cavities as ergodicity [see recent review by Tanner and Sondergaard (2007)]. As a result, the DRAWS technique performs well for cavities with only one, or at most a few, source-receiver pairs. The problem is very different in a waveguide where the pressure field is only bounded by two interfaces, above and below. Indeed, the acoustic field is no longer trapped in the volume of the cavity but can leak through the channel axis parallel to the waveguide interfaces. Going back to Figs. 3 and 5, we observe that the point-to-point signal in the waveguide is composed of a few arrivals due to interface reflections, surrounded by intervals during which there are no echoes. The use of the CTIR as a measure of the surface scattering mean free time is then problematic, since Eq. (3) can abruptly drop to zero, for time intervals where no coherent echoes are present. However, one way to mitigate the problem is to average the CTIR over a large number of sources and receivers. In so doing, the gaps between the coherent echoes are filled in when the CTIR is averaged [Eq. (4)] over a number of source-receiver pairs. Ultimately, the coherent intensity averaged over all of the source-receiver pairs shows no time discontinuity (see Fig. 6), which means that the temporal ergodicity of the cavity has been replaced by spatial diversity in the waveguide.

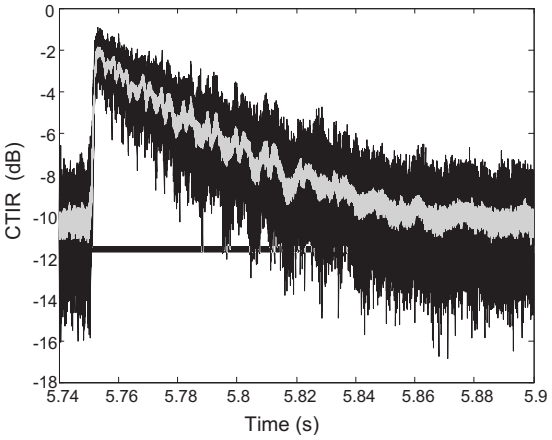

FIG. 7. Collections of 100 CTIRs measured on JD 103 for $P_{tot}=10$, and random selections of M source-receiver pairs among the 29-element source and 32-element receiver arrays: (a) $M=30$, black lines; (b) $M=700$, gray lines.

The benefit of spatial averaging is demonstrated in Fig. 7, which compares collections of CTIRs calculated for two different numbers of source-receiver pairs. A lower variance estimate of the CTIR is obtained by averaging over 700 source-receiver pairs. This confirms that spatial averaging over sources and receivers that are distributed over the water column provides arrival-time diversity, which reduces the variance of the CTIR.

Note that in Fig. 7 (and also in Figs. 8 and 9), the CTIR value at $t=t_0$ (where $t_0=5.753$ s corresponds to the travel time of the first arrival) is not equal to 1.0, which means that the coherent intensity differs from the incoherent intensity even for the direct arrival. One possible explanation is a small ($\sim 1/8F_c$) jitter that is present in the source timing. It is also possible that random fluctuations in the ocean volume along the direct path were responsible for the drop in coherence.

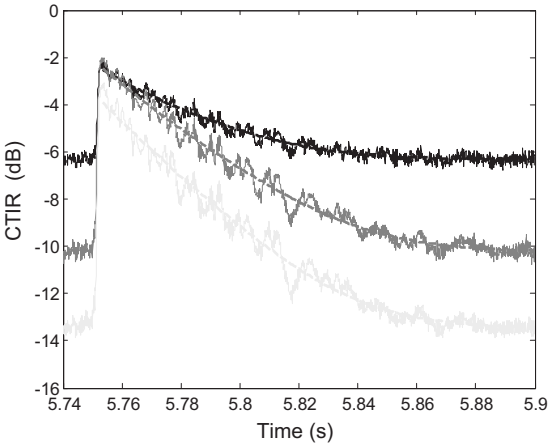

FIG. 8. CTIR calculated for the same data on JD 103 using $M=928$ source-receiver pairs and different numbers of transmissions P_{tot}: $P_{tot}=20$ (light gray, bottom curve), $P_{tot}=10$ (gray, middle curve), and $P_{tot}=5$ (black, top curve). The dashed curves correspond to the best CTIR fit obtained using the Kirchhoff approximation [Eq. (12)] and rms surface heights of $h=0.18$ m, $h=0.195$ m, and $h=0.177$ m, respectively. Note that the rms surface heights agree to within about 5%, regardless of P_{tot} and despite the significant effect of P_{tot} on the CTIR.

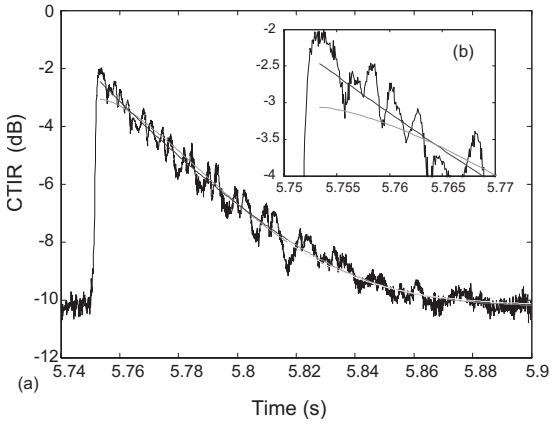

FIG. 9. (a) CTIR measurement (solid black line) compared to CTIR predictions based upon the Kirchhoff approximation (light gray) and the SSA approach (dark gray). The CTIR was calculated with $P_{tot}=10$ and $M=928$ source-receiver pairs. (b) Expanded view of the CTIR for small δt showing better agreement between the experimental data and the SSA at shallow grazing angles. Applying the Kirchhoff approximation gives $h=0.179$ m [corresponding to $U=5.63$ m/s using Eqs. (12) and (13)], while the SSA approximation Eqs. (18)–(20) yields $U=5.87$ m/s and $h=0.184$ m.

III. THEORY RELATING THE CTIR TO SURFACE SCATTERING IN AN ACOUSTIC WAVEGUIDE

Repetitive measurements of the transfer matrix between the source and receiver arrays provide a comparison between CTIR measurements and both wind speed and significant wave height over a few days. Significant wave heights were extracted from continuous recordings on a wave-rider buoy, and wind speed was measured on the research vessel Alliance. The goal of this section is to determine how the CTIR is related to the surface conditions and to derive the relationship between the measured CTIR and the significant wave height and/or wind speed.

Medwin and Clay (1994) showed that in the Kirchhoff approximation, the coherent reflection coefficient for an incident plane wave at frequency ω forward scattered by a surface having a Gaussian height probability distribution function is

$$\mathrm{CSRC}_{\mathrm{Kirchhoff}}(\theta,\omega)=\Re\,\exp(-2k^2h^2\sin^2\theta), \tag{6}$$

where $k=\omega/c$ is the acoustic wave number (ω is angular frequency and c is the speed of sound), h^2 is the mean square wave height of the ocean surface, and θ is the grazing angle. For the air-water interface, $\Re=-1$. Equation (6) is based on the assumption that a plane wave reflected by a rough surface will experience a phase shift of $2k\delta z\sin\theta$, where δz is the height of the surface at the specular point relative to the mean surface level. The coherent reflection coefficient in Eq. (6) is obtained by taking the mean value of $\exp(i2k\delta z\sin\theta)$ over the surface-wave height.

Following the Kirchhoff approximation, the coherent *intensity* surface reflection coefficient (CISRC) was defined by Thorsos (1990) as

$$\mathrm{CISRC}_{\mathrm{Kirchhoff}}(\theta,\omega)=\exp(-4h^2k^2\sin^2\theta). \tag{7}$$

The CISRC assumes a plane wave incident on a rough surface at grazing angle θ and it characterizes the average intensity of the wave reflected at the same grazing angle. The

average here corresponds to an ensemble average over many realizations of the rough surface. When there are N surface reflections, as for longer-range propagation in shallow water, the CISRC must be applied N times:

$$\mathrm{CISRC}_{\mathrm{Kirchhoff}}(\theta,\omega)=\exp(-4Nh^2k^2\sin^2\theta). \tag{8}$$

For the experimental results presented here, the quasi-uniform sound speed profile leads to the absence of refraction in the waveguide, which means that the incident and reflected angles are conserved through the waveguide propagation.

As an acoustic signal travels through a shallow, constant-sound speed channel, in addition to N scattering events at the ocean surface, it also undergoes Q reflections at the bottom. The Q bottom interactions, the volume attenuation, and the spreading loss at range r can be combined into an intensity loss $A(Q,\omega,\theta,r)$, which is in addition to the intensity loss expressed in Eq. (8). However, the intensity loss factor $A(Q,\omega,\theta,r)$ that results from propagation through the channel will be incorporated into the incoherent intensity, which has the role of a normalization factor in the CTIR. Therefore, the CTIR reduces to the averaged intensity loss due to surface scattering only, as expressed in Eq. (8).

However, Eq. (8) was derived for a plane wave propagation in the waveguide (at grazing angle θ and frequency ω), and it is no longer valid in the case of an omnidirectional source and receiver (Fig. 1) for which all angles are mixed up in the frequency domain. Fortunately, things can be sorted out in the time domain. Indeed, the relationship between grazing angle and travel time can be easily determined in a range- and depth-independent sound speed environment, such as a shallow-water channel. An eigenray at grazing angle θ that arrives at time t at the end of the waveguide satisfies the relationship

$$\sin^2(\theta)=\delta t\frac{\delta t+2t_0}{(\delta t+t_0)^2}\approx 2\frac{\delta t}{t_0}, \tag{9}$$

where $t_0=5.753$ s is the travel time of the direct path between the source and the receiver in the waveguide, and where $\delta t=t-t_0$. The approximation in Eq. (9) requires that $\delta t\ll t_0$, which is normally the case in shallow water at longer ranges [Fig. 4(a)]. Also, the number of surface reflections, N, is time dependent and increases with travel time, from $N=2$ at $\delta t=0.005$ s to $N=7$ at $\delta t=0.12$ s in our experimental configuration. More generally, for a shallow-water channel with depth D and range L, the relationship between time and the number of surface bounces N is

$$N(\delta t)=\frac{L}{2D}\sqrt{\frac{\delta t}{\frac{t_0}{2}-\delta t}}\approx\frac{L}{\sqrt{2}D}\sqrt{\frac{\delta t}{t_0}}. \tag{10}$$

Substituting Eqs. (9) and (10) into Eq. (8), and taking the CTIR to be equal to the average intensity loss due to surface scattering only, after frequency summation over a large bandwidth, the time-dependent CTIR can be written as

$$\mathrm{CTIR}_{\mathrm{Kirchhoff}}(\delta t)\approx\exp\left(-\frac{4\sqrt{2}h^2\omega_c^2(\delta t)^{3/2}}{Dc\sqrt{t_0}}\right), \tag{11}$$

where $\omega_c=2\pi F_c$ is the central frequency of the pulse. Note that the transition from continuous wave to time domain in Eqs. (8)–(11) is not a Fourier transform, since no phase information is present in the CTIR.

Actually, Eq. (11) corresponds to the *asymptotic* CTIR for an infinite number of transmissions in the acoustic waveguide. In practice though, noise must be added to Eq. (11), since the CTIR has no physical meaning when no coherent signal is present, for example, at $t_0+\delta t>5.82$ s in Fig. 5. The floor of the CTIR corresponds to the variance of the coherent to incoherent ratio of the random ocean noise recorded on the array, and it only depends on the number of transmissions, P_{tot}, over which the average is performed. Writing Eq. (11) in the form of Eq. (5), the expression for the *finite* CTIR is then

$$\widetilde{\mathrm{CTIR}}_{\mathrm{Kirchhoff}}(\delta t)\approx\exp\left[-\left(\frac{\delta t}{\tau}\right)^{3/2}\right]+\frac{1}{P_{\mathrm{tot}}}\left(1-\exp\left[-\left(\frac{\delta t}{\tau}\right)^{3/2}\right]\right) \tag{12}$$

with

$$\tau^{3/2}=\frac{Dc\sqrt{t_0}}{4\sqrt{2}h^2\omega_c^2}. \tag{13}$$

Figure 8 shows the CTIR calculated for the same data on JD 103, but using values of $P_{\mathrm{tot}}=5$ (black, upper curve), 10 (gray, middle curve), and 20 (light gray, lower curve). Clearly, the CTIR falls off more quickly with increasing P_{tot}. However, we show now that this dependence is properly reflected in Eq. (12), such that we can use the CTIR to predict surface-wave height quite well for different values of P_{tot}. Equation (12) has been used to find the values of rms wave height h that provide the CTIR that is the best match with that calculated from the data. The dashed lines in Fig. 8 indicate the CTIR calculated using Eq. (12) and the values of $h=0.18$, 0.195, and 0.177 m, and $P_{\mathrm{tot}}=20$, 10, and 5, respectively. Although these values for h are not identical, they only vary by about 5%, indicating that different values of P_{tot} can be used to compute the CTIR and to estimate the rms surface height without significantly affecting the result. The results in Fig. 8 confirm the dependence of the CTIR on the number of transmissions, P_{tot}, which must be taken into account when the CTIR is used to estimate the ocean surface condition.

The solid black line in Fig. 9 shows the CTIR calculated from the data on JD 103 for $P_{\mathrm{tot}}=10$, averaged over 928 source-receiver pairs. The light gray line is the best fit CTIR calculated using Eqs. (12) and (13). Although the best fit Kirchhoff CTIR matches the calculated CTIR over most of the curve, it does so at the expense of some disagreement at small δt. These times, which are shortly after the direct path arrival, correspond to paths which have interacted with the surface at very low grazing angles. In search of a better fit at low grazing angles, we considered the SSA to the CSRC as providing a more accurate reflection coefficient for shallow grazing angles (Thorsos and Broschat, 1995). Using the

same notations as in Eq. (6), the CSRC for an incident plane wave (at frequency ω and grazing angle θ) in the SSA becomes (Broschat, 1993):

$$\mathrm{CSRC}_{\mathrm{SSA}}(\theta,\omega) = \Re \exp(-2k^2h^2 \sin^2\theta) \times \left| 1 - 2k \sin\theta \int W(K)g(K,\theta,\omega)dK \right|, \tag{14}$$

where K is the one-dimensional (1D) surface-wave number, $W(K)$ is the 1D surface roughness spectrum, $g(K,\theta,\omega) = \sqrt{k^2-(K+k\cos\theta)^2}-k\sin\theta$, and $\Re=-1$, as in Eq. (6).

A commonly used ocean two-dimensional (2D) surface-height spectrum that represents a fully developed sea was published by Pierson and Moskowitz (1964). The Pierson–Moskowitz surface-height spectrum is completely determined by the wind speed. Given the geometry of our measurements, with coplanar sources and receivers, we can use a simplified version of the 2D Pierson–Moskowitz spectrum, which leads to the following 1D roughness spectrum (Broschat, 1993):

$$W(K) = (\alpha/(4|K|^3))\exp[-(\beta g^2)/(K^2U^4)]. \tag{15}$$

Here α and β are dimensionless constants of 8.1×10^{-3} and 0.74, respectively, $g=9.81$ m/s^2 is the gravitational acceleration constant of Earth, and U is the wind speed measured at 19.5 m above the mean ocean surface. The spectrum is normalized such that

$$\int W(K)dK = h^2. \tag{16}$$

When there are N surface reflections, as for longer-range propagation in shallow water, the asymptotic CISRC (at frequency ω and grazing angle θ) in the small-slope approximation is

$$\mathrm{CSRC}_{\mathrm{SSA}}(\theta,\omega) = \exp(-4Nh^2k^2 \sin^2\theta) \times \left| 1 - 2k \sin\theta \int W(K)g(K,\theta,\omega)dK \right|^{2N}. \tag{17}$$

Finally, using Eqs. (9) and (10) and accounting for the finite number of transmissions P_{tot} as in Eqs. (5) and (12), the expression for the time-dependent *finite* CTIR after frequency integration around ω_c (with $k_c=\omega_c/c$) is

$$\widetilde{\mathrm{CTIR}}_{\mathrm{SSA}}(\delta t) \approx \exp\left[-\left(\frac{\delta t}{\tau}\right)^{3/2}\right]F(\delta t) + \frac{1}{P_{\mathrm{tot}}}\left(1-\exp\left[-\left(\frac{\delta t}{\tau}\right)^{3/2}\right]F(\delta t)\right), \tag{18}$$

where

$$F(\delta t) \approx \left| 1 - k_c\sqrt{\frac{8\delta t}{t_0}} \int W(K)g(K,\delta t)dK \right|^{L/D\sqrt{2\delta t/t_0}} \tag{19}$$

and

$$g(K,\delta t) = \sqrt{k_c^2 - \left(K + \frac{k_c t_0}{t_0+\delta t}\right)^2} - 2k_c\frac{\delta t}{t_0}. \tag{20}$$

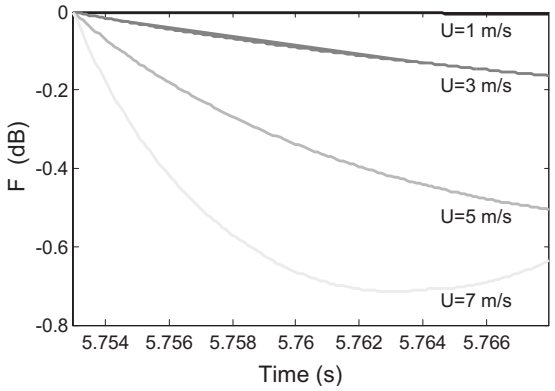

FIG. 10. Log representation of the short-time correction $F(\delta t)$ (corresponding to low grazing angle) for the time-dependent CTIR in the SSA approximation [Eq. (18)] and for different values of wind speed, U (ranging from $U=1$ m/s to $U=7$ m/s)

In Eq. (18), $F(\delta t)$ is a short-time correction factor for the time-dependent CTIR; in the same way, the second term in Eq. (17) is a low-angle correction to the frequency-dependent CISRC in the Kirchhoff approximation. As shown in Fig. 10, the factor $F(\delta t)$ is less than 1 for $\delta t>0$ but small. This serves to straighten the log representation of the CTIR at short times $0<(\delta t/\tau)\ll1$ as may be seen in Fig. 9(b), where the CTIR calculated using Eqs. (18)–(20) is compared to the time dependence in $-(\delta t/\tau)^{3/2}$ obtained from the Kirchhoff approximation [Eq. (12)].

Figure 9(b) shows that utilizing the SSA provides better agreement with the experimental data at early times. The best match using Kirchhoff approximation gives $h=0.179$ m, from which we calculate $U=5.63$ m/s using Eqs. (15) and (16), while the best match using the SSA approximation gives $U=5.87$ m/s and $h=0.184$ m. These values of rms surface-wave height h and wind speed are very similar. Indeed, the main surface scattering contribution seen in the experimental data for 10 ms$<\delta t<$70 ms comes from grazing angles $3.5°<\theta<9°$ and wind speeds $U>5$ m/s for which the SSA and the Kirchhoff approximation give similar results (Williams *et al.*, 2004).

IV. DISCUSSION

Equations (12) and (18) show that in an acoustic waveguide, the CTIR does not decrease exponentially with time, as was the case for multiple scattering theory in an acoustic cavity [Eq. (5)]. Indeed, the CTIR calculated using both the Kirchhoff and small-slope approximations for surface scattering varies exponentially with $-(\delta t/\tau)^{3/2}$ over most of the arrival times. In analogy with multiple scattering theory, we deduce an equivalent to the concept of mean free time τ [see Eq. (13)] or equivalently an e-folding time, for an acoustic waveguide with random surface scattering. In an acoustic waveguide, the scattering mean free time τ is a measure of the time interval after the direct echo after which the reverberated pressure field becomes largely incoherent. From Fig. 9 and Eq. (13), we obtain $h=0.18$ m and $\tau\sim35$ ms. This value can be compared to the attenuation mean free time ($\sim$60 ms) evident in the incoherent intensity (see Fig. 6). In our shallow-water configuration, τ is a measure of the time

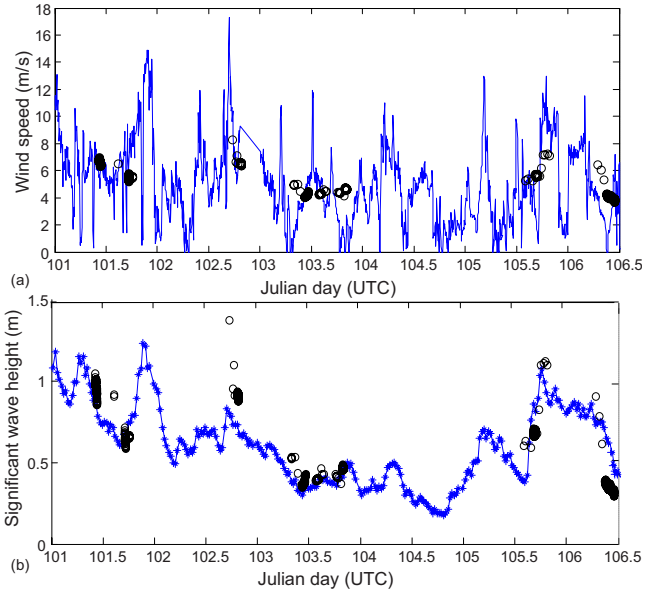

FIG. 11. (Color online) Wind speed measurements [solid line in (a)] and significant wave height H_S [dashed line in (b)] measured using a wave-rider buoy for JDs 101–106 ($H_S=4h$, with h the rms surface wave height). The open circles are wind speed and significant wave height obtained by fitting Eq. (18) to the CTIR calculated from the acoustic measurements.

after the direct arrival when the received signal becomes largely incoherent from transmission to transmission (see Fig. 5, for example). The measure of the scattering mean free time could be important when dealing with coherent underwater acoustic communications or time-reversal in shallow-water waveguides.

We have shown that Eqs. (12) and (18) allow us to invert for surface scattering properties from the CTIR measurements performed between the two vertical source-receiver arrays. In the Kirchoff approximation, the CTIR only depends on the rms surface height h, while the wind speed U is also obtained using the SSA approximation and the surface-wave height spectrum.

Carrying out this inversion for all of the acoustic data, Fig. 11 compares the wind speed and significant wave height ($H_S=4h$, with h the rms surface-wave height) estimated from the acoustic data by finding the best fit CTIR with measurements of these parameters for JDs 101–106. The wave height measurements are obtained from wave-rider-buoy data. It is clear that the CTIR-derived significant wave height estimates are in good agreement with the measured values. The wind speed is much more volatile than the wave, and of course, ocean surface waves are a response to the wind blowing over the ocean surface. The CTIR is directly affected by surface roughness, so it is not surprising that it is better correlated with surface condition wind speed. The largest discrepancy occurs for the significant wave height between JD 102.5 and JD 103. Note, however, that the higher wave height estimates do correspond to a large peak in measured wind speed that only yields a modest peak in significant wave height.

In conclusion, we have shown that the CTIR is a measure of the interference effects which cause propagating waves to fluctuate from transmission to transmission. In the case of an acoustic waveguide, the fluctuations can be caused by time-varying volume or surface scattering. Surface scattering was dominant in the experimental configuration presented here. Also, the essentially isovelocity sound speed profile seen here in April indicates that minimal volume variation can be expected during the averaging times we employed. However, we note that during the summer, the presence of a strong thermoclyne could induce internal waves that would cause significant time-varying volume refraction on a short time scale. In this case, both volume refraction and the surface scattering effects would be measured simultaneously by the CTIR. The two contributions could be sorted out if refracted or reflected rays are identified and considered separately in the CTIR calculation, as shown recently using source-receiver arrays and a double-beamforming algorithm (Roux *et al.*, 2008). Future work will combine the CTIR and eigenray identification to separately invert for surface scattering and volume scattering effects in an acoustic waveguide.

(Received 30 November 2008; revised 12 August 2009; accepted 22 December 2009)

The near field underneath the ultrasonic probe fluid coupled to an isotropic solid is approximated in the frequency domain by a closed form asymptotic solution. The approximation is based on the problem decomposition and uses the stationary phase method evaluating the response to an equivalent surface source. This results in a sum of contributions, each dominating in a specific geometrical region, the main beam or a side lobe. The transitional zones are also described. The pulse trains are computed using the harmonic synthesis and compared with the results obtained by direct calculation of Fourier integrals. It is shown that the asymptotic approach permits us to elucidate the physics of problem and leads to a numerical algorithm which is about 10^4 times faster than the direct computations. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3292997]

I. INTRODUCTION

It is well known that two types of ultrasonic probes commonly used in non-destructive evaluation (NDE) are the normal transducer and the angled beam probe,[1] operating typically from 1 to 10 MHz. The normal transducer is a piezoelectric crystal placed directly onto the inspection surface and it generates a compression beam normal to this surface. The angle beam probe[1] consists of a piezoelectric crystal mounted on a plastic wedge and it generates a beam of shear waves propagating at a specific angle to the surface. In both cases, the contact with the inspection solid is through a thin layer of low-viscous liquid couplant, which permits us modeling the equivalent surface source[2] with neglected shear stresses. For the transducer's far field, a moving point source[3–5] can be used to model such equivalent surface sources. A line source or strip source can be used[6–8] for modeling a normal rectangular probe. Both the far field[9] and near field can also be satisfactory modeled,[10] e.g., using the direct computations or the asymptotic approach.[11–13] A direct computation, performed using finite element method (FEM) (Ref. 14) or finite-differences,[15] may produce satisfactory simulations, but the computational effort at the high frequency and/or large distance can be a drawback. As shown in Ref. 16, the head waves are prominent features of the wave field, radiated by a small contact transducer and probe with steep beam angle, while the Rayleigh waves always dominate at the surface. Models that neglect the mode conversions at the free surface fail to predict this field component.[12,17,18] To describe the full wave field underneath the transducer accurately and at any range, the exact elastodynamic solution is required. Such solution could be obtained by employing the point-source superposition. However, in a three dimensional geometry this results in a triple integral over the time and aperture and requires an enormous computational time. This time increases with increasing pulse width since the spatial discretization depends on the temporal sampling rate, and in view of the Shannon sampling theorem, the latter must be relatively high. Although combining the approximations with smart programming may considerably decrease the computational effort,[19] the evaluation may still suffer from invalid approximation. For some source shapes, e.g., circular, annular, and rectangular sources,[20–25] the spatial (Rayleigh) integral can be evaluated semi-analytically, e.g., using the contour integration, non-moving line segment source, and the Cagniard–de Hoop method.[5,16] This approach is less computationally extensive but still remains time consuming. In this paper we apply a different technique, which has first been used to describe the field of the directly coupled normal probe.[11–13,26] We solve the problem in several steps. First, we evaluate the magnitude of the surface load from a *local* problem assuming that the couplant layer is thin and solving in the frequency domain a simple problem of the contact of two infinite solids through a fluid layer. Since in practice we never know the exact shape and size of a contact spot between the couplant and inspection solid, neglecting finite size looks reasonable. We thus estimate stresses on the liquid-solid interface. We then follow the traditional formulation and model the probe by an equivalent surface source—a contact spot—which generates the above stresses, assuming them to fall to zero outside the spot in a discontinuous manner—even though the real boundary conditions may be more involved. Second, we adapt the two-tier asymptotic approach to evaluate the radiation field in the frequency domain. To this end we use the solution of Lamb's problem approximated by its leading term at high frequency (like the far field) and apply the stationary phase method to evaluate the convolution integrals over equivalent contact spot considering the first Fresnel zone underneath the transducer. At the third step, we apply the time-harmonic synthesis to the one obtained above and simulate the pulse trains propagating in this region. In principle, assuming that the discontinuous change in stresses is

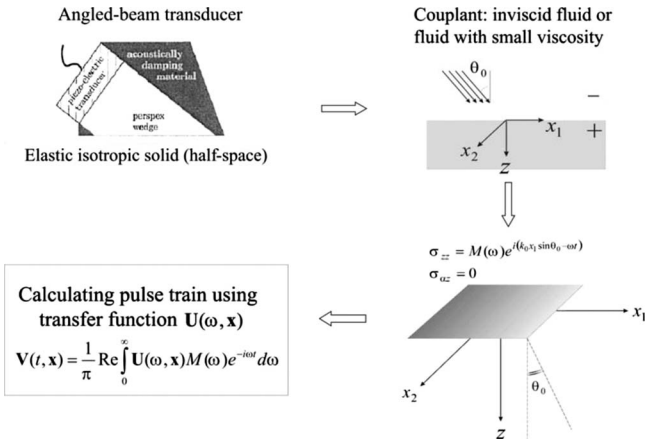

FIG. 1. The problem decomposition.

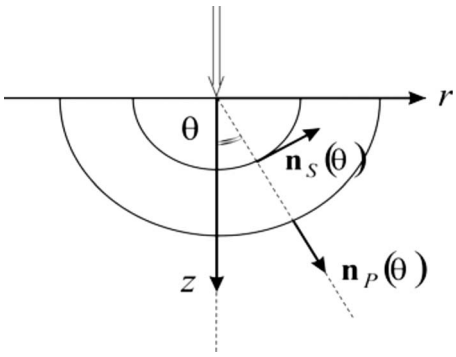

FIG. 2. The wave fronts and polarization vectors.

not necessary, the approach is applicable to probes of arbitrary apodization. Keeping this in mind, the model of the contact spot may be improved, e.g., by utilizing the measured pressure values underneath the probe.[16] Of course, if the stress decay near the boundary of the contact spot is continuous, the contribution of the side lobes is less perceptible than the discontinuous model would imply.

This paper is organized as follows. In Sec. II we present our decomposition concept using steps from 1 to 3. Then we consider the convolution integral, apply the stationary phase method, and obtain the main beam, edge and corner waves (Sec. III), and penumbra zones (Secs. IV–VI) in the frequency domain. The numerical simulation of pulse trains and their comparison with the direct evaluation of field radiated by the same contact spot are presented in Secs. VII and VIII, followed by some conclusive remarks.

II. PROBLEM DECOMPOSITION CONCEPT

The angled beam ultrasonic probe placed on the surface of the inspection solid (see Fig. 1, top left) may be modeled using the following problem decomposition. First, we study the wave generated by the piezoelectric element and incident on the transducer-fluid couplant-inspection surface on the scale of the fluid couplant. The couplant layer is assumed to be thin compared to the characteristic transducer dimensions and of infinite extent. We solve this problem to arrive at a transfer function between plastic wedge, fluid couplant, and inspection solid (see Fig. 1, top right) and to obtain the stress field on the inspection surface. We prescribe this stress distribution on the contact spot on the inspection surface which we treat as an equivalent source, whose stress falls to zero outside the spot in a discontinuous manner (marked in Fig. 1 with "+"). The model may be refined by taking into account the continuous distribution but such correction does not change the approach too much. The above distribution is a traveling wave, whose magnitude depends on the frequency, incidence angle, material parameters, and thickness of the couplant. It can be obtained in a closed form or using low frequency asymptotics (see, e.g., Ref. 27). Second, we use the so-called "two-tier high frequency asymptotic approach"[11] to model the near radiating field of the equivalent contact spot. Third, we use the time convolution of the given pulse with the above results to model the pulse trains arriving at a given point of observation. Let us overview the two-tier approach.

1) *The first tier*: The high frequency asymptotics of the time-harmonic Green function (Lamb problem). Since our interest is focused on the radiating field, that is, a few wavelengths away from the surface, in the first tier we arrive at the far field asymptotics of the Lamb's problem (the Green's function for the isotropic half space). We use it to approximate the convolution integral, interpreted as a superposition of fields radiated by point Huygens's sources covering the surface of the contact spot. The leading components of the displacement vector (the factor $e^{-i\omega t}$ is omitted) are presented in Refs. 18 and 28. In the local Cartesian base $\mathbf{x}=\mathbf{i}_\alpha x_\alpha$ ($\alpha=1,2,3$) and associated cylindrical coordinates r,θ,z with the origin at the point-source (Fig. 2), the displacement vector is a sum of P- and S-wave components

$$\mathbf{U}^{P,S}(\mathbf{x}) = -\frac{1}{2\pi\mu}\frac{e^{ik_{P,S}R}}{R}A_{P,S}(\mathbf{x})\mathbf{n}_{P,S}(\mathbf{x}) + O(k_{P,S}R)^{-2}, \quad k_{P,S}z = 2\pi z/\lambda_{P,S} \gg 1, \tag{1}$$

where μ is the shear modulus and

$$R(\mathbf{x}) = \sqrt{r^2+z^2}, \quad r(\mathbf{x}) = \sqrt{x_1^2+x_2^2}, \quad z = x_3, \quad \gamma = c_S/c_P < 1, \quad k_{P,S} = \omega/c_{P,S}, \quad 0 < \theta < \pi/2,$$

$$A_P(\mathbf{x}) = \frac{2\sin^2\theta - \gamma^{-2}}{R_P(\sin\theta)}\cos\theta, \quad R_P(\eta) = (2\eta^2-\gamma^{-2})^2 + 4\eta^2\sqrt{1-\eta^2}\sqrt{\gamma^{-2}-\eta^2}, \quad \mathbf{n}_P(\mathbf{x}) = \sin\theta\mathbf{e}_r + \cos\theta\mathbf{e}_z,$$

$$A_S(\mathbf{x}) = \frac{\sin 2\theta\sqrt{\gamma^2-\sin^2\theta}}{R_S(\sin\theta)}, \quad R_S(\eta) = (2\eta^2-1)^2 - 4\eta^2\sqrt{\eta^2-1}\sqrt{\eta^2-\gamma^2}, \quad \mathbf{n}_S(\mathbf{x}) = \mathbf{e}_r\cos\theta - \mathbf{e}_z\sin\theta.$$

At the angle $\theta \approx \pi/2$ these leading terms vanish, and the second order contribution must be taken into account, but away from this angle, the approximation is accurate and the *head wave* $\mathbf{U}^H = O(k_S R)^{-2}$ and can be neglected.[28]

2) *The second tier*: High frequency asymptotics of the radiating near field. Assume that the observation point lies in

the first Fresnel zone $z/k_{P,S}[\min(a_1,a_2)]^2 \ll 1$ underneath the equivalent contact spot $\Omega \equiv [-a_1,a_1]\times[-a_2,a_2]$ with given stresses $\sigma_{zz}=M(\omega)e^{ik_0 x_1 \sin\theta_0}$, $\sigma_{\alpha z}=0$; so the incident wave is supposed to fall along x_1. Using the superposition of point-sources and the first tier from above, we express the leading term of the displacement field normalized by $M(\omega)$ in the form of the two dimensional (2D) integral of rapidly oscillating function where the asterisk labels *P*- and *S*-wave components, $\mathbf{x}$ is the observation point, and c_0 is the sound speed in fluid:

$$\mathbf{U}^*(\mathbf{x}) \cong -\frac{1}{2\pi\mu}\int\int_{\Omega} \mathbf{f}_*(\mathbf{x},\mathbf{x}')e^{ik_*\Psi_*(\mathbf{x},\mathbf{x}')}dx_1'dx_2',$$

$$\mathbf{f}_*(\mathbf{x},\mathbf{x}') = \frac{A_*(\mathbf{x}-\mathbf{x}')\mathbf{n}_*(\mathbf{x}-\mathbf{x}')}{R(\mathbf{x}-\mathbf{x}')}, \tag{2}$$

$$\Psi_*(\mathbf{x},\mathbf{x}') = R(\mathbf{x}-\mathbf{x}') + x_1' \sin\theta_*, \quad \sin\theta_* = \frac{c_*}{c_0}\sin\theta_0,$$

$$R(\mathbf{x}-\mathbf{x}') = \sqrt{(x_1'-x_1)^2+(x_2'-x_2)^2+z^2},$$

$$\mathbf{x}' = (x_1',x_2',0) \in \Omega. \tag{3}$$

The high frequency asymptotics of this near field is our "second tier."[11]

III. STATIONARY PHASE METHOD: MAIN BEAM, EDGE, AND CORNER WAVES

Consider the double integral (2) at $z>0$ and obtain the derivatives of its phase function (δ_α^1 is a Kronecker delta with $\alpha=1,2$)

$$\Psi_\alpha \equiv \partial_{x_\alpha'}\Psi_* = (x_\alpha'-x_\alpha)R^{-1} + \delta_\alpha^1 \sin\theta_*,$$

$$\Psi_{\alpha\alpha} \equiv \partial_{x_\alpha'}\Psi_\alpha = R^{-1} - (x_\alpha'-x_\alpha)^2R^{-3},$$

$$\Psi_{12} \equiv \partial^2_{x_1'x_2'}\Psi_* = -(x_1'-x_1)(x_2'-x_2)R^{-3},$$

$$\det\Psi'' \equiv \Psi_{11}\Psi_{22}-\Psi_{12}^2 = z^2R^{-4} > 0.$$

It is well known that, apart from singularities of the amplitude function $\mathbf{f}_*$, the main contributions to the integral (2) come from the *stationary points* of the phase functions, i.e., the points where $\Psi_1=\Psi_2=0$ (when isolated, these points are called the *critical points of the first kind*[29,30]), and from the various types of *critical boundary points*.[29,30] Each equation $\Psi_\alpha=0$ causes a line of the critical points of the first kind

$$x_{1*}' = x_1 - R(\mathbf{x}-\mathbf{x}_*')\sin\theta_*, \quad x_{2*}' = x_2. \tag{4}$$

The respective contribution of the isolated critical point of the first kind $\mathbf{x}_*' \in \Omega-\partial\Omega$ into integral (2) can be found by formula[29,30]

$$\mathbf{U}^*(\mathbf{x}) = -\frac{2\pi i}{k_*}\frac{1}{2\pi\mu}\mathbf{f}_*(\mathbf{x},\mathbf{x}_*')[\det\Psi''(\mathbf{x},\mathbf{x}_*')]^{-1/2} \times e^{ik_*\Psi(\mathbf{x},\mathbf{x}_*')} + O(k_*^{-2}). \tag{5}$$

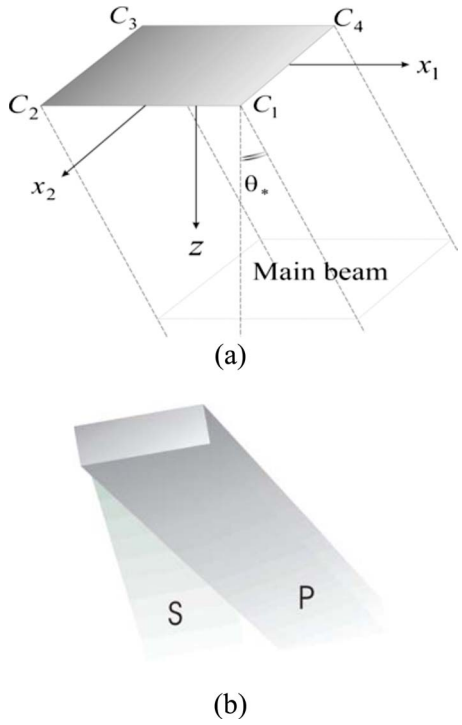

FIG. 3. (Color online) The main beams.

Neglecting the second order terms and substituting the magnitude, phase, and polarization vector into Eq. (5), we obtain

$$\mathbf{U}^*(\mathbf{x}) \cong \mathbf{U}_m^*(\mathbf{x}) = -\frac{ie^{ik_*(x_1\sin\theta_*+z\cos\theta_*)}}{\mu k_*\cos\theta_*} \times A_*(\theta_*)\mathbf{n}_*(\theta_*), \quad |x_1 - z\tan\theta_*| < a_1, \quad |x_2| < a_2, z > 0. \tag{6}$$

This is the half-space response to the normal stress $e^{ik_0x_1\sin\theta_0}$ given on its surface. However, when the critical point lies on the boundary ($\mathbf{x}_*' \in \partial\Omega$), the result halves,[29,30] and it equals zero outside the main beam [see Fig. 3(b)]. Since we deal with the asymptotic approach, this is not a contradiction, but an indication that $\partial\Omega$ is surrounded by a *boundary layer*, whose thickness is comparable with the neglected terms. We describe the boundary layers in Secs. IV–VI. Note that whether applying one dimensional stationary phase method to each one dimensional integral the result coincides with Eq. (6) from the 2D stationary phase method.[30]

Remark 1. The same approach for $\mathbf{U}^*(\mathbf{x})$ is applicable whatever the apodization $\mathbf{f}_*(\mathbf{x},\mathbf{x}_*')$, provided the latter contains no fast oscillating components (or k_*-independent). As in optics, the geometrical region where Eq. (6) applies is called *P*- or *S-main beam*, respectively [see Figs. 3(a) and 3(b)].

At *the critical points of the second kind* $\nabla\Psi(\mathbf{x},\mathbf{x}')$ may be nonzero, but $\nabla\Psi(\mathbf{x},\mathbf{x}')|_{\mathbf{x}'\in\partial\Omega} = \partial_{s'}\Psi(\mathbf{x},\mathbf{x}')|_{\mathbf{x}'\in\partial\Omega} = 0$, where s' is the curvilinear coordinate along $\partial\Omega$. Let us analyze the ribs $x_1' = \mp a_1$ and $x_2' = \mp a_2$ separately. The integral

$$\mathbf{I}_2 \equiv \int_{-a_2}^{a_2} \mathbf{f}_*(\mathbf{x},\mathbf{x}')e^{ik_*\Psi(\mathbf{x},\mathbf{x}')}dx_2' \tag{7}$$

can be evaluated using stationary phase method[29,30] to give

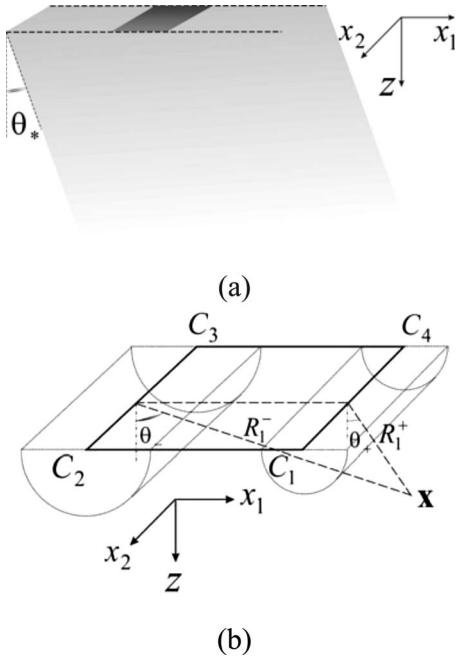

FIG. 4. (a) The side lobes containing the cylindrical edge waves and (b) diagram of waves.

$$\mathbf{I}_2 = \mathbf{I}_2(-a_2) + \mathbf{I}_2(\mathbf{x}'_{2*}) + \mathbf{I}_2(a_2) + O(k_*^{-\infty}), \tag{8}$$

where the contribution of $\mp a_2$ is analyzed below. The contribution $\mathbf{I}_2(\mathbf{x}'_{2*})$ of the "one dimensional" critical point of the first kind $\mathbf{x}'_{2*}=(x'_1,x'_{2*})$, $x'_2=x_2:|x_2|\le a_2$ of the leading asymptotic order has the form

$$\mathbf{I}_2(\mathbf{x}'_{2*}) = \sqrt{2\pi/k_*|\Psi_{22}(\mathbf{x},\mathbf{x}'_{2*})|}\mathbf{f}_*(\mathbf{x},\mathbf{x}'_{2*}) \times e^{ik_*\Psi_*(\mathbf{x},\mathbf{x}'_{2*})+i\pi/4\ \mathrm{sgn}\ \Psi_{22}(\mathbf{x},\mathbf{x}'_{1*})} + O(k_*^{-1}),$$

$$\Psi_{22}(\mathbf{x},\mathbf{x}'_{2*}) = 1/R(\mathbf{x}-\mathbf{x}'_{2*}).$$

Using the partition of unity and integrating by parts, each rib $x'_1=\pm a_1$ contributes to

$$-\frac{1}{2\pi\mu}\int_{-a_1}^{a_1}\mathbf{I}_2(\mathbf{x}'_{2*})dx'_1 \to \frac{\mp 1}{ik_*2\pi\mu}\sqrt{\frac{2\pi}{k_*|\Psi_{22}(\mathbf{x},\mathbf{x}'_{2*})|}} \times\left\{\frac{\mathbf{f}_*(\mathbf{x},\mathbf{x}'_{2*})}{\Psi_1}e^{ik_*(R_1+x'_1\sin\theta_*)+i\pi/4}+O(k_*^{-1/2})\right\},$$

$$R_1 = \sqrt{(x_1-x'_1)^2+z^2}$$

and results in the cylindrical edge wave as the leading order term of ray series

$$\mathbf{U}^*_{\mathrm{cyl}}(\mathbf{x}) = \pm\frac{e^{i3\pi/4}}{\mu\sqrt{2\pi k_*^3}}\frac{\sqrt{R_1^{\pm}}e^{ik_*(R_1^{\pm}\pm a_1\sin\theta_*)}}{R_1^{\pm}\sin\theta_*\pm a_1-x_1} \times A_*(\theta_\pm)\mathbf{n}_*(\theta_\pm), \quad R_1^{\pm}=\sqrt{(x_1\mp a_1)^2+z^2}. \tag{9}$$

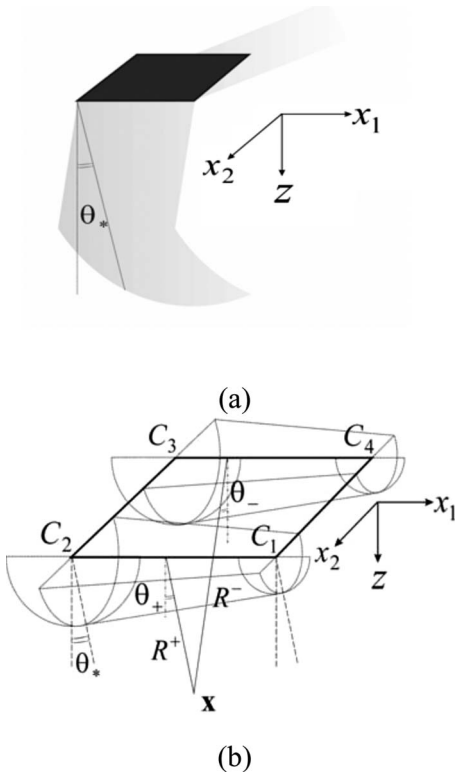

FIG. 5. (a) The side lobes containing the conical edge waves and (b) diagram of waves.

It is so called because its wave front (a surface of constant phase) is a *cylindrical surface*:

$$R_1^{\pm}\pm a_1\sin\theta_* \equiv \sqrt{(x_1\mp a_1)^2+z^2}\pm a_1\sin\theta_* = \mathrm{const}. \tag{10}$$

Thus, the half-layer $z>0$, $|x_2|\le a_2$ supports the *cylindrical edge waves* (9) from the ribs C_1C_4 and C_2C_3, each observation point inside the half-layer is reached by rays emanating from the point-source $x'_1=\pm a_1$, $x'_2=x_2$ [see Figs. 4(a) and 4(b)]. Above, $R_1^{\pm}$ is the distance between the source and observation point, and $\theta_\pm$ is the angle between $R_1^{\pm}$ and z-axis. Changing the order of integration in Eq. (2) we similarly obtain

$$\mathbf{I}_1 \equiv \int_{-a_1}^{a_1}\mathbf{f}_*(\mathbf{x},\mathbf{x}')e^{ik_*\Psi(\mathbf{x},\mathbf{x}')}dx'_1 = \mathbf{I}_1(-a_1)+\mathbf{I}_1(\mathbf{x}'_{1*}) + \mathbf{I}_1(a_1)+O(k_*^{-\infty}), \tag{11}$$

where the contribution $\mathbf{I}_1(\mathbf{x}'_{1*})$ of the critical point of the first kind $\mathbf{x}'_{1*}=(x'_{1*},x_2)$, $x'_{1*}=x_1-R(\mathbf{x}-\mathbf{x}'_{1*})\sin\theta_*$ is

$$\mathbf{I}_1(\mathbf{x}'_{1*}) = \sqrt{2\pi/k_*|\Psi_{11}(\mathbf{x},\mathbf{x}'_{1*})|}\{\mathbf{f}_*(\mathbf{x},\mathbf{x}'_{1*}) \times e^{ik_*\Psi_*(\mathbf{x},\mathbf{x}'_{1*})+i\pi/4\ \mathrm{sgn}\ \Psi_{11}(\mathbf{x},\mathbf{x}'_{1*})}+O(k_*^{-1})\},$$

$$\Psi_{11}(\mathbf{x},\mathbf{x}'_{1*}) = R^{-1}(\mathbf{x}-\mathbf{x}'_{1*})\cos^2\theta_*,$$

$$-\frac{1}{2\pi\mu}\int_{-a_2}^{a_2}\mathbf{I}_1(\mathbf{x}'_{1*})dx'_2$$

$$\to \mp\frac{1}{ik_*2\pi\mu}\sqrt{\frac{2\pi}{k_*|\Psi_{11}(\mathbf{x},\mathbf{x}'_{2*})|}}$$

$$\times\left\{\frac{\mathbf{f}_*(\mathbf{x},\mathbf{x}'_{2*})}{\Psi_2}e^{ik_*(R\cos^2\theta_*+x'_{1*}\sin\theta_*)+i\pi/4}+O(k_*^{-1/2})\right\}.$$

The leading term of the associated ray asymptotics is a *conical wave*

$$\mathbf{U}^*_{\mathrm{con}}(\mathbf{x})=\pm\frac{e^{i3\pi/4}}{\mu\sqrt{2\pi k_*^3\cos^3\theta_*}}\frac{\sqrt{R_2^{\pm}}}{\pm a_2-x_2}$$

$$\times e^{ik_*(R_2^{\pm}\cos\theta_*+x_1\sin\theta_*)}A_*(\theta_\pm)\mathbf{n}_*(\theta_\pm), \tag{12}$$

$$R^{\pm}=R|_{x'_2=\pm a_2}=\sqrt{(x_1-x'_{1*})^2+(x_2\mp a_2)^2+z^2}$$

$$=\sqrt{(R^{\pm}\sin\theta_*)^2+(R_2^{\pm})^2},\quad R_2^{\pm}=\sqrt{(x_2\mp a_2)^2+z^2}, \tag{13}$$

which is so called due to its wave front satisfying the equation of a *cone*

$$R_2^{\pm}\cos\theta_*+x_1\sin\theta_*=\mathrm{const}\to\sqrt{(x_2\mp a_2)^2+z^2}$$

$$+x_1\tan\theta_*=\mathrm{const}. \tag{14}$$

Thus, the region $z>0$ between two cones $x_1\mp a_1=R^{\pm}\sin\theta_*$ supports conical waves generated by C_1C_2 and C_3C_4. Each observation point inside these side lobes is reached by two rays from respective point-sources $x'_{1*}=x_1-R^{\pm}\sin\theta_*=x_1-R_2^{\pm}\tan\theta_*$, $x'_2=\pm a_2$ [see Figs. 5(a) and 5(b)]. Above, $R^{\pm}$ and $\theta_\pm$ denote the distance between the source and the observation point, and the angle between $R^{\pm}$ and z-axis, respectively. Clearly, when an observation point is close to the main beam lateral surface, i.e., $\pm a_1-x_1+R_1^{\pm}\sin\theta^*_{P,S}=0$ or $\pm a_2-x_2=0$, the expressions (9) and (12) are singular. Hence, the asymptotics (9) and (12) are valid everywhere except the vicinity of these surfaces where the boundary layer should be introduced.

Remark 2. When describing the edge waves, we integrated first by dx'_1 and then by dx'_2. It is easy to check that reversing the order gives the same result.

To obtain the corner waves let us apply the partition of unity to single out the contribution $\mathbf{I}_1(\pm a_1)$ to $x_1=\pm a_1$ in Eq. (11) and then do the same to $x_2=\pm a_2$ while integrating by dx'_2:

$$\mathbf{I}_1(\pm a_1)\cong\pm[ik_*\partial_{x'_1}\Psi(\mathbf{x},\mathbf{x}')]^{-1}\mathbf{f}_*(\mathbf{x},\mathbf{x}')e^{ik_*\Psi(\mathbf{x},\mathbf{x}')}|_{x'_1=\pm a_1}$$

$$+O(k_*^{-2}),$$

$$-\frac{1}{2\pi\mu}\int_{-a_2}^{a_2}\mathbf{I}_1(\pm a_1)dx'_2$$

$$\to\pm\pm\frac{1}{2\pi\mu}[k_*^2\partial_{x'_1}\Psi(\mathbf{x},\mathbf{x}')\partial_{x'_2}\Psi(\mathbf{x},\mathbf{x}')]^{-1}$$

$$\times\mathbf{f}_*(\mathbf{x},\mathbf{x}')e^{ik_*\Psi(\mathbf{x},\mathbf{x}')}|_{x'_1=\pm a_1,x'_2=\pm a_2}+O(k_*^{-2}).$$

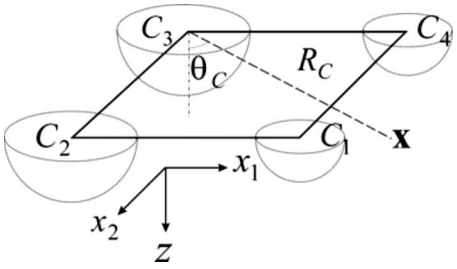

FIG. 6. The semi-spherical corner waves.

Hence, leading term of this contribution for C_{1-4}: $C(\pm a_1,\pm a_2)$ is

$$\mathbf{U}^*_c(\mathbf{x})=\frac{\mathrm{sgn}(x_{1C}x_{2C})}{2\pi\mu k_*^2}\frac{R_C}{(x_{2C}-x_2)(R_C\sin\theta_*+x_{1C}-x_1)}$$

$$\times e^{ik_*\Psi_C}A_*(\theta_C)\mathbf{n}_*(\theta_C),$$

$$R_C=\sqrt{r_C^2+z^2},\quad r_C=\sqrt{(x_1-x_{1C})^2+(x_2-x_{2C})^2}, \tag{15}$$

$$\Psi_C=R_C\pm x_{1C}\sin\theta_*,$$

whose wave front $\Psi_0=\mathrm{const}$ is a *semi-sphere* (see Fig. 6):

$$R_C=\mathrm{const}\mp a_1\sin\theta_*. \tag{16}$$

Again, when an observation point lies simultaneously on the boundary of main beam on the semi-sphere

$$\pm a_2-x_2=0,\quad R_C\sin\theta_*\pm a_1-x_1=0,$$

the formula (15) is singular and hence is no longer valid. Special boundary layer should be introduced in the vicinity of these singular points.

IV. BOUNDARY LAYERS

Above, we discussed the geometrical regions, which support a sum of finite number of waves, each described by ray series, i.e., the asymptotic series in inverse powers of the dimensionless wave number, with the coefficients depending on the observation point and the phase function (eikonal).[31] Such representations are not applicable inside the boundary layers[32,33] which are transition zones surrounding surfaces of irregularity along which rays of different nature meet. However, the fields inside boundary layers can be described by asymptotic series involving special functions (rather than just inverse powers), and the size and shape of a boundary layer are determined by the condition that the phase difference between coalescing rays is small. In our case this means that the critical point of the first kind from Ω tends to the lobe $x'_1=\pm a_1$ or $x'_2=\pm a_2$, i.e., its position is close to the critical point of the second kind. Constructing the respective boundary layer requires revising the convolution integral (2).

The penumbras associated with C_1C_2 and C_3C_4: Let us isolate the contribution $\mathbf{I}_1(\mathbf{x}'_{1*})$, $\mathbf{x}'_{1*}=(x'_{1*},x'_2)$, $x'_{1*}=x_1-R(\mathbf{x}-\mathbf{x}'_{1*})\sin\theta_*$ to the integral (11). Using the partition of unity, the contributions of vicinities $V_\varepsilon^-\equiv[-a_2,\varepsilon-a_2]$ and $V_\varepsilon^+\equiv[a_2-\varepsilon,a_2]$ are as follows:

$$\int_{-a_2}^{a_2} \mathbf{I}_1(\mathbf{x}'_{1*})dx'_2 \to e^{i\pi/4}\int_{V_\varepsilon^\pm} \sqrt{\frac{2\pi}{k_*|\Psi_{11}(\mathbf{x},\mathbf{x}'_{1*})|}} \times\{\mathbf{f}_*(\mathbf{x},\mathbf{x}'_{1*})e^{ik_*\Psi(\mathbf{x},\mathbf{x}'_{1*})} + O(k_*^{-1})\}dx'_2.$$

Introducing the main beam phase Ψ_m, phase difference, and the new variable we obtain

$$\Psi_m = z\cos\theta_* + x_1\sin\theta_* = \Psi(\mathbf{x},\mathbf{x}'_{1*})|_{x_2=x'_2},\quad \Psi(\mathbf{x},\mathbf{x}'_{1*}) - \Psi_m = (R_2^\pm - z)\cos\theta_* \geq 0,$$

$$s(x'_2) \equiv \sqrt{k_*(R_2^\pm - z)\cos\theta_*}\,\mathrm{sgn}(x'_2 - x_2),$$

$$dx'_2 = \sqrt{\frac{R_2^\pm - z}{k_*\cos\theta_*}}\frac{2R_2^\pm}{|x'_2 - x_2|}ds \to \int_{V_\varepsilon^\pm}\cdots dx'_2 = \mp\int_0^{s_\varepsilon}\sqrt{\frac{(R_2^\pm - z)R_2^\pm}{k_*}}\frac{2}{|x'_2 - x_2|}A_*(\mathbf{x}-\mathbf{x}'_{1*})\mathbf{n}_*(\mathbf{x}-\mathbf{x}'_{1*})e^{is^2}ds.$$

The assumption $|x'_2 - x_2| \ll z$ and $x'_2 \approx \pm a_2$ yields

$$\sqrt{\frac{(R_2^\pm - z)R_2^\pm}{k_*}}\frac{2}{|x'_2 - x_2|} = \frac{2}{\sqrt{k_*}}\left(1+\frac{z}{R_2}\right)^{-1/2} = \frac{2}{\sqrt{k_*}}\left\{\frac{1}{\sqrt{2}} + \frac{1}{2\sqrt{2}}\left(\frac{x'_2 - x_2}{2z}\right)^2 + O\left(\frac{x'_2 - x_2}{2z}\right)^4\right\},$$

$$\mathbf{U}^*(\mathbf{x}) \cong -\frac{ie^{ik_*\Psi_0}}{\mu k_*\cos\theta_*}A_*(\mathbf{x}-\mathbf{x}_{\pm 2})\mathbf{n}_*(\mathbf{x}-\mathbf{x}_{\pm 2}) \times\frac{e^{-i\pi/4}}{\sqrt{\pi}}\int_{s_1}^{s_2} e^{is^2}ds,$$

$\mathbf{x}_{\pm 2} \equiv (x'_{1*}, \pm a_2)$. As $s_1 \to -\infty$, $k_* \to +\infty$ (for example, at $|x_2| \leq a_2$) we may conclude that

$$\frac{e^{-i\pi/4}}{\sqrt{\pi}}\int_{s_1}^{s_2} e^{is^2}ds \approx \frac{e^{-i\pi/4}}{\sqrt{\pi}}\int_{-\infty}^{s_2} e^{is^2}ds,$$

$$F(\xi) \equiv \frac{e^{-i\pi/4}}{\sqrt{\pi}}\int_{-\infty}^{\xi} e^{is^2}ds.$$

Then the leading term of penumbral asymptotics associated with $x'_2 \approx \pm a_2$ is expressed via *Fresnel integral* $F(\xi)$,

$$\mathbf{U}^*(\mathbf{x}) \cong \mathbf{U}_m^*(\mathbf{x})F(\sqrt{k_*(R_2^\pm - z)\cos\theta_*}\,\mathrm{sgn}(\pm a_2 - x_2)). \tag{17}$$

This boundary layer is so called by the analogy with a light-shadow zone in optics. Its shape is determined by the condition that the phase difference between the main beam and the edge wave equals π so that

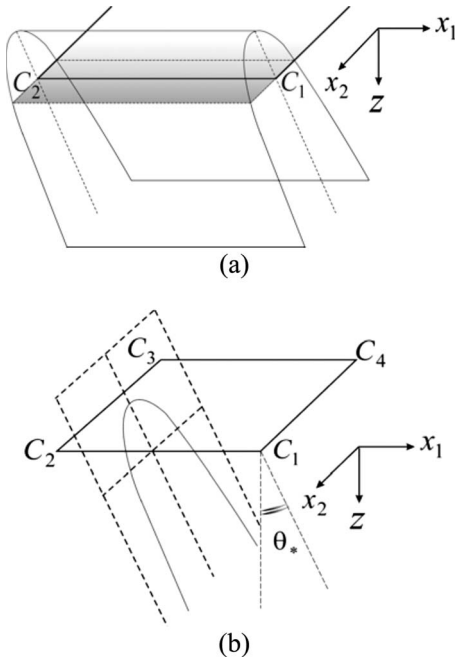

FIG. 7. (a) The penumbra associated with the edge C_1C_2 and (b) characteristic parabola.

$$\sqrt{k_*(R_2^\pm - z)\cos\theta_*}\,\mathrm{sgn}(\pm a_2 - x_2) = \sqrt{\pi} \to z = (x_2 \pm a_2)^2/2L_* - L_*/2, \tag{18}$$

where $L_* = \pi/k_*\cos\theta_*$ and $x'_{1*} = x_1 - R_2^\pm\tan\theta_*$. Hence, each of the above penumbras is a parabolic cylinder, declined by the angle θ_* with respect to z-axis [see Figs. 7(a) and 7(b)]. The larger the frequency is, the thinner these penumbras are.

The penumbras associated with C_2C_3 and C_4C_1: Similarly, consider the contribution $\mathbf{I}_2(\mathbf{x}'_{2*})$, $\mathbf{x}'_{2*} = (x'_1, x_2)$ to the integral (7) and analyze small vicinities $V_\varepsilon^- \equiv [-a_1, \varepsilon - a_1]$ and $V_\varepsilon^+ \equiv [a_1, a_1 - \varepsilon]$ in the integral

$$\int_{-a_1}^{a_1}\mathbf{I}_2(\mathbf{x}'_{2*})dx'_1 \to e^{i\pi/4}\int_{V_\varepsilon^\pm}\sqrt{\frac{2\pi}{k_*|\Psi_{22}(\mathbf{x},\mathbf{x}'_{2*})|}} \times\{\mathbf{f}_*(\mathbf{x},\mathbf{x}'_{2*})e^{ik_*\Psi(\mathbf{x},\mathbf{x}'_{2*})+i\pi/4} + O(k_*^{-1})\}dx'_1.$$

Introducing the new variables y and s we can write

$$y = x'_1 - x_1 + R_1\sin\theta_*,$$

$$R_1 = \frac{z^2 + y^2}{y\sin\theta_* + \sqrt{y^2 + z^2\cos^2\theta_*}},$$

$$R_{10} = R_1|_{y=0} = \frac{z}{\cos\theta_*},$$

$$\Psi(\mathbf{x},\mathbf{x}'_{2*}) - \Psi_m = \frac{y^2}{\sqrt{y^2 + z^2\cos^2\theta_*} + z\cos\theta_*} \sim \frac{y^2}{2z\cos\theta_*} \quad \text{as } |y| \ll z,$$

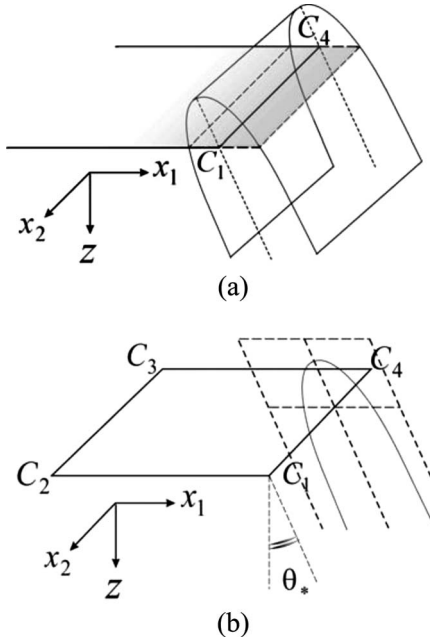

FIG. 8. (a) The penumbra associated with the edge C_4C_1 and (b) characteristic curve.

$$s = \sqrt{k_*(\Psi - \Psi_0)} = \sqrt{\frac{k_*}{\sqrt{y^2 + z^2\cos^2\theta_* + z\cos\theta_*}}}\, y\ \mathrm{sgn}\ y$$

$$\cong \sqrt{\frac{k_*}{2z\cos\theta_*}}\, y\ \mathrm{sgn}\ y,$$

$$ds = \frac{k_* y}{2sR_1}dx_1', \quad dx' = \frac{2sR_1}{k_* y}ds,$$

$$\mathbf{U}^*(\mathbf{x}) \approx -\frac{ie^{ik_*\Psi_0}}{\rho c_S^2 k_*\cos\theta_*}A_*(\mathbf{x}-\mathbf{x}_{\pm 1})\mathbf{n}_*(\mathbf{x}-\mathbf{x}_{\pm 1}) \times \frac{e^{-i\pi/4}}{\sqrt{\pi}}\int_{s_1}^{s_2} e^{is^2}ds, \quad \mathbf{x}_{\pm 1} \equiv (x_1 - R_1^{\pm}\tan\theta_* \mp a_1, x_2).$$

Simplifying, the leading penumbral term for $x_2 \in [-a_2, a_2]$ and the sides $\pm a_1$ equals

$$\mathbf{U}^*(\mathbf{x}) \approx \mathbf{U}_m^*(\mathbf{x})F(\sqrt{k_*\cos\theta_*(l_*^{\pm} - z)} \times \mathrm{sgn}(\pm a_1 \mp x_1 \pm R_1^{\pm}\sin\theta_*)), \quad (19)$$

$$l_*^{\pm} = \sqrt{(\pm a_1 \mp x_1 \pm R_1^{\pm}\sin\theta_*)^2 + z^2\cos^2\theta_*}/\cos\theta_*. \quad (20)$$

This penumbra differs from previous one and for $x_1' = x_1 - R_1\tan\theta_*$ its shape satisfies the condition that the phase difference between the main beam and the edge wave equals π,

$$\sqrt{k_*\cos\theta_*(l_*^{\pm} - z)}\,\mathrm{sgn}(\pm a_1 \mp x_1 \pm R_1^{\pm}\sin\theta_*) = \sqrt{\pi} \rightarrow l_*^{\pm} - z = \pi/k_*\cos\theta_*, \quad (21)$$

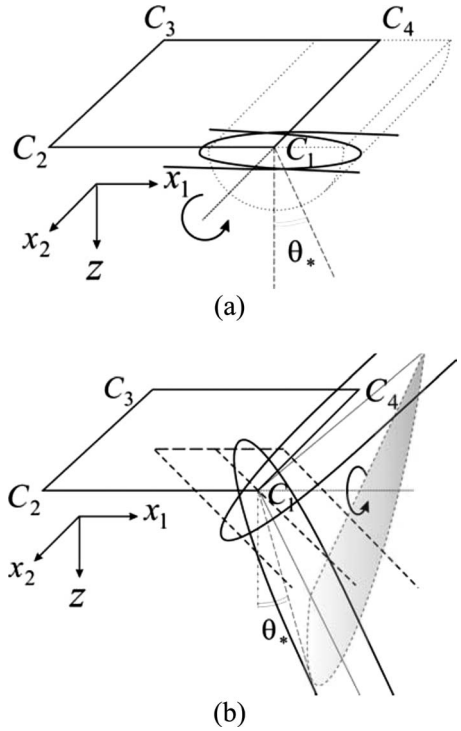

FIG. 9. (a) The edge-corner penumbra associated with C_1C_2 and corner C_1 and (b) the edge-corner penumbra for C_1C_4 and C_1.

$$z = \zeta^2/2L_* - L_*/2, \quad \zeta = (\mp a_1 - x_1 + R_1^{\pm}\sin\theta_*)/\cos\theta_*. \quad (22)$$

In the coordinates ζ, z, Eq. (22) is the equation of parabolic cylinder, but in coordinates x_1, z it is no longer so [see Figs. 8(a) and 8(b)]. When the angle is small (the case $\theta_* = 0$ corresponds to the normal probe) this shape is nearly the parabolic cylinder.

The edge-corner penumbra for C_1C_2 and corner C_1: As we have seen, for the cylindrical edge wave (9) the boundary layer should be introduced as well at $x_2 = \mp a_2$. Let us consider the interaction of boundary layers and suppose that the point-source at C_1C_2 tends to C_1. The contribution of the coalescing stationary point $x_1' = a_1$ to the integral (2) is treated similar to Eqs. (17) and (19). The leading term of ray asymptotics applicable in this *edge-corner penumbra* results in the expression

$$\mathbf{U}^*(\mathbf{x}) \cong \mathbf{U}_m^*(\mathbf{x})F(\sqrt{k_*\cos\theta_*(R_{C_1} - R_1^+)}\,\mathrm{sgn}(a_2 - x_2)), \quad (23)$$

$$R_{C_1} - R_1^+ = \sqrt{(x_1 - a_1)^2 + (x_2 - a_2)^2 + z^2} - \sqrt{(x_1 - a_1)^2 + z^2} \cong z[(x_2 - a_2)^2/2z^2 + O_4], \quad (24)$$

$$R_2^+ - z = \sqrt{(x_2 - a_2)^2 + z^2} - z \cong z[(x_2 - a_2)^2/2z^2 + O_4], \quad R_{C_1} - R_1^+ = R_2^+ - z + O_4, \quad (25)$$

where O_4 is the fourth order quantity with respect to $(x_2 - a_2)/z$. The shape of this boundary layer is determined by the condition that the phase difference between the edge and corner wave equals π,

$$k_* \cos\theta_*(R_{C_1} - R_1^+) = \pi. \tag{26}$$

The surface (26) shown in Fig. 9(a) is obtained by revolving the characteristic parabola in Fig. 7(b) about C_4C_1 in the lower half-space $z \geq 0$.

The edge-corner penumbra for C_4C_1 and corner C_1: By tending the point-source at C_4C_1 to C_1 the consideration of the coalescing stationary points yields

$$\mathbf{U}^*(\mathbf{x}) \cong \mathbf{U}_m^*(\mathbf{x}) F(\sqrt{k_* \cos\theta_*(R_*^+ - R_2^+)}\,\mathrm{sgn}(a_1 - x_1 + R_{C_1}\sin\theta_*)), \tag{27}$$

$$R_*^+ = \sqrt{\left(\frac{x_1 - a_1 - R_{C_1}\sin\theta_*}{\cos\theta_*}\right)^2 + (x_2 - a_2)^2 + z^2}, \tag{28}$$

$$R_*^+ - R_2^+ = z\left[\frac{1}{2}\left(\frac{x_1 - a_1 - R_{C_1}\sin\theta_*}{z\cos\theta_*}\right)^2 + O_4\right] = z\left[\frac{1}{2}\left(\frac{x_1 - a_1 - R_1^+\sin\theta_*}{z\cos\theta_*}\right)^2 + O_4\right], \tag{29}$$

$$l_*^+ - z = z\left[\frac{1}{2}\left(\frac{x_1 - a_1 - R_1^+\sin\theta_*}{z\cos\theta_*}\right)^2 + O_4\right], \quad R_{C_1} - R_1^+ = l_*^+ - z + O_4, \tag{30}$$

where O_4 is the fourth order quantity with respect to the coordinate difference (or difference from the rib to the main beam) from corner to depth ratio. The shape of the edge-corner penumbral layer is determined by the equation [see Fig. 9(b)]

$$k_* \cos\theta_*(R_*^+ - R_2^+) = \pi,$$

and this is a surface of revolution of the characteristic curve in Fig. 8(b) about C_4C_1 at $z \geq 0$. Other edge-corner boundary layers are obtained similar to Eqs. (23)–(30) by changing the coordinates of the respective corner and lobe.

V. THE CORNER BOUNDARY LAYERS

The shape of the penumbras associated with corners $C_1 - C_4$ is again followed from the requirement about the phase difference between the main beam and respective corner ray equals π. Introducing new variables rewrite the integral (2) as follows:

$$\begin{cases} \xi(x_1', x_2') = [x_1' - x_1 + R(\mathbf{x} - \mathbf{x}')\sin\theta_*]/\cos\theta_* \\ \eta(x_2') = x_2' - x_2 \end{cases}, \quad dx_1' dx_2' = [1 + O(\xi/z)^2 + O(\eta/z)^2]d\xi d\eta, \tag{31}$$

$$\mathbf{I} = -\int_{-a_2-x_2}^{a_2-x_2} d\eta \int_{\xi(-a_1)}^{\xi(a_1)} \frac{e^{ik_*\Psi_*}}{\mu k_*} \times \frac{k_*\cos\theta_* e^{ik_*\cos\theta_*(\xi^2+\eta^2)/2z}}{2\pi} \times \frac{A_*(\mathbf{x} - \mathbf{x}')\mathbf{n}_*(\mathbf{x} - \mathbf{x}')}{R(\mathbf{x} - \mathbf{x}')} d\xi. \tag{32}$$

Keeping in mind that an observation point is reached by a corner ray which lies closely to the main beam surface, let us simplify Eq. (32) and single out the main beam component

$$\frac{1}{R(\mathbf{x} - \mathbf{x}')} = \frac{1}{z\cos\theta_*} + O\left(\frac{\xi}{z^2}\right), \quad \frac{A_*(\mathbf{x} - \mathbf{x}')\mathbf{n}_*(\mathbf{x} - \mathbf{x}')}{A_*(\theta_*)\mathbf{n}_*(\theta_*)} = 1 + O\left(\frac{\xi}{z}\right),$$

$$\mathbf{I} \cong \frac{-iH}{\pi}\mathbf{U}_m^*(\mathbf{x}) \int_{-a_2-x_2}^{a_2-x_2} d\eta \int_{\xi(-a_1,x_2')}^{\xi(a_1,x_2')} e^{iH(\xi^2+\eta^2)} d\xi,$$

$$H \equiv \frac{k_*\cos\theta_*}{2z}.$$

For definiteness, consider the corner $C_1(a_1, a_2)$ whose contribution can be isolated by using the partition of unity[29,30] and extend the lower integration limits to $-\infty$,

$$\mathbf{I}_{C_1} \cong \frac{-iH}{\pi}\mathbf{U}_m^*(\mathbf{x}) \int_{-\infty}^{\eta_{C_1}} d\eta \int_{-\infty}^{\xi_{C_1}} e^{iH(\xi^2+\eta^2)} d\xi. \tag{33}$$

The area of integration in ξ, η is subdivided into the parts Ω_1' and Ω_1'' shown in Fig. 10(a). For region Ω_1' we pass to the polar coordinates r', ϕ' and obtain

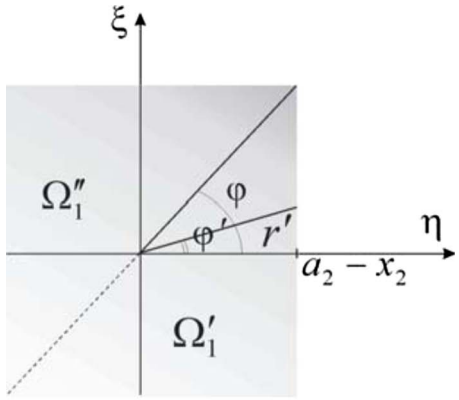
$$r'^2 = (\xi^2 + \eta^2)H, \quad \varphi' = \arg(\xi, \eta), \quad \varphi - \pi < \varphi' \leq \varphi,$$

$$r'(\varphi') = \begin{cases} (a_2 - x_2)\sqrt{H}/\cos\varphi', & -\pi/2 < \varphi' \leq \varphi \\ +\infty, & \varphi - \pi < \varphi' \leq -\pi/2, \end{cases}$$

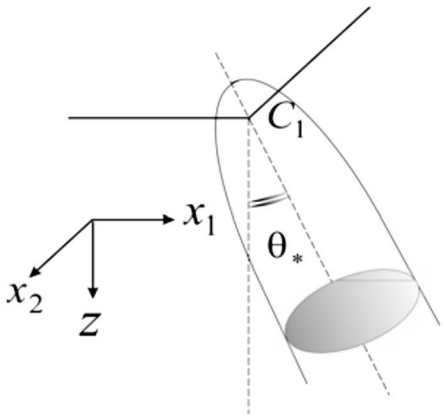
$$\mathbf{I}_{\Omega_1'} \cong -\frac{i\mathbf{U}_m^*(\mathbf{x})}{\pi} \int_{\varphi-\pi}^{\varphi} d\varphi' \int_0^{r'(\varphi')} e^{ir'^2} r' dr' = \mathbf{U}_m^*(\mathbf{x})\left\{\frac{1}{2} - \frac{1}{2\pi}\int_{-\pi/2}^{\varphi} e^{ir'^2} d\varphi'\right\}.$$

For the latter integral we introduce yet another set of variables and deduce

$$\nu'(\varphi') = r'(\varphi')\cos\varphi', \quad \lambda' = -\nu'\tan\varphi', \quad r'^2 = \lambda'^2 + \nu'^2, \quad d\varphi' = \nu' d\lambda'/(\lambda'^2 + \nu'^2),$$



(a)



(b)

FIG. 10. (Color online) (a) The integration region for corner C_1 in coordinates ξ, η and (b) penumbra associated with corner C_1.

$$\mathbf{I}_{\Omega_1'} \cong \mathbf{U}_m^*(\mathbf{x})\left\{\frac{1}{2} - G(-\nu'(\varphi)\tan\varphi, \nu'(\varphi))\right\}, \quad G(x,y) \equiv \frac{y}{2\pi}\int_x^{+\infty} e^{i(x'^2+y^2)^2}\frac{dx'}{x'^2+y^2}.$$

The function $G(x,y)$ is a *special function* called *generalized Fresnel integral*.[34] In the region Ω_1'': $\varphi < \varphi' \le \varphi + \pi$ we similarly obtain ($\varphi_2 = 0$),

$$r'(\varphi') = \begin{cases} \dfrac{\sin(\varphi-\varphi_2)\sqrt{(a_2-x_2)^2+\xi^2}}{\sin(\varphi'-\varphi_2)}, & \varphi < \varphi' \le \varphi_2 + \pi \\ +\infty, & \varphi_2 + \pi < \varphi' \le \varphi + \pi, \end{cases}$$

$$\mathbf{I}_{\Omega_1''} \cong -\frac{i\mathbf{U}_m^*(\mathbf{x})}{\pi}\int_\varphi^{\varphi+\pi} d\varphi' \int_0^{r'(\varphi')} e^{ir'^2} r'\,dr' = \mathbf{U}_m^*(\mathbf{x})\left\{\frac{1}{2} - \frac{1}{2\pi}\int_\varphi^{\varphi_2+\pi} e^{ir'^2} d\varphi'\right\},$$

$$\nu''(\varphi') = r'(\varphi')\sin(\varphi' - \varphi_2),$$

$$\lambda'' = -\nu''\cot(\varphi' - \varphi_2),$$

$$r'^2 = \lambda''^2 + \nu''^2, \quad d\varphi' = \nu'' d\lambda''/(\lambda''^2 + \nu''^2),$$

$$\mathbf{I}_{\Omega_1''} \cong \mathbf{U}_m^*(\mathbf{x})\left\{\frac{1}{2} - G(-\nu''(\varphi)\cot(\varphi-\varphi_2), \nu''(\varphi))\right\}.$$

Adding the above results we obtain

$$\mathbf{I}_{\Omega_1'} + \mathbf{I}_{\Omega_1''} \cong \mathbf{U}_m^*(\mathbf{x})\{1 - G(-\nu'(\varphi)\tan\varphi, \nu'(\varphi)) - G(-\nu''(\varphi)\cot(\varphi-\varphi_2), \nu''(\varphi))\}. \tag{34}$$

Note that the term 1 appears in Eq. (34) only if $\mathbf{x}$ is the inner point and, in fact, this is a Heaviside function. Thus, for C_1 the sum (33) yields

$$\mathbf{U}(\mathbf{x}) \cong \mathbf{U}_m^*(\mathbf{x})\{1_{C_1} - G(-\operatorname{sgn}(a_1 - x_1 + R_{C_1}\sin\theta_*) \times\sqrt{k_*\cos\theta_*(R_*^{\pm} - R_2^+)}, \operatorname{sgn}(a_2 - x_2) \times\sqrt{k_*\cos\theta_*(R_2^+ - z)}) - G(-\operatorname{sgn}(a_2 - x_2) \times\sqrt{k_*\cos\theta_*(R_*^{\pm} - l_*^{\pm})}, \operatorname{sgn}(a_1 - x_1 + R_{C_1}\sin\theta_*) \times\sqrt{k_*\cos\theta_*(l_*^{\pm} - z)})\}, \tag{35}$$

$$1_{C_1} = H(a_1 - x_1 + R_{C_1}\sin\theta_*)H(a_2 - x_2), \tag{36}$$

$$R_*^{\pm} = \sqrt{\left(\frac{\pm a_1 - x_1 + R_{C_1}^*\sin\theta_*}{\cos\theta_*}\right)^2 + (a_2 - x_2)^2 + z^2},$$

$$R_{C_{1,2}} = \sqrt{(a_1 \mp x_1)^2 + (a_2 - x_2)^2 + z^2}. \tag{37}$$

The shape of the boundary layer satisfies the equation

$$k_*\cos\theta_*(R^* - z) = \pi \tag{38}$$

and is a deformed paraboloid of revolution [Fig. 10(b)] whose axis is declined by angle θ_* from the vertical. For the normal transducer this is a straight paraboloid.

For the corner point C_2 we obtain similarly

$$\mathbf{U}(\mathbf{x}) \cong \mathbf{U}_m^*(\mathbf{x})\{1_{C_2} - G(-\operatorname{sgn}(a_1 + x_1 - R_{C_2}\sin\theta_*) \times\sqrt{k_*\cos\theta_*(R_*^{\pm} - R_2^+)}, \operatorname{sgn}(a_2 - x_2) \times\sqrt{k_*\cos\theta_*(R_2^+ - z)}) - G(-\operatorname{sgn}(a_2 - x_2) \times\sqrt{k_*\cos\theta_*(R_*^{\pm} - l_*^{\pm})}, \operatorname{sgn}(a_1 + x_1 - R_{C_1}\sin\theta_*)\sqrt{k_*\cos\theta_*(l_*^{\pm} - z)})\}, \tag{39}$$

$$1_{C_2} = H(a_2 + x_2 - R_{C_1}\sin\theta_*)H(a_2 - x_2). \tag{40}$$

The penumbras associated with C_3 and C_4 are symmetrical to those of corners C_1 and C_2, respectively.

VI. THE SUBCRITICAL AND SUPERCRITICAL INCIDENCE ANGLES

The above approximations represent the field as a sum of explicit *P*- and *S*-components: the plane waves (6), cylindrical and conical edge waves (9)–(12), and corner waves (15), each valid in the respective geometrical region. When these asymptotics become invalid we have to replace them by edge penumbral asymptotics (17)–(19) and edge-corner or

corner penumbral asymptotics (23), (27), (35), and (39). These asymptotics are nonuniform and the maximal asymptotic error is associated with the edge waves. They depend on the angle of incidence θ_0 (Fig. 1) which cannot be close to $\pi/2$ but θ_0 is often *supercritical* with respect to the inspection solid. If it is, all the results for *S -waves remain unchanged* but *no plane or edge conical P*-waves are present. The *edge cylindrical P*-waves (9) and *corner P*-waves (15) remain in place and become nonsingular. The *P-edge-corner penumbra* (23) does not change [see Fig. 9(a)], but *no other P*-penumbras exist.

VII. "EXACT" NUMERICAL SOLUTION

The exact numerical solution in the frequency domain, which can be obtained using double integral Fourier transform, results in the following integral:

$$\begin{bmatrix} U_\alpha \\ U_3 \end{bmatrix}(\mathbf{x}) = \frac{1}{4\pi^2\mu}\int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\begin{bmatrix} is_\alpha f \\ -pf_3 \end{bmatrix}\frac{T_3(\mathbf{s})}{R_0(\mathbf{s})} \times e^{i\mathbf{s}\mathbf{x}_0}ds_1ds_2, \quad \alpha = 1,2,$$

$$\begin{bmatrix} f \\ f_3 \end{bmatrix} = \begin{bmatrix} 2|\mathbf{s}|^2 - k_S^2 & -2pq \\ 2|\mathbf{s}|^2 - k_S^2 & -2|\mathbf{s}|^2 \end{bmatrix}\begin{bmatrix} e^{-pz} \\ e^{-qz} \end{bmatrix},$$

$$\mathbf{s} = (s_1, s_2), \quad \mathbf{x}_0 = (x_1, x_2),$$

$$R_0(\mathbf{s}) = (2|\mathbf{s}|^2 - k_S^2)^2 - 4pq|\mathbf{s}|^2, \quad p = \sqrt{|\mathbf{s}|^2 - k_P^2},$$

$$q = \sqrt{|\mathbf{s}|^2 - k_S^2}, \quad |\mathbf{s}|^2 = s_1^2 + s_2^2,$$

$$T_3(\mathbf{s}) = M(\omega)\int_{-a_2}^{a_2}\int_{-a_1}^{a_1} e^{i(k_0 x_1 \sin\theta_0 - \mathbf{s}\mathbf{x}_0)}dx_1dx_2 = 4M(\omega)\frac{\sin(k_0 \sin\theta_0 - s_1)a_1}{k_0 \sin\theta_0 - s_1}\frac{\sin s_2 a_2}{s_2}.$$

Similar representation based on the double Fourier transform has been obtained previously in Refs. 35 and 36. Due to the rapidly oscillating factors in the integrands, the numerical evaluation of the double integrals is extremely time consuming. In our code we have used special algorithms of the numerical algorithms group (NAG) subroutines.

VIII. SIMULATING THE PULSE TRAINS

The code based on the deduced asymptotics has been tested against the "exact" numerical solution. To model the propagation of pulses, we used the harmonic synthesis to simulate in each moment of time t. The displacement $\mathbf{U}(\mathbf{x},t)$ and particle speed are given by

$$\mathbf{U}(\mathbf{x},t) = \frac{1}{\pi}\mathrm{Re}\int_0^{+\infty} P(\omega)M(\omega)\mathbf{U}(\mathbf{x})e^{-i\omega t}d\omega, \quad \mathbf{V}(\mathbf{x},t) = \partial_t\mathbf{U}(\mathbf{x},t), \tag{41}$$

where the displacement spectrum $\mathbf{U}(\mathbf{x})$ has been obtained above, $P(\omega)$ is the Fourier transform of the load intensity, and $M(\omega)$ is a transfer function modeling the interaction of plastic wedge, fluid layer, and inspection solid. Below, the comparisons are performed for the most complicated case with the subcritical angle and wide-band pulse. The latter is chosen as 1 cycle of $Q\sin(2\pi ft)$ with $Q=500$ N, the carrier frequency $f=3$ MHz, and, consequently, the duration is 0.33 μs so that

$$P(\omega) = Q\int_0^{1/f}\sin(2\pi ft)e^{-i\omega t}dt.$$

It contains not only high but intermediate and low frequencies too. We compare the asymptotic code with the exact numerical code both combined with the fast Fourier transform to evaluate the integral (41). In the asymptotic code the bandwidth is taken to be 0.1–10 MHz, and in the exact one it is extended down to 0 MHz. The model parameters are as follows: in the plastic wedge wave speeds $c_P=2350$, $c_S=1150$ m/s, and mass density $\rho=1060$ kg/m^3; in the inspection solid $c_P=5961$, $c_S=3211$, and $\rho=7800$ (steel); and in the fluid layer of thickness h the wave speed $c=1653$ and mass density $\rho=1049$. The transducer dimensions are $a_1=10$ and $a_2=5$ mm. Typical illustration speed $v_3(t)$ normalized by its maximum value at the point $(0,0,H)$ is displayed in Fig. 11 where $\theta_0=15°$. In Fig. 11(a) $h=10^{-3}$ mm and solid line represents the asymptotics and dots indicate the pure numerical result. In our abbreviations the capital letters M, C, and E indicate the main beam, corner, and edge wave,

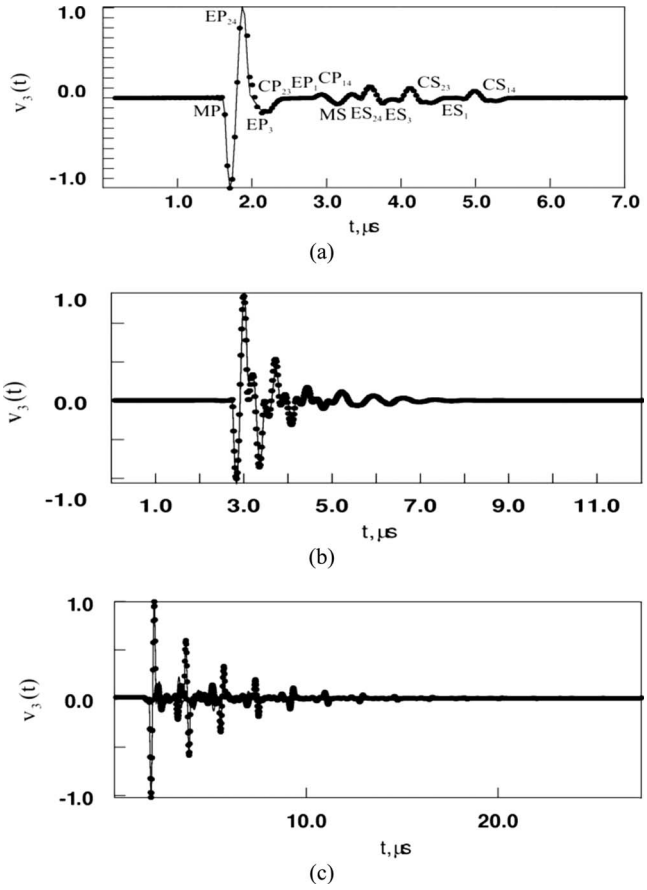


FIG. 11. The pulse trains in the polystyrene wedge/water/steel half-space. The wave arrivals are labeled by issuing corners and edges of contact spot, where the latter are (1) C_1C_4, (2) C_4C_3, (3) C_3C_2, and (4) C_2C_1.

respectively. The second letter P or S corresponds to the wave polarization. Each arrival is labeled according to its Huygens's source so that MP and MS arrivals originate at inner points of the contact spot, CP and CS at corner [the latter are numbered in Fig. 3(a)], and EP and ES at the spot edges. The depth $H=5$ mm is about five *S*-wavelengths. In Fig. 11(b) the fluid thickness is $h=0.3$, and in Fig. 11(c), $h=1.5$ mm. The time of the first arrival shifts with the fluid thickness. The response shown in Figs. 11(b) and 11(c) is more complicated than in Fig. 11(a) because of the multiple refractions, which result in overlapping the wave arrivals. However, the magnitudes of reflected pulses decrease rather fast. Therefore, if the fluid thickness is about 0.25–0.3 of the wavelength (a realistic assumption in many applications in nuclear industry), then multiple refractions do not complicate the result. The figure shows that the agreement between the exact and asymptotic codes is satisfactory, but using the same work station, the asymptotic code is $\approx 0.7\times 10^4$ faster.

IX. CONCLUSION

We have applied the two-tier asymptotic approach to evaluate the radiating near field of contact spot which models the angle beam and fluid coupled probe. The method relies on the high frequency asymptotics and the fast Fourier transform. It has been shown that in the geometrical regions underneath the contact spot the total radiated field contains several *P*- and *S*-components described in the approximate but explicit form. The edge waves are much smaller than waves in main beams. The corner waves are also small, but only these small signals are present inside certain zones. The penumbral zones have been described as well. The formulas elucidate the physics of the problem and give explicit dependence on its parameters. The code based on the deduced asymptotics has been validated against the exact numerical code. It proves to be $\sim 10^4$ times faster and provides a comparable accuracy even for the wide-band realistic pulses when most energy is concentrated at the higher end of the frequency band. Our approach represents an alternative to the Gaussian beam expansion[37] which is very computationally efficient and has been recently generalized to the case of rectangular normal probe.[38–40] However, it is based on the paraxial asymptotics and therefore is suitable only for modeling the main beam at a distance from the source. Our asymptotic approach may describe side lobes and penumbras as well and can be easily interfaced with other models of ultrasonic NDE. Note that we have not modeled the Rayleigh wave. This can be easily done by considering the contribution of the Rayleigh pole but is unnecessary when modeling the probes of consideration.

ACKNOWLEDGMENTS

This work has been carried out under EPSRC Grant Nos. GR/R17683/01 and GR/T22339/01 which are gratefully acknowledged. The authors are also thankful to Dr. Dmitri Gridin for sharing some of his codes and to Dr. Bob Chapman for useful discussions.

(Received 20 May 2009; revised 16 October 2009; accepted 31 December 2009)

Previous studies showed that the surface wave transmission coefficient across a surface-breaking crack in concrete can be used to estimate the crack depth. However, inconsistencies in the surface wave transmission measurements limit the test accuracy and application of this technique. The inconsistencies come from near-field scattering by the crack tip and inconsistent sensor coupling conditions on rough concrete surfaces. This study first investigates the near-field size based on numerical analyses, and then suggests that reliable surface wave transmission should be measured in the far field. Based on the far-field measurement, the relationship between the surface wave transmission ratio and the normalized crack depth (crack depth/wavelength) is obtained. In the experimental study, the air-coupled sensing method is proposed as a solution to the sensor coupling problem. Owing to the non-contact feature, the air-coupled sensing method not only improves testing speed but also enables more consistent signal measurement. The experimental study using air-coupled sensors shows good agreement with the results of numerical simulation and analytic solution. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3298431]

I. INTRODUCTION

The early stage of damage in reinforced concrete structures generally begins with various types of surface cracks. The appearance of cracks on the concrete members may not necessarily imply structural failure; however, it causes many serviceability and durability problems, e.g., stiffness degradation, corrosion of the reinforcement bars, and infiltration of moisture and/or deleterious ingredients. These effects cause further deterioration and lead to the early malfunction of concrete structures. From the viewpoint of civil infrastructure sustainability, it is important to monitor the extent of cracks in reinforced concrete members to evaluate the deterioration level and, if necessary, to make appropriate rehabilitation decision.

Using nondestructive evaluation (NDE) methods to estimate the depth of a surface-breaking crack has been investigated extensively in recent decades. Previous studies showed that the surface (Rayleigh) wave transmission coefficient Tr across a surface-breaking crack can be used to estimate the crack depth. Using ultrasonic transducers, Viktorov (1967) experimentally developed the relationship between the Rayleigh wave transmission coefficient and the normalized crack depth h/λ, i.e., the ratio of crack depth to the wavelength for a surface-breaking crack in a solid. Achenbach and his colleagues (Achenbach *et al.*, 1980; Mendelsohn *et al.*, 1980; Angel and Achenbach, 1984) analytically derived the Tr and h/λ relation based on diffraction and scattering of harmonic incident Rayleigh waves by a surface-breaking crack in far field. Masserey and Mazza (2005) extended the analytical solutions by prior researchers (Achenbach *et al.*, 1980; Mendelsohn *et al.*, 1980) to an arbitrary excitation function and verified that the established Tr and h/λ relation by Achenbach *et al.* (1980) is also valid for arbitrary incident waves. Yew *et al.* (1984) experimentally verified the Tr and h/λ relation for cracks in aluminum specimens, in which the surface waves were generated by dropping a steel ball on the surface of a specimen. For concrete, a heterogeneous but globally isotropic material, the surface wave transmission (SWT) method has been proved sensitive to depth variation in surface-breaking cracks, even for tightly closed and ill-defined cracks (Hevin *et al.*, 1998; Popovics *et al.*, 2000; Song *et al.*, 2003; Shin *et al.*, 2008). Hevin *et al.* (1998) obtained the transmission ratio of a surface wave in the frequency domain using boundary element analysis, and proposed the cut-off frequency ($h/\lambda=0.3$) method to estimate a crack depth. Popovics *et al.* (2000) and Song *et al.* (2003) obtained the Tr and h/λ relation based on experimental study in laboratory. They found that the relationship is not affected by the width of the crack opening and the shape of crack tips. Figure 1 shows the surface wave transmission coefficient versus normalized crack depth curves developed by these researchers. Overall, these curves show a similar trend that Tr decreases with increasing h/λ, but differences between the curves are also obvious. For example, at Tr=0.6, the crack depths h/λ given by these four curves can vary from 0.19 to 0.33. To successfully apply the SWT method, a reliable Tr versus h/λ curve should be determined first. In this study, the authors attempted to explain the discrepancies among these curves proposed by the previous researchers. Then based on the conclusions, we proposed a practical and reliable surface wave transmission method for evaluating the crack depth.

The discrepancies in previous research may be explained by the near-scattering effects of surface waves due to inter-

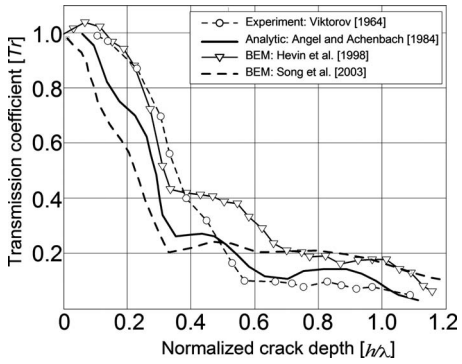

FIG. 1. Surface wave transmission coefficient versus normalized crack depth from previous literature.

action with the surface-breaking crack. Yew *et al.* (1984) observed that the signals measured in the near crack field were very complex due to the interference between surface waves and the bulk waves in the vicinity of a surface-breaking crack. Blackshire and Sathish (2002) investigated the near-field effect using a laser interferometer for a crack with $h/\lambda \gg 1$. They found that the signal amplitude at the crack location doubled the amplitude of the incident Rayleigh wave. The signal enhancement showed oscillatory variation in the vicinity of a surface-breaking crack and converged to a constant value when the measurement location is at a sufficiently far distance from the crack. Jian *et al.* (2007) studied the near-field scattering of the Rayleigh wave using numerical simulations [finite element method (FEM)]. In that investigation, they explained that the signal enhancement was mainly due to the interference effect of bulk waves (i.e., mode converted *P*- and *S*-waves in front of the crack, and bulk waves generated from the crack tip) and direct contribution of incident surface waves. Therefore, the surface wave transmission measurements will be affected by the near-field effect when the sensors are too close to the crack. In practice, however, the sensors cannot be placed too far from the crack (in true far field) due to dimension limit of the test specimen. This study investigated near-field effect variation with the sensor-to-crack spacing and proposed an approximate far-field sensor arrangement guideline.

In experiments, Achenbach *et al.* (1992) proposed a self-calibrating technique to reduce the experimental variability in surface wave measurement. The surface wave transmission ratios were measured from two opposite directions and averaged (the specific procedures are shown in the experimental section of this paper). This setup can eliminate effects of source variation and the coupling difference between two sensors, based on the assumption that coupling of the sensors during tests remains consistent (Popovics *et al.*, 2000). However, temporary sensor mounting methods, such as wax, adhesive, and magnetic mounts, will induce a low resonant frequency (usually below 10 kHz) which depends on the mounting stiffness of the contact sensors (e.g., accelerometers). The mounting resonant response affects the repeatability of tests. Poor signal consistency has been noticed in low frequency range by the authors and other researchers (Hevin *et al.*, 1998). The errors caused by this mounting resonance cannot be eliminated by the self-calibrating technique. On the other hand, permanent mounting cannot meet the requirement of rapid NDT tests and is difficult to apply to concrete. This study proposed a solution to this problem by using non-contact air-coupled sensors to improve test accuracy and efficiency.

Non-contact ultrasonic sensing techniques for concrete include air-coupled sensing and laser ultrasonic techniques. The laser technique has been shown effective to characterize Rayleigh wave attenuation in cement-based materials (Jacobs and Owino, 2000). However, the application of laser ultrasonic technique is still very limited in field testing due to expensive equipment and low reflection from rough surface of concrete. Air-coupled sensors have been successfully used to measure leaky surface waves in concrete by Zhu and Popovics (2005). Compared to contact sensors, the air-coupled sensors have the following benefits: (i) the non-contact sensing technique eliminates sensor coupling problems and thus gives more consistent measurement results; (ii) the non-contact feature enables rapid scanning of large civil engineering structures. To improve signal quality and test efficiency, this study combines the air-coupled sensing with the self-calibrating setup in surface wave transmission measurements.

This study first uses numerical simulations to investigate the parameters affecting surface wave transmission measurements, which includes the depth of crack h, impact duration of the source, and locations of sensors. An approximate far-field size is proposed. The Tr and h/λ relationship, based on measurements in the far field, is obtained. Then a simplified algorithm to calculate surface wave transmission coefficient is proposed in Sec. II E. In the experimental study, surface wave transmissions were measured from a series of notch-typed cracks in a concrete slab using air-coupled sensors. The experimental results validate the numerical results and show the promising application of air-coupled sensors.

II. NUMERICAL SIMULATION

A. FEM

The FEM was used to simulate the propagation behavior and near-scattering of surface waves caused by a surface-breaking crack in concrete. To save computational cost, a two-dimensional (2D) model was developed using rectangular quadratic axisymmetric elements (CAX4) in the commercial program (ABAQUS Inc., 2007). The validity of the model has been verified by Kim and Kwak (2008) to investigate properties of concrete using surface waves generated by a point impact source.

The model mesh size l_e and the time increment Δt for numerical integration procedure were carefully determined based on the wave velocity and frequency content (Ihlenburg, 1998). The mesh size was designed as 5 mm so that at least ten elements can participate to express the minimum wavelength λ_{min} in this study (Alleyne and Cawley, 1991). In this study, the λ_{min} for shear waves in concrete at $f_{max}=50$ kHz is about 50 mm. The maximum time increment Δt for integration was determined as 1 μs, which is smaller than the characteristic time τ ($\tau=l_e/V_p$, where V_p is *P* wave velocity of concrete). Thus, a disturbance cannot propagate

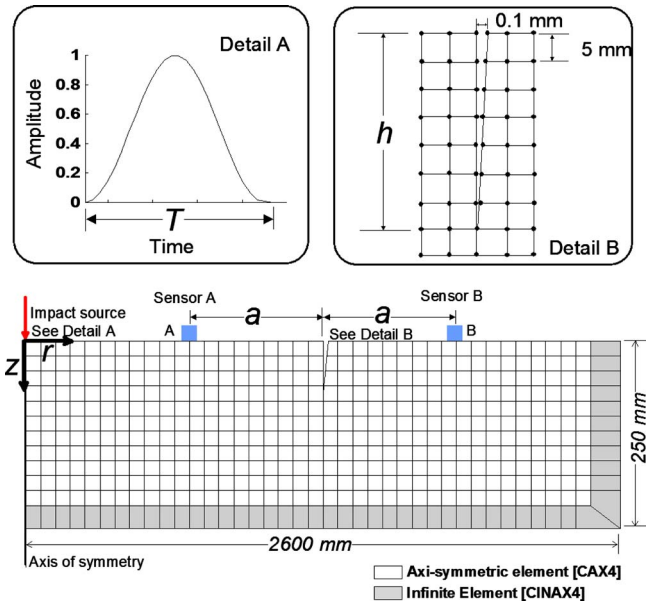

FIG. 2. (Color online) Finite element model for elastodynamic transient analysis in a solid half-space.

through a grid size during one time step. The finite element model is shown in Fig. 2. Sixteen models were analyzed for crack depth h ranging from 0 to 150 mm in a 10 mm step. To reduce wave reflections from boundaries, absorption boundary (CINAX4) elements were applied. The material properties are Young's modulus of 33 630 MPa, Poisson's ratio of 0.22, and mass density of 2400 kg/m^3. The corresponding velocities of P-, S-, and surface waves are 4050, 2420, and 2215 m/s, respectively. These material properties were chosen to simulate normal concrete.

A transient impact point source was applied on free-surface of the half-space at the axis of symmetry (i.e., $r=0$). The force function of the source is

$$f(t) = \begin{cases} \sin^2(\pi t/T), & 0 \le t \le T \\ 0, & t > T, \end{cases} \quad (1)$$

where T is the duration of impact. Note that the quadratic force function was selected to reduce Gibbs effect on FEM analysis (Kim and Kwak, 2008). The impact source is 1300 mm from the crack opening on the surface. To study the near-field effect caused by the crack tip scattering, various sensor locations on the surface of the concrete were investigated.

B. Near-field scattering of surface waves due to a surface-breaking crack

The size of near-scattering field around a crack depends on the crack depth and wavelength of the incident surface waves. Six numerical models, including two crack depths h =10 and 70 mm and four impact duration time T=40, 80 and 120 μs, were analyzed. These models correspond to six different h/λ of 0.12, 0.81, 0.06, 0.41, 0.04, and 0.27. Figure 3 shows the B-scan images of vertical velocity responses on the solid surface from the six models.

When h is much smaller than λ, e.g., h/λ=0.12 in Fig. 3(a), the dominant wave components are the reflected surface

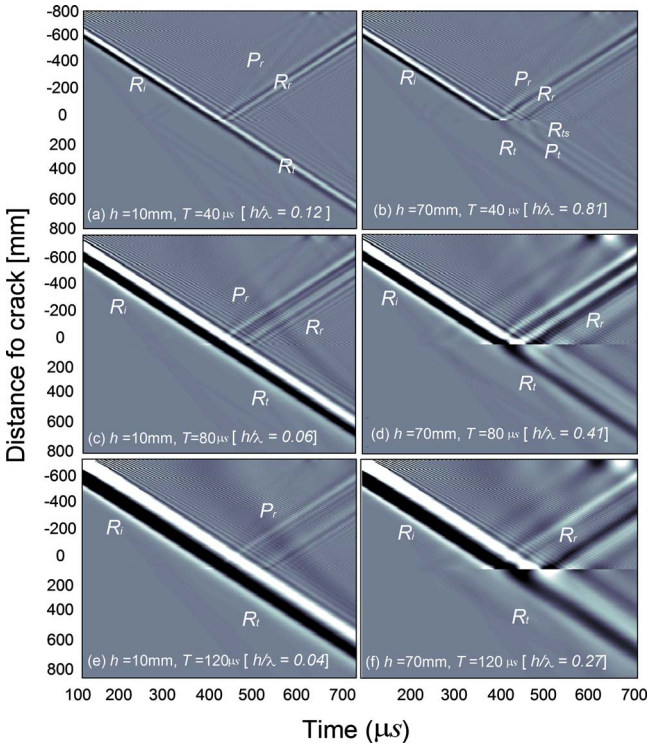

FIG. 3. (Color online) B-scan images of wave propagating on solid models with various h/λ: (a) 0.12, (b) 0.81, (c) 0.06, (d) 0.41, (d) 0.04, and (e) 0.27. (a)–(f) represent six models with two crack depths h=10 mm [(a), (c), and (e)] and 70 mm [(b), (d), and (f)], and three source duration times T =40 μs [(a), and (b)], 80 μs [(c), and (d)], and 120 μs [(e) and (f)].

waves (R_r) and the transmitted surface waves (R_t) after the incident waves (R_i) interact with the crack. The low frequency components of the surface waves can transmit through the crack, while most of high frequency components are reflected back by the crack. On the other hand, when $h/\lambda \sim 1.0$ (deep crack), most portions of the incident waves are reflected by the crack, as shown in Fig. 3(b).

In Figs. 3(a) and 3(b), the mode converted P-waves with a velocity of approximately 4000 m/s (P_r) are observed along with R_r. However, when the impact duration T increases to 80 and 120 μs, as shown in Figs. 3(c)–3(f), the mode converted bulk waves are not distinguishable from surface waves. Interferences between the incident and reflected surface waves are observed in the near region of the crack, as shown in Figs. 3(a) and 3(b). In addition to the reflected and transmitted surface waves, mode converted bulk waves and surface-skimming waves are generated by crack tip scattering.

C. Signal enhancement in the near field

Interaction between the mode converted waves (bulk waves, and multi-reflected waves) and the incident surface waves induces signal enhancement in the forward and backward scattering fields. This phenomenon has been noticed by Jian *et al.* (2007); however, the affected range (near-field size) was not studied in detail. In this paper, the authors present the signal enhancement around a crack and affecting parameters. For this purpose, the amplification coefficient (APC) is defined as the peak amplitude ratio between the

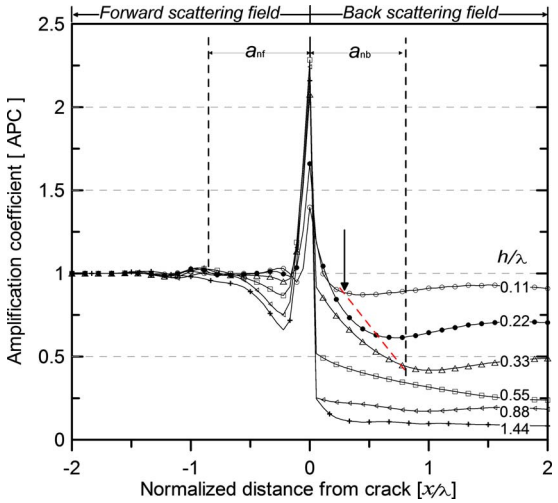

FIG. 4. (Color online) APC varies with the normalized distance from crack (x/λ) for different h/λ.

vertical displacements obtained on the cracked model (U_{zi}) and that on the crack free model (U_{z0}) as follows:

$$\mathrm{APC}(x/\lambda) = \frac{U_{zi}(x/\lambda)}{U_{z0}(x/\lambda)}. \tag{2}$$

APC was calculated for models of various impact durations T of 40–140 μs and crack depths h of 0~150 mm. Analysis based on the wide range of T and h shows that the APC depends on the distance from the crack x, the crack depth h, and the wavelength λ. Figure 4 shows amplification coefficient curves versus the normalized distance x/λ from the crack opening for various normalized crack depths (h/λ). In the backward scattering field, APC curves show very small oscillation (1%) when x is larger than 0.2λ. In the forward scattering field, APC curves decrease sharply from the upper peak at the location of the crack and then gradually reach a constant value with increasing x/λ. This constant value is the surface wave transmission coefficient in the far field.

Based on the results shown in Fig. 4, in the range of $h/\lambda = 0 \sim 1/3$, the approximate near-field size a_n measured from the crack opening can be expressed as

$$a_n/\lambda = 1.8h/\lambda + 0.1 \quad \text{for} \quad 0 \le h/\lambda \le 1/3. \tag{3}$$

Cheng and Achenbach (1996) suggested that $x/\lambda > 5$ can be approximately regarded as in the far field. However, this far-field requirement is difficult to satisfy in experiments due to the specimen size limit. Equation (3) is a less strict criterion, which provides a guideline to avoid significant signal enhancement. Surface wave transmission based on this criterion is slightly different from the curve built on far-field analysis (Angel and Achenbach, 1984), which will be shown in the following Sec. II D.

D. Calculation of transmission coefficient

The surface wave transmission function across a surface-breaking crack is defined as

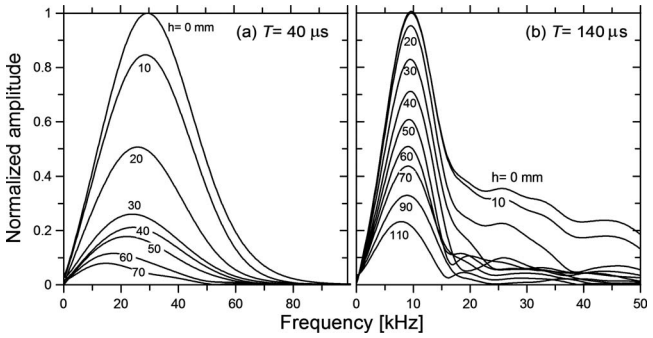

FIG. 5. Frequency spectra of windowed signals for various crack depths. The impact source duration times are (a) 40 μs and (b) 140 μs.

$$\mathrm{Tr}(f,h) = V_b(f,h)/V_a(f,h), \tag{4}$$

where Tr is the transmission coefficient in function of frequency and crack depth, and V_a and V_b are the Fourier transforms of the time domain signals measured at locations of A and B, respectively (Fig. 2). Sensors A and B are located in the far field based on the criterion in Eq. (3). To eliminate geometric attenuation effects, the transmission coefficient $\mathrm{Tr}(f,h)$ is normalized by the value obtained from a crack free model $\mathrm{Tr}(f,0)$.

Figure 5 shows the signal spectra $V_b(f,h)$ corresponding to impact source durations T of 40 and 140 μs, respectively, for crack depths h varying from 0 to 150 mm. A window function (a rectangular window) of three times of the impact duration $(3T)$ is applied to time domain signals to extract the transmitted surface wave signals. The figure shows that the center frequency f_c, the maximum amplitude, and spectral energy (area under the spectral curve) of the *transmitted surface waves* decrease with increasing crack depth h.

Figure 6 shows the normalized transmission coefficient Tr_n versus h/λ relationship when sensors are located at 650 mm $(\sim 5\lambda)$ from the crack opening. The sensors are in far-field region, according to Cheng and Achenbach (1996). The data in Fig. 6 were obtained from models with $T=60$ μs (center frequency of 17 kHz) and h from 0 to 100 mm. To investigate the effect of Poisson's ratio υ, transmission curves for υ of 0.2 and 0.3 were calculated. The results are shown as lines with open squares and open circles in Fig. 6,

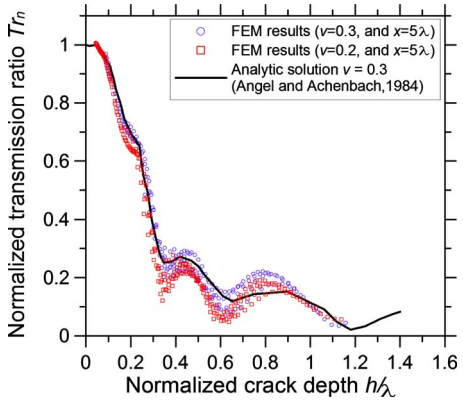

FIG. 6. (Color online) Normalized transmission coefficient versus normalized crack depth relation based on FE models and the analytic solution in far-field regions.

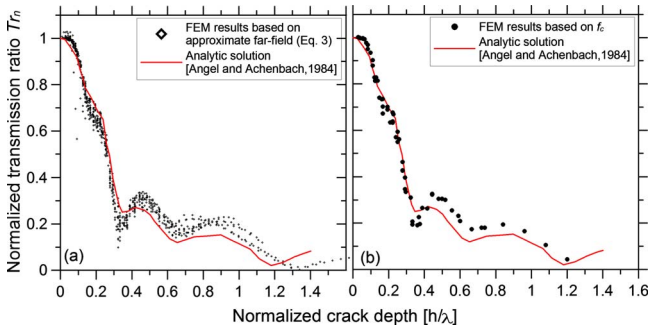

FIG. 7. (Color online) Normalized transmission coefficient versus normalized crack depth relation based on FE models in the approximate far-field region. The far-field analytic solution is also shown.

respectively. For comparison purposes, the analytical result given by Angel and Achenbach (1984) for v of 0.3 is also shown as solid line in Fig. 6. The transmission curve for $v=0.3$ shows good agreement with the analytical curve, which validate the numerical analysis models used in this study. Figure 6 also shows that Poisson's ratio has slight effect on the transmission function, but it is insignificant compared to other critical factors (h, x, and λ).

Figure 7(a) shows the Tr_n and h/λ relationship based on FEM models with T from 40 to 140 μs and h from 0 to 150 mm. The sensors are located in the approximate far-field region given by Eq. (3). For example, for $T=60$ μs and $h=50$ mm, the sensor location x was 110 mm ($a_n \sim 103.5$ mm with $\lambda \sim 135$ mm for $T=60$ μs). Overall, the data in Fig. 7(a) indicate that the FEM results agree with the analytic curve well, especially in the range of $h/\lambda=0 \sim 1/3$. Scattering of FEM data may come from two aspects: different Poisson's ratio (0.22 versus 0.3) and near-field effects. The criterion given by Eq. (3) is just an approximation to the true far field. Nevertheless, the data scattering has been significantly decreased when it is compared with previous research without considering near-field effects (Hevin *et al.*, 1998). The near-field effect may be a possible reason why the transmission curves obtained by other researchers (Song *et al.*, 2003) are different from the analytical results.

E. Simplified algorithm

The crack depth can be estimated by inversion process of the measured surface wave transmission function based on the established transmission curve. Reliable surface wave transmission measurements are the key to accurate evaluation of the crack depth. Figure 5 shows that a signal has the highest energy at the center frequency. Therefore, measurements around the signal center frequency may provide the most reliable results. Based on this assumption, we proposed a simplified algorithm to calculate the surface wave transmission. Instead of calculating wave transmission for all frequencies, we calculated Tr at the center frequency only. Then Eq. (4) is modified to

$$\mathrm{Tr}_n(f_c,h) = \mathrm{Tr}(f_c,h)/\mathrm{Tr}(f_c,0), \tag{5}$$

where f_c is center frequency of the input signal $V_a(f,0)$ (Fig. 5).

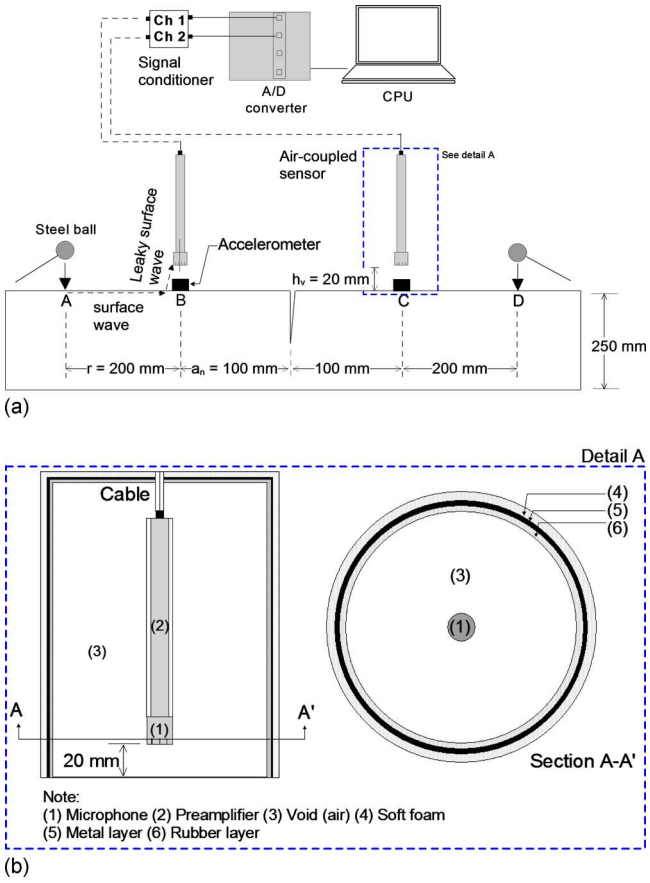

FIG. 8. (Color online) (a) Test setup based on self-compensation technique. (b) Detail of air-coupled sensor with sound insulation device.

With the measured surface wave transmission ratio at the center frequency, h/λ can be directly found from the established $\mathrm{Tr}_n \sim h/\lambda$ curve. If the surface wave velocity is known, the wavelength λ can be calculated, and then the crack depth can be determined. Figure 7(b) shows the $\mathrm{Tr}_n \sim h/\lambda$ curve based on measurements at center frequencies f_c. The impact source duration varies from 40 to 140 μs, and the crack depth h varies from 0 to 150 mm at 10 mm intervals. Good agreement is also observed between the center frequency measurement and the analytic solution, especially in the sensitive region where $h/\lambda \leq 1/3$.

III. EXPERIMENTAL VERIFICATION

A. Test setup

The surface wave transmission coefficient was measured for a notched concrete specimen using the air-coupled self-calibrating scheme. A schematic view of the test setup is shown in Fig. 8(a). Two air-coupled sensors were used to measure leaky surface waves propagating along the concrete surface. The air-coupled sensors (PCB model 377B01) have the following properties: nominal diameter of 6 mm, ± 2 dB flat frequency response over 4 Hz to 80 kHz, and resonance frequency around 83 kHz. The horizontal spacing between the sensor and the impact source is designed as 200 mm to minimize the effects of direct acoustic waves. The sensor-to-crack spacing is 100 mm according to Eq. (3) to reduce near-field effects. According to Zhu and Popovics (2005), the

air-coupled sensors should be close to the test surface to reduce ambient noise and direct acoustic wave effects. In this study, the vertical distance between the sensors and the concrete surface h_v is 20 mm. Unlike a contact sensor, which measures waves right at the sensor location, an air-coupled sensor actually measures the surface waves emitting from the concrete surface at a distance of $h_v \tan\theta$, where θ is the leaky angle determined by Snell's law. This distance is defined as shadow zone. When this value is large, sensor locations should be corrected for shadow zone. In this study, the shadow zone size is about 3.0 mm, which is very small compared to the sensor to crack spacing at 100 mm.

To further reduce effects of direct acoustic waves and ambient noise, the air-coupled sensor was shielded by a sound insulation device, as shown in Fig. 8(b) (Zhu and Popovics, 2005).

A 250 mm thick concrete slab was cast in the laboratory. The thickness of the slab is larger than the wavelength of surface waves used in this study, so that the slab can be approximately regarded as a half-space, as assumed in the analytical and numerical models. Notch-type cracks with depth varying from 10 to 100 mm were generated in the specimen by inserting a 0.5 mm thick metal sheet before casting concrete. The metal sheet was removed from the concrete 12 h later. The width of the notches was measured by a crack width gauge, and it is about 0.5 mm. So the width-to-depth ratio of the notches used in this study is smaller than 0.1. According to Masserey and Mazza (2005), narrow slots with width-to-depth ratio smaller than 0.1 can be regarded as a crack, so that results from experimental study may be directly comparable with the theoretic results. The concrete was made from normal Portland cement type I/II, river sand, and gravel with a maximum size of 10 mm. The density of concrete is 2350 $\mathrm{kg/m^3}$, which was measured from five concrete cylinders (diameter of 10 cm and height of 20 cm), cast at the same time with the concrete specimen. The phase velocity of surface waves was calculated from a dispersion curve using the multichannel analysis of surface waves method (Ryden and Park, 2004). The velocity converged to 2200 m/s when the frequency is greater than 10 kHz. The velocities of *P*- and *S*-waves measured by low frequency ultrasonic transducers (50 kHz) in a through transmission mode were 4100 and 2460 m/s, respectively.

B. Data acquisition

The self-calibrating technique was used to measure surface wave transmission across the notch in concrete. The test setup is shown in Fig. 8(a). First, surface waves generated by an impact load at location A were recorded by sensors at locations B and C. The signals are denoted as V_{AB} and V_{AC}. Consequently, the wave transmission between locations B and C can be calculated from these two signals and denoted as T_{BC}. To eliminate the unsymmetrical effect caused by sensor coupling, an impact load is then applied at location D, and the signals recorded by the sensors at locations B and C are denoted as V_{DB} and V_{DC}. The transmission ratio between locations C and B is defined as T_{CB}. The average surface wave transmission function is (Popovics *et al.*, 2000)

$$|T_{BC}(f)| = \left| \sqrt{\frac{V_{AC}V_{DB}}{V_{AB}V_{DC}}} \right|. \tag{6}$$

To improve signal consistency, five repeated signal data sets were collected at the same test location. These five transmission functions were then arithmetically averaged in frequency domain. The signal coherence function shown in Eq. (7) was used to evaluate the consistency of obtained signals

$$SC_{BC}(f) = \frac{\left|\sum G_{BC}(f)\right|^2}{\sum G_{BB}(f) \times \sum G_{CC}(f)}, \tag{7}$$

where $G_{BC}(f)$, $G_{BB}(f)$, and $G_{CC}(f)$ are the cross spectrum and autospectrum functions between V_{AB} and V_{AC}, respectively. Similarly, $SC_{CB}(f)$ can also be calculated from signals V_{DB} and V_{DC}. The averaged $SC(f)$ is defined as

$$SC(f) = SC_{BC}(f)SC_{CB}(f), \tag{8}$$

which ranges from 0 to 1.0. A value close to 1.0 indicates good signal quality and repeatability. Therefore, the signal coherence function can be used to select the acceptable frequency range of a transmission ratio curve.

The measured surface wave transmission ratio Tr was further normalized by Tr_0, which is the transmission ratio obtained from a crack free region. This procedure will eliminate the geometric effect caused by a point source. All analyses were performed in the frequency domain. A *Hanning* window was applied to the time domain signals to extract the surface wave components.

Three steel balls with different diameters (7, 12, and 14 mm) were used as impact sources. They generate incident surface waves with center frequencies around 25, 20, and 18 kHz. The acquired signals were digitized at a sampling frequency of 10 MHz using an NI-PXI 5105 oscilloscope.

C. Typical signal measured using air-coupled sensors

Figure 9 shows typical time domain signals measured by two air-coupled sensors. Figure 9(a) presents signals obtained from a crack-free region of the concrete specimen, where the incident waves were generated by a source with impact duration about 60 μs. The impact duration T was measured from the received time domain signals of surface waves. The direct acoustic waves were completely separated from the leaky surface waves. In Fig. 9(b), clear incident and transmitted surface waves were also obtained from the crack region (h=40 mm) of concrete. Then the surface wave components were extracted from the signals by using a Hanning window.

D. Air-coupled sensors versus accelerometers

For comparison purposes, two accelerometers (PCB model 352C65) were also installed on the concrete surface with wax, right below the air-coupled sensors at locations A and B, respectively (see Fig. 8). Figure 10 shows the surface wave transmission coefficient and signal coherence functions for signals obtained from the 40 mm deep crack region using microphones [Fig. 10(a)] and accelerometers [Fig. 10(b)].

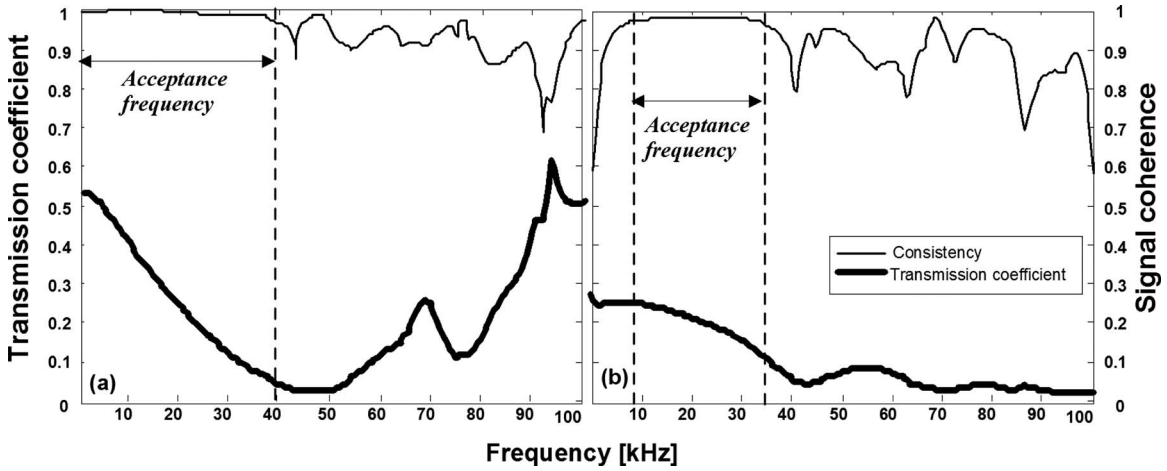

FIG. 9. Typical transmission coefficient and signal consistency versus frequency measured by (a) air-coupled sensors and (b) accelerometers. Depth of crack was 40 mm and the incident surface waves were generated by a 12 mm diameter steel ball.

The self-calibrating method was used in both tests. Both measurements show good coherence in the frequency range of 10–40 kHz. The upper limit of 40 kHz is governed by the frequency contents of the impact source. In the low frequency range (0–10 kHz); however, the air-coupled sensors show better coherence than the accelerometers. Although the accelerometers have flat frequency response in range 10–20 kHz, the temporary installation with wax causes strong resonant vibration at low frequency. This resonant vibration significantly affects signal quality around the resonant frequency, and the resonant effect cannot be removed by the self-calibrating procedure. When the center frequency of surface waves falls in this frequency range, the transmission coefficient will be unreliable. In field testing of concrete structures, the sensor coupling problem can be more critical due to rough surface of concrete and/or environmental conditions (e.g., dust, moisture, and temperature variation). Surface preparation is time consuming if large areas of concrete need to be tested. The air-coupled sensors provide a solution to this problem.

E. Calibration curve of transmission function using air-coupled sensor

The self-calibrating procedure was used to eliminate variation in the experimental setup (e.g., different impact sources, and difference between two sensors), and asymmetry in the tested specimen. Signal data were collected in the approximate far field for various crack depths with two air-coupled sensors. Three different steel balls of different diameters (7, 12, and 14 mm) were used to generate the incident surface waves. Surface wave transmission results from the three impact sources are shown in Figs. 11(a)–11(c). Overall, the experimental results show good agreement with the analytic solution, especially for shallow cracks, e.g., $h=20$ and 30 mm, and in the range of $h/\lambda<1/3$. The data corresponding to $h=10$ mm are not presented in this paper because a steel embedment under the crack distorted surface propagation. For deep cracks, the source should contain enough low frequency wave energy to give a reliable transmission measurement in $h/\lambda<1/3$ range. However, using long impact duration will induce boundary reflections from the back sur-

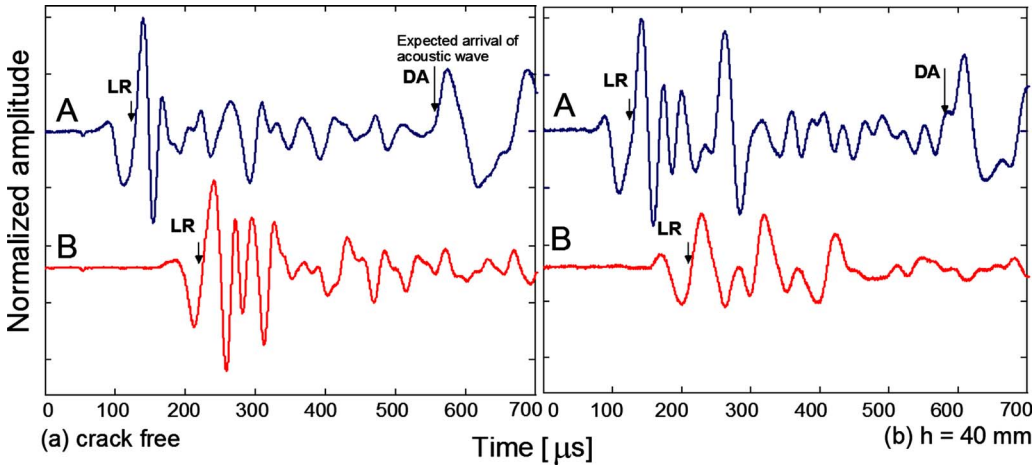

FIG. 10. (Color online) Typical signals measured by air-coupled sensors from a concrete specimen. The crack depths are (a) $h=0$ mm and (b) $h=40$ mm. The impact duration time is $T=60$ μs. Note that LR=leaky surface wave and DA=direct acoustic wave.

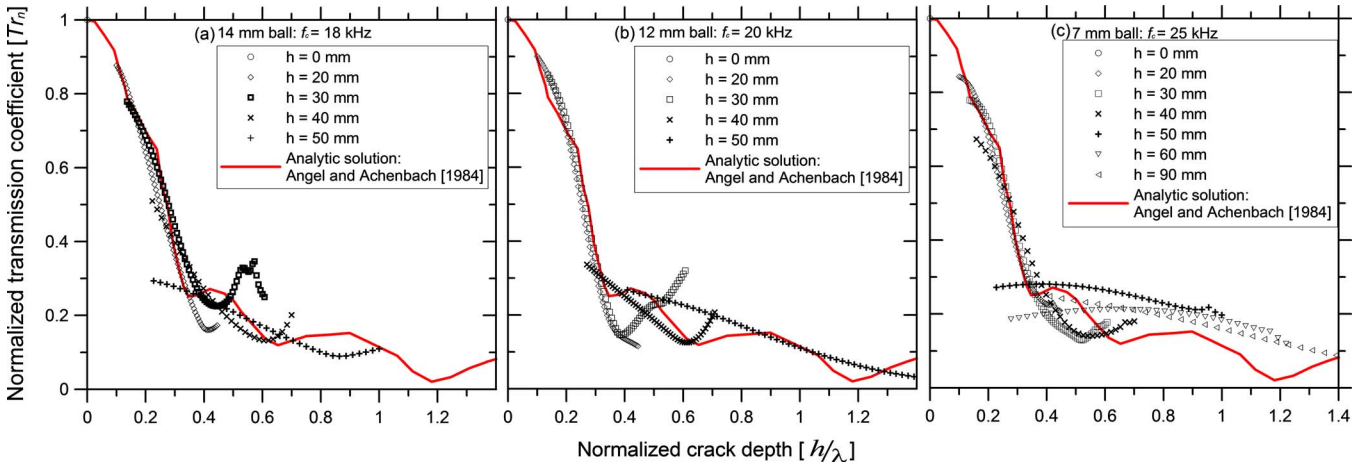

FIG. 11. (Color online) Normalized transmission coefficient and normalized crack depth relation.

face and stronger near-field effects. The crack depth that can be reliably measured using the surface wave transmission method depends on the impact source, sensor arrangement, and geometry (thickness and size) of the specimen. In this study, cracks up to 40 mm deep can be estimated with reasonable accuracy.

F. Experimental verification of the simplified algorithm using air-coupled sensor

To verify the proposed simplified algorithm for crack depth measurement, transmission coefficients measured at the center frequencies are shown in Fig. 12. The data are based on measurements at three center frequencies (18, 20, and 25 kHz) and crack depths (0, 20, 30, 40, 50, 60, and 70 mm). As shown in the figure, the experimental data are in good agreement with the analytic curve in $h/\lambda < 1/3$ range. The simplified algorithm provides a quick analysis of the measured surface wave transmission data to estimate crack depth.

IV. CONCLUSIONS

This study presents the surface wave transmission method to estimate the depth of a surface-breaking crack in concrete. First, this paper proposed a hypothesis that the near-field effect was the reason causing the discrepancy among previous research results. Numerical simulations were used to investigate the near-field effect caused by crack tip scattering and determined the near-field size. The surface wave transmission measured in the far field shows good agreement with the analytical solution, which verifies the proposed near-field effect hypothesis. Second, experimental studies were carried out on a concrete specimen to verify the numerical simulation results and demonstrate the effectiveness of the air-coupled sensing technique. The following conclusions are drawn based on the results of this study.

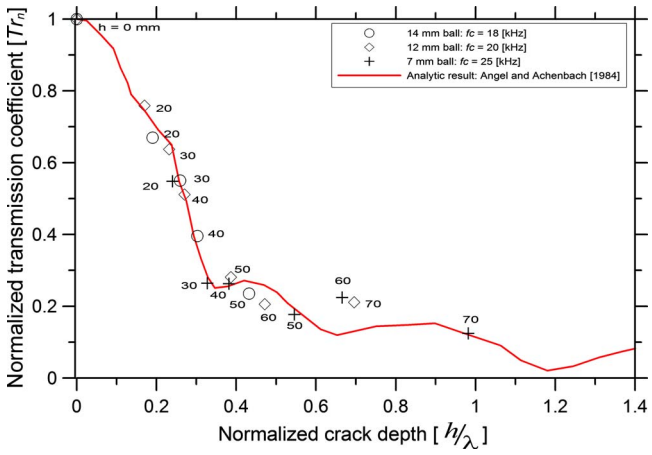

FIG. 12. (Color online) Normalized transmission coefficient based on center frequency and normalized crack depth relation.

(1) Surface wave transmission measurement is affected by near-field effects. To obtain reliable and consistent transmission coefficient, measurements should be performed in the far field. Analyses showed that the near-field size depends on the sensor location x, crack depth h, and an incident wavelength λ. An approximate near-field size [Eq. (3)] was proposed and verified effective to reduce the near-field effect in surface wave transmission measurements.

(2) The surface wave transmissions from FEM analyses and experimental studies show good agreement with the analytical curve given by Angel and Achenbach (1984). It verifies that the proposed test setup and signal processing procedure can be used to estimate of the depth of surface-breaking cracks in concrete, especially for small h/λ value ($h/\lambda < 1/3$).

(3) The air-coupled sensors show improved reliability and consistency in surface wave transmission measurements, as compared to the conventional contact sensors. Owing to the non-contact features, test speed is also improved.

(4) A simplified algorithm was proposed to estimate the crack depth based on the transmission value at the center frequency only, instead of trying to match the pre-established curve at all frequencies. If the surface wave velocity is known, the crack depth can be calculated at corresponding h/λ. The simplified algorithm has been verified by experimental data.

Viscous damping and spring force in periodic perforated planar microstructures when the Reynolds' equation cannot be applied

Dorel Homentcovschi[a] and Ronald N. Miles
Department of Mechanical Engineering, State University of New York, Binghamton, New York 13902-6000

(Received 15 July 2009; revised 13 October 2009; accepted 14 December 2009)

A model of squeeze-film behavior is developed based on Stokes' equations for viscous, compressible isothermal flows. The flow domain is an axisymmetrical, unit cell approximation of a planar, periodic, perforated microstructure. The model is developed for cases when the lubrication approximation cannot be applied. The complex force generated by vibrations of the diaphragm driving the flow has two components: the damping force and the spring force. While for large frequencies the spring force dominates, at low (acoustical) frequencies the damping force is the most important part. The analytical approach developed here yields an explicit formula for both forces. In addition, using a finite element software package, the damping force is also obtained numerically. A comparison is made between the analytic result, numerical solution, and some experimental data found in the literature, which validates the analytic formula and provides compelling arguments about its value in designing microelectomechanical devices.

I. INTRODUCTION

Recent progress in micromachining technology has enabled the fabrication of microelectromechanical systems (MEMS), such as microphones, microaccelerometers, pressure sensors, switches, mirrors, tunable interferometers, ultrasonic motors, resonators, etc. MEMS devices often use parallel plate electrodes as the capacitive sensing and electrostatic actuation mechanisms. This is why the study of a thin air layer being squeezed between a vibrating plate and a rigid plate, referred to as a planar microstructure, is important in many microelectromechanical systems. As the movable electrode displaces sinusoidally, the backforce on the plate due to the air separating it from the backplate has two components Ref. 1: the viscous damping force, which is in phase with velocity, and the spring force, which is in phase with the plate displacement. While the compressibility of the gas and inertial forces become important factors in determining the spring force at higher frequencies, the viscous forces dominate the mechanical behavior of planar microstructures at low frequencies. This paper is focused mainly on determining the viscous damping in planar, periodic perforated microstructures acting at audible frequencies.

The rigid backplate often contains numerous perforated holes which are of a few microns in diameter, uniformly distributed over the entire backplate, for reducing the time required to remove sacrificial materials between the moving structure and backplate during the wet etching process. A thicker backplate is usually preferred since it can provide much better stability and mechanical rigidity. The quasihorizontal motion of the air in the thin gap in a planar microstructure yields squeeze-film damping that can adversely affect the dynamic response of the device. Thus, in the case of microphones (and also other sensors designed for small signal applications), the mechanical-thermal noise is often one of the limiting noise components. The magnitude of thermal noise depends only on temperature and the magnitude of mechanical damping, high viscous damping being associated with large mechanical-thermal noise.[2] The perforations in one of the plates can be also used to control the viscous damping. As a result there is an extensive literature dedicated to the study of squeeze-film damping in perforated MEMS.[3–7]

While the squeeze-film damping is reduced by incorporating holes in one plate, the vertical motion of the air within the holes gives a new viscous resistance which adds to the squeeze-film damping. A rigorous solution of the total damping problem requires the solution of the Navier–Stokes' (NS) system in the three-dimensional (3D) domain comprised of the space between the plates and the volume of the holes, which is not at all a simple task. Three-dimensional flow simulations are not practical for the entire microstructure geometry[5] due to the complexity of the implementation and the computational resource requirements.

There is a large body of modeling work based on the lubrication approximation. The lubrication approximation assumes that the distance between the plane surfaces is sufficiently small, such that it is possible to integrate the NS equations over the separation distance to obtain a two-dimensional (2D) equation for pressure widely known as the Reynold's equation. In the case of perforated microstructures, the assumption that the flow domain is thin is not valid in the region of holes. As a result, the Reynold's equation

[a]Permanent address: "Politechnica" University of Bucharest and Institute of Mathematical Statistics and Applied Mathematics of Romanian Academy, Calea13 Septembrie #13, RO-76100, Bucharest, Romania. Author to whom correspondence should be addressed. Electronic mail: homentco@binghamton.edu

cannot be applied if the air gap between the planes and the pitch and radius of holes have comparable geometrical dimensions. For this case, the widely used Reynold's equation (whose solution gives Škvor's formula[8]) may not be appropriate without significant modifications.

There are two ways to overcome the difficulties associated with the application of the Reynold's equation in perforated microstructures. The first one is to add new terms and coefficients in order to account for the influence of holes, the open end of the holes, the bending of flow from horizontal to vertical. Modifications to the Reynolds' equation have been made by adding a term related to the damping effect of gas flow through holes in Refs. 9 and 10. This modified Reynold's equation was solved analytically in particular cases, but more complicated configurations require the use of numerical methods, which diminishes the utility of the lubrication approximation. In "the analytic damping model" derived in Refs. 5, 11, and 12 (see also Ref. 13), the mechanical resistance of a perforation cell consists of six lumped flow resistances. One of these resistances is derived analytically by using the Reynolds' equation. The elongations involved in the other lumped resistances contain up to 20 numerical coefficients that are determined by using some heuristic equations and fitting to finite element method (FEM) simulations. In some cases, the new models are also encumbered with a lot of experimental coefficients added to provide agreement between the numerical and experimental results as in Refs. 14 and 15. All these methods developed for determining the damping force (and at higher frequencies also the spring force) of the oscillating perforated microstructures obtained by extending the Reynolds' equation are known as "compact models." As noted in the recent paper by Veijola *et al.*,[16] "the verification of the compact models is generally questionable."

An alternative way to determine the viscous damping of perforated microstructures when the pitch of the holes, the air gap, and the radius of holes are of the same order (when the Reynold's equation cannot be applied) is to integrate the NS system and to obtain the velocity and pressure fields. In the model developed here, we take advantage of the repetitive pattern of holes which is typical in most designs. This repetitive pattern implies the existence of a basic cell associated with each hole. For example, if the holes are aligned and regularly spaced, then the lower part of the cell (inside the gap) would be a square prism while for staggered holes, the lower part of the cell will be a hexagonal prism. Due to symmetry the normal velocity and the normal pressure derivative on each side plane of these prisms vanish. For the present model, the prismatic part of the basic cell will be approximated by a circular cylinder (of the same section area and height) having zero normal velocity along the side surface. This yields a 2D (axisymmetrical) flow problem. This approach is similar to the one used in the lubrication approximation where the original problem for a square or hexagonal domain was replaced by a problem for a circular domain which led to Škvor's formula.

The analytical solution developed in Sec. III is based on using Stokes' approximation to the Navier–Stokes system describing the motion of an isothermal, compressible fluid in the approximated cell. The resultant problem for the finite circular cylinder is similar to the flow problems studied by Robey,[17] Petritskaya,[18,19] and Zukerwar[20] for determining the theoretical response of a condenser microphone. The main result of this work is an analytical formula [Eq. (67)] for the complex force whose real part gives the viscous damping and the imaginary part is the spring force. At low frequencies (i.e., in audible domain), the viscous damping is the most important part; moreover, as was shown in Refs. 8 and 20, this component is almost independent of frequency and can be determined by a steady-state approach. This opens the possibility of determining the damping force numerically by using a finite element package for steady-state flow of compressible gas in an axisymmetrical domain.

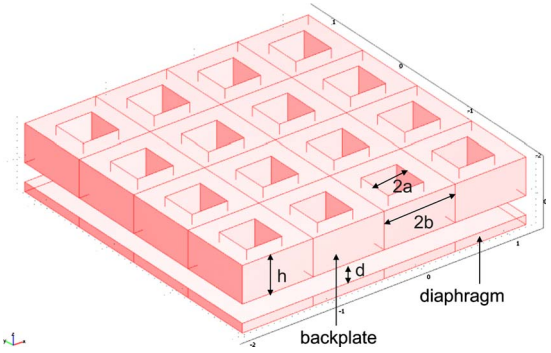

FIG. 1. (Color online) A perforated planar microstructure with aligned square holes.

The damping force given by the analytical formula is validated by results of numerical simulation and also by direct comparison with some experimental data found in the literature.

II. MODEL FORMULATION

Consider a uniform perforated (equal pitch and equal sized holes) planar microstructure having a repetitive pattern of holes. Generally, perforations are present in staggered and aligned (matrix) configurations. In the case of a staggered system of holes, a hexagonal pattern repeats while for the aligned (nonstaggered or matrix) holes, a square pattern can be noted. In Fig. 1, a regular matrix of square holes is shown. The upper plate is the perforated backplate (of thickness h) and the lower one is the diaphragm. The distance d between the average positions of the two plates is the air gap of the structure. The cylindrical holes (circular or square) lie on the vertices of a regular web of hexagons or squares of a side length denoted by $l=2b$ (the pitch of the holes) in both cases. The domain is filled by air. The geometry in the case of aligned holes (square pattern) is shown in Fig. 2. The repetitive pattern of the system of holes and the vertical motion of the diaphragm yield a similarly repetitive response in the motion of the air. The domain where a hole collects the flow will be called a cell. The basic domain for the unit cell is shown in Fig. 3. It consists of a square prism domain D_g located below the square etched cylindrical domain D_h representing the hole. All the side planes of the domain D_g are symmetry planes for the fluid motion. Consequently, on each plane surface, the normal component of velocity and the nor-

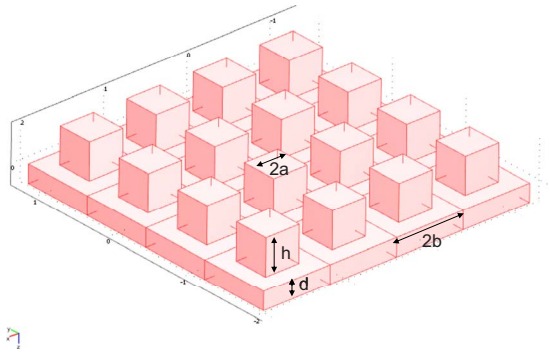

FIG. 2. (Color online) The air domain corresponding to the planar microstructure in Fig. 1.

mal pressure derivative are zero. On the other side, the velocity components vanish on the solid boundary surface of a hole (no-slip condition and no penetration conditions). Finally, the pressure on the upper base of a hole equals the external atmospheric pressure (or more generally is connected to the volume velocity by means of a known impedance Z_C of the backchamber) and the velocity on the other solid surface of the flow domain (diaphragm) equals the velocity of this surface.

In order to simplify the problem, we approximate the domain D_g by a circular cylinder C_g (see Fig. 4) of the same volume having the area of the normal section equal to the area of the hexagonal or square section of the prism D_g [the radius of the cylinder C_g is therefore $R=2b\sqrt{\sqrt{3}/(2\pi)}$ in the case of staggered holes and $R=2b/\sqrt{\pi}$ in the case of matrix holes]. The condition of vanishing of the normal velocity (and of pressure normal derivative) on all symmetry side planes will be substituted by cancellation of these quantities on the side surface of the domain C_g. The radius of the hole is denoted by r. In the case of square holes (width $2a$), as in Fig. 1, the value of r is determined by equalizing the total resistance (sum of the direct and indirect resistances from Ref. 21) for a circular hole $F^h_{\bigcirc}$ and the total resistance $F^h_{\square}$ of a square hole:

$$F^h_{\square} \equiv \frac{12}{0.4217}\mu h\left(\frac{b}{a}\right)^4 w = 8\pi\mu h\left(\frac{R}{r}\right)^4 w \equiv F^h_{\bigcirc}.$$

The resulting formula $r=1.094a$ compares well with the value $r=1.096a$ obtained in Ref. 13 by equating the acoustic

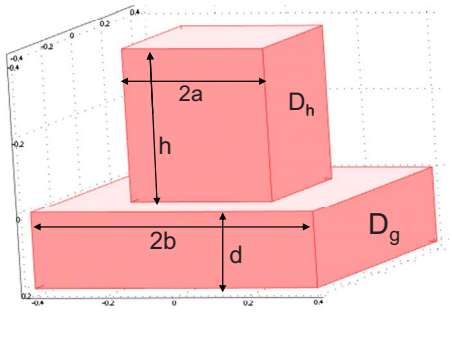

FIG. 3. (Color online) A cell of a periodic microstructure with aligned square holes.

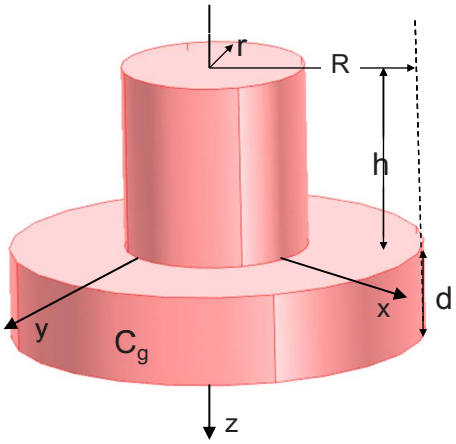

FIG. 4. (Color online) The cylindrical approximation of the basic domain (cell).

resistances (hydraulic resistances) of square and circular long channels. This approximation works in the case of small and moderate values of the area ratio A (defined as the ratio of the area of the normal section of the hole over the total area of a normal section of the domain D_g). This way we obtained an axisymmetrical problem which is easier to solve analytically and numerically.

In the case the air gap, the pitch of the holes, and the diameter of the holes are all of the same order, the lubrication approximation can no longer be used. Therefore, we no longer have a special equation for the pressure (as Reynold's equation) and in the case of isothermal flow we have to determine the complete flowfield characterized by the air velocity $\mathbf{V}$ and the pressure P. The flow inside the 3D cells is governed by the Navier–Stokes system for compressible isothermal fluid

$$\frac{\partial\tilde{\rho}}{\partial t} + \nabla\cdot(\tilde{\rho}\mathbf{V}) = 0, \tag{1}$$

$$\tilde{\rho}\left[\frac{\partial\mathbf{V}}{\partial t} + (\mathbf{V}\cdot\nabla)\right]\mathbf{V} = -\nabla P + \mu\left[\nabla^2\mathbf{V} + \frac{1}{3}\nabla\nabla\cdot\mathbf{V}\right], \tag{2}$$

where μ is the shear viscosity and $\tilde{\rho}$ is the density. Also,

$$P = c_0^2\tilde{\rho}, \tag{3}$$

c_0 denoting the isothermal speed of sound in air. The origin is placed such that the z-axis is the symmetry line of the cell in the center of the circular hole (Fig. 4). The diaphragm lies in the plane $z=d$.

III. THE ANALYTIC SOLUTION

By linearizing Eq. (2) and assuming a time harmonic solution $\mathbf{V}(\mathbf{x},t)=\mathbf{v}(\mathbf{x})\exp(-i\omega t)$, $P(\mathbf{x},t)=p(\mathbf{x})\exp(-i\omega t)$, we obtain the Stokes' system,

$$\nabla\cdot\mathbf{v} = \frac{i\omega}{\tilde{\rho}_0 c_0^2}p, \tag{4}$$

$$-i\omega\tilde{\rho}_0\mathbf{v} = -\nabla p + \mu\left(\Delta\mathbf{v} + \tfrac{1}{3}\nabla\nabla\cdot\mathbf{v}\right), \tag{5}$$

where $\omega=2\pi f$, f being the frequency and $\tilde{\rho}_0$ being the unperturbed air density. The boundary conditions on the two bases have the form

$$u(\rho,d)=0 \quad w(\rho,d)=w^{(d)}(\rho), \tag{6}$$

$$u(\rho,0)=0, \quad w(\rho,0)=w^{(0)}(\rho), \tag{7}$$

where $(u(\rho,z),0,w(\rho,z))$ are the components of velocity $\mathbf{v}$ in the cylindrical coordinates (ρ,φ,z) and the function $w^{(0)}(\rho)$ is different from zero only in the opening (the hole surface of the top of the gap).

Particularly, in the case of a small and a medium radius hole, we write

$$w^{(0)}(\rho)=\begin{cases}\tilde{w}^{(0)}(\rho) & \text{if}\rho<r\\ 0 & \text{for } r<\rho<R,\end{cases} \tag{8}$$

$\tilde{w}^{(0)}(\rho)$ being an unknown function.

Remark 1. Conditions (6) and (7) are no-slip boundary conditions assuming a continuous flow. The fluid dynamics in a narrow domain between two parallel plates yields a decrease in pressure (rarefaction effect) which changes the boundary conditions on the solid surfaces giving a certain slip (tangential velocity) of the fluid particles.[22] The presence of perforations changes the pressure distribution in the gap area next to holes. It is clear that for perforated microstructures having the pitch of holes much larger than the air gap of the microstructure, the rarefaction is still in effect. But, if the pitch of holes is not much larger than the air gap, the presence of holes makes the slip of fluid particles on solid surfaces of the microstructure at least questionable. On the other hand, an elementary calculation shows that in the case of narrow circular pipes, of infinite extent, the direct hole resistance is not affected by the slip of the fluid particles on the wall. Also, as is shown in Ref. 21, the indirect hole resistance can be considered as a particular squeeze-film damping.

A. The equations for pressure and vorticity

We write Eq. (5) as

$$\mathbf{v}=\frac{1}{i\omega\tilde{\rho}_0}\left(1-\frac{\mu}{3}\frac{i\omega}{\tilde{\rho}_0c_0^2}\right)\nabla p-\frac{\mu}{i\omega\tilde{\rho}_0}\Delta\mathbf{v}. \tag{9}$$

By using the vectorial identity,

$$\nabla\times(\nabla\times\mathbf{v})=\nabla(\nabla\cdot\mathbf{v})-\nabla\mathbf{v}, \tag{10}$$

and taking into account the equation of continuity (4), there results

$$\mathbf{v}=\frac{\beta}{i\omega\tilde{\rho}_0}\nabla p+\frac{\mu}{i\omega\tilde{\rho}_0}\nabla\times\boldsymbol{\Omega}, \tag{11}$$

where

$$\beta=1-\frac{4i\omega\mu}{3\tilde{\rho}_0c_0^2}, \tag{12}$$

and

$$\boldsymbol{\Omega}=\nabla\times\mathbf{v} \tag{13}$$

is the vorticity. In the case

$$f\ll 3\tilde{\rho}_0c_0^2/(8\pi\mu)\approx 8.95\times10^8 \text{ Hz},$$

the second term in the right-hand side of formula (12) can be neglected resulting $\beta\approx1$.

In the axisymmetrical case, in the cylindrical coordinates, there is only one nonvanishing vorticity component

$$\nabla\times\mathbf{v}=\Omega\hat{\varphi}. \tag{14}$$

Thus, we obtain expressions for the velocities in terms of the pressure p and scalar vorticity Ω as potentials,

$$\mathbf{v}=\frac{\beta}{i\omega\tilde{\rho}_0}\nabla p+\frac{\mu}{i\omega\tilde{\rho}_0}\nabla\times(\Omega\hat{\varphi}). \tag{15}$$

This relationship can also be written as

$$u(\rho,z)=\frac{\beta}{i\omega\tilde{\rho}_0}\frac{\partial p}{\partial\rho}-\frac{\mu}{i\omega\tilde{\rho}_0}\frac{\partial\Omega}{\partial z}, \tag{16}$$

$$w(\rho,z)=\frac{\beta}{i\omega\tilde{\rho}_0}\frac{\partial p}{\partial z}+\frac{\mu}{i\omega\tilde{\rho}_0}\frac{1}{\rho}\frac{\partial(\rho\Omega)}{\partial\rho}, \tag{17}$$

where $u(\rho,z)$ and $w(\rho,z)$ are the nonvanishing components of the axisymmetrical velocity field in cylindrical coordinates. By applying in formula (15), the operator $\nabla\cdot$ and accounting of relationships (4), there results the partial differential equations satisfied by pressure

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial^2p}{\partial\rho}\right)+\frac{\partial^2p}{\partial z^2}+k^2p=0, \tag{18}$$

where the scalar wave number is

$$k=\frac{\omega}{c_0\sqrt{\beta}}. \tag{19}$$

Similarly, the application of operator $\nabla\times$ and consideration of formula (14) yields the vorticity equation,

$$\frac{1}{\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial\Omega}{\partial\rho}\right)-\frac{\Omega}{\rho^2}+\frac{\partial^2\Omega}{\partial z^2}+L^2\Omega=0, \tag{20}$$

L being the vector wave number,

$$L=\sqrt{i\omega\tilde{\rho}_0/\mu}. \tag{21}$$

B. Representation formulas for pressure, vorticity, and velocity fields

The separation of variables in Eqs. (18) and (20) associated with the condition of zero normal derivative of the pressure along the external cylindrical surface,

$$\frac{\partial p}{\partial n}(a,z)=0, \tag{22}$$

yields the representation formulas,

$$\frac{\beta}{i\omega\tilde{\rho}_0}p(\rho,z)=\phi_0(z)+\sum_{n=1}^{\infty}\phi_n(z)J_0(q_n\rho), \tag{23}$$

$$\phi_n(z) = A_0 \cos(kz) + \beta_0 \sin(kz),$$

$$\phi_n(z) = A_n \cosh(k_n z) + \beta_n \sinh(k_n z), \quad n \geq 1, \tag{24}$$

where the eigenvalues q_n are determined by

$$J_1(q_n R) = 0, \quad n = 0,1,2, \ldots, \tag{25}$$

and

$$k_n = \sqrt{q_n^2 - k^2}. \tag{26}$$

Also,

$$\frac{\mu}{i\omega\rho_0}\Omega(\rho,z) = \sum_{n=1}^{\infty} \Omega_n(z) J_1(q_n\rho), \tag{27}$$

where

$$\Omega_n(z) = C_n \cosh(r_n z) + D_n \sinh(r_n z), \tag{28}$$

and

$$r_n = \sqrt{q_n^2 - L^2}. \tag{29}$$

Formulas (16) and (17) yield the following representation formulas for the components of the velocity field:

$$u(\rho,z) = \sum_{n=1}^{\infty} u_n(z) J_1(q_n\rho), \tag{30}$$

where

$$u_n(z) = -q_n[A_n \cosh(k_n z) + B_n \sinh(k_n z)] - r_n[C_n \sinh(r_n z) + D_n \cosh(r_n z)], \tag{31}$$

and

$$w(\rho,z) = \sum_{n=0}^{\infty} w_n(z) J_0(q_n\rho). \tag{32}$$

The functions $w_n(z)$ have the expression

$$w_0(z) = k[-A_0 \sin(kz) + B_0 \cos(kz)], \tag{33}$$

$$w_n(z) = k_n[A_n \sinh(q_n z) + B_n \cosh(q_n z)] + q_n[C_n \cosh(r_n z) + D_n \sinh(r_n z)], \quad n = 1,2, \ldots. \tag{34}$$

The constants A_0, B_0, A_n, B_n, C_n, and D_n will be determined by using the boundary conditions (6) and (7).

1. Determination of constants

By using formulas (30) and (32) along the plane $z=d$, we can write

$$q_n[A_n \cosh(k_n d) + B_n \sinh(k_n d)] + r_n[C_n \sinh(r_n d) + D_n \cosh(r_n d)] = 0, \tag{35}$$

$$k_n[A_n \sinh(k_n d) + B_n \cosh(k_n d)] + q_n[C_n \cosh(r_n d) + D_n \sinh(r_n d)] = w_n^{(d)}. \tag{36}$$

Similarly, along the plane $z=0$, the u and w components of the velocity give

$$q_n A_n + r_n D_n = 0, \tag{37}$$

$$k_n B_n + q_n C_n = w_n^{(0)}, \tag{38}$$

$w_n^{(0)}$ and $w_n^{(d)}$ being the Fourier expansion coefficients corresponding to the functions $w^{(0)}(\rho)$ and $w^{(d)}(\rho)$:

$$w_n^{(0)} = \frac{2}{R^2}\int_0^r \tilde{w}^{(0)}(\rho)\rho \frac{J_0(q_n\rho)}{J_0^2(q_n R)} d\rho, \tag{39}$$

$$w_n^{(d)} = \frac{2}{R^2}\int_0^R w^{(d)}(\rho)\rho \frac{J_0(q_n\rho)}{J_0^2(q_n R)} d\rho. \tag{40}$$

Equations (35)–(38) determine the unknown pressure coefficients as

$$A_n = \mathbb{A}_n^{(0)} w_n^{(0)} + \mathbb{A}_n^{(d)} w_n^{(d)}, \tag{41}$$

$$B_n = \mathbb{B}_n^{(0)} w_n^{(0)} + \mathbb{B}_n^{(d)} w_n^{(d)}. \tag{42}$$

The coefficients $\mathbb{A}_n^{(0)}, \ldots, \mathbb{B}_n^{(d)}$ are defined by formulas

$$\mathbb{A}_0^{(0)} = \frac{\cot(kd)}{k}, \quad \mathbb{A}_0^{(d)} = \frac{\csc(kd)}{k}, \quad \mathbb{B}_0^{(0)} = \frac{1}{k}, \quad \mathbb{B}_0^{(d)} = 0, \tag{43}$$

$$\mathbb{A}_n^{(0)} = \frac{\sinh(k_n d)\cosh(r_n d) - \gamma_n \cosh(k_n d)\sinh(r_n d)}{k_n[2 - 2\cosh(k_n d)\cosh(r_n d) + [\gamma_n + \gamma_n^{-1}]\sinh(k_n d)\sinh(r_n d)]}, \tag{44}$$

$$\mathbb{A}_n^{(d)} = \frac{\gamma_n \sinh(r_n d) - \sinh(k_n d)}{k_n[2 - 2\cosh(k_n d)\cosh(r_n d) + [\gamma_n + \gamma_n^{-1}]\sinh(k_n d)\sinh(r_n d)]}, \tag{45}$$

$$\mathbb{B}_n^{(0)} = \frac{1 - \cosh(k_n d)\cosh(r_n d) + \gamma_n \sinh(k_n d)\sinh(r_n d)}{k_n[2 - 2\cosh(k_n d)\cosh(r_n d) + [\gamma_n + \gamma_n^{-1}]\sinh(k_n d)\sinh(r_n d)]}, \tag{46}$$

$$\mathbb{B}_n^{(d)} = \frac{\cosh(k_n d) - \cosh(r_n d)}{k_n[2 - 2\cosh(k_n d)\cosh(r_n d) + [\gamma_n + \gamma_n^{-1}]\sinh(k_n d)\sinh(r_n d)]}. \tag{47}$$

γ_n denotes

$$\gamma_n = \frac{k_n r_n}{q_n^2}.$$

C. One term approximations for the pressure and velocity in the opening

We assume that at the lower base of a hole the pressure has the form

$$p(\rho,0) = p_1^{(0)}, \quad \rho < r, \tag{48}$$

and that the velocity of the fluid,

$$w(\rho,0) = w^{(0)}, \quad \rho < r, \tag{49}$$

is also constant.

Particularly in the case of small holes the function $\tilde{w}^{(0)}(\rho)$ being a constant (49), a simple calculation based on formulas (A5) and (A6) yields

$$w_0^{(0)} = \frac{r^2}{R^2} w^{(0)}, \tag{50}$$

$$w_n^{(0)} = \frac{2r^2}{R^2} \frac{J_1(q_n r)}{q_n r} \frac{w^{(0)}}{J_0^2(q_n R)}, \quad n = 1,2,\ldots. \tag{51}$$

Remark 2. The one-term approximation for the pressure (48) and for velocity (49) assume small values of the radius r. For larger holes more terms have to be considered involving more unknown coefficients. However, the results obtained in Secs. IV and V show that the "one-term approximation" works well even in case of medium sized holes.

The equations of the problem are obtained now by using the representation formula (23) in condition (48):

$$\frac{\beta}{i\omega\tilde{\rho}_0} p_1^{(0)} = A_0 + \sum_{n=1}^{\infty} A_n J_0(q_n \rho), \quad \rho < r. \tag{52}$$

Equation (52) can be integrated with respect to ρ (between the limits 0 and ρ) yielding

$$A_0 \frac{\rho}{2} - \frac{\beta}{i\omega\tilde{\rho}_0} \frac{\rho}{2} p_1^{(0)} + \sum_{n=1}^{\infty} \frac{A_n}{q_n} J_1(q_n \rho) = 0, \quad \rho < r. \tag{53}$$

By substituting into Eq. (53), formulas (41) and (42), there results

$$\sum_{n=1}^{\infty} \left[\frac{\mathbb{A}_n^{(0)}}{q_n} w_n^{(0)} + \frac{\mathbb{A}_n^{(d)}}{q_n} w_n^{(d)} \right] J_1(q_n \rho) = -[\mathbb{A}_0^{(0)} w_0^{(0)} + \mathbb{A}_0^{(d)} w_0^{(d)}] \frac{\rho}{2} + \frac{\beta}{i\omega\tilde{\rho}_0} \frac{\rho}{2} p_1^{(0)}, \quad \rho < r. \tag{54}$$

Also, multiplying Eq. (54) by ρ^2 and integrating over $[0,r]$ give

$$\sum_{n=1}^{\infty} \left[\frac{\mathbb{A}_n^{(0)}}{q_n} w_n^{(0)} + \frac{\mathbb{A}_n^{(d)}}{q_n} w_n^{(d)} \right] \frac{J_2(q_n r)}{q_n r} = -[\mathbb{A}_0^{(0)} w_0^{(0)} + \mathbb{A}_0^{(d)} w_n^{(d)}] \frac{r}{8} + \frac{\beta}{i\omega\tilde{\rho}_0} \frac{r}{8} p_1^{(0)}. \tag{55}$$

Finally, the substitution of formulas (50) and (51) into relationships (55) gives the equation

$$w^{(0)} C_0 - \frac{\beta}{i\omega\tilde{\rho}_0} p_1^{(0)} = -\mathbb{A}_0^{(d)} w_0^{(d)} - \frac{8}{r} \sum_{n=1}^{\infty} \frac{\mathbb{A}_n^{(d)} J_2(q_n r)}{q_n^2 r} w_n^{(d)}, \tag{56}$$

where we have denoted

$$C_0 = \mathbb{A}_0^{(0)} \frac{r^2}{R^2} + \frac{16}{R^2 r} \sum_{n=1}^{\infty} \mathbb{A}_n^{(0)} \frac{J_1(q_n r) J_2(q_n r)}{J_0^2(q_n R) q_n^3}. \tag{57}$$

If the velocity of the diaphragm is constant, we have $w_n^{(d)} = w^{(d)} \delta_{n0}$ and the sum in right-hand side of Eq. (56) cancels out.

D. Determination of the velocity in opening

Using the impedance Z of the opening, we can write

$$p_1^{(0)} = -(Z + Z_C)\tilde{w}, \tag{58}$$

where Z_C is the acoustic impedance of the backchamber and $\tilde{w}$ is the algebraic volume velocity,

$$\tilde{\omega} = \pi r^2 w^{(0)}. \tag{59}$$

The acoustic impedance of the backchamber is[20]

$$Z_C = \frac{\gamma\tilde{\rho}_0 c^2}{i\omega V}, \tag{60}$$

where $\gamma = 1.403$ is the specific heat ratio of air and V denotes the volume of the backchamber. The impedance of the opening in the backplate is given in Ref. 23.

(1) Holes of very small diameter $r < 0.002/\sqrt{f}$,

$$Z = \frac{8\mu h}{\pi r^4} - i\omega \frac{4}{3} \frac{\tilde{\rho}_0 h}{3\pi r^2}. \tag{61}$$

(2) Intermediate-sized holes $0.01/\sqrt{f} < r < 10/f$,

$$Z \frac{\sqrt{8\omega\tilde{\rho}_0\mu}}{\pi r^2} \left(1 + \frac{h}{2r}\right) - i\omega\tilde{\rho}_0 \frac{h + 1.7r}{\pi r^2}. \tag{62}$$

Expression (62) includes also the end correction.

In the case of a hole whose radius lies between $0.002/\sqrt{f}$ and $0.01/\sqrt{f}$, interpolation must be used.

Equations (56), (58), and (59) permit determination of the pressure and velocity (assumed constants) in the opening. Particularly there results

$$w^{(0)} = W_0 w^{(d)}, \tag{63}$$

where,

$$W_0 = \left\{ k \sin(kd) \left[C_0 + \frac{Z + Z_C}{i\omega\tilde{\rho}_0} \beta \pi r^2 \right] \right\}^{-1}. \tag{64}$$

E. The analytic expressions for the damping coefficient and spring force

The pressure on the diaphragm can be written by means of formula (23) as

$$p(\rho,d) = \frac{i\omega\tilde{\rho}_0}{\beta} \left\{ A_0 \cos(kd) + B_0 \sin(kd) + \sum_{n=1}^{\infty} [A_n \cosh(k_n d) + B_n \sinh(k_n d)] J_0(q_n \rho) \right\}. \tag{65}$$

The total pressure (the pressure force) $P^{(d)}$ on the diaphragm results by integration with respect to θ and ρ:

$$P^{(d)} = -\frac{i\omega\tilde{\rho}_0}{\beta} \pi R^2 [A_0 \cos(kd) + B_0 \sin(kd)] = -\frac{i\omega\tilde{\rho}_0}{\beta} \frac{\pi R^2}{k \sin(kd)} \left[\frac{r^2}{R^2} w^{(0)} - \cos(kd) w^{(d)} \right]. \tag{66}$$

By introducing expression (63) of the velocity in the opening, we get

$$P^{(d)} = \frac{i\omega\tilde{\rho}_0}{\beta} \frac{\pi R^2 \cos(kd)}{k \sin(kd)} \left[1 - \frac{r^2}{R^2 \cos(kd)} W_0 \right] w^{(d)}.$$

Finally, the total damping coefficient of a cell B and the spring force coefficient S are

$$B + iS = \frac{i\omega\tilde{\rho}_0}{\beta} \frac{\pi R^2 \cos(kd)}{k \sin(kd)} \left[1 - \frac{r^2}{R^2 \cos(kd)} W_0 \right]. \tag{67}$$

This formula provides the total damping coefficient and the spring force coefficient on the developed model based on Stokes approximation of the viscous flow equations.

IV. AXIALLY SYMMETRIC NUMERICAL SIMULATION FOR VISCOUS DAMPING

The formula given by Škvor[8] (see also Refs. 24 and 25) assumes that the equivalent mechanical resistance of a cell (in lubrication approximation) is independent of frequency. The analysis of Zukerwar[20] shows that in the case of microphones in the audio frequency range, viscous damping is practically independent of frequency. The same conclusion was obtained in Ref. 26 in the case of an incompressible fluid as long as the frequency is smaller than 10^6 Hz. In this section, the viscous damping is modeled assuming weakly compressible fluid behavior for air. The squeezed flow is driven periodically in time and based on the above comments can be analyzed from the point of view of steady-state response.

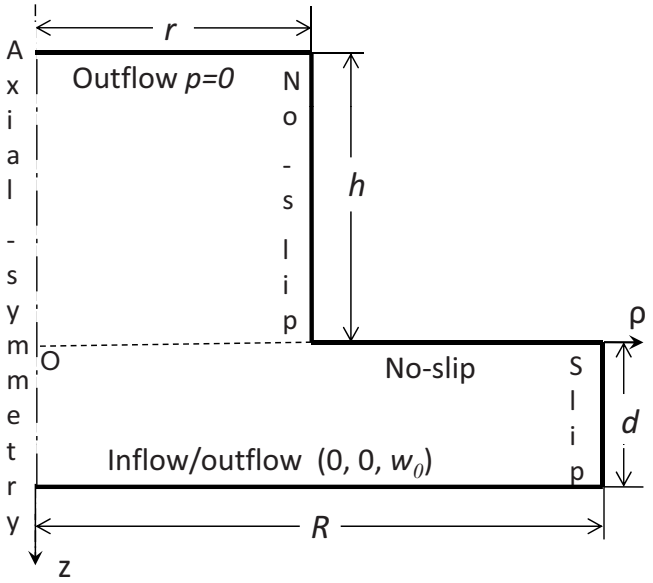

FIG. 5. The azimuthal section of the cell showing the dimensions and the boundary conditions.

The computational domain used here is the axisymmetrical region shown in Fig. 4. An azimuthal section of the cell showing the dimensions and the specified boundary conditions is given in Fig. 5. The bottom boundary corresponds to the diaphragm where the inflow/outflow condition $\mathbf{u} = (0,0,w_0)$ is specified. A constant pressure ($p=0$) outflow condition is specified along the top segment corresponding to the hole aperture. The no-slip condition is applied on solid surfaces (i.e., the wall of the hole and the lower surface of the backplate). Slip symmetry $\mathbf{V} \cdot \mathbf{n} = 0$ is specified along the outside cylindrical surface corresponding to the cell gap boundary. Finally, axisymmetry is specified along the central axis of the unit cell.

Solutions to the governing equations for the specified axisymmetric domain and boundary conditions were obtained using the weakly compressible Navier–Stokes application mode included in heat transfer module of COMSOL MULTIPHYSICS (Ref. 27) commercial software package. The software uses the finite element method for the spatial discretization of the governing equations (in cylindrical-polar coordinates). The domain is discretized using triangular elements. The COMSOL software employs an iterative procedure to solve the resulting discrete, nonlinear algebraic system of equations that result from the finite element approximation of the Navier–Stokes equations. A homogeneous, unstructured mesh was employed for most of the domain with areas of refinement in the gap region and around the re-entrant corner of the azimuthal domain. While the full Navier–Stokes equations were solved, for the conditions of the model here, the nonlinear terms are relatively small and accurate solutions are readily obtained. Grid convergence studies were performed starting with approximately 1000 elements and using up to as many as 20 000 elements for the most refined meshes.

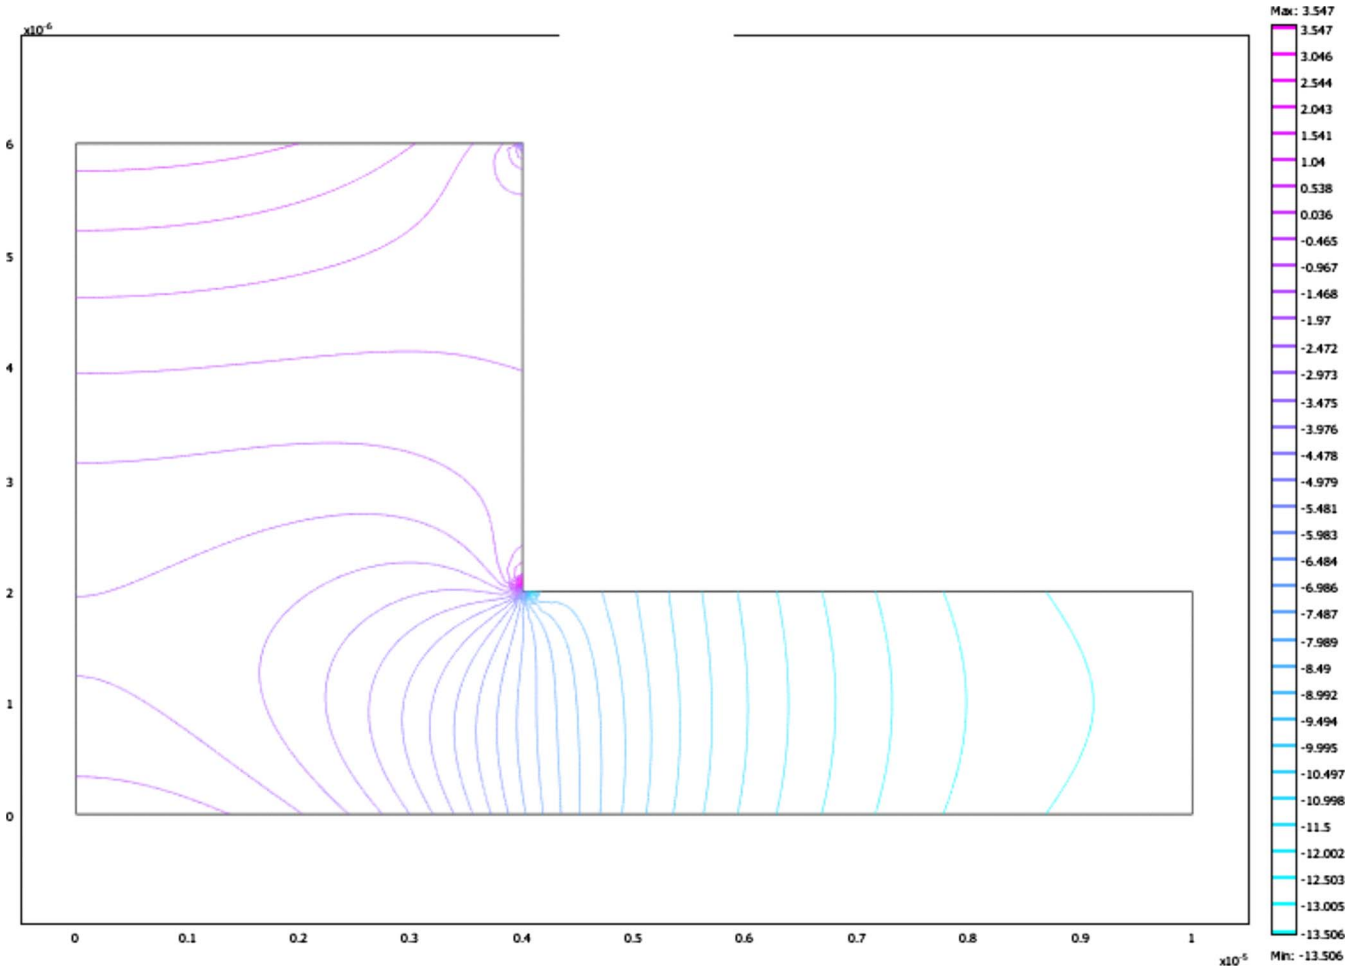

FIG. 6. (Color online) Contour plots of the pressure field in the azimuthal section resulted in numerical simulation.

Remark 3. In the numerical model presented here, standard continuum flow conditions have been assumed so that the no-slip condition applies along solid boundaries. In Ref. 16, both no-slip (models M1 and M2) and models with a slip velocity boundary condition (M3 and M4) were used along the walls in the air gap and the hole. If the scale of the flow is very small, then a slip model may be appropriate. However, for a gap on the order of 1 μm and an area ratio (area of the hole divided by the total area) around 50% half of the working area is open and rarefied gas behavior should not be important. In fact, some simple calculations show that in the case of a hole having a small radius and infinite length, the direct resistance of the hole is not influenced by the slip condition on the circular pipe. This geometry gives a redistribution of the pressure on the backplate very different from the rarefaction in a small gap between two parallel, nonperforated plane surfaces where a slip-flow may be a better model. This is evidenced by the fact that some of the results given in Table III in Ref. 16 are better when the standard continuum no-slip condition is applied along the solid surfaces. On the other hand, the indirect resistance of holes can be considered as a special squeezed film damping (see Ref. 21). See also the discussion in the book.[22]

Remark 4. In electrostatic-based transducers, application of voltages (polarization voltage for microphones and actuation voltage for actuators) is mandatory and this results in a static, nonlinear deflection of the diaphragm. In MEMS devices with very small air gap thickness, this can have a significant influence on the viscous damping. In the case of small deflections, the developed theory can be applied. For larger deflections, an axisymmetrical model can be obtained including the actual shape of the diaphragm and the FEM software will provide the viscous damping coefficient.

A. Sample results

Here we present a set of representative results by applying the axisymmetrical simulation and the analytical formula (67) to a unit cell with geometrical dimensions: $r=4$ μm, $R=8$ μm, $d=2$ μm, and $h=4$ μm. For the air in the unit cell, the following property values are used: density $\tilde{\rho}_0 = 1.155$ kg/m^3 and dynamic viscosity $\mu=18.5 \times 10^{-6}$ N s/m^2. As discussed above, a homogeneous, unstructured finite element mesh was used for the numerical computations with refinement around the re-entrant corner of the azimuthal domain. The total number of the finite elements is 9490 for the specific case presented here. Figure 6 shows contour plots of the pressure field (isobars) in the computational domain. An important element is the variation in the pressure in the axial direction (z). The result indicates

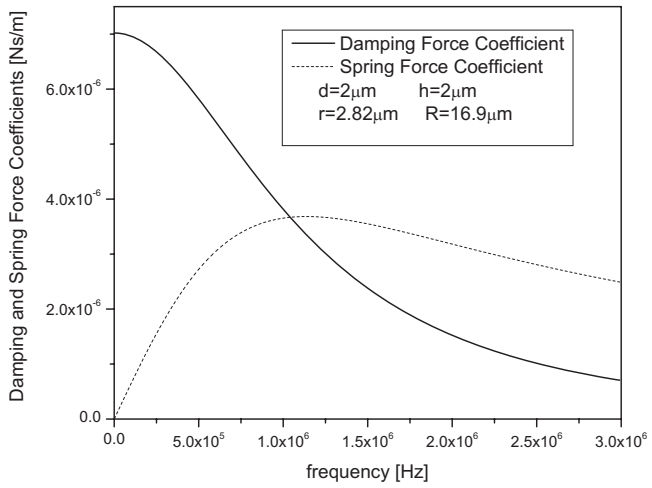

FIG. 7. Damping and spring force coefficients obtained by applying the analytical formula resulted by Stokes approximation.

a significant difference from the relationship $\partial p/\partial z=0$ assumed throughout the gap region in the lubrication type approaches.

From the numerical simulation for this case, the following values for the total damping coefficient of pressure force on the base $z=d$ of the cell (P) and the total damping coefficient of the total force (F_z) on the same base (including the viscous component) in the z-direction are obtained:

$$P = 1.058\,842 \times 10^{-7}\ \text{N s/m}, \tag{68}$$

$$B_{\text{num}} \equiv F_z = 1.058\,862 \times 10^{-7}\ \text{N s/m}. \tag{69}$$

These results show that the influence of the viscous force on the damping coefficient is very small compared with the pressure contribution. On the other hand, the calculation of the total damping coefficient as the sum of the hole resistance and the damping on the $z=0$ of the backplate gives an error of 0.23% as compared with the value given by the relationship (69).

Analytical formula (67) yields the following value of the damping coefficient:

$$B_{\text{STO}} = 1.1356 \times 10^{-7}\ \text{N s/m}, \tag{70}$$

resulting in a relative error of $e_{\text{STO}}=6.6\%$ with respect the value given by FEM simulation. The damping coefficient corresponding to the Reynolds approximation is

$$B_{\text{Rey}} = 6.15 \times 10^{-8}\ \text{N s/m}. \tag{71}$$

This value was obtained by adding the squeezed film damping given by Škvor's formula and the direct and indirect resistances of a hole defined in Ref. 21. The resulting value B_{Rey} has a relative error with respect to the FEM value of $e_{\text{Rey}}=42\%$.

The calculation of the total force on a cell by using the obtained analytical formula (67) was performed in the range of frequencies from 100 Hz to 3 MHz. The results are shown in Fig. 7, where the continuous line represents the damping force and the dotted line represents the spring force in the case where the effects of inertia and compressibility were included. The damping force dominates at low frequencies. The cutoff frequency is ≈ 1.5 MHz. For higher frequencies, the spring force is more important.

V. VALIDATION OF THE ANALYTICAL FORMULA

In this section, we compare the predictions from analytical solution and the FEM model to the published experimental data of Somà and De Pasquale.[28] In this cited paper, the details of the device configuration studied, the experimental setup, and the testing procedure are presented. The experimental configuration consists of a central suspended plate (where the structural stiffness is concentrated) covered with a pattern of square holes and connected to four lateral clamped supports of small cross-sectional area. This particular shape allows an out-of-plane deflection of lateral supports during the excitation and, consequently, a quasirigid oscillation of the central plate. The suspended plates are $h=15$ μm thick and have a gap of $d=1.6$ μm. Six different test configurations were studied: four specimens with different hole cross-sectional area size and two with the same hole dimensions but different plate widths. Table I gives the effective geometrical dimensions of the test structures obtained by profile measurements using an interferometric microscope. In the table, six cases are labeled A–F as in Refs. 16 and 28. The first four columns in Table I coincide with the corresponding columns in Table 1 of Ref. 16 including the plate length L, the plate width W, and the number of holes $M \times N$. Column five contains the perforation ratio q (same as the area ratio A) of the structure. In columns six and seven of Table I, we include the parameters b (the half-period of the structure) and $a=s_0/2$ (the half-length of a square hole side). Column nine contains the radius r of the circular cylinder which is equivalent to the square cross section of the hole of the test

E	38.22	26.35(−31.06%)	34.66(−9.30%)	33.74(−11.7%)
F	67.44	52.70(−21.86%)	69.32(2.89%)	67.48(0.06%)

specimen. Finally, the last column contains the radius R of the cylinder which substitutes the lower prism (gap region) of the domain.

In Ref. 28, the quality factor is determined from the experimentally obtained curve of displacement versus frequency, and the damping coefficient is then calculated from the quality factor, frequency, and the effective mass using the half-power bandwidth method. The values of the measured total damping coefficients, labeled as C_m, are given in column 2 of Table II for all six cases studied (note that this coincides with the second column in Table 3 of Ref. 28).

The columns 3–5 of Table II here contain the total damping coefficients C_{Rey}, C_{STO}, and C_{num} for the plate determined by multiplying the damping coefficient for a unit cell with the total number $M \times N$ of holes. In parenthesis in each case the relative error (ΔRey, ΔSTO, and Δnum) of the respective damping coefficient with respect to the measured value C_M was included. The coefficient c_{Rey} for a single cell was obtained by adding the squeezed film damping given by Škvor's formula and the direct and indirect resistances of a hole defined in Refs. 21 and 26. The coefficient c_{STO} is given by the real part of formula (67), while the coefficient c_{num} is obtained in numerical simulation as described in Sec. IV A.

It is clear that the results given by analytical formula are comparable with those obtained by finite element simulation and close to the measured values. Particularly, this validates directly the formula (67) for determining the damping and spring force for a cell. The precision of the analytical results are less in the case of perforated microstructures having a high area ratio. A better analytical approach in this case needs a more precise representation of the velocity in the opening. Also the total damping coefficient can be corrected by adding an edge correction to the boundary cells similar to the correction introduced in Ref. 21 for the case of the Reynolds' equation.

The results included in column 3 in Table II show that the Reynolds' lubrication model predictions fall below the results from the other two models. In some cases even the first digit of the total damping coefficient C_{Rey} is incorrect.

Table III presents the relative errors in the damping coefficient between the experimental values reported in Ref. 28, the four compact models presented in Ref. 16, and the relative error from the methods developed in this paper. The second column in Table III gives the relative error ΔM1 corresponding to the compact model M1 of Bao[10] for a rectangular damper that has a much larger length than width. The relative error values in column 3 (ΔM2) correspond to the model presented in Ref. 10 for an arbitrary rectangular surface. Columns 4 and 5 contain the relative errors (ΔM3 and ΔM4) of the compact models developed by Veijola:[5] model M3 corresponds to circular perforations of the backplate while model M4 was tailored specifically for square holes.[12] Column 6 includes the relative errors ΔSTO resulting from the use of the presented analytical formula and the last column includes the errors Δnum of the numerical simulation by the finite element method.

The results of numerical simulation given in this paper are in closer agreement with the measured values than those of the compact methods for all the microstructures considered. Also the values for the damping coefficient obtained by using the analytical formula for the damping coefficient of a cell compares well with the results reported in Ref. 16 for the compact models.

VI. CONCLUSIONS

A model for analyzing the viscous damping in a unit cell of a perforated microstructure has been developed. The model is based on the Stokes' equations for compressible, isothermal, viscous flow, and the approximation of the peri-

odic structure of common devices (squares or hexagonal prisms) by an equivalent axisymmetrical cylindrical domain. The analysis yields an analytical formula for the complex force (damping force and spring force) generated by the vibrating plate of the microstructure.

In addition, a FEM solution was used to determine the damping on the cell in the axisymmetrical domain.

The predictions for the damping coefficients from the analytical formula and numerical simulation were compared for some test microstructures and are found to be in good agreement. Also, these results are found to be in good agreement with some measured values found in the literature for some MEMS devices. This validates the model and demonstrates its broader range of applicability to real perforated microstructures. Also, the results obtained by these models compare well with the values given by some compact models in appropriate parameter ranges.

APPENDIX: FINITE HANKEL TRANSFORMS AND MODIFIED FINITE HANKEL TRANSFORMS

In this appendix we prove the relationships (A5) and (A6) which are used in Sec. III A.

1. Some definitions and properties

We consider the finite Hankel transform of the function $u(\rho)$ with respect to ρ-variable defined by the relationship[29] (p. 83)

$$\tilde{u}(q_i) \equiv \tilde{\mathbb{J}}_1[u(\rho)] = \int_0^R u(\rho)\rho J_1(q_i\rho)d\rho, \tag{A1}$$

where q_i is a root of the transcendental equation

$$J_1(q_iR) = 0. \tag{A2}$$

At any point of $(0,R)$ at which the function $u(\rho)$ is continuous, the original function can be recovered by means of the inversion formula

$$u(\rho) = \frac{2}{R^2}\sum_i \tilde{u}(q_i)\frac{J_1(q_i\rho)}{[J_0(q_iR)]^2}, \tag{A3}$$

where the sum is taken over all the positive roots of Eq. (A2).

We define also the modified finite Hankel transform of the function $w(\rho)$ by formula

$$\hat{w}(q_i) \equiv \hat{\mathbb{J}}_0[w(\rho)] = \int_0^R w(\rho)\rho J_0(q_i\rho)d\rho. \tag{A4}$$

Inversion formula for the modified finite Hankel transform can be written as

$$w(\rho) = \frac{2}{R^2}\sum_{i=0}^{\infty} \hat{w}(q_i)\frac{J_0(q_i\rho)}{[J_0(q_iR)]^2}.$$

2. Calculation of some transforms

In the case of the function

$$f(\rho,r) = \begin{cases} \rho, & 0 \le \rho < r \\ 0, & r < \rho < R, \end{cases}$$

there results

$$\tilde{f}(q_ir) = \int_0^r \rho^2 J_1(q_i\rho)d\rho = r^3\int_0^1 t^2 J_1(q_irt)dt.$$

The last integral is given again by formula (6.567(1)) in Ref. 30. Therefore,

$$\tilde{f}(q_i,r) = r^3\frac{J_2(q_ir)}{q_ir}. \tag{A5}$$

In the case of the function,

$$h(\rho,r) = \begin{cases} 1, & 0 \le \rho < r \\ 0, & r < \rho < R, \end{cases}$$

there results

$$\hat{h}(q_i,r) = \int_0^r \rho J_0(q_i\rho)d\rho = r^3\int_0^1 tJ_0(q_irt)dt.$$

The last integral is given by formula (6.567(9)) in Ref. 30,

$$\hat{h}(q_i,r) = r^2\frac{J_1(q_ir)}{q_ir}. \tag{A6}$$

(Received 22 January 2009; revised 20 October 2009; accepted 31 December 2009)

Squeal from railway wheels occurring in short radius curves produces a very intense and highly annoying noise in the range 400–8000 Hz. When the excitation, due to lateral forces acting on the wheel, cannot be avoided, additional systems can be added on the wheel to limit acoustic emission. A very economical approach is the use of metal rings inserted into grooves machined in the wheels. Unfortunately the effectiveness of these so called *damping rings* varies from one wheel to another and for different rings. Because the mechanisms of attenuation are not well understood, these variations have not to date been explained. The aim of this paper is to clarify the attenuation mechanisms for damping rings especially for the first three axial wheel modes, which are the predominant sound radiated ones in curve passage and for which the effectiveness of the treatment is lower. It has been generally assumed that friction between the ring and the groove has been the mechanism for squeal noise attenuation. Here it is shown that the vibration attenuation is due to modal coupling between the wheel and the ring. The validity of this proposed mechanism is investigated using experimental measurements and theoretical and numerical models. The results presented here will provide an avenue for optimization of the damping ring noise control treatment to obtain significant levels of squeal noise attenuation notably for the first three axial modes.

I. INTRODUCTION

Curve squeal is one of the most significant source of noise annoyance on metros and tramways. Noise levels can reach 140 dB close to the wheel. Squeal noise is due primarily to the excitation of one or more axial wheel modes from 400 Hz to 10 kHz (Vincent *et al.*, 2004). The origin of curve squeal was first explained by Rudd (Rudd, 1976) He concluded that in a curve in addition to rolling the wheel slides laterally across the rail, resulting in lateral contact forces that lead to self-excited vibrations of the wheel (Brunel and Dufrénoy, 2007). A great number of wheel modes are then excited leading to acoustic emissions with overall sound pressure levels up to 120 dB close to the wheel (Thompson and Jones, 2000). At macroscopic scale, friction forces depend on various parameters: curve radius, wheel modal frequencies, and damping of the wheel. At the microscopic scale, the self-excited vibrations are generated by a feedback mechanism involving dry friction and the motion of the wheel relative to the rail. Parameters are average lateral velocity, contact pressure distribution, microscopic properties of the wheel, and rail surfaces. Although many parameters strongly influence the excitation (and hence the occurrence and intensity) of squeal, it is proposed in this work to use a simplified excitation, consisting of a harmonic lateral force on the wheel as would be induced by the lateral sliding of the wheel on the rail as a rail vehicle rounds a curve (Rudd, 1976). This simplified approach is justified since the objective of this work is understanding the mechanisms of a specific acoustic attenuation system. It is also well known by experiments that the modes excited during squealing in curves are very close to the eigenmodes of the wheel with nodal lines consisting of one circle and several diameters (Wetta and Demilly, 1985). Figure 1(a) illustrates this point where the peaks correspond to n-m modes of the wheel with $n=0$ (the number of circles) and $m=2-5$ (the number of lines or diameters). These modes will, of course, be well excited by the proposed excitation.

Various treatments for the mitigation of curve squeal noise have been developed. The use of damping rings is one of the most cost effective. Viscoelastic treatments or acoustic baffles are typically much more expensive. To employ the treatment, wheels are equipped with one or two rings inserted into grooves in the rim of the wheel. Acoustic measurements on trains under normal operating conditions show that these ring-damped wheels can reduce squeal noise by about 10 dB at a distance of about 7 m from the track [Fig. 1(b)] (Wetta and Demilly, 1985) when compared to existing wheels. However, it has been observed that the effectiveness depends on the application and may vary a great deal from one wheel to another with no plausible explanation. An illustration of this point is presented in the second part of this paper. Reliable performance of the ring damping treatment can only be achieved, if the physical mechanism associated with the noise attenuation is well understood. While friction or impact between the ring and groove are usually thought to

be the mechanism for squeal noise attenuation (Akay, 2002; López, 1999; López *et al.*, 2004), recent numerical investigations have shown that these two mechanisms can only account for a reduction of about 1 dB in wheel vibration and noise (Brunel *et al.*, 2006), not the normally observed 10 dB, mentioned above.

Experimental measurements on the wheel with a ring have been performed and are presented in Sec. III where the effect of tightness of the ring in the groove is examined. Those results are discussed and used for comparison with the theoretical approach developed in Sec. IV. From these results, an original explanation of the mechanism of squeal noise attenuation by damping rings is proposed. A three-dimensional (3D) numerical model of the railway wheel is employed in Sec. V to validate the proposed explanation. Finally, conclusions and perspectives are discussed in Sec. VI.

II. DESCRIPTION AND EFFECTIVENESS OF RING DAMPERS

The damping ring treatment is a simple way to increase damping of axial modes in the wheel. To apply the treatment, one or two metal rings are inserted into grooves machined into the rim of the wheel [Fig. 2(a)]. The ring is first inserted into the groove by compressing it circumferentially. Afterwards it is welded together at its open end [Fig. 2(b)]. Attenuation is about 10 dB [as shown in Fig. 1(b)] and can reach up to 20 dB for particular conditions. Several conclusions may be summarized from previous experimental investigations (Brunel *et al.*, 2003). The noise reduction depends directly on the assembly conditions and particularly on the welding operation. The ring insertion leads to a damping increase (mean loss factors are as high as 0.3% in the frequency range of 3000–8000 Hz for the double damping ring treatment compared to 0.07% for the untreated wheel). The loss factors are increased primarily in the first three eigenmodes excited during squealing (0-2, 0-3, 0-4). For a single ring, the loss factors are around 0.12%. Significant variations in the noise reduction performance are obtained even for similar wheels with rings welded under the same conditions.

Preload between the ring and the groove seems to be the most important factor in determining the noise attenuation (in industrial conditions, preload is obtained at the welding operation but is not controlled during the process). This factor is controlled in this study by equipping a 25 mm diameter ring with a screw-nut system inserted between the two ends of the ring [Fig. 2(c)]. The preload is measured by strain gauges on the ring and by the relative displacements of the ring's extremities (Brunel *et al.*, 2004b).

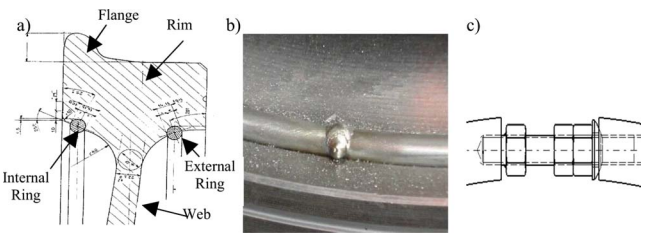

FIG. 2. (Color online) The ring-damped wheel and the system for controlling preload.

III. EXPERIMENTAL INVESTIGATION OF THE ATTENUATION MECHANISMS

A. Experimental setup

Experimental measurements were performed in a reverberant room on a wheel equipped with an external ring [Fig. 2(a)]. The focus was on one squealing mode corresponding to the 0-3 mode of the wheel, at around 1100 Hz (Thompson and Jones, 2000) (Brunel *et al.*, 2004a). The wheel was excited in the axial direction with a dynamic shaker (Fig. 3) driven with white noise (0–8000 Hz). The purpose of the shaker was to simulate a lateral force excitation as explained in the Introduction. That simulation is, of course, not perfect in that the force level is relatively low (<100 N) and that the feedback mechanism between the dry-friction force in the wheel/rail contact and the motion relative to the rail cannot be simulated. However, results show that the excited fre-

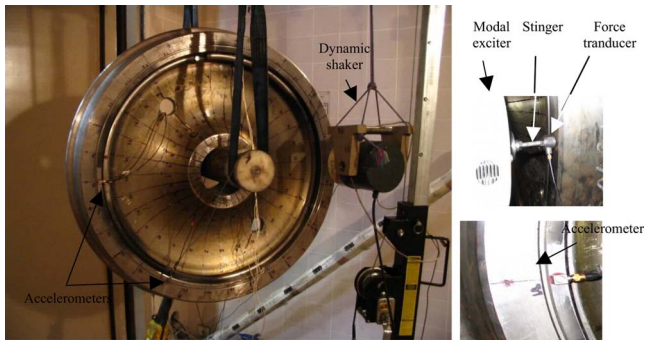

FIG. 3. (Color online) Experimental setup.

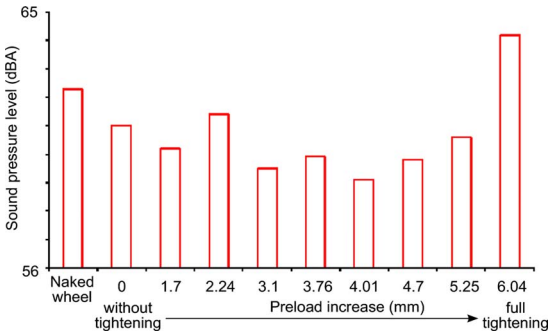

FIG. 4. (Color online) Sound pressure level vs preload.

quencies are the same as those measured near a curved track during a train passage and that the radiated noise levels are significant and concern the right frequencies.

The global noise level in the reverberant room has been determined in the range 500–4000 Hz and is plotted in Fig. 4 with various ring preload values. Values of ring preload refer to the distance between the two extremities of the ring. Note that the case "without tightening" corresponds to the case where the ring was inserted into the groove without expanding the ring to create a supplementary force.

Results show that increasing the preload first decreases the sound pressure level until a middle range of tightening with minimum noise level. For higher preload, the noise level increases to values greater than achieved with the naked wheel. Note that for the case without tightening, some acoustic attenuation exists due to the initial preload obtained during assembly. Several configurations have been tested showing the repeatability of this observation with a middle range of preload for which acoustic emissions are lower.

B. Acceleration spectra

In addition to acoustic measurements, the acceleration of the wheel and the ring were measured by accelerometers fixed on the wheel and on the ring at the same angular position. Waterfall plots of the axial wheel acceleration vs ring preload are shown in Fig. 4(a). Each spectrum of the waterfall plots of Fig. 5(a) corresponds to a preload value of the ring. The last spectrum relates to the naked wheel response. Note that the successive frequency peaks correspond to eigenmodes of the wheel as seen on the naked wheel spectrum and that due to the direction of excitation, these modes are 0-*n* type corresponding to those excited during squeal. For high frequencies (greater than 3000 Hz), the ring damper seems to be effective for a large preload band. For the first four modes, comparisons with the naked wheel show that the reduction in wheel acceleration depends strongly on the preload and that there is an "optimal range" of preload where the acceleration is minimized.

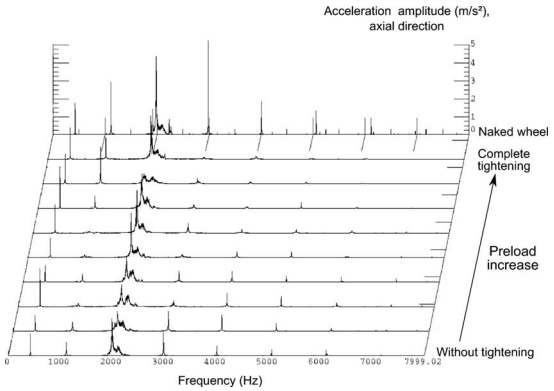

FIG. 5. Waterfall plots of the wheel acceleration vs preload and frequency.

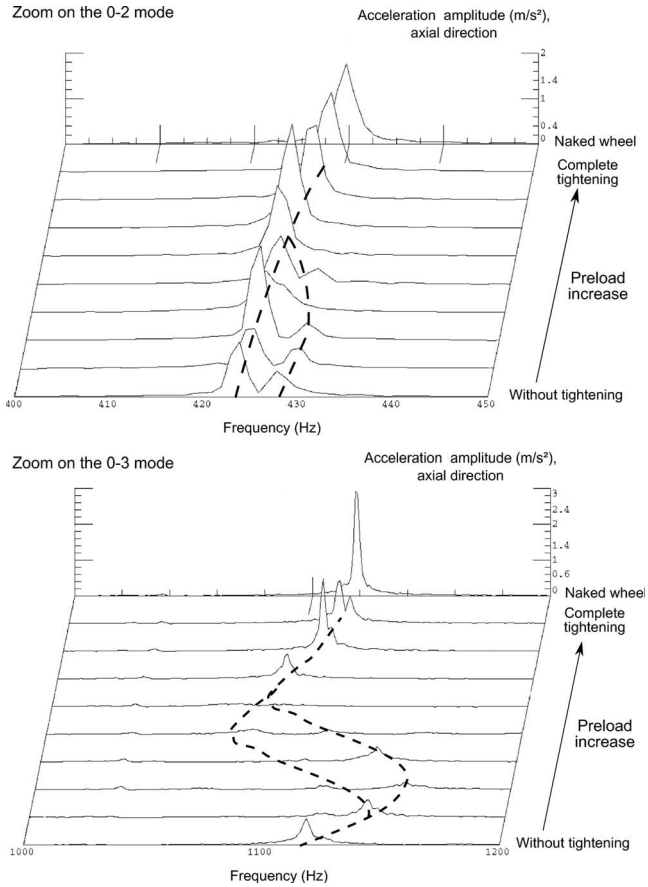

FIG. 6. Evolution of the wheel modes with preload increase.

The following highlights some of the observations with regard to the effect of ring preload.

- Slight variation of the first two modal frequencies with preload (see Fig. 6). The range of preload where the acceleration is significantly reduced is the same as the range where the modal frequencies change the most. As the preload is increased, the wheel modal frequencies first increase and then rapidly decrease. The frequencies then increase but stay below the modal frequencies of the naked wheel.
- Decrease in the acceleration levels of the wheel and ring (see Fig. 7).

In the experiments, the ring-damped wheel is excited with a sinusoidal function at the exact frequency of the wheel eigenmode (adjusted for each preload). Figure 6 presents the axial acceleration spectra of the wheel and the ring vs preload for a sinusoidal excitation of the 0-3 mode of the wheel at approximately 1100 Hz. Around the optimal preload, attenuation of the vibration of both the wheel and the

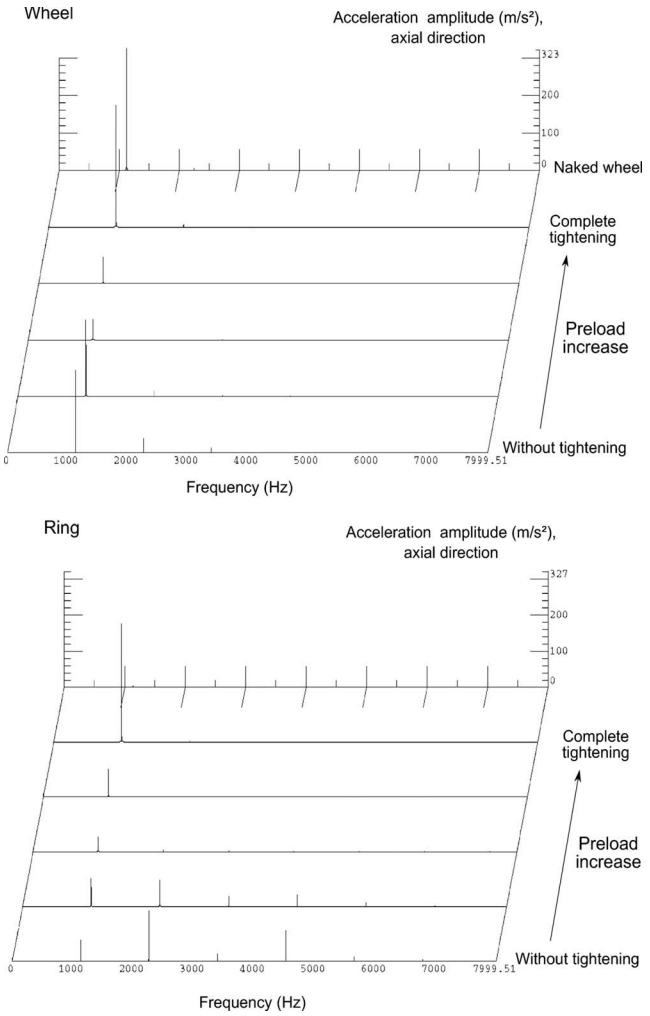

FIG. 7. Waterfall plots of wheel and ring acceleration for a sinusoidal excitation of the 0-3 mode.

ring can be seen. Note that harmonics are observed in the ring acceleration spectra for low preload. Figure 8 shows wheel and ring time acceleration for low and high preload. For low preload, ring and wheel vibratory responses are uncoupled, with independent dynamic motions contrary to the coupled motion obtained for high preload.

Attenuation mechanism seems to progress coupling between the ring and the wheel circumferentially with tightening increase. It may explain the presence of harmonics for low preload.

C. Summary of the experimental results

Several points have been highlighted during the experimental investigations:

- existence of a range of optimal preload values leading to the lowest sound pressures between the extreme configurations of none and complete tightening of the ring,
- a sound pressure level greater than the naked wheel (without ring) when the preload is maximum corresponding to a full tightening of the ring,
- modification of the wheel frequencies by varying preload, and

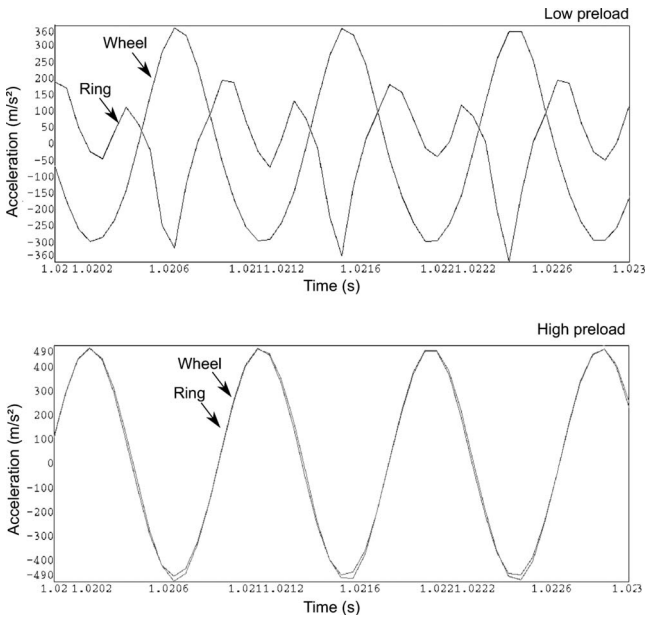

FIG. 8. Wheel and ring acceleration time history for a sinusoidal excitation of the 0-3 mode and for low and high preloads.

- attenuation of both the wheel and ring acceleration levels around the optimal preload values.

Note that none of these observations refer to impact or friction phenomena between the ring and the groove. It appears that as the preload increases the ring-wheel system changes from one in which the ring and wheel are uncoupled to one in which the two are fully coupled. To help explain these experimental results, we now turn to a simplified theoretical model in Sec. IV.

IV. THEORETICAL MODEL OF THE ATTENUATION MECHANISM

In this section, we simulate the wheel-ring system with a one-dimensional mass-spring model to illustrate the mechanism of attenuation. A comprehensive a 3D numerical model will be presented in Sec. V.

The mass-spring model is based on a two two-degree-of-freedom double mass-spring system, as shown in Fig. 9. The first mass M_w refers to the wheel and the second M_r refers to the ring. Wheel and ring displacements are noted X_w and X_r, respectively.

Mass, stiffness, and damping parameters are listed in Table I. They have been adjusted to obtain the same resonance frequency of the experimental wheel eigenmode: 0-3 at around 1100 Hz. Note that the damping ratio for the naked wheel is around 0.02%. Preload effects are introduced by the

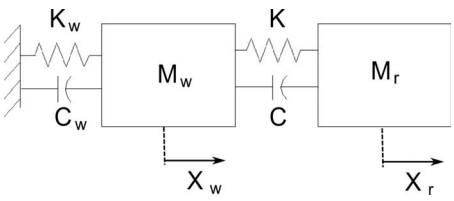

FIG. 9. 2 DOF model of the ring-damped wheel.

TABLE I. Parameters used in the mass-spring model.

M_w	300 kg
M_r	9 kg
K_w	1.5×10^{10} N/m
C_w, C	425 N s/m

stiffness between the ring and the wheel. The relationship between wheel-ring contact stiffness and preload is not known but is assumed that the stiffness increases monotonically with load. Finally, K and C correspond to contact stiffness and damping, respectively, of the ring and wheel assembly. Note that the natural frequency of the ring is not considered in the analytical approach. The main assumption is the contact induced stiffness is greater than the ring stiffness. The analytical model is only presented here to explicit the coupling mechanism but it is clear that it can be improved by introducing the mass-spring-damped system for the ring, which would eliminate the natural frequency of the ring going to zero when the contact spring stiffness goes to zero. However, it needs to characterize the ring stiffness.

Displacement amplitudes of the wheel and the ring are given by

$$\left|\frac{X_w}{F}\right| = \left|\frac{K + iC\omega - \omega^2 M_r}{(K_w + K - M_w\omega^2 + i(C_w + C)\omega)(K - M_r\omega^2 + iC\omega) - (K + iC\omega)^2}\right|,$$

$$\left|\frac{X_r}{F}\right| = \left|\frac{K + iC\omega}{(K_w + K - M_w\omega^2 + i(C_w + C)\omega)(K - M_r\omega^2 + iC\omega) - (K + iC\omega)^2}\right|. \quad (1)$$

Natural frequencies are given by the roots of the characteristic polynomial of the system (1), damping effects are neglected. Figure 10 shows the change in the natural frequencies with respect to the contact stiffness K.

For low values of K, the natural frequencies of the two systems (wheel and ring) are well separated. Wheel and ring natural frequencies increase with contact stiffness, with the ring increasing more rapidly.

For a contact stiffness value of $K=4.5\times10^8$ N/m, the main mass amplitude is zero. For higher stiffnesses, the natural frequencies are for the coupled wheel-ring system and the ring alone. As observed in the experimental investigations, the natural frequencies increase with increasing contact stiffness (increasing preload). Around the transition zone, a bifurcation of the wheel natural frequency to a wheel-ring system appears. Two close natural frequencies exist. This point is illustrated in Fig. 11 by the amplitude of vibration of each component. In the transition zone (around the white line in Fig. 11), both wheel and ring accelerations decrease.

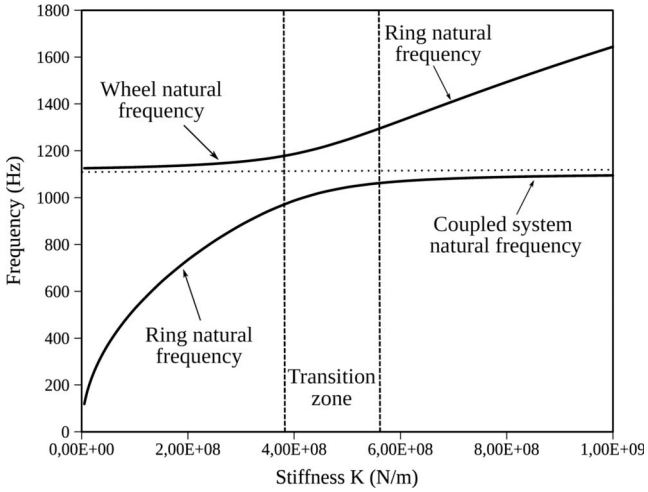

FIG. 10. Natural frequencies vs contact stiffness.

K corresponds to global value of the wheel-ring assembly considering that the ring stiffness is much lower the induced contact stiffness. However, the natural frequency of the ring is not described separately and goes to zero when the contact spring stiffness goes to zero (Figs. 10 and 11). This model may be improved by introducing a mass-spring-damped system for the ring providing its characterization.

Note that this simple model gives an explanation of most of the experimental observations: variations in the wheel natural frequency with preload, appearance of many peaks around the optimal value of preload and attenuation of acceleration levels of the wheel as well as those of the ring.

The simplified model helps to explain the origin of the attenuation of vibration as a stiffness modification leading to a bifurcation of the wheel mode to a wheel-ring mode. This bifurcation results in a decrease in the level of acceleration of both components.

V. 3D FEM APPLICATION

In this section a 3D FE model of the wheel equipped with an external ring, is used in a prestressed modal analysis to determine the natural frequencies of the system. The geometry of the model is presented in Fig. 12(a) and is described in (Brunel, 2004a, 2004b). Contact between the ring and the groove is modeled by surface-surface contact elements with a penalty algorithm (contact stiffness is introduced when the contact element status is closed allowing the ring-wheel contact forces in all directions to be included in the analysis). In this investigation the modal analysis is focused around the mode (1100 Hz) that was investigated experimentally. In addition, the normal stiffness of the contact

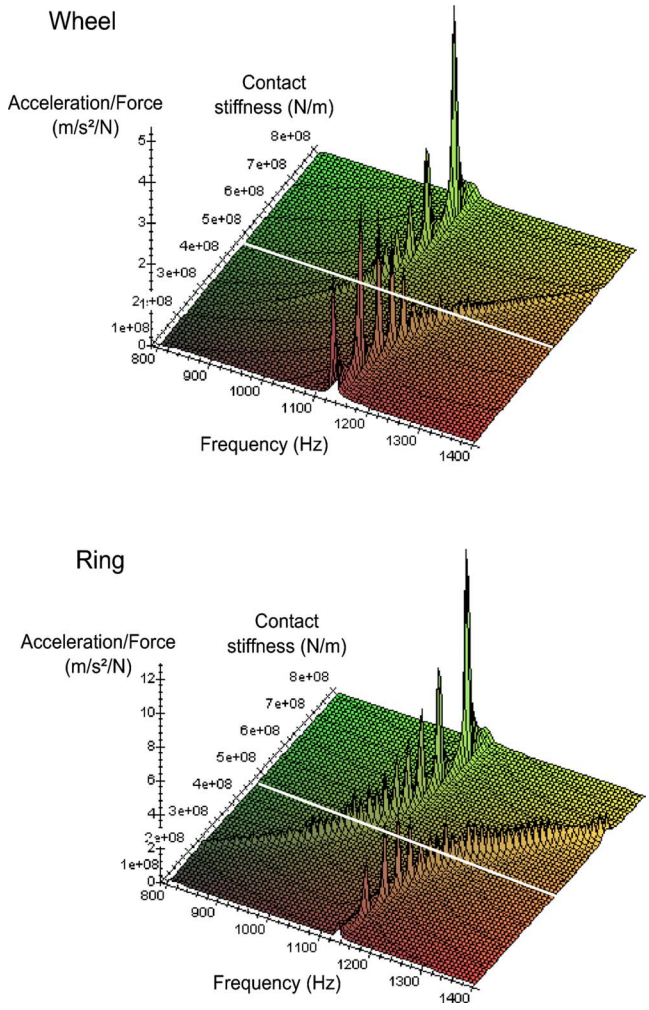

FIG. 11. (Color online) Wheel and ring acceleration response vs contact stiffness.

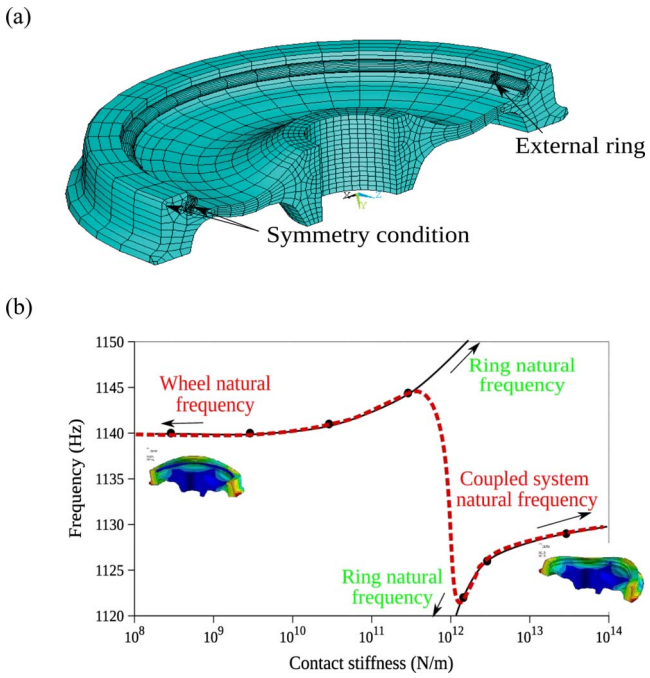

FIG. 12. (Color online) (a) 3D FE model of the ring-damped wheel. (b) 0–3 mode frequency vs contact stiffness.

elements has been varied between 1×10^9 and 1×10^{14} N/m, simulating the preload variation in the experiment.

Figure 12(b) shows that the same vibration behavior is obtained with this more complex model as was obtained with the previous simplified theoretical model. Increasing the contact stiffness causes the wheel natural frequency first to increases, followed by a decrease corresponding to a bifurcation to a coupled mode. Further increases in contact stiffness then cause the coupled wheel-ring frequency to increases. Pictures of the finite element model (FEM) results show that above the contact stiffness that results in bifurcation, the wheel and the ring vibrate together. Note that this numerical simulation also shows a jump in frequency of about 25 Hz (in the bifurcation region) that agrees with that observed experimentally.

VI. CONCLUSIONS

This paper presents a study of the effect of preloaded metal rings inserted into grooves in railway wheels. The aim is to design optimized railway wheels which are less noisy during squeal. A combined theoretical and experimental approach was taken. Experiments indicated that there is an "optimal preload," where the response of the wheel-ring system (measured in terms of axial accelerations and also in terms of radiated sound pressure) to white noise is smaller than that of the wheel without ring. A theoretical model of the wheel-ring system was created that consisted of a one-dimensional two-degree-of-freedom double mass-spring system with a spring of variable stiffness connecting the two masses. The resonance frequencies of this system were calculated, and it was found that for low stiffness the two masses move largely independently, while coupled motion was observed for higher stiffness. A FEM model was also developed that gave three-dimensional displacements and forces in the wheel system and lead to the same kind of results, with more accurate values compared to experiments. It is remarkable that the model proposed here gives the same conclusions as all of the experimental observations: modal frequency variation, optimal stiffness/preload (value corresponding to the lowest acceleration of both the wheel and the ring), and highest noise level if preload is maximum.

It is concluded that the transition from independent to coupled motion is the mechanism responsible for the reduced wheel noise at the optimal preload. It also confirms previous results of a secondary influence of friction dissipation at the wheel-ring contact.

The models can now be used to analyze the impact of the damping ring on each mode of the wheel. They also allow a sensitivity analysis to be carried out to determine the key parameters giving maximal attenuation.

Furthermore knowledge of the attenuation mechanism can be used to open new ways to improve the reliability and the efficiency of the ring dampers. For example, it explains that connecting the extremities of the ring by welding gives variable noise reduction performance because the preload is not controlled. For more reliable performance, the preload

obtained during the assembly process has to be controlled. Several ways are under investigation for improving the noise reduction performance of the damping rings, such as by using different ring geometries and by controlling values of the ring preload to attenuate the noisiest modes.

(Received 27 June 2008; revised 19 August 2009; accepted 22 December 2009)

Non-destructive evaluation of heterogeneous materials is of major interest not only in industrial but also in biomedical fields. In this work, the studied structure is a three-layered one: A laterally heterogeneous anisotropic solid layer is sandwiched between two acoustic fluids. An original method is proposed to solve the wave equation in such a structure without using a multilayered model for the plate. This method is based on an analytical solution, the matricant, explicitly expressed under the Peano series expansion form. This approach is validated for the study of a fluid-loaded anisotropic and homogeneous plane waveguide with two different fluids on each side. Then, original results are given on the propagation of elastic waves in an asymmetrically fluid-loaded waveguide with laterally varying properties. This configuration notably corresponds to the axial transmission technique to the ultrasound characterization of cortical bone *in vivo*.

I. INTRODUCTION

A lot of natural media have unidirectional varying elastic properties. The mantel crust, the oceans, and cortical bone are some of these functionally graded media. Scientists focused on the advantages presented by this type of materials in terms of mechanical behavior, and since the 1980s, they developed industrial functionally graded materials (FGMs) particularly exploited in high-technology and biomedical applications. Consequently, the non-destructive evaluation of these materials is a key issue. Surface and guided waves play a major role in non-destructive testing and evaluation of complex structures. Several studies are dedicated to the leaky Lamb wave propagation in fluid-loaded plates (Chimenti and Nayfeh, 1990; Chimenti and Rokhlin, 1990; Deschamps and Poncelet, 2000). In all these studies, the media are homogeneous or multilayered. In this work, we introduce a general method to take into account the continuity of the property variation in an anisotropic waveguide. This method is based on the knowledge of an analytical solution of the wave equation, the matricant, explicitly expressed via the Peano series (Peano, 1888). The accuracy of the numerical evaluation of this solution and its validity domain are perfectly managed (Baron, 2005; Youssef and El-Arabawi, 2007). Because it deals with an analytical solution, all the wave propagation parameters are controlled. This represents an advantage with respect to numerical methods such as finite-element and finite-difference methods for which the problem treated is a global one, making difficult to analyze and interpret the experimental data, which result from the interaction and coupling of numerous physical phenomena. To the best of our knowledge, this is the first method to evaluate the mechanical behavior of a fluid-loaded anisotropic waveguide with continuously varying properties without modeling the FGM plate by a multilayered plate. Consequently, in the context of real materials with continuously varying properties (such as bone, bamboo, or manufactured FGM), this method could allow assessing the solution to a more realistic model with a controlled accuracy and without an increase in the computation-time.

In this work, we first present the method and its setup with fluid-structure interaction; then we proceed to the validation of the method by comparing our results to the dispersion curves obtained from classical schemes on homogeneous waveguides (isotropic and anisotropic). Two advantages of the method are underlined: (i) An asymmetric fluid-loading may be taken into account without modifying the scheme for the numerical solution, and (ii) the influence of the property gradient on the ultrasonic response of the waveguide may be investigated via the frequency spectrum of the reflection coefficient modulus. Finally, we get onto the relevancy of this model applied to the ultrasound characterization of cortical bone by the axial transmission technique.

II. BACKGROUND

Contemporary work efforts over the last 2 decades illustrate some of the technology interest on guided waves to non-destructive evaluation. Namely, Rose (2002) gave a review of ultrasonic guided wave inspection potential. A lot of papers deal with the interaction between guided waves and a solid plate immersed in a fluid or embedded between two different fluids. Guided modes in an infinite elastic isotropic plate in vacuum were first treated by Rayleigh (1885) then by Lamb (1917). The Lamb wave problem is reserved, strictly speaking, for wave propagation in a traction-free homogeneous isotropic plate. To deal with guided modes in a fluid-loaded plate, we use the term "leaky Lamb waves" as the energy is partly radiated in the fluids on both sides of the plate. For the basic Lamb problem—plate in vacuum—the

[a)]Author to whom correspondence should be addressed. Electronic mail: naili@univ-paris12.fr

solutions of the dispersion equation are real whereas in the case of a plate bounded by media on both sides, the dispersion equation has complex solutions. In 1961, Worlton (1961) gave an experimental confirmation of the theoretical work of Lamb (1917), by obtaining experimentally the dispersion curves of aluminum and zirconium plates, asserting that water loading has little effect on the behavior of waves in plates. In 1976, Pitts *et al.* (1976) presented some numerical test results on the relationship between real part of the reflection coefficient poles and the phase velocity of leaky Lamb modes in a homogeneous isotropic brass plate in water. Folds and Loggins (1977) proposed analytical expressions of the reflection and transmission coefficients for plane waves at oblique incidence on a multilayered isotropic plate immersed in water based on Brekhovskikh's (1980) analysis. They found good agreement with their theoretical results and experimental data. Few years later, Fiorito *et al.* (1979) developed a resonance formalism for the fluid-loaded elastic plate and gave some theoretical and numerical results for an isotropic steel plate immersed in the water. This formalism was generalized to the interactions of acoustic plane waves with an asymmetrically fluid-loaded elastic plate by Franklin *et al.* (2001). Nayfeh, Chimenti, and Rokhlin produced a lot of works on wave propagation in anisotropic media and particularly in fiber composite plates immersed in a fluid (Chimenti and Nayfeh, 1986, 1990; Chimenti and Rokhlin, 1990; Nayfeh and Chimenti, 1988, 1989; Rokhlin and Wang, 2002). Based on their formalism, Deschamps and Poncelet (2000) placed the emphasis on the difference between what they called transient Lamb wave-solutions of the characteristic equation of the plate for complex frequency and real slowness (time attenuation), and heterogeneous Lamb waves for which the slowness is complex and the frequency is real (spatial attenuation). These two ways of resolution of the dispersion equation have two different physical meanings—space or time attenuation—and consequences of this difference are developed in their paper (Deschamps and Poncelet, 2000). A critical point is the validity of the Cremer's coincidence hypothesis: The real couples (angular frequency ω and phase velocity v_φ), such that the reflection coefficient is minimum, may be identified as velocity dispersion of plate waves. Experimentally checked in a lot of configurations, it appears to be not well satisfied in several cases (for instance, graphite-epoxy plates when the ratio between fluid and plate mass densities is not "small") (Chimenti and Nayfeh, 1986; Nayfeh and Chimenti, 1988). The results obtained by Deschamps and Poncelet (2000) on fluid-loaded plate show a good correlation between dispersion curves obtained in complex frequency and the minima of the reflection coefficient, which suggests that the Cremer's coincidence principle is still valid considering time attenuation. All these studies show the evidence that the wave propagation in fluid-loaded elastic plate emerges as a very delicate problem, which needs cautious treatment.

III. GENERAL FORMULATION OF THE PROBLEM

We consider a three-dimensional multilayer system composed of one elastic solid layer sandwiched between two acoustic fluid layers. Let $\mathbf{R}(\mathrm{O},\mathbf{x}_1,\mathbf{x}_2,\mathbf{x}_3)$ be the Cartesian frame of reference where O is the origin of the space and $(\mathrm{x}_1,\mathrm{x}_2,\mathrm{x}_3)$ is an orthonormal basis for this space. The coordinate of the generic point $\mathbf{x}$ in $\mathbf{R}$ is specified by (x_1,x_2,x_3). The acoustic fluid layers occupy an open unbounded domain. Both fluids f_1 and f_2 are supposed perfect, of respective mass densities ρ_{f_1} and ρ_{f_2}; the constant speeds of sound in each fluid are c_{f_1} and c_{f_2}, respectively. The thickness of the solid layer is denoted by d and its mass density by ρ. The interfaces between the fluids and the solid layer are infinite planes parallel to the $(\mathbf{x}_1,\mathbf{x}_2)$-plane. The $\mathbf{x}_3$-axis is oriented downward and the origin O is located at the interface between the upper fluid f_1 and the solid layer. Therefore, we assume that the structure is a two-dimensional one and that the guided waves travel in the plane $x_2=0$; in the following parts, this coordinate is implicit and is omitted in the mathematical expressions. Moreover, the solid layer will be so-called plate.

The elastic plate is supposed to be anisotropic and is liable to present continuously varying properties along its thickness ($\mathbf{x}_3$-axis). These mechanical properties are represented by the stiffness fourth-order tensor $\mathbb{C}=\mathbb{C}(x_3)$ and the mass density $\rho=\rho(x_3)$.

A. System equations

1. The wave equation in the fluid f_n (for n=1 or 2)

In the fluid f_n and the context of the linear acoustic theory, the linearized Euler's equation and the constitutive equations are written as

$$-\frac{\partial p^{(n)}}{\partial x_j}=\rho_{f_n}\frac{\partial^2 u_j^{(n)}}{\partial t^2},$$

$$p^{(n)}=K_{f_n}\,\mathrm{div}\,\mathbf{u}^{(\mathbf{n})}, \tag{1}$$

where $\mathbf{u}^{(n)}$ and $p^{(n)}$, respectively, represent the displacement vector and the pressure in the fluid f_n; its compressibility and the speed of sound in the fluid at equilibrium are, respectively, K_{f_n} and $c_{f_n}=\sqrt{K_{f_n}/\rho_{f_n}}$. The operator div is the divergence.

The solutions of system (1) for the fluid f_n are sought under the form

$$\mathbf{f}_n(x_1,x_2;t)=\mathbf{A}_n(x_3)\exp\,\imath(k_1x_1+k_3^{(n)}x_3-\omega t), \tag{2}$$

where k_1 and $k_3^{(n)}$ are the wavenumbers, respectively, along the $\mathbf{x}_1$-axis and $\mathbf{x}_3$-axis in the fluid f_n; the angular frequency is noted ω and $\imath$ is the imaginary unit.

We consider an incident wave reaching the plate at an angle θ_1 from the $\mathbf{x}_3$-axis in the fluid f_1. The incident displacement-field is defined in the following form, assuming that its amplitude is normalized:

$$\mathbf{u}_I^{(1)}=\begin{pmatrix}\sin\,\theta_1\\0\\\cos\,\theta_1\end{pmatrix}\exp\,\imath(k_1x_1+k_3^{(1)}x_3-\omega t), \tag{3}$$

with $k_1=(\omega/c_{f_1})\sin\,\theta_1$ and $k_3^{(1)}=(\omega/c_{f_1})\cos\,\theta_1$. From this, the expressions of the reflected displacement-field $\mathbf{u}_R^{(1)}$ in f_1 and of the transmitted displacement-field $\mathbf{u}_T^{(2)}$ in f_2 are deduced as follows:

$$\mathbf{u}_R^{(1)} = R\begin{pmatrix} \sin\theta_1 \\ 0 \\ -\cos\theta_1 \end{pmatrix} \exp \iota(k_1 x_1 - k_3^{(1)} x_3 - \omega t),$$

$$\mathbf{u}_T^{(2)} = T^{\frac{c_{f_2}}{c_{f_1}}}\begin{pmatrix} \sin\theta_1 \\ 0 \\ \cos\theta_1 \end{pmatrix} \exp \iota(k_1 x_1 + k_3^{(2)} x_3 - \omega t). \quad (4)$$

where $R=R(x_1,x_3;t)$ and $T=T(x_1,x_3;t)$, respectively, represent the reflection and transmission coefficients, which will be expressed explicitly in the sequel. The incident, reflected, and transmitted pressure fields, respectively, noted $p_I^{(1)}$, $p_R^{(1)}$, and $p_T^{(2)}$, are deduced from expressions (3) and (4), and the second equation of the system (1)

$$p_I^{(1)} = -\iota\omega \times \rho_{f_1} c_{f_1} \times \exp \iota(k_1 x_1 - k_3^{(1)} x_3 - \omega t),$$

$$p_R^{(1)} = -\iota\omega \times \rho_{f_1} c_{f_1} \times R \times \exp \iota(k_1 x_1 - k_3^{(1)} x_3 - \omega t),$$

$$p_T^{(2)} = -\iota\omega \times \rho_{f_2} c_{f_2} \times T \times \exp \iota(k_1 x_1 + k_3^{(2)} x_3 - \omega t). \quad (5)$$

B. The wave equation in the plate waveguide

The body forces in the solid plate are neglected. The balance equation of linear momentum associated with the constitutive law of linear elasticity (Hooke's law) gives the following equations:

$$\frac{\partial \sigma_{ij}}{\partial x_j} = \rho \frac{\partial^2 u_i}{\partial t^2},$$

$$\sigma_{ij} = \frac{1}{2} C_{ijk\ell}\left(\frac{\partial u_k}{\partial x_\ell} + \frac{\partial u_\ell}{\partial x_k}\right), \quad (6)$$

where u_i (for $i=1,\ldots,3$) and σ_{ij} (for $i,j=1,\ldots,3$), respectively, represent the components of the displacement-field $\mathbf{u}$ and of the stress $\boldsymbol{\sigma}$. In system (6), Einstein's convention of summation on repeated indices is used. The solutions are sought for the vectors of displacement $\mathbf{u}$ and traction σ_{i3} (for $i=1,\ldots,3$) (assumed to be harmonic in time t and space along the $\mathbf{x}_1$-axis) under the form

$$\mathbf{f}(x_1,x_3;t) = \mathbf{A}(x_3)\exp \iota(k_1 x_1 - \omega t). \quad (7)$$

C. Fluid-loading interface conditions

The conditions at both interfaces $x_3=0$ and $x_3=d$ are the continuity of the normal displacement and the continuity of the normal stress. We consider that the fluids f_1 and f_2 are perfect; consequently, the shear stresses are zero at the interfaces $[\sigma_{13}(x_1,0;t)=\sigma_{13}(x_1,d;t)=0$ and $\sigma_{23}(x_1,0;t)=\sigma_{23}(x_1,d;t)=0]$. The following relations are obtained:

$$u_3(x_1,0;t) = u_3^{(1)}(x_1,0;t), \quad u_3(x_1,d;t) = u_3^{(2)}(x_1,d;t),$$

$$\sigma_{33}(x_1,0;t) = -p^{(1)}(x_1,0;t), \quad \sigma_{33}(x_1,d;t) = -p^{(2)}(x_1,d;t), \quad (8)$$

with

$$u_3^{(1)} = \mathbf{u}_I^{(1)} \cdot \mathbf{x}_3 + \mathbf{u}_R^{(1)} \cdot \mathbf{x}_3, \quad u_3^{(2)} = \mathbf{u}_T^{(2)} \cdot \mathbf{x}_3 \quad \text{and}$$

$$p^{(1)} = p_I^{(1)} + p_R^{(1)}, \quad p^{(2)} = p_T^{(1)}. \quad (9)$$

D. A closed-form solution: The matricant

Introducing expression (7) in Eq. (6), we obtain the wave equation under the form of a second-order differential equation with non-constant coefficients. For particular forms of profiles, this equation has analytical solutions expressed with special functions (Bessel or Hankel functions) (Vlasie and Rousseau, 2004). But, in the general case, there is no analytical solution to the problem thus formulated. The most current methods to solve the wave equation in unidirectionally heterogeneous media are derived from the Thomson–Haskell method (Haskell, 1953; Thomson, 1950). These methods are appropriate for multilayered media (Hosten and Castaings, 2003; Kenneth, 1982; Lévesque and Piché, 1992; Wang and Rokhlin, 2001). But, for continuously varying media, these techniques mean to replace the continuous profiles of properties with step-wise functions. Thereby, the studied problem becomes an approximate one, even before the resolution step; the accuracy of the solution as its validity domain is hard to evaluate. Moreover, the multilayered model of the waveguide creates some "virtual" interfaces likely to induce artifacts. In order to deal with the exact problem, that is to keep the continuity of the properties' variation, the wave equation is re-written under the form of an ordinary differential equation system with non-constant coefficients for which an analytical solution exists: the matricant (Baron, 2005).

1. Hamiltonian form of the wave equation

We consider that the plate presents material symmetries that allow decoupling the pressure–shear vertical (P-SV) waves, polarized in the propagation plane $(\mathbf{x}_1,\mathbf{x}_3)$ and the shear horizontal (SH) waves polarized along $\mathbf{x}_2$-axis. The incident medium f_1 is a perfect fluid; only the P-SV waves travel in the plate. Applying a spatio-temporal Fourier transform on (x_1,t) of the displacement-field [noted $\hat{\mathbf{u}}(k_1,x_3;\omega)$ after Fourier transform] and on the traction field [noted $\hat{\sigma}_{i3}(k_1,x_3;\omega)$ for $i=1,\ldots,3$] and using the Voigt notation ($C_{ijk\ell}$ for $i,j,k,\ell=1,\ldots,3$ is replaced with c_{IJ} for $I,J=1,\ldots,6$), Eq. (6) leads to Stroh's (1962) sextic plate formalism (Hamiltonian formulation of the wave equation)

$$\frac{\partial \hat{\sigma}_{13}}{\partial x_3} = \rho(\iota\omega)^2 \hat{u}_1 - \iota k_1 \hat{\sigma}_{11}, \quad \frac{\partial \hat{\sigma}_{33}}{\partial x_3} = \rho(\iota\omega)^2 \hat{u}_3 - \iota k_1 \hat{\sigma}_{13}, \quad (10)$$

$$\hat{\sigma}_{11} = \iota k_1 c_{11} \hat{u}_1 + c_{33}\frac{\partial \hat{u}_3}{\partial x_3}, \quad \hat{\sigma}_{13} = c_{55}\left(\frac{\partial \hat{u}_1}{\partial x_3} + \iota k_1 \hat{u}_3\right),$$

$$\hat{\sigma}_{33} = \iota k_1 c_{13} \hat{u}_1 + c_{33}\frac{\partial \hat{u}_3}{\partial x_3}. \quad (11)$$

According to Eqs. (10) and (11), $\hat{\sigma}_{11}$ is function of $\hat{u}_1$ and $\hat{\sigma}_{33}$. The wave equation becomes a matrix system expressed using the Thomson–Haskell parametrization of Stroh's (1962) sextic plate formalism

$$\frac{d}{dx_3}\eta(x_3) = \iota\omega\mathbf{Q}(x_3)\,\eta(x_3), \tag{12}$$

that is,

$$\frac{d}{dx_3}\begin{pmatrix} \iota\omega\hat{u}_1 \\ \iota\omega\hat{u}_3 \\ \hat{\sigma}_{13} \\ \hat{\sigma}_{33} \end{pmatrix} = \iota\omega\begin{pmatrix} 0 & s_1 & 1/c_{55}(x_3) & 0 \\ -s_1c_{13}(x_3)/c_{33}(x_3) & 0 & 0 & 1/c_{33}(x_3) \\ \rho(x_3)-s_1^2\zeta(x_3) & 0 & 0 & -s_1c_{13}(x_3)/c_{33}(x_3) \\ 0 & \rho(x_3) & -s_1 & 0 \end{pmatrix}\begin{pmatrix} \iota\omega\hat{u}_1 \\ \iota\omega\hat{u}_3 \\ \hat{\sigma}_{13} \\ \hat{\sigma}_{33} \end{pmatrix}, \tag{13}$$

with the relations

$$\zeta(x_3) = c_{11}(x_3) - \frac{c_{13}^2(x_3)}{c_{33}(x_3)}, \quad k_1 = \omega s_1, \tag{14}$$

where s_1 is the x_1-component of the slowness. The matrix $\mathbf{Q}$ includes all the information about the heterogeneity of the waveguide because it is expressed from the plate mechanical properties $(\rho(x_3), \mathbb{C}(x_3))$ and from two acoustical parameters (s_1, ω).

2. Explicit solution: The Peano expansion of the matricant

The wave equation thus formulated has an analytical solution expressed between a reference point $(x_1, 0, x_3^0)$ and some point of the plate $(x_1, 0, x_3)$ in the propagation plane. This solution is called the matricant and is explicitly written under the form of the Peano series expansion (Gantmacher, 1959; Peano, 1888; Pease, 1965):

$$\mathbf{M}(x_3, x_3^0) = \mathbf{I} + (\iota\omega)\int_{x_3^0}^{x_3}\mathbf{Q}(\xi)d\xi + (\iota\omega)^2 \times \int_{x_3^0}^{x_3}\mathbf{Q}(\xi)\left(\int_{x_3^0}^{\xi}\mathbf{Q}(\xi_1)d\xi_1\right)d\xi + \ldots, \tag{15}$$

where $\mathbf{I}$ is the identity matrix of dimension (4,4). If the matrix components $\mathbf{Q}(x_3)$ are bounded in the study interval, these series are always convergent (Baron, 2005). The components of the matrix $\mathbf{Q}$ are continuous in x_3 and the study interval is bounded (thickness of the waveguide); consequently the hypothesis is always verified. We underline that the $\iota\omega$-factorization leads up to a polynomial form of the matricant. The $\iota\omega$-polynomial coefficients are matrices independent of ω.

3. Boundary conditions: Fluid-structure interaction

Using the propagator property of the matricant through the plate thickness, the state-vector [defined in Eq. (13)] at the second interface $\eta(d)$ is evaluated from the state-vector at the first interface $\eta(0)$ as follows:

$$\eta(d) = \mathbf{M}(d,0)\,\eta(0). \tag{16}$$

The fluid-structure interaction sets the conditions of zero shear stresses (see Sec. III C), used after a spatio-temporal Fourier transform on (x_1, t). Equation (16) becomes

$$\begin{pmatrix} \iota\omega\hat{u}_1(k_1,d;\omega) \\ \iota\omega\hat{u}_3(k_1,d;\omega) \\ 0 \\ \hat{\sigma}_{33}(k_1,d;\omega) \end{pmatrix} = \begin{pmatrix} M_{11} & M_{12} & M_{13} & M_{14} \\ M_{12} & M_{22} & M_{23} & M_{24} \\ M_{13} & M_{23} & M_{33} & M_{34} \\ M_{14} & M_{24} & M_{34} & M_{44} \end{pmatrix} \times \begin{pmatrix} \iota\omega\hat{u}_1(k_1,0;\omega) \\ \iota\omega\hat{u}_3(k_1,0;\omega) \\ 0 \\ \hat{\sigma}_{33}(k_1,0;\omega) \end{pmatrix}. \tag{17}$$

The condition to obtain a nontrivial solution to Eq. (17) leads to the following relation:

$$\iota\omega\hat{u}_1(k_1,0;\omega)\times M_{13} + \iota\omega\hat{u}_3(k_1,0;\omega)\times M_{32} + \hat{\sigma}_{33}(k_1,0;\omega)\times M_{34} = 0, \tag{18}$$

where M_{ij} (for $i,j = 1,\ldots,4$) represent the components of the matrix $\mathbf{M}$. The displacement component $\hat{u}_1(k_1,0;\omega)$ can be expressed as a linear combination of $\hat{u}_3(k_1,0;\omega)$ and $\hat{\sigma}_{33}(k_1,0;\omega)$; thus system (16) of dimension 4 is reduced to a matrix system of dimension 2

$$\eta(d) = \begin{pmatrix} P_1 & P_2 \\ P_3 & P_4 \end{pmatrix}\eta(0) \quad \text{where} \quad \eta(x_3) = \begin{pmatrix} \iota\omega\hat{u}_3 \\ \hat{\sigma}_{33} \end{pmatrix}, \tag{19}$$

with the relations

$$P_1 = M_{22} - M_{21}\frac{M_{32}}{M_{31}}, \quad P_2 = M_{24} - M_{21}\frac{M_{34}}{M_{31}},$$

$$P_3 = M_{42} - M_{41}\frac{M_{32}}{M_{31}}, \quad P_4 = M_{44} - M_{11}\frac{M_{34}}{M_{31}}. \tag{20}$$

Interface conditions (8) are transformed in the Fourier domain (k_1, ω). The expressions of the displacement and the pressure in the fluids [see Eqs. (3)–(5)], so that the one of the displacement and traction fields in the solid plate [see Eq. (19)], are substituted in the transformed interface conditions.

Setting $\eta(0)=(\alpha_1,\alpha_2)^T \exp \imath(k_1 x_1-\omega t)$, where the superscript ^{T} designates the transpose operator, we obtain the following matrix equation:

$$\begin{pmatrix} \imath\omega s_3^{(1)} c_{f_1} & 1 & 0 & 0 \\ -\imath\omega\rho_{f_1} c_{f_1} & 0 & 1 & 0 \\ 0 & P_1 & P_2 & -\imath\omega s_3^{(2)} c_{f_2} \exp(\imath\omega s_3^{(2)} d) \\ 0 & P_3 & P_4 & -\imath\omega\rho_{f_2} c_{f_2} \exp(\imath\omega s_3^{(2)} d) \end{pmatrix} \begin{pmatrix} \hat{R} \\ \alpha_1 \\ \alpha_2 \\ \hat{T} \end{pmatrix} = \begin{pmatrix} \imath\omega s_3^{(1)} c_{f_1} \\ \imath\omega\rho_{f_1} c_{f_1} \\ 0 \\ 0 \end{pmatrix}, \tag{21}$$

where $\mathbf{s}^{(n)}=\mathbf{k}^{(n)}/\omega$ is the slowness-vector in the fluid f_n ($n=1$ or 2). The quantities $\hat{R}$ and $\hat{T}$ are, respectively, the reflection and transmission coefficients expressed in the Fourier domain: $\hat{R}=\hat{R}(k_1,x_3;\omega)$ and $\hat{T}=\hat{T}(k_1,x_3;\omega)$. The two first lines of system (21) express the boundary conditions at the first interface ($x_3=0$) and the two last lines those at the second interface ($x_3=d$) introducing the Fourier transform of expressions (3)–(5) in the following relations:

$$\eta(0)-\begin{pmatrix} \imath\omega\hat{u}_{3_R}^{(1)} \\ -\hat{p}_R \end{pmatrix}_{x_3=0} = \begin{pmatrix} \imath\omega\hat{u}_{3_I}^{(1)} \\ -\hat{p}_I \end{pmatrix}_{x_3=0},$$

$$\begin{pmatrix} P_1 & P_2 \\ P_3 & P_4 \end{pmatrix} \eta(0)-\begin{pmatrix} \imath\omega\hat{u}_{3_T}^{(2)} \\ -\hat{p}_T \end{pmatrix}_{x_3=d} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \tag{22}$$

where $\hat{u}_{3_R}^{(1)}$, $\hat{u}_{3_I}^{(1)}$, and $\hat{u}_{3_T}^{(2)}$ are the components along $\mathbf{x}_3$-axis of $\hat{\mathbf{u}}_R^{(1)}$, $\hat{\mathbf{u}}_I^{(1)}$, and $\hat{\mathbf{u}}_T^{(2)}$ vectors, respectively. Note the equality between the quantities $u_{3_T}^{(2)}$ and $u_3^{(2)}$ where this last is defined in Eq. (9).

4. Expression of the reflection and transmission coefficients

From Eq. (21), we deduce the analytical expressions of the reflection and transmission complex coefficients

$$\hat{R}(s_1,x_3;\omega)=\frac{(P_3-P_1Z_2+P_4Z_1-P_2Z_1Z_2)}{(P_3-P_1Z_2-P_4Z_1+P_2Z_1Z_2)},$$

$$\hat{T}(s_1,x_3;\omega)=-\frac{2Z_2(\rho_{f_1}c_{f_1}/\rho_{f_2}c_{f_2})(P_1P_4-P_2P_3)}{(P_3-P_1Z_2-P_4Z_1+P_2Z_1Z_2)} \times\exp(-\imath\omega s_3^{(2)}d), \tag{23}$$

with $Z_n=\rho_{f_n}/\sqrt{1/c_{f_n}^2-s_1^2}$ (for $n=1$ or 2) and $k_1=\omega s_1$.

IV. VALIDATION OF THE METHOD

The aim of this section is to check that the Peano expansion of the matricant is well-adapted to study fluid-loaded waveguides. We take into account the fluid-structure interaction in different configurations of homogeneous plates comparing the results obtained from the numerical implementation of the Peano expansion of the matricant to results taken from literature.

TABLE I. Elastic properties of transversely isotropic plate (with $c_{23}=c_{22}-2c_{44}$).

ρ (g cm^{-3})	c_{11} (GPa)	$c_{22}=c_{33}$ (GPa)	$c_{12}=c_{13}$ (GPa)	c_{44} (GPa)	$c_{66}=c_{55}$ (GPa)
1.85	23.05	15.1	8.7	3.25	4.7

The numerical evaluation of P_1, P_2, P_3, and P_4 requires us to truncate the Peano series and to numerically calculate the integrals. Thus, the error can be estimated and controlled (Baron, 2005). We retained 70 terms in the series and evaluate the integrals over 100 points using Simpson's rule (fourth-order integration method). These choices ensure the convergence of the solution and the accuracy of the results for a reasonable computation-time (never exceeding few minutes on a desktop computer). Expressions (23) give the frequency spectrum (modulus and phase) of the reflection coefficient for different incidences (s_1 varies from zero-normal incidence to $1/c_{f_1}$ corresponding to the critical incidence in the fluid f_1).

A lot of works detailed the relationship between the poles and the zeros of the reflection coefficient and the leaky Lamb wave dispersion curves (Chimenti and Rokhlin, 1990; Deschamps and Poncelet, 2000). The results of Sec. IV A compare the dispersion curves obtained by seeking the poles of reflection coefficient (23) and the results taken from literature or from closed-form solution.

A. Validation for a homogeneous and isotropic or anisotropic fluid-loaded plate

The method is tested by plotting the dispersion curves (variation of the phase velocity versus frequency-thickness product) for an isotropic aluminum plate immersed in water. The data in the paper of Chimenti and Rokhlin (1990) are used. The results obtained (not shown) by the present method are in perfect agreement with the results presented by them (Chimenti and Rokhlin, 1990).

As mentioned by Chimenti and Rokhlin (1990), there are few differences between the zeros' loci and the poles' loci for a plate immersed in a fluid whose the mass density is lower than the plate mass density. As underlined by several authors, fluid-load does have just a weak influence on guided wave traveling in the plate immersed in water.

Taking into account the anisotropy does not change the scheme for the numerical solution of wave equation with the matricant. We consider a transverse isotropic plate immersed in water ($\rho_f=1$ g cm^{-3}, $c_f=1.485$ mm μs^{-1}) whose properties are reported in Table I. For that configuration, Nayfeh and Chimenti (1989) developed a method to obtain an analytical expression of the reflection coefficient. By using the data from this paper, the results obtained (see Fig. 1) with the present method are in perfect agreement with theirs. The curves presented in Figs. 1(a) and 1(b) are superimposed and need to be presented separately.

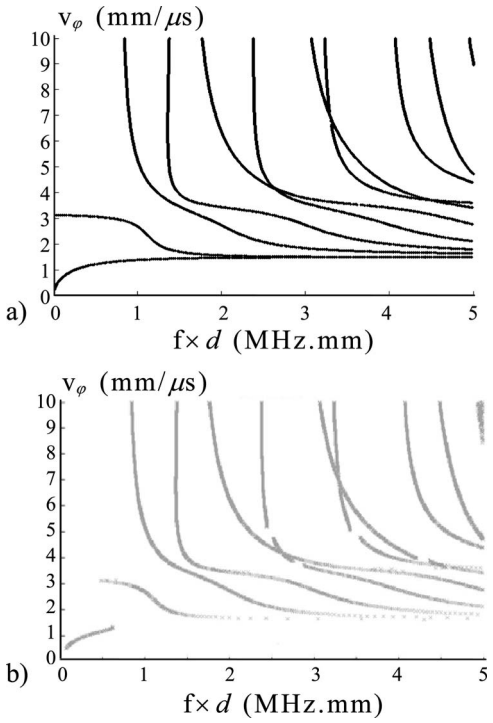

FIG. 1. Dispersion curves for a transversely isotropic plate immersed in water; comparison between (a) analytical results from Nayfeh and Chimenti (1989) and (b) results obtained via the Peano series expansion of the matricant.

B. Validation for an asymmetrically loaded homogeneous isotropic plate ($f_1 \neq f_2$)

The formalism presented here to solve the wave equation in an unidirectionally graded medium presents two main advantages: Without changing the scheme to obtain the numerical solution we can take into account (i) an asymmetric loading and (ii) the unidirectional continuous heterogeneity.

The mechanical behavior of the plate is different for symmetric and asymmetric loadings. For example, in the symmetric loading case, there is a unique critical frequency and a unique phase velocity value v_φ in the plate, which corresponds to the propagation velocity in the fluid ($v_\varphi = c_{f_1} = c_{f_2}$), for which the displacements and the stresses at the interfaces are quasi-null; whereas in the asymmetric loading ($f_1 = f_2$), there are two critical frequencies and two values of the phase velocity in the plate for which the structure does not respond (Dickey *et al.*, 1995). The validation is done on an isotropic aluminum plate with the following properties: $\rho = 2.79$ g cm^{-3}; the longitudinal and transverse wave velocities are, respectively, $v_L = 6.38$ mm μs^{-1} and $v_T = 3.10$ mm μs^{-1}. The characteristic properties of the fluid f_1 correspond to those of water (see Sec. IV A); the characteristic properties of the fluid f_2 correspond to glycerine: $\rho_{f_2} = 1.26$ g cm^{-3} and $c_{f_2} = 1.920$ mm μs^{-1}. This configuration is the same as the one studied by Franklin *et al.* (2001). The modulus of the reflection coefficient versus the incident angle is plotted in Fig. 2 for a fixed frequency-thickness product ($f \times d = 4.7$ MHz mm).

This figure shows the perfect agreement between our results and the ones presented by Franklin *et al.* (2001).

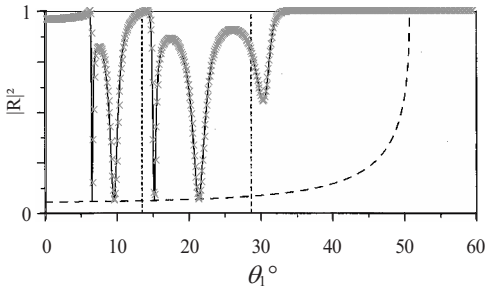

FIG. 2. Reflection coefficient modulus for an asymmetrically fluid-loaded aluminum plate (water and glycerine) versus incident angle: in dark lines results published in Franklin *et al.* (2001), and in gray crosses the reflection coefficient modulus calculated from Eq. (23). The vertical lines (dashed) represent the two critical angles for longitudinal waves and transverse waves. The dashed curve corresponds to the resonant amplitudes (Franklin *et al.*, 2001).

V. RELEVANCY OF THE METHOD FOR ULTRASOUND CHARACTERIZATION OF CORTICAL BONE

Cortical bone is a kind of hard tissue found at the edges of long bones and supports most of the load of the body. Several studies demonstrated the heterogeneous nature of the cortical bone, particularly they show evidence the gradual variation of the volumetric porosity (ratio between pores and total volume) along the cortical thickness. Yet, the porosity is intrinsically linked to the macroscopic mechanical behavior of the cortical bone (Baron *et al.*, 2007). Therefore, the continuous variation of porosity induces a continuous variation of material properties. Taking into account the gradient should prove itself to be essential in the context of diagnosis and therapeutic monitoring of osteoporosis. Indeed, the gradient characterization would allow assessing geometrical (cortex thickness) and material (elastic coefficients variation) information, which are fundamental parameters to evaluate the bone fragility. For several years, the quantitative ultrasonography (by axial and transverse transmissions) proved itself to be a hopeful alternative technique to evaluate the fracture risk (Marin *et al.*, 2006). However, the inter-individual and inter-site variations of bone mechanical properties make the standardization of the protocol of fracture risk evaluation by ultrasound very delicate.

The focus is set on a configuration closed to the axial transmission device for *in vivo* conditions. In this context, the relevancy of studying the head wave propagation has been demonstrated (Bossy *et al.*, 2004a, 2004b; Camus *et al.*, 2000). As a consequence all the reflection coefficients presented in this paper were calculated for an incident angle corresponding to the grazing-angle for longitudinal waves [critical angle of longitudinal wave propagation in the plate at the first interface ($x_3 = 0$)].

The surrounding media in the *in vivo* configuration of ultrasound characterization of cortical bone are the muscle for the upper fluid f_1 ($c_{f_1} = 1.54$ mm μs^{-1} and $\rho_{f_1} = 1.07$ g cm^{-3}) and the marrow for the lower fluid f_2 ($c_{f_2} = 1.45$ mm μs^{-1} and $\rho_{f_2} = 0.9$ g cm^{-3}) (Burlew *et al.*, 1980; Hill *et al.*, 1986). We are interested in the influence of the continuous gradient of the mechanical properties on the ultrasonic response in the configuration of *in vivo* cortical bone characterization.

A. Determination of a realistic range of variation of elastic bone properties

In order to define numerical values for a realistic value of the gradient of the different material properties, it is necessary to determine the limiting values reached by each elastic property. Our approach consists in considering *in vitro* measurements published in Dong and Guo, 2004 and performed in 18 samples. It is assumed that these limiting values for elastic properties are relevant for physiologic ranges of variations.

We assume that cortical bone is transversely isotropic. Transverse isotropy has been shown experimentally by different authors (Dong and Guo, 2004; Reilly and Burnstein, 1974; Rho, 1996) to be a realistic approximation of cortical bone degree of anisotropy.

Dong and Guo (2004) measured the homogenized bone properties by performing tensile and torsional tests with a mechanical testing system on 18 different human femoral bone specimens. The authors measured the values of the longitudinal and transverse Young's moduli (E_L and E_T, respectively) as well as the values of the longitudinal shear modulus G_L. From these measurements and by assuming constant values of Poisson's ratio, the values of the different components of the stiffness-tensor corresponding to the values of E_L, E_T, and G_L measured in Dong and Guo, 2004 were obtained following the relationships given in the Appendix.

The value of the longitudinal Poisson's ratio ν_L is taken equal to 0.37 for all computations because it corresponds to the average value found in Dong and Guo, 2004. The value of the transverse Poisson's ratio ν_T is taken equal to 0.45 following Eq. (A3) of the Appendix. The values of the stiffness coefficients corresponding to the mean values of the bone mechanical properties are referred to as "reference" set of parameters in what follows. The maximum and minimum values of the stiffness coefficients are obtained by considering, respectively, the maximum and minimum values of E_L and E_T within the range of variation measured in Dong and Guo, 2004, which is a simple way to obtain a realistic range of variation for the stiffness coefficients in cortical bone. Furthermore, the elastic properties deduced from the approach reported above were constrained to verify the thermodynamical stability conditions given in the Appendix by Eq. (A4).

We choose reference value of mass density ρ equal to 1.722 g cm^{-3}, following the value taken in Macocco *et al.*, 2006. In order to derive a realistic range of variation for mass density, we assume that the reference value is given by a porosity of 7%, which corresponds approximately to the mean porosity at the radius (Baron *et al.*, 2007). The porosity was assumed to vary between 3% and 15% (Bousson *et al.*, 2001; Dong and Guo, 2004) and a rule of mixture leads to the range of variation of mass density.

B. Modeling a gradient of material property

The impact of a controlled gradient vector $\boldsymbol{\delta}$ of any investigated material property S on the response of the structure studied is assessed. The scalar S corresponds to one of the stiffness coefficients c_{ij} of $\mathbb{C}$ or to mass density ρ. In each set of simulations, all the material properties are constant and equal to their reference value while S is subjected to the defined gradient.

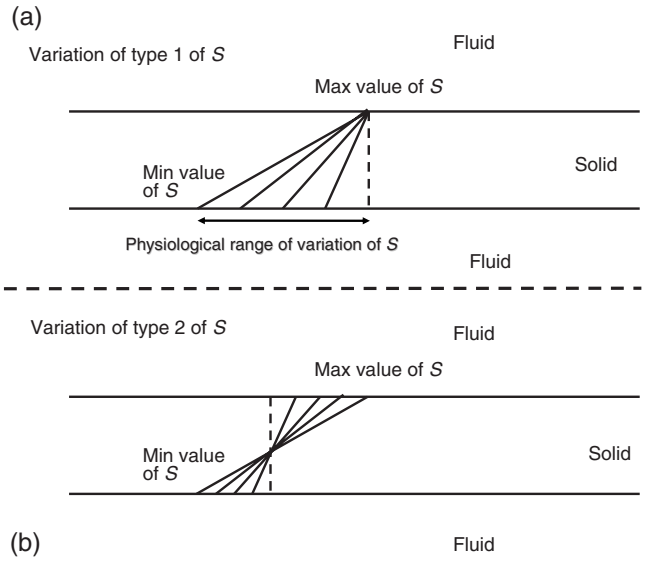

FIG. 3. Schematic representation of the two types of spatial variation considered for the material property S corresponding to the stiffness coefficient and to mass density. The solid lines in the solid layer indicate the spatial dependence of S. The dotted line in the solid layer indicates homogeneous material properties corresponding to the reference material properties. The variation of type 1 shown in (a) corresponds to a constant value at the bone-soft tissues' interface. The variation of type 2 shown in (b) corresponds to a constant value in the middle of the bone.

The gradient vector $\boldsymbol{\delta}=\text{grad}\, S=\delta \mathbf{x}_3$ is assumed to be independent of x_1 in all cases, where $\mathbf{x}_3$ is a unit vector along $\mathbf{x}_3$-axis and grad is the gradient operator acting on a scalar field. The quantity δ is always taken positive because the porosity is known to be higher in the endosteal part ($x_3=d$) than in the periosteal part ($x_3=0$) of the bone. Moreover, only the simple situation of affine spatial variations of S is considered, corresponding to a constant value of δ. This affine spatial variation of S is chosen because the actual physiological spatial dependence of S remains unknown. Two different affine spatial dependencies of the studied material property are considered and are illustrated in Fig. 3. Associated gradient δ will be referred to as type 1 or 2.

Type 1. The gradient of type 1 is such that the physical property S takes the same value S_M at the upper interface $x_3=0$ of the solid plate for all values of the gradient δ. The quantity $S(x_3)$ is therefore given by

$$S(x_3) = S_M + \delta \times x_3, \tag{24}$$

where S_M is given by the maximal value of the material property S considered. The maximal value δ_M of δ is chosen so that $S(d)$ is equal to S_m, where S_m is given by the minimal value of S. The gradient δ_M is given by

$$\delta_M = \frac{(S_m - S_M)}{d}. \tag{25}$$

Type 2. The gradient of type 2 is such that the physical property S takes the same value at the middle $x_3=d/2$ of the solid plate for all values of gradient δ. Furthermore, the

TABLE II. Mean value, maximum, and minimum values of the homogenized longitudinal and transversal Young moduli, of the four elastic constants and of mass density affecting the ultrasonic propagation in the framework of the model. These values are taken from Dong and Guo (2004).

Mechanical quantity	E_L (GPa)	E_T (GPa)	c_{11} (GPa)	c_{13} (GPa)	c_{33} (GPa)	$c_{55}=G_L$ (GPa)	ρ (g cm^{-3})
Mean value (reference)	16.6	9.5	23.1	8.7	15.1	4.7	1.722
Minimum	13.4	6.5	17.6	5.1	9.1	3.3	1.66
Maximum	20.6	12.8	29.6	15.9	25.9	5.5	1.753

mean value of the property S is identical for all δ. The quantity $S(x_3)$ is given by

$$S(x_3) = \frac{(S_m + S_M)}{2} + \delta \times \left(x_3 - \frac{d}{2} \right). \tag{26}$$

The maximal value of δ is also given by Eq. (25), so that all values of $S(x_3)$ are again always comprised between S_m and S_M. Again, the maximal value δ_M of δ is given by Eq. (25).

Gradient of type 2 leads for all magnitudes of δ to a constant value of the spatial average of the gradient.

For both types of spatial variations, five different values of δ regularly distributed between 0 and δ_M are arbitrarily considered in the thickness.

Table II recalls the maximum, minimum, and mean measured values of E_L, E_T, and G_L as given by Dong and Guo (2004). Table II also shows the maximum, minimum, and mean values of the four components (c_{11}, c_{13}, c_{33}, and c_{55}) of the stiffness-tensor $\mathbb{C}$ affecting wave propagation derived from Eq. (A3) of the Appendix.

In Table III, the minimal and maximal values of each variable corresponding to the realistic range of variation obtained (i) by considering the reference values of Table II and (ii) by verifying that the thermodynamical stability conditions are fulfilled. Values resulting from the stability conditions are marked with an asterisk.

In the simulations, the values of S_M and S_m are those reported in Table III.

C. Results and discussion

First of all, the method allows investigating the influence of the fluids on the ultrasonic response. In the case of the characterization of cortical bone, the two fluids f_1 and f_2 are different, which corresponds to an asymmetrical loading (see Sec. IV B): The fluid f_1 has been considered as muscle ($c_{f_1}=1540$ m s^{-1} and $\rho_{f_1}=1.07$ g cm^{-3}) and fluid f_2 as marrow ($c_{f_2}=1450$ m s^{-1} and $\rho_{f_2}=0.9$ g cm^{-3}). The properties of these two fluids are very close to those of water. The frequency spectrum of the reflection coefficient modulus has been plotted for the *in vivo* configuration and compared with the result obtained for a cortical bone plate immersed in water for the ten profiles of mechanical properties (figure not shown). For homogeneous plates as for linearly graded plates, the two curves are very close; however, the modulus of the reflection coefficient at null-frequency is not null and the minimum values are greater than for water but obtained for the same frequency-thickness products. That is why all the following results have been calculated for a cortical bone plate immersed in water.

The reflection coefficient calculated with the Peano series expansion of the matricant is sensitive to the variation of the properties gradient. As we consider that the osteoporosis entails a trabecularization of cortical bone from the endosteal side, the characterization of the gradient of the properties between the endosteal and periosteal regions may be an element of the diagnosis of the osteoporosis progress and of the therapeutic follow-up.

It is known that the gradient of the properties along the cortical thickness is due to the continuous variation of the porosity growing progressively from the periosteal to the endosteal region. From previous work, we know that the porosity influences all the stiffness coefficients (Baron *et al.*, 2007). The frequency spectrum of the reflection coefficient has been plotted for the ten profiles presented in Fig. 3 applied to all the stiffness coefficients implied (c_{11}, c_{13}, c_{33}, and c_{55}) and to the mass density ρ (see Table III). The reflection coefficients have been calculated at an incident angle corresponding to the grazing-angle (critical angle for the longitudinal waves in the bone plate). For the two types of gradients, differences appear between all the gradients and the homogenized plates (corresponding to the maximum value for type 1 and to the average value for type 2) particularly on the location of the extrema values of the reflection coefficient modulus (see Fig. 4).

The increase in the gradient of properties shifts the minimum and maximum values forward high frequency-thickness products. However, the results (see Fig. 4) put on evidence that the behavior of the reflection coefficient modulus is sensibly the same for frequency-thickness products be-

TABLE III. The minimal and maximal values of each variable corresponding to the realistic range of variation obtained (i) by considering the reference values of Table II and (ii) by verifying that the thermodynamical stability conditions are fulfilled. Values resulting from the stability conditions are marked with an asterisk.

Realistic range $[S_m,S_M]$ (reference)	[17.6, 29.6]	[5.1, 11.1*]	[11.8*, 25.9]	[3.3, 5.5]	[1.66, 1.753]

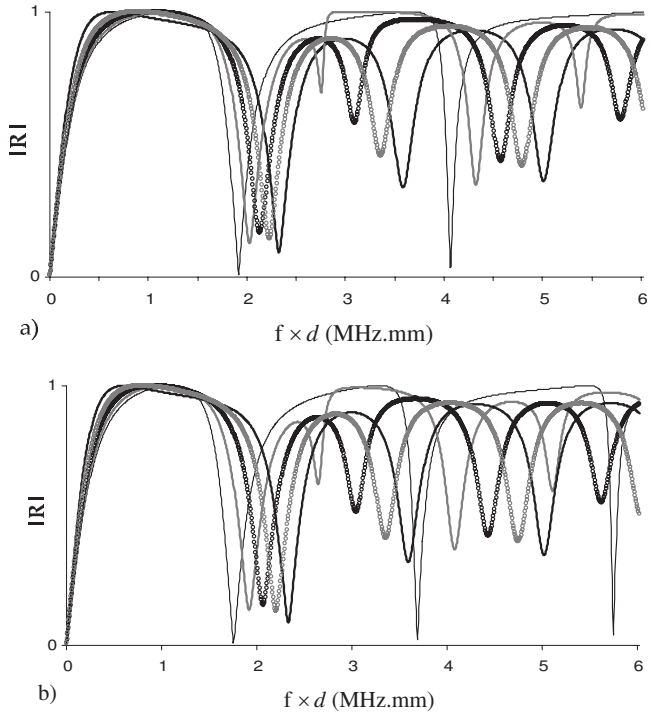

FIG. 4. Frequency spectrum of the reflection coefficient modulus for different properties' variations corresponding to (a) the five profiles of type 1 [Fig. 3(a)] and (b) the five profiles of type 2 [Fig. 3(b)].

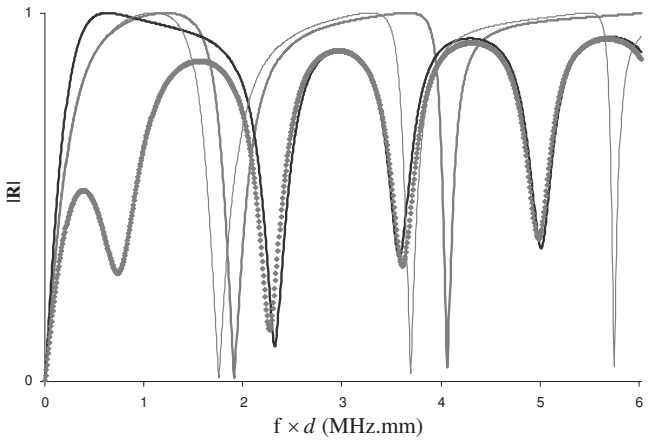

FIG. 5. Frequency spectrum of the reflection coefficient modulus for different properties' variations at grazing-incidence $\theta_1=\theta_c$: for a homogeneous plate whose properties are those at $x_3=0$ at $\theta_c=21.1°$ (thick gray line), for a homogeneous plate whose properties are the average of the properties through the plate at $\theta_c=23.6°$ (thin gray line), for a plate with all its properties linearly varying at $\theta_c=21.1°$ (black line), and for a plate with an affine variation of the c_{11} only at $\theta_c=21.1°$ (gray lozenges).

tween 0 and 1.5 MHz mm. Beyond this value, the behavior is clearly different. At sufficiently high frequency, the wavelength is smaller and more sensitive to the affine variation of the material properties. It is noteworthy that for a heterogeneous waveguide, the minima of the reflection coefficient magnitude do not reach zero (except for null-frequency) but end at a finite value and the changes in phase (not shown) are not so rapid, which means that total transmission does not take place in this situation.

The influence of the variation of each parameter (stiffness coefficients) on the frequency spectrum of the reflection coefficient has been investigated. This analysis has been led for an incidence angle corresponding to the longitudinal wave critical angle in the plate at $x_3=0$. This incidence corresponds to the generation and the propagation of the head wave.

It appears that each of them has an impact on the reflection wave, but the leading term is c_{11}. The frequency spectrum of the reflection coefficient for a varying c_{11} in an affine way is very close to the frequency spectrum of the reflection coefficient obtained for the affine variation of all the material properties (c_{ij} and ρ) and is the most different to the results from homogenized plates (average value or maximum value) compared to the frequency spectrum calculated for the *one-parameter variation* of the other elastic parameters (c_{13}, c_{33}, and c_{55}, and ρ) (see Fig. 5). It is noteworthy that c_{11} is the stiffness coefficient associated with the axial direction and determining the speed of the head wave. So, it seems that the head wave would be the indicator of the c_{11} gradient. It is important to note that for homogenized plates (extremum value or average) the frequency spectrum of the reflection coefficient is really different from that of the plate with continuously varying properties. We infer that the approximation by a homogeneous plate of cortical bone and all the more so for the osteoporotic cortical bone (for which the gradient would be greater) may induce bad interpretation of the ultrasonic response.

The authors do not know any results in literature about the measurement of the variation of the porosity within the cortical thickness. The assumption of an affine gradient is a first step; other gradients may be investigated and the method presented in this article would be applied in the same way for non-affine gradients (Shuvalov *et al.*, 2005).

VI. CONCLUSION AND PERSPECTIVES

Stroh's (1962) sextic plate formalism has been employed for analyzing the leaky Lamb waves in anisotropic heterogeneous plates immersed in fluids. This formalism and especially the polynomial form of the solution [see Eq. (15)] presents several analytical and numerical advantages. First, the low-frequency asymptotics are naturally assessed evaluating only two or three terms in the series (Shuvalov *et al.*, 2005). The information thus collected is of major interest in the analysis of the elastic behavior of waveguides (Baron *et al.*, 2008). Second, the polynomial form makes the numerical evaluation of the solution faster. Indeed, the polynomial coefficients are independent of the frequency, so they are calculated for a fixed slowness value and stored. When the frequency varies, there is no need to recalculate the polynomial coefficients, it comes to a polynomial evaluation whose coefficients are perfectly known, which is time-saving.

The Peano series of the matricant is a method that keeps the continuity of the profiles and so, the authenticity of the problem. One of the key points for methods based on multilayered media to deal with FGM is to relevantly discretize the properties' profiles. The choice of the discretization may lead to some errors especially in the evaluation of the resonances.

This elegant mathematical tool is also very adaptative to different physical problems. In the case studied—a fluid-loaded plane waveguide—the anisotropy, the heterogeneity (continuous or discontinuous variation of properties) and the asymmetric fluid-loading are taken into account without changing the resolution scheme.

Further work needs to be done to relate the results presented in this paper to dispersion curves and propagation of transient and heterogeneous waves in a fluid-loaded continuously heterogeneous waveguide.

Furthermore, from this study, the transient response of a fluid-loaded plate is considered. The frequency spectrum of the reflection coefficient is calculated for incidences between the normal and critical incidences for compression waves in the fluid f_1. Thus, the plate transfer function is calculated in the Fourier domain (x_1-wavenumber, frequency): $\hat{R}(k_1,x_3;\omega)$. A double inverse Fourier transform on (k_1,ω) is applied on $\hat{R}(k_1,x_3;\omega)$ to transform into the space-time domain; the temporal signals can be obtained at different points along the propagation $\mathbf{x}_3$-axis: $R(x_1,x_3;t)$.

Lastly, the formalism presented here is well-adapted to deal with wave propagation in anisotropic tubes with radial property gradients (Shuvalov, 2003). The wave equation keeps the same form as Eq. (12), the state-vector is expressed from the displacement and traction components in the cylindrical basis, and the matrix $\mathbf{Q}$ depends on the radial position r ($\mathbf{Q}=\mathbf{Q}(r)$). In cylindrical homogeneous structures, taking into account an anisotropy more important than transverse isotropy is fussy because there is no analytical solution to the "classical" wave equation (second-order differential equation). Stroh's (1962) formalism, upon which the Peano expansion of the matricant is based, is a promising alternative solution that allows considering altogether the geometry (cylinder), the anisotropy, and the heterogeneity (radial property gradients) of a structure.

APPENDIX: THERMODYNAMICS STABILITY CONDITIONS AND STIFFNESS COEFFICIENTS

Hooke's law is written under the form $\sigma_{ij}=C_{ijk\ell}\epsilon_{k\ell}$ for $(i,j,k,\ell=1,\ldots,3)$, where σ is the stress-tensor, ϵ is the strain-tensor, and $\mathbb{C}$ is the fourth-order stiffness-tensor. In the transversely isotropic case, with $(\mathbf{x}_2,\mathbf{x}_3)$ as isotropic plane, the stiffness-tensor is expressed as a stiffness matrix (using Voigt's notation)

$$\mathbb{C}=\begin{pmatrix} c_{11} & c_{13} & c_{13} & 0 & 0 & 0 \\ c_{13} & c_{33} & c_{23} & 0 & 0 & 0 \\ c_{13} & c_{23} & c_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{55} \end{pmatrix}. \tag{A1}$$

We introduce the matrix $\mathbb{S}$, the inverse of the matrix $\mathbb{C}$. It is expressed by

$$\mathbb{S}=\begin{pmatrix} 1/E_L & -\nu_L/E_L & -\nu_L/E_L & 0 & 0 & 0 \\ -\nu_L/E_L & 1/E_T & -\nu_T/E_T & 0 & 0 & 0 \\ -\nu_L/E_L & -\nu_T/E_T & 1/E_L & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/G_T & 0 & 0 \\ 0 & 0 & 0 & 0 & 1/G_L & 0 \\ 0 & 0 & 0 & 0 & 0 & 1/G_L \end{pmatrix}. \tag{A2}$$

with $E_{L,T}$, the longitudinal (L) and transverse (T) Young's moduli; $\nu_{L,T}$, the longitudinal (L) and transverse (T) Poisson's ratios; and $G_{L,T}$, the longitudinal (L) and transverse (T) shear moduli. By inverting Eq. (A1)and identifying it with Eq. (A2), we obtain the following relations:

$$E_L=\frac{c_{11}c_{33}-2c_{13}^2+c_{11}c_{23}}{c_{33}+c_{23}}, \quad \nu_L=\frac{c_{13}}{c_{33}+c_{23}},$$

$$E_T=\frac{c_{11}(c_{33}^2-c_{23}^2)+2c_{13}^2(c_{23}-c_{33})}{c_{11}c_{33}-c_{13}^2}, \quad \nu_T=\frac{c_{11}c_{23}-c_{13}^2}{c_{11}c_{33}-c_{13}^2},$$

$$G_T=c_{44}, \quad G_L=c_{55}. \tag{A3}$$

Knowing the stiffness coefficient values, we can verify if the thermodynamical stability conditions are satisfied as follows:

$$E_L>0, \quad E_T>0, \quad -1<\nu_T<1,$$

$$\frac{(1-\nu_T)}{2}\frac{E_L}{E_T}-\nu_L^2>0, \quad G_L>0. \tag{A4}$$

(Received 14 April 2009; revised 25 September 2009; accepted 17 December 2009)

In this work, a method is presented to extend the convolutional perfectly matched layer (C-PML) to simulate acoustic wave propagation in elastic media with a second-order equation formulation. This non-physical layer is used at the computational edge of a finite element method algorithm in frequency domain, and a pseudo-spectral algorithm in time domain, as an absorbing boundary condition (ABC) to truncate unbounded media. Numerical results show that the C-PML ABC attenuates the outgoing surface waves more effectively than classical PML ABC as proposed by Berenger [J. Comput. Phys. **114**, 195–200 (1994)] for electromagnetic waves in the case of oblique incidence, where the PML method suffers from large spurious reflections. Moreover, a modification of the proposed C-PML formulation is also discussed in order to stabilize the absorbing layer in anisotropic solids where numerical instabilities can appear.

I. INTRODUCTION

Numerical solutions of partial differential equations for wave propagation require the truncation of an unbounded media to fit into computers with a limited memory and computation time. For such problems, absorbing boundary conditions (ABCs) are needed at the truncated boundary to eliminate the reflections from this boundary to the computational domain.

In 1994, a new ABC, called perfectly matched layer (PML), has been introduced by Berenger[1] for electromagnetic waves. It has been proven to be the most robust and efficient technique for the termination of unbounded domain.[2] Since then, the technique has become classical in numerical simulation of wave propagation and has been extended, among others, for acoustic[3] and elastic waves in isotropic[4,5] and anisotropic media.[6] It has been proven that theoretically at the interface between a physical medium and a perfectly matched medium no reflection occurs, and the incident waves from the physical medium are completely absorbed, regardless of their incidence angle and frequency.[1,4] Nevertheless, this property will be lost when a discretization is needed for numerical implementation, especially in the case of oblique incidence. One then needs to optimize the PML parameters in order to decrease parasitic reflections.[7]

Convolutional perfectly matched layer (C-PML), first presented in electromagnetism by Roden and Gedney[8] and applied in the simulation of elastic wave propagation,[9–12] has been shown to improve the behavior of the discrete PML for grazing angle encountered in the case of surface waves. The main advantage of C-PML over the classical PML is that it is based on the unsplit components of the wave field and leads to a more stable scheme. Moreover, it is highly effective at absorbing signals of long time-signature,[13] surface waves,[12] or in elongated domains of calculation.[10]

Classically, C-PML has been introduced in first-order formulation of both electromagnetism and elastodynamics. In this paper, we propose to extend the C-PML absorbing layer to the second-order system describing elastic waves in displacement formulation in anisotropic solids, as it was done for classical split PML.[14] This second-order formulation will be described in frequency and time domains. In frequency domain, this technique is easy to implement in commercial software based on finite element method (FEM).

The efficiency of this second-order perfectly matched layer is demonstrated based on two dimensional (2D) benchmarks both for isotropic and anisotropic solids and for bulk and surface wave propagation. The simulations are realized with the commercially available software COMSOL MULTIPHYSICS in frequency domain and with a pseudo-spectral (PS) method in time domain. In some anisotropic media, numerical instabilities appear in the C-PML, and a modification of the proposed formulation is also discussed in order to stabilize the absorbing layer.

II. SECOND-ORDER FORMULATION OF ELASTIC WAVE PROPAGATION

Consider the propagation of 2D plane strain elastic waves in an anisotropic elastic solid medium. With Einstein's convention of summation, the equation of motion can be written as

$$\frac{\partial^2 u_i}{\partial t^2} = \frac{1}{\rho_0}\frac{\partial \tau_{ij}}{\partial x_j}, \tag{1}$$

where $i,j=1,2$, ρ_0 is the density, x_j are the components of the position vector, t is the time, u_i are the components of the particle displacement vector, and τ_{ij} are the components of

a)Author to whom correspondence should be addressed. Electronic mail: olivier.boumatar@iemn.univ-lille1.fr

the stress tensor. For a linear elastic solid, the constitutive relation is given by Hooke's law:

$$\tau_{ij} = C_{ijkl}\varepsilon_{kl}, \tag{2}$$

where C_{ijkl} are the elastic constants, and the linear approximation of the strain tensor $\boldsymbol{\varepsilon}$ is

$$\varepsilon_{kl} = \frac{1}{2}\left(\frac{\partial u_k}{\partial x_l} + \frac{\partial u_l}{\partial x_k}\right). \tag{3}$$

In the case of a transverse isotopic medium, the following second-order system of equation is obtained:

$$\frac{\partial^2 u_1}{\partial t^2} = \frac{1}{\rho_0}\left(\frac{\partial \tau_{11}}{\partial x} + \frac{\partial \tau_{12}}{\partial y}\right), \tag{4a}$$

$$\frac{\partial^2 u_2}{\partial t^2} = \frac{1}{\rho_0}\left(\frac{\partial \tau_{12}}{\partial x} + \frac{\partial \tau_{22}}{\partial y}\right), \tag{4b}$$

$$\tau_{11} = C_{11}\frac{\partial u_1}{\partial x} + C_{12}\frac{\partial u_2}{\partial y}, \tag{4c}$$

$$\tau_{22} = C_{12}\frac{\partial u_1}{\partial x} + C_{22}\frac{\partial u_2}{\partial y}, \tag{4d}$$

$$\tau_{12} = C_{66}\left(\frac{\partial u_1}{\partial y} + \frac{\partial u_2}{\partial x}\right). \tag{4e}$$

Here we have considered that $x_1 = x$ and $x_2 = y$. This system will be used as the starting point in the remainder of the paper.

III. C-PML FOR ELASTIC WAVE EQUATIONS IN FREQUENCY DOMAIN

Here, the methodology used for the introduction of C-PML zones for axisymmetric active solid media[9] is used for the system of Eq. (4). First, taking Fourier transform of the system, it is rewritten in the frequency domain. Then, the following complex coordinate transformation[15] is used:

$$\tilde{x} = \int_0^x s_x(x')dx', \tag{5a}$$

$$\tilde{y} = \int_0^y s_y(y')dy', \tag{5b}$$

where s_x and s_y are the complex frequency shifted (CFS) stretched-coordinate metrics proposed by Kuzuoglu and Mittra:[16]

$$s_x(x) = \kappa_x(x) + \frac{\sigma_x(x)}{\alpha_x(x) + j\omega}, \tag{6a}$$

$$s_y(y) = \kappa_y(y) + \frac{\sigma_y(y)}{\alpha_y(y) + j\omega}. \tag{6b}$$

α_x, σ_x, α_y, and σ_y are assumed to be positive and real, and κ_x and κ_y are real and ≥ 1. The $\sigma_{x,y}$ and $\kappa_{x,y}$ are the so-called[2] attenuation factor used for the attenuation of propagating waves and scaling factor used for the attenuation of evanescent waves, respectively. The $\alpha_{x,y}$ are frequency-dependent terms that implement a Butterworth-type filter in the layer. The originally split PML, introduced for isotropic elastic wave propagation by Chew and Liu[4] and for anisotropic solid by Collino and Tsogka,[6] is retrieved imposing $\alpha_{x,y} = 0$ and $\kappa_{x,y} = 1$. Using the complex coordinate variables $\tilde{x}$ and $\tilde{y}$ to replace x and y in Eqs. (4a)–(4e) and noting that $\partial/\partial\tilde{x} = (1/s_x)\,\partial/\partial x$ and $\partial/\partial\tilde{y} = (1/s_y)\,\partial/\partial y$, we obtain the following frequency domain equations in Cartesian coordinates:

$$-\omega^2\rho_0\hat{u}_1 = \frac{1}{s_x}\frac{\partial \hat{\tau}_{11}}{\partial x} + \frac{1}{s_y}\frac{\partial \hat{\tau}_{12}}{\partial y}, \tag{7a}$$

$$-\omega^2\rho_0\hat{u}_2 = \frac{1}{s_x}\frac{\partial \hat{\tau}_{12}}{\partial x} + \frac{1}{s_y}\frac{\partial \hat{\tau}_{22}}{\partial y}, \tag{7b}$$

$$\hat{\tau}_{11} = C_{11}\frac{1}{s_x}\frac{\partial \hat{u}_1}{\partial x} + C_{12}\frac{1}{s_y}\frac{\partial \hat{u}_2}{\partial y}, \tag{7c}$$

$$\hat{\tau}_{22} = C_{12}\frac{1}{s_x}\frac{\partial \hat{u}_1}{\partial x} + C_{22}\frac{1}{s_y}\frac{\partial \hat{u}_2}{\partial y}, \tag{7d}$$

$$\hat{\tau}_{12} = C_{66}\left(\frac{1}{s_y}\frac{\partial \hat{u}_1}{\partial y} + \frac{1}{s_x}\frac{\partial \hat{u}_2}{\partial x}\right), \tag{7e}$$

where $\hat{u}$ represents the Fourier transform of the variable u.

In order to implement this C-PML in a commercial FEM software (COMSOL MULTIPHYSICS), the resulting second-order C-PML wave equations are interpreted as an anisotropic medium, as it has already been done for PML.[17] Multiplying Eq. (7) by $s_x s_y$ and introducing new stress tensor $\hat{\tau}'_{ij}$ and density ρ'_0 (given by $\rho_0 s_x s_y$), we get the following equations:

$$-\omega^2\rho'_0\hat{u}_1 = \frac{\partial \hat{\tau}'_{11}}{\partial x} + \frac{\partial \hat{\tau}'_{12}}{\partial y}, \tag{8a}$$

$$-\omega^2\rho'_0\hat{u}_2 = \frac{\partial \hat{\tau}'_{21}}{\partial x} + \frac{\partial \hat{\tau}'_{22}}{\partial y}, \tag{8b}$$

$$\hat{\tau}'_{11} = \hat{\tau}_{11}s_y = C_{11}\frac{s_y}{s_x}\frac{\partial \hat{u}_1}{\partial x} + C_{12}\frac{\partial \hat{u}_2}{\partial y}, \tag{8c}$$

$$\hat{\tau}'_{22} = \hat{\tau}_{22}s_x = C_{12}\frac{\partial \hat{u}_1}{\partial x} + C_{22}\frac{s_x}{s_y}\frac{\partial \hat{u}_2}{\partial y}, \tag{8d}$$

$$\hat{\tau}'_{12} = \hat{\tau}_{12}s_x = C_{66}\left(\frac{s_x}{s_y}\frac{\partial \hat{u}_1}{\partial y} + \frac{\partial \hat{u}_2}{\partial x}\right), \tag{8e}$$

$$\hat{\tau}'_{21} = \hat{\tau}_{12}s_y = C_{66}\left(\frac{\partial \hat{u}_1}{\partial y} + \frac{s_y}{s_x}\frac{\partial \hat{u}_2}{\partial x}\right). \tag{8f}$$

This system of equation corresponds to the propagation of elastic waves in a "fictious" anisotropic medium and can be written in the matrix form as

$$\begin{bmatrix} \hat{\tau}'_{11} \\ \hat{\tau}'_{22} \\ \hat{\tau}'_{12} \\ \hat{\tau}'_{21} \end{bmatrix} = \begin{bmatrix} C'_{11} & C_{12} & 0 & 0 \\ C_{12} & C'_{22} & 0 & 0 \\ 0 & 0 & C'_{66} & C_{66} \\ 0 & 0 & C_{66} & C''_{66} \end{bmatrix} \begin{bmatrix} u_{1,x} \\ u_{2,y} \\ u_{1,y} \\ u_{2,x} \end{bmatrix}, \tag{9}$$

with $u_{1,x}=\partial\hat{u}_1/\partial x$, $u_{2,y}=\partial\hat{u}_2/\partial y$, $u_{1,y}=\partial\hat{u}_1/\partial y$, and $u_{2,x}=\partial\hat{u}_2/\partial x$. The new effective elastic stiffnesses are $C'_{11}=C_{11}s_y/s_x$, $C'_{22}=C_{22}s_x/s_y$, $C'_{66}=C_{66}s_x/s_y$, and $C''_{66}=C_{66}s_y/s_x$. It should be noted that this fictious anisotropic medium has a nonsymmetric stress tensor ($\hat{\tau}_{ij}\neq\hat{\tau}_{ji}$ when $i\neq j$), and the complex-valued tensor of elastic constants conserves minor symmetry properties, but not the major one.

We can easily extend this description of C-PML in anisotropic solid to three dimensions. In this case, the general form of the propagation of elastic waves can be described as

$$-\omega^2\rho'_0\hat{u}_i=\frac{\partial\hat{\tau}'_{ij}}{\partial x_j}, \tag{10a}$$

$$\hat{\tau}'_{ij}=C'_{ijkl}\frac{\partial\hat{u}_l}{\partial x_k}, \tag{10b}$$

where $i,j,k,l=1$, 2, or 3. The effective elastic tensor C' and the density ρ'_0 are given by

$$C'_{ijkl}=C_{ijkl}\frac{s_xs_ys_z}{s_is_k}, \tag{11a}$$

$$\rho'_0=\rho_0s_xs_ys_z. \tag{11b}$$

The effective constants already obtained for 2D situation can be easily derived from Eq. (11a) by considering that $s_z=1$ and $i,j,k,l=1$ or 2. Moreover, this fictious anisotropic interpretation of C-PML or PML can be extended to piezoelectric solids.[18–20]

IV. C-PML FOR ELASTIC WAVE EQUATIONS IN TIME DOMAIN

Now, to be able to obtain a C-PML formulation in time domain, the resulting equations are transformed back to time domain by inverse Fourier transform. Due to the frequency dependence of the CFS stretched-coordinate metrics, a convolution appears in the resulting equations, as shown, for example, for Eq. (7a):

$$\frac{\partial^2u_1}{\partial t^2}=\frac{1}{\rho_0}\left[F^{-1}\left[\frac{1}{s_x}\right]\otimes\frac{\partial\tau_{11}}{\partial x}+F^{-1}\left[\frac{1}{s_y}\right]\otimes\frac{\partial\tau_{12}}{\partial y}\right], \tag{12}$$

where $\otimes$ and $F^{-1}[\cdot]$ are, respectively, the convolution and inverse Fourier transform operators. In order to eliminate the convolutions appearing in Eq. (12), we use the methodology introduced by Roden and Gedney[8] in electromagnetism and extended by Bou Matar *et al.*[9] for elastic wave propagation in active (or nonlinear) media by introducing memory variables. The time evolution of each of these memory variables is realized by a first-order differential equation. The obtained result can be rewritten as

$$\frac{\partial^2u_1}{\partial t^2}=\frac{1}{\rho_0}\left(\frac{1}{\kappa_x}\frac{\partial\tau_{11}}{\partial x}+\frac{1}{\kappa_y}\frac{\partial\tau_{12}}{\partial y}+\frac{A_x}{\kappa_x}+\frac{B_y}{\kappa_y}\right), \tag{13}$$

where the memory variables A_x and B_y are given by

$$\frac{\partial A_x}{\partial t}=-\delta_x\frac{\partial\tau_{11}}{\partial x}-\beta_xA_x, \tag{14a}$$

$$\frac{\partial B_y}{\partial t}=-\delta_y\frac{\partial\tau_{12}}{\partial y}-\beta_yB_y, \tag{14b}$$

with $\delta_{x,y}=\sigma_{x,y}/\kappa_{x,y}$ and $\beta_{x,y}=\sigma_{x,y}/\kappa_{x,y}+\alpha_{x,y}$. Making the same calculation for Eqs. (7b)–(7e), we obtain the following system equations of C-PML in time domain for elastic wave propagation in anisotropic solid:

$$\frac{\partial^2u_1}{\partial t^2}=\frac{1}{\rho_0}\left(\frac{1}{\kappa_x}\frac{\partial\tau_{11}}{\partial x}+\frac{1}{\kappa_y}\frac{\partial\tau_{12}}{\partial y}+\frac{A_x}{\kappa_x}+\frac{B_y}{\kappa_y}\right), \tag{15a}$$

$$\frac{\partial^2u_2}{\partial t^2}=\frac{1}{\rho_0}\left(\frac{1}{\kappa_x}\frac{\partial\tau_{12}}{\partial x}+\frac{1}{\kappa_y}\frac{\partial\tau_{22}}{\partial y}+\frac{C_x}{\kappa_x}+\frac{D_y}{\kappa_y}\right), \tag{15b}$$

$$\tau_{11}=\frac{C_{11}}{\kappa_x}\frac{\partial u_1}{\partial x}+\frac{C_{12}}{\kappa_y}\frac{\partial u_2}{\partial y}+\frac{C_{11}}{\kappa_x}E_x+\frac{C_{12}}{\kappa_y}F_y, \tag{15c}$$

$$\tau_{22}=\frac{C_{12}}{\kappa_x}\frac{\partial u_1}{\partial x}+\frac{C_{22}}{\kappa_y}\frac{\partial u_2}{\partial y}+\frac{C_{12}}{\kappa_x}E_x+\frac{C_{22}}{\kappa_y}F_y, \tag{15d}$$

$$\tau_{12}=\frac{C_{66}}{\kappa_x}\frac{\partial u_2}{\partial x}+\frac{C_{66}}{\kappa_y}\frac{\partial u_1}{\partial y}+\frac{C_{66}}{\kappa_x}G_x+\frac{C_{66}}{\kappa_y}H_y, \tag{15e}$$

where the memory variables C_x, D_y, E_x, F_y, G_x, and H_y are obtained by the first-order differential equations similar to the one derived for A_x and B_y in Eq. (14). The memory variables will be zero outside the C-PML zones, so the first-order differential equations of memory variables need only to be solved in a small part of the calculation domain. After introducing Eqs. (15c)–(15e) into Eqs. (15a) and (15b), the resulting system of wave equations can be written as

$$\rho_0\frac{\partial^2u_1}{\partial t^2}-\left[\frac{\partial}{\partial x}\left(C_{11}\frac{\partial u_1}{\partial x}+C_{12}\frac{\partial u_2}{\partial y}\right)+\frac{\partial}{\partial y}\left(C_{66}\frac{\partial u_2}{\partial x}+C_{66}\frac{\partial u_1}{\partial y}\right)\right]=f_1, \tag{16a}$$

$$\rho_0\frac{\partial^2u_2}{\partial t^2}-\frac{\partial}{\partial x}\left(C_{66}\frac{\partial u_2}{\partial x}+C_{66}\frac{\partial u_1}{\partial y}\right)+\frac{\partial}{\partial y}\left(C_{12}\frac{\partial u_1}{\partial x}+C_{22}\frac{\partial u_2}{\partial y}\right)=f_2, \tag{16b}$$

where f_1 and f_2 are

$$f_1 = \left[-\frac{\kappa'_x}{\kappa_x}\frac{\partial}{\partial x}\left(\frac{C_{11}}{\kappa_x}\frac{\partial u_1}{\partial x} + \frac{C_{12}}{\kappa_y}\frac{\partial u_2}{\partial y} + \frac{C_{11}}{\kappa_x}E_x + \frac{C_{12}}{\kappa_y}F_y\right) - \frac{\kappa'_y}{\kappa_y}\frac{\partial}{\partial y}\left(\frac{C_{66}}{\kappa_x}\frac{\partial u_2}{\partial x} + \frac{C_{66}}{\kappa_y}\frac{\partial u_1}{\partial y} + \frac{C_{66}}{\kappa_x}G_x + \frac{C_{66}}{\kappa_y}H_y\right) - \frac{\partial}{\partial x}\left(\frac{\kappa'_x C_{11}}{\kappa_x}\frac{\partial u_1}{\partial x} + \frac{\kappa'_y C_{12}}{\kappa_y}\frac{\partial u_2}{\partial y} - \frac{C_{11}}{\kappa_x}E_x - \frac{C_{12}}{\kappa_y}F_y\right) - \frac{\partial}{\partial y}\left(\frac{\kappa'_x C_{66}}{\kappa_x}\frac{\partial u_2}{\partial x} + \frac{\kappa'_y C_{66}}{\kappa_y}\frac{\partial u_1}{\partial y} - \frac{C_{66}}{\kappa_x}G_x - \frac{C_{66}}{\kappa_y}H_y\right) + \frac{A_x}{\kappa_x} + \frac{B_y}{\kappa_y}\right], \tag{16c}$$

$$f_2 = \left[-\frac{\kappa'_x}{\kappa_x}\frac{\partial}{\partial x}\left(\frac{C_{66}}{\kappa_x}\frac{\partial u_2}{\partial x} + \frac{C_{66}}{\kappa_y}\frac{\partial u_1}{\partial y} + \frac{C_{66}}{\kappa_x}G_x + \frac{C_{66}}{\kappa_y}H_y\right) - \frac{\kappa'_y}{\kappa_y}\frac{\partial}{\partial y}\left(\frac{C_{12}}{\kappa_x}\frac{\partial u_1}{\partial x} + \frac{C_{22}}{\kappa_y}\frac{\partial u_2}{\partial y} + \frac{C_{12}}{\kappa_x}E_x + \frac{C_{22}}{\kappa_y}F_y\right) - \frac{\partial}{\partial x}\left(\frac{\kappa'_x C_{66}}{\kappa_x}\frac{\partial u_2}{\partial x} + \frac{\kappa'_y C_{66}}{\kappa_y}\frac{\partial u_1}{\partial y} - \frac{C_{66}}{\kappa_x}G_x - \frac{C_{66}}{\kappa_y}H_y\right) - \frac{\partial}{\partial y}\left(\frac{\kappa'_x C_{12}}{\kappa_x}\frac{\partial u_1}{\partial x} + \frac{\kappa'_y C_{22}}{\kappa_y}\frac{\partial u_2}{\partial y} - \frac{C_{12}}{\kappa_x}E_x - \frac{C_{22}}{\kappa_y}F_y\right) + \frac{C_x}{\kappa_x} + \frac{D_y}{\kappa_y}\right], \tag{16d}$$

where we have introduced the notation $\kappa'_{x,y}=\kappa_{x,y}-1$. The formulation of C-PML given by Eq. (16) has been introduced in order to facilitate the implementation of the resulting second-order C-PML wave equations in commercial finite element packages and in our homemade PS code.

It is important to note that in time domain the number of equation needed to be solved increases in the C-PML zones. This can considerably increase the burden of calculation. Nevertheless, when active (or nonlinear) media are considered, then time domain formulations are needed,[9] and Eq. (16) has to be used. Moreover, the number of auxiliary variables in the unsplit and convolutional PML is less than the one of the classical split PML. In the considered case, elastic wave propagation in a 2D anisotropic solid, eight auxiliary variables are needed for the unsplit PML and ten for the split PML. In both cases, these auxiliary variables need to be stored in addition to the total field variables: u_1 and u_2 for the proposed CPML or u_1, u_2, τ_{11}, τ_{22}, and τ_{12} for the classical split PML. In the classical PML case, one can choose either to store or not the total field. In this last case, the memory storage is reduced but the computation time is increased because one then needs to compute the total field variables as the sum of two splitted auxiliary variables several times in each iteration of the time loop.

V. NUMERICAL TESTS

In this section, the excellent absorbing behaviors of both formulations (frequency and time domains) are demonstrated. The frequency domain formulation has been implemented in a commercial FEM software (COMSOL MULTIPHYSICS), and a PS code has been developed for the time domain formulation. The choice of these numerical schemes has been motivated by the compromise in obtaining both efficient and accurate methods for the two different formulations.

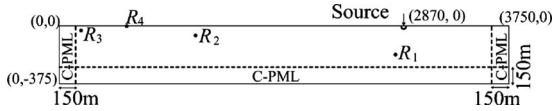

FIG. 1. Schematic of the model used in the example of surface wave in a homogeneous isotropic medium. The C-PML terminations are positioned at the left, right, and bottom sides of the simulation domain. The top boundary is a stress free boundary. The source and four receiver (R_1, R_2, R_3, and R_4) positions are also depicted.

A. Surface wave in a homogeneous isotropic medium

In order to demonstrate the improvement induced by the use of C-PML, instead of classical PML, numerical simulations of elastic wave propagation in a half space of homogeneous isotropic medium, similar to the ones proposed by Drossaert and Giannopoulos,[11] are presented. The sketch of the used elongated calculation domain (3750 m width and 375 m height, including the C-PMLs and corresponding to 200×20 grid elements) is given in Fig. 1, where the origin (0, 0) is at the left upper corner. The properties of the elastic medium have been chosen as follows: the density is $\rho_0=2000$ kg m^{-3}, and the Lame constants are $\lambda=0.6\times 10^9$ and $\mu=0.3\times 10^9$ N/m^2. A directional point source, acting as a force perpendicular to the upper free surface, is located at (2870.0, 0.0). Four receiving positions R_1, R_2, R_3, and R_4 are chosen at the following locations: (2800.0, −187.5), (1120.0, −42.5), (168.75, −18.75), and (562.5, 0), respectively. The choice of these receiving positions has been realized in order to demonstrate typical behavior of the C-PML. The temporal variation of the point source is a Ricker wavelet given by

$$f(t) = (0.5 + a_1(t-t_D)^2)e^{-a_1(t-t_D)^2}, \tag{17}$$

where $t_D=1.0$ s is the source delay time, $a_1=(\pi f_c)^2$, and $f_c=1.0$ Hz is the central frequency.

In the stretched-coordinate metrics, the following spatial coordinate dependences are used for the parameters of the C-PMLs in the x direction:

$$\kappa_x = 1 + \kappa_{\max}\left(\frac{x-x_0}{d_x}\right)^{n_1}, \tag{18a}$$

$$\sigma_x = \sigma_{\max}\left(\frac{x-x_0}{d_x}\right)^{n_1+n_2}, \tag{18b}$$

$$\alpha_x = \alpha_{\max}\left(\frac{d_x - x + x_0}{d_x}\right)^{n_3}, \tag{18c}$$

with $\alpha_{\max}=2\pi f_\alpha$ and

$$\sigma_{\max} = (1+n_1+n_2)\sqrt{(\lambda+2\mu)/\rho_0}\log(1/R_0)/(2d_x), \tag{19}$$

where R_0 is the reflection coefficient from the C-PML we want to obtain, and x_0 and d_x are, respectively, the starting position and thickness of the C-PML. κ_y, σ_y, and α_y have the

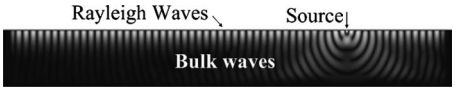

FIG. 2. Displacement amplitude snapshot at frequency 3 Hz for the model depicted in Fig. 1, showing the propagation and absorption in the C-PML terminations of both bulk and Rayleigh waves.

same form as κ_x, σ_x, and α_x, respectively, just replacing x by y. f_α is a characteristic frequency of the C-PML (here $f_\alpha = 10^{-2}$ Hz). It corresponds to a cut off frequency.[21] Indeed, when $f \gg f_\alpha$ the complex frequency shifted coefficients $\alpha_{x,y}$ are negligible, and the attenuation in the C-PML is the same as in the PML. On the other hand, when $f \ll f_\alpha$ the stretch of the coordinates is real and the medium does not absorb propagating waves, but only the evanescent waves. The spatial dependences used in Eq. (18) are the same as the ones classically proposed for PML applied to electromagnetic waves.[2] $\sigma_{\max}$ given by Eq. (19) corresponds to the optimal value proposed in Ref. 6. In the considered cases we use $\kappa_{\max}=0$. Moreover, $\kappa_{x,y}=1$ and $\sigma_{x,y}=0$ in the computational domain, outside the C-PML zone. In the presented results, a C-PML thickness of eight grid elements, both in the left, right, and bottom boundaries, $R_0=5\ \ 10^{-5}$, $n_1=3$, $n_2=0$, and $n_3=1$ has been chosen. We remind also that the classical PML case corresponds to $\alpha_{\max}=0$.

Here, Eq. (8) has been solved with COMSOL MULTIPHYSICS FEM software in frequency domain. Indeed, as demonstrated by Castaings *et al.*,[22] very efficient simulations of linear pulse propagation in solids can be obtained with only a limited number of frequency calculations. The time evolution of the point source [Eq. (17)] is first Fourier transform, and Eq. (8) is then solved for 40 frequencies equally spaced in the source spectrum. Second-order Lagrange elements have been used in all the FEM calculations. The result obtained at one frequency (3 Hz) is shown in Fig. 2, where both bulk waves in the physical domain and Rayleigh waves on the free surface boundary can be seen. In Fig. 3, the time evolutions of the horizontal [(a) and (b)] and vertical [(c) and (d)] displacements reconstructed by inverse Fourier transform of the 40 frequency responses at the fourth receiver, positioned at the free surface, in the case of both C-PML (dotted line) and PML (dashed line) layers for absorbing the surface wave are displayed and compared to an analytical solution (solid line). The FORTRAN code EX2DDIR of Berg *et al.*[23] has been used to compute this exact solution of the 2D response from a vertical directional point source in an isotropic elastic half space with a free surface. The obtained results clearly demonstrated the increased efficiency of the C-PML in comparison with the PML in order to absorb the Rayleigh wave, particularly when a zoom [Figs. 3(b) and 3(d)] is made around the end of this surface wave. This is in perfect accordance with previous results obtained with the C-PML first-order velocity-stress formulation implementation.[10–12]

The time evolutions of the horizontal [(a), (c), and (e)] and vertical [(b), (d), and (f)] displacements for the three other receivers (R_1, R_2, and R_3) in the case of FEM simulation with C-PML (dotted line) are plotted in Fig. 4 and compared, as before, with a FEM simulation with PML (dashed

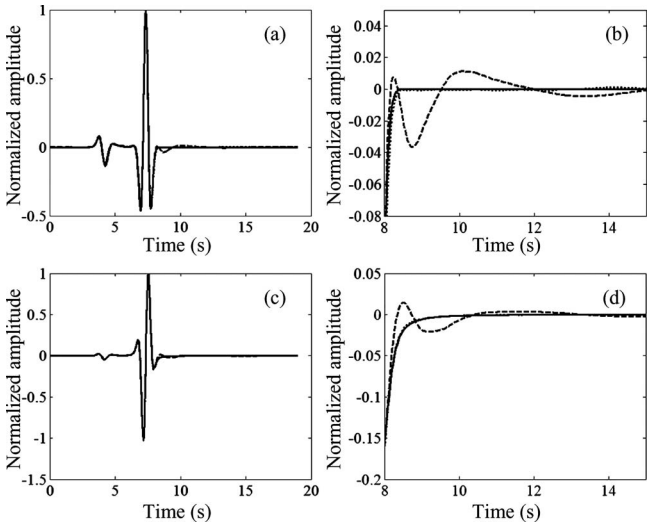

FIG. 3. Time evolution of the horizontal u_1 (a) and the vertical u_2 (c) components of the displacement vector at the fourth receiver of the analytical solution of the problem (solid line) and the numerical solution with PML (dashed line) and C-PML (dotted line). (b) and (d) are zoom of (a) and (c), respectively, showing the benefit of using C-PML instead of PML.

line) and an analytical solution (solid line). As in Fig. 3, it clearly appears in Fig. 4 that the use of C-PML greatly improves the surface wave absorption efficiency of the absorbing layer (see R_2 signal, where spurious oscillations of the horizontal displacement component are observed in the case

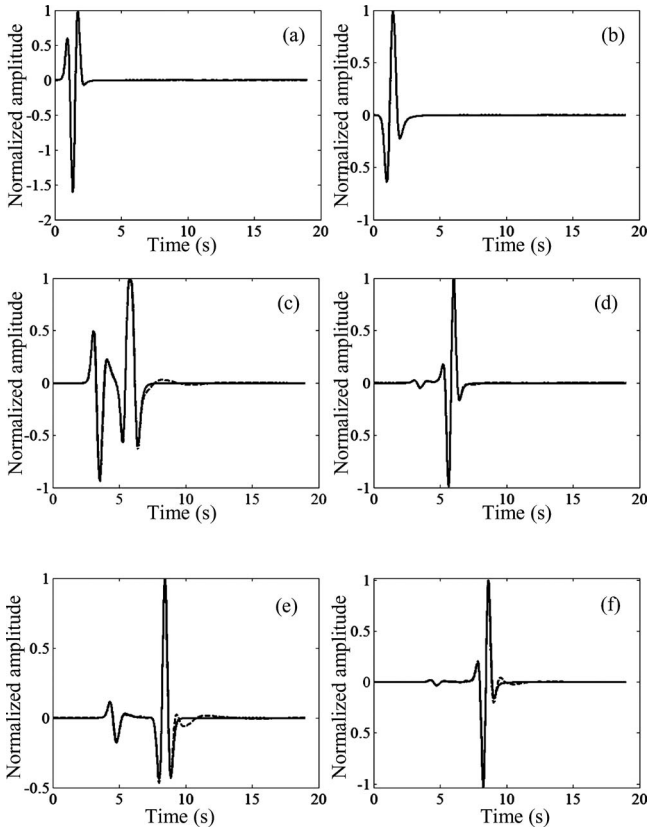

FIG. 4. Time evolution of the horizontal u_1 (left) and the vertical u_2 (right) components of the displacement vector at the first (top), second (middle), and third (bottom) receivers of the analytical solution of the problem (solid line) and the numerical solution with PML (dashed line) and C-PML (dotted line).

of PML), even if the receiver is positioned close to the absorbing layer, as for the R_3 receiver. It is linked to evanescent part of the Rayleigh wave in the bulk direction which interacts over a long distance with the PML at the bottom. In the case of the first receiver, placed in the bulk of the sample where the contribution of surface wave is negligible, the C-PML and PML have the same absorbing efficiency, and the overall agreement with the analytical solution is almost perfect.

B. Bulk wave in a homogeneous anisotropic medium

The PS code described in Ref. 9 has been modified in order to solve the second-order wave equation system of Eq. (16), in place of the classical first-order stress-particle velocity formulation used in finite difference time domain elastic wave propagation simulations. The forward integration in time, realized in our previous PS code by a staggered fourth-order Adams–Bashforth method, is here made with the use of a second-order finite difference method.

Simulations of pulse propagation in anisotropic solids have been made in order to demonstrate the efficiency of the proposed time domain C-PML formulation for second-order wave equations. The properties, density and elasticity coefficients, of the three different orthotropic materials used in the time domain simulations are shown in Table I. The choice of the material name (I, III, and V) has been made, following Bécache *et al.*,[24] in order to simplify the comparison of our results with previous ones.[24–26] In all cases, a 25 cm × 25 cm portion of an infinite solid has been discretized on a 128 × 128 element grid (including the ten element C-PML placed on each side), and a 5 ns time step was used. The following source term $f(x,y,t)$ is added to f_1 in the right hand side of Eq. (16a):

TABLE I. Properties of the orthotropic materials used in the time domain simulations.

Material	ρ (kg/m^3)	C_{11} (GPa)	C_{22} (GPa)	C_{12} (GPa)	C_{66} (GPa)
I	4000	40	200	38	20
III	4000	40	200	75	20
V	4000	300	60	99	15

$$f(x,y,t) = (0.5 + a_1(t - t_D)^2)e^{-a_1(t-t_D)^2}\frac{e^{-7[(x^2+y^2)/r_0^2]}}{r_0^2}, \quad (20)$$

where $a_1 = (\pi f_c)^2$, $f_c = 150$ kHz is the central frequency, $t_D = 1/f_c$ is the source delay time, and $r_0 = 5$ mm. It corresponds to a Gaussian spatial distribution around the (0,0) point which is placed at the center in all the simulations and to a Ricker wavelet time evolution. The same spatial coordinate dependences [Eq. (18)] are used for the C-PML parameters with now $\alpha_{\max} = 20\pi$, $n_1 = 2$, $n_2 = 1$, $n_3 = 1$, and

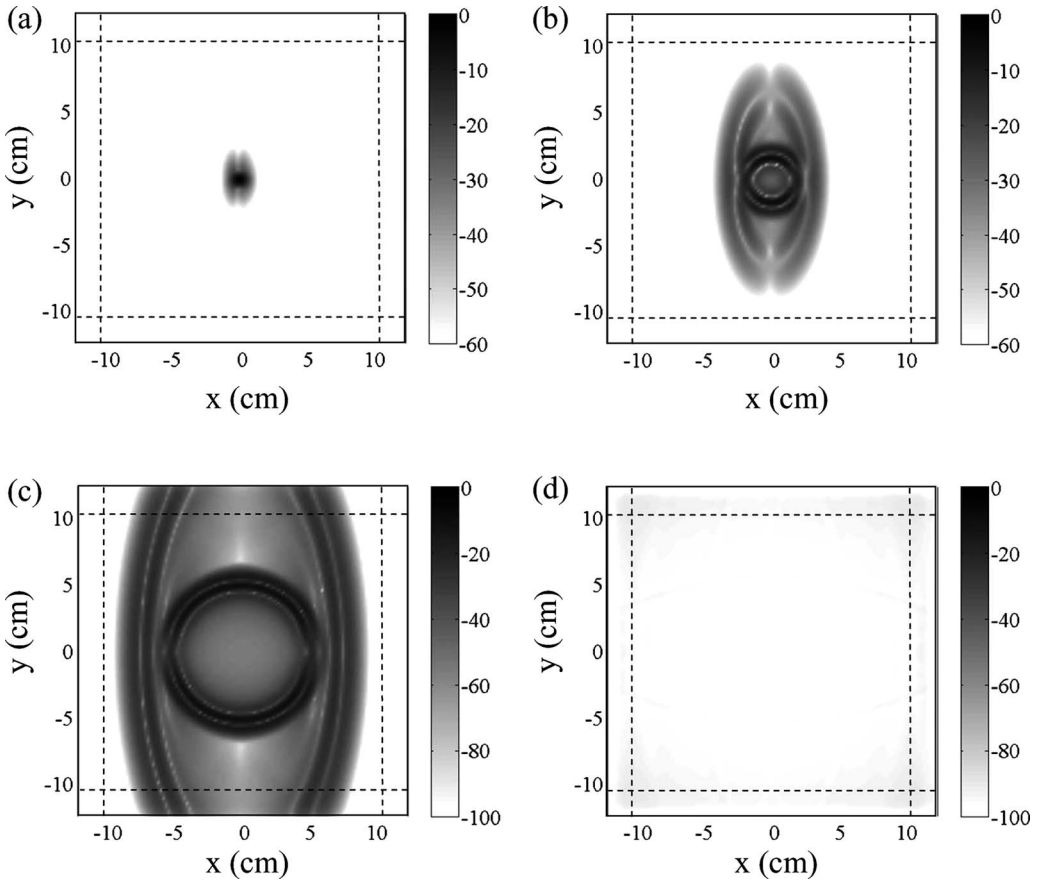

FIG. 5. Snapshots of propagation of the displacement magnitude in an orthotropic elastic medium, model I, at (a) $t = 5$ μs, (b) $t = 15$ μs, (c) $t = 30$ μs, and (d) $t = 125$ μs. The snapshots are in dB scale with a reference displacement amplitude of 10 nm.

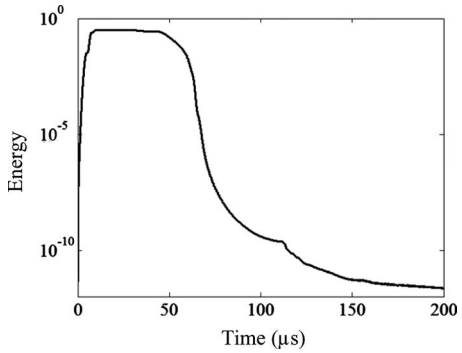

FIG. 6. Energy decay in the physical domain for the orthotropic elastic medium, model I, in the same conditions as the ones used to obtain the snapshots of Fig. 5.

$$\sigma_{\max} = (1 + n_1 + n_2)\sqrt{C_{11}/\rho_0}\log(1/R_0)/(2d_x), \tag{21}$$

where $R_0 = 10^{-12}$.

In Fig. 5, snapshots of the propagation of the amplitude of the displacement in medium I are displayed for four different times (5, 15, 30, and 125 μs). Here and in all the following figures, the snapshots presented are in dB scale with a reference displacement of 10 nm. The overall absorption of the C-PML is excellent and the level of spurious reflection is very small, only a −90 dB reflected pulse can be seen at the later time [Fig. 5(d)]. In order to see more quantitatively the quality of the C-PML, the total energy E at each time is computed according to the following expression:

$$E = \frac{1}{2}\int_\Omega \rho_0 \|\boldsymbol{v}\|^2 d\Omega + \frac{1}{2}\int_\Omega \tau_{ij}\varepsilon_{ij} d\Omega, \tag{22}$$

where Ω is the volume corresponding to the physical domain, and $\|\mathbf{v}\|$ is the magnitude of the velocity vector. Figure 6 displays the energy decay in the physical domain for the proposed C-PML model. The wave field has left the physical domain at about 60 μs here. This figure not only confirms that at later time the energy has decayed by a factor of 10^{12} but also demonstrates that no significant spurious reflection appears before.

Snapshots of the propagation of the amplitude of the displacement in medium III are displayed for four different times (5, 15, 30, and 50 μs) in Fig. 7. As all the other PML or C-PML implementations, some instabilities appear [Figs. 7(c) and 7(d)] in the absorbing layers where, as explained by Bécache *et al.*,[24] one of the incident elastic waves arrives with the components of the group velocity and the slowness vector, in the C-PML direction, of opposite signs. These instabilities are one of the major limitations in the use of PML for elastic waves propagating in anisotropic solids and in plates, even in the case of an isotropic medium.[27] In the case of elastic plate absorbing layers, solutions have been proposed in order to overcome this limitation, but at the expense

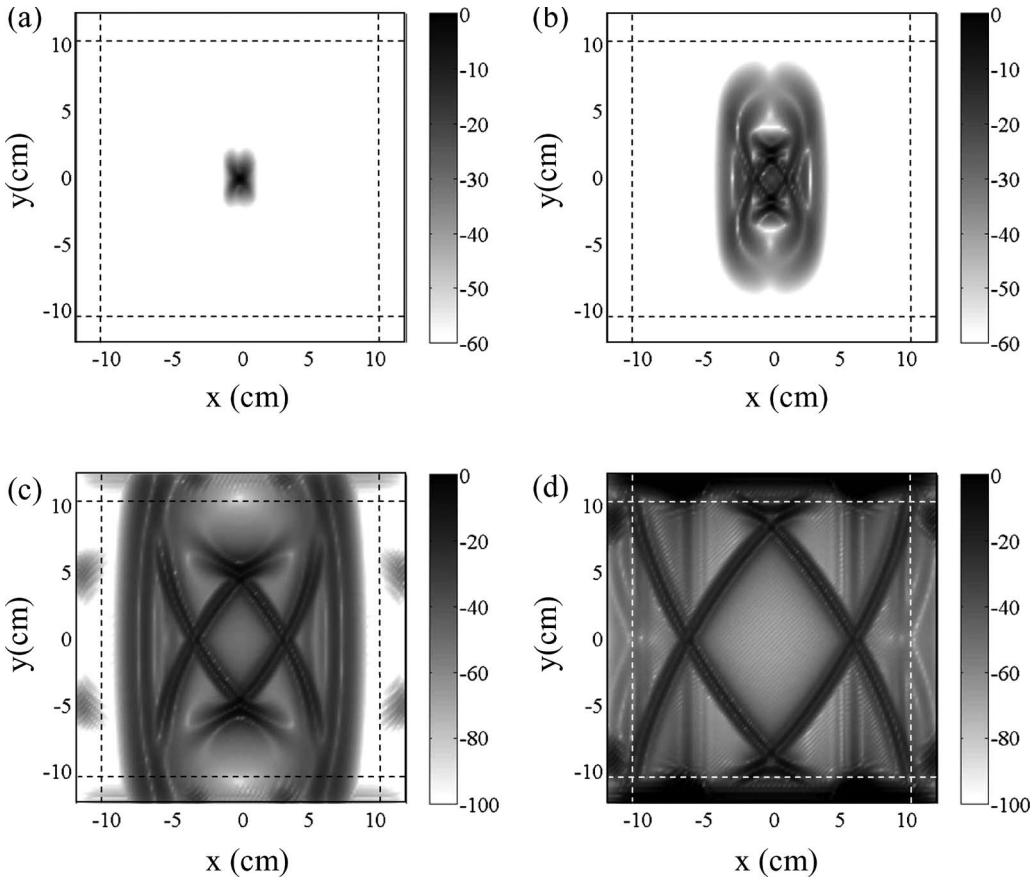

FIG. 7. Snapshots of propagation of the displacement magnitude in an orthotropic elastic medium, model III, at (a) $t=5$ μs, (b) $t=15$ μs, (c) $t=30$ μs, and (d) $t=50$ μs. The snapshots are in dB scale with a reference displacement amplitude of 10 nm. Instabilities are observed for the C-PML terminations used in the simulation.

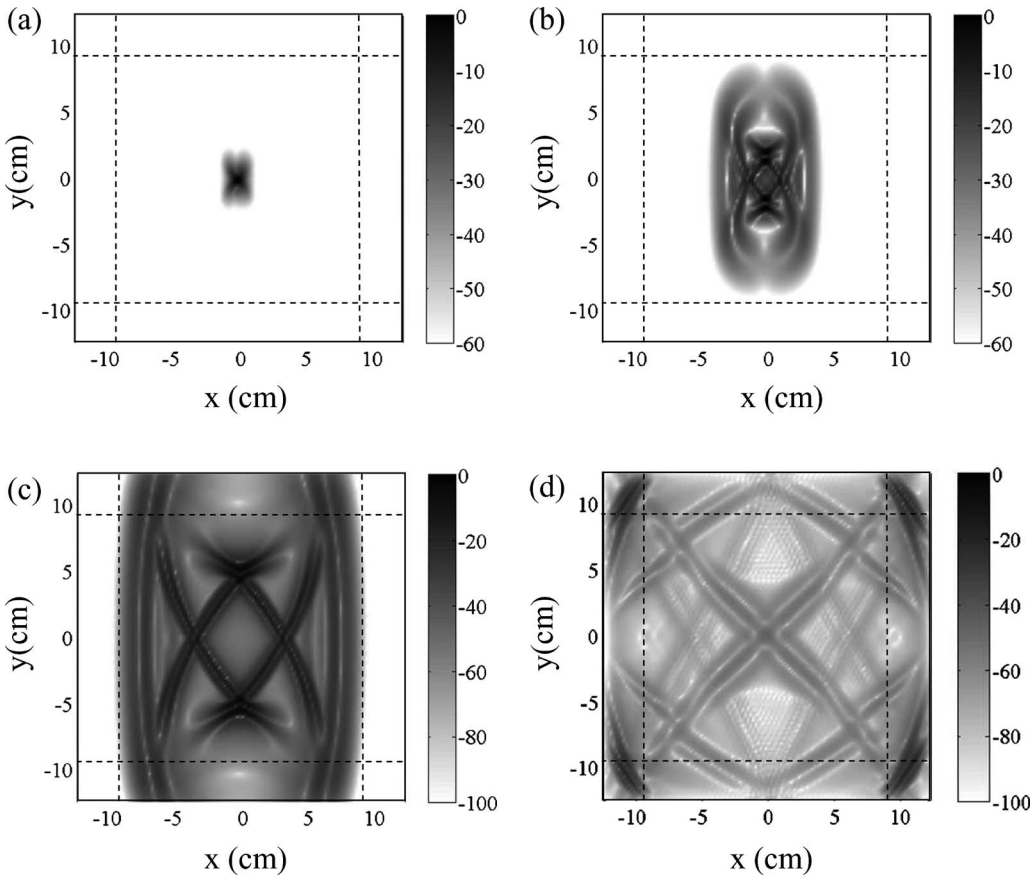

FIG. 8. Snapshots of propagation of the displacement magnitude in an orthotropic elastic medium, model III, at (a) $t=5$ μs, (b) $t=15$ μs, (c) $t=30$ μs, and (d) $t=125$ μs. The snapshots are in dB scale with a reference displacement amplitude of 10 nm. No instability is observed for the M-PML terminations used in the simulation.

of an increased length of the absorbing zone.[18,22,28] An elegant way of preserving the use of short length PML has been introduced by Skelton *et al.*,[29] but at the expense now of having one different PML for each propagating mode. For anisotropic solids an absorbing layer called multiaxial perfectly matched layer (M-PML), showing no instabilities, has recently been developed.[26] This M-PML can easily be extended to the case where the CFS stretched-coordinate metrics are used in place of the ones of PML. The introduction procedure of the M-PML is in all points similar to either PML or C-PML. However, in the M-PML, the attenuation parameters σ_x and σ_y of the stretching parameters s_x and s_y are now a function of the two space variables x and y:[18,26]

$$\sigma_x(x,y) = \sigma_{xx}(x) + \sigma_{xy}(y), \tag{23a}$$

$$\sigma_y(x,y) = \sigma_{yx}(x) + \sigma_{yy}(y). \tag{23b}$$

So, all the C-PML equations given up to now, both in frequency domain [Eq. (8)] and in time domain [Eq. (16)], can be used in the M-PML with CFS stretching, just replacing, in the expressions of s_x and s_y, $\sigma_x(x)$ by $\sigma_x(x,y)$, and $\sigma_y(y)$ by $\sigma_y(x,y)$. We define as in Ref. 26 $p^x=\sigma_{yx}(x)/\sigma_{xx}(x)$ and $p^y=\sigma_{xy}(y)/\sigma_{yy}(y)$. Results obtained for medium III with $p^x=p^y=0.25$ are shown in Fig. 8. The instabilities have completely disappeared in comparison to Fig. 7, but at the expense of a stronger reflection of the waves impinging the absorbing layer with a grazing angle [Fig. 8(d)]. More details on the behavior of these stabilized absorbing layers will be given in a future publication.

In Fig. 9, snapshots of the propagation of the amplitude of the displacement in medium V are displayed for the same four different times as in medium I. Here, contrary to the case of PML,[24] no instabilities appear even at longer time. This improved stability of the C-PML over the PML has already been demonstrated theoretically by Appelö and Kreiss.[25] In fact, the "new absorbing layer" they proposed is nothing else than a new derivation of the C-PML introduced for elastic waves in Ref. 9. It can be noted that it has also been proved that the C-PML is efficient in the case of nonlinear wave absorption.[9,30]

VI. CONCLUSION

In this paper, we extend the C-PML implementation, previously made for the first-order velocity-stress formulation, to a second-order elastic wave equation written in terms of displacements both in frequency and time domains. This new formulation has been implemented in a commercial FEM software (COMSOL MULTIPHYSICS) and in a homemade PS code. The results of the simulations demonstrate that C-PMLs have more absorbing efficiency in the cases of oblique incidence and surface wave than classical PMLs.

In the case of orthotropic material stability problems have appeared, as in the first-order velocity-stress implemen-

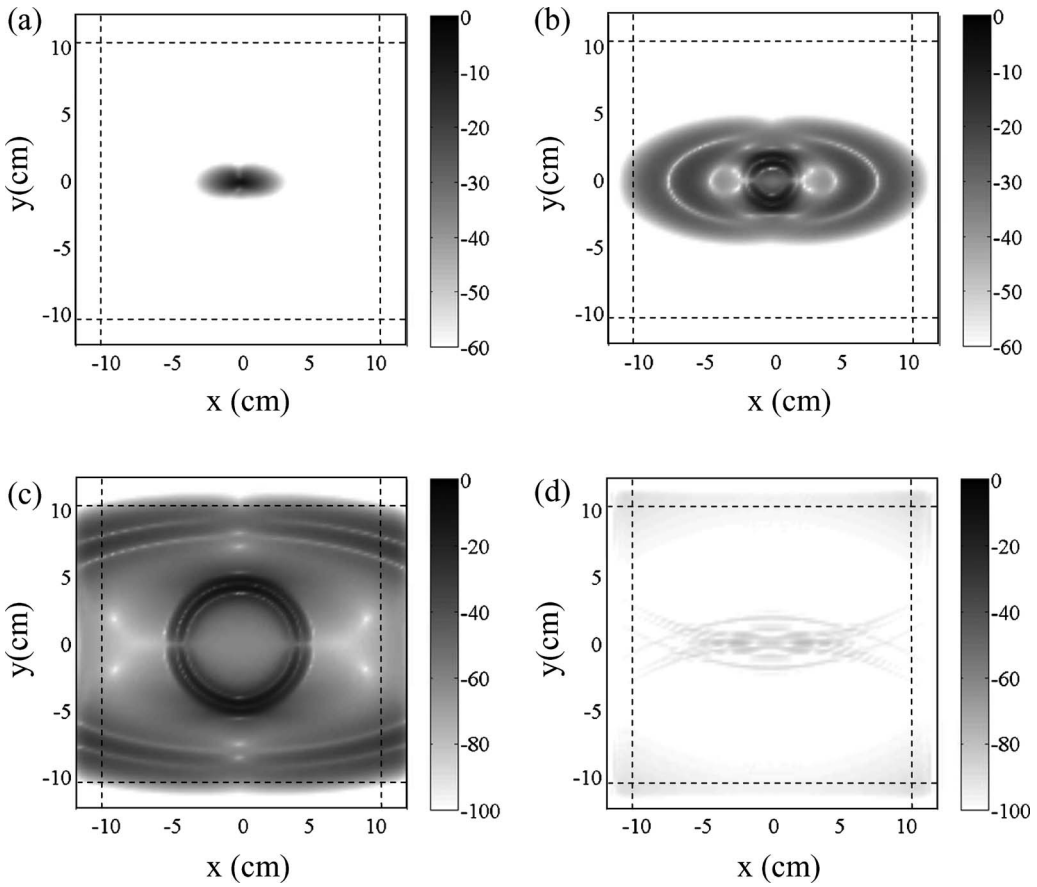

FIG. 9. Snapshots of propagation of the displacement magnitude in an orthotropic elastic medium, model V, at (a) $t=5$ μs, (b) $t=15$ μs, (c) $t=30$ μs, and (d) $t=125$ μs. The snapshots are in dB scale with a reference displacement amplitude of 10 nm.

tation. Following the "M-PML" of Meza-Fajardo and Papageorgiou,[26] we have introduced a mixture of C-PML and of sponge layer, with a controllable ratio of these two kinds of absorbing layers, in order to stabilize the C-PML, and shown that this stabilized C-PML is, in fact, not perfectly matched to the physical domain.

(Received 12 March 2009; revised 8 July 2009; accepted 31 December 2009)

A number of papers have shown that it is possible to characterize an air-filled cylindrical shell immersed in water using data obtained from a backscattering spectrum. The scattered impulse time signal is constituted of echoes linked to the reradiation of waves circumnavigating around the cylindrical target. In the first part of this work, the scattered signal is calculated and then measured under conditions where the cylindrical shell is immersed in water. In the second part, the cylindrical shell is buried in a thin sand-water mixture. It is insonified perpendicularly to its axis and perpendicularly to the water mixture interface. The scattered impulse time signal is recorded and processed using a Fourier transform algorithm to obtain a resonance spectrum. Among all the resonances that are established in the explored frequency band, only those related to the circumferential S_0 wave are observed on the resonance spectrum of a cylindrical shell buried in the sand-water mixture. Resonances of the circumferential A wave also called A_0^- wave seem to have vanished. The resonance spectrum obtained by the Method of Isolation and Identification of Resonances (MIIR) reveals that it is possible to detect and classify an object buried in thin sand-water mixture in laboratory conditions.

I. INTRODUCTION

For some years, several authors have been studying the possibility of detecting and classifying objects buried in sediment at the bottom of the sea.[1–3] In laboratory conditions, other researchers have developed methods to distinguish acoustic signals associated with buried objects from acoustic signals reverberated by the sand.[4] In this paper, the authors use the Method of Isolation and Identification of Resonances[5–9] (MIIR) to detect and to classify buried objects in a very thin sand-water mixture.

The MIIR that experimentally verifies the Resonance Scattering Theory[10] (RST) have been used in a number of papers to show that it is possible to characterize cylindrical and spherical shells using acoustic resonance spectra. The authors of the RST have demonstrated that the backscattering acoustic spectrum of a cylindrical shell, insonified by a plane wave perpendicularly to its axis, is constituted by, on the one hand, a background signal due to the reflection of the incident acoustic wave on the object and, on the other hand, by resonances associated with the propagation of circumferential waves, circumnavigating around the target in the shell or at the interface between the shell and water. The characteristics of the circumferential waves are strongly influenced by the material and the radius ratio b/a (b: inner radius; a: outer radius) of the shell.[11] In the frequency domain studied in this paper, only the resonance modes of two types of circumferential waves are observed: the A_0^- (also labeled A wave) and the S_0 wave.[12] These waves are, during their propagation, coupled with the fluid surrounding the cylindrical shell and progressively reradiate their energy into the fluid. In the case of the S_0 wave, the coupling is weak and, therefore, it can keep on propagating for several circumference turns before vanishing, whereas the A wave is significantly attenuated after only a few circumference turns (4 or 5). In this work, the influence of the sand on the propagation of circumferential waves in and around the buried cylindrical shell is closely analyzed, and resonance spectra are plotted to determine whether it is possible to detect and to classify the buried object by an acoustic method.

II. EXPERIMENTAL SETUP

The experimental arrangement is described in Fig. 1. The studied object is a finite stainless steel cylindrical shell bounded by two hemispherical endcaps.[13] Its geometrical characteristics are total length $L=70$ mm, outer radius $a=15$ mm, and the radius ratio $b/a=0.97$ (b is the inner radius). The shell wall thickness is identical on cylindrical part and on spherical part. The physical characteristics considered in the experiment are the velocity of longitudinal and shear waves, respectively, $C_L=5790$ m/s and $C_T=3100$ m/s. The stainless steel density is $\rho_{\text{target}}=7900$ kg/m^3. The object is immersed in water of density $\rho_W=1000$ kg/m^3 in which the acoustic velocity is $C_W=1470$ m/s or buried in sand-water mixture of measured density $\rho_{\text{SW}}=1250$ kg/m^3 in which the acoustic measured velocity is $C_{\text{SW}}=1650$ m/s. The degassed sand-water mixture is prepared with a clean homogeneous sand. The average dimension of sand grains is about 100 μm. The Panametrics broadband transducers (V 389) used have a central frequency equal to 500 kHz. In order to

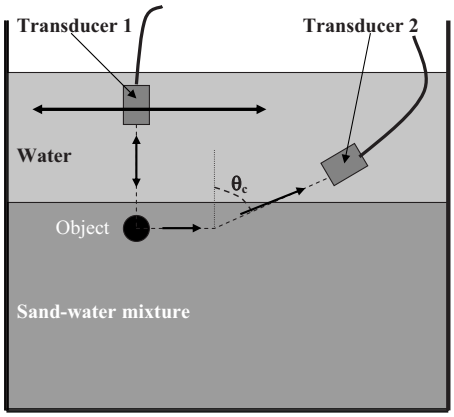

FIG. 1. Schematic of experimental setup. In monostatic method, transducer 1 is used as emitter and receiver. In bistatic method, transducer 1 is used as emitter and transducer 2 is used as receiver.

compare the acoustic attenuations in water and in the sand-water mixture, two transducers (emitter and receiver), facing each other and 30 cm apart, are successively placed in water and then in the sand-water mixture. The measured acoustic attenuation in the sand-water mixture is found to be 5 dB higher than that in water alone. In the used frequency range (100 kHz$<F<$800 kHz), the velocity and the attenuation in sand-water mixture are constant. The cylindrical object is, throughout the experiments, excited perpendicularly to its main axis.

The following experimental arrangements are realized (Fig. 1).

(i) In the monostatic method, transducer 1 working as emitter/receiver insonifies the surface of the sand-water mixture perpendicularly in the object direction.

(ii) In the bistatic method, transducer 1 is used as an emitter and transducer 2 as a receiver. A part of the energy from circumferential waves is reradiated in the sand-water mixture parallel to the sand surface, as a surface wave. The receiver detects the signal reradiated by the surface wave in water at the critical angle θ_c defined by Eq. (1):

$$\theta_c = \arcsin\left(\frac{C_w}{C_{sw}}\right) = \arcsin\left(\frac{1470}{1650}\right) = 63^\circ . \quad (1)$$

The diameter of the active surface of the transducers is 33 mm. The distance between transducers 1 or 2 and the tube is about 50 cm. This distance is larger than the beginning of the far field zone which is, for our transducers, around 37 cm. The acoustic beam diameter on the target is lightly bigger than the dimensions of the tube about 10 cm. The tube is excited by a short impulse having a large frequency band. The scattered signal is monitored and recorded by a digital oscilloscope and then transferred to a microcomputer for processing using a Fourier transform.

III. THEORETICAL RESULTS

Since the experimental cylindrical object is excited perpendicular to its axis, the associated calculated acoustic spectra are those obtained by considering an infinite length air-filled cylindrical shell immersed in a fluid. The general form of the scattered pressure field from such cylindrical shell in a plane perpendicular to the z-axis can be expressed as[5]

$$P_s(\omega) = P_0 \frac{1-i}{\sqrt{\pi k_w r}} \exp\, i(2k_w a) \exp\, i(2k_w u - \omega t) \times \sum_{n=0}^{\infty} \varepsilon_n \frac{D_n^1(\omega)}{D_n(\omega)} \cos(n\theta), \quad (2)$$

where ω is the angular frequency, $k_w = \omega / C_w$ is the wave number with respect to the wave velocity in the external fluid (C_w), P_0 is the amplitude of the incident plane wave, $D_n^1(\omega)$ and $D_n(\omega)$ are determinants obtained from the boundary conditions of the problem on the two interfaces, ε_n is the Neumann coefficient ($\varepsilon_n = 1$ if $n=0$ and $\varepsilon_n = 2$ if $n \neq 0$), u is the distance between the transducer and the surface of the cylindrical shell and r is the distance between the z-axis of the tube and the point where the acoustic pressure is calculated (the position of the emitter-receiver transducer in the case of experimental measurements). The acoustic backscattering spectrum of the studied tube obtained using Eq. (2) is presented in Fig. 2(A); a frequency window equivalent to the frequency bandwidth of the transducer is applied in the computation to simulate the sonar system response. The resonances are characterized by sharp transitions on the back-

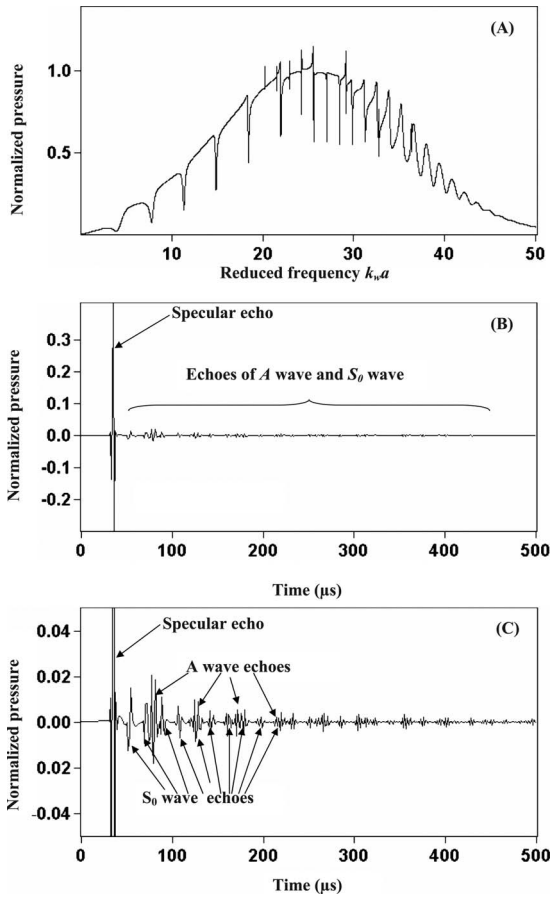

FIG. 2. Theoretical results obtained from an infinite length stainless steel cylindrical shell immersed in water and excited perpendicularly to its axis: (A) form function, (B) backscattered time signal, and (C) zoom of the backscattering time signal.

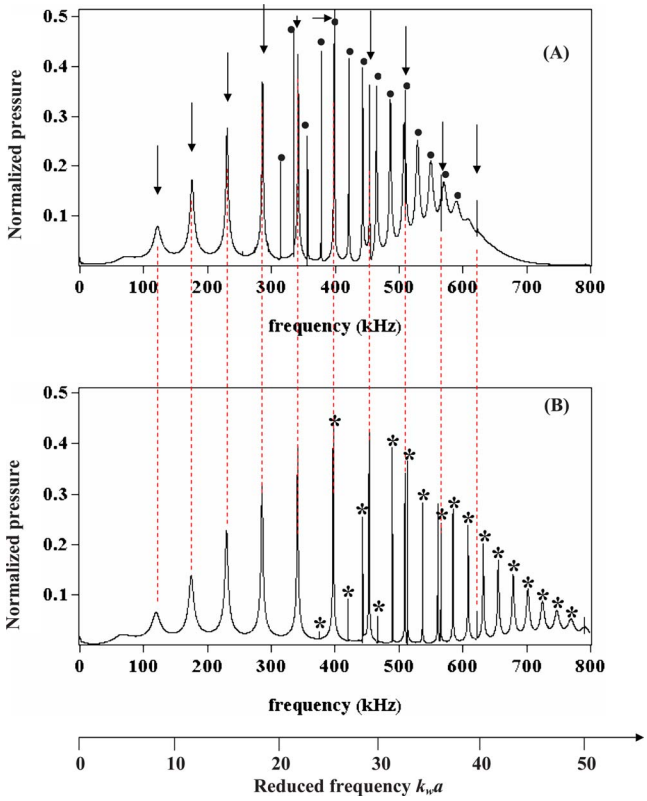

FIG. 3. (Color online) Theoretical resonance spectra. (A) Cylindrical shell in water (arrows: S_0 wave resonances, black point: A wave resonances). (B) Cylindrical shell in fluid with sand-water mixture parameters (black asterisk: A wave resonances). Dashed lines show that the resonances of the S_0 wave are at the same frequencies on the two spectra.

scattering spectrum. Resonances of the A wave are observed in the reduced frequency window $20 < k_w a < 35$. The first observed resonances of this wave are narrow (high resonance Q factor) and their width increases as the frequency rises. Resonances of the S_0 wave are wide in low frequencies and their width decreases with the increasing frequency across the studied frequency band. Figure 2(B) represents the impulse time signal backscattered from the tube, calculated applying the inverse Fourier transform on the spectrum of Fig. 2(A). On the left side of this figure, the large echo is due to the reflection of the incident wave on the cylindrical shell, it is called the specular echo. The other small echoes are associated with the A wave and the S_0 wave [Fig. 2(B)]. Figure 2(B) is plotted with a real amplitude, and it is possible to compare the amplitude of the specular echo and elastic echoes due to the energy emitted by the A wave and the S_0 wave in water. Figure 2(C) is a zoom of Fig. 2(B). The echoes of the A and S_0 waves are clearly seen. The amplitude of the S_0 echoes decreases slowly, and the coupling between this wave and the water is weak.

When the specular echo is removed and replaced with zeroes, and then the Fourier transform is applied to the time gated signal constituted of remaining elastic echoes from circumferential waves only, a resonance spectrum is obtained [Fig. 3(A)]. It is composed of peaks related to the resonance modes of the two circumferential waves. The S_0 wave resonances are indicated by arrows, whereas the A wave resonances are indicated by black points.

In the present study, this object is buried in the sand-water mixture with parameters different from those of water. Figure 3 compares the theoretical resonance spectrum of the cylindrical shell immersed in water [Fig. 3(A)] and the theoretical resonance spectrum of the same cylindrical shell immersed in a fluid with parameters of the sand-water mixture provided earlier in Fig. 3(B). The frequency scale is the absolute frequency, and the reduced frequency ($k_w a$) is calculated with the velocity of acoustic sound in water. The dashed lines show that the S_0 wave resonances are obtained at the same frequencies in the two cases. These resonances are lightly sensitive to the outside medium. This result confirms those from previous studies, indicating that the S_0 wave is mainly propagated in the shell.[14] The other resonances are due to the A wave (A_0^- wave). When the cylindrical shell is immersed in a fluid with the characteristics of the sand-water mixture ($C_{SW}=1650$ m/s, $\rho_{SW}=1250$ kg/m^3), A wave resonances are observed over a shifted frequency band ($25 < k_w a < 50$). This A wave is an interface wave, and it is sensitive to the external fluid in which the acoustic velocity is larger. In this computation, attenuation and sand particles are not taken into account.

IV. TARGET IMMERSED IN FREE WATER: EXPERIMENTAL RESULTS

Before presenting the results obtained when the cylindrical object is buried in the sand-water mixture, the experimental spectra of this target immersed in water are plotted to verify that the theoretical spectra obtained with a cylindrical shell are valid. The object is placed horizontally in a water-filled tank (diameter 3 m, height 1.5 m) and excited perpendicularly to its axis by a short impulse emitted by a broadband transducer (500 kHz). The backscattered impulse time signal from the object is detected by the same transducer operating as a receiver. A Fourier transform is applied on this time signal to obtain a backscattering spectrum [Fig. 4(A)]. In order to obtain a resonance spectrum [Fig. 4(B)], the specular echo on time signal is removed and replaced by zeroes, and a Fourier transform is applied to the filtered signal. The examination of these spectra shows a good agreement between theoretical [Figs. 2(A) and 3(A)] and experimental [Figs. 4(A) and 4(B)] results. The resonance frequencies for the two types of waves are identical. The acoustic response of the experimental object excited perpendicularly to its axis is comparable to that obtained from an infinite length cylindrical shell excited in the same conditions.[13]

V. TARGET BURIED IN THE SAND-WATER MIXTURE: EXPERIMENTAL RESULTS

In the experimental setup, the transducer beam axis is perpendicular to the surface of the sand-water mixture and to the main axis of the object (transducer 1, Fig. 1). The cylindrical shell axis is in the horizontal position and parallel to the surface of sand-water mixture. The transducer is placed at 0.5 m from this surface. The front face of the target is buried at 2 cm into the sand-water mixture. The diameter of the acoustic beam is lightly bigger than the target dimen-

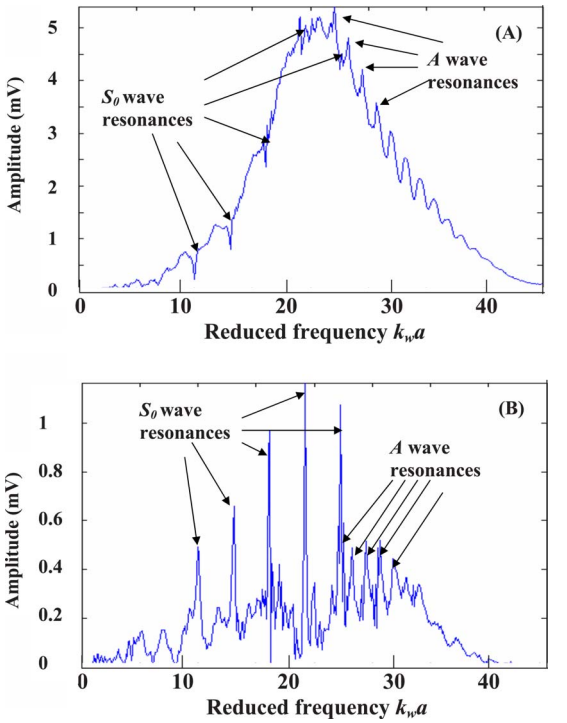

FIG. 4. (Color online) Experimental spectra obtained when the cylindrical object is in free water: (A) backscattering spectrum and (B) resonance spectrum.

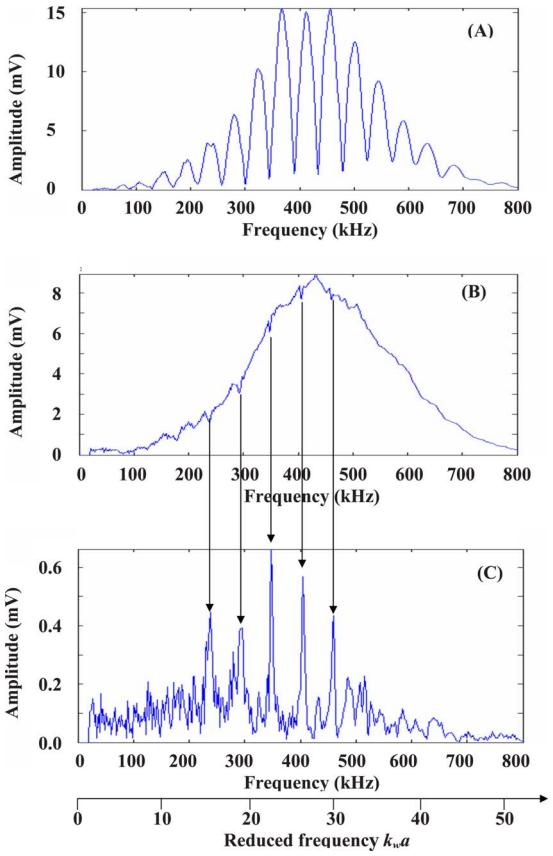

FIG. 6. (Color online) Experimental spectra obtained from the impulse time signal of Fig. 5 when the object is buried 2 cm into the sand-water mixture. (A) Backscattering spectrum obtained from the total impulse time signal. (B) Backscattering spectrum obtained after removing the reverberation echoes. Arrows indicate the S_0 wave resonance positions. (C) Experimental resonance spectra obtained after removing the specular and reverberation echoes.

sions. Figure 5 gives the backscattering time signal obtained in this condition. On left of Fig. 5(A), the first echo represents the reverberation signal, and the second major echo is the specular one. These two echoes have approximately the same amplitude and are well separated due to the burial depth. Other successive echoes are due to the propagation of the circumferential waves in and around the target [Fig. 5(B)]. Certain echoes can be due to multiple reflections between the surface of the sand-water mixture and the target surface. Figure 6(A) presents the Fourier transform of the impulse time signal from Fig. 5(A). The spectrum of Fig. 6(A) presents two differences in comparison with the spectrum obtained when the target is in free water [Fig. 4(A)].

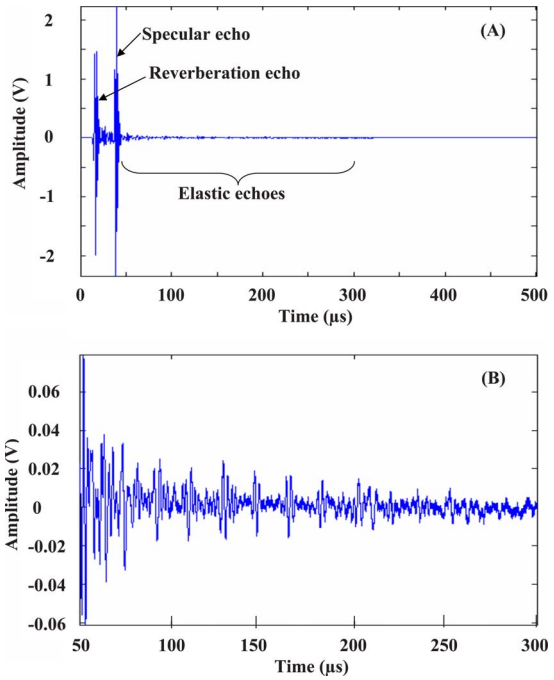

FIG. 5. (Color online) (A) Experimental impulse time signal when the object is buried 2 cm into the sand-water mixture and (B) zoom on elastic echoes.

(i) An undulation of large amplitude is observed. This undulation is due to the interference between the reverberation echo and the specular echo which have comparable amplitudes.
(ii) Resonances due to the A wave and resonances due to the S_0 wave are not visible.

The spectrum of Fig. 6(B) is obtained after having replaced the reverberation echo by zeroes in the impulse time signal in Fig. 5(A) and applying a Fourier transform on the new filtered impulse time signal. The undulation due to the interference between the reverberation echo and the specular echo is cancelled. The S_0 wave resonances are observed (arrows), whereas the influence of A wave resonances in the frequency band 25–40 has vanished.

A further time signal filtering is possible. In addition to cancel the reverberation echo from the backscattering im-

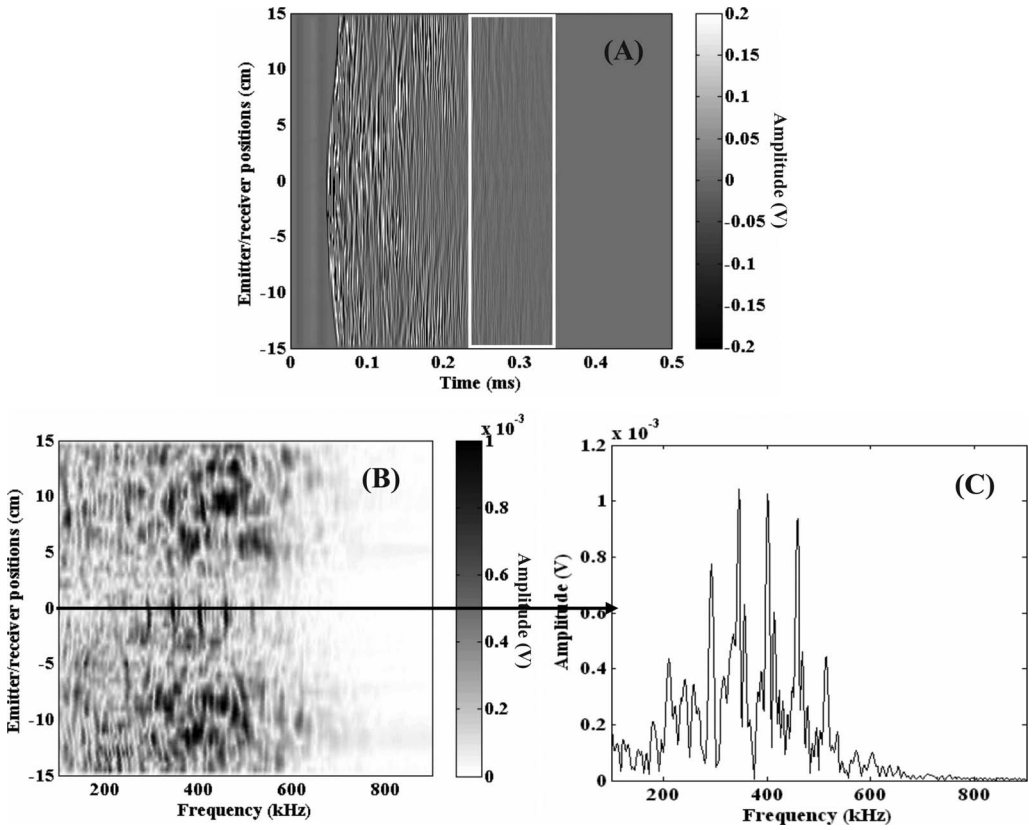

FIG. 7. Monostatic scanning of the sand-water mixture in which the object is buried (2 cm deep). (A) All the time signals, the white rectangular zone indicates the signal part used to calculate the resonance spectra. (B) All the resonance spectra. (C) A sample of resonance spectrum.

pulse time signal [Fig. 5(A)], the specular echo is also replaced by zeroes. The MIIR (Refs. 5–8) is then applied. After processing the new filtered signal using a Fourier transform, the resonance spectrum is plotted in Fig. 6(C). The background signal of the spectrum is removed, and resonances appear as isolated peaks. This spectrum shows resonances of the S_0 wave but, as seen previously, does not show resonances of the A wave. The S_0 wave is less sensitive to the outer fluid because it is a shell wave. On the contrary, the A wave which is an interface wave is strongly sensitive to the fluid surrounding the target.[12] This result is in opposition to the conclusions in Ref. 3. In this paper the echoes and the resonances of A wave (A_0^- wave) are observed for spherical and cylindrical targets buried in high-density-clutter areas of saturated sediments. To explain this difference the experimental conditions can be put forward. During its propagation around the cylindrical target, the attenuation in the sand-water mixture and the presence of the sand grains can explain the disappearance of the A wave. From the resonance spectrum, it is possible to classify the air-filled cylindrical target.

VI. SEARCHING A BURIED CYLINDRICAL OBJECT BY AN ACOUSTIC SCANNING

The experimental setup is the one presented in Fig. 1. The target is buried 2 cm into the sand-water mixture. The two following configurations are successively used.

A. Monostatic method

In the first experiment transducer 1 is used as emitter-receiver; the acoustic beam axis is perpendicular to the surface of the sand-water mixture. The transducer displacement is 30 cm around the object position (15 cm on either side from the object axis), giving the perpendicular direction to the main axis of the object. Time signals are recorded at 1 cm intervals. Figure 7(A) presents, in gray level, the assembled time signals for the explored zone (−15 cm⇔+15 cm) defined above. Echoes due to parasite reflections have been removed at the extremity of the time window. At the center of Fig. 7(A), around position 0 cm, where the cylindrical object is buried, regular echoes due to the target can be observed and, around this position a shadow effect can be seen. Figure 7(B) shows the acoustic resonance spectra calculated from the time signals surrounded by the white rectangular zone in a gray level 2D presentation. The signal outside this rectangle is replaced by zeroes. In the middle of this figure, five short black lines coming up in periodic position are observed; they are the S_0 wave resonances.

Figure 7(C), which presents the resonance spectrum at transducer position 0 cm, confirms the presence of S_0 wave resonances. As it has been mentioned before, the A wave resonances are not observed in these experimental conditions.

In Fig. 7(B) at positions ±10 cm, zones indicating black amplitudes of the same intensity as those of the resonances, due to the reverberation in the sand-water mixture,

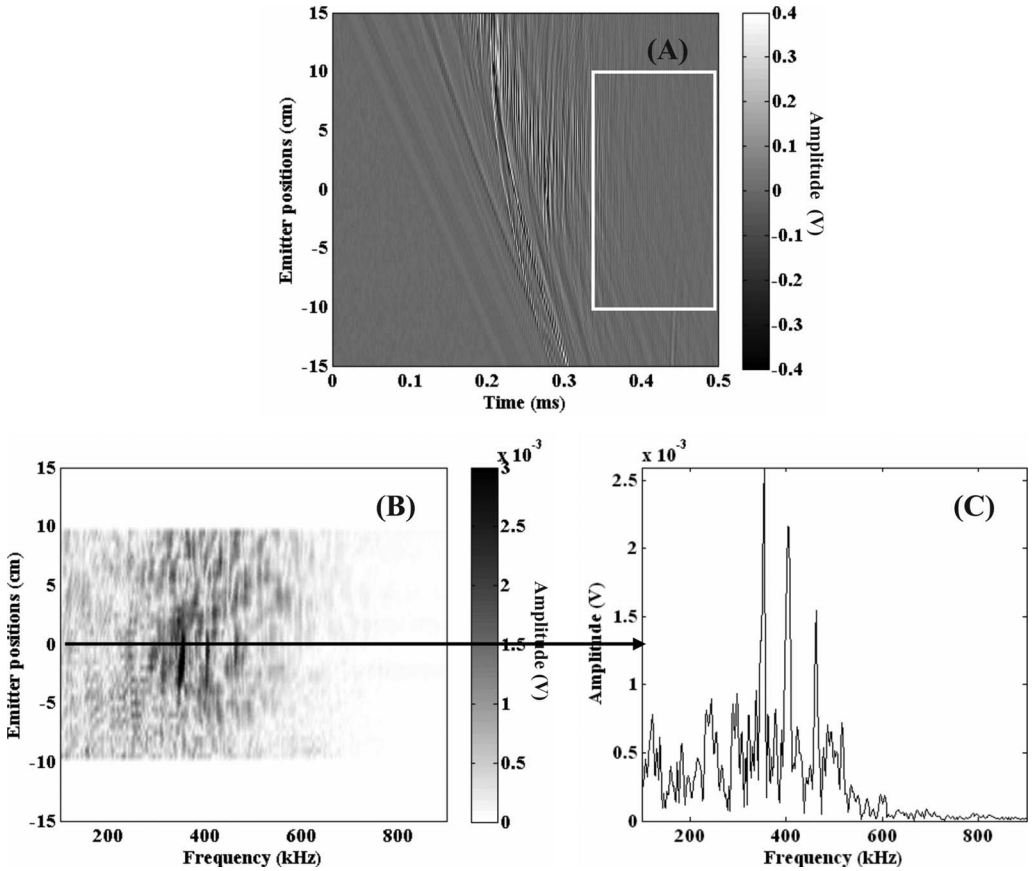

FIG. 8. Bistatic scanning of the sand-water mixture in which the object is buried (2 cm deep). (A) All the time signals, the white rectangular zone indicates the signal part used to calculate the resonance spectra. (B) All the resonance spectra. (C) A sample of resonance spectrum.

are visible. The amplitude of the reverberation signal, at these positions, is comparable to that of resonances but this signal is not periodic. At the target position, a shadow zone with a weak reverberation is observable around the periodic resonance spectra.

B. Bistatic method using surface wave propagation in the sand-water mixture

In order to complement this study, a second scanning experiment was conducted in which the incident signal is emitted by the transducer 1 (Fig. 1) perpendicularly to the sand-water mixture surface. When this incident wave excites the buried cylindrical shell, circumferential waves are generated in the shell, and part of their energy is reradiated along the sand-water mixture surface as a surface wave. Transducer 2, used as receiver, detects signals emitted by the surface wave in water at the critical angle defined earlier ($\theta_c = 63°$, Sec. II). Figure 8(A) shows the time impulse signals measured by transducer 2 for the different positions of the emitter transducer between −15 and +15 cm. Figure 8(B) is obtained after applying a Fourier transform to the signals from within the rectangular box in Fig. 8(A). This figure shows the presence of three resonance peaks associated with the S_0 wave. Figure 8(C), which is an extract from Fig. 8(B), confirms this result at emitter position 0 cm. Although the number of resonances is inferior in this bistatic method, the contrast between resonances and the reverberation signals is better and allows us to easily identify these resonances. However, this bistatic method is more difficult to realize.

VII. CONCLUSION

Experimental work presented in this paper was carried out in a laboratory tank. It shows us that resonance spectra, obtained after appropriate time signal filtering using the Method of Isolation and Identification of Resonances, can be used to classify an object buried in a sand-water mixture. To this end, two experiments were designed, one monostatic method using a single transducer working as emitter-receiver and one bistatic method using an emitter transducer and a receiver transducer detecting the reradiation of the surface wave propagating through the sand-water mixture. The resonance spectra only show resonances of the S_0 wave. This wave is very weakly sensitive to the outer medium, as it is a shell wave. Therefore, it propagates around several turns of the circumference of the tube before it vanishes. During these circumnavigations it progressively reradiates its energy. As a result, echoes due to this wave continue to be well detected after the detection of the reverberation echo and the specular one. Resonances of the A wave (A_0^- wave) are not detectable when the target is buried since the sand-water mixture strongly modifies the propagation of this interface wave.

This study has been realized to show that it is possible to identify a man-made elastic target with the resonance spec-

trum. In this paper, only the results obtained with a perpendicular excitation to the target axis are described. In a second stage, the oblique excitation to the target axis and to the sand-water mixture surface must be explored.

(Received 28 July 2009; revised 3 December 2009; accepted 4 December 2009)

Experimental measurements were conducted using acoustic pulse sources in a full-scale artificial village to investigate the reverberation, scattering, and diffraction produced as acoustic waves interact with buildings. These measurements show that a simple acoustic source pulse is transformed into a complex signature when propagating through this environment, and that diffraction acts as a low-pass filter on the acoustic pulse. Sensors located in non-line-of-sight (NLOS) positions usually recorded lower positive pressure maxima than sensors in line-of-sight positions. Often, the first arrival on a NLOS sensor located around a corner was not the largest arrival, as later reflection arrivals that traveled longer distances without diffraction had higher amplitudes. The waveforms are of such complexity that human listeners have difficulty identifying replays of the signatures generated by a single pulse, and the usual methods of source location based on the direction of arrivals may fail in many cases. Theoretical calculations were performed using a two-dimensional finite difference time domain (FDTD) method and compared to the measurements. The predicted peak positive pressure agreed well with the measured amplitudes for all but two sensor locations directly behind buildings, where the omission of rooftop ray paths caused the discrepancy. The FDTD method also produced good agreement with many of the measured waveform characteristics.

I. INTRODUCTION

An urban environment introduces many complicating effects on acoustic propagation that are not present in a flat open area with finite impedance ground. The presence of large, closely spaced obstacles (the buildings) induces multiple reflections, diffractions, and scattering of the acoustic waves and is the focus of this paper. Other urban effects include inhomogeneous ground conditions, for example, mixtures of grass and soil surfaces with concrete or asphalt road or parking surfaces; scattering from parked cars, other objects, and complicated facades; ground roughness and elevation changes; and different atmospheric conditions such as local wind and temperature variations caused by flow around buildings, industrial heat sources, emissions from automobiles, and differential solar loadings on different road, ground, and building surfaces. In addition, ambient noise levels and characteristics may be vastly different in urban areas compared to rural locations because of the wide variety of transportation, industrial, and cultural noise sources, and these may all vary on seasonal, diurnal, and shorter time intervals.

While many acoustic measurements have been previously conducted in real urban areas, most were measurements of traffic and other continuous noise sources, e.g., by Wyle Laboratories (1971) and Garcia and Faus (1991). Although these measurements reveal the typical urban noise environment, they provide little insight into the specifics of how acoustic waves interact with and are affected by obstacles such as buildings. Propagation measurements in cities have also been conducted for a long time, but usually these measurements used continuous sources to determine levels and reverberation times, e.g., those by Wiener *et al.* (1965), Bullen and Fricke (1976), and Iu and Li (2002), but could not reveal details about the wave interactions with buildings.

Acoustic pulses have been used recently to investigate a right-angle wall, including non-line-of-sight (NLOS) propagation (Liu and Albert, 2006). In that study, a two-dimensional finite difference time domain (FDTD) calculation was also developed and gave good agreement with the measured waveforms. Acoustic pulse measurements around a single isolated building have also been reported (Alberts *et al.*, 2008). Picaut *et al.* (2005) reported measurements using blank pistol shots in a real city street for line-of-sight (LOS) configurations. These measurements revealed the complex arrivals and extended reverberation time produced by propagation within a street canyon.

In this paper, the effect of multiple buildings on outdoor sound propagation is studied using full-scale experimental measurements that were conducted outdoors with impulsive sources so that the nature and properties of the various acoustic arrivals could be determined. The measurement methods are discussed in Sec. II, followed by examination of the results for sensors in both LOS and NLOS situations. The measurements are compared to two-dimensional finite differ-

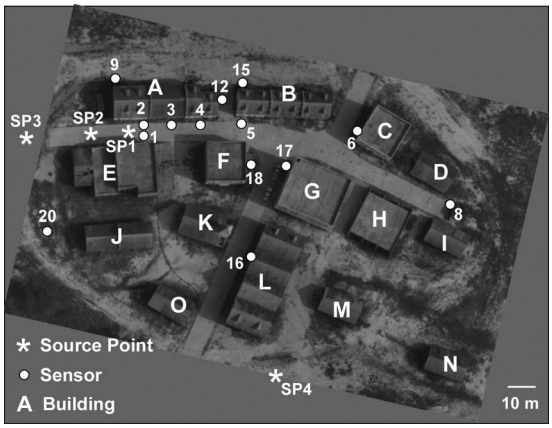

FIG. 1. Aerial photograph of the artificial training village where the measurements were conducted, showing the locations of the concrete-block buildings, shot points, and sensors. Buildings labeled D, H, I, J, M, N, and O have a single story; the other buildings were two or more stories tall. The roads are concrete, with "Main Street" running nearly horizontally in the photograph, and "Church Street" running in an approximately vertical direction. Dark ground areas are grass, and light areas are hard packed soil. The four source points are indicated by stars. Sensor numbers 7, 10, 11, 13, 14, and 19 were roof-top or interior locations and are omitted from the figure and from discussion in this paper.

ence calculations in Sec. III. The simulation results show reasonable but not exact agreement between observed and simulated time series records at 14 different sensor locations for two very different source locations. These comparisons demonstrate that the FDTD technique can be a useful tool for understanding sound propagation physics in a complex scattering environment.

II. ACOUSTIC PROPAGATION MEASUREMENTS IN AN URBAN ENVIRONMENT

A. Experimental methods

Measurements were conducted outdoors at a full-scale artificial training village composed of 15 buildings arranged over a 150×150 m^2 area. An aerial photograph (Fig. 1) shows the arrangement of the buildings along two streets; the horizontal street in the figure is referred to as Main Street, while the nearly vertical street is called Church Street. This artificial village provided a complex, realistic arrangement of full size buildings suitable for investigating one of the primary urban propagation effects: the presence of many buildings as obstacles to acoustic propagation.

The buildings were constructed of concrete blocks and most were two or three stories tall. Some of the buildings had wooden doors and strong plexiglass windows, but many had open doors and window spaces. The buildings did not have basements, but a sparse system of rain drains was located beneath the village, consisting of concrete pipes having an internal diameter of about 1 m, buried about 2 m below the ground surface.

In designing the measurements, source and sensor positions were selected to investigate both LOS and NLOS acoustic propagations, with most of the LOS measurements conducted along Main Street. These positions are also indicated in Fig. 1, and Fig. 2 shows photographic views along Main Street in the artificial village.

FIG. 2. Photographs of the artificial training village where the acoustic propagation measurements were conducted, looking in two directions along Main Street, the horizontal street in Fig. 1 (refer to Fig. 1 for the building locations). (Left) A photograph taken from the roof of building E, looking toward buildings A and B on the left side of the street. Building F is on the right side, and building C is visible in the distance at the end of the street. (Right) A photograph taken from the roof of building C looking toward building A. Building G is on the left, and building F at center left. Buildings B and C are visible on the right. Most of the line of sight measurements were conducted on this street.

Although both pressure sensors and geophones were installed at various locations within the village to record the acoustic pressure and vibration signatures produced by the explosions, only the pressure measurements at the 14 locations shown in Fig. 1 will be discussed in this paper (the other locations not discussed here included building roofs and interiors). Because of the high pressure amplitudes produced by the explosives, solid state blast pressure sensors manufactured by PCB Piezotronics (Depew, NY) were used in all locations, except at locations 8 and 20, where B&K Model 4938 microphones were used. These sensors were attached to exterior building walls at all locations, except 1, 8, and 20, and were either at 0 or 1.5 m above the ground level. Table I lists the details of the measurement installation, including the sensor models, coordinates of the source and sensor locations, and the straight-line distances between them. The actual acoustic propagation distance may be greater than that shown in Table I if the source-to-sensor path is non-line-of-sight.

The sensors were connected to two synchronized digital seismographs using multichannel geophysical cables. A Geometrics Stratavison NZ digital seismograph was used to record 48 data channels at a sampling rate of 8 kHz, while a Bison Model 9048 digital seismograph was used to record 24 additional data channels at a sampling rate of 5 kHz.

The measurements were conducted using small explosive charges consisting of 0.57 kg of C4 to produce acoustic pulses at four different source locations in the village, designated as SP1–SP4 in Fig. 1. The explosive charges were suspended from a wire at a height of 1.5 m above the ground surface and detonated using an electric blasting cap. The electrical detonation signal was also used to start the two digital seismographs. The three source positions along Main Street, spaced 15 m apart, were selected to investigate the effect of a source located in an open area or on a street with buildings on one or two sides. A fourth source location at the southern side of the village provided many complex NLOS propagation paths to the sensors on Main Street.

Table II lists the estimated minimum number of diffractions for each source-receiver pair, with LOS paths indicated by zero diffractions in the table. The source and sensor po-

sitions provide a number of different NLOS configurations with one to six diffractions along the propagation path, providing a rich selection of complex situations to study acoustic wave interactions with the buildings.

At least five separate detonations were recorded for each source position, and the measured waveforms at all sensor locations were found to be essentially identical in appearance for the repeated shots. The peak pressure output of each explosion did vary somewhat, with standard deviation for pressures measured close to the source position of approximately 10% of the peak pressure level.

The measurements were conducted during two sunny, breezy days in November, 2001, with temperatures ranging from 8 to 19 °C, wind speeds between 2 and 5 m/s, and a

TABLE II. Estimated number of diffractions for most direct acoustic path from shot points to sensor locations.

				No. of diffractions along direct path				
Loc	*X* (m)	*Y* (m)	*Z* (m)	SP1	SP2	SP3	SP4	Description of location

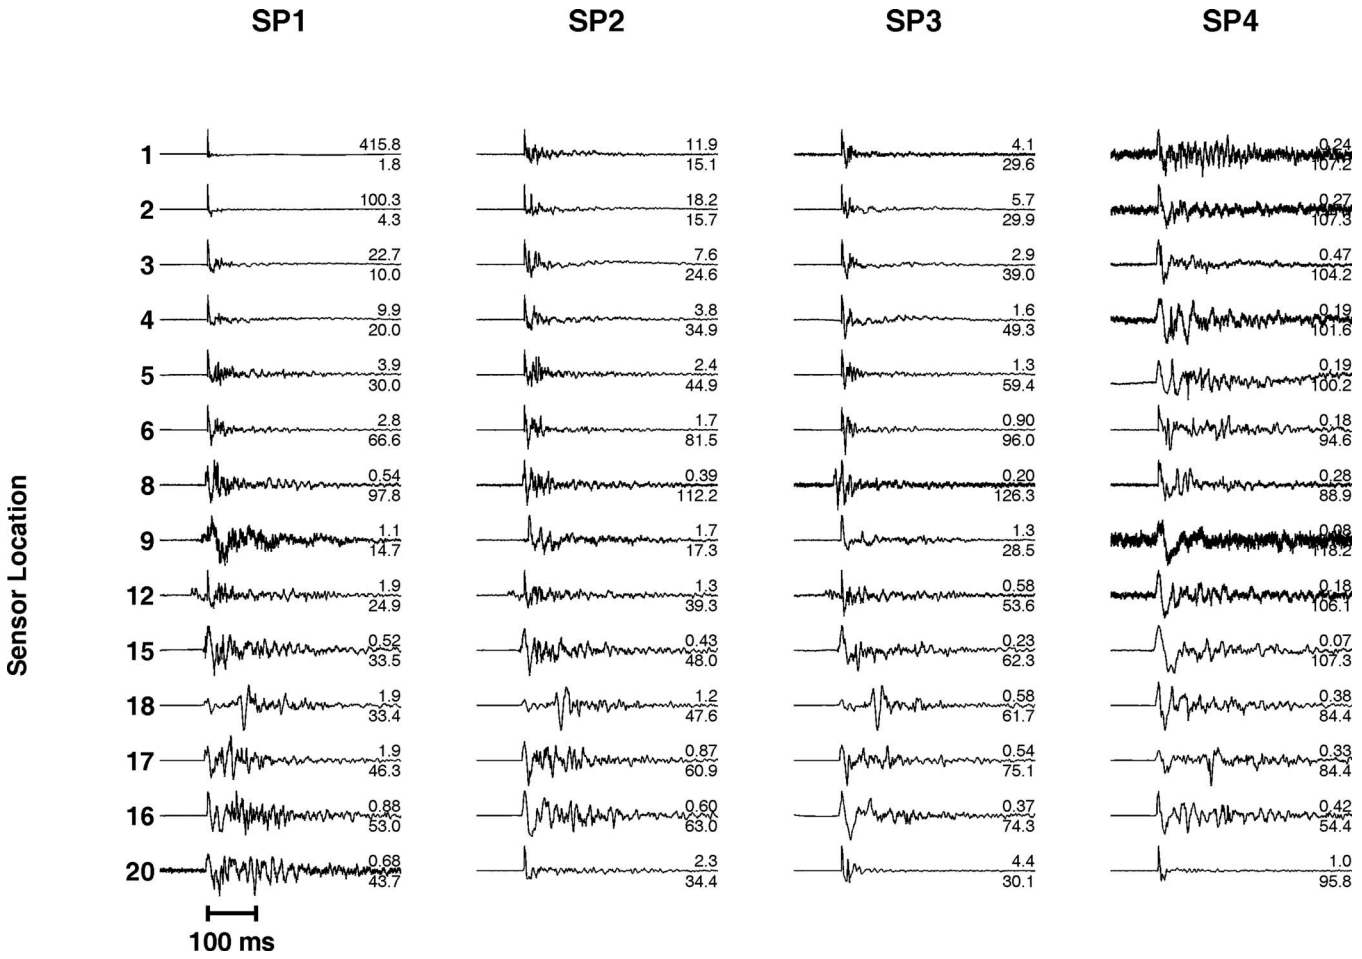

FIG. 3. Pressure waveforms recorded for all source-receiver pairs in the artificial village. The sensor number listed on the left side and the source point number at the top of each column refer to the locations in Fig. 1. The waveforms for sensors 1–6 are LOS for source points 1–3 (SP1–SP3), and the waveforms for sensor 20 are LOS for SP3 and SP4. All of the other waveforms are NLOS. The numbers at the right of each waveform are the peak pressure in kPa (top) and the straight-line source-receiver distance in m (bottom).

relative humidity of 30%–50% (Hahn and Leese, 2002). Under these weather conditions the sound wave speed varied from 336 to 348 m/s.

B. Line-of-sight propagation in a street canyon

Figure 3 shows the complete waveform data set measured for the four source positions and the 14 receiver locations. In this figure, sensors 1–6 are line-of-sight for source positions 1–3, along with sensor number 20 for source positions 3 and 4 (see Table II). The remaining source-receiver pairs are non-line-of-sight. Because of multiple reflections along Main Street, even the line-of-sight sensors show many reverberation arrivals instead of the simple pulse that is recorded for a source and receiver in an open field (a direct comparison will be presented below). The non-line-of-sight waveforms show more complexity and have longer time duration than the line-of-sight waveforms. These complex features arise from the interaction of the acoustic waves with the buildings.

All of the LOS waveforms have very short initial pulses, indicating that these arrivals are only slightly attenuated during propagation to the sensor. An examination of the LOS waveforms for SP1 shows that the visible reverberation arrivals increase as the propagation distance increases. This appearance is partially caused by the very high amplitude arrivals near the source (sensors 1 and 2) that masks the lower amplitude reverberations later in time at the plotting scale.

The measured peak positive pressure for LOS propagation, as a function of distance, is shown in Fig. 4. These measurements show that the pressure levels are slightly higher than those predicted by the ANSI Standard (ANSI, 1983) due to the hard concrete surfaces present for the measurements compared to the normal soil surface condition assumed in the predictions.

The least-squares method was applied to the measurements to determine the coefficients in the equation

$$P(r) = P_0 r^{-\alpha}, \tag{1}$$

where $P(r)$ is the peak pressure (Pa) at propagation distance r (m), and α is the attenuation coefficient. An attenuation value of 1.52 was determined, which is a high attenuation rate compared to a value of 1.12 for ANSI S2-20 predictions (ANSI, 1983) for open areas far from the source. This higher rate is likely caused by the strong amplitude decay that occurs in the high-amplitude, nonlinear propagation region close to the source.

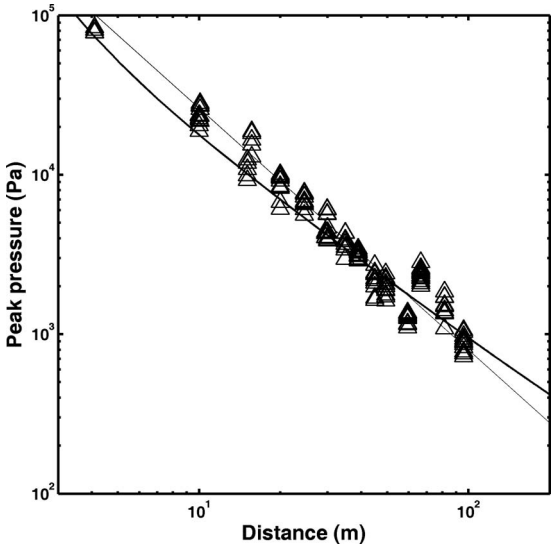

FIG. 4. Peak pressure as a function distance in an urban environment for LOS sensors. The heavy line is the ANSI Standard S2-20 prediction, while the light line is a least-squares fit to the measured data. This line gives a decay rate of $R^{-1.52}$. The sensors at 66 m (sensor location 6 in Fig. 1) were mounted on a wall nearly perpendicular to the incoming wave and show the effects of "pressure doubling" from the incident and reflected waves at the wall.

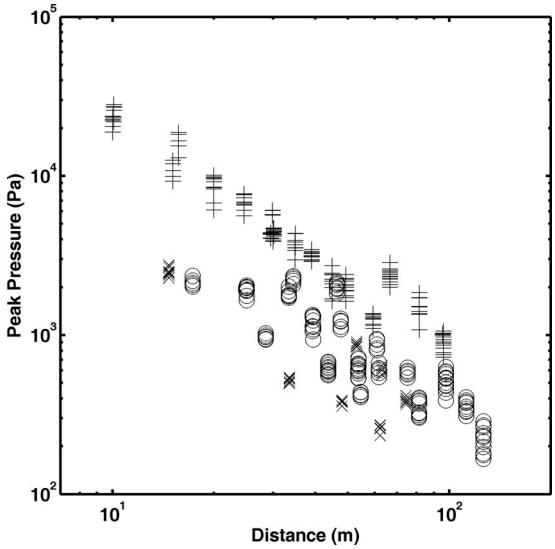

FIG. 6. Measured peak pressure as a function of distance for LOS (plus-signs) and NLOS sensors that have diffracted around one building corner (open circles) or two corners (X-signs).

Because the explosions that were used as the source of the acoustic pulses produced very high amplitudes (over 400 kPa at 1 m), nonlinear effects caused the propagation speed to depend on the pulse amplitude and to decrease with distance from the source as the pulse amplitude decreased. Figure 5 shows the acoustic velocity measured for the LOS propagation down Main Street. The wave speed rapidly decreased from around 420 to 390 m s^{-1} at a pressure level of about 10–20 kPa (at about 10 m distance from the explosion), and continued to decrease, reaching 365 m s^{-1} at 4 kPa (30 m), 360 m s^{-1} at 2.5 kPa (40 m), and 350 m s^{-1} at 1 kPa (90 m). The wave speed is also expected to decrease as a strong pulse diffracts into a shadow zone, because of the amplitude reduction caused by the diffraction itself, leading to propagation kinematics that are more complicated than a simple constant acoustic velocity situation. This variation in wave velocity can cause errors on the order of 10–30 ms (a few meters) if a constant acoustic wave speed is used for calculations or comparisons of the data with linear acoustic theory. This factor will be discussed further in the theoretical waveform comparisons presented below.

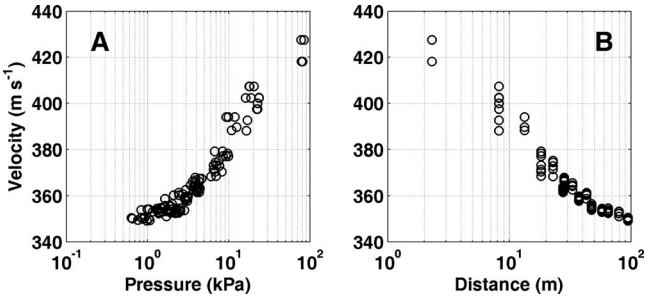

FIG. 5. (a) Measured acoustic wave velocity as a function of peak pressure for LOS paths in the village. The dependence of the velocity on amplitude is a well known nonlinear acoustic effect. (b) Measured acoustic velocity as a function of propagation distance along Main Street.

C. Non-line-of-sight propagation in an urban environment

The NLOS waveforms shown in Fig. 3 are generally more complex, with many more visible wave arrivals, and with longer time durations than the LOS waveforms recorded at similar propagation distances. In addition, the initial arrival pulse widths tend to be longer, and the peak amplitudes (indicated to the right of each trace) are lower for the NLOS than for the LOS waveforms, as shown in Fig. 6. This figure shows the measured peak pressure amplitudes for LOS and NLOS propagation paths. Here, it is difficult to assign a distance to the NLOS data because many path lengths are involved (and as shown above, the shortest path is sometimes not the peak amplitude path), so the data have been plotted using the straight-line distance as if no buildings were present. If the correct path length were used, all of the NLOS data points would shift to the right (to longer propagation distances) on the plot. The graph shows that the NLOS measurements are always smaller than the LOS measurements for identical distances, a result of the reduction in amplitude when the waves diffract into a shadow zone and also of the larger geometrical spreading from the longer path lengths involved in multiple reflections. In addition, the plot shows that multiply diffracted waves generally have smaller amplitudes than those waves that were only diffracted once.

Two exceptions to the above observations should be noted. First, the amplitude for the single-diffraction NLOS SP1-Sensor 17 path (approximately 2 kPa at 46.4 m) is nearly the same as for LOS positions at similar distances (these measurements are the circles lying surrounded by plus-signs at about 50 m distance in Fig. 6). The relatively small "extra NLOS" attenuation is reasonable since this sen-

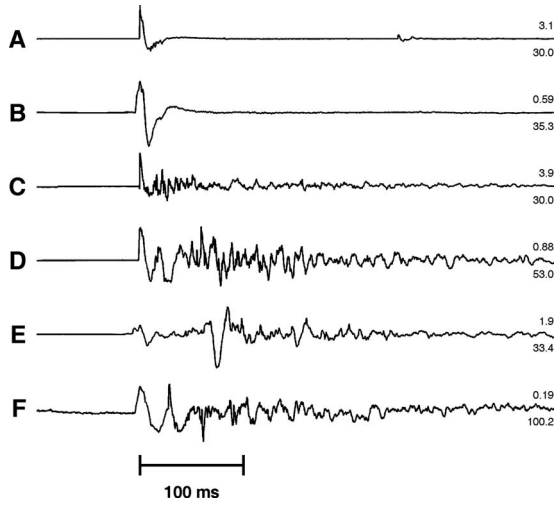

FIG. 7. Pressure waveforms produced by detonation of C4 explosive 1.5 m above the ground and recorded by pressure sensors also located 1.5 m above the ground for various geometries. The top number on the left of each trace is the peak pressure in kPa, and the lower number is the straight-line distance from the source in m. The waveforms have been time-shifted to align the first arrivals. (a) Line-of-sight propagation in open air above grass, 30 m distance. (b) Propagation around a single corner, 35 m distance (from Liu and Albert, 2006). (c) Line-of-sight propagation down a street with buildings present, 30 m. (d) Propagation around a corner with buildings present, 53 m straight-line distance (through buildings). (e) Propagation around a corner with buildings present, 33 m straight-line distance (through a building). (f) Propagation around two large buildings, 100 m straight-line distance (through two buildings). Trace B was produced using an explosive charge size of 0.28 kg, while all of the others were produced using 0.57 kg. Waveforms C, D, and E were recorded from the same detonation, but at different sensor positions (16, 18, and 5) in the urban village.

sor, located on building G, is barely within the diffraction shadow zone of building F (approximately 22°), so diffraction losses are small.

The second anomaly is that the SP1-Sensor 16 path (the X-signs above the circles in Fig. 6, with amplitude approximately 875 Pa at 53.0 m) involves two diffractions around buildings E and K (with diffraction angles of about 14° and 6°, respectively), but has a higher amplitude than the singly diffracted measurements at nearly the same distance (SP3-12, about 580 Pa at 53.6 m). In the latter case, the peak arrival is a later reflection from building B (and so travels a longer path) that has undergone a relatively large angle diffraction of about 25° around building A, thus producing a greater reduction in amplitude. The combination of these path factors is apparently enough to produce a lower amplitude for this NLOS arrival, compared to others at similar distances.

Figure 7 provides a detailed view of these properties by comparing a few typical waveforms recorded in the urban environment with those recorded in an open field or near a single, right-angle wall (Liu and Albert, 2006). The parameters of the waveforms shown in Fig. 7 are listed in Table III. Figure 7(a) shows a waveform recorded in open air over grassland, while Fig. 7(c) shows the waveform recorded for the same propagation distance, but for LOS propagation down Main Street in the village. In both cases, the propagation distance was 30 m. These measurements show that in the urban environment, the waveform contains higher frequencies (the initial part of the waveform is shorter in time), has a higher amplitude (peak positive pressure 3.9 kPa vs 3.0 kPa) probably because of the higher ground impedance of the concrete compared to the soil surface, and is more complex than the open field waveform. The many arrivals visible after the first main arrival in the urban waveform are from the multiple reflections from the buildings in the street canyon. These reflected arrivals are absent for the waveform recorded in the open field. These differences between open field and urban waveforms were observed at many different propagation ranges, from a few meters to 100 m, as long as the acoustic propagation remained line-of-sight (Fig. 3).

Waveform B in Fig. 7 was recorded over a similar distance (35.3 m) after diffraction around a single corner, displaying the low-pass filtering effect of the diffraction (Pierce, 1989; Liu and Albert, 2006). The diffraction-induced broadening of the waveform is very noticeable and can be used to identify likely diffraction arrivals in the more complex NLOS traces, such as those shown labeled D, E, and F in Fig. 7. These three NLOS urban waveforms also show a characteristic found in many NLOS situations, that the peak pressure is sometimes a later arrival rather than the first arrival as for LOS and other simpler geometries.

Referring to Fig. 1 for the locations, the waveform D shown in Fig. 7 was produced by propagation from source point 1 to sensor 16 on building L, a straight-line distance of 53 m. The most direct propagation path has diffractions around two buildings: E at about 14° and K at about 6°. The first arrival shows a waveform with similar duration as the simple diffraction waveform B, and the low frequency arriv-

TABLE III. Characteristics of the waveforms shown in Fig. 7.

		Positive peak		First arrival (if different from peak)			
	Distance (m)	Pressure (kPa)	Arrival time (ms)	Pressure (kPa)	Arrival time (ms)		
A	30.0	3.05	78.8			Open field	(Liu and Albert, 2006)
B	35.3	0.55	108.0			Around one corner	(Liu and Albert, 2006)
C	30.0	3.91	79.9			Urban LOS	SP1, sensor 5
D	53.0	0.858	209.2	0.877	150.0	Urban NLOS	SP1, sensor 16
E	33.4	1.55	197.2	0.516	112.6	Urban NLOS	SP1, sensor 18
F	100.2	0.138	321.9	0.126	293.4	Urban NLOS	SP4, sensor 5

Refer to Fig. 1 for the source point and sensor locations for the urban waveforms.

als are tentatively identified as probable diffractions. The second arrival at 19 ms later follows the same path after reflecting from building B; this identification is based on the time difference corresponding to a path length approximately 7 m longer and on theoretical calculations discussed below. Thus, waveform D is very complex, showing at least two diffracted arrivals and many multiple arrivals.

Waveform E in Fig. 7 was recorded for the same explosion as for waveform C, but with the sensor located around a corner, shielded by building F. The straight-line distance between the source and receiver, ignoring the presence of the building, was 33 m. This is a very complex waveform, with some lower frequency arrivals visible. The first arrival can be identified as a simple diffraction around the Main Street corner of building F (the upper right corner in Fig. 1); the second low frequency arrival (at approximately 180 ms) is the reflection from building G after slightly diffracting around the same corner of building F; and a third low frequency arrival is the ray path that has reflected from G to F to G and back to F (at 265 ms). The second arrival has the largest amplitude despite the longer propagation distance because the diffraction angle is only slightly into the shadow zone compared to the first arrival that diffracted around an angle of 90° deep into the shadow.

Waveform F is for a longer propagation distance of 100 m for the path from source point 4 to sensor 5. In this case, there are two very large buildings directly in the straight-line path between source and receiver, and many surrounding buildings present. Again, the peak amplitude occurs after the first arrival, and there are low frequency portions in the waveform that are likely produced by diffractions, along with higher frequency arrivals from multiple reflections.

To summarize the results of this section, Figs. 6 and 7 show the complexity involved in NLOS propagation. Wave arrival times, as a function of distance, are not straight lines as for propagation in an open field because of the many different propagation paths arriving at a sensor, including longer diffraction and multiple reflection paths. In addition, the waveforms displayed in Fig. 7 show some of the complexity that a sensor or human listener will encounter when attempting to identify and locate sources in urban areas.

III. ACOUSTIC PROPAGATION MODELING IN AN URBAN AREA

The measurements discussed in Sec. II show that a simple acoustic source pulse produces a very complex pressure time series when recorded after propagation in an urban location because of the multiple interactions with the buildings. In this section, a computational model of the acoustic propagation that includes these effects is demonstrated. The interest in this paper is in what Kang (2006) called *microscopic* urban modeling, since the intent is to predict sound propagation for relatively short propagation distances of tens to hundreds of meters, compared to less-detailed *macroscopic* models intended to produce city-scale maps of noise levels.

Although many methods for predicting sound levels in urban areas have been developed over a long period of time (Lee and Davies, 1975; Oldham and Radwan, 1994; Heutschi, 1995), theoretical predictions are still a topic of research interest. Some recent studies have used statistical methods to measure or model traffic noise, or diffusion approaches to predict noise levels in street canyons with complex building facades (Brown and Lam, 1987; Garcia and Faus, 1991; Picaut *et al.*, 1999; Kang, 2000, 2001). Kang (2006) provided a thorough review of past work on urban sound predictions. A promising approach to calculate detailed time series predictions is the FDTD method (Botteldooren, 1994; Blumrich and Heimann, 2002). This method can handle complex geometries and acoustic pulses, but is limited to some extent by computer time and memory requirements. The method has been previously used to study urban acoustic propagation by a number of authors (Albert *et al.*, 2005; Liu and Albert, 2006; Van Renterghem *et al.*, 2006).

A. FDTD propagation model

A FDTD acoustic propagation model is applied in this paper since it can include all of the waves and interactions with buildings produced by an impulsive point source.

The FDTD acoustic propagation model used in this paper has been discussed in a previous publication (Liu and Albert, 2006), so only a brief summary of the method is given here. This finite difference model is based on the expression of acoustic propagation as a set of first-order, velocity-pressure coupled differential equations, similar to the motion and continuity expressions used by other authors (Virieux, 1984; Wang, 1996). To approximate the derivatives in the acoustic wave equation with finite differences, a staggered difference algorithm proposed by Yee (1966) is used in a two-dimensional spatial domain. The marching is also staggered between the computations of the air pressure and the particle velocity in the time domain. The perfectly matched layer technique (Berenger, 1994) was adapted for the absorption boundary condition and achieved highly effective suppression of reflections from the domain boundaries.

The computational effort is reduced by restricting the calculations to a simplified two-dimensional representation of the urban area, and this simplification allows the calculations to be made on a desktop personal computer. Buildings are treated as solid concrete blocks and a source function representing an explosion waveform with a peak frequency of about 50 Hz (Liu and Albert, 2006) was used for the calculations. This power spectral density of this source function is 1/30 of the peak level at 200 Hz, limiting the calculations to this relatively low frequency bandwidth.

For many finite difference calculations the Courant stability criterion (Wang, 1996) (nominally ten time sample points per wavelength) ensures that the computations will be stable and accurate. However, a more stringent criterion (Schroder and Scott, 2002) was needed for these calculations because of the very high impedance contrast between concrete, with a wave velocity of 2950 $\mathrm{m\,s^{-1}}$ and density 2300 $\mathrm{kg\,m^{-3}}$, and air, with a speed of about 350 $\mathrm{m\,s^{-1}}$ and density of 1.2 $\mathrm{kg\,m^{-3}}$. The computations were made stable by lowering the time and spatial step sizes in the computation and by reducing the impedance contrast between the materials.

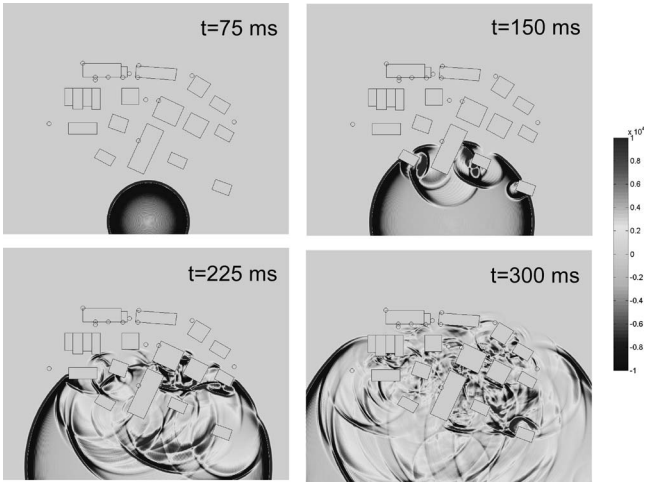

FIG. 8. Calculated acoustic propagation within the artificial village for a source located at SP4. Snapshots of the simulated wavefield are shown for times $t=75$, 150, 225, and 300 ms.

The impedance contrast was reduced by using a lower value of 23 kg m^{-3} instead of the true value of 2300 kg m^{-3} for the density of concrete. This change preserves the wave velocities and the kinematic results while still giving sufficient accuracy to the reflection amplitudes, as shown by Liu and Albert (2006). A spatial grid of 0.1 m was selected along with a time step of 0.01 ms. These choices not only improve stability, but also increase the accuracy of the calculations for buildings that are skewed with respect to the Cartesian grid coordinates. The village was thus represented by a 2000 $\times$1400 spatial grid: a total of 2.8 million grid points. The computations were performed using the MATLAB language.

Corrections for the two-dimensional geometric spreading (an additional factor of $r^{-1/2}$, where r is the propagation distance) and the effect of the ground surface (an additional factor of 2, assuming a rigid ground surface and that the direct and reflected path lengths are nearly identical) were applied in the calculations. With these corrections, the model yields accurate results for simple LOS and NLOS geometries (Liu and Albert, 2006). Because of the two-dimensional approximation, acoustic energy outside the plane of the propagation model is ignored; i.e., propagation over the top of the buildings or diffraction from upper edges is not included in the calculations.

B. Simulation of acoustic pulse propagation in a village

Movies and snapshots of the computed wavefields are some of the very useful output products produced by the FDTD computations; these displays allow the complex wave interactions with the buildings to be studied in detail. Since snapshots for a source located at SP1 have already been published (Albert *et al.*, 2005), the wavefield snapshots for a explosion source located at SP4 are shown here in Fig. 8. At $t=150$ ms, the initial pulse has entered the village, and reflections and diffractions around the buildings are clearly visible and identifiable. As the propagation time increases, the wavefield within the village reflects and scatters around the buildings producing very complex interference patterns. Urban propagation features, including the diffraction from building corners and narrow gaps between buildings, the canyon effect along a street, and the pressure shadow zones behind buildings, are visible in these snapshots.

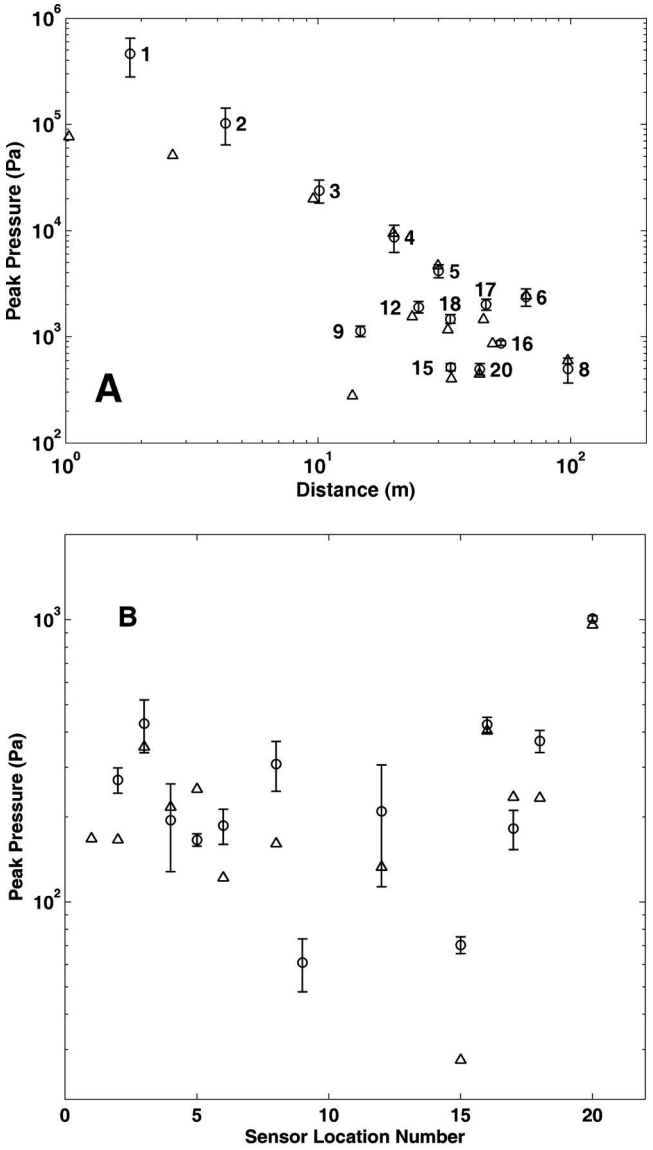

FIG. 9. (a) Comparison of measured and calculated peak pressure amplitudes as a function of propagation distance for SP1. Circles represent the mean measured peak amplitudes with error bars of two standard deviations. Triangles are the peak amplitudes calculated using the two-dimensional FDTD method. NLOS sensors (with lower amplitudes) are plotted at the LOS distance for that sensor location. Numbers near the measurements indicate the sensor location in Fig. 1. (b) Comparison of measured and calculated peak pressure amplitudes for each sensor location (see Fig. 1) for SP4. Circles represent the mean measured peak amplitudes with error bars of two standard deviations. Triangles are the peak amplitudes calculated using the two-dimensional FDTD method. All sensors except number 20 are NLOS. The calculated value for sensor No. 9 (behind building A) is 1.2 Pa, below the lower boundary of the plot.

A comparison of the measured and calculated peak amplitudes for a source located at SP1 is shown in Fig. 9(a). The initial source pulse amplitude used for the calculations was estimated as 77 kPa at 1 m, based on the measured values for the Main Street sensors at 10–30 m distance; this source amplitude was subsequently used in all of the theoretical calculations for all source positions. Figure 9(a)

shows good agreement between the measured and calculated amplitudes, except for a few locations. The largest disagreement is for the two closest sensor positions (1 and 2) along Main Street, where the calculated pressure amplitudes are much lower than the measured amplitudes. This disagreement is expected because the nonlinear pressure effects in the measurements at these sensor positions are not included in the linear acoustic calculations. The next largest disagreement occurs for the sensor directly behind building A [plotted at 12 m distance in Fig. 9(a)], where the calculated amplitude is lower than the measured amplitude by about a factor of 3. At this sensor location, the two-dimensional computational model requires the waves, either to diffract around two right-angle exterior walls or to transmit through two concrete-block walls. The path over the roof was not included in the simulation, and it will be shown below that this path has a significant effect on the measured amplitude. In addition, there was probably a much higher transmission coefficient directly through the building because there were many large open windows and doors in building A that would allow the high amplitude source pulse to penetrate into the building virtually without attenuation. In the theoretical calculations, very little acoustic energy can enter the building because of the high impedance contrast between air and the concrete building walls. For all of the other NLOS sensors, the calculated amplitudes are close to the measured amplitude range. It is noteworthy that the measured amplitude for sensor 15, behind building B, is much lower than for the sensor behind building A and that the agreement with the calculated amplitude at that location is good.

The measured and calculated pressure amplitudes for SP4 are shown in Fig. 9(b). In this case, most of the sensors are about 100 m from the source, so the results are plotted by sensor position number (Fig. 1) instead of by propagation distance. The same theoretical source amplitude of 77 kPa at 1 m distance was used for these calculations. Five of the sensor amplitudes agree within the experimental limits, six give lower theoretical amplitudes, and two give higher theoretical amplitudes. All but one of these cases (number 20) is NLOS with multiple building interactions, and the amplitude agreement is generally within better than a factor of 2, with two exceptions: sensors 9 and 15, which were mounted on walls directly behind buildings A and B, respectively. As mentioned above, computational results for these sensors are likely to be less accurate because of the neglect of propagation paths over the tops of buildings lowering the calculated levels and the actual propagation paths through the open doors and windows into the buildings increasing the measured levels.

Waveform modeling is a very stringent test of any computational propagation model, since it requires accurate amplitude and phase agreement with measurements over a broad band of frequencies. A comparison of the measured pressure waveforms with those calculated using the finite difference method for SP1 is given in Fig. 10. For these calculations, a time-varying velocity for acoustic waves in air, starting at 380 m s^{-1} and reducing to 350 m s^{-1} after 300 ms, was used to approximate the measured pressure-dependent sound speed shown in Fig. 5. In Fig. 10, the upper

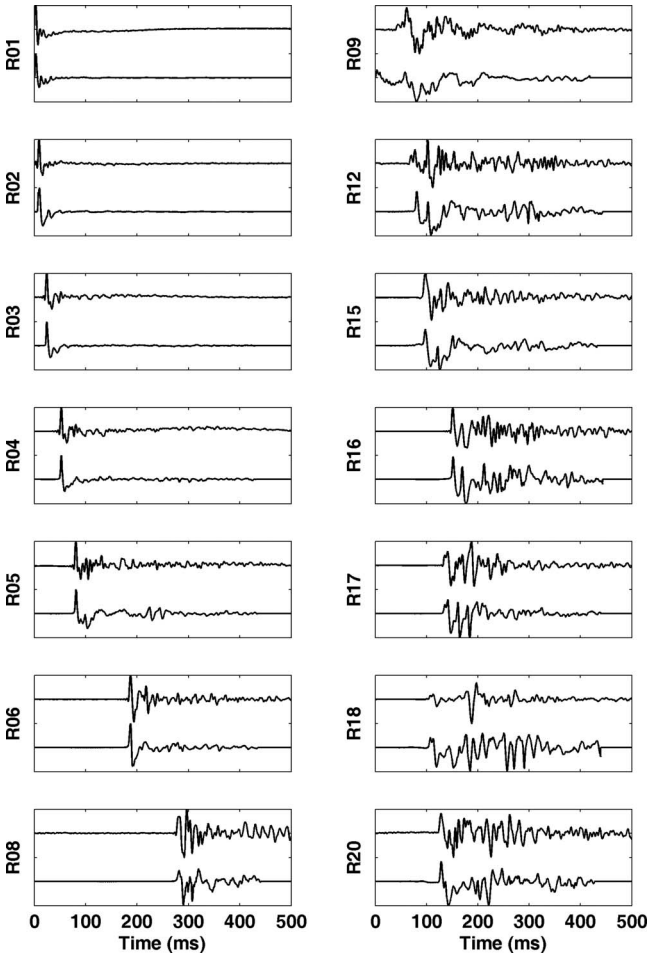

FIG. 10. Measured (upper) and theoretical (lower) waveforms at 14 locations in the artificial village for source point 1. The observed waveforms have been low-pass filtered at 200 Hz, and the calculated waveforms have been time-shifted to correct for variable acoustic velocity as explained in the text. These waveforms are all individually normalized. The side labels give the locations, as shown in Fig. 1.

traces in each panel are the measured waveforms, while the lower traces are the calculated time series for each sensor location. The measured waveforms were low-pass filtered with a passband below 200 Hz to adjust their frequency content more closely to the calculated frequency band. The difference in frequency content was expected because the calculations were restricted to low frequencies by the choice of the theoretical source function and for stability considerations, as discussed earlier.

In addition, a time shift was applied to each of the calculated waveforms to align the calculated first arrivals with the measured time series. The largest time shift applied was 12.6 ms for sensor 16, while two other NLOS sensors were shifted by 12.3 and 10.1 ms, and the remaining 11 sensors were shifted by less than 10 ms. These time shifts were needed because a single velocity function cannot account for all of the propagation paths, since the peak pressure (and thus the wave velocity) will decrease rapidly once a diffraction corner is turned, so the wave velocity may be different for different parts of the wavefield at the same time instant. In fact, the velocity for different arrivals within the same time series is often different because of the presence or ab-

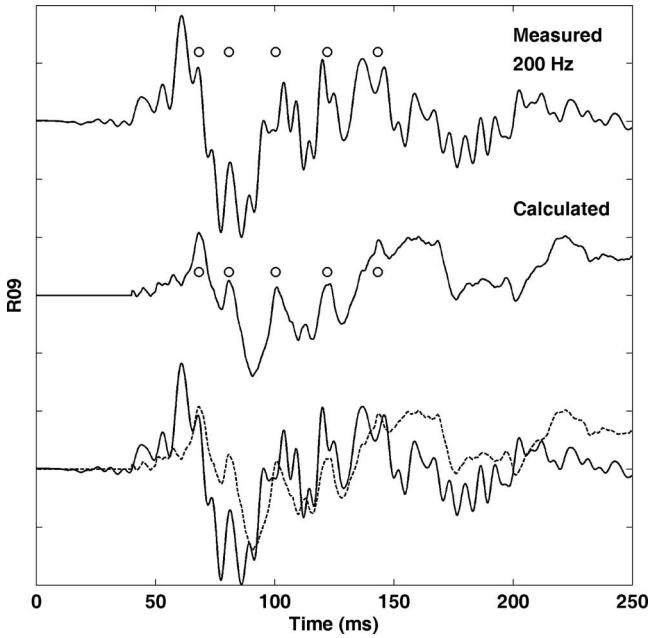

FIG. 11. Comparison of measured and theoretical waveforms for a source at SP1 and receiver at location 9, behind building A. The measured waveform (top) has been low-pass filtered at 200 Hz. The calculated waveform (center) has been muted for times before 40 ms, and time-shifted by 2.0 ms to align with the measured waveform. Open circles indicate arrival times identified from the finite difference wavefield movie as horizontal diffractions around two corners of building A, followed by arrivals along the same path after single or multiple reflections in the street between buildings A and E. The calculated (dashed line) and measured (solid line) waveforms are plotted together at the bottom of the figure.

sence of diffractions for the path of the particular arrivals that arrive at a sensor. The largest time shifts were applied to NLOS sensors. The propagation path for the first arrival at sensor 16 was diffracted around the corner of building E, very early in its travel to the sensor, so its propagation velocity was lower than estimated from Fig. 5 (for propagation without diffraction), soon after it left the source, and thus a larger time difference is expected for this particular sensor. With these adjustments, Fig. 10 shows that the overall waveform shapes and arrival times generally agree at many of the sensor locations.

The two-dimensional FDTD calculations omit acoustic propagation paths over the rooftops. Liu and Albert (2006) found that this two-dimensional calculation method produced good agreement with waveform measurements conducted using a single-storey right-angle wall as the scattering obstacle. In Fig. 9(a), the worst agreement between the calculated and measured peak amplitudes was for sensor 9 located behind building A. The measured and calculated waveforms for this position are compared in Fig. 11. Here, the measured waveform has been low-pass filtered at 200 Hz. The calculated waveform was muted (zeroed) for times before 40 ms and time-shifted by 2.0 ms so that the peak amplitude aligns with the *second* measured peak. Careful study of the wavefield movie produced by the finite difference calculations allowed the calculated wave arrivals to be identified. The small amplitude arrivals at 45 ms (and following) were produced by waves propagating through and reverberating within the building itself. The first large arrival (at 68 ms) was produced by the wave that diffracted around the two building corners, followed by large arrivals at 80, 101, 122, and 144 ms that followed the same path after single or multiple reverberations in the street between buildings A and E. These theoretical arrival times are shown as open circles in Fig. 11, and they seem to agree well with some pulses on the measured waveform, given the uncertainty in the acoustic wave speed, as discussed earlier.

The horizontal ray diffracts around corners of 66° and 90°, and arrives at the sensor after traveling 24.1 m. For the propagation path over the roof, the ray grazes the first roof edge, then is diffracted through 66° and 57° to reach the sensor, with a path length of 21.0 m. The 3 m path length difference corresponds to an arrival time difference of about 8 ms (compared to 7 ms between the first and second positive pulses on the measured waveform), with the rooftop arrival expected to arrive first. A rough calculation of the insertion loss produced by the building for the 100 Hz octave band (Kang, 2006, page 151) gives 18 and 16 dB for the horizontal and rooftop paths, respectively, close to the amplitude difference shown in Fig. 9. In this case, the rooftop path is the largest expected arrival, but it is not included in the theoretical calculations, and this omission explains the differences in the amplitude and waveform comparisons.

The waveform agreement shown in Fig. 10 is acceptable, considering all of the approximations in the computational model. These include the two-dimensional formulation that neglects rooftop wave propagation paths, the approximate corrections for the variable wave velocity in air because of nonlinear effects, and the simplified buildings used in the model (ignoring the façade details, etc.).

A similar waveform comparison is shown for SP4 in Fig. 12. In this case, the propagation distances were all about the same, ranging from 86 to 117 m, so a constant wave velocity for air of 375 m s^{-1} was used in these calculations. The measured waveforms have been low-pass filtered, and a time shift ranging from 9 to 23 ms was applied to some of the calculated waveforms. No time shift was applied to sensors 6, 15, 16, and 17. In some cases, the time shift applied to the calculated traces were selected to align the minimum (negative) pressure rather than the peak positive pressure. Many, but not all of the measured waveform details, appear on the calculated time series for SP4.

Some of the calculated waveforms for SP4 show good agreement with the measurements, including sensors 3, 8, 18, and 20 (LOS). The initial propagation paths to these sensors are all relatively "open," without path obstructions near the sensor. Most of the other sensors have calculated initial arrivals smaller than the measured amplitudes (sensors 2, 4, 6, 9, 12, and 15). The calculated waveforms for sensors 9 and 15, located on the back wall of buildings, again show the poorest agreement with the measured waveforms. Sensor 17 on building G also shows poor agreement with the measured waveform. The high pressure blast sensor 1, selected to measure the C4 blast waves at a distance of 1 m (SP 1), was unable to detect the much lower waveform produced by the explosive charge SP4. For some of the sensors (for example, sensor 12), the waveform agreement is better later in the time series, and the worst agreement is for the first arrival.

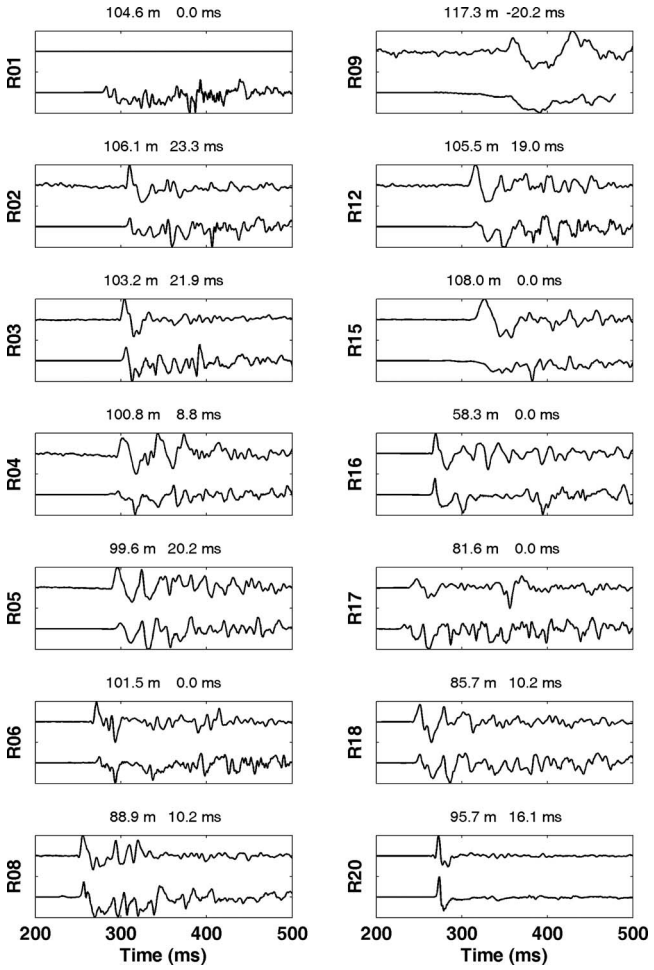

FIG. 12. Measured (upper) and theoretical (lower) waveforms at 14 locations in the artificial village for source point 4. The observed waveforms have been low-pass filtered at 200 Hz, and the calculated waveforms have been time-shifted to correct for variable acoustic velocity as explained in the text. The side labels give the locations, as shown in Fig. 1, and these waveforms are all individually normalized.

IV. CONCLUDING REMARKS

Measurements of acoustic pulse propagation in a complex urban environment demonstrate that, for propagation over straight, line-of-sight propagation paths, complex high frequency waveforms comprised of multiple reflections are recorded, with higher amplitudes than for open air situations. In non-line-of-sight situations, while the rigid ground and building surfaces tend to preserve the high frequency waveforms and produce little attenuation, diffraction introduces low-pass filtered arrivals, producing very complex waveforms. In all cases, the waveforms display more complexity and longer time durations than for open air situations.

Finite difference calculations using a simplified two-dimensional representation of the urban propagation environment were conducted on a personal computer and produced good agreement with the measured peak amplitudes. The calculation method also gave good agreement with many waveform characteristics. The major discrepancies between the calculations and measurements occurred for sensors located directly behind buildings.

The added complexity of the acoustic waveforms produced in an area with many buildings will have a large effect on the performance of acoustic sensor systems. It can be difficult for human listeners to recognize that playbacks of some of the complex signals shown in Fig. 3 were produced by acoustic pulses; instead, they often sound more like jet noise.

Methods using direction-of-arrival or beam-forming estimates to determine an acoustic source location (Haykin, 1985) are likely to perform poorly, especially in NLOS situations, because the sound will arrive at the sensor from many different directions, with possibly none of those directions correctly pointing toward the actual source location (sensor location 18 and source point 1 in Fig. 1 are examples of this situation). Even in LOS situations (for example, sensor location 5 in Fig. 1), bearing estimates may vary widely as multiple reflections with different angles of arrival reach the sensor, and only a general quadrant direction is likely to be produced. However, if the geometry of the situation is known, time-reversal processing methods can potentially be used to decode the complex signatures and produce a correct source location (Albert *et al.*, 2005).

ACKNOWLEDGMENTS

We thank the late Mr. Rich Andrejkovics and Mr. Andre Edwin, SYDET Project Officer of PM-CCS, for funding the experimental measurements presented here. This paper is dedicated to Rich's memory. The analysis was funded by the U.S. Army Corps of Engineers Engineering Research and Development Center research program. We also thank the many people who assisted with the field measurements, including David Carbee, Stephen Decato, and Dr. Joyce Nagle (ERDC-CRREL); Chris Reiff and Herb Brann (Army Research Laboratory); Gary Leadore, George Eason, Thomas Ruffing, Patrick Whaling, and James Aguiar (Aberdeen Test Center); Ron Akers, Stan Ellis, George Eason, and others from Fort Benning. In addition, Major Joseph Haydon (U.S. Army) assisted with the measurement design, Dr. Joyce Nagle conducted a review of the urban acoustic literature used in this paper, and David Leese (ERDC-ITL) provided meteorological data. We also thank two anonymous reviewers for useful comments that improved the manuscript.

In the context of better understanding and predicting sound transmission through heterogeneous fluid-loaded aircraft structures, this paper presents a method of solving the vibroacoustic problem of plates. The present work considers fluid-structure coupling and is applied to simply supported rectangular plates excited mechanically. The proposed method is based on the minimization of the error of verification of the plate vibroacoustic equation of motion on a sample of points. From sampling comes an aliasing effect; this phenomenon is described and solved using a wavelet-based filter. The proposed approach is validated in presenting very accurate results of sound radiation immersed in heavy and light fluids. The fluid-structure interaction appears to be very well described avoiding time-consuming classical calculations of the modal radiation impedances. The focus is also put on different samplings to observe the aliasing effect. As perspectives sound radiation from a non-homogeneous plate is solved and compared with reference results proving all the power of this method. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3290982]

I. INTRODUCTION

An aircraft structure is strongly heterogeneous: It can be considered as an assembly of stiffened curved panels with non-uniform skin thickness. It includes beams to support the floor as well as large size windows in the flight deck. The turbulent boundary layer excitation is one of the main sources of aircraft interior noise over a large frequency range. In the industrial context of better understanding and predicting sound transmission through heterogeneous fluid-loaded aircraft structures, a formulation is proposed with purpose of assessing quickly sound radiation from these complex aircraft structures. In particular, the present paper aims at presenting a method applied to radiation from simply supported baffled plates exposed to a half-space of fluid and excited mechanically.

Sound radiation from plates has been widely studied for many years since this simple problem can explain how and why structures radiate noise. The calculation of radiated pressure leads to complexity and is time consuming even if the structure is a plate, e.g., the aircraft applications proposed by Graham[1,2] and Maury *et al.*[3,4] The need of computationally simpler method is obvious. Nevertheless, the drastic simplification of neglecting fluid loading is not considered because it is not appropriate in lot of practical situations.

In this paper, modal decomposition of plate vibrations into *in vacuo* modes, also called dry modes, is considered. This approach is widely used in literature. Fluid-structure interaction is characterized through the modal radiation impedances, which are the time-consuming terms of the calculation. A large number of papers have put its focus on their evaluations.[5–11] Conclusions drawn from these studies have emphasized difficulties to calculate these impedances and their necessity in heavy fluid. Some models predicting sound radiation from plates with fluid loading have been proposed in literature.[12–17] A state of the art on the prediction of radiation from plates is presented by Atalla and Nicolas.[18] Mutual-radiation resistances are often considered as having negligible impact on radiated sound power, but more practically this simplification leads to a strong reduction in computation time since each mode remains uncoupled. More recently, Li and Gibeling[19] and Sha *et al.*[20] presented simple calculation methods for the mutual radiation resistances. In particular, Li and Gibeling[19] showed that they may not be meaningless as compared with the self-terms in a quite wide frequency range.

A choice has to be made between approximate models, easy to use and quick to compute but giving only tendencies, or accurate models limited by the calculation times and consequently not adapted to large parametric studies, hence the constant need of new tools for predicting accurately and rapidly vibrations and sound radiation from plates. The formulation presented by Atalla and Nicolas[18] has this objective. Their approach is based on a Taylor's expansion of Green's function, which brings some real improvement.

The present work is led within this context. It still uses displacement expansion into series of *in vacuo* plate eigenfunctions but instead of improving modal radiation imped-

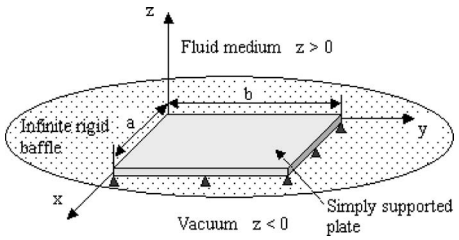

FIG. 1. Geometry of the problem.

ances it solves directly the plate equation of motion coupled to the acoustic media.

The formulation proposed is based on sampling and modal optimization. Indeed, modal amplitudes are optimized so as to satisfy the governing equation for a sampling of observation points of the plate under fluid loading. For the sake of brevity the method is called MESOP (minimization of error on a sample of observation points) in the following. This approach has been adopted due to the existence of numerous advanced algorithms treating efficiently of optimization problems.

It is shown in this paper that MESOP offers an efficient tool for assessment of sound radiation from simply supported baffled plates immersed in light or heavy fluid and a special focus is also put on presenting possibilities of extension given by the method. In Sec. II, homogeneous plates are considered and corresponding theoretical analysis associated is derived from plate sampling and modal decomposition. Then aliasing phenomenon and its solving through a wavelet-based filter are described. Finally the resolution principle is presented.

Section III is devoted to numerical validations. The model is first validated in heavy fluid. The fluid-structure coupling appears to be very well described. Different plate samplings are considered to observe the aliasing effect. Next a numerical validation is made in light fluid and a comparison in term of computation time is led on different algorithms. The present approach shows here all its interest.

Finally the model is generalized in Sec. IV to nonhomogeneous plates. The particular case of a plate with varying thickness is highlighted and used to give credit to the generalized formulation.

II. MESOP PRINCIPLE AND THEORY ASSOCIATED

A. Statement of the problem

The structure of interest is a simply supported thin rectangular plate inserted in a baffle (Fig. 1). The baffle is assumed to be infinite, plane, and rigid. The plate-baffle system separates vacuum ($z<0$) from an acoustic medium ($z>0$). As a result, the plate radiates into the fluid in the semi-infinite space. The plate produces flexural vibrations in response to a harmonic mechanical force per unit area of angular frequency ω and applied normally to the plate surface. Transverse shear and rotary inertia effects are neglected. A harmonic motion is considered but for sake of simplicity time dependence $e^{j\omega t}$ is applied. Transverse motion $W(x,y)$ of the homogeneous plate is derived using Love–Kirchhoff assumptions as follows:

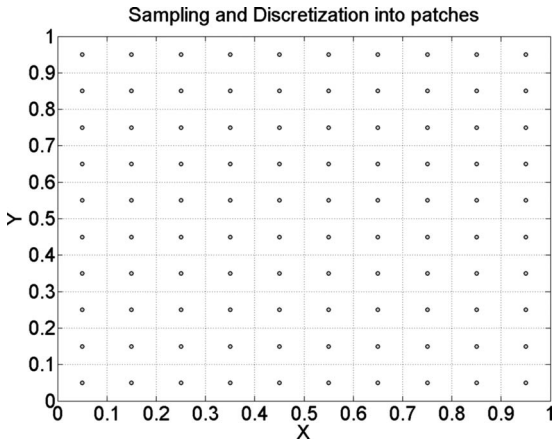

FIG. 2. Two linked approximations: discretization into patches (——) and observation on samples (○).

$$D\Delta^2 W(x,y) - \omega^2 \rho h W(x,y) = F(x,y) - p_0(x,y), \tag{1}$$

where D is the flexural rigidity, ρ is the mass density, h is the thickness, $F(x,y)$ is the driving force per unit area, and $p_0(x,y)$ is the fluid loading pressure. $p_0(x,y)$ is defined by the well-known Rayleigh integral

$$p_0(x,y) = \int_{S_p} j\rho_0 \omega V(x',y') \frac{e^{-jk_0 R}}{2\pi R} dx'dy', \tag{2}$$

where S_p is the surface of the plate, $k_0=\omega/c_0$ is the acoustic wave number, ρ_0 and c_0 are the density and the sound speed in the fluid, and $R^2=(x-x')^2+(y-y')^2$.

The vibroacoustic response of the plate is assessed in terms of three vibroacoustic indicators, namely, the mean square velocity, the radiated sound power, and the radiation factor (see definitions in Appendix B).

B. Sampling approach

To model the vibroacoustic behavior of the plate, a sampling approach is used. This method consists in observing the verification of the equation of motion on a sample of points of the plate. Equation (1) is valid for any point (x,y). Therefore, combining Eq. (1) and the sampling approach results in the following equation:

$$D\Delta^2 W(x_i,y_i) - \omega^2 \rho h W(x_i,y_i) = F(x_i,y_i) - p_0(x_i,y_i), \quad \forall\, i \in [1, N_x \times N_y], \tag{3}$$

where (x_i,y_i) are the coordinates of sample point i, and N_x and N_y are the numbers of samples in the x and y directions, respectively.

The limitation to a sample of points verifying the equation of motion will naturally produce only an approximation of the solution. To go further it is necessary to express the boundary pressure with the plate displacement.

C. Fluid loading

The fluid loading pressure $p_0(x,y)$ is calculated using the collocation method (see Appendix A). Thus, a discretization of the plate into rectangular patches is made (Fig. 2). These patches are chosen so as to let patch centers corre-

spond to sample points. Thus, same approximation level is used in the plate modeling and the fluid loading calculation.

The pressure on the plate is as a result defined by

$$p_0(x_i,y_i) = \sum_{j=1}^{N_x\times N_y} Z_{ij}V(x_j,y_j) = j\omega \sum_{j=1}^{N_x\times N_y} Z_{ij}W(x_j,y_j). \quad (4)$$

The impedance terms Z_{ij} are given by

$$Z_{ij} = \frac{p_0(x_i,y_i)}{V(x_j,y_j)} = \frac{1}{2\pi}\rho_0 j\omega \frac{e^{-jk_0 d_{ij}}}{d_{ij}} S_j, \quad (5)$$

$$Z_{ii} = \frac{p_0(x_i,y_i)}{V(x_i,y_i)} = \rho_0 c(1-e^{-jk_0 r_i}), \quad (6)$$

where r_i is the radius of the circular patch of surface S_i.

The equation of the plate coupled with the acoustic medium is thus given by

$$D\Delta^2 W(x_i,y_i) - \omega^2\rho h W(x_i,y_i) + j\omega \sum_{j=1}^{N_x\times N_y} Z_{ij}W(x_j,y_j) = F(x_i,y_i), \quad \forall\, i \in [1,N_x\times N_y]. \quad (7)$$

As seen before, a second approximation appears here due to the finite size of pistons used in the collocation technique. It is implicitly related to the sample points located at the pistons midpoints.

D. Modal decomposition

To solve the problem, thanks to modal optimization, modal decomposition of plate displacement is introduced. Let the flexural motion of the plate be expanded into series of *in vacuo* modes

$$W(x,y) = \sum_{m,n} a_{mn}\Phi_{mn}(x,y), \quad (8)$$

where a_{mn} and Φ_{mn} are the modal amplitude and the modal shape, respectively, of the (m,n) mode. For the case of a simply supported plate, Φ_{mn} is given by

$$\Phi_{mn}(x,y) = \sin\frac{m\pi x}{a}\sin\frac{n\pi y}{b}, \quad (9)$$

where a and b represent the plate dimensions in the x and y directions. Note that expansion (8) does not necessitate that functions Φ_{mn} are modal shapes but only basis functions. Nevertheless the physical nature of mode shapes helps the convergence and when mode shapes are known, like in this case, their use is very convenient compared to other basis. In addition, it can be pointed out the perspective to treat other boundary conditions in just switching the functional basis, e.g., clamped plates. An approach coupled to a finite element method (FEM) can also be envisaged for complex boundary conditions representative of aircraft applications.

Using modal decomposition in the equation of motion given by Eq. (7) leads to a set of equation written at each sample point that depends on the modal amplitudes

$$D\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\Delta^2\Phi_{mn}(x_i,y_i) - \omega^2\rho h\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\Phi_{mn}(x_i,y_i) + j\omega\sum_{j=1}^{N_x\times N_y} Z_{ij}\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\Phi_{mn}(x_j,y_j) = F(x_i,y_i), \quad \forall\, i \in [1,N_x\times N_y], \quad (10)$$

where $m_{\max}$ and $n_{\max}$ are the maximal orders of the modes in the x and y directions, respectively. For the sight of simplicity, the equation of motion can be rewritten as

$$\sum_{q=1}^{q_{\max}}\left[D\Delta^2\Phi_q(x_i,y_i) - \omega^2\rho h\Phi_q(x_i,y_i) + j\omega\sum_{j=1}^{N_x\times N_y} Z_{ij}\Phi_q(x_j,y_j)\right]a_q = F(x_i,y_i), \quad \forall\, i \in [1,N_x\times N_y], \quad (11)$$

$$[\mathbf{S}]\{\mathbf{A}\} = \{\mathbf{F}\}, \quad (12)$$

where q is the mode index, $[\mathbf{S}]$ is the sampling matrix of size equal to the number of samples times the number of modes, $\{\mathbf{A}\}$ is the modal amplitude vector of size equal to the number of modes, and $\{\mathbf{F}\}$ is the driving force per unit area vector of size equal to the number of samples. After plate sampling the modal truncation represents the second type of approximation of the method described here. Therefore, the maximal orders of the modes will be considered as a parameter of investigation.

E. The aliasing phenomenon

In the present method, the plate displacement is expressed from mode responses. Let us consider that $M\times M$ modes are used. In the wave number domain each plate mode is defined by a couple of wave numbers of the form $(m\pi/a, n\pi/b)$ where $m=1, M$ and $n=1, M$. Thus, all wave numbers used to describe the plate response are located in a rectangular domain (Fig. 3).

Let us consider a same number N of sample points in both directions. The sample of observation points is regularly distributed over the plate at points of coordinates $(pa/N, qb/N)$ where a/N and b/N are the spacings between samples in x and y directions and $N\times N$ is the number of sample points considered. In the wave number domain this sampling corresponds to a couple of wave numbers of the form $(p\pi/a, q\pi/b)$ where $p=1,N$ and $q=1,N$. Plate displacements observed in the method contain all wave numbers located in a rectangular domain (Fig. 3).

Three configurations are possible depending on the number of modes $M\times M$ and the number of sample points $N\times N$.

- $M>N$. In this case (Fig. 3) modes' wave number components remain uncontrolled by observation points and the method failed to predict vibroacoustic plate response. This

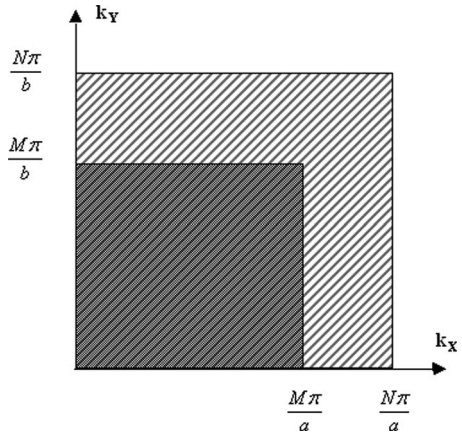

FIG. 3. Wave number domains of the modes $M \times M$ and sample points $N \times N$. Case of $M < N$.

case corresponds to an underdetermined problem: less equations (sample points) than unknowns (modal amplitudes).

- $M = N$. All modes' wave numbers are here exactly controlled by sample points and the vibroacoustic response is well described.
- $M < N$. In this case the aliasing problem is observed, the problem is also called overdetermined. As explained in signal processing textbooks, the signal observed by sampling has wave number components not taken into account by modal decomposition. The aliasing effect can be negligible is some cases (see Sec. III B 2) but leads to wrong modal amplitudes in most cases and as a result to wrong vibroacoustic response.

F. Solving the aliasing problem by using a wavelet-based filter

To avoid aliasing, all wave number contributions that cannot be taken into account by modal decomposition must be suppressed. This is achieved by filtering high wave number components not controlled by modal decomposition. In this paper, a two-dimensional (2D) filtering at level 1 based on Daubechies wavelets of order 10 is applied to Eq. (12) before resolution.

More precisely, vector $\{\mathbf{F}\}$ and each column of matrix $[\mathbf{S}]$ are filtered in order to retain only low wave number components corresponding to wave numbers of modes used in the calculation. Concerning vector $\{\mathbf{F}\}$ the filtering distributes more equally the force on the plate, the force level is therefore lowered at its primary location as illustrated in Fig. 4 where f_C is the critical frequency of the plate considered.

Matrix $[\mathbf{S}]$ is made of N rows and M columns, where N is the number of observation points and M is the number of modes considered. This matrix has to be filtered consequently for each column, that is, for the spatial distribution of observation points of the plate at one given order (m,n) of the functional basis. In that purpose, each column is first reshaped in a 2D-matrix and the matrices obtained are then filtered.

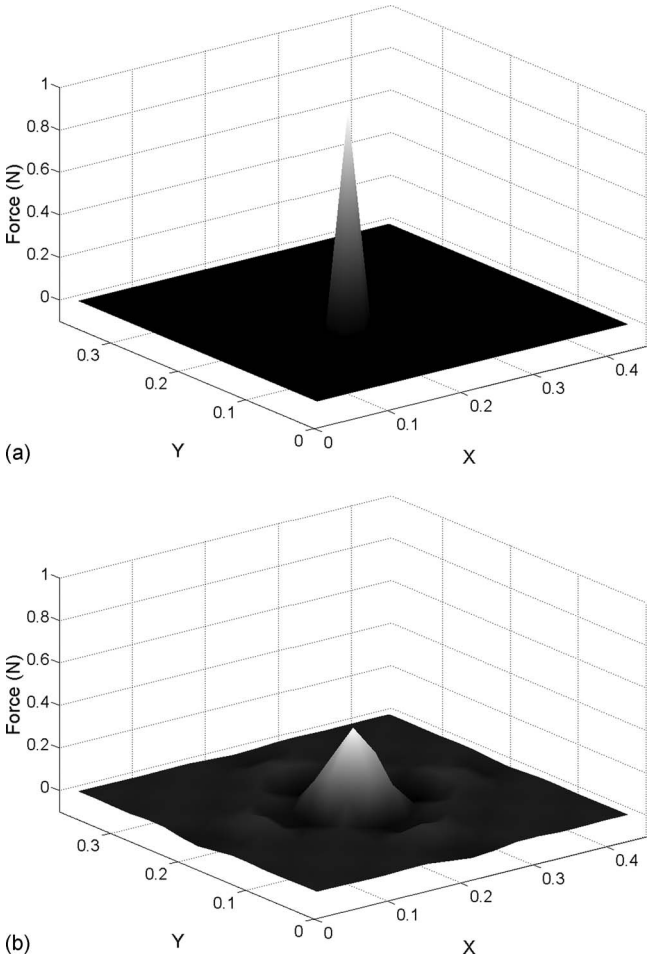

FIG. 4. Filter impact on force distribution. Case of sound radiation into water from a simply supported plate ($a/b=1.2$, $a/h=455$, $f_C>20$ kHz) driven by a point force at its center: (a) without filtering and (b) with filtering.

G. Resolution

To solve the problem the modal amplitudes must satisfy Eq. (12). However, in general, it is impossible and one has to find optimum modal amplitudes satisfying Eq. (12) as much as possible.

Several possibilities to find optimum modal amplitude values exist, generally through the minimization of residual function. Many algorithms performing this computation are available in the market. The present work will use the basic inverse function for square sampling matrix $[\mathbf{S}]$, i.e., number of modes equal to number of sample points. Nevertheless, in most cases, the sampling matrix is rectangular and Eq. (12) is solved in the least squares sense using LAPACK routines implemented in MATLAB; one gets the following minimization:

$$\min_{\{\mathbf{A}\}} \|[\mathbf{S}]\{\mathbf{A}\} - \{\mathbf{F}\}\|_2. \tag{13}$$

This algorithm will be compared in terms of computation time to other algorithms implemented in MATLAB such as the pseudoinverse function, the derivative-free method, or genetic algorithms.

Minimization yields optimum modal amplitude values, which are finally used to assess the three vibroacoustic indi-

cators. Note that a larger number of sample points than modes corresponds to most practical cases, then the filtering allows decreasing the size of matrix system (12) and therefore the associated resolution process of Eq. (13).

III. NUMERICAL VALIDATION FOR HOMOGENEOUS PLATES IN HEAVY AND LIGHT FLUIDS

To validate the proposed theory, the following vibroacoustic indicator is assessed: the radiated sound power W. Its definition is given in Appendix B. The radiated sound power is expressed in decibel with a reference level equal to 1. The validation of the present model is divided into two parts: sound radiation first into heavy fluid and then into light fluid.

Two input data need to be defined before computation: the number of samples and the number of modes considered. They are strongly responsible of accurate results. Convergence criteria will be consequently defined too. To illustrate aliasing effect and for the sake of simplicity, the same number of modes (M) is used in both directions. The same assumption is made with the number of samples (N).

A. Vibroacoustic response of plates under heavy fluid loading

The heavy fluid yields here a strong fluid-structure interaction. As a consequence, the method is really tested in a difficult case.

Experimental results under heavy fluid loading are not common in literature. Such experiments are difficult to set up; in fact, only few reference results exist but none was found allowing comparison with. However, some numerical results of sound radiation of simply supported baffled plates into water exist.[14,15,17] Berry and Foin *et al.* dealt with this problem using a variational formulation solved by the Rayleigh–Ritz method, whereas Laulagnet solved analytically this problem in calculating directly the radiation impedances. Note that the state-space approximation[21,22] permits to determine the fluid-loaded resonances through classical analyses (e.g., eigenvalue decomposition).

A numerical validation is led in heavy fluid comparing the optimized results with Berry's work in the case of a simply supported plate $455\times375\times1$ mm^3 immersed in water ($\rho_0=1000$ kg m^{-3} and $c_0=1500$ m s^{-1}) and driven by a point force F_p at its center [$F_p=\|F_p\|\delta(x-a/2)\delta(y-b/2)$ and $\|F_p\|=1$]. Using sampling approach, one gets the following expression of the driving force per unit area:

$$F(x_i,y_i)=\begin{cases}\dfrac{\|F_p\|}{S_i} & \text{if sample } i \text{ is sample excited}\\ 0 & \text{else.}\end{cases} \tag{14}$$

The frequency range of study is 10–4000 Hz. A large number of *in vacuo* plate modes are considered to be sure that no modal contribution is missing.

To investigate the influence of sampling, comparison is made in the three following configurations: $M=N$, $M>N$, and $M<N$.

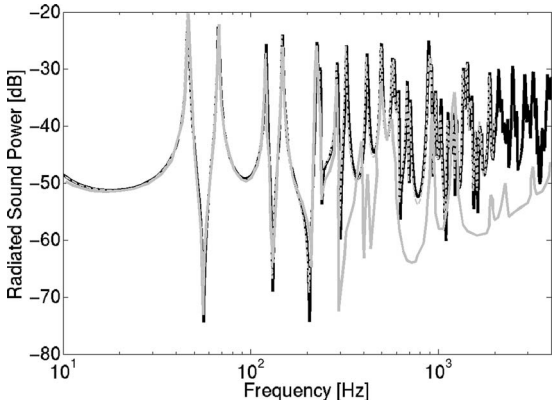

FIG. 5. Radiation into water by the proposed method with $M=N$ (black solid line) compared to Berry's results (gray solid line) and FEM results (gray dashed line). Case of a simply supported plate ($a/b=1.2$, $a/h=455$, $f_C>20$ kHz) driven by a point force at its center.

1. Calculation using as many modes as samples ($M=N$)

The resolution is quite simple since the sampling matrix is square in this case and therefore a basic inverse function leads to the solution. Figure 5 presents comparative results with those from Berry. Comparison shows a good accuracy until 300 Hz between optimized results and results from Berry. Beyond 300 Hz, a different behavior is observed. A cross validation with a commercial FEM software is consequently led proving the validity of our results. The FEM model size limits results to 2 kHz. Note that the MESOP computation runs around 70 times faster than the FEM one. As a consequence a poor convergence of Berry's results is assumed; indeed only 169 functions were used in its Rayleigh–Ritz expansion of the plate displacement whereas the present method uses 1369 functions ($M=37$). Note also that Berry uses a strong truncation to compute radiation impedance coefficients. This reference case treats only of subsonic modes because of the high value of the sound speed in water ($c_0=1500$ m s^{-1}) yielding a very high critical frequency ($f_C>20$ kHz). A case handling supersonic modes will be investigated in Sec. IV.

2. Calculation using more modes than samples ($M>N$)

With $M>N$, the sampling matrix becomes rectangular and Eq. (12) is solved in the least squares sense in optimizing Eq. (13). Results are compared to those of the previous case $M=N$ (Fig. 6). A poor agreement is observed proving the incapacity of the method to solve underdetermined problem, i.e., more unknowns (modal amplitudes) than samples.

3. Calculation using less modes than samples ($M<N$)

In this case, the sampling matrix is also rectangular and Eq. (12) is solved in the least squares sense in optimizing Eq. (13). Results are also compared to those of the case $M=N$ (Fig. 6). Moreover this case must lead to the aliasing phenomenon. The wavelet-based filter is consequently needed.

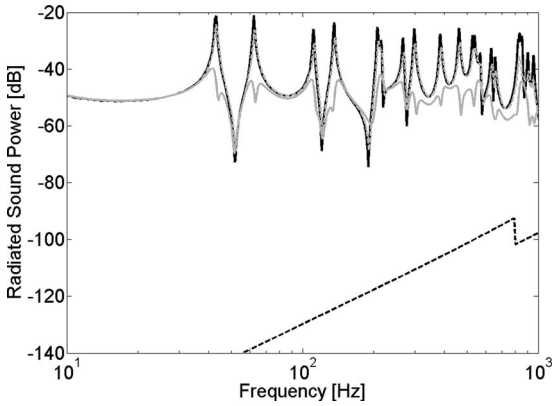

FIG. 6. Radiation into water by the proposed method with $M=N$ (black solid line), $M>N$ (black dashed line), $M<N$ without filtering (solid gray line), and with filtering (dashed gray line). Case of a simply supported plate ($a/b=1.2$, $a/h=455$, $f_C>20$ kHz) driven by a point force at its center.

To observe the influence of this filter, two calculations have been done: without and with filtering both sampling matrix $[\mathbf{S}]$ and vector $\{\mathbf{F}\}$.

On the one hand results without filtering show clearly problems of convergence due to aliasing. The global behavior is relatively well described while resonances are strongly underestimated.

On the other hand results with filtering show all the power of filtering. In fact, resonances are well described and aliasing effect is totally suppressed.

Finally, the validation into heavy fluid has proved the very good convergence of the method in a difficult case. The fluid-structure interaction is very well described. In addition to this, the mutual influence of both parameters has been illustrated: modes considered and plate sampling. The aliasing effect has been underlined when the sampling matrix is overdetermined ($M<N$) and the filter chosen has demonstrated its capacity to suppress this undesirable effect.

4. Evaluation of the radiation impedances and aliasing filter impacts on computation time

The impact on resolution time of these two MESOP steps is illustrated in Table I through the Berry's case described above. Two configurations are treated: $M=N=37$ and $M=37$ with $N=15$. Results show first of all the interest to consider the configuration $M<N$ even if it presents an aliasing effect. In fact, this effect is easily treated with the filter proposed and allows a faster computation with a gain of 85% here on the resolution time. The evaluation of the radiation impedances is naturally decorrelated of the configuration since it only depends on the number of samples considered.

TABLE I. Computation time of different MESOP steps for one frequency point depending on the choice of M and N. Simulation time obtained on a 700-Mflops computer

	$M=N=37$	$M=37/N=15$
Radiation impedances	0.63s	0.63s
Aliasing filter	0.00s	0.30s
Resolution	1.41s	0.19s
Total	2.04s	1.12s

The evaluation time of these impedances becomes therefore non-negligible when the more efficient configuration $M<N$ is treated; e.g., the radiation impedances represent here 30% of the total computation time when $M=N$ and 56% when $M<N$.

5. Criteria defining the number of modes and samples needed

The choice of the modes considered is made in applying the following criterion (15) based on *in vacuo* modes. One gets all modes placed in a quadrant depending on the maximal frequency of study and a constant γ. The constant γ is taken to be equal to 2 in heavy fluid in order to take into account added mass effect compared to vacuum. In the present paper, modes are of the form $M\times M$, and therefore $M=\max(m,n)$ must be considered.

$$\left\{(m,n)\ \text{such as}\ \left(\frac{m}{a}\right)^2+\left(\frac{n}{b}\right)^2\leq\gamma\sqrt{\frac{4\rho h}{\pi^2 D}}f_{\max}\right\}. \quad (15)$$

Concerning the influence of sampling, it is obvious that the more sample points taken, the greater accuracy. A sampling criterion of $\lambda_{\mathrm{fl}}/4$ is enough to assess accurately the vibroacoustic response below the critical frequency f_C, where the flexural wavelength λ_{fl} is given by

$$\lambda_{\mathrm{fl}}=\frac{\sqrt{\omega}}{f}\sqrt[4]{\frac{D}{\rho h}}. \quad (16)$$

Beyond the critical frequency, the acoustic wavelength is more restrictive and has to be considered.

B. Vibroacoustic response of plates under light fluid loading

In this case several results are available in literature for comparison. The method is applied to a steel plate $1000\times1000\times1$ mm^3, driven by a point force at (0.7, 0.2) of 1 N. The following properties of air are chosen to simulate the light fluid loading: $\rho_0=1.2$ kg m^{-3} and $c_0=340$ m s^{-1}. The structural loss factor is taken to be $\eta=0.01$. This factor is introduced in the complex Young modulus E^* such as

$$E^*=E(1+j\eta). \quad (17)$$

The three vibroacoustic indicators of interest are plotted between 10 Hz and 1 kHz (note that the corresponding critical frequency is 12 kHz). Simulation results are compared to reference results from C-Valor-test cases collection.[23]

1. Validation

To validate the present approach into light fluid, 20×20 modes and 41×41 samples are used ($M<N$) and the filter is applied. Results presented in Fig. 7 show an excellent agreement between optimized and reference results over the complete frequency range of interest. The present method allows an accurate assessment of the response and the radiation of the plate studied. The number of modes to be consid-

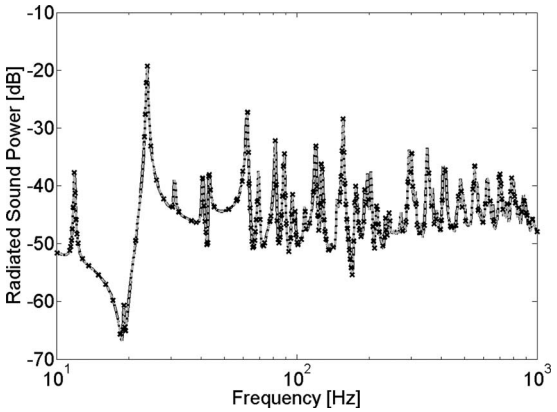

FIG. 7. Radiation into air by the proposed method with $M<N$ without filtering ($\times$) and with filtering (dashed line) compared to reference results from C-Valor (solid line). Case of a simply supported thin plate ($a/b=1$, $a/h=1000$, $f_C=12$ kHz) driven by a point force at $(7a/10, b/5)$.

ered in light fluid is defined using a constant γ equal to 1 in Eq. (15) when the added mass effect is negligible compared to vacuum.

2. Aliasing effect into light fluid

The aliasing effect is then investigated into light fluid. In that purpose, the vibroacoustic response of the previous plate is calculated using same configuration ($M<N$) without filtering the sampling matrix nor the driving force per unit area vector. Results are compared to the case $M=N(=41)$ presenting no aliasing (Fig. 7). It can be shown that aliasing effect is negligible into light fluid. Indeed a very good agreement is observed between both results. The reason is that *in vacuo* modes taken to model the plate behavior are very lowly modified by the light fluid loading and, as a consequence, aliasing effect becomes negligible in that particular case. In fact, Φ_{mn} can be considered as modal shapes for this case and not only basis functions.

C. Choice of the optimization algorithm

Several algorithms are available to solve the problem defined by Eq. (13) with $M<N$. This problem corresponds to the case where the sampling matrix $[\mathbf{S}]$ is rectangular, i.e., the most common case. The following algorithms implemented in MATLAB have been tested: least squares algorithm using LAPACK routines, the pseudoinverse function, the derivative-free method, and the genetic algorithms. To help us choose the best optimization algorithm, a comparison in terms of accuracy and computation time has been performed.

A preliminary computation has permitted to eliminate the derivative-free method and the genetic algorithms; both are not adapted because the function to optimize needs too much computation time. Indeed both methods are based on iterations and each iteration corresponds to an evaluation of the function to optimize.

Comparison between the least squares algorithm and the pseudoinverse technique has been led on the previous plate in light fluid between 10 and 100 Hz with 450 frequency points. 12×12 sample points and 6×6 modes are considered. The computation of vibroacoustic indicators using least squares algorithm represents the reference in terms of accuracy since it was used to validate the method. Results are illustrated in Fig. 8. Comparison has demonstrated the better efficiency of the first algorithm. In fact, both algorithms have an excellent agreement but the second one takes around four times longer than the first one to compute (Table II).

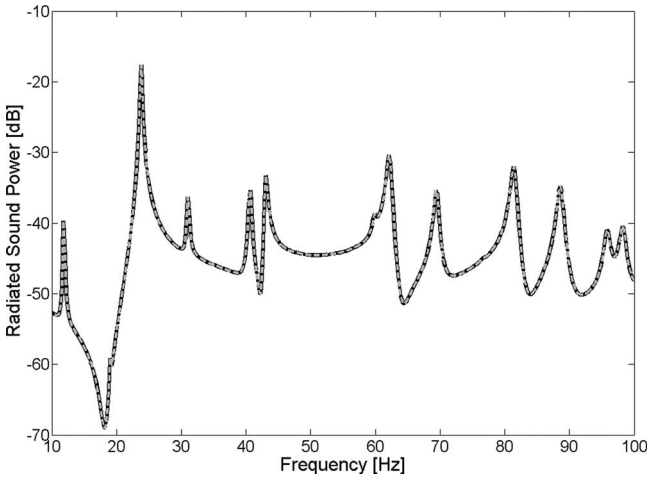

FIG. 8. Comparison in terms of radiated sound power between the least squares algorithm (dashed line) and the pseudoinverse function (solid line). Case of a simply supported thin plate ($a/b=1$, $a/h=1000$, $f_C=12$ kHz) driven by a point force at $(7a/10, b/5)$.

IV. EXTENSION TO NON-HOMOGENEOUS PLATES IN LIGHT FLUID

A. Generalization

This section aims at solving vibroacoustic problems using MESOP method for non-homogeneous plates. The present approach can be easily generalized to this case, since just the governing equation has to be changed. Non-homogeneous plate equation for bending motion according to Love–Kirchhoff assumptions is given by

$$D\Delta^2 W - \omega^2 \rho h W + 2\frac{\partial D}{\partial x}\frac{\partial(\nabla^2 W)}{\partial x} + 2\frac{\partial D}{\partial y}\frac{\partial(\nabla^2 W)}{\partial y} + (\nabla^2 D) \times(\nabla^2 W) - (1-\nu)\left(\frac{\partial^2 D}{\partial y^2}\frac{\partial^2 W}{\partial x^2} - 2\frac{\partial^2 D}{\partial y\,\partial x}\frac{\partial^2 W}{\partial y\,\partial x} + \frac{\partial^2 D}{\partial x^2}\frac{\partial^2 W}{\partial y^2}\right) = F - p_0, \tag{18}$$

where ν is the Poisson ratio. Compared to the homogeneous plate case, the difference comes from additional stiffness terms. Note that this equation is only valid for a spatial variation of the Young modulus E, the thickness h, and the Poisson ratio ν, which are very common in aircraft structures.

TABLE II. Comparison of two optimization algorithms. Computation time of 450 frequency points over 10–100 Hz. Simulation time obtained on a 700-Mflops computer.

	Least squares algorithm	Pseudoinverse technique
Computation time (s)	6.7	26.1

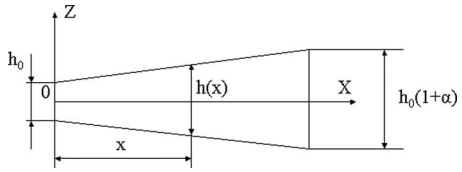

FIG. 9. Plate with linearly varying thickness.

Next the MESOP approach is applied in a straightforward manner, Eq. (7) of the homogeneous plate case being modified by introducing the new plate equation with additional terms. An example is proposed below.

B. Example of varying thickness

To validate MESOP approach for non-homogeneous plate, prior work of Miloudi *et al.*[24] is used for comparison. Miloudi *et al.* put their focus on the influence of varying thickness on sound radiation from a simply supported baffled plate into air. The studied thickness is only varying in the x direction (Fig. 9) as follows:

$$h(x) = h_0\left(1 + \frac{\alpha}{a}x\right), \tag{19}$$

where h_0 is the thickness at $x=0$ and α is a given constant. As a consequence, Eq. (18) becomes

$$D\Delta^2 W(x,y) - \omega^2 \rho h(x) W(x,y) + 2\frac{\partial D(x,y)}{\partial x}\frac{\partial(\nabla^2 W(x,y))}{\partial x} + \frac{\partial D^2(x,y)}{\partial x^2}\left(\frac{\partial W^2(x,y)}{\partial x^2} + \nu\frac{\partial W^2(x,y)}{\partial y^2}\right) = F(x,y) - p_0(x,y). \tag{20}$$

The varying thickness is assumed to have no influence on the radiation impedances estimated by the collocation method. Using the MESOP approach leads to Eqs. (21) and (22) to be solved where $[\mathbf{S_{NH}}]$ is the sampling matrix for this non-homogeneous case. Note that $\{\Phi_{mn}(x,y)\}$ still form a functional basis but are of course not modal shapes of the heterogeneous plate.

$$\begin{aligned} &D\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\Delta^2\Phi_{mn}(x_i,y_i) \\ &\quad - \omega^2\rho h(x_i)\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\Phi_{mn}(x_i,y_i) \\ &\quad + 2\frac{\partial D}{\partial x}\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\frac{\partial(\nabla^2\Phi_{mn}(x_i,y_i))}{\partial x} \\ &\quad + \frac{\partial D^2}{\partial x^2}\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\left(\frac{\partial^2\Phi_{mn}(x_i,y_i)}{\partial x^2} + \nu\frac{\partial^2\Phi_{mn}(x_i,y_i)}{\partial y^2}\right) \\ &\quad + j\omega\sum_{j=1}^{N_x\times N_y} Z_{ij}\sum_{m=1}^{m_{\max}}\sum_{n=1}^{n_{\max}} a_{mn}\Phi_{mn}(x_j,y_j) \\ &= F(x_i,y_i), \quad \forall\, i \in [1, N_x \times N_y], \end{aligned} \tag{21}$$

$$[\mathbf{S_{NH}}]\{\mathbf{A}\} = \{\mathbf{F}\}. \tag{22}$$

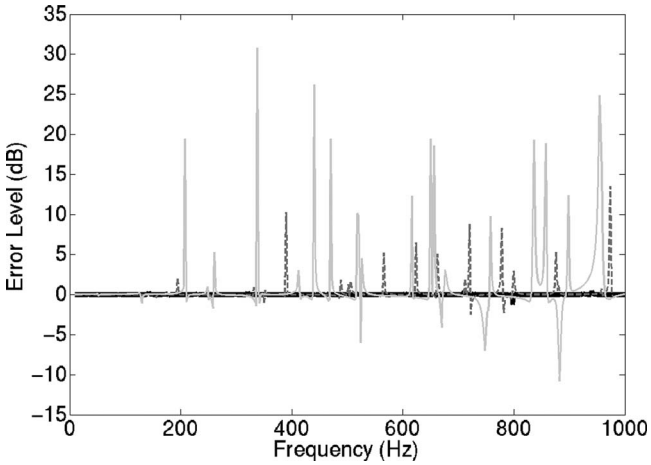

FIG. 10. Error level of the radiated sound power when $M<N$ with and without filtering. Case of a simply supported thick plate ($a/b=1$, $a/h=125$, $f_C=1.6$ kHz) with varying thickness driven by a point force at (0.33,0.38): $\alpha=0$ (black solid line), $\alpha=0.2$ (gray dashed line), and $\alpha=1$ (gray solid line).

The radiation factor (see Appendix B) of three steel plates 1×1 m^2 with $h_0=8$ mm and $\alpha=0$, 0.2, and 1, all driven by a point force at (0.33,0.38) of 1 N, is here investigated. The following results are calculated using $N=35$ and $M=12$ after filtering system (22). It can be observed that the greater alpha factor, the stronger aliasing influence, as illustrates Fig. 10 plotting the error level of mean square velocity with and without filtering. In fact, *in vacuo* modes used for homogeneous plates into light fluid become less and less valid when the plate becomes heterogeneous.

The present method allows an excellent agreement with results from Miloudi *et al.*'s work over 10 Hz–3 kHz, as illustrated in Fig. 11 where the case of higher structural heterogeneity, that is, $\alpha=1$, is treated. This observation gives credit to the generalized model, which seems to be also powerful with non-homogeneous plates.

In addition, this case shows the very good accuracy of the method proposed and the aliasing filter for supersonic modes, that is, for frequencies beyond the critical frequency; i.e., $f>1.6$ kHz here. All previous cases were validated for

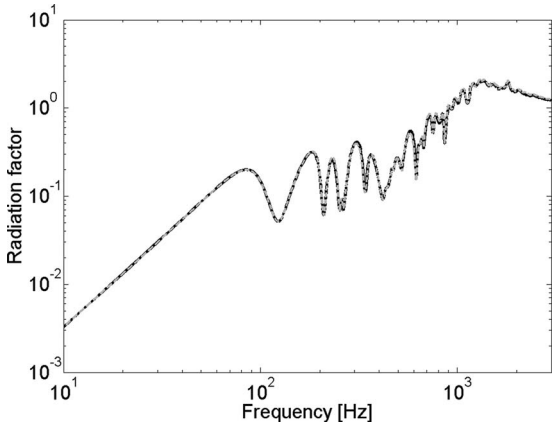

FIG. 11. Radiation factor into air by the proposed method (dashed line) compared to results from Miloudi *et al.* (solid line). Case of a simply supported thick plate ($a/b=1$, $a/h=125$, $f_C=1.6$ kHz) with varying thickness ($\alpha=1$) driven by a point force at (0.33,0.38).

cases handling only subsonic modes. The reasons were the following: On the one hand the critical frequency is too high in water because of the sound speed ($c_0=1500$ m s^{-1}) around 4.5 times higher than in air; i.e., $f_C^{\text{water}} \approx 20 \times f_C^{\text{air}}$. On the other hand the homogeneous cases immersed in air do not permit to conclude since the aliasing effect is then negligible.

Finally, one can also notice here a real advantage of this approach compared to classical ones, that is, the simplicity of changing of plate structures in just modifying the differential equation of motion.

V. CONCLUSION

An innovative formulation based on sampling and optimization has been presented. Its simplicity through the use of powerful existing algorithms was attractive, and comparison with reference results and literature in heavy and light fluids has demonstrated the power of this approach in terms of simplicity and computation time. After a plate sampling into observation points, modal optimization permits to predict accurately and above all very quickly sound radiation from simply supported baffled plates excited mechanically. The fluid-structure coupling is precisely included without neglecting mutual radiation resistances whereas the difficulties, both theoretical and numerical, of calculating the modal radiation impedances are avoided. Hence all the interest of this method.

Furthermore, the generalization to non-homogeneous plates investigated here allows one to think about new applications as sandwich plates or more generally heterogeneous structures. Extension to different boundary conditions has been emphasized and different excitations can also be envisaged. In fact, the sampling approach gives the possibility to implement deterministic excitations such as the plane wave.

Finally, the MESOP approach represents not only a powerful tool to get accurate and quick results of sound radiation from fluid-loaded structures but also a method adapted to aircraft specificities.

APPENDIX A: COLLOCATION METHOD

The collocation method used to define the radiation impedances necessary to calculate the fluid loading pressure is here described. The Rayleigh integral formulated in Eq. (2) is first split up as two integrals depending on the observation point. And then, using the discretization of the surface S_p into patches, one gets at Q_0 (point inside the patch i)

$$p_0(Q_0) = \sum_{j=1, j\neq i}^{N} \int_{S_j} j\omega\rho_0 V(Q_j) \frac{e^{-jk_0\|Q_jQ_0\|}}{2\pi\|Q_jQ_0\|} dQ_j + \oint_{S_i} j\omega\rho_0 V(Q_i) \frac{e^{-jk_0\|Q_iQ_0\|}}{2\pi\|Q_iQ_0\|} dQ_i, \tag{A1}$$

where Q_i and Q_j are points of patches i and j, respectively. The patches are assumed to be small enough so that the behavior of any point inside a patch can be approximated by its center value, that is to say the corresponding sample point. The velocity V is thus considered to be uniform inside each patch and the distance between two points from different patches is assumed to be equal to the distance between the two centers. The first integral of Eq. (A1) is consequently rewritten as

$$\int_{S_j} j\omega\rho_0 V(Q_j) \frac{e^{-jk_0\|Q_jQ_0\|}}{2\pi\|Q_jQ_0\|} dQ_j = \frac{1}{2\pi} j\omega\rho_0 V(x_j,y_j) \frac{e^{-jk_0 d_{ij}}}{d_{ij}} S_j, \tag{A2}$$

where d_{ij} is the distance between patches i and j, and S_i is the surface of the patch i.

Next, the singularity of the Rayleigh integral in case of patch's radiation on itself (i.e. emitting patch=receiving patch) can be avoided using polar coordinates in order to integrate the singularity. In that purpose, a circular patch of the same surface as the rectangular one of interest is considered; it yields

$$\oint_{S_i} j\omega\rho_0 V(Q_i) \frac{e^{-jk_0\|Q_iQ_0\|}}{2\pi\|Q_iQ_0\|} dQ_i = \rho_0 c V(x_i,y_i)(1 - e^{-jk_0 r_i}), \tag{A3}$$

where r_i is the radius of the circular patch of surface S_i.

From these results, the radiation impedance Z_{ij} corresponding to the ratio of the fluid loading pressure at patch i and the velocity at patch j is introduced and can be derived as follows:

$$Z_{ij} = \frac{p_0(x_i,y_i)}{V(x_j,y_j)} = \frac{1}{2\pi} j\omega\rho_0 \frac{e^{-jk_0 d_{ij}}}{d_{ij}} S_j, \tag{A4}$$

$$Z_{ii} = \frac{\rho_0(x_i,y_i)}{V(x_i,y_i)} = \rho_0 c(1 - e^{-jk_0 r_i}). \tag{A5}$$

APPENDIX B: VIBROACOUSTIC INDICATORS

The radiated sound power W is defined by

$$W = \frac{1}{2} \int_x \int_y \text{Re}(p_0(x,y) V^*(x,y)) dxdy, \tag{B1}$$

where Re and $*$ denote the real part and the conjugation, respectively. Using the sampling approach, which assumes a uniform behavior around each observation point, one gets a discrete formulation of the radiated sound power

$$W = \frac{1}{2} \sum_{i=1}^{N_x \times N_y} \text{Re}(p_0(x_i,y_i) V^*(x_i,y_i)) S_i. \tag{B2}$$

In the same way, the following definition of the mean square velocity $\langle V^2 \rangle$ can be formulated using plate sampling:

$$\langle V^2 \rangle = \frac{1}{2S_p} \int_x \int_y |V(x,y)|^2 dxdy \tag{B3}$$

and

$$\langle V^2 \rangle = \frac{1}{2S_p} \sum_{i=1}^{N_x \times N_y} |V(x_i,y_i)|^2 S_i. \tag{B4}$$

Finally, the radiation factor σ is defined by

$$\sigma = \frac{W}{\rho_0 c \langle V^2 \rangle S_p}. \tag{B5}$$

Perceptual assessment of quality of urban soundscapes with combined noise sources and water sounds

Jin Yong Jeon, Pyoung Jik Lee,[a] and Jin You
Department of Architectural Engineering, Hanyang University, Seoul 133-791, Korea

Jian Kang
School of Architecture, University of Sheffield, Western Bank, Sheffield S10 2TN, United Kingdom

(Received 21 March 2009; revised 30 September 2009; accepted 4 January 2010)

In this study, urban soundscapes containing combined noise sources were evaluated through field surveys and laboratory experiments. The effect of water sounds on masking urban noises was then examined in order to enhance the soundscape perception. Field surveys in 16 urban spaces were conducted through soundwalking to evaluate the annoyance of combined noise sources. Synthesis curves were derived for the relationships between noise levels and the percentage of highly annoyed (%HA) and the percentage of annoyed (%A) for the combined noise sources. Qualitative analysis was also made using semantic scales for evaluating the quality of the soundscape, and it was shown that the perception of acoustic comfort and loudness was strongly related to the annoyance. A laboratory auditory experiment was then conducted in order to quantify the total annoyance caused by road traffic noise and four types of construction noise. It was shown that the annoyance ratings were related to the types of construction noise in combination with road traffic noise and the level of the road traffic noise. Finally, water sounds were determined to be the best sounds to use for enhancing the urban soundscape. The level of the water sounds should be similar to or not less than 3 dB below the level of the urban noises.

I. INTRODUCTION

Exposure-effect relationships have been used to describe an environmental situation and to predict the effect of changes from exposure. The relationships between the exposure to noise from a single source type, such as aircrafts, road traffic, or railways, and the annoyance based on a large international data set have been reported.[1,2] Most of the previous studies applied the percentage of a population expressing high annoyance such as %HA (percentage of highly annoyed) and %A (percentage of annoyed) since Schultz proposed the concept of %HA.[1–3] The %HA is the percentage of annoyance responses that exceed a defined cutoff point. Schultz[4] used a cutoff of 72 on a scale from 0 to 100 in his synthesis to define %HA. The %A was also defined as responses in the upper 50% of the annoyance scale. Recently, some researchers have investigated the total annoyance that is caused by combined noise sources because community noises are seldom heard and are concurrent.[5–12] In addition, methods for quantifying the total annoyance caused by the exposure of a dwelling noise from combined sources were proposed. However, most of these studies only investigated transportation sources and did not deal with other urban noises such as construction noise.

Most studies evaluated the annoyance in the dwellings of the residents. The ISO 15666 standard describes the proper wording of the questions for the field survey as "at home," which means within the residents' home or outside the home, for example, in the garden or on the balcony.[13] However, outdoor environments such as public parks and plazas are also important. Contrary to home environments, the evaluation of outdoor environments is rather complicated because of the interactions between various sound sources and other acoustical and nonacoustical factors. Therefore, the evaluation of the outdoor environment has been conducted in this study based on the concept of soundscape.

The initial concept of soundscape was proposed as an attempt to construct an analytical perspective that would describe the total acoustic environment over time and across cultures.[14] Therefore, most soundscape studies concern the qualitative analysis of soundscapes. Schulte-Fortkamp and Fiebig[15] adopted the grounded theory as a sociological approach, and Berglund and Nilsson[16] proposed a tool for measuring soundscape quality by attribute profiling. Raimbault[17] also conducted qualitative judgments of an urban soundscape with nine semantic scales. However, the methods for evaluating a soundscape are different according to the purposes of the studies and the researchers, and thus it is difficult to directly compare the results of these studies. Even though many recent studies adopted the soundwalking methodology to identify the perception of an urban acoustic environment,[16,18] the standardization of the procedures for assessing soundscapes are still being discussed in the ISO TC43 SC1 WG 54 (perceptual assessment of soundscape quality).

The initial approach of soundscape studies focused on ecologically improving soundscapes as a method to reduce

[a]Author to whom correspondence should be addressed. Electronic mail: pyoungjik@daum.net

pollution. More recently, physical characteristics and mental perceptions of the auditory environment have been studied using soundscape approaches.[19] As Schulte-Fortkamp and Fiebig[15] as well as Dubois *et al.*[20] suggested, it is important to establish the interactive relationships between the sound environment and the human recognition of the positive aspects of a soundscape. In the engineering field, many studies on soundscape have attempted to control urban noises in terms of enhancing the sound environment. These attempts include the methods for physical measurement, subjective evaluation, and architectural design strategies to improve the soundscape in urban public spaces.[21] One of the proposed solutions to improve the soundscape in urban spaces is to introduce natural sounds to mask urban noises such as road traffic and construction noises. Although classifying the characteristics of a soundscape in an open public space is important, the active treatment of the sound environment is often needed in order to improve the acoustical quality. Among the various kinds of natural sounds, the sound of water from water features such as fountains was found to be the most applicable in parks or city squares to provide pleasantness.[21] This is one of the reasons why fountains or sculptures with water streams are easily found in open public spaces of many cities. Watts *et al.*[22] studied characteristics of water drop sounds in terms of the noise masking effects. However, little is known about the effective sound level of water sounds in various situations of urban soundscapes.

In this study, the noise annoyance of typical urban spaces that had construction as well as road traffic noises was investigated using field surveys through soundwalking. The methods used in previous community noise studies were adopted, such as the %HA and %A. Analysis was also made using the semantic scales for evaluating the soundscape quality. Laboratory auditory experiments were then conducted in order to quantify the total annoyance that is caused by both construction and road traffic noises. The methodologies were then applied to the actual conditions of urban soundscape, which included the sounds of water along with other noise sources. Sound preference tests were conducted with varying levels of water sounds, considering individual and combined noise sources. The results of the experiment provided optimum combinations of water sounds and urban noises.

II. FIELD SURVEY THROUGH SOUNDWALKING

A. Methodology

1. Site selection

Field surveys were performed in 16 urban sites in Seoul and Bundang (the biggest satellite city of Seoul). These sites were chosen based on the fact that the dominant noise sources in the area were both road traffic noise and construction noise, and because the number of complaints concerning the noise from the construction work had significantly increased in recent years. Eight sites were located in residential areas, and the other sites were in open public spaces such as the streets, parks, and squares. The selected construction sites had different noise sources (pile driving, drill rig, excavator, hammering, and so on) according to the construction procedure.

2. Evaluation of soundscapes

In this study, the evaluation of the soundscapes is based on both a quantitative approach and a qualitative approach through soundwalking. The exposure-effect relationship is derived from the quantitative approach using a general method of analysis that is linked with community noise. The use of semantic scales will provide various subjective perceptions including comfort and pleasantness as well as annoyance, and can also be applied to the process of characterization of urban soundscapes. The exposure-effect relationship can be explained by the results of the qualitative analysis, and the subjective perceptions can also be connected with the annoyance level.

Soundwalking was employed as a method to evaluate and describe the urban sound environment. In previous studies,[16,18] soundwalking was carried out along a number of sites; however, the soundwalking in this study was conducted at each site separately. It was conducted in silence, and the participants were asked to concentrate on what they could hear as they walked and observed the urban environment. After soundwalking for 30 min at each site, the participants were asked to evaluate the annoyance of the noise sources and the quality of the soundscape.

All the field surveys were conducted in the afternoon (13:00–18:00) based on the assumption that outdoor activities are most frequent during this period. The field survey continued for 4 days (four sites per day), with 15 subjects (seven female and eight male) aged 20–30. All the subjects participated all the soundwalks at the same time; thus their exposure would be about the same.

3. Questionnaire

The ICBEN team 6 recommends the use of two questions to measure annoyance reactions in order to be able to make comparisons between social surveys, so that both a 5-point verbal scale and an 11-point numerical scale were used for the quantitative analysis of the urban soundscapes in terms of annoyance.[13] The questions addressed in the ISO 15666 were translated into Korean and the standardized noise annoyance modifiers (in Korean) were also used in the five-point verbal scale questions.[23]

The questionnaire included questions to assess road traffic and construction noises, as well as general questions about the participants themselves. The questions were arranged in three basic sections. The first section sought to obtain their annoyance of the noise sources, which contained three questions that aimed to assess their overall impression of the sound environment and to obtain responses to the road traffic and construction noises separately. In the second section, ten semantic scales describing the quality of the soundscape were used for qualitative judgments of the urban soundscapes. The ten semantic scales were comfort, quiet, harmonious, soft, monotonous, weak, light, pleasant, unique, and warm. They were selected based on a review of previous studies on semantic differential descriptors of sound environments.[16,17] A pair of descriptive adjectives defined the semantic words used, with ten words on the right and their antonyms on the left. On a seven-point scale, three points

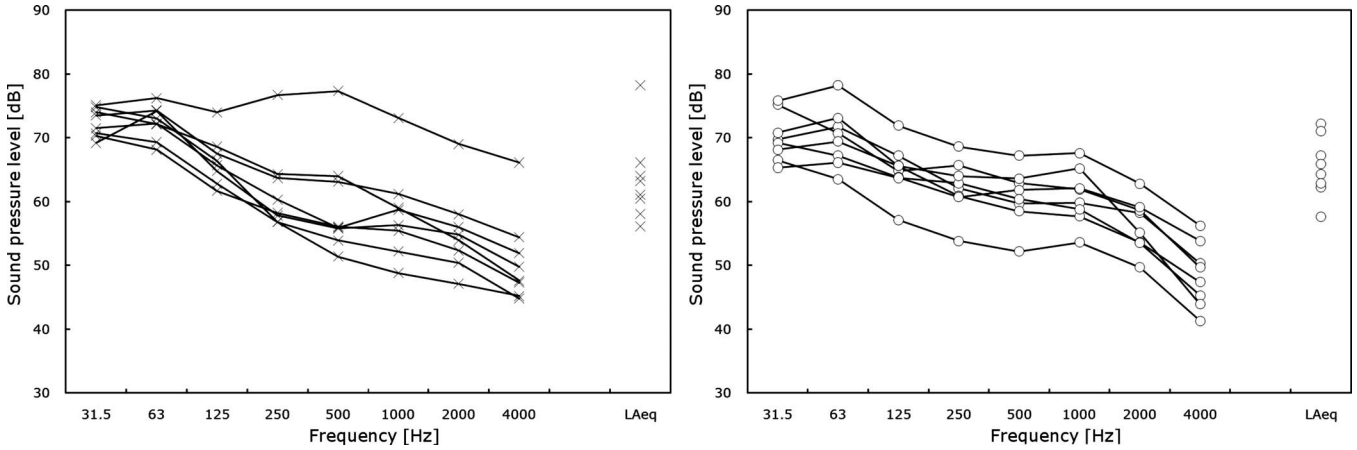

FIG. 1. Spectra of 30-min measurements conducted in eight residential areas (left) and in eight open public spaces (right).

mean the participant had a very strong impression of the soundscape. The third section dealt with demographic data (age and gender), dwelling type, health condition, acoustic comfort, and loudness. Acoustic comfort and loudness to the urban soundscape were evaluated using an 11-point numerical scale.

4. Noise measurement

In this study, a 30-min L_{Aeq} was measured by one subject during the soundwalk. Thus, the recording corresponds with the actual exposure. The sound pressure level (SPL) measurement was conducted using a binaural microphone (B&K type 4101), and the video recording was also made using a camcorder (Sony DCR-HC90) in order to present visual information of the soundscape during the auditory test (see Secs. III and IV).

The measured spectra are shown in Fig. 1. Low frequency components were dominant in most sites, but one site had significant high frequency components due to the hammering on metal and motor vehicles and this occurred in an open public space. The 30-min L_{Aeq} of the case study sites ranged from 54 to 78 dB.

B. Results and discussions

1. Quantitative analysis results

Annoyance responses to road traffic and construction noises were obtained from a 5-point verbal scale and an 11-point numerical scale that were later translated into a scale from 0 to 100 for the assessment of %HA and %A. The exposure-response relationships that were obtained as a function of L_{Aeq} from the 5-point verbal and 11-point numerical scales are shown in Fig. 2. The curves presented in Fig. 2 were obtained through quadratic ordinary least-squares regression. Questions in the 11-point numerical scale caused less annoyance than the 5-point verbal scale in terms of %HA. It is interesting to note that the participants rarely chose "8," "9," and "10" in the 11-point scale even though they were exposed to higher noise levels than noise level of "7" point they selected. The curve from the 5-point verbal scale shows that the %HA is 0 at around 60 dB but the curve from the 11-point numerical scale shows that the %HA is 0 at around 63 dB.

The %A curves from the 5-point scale and the 11-point scale were almost the same, which is different from the %HA. This indicates that the percentage of responses that select "3," "4," and "5" in the 5-point scale is almost same to

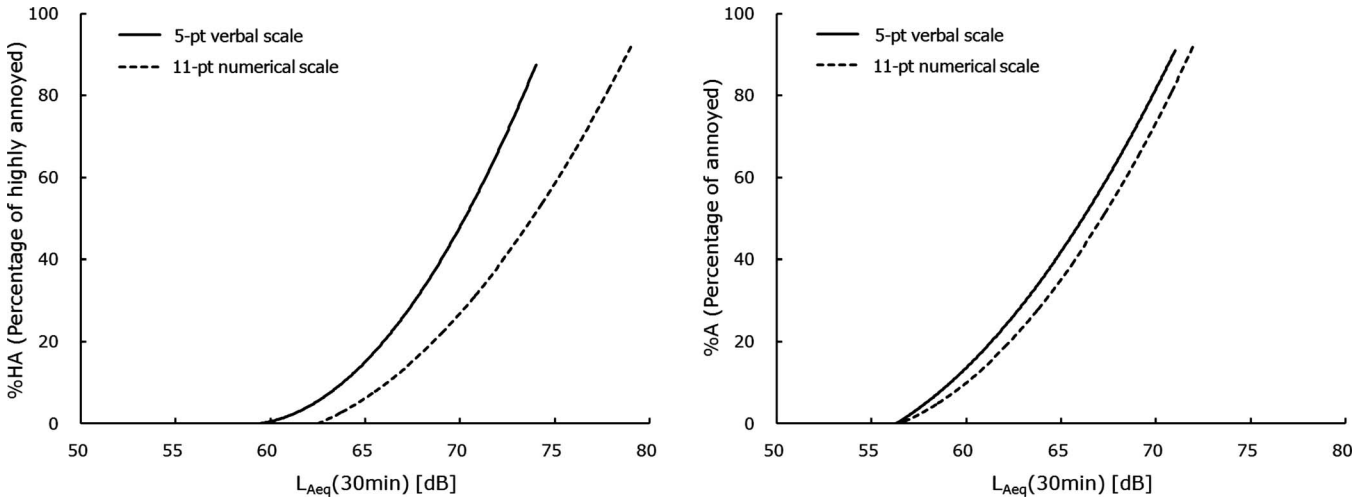

FIG. 2. The percentages highly annoyed (%HA) and annoyed (%A) as a function of L_{Aeq}.

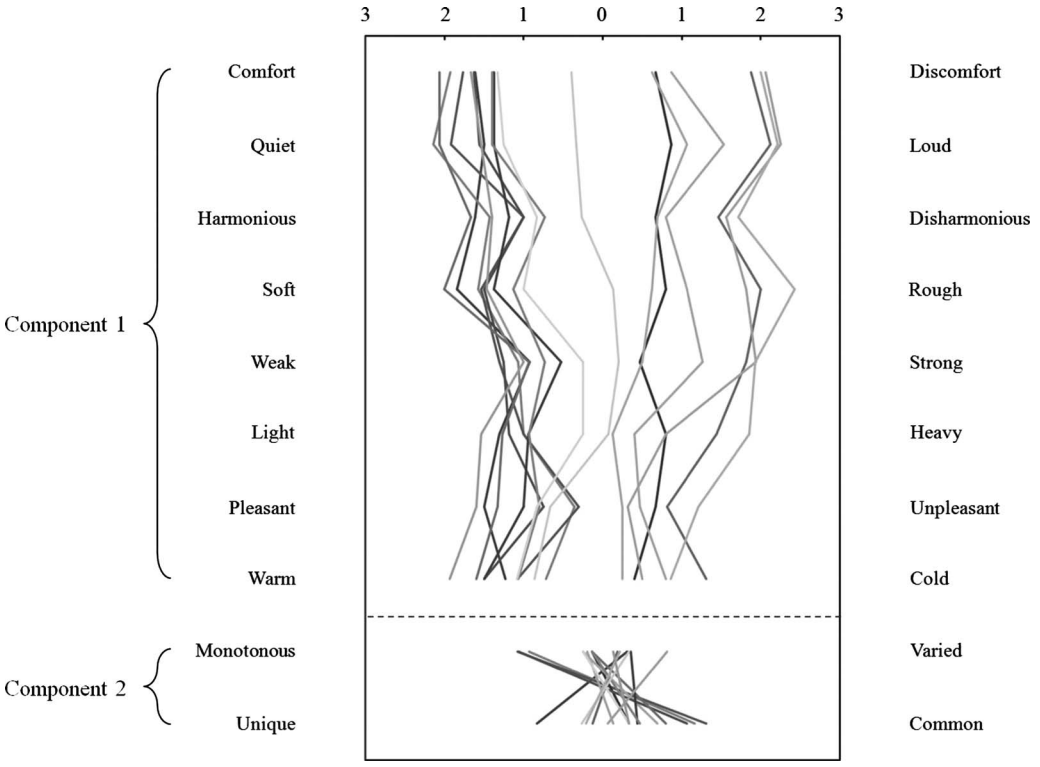

FIG. 3. Semantic differentials for the perception of urban soundscape, where each line corresponds to the mean rating for each area.

the percentage of responses that select exceeding "5" in the 11-point scale. From the obtained exposure-response relationships, the fraction of (highly) annoyed persons can be estimated based on the noise exposure. 50% of persons were highly annoyed when the short-term noise exposure was around 69–73 dB in urban spaces, and were annoyed in the situation with around 66–67 dB.

The differences of the %HA curves for the 5-point verbal and the 11-point numerical scales were statistically significant ($p<0.01$). This indicates that annoyance responses would be different according to the evaluation scale used. Therefore, the evaluation scale should be chosen appropriately in accordance with the purpose of the survey and the participants. In this study, most of the participants responded that the 11-point numerical scale was much easier to evaluate the annoyance than the 5-point verbal scale. In contrast to the results of the %HA, the %A curves from the two scales were not statistically different.

2. Qualitative analysis results

The results of the semantic differential test of urban soundscape using adjectives are shown in Fig. 3. These ten adjectives were grouped into two components through factor analysis. Component 1 included eight adjectives: comfort, quiet, harmonious, soft, weak, light, pleasant, and warm. Only two of the adjectives (monotonous and unique) were categorized into component 2. Components 1 and 2 explained 79% and 15% of the total variance, respectively. Component 1 is related to the comfort, loudness, and pitch sensations, and component 2 represents the temporal variation and the characteristics that are comparable with common urban soundscapes. The variation in subject scores for component 1 was much greater than that of component 2. This indicates that the adjectives of component 1 are more useful to characterize the soundscape than those of component 2. It was expected that the uniqueness of each site can be evaluated by a pair of adjective, "unique-common," but the differences between sites were not large in terms of uniqueness. This is because the nonacoustical components as well as dominant noise source of the sites were similar.

Table I presents the correlation coefficients between each component and the measured sound level, and between each component and the subjective evaluation results that were obtained from the field survey. Both component 1 and component 2 were correlated with the sound level and the subjective evaluation results, but component 1 had much higher correlation coefficients than component 2. Correlation coefficients between component 1 and the sound level, loudness, and annoyance were all positive values but the correlation coefficient between component 1 and the acoustic comfort was a negative value. Contrary to component 1, component 2 had negative correlation coefficients with the sound level, loudness, and annoyance, and a positive correlation coefficient with the acoustic comfort.

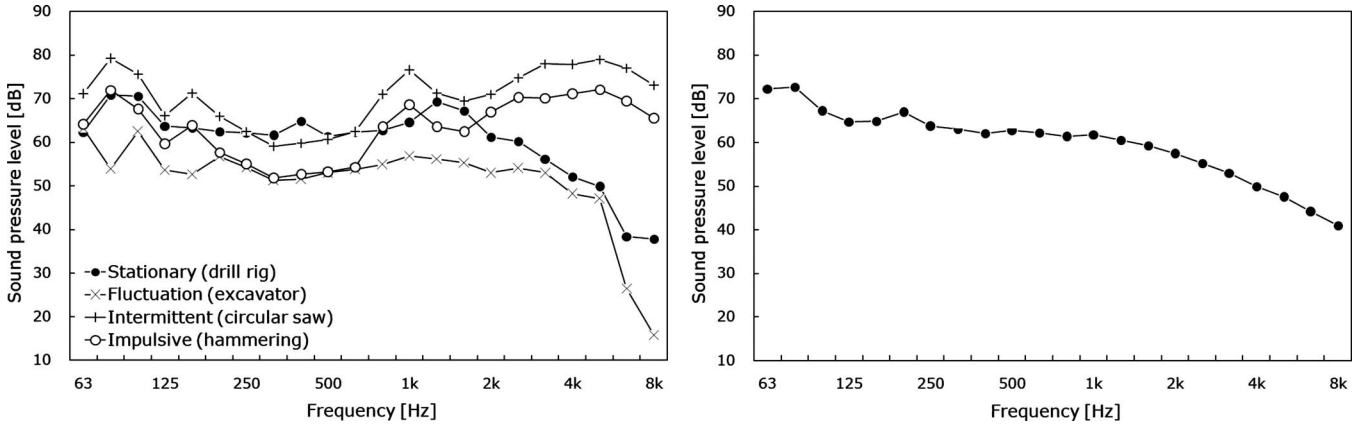

FIG. 4. Spectra of recordings: construction noises (left) and road traffic noise (right).

The difference between semantic scores of residential areas and those of open public spaces was not statistically significant. Perhaps this is because the dominant sound sources were road traffic and construction noises for nearly all the sites, so that the semantic scales used in this study were not sufficient to distinguish the differences between each soundscape. Another reason is that the subjects knew that road traffic and construction noises were the focus in the questionnaire, even though the semantic differentials concerned the appreciation of the soundscape as a whole. Therefore, it would have been better to add more questions to the questionnaire concerning the perception of other sound sources, and further multicultural and multidisciplinary research is needed in order to account for the diversity of urban soundscapes.

III. LABORATORY EXPERIMENT: ANNOYANCE FROM COMBINED NOISE SOURCES

While the total annoyance level of urban spaces with combined noise sources was obtained by conducting field surveys, as described above, it is not sufficient to investigate the effect of individual noise on the total annoyance because the type of construction noise and the noise levels of individual noises could not be controlled. Therefore, an auditory experiment was conducted under laboratory conditions in order to examine the effects of individual noises on the total annoyance.

A. Methodology

1. Recording of stimuli

Noises were recorded from nine construction sites in Korea and the UK. The sound recordings were made binaurally by using the artificial head (Neumann KU100) and ear microphones (type 4101, B&K). Recorded construction noises were classified into four groups, namely, stationary, fluctuation, intermittent, and impulsive sound, according to the temporal characteristics used in a previous study[24] and in the ISO 1996-1.[25] The noises from power generator and drill rig were classified into stationary sound, and the noises from excavator and circular saw were classified into fluctuation and intermittent sound, respectively. Hammer and concrete break noises were categorized to impulsive sound. The duration of each recorded stimulus varied from 15 s to 5 min, and the noise level ranged from 55 to 93 dBA in terms of L_{Aeq}. Road traffic noise with small fluctuations in noise level was also recorded. The road width was 40 m, and the average vehicle speed was around 60 km/h. Frequency characteristics of the measured construction noises representative of stationary, fluctuation, intermittent, and impulsive types are shown in Fig. 4, along with that of the measured road traffic noise.

2. Experimental design

The auditory experiments consisted of two parts, namely, the evaluation of individual noises and the evaluation of the combined noise sources. In the first part, the annoyance to individual noises including road traffic and the four types of construction noise was evaluated. The duration of the individual noises was 30 s, and their L_{Aeq} varied from 40 to 90 dBA, with an interval of 5 dB. The levels were adjusted in amplitude without the spectral adjustment to the stimuli, resulting similar spectral characteristics of the stimuli at different levels. A total of 55 stimuli for four types of construction noises and road traffic noise were presented to the subjects and the duration of the test for individual noises was around 30 min for each subject. The outline of the auditory experiment for the combined noise sources is shown in Table II. The independent variables were (1) the types of construction noise (stationary, fluctuation, intermittent, and impulsive), (2) the level of the construction noises and road traffic noise, and (3) the number of construction noise events. The number of events was expressed as the number of construction noises during a 1-min period. The L_{Aeq} of road traffic noise were fixed at 55 and 75 dBA corresponding to the noise exposure of most urban spaces.[26,27] Another reason for

TABLE II. Outline of the auditory experiment for combined noise sources, where the levels of the stimuli were adjusted according to the L_{Aeq} for 1 min.

Road traffic (dB)	Construction (stationary, fluctuation, intermittent, and impulsive) (dB)	No. of events (fluctuation, intermittent, and impulsive construction noise)
55	40, 50, 60, 70	2, 4, 6
75	60, 70, 80, 90	2, 4, 6

using this range was that approximately 40% of the EU population is exposed to road traffic noise with L_{Aeq} exceeding 55 dBA in the daytime, and 20% are exposed to levels exceeding 65 dBA.[28] The number of events for nonstationary construction noise (fluctuation, intermittent, and impulsive) was controlled to occur two, four, or six times, and the duration of each construction noise event was 10 s, while the duration of road traffic noise was 1 min. The levels of the stimuli were adjusted as a L_{Aeq} for 1 min regardless of the number of events. All 80 stimuli were randomly assigned to eight sessions and the duration of the test for combined noise sources was around 90 min for each subject.

3. Procedure of subjective evaluation

Subjects rated their level of annoyance when the individual noise or combined noise sources were presented to them. They were informed about the purpose of the experiments and were instructed about how to use the 11-point numerical scale. They were asked to respond to the following question when a binaural signal was played back to them through headphones (Sennheiser HD 600): *Which stimuli would be more annoying if you were exposed to it in the urban spaces?* The stimuli were presented to the subjects in the exact same order, and construction and road traffic noises were presented simultaneously. A visual image of an urban space was shown to the subjects before the auditory tests began.

Twenty subjects aged 24–30 participated in the experiment. Before the experiment, the hearing threshold level of the participants was tested with the use of an audiometer (Rion AA-77). The results showed that all of the participants had normal hearing. The experiments were conducted in a testing booth (4×3 m^2), where the background noise level was approximately 25 dBA.

B. Results

1. Individual noise sources

Annoyance ratings (with 0 as "not at all" and 10 as "extremely") for individual noises are plotted in Fig. 5 as a function of L_{Aeq}. The annoyance for both road traffic (T) and construction noises (C) increased with the increase in the noise level, as expected. The correlation coefficients between L_{Aeq} and the annoyance ratings were 0.96 for road traffic ($p < 0.01$) and 0.96–0.98 for the construction noises ($p < 0.01$). A significant difference between the annoyance ratings of the five stimuli was only found between the road traffic noise and the stationary construction noise ($p < 0.05$). The former was rated slightly higher than the latter. This result is somewhat different from the results of a previous study,[29] which showed that road traffic noise was rated lower than metal construction noise, perhaps because the metal construction noise included various noises such as hammering, banging, drilling and grinding.

2. Combined noise sources

The total annoyance ratings for stationary construction noise combined with road traffic noise are plotted in Fig. 6, where two cases are considered, with L_{Aeq} of road traffic

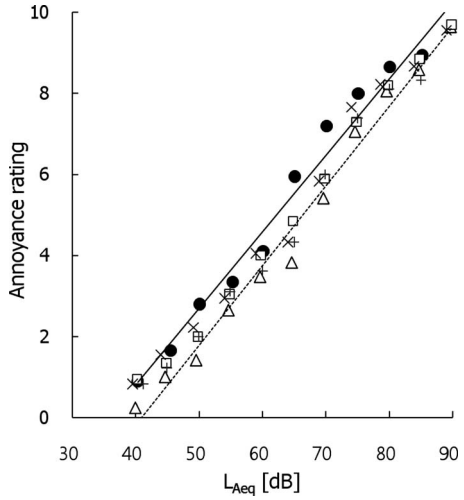

FIG. 5. Annoyance ratings for individual noises; road traffic noise and construction noises: (●) road traffic noise, (□) stationary, (□) fluctuated, (+) intermittent, (×) impulsive construction noise, (—) regression lines for road traffic noise, and (…) regression lines for stationary construction noise.

noise fixed at 55 and 75 dBA, respectively. The linear regression function (see Fig. 5) for C (stationary) in isolation and the interpolated annoyance caused by T only at L_{Aeq} of 55 and 75 dBA are shown in Fig. 6 as references. The total annoyance rating increased with the increase in the L_{Aeq} of construction noise. When the L_{Aeq} of road traffic noise was 55 dBA, the total annoyance ratings for the combined noise sources were significantly higher than the ratings for the more annoying sound in the combination when the L_{Aeq} of construction noise were 50, 60, and 70 dBA, respectively ($p < 0.05$). For the combination with construction noise at an L_{Aeq} of 60 dBA and road traffic noise at an L_{Aeq} of 55 dBA, expressed below as C60+T55 for the sake of convenience, the total annoyance ratings was considerably higher than the ratings for the more annoying sound (C60). But the difference between the annoyance ratings for the combined noise sources and the road traffic noise was not statistically signifi-

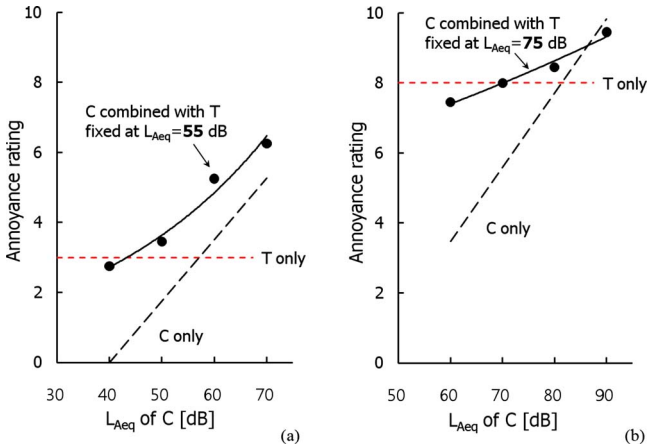

FIG. 6. (Color online) (a) Total annoyance for C (stationary) combined with T at an L_{eq} of 55 dBA. (b) Total annoyance for C (stationary) combined with T at an L_{eq} of 75 dBA. The solid lines represent the regression lines of the total annoyance.

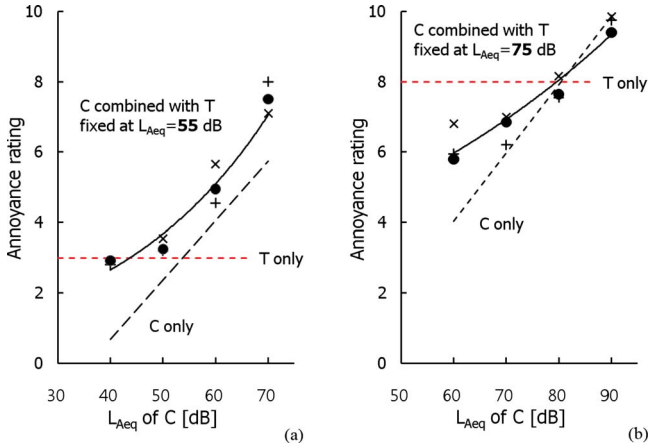

FIG. 7. (Color online) (a) Total annoyance for C (impulsive) combined with T at an L_{eq} of 55 dBA. (b) Total annoyance for C (impulsive) combined with T at an L_{eq} of 75 dBA [(●) two times, (+) four times, and (×) six times]. The solid lines represent the regression lines of the total annoyance.

cant in the case of C40+T55 because the L_{Aeq} for the combined noise sources (C40+T55) and the road traffic noise (T55) was almost the same.

When the L_{Aeq} of road traffic noise was 75 dBA, the total annoyance ratings for the combined noise sources were higher than the ratings for the more annoying sound in the combination only when the L_{Aeq} of the construction noise was 80 dBA ($p<0.05$). Under other conditions, the total annoyance for C60+T75 was rated lower than the more annoying sound, T75, ($p<0.05$). This is because that the construction noise with lower levels than road traffic noise affected total annoyance when the subjects can hear the construction noise. A previous study also showed that the ratings for combined annoyance were often lower than the annoyance caused by one of the sources alone.[11] The differences between the annoyance ratings for C70+T75 and the more annoying sound (T75), and C90+T75 and the more annoying sound (C90) were not significant.

The total annoyance ratings for the three nonstationary construction noises (fluctuated, intermittent, and impulsive) combined with road traffic noise are also obtained. The results of nonstationary construction noises showed a similar tendency; thus only the total annoyance ratings for the impulsive sound is plotted in Fig. 7, where two cases are again considered, with L_{Aeq} of road traffic noise fixed at 55 and 75 dBA. The number of nonstationary construction noise events varied and occurred two, four, or six times. The regression line for the construction noise was obtained by using the mean annoyance ratings for different numbers of events. The total annoyance ratings with the road traffic noise of 55 dBA were similar to the results of stationary construction noise. In the combinations of C50+T55, C60+T55, and C70+T55, the total annoyance ratings for the combined noise sources were significantly higher than the ratings of the more annoying sounds (T55, C60, and C70, respectively, $p<0.05$). But the difference between total annoyance ratings for C40+T55 and the more annoying sound (T55) was not statistically significant.

However, the total annoyance ratings with a higher road traffic noise of 75 dBA were somewhat different from the results of the stationary construction noise, suggesting the effects of temporal characteristics of the construction noise. In the combinations of C60+T75 and C70+T75, combined noise sources were rated significantly lower than the more annoying sound, T75 ($p<0.01$). This is also because the subjects can hear the impulsive sounds with lower levels in the specific regions where the level difference between road traffic and construction noises slightly decreased, and the impulsive sounds affected the rating of combined noise source. In the cases of C60+T75 and C70+T75, the difference between ratings for combined noise sources and more annoying sound much increased compared with the stationary noise. This is because it was easier to distinguish the impulsive sounds from the combined noise sources than stationary sounds. The total annoyance ratings for C80+T75 and C90+T75 were not statistically different from the ratings for the more annoying sound (T75 and C90).

The total annoyance was expected to increase as the number of events increased for the three kinds of nonstationary construction noises.[30] However, it can be seen from Fig. 7 that this is not the case. This is perhaps because the period of the noise exposure and construction noise is not enough for the awareness of the number of events.

The results of the auditory experiment indicate that the total annoyance ratings were almost the same or higher than that of the more annoying sound when the road traffic noise level was 55 dBA regardless the types of construction noise and level differences between road traffic and construction noises. Therefore, the level of construction noise should be reduced for the decrement of annoyance from combined noise sources. However, the total annoyance ratings were lower than that of the more annoying sounds in the case of combined noise sources with road traffic noise of 75 dBA when the level of construction noise was lower than that of road traffic noise (−15 dB for stationary, and −15 and −5 dB for impulsive sound) Thus, it is more effective to reduce the level of road traffic noise in order to decrease the total annoyance. These results would be useful for establishing the noise policy in urban spaces with combined noise sources.

IV. ENHANCEMENT OF SOUNDSCAPE USING WATER SOUNDS

In Secs. II and III, annoyance responses were investigated by applying the combined noises of urban open public spaces with the concept of soundscapes. In this section, the possibilities of applying water sounds, which usually exist in open public spaces, are examined to clarify its effects on soundscape enhancement. In other words, Secs. II and III could be regarded as the investigation of the present situation of urban soundscapes, and this section would be for one of the possible methods to overcome the problems revealed.

Natural sounds were introduced in this study in order to enhance the urban soundscape with sound masking effect. The selection of sound masker for the road traffic and construction noises, dominant sound sources of urban spaces, was conducted through auditory experiments. Appropriate signal to noise ratios (SNRs) between the sound masker and the urban noises were also investigated. Finally, the effect of

a sound masker was validated with experiments that applied the maskers to the combined noise sources with various sound levels.

A. Selection of natural sounds as maskers

Nine stimuli that cover various kinds of natural sound were introduced to investigate whether any of them were effective as maskers of urban noises. They were selected from a commercial sound effects CD (Sony Pictures Sound Effects Series), which included sounds called "Waterfall," "Rainfall', "Stream," "Waves of lake," "Birds in forest," "Birds in port," "Insects," "Bell of church," and "Wind." Spectral characteristics of the natural sounds were not modified, but their levels were adjusted for the experiments. Road traffic and construction noises were again chosen as representatives of urban noise. The road traffic noise used in Sec. III was applied in this experiment, and construction noises including various construction machineries were recorded at one of the field survey sites.

An auditory experiment was designed to determine which natural sounds were able to enhance the urban soundscape. The paired comparison method was adopted to evaluate the sound preference. 36 pairs consisting of natural sounds and road traffic noise were prepared and another 36 pairs were also made with natural sounds and construction noise. A typical stimulus is that the sounds of Rainfall and road traffic noise were presented to the subject simultaneously during the first 7 s and then after 1 s of silence, the sounds of Stream and the road traffic noise were presented in the same manner. After the presentation of each pair, subjects were asked to respond to the following question: *Which stimuli do you prefer if you were exposed to it in the urban space*? The SPL of natural sounds were 58 and 62 dBA for road traffic and construction noises, respectively, by considering the actual sound level of these noises. Each pair of stimuli was presented in a random order separated by an interval of 3 s, and a visual image of the actual site was presented to the subjects before the auditory tests began. Twelve subjects aged 20–30 participated in this experiment, and the stimuli were presented through headphones (Sennheiser HD 600) in a sound proof chamber.

The results of this auditory experiment are plotted in Fig. 8, where a larger value indicates a higher preference. The 11 subjects who passed the consistency test showed consistent judgments within a 95% confidence interval. This test also indicated that there was a significant ($p<0.05$) agreement among the subjects. As shown in Fig. 8, Stream and Waves of lake sounds were highly preferred with both road traffic and construction noises, which can therefore be used as an effective natural sound to mask urban noises. The sounds of Rainfall, Birds in port, and Wind showed relatively lower scale values of preference.

B. Effect of SNR on the preference of water sounds

Even though specific water sounds were determined as preferable sounds in urban spaces, a substantial difference in sound level between the water sound (masker) and the urban noise (masker) was needed to clarify the effect of the sound masking. Therefore, appropriate signal to noise ratios between the natural sounds and the urban noises were investigated as the next step. The road traffic noise and construction noises used above were again applied, and the two kinds of water sound, Stream and Waves of lake, were used as masker. No spectral correction was applied to the sound stimuli.

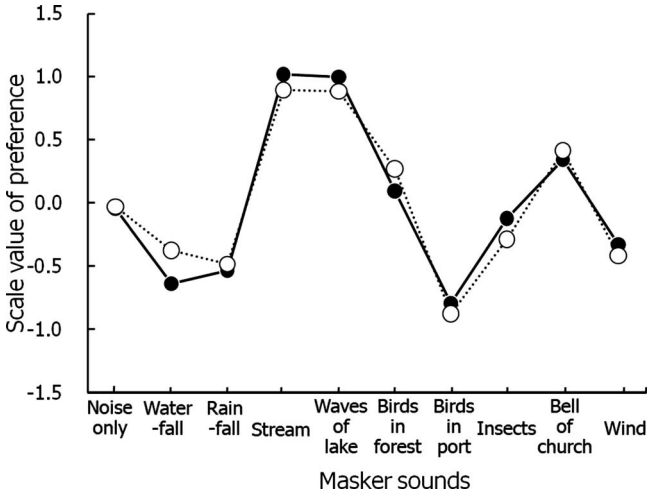

FIG. 8. Preferred natural sounds as masker of urban noises [(●) road traffic noise and (○) construction noise].

The SPL of the Stream and Waves of lake varied from 52 to 64 dBA in a step of 3 dB in the case of the road traffic noise of 58 dBA, and varied from 56 to 68 dBA in a step of 3 dB for the construction noise of 62 dBA in terms of L_{Aeq}. The paired comparison method was again employed in order to examine the effective level difference between the water sounds and the urban noises. Ten subjects aged 20–30 evaluated the sounds through headphones (Sennheiser HD 600) in a sound proof chamber.

The scale values of preference are shown in Fig. 9, where the nine subjects who passed the consistency test showed consistent judgments within a 95% confidence interval. This test also indicated that there was a significant ($p<0.05$) agreement among subjects. As shown in Fig. 9, the scale value was the highest when the relative SPL of Stream and Waves of lake was −3 dB compared to the road traffic noise. In the case of the construction noise, this value is −3 to 0 dB. It is interesting to note that the scale value decreased rapidly when the level of the water sound increased, perhaps

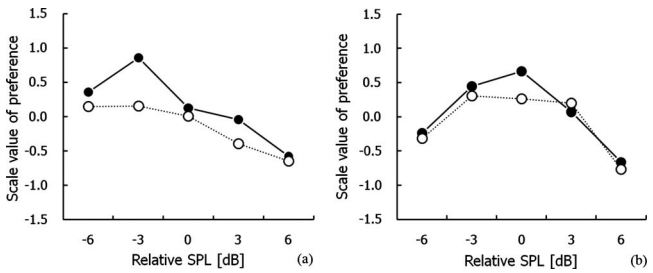

FIG. 9. (a) Scale value of preference according to relative presentation level of sounds of waters and road traffic noise. (b) Scale value of preference according to relative presentation level of sounds of waters and construction site noise [(●) Stream and (○) Waves of lake].

due to the increase in the total sound level. In other words, the results suggest that the water sounds are most effective to enhance the urban soundscape when the water sound is with the same level or 3 dB lower than the urban noises.

C. Effect of water sounds on combined noise sources

The effect of water sounds for the improvement of urban soundscape was examined by applying them to the combined urban noises, which reflects the auditory situation more realistically. An auditory experiment was performed in order to validate the results that were obtained in Secs. II and III using soundwalking and quantitative methodologies.

1. Recording and measurement of soundscapes

Two squares, one at the Town Hall and the other at the Railway Station, in Sheffield, UK, were chosen as the sites for the soundscape evaluations. The square in front of the Town Hall, which is known as the Peace Gardens, was enclosed by a two-lane motorway and several construction sites. Therefore, the Peace Gardens was suitable to investigate soundscape of urban spaces in terms of noise types. Aside from the urban noises, the Peace Gardens was also appropriate in examining the effects that water sounds have on urban noise. A fountain was located at the center of the square and there were several water features that were positioned at each of the entrances into the square. In the other site, the Sheaf Square in front of the Railway Station, there was a noise barrier integrated with a water stream and large fountains to mask the traffic noise from a busy road.

The sound recordings were made binaurally by using an artificial head (Neumann KU100) and a digital recorder (Fostex FR-2). Nine positions were chosen in the Peace Gardens for individual sound recordings. Urban road traffic noise (two positions), water sounds (four positions), babble (one position), and construction noise (two positions) were all recorded. The duration of the recordings was approximately 5 min at each position. In addition, video recordings were carried out along a path by using a video camcorder. The path was divided into three sections in order to experience the road traffic, water and babble, and construction noises, respectively. The total duration of the video recording was around 9 min, allowing 3 min for each section. Even though the video recording contained the audio track, only the video track was applied, and the sound recordings used in the stimuli were made by using the artificial head. This audiovisual stimulus was applied to the auditory tests prior to the main tests as a means to train the subjects. At the Railway Station Sheaf Square, ten positions were selected to record the road traffic noise (three positions) and water sounds (seven positions).

2. Auditory experiments

The road traffic noise and water sound recorded at the Sheaf Square, and the construction noise and babble noise recorded at the Peace Gardens were used as sound stimuli. The SPLs of each stimulus varied in the ranges of 76–85, 76–85, 66–75, and 78–87 dBA in a step of 3 dB for road traffic, water, babble, and construction noises, respectively.

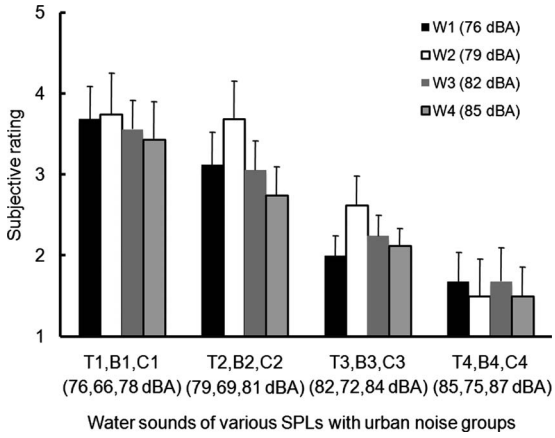

FIG. 10. Subjective rating of the combined noise sources and water sounds.

The levels of stimuli were determined by considering the actual sound levels in the case study sites. In total, 16 stimuli were used, where, for example, T1 indicates the stimulus of road traffic noise of 76 dBA, and W4 represents the water sound of 85 dBA. The duration of each stimulus was 3 s.

Auditory experiments were conducted under laboratory conditions for evaluating the effect of water sounds on combined noise sources of urban soundscapes. In order to simulate the combined noise sources, the road traffic, babble, and construction noises were combined as "T1, B1, C1," "T2, B2, C2," "T3, B3, C3," and "T4, B4, C4." Then, the water sounds with four levels were combined with the above four signals, such as "T1, B1, C1, W1," "T1, B1, C1, W2" to "T4, B4, C4, W3," and "T4, B4, C4, W4," forming 16 stimuli with combined noise sources. The overall SPLs of "T1, B1, C1," "T2, B2, C2," "T3, B3, C3," and "T4, B4, C4" were around 80.3, 83.3, 86.3, and 89.3 dBA, respectively; the SPL of the combinations with water sound was around 81.7 dBA, the lowest, in the case of T1, B1, C1, W1 and around 90.7 dBA, the highest, in the case of T4, B4, C4, W4. Each stimulus was presented to the 20 subjects through a headphone (AKG K-414P and Sennheiser HD 600). The subjects rated the preference to each combination of sounds by using a five-point scale, with 1 as not at all and 5 as extremely according to the following question: "Please, rate the sounds on your preference according to the 5-point scale."

3. Results and discussions

The preference ratings for urban noises combined with water sounds are plotted in Fig. 10. It can be seen that the preference for combined sources generally decreased with the increase in the noise level. At each combination of road traffic, babble, and construction noises, the effect of water sounds was different according to its SPL. Combined noise sources with a water sound of 79 dBA were evaluated as significantly higher than those with other water SPL in the cases of T2, B2, C2 and T3, B3, C3 ($p<0.01$). In other words, a water sound of 79 dBA was most effective in enhancing the urban soundscape when the SPL of the road traffic, babble, and construction noises varied from 79–82, 69–72, and 81–84 dBA in the combinations of T2, B2, C2 and T3, B3, C3, respectively. The effect of water sounds was

the highest in the combination of T2, B2, C2, where the level of water sounds was similar or slightly less than that of the dominant urban noises (road traffic and construction noises). This confirms the results of Sec. IV B that the urban soundscape can be enhanced when the level of the water sound is similar to or not less than 3 dB below the level of urban noises. However, the positive effects of the water sound on the urban soundscape became less when the overall level of the combined noise sources was around 90 dBA.

V. CONCLUSIONS

The total annoyance caused by combined noise sources in an urban space has been evaluated using field surveys and laboratory experiments. In order to reduce the annoyance of urban noises, the masking effects of various kinds of natural sounds have been examined, considering appropriate sound level. The study focused on the relationships between different sound sources without considering spectral variations in noises at different levels. The main conclusions are as follows.

- The synthesis curves are given for the relationship between the annoyance ratings for urban noises and short-term noise exposure. It was estimated that 50% of people were highly annoyed when the short-term noise exposure was around 70–73 dBA in urban spaces and were annoyed in the situation with around 66–67 dBA.
- From the results of semantic scales, it was revealed that the main factor was related to the acoustic comfort and loudness, and can be represented by such adjectives as "comfort," "quiet," and "weak."
- The annoyance ratings for construction noise in combination with road traffic noise were related to the types of construction noise (stationary and nonstationary) and different road traffic noise levels (55 and 75 dBA).
- The water sounds such as "Stream" and "Waves of lake" sounds were selected as an effective natural sound to mask urban noises. The level of the water sounds should be similar to or not less than 3 dB below the level of the urban noises.

Interaural coherence for noise bands: Waveforms and envelopes

Neil L. Aaronson[a] and William M. Hartmann
Department of Physics and Astronomy, Biomedical and Physical Sciences Building, Michigan State University, East Lansing, Michigan 48824

(Received 17 June 2008; revised 10 December 2009; accepted 14 December 2009)

This paper reports the results of experiments performed in an effort to find a formulaic relationship between the interaural waveform coherence of a band of noise γ_W and the interaural envelope coherence of the noise band γ_E. An interdependence described by $\gamma_E = \pi/4 + (1-\pi/4)(\gamma_W)^{2.1}$ is found. This relationship holds true both in a computer experiment and for binaural measurements made in two rooms using a KEMAR manikin. Room measurements are used to derive a measure of reliability for the formula. Ultimately, a user who knows the waveform coherence can predict the envelope coherence with a small degree of uncertainty.

I. INTRODUCTION

The waveform interaural coherence is defined as the maximum of the interaural cross-correlation function for values of lag within limits, e.g., ±1 or ±2 ms. In psychoacoustical studies, it is often measured in one-third octave bands, which approximately correspond to the critical bandwidth of the human auditory system (Glasberg and Moore, 1990). Measurements of the waveform coherence are relevant in certain aspects of acoustics, and waveform coherence is often quoted in studies of rooms. It has been useful, for instance, in determining minimum microphone spacing when taking room measurements, especially in reverberant rooms (Jacobsen and Roisin, 2000; Kuster, 2008), and predicting acoustical sound quality of concert halls (Hidaka *et al.*, 1995). It has increasingly become an important measure in studies of both human and animal hearing, with applications to a variety of binaural detection and discrimination tasks (Bernstein and Trahiotis, 2007; van de Par *et al.*, 2001), binaural unmasking (Bernstein and Trahiotis, 1992; Culling *et al.*, 2001; Durlach *et al.*, 1986), auditory motion tracking (Grantham and Wightman, 1979), and is a basic component of most binaural models, especially involving interaural time difference detection (Colburn and Durlach, 1978; Jeffress *et al.*, 1962; Shackleton *et al.*, 2005). Waveform coherence is related to the apparent auditory source width, wherein the apparent auditory source width increases as coherence decreases (Ando, 1998; Blauert and Lindemann, 1986). Recently, it has also been linked to loudness perception (Edmonds and Culling, 2009). In summary, waveform coherence is an important factor in matters regarding modeling the human auditory system, the design of various listening spaces, applications involving virtual audio systems, and measurement of acoustical systems. In these applications, the effect of coherence on the listener is of primary importance.

At high frequencies, the ear is insensitive to interaural differences in the fine structure of signals, but differences in the envelopes of the signals become important (McFadden and Pasanen, 1978; Trahiotis *et al.*, 2005). Coding of fine structure in the binaural system is lost at frequencies above 1.3 kHz (Zwislocki and Feldman, 1956), and so only acoustical envelopes are represented in binaural neural activity. Consequentially, the coherence of the envelopes of the signals in the left and right ears, the "envelope coherence," is a more interesting binaural measure than the coherence of the waveforms of those signals for high-frequency bands (van de Par and Kohlrausch, 1995). Envelope coherence has been linked, for example, to binaural unmasking at high frequencies (Bernstein and Trahiotis, 1992). Across different environments, one expects that these two forms of coherence—waveform coherence and envelope coherence—will be related. In an acoustically dry environment where there are relatively few reflections off room surfaces, one expects that both coherences will be near unity. In a highly reverberant environment, both will be small.

The goal of the present work is to explore the relationship between the waveform coherence and the envelope coherence. In the literature, reported coherences are waveform coherences, but a reader may need to know the envelope coherence present in those studies. It is easier to measure the waveform coherence than to measure the envelope coherence since no manipulation of the measured signals needs to be done prior to calculating the waveform coherence. By contrast, in order to calculate envelope coherence, it is necessary to first construct the envelope of the signals, which involves either careful low-pass filtering or taking the absolute value of the analytic Hilbert transforms of the signals. The ideal result of this work would be a formula by which one could calculate the envelope coherence having measured the waveform coherence. The present work first finds such a formula for noise bands through a computer simulation. It then reports measurements of the two forms of coherence in two very different acoustical environments, as measured with a KEMAR manikin. It is shown that the most plausible relationship between coherences in actual room environments

[a]Present address: Department of Natural Sciences and Mathematics, The Richard Stockton College of New Jersey, P.O. Box 195, Pomona, NJ 08240. Author to whom correspondence should be addressed. Electronic mail: neil.aaronson@stockton.edu

agrees with the formula that emerges from the computer simulation. Finally, the actual room measurements are used to derive a measure of reliability for the formula.

II. ELEMENTARY IDEAS

The waveform coherence γ_W is the maximum value of the cross-correlation function between a signal in the left ear $x_L(t)$ and a signal in the right $x_R(t)$. The cross-correlation function is

$$\mathrm{cc}(\tau) = \frac{1}{T_D\sqrt{P_L P_R}} \int_0^{T_D} dt\, x_R(t)\, x_L(t+\tau), \tag{1}$$

where τ is the lag, and P refers to the average power of a signal, averaged over the same span of time, 0 to T_D. In practice, the duration of integration T_D is hundreds of times longer than the longest lag τ.

Thus the cross-correlation function is a measure of the similarity of a signal in the right ear to a signal as it occurs in the left ear at a later time—a time that is later by τ. The coherence is the maximum value of the cross-correlation function over all allowed values of τ. Therefore, the definition of coherence must include a limit on τ. In this article that limit is taken to be ± 1 ms, consistent with standards in the literature, e.g., Beranek (1986), since this is approximately the largest naturally occurring interaural delay in free field.

The envelope coherence γ_E is defined in the same way as the waveform coherence except that the envelopes $E_L(t)$ and $E_R(t)$ replace the waveforms x in the equation for the cross-correlation:

$$\mathrm{cc}_E(\tau) = \frac{1}{T_D\sqrt{P_{E,L} P_{E,R}}} \int_0^{T_D} dt\, E_R(t)\, E_L(t+\tau). \tag{2}$$

The envelopes of the signals are calculated as the absolute value of the analytic signal, for example,

$$E_R(t) = |x_R(t) + \imath \mathcal{H}\{x_R(t)\}|, \tag{3}$$

where $\mathcal{H}$ represents the Hilbert transform. P is then replaced by P_E, the envelope power, for instance,

$$P_{E,L} = \frac{1}{T_D} \int_0^{T_D} dt\, {E_L}^2(t). \tag{4}$$

Some limits to these formulas can be easily derived. If the signals in the left and right ears are identical then the waveform coherence and envelope coherence are both equal to 1.0, the value of the cross-correlation function at $\tau=0$. A value of 1.0 is the largest that the cross-correlation can ever be. Therefore, the largest possible coherence is 1.0 or 100%. Also, if the signals are sine tones, the waveform coherence is 1.0 because there is always some value of the lag for which the tones in the left and right ears are identical so long as the period of the sine is shorter than twice the maximum lag. In our case, twice the maximum lag is 2 ms, and the waveform coherence cannot be limited by that maximum lag so long as the sine period is shorter than 2 ms (frequency greater than 500 Hz). The envelope coherence for a sine is always 1, whatever the frequency, because the envelope is a constant.

In the present letter, the signals of interest are bands of Gaussian noise, which were chosen as representative of a generic signal. The bandwidths are given by the auditory filter widths of Glasberg and Moore (1990), approximately 1/3-octave.

For noise bands, the waveform coherence and the envelope coherence have well defined limits. As noted above, if the noises are the same in both ears, both the waveform coherence and the envelope coherence are 1.0. In anechoic environments, where the signals arriving at the two ears are very similar, waveform coherences arbitrarily close to 1 can be observed. That limit of perfect coherence places a simple restriction on any formula designed to relate the envelope coherence to the waveform coherence—the limit of perfect correlation. If, on the other hand, the noises in the two ears are perfectly uncorrelated then the waveform coherence is 0 because epochs when the two channels have the same sign will be matched, on the average, by epochs when the two channels have opposite signs. In practice, such a case of ideally perfect incoherence can occur only if the two waveforms are deliberately made to be orthogonal. However, in highly reverberant environments the waveform coherence can become close to zero. Thus the perfectly uncorrelated limit can easily be approached in practice.

In the perfectly uncorrelated limit, the envelope coherence will not be zero because the envelope is never negative. In this limit, the integral in the cross-correlation is easy to calculate because the temporal average of the product of the envelopes is equal to the product of the temporal averages. van de Par and Kohlrausch (1998) noted that for Gaussian noise, the envelope is Rayleigh distributed. For a Rayleigh distribution, the average value is related to the rms value by a factor of $\sqrt{\pi}/2$. Therefore, the coherence is $\pi/4$ or 0.7854. This value sets a second restriction on the relationship between envelope and waveform coherences, namely, when the waveform coherence is 0, the expected value of the envelope coherence is $\pi/4$. Because of the absolute value in Eq. (3), finding an analytic relationship between waveform and envelope coherences is made difficult, or perhaps impossible.

In an unpublished memorandum of 2004, Bernstein reported a computer experiment to determine the relationship between interaural waveform coherence and interaural envelope coherence. He tested the form

$$\gamma_E = \frac{\pi}{4} + b(\gamma_W)^n, \tag{5}$$

where parameters b and n were unrestrained (n is not an integer). He found that this form provided a reasonable fit to the results of his numerical experiments with $b=0.2142$ and $n=2.2$. Making use of the limits of perfect coherence, we may refine Bernstein's equation somewhat to give

$$\gamma_E = \frac{\pi}{4} + \left(1 - \frac{\pi}{4}\right)(\gamma_W)^n. \tag{6}$$

This is now an equation with one free parameter, the power n. It should be noted that Bernstein's value, $b=0.2142$, is very close to the exact value $1-\pi/4=0.2146$.

It is important to note that across the possible range of coherences (0–1), the value of n has a rather subtle effect on γ_E in Eq. (6). Consider, for example, $n=2.0$ versus $n=2.2$; the greatest difference between these two functions occurs at $\gamma_W=0.62$, where the difference is 0.0075—less than 1%. Because Eq. (6) is somewhat insensitive in this respect to the exact value of n, all reported values of n given in this paper will be rounded to the nearest tenths, and uncertainties (in the form of standard deviations) in the value of n smaller than ± 0.05 will be ignored.

III. COMPUTER EXPERIMENT

This section describes computer experiments using bands of noise. The experiments computed the waveform coherence and the envelope coherence and plotted one against the other for thousands of trials. The plots were then fitted to a function of the form of Eq. (6). In these computer experiments, two Gaussian noises were admixed in different proportions to lead to noise waveforms x_L and x_R with differing interaural coherences. The noises were 262 143 samples in length, sampled at a rate of 97.7 kHz. A total of 1001 different admixture proportions were used ranging from 0% to 100% and leading to waveform coherences ranging from 1.0 to 0.0. The 1001 different noises were time-domain filtered using gammatone filters[1] centered on ISO one-third octave frequencies from 160 to 10 000 Hz. Because there are 19 such filters, our experiment consisted of 19 019 different computations. Plots of waveform and envelope coherences, measured from the maxima of waveform and envelope cross-correlations within the limits $-1\ \text{ms} \leq \tau \leq 1\ \text{ms}$, are shown in Fig. 1 for six representative frequency bands. For each of the 19 bands, a value of $n=2.1$ resulted in the best fit to the data. 95% confidence intervals about the average value of n within each band were all less than ± 0.05.

The spread of the data about the best-fitting curve, measured as root-mean-square error (RMSE), is generally greater at lower frequencies than at higher frequencies. RMSEs were calculated on the scale of coherence (from 0 to 1). The calculated RMSEs are as high as 0.020 in the 160-Hz band and decrease steadily to a minimum of 0.0045 for the 10 000-Hz band. This is likely a bandwidth effect. Since bandwidth is proportional to the center frequency of the filter band, the number of degrees of freedom is proportional to the center frequency. One expects then that the RMSE will be inversely proportional to the square root of the center frequency. The best fit power law is close to that rule, $\text{RMSE}=0.13\ f^{-0.36}$.

IV. ROOM EXPERIMENT

A. Methods

The computer experiments do not necessarily correspond to any real acoustical environment. Therefore, an experiment was performed with the goal of measuring waveform and envelope coherences through ears and comparing them as in the computer experiments. To accomplish this, maximum length signals of order 18 ($2^{18}-1=262\ 143$) were played at a sample rate of 97.7 kHz through a loudspeaker in two different rooms. This made for signals about 2.6 s in duration, longer than the broadband reverberation times of the rooms used in this experiment. Signals were recorded in the ears of a KEMAR and filtered into 19 different bands with a gammatone filter bank. Cross-correlations of the waveforms and of the envelopes were computed within each band.

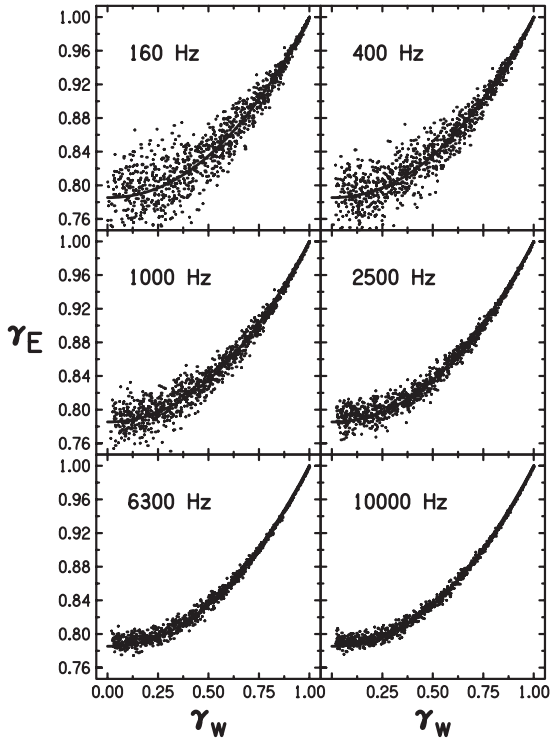

FIG. 1. Plots of envelope interaural coherence versus waveform interaural coherence for simulated binaural signals using Gaussian noise pairs in six different 1/3-octave bands. Each band contains 1001 coherence pairs, each of which is a single data point. A best-fitting line to Eq. (6) is shown as a thick solid line in each plot, though it may be obscured by the data points. The value of the power parameter n, to two significant figures, is 2.1 for each set of points in each panel.

One of the rooms used was an uncluttered laboratory space with hard surfaces and no carpeting, 6.5 m $\times$ 7.5 m $\times$ 4.5 m high. The broadband RT_{60} of this room was approximately 0.8 s; the RT_{60} in octave bands between 0.25 and 8 kHz were all between 0.7 and 0.9 s. The other room was a reverberant room, with dimensions 7.67 m $\times$ 6.35 m $\times$ 3.58 m high. The broadband RT_{60} of the reverberant room was approximately 2.0 s; the RT_{60} in octave bands was between 2.0 and 2.5 s for the bands from 0.5 to 2 kHz and was about 1.2 s in the 0.25- and 8-kHz bands. These rooms are, as reported in Hartmann *et al.*, 2005, rooms 10B and RR.

For all measurements, the KEMAR and loudspeaker were made to "face" one another. Measurements of coherence were made for four different distances between the loudspeaker and KEMAR—0.5, 1.0, 3.0, and 5.0 m. For each source distance, a measurement was made in ten different places in each room. For each measurement, both KEMAR and the loudspeaker were moved to different places in the room while keeping the distance between them the same. This yielded $19 \times 10 = 190$ waveform-envelope coherence pairs for each distance in each room.

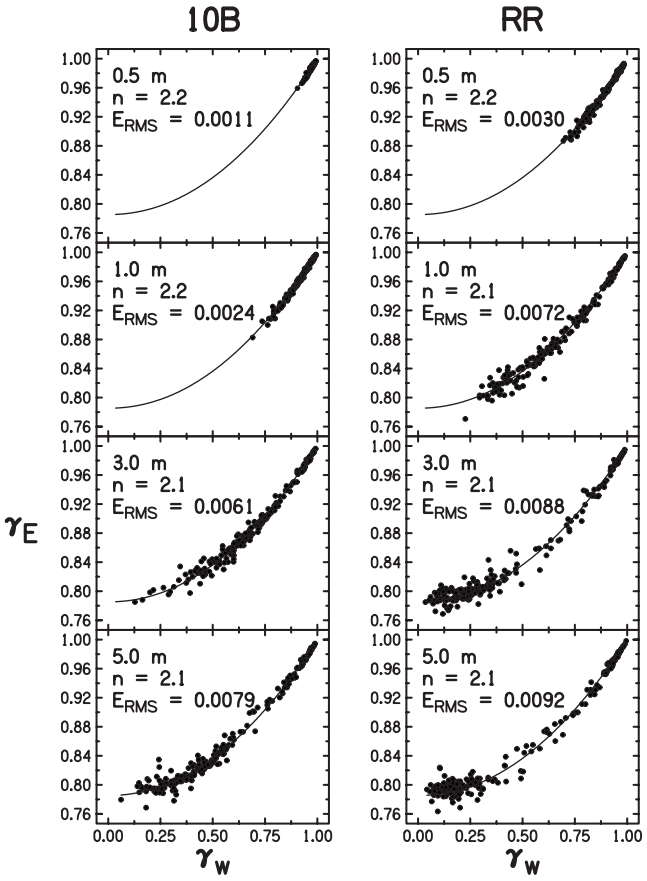

FIG. 2. Combined envelope versus waveform-coherence data across all 1/3-octave bands measured in rooms 10B and the reverberant room at each source distance. Trend lines show the best fit of the data in each panel to Eq. (6). The value of the fitting parameter n is shown in the upper-left corner of each panel. Because of the relative insensitivity of the curve to the exact value of n, only standard deviations greater than ± 0.05 are given. The rms error of the data to the best fit E_{rms} is given on the scale of coherence (0–1.0). Therefore, in room 10B at 1.0 m, where the mean γ_E is 0.96 and the rms error is 0.0024, the rms error is 0.25%.

B. Results

Within bands, Eq. (6) successfully describes the relationship between waveform and envelope coherences, though the value of the power parameter n within each band varies slightly. Consider, for example, room 10B at a distance of 3.0 m. The values of n found by fitting the data to Eq. (6) are as small as 1.9 in the 500-Hz band and as large as 2.2 in the 8000-Hz band. The variance in the best-fitting value of n is likely due to the narrow range of waveform coherences measured in individual bands. In some cases, where the total range of waveform coherences was small, the measured range of envelope coherences was also quite small. The regression which led to the value of n in those cases may be inaccurate. The average value of n across bands, plus and minus one standard deviation, was $n=2.1\pm0.1$.

The relative insensitivity of Eq. (6) makes determining an accurate value of n from a set of data with a small range of waveform coherences γ_W unreliable. Instead, data can be combined across all bands to get a picture of the waveform-envelope coherence relationship for any given room and source distance, as in Fig. 2. The resulting value of n given in Fig. 2 should apply reasonably well within any particular band. It can be seen that the combined data at every distance yield $n=2.1$ or 2.2. Standard deviations about these values were in all cases less than ±0.1. The collected coherences are lower on average as distance from the source increases and the direct-to-reverberant sound intensity ratio increases. Low-frequency bands still tend to have high coherence, and these form most of the points of high coherence in the cases where the distance was 3.0 or 5.0 m.

V. CONCLUSIONS

The relationship between envelope and waveform interaural coherences measured in real rooms agrees quite well with computer simulations which calculate coherences from Gaussian white noises, as computed in bands simulating auditory filters. The bands were approximately 1/3-octave in width. This close agreement suggests that the relationship between waveform and envelope coherences may be insensitive to the acoustic environment (reverberation time, source distance, etc.), though only two rooms and four distances were tested in this experiment. Within 1/3-octave bands, Eq. (6) provides a reliable relationship between waveform and envelope coherences, which can be expected to generalize to other rooms and distances. It may also be conjectured that Eq. (6) would generalize to bands of arbitrary width. Determination of the value of n measured within any given band is subject to error. By combining data across bands for a given source distance, a reliable value of n can be found that actually applies to any particular band. Current observations suggest that there may be little difference between rooms with vastly different reverberation times.

The exact value of n (i.e., a value with greater precision than mentioned here) is very sensitive to small variations in the data. This is because the exact value of n does not have a large impact on the shape of the curves, and so curves of similar shape can have quite different values of n. This also implies that the exact value of n may not be important to describe the behavior of the relationship between envelope and waveform coherences, but a "ballpark" estimate may suffice in most cases. In this study, a ballpark estimate is arrived at by rounding the relevant values of n to the nearest tenth. In both the computer experiment and in the rooms, the average value of n was 2.1. Thus, it is suggested that a reliable equation describing the relationship between waveform coherence γ_W and envelope coherence γ_E in any room and for any source distance is

$$\gamma_E = \frac{\pi}{4} + \left(1 - \frac{\pi}{4}\right)\gamma_W{}^{2.1}. \tag{7}$$

The envelope coherences arrived at using Eq. (7) are not exact. Especially for situations in which the value of the waveform coherence γ_W is small, the variance in the related envelope coherence γ_E seems significant (see Figs. 1 and 2). It would be useful to quantify an expected error in envelope coherence.

In order to quantify the expected deviation of envelope coherences from Eq. (7), waveform-coherence–envelope-coherence pairs were combined across all frequencies into one large set. Three such sets were constructed—one for

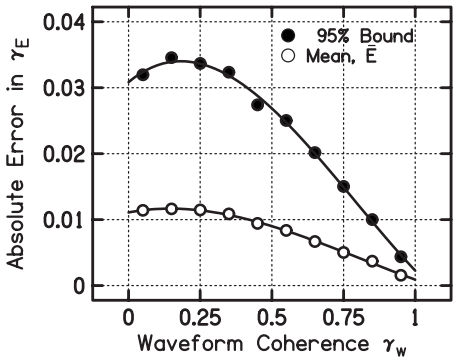

FIG. 3. The 95% bound curve (closed circles) gives the absolute error in envelope coherence for which 95% of the simulated coherences deviate by that amount or less from the coherence predicted by Eq. (7). The mean curve (open circles) gives the mean absolute error $\bar{E}$ relative to Eq. (7) for simulated envelope coherences. Both curves are third-order polynomials fitted to the absolute errors of the binned data.

each of the rooms and one for the computer simulation data. The data in each set were binned by the value of their waveform coherence into bins of width 0.1, thus creating ten bins across the range of waveform coherences. Within each bin, two methods of measuring error were employed: (1) calculation of the mean absolute difference $\bar{E}$ between the measured envelope coherences and envelope coherences as predicted by Eq. (7) and (2) calculation of the absolute difference from Eq. (7) for which 95% of the data deviate less than that, i.e., the "95% bound."

The absolute errors for the rooms turned out to be equal to or slightly less than the errors in the simulated coherences for both methods of error estimation. Thus, a conservative estimate of the absolute error in Eq. (7) is given by the errors measured in the computer simulation of coherences. The absolute errors for both the mean and 95% bound method are shown as a function of the waveform coherence γ_W in Fig. 3. This figure shows third-order polynomial function fits to the absolute errors. The mean absolute error $\bar{E}$ can then be described as a function of the waveform coherence by

$$\bar{E} = 0.011 + 0.0083\gamma_W - 0.031\gamma_W^2 + 0.013\gamma_W^3. \quad (8)$$

The 95% bound is approximately three times as large as the mean absolute error and reaches an upper limit less than 0.04. It is unlikely that listeners could discriminate between envelope coherences that are different by this amount. A user of Eq. (7) may expect the difference between envelope coherences calculated from Eq. (7) and the actual envelope coherences to be approximately $\pm\bar{E}$ on average and may expect envelope coherences to deviate no more than $\pm 3\bar{E}$ from Eq. (7). It should be noted that Eq. (7) works quite well, even for cases where the waveform coherence is low. At worst, the expected error is about ± 0.035.

It is interesting to wonder whether different waveforms would yield different results. An obvious choice to test would be speech signals. In a short study involving a measurement procedure identical to that used in the room experiment, male speech was used as a signal in place of broadband noise. The same distances between the speaker and KEMAR were used as in the above experiments, and measurements were made in both rooms, 10B and RR. Speech signals do not yield good signal-to-noise ratios at very high frequencies, so the analysis was limited to bands no higher than 10 kHz. Though an in-depth error analysis was not performed as it was for noise bands, it was found that $n=2.1$ works quite well to describe the relationship between waveform coherence and envelope coherence for these speech signals.

This paper presents a microphone array technique aimed at enhancing speech quality in a reverberant environment. This technique is based on the central idea of single-input-multiple-output equivalent source inverse filtering (SIMO-ESIF). The inverse filters required by the time-domain processing in the technique serve two purposes: de-reverberation and noise reduction. The proposed approach could be useful in telecommunication applications such as automotive hands-free systems, where noise-corrupted speech signal generally needs to be enhanced. SIMO-ESIF can be further enhanced against uncertainties and perturbations by including an adaptive generalized side-lobe canceller. The system is implemented and validated experimentally in a car. As indicated by numerous performance measures, the proposed system proved effective in reducing noise in human speech without significantly compromising the speech quality. In addition, listening tests were conducted to assess the subjective performance of the proposed system, with results processed by using the analysis of variance and a *post hoc* Fisher's least significant difference (LSD) test to assess the pairwise difference between the noise reduction (NR) algorithms. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3291684]

I. INTRODUCTION

Signal processing using microphone arrays has found applications in teleconferencing, telecommunication, speech recognition, speech enhancement, hearing aids, and so forth.[1] In these applications, how to effectively communicate in noisy or reverberant environments has been one of the pressing issues. Array techniques such as the well known delay-and-sum (DAS) beamformer do not function well in such environments due to multiple reflections.[2] To enhance interference rejection, a superdirective beamformer was suggested for its excellent spatial filtering capability.[3] Adaptive arrays provided useful alternatives for interference rejection.[1–13] The generalized side-lobe canceller (GSC) is an elegant approach in beamformer design in which a constrained optimization problem is converted into an unconstrained one from a linear algebraic perspective.[4] Its idea originated from linearly constrained minimum variance (LCMV) beamformer[5] and was first utilized by Owsley.[6] Griffiths and Jim[7] analyzed them and coined the term GSC. Their GSC corresponds to what we called in the present paper the Griffiths–Jim beamformer (GJBF). The key notion of GSC hinges at the use of the blocking matrix that further enhances the performance achievable by the fixed beamformer regardless of how it is implemented. However, oftentimes, adaptive implementation of GSC is preferred for two practical reasons. First, a fixed GSC requires the knowledge of covariance matrix, which is computationally prohibitive in real-time applications. Second, adaptive GSC is more robust in the presence of background noises, pointing errors, and other system uncertainties. There are various forms of adaptive implementation. Among them, GJBF is perhaps the most well known, which eliminates the need for on-line calculation of the signal correlation matrix and is robust against uncertainties and perturbations of the system. However, the GJBF still could fail in a reverberant environment in which multiple reflections cause problems of beamforming.[8] One example of such environment is the interior of a car cabin that is notoriously known to be a noisy and reverberant environment for speech communication. The speech signals tend to be corrupted by noises from the engine, tire, wind, etc., and reflections from the window, dashboard, seats, ceiling, etc.

In this paper, a microphone array technique is proposed for processing speech signals in noisy and reverberant environments. The idea of the technique originated from an equivalent source inverse filtering (ESIF) technique[9] developed for noise source identification purposes. However, the model in this paper is based on a single-input multiple-output (SIMO) structure, while the previous paper is based on a multiple-input multiple-output (MIMO) structure. This seemingly minor difference leads to many distinctive features in the implementation. First, unlike MIMO approach, the SIMO-ESIF formulation results in only one single focus, which simplifies tremendously the filter design that requires only simple phase conjugation and scaling, without having to design explicitly complicated inverse filters. The propagation matrices are basically represented by a vector $\mathbf{h}$, which renders the term $\mathbf{h}^H\mathbf{h}$ in the inverse filter a nonzero scalar and regularization is literarily unnecessary. Second, by posing the problem within a SIMO framework, inverse filters are designed based on measured acoustical plants, or systems to be controlled,[14] that include the effects of not only direct propa-

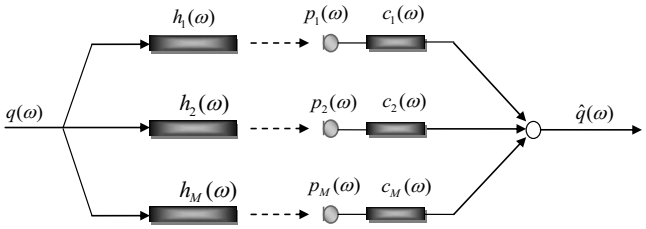

FIG. 1. The block diagram of the SIMO-ESIF algorithm. The parameter $q_m(\omega)$ is the input source, $h_m(\omega)$ is the propagation matrix, and $c_m(\omega)$ is the inverse filters.

gation from the source but also the reflections from the boundaries, which is different from the previous MIMO nearfield equivalence source imaging (NESI) that employs only free-field point source model. It follows that, with inverse filtering, both noise reduction and de-reverberation are fulfilled at the same time. Finally, the present work and the previous approach have totally different purposes in application. The ESIF algorithm aims at speech enhancement for telecommunication, whereas the previous NESI algorithm is intended for noise source identification (NSI) and sound field visualization. Another unique feature of the proposed technique is the use of the GSC to further enhance the performance of the proposed technique. An exact blocking matrix (BM) differing from those used in traditional beamformers is derived in this paper by solving a LCMV problem with two mutually orthogonal subspaces.[5] The leaky least-mean-squares (LMS) algorithms is exploited for adaptive filtering in the multiple-input canceller (MC).[15,16]

The proposed algorithms were implemented for enhancing speech communication quality in a car by using a multichannel data acquisition system. Objective tests were carried out to evaluate the algorithms.[1] In addition, listening tests were conducted to assess the subjective performance of the algorithms with data processed by the multivariate analysis of variance (MANOVA) (Ref. 17) and the least significant difference (Fisher's LSD) *post hoc* test.

II. EQUIVALENT SOURCE INVERSE FILTERING

The central idea of the proposed SIMO-ESIF algorithm is introduced in this section. In Fig. 1, M microphones are employed to pick up the sound emitting from a source positioned in the farfield. In the frequency domain, the sound pressure received at the microphones and the source signal can be related by a $M \times 1$ transfer matrix $\mathbf{H}$ as follows:

$$\mathbf{P} = \mathbf{H}q(\omega), \tag{1}$$

where $q(\omega)$ is the Fourier transform of a scalar source strength, $\mathbf{P}=[p_1(\omega)\cdots p_M(\omega)]^T$ is the pressure vector with T denoting matrix transpose, and $\mathbf{H}=[h_1(\omega)\cdots h_M(\omega)]^T$ is the $M \times 1$ propagation matrix. The aim here is to estimate the source signal $q(\omega)$ based on the pressure measurement $\mathbf{P}$ by using a set of inverse filters

$$\mathbf{C} = [c_1(\omega)\cdots c_M(\omega)]^T, \tag{2}$$

such that $\mathbf{C}^T\mathbf{H} \approx \mathbf{I}$ and therefore

$$\hat{q} = \mathbf{C}^T\mathbf{P} = \mathbf{C}^T\mathbf{H}q \approx q. \tag{3}$$

On the other hand, this problem can also be written in the context of the following least-squares optimization problem:

$$\min_q \|\mathbf{P} - \mathbf{H}q\|_2^2, \tag{4}$$

where $\|\ \|_2$ denotes vector 2-norm. This is an overdetermined problem whose least-squares solution is given by

$$\hat{q} = (\mathbf{H}^H\mathbf{H})^{-1}\mathbf{H}^H\mathbf{P} = \frac{\mathbf{H}^H\mathbf{P}}{\|\mathbf{H}\|_2^2}, \tag{5}$$

where the superscript H denotes Hermitian transpose. Comparison of Eqs. (3) and (5) yields the following optimal inverse filters:

$$\mathbf{C}^T = \frac{\mathbf{H}^H}{\|\mathbf{H}\|_2^2}. \tag{6}$$

If the scalar $\|\mathbf{H}\|_2^2$ is omitted, the inverse filters above reduce to the "phase-conjugated" filters, or the "time-reversed" filters in the free-field context. Specifically, for a point source in the free field, it is straightforward to show that

$$\|\mathbf{H}\|_2^2 = \sum_{m=1}^{M} \frac{1}{r_m^2}, \tag{7}$$

where r_m is the distance between source and the mth microphone. Since $\|\mathbf{H}\|_2^2$ is a frequency-independent constant, the inverse filters and the time-reversed filters differ only by a constant. In a reverberant environment, these filters are different in general. Being able to incorporate the reverberant characteristics in the measured acoustical plant model represents an advantage of the proposed approach over conventional methods such as the DAS beamformer.

In real-time implementation, the inverse filters are converted to the time-domain finite-impulse-response (FIR) filters with the aid of inverse fast Fourier transform (IFFT) and circular shift. Thus, the source signal can be recovered by filtering the pressure signals with the inverse filters $\mathbf{c}(k)$ as follows:

$$\hat{q}(k) = \mathbf{c}^T(k) * \mathbf{p}(k), \tag{8}$$

where k is discrete-time index, $\mathbf{c}(k)$ is the impulse response of the inverse filter, and " *" denotes convolution.

III. ADAPTIVE GSC-ENHANCED SIMO-ESIF ALGORITHM

The SIMO-ESIF algorithm can be further enhanced by introducing an adaptive GSC to the system. The benefit is twofold. The directivity of the array is increased by suppressing the interferences due to side-lobe leakage. Robustness of the array is improved in the face of uncertainties and perturbations. The block diagram of the GSC with M microphones is shown in Fig. 2. The system comprises a fixed beamformer (FBF), a MC, and a BM.[11] The FBF aims at forming a beam in the look direction so that the target signal is passed and signals at other directions are rejected. The $p_m(k)$ is the signal received at the mth microphones and $\hat{q}(k)$ is the output signal of the FBF at the time instant k. The MC consists of

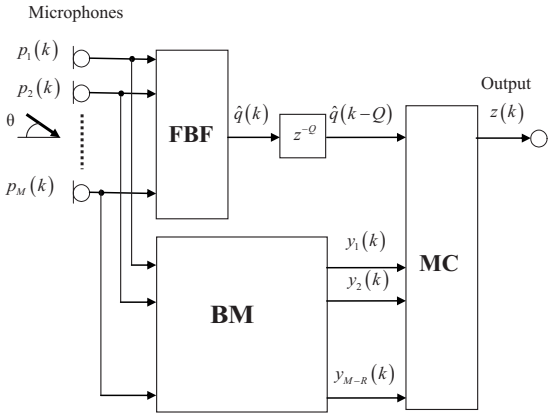

FIG. 2. The block diagram of the GSC, comprised of the FBF, the BM, and the MC.

multiple adaptive filters that generate replicas of components correlated with the interferences. The components correlated with the output signals $y_m(k)$ of the BM are subtracted from the delayed output signal $\hat{q}(k-Q)$ of the FBF, where Q is the number of modeling delay. Contrary to the FBF that produces a main-lobe, the BM forms a null in the look direction so that the target signal is suppressed and all other signals are passed though, hence the name "blocking matrix." The GSC subtracts the interferences that "leak" to the side-lobes in the subtractor output $z(k)$ and effectively improves spatial filtering.

A. Formulation of the blocking matrix

The purpose of the GSC depicted in Fig. 3 lies in minimizing the array output power, while maintaining the unity gain at the look direction (0-deg broadside is assumed here), which can be posed in the following constrained optimization formalism:[5]

$$\min_{\mathbf{w}} E\{|z|^2\} = \min_{\mathbf{w}} \mathbf{w}^H \mathbf{R}_{pp} \mathbf{w} \tag{9}$$

subject to

$$\mathbf{H}^H \mathbf{w} = 1, \tag{10}$$

where z is the array output signal, $\mathbf{R}_{pp}=E\{\mathbf{p}\mathbf{p}^H\}$ is the data correlation matrix, $E\{\}$ symbolizes the expected value, $\mathbf{H}$ is the frequency response vector corresponding to the propagation paths from the source to each microphone, and $\mathbf{w}$ is coefficient vector of the array filters. This constrained optimization problem can be converted into an unconstrained one by decomposing the optimal filter $\mathbf{w}$ into two linearly independent components belonging to two mutually orthogonal subspaces: the constraint range space $R(\mathbf{H})$ and the orthogonal null space $N(\mathbf{H}^H)$.

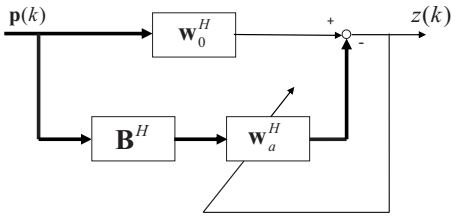

FIG. 3. The block diagram of the SIMO-ESIF-GSC algorithm. The parameter $\mathbf{p}(k)$ is the microphone signal, $\mathbf{B}^H$ is the BM, and $\mathbf{w}_0^H$ is the FBF.

$$\mathbf{w} = \mathbf{w}_0 - \mathbf{v}, \tag{11}$$

where $\mathbf{w}_0 \in R(\mathbf{H})$ is a fixed filter and $\mathbf{v}=\mathbf{B}\mathbf{w}_a \in N(\mathbf{H}^H)$ with $\mathbf{w}_a$ being an adaptive filter. It follows that

$$\mathbf{H}^H \mathbf{w} = \mathbf{H}^H(\mathbf{w} - \mathbf{B}\mathbf{w}_a) = \mathbf{H}^H \mathbf{w}_0 - \mathbf{H}^H \mathbf{B}\mathbf{w}_a \approx 1. \tag{12}$$

The fixed filter $\mathbf{w}_0$ represents the quiescent component that guarantees the essential performance of beamforming. The filter design is off-line since it is independent of the data correlation matrix. It turns out that the minimization can then be carried out in the orthogonal subspace ($\mathbf{v}$) without impacting the constraint.

Traditionally, various *ad hoc* blocking matrices have been suggested. These matrices are based on the simple idea that, for free-field plane waves incident from the farfield broadside direction, $\mathbf{H}=[1\ \ 1\cdots 1]^H$. Since $\mathbf{H}^H\mathbf{B}=\mathbf{0}$, blocking is ensured if the columns of $\mathbf{B}$ sum up to zero; e.g., subtraction of signals of adjacent channels is a widely used approach. However, for a complex propagation matrix in a reverberant field, these *ad hoc* blocking matrices are inadequate. As a major distinction between the present approach and the conventional approaches, we shall derive an exact blocking matrix for a more general acoustical environment.

To fulfill the condition that $\mathbf{B}\mathbf{w}_a \in N(\mathbf{H}^H) \Leftrightarrow \mathbf{H}^H\mathbf{B}\mathbf{w}_a=0$, the columns of $\mathbf{B}$ must be constructed from the basis vectors of $N(\mathbf{H}^H)$ such that $\mathbf{H}^H\mathbf{B}=\mathbf{0}$.

$$\text{Let } \mathbf{H} = [a_1, a_2, \ldots, a_n]^H, \quad \mathbf{x} = [x_1, x_2, \ldots, x_n] \in N(\mathbf{H}^H)$$

$$\mathbf{H}^H\mathbf{x} = 0 \Rightarrow a_1x_1 + a_2x_2 + \ldots + a_nx_n = 0$$

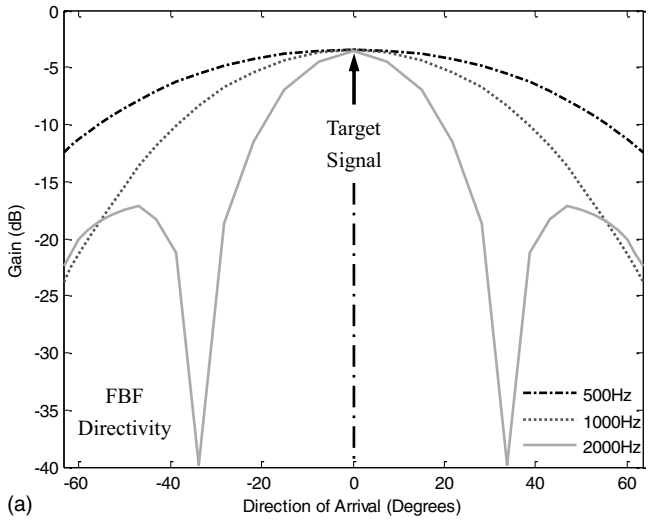
$$\text{If } a_1 \neq 0, \quad x_1 = -\frac{a_2}{a_1}x_2 - \frac{a_3}{a_1}x_3 - \cdots - \frac{a_n}{a_1}x_n$$

$$\text{Let } x_2 = \alpha_2, \quad x_3 = \alpha_3, \ldots, x_n = \alpha_n$$

$$\Rightarrow x_1 = -\frac{a_2}{a_1}\alpha_2 - \frac{a_3}{a_1}\alpha_3 - \cdots - \frac{a_n}{a_1}\alpha_n$$

$$\begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \alpha_2 \underbrace{\begin{bmatrix} -\frac{a_2}{a_1} \\ 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}}_{\mathbf{v}_2} + \alpha_3 \underbrace{\begin{bmatrix} -\frac{a_3}{a_1} \\ 0 \\ 1 \\ \vdots \\ 0 \end{bmatrix}}_{\mathbf{v}_3} + \cdots + \alpha_n \underbrace{\begin{bmatrix} -\frac{a_n}{a_1} \\ 0 \\ \vdots \\ 0 \\ 1 \end{bmatrix}}_{\mathbf{v}_n}.$$

It is not difficult to see that $\mathbf{v}_2, \mathbf{v}_3, \ldots, \mathbf{v}_n$ are linearly independent and form the basis of the null space $N(\mathbf{H}^H)$. Thus, the matrix $\mathbf{B}=(\mathbf{v}_2, \mathbf{v}_3, \ldots, \mathbf{v}_n)$ comprised of $\mathbf{v}_2, \mathbf{v}_3, \ldots, \mathbf{v}_n$ as its columns can be used as the blocking matrix; i.e.,



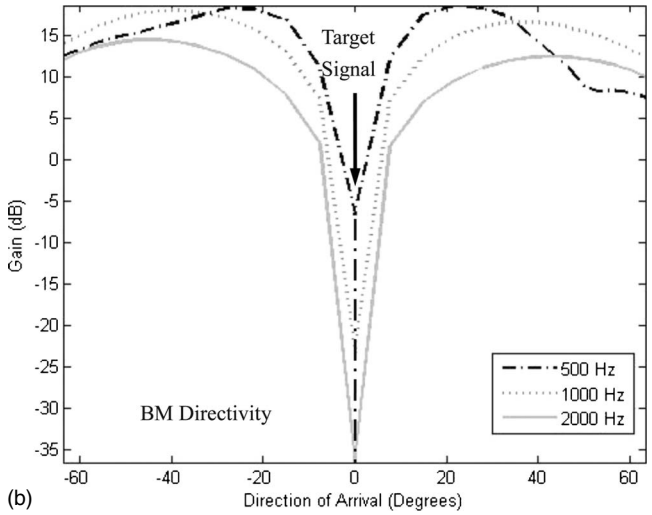


FIG. 4. The directivity pattern of the SIMO-ESIF-GSC algorithm at difference frequencies. (a) FBF with a main-lobe at the look direction. (b) BM with a null at the look direction.

$$\mathbf{B} = \begin{bmatrix} -\frac{a_2}{a_1} & -\frac{a_3}{a_1} & \cdots & -\frac{a_n}{a_1} \\ 1 & 0 & & 0 \\ 0 & 1 & \cdots & \vdots \\ \vdots & \vdots & & 0 \\ 0 & 0 & \cdots & 1 \end{bmatrix}. \tag{13}$$

Physical insights can be gained by observing the beam patterns of the FBF and the BM shown in Fig. 4. Three sine wave signals at 500 Hz, 1 kHz, and 2 kHz are used to compare the performance of the BM between FBF, respectively. In the look direction, the FBF forms a main-lobe, whereas the BM forms a null so that the signal in the look direction is "blocked." The blocked path will attempt to further reduce the noise or interference outside the principal look direction (side-lobes). Note that the formulation above is in the frequency domain. For real-time implementation, the blocking matrix **B** needs to be converted to impulse responses using IFFT and circular shift.

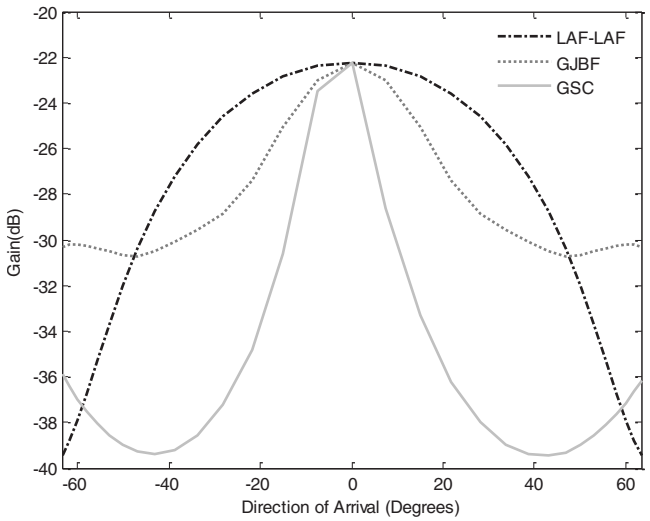

FIG. 5. The comparison of the beam patterns at 500 Hz obtained using the GJBF, LAF-LAF, and SIMO-ESIF-GSC algorithms.

B. Multiple-input canceller

In practice, the GSC is implemented using adaptive filters that are generally more robust than fixed filters. The need to compute the data correlation matrix $\mathbf{R}_{pp}$ is eliminated using such approach. For example, the leaky adaptive filters (LAFs) (Ref. 16) can be used in the MC block. LAFs subtract the components correlated with $y_n(k)$, $(n=0,\ldots,N)$ from $\hat{q}(k-Q)$, where Q is the modeling delay for causality. Let M_2 be the number of taps in each LAF and $\mathbf{w}_n(k)$ and $\mathbf{y}_n(k)$ be the coefficient vector and the signal vector of the nth LAF, respectively. The output of the MC module can be written as

$$z(k) = \hat{q}(k-Q) - \sum_{n=0}^{N-1} \mathbf{w}_n^T(k)\mathbf{y}_n(k), \tag{14}$$

$$\mathbf{w}_n(k) \triangleq [w_{n,0}(k), w_{n,l}(k), \ldots, w_{n,M_2-1}(k)]^T, \tag{15}$$

$$\mathbf{y}_n(k) \triangleq [y_n(k), y_n(k-1), \ldots, y_n(k-M_2+1)]^T. \tag{16}$$

The filter coefficients can be updated using the LMS algorithm

$$\mathbf{w}_n(k+1) = \mathbf{w}_n(k) + \mu z(k)\mathbf{y}_n(k), \tag{17}$$

where μ is the step size.

In Fig. 5, the beam pattern at 500 Hz of the proposed adaptive GSC algorithm is compared with two other conventional algorithms: GJB (Ref. 7) and LAF-LAF.[16] The GJBF algorithm adopts subtracted signals of adjacent channels as its BM block, whereas LAF-LAF algorithm uses adaptive filters to block the target signals. Both algorithms use adaptive algorithm identical to the MC block in Eq. (17). Clearly seen in Fig. 5, the proposed adaptive GSC algorithm attains the sharpest beam in the look direction with minimum side-lobes.

IV. ARRAY PERFORMANCE MEASURES

In the section, objective performance measures are defined for evaluating the array performance.[1] With the first microphone as the reference, the input signal to noise ratio (SNR) is defined as

$$\mathrm{SNR}_1(\mathrm{dB}) = 10 \log \frac{E\{x_1(k)^2\}}{E\{v_1(k)^2\}}, \tag{18}$$

where k is the discrete-time index, and $x_1(k)$ and $v_1(k)$ are the speech signal and the noise, respectively, received at microphone 1. The output SNR can also be defined for the array output

$$\mathrm{SNR}_A(\mathrm{dB}) = 10 \log \frac{E\{|\mathbf{c}(k)^T * \mathbf{x}(k)^2|\}}{E\{|\mathbf{c}(k)^T * \mathbf{v}(k)^2|\}}, \tag{19}$$

where $\mathbf{c}(k)$ is the impulse response of the inverse filter and " *" denotes convolution. Hence, the SNR gain is obtained by subtracting the output SNR from the input SNR.

$$\mathrm{SNR}(\mathrm{dB}) = \mathrm{SNR}_A - \mathrm{SNR}_1. \tag{20}$$

The SNRG quantifies the noise reduction performance due to array processing. However, noise reduction comes at the price of speech distortion in general. To assess speech distortion, a speech-distortion index (SDI) is defined as

$$\mathrm{SDI}(\mathrm{dB}) = 10 \log \frac{E\{x_1(k)^2\}}{E\{|x_1(k) - \mathbf{c}(k)^T * \mathbf{x}(k)|^2\}}. \tag{21}$$

It is impractical to maximize both indices at the same time. The aim of array processing is then to reach the best compromise between the two indices.

V. OBJECTIVE AND SUBJECTIVE PERFORMANCE EVALUATIONS

The proposed algorithms have been examined experimentally in the vehicle compartment of a 2-l sedan. Figure 6 shows the experimental arrangement inside the car. Array signal processing algorithms are all implemented on National Instruments LABVIEW 8.6 and NI-PXI 8105 data acquisition system.[18] The sampling rate is 8 kHz. The sound pressure data were picked up by using a four-microphone (PCB 130D20) linear uniform array with inter-element spacing of 0.08 m. A loudspeaker positioned at (0.4 m, 0-deg) with respect to the array center was used to broadcast a clip of male speech in English, while another loudspeaker positioned at (0.3 m, 53-deg) was used to generate white noise as the interference.

Objective and subjective experiments were undertaken to evaluate the proposed methods. The SIMO-ESIF algorithm is used as the FBF and 512-tapped adaptive filters with step size μ=0.001 are used in the MC and LAF. There are variations of the SIMO-ESIF algorithm, depending on the plant model used and the filtering method in the FBF, as summarized in Table I. Two kinds of plant models, the free-field point source model and the measured plant in the car, are employed for designing the inverse filters. Two filtering methods, the inverse filtering and the time-reversed filtering,

(a)

are employed in the FBF design. In addition, three variations of the processing methods with GSC are also included in Table I.

A. Objective evaluation

The objective measures SNR_1, SNR_A, SNRG, and SDI are employed to assess the performance of six proposed algorithms. The experimental results are summarized in Table II. By comparing the SIMO-ESIF and the SIMO-ESIF-GSC algorithms, the algorithms with GSC have attained signifi-

TABLE I. The acronyms and descriptions of six SIMO-ESIF algorithms.

Algorithm	Acronym	Description
SIMO-ESIF	PIF	Point source model-based inverse filtering

	MTR	Measured plant-based time-reversed filtering
	GSC-PIF	Point source model-based inverse filtering
SIMO-ESIF-GSC	GSC-MIF	Measured plant-based inverse filtering
	GSC-MTR	Measured plant-based time-reversed filtering

TABLE II. The objective performance summary of the six algorithms.

	PIF		MIF		MTR	
SIMO-ESIF GSC	Without	With	Without	With	Without	With
SNR_I(dB)	3.79	3.79	3.79	3.79	3.79	3.79
SNR_A(dB)	12.96	15.28	15.56	19.19	13.58	13.66
SNRG(dB)	9.16	11.49	11.77	15.41	9.78	9.87
SDI(dB)	2.87	2.60	1.72	1.59	0.86	1.56

cantly higher noise reduction (SNRG) and lower speech distortion (SDI) than the algorithms without GSC. The time-reversed filters in general yield inferior performance than the inverse filters. The inverse filtering with the measured plant model considerably outperforms the point source model, e.g., SNRG of GSC-MIF=15.41 dB vs SNRG of GSC-PIF =11.49 dB. The implication of this result is that the inverse filters based on measured plant models have provided "dereverberation" effect in addition to noise reduction. Although the point source model-based inverse filtering (PIF) method tends to yield the least distortion, its noise reduction performance is also the worst. Figure 7 compares the time-domain wave forms obtained using SIMO-ESIF algorithm with and without GSC. Evidently, introduction of GSC has positive impact on noise reduction performance of the array.

Table III compares the proposed adaptive GSC algorithm and two other conventional algorithms, GJBF (Ref. 7) and CCAF.[11] The GJBF algorithm subtracts signals of adjacent channels as its BM block, whereas coefficient-constrained adaptive filtering (CCAF) algorithm uses constrained adaptive filters to block the target signals. Both algorithms use the adaptive algorithm identical to the MC block. The result revealed that the SIMO-ESIF algorithm augmented with the GSC outperformed the SIMO-ESIF algorithm without GSC. Among the GSC-based algorithms, the proposed GSC had attained the highest SNRG performance. The proposed GSC algorithm performed the best in noise reduction.

B. Subjective evaluation

Apart from the preceding objective tests, listening tests were conducted according to the ITU-R BS1116 (Ref. 19) to validate the algorithms. Subjective perception of the proposed algorithms was evaluated in terms of noise reduction and speech distortion. Specifically, three subjective attributes including signal distortion (SIG), background intrusiveness (BAK), and overall quality (OVL) were employed in the test. Fourteen participants in the listening tests were instructed with definitions of the subjective attributes and the procedures prior to the test. The subjective attributes are measured on an integer scale from 1 to 5. The participants were asked to respond in a questionnaire after listening. The six proposed algorithms previously used in the objective test are compared in the listening test. The test signals and conditions remain the same as in the preceding objective tests. A reference signal and an anchor signal are required in the ITU-R BS1116. In the test, the unprocessed signal received at the first microphone was used as the reference, while the lowpass-filtered reference was used as the hidden anchor. The mean and spread of the results of listening test are illustrated in Fig. 8. In order to access statistical significance of the results, the test data were processed using MANOVA (Ref. 17) with significance levels summarized in Table IV. Cases with significance levels below 0.05 indicate that statistically significant difference exists among the algorithms. In particular, the difference of the indices SIG and BAK

TABLE III. The objective performance summary of the four beamforming algorithms including the ESIF, ESIF-GSC, GJBF, and CCAF algorithms.

	MIF			
Objective index	ESIF	ESIF-GSC	GJBF	CCAF
SNR_1(dB)	−1.04	−1.04	−1.04	−1.04
SNR_A(dB)	6.20	12.72	10.27	9.92
SNRG(dB)	7.24	13.76	11.31	10.96
SDI(dB)	1.86	1.42	2.49	1.90

among the six proposed methods was found to be statistically significant. Multiple regression analysis was applied to analyze the linear dependence of the OVL on the SIG and BAK. The regression model was found to be OVL=1.71+0.2 ×SIG+0.28×BAK. It revealed that the SIG has comparable but only slightly higher influence on the OVL than the BAK, whereas the indices SIG and the BAK are normally trade-offs. This explains why no significant difference can be found among methods in the OVL.

After the MANOVA, a *post hoc* Fisher's LSD test was employed to perform multiple paired comparisons. In Fig. 8, as opposed to the results of objective evaluation, the GSC-MIF algorithm performed not quite as expected in SIG. The price paid for the high noise reduction seems to be the signal distortion, which was noticed by many subjects. For the SIG index, the results of the *post hoc* test reveal that the GSC-PIF method outperforms the other methods. For the BAK index, the GSC-MIF method received the highest grade among all methods, which means that the inverse filtering approach has achieved both de-reverberation and noise reduction successfully. Despite the excellent performance in SIG, the PIF algorithm received low scores in BAK, which is consistent with the observation in the objective test. On the other hand, the GSC-PIF algorithm received higher SIG grade than plain PIF algorithm, indicating the GSC algorithm enhanced the SIMO-ESIF algorithm. However, the grades in the SIG and BAK indices showed no significant difference between the measured plant-based time-reversed filtering (MTR) and

TABLE IV. The MANOVA output of the listening test of the six algorithms. Cases with significance value p below 0.05 indicate that statistically significant difference exists among all methods.

	Significance value p		
Noise type	SIG	BAK	OVL
White noise	0.000	0.000	0.847

GSC-MTR algorithms. By comparing the BAK grade, all the proposed methods performed better than the reference signal.

Figure 9 compares the proposed GSC algorithm, GJBF,[6] and CCAF (Ref. 11) algorithms. The proposed GSC algorithm attained the highest BAK grades, while it also yielded lower SIG grades than the other algorithms. Apparently, the proposed GSC had attained the best performance in noise reduction at the expense of signal distortion. This is a typical trade-off for speech enhancement algorithms in general one has to face between signal distortion and noise reduction performance.

VI. CONCLUSIONS

A SIMO-ESIF microphone array technique has been developed for noisy automotive environments. Speech communication quality has been improved owing to the noise reduction and de-reverberation functions provided by the proposed system. With the use of specially derived BM of the GSC, the performance of SIMO-ESIF has been further enhanced.

The proposed algorithms have been validated via extensive objective and subjective tests. Overall, the results reveal that both de-reverberation and noise reduction can be achieved by using the SIMO-ESIF techniques. The methods exhibit different degrees in trading off noise reduction performance and speech-distortion quality. The MIF and GSC-MIF algorithms seem to have achieved a satisfactory compromise between these two attributes. All this leads to the conclusion that SIMO-ESIF-GSC-MIF proves effective in reducing noise and interference without markedly compromising speech quality.

A relationship between the far field diffraction pattern and the axial pressure radiating from a two-dimensional aperture[a)]

Edward H. Pees[b)]
Naval Undersea Warfare Center, 1176 Howell Street, Newport, Rhode Island 02841

(Received 16 June 2009; revised 16 December 2009; accepted 20 December 2009)

The diffraction of an acoustic wave by a two-dimensional aperture produces a sound field that can generally be represented at any point in space as a superposition of a continuum of plane waves. The mathematical formulation that facilitates this representation is known as the *angular spectrum of plane waves* method. The spectrum, in this representation, is a wavenumber spectrum obtained from a two-dimensional Fourier transform of the acoustic pressure (or velocity) distribution over the surface of the aperture boundary; a quantity which is also known to characterize the Fraunhofer diffraction pattern of the aperture. In this article, the angular spectrum method is used to formulate a mathematical relationship for two-dimensional apertures between the Fraunhofer diffraction pattern and a one-dimensional Fourier transform of the axial pressure. This relationship can be used to rapidly compute the axial pressure profile of the aperture if the boundary condition on the aperture is known and, in some cases, can be used as an inverse method. The approach is demonstrated for the cases of a flat circular piston and a flat rectangular piston undergoing harmonic motion in an infinite, rigid baffle. In the latter case, an analytical solution is also obtained.

I. INTRODUCTION

The phenomenon of diffraction is the distortion of a wave field that cannot be attributed to either reflection or refraction, occurring when a wave, propagating in an otherwise homogeneous medium, encounters a disturbance in some property of the medium. It has long been known that when the undisturbed wave field takes the form of an infinite plane wave, this distortion is expressible as a transformation of the single plane wave into an infinite number of plane waves, each propagating in a unique direction.[1] This formulation, which has commonly come to be known as the *angular spectrum of plane waves* representation, has as its basis the early work of Weyl,[2] who in 1919 showed that the free space Green's function in three dimensions could be expressed as an expansion of plane waves, infinite in number and propagating in different directions. During the advent of modern computing and the development of the fast Fourier transform, the angular spectrum approach to solving diffraction problems gained additional popularity, since it is a computationally efficient Fourier transform-based method of propagating fields from one location to another. Though such applications began several decades ago,[3,1,4] the use of the angular spectrum method for investigating the characteristics of diffracting wave fields still continues among researchers in the fields of both acoustics and electromagnetism.[5–11]

In this article, we revisit the familiar problem of diffraction by a two-dimensional aperture in the context of the angular spectrum approach, for the purpose of demonstrating that the diffraction effect leads to the presence of a wavenumber spectrum, observable along the normal axis of the aperture, that can be directly related to the Hankel transform of the aperture function (the wavenumber spectrum in the plane of the aperture). As will be shown, this spectral relation provides a convenient means of computing the axial pressure profile of the aperture from values of the far field diffraction pattern and, in some cases, vice versa. Also, because the diffraction pattern has a direct relationship to the boundary condition on the aperture, it follows that knowledge of the axial field can potentially provide the means to quickly reconstruct a band-limited version of the boundary condition.

In Sec. II, we derive the theoretical relationship between the wavenumber spectrum of the acoustic pressure propagating along the axis of a rotationally symmetric, two-dimensional aperture and that of the normal velocity on the aperture boundary. In Sec. III, we utilize the widely recognized solution for diffraction by a flat circular piston in an infinite baffle to demonstrate computationally the validity of the results derived in Sec. II. Finally, in Sec. IV, we extend the formalism of Sec. II to address two-dimensional apertures of any shape, and utilize the result to derive a closed form solution for the axial pressure propagating from a rectangular aperture.

II. THEORY

We begin by considering monochromatic acoustic radiation, or single-frequency harmonic motion, for which the spatial distribution of the acoustic pressure field at any instant in time and any point $z>0$ can be represented in terms of an angular spectrum of plane waves as[12]

[a)]Portions of this work were presented in "Diffraction pattern of an axisymmetric aperture from axial measurements," 151st Meeting of the Acoustical Society of America, Providence, RI, June 2006.

[b)]Electronic mail: edward.pees@navy.mil

$$p(\mathbf{r}) = \frac{1}{(2\pi)^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} P(k_x,k_y;z=0) \times e^{ik_x x}e^{ik_y y}e^{iz\sqrt{k_o^2-k_x^2-k_y^2}}dk_x dk_y, \quad (1)$$

where $P(k_x,k_y;z=0)$ is the two-dimensional spatial Fourier transform of the acoustic pressure $p(x,y,0)$ in the plane containing the aperture.

Given circular symmetry with respect to the z-axis, Eq. (1) can be more conveniently written in terms of a one-dimensional inverse Hankel transform as[13,14]

$$p(\rho,z) = \frac{1}{2\pi}\int_0^{\infty} P(k_\rho;z=0)J_0(k_\rho\rho)e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho, \quad (2)$$

where $\rho=\sqrt{x^2+y^2}$, and which, for points along the z-axis, simply reduces to

$$P(\rho=0,z)\frac{1}{2\pi}\int_0^{\infty} P(k_\rho;z=0)e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho. \quad (3)$$

We should note that $P(k_\rho;z=0)$ is no longer a two-dimensional Fourier transform of the acoustic pressure over the entire plane of the aperture, but the corresponding one-dimensional Hankel transform of the acoustic pressure along a radial line in the plane of the aperture.

From the linear inviscid force equation,[15] we have the relationship between the acoustic pressure and the normal component of the particle velocity

$$\frac{\partial p(\mathbf{r})}{\partial z} = i\omega_o\rho_o u_z(\mathbf{r}), \quad (4)$$

where ρ_o is the mass density of the medium, not to be confused with the spatial coordinate $\rho=\sqrt{x^2+y^2}$. In terms of Eq. (2), the partial derivative can be expressed as

$$\frac{\partial p(\rho,z)}{\partial z} = \frac{i}{2\pi}\int_0^{\infty}\sqrt{k_o^2-k_\rho^2}P(k_\rho;z=0) \times J_0(k_\rho\rho)e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho, \quad (5)$$

and, therefore, the normal velocity becomes

$$u_z(\rho,z) = \frac{1}{2\pi\omega_o\rho_o}\int_0^{\infty}\sqrt{k_o^2-k_\rho^2}P(k_\rho;z=0) \times J_0(k_\rho\rho)e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho. \quad (6)$$

Furthermore, since $u_z(\mathbf{r})$ satisfies the Helmholtz equation, it can also be expressed in terms of a plane wave spectrum[1]

$$u_z(\rho,z) = \frac{1}{2\pi}\int_0^{\infty} U(k_\rho;z=0)J_0(k_\rho\rho)e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho, \quad (7)$$

where $U(k_\rho;z=0)$ is the one-dimensional spatial Hankel transform of the normal velocity $u_z(\rho,z=0)$ along a radial line in the plane containing the aperture. Thus, comparing Eqs. (6) and (7), it is seen that

$$P(k_\rho;z=0) = \omega_o\rho_o\frac{U(k_\rho;z=0)}{\sqrt{k_o^2-k_\rho^2}}. \quad (8)$$

From this, we can then return to Eq. (3) and write the complex axial pressure for $z\geq 0$ as

$$P(\rho=0,z) = \frac{\omega_o\rho_o}{2\pi}\int_0^{\infty}\frac{U(k_\rho;z=0)}{\sqrt{k_o^2-k_\rho^2}}e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho, \quad (9)$$

which one may recognize as a form of King's integral[16] in the limit $\rho\to 0$.

Now that we have a relationship between the axial pressure and the normal velocity on the aperture boundary we will limit ourselves to values of the pressure field such that the upper limit of integration in Eq. (9) can be truncated at k_o, the cut-off wavenumber, beyond which the pressure field is evanescent,[17]

$$P(\rho=0,z) = \frac{\omega_o\rho_o}{2\pi}\int_0^{k_o}\frac{U(k_\rho;z=0)}{\sqrt{k_o^2-k_\rho^2}}e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho. \quad (10)$$

This approximation merely precludes the use of Eq. (10) for representing the *total* pressure field at values of z within a few wavelengths of the origin,[18] though it is still a valid representation for the propagating or *homogeneous* field.

Now, in the angular spectrum of plane wave representation, each plane wave component of the field has a wavevector magnitude of k_o; therefore, the magnitudes of the ρ- and z-components of a constituent wavevector always obey the constraint

$$k_o^2 = k_\rho^2 + k_z^2. \quad (11)$$

This constraint allows us to rewrite Eq. (10) in terms of an integration over k_z as

$$P(\rho=0,z) = \frac{\omega_o\rho_o}{2\pi}\int_0^{k_o} U(\sqrt{k_o^2-k_z^2};z=0)e^{ik_z z}dk_z. \quad (12)$$

The point to be made here is that Eq. (12) relates the axially observed, homogeneous pressure radiating from the aperture to the radially observed particle velocity in the plane containing the aperture, through a nonlinear mapping of a one-dimensional Hankel transform of the normal component of the particle velocity.

Note also that Eq. (12) takes the form of a band-limited inverse Fourier transform. Clearly this is equivalent to the proper inverse Fourier transform of a function that is identically zero outside the band of interest. We can therefore modify Eq. (12) to represent such a transform by the introduction of an appropriate windowing function.

That is, if $H(k_z)$ is the rectangular window defined as

$$H(k_z) \equiv 1 \quad \text{for} \quad 0\leq k_z\leq k_o;$$
$$\equiv 0 \quad \text{otherwise},$$

then multiplying this function with the integrand in Eq. (12) permits us to write the propagating part of the axial pressure field as

$$P(\rho=0,z)=\frac{\omega_o\rho_o}{2\pi}\int_{-\infty}^{\infty}U(\sqrt{k_o^2-k_z^2};z=0)H(k_z)e^{ik_zz}dk_z. \tag{13}$$

We are free to take the Fourier transform of Eq. (13), from which we obtain the rather simple result

$$P(k_z;\rho=0)=\omega_o\rho_oU(\sqrt{k_o^2-k_z^2};z=0) \quad \text{for} \quad 0\le k_z\le k_o. \tag{14}$$

Equation (14) is the principal result of this article. It reveals that the wavenumber spectrum of the acoustic pressure propagating along the axis of a rotationally symmetric, two-dimensional aperture can be obtained directly from that of the normal velocity on the boundary of such an aperture. Conversely, and under limited circumstances (discussed in the Appendix), the velocity spectrum and, by extension, the far field diffraction pattern can be obtained from knowledge of the axial pressure spectrum. This is clearly a relationship of some utility since, by Fourier inversion [i.e., Eq. (13)], the propagating part of the axial pressure associated with any two-dimensional, axisymmetric aperture can be directly computed if one can only specify the velocity boundary condition. Furthermore, from an analogous expression for the normal velocity, a band-limited version of a limited class of boundary conditions can be readily computed if one can specify the axial pressure. These assertions are demonstrated in Sec. III by considering the familiar problem of radiation from a flat, circular piston undergoing harmonic motion.

III. CIRCULAR PISTON

As an example, we now consider the problem of the flat, circular piston in an infinite rigid baffle, for which an analytical result for the axial pressure is widely available.[15,19,20] The far field directivity pattern for such an aperture is known to be given by[21]

$$D(\theta)=2\frac{J_1(k_oa\sin\theta)}{k_oa\sin\theta}. \tag{15}$$

We wish to demonstrate the validity of Eq. (14) by computing the radiation pattern of this aperture given only values of the axial pressure. Normalizing by $2\rho_oc u_o$, the axial pressure takes the form

$$p(\rho=0,z)=\frac{e^{ik_oz}-e^{ik_o\sqrt{z^2+a^2}}}{2}, \tag{16}$$

where a is the radius of the piston. Since an analytical result for the Fourier transform of Eq. (16) is not available, we compute a table of values and perform the Fourier transform numerically. Figure 1 shows a portion of the computed pressure values, and Fig. 2 shows the wavenumber spectrum obtained upon evaluation of the discrete, spatial Fourier transform.

As mentioned earlier, we are not considering evanescent energy in this problem; thus upon computing the Fourier transform of the axial pressure values, we truncate the resulting spectrum at the cut-off wavenumber k_o. What Fig. 2 effectively shows us then is the amplitude distribution of the plane waves comprising the angular spectrum of the diffracted pressure field, as a function of their propagation directions given by $k_z=k_o\cos\theta$; with θ being the angle measured from the normal axis of the aperture.

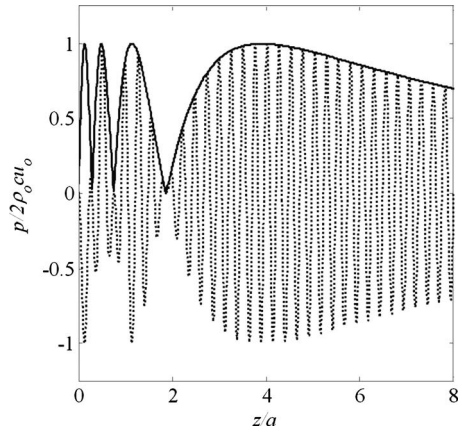

FIG. 1. Real part (dashed) and absolute value (solid) of complex axial pressure radiating from a baffled circular piston.

Applying the transformation given by Eq. (14) to these data yields the Hankel transform $U(k_\rho)$ of the aperture function, or aside from a multiplicative phase factor,[22] the Fraunhofer radiation pattern of the aperture. This is shown in Fig. 3, along with the theoretical result given by Eq. (15), with $k_\rho=k_o\sin\theta$.

As expected, the results are a precise match. One may notice, however, the uneven distribution of data points that occurs due to the nonlinear variable transformation given by Eq. (14). We further note that a band-limited approximation to the boundary condition can be recovered via an inverse Hankel transform of this quantity. Because of the uneven sample spacing, however, one must first interpolate these values to obtain a uniformly spaced set of data points to which a discrete Hankel transform can be applied. This could be considered a one-dimensional analog of the two-dimensional frequency domain interpolation technique associated with diffraction tomogramphy.[23] Figure 4 shows the

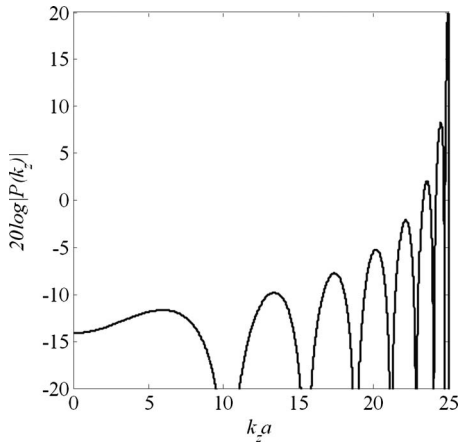

FIG. 2. Magnitude of the wavenumber spectrum obtained from a discrete Fourier transform of the axial pressure radiating from a baffled circular piston.

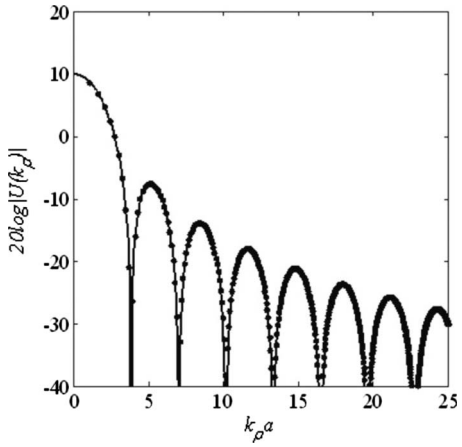

FIG. 3. Magnitude of the radial wavenumber spectrum (dots) of the acoustic velocity on the boundary of a baffled circular piston, obtained from the axial pressure spectrum via Eq. (14) vs the theoretical diffraction pattern (solid).

result of computing the inverse Hankel transform of $U(k_\rho)$ using linear interpolation to first obtain a uniformly sampled data set.

As a final demonstration, we show how the reconstruction process just described can be reversed to alternatively permit the computation of axial pressure fields from specified boundary conditions and their corresponding wavenumber spectra. That is, we show how the Fraunhofer diffraction pattern of an axisymmetric aperture can be used to compute the propagating part of the axial pressure radiating from the aperture. To see how this is achieved, let us assume that we are again dealing with the baffled circular piston having a Neumann boundary condition with a normal velocity amplitude that is unity on the piston face and zero on the baffle; we then have the well known Fraunhofer result for $U(k_\rho;z=0)$ (Refs. 13, 17, 19, and 24) [shown in Fig. 5(a) for $k_o a=25$] as follows:

$$U(k_\rho;z=0)=2\pi a\frac{J_1(k_\rho a)}{k_\rho}, \tag{17}$$

where a is the radius of the piston. Substituting this into Eq. (14) gives us an expression for the wavenumber spectrum of the axial pressure [see Fig. 5(b)]

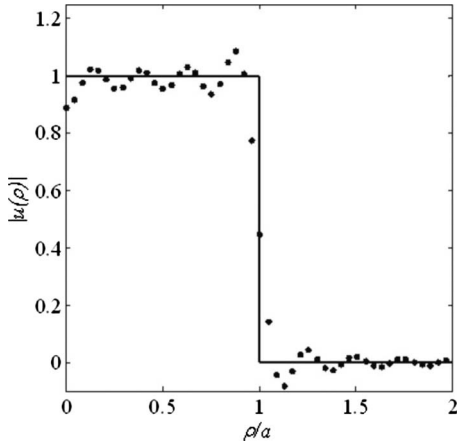

FIG. 4. Band-limited reconstruction (dots) of the velocity boundary condition at the surface of a baffled circular piston obtained from the axial pressure spectrum via a discrete inverse Hankel transform of Eq. (14). The solid line segments represent the ideal rectangular boundary condition.

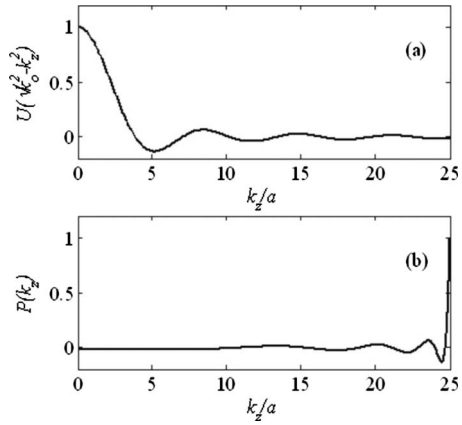

FIG. 5. Theoretical result for the Hankel transform of the ideal Neumann boundary condition associated with the baffled circular piston (a), and the corresponding axial wavenumber spectrum (b) obtained via Eq. (14).

$$P(k_z)=2\pi a\omega_o\rho_o\frac{J_1(a\sqrt{k_o^2-k_z^2})}{\sqrt{k_o^2-k_z^2}}. \tag{18}$$

We can see that by its very nature, the Fraunhofer diffraction pattern only provides that portion of the axial wavenumber spectrum up to the cut-off wavenumber. This is no surprise, of course, since the evanescent field, which corresponds to higher wavenumbers, is not observable in the Fraunhofer region. It implies, therefore, that the axial pressure obtained from a discrete Fourier transform of this wavenumber spectrum will have limited spatial resolution. To show this, we construct a discretely sampled spectrum using Eq. (18) for $k_o a=25$, and compute the axial pressure by performing a discrete inverse Fourier transform on the data. Figure 6 shows both the theoretical result from Eq. (16) and the result of numerically computing the inverse transform.

As can be seen, the resulting spatial resolution (which is $\Delta z/a=\pi/k_o a\cong 0.13$ in this case) is inadequate for capturing the lobe structure below $z/a\cong 2$. In an attempt to remedy this, our first inclination might be to simply zero-pad the wavenumber spectrum prior to Fourier inversion. However, as is evident in Fig. 7, the unwanted Gibbs phenomenon[25] arises due to the discontinuity that zero-padding introduces to the wavenumber spectrum at $k_z=0$.

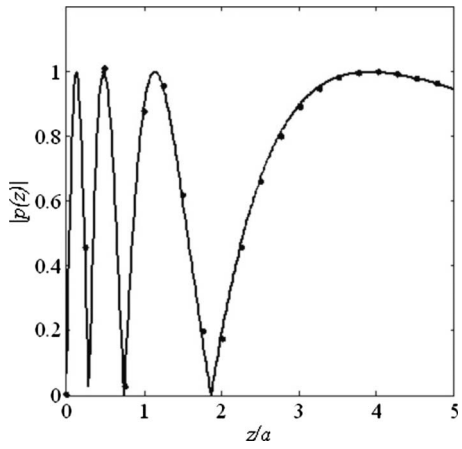

FIG. 6. Magnitude of the acoustic pressure propagating along the axis of a baffled circular piston, obtained from a discrete implementation of Eq. (12) (dots) vs the theoretical result given by Eq. (16) (solid).

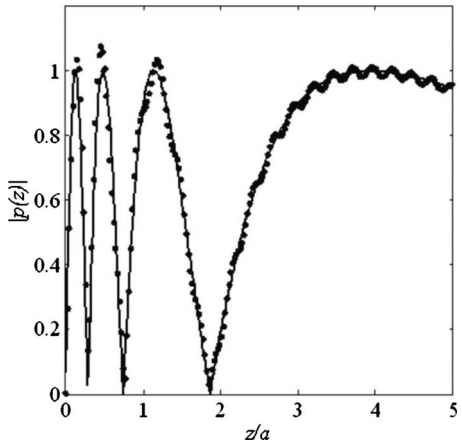

FIG. 7. Magnitude of the acoustic pressure propagating along the axis of a baffled circular piston, obtained from a discrete implementation of Eq. (12) with zero-padding to illustrate the effect of Gibbs phenomenon (dots) vs the theoretical result given by Eq. (16) (solid).

It is possible, however, to mitigate this effect somewhat if we consider the relative contributions of different portions of the wavenumber spectrum to the axial pressure. As noted earlier, the principal contribution comes from the plane wave component of the angular spectrum that propagates directly along the piston axis. Conversely, as the direction of propagation of the remaining plane wave components moves further from the axis of symmetry (i.e., the k_z-components of the wavevectors decrease), their contributions to the axial field generally diminish. This suggests that, if we can suppress the discontinuity at $k_z=0$ without affecting the spectrum at higher values of k_z, we may be able to recover a more precise representation of the axial pressure field. Such an objective is commonly met in signal processing applications with the use of shading functions.

To illustrate its effect, we apply a shading function to the pressure spectrum shown in Fig. 5 and recompute the inverse Fourier transform. The function used in this example is a 50% cosine-tapered (Tukey) window (see Fig. 8), and its effect on the axial pressure spectrum is illustrated in Fig. 9.

Performing the inverse Fourier transform on this shaded quantity yields the axial pressure profile shown in Fig. 10. As

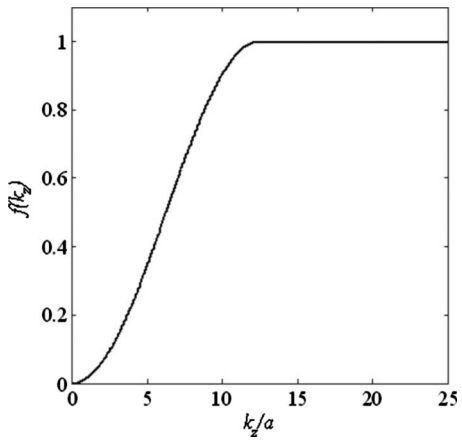

FIG. 8. Illustration of a 50% cosine-tapered (Tukey) shading function used in place of the ideal Heaviside function in Eq. (13) to mitigate the effects of Gibbs phenomenon observable in Fig. 7.

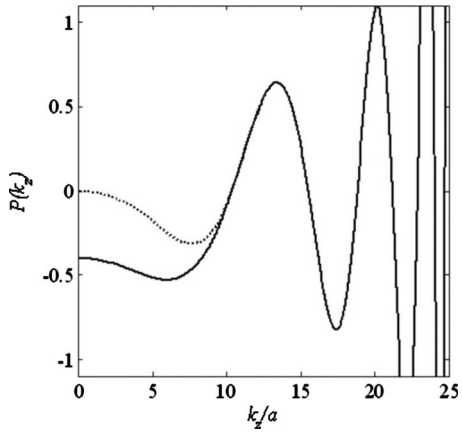

FIG. 9. Wavenumber spectrum of the axial pressure associated with a baffled circular piston, with (dashes) and without (solid) the application of the Tukey shading function shown in Fig. 8.

can be seen, the result is a successful elimination of the rippling observed in Fig. 7, along with, however, a loss of some information for small values of z/a. While this information loss is due, in part, to the absence of evanescent energy in our solution, it is also due to the additional restriction imposed on the bandwidth of the spectrum by the shading function, needed to obtain a well behaved quantity to which a discrete Fourier transform could successfully be applied.

Since the choice of shading function was somewhat arbitrary in this example, it is reasonable to expect that the accuracy of the computed pressure profile could be improved by developing a more optimal selection method. However, since our intent here is to merely demonstrate the validity of the formalism presented in Sec. II, we make no effort to do so in this article.

It may be informative though, to point out that while, in principle, Eq. (13) gives us a general result for the nonevanescent (propagating) part of the axial pressure; in practice, the Heaviside function $H(k_z)$ in the integrand should be

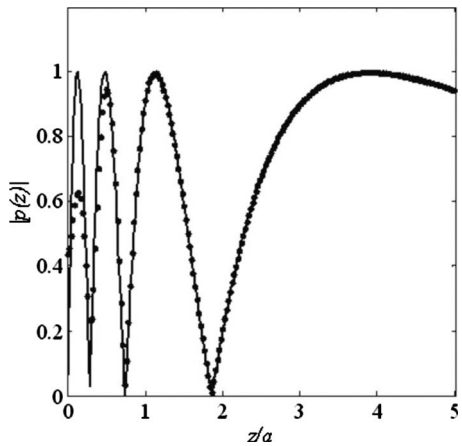

FIG. 10. Magnitude of the acoustic pressure propagating along the axis of a baffled circular piston, obtained from a discrete implementation of Eq. (13) (dots) with the Heaviside function replaced with a Tukey shading function. The departure between the discrete values and the theoretical curve (solid) occurs mostly due to the absence of evanescent energy in the formulation, but partially to the suppression by the Tukey function of some propagating modes as well.

modified to optimize the discrete implementation of this equation. In this sense, $H(k_z)$ is an ideal lowpass filter that suppresses only those spectral components above the cut-off wavenumber, while the shading function is a nonideal filter further suppressing some components of the spectrum below the cut-off wavenumber to permit a more accurate numerical reconstruction of the axial pressure.

IV. RECTANGULAR PISTON

Having now developed a technique for computing the axial pressure of a rotationally symmetric aperture from its Fraunhofer pattern (or the Hankel transform of the boundary condition), it will finally be shown how the same approach can be used to compute an "axial" pressure associated with any two-dimensional aperture for which the boundary condition (hence the far field diffraction pattern) is known. In the case of apertures that possess no particular symmetry the term axial becomes ambiguous, but will be retained nonetheless to facilitate the discussion. The baffled rectangular piston will be used as an example, wherein the technique will provide not only a computational result for the homogeneous axial pressure, but will also lead to an analytical solution.

Returning to Eq. (1), we write the axial pressure in Cartesian coordinates [rather than cylindrical coordinates, as in Eq. (3)] by setting $x=y=0$ as follows:

$$p(x=y=0,z\geq 0)=\frac{1}{(2\pi)^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}P(k_x,k_y;z=0)\times e^{iz\sqrt{k_o^2-k_x^2-k_y^2}}dk_x dk_y. \tag{19}$$

We know from Eq. (8) that the relationship between the two-dimensional spatial Fourier transform of the pressure distribution in the plane at $z=0$ and that of the acoustic velocity normal to this plane can be expressed as

$$P(k_x,k_y;z=0)=\omega_o\rho_o\frac{U(k_x,k_y;z=0)}{\sqrt{k_o^2-k_x^2-k_y^2}}. \tag{20}$$

If we therefore substitute this expression into Eq. (19), we obtain, similar to Eq. (9), the acoustic pressure observable along the positive z-axis in terms of the velocity spectrum in the plane at $z=0$ as follows:

$$p(x=y=0,z\geq 0)=\frac{\omega_o\rho_o}{(2\pi)^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{U(k_x,k_y;z=0)}{\sqrt{k_o^2-k_x^2-k_y^2}}\times e^{iz\sqrt{k_o^2-k_x^2-k_y^2}}dk_x dk_y. \tag{21}$$

Now, even though we assume no symmetries of any kind, way may still rewrite this equation in cylindrical coordinates as

$$p(\rho=0,z\geq 0)=\frac{\omega_o\rho_o}{(2\pi)^2}\int_{0}^{\infty}\int_{0}^{2\pi}\frac{U(k_\rho,\varphi;z=0)}{\sqrt{k_o^2-k_\rho^2}}\times e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho d\varphi. \tag{22}$$

Or, limiting the integration over k_ρ to address only propagating waves,

$$p(\rho=0,z\geq 0)=\frac{\omega_o\rho_o}{(2\pi)^2}\int_{0}^{k_o}\int_{0}^{2\pi}\frac{U(k_\rho,\varphi;z=0)}{\sqrt{k_o^2-k_\rho^2}}\times e^{iz\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho d\varphi. \tag{23}$$

Here, $U(k_\rho,\varphi)$ can be thought of as a radial slice of $U(k_x,k_y)$ taken at an angle φ from the k_x-axis. If we rearrange this slightly to read

$$p(\rho=0,z\geq 0)=\frac{\omega_o\rho_o}{(2\pi)^2}\int_{0}^{k_o}\left[\frac{1}{2\pi}\int_{0}^{2\pi}U(k_\rho,\varphi;z=0)d\varphi\right]\times\frac{e^{iz\sqrt{k_o^2-k_\rho^2}}}{\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho, \tag{24}$$

then we recognize the quantity in brackets to be just the mean value of $U(k_\rho,\varphi;z=0)$ over its φ-dependence, which we will henceforth denote as $\langle U(k_\rho;z=0)\rangle_\varphi$. This allows us to write Eq. (24) as

$$p(\rho=0,z\geq 0)=\frac{\omega_o\rho_o}{(2\pi)^2}\int_{0}^{k_o}\langle U(k_\rho;z=0)\rangle_\varphi\frac{e^{iz\sqrt{k_o^2-k_\rho^2}}}{\sqrt{k_o^2-k_\rho^2}}k_\rho dk_\rho. \tag{25}$$

We are now able to use the constraint $k_o^2=k_\rho^2+k_z^2$ to change variables as before and write the axial pressure as

$$p(\rho=0,z\geq 0)=\frac{\omega_o\rho_o}{2\pi}\int_{0}^{k_o}\langle U(\sqrt{k_o^2-k_z^2};z=0)\rangle_\varphi e^{ik_z z}dk_z. \tag{26}$$

Equation (26) thus reveals how the propagating axial pressure arising from a two-dimensional velocity distribution *of arbitrary shape* can be directly computed via a one-dimensional inverse Fourier transform of the velocity spectrum on the aperture boundary averaged over its φ-dependence around the normal axis of observation.

As an informative example, we consider the case of a flat, rectangular piston undergoing unit-amplitude, harmonic motion in an infinite, rigid baffle, for which the velocity spectrum on the boundary takes the form[26]

$$U(k_x,k_y)=4\frac{\sin(k_x a)}{k_x}\frac{\sin(k_y b)}{k_y}. \tag{27}$$

If φ is taken to be the angle that k_ρ makes with the k_x-axis in the k_x-k_y plane, then this can be written in polar coordinates as

$$U(k_\rho,\varphi)\frac{4}{k_\rho^2}\frac{\sin(k_\rho a\cos\varphi)}{\cos\varphi}\frac{\sin(k_\rho b\sin\varphi)}{\sin\varphi}. \tag{28}$$

If (for simplicity), we further let $a=b=1$, and generate an array of values with $k_o=25$ for $U(k_\rho,\varphi)$, we can then easily compute the average value of the array over the φ-dimension. A discrete, inverse Fourier transform of the resulting one-dimensional array is then computed to produce the axial pressure profile shown in Fig. 11. Not surprisingly, the behavior of the pressure amplitude is similar to that of a baffled circular piston of comparable size (see Fig. 7), but demonstrates less pronounced nulls and virtually no Gibbs

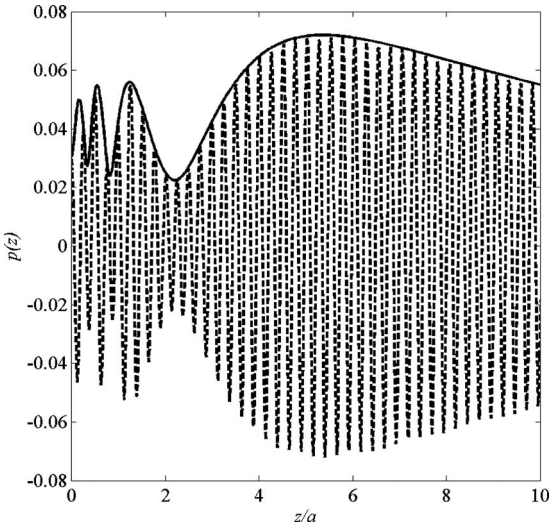

FIG. 11. Real part (dashed) and absolute value (solid) of complex axial pressure radiating from a baffled square piston for $k_0a=25$.

rippling, despite not having used a shading function in the computation (this would not be the case, in general; in this example, the axial spectrum simply happens to be very small near $k_z=0$). Unfortunately, unlike the circular piston, a full solution for the axial pressure associated with a rectangular piston is not available for comparison. However, as mentioned earlier, the technique introduced here does facilitate the derivation of an analytical solution for the propagating portion of the axial pressure.

We can obtain this solution by first noting that [in Eq. (27)] $\sin x$ can be written as

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots = \sum_{m=0}^{\infty} (-1)^m \frac{x^{2m+1}}{(2m+1)!}, \tag{29}$$

from which it follows that $\sin(\alpha x)/x$ takes the form

$$\frac{\sin(\alpha x)}{x} = \sum_{m=0}^{\infty} (-1)^m \frac{\alpha^{2m+1} x^{2m}}{(2m+1)!}. \tag{30}$$

With this result, the velocity spectrum can be expressed as

$$\begin{aligned} U(k_\rho,\varphi) &= \frac{4}{k_\rho^2} \sum_{m=0}^{\infty} (-1)^m \frac{(k_\rho a)^{2m+1} \cos(\varphi)^{2m}}{(2m+1)!} \\ &\quad \times \sum_{n=0}^{\infty} (-1)^n \frac{(k_\rho b)^{2n+1} \sin(\varphi)^{2n}}{(2n+1)!} \\ &= 4 \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} (-1)^{m+n} \frac{a^{2m+1} b^{2n+1} k_\rho^{2(m+n)}}{(2m+1)!(2n+1)!} \\ &\quad \times \cos(\varphi)^{2m} \sin(\varphi)^{2n}. \end{aligned} \tag{31}$$

The average value of this quantity with respect to the variable φ can now be evaluated by integrating from 0 to 2π, and making use of the integral formula

$$\int_0^{2\pi} \cos(\varphi)^{2m} \sin(\varphi)^{2n} d\varphi = 2B\left(m+\frac{1}{2}, n+\frac{1}{2}\right), \tag{32}$$

where $B(\alpha,\beta)$ is the Euler beta function.

The result is

$$\begin{aligned} \langle U(k_\rho; z=0)\rangle_\varphi &= 8 \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} (-1)^{m+n} \frac{a^{2m+1} b^{2n+1} k_\rho^{2(m+n)}}{(2m+1)!(2n+1)!} \\ &\quad \times B\left(m+\frac{1}{2}, n+\frac{1}{2}\right). \end{aligned} \tag{33}$$

Similar to Eq. (14) then, the axial pressure spectrum can be written as

$$\begin{aligned} P(k_z; \rho=0) &= \omega_o \rho_o \langle U(\sqrt{k_0^2 - k_z^2}; z=0)\rangle_\varphi \\ &= 8\omega_o \rho_o \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} (-1)^{m+n} \\ &\quad \times \frac{a^{2m+1} b^{2n+1} (k_0^2 - k_z^2)^{(m+n)}}{(2m+1)!(2n+1)!} \\ &\quad \times B\left(m+\frac{1}{2}, n+\frac{1}{2}\right). \end{aligned} \tag{34}$$

Therefore, by Eq. (26), the propagating part of the axial pressure can be computed by evaluating the band-limited inverse Fourier transform of this equation

$$\begin{aligned} p(z; \rho=0) &= \frac{4\omega_o \rho_o}{\pi} \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} (-1)^{m+n} \frac{a^{2m+1} b^{2n+1}}{(2m+1)!(2n+1)!} \\ &\quad \times B\left(m+\frac{1}{2}, n+\frac{1}{2}\right) \int_0^{k_0} (k_0^2 - k_z^2)^{m+n} e^{ik_z z} dk_z. \end{aligned} \tag{35}$$

The integral in this equation can be evaluated by making the substitution $k_z \to k_0 \cos\theta$, from which we obtain

$$\begin{aligned} &\int_0^{k_0} (k_0^2 - k_z^2)^{m+n} e^{ik_z z} dk_z \\ &= \int_0^{\pi/2} k_0^{2m+2n+1} \sin^{2m+2n} \theta e^{ik_0 z \cos\theta} \sin\theta d\theta \\ &= k_0^{2m+2n+1} \left[\int_0^{\pi/2} \cos(k_0 z \cos\theta) \sin^{2m+2n+1}\theta d\theta \right. \\ &\quad \left. + i \int_0^{\pi/2} \sin(k_0 z \cos\theta) \sin^{2m+2n+1}\theta d\theta \right]. \end{aligned} \tag{36}$$

One may recognize the last two terms as the integral representations of the Bessel and Struve functions, respectively.[27] Thus, the integral can be written as

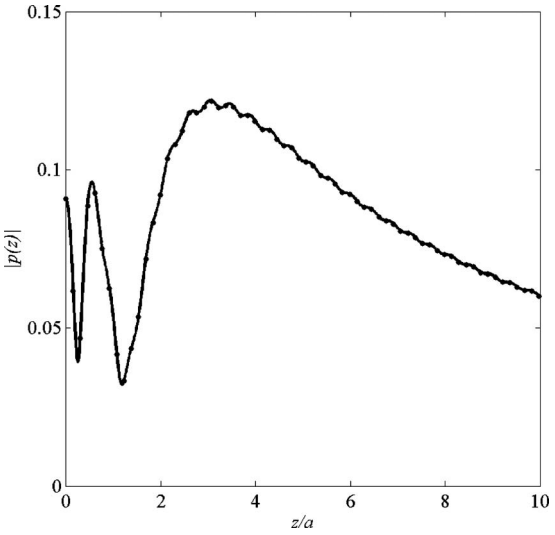

FIG. 12. Magnitude of the acoustic pressure propagating along the axis of a baffled square piston, obtained from a discrete implementation of Eq. (26) (dots) with $k_0a=15$ vs the theoretical result given by Eq. (38) (solid).

$$\int_0^{k_0} (k_0^2 - k_z^2)^{m+n} e^{ik_z z} dk_z = \frac{k_0^{2m+2n+1}\sqrt{\pi}\Gamma(m+n+1)}{2\left(\frac{z}{2}\right)^{m+n+1/2}} \times [J_{m+n+1/2}(k_0 z) + iH_{m+n+1/2}(k_0 z)] \tag{37}$$

[where $\Gamma(\alpha)$ is the Euler gamma function, $J_\nu(\alpha)$ is the Bessel function, and $H_\nu(\alpha)$ is the Struve function] so that the propagating part of the axial pressure can be written as

$$p(z;\rho=0) = \frac{2\omega_o\rho_o}{\sqrt{\pi}} \sum_{m=0}^{\infty}\sum_{n=0}^{\infty} (-1)^{m+n} \left(\frac{2k_0^2}{z}\right)^{m+n+1/2} \times \frac{a^{2m+1}b^{2n+1}}{(2m+1)!(2n+1)!} B\left(m+\frac{1}{2}, n+\frac{1}{2}\right) \times \Gamma(m+n+1)[J_{m+n+1/2}(k_0 z) + iH_{m+n+1/2}(k_0 z)]. \tag{38}$$

This result represents an exact solution to Eq. (26), when $\langle U(\sqrt{k_o^2 - k_z^2}; z=0)\rangle_\varphi$ is given by Eq. (33). A computational evaluation of this formula can be problematic though, principally due to the factorial terms in the denominator, which can rapidly lead to a loss of accuracy as m and n become large. It was evaluated, however, for $k_0a=15$, the result of which is shown in Fig. 12, along with result obtained via the discrete Fourier transform approach. As expected, the two approaches yield the same result.

V. CONCLUSIONS

By way of the angular spectrum of plane waves representation of the pressure field diffracted by an axisymmetric two-dimensional aperture, we developed a direct mathematical relationship between the normal component of the acoustic velocity on the aperture boundary and the propagating portion of the acoustic pressure along the axis of symmetry. While, in its simplest form, this relationship is expressed in wavenumber space, we have seen that through the use of Fourier and Hankel transforms, one can obtain spatial representations of either of these quantities via numerical methods. We have further found that in implementing these methods, some care must be exercised in order to avoid the introduction of numerical errors associated with the conversion from a continuous to a discrete representation.

In terms of the axial pressure, this involved the application of a shading function to the argument of the discrete Fourier transform to achieve a smoothly terminating spectrum, and hence, to avoid the appearance of Gibbs phenomenon in the computed pressure values. Though not optimized, the approach was shown to enable us to characterize the axial pressure behavior of the aperture for values of z/a down to approximately 0.5; roughly an order of magnitude closer than an asymptotic approximation would permit. For values below this, the absence of higher frequency information prevents us from accurately characterizing the field. This approach was shown to hold for any two-dimensional aperture for which either the velocity boundary condition or its Hankel transform can be specified.

Alternatively, using the axial pressure to compute either the boundary condition or the far field diffraction pattern of the aperture was found to be more restrictive. As shown in the Appendix, these computations are only possible for problems in which the boundary condition on the plane of the aperture is axisymmetric, and known to be expressible as an entirely real quantity. While the example of the baffled piston is one such case, there are others of potential practical interest, such as certain axisymmetric vibrational modes of circular plates and membranes.

The efficiency afforded by this approach, however, may be its most redeeming feature. For instance, if one were to employ the conventional angular spectrum method to obtain the axial pressure associated with a rotationally symmetric aperture, the spectrum obtained by first computing the two-dimensional Fourier transform of the boundary condition would have to be propagated successively along the axis of symmetry and inverse transformed at each point to obtain one discrete value of the axial pressure. This new method, on the other hand, requires only a single Fourier transform to obtain the same set of axial pressure values after first computing the Hankel transform of the boundary condition. The computational savings, in this case, are evident since multiple two-dimensional Fourier transforms are reduced to a single one-dimensional Fourier transform.

ACKNOWLEDGMENTS

The author would like to thank Peter Stepanishen of the University of Rhode Island for his invaluable technical feedback in the preparation of this paper. It would certainly be of lesser quality without the benefit of his extensive experience in this field. This work was supported by the Naval Undersea Warfare Center, Newport, RI.

APPENDIX

From the form of Eq. (13) it is apparent that an evaluation of the Fourier transform on the right side of the equation will yield complex pressure values for all z. And though a relationship can be shown to exist between those pressure values corresponding to positive z, and those corresponding to negative z, the latter cannot be assumed to have any physical significance since by our definition of the boundary value problem, we have no knowledge of the conditions corresponding to negative z.

Thus, if we wish to compute the pressure spectrum in Eq. (14) (and subsequently the diffraction pattern) from values of the axial pressure, then we require pressure values for negative z as well as positive z. To see how the former values can be obtained, consider the simple example of a circular piston transducer vibrating at a fixed frequency, surrounded by an annular ring transducer vibrating with the same frequency, but slightly out of phase with the piston. In this type of situation, the specified boundary condition will be a complex quantity expressible as

$$\tilde{u}(\rho,z=0)=\mathrm{Re}[\tilde{u}(\rho,z=0)]+i\ \mathrm{Im}[\tilde{u}(\rho,z=0)], \tag{A1}$$

where the tilde is used here to explicitly denote complex quantities.

The Hankel transform of this quantity will also be complex, and can be written as

$$\tilde{U}(k_\rho,z=0)=\mathrm{Re}[\tilde{U}(k_\rho,z=0)]+i\ \mathrm{Im}[\tilde{U}(k_\rho,z=0)], \tag{A2}$$

where $\mathrm{Re}[\tilde{U}(k_\rho,z=0)]$ is the Hankel transform of $\mathrm{Re}[\tilde{u}(\rho,z=0)]$, and $\mathrm{Im}[\tilde{U}(k_\rho,z=0)]$ is the Hankel transform of $\mathrm{Im}[\tilde{u}(k_\rho,z=0)]$.

When this quantity is inserted into Eq. (13), we obtain

$$\tilde{p}(\rho=0,z)=\frac{\omega_o\rho_o}{2\pi}\int_{-\infty}^{\infty}\mathrm{Re}[\tilde{U}(k_\rho,z=0)]H(k_z)e^{ik_zz}dk_z + i\frac{\omega_o\rho_o}{2\pi}\int_{-\infty}^{\infty}\mathrm{Im}[\tilde{U}(k_\rho,z=0)]H(k_z)e^{ik_zz}dk_z. \tag{A3}$$

So, since each of these two integrals represents the inverse Fourier transform of an asymmetric, real quantity, the result of each will be a Hermitian quantity, which we write as

$$\begin{aligned}\tilde{p}(\rho=0,z)&\equiv\tilde{p}_1(z)+i\tilde{p}_2(z)\\&=\mathrm{Re}[\tilde{p}_1(z)]+i\ \mathrm{Im}[\tilde{p}_1(z)]+i\ \mathrm{Re}[\tilde{p}_2(z)]\\&\quad-\mathrm{Im}[\tilde{p}_2(z)],\end{aligned} \tag{A4}$$

where the first and third terms (i.e., the real terms) are even functions of z, and the imaginary terms are odd.

Equation (A4) reveals the form of the complex axial pressure produced by evaluating the inverse Fourier transform of Eq. (13) for a complex boundary condition $\tilde{u}(\rho,z=0)$. The term $\tilde{p}_1(z)$ is that portion of the axial pressure produced by the real part of the boundary condition, whereas $\tilde{p}_2(z)$ is the portion produced by the imaginary part of the boundary condition. Thus, if the boundary condition is a purely real quantity, then the resulting complex axial pressure simply becomes the sum of an even, real function and its Hilbert transform. Computationally (or experimentally), this is readily accommodated. Having computed (or measured) the real axial pressure values for positive z, one simply adds the Hilbert transform and folds the conjugate of the result over to the negative z-axis. This operation yields a set of complex axial pressure values for both positive and negative z, consistent with Eq. (13), and therefore permits the Fourier transform leading to Eq. (14).

If we now consider the general case of a complex boundary condition, then by Eq. (A4), the real part of the complex axial pressure predicted by Eq. (13) assumes the form

$$\mathrm{Re}[\tilde{p}(\rho=0,z)]=\mathrm{Re}[\tilde{p}_1(z)]-\mathrm{Im}[\tilde{p}_2(z)]. \tag{A5}$$

Here, the pressure is seen to be the difference between an even and odd function. Such a difference results in an overall function that, in general, has no symmetry with respect to z. As such, the real pressure values measured along the positive z-axis cannot be used to construct values corresponding to the negative z-axis. To reiterate then, the diffraction pattern of an axisymmetric aperture can only be obtained from values of the axial pressure if the aperture function is expressible as a purely real (or purely imaginary) quantity, in general.

Nondiffuse elastic and anelastic passive imaging

Francesco Mulargia[a] and Silvia Castellaro
Dipartimento di Fisica, Settore di Geofisica, Università di Bologna, Bologna 40121, Italy

(Received 24 July 2009; revised 23 December 2009; accepted 5 January 2010)

The property at the basis of passive acoustic imaging is that, taken any two points, one of them can be seen as the source of the waves and the other as the recording station. This property, which was shown to hold also in nondiffuse fields, is here exploited: (1) to allow an undistorted passive imaging through the simple use of the statistical mode to estimate wave velocity, (2) to determine the azimuth of the instantaneous Huygens sources of the noise wavefield, and (3) to measure, provided that the noise bandwidth is wide with respect to that of the local system, the material dissipation constant as a function of frequency. The authors applied this theory to study the seismic noise field in the Ravenna, North-Central Italy, shore area and found it capable to provide velocity dispersion curves matching those of independent surveys, to track the sources of seismic noise to a few major firms in Ravenna port, with the prevailing source switching at the time scale of seconds, and to measure the dissipation quality factor Q at ~20 independent of frequency in the range 1–30 Hz. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3298939]

I. INTRODUCTION

The analysis of the spatial correlation of seismic noise has been recently formalized within the general framework of the theory of acoustic diffuse fields[1–5] and shown capable to provide a detailed imaging of Earth's crust.[6] This is somehow surprising since the diffuse field approach requires strong constraints hardly realized in a seismic noise wavefield, such as modal energy equipartition,[7–9] which is only encountered in highly fractured and nondissipative subsoil environments.[10] Such a passive imaging capability of noise spatial correlation appears more simply to lie in the fact that cross-correlating the noise field at two different spatial points leads to a nonuniform mapping in apparent velocity. In particular, a field with wave velocity uniformly distributed with azimuth θ over the angular aperture $(\theta_2-\theta_1)$, but with no constraint on wave amplitude (cf. Fig. 1), is mapped into a field with probability density function g strongly nonuniform in apparent velocity[11]

$$g(\Xi)=\left|\frac{1}{(\theta_2-\theta_1)}\frac{1}{\Xi\sqrt{(\Xi^2-1)}}\right|, \tag{1}$$

where Ξ is the normalized apparent velocity, i.e., the inverse of the adimensional azimuthal slowness

$$\Xi=\frac{v_{\text{apparent}}}{v_{\text{true}}}=\frac{1}{\cos(\theta)}. \tag{2}$$

For any finite field aperture $0°<(\theta_2-\theta_1)\leq 360°$ and considering this field explored at the two points A and B, the distribution $g(\Xi)$ is strongly peaked at $\Xi=1$; i.e., the cross-correlation between the recorded waveforms at A and at B is dominated by waves traveling along the array AB in either direction. According to Huygens principle, A or B will act as point sources and, respectively, B or A as recording stations, allowing to derive the elastodynamic retarded and advanced Green's functions by definition.[11] In the case of an azimuthally isotropic wavefield the latter functions will be identical in concordance with the general property of diffuse fields,[11] granted by reciprocity.[12]

The present work aims at exploiting the above statistical-ballistic property and to show that this property allows the following.

(1) An unbiased measure of wave velocity (both phase velocity, by considering the onset, and group velocity, by introducing an appropriate filter to locate the centroid of the wavepacket[13]). The deployment of semicircular arrays together with the use of the statistical mode as an estimator provides, in fact, an undistorted passive imaging without the need of an explicit correction for astigmatism such as the one suggested by Mulargia and Castellaro.[11]
(2) The azimuthal identification of the instantaneous Huygens sources of the noise wavefield and, under favorable conditions, to ascertain the origin of each of them.
(3) A measure of the material dissipation quality factor Q as a function of frequency, provided that the noise bandwidth is wide compared to the response of the local system in the neighborhood of the points A and B.

II. THE STATISTICAL MODE AS UNBIASED Ξ ESTIMATOR

Consider a wavefield composed of plane waves with uniformly distributed random azimuth in a given angular interval $\theta_1\leq\theta\leq\theta_2$, while no constraint is imposed on the distribution of wave amplitude, which can be of any functional form (see Fig. 1). Let us measure the velocity of such waves by considering in a given time interval T the cross-correlation R_{OS_j} at the radial two-point couples of a semicircular array composed of $n+1$ stations with center in O and peripheral stations S_j (Fig. 2).

[a]Author to whom correspondence should be addressed. Electronic mail: francesco.mulargia@unibo.it

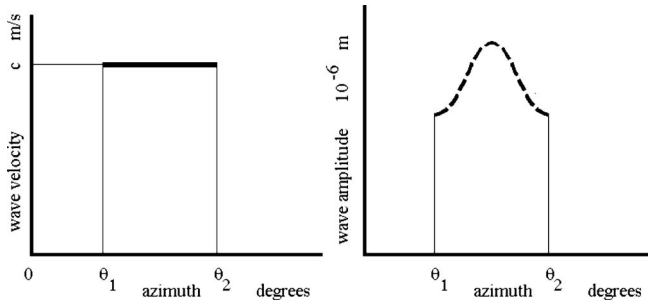

FIG. 1. The wavefields considered here have (left) a uniform probability density function $f(x)=1/(\theta_2-\theta_1)$ on velocity in the angular domains $\theta_1 \le \theta \le \theta_2$ and $0 \le \theta_1 \le \theta_2 \le \pi$. No constraint (right) is imposed on the distribution of wave amplitude, which is here pictorially shown as a Gaussian beam.

Using the above theory, the apparent normalized wave velocity Ξ on a number r of radial station couples will fall near the peak of $g(\Xi)$. The latter couples measure nearly identical Ξ values, thus giving the definition of the statistical mode as the most probable value of a set of random variables.[14]

Given the definition of Ξ [Eq. (2)] in a uniform wavefield, the values of Ξ determining the statistical mode will occur for the angularly consecutive radial station couples $O-S_k, O-S_{k+1}, O-S_{k+2}, \ldots, O-S_{k+r}$ (Fig. 2 middle) as follows:

$$|\Xi_{j=k} - \Xi_{j=k+d}| \simeq 0, \quad d = 0,1,2, \ldots, r. \tag{3}$$

We may therefore define the mode of the normalized apparent velocity as

$$\text{mode}(\Xi) = \Xi_{j=k+d}, \quad d = 0,1,2, \ldots, r. \tag{4}$$

Note that the use of such an array introduces a discrete sampling of the field, which results in a coarsening $\Delta\phi$ inversely proportional to station number. The maximum misalignment that each ray may have with the closest oriented radial couple $O-S_j$ is (see Fig. 2)

$$\Delta\phi = \frac{\pi}{2(n-1)}. \tag{5}$$

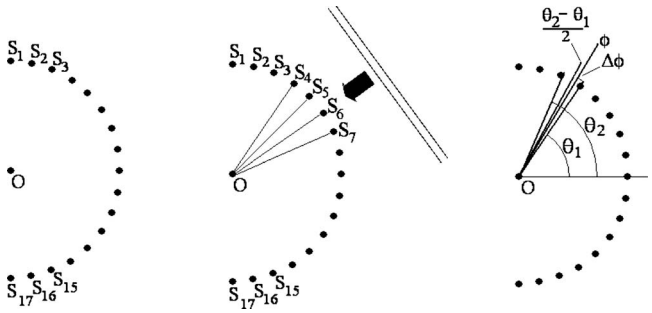

FIG. 2. The semicircular array with center in O, depicted in the case with $n=17+1$ stations S_j (left). The measurement of velocity by cross-correlation on radial station couples $O-S_j$ yields that the statistical mode is defined by the radial array couples most closely aligned with the field. The case of a plane wave is shown, together with the most closely aligned radial array couples $O-S_4/O-S_7$ (middle). Each array implies an azimuthal discretization coarsening with a maximum misalignment $\Delta\phi$ equal to $|\theta_2-\theta_1|/2$ (right).

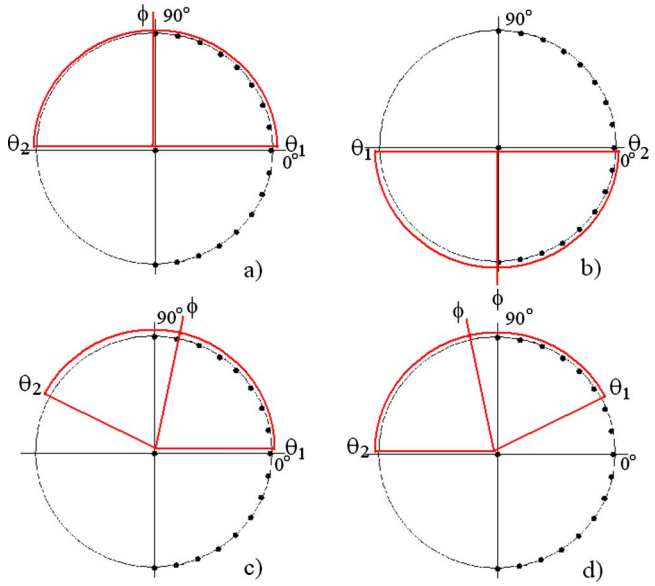

FIG. 3. (Color online) The field geometry: the limiting azimuths θ_1 and θ_2 and the central azimuth ϕ. The cases shown are (a) uniform{[0°;180°]}, $\phi=90°$; (b) uniform{[180°;360°]}, $\phi=270°$; (c) uniform{[0°;158°]}, $\phi=79°$; and (d) uniform{[22°;180°]}, $\phi=101°$. The angles are measured according to the standard trigonometric notation.

Let us study how the statistical mode depends on field aperture $\theta_1 \le \theta \le \theta_2$ and azimuth ϕ by analyzing a large number N of realizations of uniform wavefields in which the number of stations n of a semicircular radial array is kept constant. In this study we use $N > 10^7$, $n=17+1$, and explore a variety of cases of $\theta_1 \le \theta \le \theta_2$ and ϕ.

Consider first of all the case of an azimuthally isotropic field, θ:uniform{[0;360°]}. A bimodal Ξ distribution [Fig. 4(a)] is found, with mode Ξ values equal to -1 and 1. As recalled above, the latter represent two equivalent solutions, corresponding by definition, respectively, to the advanced and retarded Green functions.[11] Note how this reflects the symmetry with respect to time that characterizes diffuse fields, and note also that the "forbidden" region between -1 and 1 [deriving from $\cos(\theta) \le 1$ in Eq. (2)] stands for a bias on Ξ, which is always positive; i.e., the value of the apparent velocity is never lower than the true value in either direction of propagation along the array AB.

Let us next consider the simulation of azimuthally anisotropic wavefields, and start by observing that both the half-space fields uniform{[0;180°]} and uniform{[180;360°]}, i.e., respectively, with orthogonal azimuth 90° and 270° [see Figs. 3(a) and 3(b)] produce a pattern identical to that of the azimuthally isotropic case [Fig. 4(a)]. This is due to the numerical balance between the rays crossing radially the array in direction S_j-O and those crossing it in direction $O-S_j$. Such a balance occurs for arrays with azimuth $\phi=90°$ or $\phi=270°$ irrespective of aperture, and a bimodal symmetric distribution peaked at 1 and -1 is found in each case. The independence of wavefield aperture is illustrated by the extreme case of a zero aperture field uniform{[90°;90°]}, i.e., a plane wave with azimuth $\phi=90°$, which still produces a pattern identical to that of the azimuthally isotropic case [Fig. 4(a)].

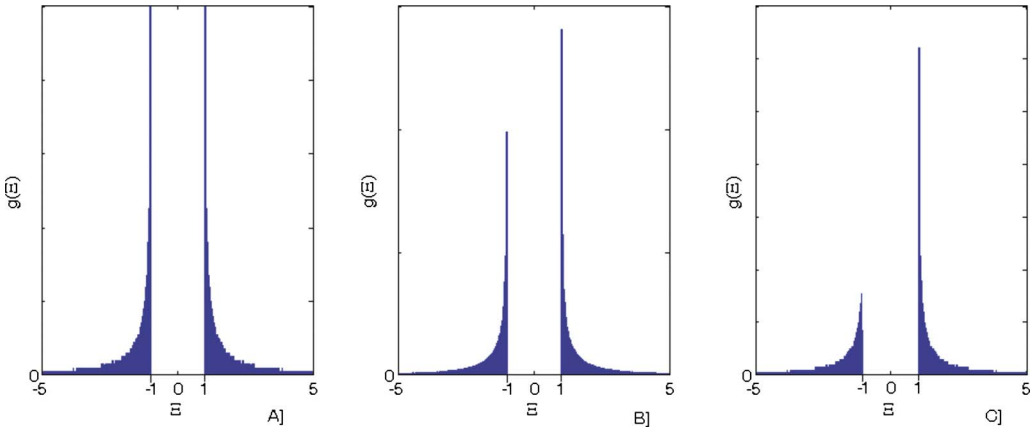

FIG. 4. (Color online) The probability density function of the normalized apparent velocity for [*A*] an azimuthally isotropic field or for the orthogonal fields uniform{[0;180°]} and uniform{[180;360°]}, [*B*] θ:uniform{[0;158°]}, and [*C*] θ:uniform{[0;152°]}. Fields with the same azimuth but smaller apertures lead the lower amplitude statistical mode to visually disappear and are not shown. Two ticks at $|\Xi|=1$, corresponding to true velocity, are also shown.

The inward/outward radial balance is rapidly lost if the field azimuth is rotated from 90° or 270°. For example, the uniform fields with aperture 158° and azimuth $\phi=76°$ [see Fig. 3(c)] result still in a bimodal $g(\Xi)$ distribution [Figs. 4(b) and 4(c)], but with one prevailing mode. The wave is seen as still traveling in both directions, and both the advanced and retarded Green functions can be recovered, but one has a higher intensity and the picture is no more time invariant.[11] Note that fields with the same azimuth but smaller apertures lead the lower amplitude statistical mode to visually disappear and are not shown.

In other words, Ξ is peaked at either -1 or at 1 depending on the fact that "more rays" cross the array radially inward or outward. The variation of ϕ above and below 90° and 270° rules this inward/outward balance, and, if aperture remains the same, it has the only effect of switching the prevailing mode. For example, the field uniform{[0°;158°]}, $\phi=79°$ and its specular θ:uniform{[−22°;180°]}, $\phi=101°$ [Figs. 3(c) and 3(d)] have specular bimodal density functions.

We may therefore conclude that, independent of wavefield aperture and azimuth and even in the extreme case of a single plane wave, the estimate of scalar wave velocity using the statistical mode over all radial couples is always unbiased.

It must be noted that the coarsening introduced by station number results in a lower accuracy in the measure of Ξ, which reflects in the mode. From Eq. (5) this inaccuracy is equal to

$$\Delta\Xi = \frac{1}{\cos(\pi/[2(n-1)])}, \tag{6}$$

so that an array with $n=17+1$ stations will have a (positive) coarsening bias $\Delta\Xi<2\%$ and an array with $n=7+1$ stations will have a (positive) coarsening bias $\Delta\Xi<4\%$.

It must also be noted that using the mean of Ξ as a location parameter instead of the mode would always give biased estimates. In fact, the mean is the first moment of the Ξ distribution[11]

$$E(\Xi) = \frac{\log(\Xi+\sqrt{\Xi^2-1})}{\sec^{-1}(\Xi_2)-\sec^{-1}(\Xi_1)} \quad I_{\Xi}[\sec^{-1}(\Xi_1),\sec^{-1}(\Xi_2)], \tag{7}$$

which is clearly unbounded at $k\pi/2$, with $k=1,2,\ldots$. The mean of Ξ in azimuthal domains not comprising $k\pi/2$ is bounded but biased, and with a bias always larger than that of the mode. The use of the median as a location parameter, placing the central value in the middle of the distribution domain, would also provide biased estimates, albeit with a generally smaller bias than the mean.[15] Note how in all cases the bias would be positive.

The above argument can be summarized as follows. In a radial semicircular array the statistical mode of the normalized apparent velocity Ξ measured over the radial station couples provides always an unbiased estimate of wave velocity on wavefields with azimuthally uniform velocity distribution and whatever aperture and intensity. The efficiency of the statistical mode as an estimator provides the weight factor that guarantees the effectiveness of Aki's spatial autocorrelation[16] technique. At the same time, the peak of $g(\Xi)$ is always placed in correspondence of the minimum norm of Ξ, so that the mode of Ξ coincides with the minimum, an issue somehow empirically acknowledged by the refraction microtremor technique.[17]

III. AZIMUTHAL IDENTIFICATION OF THE INSTANTANEOUS HUYGENS SOURCES

In light of the above discussion, the Ξ distribution is always bimodal asymmetric, with symmetry achieved only by isotropic fields and orthogonal fields. Hence, the probability density function $g(\Xi)$ will generally provide one prevailing mode, which will reflect the dominant instantaneous Huygens source(s). As a consequence, splitting a recorded signal of length T into $N=T/\Delta t$ subsequent subintervals, each of these will be characterized by a probability density function with a prevailing mode and the azimuth of the instantaneous Huygens source in each subinterval will be sim-

ply given by the central azimuth ϕ_{mode} of the sector corresponding to the mode Ξ (cf. Fig. 2 middle) as follows:

$$\phi_{\text{mode}} = \frac{\phi_k + \phi_{k+r}}{2}. \tag{8}$$

IV. ESTIMATE OF THE MATERIAL DISSIPATION CONSTANT

A well known result in the theory of dynamical systems is that the response $y(t)$ of a linear time invariant system can be written as the convolution

$$y(t) = \int_{-\infty}^{\infty} h(u)x(t-u)du, \tag{9}$$

where $x(t)$ is the input signal and h is the system response to a unit impulse (i.e., Green's function). By definition of the input-output cross-correlation $R_{xy}(\tau)$

$$R_{xy}(\tau) = \lim_{T\to\infty} \frac{1}{T}\int_0^T x(t-\tau)y(t)dt \tag{10}$$

and therefore

$$R_{xy}(\tau) = \lim_{T\to\infty} \frac{1}{T}\int_0^T x(t-\tau)\int_{-\infty}^{\infty} h(u)x(t-u)dudt. \tag{11}$$

Hence, interchanging the order of integration

$$R_{xy}(\tau) = \int_{-\infty}^{\infty} h(u)\left[\lim_{T\to\infty} \frac{1}{T}\int_0^T x(t-\tau)x(t-u)dt\right]du, \tag{12}$$

and, after a change in variables,

$$R_{xy}(\tau) = \int_{-\infty}^{\infty} h(u)R_{xx}(\tau-u)du, \tag{13}$$

where R_{xx} is the autocorrelation of the input.

If the noise bandwidth is large with respect to the impulse response of the local mechanical system, i.e., the material between the two points A and B considered, h can be taken as constant and factored so that, for values of t around τ,

$$R_{xy}(\tau) = h(\tau)\int_{\infty}^{\infty} R_{xx}(\tau-u)du, \tag{14}$$

yielding that the cross-correlation of the displacement at A and B will be directly proportional to the impulse system response. This result, ascribed to equipartition by the diffuse field theory, thanks to the above statistical-ballistic property applies for example to seismic noise, which has a very large bandwidth extending from 10^{-5} to 10^{3} Hz.[18]

This allows estimating not only the elastic but also the anelastic material properties from cross-correlation recorded over a commendably long period of time to guarantee wide bandwidth. In fact, the quality factor Q, the reciprocal of the specific dissipation constant, is defined as a function of the relative energy loss per cycle at the frequency ν normalized to the absolute energy $\Delta E(\nu)/E(\nu)$ as

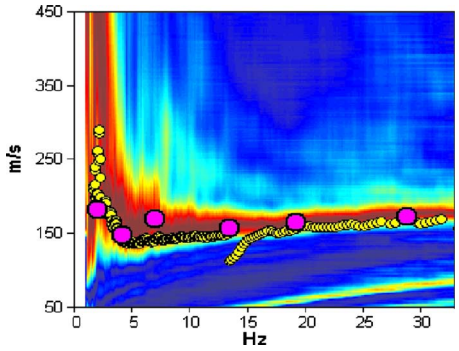

FIG. 5. (Color online) The local elastic wave velocity dispersion at the Marina di Ravenna experimental site measured by using the independent estimates of ReMi (contour plot) and ESAC (yellow circles — light gray in b/w) and by using the azimuthal mode (magenta circles — dark gray in b/w) as described by the present work.

$$\frac{\Delta E(\nu)}{E(\nu)} = \frac{2\pi}{Q(\nu)}, \tag{15}$$

which is the tangent of the phase angle by which the strain lags behind the applied stress in the case of sinusoidal excitation. In light of the above discussion, Q can be measured as a function of frequency ν both in the frequency domain using cross-spectral density and, after bandpass filtering, directly in the time domain from the cross-correlation function.

We tested the above theory through an experiment on seismic noise.

V. EXPERIMENTAL VALIDATION

Our experiment was designed to minimize two effects, which are spurious to the present problem. First, we aimed at minimizing the effect of lateral heterogeneities, which may act as multiple scatterers of unknown position making it impossible to check the capability of the above formulation to effectively locate the Huygens sources. In a homogeneous subsoil, the Huygens sources are true sources, i.e., the points where the beams originate before hitting the stations, which makes this check possible. Second, we aimed at minimizing the effect of subsoil layering, which may induce the excitation of higher order wave eigenmodes, thus introducing further an unnecessary variability.

To this extent, we selected a site in North-Central Italy, on the Marina di Ravenna beach at approximately 150 m from the Adriatic Sea shore, where the superficial layer of sand is virtually isotropic and homogeneous down to a depth of the order of 10^2 m and for a horizontal extension of several tens of kilometers.[19]

The validity of the subsoil homogeneity and isotropy approximations in terms of seismic wave propagation was first of all verified through a refraction microtremor[17] and an extended spatial autocorrelation[20] analysis by using a Micromed Rosina 24 bit resolution digital array with 16 vertical 4.5 Hz geophones arranged, respectively, with a 12+4 L-shaped geometry, a 5 m interdistance, and using a 1024 Hz sampling rate. The two analyses showed a remarkably narrow scatter and a virtual absence of dispersion (Fig. 5) in the frequency range 1–40 Hz, with a nearly constant phase ve-

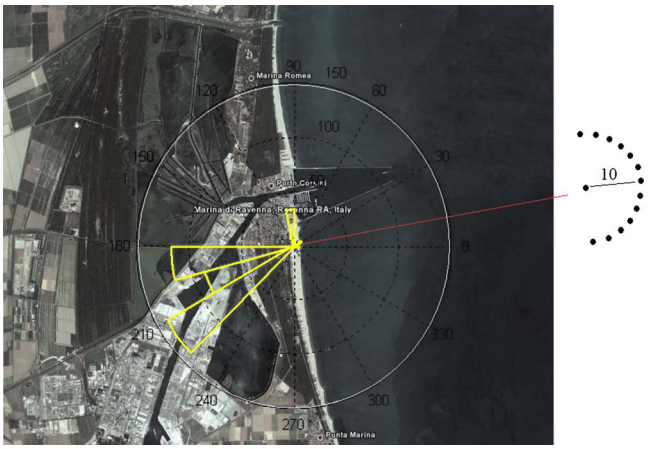

FIG. 6. (Color online) The azimuthal distribution of noise over the whole measurement period of 820 s as measured with the semicircular array with 10 m radius oriented as shown at the right of the figure and positioned at the center of the rose. The subsoil homogeneity makes these real sources rather than scatterers and allows identification as sources some specific industrial firms of the Ravenna port.

locity of 160 m/s. This stands for a half-space configuration well approximated over wavelengths $\lambda \simeq 4-160$ m.

We then started the test of the above theory by deploying the digital array Rosina in a semicircular layout using 13+1 vertical sensors with a 10 m radius (Fig. 6). A recording of seismic noise 820 s long was taken on calm sea conditions. The dispersion of phase velocity was measured in the time domain through a correlation analysis following 1/7 octave 40 dB narrow band filtering centered at the frequencies of 1, 3, 7, 13, 19, and 29 Hz. The cross-correlation was then performed on all the array radial couples, and the scalar velocity estimated from the mode Ξ over the whole 820 s recording time interval. The results are reported by the pink dots in Fig. 5, and were found to be in good agreement with the independent extended spatial autocorrelation and refraction microtremor measurements performed in our preliminary analysis.

The existence of horizontally traveling noise waves with a vertical displacement component along the surface of a nearly isotropic and homogeneous material suggests that they are Rayleigh waves in the fundamental eigenmode.[21]

We then proceeded to determine the instantaneous Huygens sources. To this extent, the recording was split into 820 nonoverlapping subintervals 1 s long, and central azimuth corresponding to the mode Ξ in each subinterval was determined according to Eq. (8). This analysis showed that seismic noise originated from three main azimuths at 190°, 220°, and 100° (Fig. 6). These, in light of the lack of subsoil scatterers, should be identified as three true sources, a result which appeared consistent with reality, since they were pointing to the industrial area of the Ravenna port.

We then plotted the mode azimuth versus time to characterize the dynamics of the seismic noise field, and found (Fig. 7) that the source azimuth varied randomly and abruptly at the time scale of a few seconds—the persistence time varied from 1 to 10 s—suggesting that instantaneous Huygens source interference[5] of impulsive wavepackets is at the origin of seismic noise.

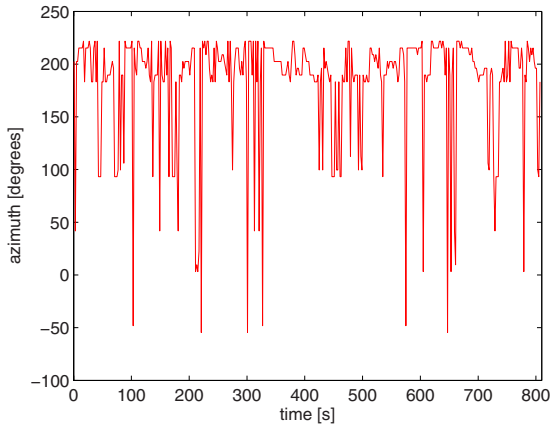

FIG. 7. (Color online) The azimuthal distribution of noise versus time during the measurement period of 820 s.

Finally, we estimated the anelastic constant Q according to Eq. (15). For compatibility with the previous dispersion analysis, the estimate was made in the time domain, using the whole T recording interval together with the 1/7 octave 40 dB narrow band filtering centered at the frequencies of 1, 3, 7, 13, 19, and 29 Hz. This resulted to nearly frequency independent of $Q \simeq 15-20$ (see Fig. 8). In light of the Rayleigh nature of the noise wavepackets, this provides an estimate of the shear wave Q_S.[22]

VI. DISCUSSION AND CONCLUSIONS

Extending our previous work on passive acoustic imaging on nondiffuse fields, we show here that undistorted elastic imaging is possible through the simple use of the statistical mode, instead of the mean or the median, to estimate wave velocity from noise correlation at different radial couples of a semicircular array. This provides an immediate measure, which in turn allows azimuthally locating the instantaneous Huygens sources of noise. At the same time, since seismic noise bandwidth is generally much wider than the response of the medium between the correlated points, a passive measure of the anelastic dissipation constant is also

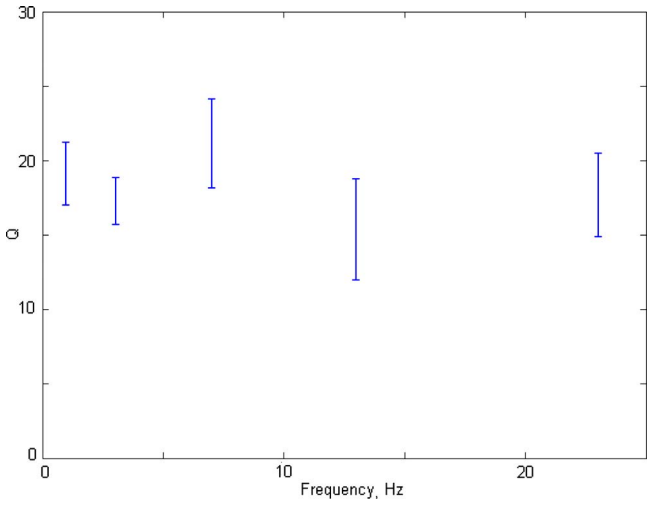

FIG. 8. (Color online) The local anelastic parameter Q as a function of frequency.

possible. The theoretical predictions were confirmed by an experiment performed on a Ravenna beach in North-Central Italy, which showed how this approach yields measured values of the dispersion of the phase velocity of Rayleigh waves identical to those obtained with established techniques, allowing the simultaneous identification of the instantaneous sources of noise and their time evolution. In such experiment, the sources of seismic noise were tracked to three major firms in the Ravenna port, and the prevailing source was found to switch at the time scale of seconds, suggesting instantaneous impulsive wavepacket interference as the basic mechanism of seismic noise. A passive measure of the anelastic dissipation was also obtained, with values of the quality factor $Q \simeq 15-20$ approximately independent of frequency in the range 1–30 Hz, but quite unfortunately no independent measurements could be found for this parameter, making a cross-check of the measured values impossible.

(Received 31 July 2009; revised 2 December 2009; accepted 7 December 2009)

Simultaneous measurements of middle ear-conducted sound pressure in the cochlear vestibule $\mathbf{P_V}$ and stapes velocity $\mathbf{V_S}$ have been performed in only a few individuals from a few mammalian species. In this paper, simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ in six chinchillas are reported, enabling computation of the middle ear pressure gain $\mathbf{G_{ME}}$ (ratio of $\mathbf{P_V}$ to the sound pressure in the ear canal $\mathbf{P_{TM}}$), the stapes velocity transfer function **SVTF** (ratio of the product of $\mathbf{V_S}$ and area of the stapes footplate A_{FP} to $\mathbf{P_{TM}}$), and, for the first time, the cochlear input impedance $\mathbf{Z_C}$ (ratio of $\mathbf{P_V}$ to the product of $\mathbf{V_S}$ and A_{FP}) in individuals. $|\mathbf{G_{ME}}|$ ranged from 25 to 35 dB over 125 Hz–8 kHz; the average group delay between 200 Hz and 10 kHz was about 52 μs. **SVTF** was comparable to that of previous studies. $\mathbf{Z_C}$ was resistive from the lowest frequencies up to at least 10 kHz, with a magnitude on the order of 10^{11} acoustic ohms. $\mathbf{P_V}$, $\mathbf{V_S}$, and the acoustic power entering the cochlea were good predictors of the shape of the audiogram at frequencies between 125 Hz and 2 kHz.

I. INTRODUCTION

In terrestrial vertebrates, sound pressure waves are transmitted from the outside world to the fluid-filled inner ear primarily via the tympanic membrane (TM) and the ossicular chain of the middle ear. In mammals, the ossicular chain is made of three small bones: the malleus, the incus, and the stapes. Motion of the stapes footplate in the oval window produces pressure waves in the perilymph of the vestibule, the entrance to the cochlea. These waves propagate in the cochlea and are sensed by the organ of Corti, transduced into neural impulses, and sent to the central auditory system via the auditory nerve.

The middle ear acts as a transformer by increasing sound pressure and decreasing volume velocity (see, e.g., von Helmholtz, 1877; Wever and Lawrence, 1954; Dallos, 1973; Shera and Zweig, 1992; Rosowski, 1994). Middle ear function has been characterized in several species by measuring frequency-dependent transfer functions between the sound pressure in the ear canal (the input to the middle ear) and the input to the cochlea. One such function is the stapes volume-velocity transfer function (**SVTF**)[1] defined as the ratio between stapes volume velocity $\mathbf{U_S}$ and ear canal sound pressure near the TM $\mathbf{P_{TM}}$ ($\mathbf{SVTF}=\mathbf{U_S}/\mathbf{P_{TM}}$). **SVTF** has been studied in many species, using a variety of techniques. Another transfer function of interest is the middle ear pressure gain ($\mathbf{G_{ME}}$) defined as the ratio between the pressure in the vestibule ($\mathbf{P_V}$) and $\mathbf{P_{TM}}$ ($\mathbf{G_{ME}}=\mathbf{P_V}/\mathbf{P_{TM}}$).

Because of the difficulties associated with intracochlear pressure measurements, $\mathbf{G_{ME}}$ has been reported in only a few individuals from a few species: in cat (Nedzelnitsky, 1980; Décory, 1989; Décory *et al.*, 1990), guinea pig (Dancer and Franke, 1980; Décory, 1989; Décory *et al.*, 1990; Magnan *et al.*, 1997), chinchilla (Décory, 1989; Décory *et al.*, 1990), gerbil (Olson, 1998, 2001; Dong and Olson, 2006; de La Rochefoucauld *et al.*, 2008) and human temporal bone (Puria *et al.*, 1997; Aibara *et al.*, 2001; Puria, 2003; Nakajima *et al.*, 2009). The difficulties in $\mathbf{P_V}$ measurements arise from the requirement of drilling a hole in the base of the cochlea to insert a pressure sensor. The hole needs to be small enough so that the middle and inner ear structures are not damaged, and the sensor needs to be small with a large impedance so as not to disturb the pressure waves being measured.

The cochlear input impedance $\mathbf{Z_C}$, the frequency-dependent complex ratio of $\mathbf{P_V}$ to stapes volume velocity $\mathbf{U_S}$ ($\mathbf{Z_C}=\mathbf{P_V}/\mathbf{U_S}$), quantifies the acoustic load of the inner ear on the middle ear and is important for our understanding of middle ear function. Changing this load can induce changes in middle ear input admittance $\mathbf{Y_{ME}}$ (the ratio of the TM volume velocity to $\mathbf{P_{TM}}$), stapes motion, and auditory sensitivity: For example, draining the cochlea introduced a resonance at 250 Hz in the middle ear input admittance of chinchillas and suppressed the non-linear dependence on level of $\mathbf{Y_{ME}}$ observed below 300 Hz (Rosowski *et al.*, 2006). The same manipulation in cats resulted in the introduction of various resonances and anti-resonances in $\mathbf{Y_{ME}}$ between 1 and 30 kHz (Peake *et al.*, 1992; Puria and Allen, 1998). In human temporal bones, complex rotary stapes motion, in addition to the piston component, was observed at high frequency when the cochlea was fluid-filled, but not after it was drained (Hato *et al.*, 2003). A less dramatic change in $\mathbf{Z_C}$ can also have an effect: In chinchillas, introducing an opening in the bony superior semi-circular canal, which reduces $\mathbf{Z_C}$ in a

frequency-dependent manner (Songer and Rosowski, 2007b), produced an increase in the magnitude of $\mathbf{Y_{ME}}$ between 100 Hz and 1 kHz and an increase in the magnitude of **SVTF** between 120 Hz and 5.8 kHz (Songer and Rosowski, 2006), as well as a broadband decrease in auditory sensitivity as measured by cochlear potentials (Songer and Rosowski, 2005).

Knowledge of $\mathbf{Z_C}$ is also important to the understanding of sound power flow through the middle and inner ears: The real part of $\mathbf{Z_C}$ can be used to compute the acoustic power entering the cochlea W_C (see Sec. IV G), where reasonable matches between auditory thresholds and the sound pressure necessary to produce a constant W_C in various species suggest middle ear power transfer is an important determinant to auditory sensitivity (Khanna and Tonndorf, 1969; Rosowski, 1991).

$\mathbf{Z_C}$ has been computed previously from simultaneous or non-simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ in several mammalian species. By definition, $\mathbf{U_S}$ rather than $\mathbf{V_S}$ is needed to compute $\mathbf{Z_C}$. Assuming piston-like motion of the stapes, $\mathbf{U_S}$ is deduced from $\mathbf{V_S}$ by multiplication of the stapes footplate area A_{FP}: $\mathbf{U_S}=A_{FP}\mathbf{V_S}$. Estimates of $\mathbf{Z_C}$ have been computed from the combination of non-simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ in guinea pig (Dancer and Franke, 1980), chinchilla (Ruggero *et al.*, 1990), human temporal bone (Puria *et al.*, 1997), and gerbil (Overstreet and Ruggero, 2002; Decraemer *et al.*, 2007). Simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ were performed in only a few individuals from cats (Lynch *et al.*, 1982) and gerbils (de La Rochefoucauld *et al.*, 2008), as well as in human temporal bone (Aibara *et al.*, 2001; Puria, 2003; Nakajima *et al.*, 2009). In these studies, estimates of $\mathbf{Z_C}$ are different than in studies combining non-simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$: In human temporal bone, estimates from simultaneous and non-simultaneous measurements showed differences in magnitude and phase (Puria *et al.*, 1997; Aibara *et al.*, 2001), but there were also important differences between the three studies using simultaneous measurements (Aibara *et al.*, 2001; Puria, 2003; Nakajima *et al.*, 2009). In gerbil, the magnitude of the non-simultaneous estimate (Overstreet and Ruggero, 2002) agreed with the simultaneous estimate (de La Rochefoucauld *et al.*, 2008), but there were differences in the phase, especially above 6 kHz. Moreover, an estimate of $\mathbf{Z_C}$ from simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ in one animal showed differences in its detailed structure from an estimate from non-simultaneous measurements in the same animal (de La Rochefoucauld *et al.*, 2008). Based on these comparisons, it seems important to measure $\mathbf{P_V}$ and $\mathbf{V_S}$ simultaneously to characterize $\mathbf{Z_C}$ more precisely.

We measured $\mathbf{P_V}$ and $\mathbf{V_S}$ simultaneously in chinchillas, a species whose hearing range (20 Hz–30 kHz) is similar to that of humans, using miniature fiber-optic pressure sensors and laser Doppler vibrometry in response to acoustic stimulation. Based on these measurements, we present a new estimate of $\mathbf{G_{ME}}$ in this species, extending previous measurements to higher frequencies, and, to our knowledge, the first estimate of $\mathbf{Z_C}$ in chinchillas derived from simultaneous measurements. $\mathbf{G_{ME}}$ had a magnitude of the order of 30 dB and a phase close to 0 between 300 Hz and 4 kHz, similar to the predictions of a simple transformer ratio model. Our $\mathbf{G_{ME}}$ was similar to published data in the chinchilla (Décory, 1989; Décory *et al.*, 1990) at stimulus frequencies of 500 Hz to 3 kHz and 12 to 20 kHz, but had a larger magnitude at other frequencies. $\mathbf{Z_C}$ had a flat magnitude and a phase close to 0, which are the characteristics of an acoustic resistance, over a broad frequency range. Our $\mathbf{Z_C}$ had a larger magnitude with a smaller slope below 1 kHz and a phase angle closer to 0 than a previous estimate from non-simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ (Ruggero *et al.*, 1990). We also compare measurements of auditory threshold in chinchilla (Miller, 1970) with estimates of the sound pressure required to produce a constant $\mathbf{P_V}$ across frequency, a constant $\mathbf{V_S}$, and a constant power into the vestibule. Overall, these new findings extend our knowledge of the chinchilla middle ear, and, together with other measured middle and inner ear mechano-acoustic quantities in this species, help draw a more complete picture of middle ear function. Understanding sound transfer through the middle ear could eventually improve therapeutic approaches to diseases and malfunctions of the middle ear.

II. MATERIALS AND METHODS

A. Fiber-optic pressure sensors

Measurements of $\mathbf{P_V}$ are constrained by the limited space available for the pressure sensors (the volume of the chinchilla vestibule is on the order of 5 μl: see Plontke *et al.*, 2002) and the fragility of the inner and middle ear structures. We chose to use fiber-optic pressure sensors (Olson, 1998) because they have good sensitivity, good high frequency response (up to about 100 kHz), and because they are very small. Their small size (about 145 μm in diameter) ensures the following:

(a) minimal disruption of the pressure field in the inner ear at frequencies in the chinchilla's hearing range, because of both the small size (145 μm is less than 1% of the wavelength in water at 30 kHz) and the relatively high impedance associated with such a small microphone, and
(b) minimal damage to the middle and inner ear structures during insertion into the vestibule.

The fiber-optic pressure sensors were fabricated following the techniques of Olson (1998). They are composed of a glass capillary tube (145 μm outer diameter) with a gold-coated polymer diaphragm affixed to one end. A single optical fiber (100 μm outer diameter) is inserted into the other end. The optical fiber is spliced to a *Y* coupling. A light emitting diode (LED) attached to one coupler branch produces incoherent light, and a photodiode attached to the other branch measures the light reflected from the diaphragm. Sound pressure flexes the diaphragm and modulates the reflected light.

Similarly to Olson (1998), calibration of the sensors was performed in water, according to the method described by Schloss and Strasberg (1962): The sensor is immersed in a column of liquid that is shaken vertically by a known amount (Brüel & Kjær Vibration Calibration Exciter Type 4290 with built-in reference accelerometer; Brüel & Kjær Measuring

Amplifier Type 2525); the pressure at the diaphragm depends on both the depth of immersion and on the acceleration of the column. Calibration functions were defined as the ratio between the sound pressure at the sensor diaphragm and the voltage at the output of the photodiode. For typical sensors, the calibration function magnitude was essentially flat up to 10 kHz, with a value of about 150 dB re 20 μPa/V, and then decreased between 10 and 30 kHz by about 8 dB. The phase was roughly flat and close to 0 on the entire range of measurements. In earlier experiments, we also calibrated the sensors in air, against a reference microphone of known sensitivity. In our experience, the two calibration methods (in water or in air) led to very similar sensitivities in magnitude and phase. Therefore, we only performed water calibration in subsequent experiments.

The main issues with the fiber-optic pressure sensors are their fragility and their stability. We periodically recalibrated the sensor to test for variations in its sensitivity. We report data only from sensors whose calibration was stable throughout the measurement session: In three animals, there was less than a 2 dB variation over the entire tested frequency range between repeated calibrations throughout the experiment; in two other animals, calibration was repeatable within 2 dB in the mid- and high frequencies, and within 5–8 dB in the lows; in another animal, calibration was repeatable within 10 dB. The calibration function used to compute $\mathbf{P_V}$ was the closest in time to the measurement.

Stability of the pressure sensor was also continuously monitored via the direct current (DC) component of the sensor photodiode output. In many sensors, a large change in the DC value was correlated with a change in sensitivity. Therefore, we report $\mathbf{P_V}$ measurements for which the DC value of the sensor during the measurements was close to the DC value during calibration: In the 6 animals from which data are presented, the change in DC between calibration and measurement was less than 8% (8% in one animal, 4% in two animals, 3% in one animal, 2% in one animal, and $<1\%$ in one animal).

B. Laser Doppler vibrometry

To measure stapes velocity, we used a single-beam laser Doppler vibrometer (Polytec CLV 700) aimed at small reflective plastic beads (<50 μm diameter) placed on the posterior crus and the footplate. Sound-induced velocity of the stapes was measured using the Doppler shift of light reflected from the moving beads. The sensitivity of the laser was checked by comparing the velocity of a shaker as measured by the laser with its acceleration as measured by the reference accelerometer. The sensitivity was constant over the frequency range of measurement.

Our surgical exposure of the stapes allowed measurement of the piston-like component of stapes motion within an angle of about 30° relative to the piston-like direction. The volume velocity $\mathbf{U_S}$ was estimated assuming piston-like motion of the stapes. In this case, the volume velocity $\mathbf{U_S}$ is simply the product of measured linear velocity $\mathbf{V_S}$ and the average area of the chinchilla footplate (A_{FP}=2 mm^2, Vrettakos *et al.*, 1988).

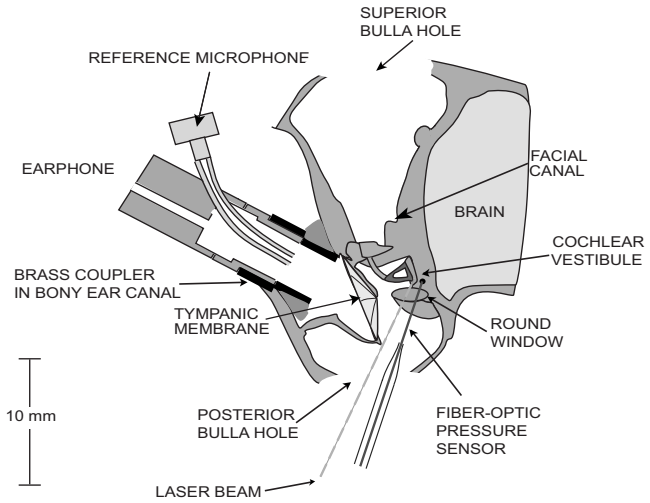

FIG. 1. Schematic of the animal preparation. The bulla was opened superiorly and posteriorly, and a hole approximately 200 μm in diameter was made in the vestibule for the fiber-optic pressure sensor. The cartilaginous ear canal was cut and a brass tube was glued in the bony ear canal to allow repeatable couplings of the earphone delivering the sound stimuli. A built-in reference microphone measured sound pressure in the ear canal. A laser Doppler vibrometer was aimed at reflective beads placed on the posterior crus and the footplate of the stapes.

C. Animal preparation

The surgeries and experiments were performed in accordance with guidelines published by the U.S. Public Health Service and were approved by the Massachusetts Eye and Ear Infirmary (MEEI) Animal Care Committee.

The animals were anesthetized with intraperitoneal injections of sodium pentobarbital (50 mg/kg) and Ketamine (40 mg/kg). After a tracheotomy to facilitate respiration, an opening was made in the superior bulla. The tensor tympani muscle and the tympanic branch of the facial nerve, which innervates the stapedius muscle, were cut to prevent random contractions of these muscles during the experiment (Rosowski *et al.*, 2006). A second hole in the posterior bulla was made to view the stapes and round window. Part of a bony wall posterior to the round window, in which the facial nerve passes, was removed in order to see the wall of the vestibule posterior to the stapes. In doing so, extreme care was taken to avoid pulling or damaging the stapedius tendon. A hole for placement of the $\mathbf{P_V}$ fiber-optic pressure sensor, of approximate diameter 180–250 μm, was made in the vestibule 1–2 mm away from the oval window with a fine sharp pick (Fig. 1). On several occasions, we verified that this hole opened into the vestibule by breaking the annular ligament and pushing the stapes into the vestibule; the footplate was then seen through the $\mathbf{P_V}$ hole.

The cartilaginous ear canal was cut and a brass tube was placed and glued in the bony ear canal to allow repeatable couplings of the earphone delivering the sound stimuli. The middle ear was open during the measurements.

D. Stimuli and responses

In early experiments we used an electrodynamic hearing-aid earphone (Knowles, Itasca, IL) coupled to a power amplifier as our sound source. In later experiments, an

electrostatic earphone (Tucker-Davis Technologies Type EC1, driven by a Tucker-Davis Technologies ED1 earphone driver) was used. The selected speaker was sealed to the brass tube in the ear canal, and the input of the speaker driver was coupled to the output of a programmable attenuator (Tucker-Davis Technologies Type PA5). We used LABVIEW (National Instruments, Austin, TX) to construct stimuli, control the attenuator, and measure the voltage outputs of our different sensors. The stimuli consisted of stepped pure tones (six points/octave) from 62.5 Hz to 28.5 kHz, with sound pressure levels (SPLs) ranging from 65 to 110 dB SPL at the entrance of the brass tube. The duration of each tone was 1–2 s; the responses were averaged and Fourier analysis was used to quantify the magnitude and phase of the fundamental and harmonic components of the response as well as the stimulus noise floor.

E. Correction of ear canal pressure measurements

Although the middle ear pressure gain $\mathbf{G_{ME}}$ is defined as the ratio between $\mathbf{P_V}$ and $\mathbf{P_{TM}}$ (the sound pressure at the TM near the umbo), during most of our measurements, we measured ear canal sound pressure ($\mathbf{P_{EC}}$) using a reference microphone built into the entrance of the brass coupling tube, about 7 mm from the umbo (Fig. 1). At frequencies less than 5 kHz (where the wavelength of sound is about 70 mm), the sound pressure in the ear canal and the sound pressure near the TM are essentially equal ($\mathbf{P_{TM}} \sim \mathbf{P_{EC}}$), but at higher frequencies significant differences occur between $\mathbf{P_{TM}}$ and $\mathbf{P_{EC}}$. To account for these differences, we used an average correction computed from simultaneous measurements of $\mathbf{P_{TM}}$ and $\mathbf{P_{EC}}$ in nine ears used in other studies (included in Ravicz *et al.*, 2009) to compute a correction factor $\mathbf{P_{TM}}/\mathbf{P_{EC}}$ that was used to correct our measurements of $\mathbf{G_{ME}}$ and **SVTF** (see Sec. IV). No correction was necessary for $\mathbf{Z_C}$, whose computation from simultaneously measured $\mathbf{P_V}$ and $\mathbf{V_S}$ does not involve $\mathbf{P_{TM}}$.

F. Frequency range and choice of earphone

We estimated the signal-to-noise ratios (SNRs) for all of our measured quantities ($\mathbf{P_V}$, $\mathbf{V_S}$, and $\mathbf{P_{EC}}$) by comparing the magnitude of the response spectrum at the stimulus frequency to the magnitude at nearby frequencies that were not in the stimulus and not harmonics of the stimulus frequencies. The electrodynamic earphone used in earlier experiments had low outputs at frequencies above 15 kHz, which led to low signal levels and low SNRs in our measurements at higher frequencies. In later experiments, we used an electrostatic earphone and obtained a good SNR over most of the stimulus frequency range (out to 28.5 kHz).

We include only data for which the SNR was larger than 10 dB. Moreover, in all the plots presented in this paper, we marked with a circle all the mean data points for which the SNR of the measurements involved was less than 20 dB in at least one of the animals. We further tested the reliability of the measurements by testing their repeatability: In most cases, $\mathbf{G_{ME}}$ and **SVTF** were nearly exactly repeatable when the SNR was greater than 10 dB in all channels, but in some cases, we further restricted the frequency range to exclude data points that lacked repeatability.

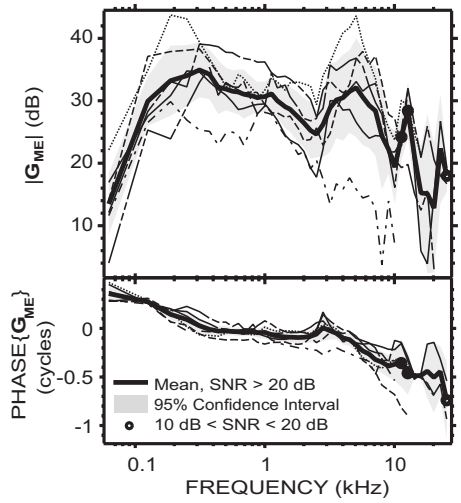

FIG. 2. $\mathbf{G_{ME}}$ in six animals (individual data: thin lines; mean: thick solid line; 95% CI: shaded areas). Data points with a SNR < 10 dB were not included; frequencies for which SNR < 20 dB in at least one of the individual data point were marked by a circle (see Sec. II).

G. Statistics

The mean and standard deviation of $\mathbf{G_{ME}}$'s decibel magnitude was computed from the decibel magnitudes of each animal. For **SVTF** and $\mathbf{Z_C}$, we used the mean and standard deviation of the logarithm of the magnitudes, and took their exponential to go back to the linear domain. For the phases of those three functions, we computed the means and standard deviations of the unwrapped individual phases. In all cases, we included only the data points that passed our SNR and repeatability criteria in the computation of the mean and standard deviation. Therefore, the number of animals included depended on frequency and was, in particular, lower at high frequencies.

In our plots, we usually show the mean and 95% confidence interval (CI). The 95% CI is defined by two standard errors of the mean above and below the mean. We computed the standard error by dividing the standard deviation by the square root of the frequency-dependent number of animals.

III. RESULTS

Thirteen animals were used in this study. Among these, four had their middle or inner ears damaged during surgery. In three other experiments the pressure sensor proved unstable. We therefore present $\mathbf{G_{ME}}$, **SVTF**, and $\mathbf{Z_C}$ results in six animals. For each experiment, we restrict the results shown to the frequency range over which the measurements were repeatable and had a SNR larger than 10 dB (see Sec. II).

A. Middle ear pressure gain $\mathbf{G_{ME}}$

$\mathbf{G_{ME}} = \mathbf{P_V}/\mathbf{P_{TM}}$ was computed from simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{P_{EC}}$, and corrected for the differences between $\mathbf{P_{TM}}$ and $\mathbf{P_{EC}}$, as explained in Sec. II. $\mathbf{G_{ME}}$ in each animal is plotted in Fig. 2. Both magnitude and phase angle

were similar among the six animals. The 95% CI was between 2 and 8 dB for the magnitude over almost the entire frequency range of measurement, and less than 0.1 cycles for the phase below 8 kHz. One animal was an outlier with low gain magnitude and more negative phase angles at high frequencies. The mean $|\mathbf{G_{ME}}|$ across these six ears ranged from 13 to 35 dB over the measurement frequencies. Between 62 and 125 Hz, the mean $|\mathbf{G_{ME}}|$ rapidly increased from 14 dB to 30 dB, with a slope of 16 dB/octave. It then continued to increase with a slower 4 dB/octave slope to reach a maximum of 35 dB at 375 Hz. Between 375 Hz and 2.5 kHz, $|\mathbf{G_{ME}}|$ slowly decreased to 25 dB with an average slope of −3.7 dB/octave. It then increased sharply to reach 32 dB at 5 kHz (10 dB/octave slope), and decreased sharply to reach a 19 dB local minimum at 10 kHz (−13 dB/octave slope). Above 10 kHz, the mean $|\mathbf{G_{ME}}|$ displays a 28 dB peak at 12.7 kHz, a 13 dB notch at 20.2 kHz, and a 22 dB peak at 22.6 kHz.

$\mathbf{G_{ME}}$'s mean phase angle (which is the phase difference between $\mathbf{P_V}$ and $\mathbf{P_{TM}}$) decreased from 0.4 to 0 cycles from 62 to 300 Hz, was near 0 between 0.3 and 3 kHz, and accumulated with frequency above that, reaching −0.4 cycles by 10 kHz and −0.7 cycles by 25 kHz. The ripple near 3 kHz associated with a dip in $|\mathbf{G_{ME}}|$ is likely due to a resonance between the bulla air space and the open holes in the bullar walls (Rosowski *et al.*, 2006). The group delay[2] was about 45 μs between 500 Hz and 2 kHz and about 61 μs between 3 and 9 kHz.

von Helmholtz (1877) proposed that the middle ear works as an acoustico-mechanical transformer composed of several levers in cascade, to increase sound pressure from the ear canal to the cochlea. It is interesting to note that our mean $|\mathbf{G_{ME}}|$ reached a maximum comparable to this "transformer ratio" of 38 dB computed from anatomical data (Vrettakos *et al.*, 1988)[3] at 300 Hz (see Fig. 2) and was within 10 dB of this value over a wide frequency range (roughly 125 Hz–8 kHz). Moreover, the phase was close to 0 (within 0.1 cycles) in a similar frequency range (roughly 250 Hz–4 kHz), which is also consistent with an ideal transformer at these frequencies. However, outside this frequency range, the magnitude and phase characteristics largely differed from that of an ideal transformer, confirming that the ideal transformer hypothesis does not accurately describe middle ear function at all frequencies (e.g., Funnell, 1996).

We tested the stability of the preparation and the pressure measurement sensor by taking the pressure sensor out of the inner ear, recalibrating, reinserting the sensor into the vestibule, and remeasuring $\mathbf{P_V}$. Figure 3(A) compares the initial and repeated measurements in an experiment where the pressure sensor was very stable (recalibration sensitivity was within 2 dB of the original sensitivity estimate, and the photodiode DC output was constant). $|\mathbf{G_{ME}}|$ upon reinsertion was within 2 dB of the original measurement over the entire range of frequency. The phase angles were also almost identical, with variations of less than 0.01 cycles at most test frequencies. These results are consistent with a highly stable preparation.

In some experiments we also verified that the gain we measured was indeed due to the middle ear and not some other artifactual signal path (e.g., bone conduction) by measuring $\mathbf{G_{ME}}$ before and after interrupting the incudo-stapedial joint. Figure 3(B) shows an example from one experiment. Before the interruption, $\mathbf{G_{ME}}$ had the characteristic magnitude and phase described earlier. After interrupting the incudo-stapedial joint (and making sure that the lenticular process was not touching the stapes head), $|\mathbf{G_{ME}}|$ dropped dramatically at all frequencies, essentially reaching the noise floor of our sensor (about 50 dB below the pressure measured with an intact joint, except as shown). This control is a clear demonstration that we measured ossicular sound conduction.

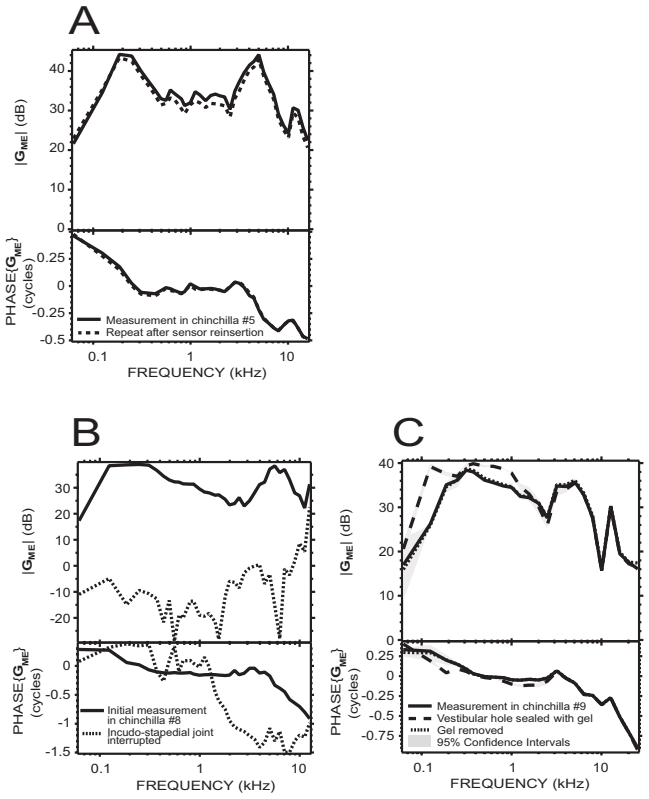

FIG. 3. $\mathbf{G_{ME}}$ controls. (A) Stability: comparison of $\mathbf{G_{ME}}$ measured in chinchilla No. 5 before (solid line) and after (dotted line) taking the pressure sensor out of the vestibule and recalibrating it. Differences were less than 2 dB in magnitude and less than 0.01 cycles in phase. (B) Effect of interrupting the ossicular chain: $\mathbf{G_{ME}}$ in chinchilla No. 8 with an intact ossicular chain (solid line), and after interrupting the incudo-stapedial joint (dotted line). (C) Effect of plugging the vestibular hole on $\mathbf{G_{ME}}$: in one animal (chinchilla No. 9), after sealing around the pressure sensor with a gel of high molecular weight (dashed line), there was a limited increase in $|\mathbf{G_{ME}}|$. After removing the gel (dotted line), $\mathbf{G_{ME}}$ went back to baseline (solid line). The 95% CI (shaded areas) represent the variability of repeated measurements in the same condition.

To determine the influence of the vestibular hole with the inserted pressure sensor on $\mathbf{G_{ME}}$, we tried to seal the pressure sensor in place with dental impression material (Jeltrate), dental cement, or a sodium hyaluronate viscoelastic gel of high molecular weight (Healon GV 14 mg/ml). With a hole of approximate diameter 180–250 μm and a 145 μm diameter sensor, the area of the hole not occupied by the sensor was roughly 0.009–0.026 mm^2. In most preparations, it was not possible to seal around the sensor effectively because of the limited space available and because the outward flow of perilymph pushed the sealant material away. In one

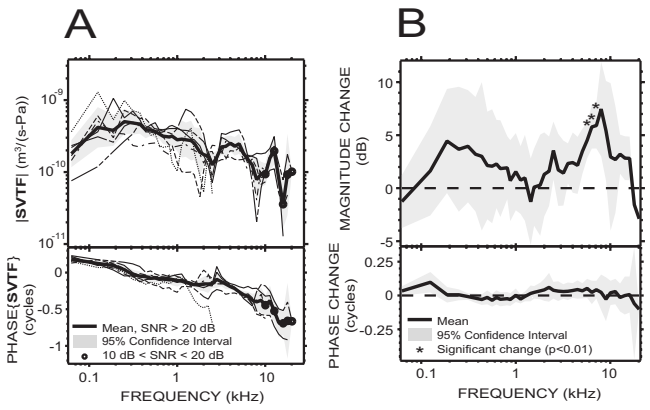

FIG. 4. **SVTF** in six animals. (A) **SVTF** before the vestibular hole was made (individual data: thin lines; mean: thick solid line; 95% CI: shaded areas). (B) Mean effect of introducing the vestibular hole on **SVTF** in six animals. We computed the change in magnitude and phase before the hole was made and afterward with the pressure sensor in place. Changes in magnitude were significant ($p<0.01$) only in a small region around 6 kHz (asterisks).

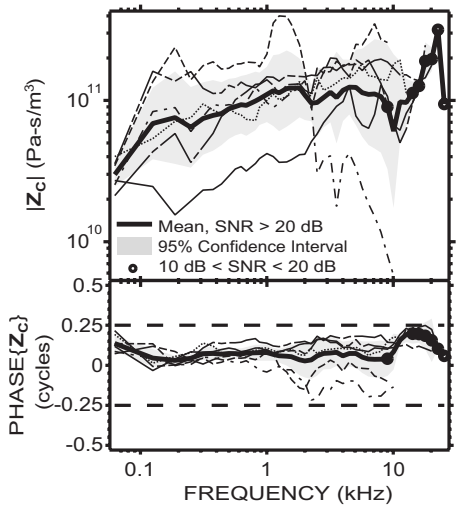

FIG. 5. $\mathbf{Z_C}$ in six animals (individual data: thin lines; mean: thick solid line; 95% CI: shaded areas) from simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$. $\mathbf{Z_C}$ was resistive (roughly flat magnitude, phase close to 0) up to at least 10 kHz.

case, as shown in Fig. 3(C), the viscoelastic gel appeared to cover most of the hole, resulting in an increase in $\mathbf{P_V}$, and therefore in $\mathbf{G_{ME}}$, especially at frequencies below 1 kHz: $|\mathbf{G_{ME}}|$ increased by as much as 15 dB at 125 Hz and the phase decreased by about 0.15 cycles at 200 Hz. After removing the gel, $\mathbf{P_V}$ went back to the lower level, and $\mathbf{G_{ME}}$ was very similar in amplitude and phase to the initial measurement. Several other attempts at sealing the hole produced smaller changes. Overall, the effect of sealing the hole on $\mathbf{G_{ME}}$ was small and limited to the lowest measured frequencies.

B. Stapes velocity transfer function SVTF

$\mathbf{SVTF}=\mathbf{U_S}/\mathbf{P_{TM}}$ was computed in each animal from the measured stapes velocity $\mathbf{V_S}$ and a 2 mm^2 mean stapes footplate area as described in Sec. II, normalized by the measured $\mathbf{P_{EC}}$, and corrected by the $\mathbf{P_{TM}}/\mathbf{P_{EC}}$ transfer function. $\mathbf{V_S}$ was measured in two conditions:

(1) with an intact vestibule, and
(2) after the vestibular hole was drilled and the pressure sensor inserted in the vestibule.

In the intact vestibule condition [Fig. 4(A)], **SVTF** was very similar among the six ears, except for one phase outlier (the outlier is terminated at 2.5 kHz due to SNR problems). The range of the 95% CI was within a factor of 2–3 for the magnitude, and less than 0.1 cycles for the phase angle (equal to the phase difference between $\mathbf{V_S}$ and $\mathbf{P_{TM}}$), over most of the frequency range of measurement. $|\mathbf{SVTF}|$ increased by about a factor of 2.8 with frequency over the two-octave range of 62–250 Hz, and the phase decreased from +0.25 to 0 cycles over the same frequency range. The phase of the admittance (inverse of an impedance) of a combination of compliance and resistance is between 0 and +0.25 cycles. **SVTF** is an admittance as it is the ratio of a volume velocity ($\mathbf{U_S}$) to a pressure ($\mathbf{P_{TM}}$); therefore the phase over 62–250 Hz is consistent with a compliance-resistance combination. $|\mathbf{SVTF}|$ decreased by a factor of 3.4 over the three octaves between 0.3 and 2.4 kHz and the phase was between 0 and −0.25 cycles, consistent with a mass-resistance combination. $|\mathbf{SVTF}|$ increased by a factor of 1.7 between 2.5 and 5 kHz, and decreased by a factor of 3 between 5 and 8 kHz, while the phase decreased toward −0.4 cycles. The notch in $|\mathbf{SVTF}|$ associated with a ripple in the phase near 3 kHz is similar to what was observed in $\mathbf{G_{ME}}$ and is consistent with a resonance of the compliant air within the bulla and the acoustic mass associated with the holes in the bullar wall. Between 8 and 20 kHz, $|\mathbf{SVTF}|$ is characterized by a peak centered at 12.7 kHz and a notch centered at 16 kHz; the phase further decreased, reaching −0.7 cycles by 14 kHz, and then flattened. The group delay was about 51 μs between 500 Hz and 2 kHz and about 44 μs between 3 and 9 kHz.

To assess the influence of the hole in the vestibule wall on **SVTF**, we compared measurements of **SVTF** before the hole was made and afterward with the pressure sensor in place. We found small (<7 dB) increases in $|\mathbf{SVTF}|$ in the condition with the vestibular hole [Fig. 4(B)], which is consistent with the hole decreasing cochlear input impedance and facilitating stapes motion. A paired t-test performed at each frequency showed that the changes were significant ($p<0.01$) only in a small region around 6 kHz.

C. Cochlear input impedance $\mathbf{Z_C}$

$\mathbf{Z_C}=\mathbf{P_V}/\mathbf{U_S}$ was computed from simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$. As mentioned earlier, the computation of $\mathbf{Z_C}$ does not use $\mathbf{P_{TM}}$; therefore our results are not affected by the correction employed to convert $\mathbf{P_{EC}}$ to $\mathbf{P_{TM}}$. $\mathbf{Z_C}$ was similar among six ears (Fig. 5), except for a low outlier for $|\mathbf{Z_C}|$ in one ear at low frequencies and a low outlier in a different ear at high frequencies (corresponding to the ear with a low $|\mathbf{G_{ME}}|$ at high frequencies).

The average $|\mathbf{Z_C}|$ was about 10^{11} acoustic ohms. The factor of 3 range of the 95% CI is similar to the range of 95% CI in $\mathbf{G_{ME}}$ and **SVTF**. Between 62 and 125 Hz, $|\mathbf{Z_C}|$ in-

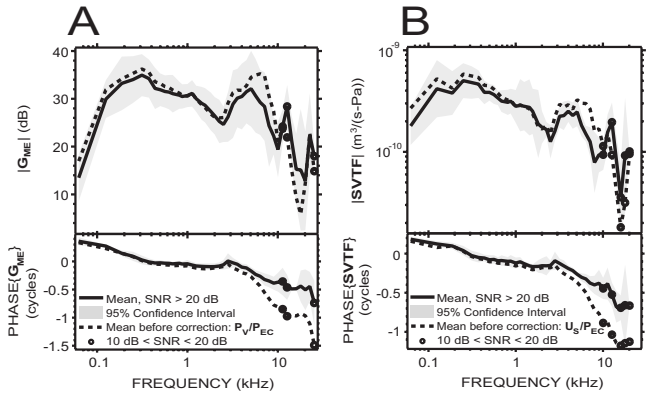

FIG. 6. Effect of an ear canal correction (to account for the differences between $\mathbf{P_{EC}}$ and $\mathbf{P_{TM}}$—see Sec. II) on $\mathbf{G_{ME}}$ and **SVTF**. (A) Mean $\mathbf{G_{ME}}$ before (dotted line) and after (solid line, from Fig. 2) correction. (B) Mean **SVTF** in the intact vestibule condition before (dotted line) and after [solid line, from Fig. 4(A)] correction.

creased and the phase (equal to the phase difference between $\mathbf{P_V}$ and $\mathbf{U_S}$) decreased from close to 0.125 cycles to about 0; this is consistent with a mass-resistance combination (phase between 0 and +0.25 cycles) at the lowest frequency tested. $|\mathbf{Z_C}|$ was roughly constant with frequency between 125 Hz and 10 kHz, and the phase was near zero in this frequency range; this is consistent with a resistance. $|\mathbf{Z_C}|$ increased sharply from 10 to 22 kHz and fell sharply at 25 kHz. Consistent with the input impedance of a passive system, the phase had values between −0.25 and +0.25 cycles at all frequencies measured.

IV. DISCUSSION

We simultaneously measured the sound pressure in the vestibule $\mathbf{P_V}$ and stapes velocity $\mathbf{V_S}$ in chinchilla preparations in response to acoustic stimulations. The middle ear gain $\mathbf{G_{ME}}$, stapes velocity transfer function **SVTF**, and cochlear input impedance $\mathbf{Z_C}$ were computed from these measurements in six ears where the middle and inner ear structures were intact and the pressure sensors stable. In this section, we (a) discuss the role of the ear canal correction we applied to **SVTF** and $\mathbf{G_{ME}}$; (b) address some other factors that may bias our high frequency responses; (c) assess the influence of the vestibular hole on our estimates in the context of (d) an acoustic model; (e) compare our results with other studies in chinchilla and (f) other mammals; and (g) test the hypothesis that auditory thresholds can be predicted by $\mathbf{P_V}$, $\mathbf{U_S}$, or the acoustic power delivered to the cochlea.

A. Effect of ear canal correction on $\mathbf{G_{ME}}$ and SVTF

The $\mathbf{G_{ME}}$ and **SVTF** data presented in Figs. 2 and 4(A), respectively, have been corrected by the mean ratio of sound pressures measured near the umbo ($\mathbf{P_{TM}}$) and about 7 mm from the umbo ($\mathbf{P_{EC}}$) measured in nine other ears (a location that corresponded to the $\mathbf{P_{EC}}$ microphone in these experiments), as described in Sec. II. The effects of this $\mathbf{P_{TM}}/\mathbf{P_{EC}}$ correction function on $\mathbf{G_{ME}}$ and **SVTF** are shown in Fig. 6. As expected, the effect was small below 3 kHz, because the wavelength of sound at these low frequencies is much longer than the dimensions of the ear canal and the sound pressure is approximately constant throughout the ear canal (e.g., Beranek, 1986). Above 3 kHz, the correction caused significant changes in both $\mathbf{G_{ME}}$ and **SVTF** and reduced the measured group delay of both $\mathbf{G_{ME}}$ and **SVTF** by about 45 μs.

Above 3 kHz, the corrected and uncorrected mean $|\mathbf{G_{ME}}|$s [Fig. 6(A)] are similar in shape, but the correction had the effect of (a) shifting the 7 kHz maximum to 5 kHz, while decreasing $|\mathbf{G_{ME}}|$ by 4 dB on average between 2 and 10 kHz, (b) shifting the 11.5 kHz maximum to 12.5 kHz, while increasing $|\mathbf{G_{ME}}|$ by 4 dB between 10 and 20 kHz, and (c) shifting the 18 kHz minimum to 20 kHz, while increasing $|\mathbf{G_{ME}}|$ by about 7 dB. The effects of the correction on |**SVTF**| [Fig. 6(B)] above 3 kHz were to enhance the maximum at 5 kHz and the minimum at 16 kHz. High frequency correction effects are discussed further below.

B. High frequency responses

The high frequency responses we obtained for $\mathbf{G_{ME}}$ and **SVTF** are characterized by an increased variance in magnitude and/or phase relative to lower frequencies. For $|\mathbf{G_{ME}}|$, the 95% CI was 7–12 dB above 16 kHz, and generally 3–6 dB at lower frequencies (Fig. 2). Similarly for the phase, the 95% CI was greater than 0.1 cycles above 10 kHz, smaller below. As for **SVTF**, the 95% CI of the magnitude was roughly similar across frequencies, but the 95% CI of the phase was usually higher above 9 kHz [Fig. 4(A)]. These increased confidence intervals at high frequencies may be due to several factors.

(i) Differences between ear canal sound pressure at our measurement location $\mathbf{P_{EC}}$ and near the TM $\mathbf{P_{TM}}$: The correction factor $\mathbf{P_{TM}}/\mathbf{P_{EC}}$ we used to account for these differences was averaged over measurements in nine ears that were different from the ears in which we made the $\mathbf{P_V}$ and $\mathbf{V_S}$ measurements reported here. The peaks and valleys observed in $|\mathbf{P_{TM}}/\mathbf{P_{EC}}|$, in particular, above 10 kHz, are dependent on the anatomy of the ear canal, which varies among individuals. Consequently, we can expect the correction to be imperfect.

(ii) Fewer animals were included: In earlier experiments, the earphone we used did not provide sufficient sound pressure stimulus at frequencies above 15 kHz, so there are fewer data at high frequencies with a SNR greater than 10 dB (our criteria: see Sec. II). In particular, for $\mathbf{G_{ME}}$, data from six animals were included up to 10 kHz, but only two animals met the SNR criterion above 22 kHz; for **SVTF**, six animals were included up to 9 kHz, two are included at 20 kHz, and only one above that. The breakdown in number of animals included in the estimates of $\mathbf{Z_C}$ is similar to that for **SVTF**.

(iii) The signal-to-noise ratios in the included animals were lower: The data points for which the SNR is between 10 and 20 dB are all concentrated in the high frequencies (see the circles in Figs. 2, 4(A), and 5). Even though a 10 dB SNR means that the signal was

more than three times higher than the noise, noise may have contributed to the increased variance at high frequencies.

(iv) For $\mathbf{U_S}$, we assume piston-like motion of the stapes, and measure velocity in only one direction. During an experiment, the laser angle was set so as to have a clear view of reflectors on the stapes footplate or posterior crus. The actual measurement angle was therefore highly dependent on the animal's specific anatomy and position of the reflectors, usually within $30 \pm 10°$. If the motion is truly piston-like, our measurements are not very sensitive to the laser beam angle. For example, measuring with a 30° angle relative to the piston axis introduces an error corresponding to a factor of cos(30°) or −1.2 dB in measuring the piston component, and small variations about that angle only produce small changes in estimated piston-like velocity: A 40° angle leads to an error in the estimate of piston-like velocity of −2.3 dB, while a 20° angle results in a −0.5 dB error. Therefore, if stapes motion was truly piston-like, the uncertainty on the measurement angle would only result in less than a 3 dB error for these angle values.

Piston-like motion of the stapes is probably a valid assumption at low frequencies; however, it is unlikely that this assumption is valid at high frequencies, and other modes that cause transverse and rotational motion of the stapes at the measurement points may make large contributions to the measured $\mathbf{V_S}$ (e.g., in human temporal bone: Heiland *et al.*, 1999; Hato *et al.*, 2003; Chien *et al.*, 2006; in gerbil: Decraemer *et al.*, 2007; Ravicz *et al.*, 2008; and in cat and cat temporal bone: Guinan and Peake, 1967; Decraemer *et al.*, 2003; Decraemer and Khanna, 2003). The existence and variability of such non-piston modes of motion at high frequency could explain the larger variance for $\mathbf{U_S}$ and **SVTF** in that frequency range.

The 12 kHz peak and the 16 kHz notch we found in $|\mathbf{SVTF}|$ [Fig. 4(A)], as well as the sharp peak in $|\mathbf{Z_C}|$ at high frequencies (Fig. 5), may also be explained by complex motion of the stapes at high frequency. A hypothesis is that the rocking component of stapes motion above 12 kHz is significant, and would result in a measured linear motion of greater or smaller amplitude than the actual $\mathbf{V_S}$, depending on the relative phase between the translational and rocking movements. This hypothesis is credible in light of the aforementioned studies in human temporal bone, gerbil, and cat; however, a detailed description of non-piston modes for the chinchilla has not been done.

C. Influence of the vestibular hole

It was necessary to make a hole in the vestibule to introduce the pressure sensor and measure $\mathbf{P_V}$. Overall, the effects of the vestibular hole on $\mathbf{G_{ME}}$ and **SVTF** were small and limited in frequency: Sealing the hole in one ear produced a small increase in $|\mathbf{G_{ME}}|$ below 1 kHz [Fig. 3(C)], and introducing the hole produced an average increase in $|\mathbf{SVTF}|$ of less than 7 dB in 6 ears [Fig. 4(B)], which was not statistically significant ($p < 0.01$) at most measured frequencies.

The changes we observed for **SVTF** were consistent with a study by Songer and Rosowski (2006). In that study, they looked at the effect of semi-circular canal dehiscence on **SVTF** in chinchillas. They found an increase in $|\mathbf{SVTF}|$ above 100 Hz that was maximal at frequencies between 150 and 500 Hz (5–10 dB), decreased with frequency between 500 and 1000 Hz to a value of roughly 2 dB, and persisted at about 2 dB above the intact case from 1 to 7 kHz. It could not be determined if the increase in $|\mathbf{SVTF}|$ persisted to higher frequencies because measurements were noisy above 7 kHz. In our study, the increase in $|\mathbf{SVTF}|$ had a similar shape below 1 kHz, but had a lower value (the maximum of the mean was less than 5 dB at these frequencies) and this lower value was not statistically significant. We also found a small 0.1-cycle increase in phase angle between 100 and 200 Hz, smaller but consistent with Songer and Rosowski's (2006) 0.4 cycle increase at similar frequencies. The significant changes we observed in $|\mathbf{SVTF}|$ around 6–7 kHz are not visible in Songer and Rosowski's study, but this could be because of their noise issue at these high frequencies. There are also differences in the experimental setup: We introduced a small (180–250 μm diameter) hole, partially plugged (by a 145 μm diameter pressure sensor), in the wall of the vestibule, whereas they introduced a larger (500 μm diameter) open hole in the narrow superior semi-circular canal about 3–5 mm from the vestibule. The smaller changes we observed at low frequencies (5 dB on average in our case, and ~10 dB in their study) are consistent with the introduction of a smaller hole, while the lack of change at higher frequencies in the Songer and Rosowski data may be explained by the 3–5 mm narrow tube that separated their semi-circular canal dehiscence from the vestibule.

Changes in $\mathbf{G_{ME}}$ can be due to changes in $\mathbf{P_V}$, $\mathbf{P_{EC}}$, or both; similarly, changes in **SVTF** can be due to changes in $\mathbf{V_S}$, $\mathbf{P_{EC}}$, or both. It was not possible to ascertain accurately whether part of the changes we measured in $\mathbf{G_{ME}}$ and **SVTF** was due to changes in $\mathbf{P_{EC}}$: Comparison of the measured $\mathbf{P_{EC}}$ before the hole is made and afterward is not valid because we had to move the animal's head to make the hole, which sometimes changed the quality of the seal of the ear-phone in the brass-tube coupler, and affected $\mathbf{P_{EC}}$. Nevertheless, in three experiments, $\mathbf{P_{EC}}$ was nearly identical after the hole was introduced. It is highly unlikely that a change in the ear canal coupler seal would perfectly counteract an effect of the hole on $\mathbf{P_{EC}}$. There is a greater likelihood that in those experiments, the coupler seal did not vary after the hole introduction, and the changes we observed in $\mathbf{G_{ME}}$ and **SVTF** were mostly due to actual changes in $\mathbf{P_V}$ and $\mathbf{U_S}$.

D. Predictions of an acoustic model of a hole in the vestibule

Direct measurement of the effect of the vestibular hole on $\mathbf{G_{ME}}$, by plugging the hole around the pressure sensor, was difficult because of the proximity of the stapes, the flow of lymph out of the hole, and other anatomical and positional constraints. As we have controlled data for the effect of such

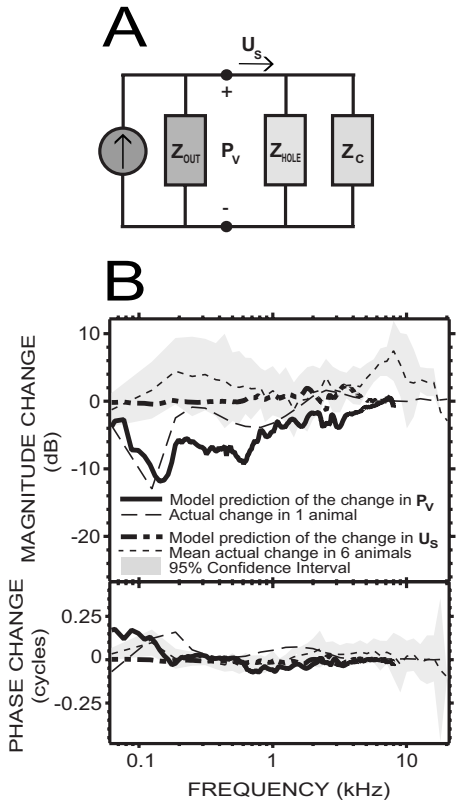

FIG. 7. Model predictions of the effect of the vestibular hole. (A) Simple model of the middle ear as a Norton equivalent circuit, providing volume velocity $\mathbf{U_S}$ to the parallel combination of the inner ear load ($\mathbf{Z_C}$) and the impedance of the hole ($\mathbf{Z_{hole}}$). The Norton equivalent is composed of an ideal volume-velocity source and the output impedance of the middle ear ($\mathbf{Z_{out}}$). (B) Predictions of our simple model with a 180 μm diameter hole partially plugged by a pressure sensor (equivalent radius=53 μm) were at least qualitatively similar to the experimental changes we found in $\mathbf{P_V}$ and $\mathbf{U_S}$ [see text and Figs. 3(C) and 4(B)]: The changes in $\mathbf{P_V}$ were limited to low frequencies (solid and dashed-dotted lines); the changes in $\mathbf{U_S}$ were small (dashed and dotted lines).

plugging on $\mathbf{G_{ME}}$ in only one animal, we now describe a lumped-element acoustic model that provides further insight into the influence of the hole.

The model we use to investigate the effect of the open hole around our $\mathbf{P_V}$ sensor [Fig. 7(A)] represents the middle ear as a Norton equivalent circuit (made up of an equivalent volume-velocity source and a parallel impedance equal to the output impedance of the middle ear and sound source $\mathbf{Z_{out}}$) that provides the stapes volume velocity $\mathbf{U_S}$ to the parallel combination of the inner ear load ($\mathbf{Z_C}$) and the impedance of the hole ($\mathbf{Z_{hole}}$). The pressure across each of the parallel branches of the circuit in Fig. 7(A) is $\mathbf{P_V}$. The changes in $\mathbf{P_V}$ and $\mathbf{U_S}$ introduced by opening the hole can be inferred from this circuit by simple linear current divider equations. If we further assume the output of the source $\mathbf{P_{EC}}$ is not affected by the introduction of the hole, as suggested by some of our experiments (see Sec. IV C above), we can define

$$\frac{\mathbf{P_{V,hole}}}{\mathbf{P_{V,normal}}} = 1 - \frac{\mathbf{Z_C Z_{out}}}{\mathbf{Z_C Z_{out}} + \mathbf{Z_C Z_{hole}} + \mathbf{Z_{hole} Z_{out}}}, \tag{1a}$$

$$\frac{\mathbf{U_{S,hole}}}{\mathbf{U_{S,normal}}} = 1 + \frac{\mathbf{Z_C}^2}{\mathbf{Z_C Z_{out}} + \mathbf{Z_C Z_{hole}} + \mathbf{Z_{hole} Z_{out}}}, \tag{1b}$$

where these ratios represent the change in $\mathbf{G_{ME}}$ and **SVTF**.

These ratios depend on three unknown impedances: $\mathbf{Z_C}$, $\mathbf{Z_{out}}$, and $\mathbf{Z_{hole}}$. We used estimates of $\mathbf{Z_C}$ and $\mathbf{Z_{out}}$ by Songer and Rosowski (2007a), which they computed based on a transmission matrix model of the middle ear, fed by measurements of ear canal pressure and stapes velocity in chinchillas below 8 kHz.[4] To compute $\mathbf{Z_{hole}}$, we modeled the hole as a lossy transmission line.[5] This model was originally developed by Egolf (1977), and used to model fluid-filled tube segments by Songer and Rosowski (2007b). In our case, $\mathbf{Z_{hole}}$ is computed as follows:

$$\mathbf{Z_{hole}} = \frac{\mathbf{A z_0} + \mathbf{B}}{\mathbf{C z_0} + \mathbf{D}}, \tag{2}$$

with $\mathbf{z_0}$ the termination impedance of the hole, and **A**, **B**, **C**, and **D** parameters depending on various thermodynamic parameters of the medium, frequency, and the dimensions of the hole. A detailed description of these parameters can be found in Songer and Rosowski (2007b).

The original model is for a tube of radius a and length l. For our purpose, this description is not entirely satisfying because the hole is partially obstructed by the pressure sensor. In order to apply the model, we computed an "equivalent radius" corresponding to the radius of a hole of cross-section area equal to the area of the annulus delimited by the pressure sensor and the circular edge of the hole. Specifically,

$$a_{\text{equivalent}} = \sqrt{a_{\text{hole}}^2 - a_{\text{sensor}}^2}, \tag{3}$$

with $a_{\text{sensor}}=145/2=72.5$ μm the radius of the pressure sensor.

During the experiments, making the hole usually resulted in perilymph leaking out from the cochlea at a slow rate. Therefore, the termination impedance $\mathbf{z_0}$ that we used was the mass of the fluid terminating the tube.[6]

The results obtained with this model share similarities with the experimental data for both $\mathbf{P_V}$ and $\mathbf{U_S}$ [Fig. 7(B)]. Introducing a 180 μm diameter hole (corresponding to the smallest hole size we achieved experimentally, and leading to $a_{\text{equivalent}}=53$ μm) reduced $|\mathbf{P_V}|$ near 150 Hz by about 10–12 dB, which is consistent with the 10–15 dB increase in the experimental data upon introduction of the gel to seal the hole. The effect of the hole was smaller as frequency increased, with less than a 3 dB difference by 1 kHz in both the experimental and predicted data. Nonetheless, the detailed shape of the predicted change in $|\mathbf{P_V}|$ is different from the measured change, where much of the differences come from frequency-dependent variations in $\mathbf{Z_C}$ and $\mathbf{Z_{out}}$ that originate in the details of the data used in their calculation (Songer and Rosowski, 2007a). As for the phase, the ~0.15 cycles increase predicted by the model at 150 Hz is consistent with the experimental data around this frequency, but the measured and predicted changes differ slightly at other frequencies.

The predicted changes in $\mathbf{U_S}$ are very small: The change in phase was close to 0 over the entire frequency range of the data (except the first data point at 62 Hz), and the change in magnitude was less than 1 dB below 1.5 kHz, and between 1 and 2 dB at frequencies 1.5–8 kHz (except for a small notch of −1 dB at 2.5 kHz). This is consistent with the experimen-

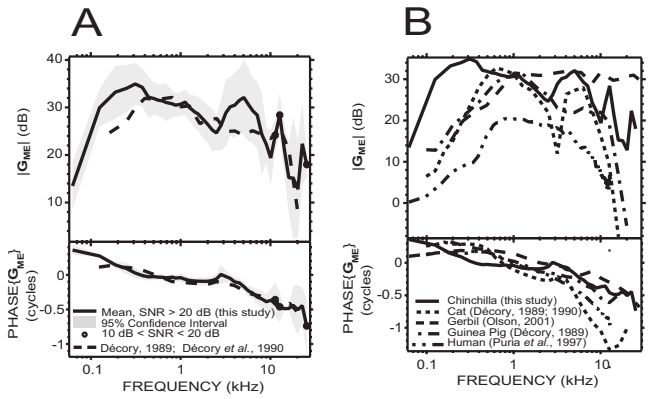

FIG. 8. Comparison of our measurements of $\mathbf{G_{ME}}$ (solid lines) with other studies. (A) In chinchilla: comparison with a previous study by Décory (1989) and Décory *et al.* (1990): dashed line. The two data sets were very similar at stimulus frequencies of 500 Hz–3 kHz and 12–20 kHz, but different at other frequencies. (B) In other mammals: comparison with studies in cat, guinea pig (from Décory, 1989 and Décory *et al.*, 1990: dotted and dashed-dotted lines), gerbil (from Olson, 2001: dashed line), and human temporal bone (from Puria *et al.*, 1997: dashed-double dotted line). All these measurements were carried out with open holes in the bullar walls. The septum of the middle ear (Møller, 1965; Huang *et al.*, 1997) was intact in the cat study.

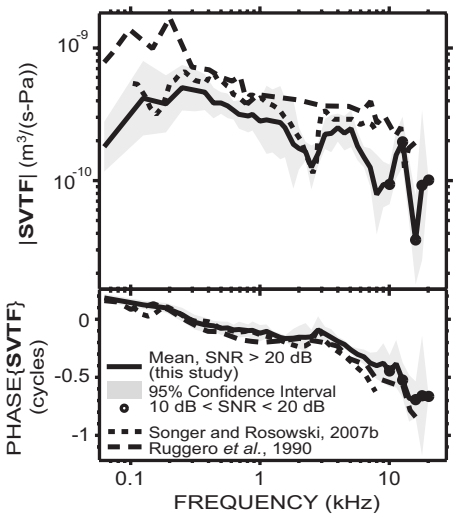

FIG. 9. Comparison of our measurements of **SVTF** (solid line) with previous studies in chinchilla by Songer and Rosowski (2007a): dotted line and Ruggero *et al.* (1990): dashed line. The differences in magnitude between ours and the Ruggero *et al.* (1990) study may be due to differences in the experimental setup (see text).

tal data over a wide range of frequencies: The average change in six animals was about 5 dB in magnitude below 6 kHz, but not statistically significant at these frequencies, and the phase was close to 0. Nonetheless, the slightly larger and significant experimental changes obtained around 6 kHz were not predicted.

To conclude, the predictions of this simple model are qualitatively similar to the experimental data in frequency dependence, and the predicted and measured changes in magnitude and phase angle are quantitatively similar: The model predicts that the small acoustic leak created by the vestibular hole would change $\mathbf{P_V}$ magnitude by no more than 12 dB at low frequencies, and phase angle by generally less than 0.15 cycles, and would cause only very small changes in $\mathbf{U_S}$ over 62 Hz–8 kHz.

E. Comparison with other studies in chinchilla

Our $\mathbf{G_{ME}}$ results are very similar to a previous study in chinchilla by Décory (1989; Décory *et al.*, 1990) between 500 Hz and 3 kHz, and between 8 kHz and 20 kHz, for both the magnitude and the phase [Fig. 8(A)]. Moreover, the slightly negative slope of $|\mathbf{G_{ME}}|$ between 500 Hz and 3 kHz, as well as the sharp decrease between 12 kHz and 20 kHz, was similar in both studies. Between 500 Hz and 3 kHz, the phase we measured was closer to 0 than Décory's (1989; Décory *et al.*, 1990), but the two did not differ by more than 0.1 cycles. Below 500 Hz, and between 3 and 8 kHz, we found a larger $|\mathbf{G_{ME}}|$, by as much as 7 dB at 250 Hz and 8 dB at 5 kHz. The low frequency difference may be explained by a difference in the acoustic leak introduced by the vestibular hole (see Sec. IV D). The difference near 5 kHz may be due to the animal preparation in Décory's (1989; Décory *et al.*, 1990) study: In their study, the vestibular hole was drilled about 5.5 mm away from the base of the cochlea, at a location corresponding to the 5 kHz place along the tonotopic axis. Therefore, as they propose, their measurements around 5 kHz may have been biased by a component due to the peak of the basilar membrane traveling wave, whereas our measurements were performed through a hole closer to the oval window (within 1–2 mm), far from the peak of the traveling wave over most of the measurement range (Rhode and Recio, 2000).

Our measurements of **SVTF** are similar to those in a study by Songer and Rosowski (2007a) in magnitude as well as phase (Fig. 9). Our results are also roughly similar to those of Ruggero *et al.* (1990) at frequencies below 12 kHz. However, we generally obtained a smaller $|\mathbf{SVTF}|$, especially below 300 Hz [$(2-5)\times10^{-10}$ $m^3/(s\ Pa)$ in our study, and 6×10^{-10} to 2×10^{-9} in Ruggero *et al.*, 1990] and near 3 and 8 kHz where we can see small notches in our study. These differences in magnitude may be due to the correction Ruggero *et al.* (1990) applied to take into account that the tensor tympani muscle was cut. Differences in the experimental setup may also explain some variations: We measured $\mathbf{V_S}$ with a laser Doppler vibrometer directed through the bulla, whereas Ruggero *et al.* (1990) used a Mössbauer source placed on the stapes footplate through a small slit in the TM. The bulla was widely open in both studies; however, the notch in our data at 2.5 kHz is likely the result of a bulla cavity-bullar-hole resonance (Rosowski *et al.*, 2006). The notch we found between 14 and 18 kHz is in contradiction with another study by Ruggero *et al.* (2007), in which they measured ossicular vibrations in chinchillas up to 40 kHz and obtained a roughly flat **SVTF** magnitude at least up to 25 kHz. As we discussed earlier, our high frequency results are not as reliable as the lower frequency range of our data, which could explain the difference. Another potential reason for these differences at high frequency is that Ruggero *et al.* (2007) measured velocity of the lenticular process, and added gains measured across the incudo-stapedial joint, whereas we measured velocity from locations on the footplate and parts of the crura close to the footplate.

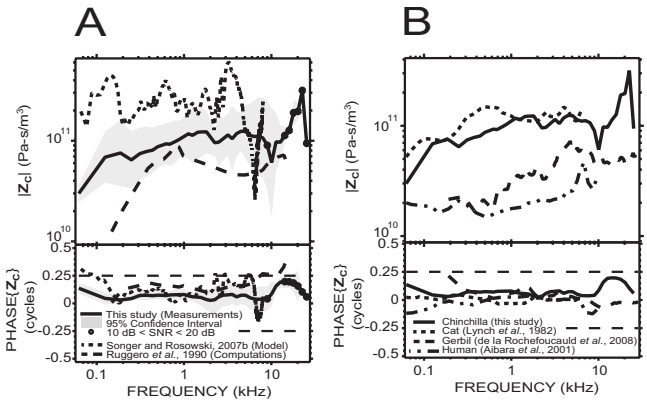

FIG. 10. Comparison of our measurements of $\mathbf{Z_C}$ (solid lines) with other studies. (A) In chinchilla: comparison with the prediction of a model by Songer and Rosowski (2007a): dotted line and computations by Ruggero *et al.* (1990): dashed line, who used their own $\mathbf{U_S}$ measurements and Décory's (1989) $\mathbf{P_V}$ measurements in other animals [see Fig. 8(A)]. (B) In other mammals: comparison with studies in cat (from Lynch *et al.*, 1982: dotted line), gerbil (from de La Rochefoucauld *et al.*, 2008: dashed line), and human temporal bone (from Aibara *et al.*, 2001: dashed-double dotted line).

We compared our measured $\mathbf{Z_C}$ with previous estimates in chinchilla by Ruggero *et al.* (1990) and Songer and Rosowski (2007a). Our $\mathbf{Z_C}$ is a more direct estimate than either of these previous studies because we derived $\mathbf{Z_C}$ from simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ whereas (1) Ruggero *et al.* (1990) combined their own $\mathbf{V_S}$ measurements (see Fig. 9) with Décory's (1989; Décory *et al.*, 1990) $\mathbf{P_V}$ measurements in other animals [see Fig. 8(A)], and (2) Songer and Rosowski (2007a) computed $\mathbf{Z_C}$ from a transmission matrix model of the middle ear fed by measurements of ear canal sound pressure and stapes velocity. The three data sets share many similarities [Fig. 10(A)]: In particular, the impedances are mostly resistive (phase angles close to 0 and approximately flat magnitude on a broad frequency range) with a magnitude of about 10^{11} acoustic ohms; the phase angles of all three estimates are similar at frequencies between 0.3 and 4 kHz. There are also marked differences.

(1) Ruggero *et al.*'s (1990) estimate has a lower magnitude than ours below 500 Hz and between 3 and 10 kHz, consistent with the larger $|\mathbf{G_{ME}}|$ we measured at these frequencies. Their phase angles are higher, and take values greater than +0.25 cycles above 7 kHz, whereas our estimate remains within ±0.25 cycles at all frequencies.
(2) There is a consistent factor of 2–3 difference between the impedance computed by Songer and Rosowski (2007a) and our direct measurements. Their phase angle, although generally near 0, displays some irregularities near 3 kHz and near 7 kHz.

F. Comparison with other mammals

$\mathbf{G_{ME}}$ is shown for chinchilla (our data) along with cat and guinea pig (from Décory, 1989; Décory *et al.*, 1990), gerbil (from Olson, 2001), and human temporal bone (from Puria *et al.*, 1997) in Fig. 8(B). All these data were measured with the middle ear space open. The septum was intact in the cat study. $|\mathbf{G_{ME}}|$ is largest for the chinchilla, especially at low frequencies, but $|\mathbf{G_{ME}}|$ in all these species is similar (within 10 dB) for frequencies between 500 Hz and 3 kHz.

Except for human temporal bone, the overall shape of $|\mathbf{G_{ME}}|$ can be roughly described in these species by two more-or-less broad lobes. For chinchilla, the first lobe ranges from 62 Hz to 2.5 kHz and peaks at 35 dB, while the second one ranges from 2.5 to 9 kHz and peaks at a slightly lower value (32 dB); at higher frequencies, the gross tendency is a decrease in gain, but there is no evidence of a sharp roll-off. For cat and guinea pig, the first lobe has a larger maximum than the second one (about 32 dB for cat and 31 dB for guinea pig). The separation between the two lobes is more prominent in the cat data (the large notch centered at 3 kHz is related to a resonance between the tympanic middle ear cavity and the foramen in the septal wall of the bulla, e.g., Møller, 1965; Guinan and Peake, 1967; Huang *et al.*, 1997). There are sharp high frequency roll-offs for cat and guinea pig. For the cat, the roll-off occurs at slightly lower frequencies (0 dB is reached by 15 kHz) than for guinea pig. For the gerbil data, the separation between the two lobes is at about 7 kHz, but the second lobe extends to at least 46 kHz [data not shown in Fig. 8(B)] and there is no evidence of a roll-off at these frequencies. The more-or-less pronounced notch separating the two lobes in the animal data described above is likely due to a resonance between the bulla and the open hole in the bullar wall (e.g., Møller, 1965; Ravicz *et al.*, 1992; Rosowski *et al.*, 2006).

The phases of $\mathbf{G_{ME}}$ in these species have similarities in shape, but the decrease with frequency varies across species (fastest for the cat and slowest for the gerbil). The average group delay between 0.2 and 10 kHz is about 52 μs in our study, 131 μs in cat, 51 μs in gerbil, 82 μs in guinea pig, and 92 μs in human. For cat and guinea pig, the phase increases slightly at high frequency after reaching a minimum. It is difficult to tell whether this increase is real or if it is an artifact of phase unwrapping.

We compared our $\mathbf{Z_C}$ results with other studies where $\mathbf{P_V}$ and $\mathbf{V_S}$ were simultaneously measured [Fig. 10(B)] in cat (from Lynch *et al.*, 1982), gerbil (from de La Rochefoucauld *et al.*, 2008), and human temporal bone (from Aibara *et al.*, 2001). $\mathbf{Z_C}$ in chinchilla and cat are very similar up to 8 kHz for both magnitude and phase. For all these species, the magnitudes are approximately flat with frequency and the phase angles close to 0. The mostly resistive cochlear input impedance in all those mammalian species ensures that most of the energy transmitted through the middle ear is dissipated into the cochlear fluid, and may be important for cochlear traveling wave propagation (Décory, 1989; de La Rochefoucauld *et al.*, 2008).

G. Acoustic power W_C, $\mathbf{P_V}$, $\mathbf{U_S}$, and the audiogram

We tested the hypothesis that the shape of the audiogram is set by a constant threshold value of some input quantity such as the average acoustic power delivered to the cochlea W_C (Khanna and Tonndorf, 1969; Rosowski, 1991), $\mathbf{P_V}$, or $\mathbf{U_S}$.

W_C can be computed from $\mathbf{P_V}$ and the cochlear input impedance $\mathbf{Z_C}$ as follows:

$$W_C = \frac{1}{2}\mathrm{Re}\{\mathbf{P_V}\mathbf{U_S}^*\} = \frac{1}{2}|\mathbf{P_V}|^2\mathrm{Re}\left\{\frac{1}{\mathbf{Z_C}}\right\}, \quad (4)$$

where Re{**X**} indicates the real part of **X**. In terms of our measured quantities,

$$\frac{W_C}{|\mathbf{P_{TM}}|^2} = \frac{1}{2}\left|\frac{\mathbf{P_V}}{\mathbf{P_{TM}}}\right|^2\mathrm{Re}\left\{\frac{1}{\mathbf{Z_C}}\right\} = \frac{1}{2}|\mathbf{G_{ME}}|^2\mathrm{Re}\left\{\frac{1}{\mathbf{Z_C}}\right\}, \quad (5)$$

and the sound pressure at the TM $\mathbf{P_{TM,0}}$ required to produce a criterion value of acoustic power $W_{C,0}$ is

$$|\mathbf{P_{TM,0}}| = \sqrt{\frac{W_{C,0}}{\frac{1}{2}|\mathbf{G_{ME}}|^2\mathrm{Re}\left\{\frac{1}{\mathbf{Z_C}}\right\}}}. \quad (6)$$

By definition of $\mathbf{G_{ME}}$ and **SVTF**, the sound pressure at the TM $\mathbf{P_{TM,0}}$ required to produce a criterion value of vestibular pressure $\mathbf{P_{V,0}}$ or of stapes volume velocity $\mathbf{U_{S,0}}$ is given by

$$\mathbf{P_{TM,0}} = \frac{\mathbf{P_{V,0}}}{\mathbf{G_{ME}}}, \quad (7)$$

$$\mathbf{P_{TM,0}} = \frac{\mathbf{U_{S,0}}}{\mathbf{SVTF}} \quad (8)$$

We compare free-field sound pressure at auditory threshold in chinchilla (Miller, 1970) with the sound pressure required to produce a constant level of W_C [by Eq. (6)], $\mathbf{P_V}$ [by Eq. (7)], and $\mathbf{U_S}$ [by Eq. (8)]. A complication is that the chinchilla audiogram from Miller (1970) was measured in free field, whereas our experiments were done with the sound stimuli specified at the TM. To account for the differences between free-field pressure $\mathbf{P_{FF}}$ and ear canal pressure near the TM $\mathbf{P_{TM}}$, we used an average head related transfer function (HRTF) measured in the chinchilla by von Bismark and Pfeiffer (1967). This HRTF quantifies the filtering effect of the head and pinnae on the incoming sound. Another complication is that all our measurements were done with the bulla open, whereas Miller's (1970) audiogram was measured in behaving animals with an intact bulla. We used a correction factor from Ruggero *et al.* (1990) to account for the effect of opening the bulla on $\mathbf{G_{ME}}$ and **SVTF**: $|\mathbf{G_{ME}}|$ and $|\mathbf{SVTF}|$ in the open bulla condition were larger than in the closed bulla condition by as much as 16 dB in the low frequencies; the effect was less than 3 dB above 600 Hz.

Figure 11 compares three free-field sound pressure estimates $|\mathbf{P_{FF}}|$ to Miller's (1970) audiogram: the $|\mathbf{P_{FF}}|$ required to generate $W_{C,0}=5\times10^{-18}$ W of acoustic power in the vestibule, the $|\mathbf{P_{FF}}|$ required to generate $|\mathbf{P_{V,0}}|=34$ dB re 20 μPa, and the $|\mathbf{P_{FF}}|$ required to generate $|\mathbf{U_{S,0}}|=10^{-14}$ m^3/s. These values were chosen by eye for a close fit to the audiogram over the frequency range 125 Hz–2 kHz. The HRTF was available only between 250 Hz and 8 kHz, which limited the range of $\mathbf{P_{FF}}$. Nonetheless, given that the wavelength of sound at low frequencies (>1.4 m below 250 Hz in air) is large compared to the size of the head and pinnae, we can assume that the HRTF has a 0 dB gain below 250 Hz, and therefore $\mathbf{P_{TM}}$ well approximates $\mathbf{P_{FF}}$ below 250 Hz.

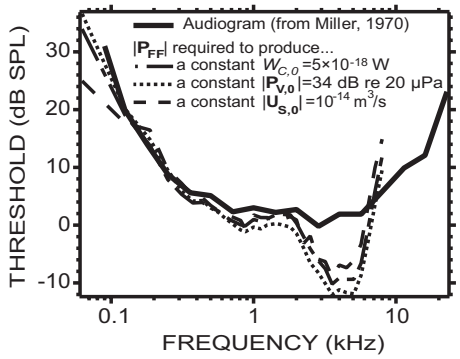

FIG. 11. An average chinchilla audiogram (thick solid line, from Miller, 1970) was compared to the free-field sound pressure $|\mathbf{P_{FF}}|$ required to produce a constant level of $|\mathbf{P_V}|$ (thin dotted line), $|\mathbf{U_S}|$ (thin dashed line), and W_C (thin dashed-dotted line).

The audiogram is well predicted by the three quantities tested between 125 Hz and 2 kHz. Below 125 Hz, both W_C and $\mathbf{P_V}$ produce similar slopes to the audiogram, whereas $\mathbf{U_S}$ produces a shallower slope and therefore is not a good predictor at those frequencies. Above 2 kHz, none of the three quantities are good predictors: The audiogram is almost flat with thresholds between 0 and 5 dB SPL, whereas $\mathbf{P_{FF}}$ in the three cases decreases to a minimum near 2 kHz before increasing again with frequency, crossing the audiogram at about 7 kHz.

In Rosowski (1991), W_C was estimated from a power flow model using various mechano-acoustic quantities in cat, chinchilla, and human temporal bone. The $\mathbf{P_{FF}}$ required to produce a constant $W_C=5\times10^{-18}$ W was plotted against Miller's (1970) audiogram in the case of the chinchilla (see his Fig. 12, middle panel). The fit between $\mathbf{P_{FF}}$ and the audiogram was determined so as to minimize the mean square error over the full range of tested frequencies, whereas we minimized (by eye) the error below 2 kHz (which by chance led to the same value of 5×10^{-18} W). In both studies, W_C is a poor predictor of the audiogram above 2 kHz. Below 2 kHz, the shape of our $\mathbf{P_{FF}}$ more reliably predicts the shape of the audiogram.

V. CONCLUSIONS

We used the miniature fiber-optic pressure sensors described by Olson (1998) to measure the sound pressure within the vestibule $\mathbf{P_V}$ of the inner ears of chinchillas, and laser Doppler vibrometry to measure stapes velocity $\mathbf{V_S}$, while presenting sound stimuli to the ear canal (Fig. 1). Our simultaneous measurements of $\mathbf{P_V}$ and $\mathbf{V_S}$ led to new estimates of the middle ear pressure gain $\mathbf{G_{ME}}$ and of the stapes velocity transfer function **SVTF** in chinchillas, and to the first direct measurement of cochlear input impedance $\mathbf{Z_C}$ in this species. Measurements of $\mathbf{V_S}$ before and after introducing the hole in the bony vestibular wall and placing the fiber-optic pressure sensor in the vestibule (Fig. 4), as well as measurements of $\mathbf{P_V}$ before and after sealing the pressure sensor in place (Fig. 3), suggest that the introduction of the vestibular hole and placement of the sensor had a small effect on middle ear sound transmission. We were able to

qualitatively predict this effect using a simple acoustic model (Fig. 7).

The measured $\mathbf{G_{ME}}$ (Fig. 2) was band-pass in nature with a peak magnitude similar to the 38 dB middle ear gain predicted from the product of the TM/footplate area ratio and the malleus/incus lever ratio. The phase angle of $\mathbf{G_{ME}}$ varied by more than a cycle over the 62 Hz–30 kHz measurement range and was generally consistent with a group delay of 52 μs. When compared with cat, gerbil, guinea pig, and human temporal bone (Fig. 8), $|\mathbf{G_{ME}}|$ was largest for the chinchilla, especially at low frequencies. However, $|\mathbf{G_{ME}}|$ in all these species was similar (within 10 dB) over 500 Hz–3 kHz.

Our $\mathbf{Z_C}$ was resistive from 0.2 to at least 10 kHz, with a magnitude on the order of 10^{11} acoustic ohms (Fig. 5). Together with previous direct measurements of $\mathbf{Z_C}$ in cat, gerbil, and human temporal bone (Fig. 10), this suggests that a resistive $\mathbf{Z_C}$ is characteristic of the mammalian ear. Over 125 Hz–2 kHz, estimates of the free-field sound pressures necessary to maintain a constant sound power into the inner ear, a constant $\mathbf{P_V}$, or a constant $\mathbf{V_S}$ had a frequency dependence similar to that of auditory thresholds (Fig. 11); this similarity did not hold at higher sound frequencies. A better predictor of the shape of the audiogram may be the basilar membrane differential pressure (difference between $\mathbf{P_V}$ and the sound pressure in scala tympani), which will be the object of a future study in a similar chinchilla preparation.

ACKNOWLEDGMENTS

We thank Elizabeth Olson, Wei Dong, and Heidi Nakajima, for their assistance in making the fiber-optic pressure sensors and their advice in using them in our experiments. We also thank Melissa Wood for her mastery of chinchilla surgery and her help with the experiments. We would also like to express our appreciation to the staff of the Microsystems Technology Laboratories at MIT and, in particular, to Kurt Broderick. This work was supported by Grant Nos. RO1-DC00194 and T32-DC00038 from the National Institute on Deafness and other Communication Disorders (NIDCD).

[1]In this paper, bold variables ($\mathbf{X}$) are complex functions of frequency and variables in italics (Y) are real.

[2]The average group delays reported in this paper over an x Hz$-y$ Hz frequency range were computed as $-(\phi(y)-\phi(x))/(y-x)$, where $\phi(z)$ is the phase angle in cycle at frequency z Hz.

[3]The theoretical anatomical "transformer ratio" was computed as the product of the "area ratio" (the area of the TM divided by the area of the stapes footplate) and the "lever ratio" (malleus length divided by incus length). Anatomical values in the chinchilla lead to an "area ratio" of 29 dB (using an estimated TM area of about 60 mm^2 and a footplate area of 2 mm^2 from Vrettakos *et al.*, 1988) while differences in malleus and incus length suggest a "lever ratio" of 9 dB (using 4.5 mm as the estimated length of the manubrium of the malleus and 1.58 mm as the estimated length of the long process of the incus, from Vrettakos *et al.*, 1988). The total "transformer ratio" is therefore 38 dB.

[4]We did not use our own $\mathbf{Z_C}$ because it was measured with a hole in the vestibule.

[5]We also tried a simpler model of $\mathbf{Z_{hole}}$ to predict the change in $\mathbf{P_V}$ and $\mathbf{U_S}$: We used equations for a tube of very small diameter from Beranek (1986) [Eqs. (5.48) and (5.49), p. 135]. Even though this simpler model has some frequency limitations, the predictions were very similar to those based on the lossy transmission line model of $\mathbf{Z_{hole}}$ from Eq. (2).

[6]We used the termination impedance for a tube terminating in an infinite baffle from Beranek (1986) [Eq. (5.17), p. 121]. The acoustic mass obtained for a 180 μm diameter hole, leading to an equivalent radius $a_{\text{equivalent}}=53$ μm, was about 5.1×10^6 kg/m^4.

(Received 25 August 2009; revised 15 December 2009; accepted 15 December 2009)

Most mathematical models of the mammalian cochlea neglect structural longitudinal coupling. However, recent experimental data suggest that viscoelastic longitudinal coupling, in the basilar membrane (BM) and the tectorial membrane (TM), is non-negligible. In this paper, mathematical models for BM and TM longitudinal coupling are presented to determine the influence of such a coupling on the tuning of the BM. The longitudinal coupling models are added to a macroscopic linear model of the guinea pig cochlea that includes the micromechanics of the organ of Corti and outer hair cell (OHC) somatic motility. The predictions of the BM response to acoustic stimulus show that the characteristic frequency is controlled by a TM radial resonance and that TM longitudinal coupling has a more significant effect than BM longitudinal coupling. TM viscoelasticity controls the sharpness of the BM frequency response and the duration of the impulse response. The results with realistic TM longitudinal coupling are more consistent with experiments. The model predicts that OHC somatic electromotility is able to supply power to the BM at frequencies well above the cutoff of the OHC basolateral membrane. Moreover, TM longitudinal coupling is predicted to stabilize the cochlea and enable a higher BM sensitivity to acoustic stimulation. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3290995]

I. INTRODUCTION

The mammalian hearing system combines high sensitivity to low level acoustic pressure stimulus with a dynamic range that extends over six orders of magnitude. In addition, cochlear responses are highly tuned in the frequency domain yet the system as a whole still possesses excellent transient capture, able to discriminate timing differences of $6-10\ \mu s$.[1] The solution to these seemingly conflicting characteristics involves both the unique transduction properties of the auditory periphery and the processing capabilities of the central nervous auditory system. In the periphery, where the acoustic signals are converted to neuronal input, an intricate micromechanical and microfluidic cochlear anatomy has evolved. In the healthy cochlea, outer hair cells (OHCs) present a nonlinear electrical and mechanical response to acoustic stimulation. The mechanical force from the OHC is thought to be the main factor leading to both the nonlinear input-output characteristic and the sharp frequency filtering seen in the cochlea. The focus of current research aimed at uncovering the workings of the cochlea has been on two mechanisms of OHC mediated force generation, basolateral (somatic) and hair bundle (HB) motility. Both hypotheses hinge on the conversion of some form of stored nonmechanical energy (e.g., the endocochlear electrical potential[2]) to mechanical energy. The HBs are comprised of numerous stereocilia-like projections from the apex of each OHC. The HBs are of central interest, as shear deflection of the HB gates the large potassium current necessary for somatic OHC force generation, and the same shear motion of the HB is thought to initiate a cascade of events resulting in HB force generation. The apical termination of the tallest row of stereocilia of each HB is in the tectorial membrane (TM) which, therefore, plays a critical role in active cochlear mechanics. The basilar membrane (BM) is a main structural component of the cochlea since it is directly coupled to the fluid of the cochlear ducts. The sensory hair cells are sandwiched between the TM and the BM. In this paper we use a mathematical model of the cochlea that explicitly includes the micromechanics of the organ of Corti (OoC) with independent degrees of freedom for the BM and TM vibrations. We introduce longitudinal coupling in the TM and/or in the BM using material properties based on experimental data to predict the effect of such coupling on the BM response to acoustic input.

Some researchers have postulated a central role for the TM in cochlear mechanics, and some before the electromotility of the OHC had been presented in 1985.[3] Zwislocki[4,5] hypothesized that the TM acts as a second resonator coupled to the BM through the OHC HB linkage. He used this to explain the sharp tuning and secondary peaks in tuning curve. Allen[6] postulated that a two degree of freedom resonator system consisting of the TM mass and BM-OoC mass would be sufficient to explain the sharpness seen in cochlear tuning.

Gummer *et al.*[7] presented experimental results on TM resonance in the apex of the postmortem cochlea. If these results can be extended to the basal region of the living cochlea, they indicate the presence of two TM modes having different resonant frequencies. Mammano and Nobili[8] developed a model of TM interaction with HB giving rise to OHC somatic electromotility. Chadwick *et al.*[9] also developed a model that highlighted the importance of the TM for predicting the frequency response of the cochlea. In the former models, certain assumptions are made regarding the amplitude and/or phase of the OHC somatic forcing that limit their predictive capability, especially with regard to the TM mechanics and OHC electromotility.

The TM is a gelatinous structure with three different noncollageneous glycoproteins (α-tectorin, β-tectorin, and otogelin). β-tectorin is an essential structural component providing longitudinal coupling in the TM (as shown by Ghaffari[10]). A mouse with genetically modified β-tectorin exhibits an enhanced tuning and reduced sensitivity in the high frequency region,[11] which suggests that the TM plays a key role in tuning and that TM longitudinal coupling is important for cochlear mechanics. The mechanical properties of the TM have been measured in gerbils[12,13] and in guinea pigs[14,15] as well as in mice.[16–18] The measurements in Ref. 17 show that the TM has frequency dependent properties. Moreover, although direct comparison between different measurements is difficult because of the difference in the experimental methods, the data show that the TM of mice (that have a higher frequency range than guinea pigs) is much stiffer than the TM of the guinea pigs and gerbils (that have a lower frequency range than guinea pigs). Zwislocki and Cefaratti[13] found that the TM is significantly less stiff than the HBs in the gerbil cochlea. However, some more recent measurements lead to contradictory conclusions about the relative stiffness of the TM (which in turn influences the kinematics). Some studies in the mouse cochlea have found that the TM is significantly stiffer than the HB.[16,17] If this is the case, then the TM would then move as rigid body from the limbal attachment provided that the TM region near the spiral limbus is more compliant than the main body of the TM (see Ref. 19). Recent measurements in the gerbil and guinea pig cochlea found that the TM has a stiffness within an order of magnitude of the HB.[12,15] In this case, the TM would then deform elastically from the limbal attachment (if the limbal attachment is stiffer than the TM, as suggested in Refs. 14 and 18). Richter *et al.*[12] showed that the TM stiffness varies longitudinally with a higher radial stiffness at basal locations than at more apical locations. Shoelson *et al.*[15] did not observe the presence of a stiffness gradient in the TM of the guinea pig but observed a longitudinal and radial inhomogeneity. An estimate of the shear modulus and Young's modulus was derived in Refs. 12 and 15 based on an isotropic model of the TM. As noted in these papers some caution must be taken in interpreting these results because of the isotropic and homogeneous assumptions of the model. Because of its microstructure the TM is anisotropic, as shown by Gavara and Chadwick[14] using atomic force microscopy measurements of the elastic moduli. Ghaffari *et al.*[20] demonstrated that the TM isolated from the mouse cochlea is capable of supporting shear waves that propagate in the longitudinal direction of the cochlea (see Fig. 1). Such waves would not be possible without significant longitudinal stiffness in the TM. While the mechanical properties of the TM estimated from these experiments are somewhat different with those from Gavara and Chadwick,[14] both group's estimates of modulus are consistent with a slow shear wave whose phase velocity is comparable to that of the traveling wave in the cochlea near the frequency dependent peak response location.

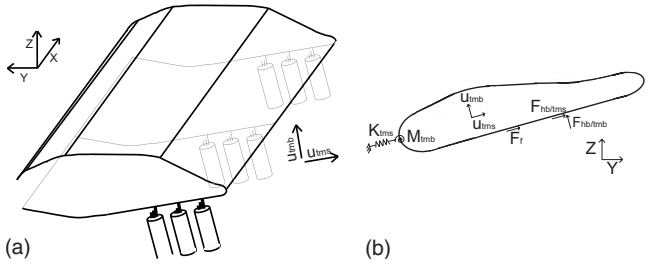

FIG. 1. (a) Illustration of the TM model. The x-coordinate corresponds to the longitudinal direction. (b) Cross-sectional view of the TM showing external forces (per unit length) acting on the TM. The HBs apply forces in the shear ($F_{hb/tms}$) and bending ($F_{hb/tmb}$) directions. Fluid forcing due to the viscous fluid interaction in the subtectorial space is given by a force ($F_f = C^f_{sub}\dot{u}_s$) in the shear direction proportional to the relative shear velocity between the TM and the RL, $\dot{u}_s$. The TM elasticity in the cross section is modeled by a linear spring (K_{tms}) applying a force in the shear direction and a rotational spring (M_{tmb}) applying a force in the bending direction. The plane sections (y-z) shear relative to one another. As in Ref. 20, internal viscous ($A^{eff}_{tm}\eta_{xy}\partial\dot{u}_{tms}/\partial x$) and elastic ($A^{eff}_{tm}G_{xy}\partial u_{tms}/\partial x$) coupling is included.

In the BM stiffness measurements in dead animals from von Bekesy,[21] longitudinal coupling appears to be significant. However, in the study from Voldrich[22] in live guinea pigs, longitudinal coupling in the BM is negligible. More recent work in mongolian gerbil cochlea[23] quantifies longitudinal coupling in the BM and organ of Corti and indicates that longitudinal coupling is significant and increases from the base to the apex of the cochlea. Liu and White[24] used the published experimental data to compute the material properties of the BM described by an orthotropic plate model.

Recent experimental data indicate that viscoelastic coupling in the TM and elastic coupling in the BM is important. However, most cochlear models[25,19] are based on a locally reacting representation of the cochlear partition and neglect structural longitudinal coupling. Allen and Sondhi[26] modeled the BM as an orthotropic plate but the TM is not included and the model is passive. The model of Wickersberg and Geisler[27] includes elastic longitudinal coupling in the BM in a one dimensional model. In this model the effect of introducing longitudinal coupling in the BM governing equation for the low damping case is to broaden the BM frequency response and to reduce the magnitude of the peak. But the interpretation of this result is limited since the organ of Corti is reduced to one degree of freedom and the magnitude of longitudinal coupling is not based on any measurement. Steele and Taber[28] included longitudinal coupling in the BM (treating it as a plate). The model of Mammano and Nobili[8] introduces only viscous longitudinal coupling in the organ of Corti. If structural longitudinal coupling is important in the

mechanics of the cochlea, what is the role of such coupling? We propose a role for the TM in electromotile processes and in shaping the frequency response of the BM to acoustic stimulus. We also predict the relative importance of the BM versus TM longitudinal coupling in influencing the sharpness of tuning of the BM.

II. METHODS

The fluid domain is idealized as uncoiled with two internal ducts separated by the basilar membrane. The macroscopic response of the fluid is modeled as inviscid and incompressible and is coupled to the mechanical response of the basilar membrane through the linearized Euler relation.[19] A micromechanical model of the organ of Corti is coupled mechanically to the TM and the BM. Viscous fluid effects (e.g., shearing of the fluid in the subtectorial space) are also included in the micromechanical model. Electrical conduction through the scalae is modeled using a set of coupled cable equations. The electrical and mechanical domains are coupled through a piezoelectric model for the OHC somatic motility and a displacement dependent conductance of the HB. Details of the mechanical, electrical, and fluidic model are presented by Ramamoorthy *et al.*[19] The main change to the model of Ramamoorthy *et al.* is the addition of longitudinal coupling in the TM and BM mechanics as is described next.

A. Tectorial membrane mathematical model

As shown in Fig. 1, each cross section of the TM is modeled as a two degree of freedom system with deformation in the radial or shear direction (u_{tms}) and in the normal or bending direction (u_{tmb}). The TM is characterized at each (y-z) plane by its effective stiffness and mass per unit length. The bending and shear motion varies in the longitudinal direction (x) and hence the cross sections move relative to one another. Longitudinal viscoelastic coupling of the shear motion of the TM is included (with a shear modulus G_{xy} and a shear viscosity η_{xy}) while TM bending rigidity is neglected. The governing equation for the shear motion of the TM is

$$F_{hb/tms}(x) = K_{tms}u_{tms} + C_{sub}^{f}\dot{u}_{s} + M_{tms}\ddot{u}_{tms} - \frac{\partial}{\partial x}\left(A_{tm}^{eff}G_{xy}\frac{\partial u_{tms}}{\partial x} + A_{tm}^{eff}\eta_{xy}\frac{\partial \dot{u}_{tms}}{\partial x}\right), \quad (1)$$

where $F_{hb/tms}$ is the external force (per unit length) applied by the HB of the OHC in the shear direction,[19] C_{sub}^{f} is the damping coefficient due to the viscosity of the fluid in the subtectorial space, u_s is the relative shear displacement between the TM and the reticular lamina (RL), and A_{tm}^{eff} is an effective cross-sectional area of the TM. Because of its inhomogeneity,[15] anisotropy,[14] and of its frequency dependent properties,[16,17] it is difficult to estimate the values for the effective TM shear stiffness and mass. Here we chose the TM stiffness per unit length, K_{tms}, based on the values published by Richter *et al.* for the radial TM stiffness of the gerbil (as discussed in the Appendix). Hence the TM stiffness is within one order of magnitude of the HB stiffness published in Ref. 29. For the TM shearing mass, we take into account the longitudinal variation observed in the TM cross section area in Ref. 12 and choose the value to fit the predictions of the BM response to acoustic stimulation with published experimental data. The values of the TM parameters are listed in Table I.

B. Basilar membrane mathematical model

To introduce elastic longitudinal coupling in the BM mechanics, we use an orthotropic plate model. The governing equation for the BM motion is

$$P_{bm}(x,y) = \frac{2}{b}C_{bm}\dot{u}_{bm} + M_{bm}\ddot{u}_{bm} - \frac{\partial^2}{\partial x^2}\left(D_{xx}\frac{\partial^2 u_{bm}}{\partial x^2} + D_{xy}\frac{\partial^2 u_{bm}}{\partial y^2}\right) - 2\frac{\partial^2}{\partial x\,\partial y}\left(D_{s}\frac{\partial^2 u_{bm}}{\partial x\,\partial y}\right) - \frac{\partial^2}{\partial y^2}\left(D_{yy}\frac{\partial^2 u_{bm}}{\partial y^2} + D_{xy}\frac{\partial^2 u_{bm}}{\partial x^2}\right), \quad (2)$$

where P_{bm} is the pressure applied by the fluid and the OHC on the BM,[19] C_{bm} is the BM viscous damping per unit area, M_{bm} is the mass of the BM per unit area, b is the width of the BM, and $u_{bm}(x,y)$ is the BM displacement. D_{xx}, D_{yy}, D_{xy}, and D_s are the orthotropic plate bending stiffnesses of the BM. As in Ref. 19, we assume that the BM vibrates with the mode shape $u_{bm}(x,y)=u_{bm}^{0}(x)\sin(\pi(y+\frac{b}{2})/b)$ for $-b/2\le y \le b/2$. The values of the BM parameters are listed in Table II.

C. Uncoupled structural longitudinal coupling space constants

In the macroscopic model of the cochlea, the motions of the TM and of the BM are coupled, especially in the active model. However, to evaluate the contributions of TM longi-

tudinal coupling and of BM longitudinal coupling to cochlear mechanics, we determine here the equations used to compute the space constants for the shear motion of the TM and the transverse motion of the BM uncoupled from the other structures and the fluid. Analysis of these predictions will allow us to estimate the spatial extent of a single row of OHC forcing due to longitudinal mechanical coupling in the TM and BM.

The TM is attached to the reticular lamina by three rows of HBs (each with a stiffness per unit length K_{st}) and to the spiral limbus and has a stiffness per unit length, K_{tms}. The force applied by the HB on the TM in the shear direction is given by $F_{hb/tms}=-3K_{st}u_s$. Therefore, according to Eq. (1), if the longitudinal variations in A_{tm}^{eff}, G_{xy}, and η_{xy} are neglected locally, the complex wavenumber characteristic of TM longitudinal coupling (when the TM and HB are uncoupled from the other structures), k_{tms-hb}, is given by

$$k_{tms-hb}=\left(-\frac{K_{tms}+3K_{st}-c_{tms}i\omega-M_{tms}\omega^2}{A_{tms}^{eff}(G_{xy}-i\omega\eta_{xy})}\right)^{1/2}. \quad (3)$$

If we integrate out the radial dependence of the BM displacement and neglect locally the longitudinal variations in b and of the basilar membrane properties, the BM governing equation is reduced to

$$F_{bm}(x)=C_{bm}\dot{u}_{bm}^0(x)+\frac{b}{2}M_{bm}\ddot{u}_{bm}^0(x)-\frac{b}{2}\left[D_{xx}\frac{\partial^4u_{bm}^0}{\partial x^4}-2(D_{xy}+D_s)\left(\frac{\pi}{b}\right)^2\frac{\partial^2u_{bm}^0}{\partial x^2}+D_{yy}\left(\frac{\pi}{b}\right)^4u_{bm}^0\right], \quad (4)$$

where F_{bm} is the force per unit length applied by the pressure and the OHC.[19] The complex wave number characteristic of BM longitudinal coupling (for the BM uncoupled from the organ of Corti), k_{bm}, is the solution of the following equation:

$$D_{xx}k_{bm}^4+2\left(\frac{\pi}{b}\right)^2(D_{xy}+D_s)k_{bm}^2+D_{yy}\left(\frac{\pi}{b}\right)^4-M_{bm}\omega^2-\frac{2}{b}C_{bm}i\omega=0. \quad (5)$$

The space constants characteristic of structural longitudinal coupling are then given by

$$\lambda_{tms-hb}=\frac{1}{|Imag(k_{tms-hb})|} \quad \text{and} \quad \lambda_{bm}=\frac{1}{|Imag(k_{bm})|}, \quad (6)$$

where *Imag* represents the imaginary part of the complex wave number.

D. Model activity: OHC somatic motility and HB conductance

The electrical and mechanical degrees of freedom of the model are coupled through the somatic electromotility of the OHCs and the conductance change in the HBs. HB motility is not included and the HBs are modeled as passive springs with stiffness (per unit length) K_{st} connecting the RL and the TM. Each OHC is modeled by linearized piezoelectric-like expressions relating the OHC deformation, $u_{ohc_j}^{comp}$, and fluctuating part of the transmembrane voltage, $\Delta\phi_{ohc_j}$, to the OHC force (per unit length), F_{ohc_j}, and current (per unit length), I_{ohc_j}:

$$F_{ohc_j}=K_{ohc}u_{ohc_j}^{comp}+\epsilon_3\Delta\phi_{ohc}, \quad (7)$$

$$I_{ohc_j}=\frac{\Delta\phi_{ohc}}{Z_m}-i\omega\epsilon_3u_{ohc_j}^{comp}, \quad (8)$$

where K_{ohc} is the OHC stiffness (per unit length), ϵ_3 is the electromechanical coupling coefficient (per unit length), Z_m is the basolateral impedance of the OHC, and the subscript ohc_j refers to each OHC where j corresponds to the row number, $j=1,2,3$.

The conversion of electrical power to mechanical power delivered by the OHC somatic force to the BM, $P_{ohc/bm}^{som}$, is then

$$P_{ohc/bm}^{som}=\tfrac{1}{2}\mathrm{Re}[\epsilon_3\Delta\phi_{ohc}\times v_{bm}^*], \quad (9)$$

where Re denotes the real part, v_{bm} the BM velocity, and * the complex conjugate. The value of the electromechanical coupling coefficient ϵ_3 determines the intensity of the active OHC force and we use a frequency independent value.[31]

The conductance of the HB (per unit length), G_{a_j}, is considered to change linearly with the rotation of the HB relative to the RL:

$$G_{a_j}=G_a^0+g_a\theta_{hb_j/rl_j}, \quad (10)$$

where G_a^0 is the conductance (per unit length) at the resting state, g_a represents the angular sensitivity of the mechano-electrical transducer (MET) channel (per unit length) (note that $g_a=G_a^1\times L_{hb}$, where L_{hb} is the length of the hair bundle and G_a^1 is the slope of the change in conductance with respect to the HB deflection, as defined in Ref. 19), and θ_{hb_j/rl_j} is angle of the HB relative to the RL. The data from He *et al.*[32] indicate that the transduction channel angular sensitivity is proportional to the maximum conductance and that the maximum conductance decreases from the base of the cochlea to the apex. The following spatial dependence for the MET angular sensitivity is used:

$$g_a(x)=g_a(0)e^{-\alpha x}, \quad (11)$$

where α is the spatial decay rate of the maximum conductance. $g_a(0)$ is kept as a free parameter and is considered to

be independent of frequency. The nonlinearity of the conductance-deflection relationship is approximately taken into account by using larger values for $g_a(0)$ for acoustic stimulations with low sound pressure level (SPL) stimulations and a value of zero for a passive model, as discussed by Ramamoorthy *et al.*[19] The value needed to simulate (with the model, denoted as TM-LC model, that includes TM longitudinal coupling) the BM gain seen in experiment of Zheng *et al.*[33] at 10 dB SPL is denoted as 100% activity. The values of the OHC and MET channel parameters are listed in Table III.

E. Finite element solution

A full three dimensional box model solution of the cochlear would be computationally expensive. To reduce the size of the problem, modal decomposition is first used in the radial direction (y) as in Ref. 19. Three symmetric mode shapes are used for the pressure in the fluid: $\psi_n(y)=\cos(n\pi(y+w/2)/w)$ $(n=1,3,5)$ for $-w/2\leq y\leq w/2$, where w is the width of the duct. One mode shape is used for the BM transverse displacement. With this modal decomposition the three dimensional model is reduced to a series of two dimensional models which can then be post-processed to synthesize the full result. A Bubnov–Galerkin finite element method[34,35] is then used. The weak form is first derived from the strong form of the equations. In this study, a discretization of 741 nodes in the longitudinal direction (x) and 41 nodes in the z-direction was used (this was determined to be sufficiently converged for our purposes). Linear shape functions are used for the TM shear and bending displacements and for the electrical degrees of freedom. Bilinear shape functions are used for the fluid. Hermite cubic shape functions are used for the BM displacement since the governing equation [Eq. (2)] requires higher order continuity.

III. RESULTS

A. Longitudinal coupling (particularly in the TM) decreases the sharpness of the frequency response

In Fig. 2, frequency domain model predictions of the gain in BM velocity relative to the stapes' velocity at a basal location ($x=0.4$ cm) with and without longitudinal coupling in the TM and/or in the BM are compared. Four active models are used to predict the response of the BM to low level acoustic input. In the first (results shown with a thin solid line), a locally reacting model of the TM and of the BM (denoted as the LR model) is used. By this we mean that there is no longitudinal mechanical coupling in the TM or the BM (as in Ref. 19). In a model such as this, the dominant longitudinal coupling arises from two sources: fluid pressure and electrical conduction in the scalae of the cochlea. The fundamental components of the second model (denoted as the TM-LC model) are identical to the first, except that longitudinal coupling is now included in the representation of the TM according to Eq. (1) (results shown with a thick dashed line). In the third model (denoted as BM-LC model), longitudinal coupling is introduced in the BM according to Eq. (4) (results shown with a thin dashed line). In the fourth model (denoted as TMBM-LC model), longitudinal coupling is included in both the TM and the BM (results shown in thick solid line). In order to achieve the same BM gain at the characteristic frequency (CF) for the four models, the electromechanical coupling factors of the OHC [ϵ_3 in Eq. (8)] for the TM-LC, BM-LC, and TMBM-LC are, respectively, about 69%, 27%, and 79% higher than for the LR model (see Sec. IV). As shown in Fig. 2 and Table IV, the LR predicts a high mechanical quality factor ($Q_{10\ \mathrm{dB}}=15.2$). In the BM-LC model the $Q_{10\ \mathrm{dB}}$ is reduced ($Q_{10\ \mathrm{dB}}=9.2$). The TM-LC model predicts that the $Q_{10\ \mathrm{dB}}$ ($Q_{10\ \mathrm{dB}}=7.0$) is much lower than in the LR model and lower than in the BM-LC model. The $Q_{10\ \mathrm{dB}}$ predicted by the TMBM-LC ($Q_{10\ \mathrm{dB}}=5.7$) is

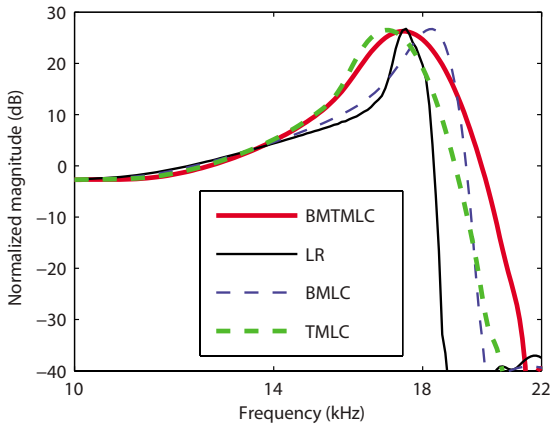

FIG. 2. (Color online) Model predictions for the BM gain in the active case (80% activity). As in Ref. 19, the gain is normalized to the maximum passive model gain. Thin solid line: Active LR model response. Thick dashed line: Active TM-LC model response. Thin dashed line: Active BM-LC model response. Thick solid line: Active TMBM-LC model response. The values for $\epsilon_3(x)$ for the different models are given in Table III. The four models are capable of predicting realistic maximum gains but at these activity levels the $Q_{10\ \mathrm{dB}}$ for the LR and BM-LC models are always much higher than that predicted by the TM-LC and TMBM-LC models.

TABLE IV. Mechanical quality factor ($Q_{10\ dB}$) and CF in the different models and in the experimental data.

Model	$Q_{10\ dB}$	CF
LR	15.2	16.7 Hz
TM-LC	7.0	16.2 kHz
BM-LC	9.2	17.5 kHz
TMBM-LC	5.7	16.6 kHz
Experimental data[a]	6.5	16.5 kHz

[a]Reference 33.

slightly lower than that by the TM-LC model. Longitudinal coupling has a small effect on the CF for a given location. Longitudinal coupling in the TM slightly reduces CF (by about 4%) while longitudinal coupling in the BM slightly increases the CF (by about 5%), as shown in Fig. 2 and in Table IV. For reference, the magnitudes of the BM gain predicted by the four models with no activity $[g_a(0)=0]$ are shown in Fig. 3. The passive response predictions are almost indistinguishable. The passive LR model is slightly more sensitive than the other models (by less than 2 dB).

The prediction for the phase of the BM relative to the stapes in the active models is shown as a function of frequency in Fig. 4. In the LR model (shown with a thin solid line) the phase accumulation at high frequency is about 8 cycles while it is only about 5–6 cycles in the other three models. The absolute value of the slope of the phase in the LR model and of the BM-LC model (shown with a thin dashed line) is higher than in the TM-LC (shown with a thick dashed line) and TMBM-LC (shown with a thick solid line) models. Hence models with longitudinal coupling in the TM have a different behavior than those with no longitudinal coupling or coupling in the BM only.

The predictions of the space constants for BM longitudinal coupling and TM longitudinal coupling [given by Eqs. (3), (5), and (6)] as a function of the frequency (normalized to CF) are shown in Fig. 5. These equations represent the effect of the two structures in isolation from the fluid and

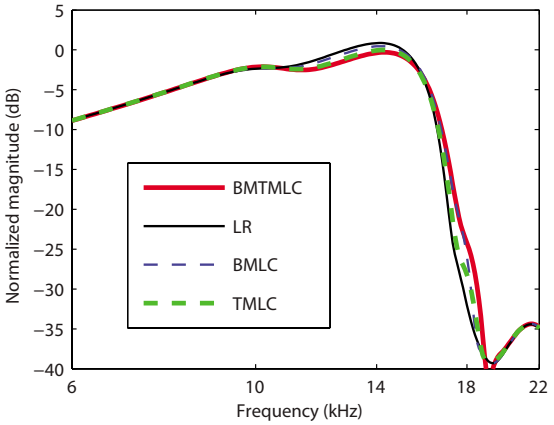

FIG. 3. (Color online) Model predictions for the BM gain in the passive case (0% activity). As in Ref. 19, the gain is normalized to the maximum passive gain. Thin solid line: Passive LR model response. Thick dashed line: Passive TM-LC model response. Thin dashed line: Passive BM-LC model response. Thick solid line: Passive TMBM-LC model response. The effect of longitudinal coupling (in the BM or in the TM) is not significant on the passive BM frequency response.

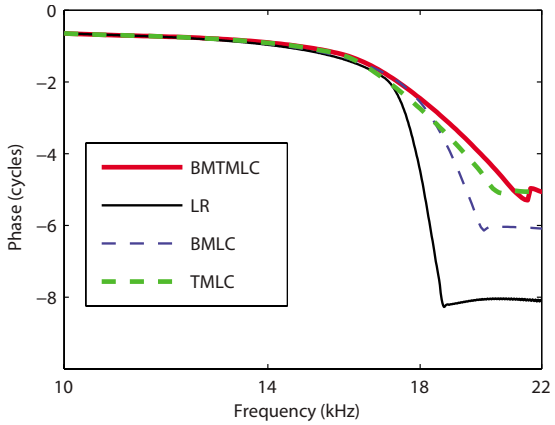

FIG. 4. (Color online) Model predictions for the BM phase relative to the stapes in the active case (80% activity). Thin solid line: Active LR model response. other structures. Even though the two constants are similar at low frequencies, the space constant characteristic of TM longitudinal coupling is more than three times higher close to CF. The TM resonance frequency is close to the CF, whereas the BM resonance frequency is much higher. Hence TM longitudinal coupling couples a higher number of OHC. Longitudinal coupling with a space constant λ can be considered significant over a distance of about 5λ.[36] Hence, at CF the TM longitudinal coupling can couple about 30 rows of OHC and the BM longitudinal coupling can only couple about 10 rows of OHCs. Therefore, as seen in Fig. 2, the presence of TM longitudinal coupling has a more significant impact on the BM response than the presence of BM longitudinal coupling.

Our results (Figs. 2, 4, and 5) show that the dominant source of structural longitudinal coupling in the cochlea is the TM viscoelasticity. Our goal is to develop a mathematical

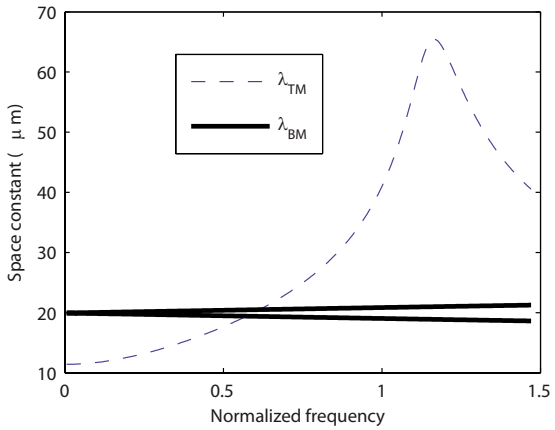

FIG. 5. (Color online) Space constants characteristic of BM longitudinal coupling (λ_{BM}) and TM longitudinal coupling (λ_{TM}) as a function of the frequency (normalized to the CF). For BM longitudinal coupling there are two space constants because Eq. (5) is quadratic in k_{bm} (Ref. 2). At low frequencies the space constants for the BM and the TM are similar (about 20 μm for the BM and 12 μm for the TM). But close to CF, the space constants characteristic of TM longitudinal coupling are more than three times as high as the space constant characteristic of BM longitudinal coupling.

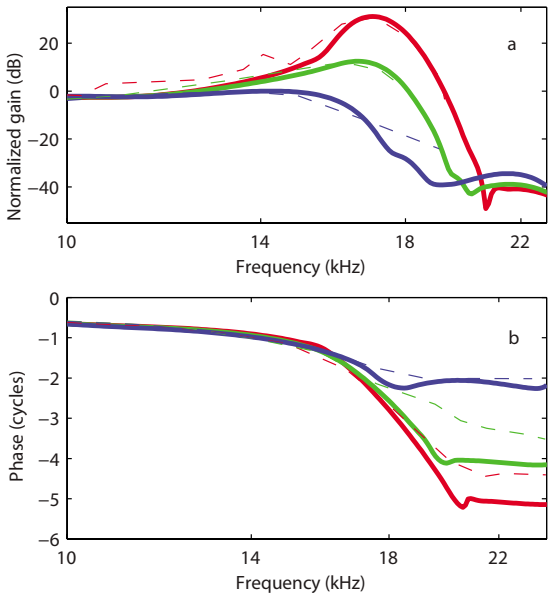

FIG. 6. (Color online) Comparison of the TM-LC model response (G_0 =7 kPa, η=0.05 Pa s) with experimental data from de Boer and Nuttall (Ref. 37). Solid lines: Model BM gain for 86% activity, 56% activity, and 0% activity. Dashed lines: Guinea pig data at 20, 80, and 100 dB. (a) Normalized (to the maximum passive response) BM magnitude in dB. (b) BM phase relative to the stapes in cycles.

model of the cochlea that is as simple as possible but can accurately predict the measurements of the BM response. Hence in the following results only the TM-LC model is used.

In Figs. 6(a) and 7, predictions of the BM gain by the TM-LC model are compared to experimental data for guinea pigs from de Boer and Nuttall[37] and Zheng *et al.*[33] Even though the protocols for these two experiments were different (in Ref. 37 bands of flat-spectrum pseudo-random noise stimulations were used while Zheng *et al.*[33] used pure tone acoustic signals), the same model is able to replicate important characteristics for both experiments. The model is a linear model and the variation from the fully active model to the passive model is achieved by decreasing the MET sensitivity $g_a(0)$ (as discussed in Ref. 19 and in Sec. II). The frequency responses of the basilar membrane track with the experimental data from de Boer and Nuttall at different SPLs [Fig. 6(a)] when the gain of the MET channels is reduced. The TM-LC model predicts around 35 dB gain for low level acoustic stimulation. As seen in experimental results, the shift in the peak frequency between the fully active and passive cases is about half an octave. The BM gain curve becomes sharper as the activity is raised. The mechanical quality factor predicted by the TM-LC model is more consistent with the experimental measurements than the results from the locally reacting model (see Fig. 2). The $Q_{10\ \mathrm{dB}}$ values predicted by the TM-LC model at the highest activity match approximately the experimental values for low SPL stimulation. For instance, $Q_{10\ \mathrm{dB}}$ is 7.7 in the fully active TM-LC model compared to 6.5 in Zheng *et al.*[33] experiment (compare the heavy solid and dashed curves in Fig. 7). The TM-LC model prediction for the BM phase follows closely the data from de Boer and Nuttall [see Fig. 6(b)]. Note that the phase data are not available from Zheng *et al.*[33] The phase accumulation at high frequency is about 5.0 cycles in the active TM-LC model compared to 4.5 cycles in the 20 dB SPL experiment. The phase accumulation at CF is about 2 cycles in both the model and the experiment. The model predictions for the phase slope at CF are slightly higher than in the experimental data.

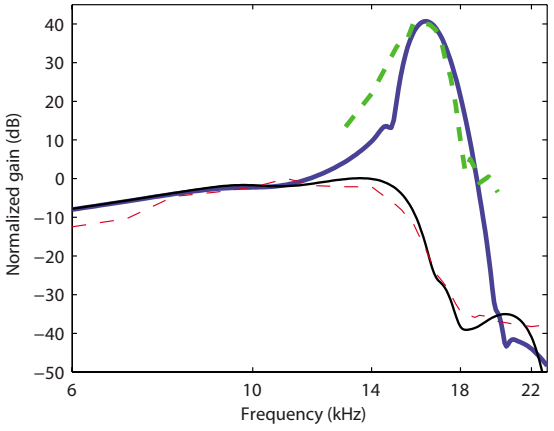

FIG. 7. (Color online) Comparison of the TM-LC model response for the gain (G_0=7 kPa, η=0.07 Pa s) with experimental data from Zheng *et al.* (Ref. 33). Solid lines: Model BM responses for 100% activity (thick line) and 0% activity (thin line). Dashed lines: Experimental data at 10 dB (thick line) and 100 dB SPL (thin line).

By taking the inverse Fourier transform of the frequency response, an impulse response can be derived from the experiments and simulations. Results from the TM-LC theory are compared to measurements from de Boer and Nuttall[37] in Fig. 8. The oscillations of the response continue up to about 1 ms in experimental data [Fig. 8(b)] and 1.4 ms [Fig. 8(a)] for the model simulations in the active case. This is a considerable improvement over the TM-LR theory, which incorrectly predicted a much longer impulse response in the active case, with oscillations that continue up to 3 ms.[19] In the passive case the oscillations are about 0.4–0.5 ms both in the experimental results and the model simulations. Note that for the passive case, the model is relatively insensitive to TM longitudinal coupling as both models match the experimental results quite well for the impulse response. The model also predicts the same zero crossings of the passive and active responses for the first few cycles, consistent with observations from de Boer and Nuttall.[37]

The simulations of the gain at different longitudinal locations of the cochlea follow the expected trend, as shown in Fig. 9. The peak of the BM gain curves shifts to lower frequency as the location approaches the apex, accompanied by a lower gain and $Q_{10\ \mathrm{dB}}$ (see also Ramamoorthy *et al.*[19]).

B. Parameter sensitivity

TM longitudinal coupling is characterized by the shear modulus (G_{xy}) and shear viscosity (η_{xy}) coefficients. Ghaffari *et al.*[20] determined the longitudinal shear modulus (G_{xy}) and shear viscosity (η_{xy}) using a mathematical model of the TM similar to what we propose and their measurements of the shear traveling wave in a mouse TM at acoustic frequencies. The results show that the shear modulus is higher at the

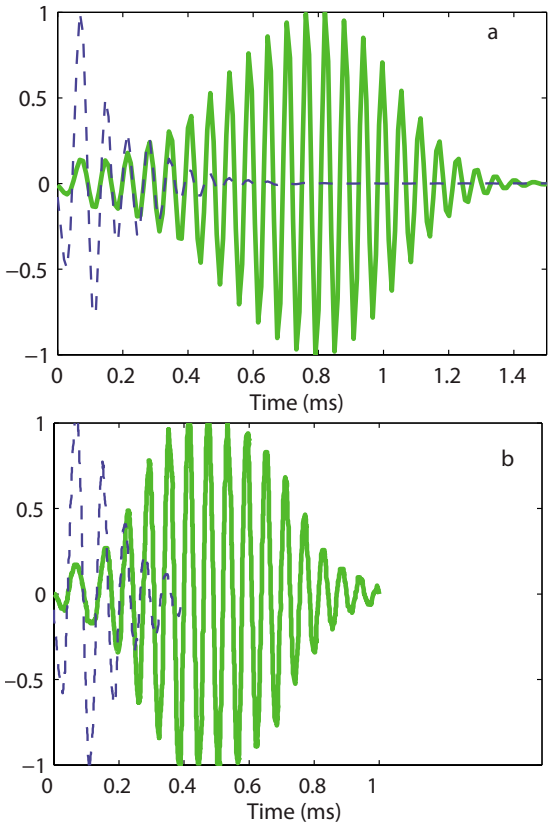

FIG. 8. (Color online) Normalized theoretical and experimental impulse response functions. (a) TM-LC model impulse response. Dashed line: Passive response. Solid line: Active response (86% activity). (b) Normalized experimental BM impulse responses from de Boer and Nuttall (Ref. 37) at 10 dB SPL (solid line) and 100 dB SPL (dashed line).

base than at the apex. Using the TM material property measurements, Gavara and Chadwick[14] estimated the shear wave velocity at a basal and more apical location in the guinea pig. Based on their value for the shear wave velocity, the shear modulus ($G_{xy}=v_s^2\rho$) is 0.67 kPa for a basal location and 0.44 kPa at a more apical location. We use for the shear modulus

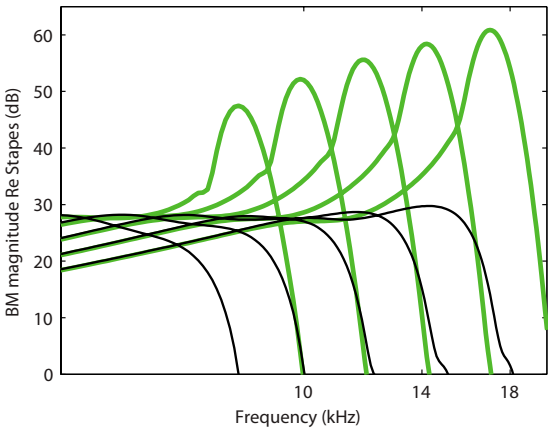

FIG. 9. (Color online) Prediction of the BM response relative to the stapes as a function of frequency in the TM-LC model at different longitudinal locations (x=0.4, 0.5, 0.6, 0.7, and 0.8 cm). The active (81% activity) model responses are shown with a thick solid line. The passive model responses are shown with a thin solid line. As the location approaches the apex, the peak of the BM gain curve shifts to a lower frequency, the magnitude of the BM gain is lower, and the tuning of the response is less sharp.

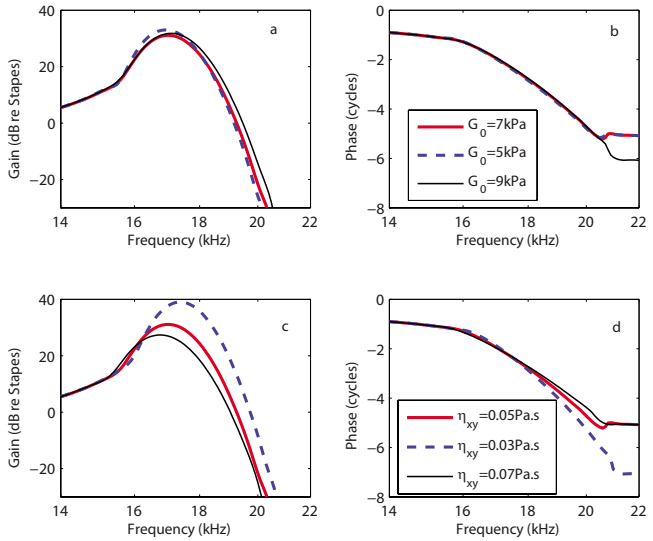

FIG. 10. (Color online) Model sensitivity to TM parameter variations. [(a) and (b)] Effect of changing the shear modulus G on the amplitude (a) and phase (b) of the BM gain relative to the stapes [legend in (b)]. [(c) and (d)] Effect of changing the shear viscosity η on the amplitude (c) and phase (d) of the BM gain relative to the stapes [legend in (d)]. For all simulations the activity is kept constant (86% activity).

the same spatial variation as for the radial stiffness of the TM [$G_{xy}(x)=G_0\exp(\alpha_{tm}x)$]. The values of the shear modulus are of same order of magnitude as the values in Ref. 14. In Ref. 20, the phase angle of the complex shear modulus at the CF of the basal location (about 80 kHz) is approximately 65°. For the guinea pig, at x=0.4 (CF=17 kHz), and if the phase angle at 17 kHz of the shear modulus is the same as in the mouse at 80 kHz, the shear viscosity should be about 0.04 Pa s.

In the theoretical results shown thus far, the shear modulus at the base is G_0=7 kPa and a constant value of 0.05 Pa s is used for the shear viscosity. Varying these parameters affects the predictions of the BM magnitude in response to acoustic stimulations only for frequencies near the CF as the results in Fig. 10 show. Increasing the shear modulus G reduces the gain at the peak location (a few dB) and makes the response less sharp, as seen in Fig. 10(a). Increasing the shear modulus is akin to increasing the longitudinal coupling of the TM; hence this result is consistent with differences seen in the TM-LC and LR models (see Fig. 2). Increasing the shear viscosity η reduces the gain, $Q_{10\ \mathrm{dB}}$, of the BM response and the phase accumulation at frequencies higher than the CF, as shown in Figs. 10(c) and 10(d). The TM shear viscosity plays an important role in modifying the slope of the phase at the CF; increasing the shear viscosity reduces the phase slope. For this range of parameters, the overall qualitative nature of the response predictions is not altered even though some of the quantitative details are affected.

IV. DISCUSSION

A. TM longitudinal coupling is necessary to predict a BM gain curve and impulse response consistent with experimental data

As shown in Figs. 2, 4, 6, and 7, only the TM-LC and the TMBM-LC models reproduce the $Q_{10\ \mathrm{dB}}$ seen in experi-

mental data for a basal location. In the model, the shear resonance of the TM (i.e., the resonance of the TM mass attached to the spiral limbus and to the HBs) occurs at a frequency close to the CF. Hence one can loosely think of the radial resonance of the TM setting the CF for a given location (in the four models). Indeed changing the TM mass directly impacts the CF, but has little effect on the passive response.[19] Somatic motility driven by the MET current is the only electromotile force in the model. For all four models it is possible to choose parameters to replicate the level of gain seen in the experimental results for low level sound [see Ramamoorthy *et al.*[19] and Fig. 6(a)]. But, as seen in Fig. 2, only the TM-LC and BMTM-LC models replicate the $Q_{10\ \mathrm{dB}}$ as well as the duration of the impulse response of the experimental data. Figure 8 shows that the duration of the impulse for the model and experiments is roughly the same. However, there are differences as the predicted maximum amplitude is reached at 0.8 ms while experimentally the peak occurs at 0.5 ms. This may be due to the slight differences in the signal processing, but more likely it is due to some deficiencies in the model (notably the nonlinearity), as minor differences in phase-frequency relations between theory and experiments are also seen. The role of TM longitudinal viscoelastic coupling is partially corroborated by the experimental results of Russell *et al.*[11] where they used a β-tectorin knockout mouse which possesses reduced longitudinal coupling (as measured by Ghaffari[10]) and showed sharper tuning, as we have predicted. Our model shows that the TM properties do not have a significant influence on the shape of the passive frequency response; such a finding is consistent with measurements of the BM response in mutant mice with a detached TM.[38] The BM-LC model predicts a $Q_{10\ \mathrm{dB}}$ that is lower than in the LR model but still much higher than in the experimental data. Since the BM resonance is at a much higher frequency than CF, the effect of longitudinal coupling in the BM equation is not as dramatic on the tuning of the BM response as the effect of longitudinal coupling in the TM. Because of the mechanical connection to the HB and the fact that our model predicts that the shear resonance of the TM corresponds to the CF at the base of the cochlea, the TM appears to be the most important structure determining the broadness of the active frequency response (at a basal location).

B. Longitudinal coupling stabilizes the linearized cochlear model

Introducing longitudinal coupling, particularly in the TM, stabilizes the linear model. For the parameters chosen in this paper, the linearized LR model is at the limit of stability for a 25 dB BM gain, whereas the linearized TM-LC model is well under the stability limit for the BM gains seen experimentally (e.g., 35 dB). The stability limit is found by increasing the MET sensitivity until the impulse response is no longer finite and bounded (i.e., the system is unstable). Numerical experiments (results not shown) indicate that this change in the stability of the system is only due to the addition of longitudinal coupling and not to the modifications of the OHC parameters between the two models. A key finding of this work is that the cochlea is stabilized, in part, by the longitudinal coupling of the TM and that this stabilization allows for the cochlea to achieve higher stable levels of gain than would be possible without the longitudinal coupling. Since we predict that the system is not near a stability limit, this suggests that spontaneous otoacoustic emissions cannot be produced by a local spontaneous oscillation but may only be explained by a global phenomenon such as the coherent wave reflection theory.[39]

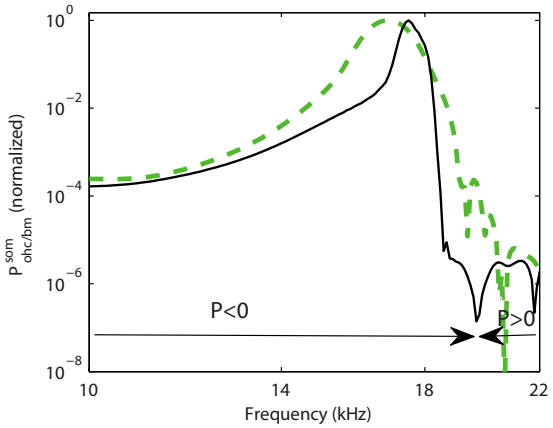

FIG. 11. (Color online) Absolute value of the power of the OHC active (somatic) force on the BM ($P^{som}_{ohc/BM}$) normalized to the value at the CF. Thick dashed line: $P^{som}_{ohc/BM}$ in the TM-LC model. Thin solid line: $P^{som}_{ohc/BM}$ in the LR model. For both models the parameters are the same as in Fig. 2. The sign of the power (P in the figure) is indicated in the figure to show the frequency region where the OHC somatic forces add power to the BM ($P^{som}_{ohc/BM}<0$) and the frequency region where it removes power from the BM ($P^{som}_{ohc/BM}>0$). For both models the OHC somatic force adds power to the BM for frequencies less than the CF and up to about 20 kHz.

When we implement our TM-LC model with a significantly reduced shear modulus and shear viscosity while keeping other parameters constant, the BM gain is higher and the cochlear model is unstable at high activity. If such an instability were present when TM longitudinal coupling is reduced, then we should expect an increase in the gain and the presence of broad band otoacoustic emissions. However, in measurements by Russell *et al.*,[11] the mutant mouse with reduced TM longitudinal coupling (as shown by Ghaffari[10]) has a reduced BM sensitivity compared to the wild-type mouse, and broad band otoacoustic emissions have not been reported. This apparent contradiction between model predictions and experimental results indicates that the mutant mouse cochlea might develop with a reduced MET sensitivity and/or OHC somatic force compared to a wild-type mouse. In order to predict the same gain at the CF, a lower value of the electromechanical coupling coefficient of the OHC [ϵ_3 in Eq. (8)] is used in the LR model than in the TM-LC model. Note that both values of ϵ_3 are realistic, within 50% of the experimental estimate from Iwasa and Adachi.[40]

C. Somatic motility of the OHC can operate at high frequencies and deliver power to the BM

Further processing of the results for the LR and TM-LC models to determine the power delivered to the BM by the OHC (see Sec. II) is shown in Fig. 11 (results shown with thin line and thick line, respectively) for a location near the

17 kHz best place. For both models, the OHCs are predicted to convert electrical to mechanical power and deliver power to the BM for frequencies lower than the CF. In the LR model, the OHCs deliver significant mechanical power to the BM in a narrower range of frequencies near the CF than in the TM-LC model (as normalized by the maximum mechanical power delivered to the system by the OHC). We attribute this to the coupling of multiple OHCs by the structural longitudinal coupling. The TM-LC and LR models predict that somatic motility of the OHC is able to deliver significant power to the BM even in the face of the RC-filtering of a 280 Hz corner frequency of the OHC at this location. The combination of a large electromechanical coupling coefficient, ϵ_3, and HB transduction current (which arises from the shear resonance of the TM at the CF) overcomes the filtering. At 86% level of activity (see Fig. 6), the prediction of the transduction current sensitivity is 2.7 nA per nm of BM deflection. The magnitude of the HB current is 1.35 nA for a 0.5 nm BM displacement (a displacement which corresponds approximately to a 20 dB SPL acoustic stimulation[41,42]). These values are lower than the maximal experimental estimates[32] (see also Ramamoorthy *et al.*[19] for further discussion).

V. Conclusions

This model demonstrates that the TM has a significant influence on cochlear tuning as the tuning of the BM response arises from an electromechanical resonance mode of the OoC controlled mostly by the TM shear mode properties. BM longitudinal coupling has a more limited impact on the BM response. Rather than intrinsically tuned electromotility or mechanotransduction (as suggested by Müller and Gillespie[43]), our results show that the sharp BM frequency response is due to the dynamics of the combined electromechanical system (which does not require the electromotility itself to be tuned). The TM is a crucial structure for active cochlear mechanics because of its connectivity to the HBs. The TM motion relative to the reticular lamina deflects the HBs and opens the transduction channels, which increases the transmembrane potential. This drives OHC somatic motility by converting stored electrical energy from the endocochlear potential to mechanical power delivered to the BM. Hence the presence of the TM and of OHC somatic motility is essential to assure a high BM sensitivity. Our model predictions for the BM frequency response and impulse response show that TM longitudinal coupling is critical for a well-functioning cochlea. The human ear needs to have both a high frequency selectivity and a short impulse response as well as a high sensitivity. This tradeoff between frequency discrimination and transient capture is controlled mostly by the longitudinal viscoelastic properties of the TM. The same longitudinal coupling is responsible for stabilizing the highly sensitive cochlea.

APPENDIX: ESTIMATION OF THE TM STIFFNESS PER UNIT LENGTH, K_{tms}

Richter *et al.*[12] measured the TM radial stiffness in the gerbil hemicochlea using a piezoelectric probe of diameter $d=25$ μm. For static measurements, the governing equation [Eq. (1)] for the TM radial displacement of the TM is given by (neglecting the variations in A_{tm}^{eff} and G_{xy} as a function of x)

$$f_{ext}(x) = K_{tms}u_{tms} - A_{tm}^{eff}G_{xy}\frac{\partial^2 u_{tms}}{\partial x^2}, \tag{A1}$$

where f_{ext} is the force per unit length applied by the probe. The probe deforms the TM with the following mode shape:

$$u_{tms}(x) = U \quad \text{if } |x-x_0| < \frac{d}{2},$$

$$u_{tms}(x) = Ue^{-|x-x_0|/\lambda} \quad \text{if } |x-x_0| > \frac{d}{2}, \tag{A2}$$

where x_0 is the center of application of the probe force, U is the displacement of the TM at the probe tip, and $\lambda_{tm} = \sqrt{A_{tm}^{eff}G_{xy}/K_{tms}}$. Therefore the stiffness measured by the probe is

$$K = \frac{\int_{(x_0-d/2)^-}^{(x_0+d/2)^+} f_{ext}(x)dx}{U} = K_{tms}d\left(1+2\frac{\lambda_{tm}}{d}\right), \tag{A3}$$

with the parameters used in our simulations, at $x=0.4$ cm (which corresponds to the 17 kHz BP in the guinea pig), $K_{tms}=4.2$ kPa, $G_{xy}=2.1$ kPa, $A_{tm}^{eff}=3120$ μm^2 so that $\lambda_{tm}=40$ μm, and $K=4.2K_{tms}d=0.44$ N/m. In the gerbil cochlea, at the 17 kHz BP, Richter *et al.* measured $K=0.255$ N/m (when the TM is detached from the stereocilia).

(Received 28 September 2009; revised 18 December 2009; accepted 19 December 2009)

Distortion product otoacoustic emissions (DPOAEs) originate in cochlear nonlinearity and emerge into the ear canal as an apparent sum of emission types, one of which (generator) travels directly out and the other (reflector) travels out following linear reflection. The present study explores intracochlear sources of DPOAEs via simultaneous ear canal and intracochlear pressure measurements in gerbils. A locally damaged cochlea was produced with reduced local intracochlear nonlinearity and significant elevation of the compound action potential thresholds at frequencies represented within the damaged region. In the DPOAE the comparison of healthy to locally damaged cochleae showed the following: (1) In the broad frequency region corresponding to the locally damaged best frequency, DPOAEs evoked by wider f_2/f_1 stimuli decreased, consistent with the reduction in local nonlinearity. (2) DPOAEs evoked by narrow f_2/f_1 stimuli often had a bimodal change, decreasing in a lower frequency band and increasing in a band just adjacent and higher, and the DPOAE phase-vs-frequency slope steepened. These changes confirm the complex nature of the DPOAE. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3291682]

I. INTRODUCTION

Otoacoustic emissions (OAEs) are one piece of evidence for the cochlea's active nonlinearity (Kemp, 1978) and have been widely used clinically for noninvasive hearing screening (Lonsbury-Martin and Martin, 1990). In a healthy ear with normal hearing thresholds, the cochlea's mechanical response is sharply tuned and compressively nonlinear (reviewed in Robles and Ruggero, 2001; Cooper, 2003). The nonlinearity is produced by outer hair cells (OHCs) (reviewed in Patuzzi, 1986). Cochlear nonlinearity generates frequency components that are not present in the stimulus. For single tones, the response includes harmonics in addition to the fundamental component (Cooper, 1998; Olson, 2004). For two tones, the response includes a family of tones at combination frequencies of the primaries, known as distortion products (DPs) and called distortion product otoacoustic emissions (DPOAEs) when measured in the ear canal. DPOAEs are known to depend on the active process in the cochlea, which is tied to the normal function of OHCs (reviewed in Dallos, 1992), even with high primary intensities (Avan *et al.*, 2003). The $2f_1-f_2$ component is the most commonly studied, is often largest, and is emphasized in this paper. When measured over a range of primary frequencies with constant primary ratio (f_2/f_1) the frequency response of a given component can be explored as a function of frequency. This "DPOAE-gram" has a complex nature, with fine structure in amplitude and a phase whose character depends on the stimulus parameters and on which DPOAE component is plotted (e.g., Mauermann *et al.*, 1999b, 1999a; Shera and Guinan, 1999; Talmadge *et al.*, 1999; Knight and Kemp, 2000). The DPOAE phase-vs-frequency can be either approximately constant or rapidly varying. These amplitude and phase characteristics can be readily explained if the DPOAE is contributed to by more than one source. Kim (1980) suggested that the DPOAE has substantial contributions from two regions, the f_2 place and the f_{dp} place. Kemp (1986) categorized these contributions as "wave-fixed" and "place-fixed" emission types, with the wave-fixed emission having a constant phase and the place-fixed emission having a rapidly varying phase. The two-source model was further developed as a two mechanism concept (Talmadge *et al.*, 1998; Shera and Guinan, 1999): The wave-fixed emission was due to nonlinear generation and the place-fixed emission to linear coherent reflection. In this conceptualization, the source of the wave-fixed or "generator" emission moved along the cochlea with approximately unchanging phase as the primary frequencies were swept at fixed ratio. The generator-type emission arose directly from the source of nonlinearity. It was expected to come from a place where both f_1 and f_2 are relatively large—which, due to the steep apical cut-off of cochlear filtering is in the region of the f_2 place. The "place-fixed" or "reflector" emission was thought to arise via linear reflection from random impedance variations, mainly within the peak of the response at the DP place (Zweig and Shera, 1995). The measured emission is the summation of generator-type and reflection-type emissions. Re-

cent studies have noted a strong correlation between emission type and the primary ratio f_2/f_1. For example, human studies showed that the $2f_1-f_2$ DPOAE phase character changed systematically from rapidly varying (reflector-type emission) with primary ratio less than 1.1, to slowly varying (generator-type emission) at wider primary ratios (Knight and Kemp, 2000; Kalluri and Shera, 2001; Dhar *et al.*, 2005). Several studies have been designed to unmix the two emission types, with results that support the two-source framework. (Stover *et al.*, 1996; Talmadge *et al.*, 1999; Knight and Kemp, 2000; Kalluri and Shera, 2001; Knight and Kemp, 2001; Konrad-Martin *et al.*, 2001; Dhar *et al.*, 2005; Long *et al.*, 2008).

Numerous studies support OHC electromechanics as the fundamental source of the emissions. For example, in cochleae in which inner hair cells were selectively destroyed, the emissions were still strong (Jock *et al.*, 1996; Trautwein *et al.*, 1996). In addition, when OHCs were damaged or the endocochlear potential was reduced, emissions were reduced (Henley *et al.*, 1996; Avan *et al.*, 2003; Mills, 2003). When it comes to studies that probe the cochlear region of emission generation and thus test the emission theory, there is more uncertainty. For example, a study on the relationship between OAEs and OHC loss in damaged cochleae found that the DPOAE was insensitive to fairly extensive OHC loss (e.g., Harding *et al.*, 2002; Harding and Bohne, 2004). Other studies have suggested that the cochlear base contributes substantially to emissions, especially at moderate and high stimulus levels (Martin *et al.*, 1999; Fahey *et al.*, 2000; Martin *et al.*, 2008). The DPOAE is a simple signal emerging from a complicated system, and we still have much to learn about it.

In the present study, we developed a protocol to locally damage the cochlear partition (CP) and observed the resulting changes in DPOAEs and in the local intracochlear pressure responses measured close to the basilar membrane (BM). We made simultaneous measurements of DPOAEs and intracochlear DPs in gerbil using swept two-tone stimulation of fixed primary ratio, with the ratio either narrow (1.05) or relatively wide (1.25). The cochlear condition was evaluated by compound action potential (CAP) thresholds and single-tone intracochlear pressure responses measured at the location of damage. We found the following: (1) Local damage caused a decrease in the degree of locally measured cochlear nonlinearity upon single-tone stimulation and decrease in the intracochlear DPs upon two-tone stimulation. (2) When the primary ratio was narrow, DPOAEs had a bimodal change following damage, decreasing in a frequency band slightly lower than the damaged region and increasing within the damaged region. When the primary ratio was wider, the DPOAEs decreased when f_2 was approximately within the damaged region. (3) In the damaged cochleae the DPOAE phase tended to shift from gradually to steeply sloping in affected frequency regions when the primary ratio was narrow while it did not change substantially with wider ratio primaries. The results indicate that damage can actually lead to an increase in an emission that, based on its phase characteristics, is a reflector-type emission. In contrast, the wider ratio DPOAE, whose phase characteristics are indicative of a generator-type, was always reduced by the local damage.

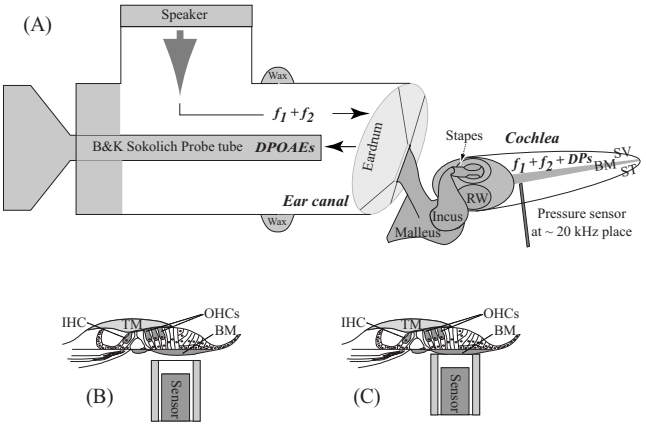

FIG. 1. Simultaneous measurement of DP and DPOAE and locally damaged cochlea. (A) DPAOE was measured in the ear canal pressure responses close to the eardrum with a sensitive microphone with two-tone stimuli to the ear canal in a closed-field sound configuration (sound system coupled to the ear canal opening with bone wax). Simultaneously, the intracochlear DP was measured in ST pressure responses in turn one with a micro-pressure-sensor. (B) Sensor positioned close to the basilar membrane. (C) Sensor indenting the cochlear partition. BM: basilar membrane; IHC: inner hair cells; OHC: outer hair cells; ST: scala tympani; SV: scala vestibuli; TM: tectorial membrane.

II. METHODS

Most of the methods have been described elsewhere (Dong and Olson, 2005b, 2006, 2008). Thus only a brief outline is given here, along with details of specific modifications.

Experiments were performed in deeply anesthetized young adult gerbils. Ketamine (40 mg/kg) was administered first to sedate the animal. Sodium pentobarbital (initial dose 60 mg/kg, supplemental 10 mg/kg) was used throughout the experiment for maintenance of anesthesia and the analgesic buprenorphine (20 mg/kg) was administered every 6 h. At the end of the experiment the animal was sacrificed with sodium pentobarbital. The care and use of the animals were approved by the Institutional Animal Care and Use Committee of Columbia University. During the experiment, animal core temperature was maintained at ~37 °C using a thermostatically controlled heating blanket. A tracheotomy was performed to maintain a patent airway. The left pinna was removed and the bulla was widely open. A small hole was hand drilled in turn one scala tympani (ST) where the best frequency (BF) is ~20 kHz to introduce the micro-pressure-sensor into the cochlea.

Acoustic intracochlear pressure and ear canal (EC) pressure responses were simultaneously recorded [Fig. 1(A)]. A sensitive Bruel & Kjaer probe tube microphone positioned within 3 mm of the tympanic membrane in a closed-field sound configuration served as the EC pressure monitor. The frequency-dependent transfer function of the probe tube microphone was accounted for when setting the sound pressure level (SPL) and analyzing the data. SPLs are reported as dB SPL (decibels relative to 20 μPa peak). Intracochlear pressure responses were measured with the micro-pressure-sensor technique (Olson, 1998). A sensor of ~125 μm outer diameter was introduced via a hand-drilled hole and positioned close to the BM at a distance of ~10 μm using a

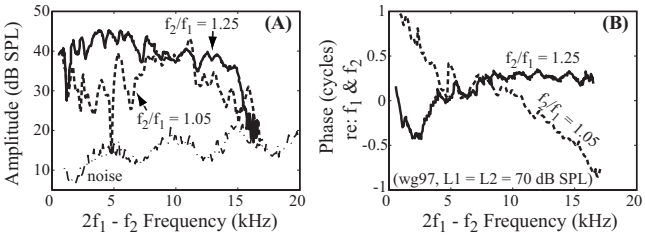

FIG. 2. Gerbil DPOAE includes multiple types. (A) Amplitude and (B) phase of DPOAE obtained from one animal (wg97, $L1=L2=70$ dB SPL, $f_2/f_1=1.05$ and 1.25, frequency step=400 Hz). Phases were normalized to ear canal f_1 and f_2 phases. Dashed and solid lines represent responses with f_2/f_1 of 1.05 and 1.25, respectively. The fine structure in the amplitude and different phase slopes indicate that the DPOAE is a combination of multiple types.

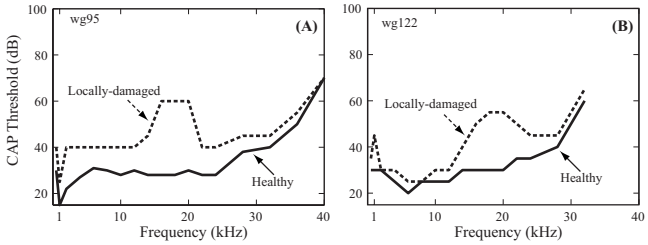

FIG. 3. CAP thresholds before and after local damage. Solid and dashed lines indicate healthy and locally damaged conditions (wg95 and wg122).

motorized micromanipulator that advanced in micrometer steps (Fig. 1). Sensor construction and calibration have been reported previously (e.g., Olson, 1998; Dong and Olson, 2006). In brief, after construction, the sensors were calibrated in water and air (air at room and body temperature) from 200 Hz to 50 kHz. The air calibration is usually similar to the water calibration. The sensitivity is typically flat with frequency to within ~2 dB through 40 kHz and often dropped a few dB between 40 and 50 kHz (Fig. 2 of Olson, 1998). Water calibration was performed before and after experiments. The sensitivity can change due to very small disturbances of the sensitive membrane; this typically produces an uncertainty of ± ~10 dB in the pressure measurements. In the present study the sensor was used to indent the cochlear partition in the turn one location of measurement [see Fig. 1(C)]. Local indentation was done in four animals. In two of these the indentation damaged the sensor's fragile membrane so that it was no longer sensitive, limiting the experiments with complete data sets pre- and post-damage to two (wg95 and wg122). A subset of results from the other two experiments is reported, and results from several other experiments are included to illustrate particular points.

The stimuli consisted of single or two-equal-intensity tones of 1–2 s duration, generated by a Tucker Davis Technology (TDT) system III and delivered via a closed system with a Radio Shack tweeter. With a fixed primary ratio paradigm, the primaries were swept in steps of ~500 Hz with f_2/f_1 fixed at either 1.05 or 1.25 (frequency spacing down to 50 Hz has been used and showed similar phase as that with step of ~500 Hz; thus there is no unwrapping phase error). The sampling frequency of the TDT system was 200 kHz. Stimulus and acquisition programs were written in MATLAB and the TDT visual design studio. Responses were later analyzed by Fourier transform with MATLAB. The phases of the DP or DPOAE are presented referenced to the EC primary phases: $\Phi_{2f1-f2\text{-re-EC}}=\Phi_{2f1-f2}-(2\Phi_{f1}-\Phi_{f2})$, where Φ_{f1} and Φ_{f2} are the phases of EC primaries.

With 1 s data acquisition time, the microphone noise level (with probe tube) was ~5–10 dB SPL up to 30 kHz and higher at higher frequencies. The noise level of the intracochlear pressure measurement is 50–60 dB SPL. System distortion has been discussed previously (Dong and Olson, 2006, 2008). Acoustic two-tone distortion was checked in a small cavity and was ~70 dB below the primary levels when both primaries were 100 dB SPL. System distortion was also checked with postmortem responses after each *in vivo* experiment.

Single- and two-tone responses were collected consecutively with the sensor close to the BM under normal condition [Fig. 1(B)] and locally damaged condition [Fig. 1(C)]. The locally damaged cochlea was produced by indenting the cochlear partition ~10 μm several times with the micropressure-sensor [Fig. 1(C))]. The physiological condition of the cochlea was monitored using CAP threshold responses (threshold criterion ~5 μV p-p) to tone pips, measured with a silver electrode on the bone surrounding the round window (RW) opening. The CAP thresholds were measured a few times during the experiments, especially before and after introducing the sensor into the ST and after damaging the CP. Damage was confirmed by an elevation in CAP thresholds. We have shown that the mere presence of the sensor close to the BM has minimal effect on CAP thresholds and DPOAEs (Dong and Olson, 2008).

III. RESULTS

A. Basic characteristics of DPOAE—Evidence for multiple types

Typical $2f_1-f_2$ DPOAE data from an intact gerbil cochlea are shown in Fig. 2. The primary levels were $L_1=L_2=70$ dB SPL, and the primary ratio (f_2/f_1) was fixed at either 1.05 (dashed line) or 1.25 (solid line). DPOAEs are robust in gerbils, and their levels could exceed 40 dB SPL at both ratios (Mills, 2002). Above 15 kHz, the DPOAEs diminished, sometimes slightly and other times more acutely; this cut-off frequency varied across animals, similar to the observed variation in CAP threshold at frequencies above 20 kHz. Deep notches in the amplitude are suggestive of cancellation, and the amplitude fine structure is one of the observations leading to a two-source emission framework. The phase was quite flat for the wider ratio DPOAE (1.25) consistent with past observations (Dong and Olson, 2008), while the narrow ratio DPOAE (1.05) had a more rapidly varying phase. These characteristics are consistent with DPOAE observations in the literature discussed in the Introduction.

B. Changes post-damage

The impact of the local damage was assessed using CAP threshold responses to tone pips (Fig. 3) and single-tone in-

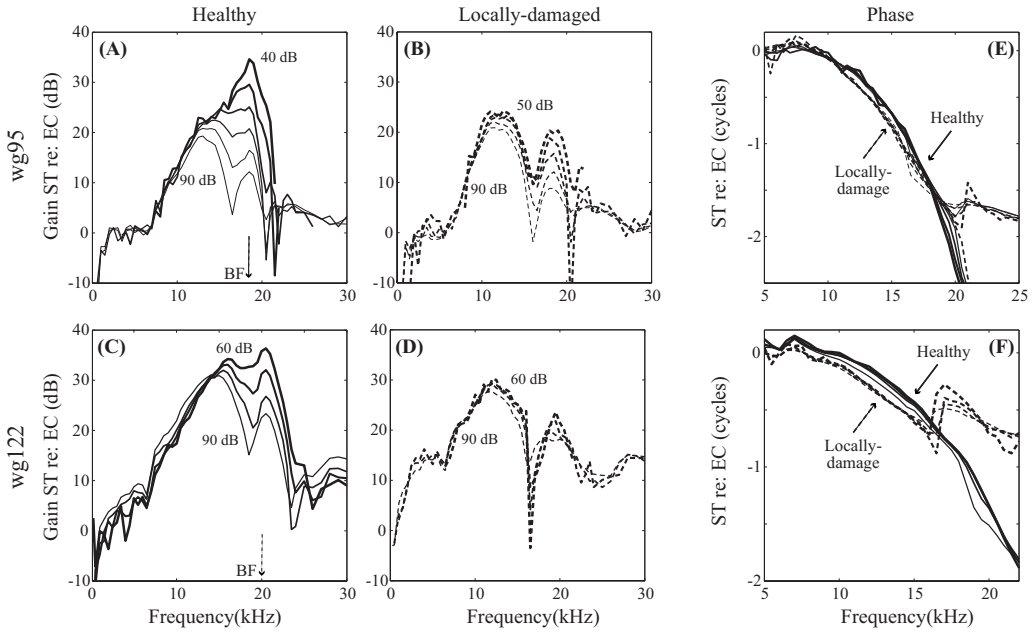

FIG. 4. Cochlear mechanics before and after local damage. Single-tone intracochlear pressure responses measured at the same location, close to the BM (~10 μm) pre- and post-damage in two animals (wg95 and wg122). [(A) and (C)] Pre-damage gain relative to stimulus pressure in the ear canal; [(B) and (D)] Post-damage gain. Stimulus SPLs are labeled. [(E) and (F)] Single-tone pressure phase referenced to EC. Solid and dashed lines represent the cochlear conditions, healthy or locally damaged, respectively.

tracochlear pressure responses measured close to the BM (Fig. 4).

1. CAP thresholds after local damage

CAP thresholds from 0.5 to 40 kHz under healthy (pre-damaged) and locally damaged (post-damage) conditions in two animals are illustrated in Fig. 3. The CAP thresholds in the healthy condition were ~30 dB SPL at frequencies below 20 kHz, and higher at higher frequencies (solid line in Fig. 3). Making the ST hole and introducing the sensor to a position close to the BM changed the CAP thresholds very little (e.g., Fig. 4 in Dong and Olson, 2008). After using the sensor to indent the cochlear partition as illustrated in Fig. 1(C), the CAP thresholds were elevated up to 20–30 dB at frequencies around 20 kHz, the BF place of the sensor, and ~10 dB or less at lower and higher frequencies (dashed line in Fig. 3). The range of substantial (>10 dB) threshold elevation is between ~12 and 24 kHz in both preparations. Thus, indenting the cochlear partition from the BM side produced a pronounced elevation in CAP threshold in the ~20 kHz BF region where the probe was positioned, leading to a locally damaged condition.

2. Single-tone responses in locally damaged cochleae

Pre- and post-damage intracochlear pressure responses to single tones can be seen in Fig. 4. The sensor was positioned close to the BM in turn one of the gerbil cochlea, where the BF is ~20 kHz. As shown in the normalized results of Figs. 4(A) and 4(C), the responses were compressively nonlinear at frequencies around the BF (19 and 20 kHz, respectively) in the healthy condition. At frequencies more than approximately a half octave (factor of 0.7) below the BF the pressure responses overlaid each other, indicating linear scaling for these frequencies. Above that frequency there is a dramatic fanning out of the normalized responses in the peak region. In the plateau region above the peak, responses typically scale linearly as in Fig. 4(A). After indenting the cochlear partition with the sensor ~10 μm, the degree of nonlinearity in single-tone responses was diminished [Figs. 4(B) and 4(D)]. On the other hand, the responses at frequencies well below and well above the BF changed little. Therefore, the local damage to the cochlear partition led to a decrease in the degree of nonlinearity at frequencies around the BF, with little change in the responses at frequencies above and below.

The phase responses in Figs. 4(E) and 4(F) (ST pressure re: EC pressure) show traveling wave delay through ~2 cycles. Post-damage, two changes occur. The high frequency phase plateau is encountered at lower frequencies, signifying that the fast, compression wave dominates the traveling wave at lower frequencies, which is to be expected since the nonlinear traveling wave response mode is diminished by the damage, but the linear fast response mode is not. (See our previous papers, Olson, 1999, 2001and Dong and Olson, 2005b for background on the multi-mode nature of intracochlear pressure.) A second change is that within the traveling wave region the phase accumulates more rapidly in the damaged preparation. This is consistent with reduced CP stiffness (Kolston, 2000). Thus the local damage has reduced the local cochlear nonlinearity, and also seems to have produced a reduction in the local stiffness of the CP.

3. Intracochlear DP and DPOAE of $2f_1 - f_2$

Simultaneous measurements of DP and DPOAE were obtained under normal and locally damaged conditions with f_2/f_1 fixed at 1.25 (Fig. 5) and 1.05 (Fig. 6). The micro-pressure-sensor was positioned ~10 μm from the BM. The

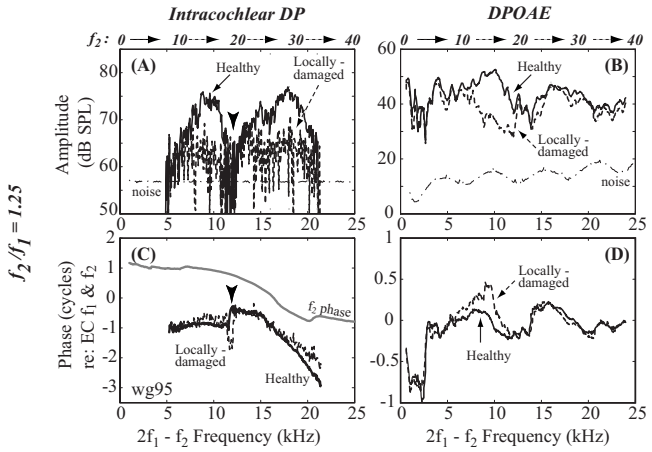

FIG. 5. $2f_1-f_2$ with $f_2/f_1=1.25$ in the cochlea (DP) and ear canal (DPOAE) pre- and post-damage. (A) DP amplitude, measured at a distance ~10 μm from the BM; (B) DPOAE amplitude; (C) DP phase; and (D) DPOAE phase. All phases are referenced to EC f_1 and f_2 phases. Solid and dashed lines represent cochlear condition, healthy or locally damaged. Gray line in panel (C) shows f_2 phase. There was no change in the low frequency region below 6 kHz (wg95, $L_1=L_2=80$ dB SPL).

response amplitudes and phases are plotted vs their own frequencies. Phases are referenced to EC f_1 and f_2 phases.

When f_2/f_1 was fixed at 1.25, DP in the healthy cochlea showed fine structure superposed on double peaks separated by a deep notch [solid line in Fig. 5(A)]. One peak reached its maximum at ~19 kHz BF and the other at ~9 kHz. The phase [solid line in Fig. 5(C)] changed character at the notch frequency [arrowhead in Fig. 5(C)]. At frequencies around the BF the DP phase was similar to that of f_2 [gray line in Fig. 5(C)], suggesting that the DP in this region was dominated by forward going distortion originating from more basal locations (Ren, 2004; Dong and Olson, 2005b; de Boer *et al.*, 2008; Dong and Olson, 2008). In the frequency region well below the BF, the DP phase departed from the f_2 phase and was more similar to the DPOAE phase [solid in Fig. 5(D)], suggesting that the DP was a combination of locally generated distortion, and apically generated distortion that was recorded on its way out of the cochlea (Dong and Olson, 2008). The f_2 frequencies are indicated above the panels, and when combined with the results in Fig. 4, help to guide expectations on whether local nonlinearity probably contributed to those DPs, or whether they were probably produced remotely. Examination of Fig. 4(A) reveals that ~12 kHz is the lowest frequency with substantial nonlinearity in single-tone responses. A 12 kHz f_2 corresponds to a 7–8 kHz $2f_1-f_2$ DP. Thus, the lower peak in Fig. 5(A), which extends from 5 to 12 kHz, is probably a combination of both apically and locally generated nonlinear distortions. The pronounced notch in the amplitude at ~12 kHz corresponded to a 180° phase shift [arrowheads in Figs. 5(A) and 5(C)], and appeared to result from cancellation of anti-phase components, probably a combination of basally generated/forward traveling, apically generated/backward traveling, and locally generated components. This notch was not seen in the DPOAE [see Figs. 5(B) and 5(D)], which reinforces that the locally measured DP has a different composition than the DPOAE. Post-damage, the amplitude of the DP decreased in both peaks. The lower frequency peak was greatly diminished above 7 kHz, but below 6 kHz the DP was little affected by the damage, consistent with the DP at these frequencies arising from more apical, undamaged regions. The phase changed relatively little [dashed lines in Fig. 5(C)] and still underwent a change in character at the notch frequency, which shifted up slightly in frequency.

In the healthy condition, the DPOAE was ~40 dB SPL up to 24 kHz with fine structure in amplitude [solid line in Fig. 5(B)] and phase varying little and nonmonotonically with frequency [solid line in Fig. 5(D)]. After the cochlea was locally damaged the DPOAE changed. In the frequency region from ~7 to 12 kHz, the DPOAE decreased, similar to the DP in that region [dashed line in Fig. 5(B)]. The small change in phase was similar in the DP and DPOAE. However, for DPOAEs with frequencies within the damaged region, the pre- and post-damage DPOAEs were similar, both in amplitude and phase. It appeared that the decrease in DP had little effect on the DPOAE in this frequency region, indicating that the DPOAE did not arise from its own best place. The relationship between local damage (as indicated in CAP changes) and DPOAE changes will be summarized in Fig. 8.

When the primary ratio was 1.05, the changes in the locally damaged condition were different (Fig. 6). The pre-damage DP amplitude had similar tuning as the single-tone response (Fig. 4), but with more fine structure [solid line in Fig. 6(A)]. At 12 kHz, there was a shallow notch in the amplitude corresponding to an inflection in the phase slope [arrowheads in Figs. 6(A) and 6(C)]. At frequencies above 12 kHz, the DP peaked at the BF (19 kHz) and its phase was similar to that of f_2 [gray line in Fig. 6(C)]. The DP tuning and its phase-vs-frequency slope at frequencies around the BF suggested that the DP was largely locally generated or basally generated/forward going. At frequencies below 12 kHz, the well-sub-BF region, the phase differed from that of the forward f_2 phase, which suggested that in this region the DP was not locally generated/forward traveling and likely originated from a more apical place (Dong and Olson, 2008). After locally damaging the cochlea, the DP in the sub-BF region decreased around 10 kHz, and the phase steepened markedly [dashed line in Fig. 6(C)]. The steepened phase

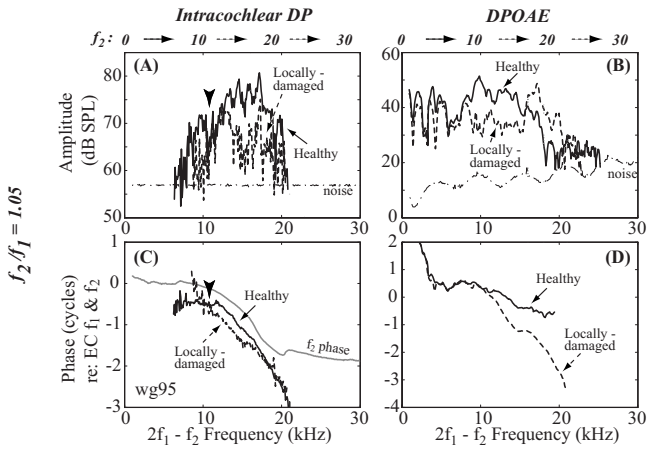

FIG. 6. $2f_1-f_2$ with $f_2/f_1=1.05$ in the cochlea (DP) and ear canal (DPOAE) pre- and post-damage. Same format as Fig. 5 (wg95, $L_1=L_2=80$ dB SPL).

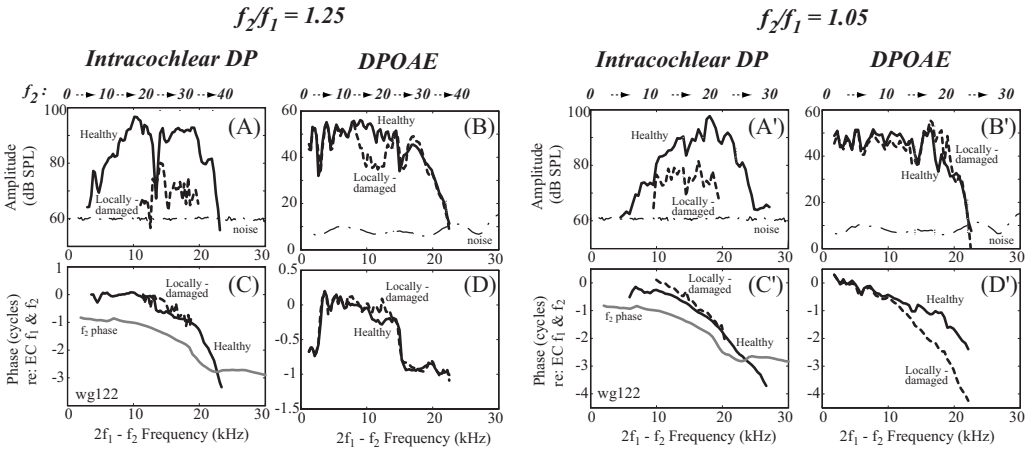

FIG. 7. $2f_1-f_2$ DP and DPOAE of animal wg122. DP was measured at ~10 μm from the BM pre- and post-damage ($L_1=L_2=80$ dB SPL, f_2 frequency step was 0.5 kHz). Same format as Fig. 5.

may indicate that the locally generated/forward going type of the DP was diminished relative to the component that was traveling out of the cochlea from more apical regions. At frequencies above 12 kHz the amplitude of the DP decreased and its phase changed slightly, but maintained its forward going character.

Pre- and post-damage DPOAEs are shown in Figs. 6(B) and 6(D). Pre-damage the DPOAE was at a level of ~40 dB SPL, with fine structure and a sharp decrease for frequencies above ~18 kHz. The phase had a fairly shallow slope, accumulating about 1 cycle over 20 kHz. There was a stair-step pattern superimposed on the shallow slope (see Talmadge *et al.*, 1999), suggesting that the emission had contributions from components with both rapidly varying and slowly varying phase-vs-frequency slopes. Following damage, at frequencies from ~9 to 17 kHz (just below the damaged region) the DPOAE amplitude decreased ~10 dB and the phase steepened substantially. At frequencies in the damaged region (~17–20 kHz) the DPOAE amplitude *increased* and the phase steepened.

The variations in DP and DPOAE after local damage were confirmed by results in a second animal (wg122) shown in Fig. 7. When the wider ratio was examined the changes are very similar to those in Fig. 5. With the narrow ratio, the DPOAE changes are more subtle, but qualitatively similar to Fig. 6.

To summarize the findings, local damage reduced cochlear nonlinearity both in single-tone responses and in the locally measured DP. With primary ratio of 1.25, the DPOAE at frequencies slightly lower than the BFs of the damaged region decreased and changed little for frequencies close to the BFs of the damaged region, with little variation in phase. With relatively narrow primary ratio (1.05), the DPOAE decreased at frequencies slightly lower than the BFs of the damaged region, and increased at frequencies close to the BFs of the damaged region. The phase changed from slowly varying to rapidly varying with frequency.

4. Correlation between DPOAE and cochlear condition

A full understanding of the changes seen benefits from a direct comparison of changes in both CAP thresholds and DPOAE amplitudes. Using the results from the two animals that were shown in Figs. 3 and 5–7, the level shifts of CAP threshold (pre-damage—post-damage) and DPOAE (post-damage—pre-damage) upon local damage are plotted together in Figs. 8(A), 8(B), 8(E), and 8(F). The DPOAE variations upon damage from two additional local damage experiments are plotted in the other four panels. The sensor was broken and CAP data were not gathered post-damage in these animals but in all cases the sensor, which was used to

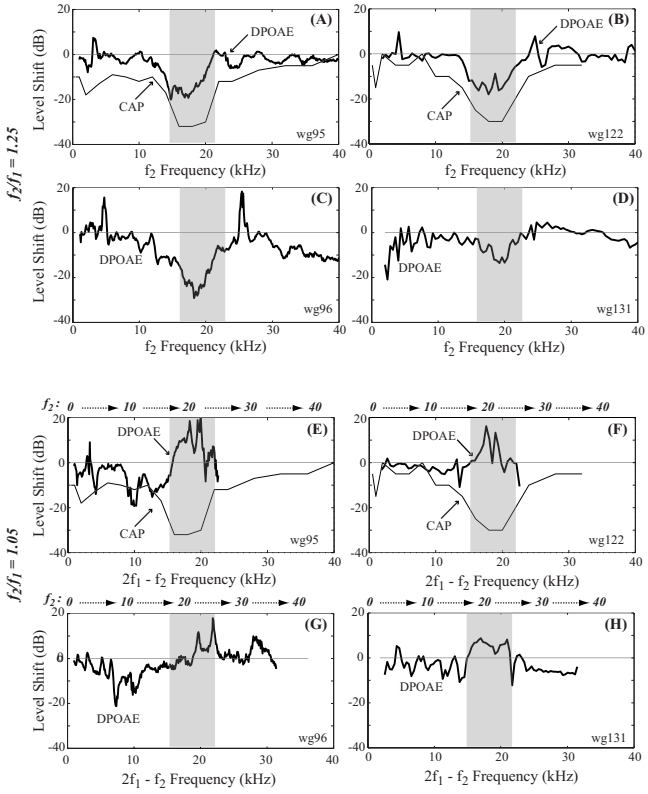

FIG. 8. CAP threshold shifts and changes in $2f_1-f_2$ DPOAE level upon local damage. Thick and thin lines show changes in DPOAE and CAP thresholds upon damage. [(A)–(D)] $f_2/f_1=1.25$, plotted vs f_2; [(E)–(H)] $f_2/f_1=1.05$ plotted vs $2f_1-f_2$ frequency. Data were from locally damaged experiments wg95, wg96, wg122, and wg131. Gray bands show the damaged region based on the sensor location (~20 kHz region) and verified with CAP changes in animals wg95 and wg122.

cause damage, was positioned at the region with ~20 kHz BF, indicated by gray bands. The DPOAE results are supportive of the results of the two main animals. The level shifts are plotted vs f_2 when the primary ratio was 1.25, and vs $2f_1-f_2$ when the primary ratio was 1.05, because these respective correlations were more instructive. (The f_2 frequency is included at the top of each panel for reference.)

When the primary ratio was 1.25 [Figs. 8(A)–8(D)], the reduction in DPOAE lined up with the damaged region (~12–24 kHz according to CAP changes) with the maximum increase in CAP thresholds. Thus, when the f_2 region was damaged, the DPOAE was reduced. With narrower primary ratio of 1.05, DPOAE *enhancement* lined up with the damaged area indicated by the CAP threshold shift [Figs. 8(E) and 8(F)]. A reduction in DPOAE level occurred at slightly lower frequencies.

IV. DISCUSSION

The present study used localized intracochlear damage, localized measurements of intracochlear responses, and emission and CAP measures to explore the two-source model and more general questions of where emissions come from in the cochlea. The present study advances these questions with a well controlled damage location, and by probing the changes in intracochlear mechanics precisely at that location, while correlating the intracochlear measurements with DPOAE and CAP.

Our research used relatively high sound pressure levels. There is strong evidence for the two-source model at low sound pressure levels, where cochlear excitation patterns are expected to be fairly well localized (Mauermann *et al.*, 1999b, 1999a; Kalluri and Shera, 2001). At moderate to high sound pressure levels the cochlear regions responsible for the emission appear to broaden due to the broadening of cochlear tuning with level (e.g., Knight and Kemp, 2001; Zhang and Mountain, 2008; Martin *et al.*, 2008). In studies in humans, at moderate to high sound levels, an emission with rapidly varying phase was observed (Martin *et al.*, 2008). Based on this phase character, the two-source model would categorize the emission as a reflector-type, and predict that it arose from reflection from around the f_{dp} place. However, the suppression behavior of the emission indicated that it arose from basal to the f_2 region. This suggests that the two-source model should be used with caution at moderate-high levels. The present study advances the understanding of DPOAE sources at relatively high primary levels, probing the limitations of the two-source model, and hopefully facilitating the use of high levels in the clinic, where high levels are often required to elicit emissions in impaired ears.

Previous studies have demonstrated the qualitative differences between emissions produced with narrow and relatively wide ratios, with narrow ratios giving rise to emissions with rapid phase variations, thought to be reflector-type emissions, and ratios above ~1.2 giving rise to emissions possessing slow phase variations, thought to be generator-type emissions (Knight and Kemp, 2000; Kalluri and Shera, 2001; Knight and Kemp, 2001; Dhar *et al.*, 2005). This dependence of emission type on ratio is expected when the phase interferences of the spatially disparate sources are taken into account (de Boer *et al.*, 2005; Shera and Guinan, 2007a, 2007b). Our own previous work also showed this dichotomy, with the wider primary ratio giving rise to a generator-type emission, and the narrow primary ratio giving rise to a mixture of emission types (Dong and Olson, 2008). The present study supports the dichotomy.

A. Relationship between DPs and DPOAEs, regions that source the DPOAEs

The relationship between the intracochlear DP at one site in the cochlea, and the DPOAE was explored in a previous publication from our laboratory (Dong and Olson, 2008). A short review follows. After generation, a DP is subject to cochlear filtering and the measured DP frequency response is determined by both the tuning of the primaries and the subsequent tuning of the DP (Dong and Olson, 2005b, 2005a). As illustrated in Fig. 5 (wider primary ratio) and Fig. 6 (narrow primary ratio), *at frequencies* approximately the BF, DP amplitude tuning and phase are similar to those of the primaries (Cooper and Rhode, 1997; Robles *et al.*, 1997; Dong and Olson, 2005b, 2005a, 2008). The DP appears to be dominated by local generation and/or forward traveling, basally generated distortion [Figs. 5(C), 6(C), 7(C), and 7(C′)]. *At frequencies well below* the BF, DP behavior is less primary-like. The DP normally shows more fine structure, similar to that in the DPOAE, and its phase departs from that of the primaries and is more like that of the DPOAE (e.g., Fig. 9 in Dong and Olson, 2008 and Fig. 8 in Rhode, 2007). Thus, at low frequencies, the DP appears to have a substantial contribution from apically generated distortion [Figs. 5(C) and 6(C)], traveling out of the cochlea. These basic observations underscore the fact that, except at primary frequencies substantially lower than the local BF, the *local* DP appears to be mainly locally generated or forward traveling and thus is not tightly linked to the DPOAE.

The results after local damage in the present paper are consistent with this picture. We have noted that at the wider primary ratio (1.25), the $2f_1-f_2$ emission appears to be dominated by the generator-type, and consider this case first. When the intracochlear probe and damage location (~20 kHz place) was at the f_2 place or somewhat basal to the f_2 place (for example, f_2 from 12 to 20 kHz in Fig. 5) both the DP and the DPOAE were reduced (Figs. 5 and 7). When f_2 was less than 12 kHz (a situation with excitation patterns that peak substantially apically of the damage location) the emission was not affected. From this result it is clear that the emission source is localized to a region that includes the f_2 place and extends somewhat basal (almost an octave). When the damaged location was somewhat apical to the f_2 place, the intracochlear DP could be much reduced with little or no change in the DPOAE (Fig. 5, and Fig. 7 unprimed panels). Thus, regions apical to the f_2 place appear to be not at all responsible for the generator-type emissions. This result makes sense, given the sharp apical drop off of the f_2 response beyond its best place. Thus, these damage studies show that substantial DPs exist within the cochlea

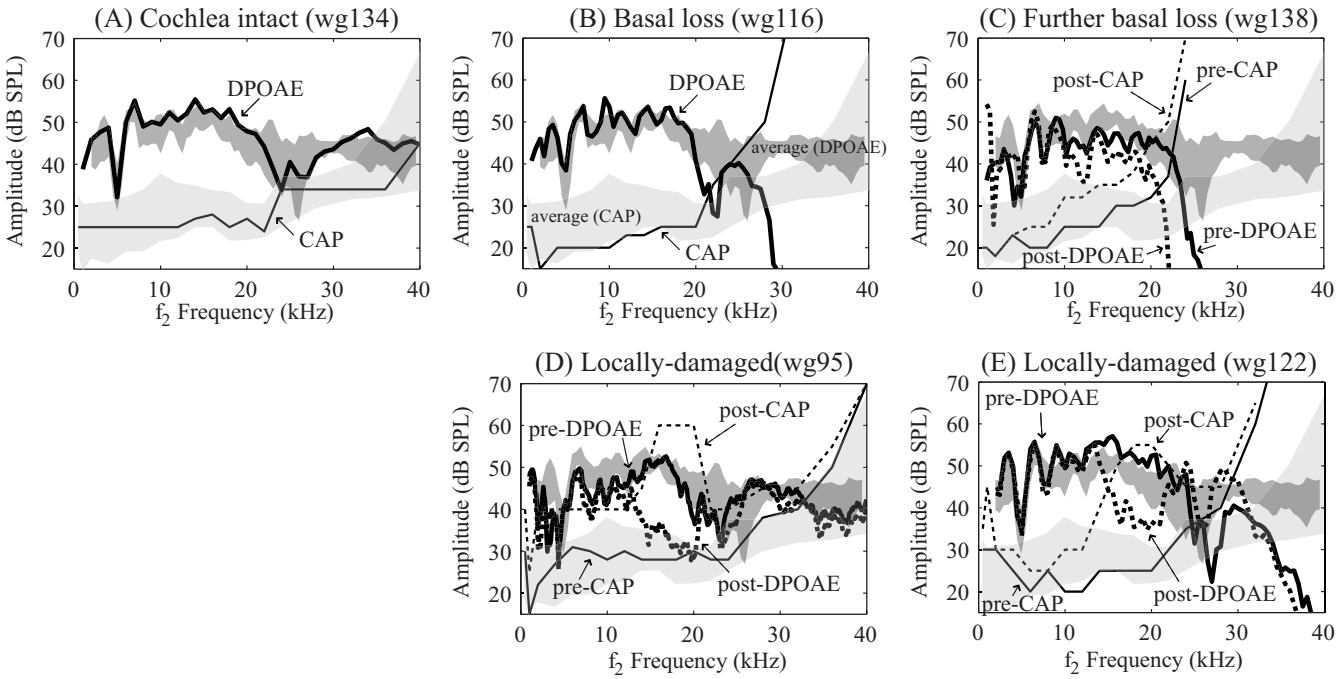

FIG. 9. Using DPOAE to gauge the cochlear condition (five animals). The darker gray bands display average DPOAE and the lighter gray bands the average CAP thresholds across eight animals with normal CAP thresholds. The width of the bands indicates the standard deviation. The lines show DPOAE and CAP results from individual animals. The thicker lines show DPOAE levels, with the solid line pre-damage and the dotted line post-damage. The thinner lines show the corresponding CAP thresholds curves, solid pre-damage, and dotted post-damage. The DPOAE shown is at frequency $2f_1-f_2$ with $L_1=L_2=80$ dB, $f_2/f_1=1.25$.

that are not detected in the emission—most certainly because they are traveling forward to be absorbed and not outward to become an emission.

With narrow primary ratio the mixture of emission types in the DPOAE is pronounced. In this case the DPOAE increased at frequencies in the damaged region, and decreased at frequencies slightly lower. Increases in DPOAEs after sound-induced cochlear lesions near the base have been reported previously (Kakigi *et al.*, 1998b, 1998a). Based on the steepened phase post-damage, the changes (Figs. 6 and 7 primed) are interpretable as a relative increase in reflector-type emission and decrease in generator-type emission. With narrow ratio primaries the physical sites of generation and reflection emissions are not well separated, and the sizes of generator- and reflector-type of emissions in the healthy cochlea appear to be similar. The damaged region appears to cause a pronounced reflection. In the case of wider primary ratio of 1.25, there is no evidence for enhanced reflection—the emission goes down, and based on its phase, remains dominantly a generator-type emission.

B. Cochlear damage changed the relative contribution from different emission types

1. Relatively wide f_2/f_1 ratio emissions can be used to gauge cochlear condition

The flat phase-vs-frequency response of the DPOAE observed when the primary ratio is fixed is the signature of a generator-type emission (Shera and Guinan, 1999). This occurs due to approximate "scaling symmetry," which refers to the way the response pattern (amplitude and phase) shifts along the cochlea but does not change shape when primary frequencies are swept at constant ratio. The generator phase is therefore constant, giving rise to a flat phase-vs-frequency response in the emission. Consistent with the findings of others, we found that the generator-type emission dominated the DPOAE at the wider primary ratio in gerbils. We also found that when the region corresponding to f_2 and basal—the putative generator region—was damaged, the DPOAE was reduced. This is illustrated in Fig. 9, which shows the covariance of the DPOAEs and CAP thresholds. The averaged DPOAE ± standard deviation from eight healthy ears is shown as the dark-gray band in each panel (stimulus level $L_1=L_2=80$ dB SPL, $f_2/f_1=1.25$). Cochlear health was determined with CAP: When the cochlear condition was good, CAP thresholds were less than 40 dB up to 35 kHz. The CAP ± standard deviation of these animals is shown in the light gray band. In Fig. 9(A) results from a healthy cochlea are shown, with CAP the thin line and DPOAE the thick line. The DPOAEs were around 40 dB and could be recorded up to 40 kHz, and were similar to the averaged DPOAEs from healthy ears. Some animals had high frequency hearing loss at the start of measurement, caused by inadvertent surgical trauma or cooling upon opening the bulla, without or prior to purposeful local damage [Figs. 9(B), 9(C), and 9(E)]. In these cases the DPOAE dropped off sharply above 25–30 kHz, and CAP thresholds increased sharply at these frequencies. Figure 9(C) documents increasing damage through two stages, indicated with solid and dotted lines (thick for DPOAE and thin for CAP). Figures 9(D) and 9(E) repeat the information in Fig. 8 showing the close correspondence between CAP threshold elevation and DPOAE decrease following local damage. These results indicate that the DPOAE with wider primary ratio can be used to gauge the cochlear

condition in the f_2 region. Looking at the DPOAE data from the panels in Fig. 9 with a "clinical" eye, it would be easy to pick out a cochlea with broad basal damage of unknown etiology [Figs. 9(B), 9(C), and 9(E)] compared to the healthy/normal DPOAE in the "healthy" ears in the dark-gray band. On the other hand, the bounded dips in DPOAE in Figs. 9(D) and 9(E) would be easy to pick out only if the pre-damage DPOAE data were also available from the same individuals. If only the post-damage data were available the dips observed would point to a region of possible cochlear damage to be followed up with further testing.

2. Changes in emission and intracochlear phase confirm changes in the dominance of the two emission types with narrow ratio

Steep phase-vs-frequency in the DPOAE at fixed f_2/f_1 is the signature of dominance by reflector-type emissions (Stover *et al.*, 1996; Shera and Guinan, 1999). In the two-source theory, this emission type arises due to linear coherent reflection from random perturbations along the cochlear partition (Zweig and Shera, 1995). The largest reflection is expected to be from the region where the traveling wave peaks, where the phase changes rapidly with frequency. On average, the phase-vs-frequency slope of the emission is predicted to be slightly less than twice the slope of the forward wave, due to the round trip travel in and out of the cochlea (Shera *et al.*, 2008). With narrow primary ratios, the DPOAE phase at low SPL normally varies rapidly with frequency in humans (Knight and Kemp, 2000, 2001) and other mammals (e.g., Withnell *et al.*, 2003) [and even non-mammals, but this is not the focus of the present paper (e.g., Meenderink *et al.*, 2005)]. Often the emission type at narrow primary ratio appears mixed, with a shallow slope with superimposed variations. Many studies have been devoted to unmixing these components (e.g., Kalluri and Shera, 2001). By locally indenting the cochlear partition using our micro-pressure-sensor, the local cochlear nonlinearity was reduced, and stiffness perhaps reduced as noted above. The induced changes in cochlear mechanics led to the apparent decrease in the generator-type emission at frequencies somewhat less than the BF of the damaged region and relative increase in the reflector-type at frequencies in the vicinity of the damaged location's BF [Figs. 6(B), 6(D), and 7(B′) and 7(D′)]. Thus, in the BF frequency region, post-damage the phase was steep and the reflector-type emission appeared to be dominant. We evaluate this damage-induced phase change in Fig. 10, which shows a group of DPOAE phase results under pre- (solid lines) and post-damage conditions (dotted lines). Results from six animals are shown. A representative curve showing twice the forward traveling wave phase at the 20 kHz BF from one animal is also shown (gray line). The emission phase post-damage is quite similar to twice the forward traveling wave phase, confirming the notion that the rapidly varying emission phase is representative of the traveling wave in the cochlea, and can be used to estimate traveling wave delays.

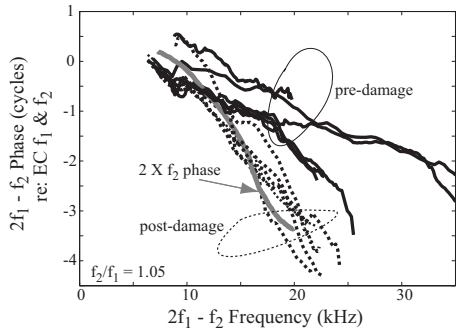

FIG. 10. DPOAE pre- and post-damage phases. Data from experiments wg91, wg92, wg93, wg95, wg122, and wg131. The 20 kHz region was damaged either by locally indenting the BM or by the invasive intracochlear measurement. Solid and dashed lines represent the phase under healthy and locally damaged conditions, respectively. The DPOAE shown is at frequency $2f_1-f_2$ with $L_1=L_2=80$ or 90 dB and $f_2/f_1=1.05$. The gray line shows an example of two times forward f_2 phase with BF ~20 kHz.

V. SUMMARY

Locally indenting the cochlear partition raised CAP thresholds at frequencies within the targeted region and reduced local cochlear nonlinearity, including local DPs, and appeared to reduce the stiffness of the cochlear partition slightly. DPOAE changes following the local damage corresponded to the damaged region, with reductions at some frequencies and enhancements at others. The changes could be interpreted within the two-source framework of cochlear emissions, and indicated an increase in reflector- and a decrease in generator-type emissions. In addition, the results confirmed that for the low frequency sidebands, e.g., $2f_1-f_2$, the generator-type dominates the DPOAE at relatively wide primary ratio (1.25) and both the generator- and reflector-type emissions contribute substantially at narrow primary ratio (1.05).

(Received 18 November 2008; revised 15 October 2009; accepted 29 December 2009)

This paper investigates the significance of the magnitude or the phase in the short term Fourier spectrum for speech intelligibility as a function of the time-window length. For a wide range of window lengths (1/16–2048 ms), two hybrid signals were obtained by a cross-wise combination of the magnitude and phase spectra of speech and white noise. Speech intelligibility data showed the significance of the phase spectrum for longer windows (>256 ms) and for very short windows (<4 ms), and that of the magnitude spectrum for medium-range window lengths. The hybrid signals used in the intelligibility test were analyzed in terms of the preservation of the original narrow-band speech envelopes. Correlations between the narrow-band envelopes of the original speech and the hybrid signals show a similar pattern as a function of window length. This result illustrates the importance of the preservation of narrow-band envelopes for speech intelligibility. The observed significance of the phase spectrum in recovering the narrow-band envelopes for the long term windows and for the very short term windows is discussed.

I. INTRODUCTION

The research question of this paper is the significance of the magnitude and the phase in the short term Fourier spectrum for speech intelligibility. The magnitude spectrum is considered important in almost all types of applications of speech processing, while phase has received less attention. Speech signals are commonly analyzed using short-time Fourier transforms (STFTs), and their characteristics are conventionally represented by the magnitude spectrum for speech analysis and/or synthesis.[1] The difference between phonemes is reflected in the structure of the magnitude spectra, and power (or magnitude) spectrum subtraction is commonly used for noise reduction.[2,3]

From a point of view of audio engineering type of applications, it is well known that the phase spectrum of sound is important for rendering (or removing) room-reverberation effects from a reverberation-free (or reverberant) signal. It seems that human listeners are able to appropriately detect phase changes in longer signal segments than those commonly used for speech analysis.[4–8] Schroeder and Strube[5] and Traumueller and Schouten[9] reported that vowels could be synthesized using phase information, and Oppenheim and Lim[10] found that when a speech signal was of sufficient length, speech intelligibility was lost in Fourier-transform magnitude-only reconstruction but not in phase-only reconstruction. However, it is still unclear how effectively the phase information is used for the synthesis of intelligible speech, and formal listening tests were not performed.

On the other hand, Liu *et al.*[11] intensively investigated the effect of the phase on intervocalic stop consonant perception for VCV speech signals. It was shown that the perception of intervocalic stop consonants varies from magnitude dominance to phase dominance as the Fourier-analysis window size increases across the cross-over point between 192 and 256 ms. An effect of phase on perception was also observed for shorter time windows, in the range of 10 to 30 ms. The present study builds on and expands the Liu *et al.* study with respect to two main issues: (1) it investigates the significance of magnitude versus phase in the short term Fourier spectrum for *sentence intelligibility,* rather than for the perception of intervocalic consonants, and (2) it covers a wider range of time-window lengths, with a window covering the complete sentence as the upper limit, down to the lower limit of a single-sample window length.

It is generally believed that speech intelligibility is related to narrow-band envelopes.[12] Drullman[13] found that intelligible speech signals can be synthesized by modulating 24 1/4-octave noise bands covering 100–6400 Hz range, using the temporal speech envelopes obtained in the corresponding 1/4-octave bands. This was the motivation for investigating the role of the phase spectrum in relation to the preservation of narrow-band envelopes. For instance, it will be shown that in case where the window length used in the Fourier transform is substantially larger than the period of the envelope modulation of interest, it is the phase spectrum that carries the information about the temporal envelope, not the magnitude spectrum. It will be shown that the same applies in the case of very short window lengths.

The experimental approach adopted in this paper is similar to the one used by Liu *et al.*,[11] but applied to a spoken sentence and random noise. From these signals, two new signals were created by a cross-wise combination of the magnitude and phase spectra of the speech and noise signals. These two hybrid signals are made for a wide range of win-

 0001-4966/2010/127(3)/1432/8/$25.00

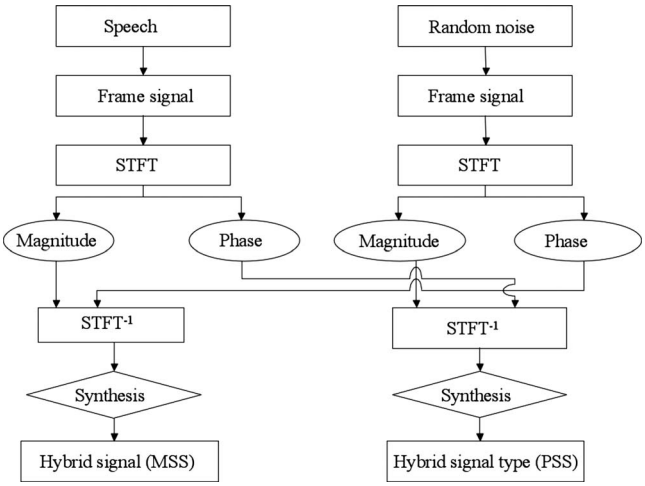

FIG. 1. Method for deriving two types of hybrid signals from speech and random noise using a cross-wise combination of the amplitude and phase spectra in the STFT overlap-add procedure.

dow lengths used in the STFT overlap-add procedure. Sentence intelligibility tests and envelope-correlation studies are performed to investigate the characteristics of the two hybrid signals as a function of window length.

II. LISTENING EXPERIMENT

Synthesized hybrid (magnitude- or phase-only) speech signals were obtained by using female-spoken speech and random-noise samples, as shown in Fig. 1. Sentence intelligibility for the two hybrid signals, as a function of the window length used in the STFT analysis and reconstruction, was estimated using listening tests.

A. Method

1. Test materials and signal processing

The original speech signals consisted of 96 sentences spoken by two female speakers. All of the speech materials were in Japanese and digitized at a sampling rate of 16 kHz, which seems well suited to the sentence intelligibility tests carried out in this study, using a 16-bit A/D converter. Each 1.5-s-long speech phrase had additional silent parts at the start and end, so the total length was 4 s. The speech tokens were simple everyday sentences, with a length of typically six to ten words, e.g., (translated), "This letter cannot be clearly seen from far away." A white-noise signal was produced using MATLAB software.

The speech and random-noise pairs were analyzed using STFT (Fig. 1) where a rectangular-window function was applied to cut the signals into frames. A 50% overlapped windowing was applied (except for the two- or the single-point frames). Two hybrid signals were synthesized by inverse STFT using the magnitude spectrum of the speech (or the noise) and the phase spectrum of the noise (or the speech). The first type will be referred to as magnitude-spectrum speech (MSS) and the second type as phase-spectrum speech (PSS). A triangular window, with a frame length equal to the rectangular window used for the analysis, was applied to each synthesized frame to avoid discontinuities between successive frames. Sixteen frame lengths (1/16–2048 ms) were used, including the limit case of only a single-sample time frame of 1/16 ms. The total set of materials consisted of 192 processed sentences (96×2): six sentences for each of the 16 frame lengths and two types of hybrid signals.

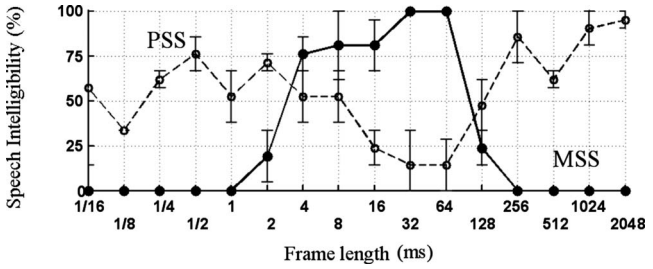

FIG. 2. Sentence intelligibility for PSS and MSS, as a function of the frame length used in the STFT procedure.

2. Subjects and procedure

The listeners were seven men, aged 24–49. They were all native speakers of Japanese. The total set of processed sentences were presented in random order through headphones (AKG-K240) under diotic listening conditions at an individually preferred level. Each subject was asked to write down the sentences as they listened. A sentence was considered intelligible only if the complete sentence was written down correctly.

B. Results

Figure 2 shows the sentence intelligibility scores (with the standard deviation) for each signal type and frame length. The horizontal axis shows the frame length. Each data point is based on six presentations to seven listeners. A score of 100% indicates that all subjects could correctly write down each sentence.

The MSS hybrid signal shows the strongest effect of frame length, ranging from perfectly intelligible for medium-range frames (4–64 ms) to totally unintelligible for long frames (256–2048 ms) and very short frames (1/16–1 ms). The PSS signals show the opposite behavior, though less extreme. For the shorter time frames, the results above suggest that frequency resolution finer than 250 Hz (frame length longer than 4 ms) is needed to get intelligible speech from the spectral magnitude. For the longer time frames, the results suggest that the temporal resolution required to obtain intelligible speech from the magnitude spectrum should be better than about 128 ms, corresponding to a modulation frequency of 8 Hz.

It is interesting to note that, where the magnitude spectrum fails in reproducing intelligible speech, the phase spectrum (partly) takes over this role. For the longer time frames, this corresponds with the earlier observations of Oppenheim and Lim[10] and Liu *et al.*[11] This is consistent with the idea that the temporal properties or signal dynamics represented by the envelopes can be expressed as the very local characteristics of the phase spectrum, such as the group delay. That

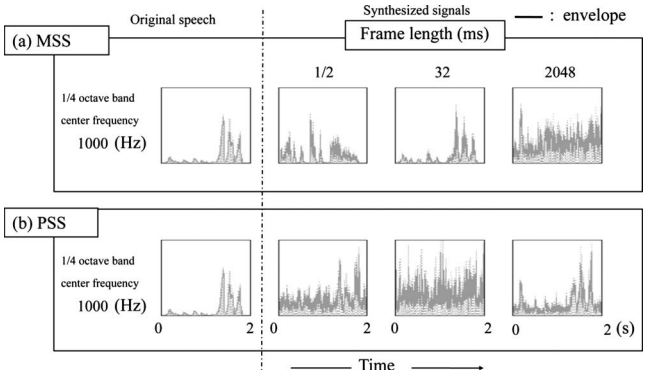

FIG. 3. Samples of squared sub-band waveforms with envelopes for the original speech, and for the MSS and PSS synthesized signals for three frame lengths used in the STFT. The sub-band considered is the 1/4-octave band with 1 kHz center frequency.

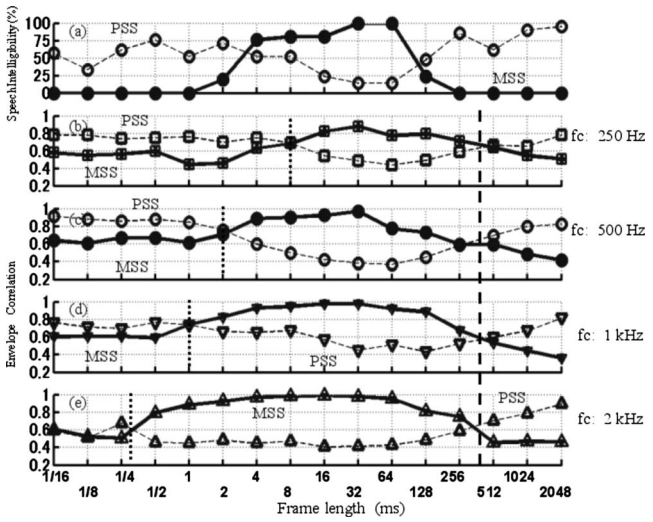

FIG. 4. Sentence intelligibility (a) and examples of envelope-correlation analysis [(b)–(e)] for MSS and PSS. Envelope correlation analysis was made in 1/4-octave bands following Eq. (1) in the text.

is, phase spectra with a fine spectral-resolution (as resulting from long time frames) will allow a partial reconstruction of the narrow-band temporal envelope.

The observed significance of the phase spectrum for the very short time frames is more surprising. This will be discussed later.

III. PRESERVATION OF NARROW-BAND ENVELOPES

As mentioned before, it is generally believed that preservation of intelligibility is related to preservation of narrow-band envelopes.[12–14] In this section, it will be investigated to what extent the narrow-band envelopes are preserved for the two types of hybrid signals. Sub-band signals of 1/4-octave bands between 250 and 4000 Hz were derived by applying a finite impulse response (FIR) filter bank (fourth-order Butterworth filter).[13] The envelope in each frequency band was defined by a Hilbert transform.

A. Observation of synthesized signals and their envelopes

Examples of the envelopes of the original and the hybrid speech signals of MSS and PSS are shown in Fig. 3 for one of the sentences in the stimulus set. This example takes one frequency band (1 kHz 1/4-octave band) and three choices of the time window (1/2, 32, and 2048 ms), motivated by the intelligibility data in Fig. 2. The narrow-band envelope of the MSS illustrated in Fig. 3(a) resembles the original envelope, only for the frame length of 32 ms. The envelope samples of PSS [Fig. 3(b)] show the opposite behavior: resemblance with the original envelope is seen only for the very short and long time frames. The observed qualitative agreement between envelope preservation and the intelligibility data motivated a more detailed study of the two types of hybrid signals in terms of narrow-band envelope correlations as a function of window length.

B. Narrow-band envelope-correlation analysis

The narrow-band envelope-correlation analysis is performed between the original and synthesized speech materials. The nature of the narrow-band temporal envelopes of the signals was evaluated by determining the correlation coefficients between the original and hybrid-signal envelopes. The correlation was calculated for every 1/4-octave band. The correlation coefficient of the ith frequency band for a sentence l is defined as

$$\rho_i(l) = \frac{\overline{\hat{e}_{oi}(l,n)\hat{e}_{si}(l,n)}}{\sqrt{\hat{E}_{oi}(l)\hat{E}_{si}(l)}}, \tag{1}$$

where

$$\hat{e}_{oi}(l,n) = e_{oi}(l,n) - \overline{e_{oi}(l,n)}, \tag{2}$$

$$\hat{e}_{si}(l,n) = e_{si}(l,n) - \overline{e_{si}(l,n)}, \tag{3}$$

$$\hat{E}_{oi}(l) = \overline{\hat{e}_{oi}(l,n)^2}, \tag{4}$$

$$\hat{E}_{si}(l) = \overline{\hat{e}_{oi}(l,n)^2}, \tag{5}$$

and $e_{oi}(l,n)$ and $e_{si}(l,n)$ denote the squared envelopes of the original and synthesized speech signals in the ith band for the sentence l, and the over-line shows taking an appropriate time average. For each frame length and for each of the two hybrid-signal types, the average was taken of the correlation coefficients for the six sentences used for that condition.

Figures 4(b)–4(e) present examples of the correlation coefficients between the narrow-band envelopes of the hybrid signals and the original speech for each of four 1/4-octave bands. Figure 4(a) is just a replication of the intelligibility test results in Fig. 2. The pattern of the correlation coefficients, as a function of the time-window length, is somewhat frequency-band dependent, but the complementary nature of the correlation values for MSS and PSS is observed for each frequency band. The intelligibility data and the narrow-band envelope correlations show the same trend with respect to the effect of frame length. This correspondence between the intelligibility data and the narrow-band envelope data confirm that the preservation of the narrow-band temporal envelopes is closely related to speech intelligibility.

The correlation data for MSS and PSS show two cross-over points. The cross-over point at a frame length of about 256 ms is almost independent of the frequency band considered, as can be seen by the vertical broken line through the figures. Since the observed decrease in the correlation for MSS toward long frame lengths reflects the loss of time resolution required for representing the temporal envelope, this crossover point is supposed to be related to the dominant frequency of the envelope modulations. The corresponding cross-over point in the intelligibility data is considerably lower, suggesting that the speech envelope includes slow modulations, which are included in the correlation values, but contribute little to speech intelligibility. This point is addressed in Sec. IV.

The other cross-over point is frequency dependent as can be seen by the vertical dotted lines in each of the figures. The cross-over points happen to correspond roughly with the duration of the period of the center frequency. We cannot provide a firm theoretical basis for this relation. In general terms, however, the frequency dependency of the cross-over point can be understood as a reflection of the limited frequency resolution associated with a short frame length. Given the increase in bandwidth for increasing center frequency f_c of the 1/4-octave bands considered in Fig. 4, a certain loss of frequency resolution (typically equal to the inverse of the frame length in the STFT) will have less effect for higher $f_c's$. Thus, in order to recover 1/4-octave band envelopes from the magnitude spectrum, the frame length used in the STFT should provide an adequate degree of frequency resolution, related to the width of the frequency band considered. Hence, shorter frames are allowed toward higher $f_c's$.

The results so far can be summarized as follows.

(1) *The MSS data are quite understandable*. For longer time frames (>256 ms), the temporal resolution is insufficient to follow the relevant envelope modulations, and for shorter time frames (<4 ms), the frequency resolution becomes insufficient (this appears to depend on the center frequency of a band).
(2) *The PSS data are more surprising*. The envelope is (partly) recovered for windows longer than 256 ms, and also for the very short time frames (which may not be intuitively obvious for many readers).

These observations on the phase dominance for longer and for very short time frames will be studied further by analyzing narrow-band envelope recovery from the phase spectrum only.

C. Recovery of narrow-band envelopes from the phase spectrum

1. Significance of phase spectrum for long window lengths

The importance of the phase spectrum for modulated signals is well illustrated by the difference between an amplitude- and a quasi-frequency-modulated (AM and QFM) sinusoid. It is well known that the phases of the two side-band components determine the temporal envelope: essentially flat in the QFM case and modulated in the AM case. Figures 5(a) and 5(b) show a stationary random noise and a noise modulated by a co-sinusoidal function, respectively. The corresponding magnitudes and phase spectra are shown in Figs. 5(c)–5(f). The envelope-modulation frequency in this example is given by $2(1/N)$, where N denotes the signal length. Here, STFT analysis was applied to the whole signal length.

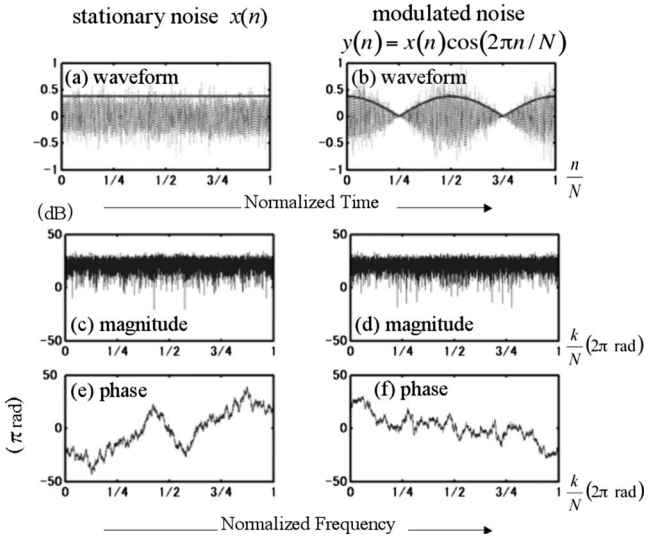

FIG. 5. Examples of stationary random noise (a) and modulated noise (b) with the magnitude [(c) and (d)] and phase [(e) and (f)] spectral characteristics.

Although there are no clear indications of the envelope frequency in the magnitude and phase spectra, the frequency can be observed by applying an auto-correlation analysis to the phase spectrum. This is illustrated in Fig. 6, where the modulation frequency is converted to a real quantity. When the phase difference between components (k_o) and $(k+k_o)$ is given by

$$\Delta\theta(k,k_o) = \theta(k+k_o) - \theta(k_o), \tag{6}$$

then the phase correlation function phc(k) can be obtained by

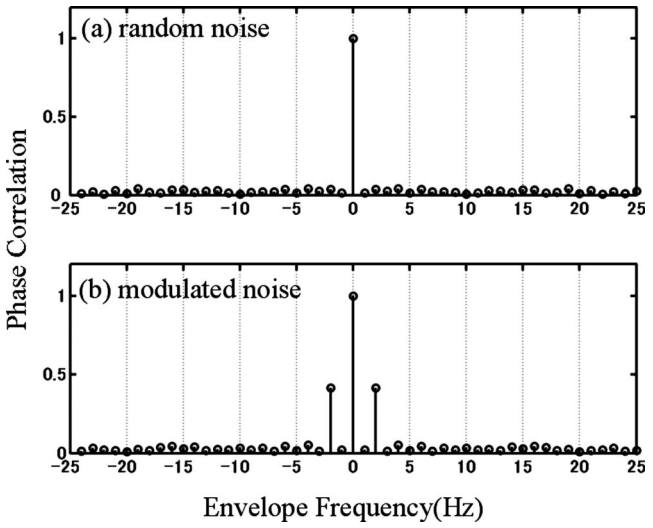

FIG. 6. Phase spectrum auto-correlation analysis for the signals shown in Fig. 5 according to Eqs. (6)–(9) in the text.

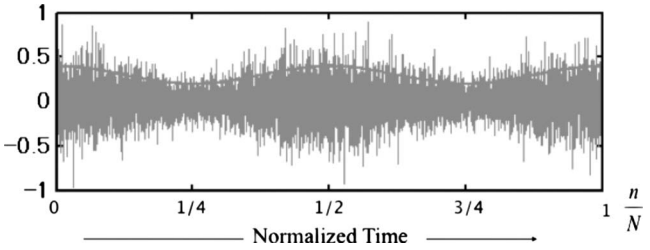

FIG. 7. Reconstruction of the modulated noise of Fig. 5(b), using the corresponding phase spectrum and a random magnitude spectrum.

$$\mathrm{phc}_c(k) = \frac{1}{K}\sum_{k_o=0}^{k_o=K-1} \cos\Delta\theta(k,k_o), \tag{7}$$

$$\mathrm{phc}_s(k) = \frac{1}{K}\sum_{k_o=0}^{k_o=K-1} \sin\Delta\theta(k,k_o), \tag{8}$$

$$\mathrm{phc}(k) = \sqrt{\mathrm{phc}_c(k)^2 + \mathrm{phc}_s(k)^2} \tag{9}$$

in a discrete form. Here, K denotes the number of frequency components of interest. In the figure, the horizontal axis shows the frequency shift, which can be interpreted as the envelope frequency.

Note that Fig. 6(a) shows that the fluctuations seen in the phase spectrum for stationary noise are random. Only the modulated-noise case [Fig. 6(b)] shows that the modulation frequency can be estimated from phase information alone. Figure 7 is an example of a hybrid signal made by substituting random magnitude for the original magnitude spectrum of the modulated noise shown in Fig. 5(b). This illustrates that the original envelope is partly preserved on the basis of the phase spectrum only. The spacing of the frequency components in the phase spectrum resulting from the STFT should be small enough to reflect the envelope frequency in the phase spectrum auto-correlation function. Since this frequency spacing is related to the inverse of the frame length used in the STFT, this implies that for envelope recovery from the phase spectrum, the frame length should be longer than the period of the envelope modulation of interest.

2. Significance of phase spectrum for very short window lengths

Phase dominance for very short frame lengths can be interpreted as the narrow-band envelope recovery from the zero-crossings of a waveform. As Figs. 4(b)–4(e) indicate, this requires that the frame length is shorter than the period of the center frequency of interest. For the present study, the limit case of a very short analysis window-lengths is a length of 1/16 ms (i.e., the sampling rate), corresponding to a single-point STFT. The result of a single-point STFT is for each sample, its magnitude, and the phase is just the sign of the sample, ±. Thus, the phase information of a single-point STFT keeps the zero crossings of the original signal, if the sample frequency is adequate. This is the same as applying infinite peak clipping to a signal, which also preserves the zero-crossing information while losing all amplitude information. It will be shown that the narrow-band envelopes can be partly recovered from the zero crossings of the original signal.

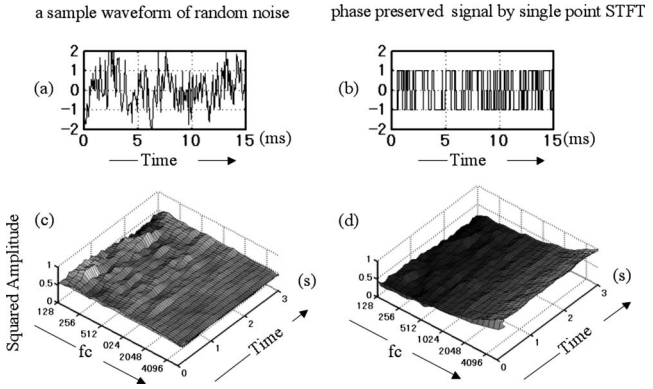

FIG. 8. Representation of stationary noise. Left part: original. Right part: after single-point STFT, with the phase (+ or −) of each sample preserved, and the magnitude set at unity.

Figure 8(a) shows a snap shot of a waveform from a stationary random noise. Figure 8(b) represents the random noise re-synthesized by preserving the phase only for a single point of STFT (just ±) with the magnitude of unity. This resulted in an infinitely peak-clipped version of the original signal. The three dimensional plots in Figs. 8(c) and 8(d) show the temporal change in the short-time sub-band energy of these two signals, indicating that the original spectro-temporal characteristics, especially in the low frequency range, are preserved to some extent in the signal synthesized from the phase information of the single-point STFT. The increase in the energy for the high frequency bands in Fig. 8(d) can be interpreted as a processing noise due to the hard clipping of the waveform shown in Fig. 8(b).

The example above refers to a stationary signal. It illustrates that the shape of the spectral magnitude information is hidden in the pattern of the zero-crossings, particularly for the low frequency bands. Figure 9 is another example for a random noise, but now including a modulated sub-band. The original zero-crossings are preserved in Fig. 9(b) by the single-point STFT. Despite losing the original magnitude information, the temporal envelope of the sub-band can be recovered to some extent from the zero-crossing information, as shown in Fig. 9(d). In other words, the narrow-band en-

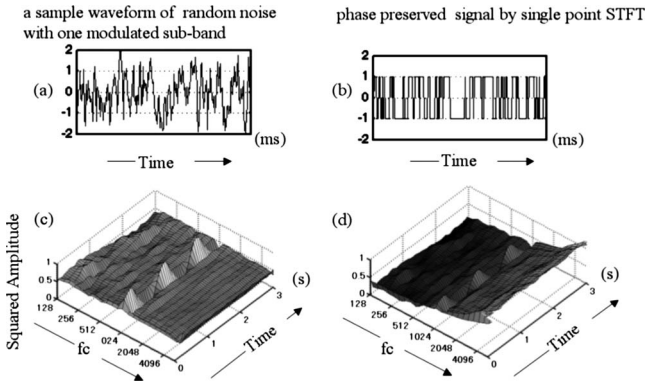

FIG. 9. A sample waveform of random noise with a modulated sub-band. Left part: original. Right part: similar to Fig. 8.

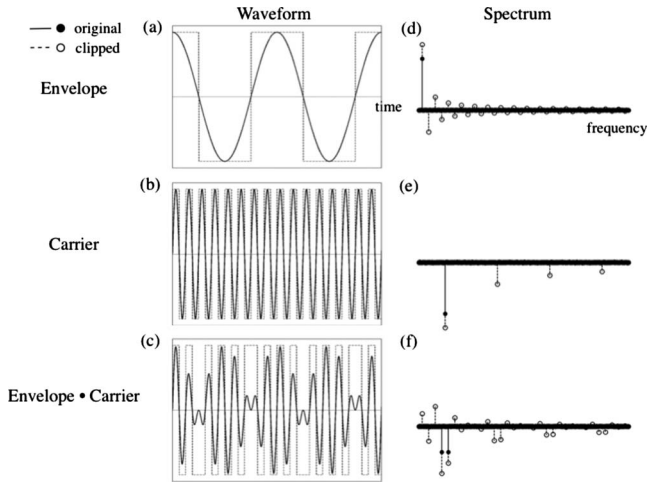

FIG. 10. Spectrum of the infinitely clipped version of a modulated sinusoidal signal.

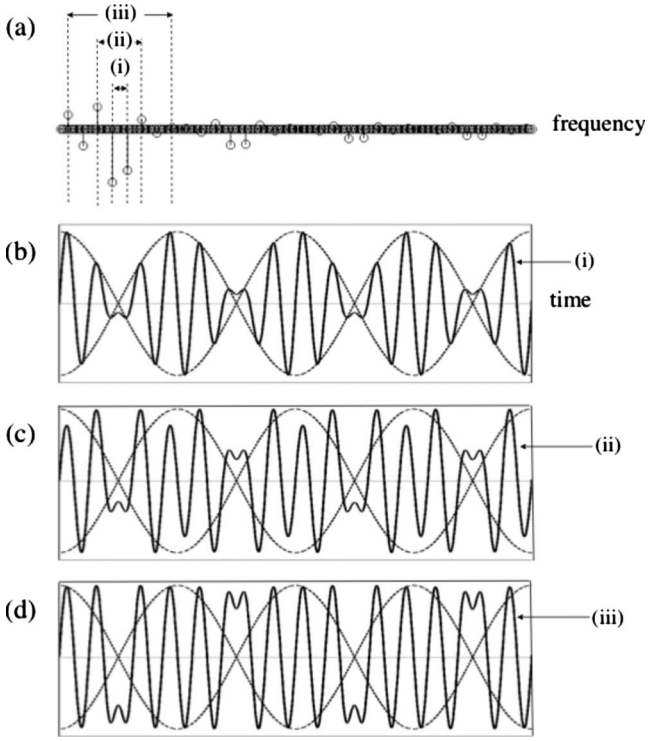

FIG. 11. Sinusoidal envelope recovery from the clipped wave as shown in Fig. 10, after applying sub-band filtering with increasing bandwidth, indicated by (i), (ii), and (iii).

velope can be partly recovered from the fine-structure (zero crossings) of the modulated noise samples after sub-band analysis.

This example may explain the significance of the phase for the very short time frames, as observed in Fig. 4. However, Fig. 4 also indicates that for the very short time frames the envelopes for the higher frequency bands are not well recovered from the phase-only information. This may be related to the fact that, given the typical shape of the power spectrum of speech, the higher bands represent only a small fraction of the total power, and consequently the modulation properties of these higher bands may only be marginally represented in the zero-crossing statistics of the over-all signal. Another possibility is that envelope reconstruction from phase is disrupted by the processing noise that yields higher energy at higher frequencies, as shown in Figs. 8(c), 8(d), 9(c), and 9(d).

Another example of envelope recovery from zero-crossing information is provided in Figs. 10 and 11. It concerns a modulated sinusoidal waveform, as shown in Figs. 10(a)–10(c). Spectral records for the envelope [Fig. 10(d)], its carrier [Fig. 10(e)], and the modulated signal [Fig. 10(f)] are represented by the line-spectral characteristics. Here, the solid lines and solid circles show the original ones, while the dotted lines and open circles indicate the infinitely clipped case. The spectral structure of the modulated signal can be expressed as the convolution of the spectral sequences for the envelope and the carrier. The convolution is performed periodically, because this numerical sample is composed of a discrete sequence. If only the zero-crossing property is preserved with the magnitude of unity (discarding the envelope of the modulated sinusoid), the convolved spectral-structure is expanded, including its higher harmonics. Although those higher harmonics are not contained in the original modulated signal, the modulation property, such as the temporal envelope, can be recovered by applying appropriate filtering, as shown in Fig. 11.

Figure 11(a) is close-up of Fig. 10(f). If we take a bandwidth denoted by (i) in the figure, representing sub-band analysis, then we get the waveform shown in Fig. 11(b). Here, the broken line represents the original envelope shown in Fig. 10(a). However, if we increase the bandwidth according to the examples denoted by (ii) or (iii) in Figs. 11(c) and 11(d), the original envelope is no longer recovered. This illustrates that the original envelope can be recovered from zero-crossing information when applying sub-band filtering, provided that the bandwidth is adapted to the modulation frequency of interest. Since in our analysis, higher frequencies are associated with broader absolute bandwidth, this may be a reason why envelope recovery from phase for very short windows is poorer at high frequencies (Fig. 4), and why the processing noise increases toward high frequencies [Figs. 8(d) and 9(d)].

In principle, characteristics of speech waveforms can be understood as a mixture of a random noise-like feature or a periodic structure. Thus, the two simplified examples presented above represent two extreme cases of signals with speech-like characteristics. For both some form of sub-band-envelope recovery from the zero-crossing information only was demonstrated.

IV. DISCUSSION

The results of the listening experiment, as presented in Fig. 2, provide the key data of the present study. We will first consider the strong effect shown in the MSS data, in particular, the decrease to 0% intelligibility for the long and the short frame lengths when using the magnitude spectra only.

In interpreting the loss of intelligibility of MSS speech for time windows of over about 250 ms, it was assumed that this reflects the loss of temporal resolution required for following the essential speech-envelope modulations. This

would suggest that the envelope modulations above 4 Hz are indispensable for maintaining intelligible speech. A related study on the effect of low-pass filtering narrow-band envelopes[15] indicated that only for a 2-Hz (or lower) low-pass cut-off frequency is sentence intelligibility severely reduced. The difference may be understood by realizing that, in this previous study, the envelope filtering was the only "distortion" applied to the speech, while in the present study many additional "distortions" are introduced in the MSS condition, as a result of disregarding the phase spectrum.

The loss of intelligibility of MSS speech for time windows of 1 ms or less was interpreted as reflecting the very limited frequency resolution associated with such brief time windows. This would imply that a frequency resolution of worse than about 1000 Hz makes speech unintelligible. In related studies, e.g., on the effect of spectral smearing on speech intelligibility,[16] or on the minimum number of bands required to produce intelligible speech,[17] the operations are performed on a logarithmic frequency scale, complicating the comparison with the present study (window-associated loss of spectral-resolution is constant over frequency). Still, the 1000-Hz limit suggested by the present data does not disagree with the findings of these other studies.

For a frame length in the range of 4–64 ms, the magnitude spectrum carries the essential information for speech intelligibility. Thus, for the commonly observed approach in speech processing, i.e., a spectral analysis with a window length of a few tens of ms, the use of the power spectrum does maintain the essential cues for speech intelligibility. Following the traditional view of the peripheral auditory system as a set of band pass filters, the auditory temporal window in the mid-frequency range amounts to typically 10 ms.[18] Figure 4 indicates that for this window length, both the speech intelligibility and the narrow-band envelope preservation are dominated by the magnitude spectrum, while the phase only plays a minor role. This implies that the envelopes of the auditory filter outputs carry the intelligibility-relevant information.

The main goal of the present study was to investigate the relative importance of magnitude versus phase in the short term Fourier-spectrum approach in speech analysis and synthesis, given that most studies concentrate on the magnitude or power spectrum only. The experimental signal manipulations used in this study (resulting in the hybrid signals) will have consequences for the preservation of the envelope and the fine structure in narrowband (auditory) filters. In this respect, there is a relation between this study and research on the relative importance for speech intelligibility of envelope cues and fine-structure (phase) cues at the auditory filter outputs. The consensus on this issue (see, among others, Refs. 14, 13, and 19) is that preservation of the envelopes at the filter outputs is the main factor for speech intelligibility, while the phase or the fine structure is of secondary importance. This firm distinction is somewhat complicated by studies, indicating that envelope and phase information at the filter outputs are not independent,[20] and that temporal-envelope cues can be recovered from the speech fine structure.[21] A detailed study on the effect of additive noise on speech intelligibility, quantifying the relative importance of disrupting the narrow-band envelopes or the fine structure, confirmed the importance of the envelopes.[22] However, besides the main role of envelope cues, that study also showed some reduction in intelligibility after disrupting the fine structure cues. This is in line with various other studies, indicating that temporal fine-structure cues do play a role in speech intelligibility, especially in case of complex (i.e., non-stationary) maskers.[23–25]

The relevance of narrow-band envelopes for speech intelligibility motivated the use of this concept (i.e., the degree of preservation of narrow-band envelopes) for interpreting the present intelligibility data on the relative importance of the magnitude or phase spectrum. However, it should be realized that, besides the loss of envelope correlation for the pre- and post-processed speech, other types of distortions are introduced as well. For instance, it has been shown that a loss of cross-spectral modulation phase coherence may reduce speech intelligibility.[26] It is very probable that the observed loss of correlation between the pre- and post-processed narrow-band envelopes is associated with a loss of cross-spectral modulation phase coherence. Also, as mentioned before, the processing will affect the narrow-band fine structure. Consequently, part of the observed relation in the present study between loss of intelligibility and loss of band-envelope correlation may well be caused by the associated effects of loss of cross-spectral modulation phase coherence or loss of fine structure. The present study does not allow to specify this any further.

V. CONCLUSION

Speech was subjected to Fourier analysis and synthesis, using the overlap-add procedure with window lengths ranging from 1/16 to 2048 ms. Experiments were performed on the intelligibility of the speech for two conditions applied for the synthesis: (a) MSS-mode, using the speech-magnitude spectra with randomized phase spectra, and (b) PSS-mode, using the speech-phase spectra with randomized magnitude spectra. Besides the intelligibility measurements, the signals were subjected to an analysis of the correlation between the narrow-band envelopes, before and after the MSS or the PSS synthesis mode. The main findings were as follows.

(1) Using the MSS synthesis mode (magnitude spectra only), intelligible speech was obtained only for frame lengths of 4–64 ms.
(2) When using the PSS synthesis mode (phase spectra only), reasonably intelligible speech was obtained for frames longer than 128 ms or shorter than 4 ms.
(3) Thus, the two curves of intelligibility, as a function of frame length for the MSS and PSS synthesis mode, show a complementary character. This means that, for speech intelligibility, for the medium-range windows (4–64 ms), the magnitude spectrum dominates, and for the two extreme regions (<4 and >64 ms), the phase spectrum dominates.
(4) Intelligibility scores and correlation coefficients between the synthesized and original envelopes in 1/4-octave bands showed the same trend with respect to the effect of frame length, although not identical. This qualitative cor-

respondence confirms that the preservation of narrow-band temporal envelopes constitutes an important factor for the preservation of speech intelligibility.

The interpretation of these findings may be summarized as follows.

(a) *Considering the MSS synthesis mode (magnitude spectra only)*. For long time frames, the speech becomes unintelligible due to a loss of time resolution, as the frame length becomes longer than the period of the dominant speech envelope modulations (about 256 ms, a 4-Hz modulation frequency). For frame lengths shorter than 4 ms, the speech becomes unintelligible because the corresponding frequency resolution is insufficient.
(b) *Considering the PSS synthesis mode (phase spectra only)*. For long time frames, it is shown that the phase spectrum contains envelope information, as reflected in phase-spectral auto-correlation analysis. For the very short frames, it is shown that the phase-only synthesized speech essentially keeps the zero-crossing interval information, from which the shape of the original power spectrum can be obtained. It is shown that the temporal envelope of a sub-band can be partly recovered from the zero crossings of the total signal.

The main result of this study is that, besides the dominance of the magnitude spectrum for the middle range of window lengths, there appear to be two regions of phase dominance with respect to intelligibility and preservation of narrow-band envelopes. This phase dominance applies to very short and long time windows.

The acoustical bright spot and mislocalization of tones by human listeners

(Received 11 September 2009; revised 27 December 2009; accepted 29 December 2009)

Listeners attempted to localize 1500-Hz sine tones presented in free field from a loudspeaker array, spanning azimuths from 0° (straight ahead) to 90° (extreme right). During this task, the tone levels and phases were measured in the listeners' ear canals. Because of the acoustical bright spot, measured interaural level differences (ILD) were non-monotonic functions of azimuth with a maximum near 55°. In a source-identification task, listeners' localization decisions closely tracked the non-monotonic ILD, and thus became inaccurate at large azimuths. When listeners received training and feedback, their accuracy improved only slightly. In an azimuth-discrimination task, listeners decided whether a first sound was to the left or to the right of a second. The discrimination results also reflected the confusion caused by the non-monotonic ILD, and they could be predicted approximately by a listener's identification results. When the sine tones were amplitude modulated or replaced by narrow bands of noise, interaural time difference (ITD) cues greatly reduced the confusion for most listeners, but not for all. Recognizing the important role of the bright spot requires a reevaluation of the transition between the low-frequency region for localization (mainly ITD) and the high-frequency region (mainly ILD). © *2010 Acoustical Society of America.*

I. INTRODUCTION

Sine tones with slow onsets or with masked onsets are localized on the basis of ongoing interaural level differences (ILDs) and interaural time differences (ITDs). The ILDs are mainly useful cues at high frequencies, where the head casts a significant shadow on the ear further from the source of sound.

The ITDs appear to provide the dominant localization cues for sine tones in free field at low frequencies (Wightman and Kistler, 1992; Hartmann and Wittenberg, 1996). However, as the frequency of the tone increases toward 1000 Hz and beyond, the ITD becomes an unreliable cue because the corresponding interaural phase difference (IPD) is close to 180°, causing the perceived direction of the ITD cue to be ambiguous. For a frequency of 1000 Hz, an IPD of 180° occurs for an azimuth near 41°, and as the azimuth increases to 50°, the IPD becomes −150°, i.e., reversed in sign.[1] Perhaps because of this phase problem, the human nervous system becomes rapidly insensitive to ITDs in a steady sine tone as the tone frequency increases. Little or no ITD sensitivity is found at 1300 Hz and higher (Zwislocki and Feldman, 1956). There is a strong evolutionary advantage for such insensitivity because if the IPD sign is reversed, the ITD cue indicates a source direction that is opposite to the true direction. Better to have no cue at all than to have such a misleading cue.

The loss of the ITD cue is not the only interaural change that occurs as the frequency of a tone increases beyond 1000 Hz. A second change is that the interaural level difference becomes a seriously non-monotonic function of azimuth because of the peculiar physics of wave diffraction around the head. Figure 1 shows the calculated ILD vs azimuth for six different frequencies. The ILD is a non-monotonic function of azimuth for all six. Theoretically, the ILD function shows non-monotonic behavior for all frequencies (even 500 Hz in Fig. 1), but that behavior becomes perceptually important only for 1000 Hz and higher. For a 1500-Hz tone, the peak ILD (at an azimuth of 50°) is larger than 8 dB. This can be compared to an ILD of less than 4 dB at 90°. The functions in Fig. 1 were calculated from a spherical-head diffraction model (Rschevkin, 1963; Kuhn, 1977) with antipodal ears (±90° from the forward direction). If the ears are further back on the head, the peak moves to smaller azimuths. For instance, for 1500 Hz, the peak moves from 50° to 41° as the ear angle increases from 90° to 100°.

The origin of the non-monotonic ILD is the acoustical "bright spot." According to Fresnel's theory of diffraction, the intensity of a wave diffracted by a sphere is anomalously large at a location on the sphere directly opposite the direction of wave incidence. The bright spot, often called Poisson's bright spot or Arago's bright spot, was an important effect in demonstrating the wave nature of light (Hecht,

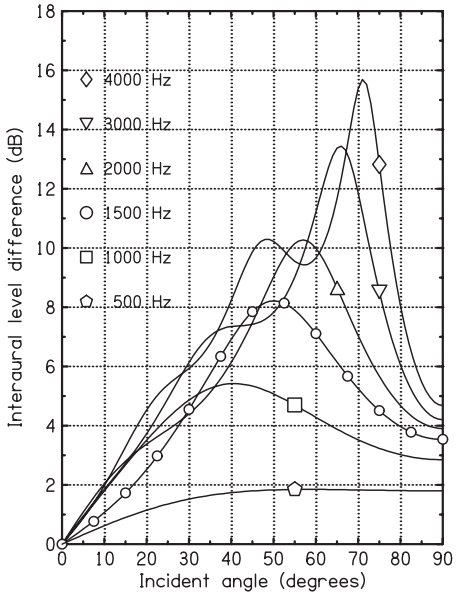

FIG. 1. The interaural level difference plotted as a function of source azimuth (Incident angle) for tones of six different frequencies, as computed in the spherical-head model with antipodal ears. All six curves have a peak, but it is hard to see for 500 Hz.

2002; Kelly *et al.*, 2009).[2] The acoustical effect is shown in panel (b) of Fig. 2 for a 1500-Hz tone. The solid lines show spherical-head calculations. The symbols show measurements made with a Knowles Electronics Manikin for Acoustics Research (KEMAR) (Burkhard and Sachs, 1975). Although the level in the ear near the source tends to grow with increasing azimuth, the level in the ear far from the source first decreases, then increases. The maximum far-ear level at 90° is the bright spot itself, but the approach to the bright spot is seen in the far ear for all angles greater than 50° or 60°. The difference between the near-ear and far-ear levels is the ILD, as shown in Fig. 2(c). Because of the bright spot, the ILD is a non-monotonic function of azimuth. As Kuhn (1987) observed, significant non-monotonic behavior is characteristic of the ILD throughout the high-frequency region.

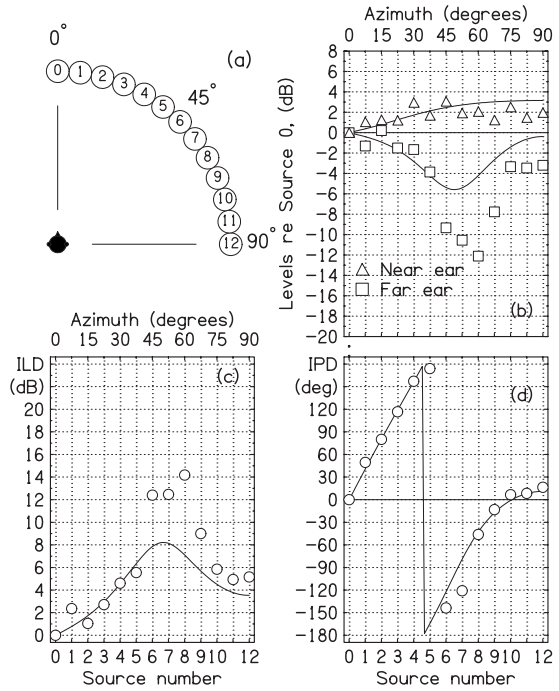

FIG. 2. Spherical-head computations (solid lines) and recordings in KEMAR ears (symbols). The sizes of the symbols indicate about 4 standard deviations. (a) The arrangement of loudspeakers and listener in the anechoic room. (b) The levels in near and far ears. Levels are plotted as functions of source azimuth for a 1500-Hz tone. They are referenced to the level at zero azimuth. (c) The ILD is the difference between near and far curves from part (b). The "near" ear is the right ear, and the "far" ear is the left ear. (d) Interaural phase difference.

The goal of the experiments reported in this article was to determine the perceptual consequences of the bright spot for large azimuths and relatively high frequency. Specifically, we hypothesized that at a frequency of 1500 Hz, the ITD would not be a useful cue and listeners could only rely on the ILD to encode the azimuth. Therefore, we expected that localization judgments would be dramatically misled by the non-monotonic character of the ILD. It was not completely obvious that this hypothesis would be supported experimentally. First, the theoretical curves and data in Fig. 2 might not apply to real listeners. Second, if they do apply, then perhaps listeners recognize the ambiguity of the ILD cues and have learned to cope with them. For example, Fig. 2(b) shows that there might be an opportunity for listeners to use the level information in the two ears separately to solve the azimuthal problem. As McFadden (1981) pointed out, peripheral interaural cues always require interpretation by higher-level functions.

II. EXPERIMENT 1: IDENTIFICATION

In an identification experiment, listeners were asked to identify the location of a loudspeaker producing a 1500-Hz sine tone. A frequency of 1500 Hz was chosen because of the large range of azimuths where the ILD slope is negative, as shown in Figs. 1 and 2(c). Also, 1500 Hz is low enough that the spherical-head model predicts only a simple peak as a function of azimuth.

A. Method

Listeners were seated near the center of an anechoic room (IAC 107840) with interior dimensions of $3.0 \times 4.3 \times 2.4$ m^3. An L-shaped rod mounted to the back of the chair touched the top of the listener's head to help him keep his head position fixed and facing in the forward direction. At a distance of 112 cm from the listener was an arc of 13 single-driver loudspeakers (Minimus 3.5), with azimuths varying in 7.5° increments over the range from 0° (forward direction) to 90°, as shown by the numbered circles in Fig. 2(a). The loudspeaker cones were at the height of the listener's ears, within a few centimeters. Listeners were familiar with the loudspeaker positions. A small drawing of the speaker array, with positions numbered 0–12 [Fig. 2(a)], was mounted below the front speaker (number 0) to remind listeners of the geometry.

Prior to the experiment, the level of each loudspeaker was measured using an omnidirectional microphone at the listener's position with the chair removed. In the experiments that followed, the levels of the signals sent to loudspeakers

were equalized so that all the loudspeakers produced the same level at the listener's position, ±0.5 dB. Of course, the levels in the listener's ears were ultimately not all the same, but depended on the speaker azimuth and the listener's head. The reason for using constant source level (and not roving) was that preliminary experiments suggested that listeners would be confused by the non-monotonic ILD, and we wanted to give the listeners every possible advantage in performing the task. In principle, equal-level sources might allow the listeners to localize by using the levels in the two ears independently if they are able to do so.

During the experiment, a computer program generated the tone, selected one of the 13 sources at random, and played the tone twice via Tucker-Davis digital-to-analog converters (DD1). The listener's task was to listen to the tones and to report the perceived azimuth verbally by an intercom. The experimenter then entered that choice into the computer for later analysis.

The tone level was 72 dBA at the listener's position. To avoid onset and offset cues, the tone had rise and fall durations of 250 ms. Each of the two tones had a full-on duration of 500 ms, and there was a gap of 1.8 s between the two tones. It was expected that presenting the tone twice from the same loudspeaker would make listener judgments more reliable. The presentations were paced by the listener's responses.

Each experimental run consisted of five passes through the set of loudspeakers. In any pass, each of the 13 speakers was presented once in random order. Thus, there were 65 decisions per run. A typical run lasted about 10 min. After a run, the listener could come out of the anechoic room and rest. There was no trial-by-trial feedback.

B. Physical measurements

While the experiment was in progress, each tone was measured using probe microphones in the listener's two ear canals (Etymotic ER-7c system with matching preamplifier). Prior to conversion to digital form (Tucker-Davis DD1), the microphone signals were given an additional 40 dB of gain. The digital recordings were processed by matched filtering, which led to recorded amplitudes and phases in each ear. The left and right amplitudes and phases were used to compute ILD and IPD values. Because each speaker was chosen for five trials in a run and a tone was presented twice for each trial, there were ten independent measurements of ILD and IPD per run. These were then averaged over two runs (20 measurements) to find the interaural parameters for each speaker. All measured values of IPD were reduced to the range from −180° to +180°.

The ILD and IPD values obtained for source number 0 (directly ahead) were small. Their mean values were subtracted from the mean values of all the other sources so that the ILD and IPD values reported in this article represent the changes in interaural parameters caused by the angular displacement away from the forward direction.

Reliability of the acoustical measurements was tested by using the probe microphones to measure the signals in the ear canals of a KEMAR manikin. The probes were inserted

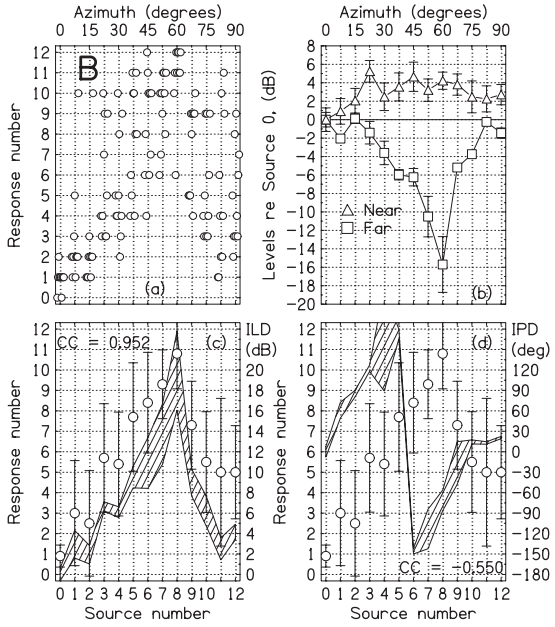

FIG. 3. Identification responses and probe-microphone measurements for listener B. (a) Scatter plot showing all responses. Points have been slightly displaced horizontally for clarity. (b) Measured levels in near (right) and far (left) ears. Error bars are 2 standard deviations in overall length. (c) Listener identification responses on the scale 0–12, with error bars 2 standard deviations in overall length. Perfect performance would correspond to a 45° line. The hatched region shows the ILD. For each source, it is centered on the mean ILD, and the overall height of this region is 2 standard deviations. The ILD values were measured while the response data were being collected. (d) Identification responses as in part (c) plotted together with IPD. The hatched region shows the IPD. For each source, it is centered on the mean IPD, and the overall height is 2 standard deviations. The IPD values were measured while the response data were being collected.

ten different times to simulate different fittings for human listeners, and measurements were made each time. The measured values are shown by the symbols in Fig. 2(b). The standard deviation across the ten different measurements was the size of a symbol or smaller.

C. Listeners

There were five listeners, all male. Listeners E, M, and N were in their twenties. Listener X was 35, and B was 56. All listeners had pure-tone thresholds within 15 dB of normal according to audiometric tests in the range 200–8000 Hz.

D. Results and discussion

In collecting the physical measurements, the experimenters monitored the measured levels and phases to verify correct operation. The standard deviations were examined to make sure that the measurements were not adversely affected by motion of the listener. Although the listeners' head positions were minimally constrained, the data were collected without having to repeat any runs except for one listener.

1. Levels in the ear canals

All data reported here are based on the two runs; a total of ten trials for each loudspeaker. The ear-level data are presented in the (b) parts of Figs. 3–7 for listeners B, E, M, N,

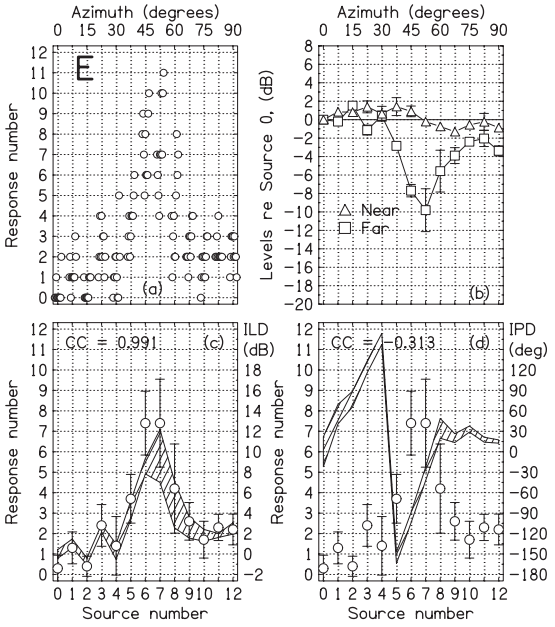

FIG. 4. Same as Fig. 3, but for listener E.

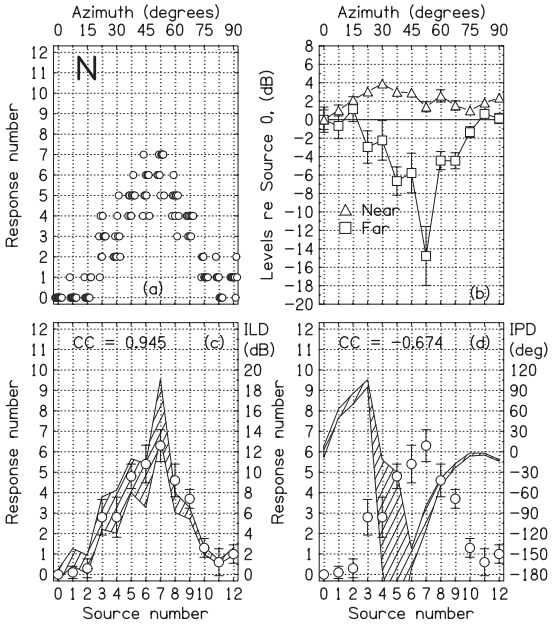

FIG. 6. Same as Fig. 3, but for listener N.

and X, respectively. The KEMAR data from Fig. 2 are the contribution to physical measurements from listener K.

In approximate agreement with the spherical-head diffraction model, the levels measured in the *far ear* showed a minimum near an azimuth of 50° (60° for listener B). The minima were of similar depth, ranging from –10 dB for listener E to –16 dB for listener B, and were all deeper than the prediction of –6 dB from the spherical-head model.

Although one might expect the levels in the near ear to be similar across the listeners because of the simple geometry, they were actually quite different. Two listeners, M and X, followed the prediction of the spherical-head model in that the levels tended to increase monotonically with azimuth, although the levels for these listeners rose by about 10 dB, to be compared with only 3 dB for the model. All the other listeners, including K, showed near-ear levels that were rather flat functions of azimuth, with some tendency to decrease near 70°.

2. ILD analysis

The ILDs shown in the (c) panels of Figs. 3–7 are the differences between near and far-ear levels. For all listeners, the ILDs have a peak where the far-ear level was a minimum. Peaks are in the range of 20–23 dB for listeners B, M, and X. They are in the range of 10–16 dB for listeners E, K, and N. All peak ILDs are greater than the value of 8 dB

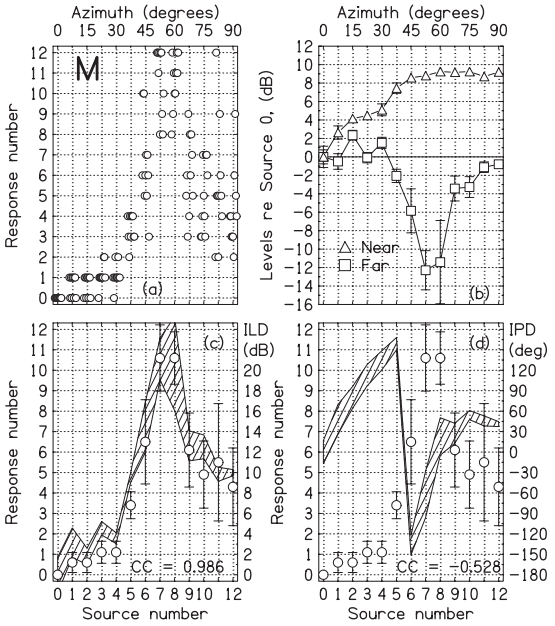

FIG. 5. Same as Fig. 3, but for listener M.

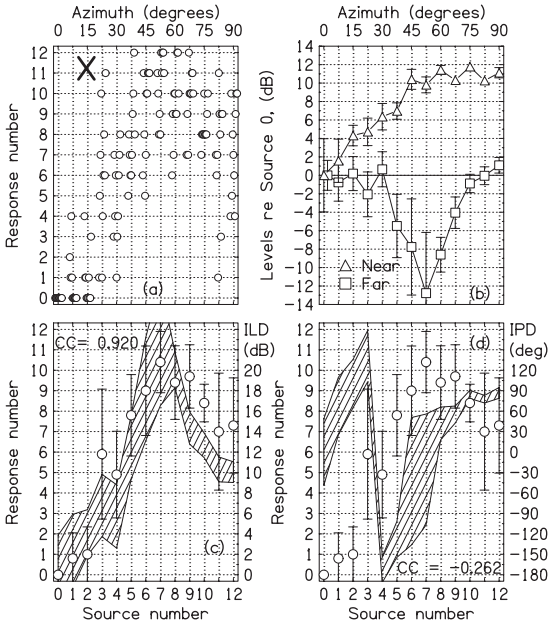

FIG. 7. Same as Fig. 3, but for listener X.

predicted by the spherical-head model. The discrepancy is likely to be a result of the torso, which is not included in the model.

The ILDs in the (c) panels are plotted as hatched polygons, 2 standard deviations in height. Given the reliability of the microphone method indicated by the KEMAR test, the standard deviations are likely caused by listener motion. Some of the deviation occurred as the listener was reseated between the first and second runs.

a. Listener responses The identification data reported here are based on the ten trials for each loudspeaker. The data are presented along with the physical measurements in Figs. 3–7 for the five listeners. In the (c) panels, the identification responses are superimposed on the ILD plots. No attempt was made to plot the listener responses in a way that would coincide with the polygons depicting measured ILDs for individual listeners. The scaling rule for drawing the plots was 7.5° of response angle for 2 dB of ILD for all the listeners. Nevertheless, the responses and ILDs overlap rather well.

The correlation (Pearson product moment) between the average response and the average ILD, computed over the 13 sources, is given in the plots. Over the five listeners, the average correlation was 0.96 (sd=0.03). These high correlations clearly suggests that localization decisions were strongly influenced by the ILD.[3]

b. Sensitivity to ILD For all listeners, the peak identification response occurred for the source (or sources) that led to the largest ILD. Listeners B, M, and X, with peak ILDs greater than 20 dB, all made peak responses greater than 10. Listeners E and N, with peak ILDs less than 16 dB, both made peak responses less than 8. The corresponding peak ILDs and peak responses suggest a common-sensitivity hypothesis. According to this hypothesis, all listeners have similar internal scales relating ILDs to azimuths, and listeners E and N gave smaller responses, simply because they experienced smaller ILDs.

To test the common-sensitivity hypothesis, the individual responses R were plotted as a two-parameter function, $R=A[1-\exp(-\mathrm{ILD}/C)]$. The initial slope of this function is A/C, and it serves as a measure of sensitivity to ILD. The largest slope was for listener B, 10°/dB. The smallest was for listener N, 5°/dB. The data for listener M did not have negative curvature and could not be fitted with the function. Listeners B, E, and X had similar slopes of 10°/dB, 7.6°/dB, and 7.1°/dB, respectively. Therefore, the common-sensitivity hypothesis could account for the small peak response made by listener E. By contrast, the small peak response for listener N reflects a relative insensitivity to stimulus ILD.

3. IPD analysis

The IPDs in the (d) panels of Figs. 3–7 are also plotted as polygons, again with overall heights showing 2 standard deviations in the measurements. In agreement with the spherical-head model, the IPDs all cross the 180° line for azimuths between 30° and 45°. There is one exception; the crossing occurs between 22° and 30° for listener X. Listener X also had the largest peak ILD and the widest head. The correlation between interaural parameters and head size was made clear in the scaling study by Middlebrooks (1999a, 1999b).

The identification responses from the (c) panels are repeated on the (d) panels for comparison with measured IPD. As shown by the correlation coefficient (cc) values on the (d) panels, the correlation between the responses and IPDs was negative for all the listeners. That negative correlation suggests that identification judgments were not much influenced by IPDs.

4. Individual-ear analysis

The strong correlation between ILD and response for all the listeners points to the ILD as a dominant cue for localization. However, there is additional localization information in the individual levels in left and right ears, and listeners might possibly benefit from that. A simple way to combine ILD with individual ear levels is, first, to observe that the nonmonotonic ILD presents the listener with an ambiguity and, second, to assume that individual ear levels might resolve that ambiguity. We called that strategy the "supplemental strategy."

a. Supplemental strategy We studied the supplemental strategy by beginning with the ILDs of all the sources to the right of the ILD peak, as shown in part (c) of Figs. 3–7. For each of these source azimuths to the right of the peak, there corresponds at least one azimuth to the left of the peak (not necessarily at a source location) for which the ILD is the same. We asked whether either the near-ear levels or the far-ear levels (usually interpolated) for those ILD-ambiguous azimuths differed by more than 1 dB. If so, we assumed that the individual ear difference could resolve the ILD ambiguity. An ideal listener with complete information could successfully employ such a strategy.

Summed over the five listeners in Experiment 1, there were 24 ILD-ambiguous sources. The supplemental strategy successfully resolved the ambiguity for 19 of these. Therefore, this hypothesis predicts that Experiment 1 should show only a few non-monotonic identification responses, contrary to observation. Apparently, human listeners are not able to use all the information assumed by the supplemental strategy.

b. Separate-ears strategy An alternative strategy, the "separate-ears strategy," involves only the levels in the two ears separately. A simple separate-ears strategy begins by assuming that the listener determines source location based on the level in the far ear because the far ear shows the stronger azimuth dependence. However, as shown in parts (b) of Figs. 3–7, the far-ear level is ambiguous because of the minimum in the level function. For every source azimuth to the right of the minimum, there is at least one azimuth (not necessarily at a source location) to the left of the minimum for which the far-ear level is the same. We assumed that a listener would try to resolve the ambiguity between two azimuths by considering the levels in the near ear. If the near-ear level for the larger azimuth is at least 1 dB greater than the near-ear level for the smaller azimuth (as it is for all but

TABLE I. Correlation between the source number and the listener's response in four identification experiments. Experiments 1 and 2 used sine waves. Experiment 2 included training and feedback. Experiment 4 used AM. Experiment 5 used narrow-band noise.

Listener	Expt.1	Expt.2	Expt.4	Expt.5
B	0.49	0.49	0.98	0.91
E	0.29	0.49	0.82	0.86
M	0.64	0.71	0.63	0.67
N	0.20	0.28	0.99	0.99
X	0.76	0.78	0.86	0.93
Av	0.48	0.55	0.86	0.87

one of the sources in the spherical-head model), then we assumed that the separate-ears analysis would resolve the ambiguity.

Calculations using the separate-ears strategy indicated that listeners E and N should not be able to resolve the ambiguity for any of the ambiguous sources. However, calculations for listeners M and X predicted successful resolution for four of the five ambiguous sources for each listener. Calculations for listener B were intermediate between those for E and N on the negative side, and M and X on the positive side. They predicted successful resolution for two of the four sources that were ambiguous for listener B. A glance at the first column of Table I shows that the predictions of the separate-ears strategy are ordered the same as performance in Experiment 1. The average correlation for listeners E and N was 0.25. The average correlation for listeners M and X was 0.7. The correlation for listener B was intermediate; a value of 0.49.

The above analysis of the separate-ears strategy, based on precise rules, does not differ from the impression that one gets merely by looking carefully at the (b) parts of Figs. 3–7. Listeners M and X exhibited a large, approximately monotonic increase in near-ear level with increasing azimuth. Other listeners, especially E and N, did not. The problem with the separate-ears strategy as a hypothesis is that it predicts mostly monotonic responses for listeners M and X, but these listeners gave non-monotonic responses like those of the other listeners.

What can be said in conclusion is that all listeners were misled by the non-monotonic ILD, but some listeners may have found it possible to use the information in separate ears to improve their decisions. Evidence for some use of separate-ear information comes from the fact that the predictions of the separate-ears strategy correlate rather well with performance in Experiment 1.

III. EXPERIMENT 2: INFORMED IDENTIFICATION

Because listeners obviously were confused by the stimuli in Experiment 1, Experiment 2 attempted to teach listeners to make better use of the available cues. There were two phases: training and feedback (T/F). The training phase was incorporated into the experiment runs. Each experiment run consisted of two data-collection passes through the 13 sources where the order of presentation of the sources was randomized on a pass. Prior to each of the two passes, there was a 1 min training pass, in which the sources were presented in ascending numerical order. The listener was alerted to the start of a training pass and knew what to expect. Each listener completed five runs, a total of ten data passes (by contrast, Experiment 1 had two runs of five passes).

A simple form of feedback was given after each trial as data were collected—one pilot lamp if the source had been in the range 0–6, the other pilot lamp if the source had been in the range 7–12. This binary feedback was adequate to resolve almost all of the ILD ambiguity.

A. Results

Table I shows the correlation between the listener's response and the true source number for the ten passes of Experiment 1 (no T/F) and the ten passes of Experiment 2 (with T/F). It shows modest improvement in Experiment 2 for three of the five listeners. To better determine whether identification accuracy benefited from T/F, the first five passes in Experiment 2 were compared with the first five passes in Experiment 1. Also, the second five passes in Experiment 2 were compared with the second five passes in Experiment 1. To determine whether continued T/F led to improved accuracy, the first and second five passes were compared within Experiment 2. The statistic used to assess accuracy was again the correlation between the listener response and the source number.

For the first five passes, the correlation was improved by T/F for three of the five listeners, and the mean increased from 0.46 to 0.52. For the second five passes the correlation improved for four of the five listeners, and the mean increased from 0.48 to 0.56. The correlation on the first pass of Experiment 2 was 0.52, and on the second pass, it was 0.56, a difference of 0.04 that might be attributed to learning.

The increases in correlations attributable to T/F, as reported above, were clearly modest at best. By contrast, correlations between responses with and without T/F were high. A round-robin comparison of first and second passes led to four correlations that ranged from 0.86 to 0.88. The conclusion of Experiment 2, incorporating training and feedback, was that listeners did learn from the experience, but they did not learn much. However, the training in Experiment 2 was not extensive, and it is possible that further training, or different training, might have been more effective.

IV. EXPERIMENT 3: DISCRIMINATION

Experiment 3 was similar in its setup to Experiments 1 and 2. The stimuli were also similar, except that the two tones on each trial came from different loudspeakers. Thus, Experiment 3 had the form of a classic two-source two-interval discrimination experiment intended to determine acuity. From the listener's perspective, the tones of a trial moved from left to right or moved from right to left along the arc. The listener's task was to report the direction of motion by means of push buttons.

A. Method

With 13 loudspeakers, there were 78 ways to choose different pairs. To obtain adequate statistics, it was necessary

to limit this number and select pairs. For each experimental run, six pairs of loudspeakers were selected based on predictions from the spherical-head calculations and from the identification data for the individual listener. Two pairs were selected because the previous data predicted that discrimination responses would be correct. Two others were selected because the data predicted incorrect responses, and two others were selected expecting uncertain responses. An experimental run included ten trials for each pair, presented in random order.

There were two experimental runs with different loudspeaker pairs selected for each. Therefore, each listener discriminated among 12 pairs, normally different for different listeners. The listeners from the identification experiments, Experiments 1 and 2, were also the listeners in Experiment 3. The timing and tone levels were the same as in Experiments 1 and 2. As in Experiments 1 and 2, ILD and IPD were measured in the discrimination experiment.

B. Predicting discrimination results

It is straightforward to use the results of the identification experiments to predict the results of discrimination experiments, assuming that the same sensory process applies to both experiments. If μ_m and μ_n are the mean identification responses for sources m and n, and if σ_m and σ_n are the corresponding standard deviations, then the expected value of d' in an experiment that requires the listener to discriminate between sources m and n is

$$d'_{m,n} = \frac{\mu_m - \mu_n}{\sqrt{\sigma_m^2 + \sigma_n^2}}. \quad (1)$$

This value of d' can be converted to percent correct on a two-interval forced-choice task. Such predicted values of percent correct appear on the horizontal axis in Fig. 8(a).

C. Results

The comparison between the discrimination responses of Experiment 3 and the predictions are shown in Fig. 8(a) for the five listeners. The predictions were successful to some degree because almost all of the data points fell into the upper-right and lower-left quadrants of the plot. Points in the low-left quadrant correspond to systematic discrimination errors and show that the confusions in identification caused by the bright spot reappear in discrimination.

The shape of the predictions in Fig. 8(a) is different from the responses. The predictions were on a continuum from 0% to 100% correct. The responses tended to be bimodal. Evidently listeners were much more certain about whether one source was to the right or left of another than they were about the absolute locations of the two sources involved. Informally, listeners remarked that the discrimination task seemed easier than the identification task.

The discrepancy between the actual and predicted results in Fig. 8(a) is unlikely to be the result of technical error. As per Moore *et al.* (2008), who obtained a good correspondence between identification and discrimination, values of μ and σ in Eq. (1) were taken from source-dependent behavioral data. The problem is likely that the values of σ were

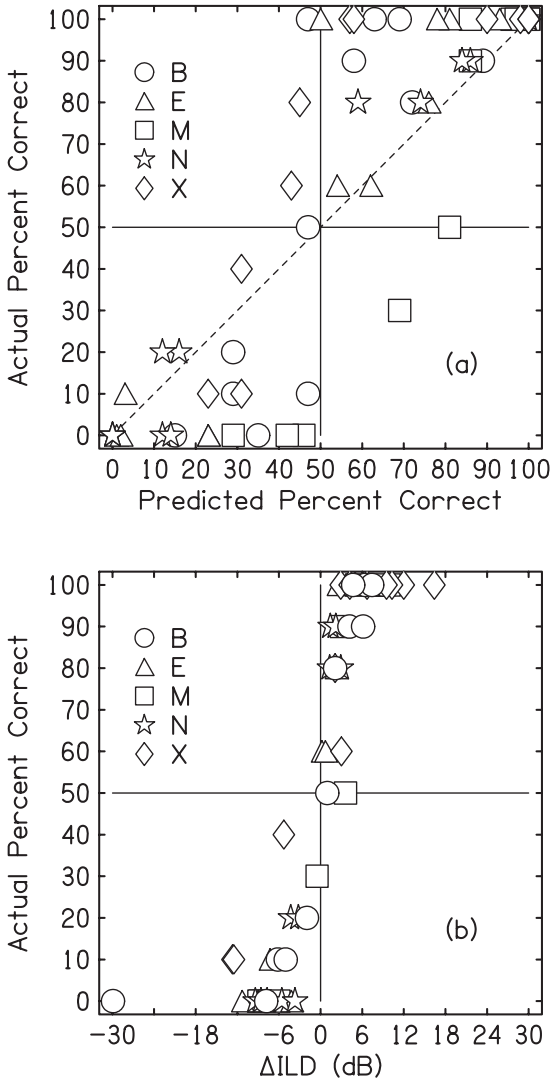

FIG. 8. Experiment 3, Discrimination. (a) The predicted percent correct and the actual percent correct are plotted against each other for the five listeners. Predicted values were based on individual identification data from Experiment 1. (b) Same as part (a) except that the actual percent correct is plotted against the change in ILD between the greater and lesser source numbers.

obtained from identification experiments that covered a wide angular span. As noted by Shelton and Searle (1978), the standard deviation in identification experiments grows with both azimuth and with angular span. The effect was modeled by Hartmann and Rakerd (1989) as a sensory bias, which may rove in an experiment that is extensive over both azimuth and time. The increased standard deviation in identification would lead to a continuous form of the predicted results, as in Fig. 8(a).

In addition to sensory bias, the identification experiment may have suffered from a peculiar form of response bias. Subjects who know that there are 13 sources may expect to perceive all 13 over the course of an experiment. When many trials have occurred, and all of them point to only half of the sources, subjects may try to compensate. Response bias like this is one way to account for the scatter of data in the (a) parts of Figs. 3–7, particularly for listeners B, M, and X. These are the listeners whose data depart most dramatically from the 45° line in Fig. 8(a).

An alternative to a discrimination prediction based on identification data is a prediction based on physical data. Figure 8(b) shows the comparison between the discrimination responses and the change in ILD between the two sources. A comparison with Fig. 8(a) indicates that the change in ILD, especially the sign of the change, is a much better predictor of discrimination than is the identification performance. Only when the change in ILD was less than about 4 dB did the listeners tend to give ambiguous responses.

V. EXPERIMENT 4: AMPLITUDE MODULATION

Experiment 4 was an identification experiment like Experiment 1, except that the tone was given 100% amplitude modulation (AM) with a modulating frequency of 100 Hz. The temporal window for the AM tone was the same as for Experiment 1.

The motivation for the experiment was that the envelope of AM tones provides a temporal pattern that enables the binaural system to use ITDs, even at a relatively high frequency such as 1500 Hz (Henning, 1974; McFadden and Pasanen, 1976; Stellmack *et al.*, 2005). The 100-Hz modulation frequency was well below the 800-Hz limit found in the superior olive by Joris and Yin (1998) and in references contained therein. The 200-Hz bandwidth is close to the auditory filter width at 1500 Hz, measured by Glasberg and Moore (1990). The listeners for previous experiments were listeners in Experiment 4.

A. Results

The results of Experiment 4 are shown for the five listeners by individual plots, showing response number vs source number in Fig. 9(a). The figure shows that the responses for listeners B, N, and X became monotonic functions of azimuth or nearly so. However, the responses for listeners E and M remained non-monotonic. As shown in Table I, the correlation between response and source numbers was 0.98 or greater for listeners B and N. Although listener E's responses remained non-monotonic, the correlation increased considerably, compared to Experiment 1, an increase from 0.29 to 0.82. By contrast, the addition of AM led to no change in the responses of listener M by any of our measures.

VI. EXPERIMENT 5: NARROW-BAND NOISE

In Experiment 5, the sine tone of Experiment 1 was replaced by a narrow-band noise (NBN). Again, the motivation for the experiment was to determine if temporal features in the envelope of the stimulus could provide an ITD cue that would enable localization at large azimuth. It might be expected that NBN would be more effective than AM because of the wider range of envelope-variation frequencies.

The experiment used equal-amplitude, random-phase noise with a spectrum consisting of 201 components spanning the range 1400–1600 Hz. Therefore, the bandwidth was the same as for Experiment 4. There were actually 13 different noises, based on different phase randomizations, selected

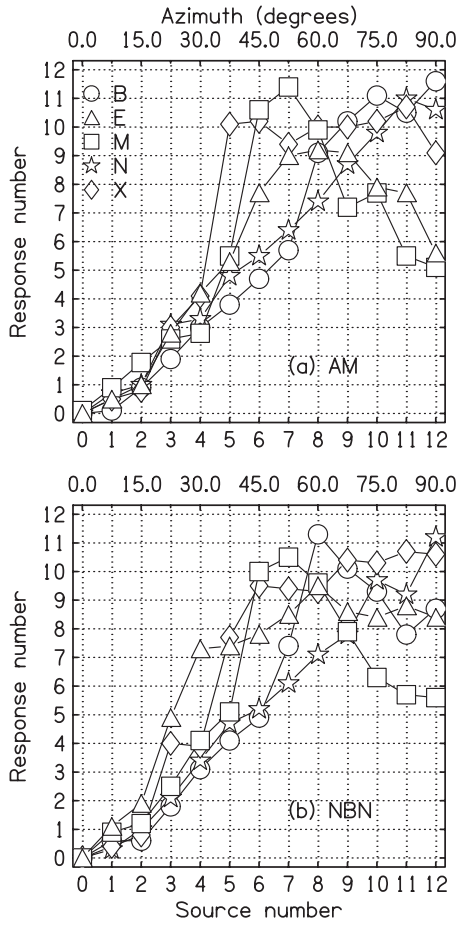

FIG. 9. (a) Experiment 4, AM: Listener identification responses on the scale 0–12 to sources as numbered on the horizontal axis for five listeners. The stimulus was a 1500-Hz sine tone amplitude modulated by a 100-Hz sine tone. (b) Experiment 5, NBN: Same as (a) except that the stimulus was a 200-Hz band of noise centered on 1500 Hz.

randomly for each experimental trial. The temporal window for the noise was the same as for Experiment 1. The same listeners participated.

A. Results

The results of Experiment 5 (NBN) are presented in Fig. 9(b), which can be compared with Experiment 4 (AM) in Fig. 9(a). The data for listeners N and X look very similar for AM and NBN, which was the expected result. Compared to the results for AM, the results for listener E became more monotonic, and the results for listener B became less. Listener M was no more aided by NBN than by AM. His results were unchanged by any measure. Table I shows that the correlations between listener responses, and source numbers were similar in Experiments 4 and 5.

The experiments incorporating AM or NBN show that for most of the listeners, the temporal structure in the envelope can be used to solve the localization problem given an ambiguous ILD. [Experiments by Eberle *et al.* (2000) suggest that there would be little value in attempting to combine NBN with AM to obtain additional time structure.] However, for some listeners, listener M in particular, the timing information in the envelope proved to be insignificant, compared to the ILD cue.

VII. DISCUSSION AND CONCLUSION

The experiments of this article demonstrated the importance of the information, and misinformation, contained in the ILD for medium-frequency pure tones such as 1500-Hz pure tones. Experiment 1 showed that the non-monotonic ILD, predicted by the bright-spot theory and the spherical-head model, occurred for real listeners, and that it led to a parallel non-monotonic perception of azimuth in a source-identification experiment. Experiment 2 showed that the misleading effects of the non-monotonic ILD were not alleviated by training the listeners nor by giving them feedback after every trial. Experiment 3 showed that the confusion indicated in the identification experiments translated to predictable confusion in the discrimination experiments. However, the ILD values themselves were better predictors of discrimination performance than were the results of identification experiments, because the discrimination experiments showed smaller within-subject variability than the identification experiments. The increased variability in identification could be attributed to both sensory bias and response bias.

A foreshadowing of the bright-spot effects seen in Experiments 1–3 on pure tones appeared in the discrimination experiments by Mills (1958, 1972). Mills measured the minimum audible angle (MAA) as a function of reference angle and frequency with the following results.

- For reference angles in the forward direction (azimuth 0), the MAA demonstrated a familiar behavior: For low frequencies, the MAA was matched by the just noticeable difference (JND) in ITD, as measured by headphone experiments. When the frequency increased to 1500 Hz, the MAA (about 3°) was matched by the JND in ILD, indicating that the ITD had lost its effectiveness.
- When the reference azimuth increased to 30°, the MAA between 1500 and 4000 Hz increased to about 6°, but was otherwise well behaved, indicating that the ILD provided a useful cue.
- However, when the reference angle increased to 60° or 75°, the MAA went off the chart as the frequency rose to 1500 Hz. In Mills' own words, "for tones between 1500 and 2000 Hz, from sources at azimuths of more than 45°, the minimum audible angle is indeterminately large."

The anomalous behavior reported by Mills finds a ready explanation in the calculations, measurements, and perceptual consequences of the bright spot, as reported in the present article. It is exactly these frequencies and these reference azimuths, where the ILD is a decreasing function of azimuth. The more the source moves to the right, the more the listener hears it to the left. Discrimination measurements like the MAA are bound to fail under such conditions, as shown by the results in Experiment 3 above.

The results of Experiments 1–3 have implications for the duplex theory of pure-tone localization. According to the version of duplex theory by Stevens and Newman (1936), there are three frequency regions. In a low-frequency region, below about 1 kHz, localization is cued by the ITD. In a high-frequency region, above 4 kHz, localization is cued by the ILD. In a middle region, extending from about 1 to 4 kHz, neither ITD nor ILD is an effective cue. Stevens and Newman based this viewpoint on localization experiments that showed a broad peak in localization error, centered on 3 kHz. Errors were notably smaller when the frequency increased to 4 or 5 kHz. These experiments measured localization errors over the full 180° from front to back, around the right side of the listener. Therefore, these experiments encountered the angles and the frequencies where the experiments of the present article find that ILD is a non-monotonic function of azimuth. This non-monotonic behavior above 1 kHz leads to large localization errors. We suggest that Stevens and Newman would have found very different results if they had limited their localization task to azimuths within 40° of the midline. ILDs in the region from 1 to 4 kHz can be large enough to support good localization near the forward direction, with errors much smaller than reported by Stevens and Newman.

It is possible that a localization experiment that avoided the azimuthal region of non-monotonic ILD would find that the midfrequency region identified by Stevens and Newman (also observed by Mills) would disappear. Alternatively, a region of relatively poor localization might emerge centered near 1 kHz because of the peak in ILD difference limen observed by Grantham (1984). Grantham speculated that this peak reflected a greater localization utility for interaural cues at frequencies, both above and below 1 kHz. Frequencies above 1 kHz are useful because of the increased ILD; frequencies below 1 kHz are useful because latency in peripheral neurons converts an ILD into an ITD.

A different explanation for the 1-kHz peak observed by Grantham is also based on localization utility. Figure 1 suggests that near 1 kHz, non-monotonic ILDs are present at rather small azimuths, 40° to 50°. Even smaller azimuths would be expected from more realistic models of the human head. At frequencies well above 1 kHz, the non-monotonic behavior is much more dramatic, but it occurs only for larger azimuths. One can speculate that azimuths within 45° of the midline are particularly important, and that binaural development has been influenced by the unreliability of ILDs at these relatively small azimuths and at frequencies near 1 kHz.

An anonymous reviewer of this article pointed out that the non-monotonic ILD caused by the bright spot has implications for front-back localization. Normally, a listener is able to resolve front-back ambiguities by rotating the head slightly because rotation causes the ILD to change in a way that favors the ear that is approaching the source (Wallach, 1939, 1940; Perrett and Noble, 1997). However, if the ILD is a decreasing function of the azimuth, the sign of the ILD change will be reversed, thus cueing the front direction when the source is in the back and vice versa. For a frequency of 1500 Hz, this kind of reversal would be expected for all sources having a lateral angle of 55° or more (e.g., 65° azimuth vs 115°).

Experiments 4 and 5 modified the stimulus by adding temporal structure to the envelope of the tone, which significantly reduced the confusion in source identification on the

average. However, the effectiveness of the temporal structure varied. For different listeners, it ranged from completely effective to not-at-all effective.

The modulated pure tone is a stimulus with two localization cues, the ILD in the entire tone, and the ITD in the envelope modulation. Experiments 4 and 5 indicated that different listeners weight these two cues differently. This observation is consistent with a general model of sound localization, wherein different, possibly conflicting, localization cues arrive at a central processor in the nervous system where they are combined to form a localized image. The process of weighting and combining the cues is normally entirely subconscious. A model of localization or lateralization that depends on idiosyncratic central weighting of cues has long been a possible interpretation of ITD-ILD trading experiments (e.g., Hafter and Carrier, 1972). Survey experiments by McFadden *et al.* (1973) found an anomalously large sensitivity for one of these cues or the other in 50% of the population, and of these, 75% were more sensitive to the ILD. The failed attempts to retrain listeners described by Jeffress and McFadden (1971) indicate that, although the weighting is not necessarily hard wired, it is very resistant to change. The central weighting hypothesis gained practical value in connection with experiments on the localization of sound in rooms, where standing waves lead to conflicting cues (Hartmann, 1983; Rakerd and Hartmann, 1985). Such a central model of cue combination would seem to apply to the highly individualized weighting of cues observed in Experiments 4 and 5.

[1]The calculations are from the low-frequency limit of the diffraction formula, where the ITD is given by $(3r/c)\sin\theta$, where r is the radius of the head, c is the speed of sound, and θ is the azimuth with respect to the forward direction (Kuhn, 1977).

[2]The classic optical bright spot is at the center of a shadow cast by the sphere on a screen. A bright spot on the dark surface of the sphere itself is caused by the same physics—constructive addition of diffracted waves at a symmetry point.

[3]Because a sine tone, as used in these experiments, conveys so little localization information, a listener's association of an ILD cue with a location in the horizontal plane occurs partly because the listener can see sources in that plane. Because of the cone of confusion, or the equivalent for real heads, many other source locations would also correspond to a given ILD cue.

(Received 27 June 2009; revised 24 November 2009; accepted 15 December 2009)

An experiment was performed that measured, for the frontal audio-visual horizon, how accurately listeners could localize a female-voice target amidst four spatially distributed male-voice maskers. To examine whether listeners can make use of *a priori* knowledge about the configuration of the sources, performance was examined in two conditions: either the masker locations were fixed (in one of five known patterns) or the locations varied from trial to trial. The presence of maskers disrupted speech localization, even after accounting for reduced target detectability. Averaged across all target locations, the rms error in responses decreased by 20% when *a priori* knowledge about masker locations was available. The effect was even stronger for the target locations that did not coincide with the maskers (error reduction of 36%), while no change in errors was observed for targets coinciding with maskers. The benefits were reduced when the target-to-masker intensity ratio was increased or when the maskers were in a pattern that made it difficult to make use of the *a priori* information. The results confirm that localization in speech mixtures is modified by the listener's expectations about the spatial arrangement of the sources.

I. INTRODUCTION

It is known that spatial factors play a role in the ability of listeners to understand speech in noisy or complex listening environments. For example, acoustical advantages are provided by the spatial separation of speech from competing noise (Zurek, 1993; Bronkhorst, 2000). In the case of multiple competing talkers, it is believed that spatial differences also enable the correct "sorting" of the acoustic mixture into different sources and enable listeners to direct attention selectively to one source to enhance its processing (Yost *et al.*, 1996; Freyman *et al.*, 1999; Brungart, 2001; Shinn-Cunningham, 2008). In addition, the ability to rapidly locate a talker of interest in order to focus on them visually is clearly an important aspect of human communication. Despite the various roles of spatial hearing in dealing with competing speech sources, we know surprisingly little about how accurately listeners can localize in speech mixtures.

Under ideal conditions, humans can localize single broadband sounds within a few degrees of accuracy (Mills, 1958; Wightman and Kistler, 1989; Carlile *et al.*, 1997; Best *et al.*, 2005). When presented against a background of noise, localization does not suffer until the signal-to-noise ratio is negative, due in part to the fact that the *detection* of the target becomes compromised (Good and Gilkey, 1996; Good *et al.*, 1997; Abouchacra *et al.*, 1998; Lorenzi *et al.*, 1999). Few studies have examined more complex situations involving multiple talkers (for a summary see Faller and Merimaa, 2004). Hawley *et al.* (1999) measured localization of a known target sentence in the presence of one to three unknown sentences. Their task was a 1-of-7 loudspeaker identification (30° spacing), and they found that performance was relatively accurate (around 70%) and not affected significantly by the number or configuration of the maskers. In a similar paradigm with one to four distractors, Drullman and Bronkhorst (2000) found poorer performance (around 50%) for a 1-of-5 loudspeaker identification task (45° spacing). Finally, Simpson *et al.* (2006) required listeners to detect and localize a known word in a mixture of one to five synchronous words. The number and configuration of the maskers were varied from trial to trial. The authors found that localization errors increased systematically with the number of maskers even when miss trials (where the subject could not detect the target) were excluded from the analysis.

Few previous studies asked whether providing *a priori* information that can be used to direct automatic or strategic attention can improve sound localization (Spence and Driver, 1994; Sach *et al.*, 2000; Kopčo *et al.*, 2001). In these studies, the effect of cuing the target location was small: improvements in reaction times were observed (Spence and Driver, 1994), but little (Sach *et al.*, 2000) or no (Kopčo *et al.*, 2001) improvement in localization accuracy was found. A possible explanation for these weak effects is that the target was presented in isolation, and thus a lot of redundant information about its location was available. More complex scenes, in which sources compete for attention, may be more likely to reveal effects of *a priori* information.

The current study aimed to examine, in a realistic, complex listening situation containing competing sound sources, whether *a priori* knowledge of the location of maskers might

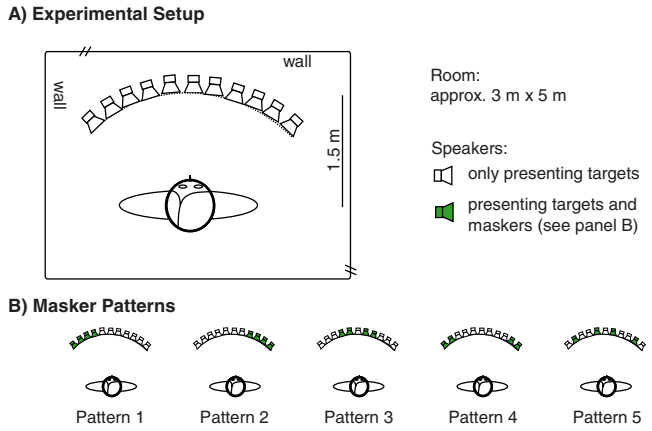

FIG. 1. (Color online) (A) Eleven loudspeakers evenly spaced in front of the listener (10° separation) were used to present stimuli. (B) Maskers were presented from loudspeaker locations arranged into one of five masker patterns. Each pattern had four maskers, presented concurrently with the target.

modify how they affect target localization performance. To this end, we measured the accuracy with which listeners can localize a speech target presented from a random location in the presence of four speech maskers. While all maskers were spatially separated from each other, targets could occur anywhere (including at masker locations). The maskers were presented in one of five masker patterns (see Fig. 1). In separate blocks, we either varied the masker pattern randomly from trial to trial (Mixed condition) or kept one of the masker patterns fixed throughout a block, providing the subject with information about the maskers' locations at the beginning of the block (Fixed condition). We expected that subjects would be able to use the masker location information in the Fixed condition to improve their localization performance (with regard to Mixed condition). For example, by actively suppressing the masker locations or actively attending away from masker locations, performance might improve for targets at nonmasker locations (but perhaps worsen for targets colocated with maskers).

The second goal of this study was to examine whether the extent to which *a priori* information can be utilized is influenced by the complexity of the masker distribution. Therefore, we included two simple masker configurations (patterns 1 and 2 in Fig. 1, in which all masker locations and all nonmasker locations were clustered together), two intermediate configurations (pattern 3, in which the masker locations were in one cluster while the nonmasker locations were in two clusters, and pattern 4, with the opposite arrangement), and one complex configuration (pattern 5, in which both the masker and the nonmasker locations were approximately evenly distributed). We expected the benefit of *a priori* knowledge to be larger for the simpler configurations, based on the assumption that spatial attention or masker suppression can be more efficiently applied to a single region than to multiple regions.

II. METHODS

A. Subjects

Seven subjects participated, one female and six males between the ages of 18 and 50 years. All had normal hearing by self-report and gave informed consent as required by the University of Sydney's Human Research Ethics Committee.

B. Environment, stimuli, and setup

The experiment took place in an empty office of dimensions $3 \times 5 \times 2.5$ m (width × length × height). The room had carpet on the floor, a concrete ceiling, and plasterboard on the lateral and back walls. The front wall was exposed brick and contained a large window that was filled with thick wool matting to reduce reflections and block out most of the incoming light; as a result visibility of the loudspeakers was minimal. Eleven loudspeakers on stands were positioned with a spacing of 10° to form a horizontal arc of radius 1.5 m [Fig. 1(A)] at the level of an average listener's ears when standing (1.6 m). The target was presented from 1 of the 11 loudspeakers at random. On masker trials, four simultaneous maskers were arranged in one of five configurations [Fig. 1(B)]. Listeners were aware that targets could fall on masker locations.

Speech materials were taken from a corpus of monosyllabic words recorded at Boston University's Hearing Research Center (Kidd *et al.*, 2008a). The target was the word "two" spoken by one of the female voices in the corpus. Maskers were nondigit words spoken by the eight male talkers in the corpus, and included names (e.g., "Jane"), verbs (e.g., "found"), adjectives (e.g., "red"), and nouns (e.g., "toys"). The four masker words were drawn randomly from this set with the constraints that they were four different words spoken by four different male voices. On catch trials (see below), the target was replaced by another randomly chosen masker word.

The maskers were all longer in duration than the target, and because they were spoken by male talkers they generally had a broader spectrum than the target. Thus, they did not provide substantial spectral or temporal gaps in which the listener could have a good "glimpse" at the target (as would be the case if the target and maskers were sentences containing natural silent breaks). On the other hand, keeping the target word fixed made the task of identifying the target easier than in natural situations in which the word spoken by the target speaker varies continuously (as do acoustic, phonetic, prosodic, and other characteristics of the utterance). This as well as the difference in gender between the target and the maskers enabled listeners to focus on localizing the target accurately without any ambiguity about which sound to localize.

Target words were presented at a level of approximately 60 dB SPL(A). Maskers were all equal in level, but presented at one of two levels relative to the target in order to vary the difficulty of the task. In the easier task, each masker was equal in level to the target [target-to-masker ratio (TMR) of 0 dB]; in the more difficult task, each masker was 5 dB louder (TMR of −5 dB).

The experiment was run in MATLAB on a PC-compatible control computer. On each trial, the appropriate stimuli were loaded from files stored on the computer hard disk (at a sampling rate of 48 kHz) and sent via a multichannel soundcard (RME Fireface 400), D/A converter (Apogee DA-16x),

and amplifier (Ashley Powerflex 6250), to Tannoy V6 loudspeakers.

Subjects indicated their responses by pointing their head in the perceived direction of the target and pressing a handheld response button. A headtracker (Intersense IC3) mounted on a plastic headband was used to measure the orientation of the head at the time of response.

C. Procedures

Before a session, the experimenter positioned the subject such that he/she was in the center of the loudspeaker array with his/her head pointing to 0° azimuth, and this location was recorded by the headtracker as the reference position. Before the stimulus was played on each trial, the subject was required to orient their head to this position and feedback was given by way of a small light-emitting diode display positioned above and behind the speaker array.

In runs containing maskers, it was expected that there would be a number of trials in which the listener would not be able to detect the target, and localization responses would either be to one of the masker locations or to some random location. To avoid these trials affecting the localization data, listeners were instructed to give a specific response if they did not detect the female target (miss trials). This response was to point to a location directly above the head—a response that was easily distinguished from regular localization responses that all had an elevation component on or near 0° (on the audiovisual horizon). To ensure that listeners were following this instruction, a number of catch trials were included in which the target was replaced by another random male masker, and thus false alarm rates could be monitored.

Control runs consisted of 55 trials (5 trials per target location). In masker runs, five catch trials were also included and thus these runs were 60 trials long. Each session consisted of 12 runs. The first and last of these were control runs with no maskers present. In five runs the masker pattern was kept fixed (Fixed) for the duration of the run. Each run used one of the five masker patterns, and the pattern was indicated at the start of the run by presenting a recording of the phrase "fixed maskers" sequentially at each of the four masker locations. In the remaining five runs the masker pattern was randomly chosen on each trial (Mixed) and the run was preceded by a presentation of the phrase "mixed maskers." The Fixed and Mixed runs were interleaved. Each subject completed four sessions, two at each TMR.

III. RESULTS

A. Control data

Figure 2 plots rms errors relative to the mean response to a single unmasked target as a function of location. Separate lines are shown for the control runs of the 0 dB TMR sessions and of the −5 dB TMR sessions (although the target level did not change). rms errors were consistent across the two masker sessions, growing with target laterality from about 2° to 5°. Also, there was a slight asymmetry in errors; on the left-hand side, rms errors grew approximately linearly with target eccentricity, whereas on the right-hand side the growth was initially steep (resulting in noticeably larger errors for the +30° and +40° targets compared to the −30° and −40° targets) and then leveled off (at +50°). This asymmetry could be related to minor asymmetries in the experimental setup or the room acoustics (even though the room was mostly left-right symmetric) or it could suggest that there is some perceptual asymmetry in speech localization.

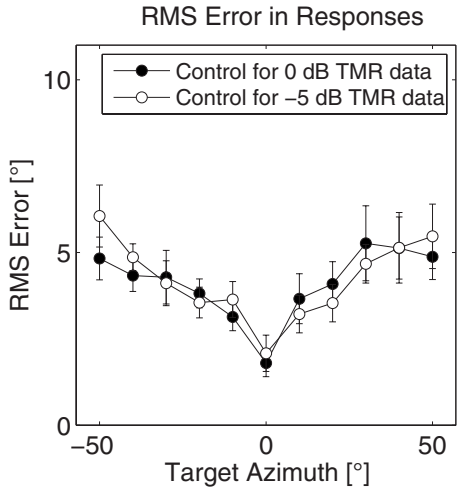

FIG. 2. Localization performance in the control condition with no maskers. Plotted are across-subject averages (±1 SEM) of the rms error as a function of the target location. Results are plotted separately for the two TMR sessions even though the target level was identical.

B. Miss rates and false alarms

Table I shows mean miss rates and false alarm rates for the two masker conditions (Fixed and Mixed). Miss rates and false alarm rates were larger at −5 dB TMR than at 0 dB TMR but were relatively low overall. It was especially important that the false alarm rate was low, as this was our indicator that subjects were reliable at indicating that they did not hear the target (and thus that they were unlikely to give random localization responses). Note that only five catch trials were included in each experimental run, and thus the false alarm rate of 20% observed at the −5 dB TMR corresponds to just one false alarm per run. It is hard to estimate the impact this nonzero false alarm rate has on performance. However, importantly, miss rates and false alarm rates were similar for Fixed and Mixed conditions, meaning that differences between these conditions were unlikely to be attributable to differences in detection criteria.

TABLE I. Detection performance averaged across subjects, masker patterns and masker locations. Miss rate shows the percentage of trials on which the target was presented but not heard (out of 55 trials per run). False alarm rate shows the percentage of catch trials (out of five trials per run) on which no target was presented but the subject gave a localization response indicating that he/she heard a target.

	Miss rate (%)		False alarm rate (%)	
Masker condition	TMR 0 dB	TMR −5 dB	TMR 0 dB	TMR −5 dB
Fixed	1	8	5	21
Mixed	1	9	8	19

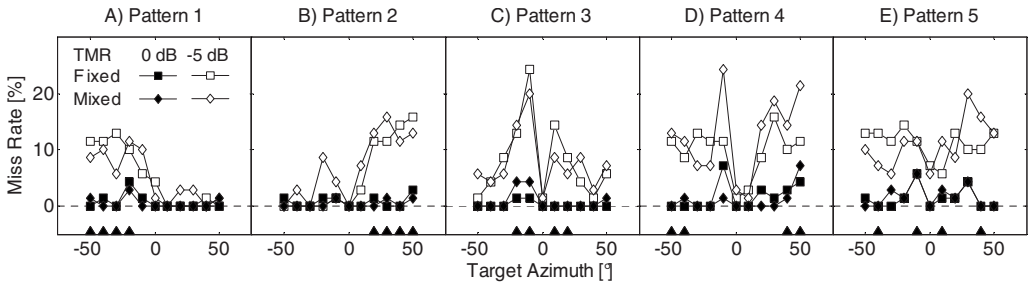

FIG. 3. Across-subject average of the miss rate (percentage of trials on which target was presented but not heard) as a function of target location. Each panel shows data for one masker pattern (masker locations indicated by the filled triangles along the abscissa), separately for all combinations of the Fixed and Mixed conditions and of the 0 and −5 dB TMR. Mean miss rates collapsed across target locations are shown in Table I.

Figure 3 shows the miss rate as a function of target location for TMRs of 0 dB (filled symbols) and −5 dB (open symbols). The five panels show data for the five different masker patterns. Misses were more common for targets falling on masker locations (or within one loudspeaker from a masker) and very rare elsewhere. This effect, and its exaggeration at the lower TMR, is likely to be an effect of energetic masking, where colocated maskers simply reduce the audibility of the target.

C. Effects of masking and *a priori* information on rms errors

Figure 4 shows the effect of maskers on rms errors for each target location. For each subject, rms errors in the control condition (see Fig. 2) were subtracted from rms errors in the different masker conditions[1] and plotted are the across-subject means of these differences. The two rows show data for the two TMRs, and the five columns show data for the five different masker patterns.

The effect of masking on rms errors depended in a complex way on all four parameters manipulated in this study, resulting in increases as large as 15° [patterns 4 and 5, Figs. 4(I) and 4(J)]. Overall, the presence of maskers always resulted in an increase in error, even at 0 dB TMR (all data points are positive in Fig. 4). It appears that the rms errors tended to increase most at target locations that corresponded to masker locations. Moreover, the largest increases occurred for masker patterns 4 and 5, the patterns in which the maskers were distributed so that they did not form one group. Lowering the TMR resulted in an approximately constant increase in rms error across all patterns.

Increases in rms error were not perfectly left-right symmetric for the symmetrical patterns 3–5 or for patterns 1 vs 2 which are mirrored versions of one another. The asymmetry appears to parallel that seen in the control data (Fig. 2), where errors are slightly higher on average for targets on the right. It is difficult to determine from these results whether such asymmetries are perceptual or reflect asymmetries in the setup and the room. The main effects of interest here (like the differences between the Fixed and Mixed performance) did not appear to be influenced by this asymmetry.

Figure 4 shows that the effect of maskers on rms errors also depended on whether the masker locations were fixed or mixed within a run. For example, for pattern 1 at the poorer TMR [Fig. 4(F)], rms errors were larger in the Fixed condition when the target was presented from the left, but were larger in the Mixed condition when the target was presented from the right. In general there was a tendency for a transition such as this to occur at or near the boundary between masker regions and nonmasker regions.

Figure 5(A) provides a summary by showing the increase in the rms error in localization responses (relative to

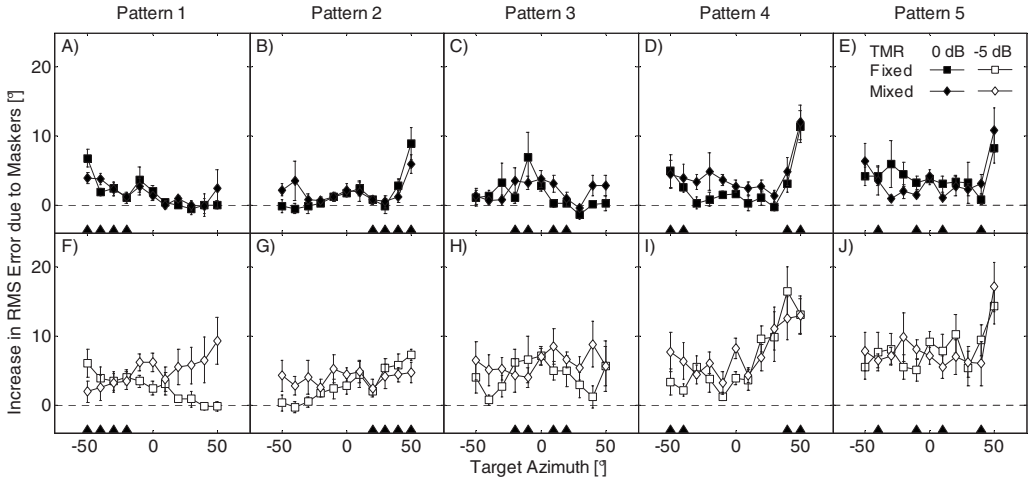

FIG. 4. Across-subject average (±1 SEM) of the increases in response rms errors (*re.* the control condition) as a function of the target location. Each column of panels shows the Fixed and Mixed condition data for one masker pattern (masker locations indicated by the filled triangles along the abscissa) and for the TMR of 0 dB (upper panels) and −5 dB (lower panels).

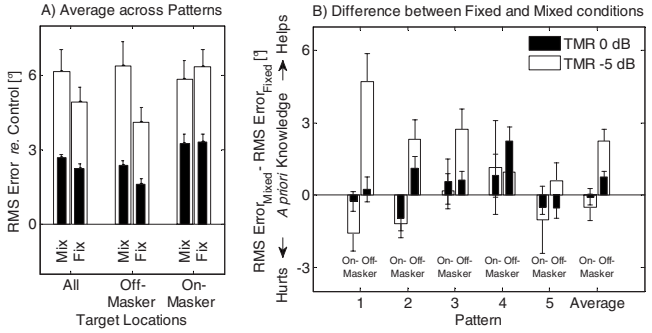

FIG. 5. (A) Effect of the maskers on localization accuracy shown as the increase in rms error in the responses to masked targets (*re.* rms error in the no-masker control condition) averaged across all patterns and across either all target locations (all), across the target locations from which no masker was presented for a given masker pattern (off-masker), or across the target locations from which a masker was presented for a given pattern (on-masker). Data are plotted separately for the Fixed and Mixed conditions and the two TMRs. (B) Effect of *a priori* knowledge on localization accuracy. The difference between rms errors in the Fixed and Mixed conditions is plotted separately for the on-and off-masker locations of each pattern and for the across-pattern average. All bars show the across-subject average (±1 SEM).

the rms error in the control condition) averaged across masker patterns. Data are averaged across all target locations (All), across the locations at which the target was not colocated with a masker (off-masker), and across the locations at which the target was presented with a colocated masker (on-masker). Separate bars represent the Fixed and Mixed conditions and the two different TMRs.

Averaged across all target locations, the reductions in the rms error in the Fixed condition with regard to the Mixed condition were 15% at 0 dB TMR and 20% at −5 dB TMR [see the filled and open "All" bars in Fig. 5(A)]. When only the off-masker target locations were considered, the effect of *a priori* knowledge was even larger, reducing the rms errors by approximately 31% at 0 dB TMR and by approximately 35% at −5 dB TMR ["Off-Masker" bars in Fig. 5(A)]. On the other hand, the availability of *a priori* information had a modest effect on the on-masker targets, increasing the rms errors by approximately 2% at 0 dB TMR and by approximately 9% at −5 dB TMR ["On-Masker" bars in Fig. 5(A)].

Figure 5(B) evaluates the effect of *a priori* knowledge directly by showing the difference between the Mixed and Fixed condition rms errors as a function of the masker pattern (including the across-pattern average), separately for the on- and off-masker locations. At the off-masker locations, *a priori* information provided a benefit for all masking patterns at −5 dB TMR and a smaller and less consistent benefit at 0 dB TMR. At −5 dB TMR, the largest benefit was observed with patterns 1–3 and at 0 dB TMR the largest benefit was for pattern 4. At both TMRs, the smallest off-masker benefit of *a priori* information was observed for masker pattern 5. At the on-masker locations, no consistent effect of *a priori* knowledge was observed.

These results were confirmed by submitting the data from Fig. 5(B) to a three-way repeated measures analysis of variance (ANOVA), with the factors of target location (on-masker vs off-masker), masker pattern (1–5) and TMR (0 and −5 dB). This ANOVA found a significant main effect of the target location and of the TMR, as well as a significant three-way interaction between the factors (Table IIA). Additional two-way ANOVAs were performed separately on the on-masker and off-masker data (Table IIB). No significant main effect or interaction was found for the on-masker data, while all main effects and interactions were significant for the off-masker data, confirming the trends shown in Fig. 5(B).

IV. DISCUSSION

A. Impact of maskers on detection and localization

One effect of presenting a speech target in the presence of four concurrent speech maskers was a reduction in the detectability of the target, as evidenced by the presence of miss trials (Table I), particularly at the poorer TMR. This was not surprising, given that concurrent speech maskers are well known to cause energetic and informational masking, both of which impede detection. We saw more misses for

TABLE II. (A) Three-way repeated measures ANOVA on the differences between the rms errors in the Mixed vs Fixed conditions (location × pattern × TMR). (B) Two two-way ANOVAs performed on the same data, but separately for the on-masker and off-masker locations (pattern × TMR).

on-masker locations (Fig. 3) consistent with previous studies showing greater masking for colocated stimuli whether the task is detection (Simpson *et al.*, 2006; Balakrishnan and Freyman, 2008) or intelligibility (Bronkhorst, 2000; Brungart, 2001; Freyman *et al.*, 2001; Arbogast *et al.*, 2002).

In most previous studies that examined localization in the presence of maskers, disruptions to localization could largely be explained in terms of such reductions in detectability (Good and Gilkey, 1996; Good *et al.*, 1997; Lorenzi *et al.*, 1999). In the present study, however, localization performance was only measured for trials in which listeners reported to have heard the target (see also Simpson *et al.*, 2006). Using this approach, we still found that target localization was strongly degraded by the presence of the speech maskers. The maskers increased rms errors, depending on the configuration of the target and maskers and the TMR. The presence of false alarms on the catch trials (Table I) suggests that some of these effects may be a result of the listeners' tendency to respond and indicate a (probably random) target location even on trials on which they did not hear the target. However, these false alarms were very rare in the 0 dB TMR condition, and this condition gave rise to qualitatively similar patterns of results to the −5 dB TMR condition. Thus we are confident that random responses had only a minor impact on the results. Another possibility is that listeners would on occasion erroneously attribute the location of a masker to the target. It is likely that this "feature-binding" confusion would be more of a problem at the lower TMR where the target voice is more poorly segregated from the mixture and hence less distinct.

We compared the overall effect of maskers on speech localization in our study to that reported by Simpson *et al.* (2006). On average, our listeners showed rms errors of 7° in the control condition and 13° in the Mixed condition at 0 dB TMR. In a similar condition, with four different-sex maskers at 0 dB TMR, Simpson *et al.* (2006) reported rms errors (in the left-right dimension) of 8° in the control condition and 14° in the mixture case. This good correspondence in performance between our subjects and those of Simpson *et al.* (2006) suggests that the fact that our study was conducted in a reverberant office (rather than in an anechoic environment) did not increase errors in quiet or in a mixture. This was somewhat surprising given that reverberation has been shown to affect the segregation of competing speech sounds (Lavandier and Culling, 2007) as well as the localization of one sound in the presence of another (Braasch and Hartung, 2002; Kopčo *et al.*, 2007) in other studies using simpler stimuli.

B. Effects of *a priori* information on localization

Many previous studies have demonstrated detrimental effects of stimulus uncertainty on target detection and identification in complex auditory mixtures (for review, see Kidd *et al.*, 2008b). Most of these studies have examined spectral or temporal uncertainty in the target or the masker(s). A handful of studies that examined uncertainty in the spatial domain found that within- or across-trial variability in the target location can disrupt intelligibility (Kidd *et al.*, 2005; Brungart and Simpson, 2007; Best *et al.*, 2008). Variability or uncertainty in masker location, on the other hand, appears to have only a minor effect on target detection for the case of simultaneous noises (Fan *et al.*, 2008) and no effect at all on target intelligibility in the case of competing sentences (Jones and Litovsky, 2008). Furthermore, previous studies of spatial cuing for simple sound localization tasks have not found robust benefits (Spence and Driver, 1994; Sach *et al.*, 2000; Kopčo *et al.*, 2001).

The main hypothesis examined in this study was that the disruptive effect of maskers on speech localization in a multitalker mixture would be mitigated by providing the listener with *a priori* information about the masker locations. The rationale was that attentional processing may become important for localization in complex environments in which there is strong competition for processing resources. Consistent with this hypothesis, we found that the rms error was reduced by approximately 0.5° (or 15%) at 0 dB TMR and by 1° (or 20%) at −5 dB TMR.

We also predicted that the benefit of *a priori* information would be more pronounced for the off-masker target locations. In fact, we found that all of the benefit was restricted to the off-masker locations, at which the error was reduced by approximately 1° (or 31%) at 0 dB TMR and by approximately 2° (or 35%) at the −5 dB TMR. The improvement in performance for the off-masker targets is likely due to reassignment of processing resources to the off-masker locations (away from the known masker locations). However, the observed recovery from masking was not complete, showing that factors outside listener's strategic control also limited performance. These factors likely include direct acoustic interference of the competing sounds with the target sound and limitations in the binaural system's abilities to extract the relevant acoustic cues.

Another hypothesis was that the listeners would benefit more from the *a priori* information about the masker locations if the masker distribution was simple. This hypothesis was confirmed only partially. As expected, the smallest benefit was observed for pattern 5, where maskers were most distributed, thus making it difficult to strategically allocate attention to (or away from) a particular region. Interestingly, for the remaining patterns, the size of the benefit of *a priori* information depended on the TMR. At 0 dB TMR, the largest benefit was observed for pattern 4, whereas at −5 dB TMR the largest benefit was provided for patterns 1–3. While this result makes it difficult to identify the strategy employed by the listeners, it suggests that the strategy might change as the difficulty of the task increases.

C. Potential mechanisms

As a final note, it is worth considering the mechanisms that might underlie sound localization in a complex speech mixture, with a view to understanding both the impact of maskers on accuracy and the moderating influence of prior knowledge about the their spatial arrangement.

Faller and Merimaa (2004) proposed a model that showed that the robust localization of sounds in the presence of distractors reported in previous studies (e.g., Hawley

et al., 1999) could be predicted by considering binaural processing only at points in time when interaural coherence is higher than a (relatively high) critical threshold. Their model was successful at extracting independent binaural parameters for five simultaneous speech stimuli (in their case positioned at 0°, ±30°, and ±80° azimuth). This model is unlikely to handle stimuli like ours because it assumes that there are gaps in the masker profile that allow the listener to have a clear glimpse at the target. Such gaps were minimal in our stimuli because of the brief and synchronized nature of the five utterances. However, it is possible that if the threshold coherence criterion was sufficiently lowered, the model would give reasonable outputs and might even predict the increases in localization error in the presence of maskers observed here.

In order to describe the effects of masker spatial uncertainty on localization accuracy, it seems necessary to invoke more central mechanisms such as endogenous orientation (Posner and Petersen, 1990) whereby responses are modulated by attention and/or expectation. One challenge for any simple model of orienting, however, is to explain why the benefit of *a priori* information depended on the TMR and the specific masker pattern.

V. SUMMARY

Localization of a monosyllabic speech target is degraded by the presence of concurrent speech maskers, particularly for poorer TMRs, even when reduced detectability is accounted for. The impact of the concurrent maskers depends in a complex way on the target/masker configuration and whether or not the target is spatially coincident with a masker. Listeners can use *a priori* information about the location of maskers to mitigate their adverse effects on target localization, in particular, for targets that do not coincide with maskers.

[1]The rms errors reported here were computed relative to the mean control responses. When rms errors were defined with respect to the actual target locations, the results were similar. We chose to use the rms errors relative to the control responses since they reflect the perceived locations and account for possible inaccuracies in the placement of the target speakers and in the response measurement system.

Feedback whistling is one of the severe problems with hearing aids, especially in dynamic situations when the users hug, pick up a telephone, etc. This paper investigates the properties of the dynamic feedback paths of digital hearing aids and proposes a model based on a reflection assumption. The model is compared with two existing models: a direct model and an initialization model, using the measured dynamic feedback paths. The comparison shows that the proposed approach is able to model the dynamic feedback paths more efficiently and accurately in terms of mean-square error and maximum stable gain. The method is also extended to dual-microphone hearing aids to assess the possibility of relating the two dynamic feedback paths through the reflection model. However, it is found that in a complicated acoustic environment, the relation between the two feedback paths can be very intricate and difficult to exploit to yield better modeling of the dynamic feedback paths. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3290989]

I. INTRODUCTION

Feedback is a severe problem in hearing aids, which limits the maximum gain that can be achieved.[1] The acoustic feedback path is the most significant contributor to the feedback signal although electrical and mechanical paths also exist.[2] A widely adopted approach to acoustic feedback suppression is feedback cancellation, where the acoustic feedback signal is estimated and then subtracted from the input signal to remove feedback.[3] The maximum stable gain (MSG) that can be obtained by feedback cancellation depends on how accurately the feedback path is estimated. A perfect match between the modeled and the real feedback path will cancel the feedback signal completely, and the system will be stable for any amount of amplification.[4]

A typical acoustic feedback path in the hearing aids includes the effects of the hearing-aid amplifier, receiver, microphone, the acoustics of the vent or leak, as well as the external acoustics. Except for the fitting and external acoustics, all the parts are nearly constant or very slowly varying with a time frame of weeks or years[5] when the user has put on the hearing aid. Assume that the user stays still in a stationary acoustic environment, and the feedback path will be almost static. This feedback path is referred to as a "static feedback path." However, in practice, the feedback path is usually subject to dynamic changes. The causes of these changes fall into two categories: (a) changes in the hearing-aid fitting, including jaw movement, smile, yawn, and cerumen; (b) changes in the external acoustics, including the factors such as room reverberation, a hand, or telephone handset near the ear. The variant feedback path due to these changes is called "dynamic feedback path." In this paper, only the dynamic feedback path for a specific position along the changing course is studied. The temporal characteristics, such as the changing rate at that position, are not addressed.

The properties of feedback paths have been investigated intensively in previous studies,[5,2,6] where the effect of vent size, the variability of feedback due to smiling, and handset proximity, were discussed. A common observation in these studies is that the largest variation in the acoustic feedback path was found when a hand or telephone handset was placed near the ear. For behind-the-ear (BTE) devices, the maximum variation can go up to 20 dB, whereas for in-the-ear (ITE) device, it can even go up to 27 dB in the 2–5 kHz frequency range compared with the static feedback path.[6]

The modeling of the feedback path has also been discussed intensively. However, the majority of the previous work has focused on the static feedback path, trying to model each static component, such as cavities and transducers, by an equivalent electroacoustic model.[7–9] For dynamic feedback path modeling, there is not very much research up to the present. One study that is relevant measured the variability of feedback path under various conditions and introduced an uncertainty bound model to calculate the robust stability condition for the hearing-aid system.[2] It provided knowledge about one aspect of the dynamic feedback path properties, i.e., the extent of variability, but did not discuss other acoustic properties and did not investigate the modeling issue either. Another relevant study dealt with feedback cancellation

 0001-4966/2010/127(3)/1458/11/$25.00

in room reverberation.[10] The focus of that study was the performance of feedback cancellation instead of the properties of the feedback path and its modeling in reverberation.

To track the dynamic aspect of feedback paths in the real world, feedback cancellation in many hearing aids today includes an adaptive feedback path model, where a simple adaptive finite-impulse-response (FIR) filter is used instead of an infinite-impulse-response (IIR) filter, since adaptive IIR filter suffers from the problem of computational complexity, instability, and local minima.[11] Thus, the estimate of dynamic feedback path is essentially a procedure of updating the coefficients of the adaptive FIR filter.

In general, two models with different ways of using the adaptive FIR filter have been proposed to model the dynamic feedback paths. In the first model, such as the systems proposed in some previous studies,[12,13] the overall feedback path is represented with the FIR filter. This model is referred to as the "direct model." The second model, such as the systems proposed in other studies,[3,14] incorporates a fixed model and an adaptive FIR filter. The fixed model represents the slowly varying portion of the feedback path (microphone, amplifier, and receiver), whereas the adaptive filter represents the rapidly varying portion (mainly the change of fitting and external acoustics). The fixed model can be either captured by an initialization,[3] referred to as an "initialization model" in this paper, or roughly approximated as a high-pass filter.[14] Compared with the direct model, the initialization model generally needs a shorter FIR filter and is computationally more efficient but requires an additional procedure in the hearing-aid fitting.

No matter which model is used, effective feedback cancellation requires that the FIR filter should adapt fast enough given the variability of the feedback paths and should be long enough to model all of the salient features.[10] The feedback path varies at different rates under different conditions. For example, jaw movements will produce changes with a time frame of seconds/minutes.[15] The picking up of a telephone handset changes the feedback path with a time frame of milliseconds/seconds. Production and disposal of cerumen will result in changes with a time frame of weeks and months, while aging causes changes with a time frame of years.[5] Usually the adaptation speed is not a problem even in the extreme cases as long as a proper adaptation scheme, for example, frequency-domain adaptation, is used. However, in practice, to maintain sound quality and minimize the artifacts resulted from adaptation errors when a spectrally colored signal is inputted,[13] the adaptation usually has to slow down and is not fast enough in some occasions. These adaptation problems, although prominent and complicated in the feedback cancellation system, are more related to the on-line adaptation scheme and the characteristics of the input signals, instead of the models of the feedback paths. The focus of this paper is on the modeling. Therefore, these adaptation issues are not addressed in this paper.

As for the sufficient length of the FIR filter in the model, the natural questions are as follows: how many orders of the FIR filter would be "enough" in various dynamic situations, and is there any other model that is more effective in modeling the dynamic feedback paths? In order to address these issues, the characteristics of the dynamic feedback path in addition to variability should be examined. This paper investigates these properties for the most adverse proximity situation that happens frequently and challenges the feedback cancellation most. This paper also describes a novel reflection based model (proposed in a previous publication[16]) in detail and extends the previous work thoroughly. The basic idea of the reflection model is to assume that the dynamic feedback path consists of multiple propagation paths and estimate the delays and gains associated with these paths directly. It differs from the two existing models in that the reflection model has an underlying physical assumption, and is more generalized by allowing fractional delays in the model, which will be described in more detail in Sec. II. The effectiveness of the new model is compared with the existing two models mentioned above, i.e., the direct model and the initialization model, using data from measurements. The comparison shows that the proposed model is superior in terms of mean-square error (MSE) and MSG.

For a hearing aid with dual microphones, due to the short distance between the two microphones (normally less than 2 cm), the two feedback paths are similar in most situations. This paper investigates the possibility of relating the two dynamic feedback paths using the initialization model and the reflection model. It is shown that in a complicated acoustic environment, the relation between the two feedback paths can be very intricate and difficult to exploit to yield better modeling of the dynamic feedback paths.

The outline of this paper is as follows: in Sec. II, two traditional models are explained and a new reflection model is proposed. In Sec. III, the measurement configuration and procedure are described. The properties of the dynamic feedback paths are discussed in Sec. IV. In Sec. V, the performance of the proposed model is compared with the existing two models and the possibility of using this model for relating the two dynamic feedback paths of a dual-microphone hearing aid is explored based on the measured data. Concluding remarks and directions for future work are given in Sec. VI.

II. MODELS FOR THE DYNAMIC FEEDBACK PATH

The general diagram of adaptive feedback cancellation is depicted in Fig. 1. It should be noted that the impulse responses of the microphone and receiver have been included in the impulse response of the feedback path $b(n)$. Although there are various feedback models as mentioned in Sec. I, their estimation of $b(n)$ can all be represented in a compact form $\hat{b}(n,\theta)$, where n denotes the discrete-time index and θ is a particular parameter set of a model. For example, when the feedback path is modeled by a FIR filter, θ represents the FIR coefficients. The principle of feedback cancellation is to adjust the parameters θ in the feedback model so that the modeled feedback path $\hat{b}(n,\theta)$ approximates the true feedback path $b(n)$. The output $v(n)$ is the instantaneous estimation of the feedback signal $f(n)$ and is subtracted from the input signal $s(n)$ to remove the feedback.

In principle, the impulse response $b(n)$ has infinite duration. However, the amplitude of $b(n)$ decays very fast, as

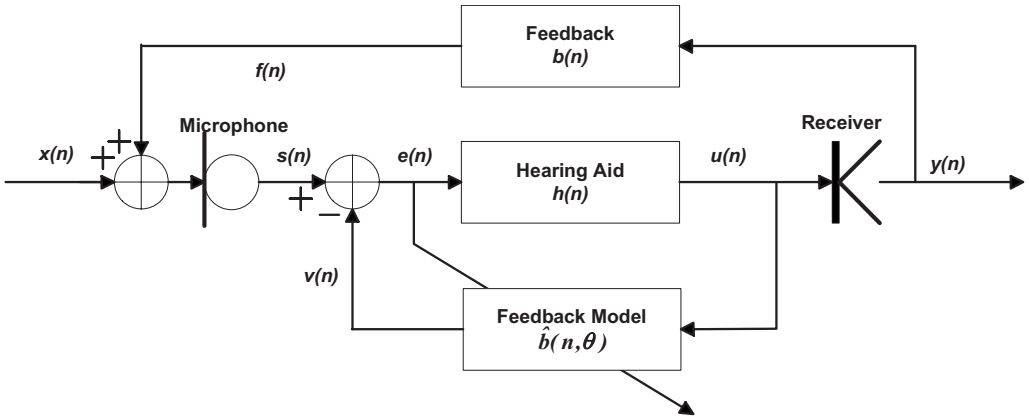

FIG. 1. General diagram of adaptive feedback cancellation. The input to the hearing-aid processing is $s(n)$, which is the sum of desired input signal $x(n)$ and the feedback signal $f(n)$. The processed hearing-aid signal is $u(n)$. The signal output into the ear canal is $y(n)$. The impulse response of the feedback path is $b(n)$, and $v(n)$ is the estimate of $f(n)$ from the modeled feedback path $\hat{b}(n,\theta)$.

shown later in Fig. 5. It is assumed in the following that both $b(n)$ and $\hat{b}(n,\theta)$ are truncated to a sufficient length so that the energy loss in the impulse response due to the truncation is at least 35 dB below the total energy of $b(n)$ or $\hat{b}(n,\theta)$.

To investigate each feedback model's capability in capturing the true feedback path, the parameters θ for each model is optimized by minimizing the difference between the modeled feedback $\hat{b}(n,\theta)$ and the actual feedback path. This minimization formulated in the frequency domain is as follows:

$$\theta_{\text{opt}} = \arg\min_{\theta} \|\mathbf{F}^H(\hat{\mathbf{b}}(\theta) - \mathbf{b})\|_2^2, \tag{1}$$

$$\mathbf{b} = [b(0), \ldots, b(L-1)]^T, \tag{2}$$

$$\hat{\mathbf{b}}(\theta) = [\hat{b}(0,\theta), \ldots, \hat{b}(L-1,\theta)]^T, \tag{3}$$

$$\mathbf{F} = [\mathbf{f}_0, \mathbf{f}_1, \ldots, \mathbf{f}_{L-1}] \tag{4}$$

$$\mathbf{f}_k = [1, e^{j\omega_k}, \ldots, e^{j\omega_k(L-1)}]^T, \tag{5}$$

where $\|\ \|_2$ denotes the Euclidean norm, L is the length of the truncated impulse responses in samples, $\omega_k = 2\pi k/L$, $k = 0, 1, \ldots, L-1$, $\mathbf{F}$ is the discrete Fourier transform matrix, and the superscripts T and H denote the transpose and conjugate transpose of a matrix or vector, respectively.

Based on the framework above, Secs. II A–II C will detail each feedback path model by specifying its parameter structure θ, the corresponding optimization procedure, and the analytic optimal solution if it exists. The optimal solution, either in analytic or in numerical form, represents the capability of each feedback model to represent the actual feedback path $b(n)$.

A. Existing models for dynamic feedback paths

The existing two models for dynamic feedback path are the direct model and the initialization model, both of which can be formulated as a cascade of prefiltering and an adaptive FIR filter.

Let $b_0(n)$ and $w(n)$ denote the impulse response of the prefiltering and the adaptive filter, respectively. The modeled feedback $\hat{b}(n,\theta)$ is then the convolution of $b_0(n)$ and $w(n)$, i.e.,

$$\hat{b}(n,\theta) = w(n) \odot b_0(n) = \sum_{l=0}^{M-1} w(l) b_0(n-l), \tag{6}$$

where M is the order of $w(n)$, and $\odot$ is the convolution operator.

1. Direct model

The feedback path $b(n)$ is always associated with a leading delay, which is the sum of the processing delay in $h(n)$ and the acoustic delay in the transmission path. In the "direct model," the FIR filter $w(n)$ is used to model the "active" portion of the feedback path, whereas the prefiltering $b_0(n)$ is simply a delay of D samples introduced to match the leading delay in $b(n)$ and provide a more efficient use of the limited number of taps in $w(n)$. The parameters are therefore of the form

$$b_0(n) = \begin{cases} 1, & n = D \\ 0, & \text{otherwise}, \end{cases} \tag{7}$$

$$\theta = \{w(n), D\}. \tag{8}$$

The optimal parameters $w_{\text{opt}}(n)$ and D_{opt} can be obtained by solving the optimization problem in Eqs. (1)–(8).

If the delay D is fixed, the least-squares solution is straightforward:

$$\mathbf{w}_{\text{opt}} = [b(D), \ldots, b(D+M-1)]^T. \tag{9}$$

If D is not fixed, an easy procedure to obtain the optimal solution is to search for an integer delay D that minimize the distance between $\hat{b}(n,\theta)$ and $b(n)$.

2. Initialization model

To model the feedback path accurately, the direct model in Sec. II A 1 usually needs a very high-order adaptive FIR filter $w(n)$ to cover the active range of the feedback path. One way to improve the modeling efficiency is to use the initialization model.

The feedback path $b(n)$ consists of slowly varying portions such as the responses of microphone, amplifier, receiver, etc. The idea of the initialization model is to use a fixed model, which is initialized during an additional off-line initialization procedure in the hearing-aid fitting, to model these slowly varying portions, and use a short adaptive FIR filter to represent the rapidly varying portions (mainly the change in fitting and external acoustics).

In such an initialization procedure, a "nominal feedback path" is first measured, which is defined as the feedback path without any external reflectors or enclosures near the hearing aid. When the hearing aid is put into use in daily life, the adaptive filter $w(n)$ only needs to model the part that is different from the nominal initialization to capture the time-varying dynamic feedback path. Since the impulse responses of microphone, receiver, etc., are nearly invariant from the initialization to dynamic situations, this different part is mainly resulted from the change in the hearing-aid fitting and external acoustic environments,[2] which can be modeled by an adaptive filter with a lower order.

In the initialization model, the prefiltering $b_0(n)$ in Eq. (6) is a fixed model to represent the impulse response of the nominal feedback path obtained in the initialization. In practice, it can be realized by an autoregressive moving average model (ARMA) model.[3] To avoid the complicated issue of how to model the initialized feedback path with an ARMA model to get the best generalized performance in feedback cancellation,[3,17] it is simply assumed that $b_0(n)$ is exactly the impulse response of the nominal feedback path. Therefore, the parameter for initialization model is of the form

$$\theta = \{w(n)\}. \tag{10}$$

Assume that the filter length of $w(n)$ is M, and the impulse response $b_0(n)$ is truncated to $L-M+1$ samples and padded with $M-1$ zeros so that the length of $\hat{b}(n,\theta)$, which is the convolution of $w(n)$ and $b_0(n)$, equals L. The impulse response of the dynamic feedback path $b(n)$ is also assumed to be of length L.

The optimal parameter $w_{\mathrm{opt}}(n)$ for real valued $w(n)$ with length M in the initialization model can be found by solving the least-squares problem with Eqs. (1)–(6) and (10):

$$\mathbf{w}_{\mathrm{opt}} = (\mathrm{diag}(\mathbf{F}^H\tilde{\mathbf{b}}_0)\tilde{\mathbf{F}}^H)^+(\mathbf{F}^H\mathbf{b}), \tag{11}$$

$$\tilde{\mathbf{b}}_0 = [\mathbf{b}_0^T, \mathbf{0}_{1\times(M-1)}]^T, \tag{12}$$

$$\mathbf{b}_0 = [b_0(0), \ldots, b_0(L-M)]^T, \tag{13}$$

$$\tilde{\mathbf{F}} = [\tilde{\mathbf{f}}_0, \tilde{\mathbf{f}}_1, \ldots, \tilde{\mathbf{f}}_{L-1}], \tag{14}$$

$$\tilde{\mathbf{f}}_k = [1, e^{j\omega_k}, \ldots, e^{j\omega_k(M-1)}]^T, \tag{15}$$

where $\omega_k = 2\pi k/L$, $k=0,1,\ldots,L-1$, $\mathrm{diag}(\cdot)$ forms a diagonal matrix with diagonal elements specified in $(\cdot)$, $(\cdot)^+$ is a pseudoinverse defined as $(\cdot)^+ = ((\cdot)^H(\cdot))^{-1}(\cdot)^H$, and $\mathbf{0}_{1\times(M-1)}$ represents a zero vector of size $1\times(M-1)$. The matrix $\tilde{\mathbf{F}}$ is a partial discrete Fourier transform matrix which results from the fact that $w(n)$ is only of the length M.

B. Reflection model for dynamic feedback paths

1. Model formulation

The initialization model $\hat{b}(n,w(n))$ formulated in Eq. (6) can also be regarded as a weighted sum of the nominal impulse response $b_0(n)$ and its delayed replicas with integer delays.

In typical dynamic situations where there is room reverberation or a handset placed close to the hearing aid, the feedback path is a composition of reflection and refraction, where reflection usually dominates. In addition to attenuation or amplification in the amplitude, a certain delay is associated with each reflected component. These physical delays, when transformed into the digital domain, are possibly fractional in terms of samples. Therefore, the model in Eq. (6) is generalized to a new model as follows:

$$\hat{b}(n,\theta) = \sum_{l=0}^{M-1} w(l) b_0(n-d_l), \tag{16}$$

$$\theta = \{w(l), d_l\}, \tag{17}$$

where d_l is the delay of the lth replica, $d_l > d_{l-1} \geq 0$, and $l = 1,\ldots,M-1$. Although the delays d_l in the model equations (16) and (17) are allowed to be fractional, the actual subsample implementation needs time-domain interpolation or frequency-domain multiplication. The latter is more efficient and is given in Sec. II B 2.

In this model, the impulse response of the nominal feedback path, measured during initialization without significant disturbances such as reflections, is regarded as an approximation of the direct path. The dynamic feedback path is modeled as a sum of reflection components with delay d_l and gain $w(l)$. This model is thus named "reflection model." When $d_l = l$, the reflection model reduces to the initialization model. Therefore, the reflection model is more general and expected to capture the dynamic feedback path better than the initialization model since it represents more accurately what happens in the physical world.

2. Delay estimation

The optimal delays $d_{l,\mathrm{opt}}$ and weights $w_{\mathrm{opt}}(l)$ for the reflection model can be found by solving the optimization problem given by Eqs. (1)–(5), (16), and (17), which is a nonlinear optimization problem.

However, efficient time delay (TDE) and amplitude estimation techniques have been investigated intensively in many fields such as radar, sonar, radio navigation, geophysical/seismic exploration, wireless communication, and medical imaging. The most well-known approach is

based on the matched filter,[18] whose resolution capability is unfortunately limited to the reciprocal of the signal bandwidth. For dynamic feedback path modeling, the difference between delays can be very small due to the handset proximity effect. Therefore, TDE techniques with high resolution should be used. Among these techniques, algorithms such as multiple signal classification, linear prediction, and maximum likelihood are not very well suited here since they are best for complex-valued signals with special spectral shapes.[19] A weighted Fourier transformation and relaxation (WRELAX) based method[20] is found to be very robust to address the problem. First, the cost function is defined as follows:

$$C_1(\{w(l),d_l\}_{l=0}^{M-1}) = \left\| \mathbf{B} - \sum_{l=0}^{M-1} w(l)[\mathbf{Sa}(d_l)] \right\|_2^2, \tag{18}$$

where

$$\mathbf{B} = \mathbf{F}^H \mathbf{b}, \tag{19}$$

$$\mathbf{S} = \mathrm{diag}(\mathbf{F}^H \tilde{\mathbf{b}}_0), \tag{20}$$

$$\mathbf{a}(d_l) = [1, e^{-j(2\pi/L)d_l}, \ldots, e^{-j(2\pi/L)d_l(L-1)}]^T. \tag{21}$$

Equation (18) is simply a formulation of the inner part of Eq. (1) with Eqs. (16) and (17) inserted. Minimizing the cost function $C_1(\{w(l),d_l\}_{l=0}^{M-1})$ with respect to $w(l)$ and d_l is the problem of interest. To address this optimization problem, denote

$$\mathbf{B}_l = \mathbf{B} - \sum_{i=0,i\neq l}^{M-1} \hat{w}(i)[\mathbf{Sa}(\hat{d}_i)], \tag{22}$$

$$C_2(w(l),d_l) = \|\mathbf{B}_l - w(l)\mathbf{Sa}(d_l)\|_2^2. \tag{23}$$

The cost function $C_2(w(l),d_l)$ assumes that the other reflection components have been estimated as $\hat{w}(i)$ and $\hat{d}_i$, where $i=0,1,\ldots,M-1, i\neq l$, except the lth component, and minimizing this cost function yields the estimates $\hat{w}(l)$ of $w(l)$ and $\hat{d}_l$ of d_l as[20]

$$\hat{d}_l = \arg\max_{d_l} |\mathbf{a}^H(d_l)(\mathbf{S}^*\mathbf{B}_l)|^2, \tag{24}$$

$$\hat{w}(l) = \left. \frac{\mathbf{a}^H(d_l)(\mathbf{S}^*\mathbf{B}_l)}{\|\mathbf{S}\|_2^2} \right|_{d_l=\hat{d}_l}, \tag{25}$$

where the asterisk denotes the complex conjugate. If $w(l)_{l=0}^{M-1}$ are assumed to be real numbers, minimizing $C_2(w(l),d_l)$ with respect to $w(l)$ and d_l yields[20]

$$\hat{d}_l = \arg\max_{d_l} \{\Re[\mathbf{a}^H(d_l)(\mathbf{S}^*\mathbf{B}_l)]\}^2, \tag{26}$$

$$\hat{w}(l) = \left. \frac{\Re[\mathbf{a}^H(d_l)(\mathbf{S}^*\mathbf{B}_l)]}{\|\mathbf{S}\|_2^2} \right|_{d_l=\hat{d}_l}, \tag{27}$$

where $\Re[\cdot]$ denotes the real part of $(\cdot)$.

To estimate $\hat{d}_l$ using Eq. (26), an initial estimate of d_l is first obtained by locating the maximum peak in the magnitude of the K-point ($K \geq L$) fast Fourier transform (FFT) of $\mathbf{S}^*\mathbf{B}_l$ with padded zeros. This process can also be regarded as a matched filtering in the frequency domain. Then a search for the $\hat{d}_l$ that maximizes $\Re\{[\mathbf{a}^H(d_l)(\mathbf{S}^*\mathbf{B}_l)]\}^2$ is made in a small range around the initial estimate based on golden section search and parabolic interpolation.[21,22]

The WRELAX estimates the delays d_l and amplitudes w_l in the frequency domain to avoid fractional delay interpolation. The general idea is to cross-correlate $b(n)$ and $b_0(n)$ in the frequency domain to find the coarse delays and gains of the replicas by identifying the peaks of the cross-correlation. Later an iterative search is performed by keeping one replica of $b_0(n)$ at a time (removing the other identified replicas from $b(n)$), repeating the cross-correlation and locating the peak to find a better delay and gain estimation for that replica. This process is iterated until the relative change in the cost function in Eq. (18) is below the threshold ϵ. The detailed steps are given below.

Step 1: For $M=1$ obtain $\{\hat{w}(l),\hat{d}_l\}_{l=0}$ from $\mathbf{B}$ by using Eqs. (26) and (27).

Step 2: For $M=2$ compute $\mathbf{B}_1$ with Eq. (22) by using $\{\hat{w}(l),\hat{d}_l\}_{l=0}$ obtained in Step 1. Obtain $\{\hat{w}(l),\hat{d}_l\}_{l=1}$ from $\mathbf{B}_1$ by using Eqs. (26) and (27). Next recompute $\mathbf{B}_0$ by using $\{\hat{w}(l),\hat{d}_l\}_{l=1}$ and redetermine $\{\hat{w}(l),\hat{d}_l\}_{l=0}$ from $\mathbf{B}_0$. Iterate these two substeps until the relative change in $C_1(\{w(l),d_l\}_{l=0}^{M-1})$ between two consecutive iterations is below the threshold ϵ.

Step 3: For $M=3$ compute $\mathbf{B}_2$ with Eq. (22) by using $\{\hat{w}(l),\hat{d}_l\}_{l=0}^{1}$ obtained in Step 2. Obtain $\{\hat{w}(l),\hat{d}_l\}_{l=2}$ from $\mathbf{B}_2$. Next recompute $\mathbf{B}_0$ by using $\{\hat{w}(l),\hat{d}_l\}_{l=1}^{2}$ and redetermine $\{\hat{w}(l),\hat{d}_l\}_{l=0}$ from $\mathbf{B}_0$. Then compute $\mathbf{B}_1$ by using $\{\hat{w}(l),\hat{d}_l\}_{l=0,2}$ and redetermine $\{\hat{w}(l),\hat{d}_l\}_{l=1}$. Iterate these three substeps until the relative change in $C_1(\{w(l),d_l\}_{l=0}^{M-1})$ between two consecutive iterations is below the threshold ϵ.

Remaining Steps: Continue similarly until M is equal to the desired number of paths.

In contrast to some estimation algorithms, such as the expectation-maximization algorithm,[23] the WRELAX is not sensitive to the initial parameters since it uses a matched filter to find these initial values. It is bound to converge to at least a local minimum point, which is at least a better solution than what the traditional matched filter can yield. The convergence speed of WRELAX depends on the time delay spacing of the different reflected paths.[20]

C. Models for dual-microphone hearing aids

For hearing aids with dual microphones, the feedback problem involves a dynamic feedback path for the front microphone, denoted as $b_f(n)$, and a path for the rear microphone, denoted as $b_r(n)$. One way of dealing with the two paths is to model them individually by using one of the three models described above. An alternative approach involves

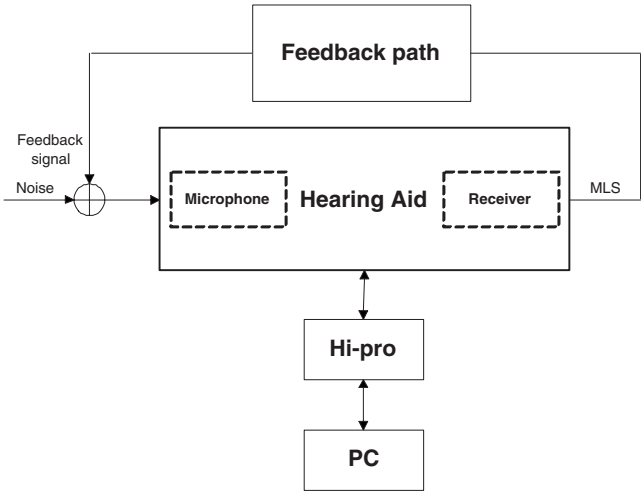

FIG. 2. The block diagram of the measurement system for measuring the feedback paths. The feedback path is illustrated which includes the external acoustics, for example, a Kemar head. The receiver sends out a MLS and the feedback signal is picked up by the microphone with ambient noise together. The data are fed into the computer through HI-PRO.

exploiting the relation between the two similar feedback paths by fitting one dynamic feedback path with the other dynamic path. There are two ways of fitting.

The first approach for the fitting, which is similar to the initialization model [cf. Eq. (6)], is

$$\hat{b}_r(n) = \sum_{l=0}^{M-1} w(l) b_f(n-l). \tag{28}$$

The second approach for the fitting, which is similar to the reflection model [cf. Eq. (16)], is

$$\hat{b}_r(n) = \sum_{l=0}^{M-1} w(l) b_f(n-d_l). \tag{29}$$

The estimate of $w_{\text{opt}}(n)$ and/or delays $d_{l,\text{opt}}$ can be found in similar ways described in Secs. II A 2 and II B.

III. MEASUREMENT OF DYNAMIC FEEDBACK PATHS

The nominal and dynamic feedback paths have been measured using a commercial open-fitting BTE device with two microphones from GN ReSound A/S. The hearing aid was mounted on the head of Kemar Manikin type 45BA made by G.R.A.S. Sound & Vibration A/S.[24]

The impulse responses of the feedback paths were measured by sending out a maximum-length sequence (MLS) with a period of 255 samples through the receiver, repeating it 1000 periods, and averaging the responses to get a high signal-to-noise ratio (SNR) for the feedback path response relative to random ambient noise. The sampling frequency was 15625 Hz. Figure 2 illustrates the measurement diagram where a HI-PRO universal programming interface for hearing instruments made by GN Otometrics A/S (Ref. 25) is used to feed the collected data into a computer to calculate the impulse responses. The detailed procedure of the impulse response measurement can also be found in Ref. 10.

The MLS is emitted at around 85 dB sound pressure level (SPL) and transmitted to the microphone through the

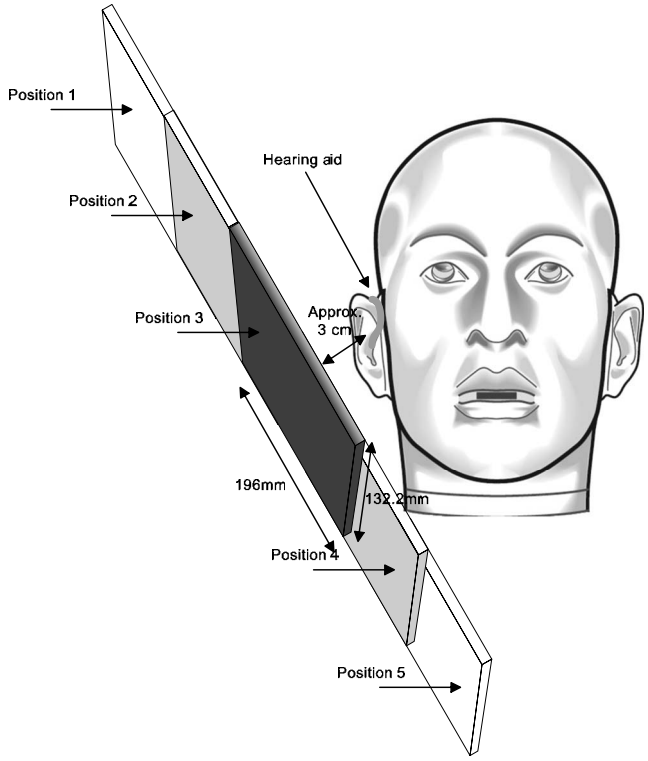

FIG. 3. The measurement setup for dynamic feedback paths with rigid surface. The hearing aid is mounted on the Kemar head. Positions 1 and 2 are symmetrical to positions 4 and 5 with regard to position 3, which is right at the side of the hearing aid.

feedback. The feedback path shapes the signal based on its frequency response. The internal noise in the microphone is less than 28 dB SPL and the ambient noise is less than 30 dB SPL. The average over 1000 cycles of MLS increases the overall SNR by 30 dB. This setup has been found to be very reliable. The preliminary test shows that when the measurements are repeated for ten times for a single feedback path, the variance in the measured impulse responses is around 36 dB below the average response, which is sufficient for feedback path modeling.

The nominal feedback paths for both the front and rear microphones are measured. The measured nominal feedback path for the front microphone is denoted as $b_{f,0}(n)$ and for the rear microphone $b_{r,0}(n)$.

Since it was found that the movement of jaw, mouth, etc., had little effect on the feedback path variations,[5,2] and the adaptive feedback cancellation in hearing aids today usually handles these situations very well in practice, the measurement of dynamic feedback paths focused on the proximity effect.

Seven dynamic feedback paths were measured for both the front and rear microphones. A rigid metal surface of dimension 196×132.6 mm^2 was used and faced to the hearing aid mounted on the Kemar head. The surface was moved along the lateral side gradually toward the hearing aid from position 1 to position 3 and later from position 3 to position 5, as shown in Fig. 3. The perpendicular distance between the rigid surface and the hearing aid was kept at around 3 cm during the movement. The impulse responses of the dynamic feedback path at these five positions measured from the front

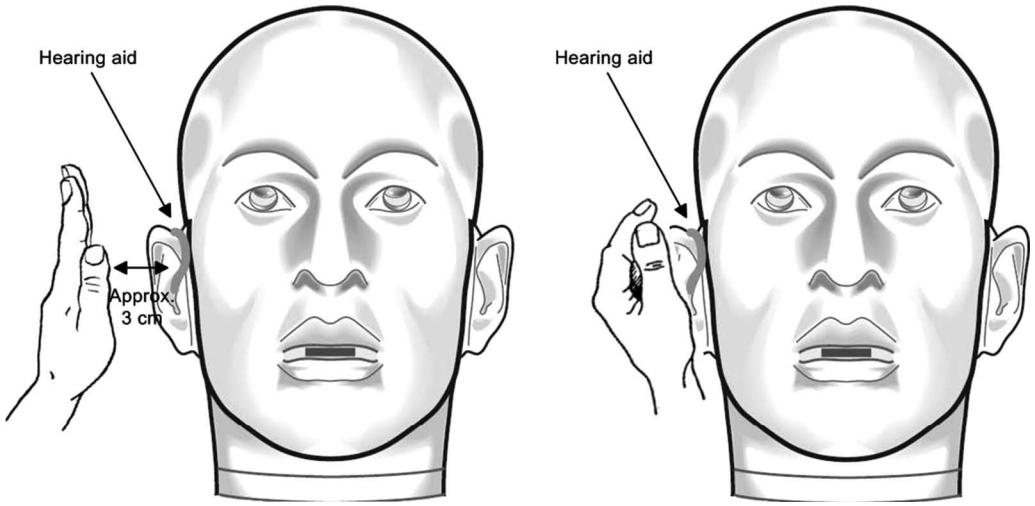

FIG. 4. The measurement setup for dynamic feedback paths with palm. The left figure represents an outstretched palm facing the hearing aid, and the right figure depicts the cupped hand around the hearing aid.

microphone are denoted as $b_{f,1}(n)-b_{f,5}(n)$ and from the rear microphone $b_{r,1}(n)-b_{r,5}(n)$. Apart from the rigid surface, two additional dynamic feedback paths were measured with an outstretched palm facing the hearing aid on its lateral side at a distance of around 3 cm $[b_{f,6}(n),b_{r,6}(n)]$ and with a palm wrapping around the hearing aid $[b_{f,7}(n),b_{r,7}(n)]$, as illustrated in Fig. 4.

Therefore, altogether eight impulse responses were measured for both front and rear microphones including the static feedback path (nominal feedback) and seven dynamic feedback paths. All the impulse responses are of the length 255 samples. The rigid surface measurements are artificial tests for reflections whereas the palm measurements mimic the most adverse situations for feedback cancellation in real life.

The frequency responses of these feedback paths are shown in Fig. 5, where only the responses from the front microphone are illustrated since the responses from the rear are similar.

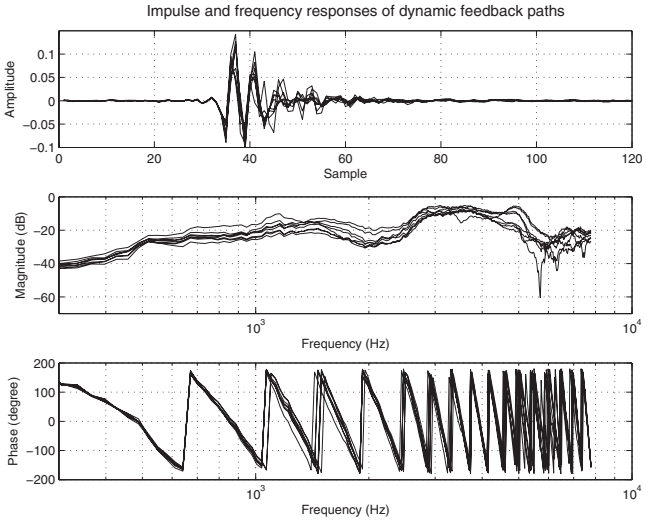

FIG. 5. Impulse responses and frequency responses of measured eight feedback paths (one nominal and seven dynamic feedback paths).

IV. PROPERTIES OF DYNAMIC FEEDBACK PATHS

In this section, the general characteristics of the measured dynamic feedback paths are investigated first. Later, the reflection model proposed in Sec. II B is used to model these paths and reveal other aspects of the characteristics of dynamic feedback paths.

A. Variability of dynamic feedback paths

The sample mean and sample estimate of the standard deviation of the measured dynamic feedback paths have been calculated as a function of frequency. The mean and standard deviation do not reveal all the properties of the dynamic feedback paths but give an indication of the dynamic range of the data. If it can be assumed that the variation in spectrum magnitude for each frequency is normally distributed, then the 95% confidence interval of the expected value for seven measurements is $[\bar{\mathbf{B}}_f-0.925\mathbf{S}_f,\bar{\mathbf{B}}_f+0.925\mathbf{S}_f]$ and $[\bar{\mathbf{B}}_r-0.925\mathbf{S}_r,\bar{\mathbf{B}}_r+0.925\mathbf{S}_r]$ for the front- and rear-microphone dynamic paths, respectively, where $\bar{\mathbf{B}}_f$ and $\bar{\mathbf{B}}_r$ are sample means, and $\mathbf{S}_f$ and $\mathbf{S}_r$ are sample estimates of the standard deviation.

They are calculated as follows:

$$\bar{\mathbf{B}}_f=\frac{1}{7}\sum_{l=1}^{7}|\mathbf{F}^H\mathbf{b}_{f,l}|, \tag{30}$$

$$\mathbf{S}_f=\sqrt{\frac{1}{7-1}\sum_{l=1}^{7}(|\mathbf{F}^H\mathbf{b}_{f,l}|-\bar{\mathbf{B}}_f)^2}, \tag{31}$$

where

$$\mathbf{b}_{f,l}=[b_{f,l}(0),\ldots,b_{f,l}(L-1)]^T. \tag{32}$$

Note that $\bar{\mathbf{B}}_f$ and $\mathbf{S}_f$ are both vectors. The symbol $|\cdot|$ in Eq. (30) and $(\cdot)^2$ in Eq. (31) denote the elementwise absolute operation and elementwise square of the vector in $(\cdot)$, respectively. The $\bar{\mathbf{B}}_r$ and $\mathbf{S}_r$ can be calculated similarly.

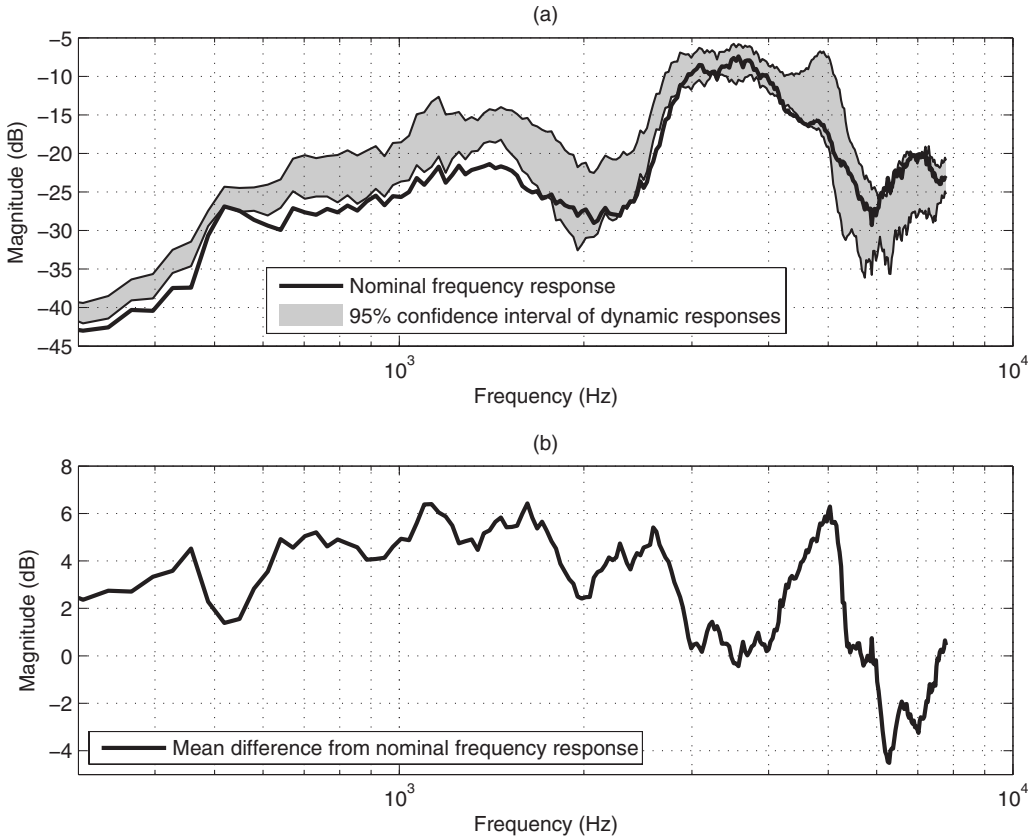

FIG. 6. Variability of dynamic feedback paths: (a) shows the nominal frequency response and a shaded region representing the 95% confidence interval of the expected frequency response of dynamic feedback paths; (b) illustrates the mean difference between the responses of dynamic feedback paths and the nominal feedback path.

The variability results are shown in Fig. 6(a). The shaded region represents the uncertainty in the expected magnitude of frequency responses of the dynamic feedback paths. It should be noted that the variability illustrated here is obtained with one single head and does not include the intersubject variability. The general trend is that at low frequencies, the uncertainty is small, but above 1 kHz, the uncertainty increases and goes up to 10 dB at some frequencies. The magnitude curve of the frequency response of the nominal feedback path lies below this shaded region at frequencies lower than 1750 Hz, which means that the rigid surface or hand in the measurements generally boosted the feedback responses at low frequencies. Above 1750 Hz, most of the nominal curve lies within the shaded region, and above 5 kHz, nearly all of the curve lies inside the region. This indicates that the change in feedback path at high frequencies is not a general boost but resulted from complicated effects such as peaks and valleys. This trend agrees with the results from other studies,[5,2,6] despite the minor differences in the measured feedback paths due to different devices, test environments, etc.

The difference in dB between the sample mean of the magnitude of dynamic feedback paths $\bar{\mathbf{B}}_f$ and the magnitude of the nominal feedback path is illustrated in Fig. 6(b), which essentially removes the effects of microphone, receiver, etc. A dominant peak was found at 5035 Hz. This can be interpreted as a strong reflection from an object placed at a distance of $1/5035 \times 343/2$ m ≈ 0.034 m, where 343 m/s is the speed of sound at 20 °C and the factor of 2 is used to calculate a single-way transmission length. This is approximately the distance between the hand/rigid surface and the hearing aid in the measurement.

B. Reflections in dynamic feedback paths

The reflection phenomenon in dynamic feedback paths with a telephone handset near the hearing aid has been pointed out in several previous papers.[3,5,6] It features peaks or other complicated effects in the high frequency range of the measured feedback responses. The dominant peak in the Fig. 6(b) also indicates the occurrence of a reflection.

However, physically, there could be many other reflections besides the dominant one, especially when the object is placed very close to the hearing aid. The reflection model proposed in this paper can be used to estimate these reflections.

In WRELAX of the reflection model, one zero is padded to all of the impulse responses of the measured feedback paths so that the truncated length L becomes 256. The number of points in the FFT for initial delay estimation, K, is set to 4096 to get a good initial guess, the search region around the initial estimate $\hat{d}_{l,\mathrm{ini}}$ in samples is set to be $[\hat{d}_{l,\mathrm{ini}} - \frac{1}{32}, \hat{d}_{l,\mathrm{ini}} + \frac{1}{32}]$, and the threshold for the stopping criterion ϵ is set as 10^{-4}.

The reflection model estimates the $w(l)$ and d_l, where $l = 0, 1, \ldots, M-1$, for all the measured data. In Figs.

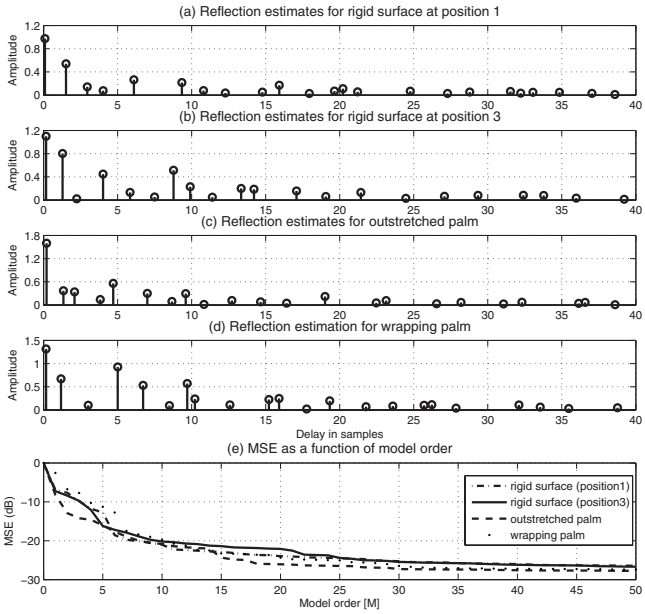

FIG. 7. (a)–(d) illustrate the reflection estimates in terms of delay in samples $\hat{d}_l$ and amplitude $\hat{w}(l)$ based on the measured data for rigid surface at positions 1 and 3, outstretched palm, and wrapping palm; (e) shows how the MSE, i.e., $C_1(\{w(l),d_l\}_{l=0}^{M-1})$ decreases as the number of reflection components M increases.

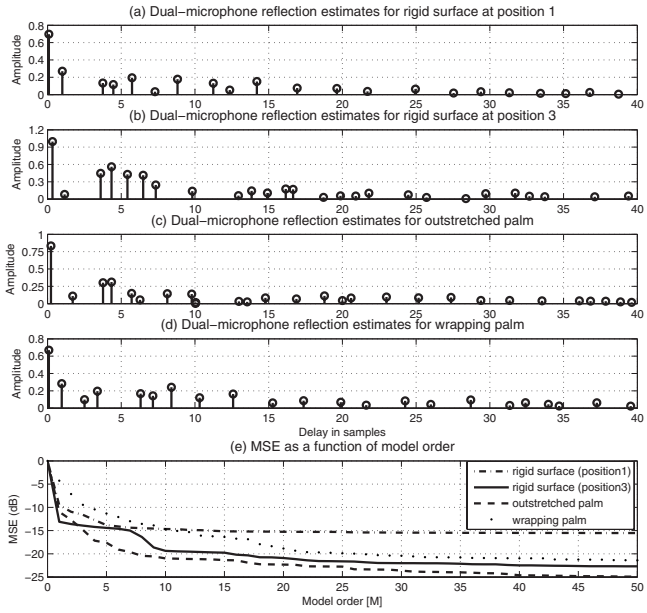

FIG. 8. (a)–(d) illustrate the reflection estimates for the dual-microphone BTE hearing aid assuming that the rear response is a sum of reflected replicas of the front response in terms of delay in samples $\hat{d}_l$ and amplitude $\hat{w}(l)$ based on the measured data for rigid surface at positions 1 and 3, outstretched palm, and wrapping palm; (e) shows how the MSE, i.e., $C_1(\{w(l),d_l\}_{L=0}^{M-1})$ decreases as the number of reflection components M increases.

7(a)–7(d), the results for the rigid surface at positions 1 and 3, and palm outstretched and wrapped around the hearing aid, are illustrated. The MSE of the estimated feedback path, i.e., $C_1(\{w(l),d_l\}_{l=0}^{M-1})$ defined in Eq. (18), is given in Fig. 7(e) as a function of the model order. As can be seen from the figure, in all the four cases, the highest peak is located near 0 sample delay, which implies that the assumption that the nominal feedback path is approximately the direct path is valid. The reason why the amplitude is not exactly unity and the delay is not exactly 0 is that the nominal feedback path itself consists of a number of small reflections due to the presence of pinna and head.

As the delay increases, the estimated amplitude generally decays, which complies with the physical law that longer transmission path results in larger attenuation (transmission loss).[26] Almost all of the significant peaks in the four cases happen before a delay of ten samples, corresponding to a single-way transmission length of 0.106 m, which is a reasonable range for late reflection paths, e.g., a path consisting of multiple reflections between reflecting objects, the ear, and the hearing aid before it reaches the microphone.

There are fewer significant reflections (with amplitude larger than 0.4) in the cases of the rigid surface at position 1 and outstretched palm than in the cases of the rigid surface at position 3 and wrapping hand. This agrees with the fact that the reflections in the latter two cases are more complicated.

The case with the wrapping hand has the most irregular reflection pattern, in which large reflections are distributed widely in the delay range from zero to ten samples. The reflections for this situation after a delay of ten samples are generally as small as in the other cases. This shows that the wrapping hand introduces large reflections with short delays.

In the experiments with the rigid surface and outstretched palm, the distance was kept at around 3 cm, corresponding to a delay of 2.73 samples and a peak at 5717 Hz in the magnitude response. The peak has been verified in Sec. IV A, whereas for all the cases in Figs. 7(a)–7(d), the peak does not seem to be very dominant, although there is a reflection component located at around 2.73 samples. A possible reason is that the dominant reflections were influenced by the presence of the pinna and the head, depending on how the reflecting object was positioned. However, this influence is different for different measurements. Therefore, it is averaged out and the dominant peak shows up at a correct location in the average magnitude response [see Fig. 6(b) at 5035 Hz].

For the dual-microphone situation, the estimation results are shown in Fig. 8. For each case, the response of the feedback path at the rear microphone is fitted by that at the front microphone using the proposed reflection model. As seen from Fig. 8(e), the MSE converges at a relatively higher level compared with Fig. 7(e), especially for the case where the rigid surface is placed at position 1. Therefore, the usage of a reflection model to relate the two feedback paths of a dual-microphone BTE hearing aid is not very effective.

V. PERFORMANCE OF THE PROPOSED MODEL

In this section, the proposed reflection model is compared with the two existing model in terms of MSE and MSG. The performance of the reflection model for dual-microphone situation is also investigated.

A. Performance metric of feedback path models

To evaluate the performance of a feedback model, two metrics are usually used: MSE and MSG. The MSE de-

scribes the average distance between the modeled and the real feedback paths. The MSG indicates the maximum gain without instability assuming a flat frequency response in the hearing-aid processing and the worst case for the phase. The MSG is determined by the frequency at which the mismatch between the feedback model and the actual feedback path is the largest.[10] Assume that all the models are optimized, the resultant MSE and MSG are defined as MSE_c and MSG_c, respectively,

$$\mathrm{MSE}_c = 20\log_{10}\left(\frac{\|\mathbf{F}^H\hat{\mathbf{b}}(\theta_{opt}) - \mathbf{b}\|_2^2}{\|\mathbf{F}^H\mathbf{b}\|_2^2}\right), \tag{33}$$

$$\mathrm{MSG}_c = 20\log_{10}\left(\min_k \frac{1}{|\mathbf{f}_k^H(\hat{\mathbf{b}}(\theta_{opt}) - \mathbf{b})|}\right). \tag{34}$$

With a specific model and parameters θ, the MSE_c and MSG_c are the lowest achievable MSE and the highest achievable MSG, respectively. MSE_c and MSG_c are, in fact, limited by the amount of undermodeled feedback path, the residual feedback path that cannot be modeled due to the limited number of degrees of freedom in the parameter θ and/or the lack of flexibility in the model form. A more descriptive model with larger degrees of freedom in the parameters θ will yield less undermodeling, lower MSE_c and larger MSG_c.

B. Results

For each measured dynamic feedback path, the parameters in the models were first optimized to calculate the MSE_c and MSG_c. The filter length M was varied from 1 to 50. To achieve the best performance, the delay D was not fixed in the direct model.

It is found that for all the seven dynamic paths and all the values M, the reflection model outperforms the initialization model and the direct model in terms of MSE_c and MSG_c. The direct model performs worst in all the cases. To demonstrate the performance of each model in dynamic situations, MSE_c and MSG_c are averaged over the seven dynamic paths. The results are illustrated in Figs. 9 and 10. The results for the dual-microphone models are also included.

As seen in the figures, the general trend of MSE_c and MSG_c is similar, the larger M the smaller MSE_c and the larger MSG_c. The slight difference in the pattern between MSE_c and MSG_c is because the optimization of parameters in the models is based on MSE instead of MSG directly.

The reflection model is superior to the other two models, especially when M is between 6 and 21. In practice, M is usually chosen between 10 and 20 to assure a fast convergence. In this region, the reflection model yields 5–6 dB higher MSE_c, 5–7 dB higher MSG_c than the initialization model, and 8–10 dB higher MSE_c, and 9–11 dB higher MSG_c than the direct model. To achieve a 25 dB MSG_c, the direct model needs 31 orders and the initialization model needs 16 orders, whereas the reflection model only needs seven reflection replicas of the nominal impulse response. Moreover, including 11 reflection replicas in the reflection model yields around the same MSG_c as the initialization model with 50-order FIR filter. This shows that 11 reflections are enough to model the dominant characteristics of the dynamic feedback paths resulted from a hand or rigid surface placed close to the hearing aid.

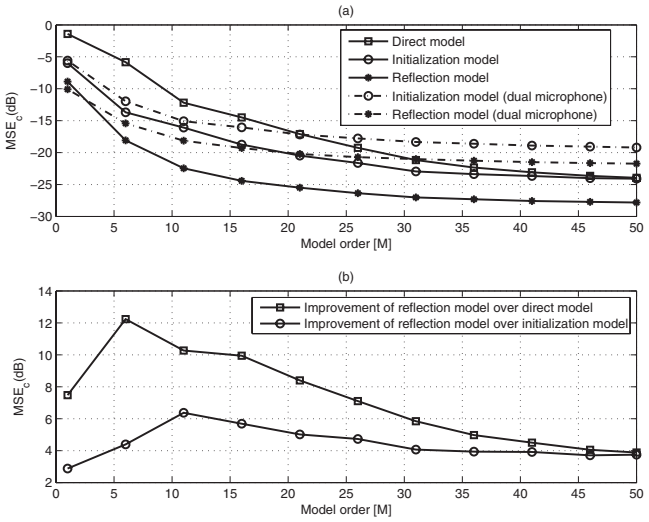

FIG. 9. Comparison of the models for dynamic feedback path modeling in terms of MSE_c. (b) shows the MSE_c improvement of the reflection model over direct model and initialization mode. The horizontal axis is the filter length in the direct model and initialization model or the number of reflection components in reflection model.

It should be noted that the reflection model does not yield significant improvement when used in the dual-microphone case. This is because in a complex acoustic environment, the relation between the two feedback paths is very complicated and even more difficult to model than the feedback paths themselves.

VI. CONCLUSIONS AND FUTURE WORK

This paper describes a novel reflection model for the dynamic feedback path in digital hearing aids. The reflection

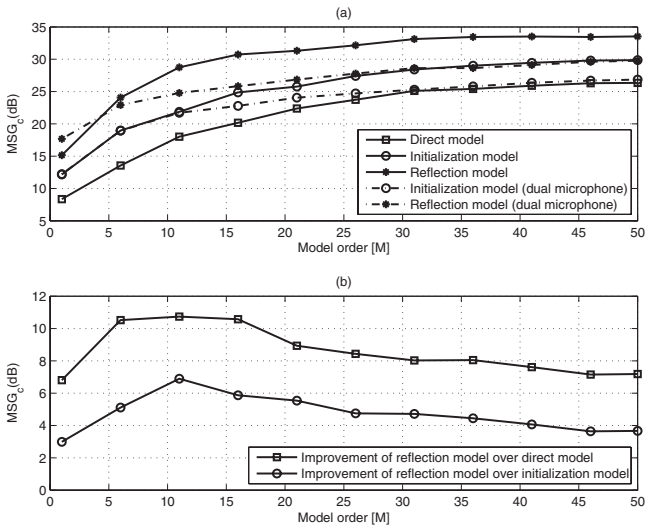

FIG. 10. Comparison of the models for dynamic feedback path modeling in terms of MSG_c. (b) shows the MSG_c improvement of the reflection model over direct model and initialization mode. The horizontal axis is the filter length in the direct model and initialization model or the number of reflection components in reflection model.

properties in addition to the variability of feedback path, when the objects such as a palm or handset are placed close to the hearing aid, have been investigated.

The results based on the measurement of a commercial hearing aid show that the proposed model has a better ability of capturing the dynamic feedback path in these difficult real-life situations and is superior to the existing two models in terms of MSE and MSG. To achieve the same level of MSE or MSG, the number of components required in the proposed model is fewer than the orders of the FIR filter required in the two traditional models.

The results also show the minimum order of the adaptive filter in the two existing models to achieve a certain MSG in the dynamic situations, which could serve as a useful indication in practice for choosing the order of the adaptive filter in feedback cancellation. For the reflection model, 11 reflection replicas are enough to model the dominant characteristics of the proximity effect in dynamic feedback paths.

This paper also investigates the possibility of relating the two feedback paths of a dual-microphone hearing aid for modeling the dynamic feedback paths. It is shown that in a complicated acoustic environment, the relation between the two feedback paths can be very intricate and difficult to exploit to yield better modeling of the dynamic feedback paths.

The future work is to develop an on-line adaptation scheme for this reflection model so that it can improve the performance of feedback cancellation in adverse dynamic situations. The first step to this adaptation scheme is to find a more efficient way of estimating the fractional delays. The frequency-domain approach will be preferred since the implementation of a fractional delay in the time domain requires interpolation. The next step is to find a proper frequency-domain adaptive filtering approach to estimate the dynamic feedback paths based on the estimated delays.

The upper limit of temporal pitch for cochlear-implant listeners: Stimulus duration, conditioner pulses, and the number of electrodes stimulated

(Received 8 May 2009; revised 15 October 2009; accepted 18 December 2009)

Three experiments studied discrimination of changes in the rate of electrical pulse trains by cochlear-implant (CI) users and investigated the effect of manipulations that would be expected to substantially affect the pattern of auditory nerve (AN) activity. Experiment 1 used single-electrode stimulation and tested discrimination at baseline rates between 100 and 500 pps. Performance was generally similar for stimulus durations of 200 and 800 ms, and, for the longer duration, for stimuli that were gated on abruptly or with 300-ms ramps. Experiment 2 used a similar procedure and found that no substantial benefit was obtained by the addition of background 5000-pps "conditioning" pulses. Experiment 3 used a pitch-ranking procedure and found that the range of rates over which pitch increased with increasing rate was not greater for multiple-electrode than for single-electrode stimulation. The results indicate that the limitation on pulse-rate discrimination by CI users, at high baseline rates, is not specific to a particular temporal pattern of the AN response.

I. INTRODUCTION

An important finding in the cochlear-implant (CI) literature concerns the ability of CI users to process differences in the repetition rate of an electrical stimulus, such as a pulse train. For pulse rates lower than about 300 pps, listeners can detect rate differences of a few percent, and some listeners can use pulse-rate differences to recognize melodies and to estimate or even produce musical intervals (Pijl and Schwarz, 1995; McDermott and McKay, 1997; Moore and Carlyon, 2005). However, at higher pulse rates, these abilities usually decline dramatically; although marked individual differences exist, the vast majority of CI users do not reliably associate increases in pulse rate above about 400 pps with increases in pitch, and in many listeners this "upper limit" is considerably lower (Shannon, 1983; Townshend *et al.*, 1987; McKay *et al.*, 2000; Zeng, 2002; but see Kong *et al.*, 2009).

The upper limit of temporal pitch in CI users is of both clinical and scientific importance. Clinically, attempts to encode "temporal fine structure" in CIs (Nie *et al.*, 2005; Stickney *et al.*, 2005; Riss *et al.*, 2008) are likely to be limited by the range of temporal repetition rates that can be processed by CI users. Scientifically, several authors have pointed out the apparent paradox between the inability of CI users to encode high pulse rates and both the accurate encoding of such stimuli in the auditory nerve of deafened animals, and evidence that normal-hearing (NH) listeners use phase locking cues to estimate the frequency of pure tones up to at least 2000 Hz (Moore, 1973; Hartmann *et al.*, 1990; Shepherd and Javel, 1997; Micheyl *et al.*, 1998). This in turn has led to suggestions that accurate temporal processing may be subjected to additional requirements that are not met by CI stimulation; these have included (i) stochastic activity in the auditory nerve (AN) (Rubinstein *et al.* 1999), (ii) comparison of timing differences across different AN fibers produced by the basilar-membrane (BM) traveling wave (Shamma, 1985; Moore and Carlyon, 2005), (iii) a "match" between the temporal pattern of activity in a given nerve fiber and the place on the BM that it innervates (Moore, 1982; Oxenham *et al.*, 2004; Moore and Carlyon, 2005), and (iv) stimulation of auditory nerve fibers that innervate very apical regions of the cochlea (Middlebrooks and Snyder, 2009).

Despite its importance, the locus of the high-rate limitation remains largely unknown. Circumstantial evidence for a peripheral limitation, at the level of the AN, comes from measures of the electrically evoked compound action potential (ECAP). Wilson *et al.* (1997a) reported that although the ECAP to each pulse of a low-rate (e.g., 100 pps) pulse train was of roughly equal size, at higher pulse rates (e.g., 1000 pps) the ECAP to odd-numbered pulses was larger than that to even-numbered pulses. This "alternating-amplitude" pattern was attributed to a large number of neurons being activated by the first pulse, refractory when the second pulse was presented, recovered by the third, and so on. It could affect pitch perception at high rates by conveying two intervals to the brain, corresponding to the time between every pulse and to that between every second pulse [Fig. 1(a)]. For example, if the compound activity of the AN were processed by an array of "more central" neurons having different thresholds (Carlyon *et al.*, 2008b), those with higher thresholds would respond only to the odd-numbered pulses and therefore convey a pulse rate an octave lower than that actually presented. If the depth of the alternating-amplitude pattern increased with pulse rate, then more and more of these neurons would

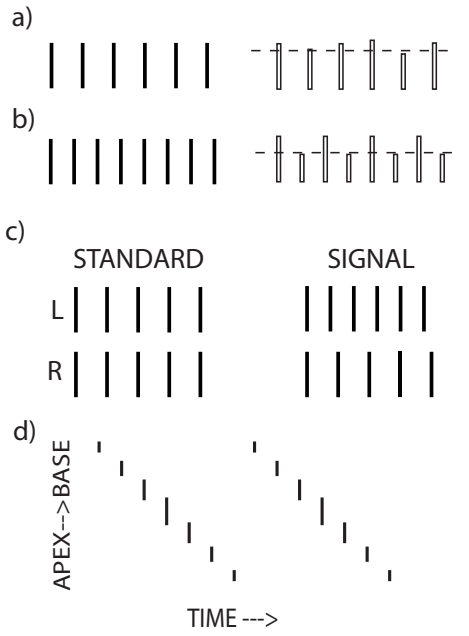

FIG. 1. (a) and (b) show schematic pulse trains (left-hand side, filled bars) together with hypothetical "alternating-amplitude" ECAPs (right-hand side, open bars). More central neurons having thresholds above the dashed lines would respond to every other pulse. If the ECAP becomes more modulated with increasing rate (b) then the increase in the number of more central neurons responding only to every other pulse might counteract the increase in pitch resulting from the shorter interpulse interval. (c) shows pulse trains presented in the standard and signal intervals of the "dichotic" conditions studied by van Hoesel and by Carlyon (van Hoesel and Clark, 1997; van Hoesel, 2007; Carlyon *et al.*, 2008a). The pulse rate presented to the left ear in the signal interval differs not only from that presented to the same ear in the standard interval but also from that presented to the right ear in the signal interval. The resulting binaural cue aids performance at low, but not at high, pulse rates (Carlyon *et al.*, 2008a). (d) represents the pulse trains presented on seven electrodes in the "peaked" condition of experiment 3.

convey rates corresponding to every second pulse, and this could counteract the increase in pitch expected from shorter interpulse intervals [Fig. 1(b)].

Evidence also exists for a more central limitation. Oxenham *et al.* (2004) required NH listeners to discriminate differences in the modulation rate of so-called "transposed tones" (Bernstein and Trahiotis, 2002)—high-frequency tones multiplied by a half-wave-rectified low-frequency sinusoid. They argued that these stimuli should produce similar patterns of AN activity to a pure tone, but in fibers having characteristic frequencies (CFs) corresponding to the carrier (but see Dreyer and Delgutte, 2006). Frequency difference limens (DLs) were considerably higher than for pure tones, and, importantly, listeners could not extract a "missing fundamental" from three harmonically related modulators each applied to a separate high-frequency carrier. They argued that the processing of phase locking at the level of the brainstem and above required either a match between the place and rate of stimulation or a comparison between the relative timing of activity in different AN fibers. More recently, Kong *et al.* (2009) showed that although the variation in rate discrimination as a function of baseline rate differed across listeners, for a given listener this variation was similar for rate discrimination of simple pulse trains and for the discrimination of the rate of sinusoidal amplitude modulation applied to a 5000-pps carrier. Presumably, the two types of stimulus produced different patterns of AN activity, tentatively suggesting that the across-listener differences may have arisen from more central processes.

The present study evaluates stimulus manipulations that would be expected to markedly affect the pattern of AN activity and which could feasibly extend the upper limit of temporal pitch. Experiment 1 examines the effect of increasing stimulus duration from 200 to 800 ms, and of turning the pulse trains on and off with long (300-ms) ramps. Physiological data indicate that the alternation in the ECAP amplitude to successive pulses gets smaller later in the pulse train (Wilson *et al.*, 1997b), so using a longer stimulus should provide a portion of the stimulus during which the alternation is reduced. Furthermore, we would expect the use of gradual onsets to also reduce this alternation because the effective "first pulse" will differ across neurons according to their threshold. Experiment 2 investigated whether the addition of a background 5000-pps pulse train would improve rate discrimination of moderate-rate (100–500 pps) pulses. The use of these so-called "conditioning pulses" has been shown to abolish the alternating-amplitude ECAP pattern (Rubinstein *et al.*, 1999). Experiment 3 studied whether pitch increased monotonically to higher overall pulse rates when multiple electrodes, rather than a single electrode, were stimulated (McKay *et al.*, 2005). Overall, none of the manipulations performed in the three experiments produced a substantial improvement in performance at the upper end of the rates studied. Section V discusses the generality of the present findings and considers additional steps that may be necessary to extend the range of rates that can be accurately encoded by CI users.

II. EXPERIMENT 1: EFFECTS OF SIGNAL DURATION AND ONSET/OFFSET ENVELOPE

A. Method

Six users of the Nucleus CI24M implant (Table I) were presented with biphasic pulse trains to electrode 11, in monopolar (MP1+2) mode, with a pulse duration of 45 μs per phase and an interphase gap of 8 μs. In different conditions, the pulse trains were either turned on abruptly and had a duration of 200 or 800 ms or, for the 800-ms duration, were turned on and off with 300-ms ramps. The ramps were linear in terms of Cochlear Corporation's (roughly logarithmic) clinical "current units" (CUs), with end points corresponding to threshold and the steady-state amplitude of the central portion of the pulse train (see below). Stimuli were controlled using the APEX software package (Laneau *et al.*, 2005) and checked using a test implant and digital storage oscilloscope.

Rate discrimination was measured for 100-, 200-, 300-, 400-, and 500-pps standards using the "mixed-block" procedure described by Kong *et al.* (2009). On each trial, the listener was presented with the standard and a signal, having a 35% higher rate, in random order, and was required to indicate which interval contained the higher pitch. Responses were scored as correct when the signal interval was chosen, and correct-answer feedback was provided. The order in

TABLE I. Details of the cochlear-implant users who took part in the experiments.

Subject	Age (years)	Etiology	Duration of profound deafness (years)	Duration of implant use	BKBq (%)	BKBn (%)
S1	61	CSOM	10	8 years	90	85
S2	77	Otosclerosis/noise induced	22	5 years	90	69
S3	41	Congenital progressive	35	2 years	97	46
S4	76	Progressive unknown	5	5 years	84	78

S7	60	Sudden, viral	>30	1 year	58	14
M1	44	Progressive unknown	2 years	18 months	98.7%	88.0%
M2	72	Unknown	Unknown	2 years	Unknown	Unknown

which the different standard rates were presented from trial to trial was randomized.[1] Each block consisted of 10 trials per standard rate, and the results from 10 blocks were averaged; each data point presented here therefore corresponds to the mean of 100 trials.

Prior to the main part of the experiment, the stimuli were loudness balanced using the method described by Landsberger and McKay (2005). A pair of stimuli was presented to each subject. At the initial presentation, the first stimulus in the pair was fixed at "comfort ("C") level" and the second was presented at a much quieter level. The subject was instructed to raise the level of the variable sound (second stimulus) until it was slightly louder than the fixed sound and then reduce the level until the two sounds were equally loud. All baseline rates were loudness matched to the baseline rate of 100 pps, and then each signal was loudness matched to the corresponding baseline.

B. Results

Data for each listener are shown separately in the six panels of Fig. 2(a). Listeners S1–S5 show the "classic" pattern in most conditions, with very good performance at the lowest standard rates, that deteriorates to near-chance levels at the highest rates tested. Exceptions are listener S1, who performs close to ceiling at all rates tested for the 200-ms duration, and listener S3, who for the 200-ms duration shows the nonmonotonic pattern recently described by Kong *et al.* (2009). Listener S6 shows an unusual pattern, in all three conditions, with below-chance performance at intermediate rates. Note that this occurred despite the fact that correct-answer feedback was provided after every trial. This result is consistent with a decrease in pitch with increasing pulse rate over some range of rates, and we will return to this finding in Sec. IV.

Data averaged across listeners are plotted in Fig. 2(b), which shows that mean performance declines monotonically with increasing standard rate. Although performance appears to be slightly better at high rates for the 200-ms duration, a two-way (rate × condition) repeated-measures analysis of variance (ANOVA) found no interaction between rate and condition [$F(8,5)=1.6$, $p=0.2$], and the main effect of condition just failed to reach significance [$F(2,10)=3.7$, $p=0.06$].

The rationale for experiment 1 was that the alternating-ECAP pattern should be reduced by turning the pulse trains on gradually and that the reduction in the alternation observed later in the pulse train in animal experiments might reduce the influence of the alternation on perception, by allowing the listener to focus on the later portions of the stimulus. However, neither of these two manipulations helped. Overall, performance at high rates was, if anything, slightly better for the shorter (200-ms) stimulus, and the addition of 300-ms ramps produced only a small and nonsignificant improvement (compare upright and inverted triangles in Fig. 2).

III. EFFECT OF HIGH-RATE "CONDITIONING" PULSES

A. Rationale

As noted in the Introduction, it has been suggested that the deterministic nature of the AN response to electrical stimulation may impair the encoding of temporal information. Two approaches—the addition of noise to the signal and the addition of high-rate background pulses—have been proposed (Morse and Evans, 1996; Rubinstein *et al.*, 1999; Zeng *et al.*, 2000; Chatterjee and Robert, 2001). In both cases, it has been suggested that there is an optimal level of the added stimulus that increases the stochasticity of the response to the signal without "swamping" it. Experiment 2 was motivated by suggestion of Rubinstein *et al.* (1999) that a more stochastic pattern of firing could be introduced by the addition of high-rate background pulses, and by their demonstration that the alternating-amplitude ECAP pattern in response to a 1016-pps pulse train could be eliminated by the addition of a 5081-pps conditioner. Note that, although the high-rate pulse trains used to study the effects of conditioners on threshold and on neural responses are typically presented continuously (Runge-Samuelson *et al.*, 2004; Hong and Rubinstein, 2006), this is not crucial for an effect on the ECAP amplitude alternation to be observed; the conditioner used by Rubinstein *et al.* (1999) was turned on only 29 ms before the 1016-pps pulse train. Experiment 2 used the same "mixed-block" procedure as in experiment 1, with the following differences.

Four users of the Nucleus CI24M implant and two users of the MedEl Pulsar implant (M1 and M2, see Table I) took part. In both cases the stimulus duration was 300 ms. For the CI24M users, rate discrimination was measured for baseline

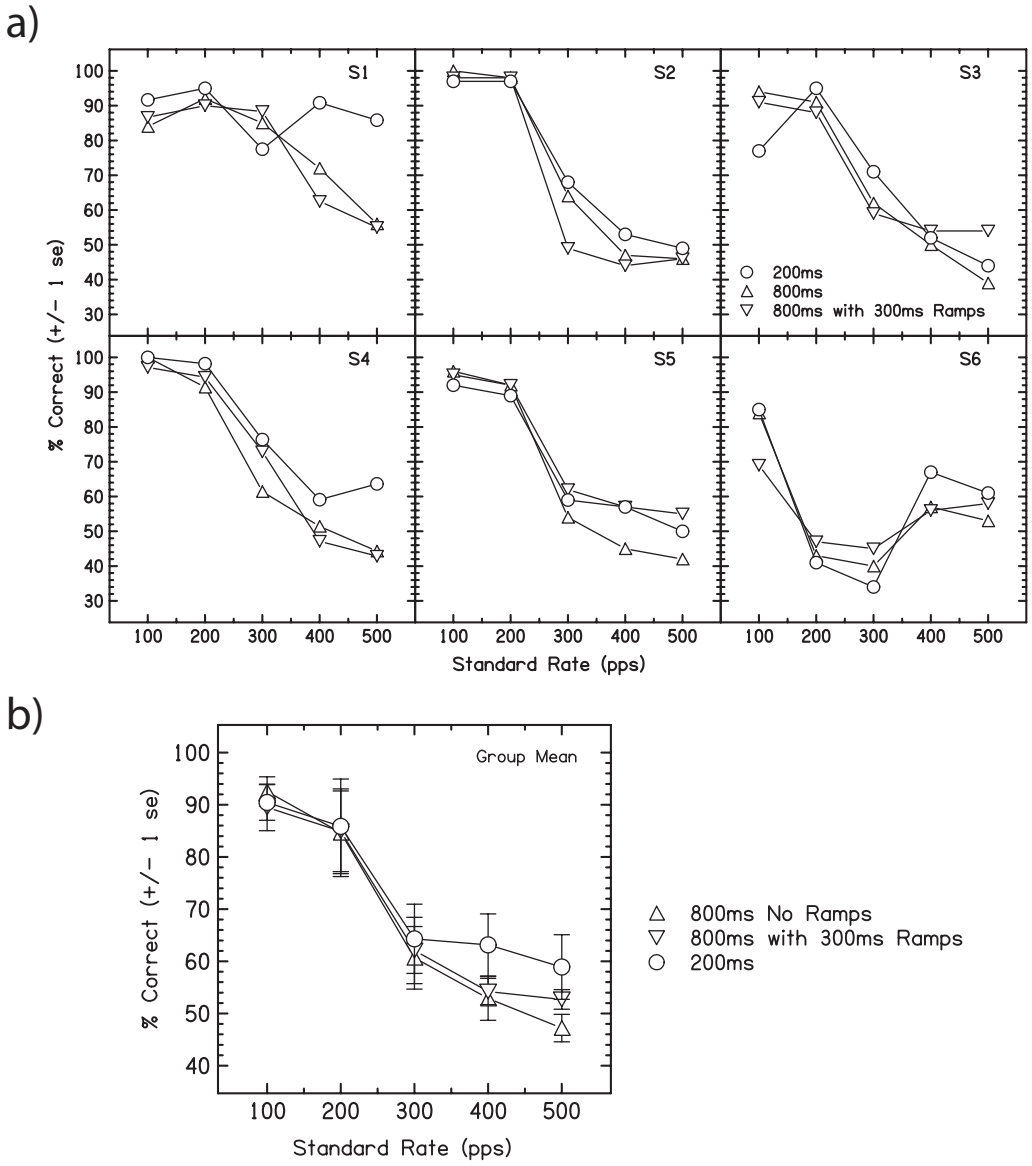

FIG. 2. (a) shows rate discrimination, obtained using the "mixed rate" procedure, for the six subjects of experiment 2. Data are shown for signal durations of 200 and 800 ms, and, in the latter case, with and without 300-ms onset and offset ramps. (b) shows the data averaged across listeners, with standard errors indicated by error bars.

rates of 100–500 pps in the absence of a conditioner and in the presence of a 5000-pps conditioner that, in different conditions, could have one of a range of different levels. These levels were based on a preliminary experiment that measured the threshold and comfort ("C") level for a 300-ms 5000-pps pulse train. The conditioner levels were then chosen to be at −20%, 0%, 20%, 40%, 60%, and 80% of the dynamic range, where 0% corresponds to threshold and 100% to C level. These percentages were calculated in terms of Cochlear Corporations CUs, which are a roughly logarithmic function of current. The conditioners were turned on 300 ms before and off 200 ms after, each standard and signal pulse train. Interpulse intervals were filled with an integer number of conditioner pulses at the conditioner rate. The different conditioner levels were run in separate blocks of 10 trials per point, in a counterbalanced order, until 100 trials per point had been collected for each subject and condition. Pulse duration was 45 μs/phase and the interphase duration was 8 μs. Stimuli were checked as in experiment 1.

Stimulation of the MedEl implant was implemented using the "RIB2" software and hardware produced by the University of Innsbruck, and checked by connecting the output of a "detector box" whose internal electronics are the same as for a Pulsar implant, to a digital storage oscilloscope. The experimental method was similar to that for the CI24M users, except that dynamic range was defined in terms of MedEl's (approximately linear) current units, and that the conditioner pulse trains were turned on 4 min before each block of trials.[2] For these listeners, within each session two blocks of ten trials/point were run for each conditioner level before moving to the next-highest level, to avoid any residual effects from the conditioner in one block of trials on the neural responses during the next block. In addition, one listener (M1) was subsequently retested about 1 month later using conditioners turned on and off before each stimulus, as for the CI24M users. Pulse duration was 43 μs/phase with no interphase gap. For both groups of listener, the stimuli were loudness balanced in the absence of a conditioner using

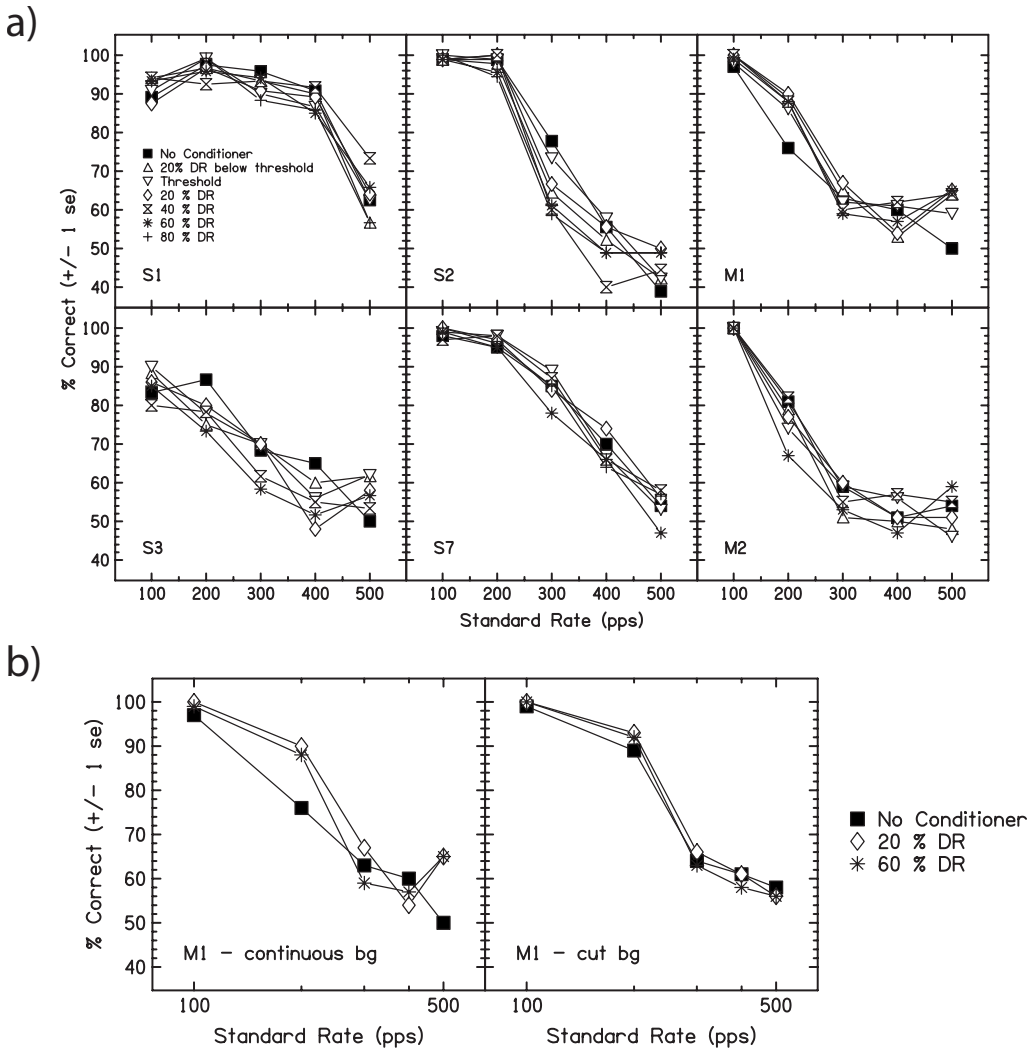

FIG. 3. (a) shows rate discrimination data from experiment 2, for conditions without a conditioner (solid squares) and for conditioners of various levels (open symbols and asterisks; color online). (b) shows the original data for listener M2 obtained with a continuous conditioner in the left-hand panel, together with, in the right-hand panel, a retest in which the conditioner was turned on and off before each stimulus.

the same method as for experiment 1. These loudness balanced levels were used regardless of the presence or level of the conditioner.

B. Results

Results from the six listeners who took part in experiment 2 are shown in Fig. 3(a). Performance in the absence of a conditioner, shown by the filled squares, was universally good at the lowest rate tested (100 pps) and declined monotonically at higher standard rates. Generally speaking, the conditioner pulses had no substantial effect on performance. Minor exceptions were listeners S2 and S3, for whom most conditioners impaired performance, and listener M1, for whom all levels of conditioner produced slightly better performance at 200 and 500 pps than when no conditioner was present. To test whether this small improvement depended on the conditioner pulses being presented continuously, this listener was retested several months later with conditioners that were turned on 300 ms before and off 200 ms after, each standard and signal pulse train. The retest was performed with no conditioner and with conditioner levels corresponding to 20% and 60% of the dynamic range. The results are shown in the right-hand panel of Fig. 3(b), with the original data for the same conditions replotted in the left-hand panel. The main difference between the two plots is that performance at 200 and 500 pps, in the absence of the conditioner, was better in the second set of measures. Combined with the fact that performance for all levels of the continuous conditioner was similar, the most parsimonious explanation for the apparent effect of the continuous conditioner is that the initial estimate of no-conditioner performance was, for some reason, too low at 200 and 500 pps, and that there was no reliable effect of adding a conditioner.[3]

IV. EXPERIMENT 3: CONCURRENT STIMULATION OF MULTIPLE ELECTRODES

A. Rationale and method

McKay *et al.* (2005) investigated an informal clinical observation that, when a patient's CI is reprogramed to use a speech-processing strategy with a faster pulse rate, the patient sometimes reports hearing a change in pitch even though both the original and new pulse rates are much higher

than 300 pps. They considered the possibility that the reported pitch change arose from the change in current level necessitated by the new rate, which may have resulted in "place-of-excitation" differences. To test this idea, they generated nine seven-electrode stimuli, comprising three "spectral profiles" (with current maxima at apical, middle, and basal locations) and three pulse rates of 450, 900, and 1800 pps per electrode. A multidimensional scaling study revealed separate perceptual dimensions for spectral profile and pulse rate. The authors concluded that the increases in pulse rate above 450 pps, when applied to multiple electrodes, produced detectable changes in a perceptual dimension that were not conveyed by place-of-excitation cues. This dimension could, of course, be pitch, but other possibilities exist, including the greater adaptation observed for higher rates of stimulation (Zhang *et al.*, 2007) and changes in other temporal properties such as perceived roughness.

Experiment 3 tested whether increases in pulse rate produce increases in pitch over a wider range with multiple electrodes, compared to single-electrode, stimulation. In the single-electrode condition, 500-ms 25 μs/phase pulse trains applied to electrode 11 of a CI24M implant in monopolar ("MP1+2") mode. The interphase gap was 25 μs. Nine pulse rates, ranging from 112.5 to 1800 pps in half-octave steps, were used. In the "flat" and "peak" spectral profile conditions, the same pulse rates were applied concurrently to electrodes 8–14 inclusive. Electrodes were stimulated in a basal to apical order and the interpulse interval between electrodes corresponded to 1/8 of the stimulus period. Before testing, comfort (C) levels were obtained for each subject, spectral profile, and rate. Initially, subjects indicated the comfort level of each electrode presented in isolation and at a rate of 450 pps. For multiple-electrode configurations, C level was determined by presenting all seven electrodes at their respective relative levels and at a rate of 450 pps, initially at a level well below expected comfort level. For "flat" spectral profiles, each electrode was presented at the C level determined for single-electrode presentation minus a global adjustment (in CUs) compensating for the combined loudness effects of several electrodes. "Peaked" profiles were based on these same individual electrode levels but with attenuations of 25, 18, 5, 0, 5, 18, and 25 CUs applied to electrodes 8–14, respectively. The levels of all electrodes were then varied together until the subject reported that the C level had been reached. Using the C level obtained at 450 pps as a reference, the C level for 112.5 225, 900, and 1900 pps trains were obtained by the method of adjustment described above.

For each condition, the pitches of the different pulse-rate stimuli were compared in experiment 3a using the "Midpoint comparison" (MPC) procedure described by Long *et al.* (2005). The MPC procedure ranks stimuli along a single perceptual dimension (e.g., pitch) in an optimally efficient manner, by means of paired comparisons. Initially, two stimuli are selected at random and the subject indicates which has the higher pitch. Next, a new stimulus is compared to the higher ranked of these two and, if judged higher, is put in first place; otherwise it is then compared to the lower-ranked stimulus and positioned either second or third. As an example, later on in the procedure, a provisional ranking of seven stimuli might be [C I E A F B D]. The new stimulus, G, would first compared to the middle rank (A), and if judged higher the list is bisected so that it would be compared to B; if judged lower than B, it would then be compared to F. The procedure is continued until a rank is obtained for all electrodes and was repeated 20 times for each condition, allowing us to estimate a mean and standard error for each rank. For each repetition, the various rates were introduced to the procedure in a fresh random order. The procedure has several desirable properties, that it shares with the mixed-block procedure used in experiments 1 and 2: (i) it is not subjected to many of the biases that plague magnitude-estimation ("pitch scaling") tasks (Poulton, 1979); (ii) there is no single stimulus that is presented repeatedly throughout each block, as is the case with adaptive procedures or the method of constant stimuli; this reduces the likelihood of the subject focusing on some idiosyncratic feature of one stimulus; (iii) pitch varies substantially throughout each run, helping the subject focus on that dimension; and (iv) each run includes some easily discriminable pitches, preventing the subject from becoming discouraged. We chose to use it instead of the mixed-block procedure for three reasons: (i) the absence of feedback makes the procedure more appropriate for revealing pitch reversals, (ii) it provides an overview of how pitch varies over a wide range of closely spaced rates, and (iii) because we were studying a wide range of rates, many of which we expected to produce very similar pitches, the mixed-block procedure, in which only adjacent rates are compared, would result in the subject spending much of the time guessing. This problem was partially alleviated by the midpoint comparison procedure because nonadjacent rates were often compared.

To determine whether the different pulse rates were discriminable, experiment 3b used the mixed-block procedure described in Sec. II, with the important difference that a three-interval two-alternative forced-choice (3I2AFC) trial structure was used. This "odd-man-out" procedure allowed the subject to use any difference between the stimuli to identify the stimulus with the higher rate, which could occur in either the second or third intervals. Both single-electrode and peaked stimuli were used, with standard rates of 112.5, 225, 450, 900, and 1272 pps. Signal rates were always half an octave higher than the corresponding standard, and correct-answer feedback was provided after every trial.

B. Results

The results of the MPC procedure of experiment 3a are shown in Fig. 4(a). For the single-electrode condition (filled triangles), the results are generally consistent with those obtained using the mixed-block procedure of experiments 1 and 2. Listeners S1, S2, S4, and S7 all show an increase in pitch up to some value, above which the functions asymptote. Furthermore, listener S2, whose functions asymptote at a lower rate than the others, also showed discrimination performance that declined at a low rate in experiments 1 and 2. Listeners S1 and S7, whose pitch rankings increased up to rates of about 636 and 318 pps, respectively, also showed good per-

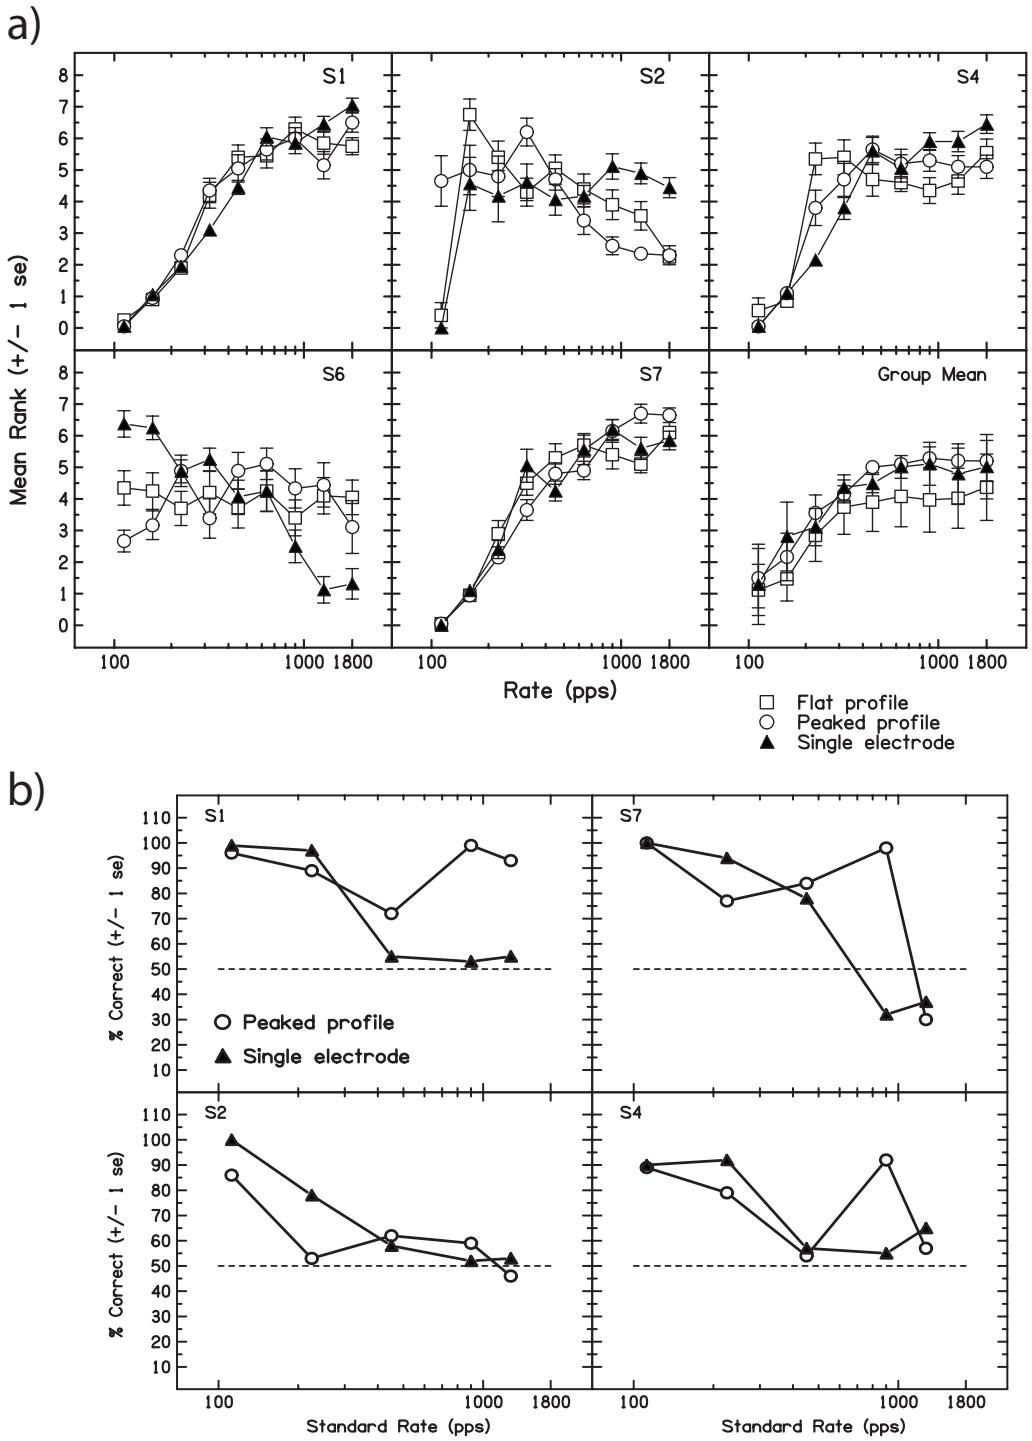

FIG. 4. (a) shows the results of the midpoint-comparison procedure of experiment 3a for single-electrode and multielectrode stimulation. (b) shows the results of the odd-man-out-discrimination task used in experiment 3b.

formance up to relatively high rates in experiment 2 [Fig. 3(a)]. Listener S6 shows an unusual pattern, in that pitch appears to decrease with increasing pulse rate between 159 and 225 pps, and also above 636 pps. This listener also showed an unusual pattern in experiment 1 [Fig. 2(a)], with below-chance performance for standard rates of 200 and 300 pps.

The topic of primary interest concerns the comparison between the functions obtained with single-electrode and multielectrode stimuli. Inspection of Fig. 4(a) shows that in no case does pitch continue to increase up to a higher rate for the multielectrode (open symbols) stimuli than for the single-electrode (filled triangles) stimulus. The only discernable effects are a lower asymptote for listener S4, flat functions for S6, and a decrease in pitch at higher pulse rates for S2. A two-way repeated-measures ANOVA on the mean ranks for each subject, excluding the anomalous data of S6, revealed the expected main effect of pulse rate [$F(8,24)=11.78$; $p<0.02$], but no main effect of spectral profile [$F(2,6)=1.0$, n.s.] and no interaction [$F(16,48)=1.22$, n.s.].[4]

The discrimination results from the odd-man-out task of experiment 3b are shown in Fig. 4(b). For three listeners (S1, S7, and S4), there are one or more high rates where discrimination is better with multielectrode (peaked) than with single-electrode stimulation, even though pitch ranking over these range of rates had reached an asymptote in experiment 3a. This may help reconcile the negative findings of experiment 3a with observation of McKay *et al.* (2005) that changes to pulse rate applied to multiple electrodes gave rise to a discriminable perceptual dimension, even though rate changes to a single electrode were not detectable in a forced-choice task. That is, adding electrodes may allow a rate change to become discriminable, without necessarily providing a consistent change in pitch. One way in which this could happen comes from finding of Zhang *et al.* (2007) that adaptation in AN fibers depends on pulse rate: with interleaved stimulation on different electrodes the "effective" pulse rate for any given neuron is increased, and this could result in more adaptation. Alternatively, multielectrode stimulation could influence the temporal pattern of firing, e.g., by abolishing the alternating-amplitude ECAP pattern, and this difference could be detectable without improving pitch perception. Another possible explanation is that subjects used small loudness differences in the forced-choice procedure, which did not lead to differences in pitch, and that the salience of these differences depended on the number of electrodes being stimulated.

V. DISCUSSION

A. Neural basis of temporal pitch perception by CI users

The results presented here show that a number of stimulus manipulations, that one would reasonably expect to have a substantial impact on the AN response to a pulse train, do not produce a marked improvement in rate discrimination at high rates. A related finding was obtained by Kong *et al.* (2009), who compared rate discrimination of regular pulse trains with the ability to discriminate changes in modulation rate imposed on a 5000-pps carrier. They found that, in both conditions, the variation in performance as a function of the standard (modulation) rate differed markedly across listeners, but that, for a given listener and electrode, the pattern of results was similar for the two stimuli. Similarly, in experiment 2 of the present study, the upper limit differed across listeners in a way that was immune to the addition of conditioning pulses of a range of levels. Overall, the results lead to the conclusion that the upper limit of temporal pitch is not specific to any particular temporal pattern of AN activity. However, this does not, of course, mean that features of the auditory nerve response can never affect pitch perception. Indeed, we have argued elsewhere that, at low rates, neural refractoriness does affect temporal pitch (Carlyon *et al.*, 2002; van Wieringen *et al.*, 2003; Carlyon *et al.*, 2008b), and the presence of some pitch reversals in experiment 3 could result from an alternating-amplitude ECAP without this particular pattern being the reason why temporal pitch generally asymptotes at high rates.

Although the present data argue against an explanation of the upper limit in terms of peripheral phenomena such as reflected by the alternating-amplitude ECAP pattern, data from other studies indicate that the limitations to high-rate processing are not specific to pitch judgments. For bilateral CI users, discrimination of interaural time differences between pulse trains presented to each ear also deteriorates with increases in pulse rate (van Hoesel and Clark, 1997; van Hoesel and Tyler, 2003; van Hoesel, 2007), and, even when a rate difference between matched electrodes in the two ears provides a usable binaural cue at low rates, this is not the case when the pulse rate is high enough for monaural rate discrimination to break down [Carlyon *et al.*, 2008a: see Fig. 1(c) of the present article]. Hence we can tentatively conclude that the upper limitation arises at a site of processing that is central to the AN but common to binaural and pitch processes. One possibility is suggested by tantalizing observation of Snyder *et al.* (1995) that cells in the inferior colliculus (IC) differ in the highest rate to which they will phase lock, but that this "upper limit" is similar, for a given cell, regardless of whether the phase locking is to the pulse rate of a simple pulse train or to the modulation rate imposed on a high-rate carrier. Hence a stimulus-independent limitation may occur at or before the IC, although we should of course stress that this suggestion remains speculative.

The data presented here and elsewhere are also consistent with the idea, mentioned in the Introduction, that the electrical stimulus would need to be modified in order for more central processes to effectively process the temporal activity present in the AN. As long ago as 1982, Moore (1982) suggested that the range of interpulse intervals that is effectively processed by the brain is linked to the characteristic frequencies of the AN fibers that convey that information, and this idea has been more recently implemented in a quantitative model (Bernstein and Oxenham, 2005). Interestingly, although this idea suggests that high-rate information should be more effectively conveyed by stimulating the base of the cochlea, recent recordings from the IC suggest that, conversely, stimulation of AN fibers that innervate the apex of the cochlea may better convey temporal information (Middlebrooks and Snyder, 2009). Another suggestion is that the brain may exploit the phase differences in the response of AN fibers having different CFs, which arise from the slowing of the traveling wave on the BM (Shamma, 1985; Moore and Carlyon, 2005; Cedolin and Delgutte, 2007). Clearly, the stimuli used here and in other studies have neither reproduced these timing differences nor produced either an exact "place-rate" match or stimulation of apical AN fibers. Hence the present results should not be interpreted as meaning that *no* stimulus manipulation can improve temporal processing of high-rate electrical stimuli. It is also true that none of our listeners fell into the "star" category who can reliably discriminate rates higher than 500 pps (Hochmair-Desoyer *et al.*, 1983; Wilson *et al.*, 1997b; Kong *et al.*, 2009). It is therefore possible that either our method of stimulation or the neural status of our particular listeners imposed some additional limitation on performance that masked any potential improvement in the peripheral neural code. This issue is currently under active investigation in our laboratory (Macherey and Carlyon, 2009). What is clear, however, is that for

typical CI users, and in the absence of special types of stimulation that are yet to be implemented, manipulations that we would expect to substantially change the temporal pattern of auditory nerve activity do not have a marked or consistent effect on temporal pitch perception at high rates.

ACKNOWLEDGMENT

We thank Antje Ihlefeld for programming the RIB2 system used in experiment 3.

[1]As discussed by Kong *et al.* (2009), this procedure has several strengths: (i) unlike an adaptive procedure, it is possible to measure performance in conditions where it is likely to be close to chance, (ii) the variation in the standard from trial to trial helps keep the listener's attention focused on the pitch dimension and encourages him/her to use that perceptual dimension for all judgments, (iii) the presence of some "easy" (low-rate) standards in each block prevents discouragement, and (iv) the use of a two-interval, rather than odd-man-out procedure, makes it less likely that the listener will use some extraneous cue such as loudness or roughness differences. A weakness is that performance at some rates may be obscured by ceiling effects. However, this was considered not to be critical for the present study, whose purpose was to study performance at rates that, in some conditions, were expected to be close to chance.

[2]For listener M1, all conditioners having a level above threshold (0% of dynamic range) were still audible at the end of this 4-min period, and no marked reduction in loudness was observed. Listener M2 described conditioner levels of 20% and 40% as just audible at the start and inaudible at the end of the 4-min adaptation period, with some reduction in loudness for the 60% level

[3]The conclusion that conditioner pulses did not improve rate discrimination was supported by the results of a two-way repeated-measures ANOVA. The use of this statistic is complicated by the facts that the "optimal" conditioner listener may vary across listeners (Hong and Rubinstein, 2006) and that different conditioner levels were used for the Cochlear and MedEl listeners. We therefore used only two levels of the "conditioner" variable: no conditioner at all, and the level that, for each listener, gave the highest percent-correct score averaged across all rates. Such a method runs the risk of obtaining a significant effect of conditioner by chance because we are selecting the conditioner level producing the best performance from a set of six. Nevertheless, the ANOVA, while producing a main effect of rate $[F(4,20)=15.575;\ p<0.001]$, produced no effect of conditioner $[F(1,5)=2.96,$ n.s.] and no significant interaction $[F(4,20)=1.86,$ n.s.].

[4]When all subjects were included, there was still no effect of profile and no interaction, but the main effect of rate just failed to reach significance.

(Received 11 May 2009; revised 13 December 2009; accepted 15 December 2009)

At present commercially available bilateral cochlear implants (CIs) improve their users' speech understanding in noise but they employ two independent speech processors that cannot provide accurate and appropriate interaural level and time differences as seen binaurally in normal hearing (NH) listeners. Previous work suggests that binaural cues are accessible to bilateral CI users when presented to single pairs of pitch-matched electrodes, but the scope was limited and the mechanisms remained unclear. In this study, binaural masking level differences (BMLDs) were measured in five bilateral Nucleus-24 CI users over multiple pairs of pitch-matched electrodes. Average BMLD was 4.6 ± 4.9 dB, but large individual variability prevented significance ($p=0.09$). Considering just the 125 Hz condition, as in previous work, phase (N0S0 vs N0Sπ) and electrode effects were significant. Compared with simulated bilateral CI users, actual bilateral CI users had proportionally higher thresholds for N0Sπ than N0S0. Together the present results suggest that the performance gap in BMLDs between CI and NH listeners is not due to a lack of sufficient acoustic cues in the temporal envelope domain but to a true binaural deficit related to a central mechanism in deprived binaural processing. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3290994]

I. INTRODUCTION

Cochlear implant (CI) users can understand most speech in quiet, but the presence of noise can greatly challenge that understanding (i.e., Zeng and Galvin, 1999; Spahr and Dorman, 2004; Stickney *et al.*, 2004). Although a second implant can benefit CI users for hearing in noise (Müller *et al.*, 2002; Litovsky *et al.*, 2004, 2006a; Buss *et al.*, 2008; Litovsky *et al.*, 2009), binaural sensitivity in these bilateral CI users falls short of normal hearing (NH) levels (van Hoesel *et al.*, 1993; Buss *et al.*, 2008; Nopp *et al.*, 2004; Laszig *et al.*, 2004; van Hoesel, 2004; Verschuur *et al.*, 2005; Neuman *et al.*, 2007; van Hoesel *et al.*, 2008). In addition, there is a performance gap between testing the binaural sensitivity of CI users under ideal circumstances (i.e., Long *et al.*, 2006) and their performance under real world conditions (i.e., van Hoesel *et al.*, 2008). So far, measures of true binaural hearing, such as squelch, which requires computation of differences between sounds entering the left and right ears, appear to be of marginal benefit to bilateral CI users (Nopp *et al.*, 2004; Laszig *et al.*, 2004; Long *et al.*, 2006; van Hoesel, 2004; Buss *et al.*, 2008; van Hoesel *et al.*, 2008). Uncoordinated stimulation timing produced by independent speech processors may be one limiting factor for binaural sensitivity. However, data from experiments using the Spear3 research interface (Hearworks, Pty, Melbourne, Australia), which can deliver highly synchronized stimulation pulses to both ears, still show lower than normal levels of binaural function in CI (Long *et al.*, 2006; van Hoesel *et al.*, 2008; Litovsky *et al.*, 2010).

Binaural masking level difference (BMLD) is one measure of binaural sensitivity (Hirsh, 1948). Unlike head shadow cues or redundancy, BMLD requires precise computations of differences in the sounds entering the left and right ears (Durlach, 1963). For a signal-in-noise detection task, when the signal phase is inverted between the two ears, there is a higher likelihood for detection than when the signal phase is identical between the two ears. BMLD is calculated as the difference in threshold between the two conditions. In NH listeners this difference can be as large as 20 dB for tones (van de Par and Kohlrausch, 1997). Under similar stimuli conditions, BMLDs measured in bilateral CI users averaged ~9 dB when stimulating with single pairs of electrodes (Long *et al.*, 2006). Similar tests in children show 6.4 dB for CI and about 10 dB for NH (Van Deun *et al.*, 2009a, 2009b). The cause of this gap between normal and CI listeners is not well understood.

Furthermore, BMLD in CI users appears to be much smaller for more complex sounds. An experiment that used speech under realistic listening conditions reported <1.5 dB of binaural unmasking (van Hoesel *et al.*, 2008), which is significantly less than the 9 dB found in Long *et al.*, 2006. In contrast, NH listeners typically had BMLD values that fell

[a)]Author to whom correspondence should be addressed. Electronic mail: telu@uci.edu

between the range seen for tones and speech (Levitt and Rabiner, 1967). This would suggest that in NH listeners binaural processing of BMLD for speech can be predicted by BMLD for tones. In the present study, we examined several factors that could potentially affect BMLDs in bilateral CI users under more realistic stimulation conditions than previously studied.

The first factor is that BMLD values may be influenced by electrode position along the cochlea. Complex stimuli such as speech have multiple frequency components, and in normal hearing listeners, BMLD decreases with increasing signal frequency (van de Par and Kohlrausch, 1997). BMLDs were shown to be similar between a 125 Hz sinusoid and a 125 Hz envelope in the form of "transposed" stimuli with a 4000 Hz carrier. This "transposition" of the stimuli places the 125 Hz signal at the 4000 Hz cochlear region. The similarity in BMLDs for NH listeners suggests that the 125 Hz sinusoid and the 125 Hz envelope of the transposed stimuli were processed similarly despite the activity at different cochlear regions (125 Hz vs 4 kHz). This is relevant to continuous interleaved sampling (CIS) based processing strategies in CI as sounds are typically transmitted via envelopes on top of a high pulse rate carrier (Wilson *et al.*, 1991). For CI users, BMLDs were reported for basal, middle, and apical electrode pairs, but only one pair was tested in each subject (Long *et al.*, 2006). Although BMLDs are expected to be similar over multiple cochlear regions in a single CI user as they are in NH listeners, it has not yet been experimentally verified.

A second factor that may influence BMLD levels in CI is the stimulus signal frequency. In normal hearing listeners, ~10 dB BMLDs were reported with signal frequencies as high as 4000 Hz (van de Par and Kohlrausch, 1997). Existing studies show that CI users have difficulty discriminating higher pulse rates and modulation frequencies starting around 300 Hz under monaural (Zeng, 2002) and binaural (Carlyon *et al.*, 2008) conditions. The 125 Hz signal frequency used in Long *et al.*, 2006 is well within the temporal discrimination ability of CI users, but BMLD at higher signal frequencies has not been systematically addressed. If the mechanisms that cause this limitation play a role in binaural sensitivity, BMLD values may deteriorate with higher stimulus frequencies and with complex sounds that have higher frequency components.

Third, there is the possibility that the interaction between narrowband noise and a 125 Hz signal combined with the envelope extraction by the speech processor produces enough detectable difference cues between NmSm and NmS-m, where m and -m indicate monaural and the phase reversed monaural noise and signal stimuli. If these NmSm and NmS-m are discriminable monaurally, it could inflate BMLD values. For this reason, it is important to test whether BMLDs could be a result of monaural discrimination of the signal envelope.

Fourth, prior auditory deprivation can negatively impact binaural processing (Silman *et al.*, 1984; Hall and Grose, 1993; Gray *et al.*, 2009). It is known that the lack of auditory inputs can lead to neural degeneration in the periphery (Hinojosa and Lindsay, 1980). Furthermore, there is evidence, at least in children, that binaural processing continues to develop with experience and age (Hogan *et al.*, 1996; Litovsky, 1997; Hall *et al.*, 2004; Litovsky *et al.*, 2006b), and a loss of binaural input could arrest this development.

A recent study of patients with unilateral hearing loss due to atresia suggested that there is a loss of 2 dB binaural advantage due to squelch for each decade of life with only unilateral hearing (Gray *et al.*, 2009). The recovery of binaural sensitivity was not studied. However, it was earlier reported that adult patients with unilateral conductive hearing loss experience a blunting of binaural sensitivity, which eventually recovers to normal or near-normal levels by 1 year after surgical intervention (Hall and Grose, 1993). These subjects had normal cochlear function and once the conductive hearing loss was remedied, their hearing function was essentially restored to normal. Despite restoring the ability to hear, the cochlear implants do not restore normal hearing due to coarse frequency resolution, and furthermore, the use of independent speech processors virtually guarantees uncoordinated stimulation in pulse timing, thus providing abnormal interaural time difference (ITD) cues in the fine-structure of sound. Therefore even if the auditory system is capable of recovering normal binaural function, it would not be able to do so given abnormal and coarse frequency inputs provided by both CIs.

Auditory deprivation on unilateral cochlear implant use has been documented (Tyler and Summerfield, 1996), the effects of which on binaural function in adults has not been adequately explored and there are limited studies. The main effect is that some binaural function such as squelch is recovered over the course of 1 year (Buss *et al.*, 2008). The evidence for bilateral hearing aids is a little clearer. Comparing two groups, one fitted unilaterally with hearing aids and the other bilaterally, there was a difference between ears in the unilaterally implanted group (Silman *et al.*, 1984). As a result of auditory deprivation, it is unknown to what extent limited binaural processing is due to the implant and speech processor and how much is due to degeneration of binaural processing in the central auditory system. This may be addressed, in part, by comparing the performance of NH listeners under acoustic CI simulation to that of actual CI users.

The overall aim of this study is to investigate the extent of binaural sensitivity quantifiable by BMLD in bilateral CI users and why it falls short of normal performance on binaural listening tasks. Building upon the results from Long *et al.* (2006), the questions that this study will directly address are as follows: (1) How BMLDs compare across basal, middle, and apical pairs of pitch-matched electrodes; (2) how BMLDs change with signal frequency; (3) would masking level differences under monaural conditions predict binaural BMLDs; and (4) how do normal hearing listeners compare when subjected to acoustic CI simulations.

II. METHODS

A. Subjects

Five bilaterally implanted Nucleus 24 patients were tested (Table I). Several of these patients wore hearing aids for a number of years. The two implantations were spaced 1

TABLE I. CI subjects.

	Gender	Age	Age at deafness	Etiology	Age at hearing aid use	Left/right implanted (years ago)	Basal pair (L/R)	Middle pair (L/R)	Apical pair (L/R)	HINT speech scores quiet/noise (%)

year apart in three subjects and 12 years in one subject. The fifth subject had both ears implanted simultaneously. Speech performance scores for these subjects are listed in Table I. Sound input levels were set so that maximum stimulation levels were approximately 95% of most comfortable level (MCL) for that electrode pair.

For each subject, pairs of pitch-matched electrodes were found and balanced for loudness at MCL since binaural sensitivity is higher for pitch-matched pairs in CI (van Hoesel and Clark, 1997; Lawson *et al.*, 1998; Long *et al.*, 2003, 2007) and frequency-matched stimuli in NH (Henning, 1974; Nuetzel and Hafter, 1981). As an example, an apical pair (i.e., 20L, 20R) was selected and threshold and comfort levels were determined individually. Each electrode in a pair was played sequentially and the subject was asked to make a pitch judgment. If there was a perceived pitch difference, the next adjacent electrode on one side was selected, typically the more recently implanted ear, and the pitch was compared again. This search for a pitch-matched pair was iterated as many times as necessary until a suitable match was found. If needed, the loudness was balanced by lowering the MCL of the louder electrode to match. The pitch and loudness match was confirmed again. In a few cases, subjects reported that the similarity of pitch match changed when balancing loudness, requiring a search for a different pitch-matched pair. Three pairs of electrodes—apical, middle, and basal—were tested in each subject. The exact locations of these matched pairs are listed in Table I. Finding and balancing each pair of pitch-matching electrodes could take anywhere from 30 min to over 1 h, and sometimes longer.

B. Stimulus and hardware configuration

All stimuli were generated digitally using MATLAB (Mathworks, Inc., Natick, MA) with 44.1 kHz sampling rate through a PC sound card. Stimuli consisted of 300 ms sinusoids at 125, 250, or 500 Hz. Masking sounds were 400 ms band-passed noise with bandwidths of ±25, 50, and 100 Hz, centered at each sinusoid, respectively. N0S0 signals denote masking noise that was identical for both ears, and sinusoids that had a zero-phase difference (also identical) between the two ears. N0Sπ denotes the same masking noise, but sinusoids that are 180° out of phase (inverted) between the two ears. The ratio of amplitude of the sinusoid to the noise is the signal to noise ratio (SNR) in decibel.

The signal processing algorithm is similar to that described in Long *et al.*, 2006. The stimuli were presented through line-in jack, bypassing the microphone, on the Spear3 research interface (Hearworks, Pty, Melbourne, Australia) running a custom program that implemented a bilateral one-channel CIS program. Audio signals were digitized by the on-board analog-to-digital converters. The signal was half-wave rectified and low-passed filtered using a four-pole Butterworth filter. For the 125 and 250 Hz stimulus conditions, the signal was low-passed at 500 Hz, and the envelope of the signal was used to modulate a pulse train with a rate of 1000 pulses per second (pps). For the 500 Hz stimulus condition, the signal was low-passed at 1000 Hz before modulating a 2000-pps pulse train. A standard loudness growth map was used to compress the amplitude of the signal (as in Long *et al.*, 2006). The stimulation mode used was MP1+2 (monopolar), with 25 μs per phase and an 8 μs pulse gap. The left and right pulsatile outputs of the Spear3 were verified to be synchronized to within 1 μs by viewing signals on an oscilloscope after being fed through an "implant-in-a-box" (Cochlear Pty, Lane Cove, Australia).

C. Implementation of acoustic CI simulation

Ten normal hearing subjects (20–26 years old) were tested using unprocessed stimuli along with several different

vocoder configurations to acoustically simulate a bilateral CI listening condition. Only two subjects (NH1 and NH2) who were tested under unprocessed conditions returned for testing with the vocoder. A single-channel noise-excited vocoder was used to determine the extent to which envelope cues were preserved. Inputs were identical to those used for the experiments with CI listeners. Stimuli were half-wave rectified and low-passed at 500 Hz to extract the envelope. The resulting signal was used to modulate a broadband noise. Since the one-channel noise vocoder used here does not accurately simulate the conditions in which basal, middle, or apical pairs of electrodes were stimulated, a second vocoder model based on Gaussian-enveloped tones (Lu *et al.*, 2007) was used to simulate synchronized and pulsatile stimulation for different electrode pairs. As with the noise vocoder, stimuli were half-wave rectified and low-pass filtered. The resulting envelope signal was used to modulate the amplitude of tone pulses that had Gaussian-shaped time-amplitude envelopes. The pulse rate was set at 1000 Hz for the Gaussian-enveloped tone pulses. The duration of each pulse was approximately 1 ms. The simulated basal, middle, and apical channels had center frequencies of 5367, 1426, and 369.5 Hz, based on Greenwood's map (Greenwood, 1990).

Gaussian-enveloped tones have been used in binaural psychophysical experiments (Buell and Hafter, 1988; van den Brink and Houtgast, 1990), but its application in a vocoder has not been reported previously. It is similar to the transposed tones used in van de Par and Kohlrausch, 1997. Two important characteristics of cochlear implants, which can be modeled with the vocoder, are not accounted for in current noise-based CI simulations. The first is pulsatile stimulation. With CI the signal envelope is sampled at the pulse rate. Noise-excited vocoders have a continuous representation of the signal envelope, which at low stimulation rates, the deficiency to simulate well separated pulses becomes readily apparent. The spread of excitation can be controlled by the duration of the pulse, which can widen or narrow the spectral spread produced by each pulse. Since ITD sensitivity is better at lower stimulation rates, and pitch perception is affected by the spread of excitation, the ability to control these factors makes the Gaussian-enveloped tone vocoder a potentially useful platform for acoustically simulating bilateral CI use.

D. Testing procedure

Masking level thresholds were estimated by a three-interval, forced-choice adaptive procedure with a two-down/one-up decision rule (Levitt, 1971). The custom software was implemented in MATLAB (Mathworks, Inc., Natick, MA). All three intervals contained N0. The signal S0 or Sπ was added to a single, randomly assigned interval; thus the target interval was either N0S0 or N0Sπ. The subject's task was to identify which one of the three intervals contained the tone (N0S0 or N0Sπ vs N0). Two correct successive responses decreased the SNR for the next trial, while one incorrect response immediately increased the SNR for the next trial. Each change in direction of SNR (decreasing to increasing or vice versa) counted as a reversal. After eight total reversals, with stepsize decreasing from 5 to 1 dB after the initial three reversals, the SNR at which the last four reversals occurred were averaged to produce an estimate of the SNR threshold. Smaller values indicate better detection of the signal in noise compared to a larger SNR. Each run of the test consisted of two, randomly interleaved tracks, N0S0 and N0Sπ to help control for subject state between the two conditions. Once eight total reversals were observed in one track, the program presented stimuli exclusively from the other track until eight total reversals were also observed. With every subject, three threshold estimates were obtained for each phase (N0S0 vs N0Sπ), signal frequency, and electrode pair combination.

Data for monaural conditions were obtained by disconnecting either the left or right transmitting coil from the subject's head and repeating the same test protocol described above. Normal hearing subjects were tested in a sound-proof chamber using calibrated headphones (HDA 200, Sennheiser, Old Lyme, CT). Sound levels were set to 70 dB sound pressure level (SPL), calibrated to a 1 kHz tone having the same rms level as the stimuli used in the experiment.

E. Data analysis

Average values were calculated for N0S0 and N0Sπ. The BMLD was calculated as the overall difference between the average N0S0 and N0Sπ values. An unpaired t-test was used to determine whether the three thresholds from N0S0 were statistically different from the three N0Sπ thresholds, with $p<0.05$ being the criterion for significance (see asterisk symbols).

For the pooled data, average thresholds and BMLD were calculated over all stimulus frequencies, electrode pairs, and subjects. A repeated-measures analysis of variance (r.m. ANOVA) was performed on the thresholds to determine the effect of phase (N0S0 and N0Sπ), electrode (basal, middle, and apical), and signal frequency (125, 250, and 500 Hz). A second r.m. ANOVA was repeated on just the data set containing 125 Hz.

III. RESULTS

A. Binaural masking level differences

Masking level thresholds for various combinations of signal frequency and electrodes for N0S0 and N0Sπ are shown in Fig. 1. Masking level thresholds over subjects and conditions were all above 0 dB for N0S0, ranging from 0.3 to 11.6 dB SNR (signal to noise ratio), and both below and above 0 dB SNR (-10.6 to 12.5 dB) for N0Sπ. In fact, thresholds in the N0Sπ condition only reached negative values, where the amplitude of the signal was less than that of the noise, in two subjects (CI1 and CI5). On an individual basis, masking thresholds were generally lower for N0Sπ compared to N0S0, indicating a BMLD (see Table II).

BMLD values are shown in Fig. 2, where vertical bars show the BMLD calculated for each electrode pair grouped by stimulus. Asterisks indicate statistically significant BMLDs (unpaired t-test, $p<0.05$), that is, higher average thresholds for N0S0 than N0Sπ. This comparison helps to identify cases in which there existed a meaningful difference

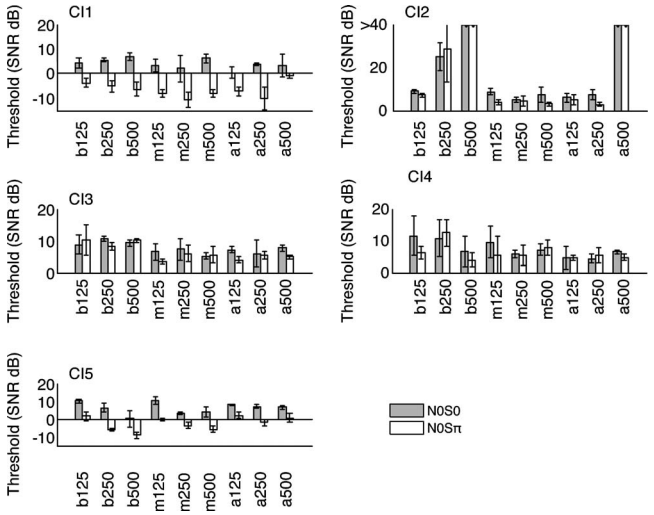

FIG. 1. Masking level thresholds for CI. Masking level thresholds are indicated by each bar. These indicate the smallest signal-to-noise ratio (in decibel) at which the subject was able to detect the signal in noise (see Sec. II). Each group represents a different electrode pair and signal frequency condition. The labels designate the electrode pair (base/middle/apex) and stimulus condition (125/250/500 Hz). For example, a250 indicates apical pair of electrodes and stimulus condition of 250 Hz. In each group, the shaded bars represent the average of three trials from N0S0 while the unshaded bars designate the N0Sπ condition. The error bars represent standard deviation. For subject 2, some data points were truncated at 40 dB as the subject was unable to complete the signal detection task under those conditions.

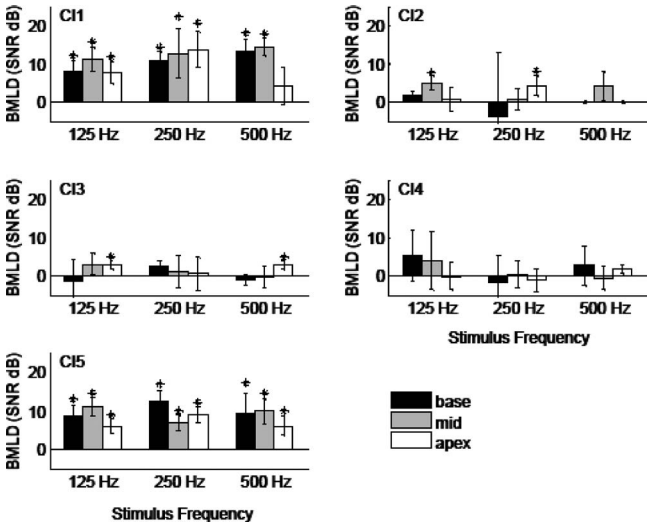

FIG. 2. Binaural masking level differences from five CI subjects. Each bar represents a BMLD value (y-axis) averaged over three trials, and is the mean difference of the N0S0 and N0Sπ thresholds in Fig. 1. BMLDs are grouped by stimulus condition along the x-axis. Data from different electrode pairs are indicated by the shading. The error bars represent the standard deviation. "$*$" denote statistically significant BMLD values (unpaired t-test, $p<0.05$).

in performance between the two conditions, regardless of the magnitude of the difference (i.e., small but significant vs large and insignificant BMLDs). For CI1 and CI5, BMLDs were statistically significant over almost all basal, middle, and apical electrode pairs and stimulus conditions. Average BMLDs (mean $\pm$ s.d.) were 10.7 ± 3.4 and 8.8 ± 2.2 dB, respectively, for CI1 and CI5. BMLDs observed for CI2 and CI3 were generally lower (mean$=1.5 \pm 2.8$ and 1.2 ± 1.8 dB, respectively), with only two out of nine conditions showing statistically significant BMLDs. CI4 showed no statistically significant BMLDs (mean$=1.2 \pm 2.4$ dB) under any stimulus conditions.

Over all subjects and conditions tested, the average BMLD was 4.6 ± 4.9 dB. The main effect of phase on thresholds (N0S0 vs N0Sπ) was not significant (ANOVA, $F_{1,4}=4.954$, $p=0.09$). There was no significant effect detected of either electrode or rate (ANOVA, $p>0.05$). The lack of significance in this case is most likely due to the large range of performance across individuals. It is worth noting that for each subject, thresholds for N0S0 were always higher than N0Sπ, but the standard deviations were always the same or higher for N0Sπ (see Table II).

When only the 125 Hz condition was considered, as in Long *et al.*, 2006, four of five subjects in the present study showed a significant BMLD in at least one cochlear region or electrode pair, with the average being 4.9 ± 3.8 dB. Results from repeated-measures ANOVA showed a significant

TABLE II. Average thresholds and BMLDs over all stimulus conditions and electrode pairs.

Subject	N0S0 (dB SNR)	N0Sπ (dB SNR)	BMLD (dB SNR)	R NmSm R NmS-m	L NmSm L NmS-m
CI1	3.9 ± 2.1	-6.7 ± 3.1	10.7 ± 3.4	3.1 ± 2.2 3.6 ± 2.3	3.2 ± 3.0 1.7 ± 1.1
CI2	16.4 ± 14.6	15.0 ± 16.3	1.5 ± 2.8	28.3 ± 14.5 25.0 ± 16.6	25.7 ± 15.9 26.3 ± 15.6
CI3	7.6 ± 1.7	6.4 ± 2.5	1.2 ± 1.8	22.7 ± 14.8 24.8 ± 12.9	23.38 ± 18.2 23.39 ± 18.2
CI4	7.4 ± 2.6	6.2 ± 2.6	1.2 ± 2.4	24.2 ± 17.4 24.3 ± 17.3	34.3 ± 6.6 31.2 ± 10.3
CI5	6.2 ± 3.3	-2.6 ± 3.9	8.8 ± 2.2	6.8 ± 1.6 6.6 ± 2.1	5.8 ± 2.6 6.5 ± 1.8

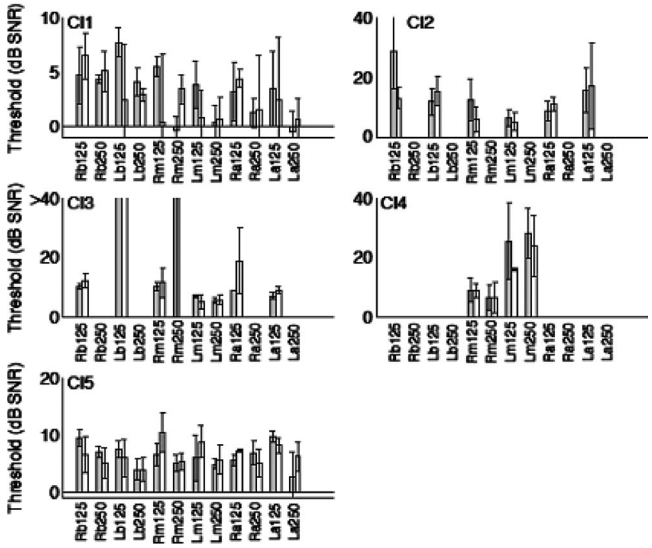

FIG. 3. Monoaural masking level thresholds. Format is similar to Fig. 1. The labels along the *x*-axis include "R" and "L" to specify right or left ear for the monaural condition. Note that some bars representing high threshold values were truncated (e.g., CI3).

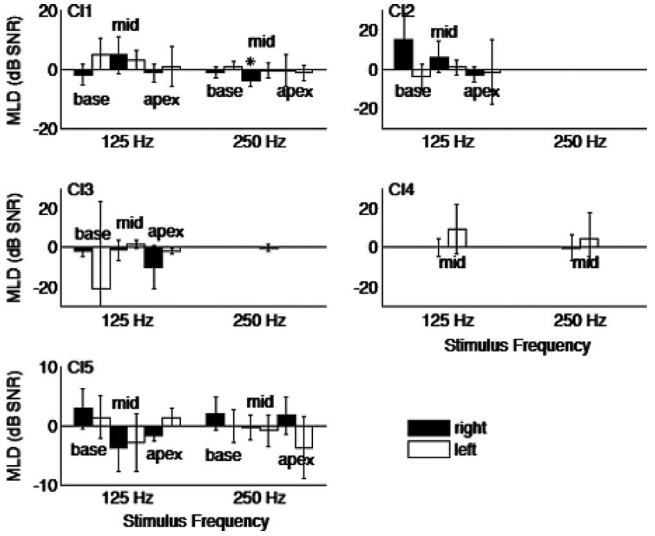

FIG. 4. Monaural MLDs. Format is similar to Fig. 2. For each group, shaded bars indicate data from the right ear, while unshaded bars are data from the left ear. Within each group, the left two bars are data from basal pair of electrodes, the third and fourth bars are from the middle pair of electrodes, and the last two bars are from the apical pair of electrodes.

effect of phase ($F_{1,4}=10.130$, $p=0.033$) and electrode ($F_{2,8}=13.366$, $p=0.003$), but no interaction between the two factors ($F_{2,8}=3.844$, $p=0.068$). *Post-hoc* t-tests with Bonferroni correction showed a significant difference ($p=0.023$) between average N0S0 (mean$=7.1\pm3.2$ dB) and N0Sπ (mean$=2.24\pm5.2$ dB) thresholds. Pair-wise comparisons of the electrodes revealed a significant difference ($p=0.023$) between thresholds of apical (mean$=3.41\pm4.4$ dB) and basal (mean$=6.50\pm4.7$ dB) electrodes. There were no significant differences between the thresholds of the middle electrode (4.2 ± 5.5 dB) and either apical ($p=0.82$) or basal ($p=0.71$) electrodes. Although electrodes had an effect on threshold, there was no significant effect on BMLD as a function of cochlear region (r.m. ANOVA, $F_{2,8}=3.842$, $p=0.068$).

Separate analysis of the 250 (mean$=4.6\pm5.9$ dB) and 500 Hz (mean$=4.5\pm5.1$ dB) conditions did not yield any statistical significance (ANOVA, $p>0.05$). Despite the large individual variability, these data suggest that at least some CI subjects can take advantage of binaural processing over multiple electrode pairs and signal frequency conditions.

B. Monaural detection thresholds

This study was also concerned with whether subjects can detect differences in amplitude modulation using a single ear. It is known that CI users can have very high sensitivity to amplitude modulations (Shannon, 1992). The performance under monaural conditions can reveal the contribution of binaural processing compared to what can be detected monaurally. Figure 3 shows masking level difference (MLD) thresholds from each ear separately for all five subjects. Only CI1 and CI5 were able to complete all test conditions, and thresholds for subjects C2–C4 were capped at 40 dB. Absolute thresholds tended to be higher than with the binaural condition, and MLDs between the two stimulus conditions, NmSm vs NmS-m, were not much different, where Nm indicates monaural noise, Sm is the monaural sinusoid, and S-m is the inverted monaural sinusoid. Under monaural conditions, no significant MLDs (unpaired t-test, $p>0.05$) were observed in any of the five subjects except for a single condition (CI1, 250 Hz) (Fig. 4).

Table II lists the average values obtained for monaural conditions. For CI1 and CI5, thresholds obtained for both right and left ears under monaural conditions are similar to the data from N0S0 condition, but not N0Sπ. These data from the monaural tests demonstrate that the BMLDs observed for the binaural condition cannot be explained by parallel but independent signal detection (via amplitude modulation of the signal envelope) between the left and right ears.

C. Binaural unmasking with acoustic simulation of CI

Because a prolonged lack of auditory input can have a negative impact on the normal functioning of the auditory system, the present manipulations were also conducted in normal hearing listeners using acoustic stimuli that were either unprocessed or with CI simulations. This approach would enable a distinction of issues stemming from CI-specific limitations related to the BMLD phenomenon. Thresholds, measured using unprocessed sounds, were on average 1.6 ± 3.5 dB for N0S0 and -6.3 ± 5.8 dB for N0Sπ (Fig. 5). BMLDs in unpracticed listeners ranged from 1.5 ± 1.1 to 13.9 ± 1.3 dB SNR (Fig. 6), which had a slightly wider range than that for CI listeners. Average BMLD was 7.9 ± 4.7 dB (see Table III for individual values). There was a significant effect of both phase (ANOVA, $F_{1,5}=19.855$, $p=0.007$) and signal frequency ($F_{2,10}=35.494$, $p\ll0.05$), but no significant interaction. Considering that these NH subjects had minimal practice, the range data reported here are still consistent with that reported in other studies (i.e., van de Par and Kohlrausch, 1997).

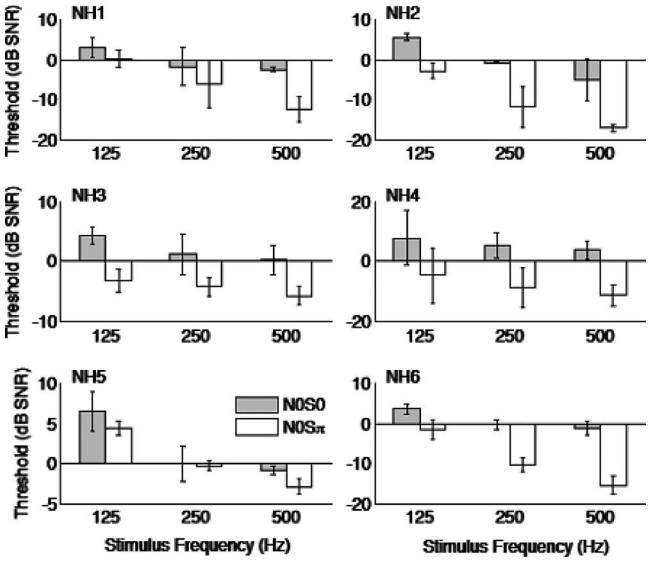

FIG. 5. Masking thresholds for unprocessed stimuli in NH listeners. Format is the same as Fig. 1.

When tested with a noise-excited, one-channel acoustic CI simulation, thresholds tended to be higher than in the unprocessed condition and quite variable (Fig. 7). Average thresholds were 12.2 ± 6.7 dB for N0S0 and -2.2 ± 12.9 dB for N0Sπ. This indicated that subjects tended to have much more difficulty with N0S0. However, subjects showed a large drop in thresholds with N0Sπ as seen in NH7 and NH8 for the noise-excited vocoder with 125 Hz signal condition. Average BMLD was 14.4 ± 14.7 dB. The effect of phase approached but did not reach statistical significance (ANOVA, $F_{1,5}=6.538$, $p=0.051$), and signal frequency had no significant effect ($F_{1,5}=1.179$, $p=0.327$).

Since using a single-channel noise vocoder does not accurately simulate the single-electrode stimulus conditions with electrically pulsed signals under which the CI users were tested, a vocoder based on Gaussian-enveloped tones was used to test simulated effects of basal, middle, and apical

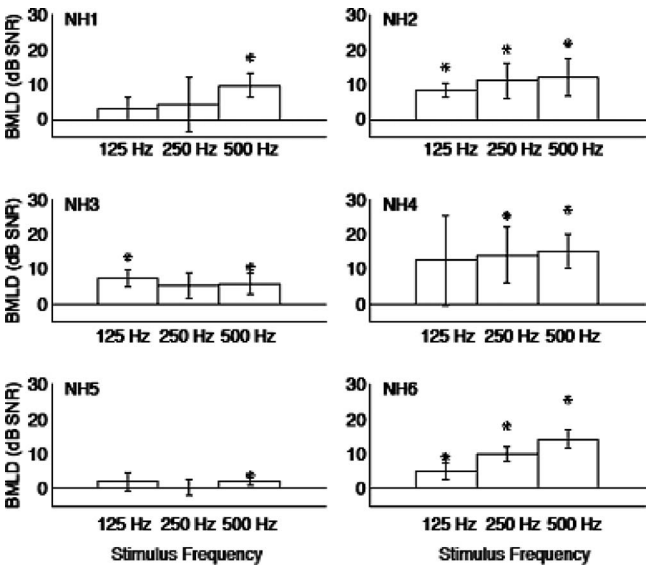

FIG. 6. BMLD for unprocessed stimuli in NH listeners. Format is the same as Fig. 2.

TABLE III. Average BMLDs over all stimulus conditions and electrode pairs for NH listeners.

Subject	Unprocessed (dB SNR)	Noise vocoder (dB SNR)	Gaussian vocoder (dB SNR)
NH1	5.8 ± 3.6	8.5 ± 1.2	8.9 ± 3.1
NH2	10.6 ± 1.9	9.3 ± 4.5	11.7 ± 6.3
NH3	6.2 ± 1.1	⋯	⋯
NH4	13.9 ± 1.3	⋯	⋯
NH5	1.5 ± 1.1	⋯	⋯
NH6	9.8 ± 4.6	⋯	⋯
NH7	⋯	26.6 ± 4.0	19.3 ± 4.0
NH8	⋯	21.8 ± 15.4	15.9 ± 9.8
NH9	⋯	28.0 ± 2.7	16.4 ± 4.2
NH10	⋯	-7.9 ± 14.4	3.1 ± 5.8

pair stimulations (Fig. 8). Thresholds for the Gaussian-enveloped tone vocoder averaged 4.0 ± 4.1 dB for N0S0 and -8.6 ± 7.2 dB for N0Sπ. Phase showed a statistically significant effect (ANOVA, $F_{1,5}=27.080$, $p=0.003$) but there was no effect of channel ($F_{2,10}=2.898$, $p=0.102$) or signal frequency ($F_{1,5}=2.772$, $p=0.157$). In addition, there were no significant interactions. Average BMLD was 12.6 ± 7.8 dB. Although BMLD values from the Gaussian-enveloped tone vocoders were similar to the noise vocoder condition, average N0S0 threshold was nearly 8 dB higher for noise vocoder.

A comparison of the N0S0 and N0Sπ threshold values from CI and NH using vocoder stimuli is shown in Fig. 9. Each data point represents a single-electrode pair and signal frequency combination from the five CI subjects and six NH subjects. The mean values for CI subjects were 6.6 ± 2.8 dB for N0S0 and 1.6 ± 6.1 for N0Sπ. The mean values for simulated CI (Gaussian vocoders) with NH listeners were 4.0 ± 4.1 dB for N0S0 and -8.6 ± 7.2 for N0Sπ. The mean values for unprocessed stimuli with NH listeners were 1.6 ± 3.5 dB for N0S0 and -6.3 ± 5.8 for N0Sπ. These mean values of N0S0 were significantly different from each other (unpaired t-test, $p < 0.05$). Mean values of N0Sπ were also significantly different (unpaired t-test, $p \ll 0.05$), except between the simulated CI and unprocessed stimuli in NH listeners (unpaired t-test, $p=0.26$). Despite the large individual variability, Fig. 9 illustrates three important points. First, CI implant users tended to produce the highest (or worst) thresholds in both binaural conditions, particularly in the N0Sπ condition. Second, the CI simulations captured the best performance seen in the CI user group, but not the poorest performance (three of five subjects in the present study). Third, the similar performance between CI simulations and unprocessed conditions in NH listeners suggests that the acoustic cues in the envelope are adequate to support normal BMLD performance. These results have important implications for CI signal and neural processing and will be discussed next.

IV. DISCUSSION

The purpose of this study was to establish BMLDs using an expanded set of electrodes and signal frequencies in order help understand why BMLDs are limited in bilateral CI users

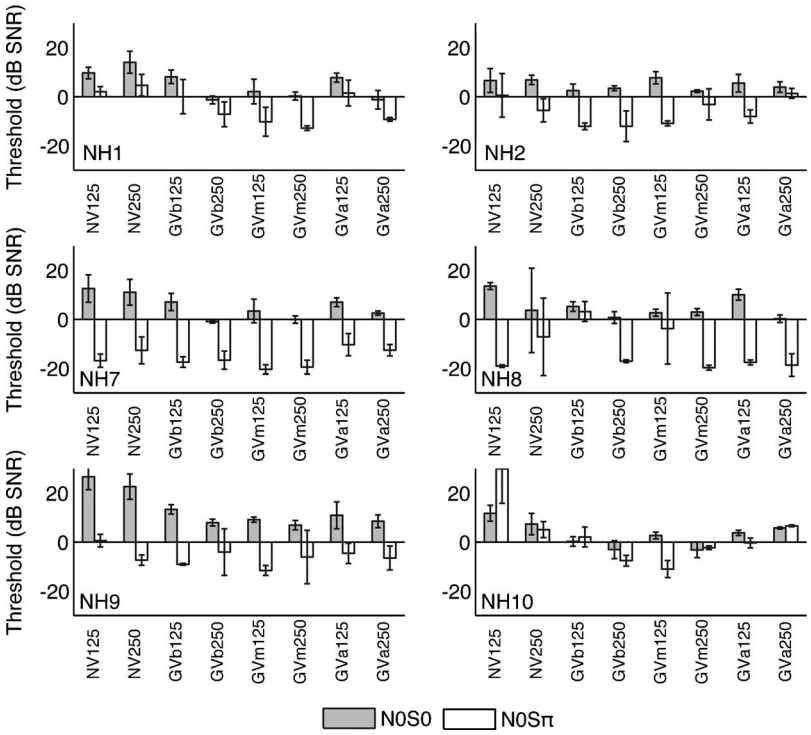

FIG. 7. Masking thresholds for NH listeners using acoustic CI simulation. Format is the same as Fig. 1. Labels along the *x*-axis include NV-noise-excited vocoder, GVb—Gaussian-enveloped tone vocoder (basal), GVm (middle), and GVa (apical). See Sec. II for details on the Gaussian-enveloped tone vocoder.

compared to NH listeners. The main findings of this study are that (1) BMLDs were measurable at multiple electrode locations for various signal/masker conditions, (2) BMLDs were more likely to be observed for the 125 Hz signal condition than for 250 and 500 Hz, (3) MLDs obtained through monaural testing were insufficient to account for BMLD, and (4) NH listeners using an acoustic CI simulation performed better than CI users, particularly with the N0Sπ condition.

BMLDs and the related phenomenon of noise squelch in bilateral CI users have been reported in just a handful of studies (Nopp *et al.*, 2004; Laszig *et al.*, 2004; van Hoesel, 2004; Long *et al.* 2006; Buss *et al.*, 2008; van Hoesel *et al.*, 2008), and of these, only a few groups have investigated BMLDs using precisely controlled stimulation via single pairs of pitch-matched electrodes that are temporally synchronized through a research interface (van Hoesel, 2004; Long *et al.*, 2006; van Hoesel *et al.*, 2008) as opposed to using the patient's own pair of clinical processors (Laszig *et al.*, 2004; Schleich *et al.*, 2004; Buss *et al.*, 2008). The average BMLD obtained in this study, 4.6 ± 4.9 dB falls

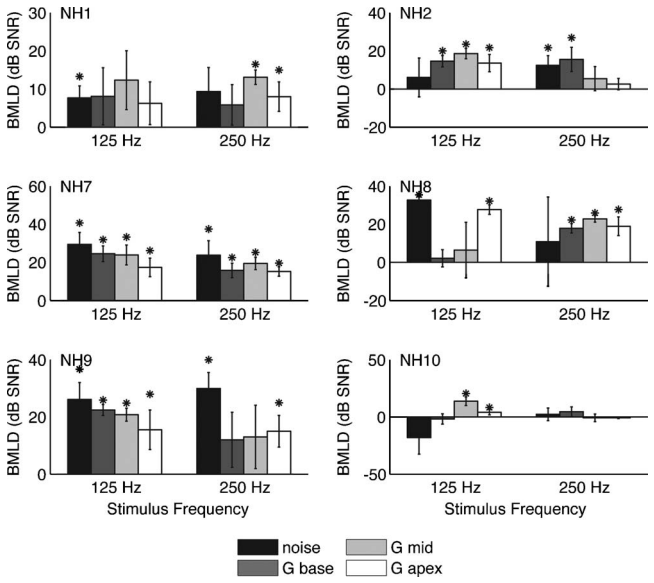

FIG. 8. BMLD for NH listeners subjected to acoustic CI simulation. Format is the same as Fig. 2.

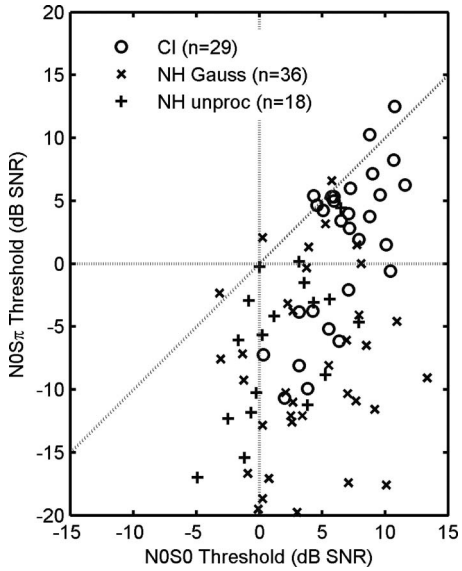

FIG. 9. Comparison of CI users to NH listeners with acoustic CI simulation. N0S0 thresholds are on the *x*-axis. N0Sπ thresholds are on the *y*-axis. Data points are from the 125 and 250 Hz stimulus conditions only. "O's" are data from the five CI subjects. (Mean [N0S0; N0Sπ]=[6.6 ± 2.8; 1.6 ± 6.1] dB SNR.) "X's" are data from six NH listeners using the Gaussian-enveloped tone vocoder. (Mean [N0S0; N0Sπ]=[4.0 ± 4.1; −8.6 ± 7.2] dB SNR.) "+'s" are data from six NH listeners with unprocessed stimuli. (Mean [N0S0; N0Sπ]=[1.6±3.5; −6.3±5.8] dB SNR.)

within the range of BMLDs (1.5–9 dB) reported in literature for bilateral CI users (van Hoesel, 2004; Long *et al.*, 2006; van Hoesel *et al.*, 2008).

Although the stimuli used in this experiment followed that of Long *et al.* (2006), which reported an average BMLD of 9 dB, the data from this study's subject pool displayed considerably more variability. Closer inspection of the data in Long *et al.*, 2006 reveals that average thresholds (as opposed to BMLDs) were higher in this study (Fig. 9). N0S0 threshold was 6.6 dB compared to 3 dB in Long *et al.*, 2006, and N0Sπ threshold was 1.6 dB compared to −6 dB. Individually, data from CI1 and CI5 were most similar to those in Long *et al.*, 2006 where three of four subjects had N0S0 thresholds greater than 0 dB and N0Sπ thresholds near −9 dB. Their consistent performance over most electrode and signal frequency conditions suggests that binaural unmasking can be a useful mechanism for signal detection in noise. The smaller BMLD values from the other subjects, CI2–CI4, contributed to the lack of statistical significance ($p=0.09$) of BMLD over all stimulation conditions and underscore the fact that binaural unmasking may be of limited or no benefit to some bilateral CI users.

In comparing BMLDs with tones and speech, one methodological consideration is that, rather than using an out-of-phase signal as was done in both Long *et al.*, 2006 and the present study, the speech stimuli in van Hoesel *et al.*, 2008 were delayed by 700 μs, which may have contributed to a smaller unmasking effect. For a 125 Hz tone, 700 μs corresponds to a 31.5° phase shift. An out-of-phase signal maximizes the difference between two ears since $\sin(x)-\sin(x+180°)\leq 2$. In addition, since BMLDs for higher frequencies (250, 500 Hz) in this study were not statistically significant, having those higher frequencies present in speech would may not result in observable BMLDs for bilateral CI users. It remains unclear exactly how much contribution 700 μs makes as it is only one of multiple factors that could potentially impact BMLDs for speech.

A. Effect of signal frequency

If the analysis was restricted to just the 125 Hz signal condition (the only tested frequency in Long *et al.*, 2006), the effect of signal phase was statistically significant ($p=0.033$). Because the higher signal frequencies were not tested in Long *et al.*, 2006 it is unknown how their subjects would have performed at 250 and 500 Hz, although it could be speculated that BMLD levels may be similar to CI1 and CI5. With CI1 and CI5, BMLDs were observed for most electrode pair and signal frequency combinations, while two others had BMLDs for only a few combinations, which included 125 Hz. This suggests that the lower signal frequency may be more useful to bilateral CI users as a group, while some individuals could experience binaural unmasking at higher signal frequencies.

The limited BMLD at higher signal frequencies may be related to synchronous activation over broad regions at 300 Hz compared to lower rates (van Hoesel *et al.*, 2009), or poor temporal discrimination of signals above 300 Hz (Zeng, 2002). The same temporal limitations apply even when the stimuli are presented diotically (Carlyon *et al.*, 2008). Although the auditory nerves show highly synchronized responses to electrical stimulation (Hartmann *et al.*, 1984), it is unclear where this temporal limitation is generated along the auditory pathway. If the temporal features are lost before the CI user's auditory system can process the binaural signal, smaller BMLDs could result. In comparison, NH listeners have BMLDs near 10 dB at frequencies as high as 4 kHz (van de Par and Kohlrausch, 1997) as well as larger BMLDs for speech (Levitt and Rabiner, 1967). As speech has a broad spectral composition, the smaller BMLDs of CI users at higher signal frequencies may also help to explain smaller speech BMLDs.

B. Effect of electrode position

BMLDs were also analyzed by electrode position to look for any systematic changes with cochlear region. Although there was a significant effect of cochlear region on thresholds, there was no significant interaction between phase and electrode on thresholds for the 125 Hz condition, meaning that BMLD was not statistically different between electrodes. This indicated that cochlear region was likely not a limiting factor for speech BMLD. The data presented here showed that in at least two subjects, BMLDs were observed at all basal, middle, and apical pairs and could be 10 dB or higher. Since there was no significant effect of electrode position on BMLD, it follows that binaural unmasking was not limited by cochlear region. This result is consistent with NH listeners exhibiting binaural unmasking to the signal in envelope of a high frequency carrier (van de Par and Kohlrausch, 1997).

C. Peripheral mechanisms affecting BMLD

As demonstrated by the present data and prior studies, binaural unmasking can be observed in bilateral CI users, but even the best CI performers in these studies had BMLD values that fell below the 15–20 dB reported for NH listeners (van de Par and Kohlrausch, 1997). This could be due to either inadequate delivery of binaural cues to the peripheral nervous system, inadequate processing by the central nervous system, or a combination of both. It is thus important to consider what underlying mechanisms could be responsible for this performance gap.

The first possibility is that acoustic cues in the envelope are not sufficient to convey binaural information about N0S0 and N0Sπ. However, this is unlikely since NH listeners using the CI simulation had thresholds that were nearly the same as in the unprocessed condition (see Fig. 9). In NH listeners, BMLDs for both the unprocessed and transposed tones were nearly the same, but a reduction of about 6 dB for the transposed tone was noted for a 250 Hz signal (van de Par and Kohlrausch, 1997). In order for the results to be comparable, there must be sufficient acoustic cues remaining in the envelope since fine timing information is discarded by the CI simulation. Despite the same envelope extraction of the signal, actual CI users had higher thresholds than simulated CI, particularly with N0Sπ. For the unprocessed condition, the NH group had BMLD values lower than in litera-

ture. Some of this may be due to the minimal training and inexperience of the subjects, compared to those in van de Par and Kohlrausch, 1997, most of whom were reported to have experience in masking experiments.

A second possible mechanism is that the CI processor cannot adequately convey the acoustic cues in the envelope in time or amplitude. Under these experimental conditions, the pulse rate was set at 1000 and 2000 pps, which was fast enough to represent the signal frequencies used in this study. At high pulse rates (800 pps) ITD sensitivity to the pulses is very poor (van Hoesel and Tyler, 2003), and although this may contribute to some drop in performance, the cues in this study were all based on the envelope rather than in the interaural pulse timing.

A third possibility related to mechanism lies in the electrode-neural interface, such as the availability of suitably pitch-matched electrodes and effects of channel interactions. Because electrode array insertions are rarely identical, electrically elicited pitches are often offset between the two sides. The CI users tested here, and CI1, in particular, commented that when alternately switching between their own left and right processors they perceived there to be a noticeable pitch difference. Although pitch-matching was not directly addressed by the experiments in the present study, it has been shown psychophysically (Henning, 1974; Nuetzel and Hafter, 1981) and physiologically (e.g., Blanks *et al.*, 2007) that the binaural system is most effective when the frequency of sounds between the left and right are nearly the same. In fact, in normal hearing listeners, ITD judgments deteriorate with mismatch in carrier frequency (Henning, 1974; Nuetzel and Hafter, 1981). For CI users, pitch-matched pairs of electrodes are necessary for ITD sensitivity (van Hoesel and Clark, 1997; Lawson *et al.*, 1998; Long *et al.*, 2003) and BMLD (Long *et al.*, 2007).

Since it appeared that envelope was sufficient for transmitting cues for BMLD in this study, we examined whether there were others cues that were contributing to BMLD values. Despite the poor ability to discriminate modulation frequencies (Zeng, 2002), CI users can detect temporal fluctuations occurring up to 4000 Hz (Shannon, 1992). Measuring monaural performance can help to reveal the contribution of binaural processing. To be able to detect the signal in noise under these conditions puts more emphasis on temporal discrimination since a single channel was used and no binaural cues were available. Because MLDs were not significant in this study, BMLDs measured here likely result from true binaural hearing rather than independent and monaural discrimination of envelopes by each ear. Only when both ears were used was there a significant difference in threshold. Since the noise masker was randomly generated for each trial, there is no practical difference between NmSm and NmS-m.

D. Central auditory mechanisms affecting BMLD: Auditory deprivation

The issues discussed so far have been related to technical limitations of the cochlear implant system in processing and delivering binaural stimuli rather than the central auditory mechanisms that underlie binaural sensitivity. Even if normal peripheral processing could be restored in CI users, the central auditory system can still fail to effectively process binaural information. Both the limitations of CI users to discriminate high modulation frequencies (Zeng, 2002) and poor ITD sensitivity (van Hoesel *et al.*, 2002; van Hoesel, 2007; Laback and Majdak, 2008; Litovsky *et al.*, 2010) are examples where central auditory processing showed deficits despite temporally precise delivery of electrical stimuli to the auditory periphery.

In comparing NH listeners using simulations to actual CI users, there are two assumptions to be made about the simulation and the comparison. First is that the vocoder is an accurate simulation of what CI users hear. Gaussian-enveloped tones have not been used in the context of a vocoder, but they have been used for psychophysical, including binaural, experiments (Buell and Hafter, 1988; van den Brink and Houtgast, 1990). Although it would be possible to conduct a similar experiment with a one-channel noise-excited vocoder using band-limited noise, the Gaussian-enveloped tone vocoder may be a better choice. With a noise-excited vocoder, the carrier is noise. There may be interactions between noise in the carrier and any masking noise present in the envelope, particularly in the N0S0 condition. That is, the noise in the carrier may contribute to noise in the envelope such that for normal hearing listeners using the noise vocoder, this becomes a more difficult task without contributing additional insight to BMLD performance. The Gaussian tone pulses do not have this issue as the fine-structures of the tones are controlled and the amplitudes at each time point are defined algorithmically and not influenced by stochastic fluctuations in a noise carrier. For comparison, the N0S0 thresholds were higher for the noise vocoder than it was for the Gaussian-enveloped tone. Although the noise vocoder was implemented with broadband noise, the problem using a band-limited signal to simulate a specific channel remains the same since there is still an issue of a noise carrier interacting with masking noise in the envelope.

If the validity of the vocoder as a simulation is accepted, then it can be assumed that the peripheral auditory systems of NH and CI are receiving equivalent inputs. Therefore, performance differences between the two groups will depend on their ability to process binaural information. With an acoustic CI simulation, differences between NH and CI not explained by pitch-matching and channel interaction may point toward the central auditory system. As a population, the thresholds of CI users lagged behind NH listeners by nearly 10 dB for N0Sπ and but only 2.4 dB for N0S0. This suggests that the binaural performance difference may be in part due to physiological limitations of processing binaural information in the central auditory system. BMLDs for unprocessed stimuli reported here are smaller than those reported in literature (van de Par and Kohlrausch, 1997). Individually, at least one subject (NH4) had a BMLD of 13.9 dB for the unprocessed stimuli. The lower scores may be attributable to the inexperience of the test subjects (most were undergraduate students) compared to the more experienced subjects in van de Par and Kohlrausch, 1997, all but one of whom were indicated as laboratory colleagues.

Examining the clinical data, the best performers in this

study, CI1 and CI5, had the longest experience with bilateral CI use and had prior experience with research testing. Their better performance would be consistent with having a longer recovery of binaural function (Laszig *et al.*, 2004; Buss *et al.*, 2008). The small BMLD values of CI2 may be related to the early onset of hearing impairment. CI3 had late onset of hearing loss, and only 1 year less bilateral experience than CI1 and CI5. Based on this subject's clinical history larger BMLDs would have been expected. CI4 had 3 years of bilateral CI experience. There was some difficulty in finding suitably pitch-matched electrode pairs as noted by the right electrode being matched to apical and middle electrodes on the left over the course of the testing. Although the clinical data do appear to be on first inspection consistent with the BMLD levels of the subjects, due to the small sample size, the various causes of deafness, hearing aid history, and duration of implant use, it would be difficult to predict BMLD performance with any confidence from duration of deafness from the clinical data.

E. Future directions

Despite the large variability between subjects, BMLDs from these single pairs of electrodes (4.6 dB average, and ~9 dB for the top two performers) were still larger than BMLDs for speech (<1.5 dB) reported in CI. The data presented here thus do not fully account for this performance gap. One direction that should be taken is to evaluate BMLDs with multiple and simultaneous masking electrodes. Would the binaural cues presented in one pair of electrode be sufficiently degraded by adjacent masking electrodes such that BMLDs are reduced? Addressing this issue would help to answer to what degree channel interactions affect binaural hearing and provide some clue as to what other factors are limiting BMLD in CI.

V. CONCLUSION

BMLDs were measured in five bilateral CI subjects using the Spear3 research processor. Stimuli were delivered though pitch-matched and loudness-balanced electrode pairs. The cochlear position of the electrode pair was varied as was the signal frequency. Normal hearing listeners were tested with unprocessed and acoustic CI simulations. The conclusions are as follows.

(1) Average BMLD over all stimulus conditions was 4.6 ± 4.9 dB. Significant BMLDs were observed in at least one electrode pair and signal frequency condition for four out of five subjects, with BMLDs varying no more than 3–5 dB over electrode pairs and stimulus conditions. Performance variability was high between subjects and average BMLD values per subject ranged from 1.2 to 10.7 dB;
(2) For the subject group in this study, the effects of phase and electrode pair were significant when considering only the 125 Hz signal frequency condition, as in a prior study, suggesting that BMLDs are more likely to be observed for lower signal frequencies.
(3) Monaurally detectable differences in NmSm and NmS-m were not sufficient to account for BMLDs.
(4) NH listeners had similar unprocessed and simulated CI thresholds for N0S0 and N0Sπ. Actual CI users had higher thresholds than NH with simulated CI, but the difference was more pronounced for N0Sπ, implying a central binaural processing deficit.

The present results support prior studies that demonstrate binaural processing in CI users. However, a performance gap in BMLD still exists between even the best CI users in this study and NH listeners and may be related to a peripheral mechanism such as pitch mismatch, a central mechanism in a deprived auditory system, or a combination of both. The differences in actual and simulated CI performances point to a deficit in true binaural hearing that may have resulted from long-term deprivation of the auditory system.

(Received 23 February 2009; revised 6 January 2010; accepted 6 January 2010)

In the framework of the European HearCom project, promising signal enhancement algorithms were developed and evaluated for future use in hearing instruments. To assess the algorithms' performance, five of the algorithms were selected and implemented on a common real-time hardware/software platform. Four test centers in Belgium, The Netherlands, Germany, and Switzerland perceptually evaluated the algorithms. Listening tests were performed with large numbers of normal-hearing and hearing-impaired subjects. Three perceptual measures were used: speech reception threshold (SRT), listening effort scaling, and preference rating. Tests were carried out in two types of rooms. Speech was presented in multitalker babble arriving from one or three loudspeakers. In a pseudo-diffuse noise scenario, only one algorithm, the spatially preprocessed speech-distortion-weighted multi-channel Wiener filtering, provided a SRT improvement relative to the unprocessed condition. Despite the general lack of improvement in SRT, some algorithms were preferred over the unprocessed condition at all tested signal-to-noise ratios (SNRs). These effects were found across different subject groups and test sites. The listening effort scores were less consistent over test sites. For the algorithms that did not affect speech intelligibility, a reduction in listening effort was observed at 0 dB SNR.

I. INTRODUCTION

The main complaints of hearing aid users are problems with speech understanding in noisy listening environments and reduced spatial awareness (Kochkin, 2005; Noble and Gatehouse, 2006). With the advent of fully digital hearing aids around 1995, there was a general belief that new signal processing strategies would be developed and (older) schemes would be integrated as software modules in the new digital engines. Several speech-in-noise enhancement strategies, including directional microphone systems, can be considered as a front-end to the core processing of the hearing aid or cochlear implant. Whereas a lot of research has been carried out on speech enhancement approaches in challenging noisy environments, until now only a limited number of algorithms have been implemented in commercial devices (Dillon, 2001; Blamey, 2005; Spriet *et al.*, 2007; Hu and Loizou, 2008). The implementation of a signal processing scheme in a hearing aid or cochlear implant makes strong demands in terms of computational complexity and processing delay, and requires extensive validation through physical and perceptual validation tests.

The reason for the limited application of digital signal enhancement techniques in commercial hearing instruments is twofold. First, few signal processing schemes have been developed and sufficiently evaluated for real-world application. Second, only a limited number of these signal processing schemes have actually demonstrated real benefits for hearing aid users both in laboratory environments and under daily listening conditions. Moreover, the results are hard to compare across different developers and test sites. Based on results published in the engineering literature, replication is sometimes difficult because of incomplete knowledge of details. In addition, the physical evaluations and objective measures are not always relevant to the perception of speech in noise. For instance, not only is the signal-to-noise ratio (SNR) usually important, but also perception-related measures such as the intelligibility-weighted SNR (Greenberg *et al.*, 1993) and the speech intelligibility index (SII) (ANSI S3.5-1997, 1997). The evaluation should not be limited to experiments with artificial noise (e.g., white noise), but should include extensive testing with real-world signals as well. Additionally, perceptual evaluation experiments should be included, with both normal-hearing (NH) and hearing-impaired (HI) subjects, i.e., representative of the target population.

One of the subprojects within the framework of the European research project HearCom (Hearing in the Communication Society) has focused on the development and evaluation of signal enhancement techniques for improving speech understanding by use of hearing aids. Based on physical performance measures (Eneman *et al.*, 2008a, 2008b), five signal enhancement techniques (single- as well as multi-channel) were selected from a large set of state-of-the-art algorithms and implemented on a common real-time low-delay test platform (Grimm *et al.*, 2006). The study presented in this paper comprises the perceptual evaluation of these five algorithms at four different test sites with large numbers of normal-hearing listeners and hearing aid users with flat or sloping moderate hearing losses.

Adaptive speech reception threshold (SRT) tests were performed to evaluate the effect of the signal enhancement algorithms on speech intelligibility. Several previous studies on the perceptual benefits of single-channel noise reduction algorithms described increased comfort or ease of listening, while finding no evidence for improvement in speech intelligibility (Marzinzik and Kollmeier, 1999; Walden *et al.*, 2000; Ricketts and Hornsby, 2005; Bentler *et al.*, 2008). Therefore, in the current study, listening effort and overall preference were also assessed. The listening effort scaling (LES) and preference rating (PR) measurements were carried out at a number of fixed SNRs up to +10 dB, which are representative of many daily listening conditions.

The following research questions are addressed and discussed in this paper: Do signal processing strategies lead to similar outcomes across different test sites, given the different test environments/rooms, test materials, and evaluation test platforms? Do the enhancement strategies yield different outcomes for different subject groups? How do the results for both objective and subjective perceptual measures vary across the signal processing algorithms?

II. SIGNAL ENHANCEMENT TECHNIQUES

This section describes the five signal enhancement algorithms that were selected and evaluated.

A. Single-channel noise suppression based on perceptually optimized spectral subtraction (SC1)

Spectral subtraction is a well-known computationally-efficient noise reduction technique, based on the idea of subtracting an estimate of the noise spectrum from an estimate of the spectrum of the noisy signal (e.g., Boll, 1979). The present implementation of this principle is a variant known as magnitude spectral subtraction. To reduce the well-known phenomenon of musical noise artifacts, the present version was perceptually optimized to control the trade-off between speech distortion and noise suppression. The input signal is analyzed in 50% overlapping Hann-windowed blocks of duration 4 ms, with 2-ms frame update steps. The enhanced speech discrete Fourier transform (DFT) coefficients $\hat{S}(m,k)$, with frame index m and DFT bin k, are obtained as $\hat{S}(m,k) = H_{SS}(m,k) \cdot Y(m,k)$, where $Y(m,k) = S(m,k) + N(m,k)$ are the DFT coefficients of the input speech $S(m,k)$ and noise $N(m,k)$. $H_{SS}(m,k)$ is a real-valued time- and frequency-dependent adaptive filter gain, calculated as

$$H_{SS}(m,k) = qH_{SS}(m-1,k) + (1-q)\left(1 - \alpha(m,k)\frac{\sqrt{|\hat{N}(m,k)|^2}}{|Y(m,k)|}\right),$$

and limited to ensure that $H_{SS}(m,k) \geq 0$. Here, the first-order recursive low-pass smoothing parameter is $q = 0.9$, giving an effective time constant of 19 ms for the adaptive gain variations. $|\hat{N}(m,k)|^2$ represents the noise power spectrum as esti-

mated from the modulation pattern of the noisy input signal, using the minimum statistics algorithm (Martin, 2001) based on a memory buffer of the most recent 1.5 s of the input signal. The degree of spectral subtraction is controlled by the frequency-dependent "aggressiveness factor" $\alpha(m,k)$, with values between 0 and 1.6, determined as a function of the estimated frequency-dependent noisy-signal-to-noise ratio (NSNR) $z(m,k)=|Y(m,k)|^2/|\hat{N}(m,k)|^2$, as

$$\alpha(m,k) = a - a\ \tanh[b(10\ \log_{10}\ z(m,k) - c)^2].$$

The parameters a, b, and c have been manually tuned to optimize the perceptual performance of the algorithm. Their values are adapted slowly, depending on the overall (not frequency-dependent) SNR, calculated using first-order recursive low-pass filter smoothing of the estimated speech and noise frame power values, with time constants of 1.6 s. For low overall SNRs, of 0 dB or less, the maximum aggressiveness is 0.6 for $z(m,k)$ corresponding to 3 dB. For SNRs of 20 dB or higher, the maximum aggressiveness is 1.6 for $z(m,k)$ corresponding to 7.5 dB. The aggressiveness factor is zero for any $z(m,k)$ below −15 dB and above +25 dB. Finally, the enhanced time-domain output signal is reconstructed from $\hat{S}(m,k)$ by the inverse discrete Fourier transform (IDFT) and overlap-add operations.

B. Wiener-filter-based single-channel noise suppression (SC2)

A second single-channel noise suppression algorithm was based on the Wiener filter, which minimizes the mean-squared error between the (unknown) desired speech signal and a filtered version of the observed noisy speech. Since speech is stationary only over short time intervals, statistical expectation operations have to be replaced with short-term averages. Therefore, instead of using the actual a priori SNR, estimated a priori SNR values were computed as described by Ephraim and Malah (1984). The samples of the observed noisy speech signal were partitioned into frames of 8-ms length, overlapping by 6 ms. The frame shift was 2 ms. Each frame of data was weighted with the square root of a Hann window and was then transformed to the DFT domain. The enhanced speech spectral coefficients $\hat{S}(m,k)$, with frame index m and DFT bin k, were obtained as $\hat{S}(m,k) = H(m,k)\cdot Y(m,k)$, where $Y(m,k)=S(m,k)+N(m,k)$ are the DFT coefficients of speech $S(m,k)$ and noise $N(m,k)$. $H(m,k)$ is a time- and frequency-dependent gain. For the Wiener filter approach, $H(m,k)$ is real-valued. Only the amplitudes of the noisy DFT coefficient are changed and the phases are left unchanged. The Wiener filter solution

$$H(m,k) = \frac{E\{|S(m,k)|^2\}}{E\{|S(m,k)|^2\} + E\{|N(m,k)|^2\}}$$

is obtained by a minimization of the mean-square error between estimated and true speech spectral coefficients (e.g., Vary and Martin, 2006). $E\{X\}$ denotes the expectation of variable X. After IDFT and weighting the data again with the square root of a Hann window, the time-domain signal was reconstructed via overlap-add operations. The estimation of the noise power spectral density $E\{|N(m,k)|^2\}$ via minimum statistics (Martin, 2001) rests on the observation that the power of the noisy speech signal frequently decays to the level of the noise. An estimate of the noise power can hence be obtained by tracking minima of the spectral power. Then, the bias between minimum and mean is compensated for. Due to the minimum principle, noise power estimation via minimum statistics does not require explicit voice activity detection.

The algorithm variant used was a complexity- and delay-optimized solution. The reduced frame length and frame shift result in a larger frame overlap and hence a significantly increased correlation of the spectral data of successive frames. In Mauler and Martin (2006), it was shown that highly correlated spectral data require an adjustment of the noise power bias correction in the minimum statistics algorithm. Alternatively, without modification of this bias correction, the correlation of spectral data can be reduced if its estimation is based on subsampled frames (i.e., less overlapped). In the algorithm under test, the noise power estimate was updated only after three frame shifts, i.e., after every 6 ms, while the enhanced speech spectrum was computed after every frame shift.

C. Broadband blind source separation (BSS) based on second-order statistics

The aim of blind source separation is to recover the original source signals from an observed set of signal mixtures, solely based on the assumption of statistical independence of the original source signals. The term "blind" implies that the mixing process and the original source signals are unknown. In acoustical scenarios, like in a hearing aid application, signals propagate through multiple paths due to acoustical reflections. The microphone signals result therefore from a superposition of multiple scaled and delayed versions of the original source signals. This superposition of sounds emitted from the same source can be described as a convolutional product. Hence, in a multiple-source scenario, the source signals are mixed in a convolutive manner. Separation is achieved by applying a set of adaptive filters to the microphone signals. The adaptation of the BSS filters is performed by forcing the BSS outputs to become statistically independent, as described in Buchner *et al.* (2004, 2005a) and Aichner *et al.* (2006), where a class of broadband BSS algorithms was derived. Broadband BSS approaches process all frequency bins jointly, in contrast to the so-called narrowband approaches, which consider each frequency bin independently.

The (broadband) BSS algorithm selected here is a computationally efficient, low-delay variant using frequency-domain-based fast convolution techniques and second-order statistics (see Aichner *et al.*, 2006). The BSS algorithm was applied to binaural hearing aids, using the front microphone signal from each hearing aid as its inputs. This two-microphone implementation allows the separation of two point sources and offers two output signals. Thus, the output containing the desired signal had to be selected and presented to the hearing aid user.

Based on the approach described by Buchner *et al.* (2005b), the time-difference-of-arrival (TDOA) of the sound waves originating from the separated sources can be determined from the BSS filters, without any prior knowledge of the microphone positions. Note that, as the microphone spacing is not accurately known, and since head-shadow effects influence the TDOA estimate, accurate direction-of-arrival (DOA) cannot be calculated for each separated source. However, it is assumed here that the desired source is located approximately in front of the hearing aid user. The TDOA estimates are then sufficient for identifying the most frontal source (i.e., the source with the smallest TDOA). The BSS output channel containing the desired source is selected based on this information.

D. Spatially preprocessed speech-distortion-weighted multi-channel Wiener filtering (MWF)

The MWF is an adaptive noise suppression technique that is based on work described in Spriet *et al.*, 2004, 2005 and Doclo *et al.*, 2005, 2007. It consists of a fixed spatial preprocessor, i.e., a fixed beamformer and blocking matrix, and an adaptive stage. The fixed beamformer creates a so-called speech reference by steering a microphone beam toward the front. The blocking matrix creates so-called noise references by steering zeros toward the front so that the noise contributions are dominant compared to the speech leakage contributions. As a consequence, the MWF can be viewed as a variant of the well-known generalized sidelobe canceler (GSC) structure. Whereas in the case of the GSC the filter weights converge to a solution that merely reduces the residual noise, the cost function of the adaptive stage in the MWF approach minimizes a weighted sum of the residual noise energy and the speech-distortion energy. In this way, a trade-off is provided between noise reduction and speech distortion. If the trade-off parameter in the cost function is set to infinity, speech distortion is completely ignored and the algorithm reduces to a GSC structure. The MWF algorithm can therefore be considered as an extension of the GSC. As the MWF approach incorporates a trade-off between noise suppression and speech distortion, the algorithm is more robust against speech leakage than the standard GSC (Spriet *et al.*, 2004). Several algorithm variants have been developed, leading to low-cost implementation and/or improved performance (Spriet *et al.*, 2004, 2005; Doclo *et al.*, 2005, 2007). Here, a three-microphone version of the algorithm was used that relies on a frequency-domain variant of the cost function and that uses efficient updating of the correlation matrix (Doclo *et al.*, 2007).

E. Binaural coherence dereverberation filter (COH)

Dereverberation algorithms are designed to increase listening comfort and speech intelligibility in reverberant environments and diffuse background noise (e.g., babble). The dereverberation technique used here was a binaural-coherence-filtering-based approach that builds on work described by Wittkop and Hohmann (2003). It estimates the coherence, i.e., the signal similarity, between the signals captured at the left and right ears. The estimate is computed in different frequency bands using a fast Fourier transform (FFT)-based filterbank with a non-linear frequency mapping that approximates the Bark scale. As a coherence estimate, the absolute value of the time average of the complex phase difference vector e^(i IPD) is computed. If the signals are coherent in a specific frequency band, the sound is expected to be directional. Hence the gain in the frequency band is set to a high value. If the coherence is low, a diffuse sound field is present, and accordingly, the frequency band is attenuated. The phase in a frequency band is estimated by taking the complex-valued average across frequency of the complex-valued signal spectrum, weighted with a frequency-dependent filter shape function. This filter shape function is an asymmetric Hann window with the maximum value of 1 at the center frequency and the value of 0 at the neighboring band center frequencies. The IPD is calculated in each frequency band by taking the difference of the phases of the respective frequency bands. The IPD is then translated into the complex plane, e^(i IPD), and this complex phasor is filtered with a first-order low-pass with a time constant of 40 ms (Grimm *et al.*, 2009b). The vector strength, i.e., the absolute value of the low-pass filtered complex IPD, is the estimate of the coherence. The frequency-dependent gains are derived from the phase difference vector strength by applying an exponent (between 0.5 and 2) to the coherence estimate. High values of the exponent provide efficient filtering, but lead to more audible artifacts. Because of diffraction effects around the head, the coherence is always high at low frequencies, independent of the type of signal. At medium and high frequencies the coherence is low for diffuse babble noise and for reverberant signal components (late reflections), while it is high for the direct-path contribution of the signal of interest. Due to the temporal and spectral fluctuations of speech, the ratio between non-coherent noise-like signal components and the desired target signal components may vary across time and frequency. Hence, by applying appropriate gains in frequency bands and at times where the non-coherent signal components are dominating, reverberant signal components and diffuse noise can be suppressed relative to direct-path signal components.

III. IMPLEMENTATION ON A COMMON EVALUATION PLATFORM

The signal enhancement algorithms were implemented on a common real-time hardware/software platform, called the personal hearing system (PHS). The hardware platform consists of a (laptop) PC running a real-time low-latency Linux operating system. The PC is equipped with a multichannel RME sound card, which is connected to a pair of hearing aids via a pre-amplifier box. The signals were sampled with 24-bit resolution at 32-kHz sampling rate, resampled to 16 kHz, and the signal processing was performed with single precision floating point resolution (32 bits/sample). With this setup, a glitch-free total delay of approximately 10 ms from the microphones to the receiver was attained. All algorithm developers incorporated a C/C++ implementation of their algorithm into the master hearing aid (MHA). This software environment simulates the processing

TABLE I. Characteristics of the different signal enhancement approaches when implemented on the PHS system.

Algorithm	Monaural/ binaural processing	No. of microphones used	Computational complexity (% CPU time required)	Input/ output delay (ms)
SC1	Monaural	1	8.3	10.8
SC2	Monaural	1	4.2	16.8
BSS	Binaural	2	59.9	10.8
MWF	Monaural	3	4.3	13.2
COH	Binaural	2	1.2	10.6

performed by a hearing aid, and is controlled by the PHS. Hence, apart from passing signals to and from the algorithms, the MHA software is also responsible for applying basic hearing aid processing to the signals, such as frequency-dependent gain setting according to the audiogram of the subject and compensative calibration of microphones and receivers. More details are given later. More information about the MHA and PHS can be found in Grimm *et al.* (2006, 2009a).

The devices used in this study were Siemens Acuris behind-the-ear hearing aids each with three microphones (in end-fire configuration) and a single receiver. There was no processor in the hearing aids themselves. All signal processing was done externally on the PC. The single-channel noise suppression algorithms, SC1 and SC2, only used the front microphone signal, and the same algorithm was used for each aid signal, with identical parameters, independently of each other (double monaural system). The BSS and COH approaches were truly binaural algorithms using the front microphones of the left and right hearing aids as their inputs. The MWF beamformer processed all three microphone signals of each of the hearing aids. The same algorithm was run for the left and right hearing aid signals, independently of each other (for an overview, see Table I).

For possible future implementation in commercial hearing aids, the computational complexity and the input/output delay of the algorithms have to be considered (see Table I). The computational complexity measurements were performed on a Dell Latitude D610 with Intel Pentium M 1.6 GHz processor. The baseline processing of the PHS-MHA system when all signal enhancement algorithms were switched off required 10.3% of CPU time. The total input/output delay from the signal sent into the AD converter to the signal that appears at the DA converter output was measured on a Dell Latitude D620 with Intel Core Duo 1.83 GHz processor. Table I shows the total input/output delay, which includes the combined delay of the PHS-MHA system and of the selected signal enhancement algorithm. With all signal enhancement algorithms switched off an input/output delay of 10.6 ms was measured. Both the PHS-MHA system and the signal enhancement algorithms operate in the frequency domain and thus require an analysis and re-synthesis filterbank. The algorithms SC1 and COH use the analysis and synthesis filterbank of the PHS-MHA system. The current implementations of SC2, BSS, and MWF, however, use a separate filterbank, which causes an additional delay. In an optimized implementation with a shared filterbank, this delay could be reduced. According to Stone and Moore (1999), the auditory effects of hearing aid delays are likely to become disturbing for delays exceeding 20 ms. In the current study, none of the processing delays exceeded 20 ms.

IV. MATERIALS AND METHODS

All five signal enhancement algorithms described in Sec. III were evaluated through listening tests in Dutch and German across four different test sites in Belgium (ExpORL, Department of Neurosciences, K.U.Leuven, "BE"), The Netherlands (AMC, KNO-Audiologie, Amsterdam, "NL"), Germany (Hörzentrum Oldenburg GmbH, "DE"), and Switzerland (Department of Otorhinolaryngology, University Hospital Zürich, "CH").

A. Subjects

In total, 109 subjects participated. Three groups were defined, based on audiogram information only. One group consisted of 38 NH subjects with average hearing thresholds better than or equal to 20 dB hearing level (HL) for octave frequencies between 250 and 8000 Hz. The other 71 subjects had a moderate sensorineural hearing loss and were experienced bilateral hearing aid users (at least 6 months of experience). Bilateral acoustic inputs were used for all tests. Therefore, only a limited amount of asymmetry between the two ears could be tolerated. To this end, the average absolute difference between the left and the right hearing thresholds at the octave frequencies between 500 and 4000 Hz (referred to as symmetry) was intended to be below 10 dB (range 1–19 dB, exceeding 10 dB only in four subjects). The HI subjects were divided into two groups based on the slope of their hearing loss. Slope was defined as the difference between the maximum and minimum hearing thresholds for octave frequencies between 500 and 4000 Hz. The group of hearing-impaired subjects with a flat hearing loss (HI-F) had a slope (averaged for the two ears) of no more than 25 dB. The group with a sloping hearing loss (HI-S) had a slope of more than 25 dB. More details of the subject groups can be found in Table II. The numbers of subjects tested at each test site were 30, 30, 28, and 21 for BE, NL, DE, and CH, respectively.

B. Fitting

Bilateral fittings were based on the audiogram (octave frequencies between 250 and 8000 Hz). The hearing aids were fitted with the NAL-RP prescription rule (Byrne *et al.*, 1991). No compression was included, only a limiter set at 100 dB sound pressure level (SPL) within each frequency band. The gain was adjusted in eight frequency bands, centered at the frequencies 250, 500, 1000, 1500, 2000, 3000, 4000, and 6000 Hz. Fine-tuning was limited to two situations, namely, overall gain experienced as too loud by the subject, or the occurrence of feedback. These situations occurred for approximately 25% and 15% of the HI subjects, respectively. Instead of earmolds, disposable foam earplugs with tubing were used for all ears. For NH subjects, the insertion gain was set to 0 dB.

TABLE II. Description of the subject groups. Degree, slope, and symmetry were calculated for octave frequencies from 500 to 4000 Hz. Slope was defined as the difference between the maximum and minimum hearing thresholds. Symmetry was defined as the average absolute difference between the left and the right hearing thresholds.

		Age (years)		Degree (dB HL)		Slope (dB)		Symmetry (dB)	
Group	*N*	Average	Range	Average	Range	Average	Range	Average	Range
NH	38	30	16–52	4	−3 to 12	9	0–18	4	0–9
HI-F	34	62	22–79	49	34–65	17	5–25	5	1–11
HI-S	37	68	51–80	45	34–61	44	28–70	6	1–19

C. Room characteristics

To investigate the effect of reverberation time on the performance of the algorithms, evaluation tests were conducted in two types of listening room: office-like rooms, representative of many everyday listening conditions, and highly reverberant rooms, which were included to assess the algorithms under more challenging acoustic conditions. At all test sites, the tests were conducted in an office-like room, with a reverberation time (RT_{60}) for frequencies between 300 and 8000 Hz (measured according to the ISO 3382-1997 standard) between 300 and 600 ms. The critical distances for these rooms were 128, 102, 186, and 145 cm for BE, CH, DE, and NL, respectively. Additionally, at two test sites (BE and DE), the algorithms were assessed in a highly reverberant room with an RT_{60} greater than 1 s. The critical distances of these rooms were 37 and 119 cm, for BE and DE, respectively. The maximum background noise level in the rooms was 35 dB(A). For both types of rooms, no additional specifications (room dimensions, room organization, position of test subject, etc.) were defined. At DE the measurements in office-like and reverberant conditions were carried out in a room whose acoustics can be changed systematically.

D. Environmental conditions

During the tests, the listener was given a hearing aid pair controlled by the PHS-MHA. The subject was seated in the test room amidst four loudspeakers that were positioned at 0°, 90°, 180°, and 270°, at 1 m distance from the center of the listener's head. In the highly reverberant room of partner DE, the distance between loudspeakers and listener was 2 m. All loudspeakers were directed toward the listener. Speech was always presented through the front loudspeaker. Two different noise configurations were used. One consisted of three uncorrelated noise sources at 90°, 180°, and 270° (S0N90/180/270). All algorithms were evaluated in this noise scenario, in both room types. In the highly reverberant room, this led to a diffuse noise, as the loudspeakers were positioned outside of the critical distance. In the office-like room, however, this was not the case and the noise field is called pseudo-diffuse. A second noise configuration, which was only used in the office-like room, consisted of one interfering noise source at 90°, i.e., to the listener's right (S0N90). Only two algorithms (BSS and MWF) were evaluated in this single point-source scenario.

A perceptually relevant noise type was chosen for the evaluation of the algorithms. A multitalker babble from the CD *Auditory Tests (Revised)* (Auditec, St. Louis, MO) was used. The noise sources were calibrated to produce a combined sound level of 65 dB(A) at the center of the listener's head (without the listener being present). The speech level was then adjusted to obtain the desired SNR. The noise started 5 s before the first speech sound was presented, to allow the algorithms to initialize properly.

E. Evaluation measures and speech materials

All subjects performed three types of listening tests: adaptive SRT tests, LES, and PR. SRT, LES, and PR were measured for all algorithms (and for the unprocessed condition) at all four test sites in an office-like room with three sources of multitalker babble. The LES and PR tests were carried out after the SRT test so the subjects were already familiar with the listening situation. For the SRT test, additional measurements were performed in other test conditions at a subset of test sites.

1. Adaptive SRT test

At the Dutch-speaking test sites, BE and NL, the open-set VU-sentences (male speaker) were used (Versfeld *et al.*, 2000). Sentence scoring was applied. This speech material consists of 39 lists of 13 sentences. An adaptive one-up one-down test procedure was used. The noise was presented at a fixed level of 65 dB(A) and the level of the target speech was adapted in 2-dB steps. The SRT was defined as the average of the ten last speech presentation levels (including the 14th level, calculated based on the response to the 13th sentence). At BE, the APEX software was used for the SRT testing (Francart *et al.*, 2008). At NL, custom software was used.

At the German-speaking test sites, CH and DE, the closed-set OLSA sentence test was used (Wagener *et al.*, 1999). This speech material (male speaker) consists of 10 lists of 10 sentences with a fixed structure (5 words), combined to give lists of 20 sentences. Sentence scoring was used. The adaptive procedure and the fit of the psychometric curve were as described by Brand and Kollmeier (2002). The OLSA sentence test was used as incorporated in the Oldenburg measurement applications software package developed by Hörtech Oldenburg. Two training lists were used in quiet (20 sentences each).

SRTs using the algorithms were always compared to the SRT for the unprocessed condition, i.e., when all signal enhancement algorithms were switched off and only the basic processing of the PHS-MHA system was activated. In this

TABLE III. Overview table indicating which partners performed which SRT test conditions.

Test condition			Algorithm					
Room	Noise scenario	Masker azimuth	Unpr	SC1	SC2	BSS	MWF	COH
Office-like room	Pseudo-diffuse	90°/180°/270°	All	All	All	All	All	All
Office-like room	Point-source	90°	BE			BE	BE	
			CH			CH	CH	
			NL			NL	NL	
Reverberant room	Diffuse	90°/180°/270°	BE	BE	BE	BE	BE	BE
			DE	DE	DE	DE	DE	DE

way, changes in speech understanding in noise were assessed. An overview of all test conditions is shown in Table III. All conditions were tested in randomized order and conducted twice (test and retest) in one or more test sessions, depending on the total number of conditions to test.

2. LES

Each subject had to rate the listening effort for each algorithm and for the unprocessed condition at five different SNRs: −10, −5, 0, +5, and +10 dB. The LES was performed using a 13 point scale (7 subcategories, with 1 empty button in between). The subcategories ranged from "extreme effort" (score 6) to "no effort" (score 0). LES was performed in the office-like room, with the three interfering noise sources (S0N90/180/270). The same speech material as for the SRT test was used. All conditions were tested and retested, resulting in a total of 60 ratings.

3. PR

As the perceptual differences between the algorithms were expected to be small, a paired-comparison test was used for the PR. Each algorithm was compared to the unprocessed condition. Preference rating was done under office-like room conditions only, with the three interfering noise sources (S0N90/180/270). Each pair of algorithms was presented at three different SNRs (0, +5, and +10 dB), and every presentation was conducted twice (test and retest). This gave a total of 30 ratings.

During the PR, the subject could listen to the algorithms as long as needed and could toggle between the algorithms as often as wanted. After indicating a preference, the subject had to rate how much better the preferred algorithm was compared to the other one. This rating can be interpreted as the confidence of the subjective preference judgments. The outcome of the test is the amount of preference for an algorithm over the unprocessed condition. This preference score can vary between "very much worse" (scored as −5) and "very much better" (scored as +5). The PR test used a forced-choice paradigm, so equal preference (that would be represented by score 0) was not an option.

The preference-rating data were rescaled with a linear Gaussian model (LGM) in order to obtain a perceptually correct scale. The data were evaluated according to the method of Dahlquist and Leijon (2003), where it is assumed that the perceptual quality of each algorithm has a specific neural representation in the listener's sensory system. This representation can be modeled as the outcome of a normally distributed (Gaussian) random variable X with mean μ_i, whenever algorithm A_i is presented, and a constant variance σ^2. The LGM places the algorithms on an interval scale.

It is assumed that each paired-comparison decision is determined by the outcome of two independent random variables (X_1, X_2) with Gaussian distributions with variance σ^2 and means (μ_i, μ_j), whenever algorithm pair (A_i, A_j) is presented. The LGM estimates the (unknown) parameters, leading to a nonlinear and multidimensional maximization problem, which can be solved using routines provided by the MATLAB optimization toolbox. The LGM provides the limits of the estimated confidence intervals. These limits can be used to evaluate the differences between two specific algorithms in terms of the five categories that were used by the subjects to rate the algorithms. As the unprocessed condition was used as a reference, all results were shifted so that the reference was placed at scale value zero. The LGM was applied to each set of data for every subject. Afterwards the results for the individuals were pooled.

F. Statistical analyses

Statistical analyses were carried out with the SPSS software. To test whether the distribution of the variables was normal, Kolmogorov–Smirnov tests were used. To analyze the SRT data, repeated-measures analyses of variance (ANOVAs) were carried out. For tests of within-subjects effects, lower-bound corrections for violations of sphericity were applied. *Post hoc* tests consisted of pairwise comparisons. To keep the type I error rate across all comparisons at 0.05, Bonferroni correction was applied. For LES and PR data, non-parametric statistics were applied. When several conditions were compared and consequently several tests were required, the significance level was also adjusted using Bonferroni correction (unless mentioned differently).

V. RESULTS

A. Test-retest reliability

Test and retest scores for SRT, LES, and PR were compared for results obtained in the office-like room, with three interfering noise sources. Test and retest scores for all algorithms were taken together. In this way, for SRT, only one paired-comparison was carried out (using a paired-samples

t-test). For LES and PR, data were compared for each tested SNR with a non-parametric Wilcoxon signed rank test.

Test-retest scores for SRT were significantly different ($p \leq 0.001$). The mean difference was 0.8 dB with the retest scores being lower than the test scores. This might be due to a learning effect. For LES there was a significant difference between test and retest at −10, −5, and 0 dB SNR ($p \leq 0.001$) with the retest scores being, respectively, 0.1, 0.2, and 0.3 points higher than the test scores. For PR, test and retest were not significantly different at any SNR ($p > 0.5$).

Test-retest reliability was assessed by calculating the variability of the scores, measured as the within-subjects standard deviation of the scores (σ_w) with the formula

$$\sigma_w = \sqrt{\frac{1}{2}\sum_{i=1}^{n}\frac{(x_{i1}-x_{i2})^2}{n}},$$

where x_{i1} is the ith test score, x_{i2} is the ith retest score, and n is the total number of scores to compare. For SRT, σ_w of the absolute scores was 1.8 dB. For LES, which is scored on a scale from 0 to 6, σ_w was 0.6, 0.9, 1.2, 1.0, and 0.7 points at −10, −5, 0, 5, and 10 dB SNR, respectively. The reliability was lower for the middle SNRs. At the lowest and the highest SNRs, subjects tended to give the maximum and minimum scores, respectively. At the extremes the variability between subjects, as well as within subjects, was thus small. For PR, which is scored on a scale from −5 to +5, σ_w was 1.9, 2.0, and 2.0 points for 0, +5, and +10 dB SNR, respectively.

For further analyses of the SRT results, test-retest was included in the ANOVAs as a within-subjects factor. For further analyses of LES and PR, test and retest scores were averaged prior to analysis.

B. Speech reception threshold tests

1. Office-like room and three interfering noise sources

To compare the results of the different subject groups and test sites, a mixed-model ANOVA was carried out including the absolute SRT scores measured in the office-like room with three noise sources, because these measurements were performed at all test sites. The analysis included two within-subjects factors (test-retest and algorithm) and two between-subjects factors (subject group and test site).

Both between-subjects factors were highly significant ($p \leq 0.001$). Pairwise comparisons of the test sites showed that the SRTs (mean ± SE) averaged over all subject groups and all algorithms for the German-speaking test sites DE (−4.7 ± 0.4 dB SNR) and CH (−3.4 ± 0.5 dB SNR) were not significantly different ($p = 0.290$). Similarly the average SRTs for the Dutch-speaking test sites BE (0.2 ± 0.4 dB SNR) and NL (−0.7 ± 0.4 dB SNR) were not significantly different ($p = 0.659$). Differences between German-speaking and Dutch-speaking test sites were highly significant ($p \leq 0.001$). As expected, pairwise comparisons of the subject groups (averaged over all test sites) showed that the NH subjects (−5.2 ± 0.4 dB SNR) had significantly lower SRTs than the HI subject groups ($p \leq 0.001$). The difference between the two HI subject groups was not significant ($p = 1.000$). The average SRT was −0.5 ± 0.4 dB SNR for the group with flat hearing losses and −0.8 ± 0.4 dB SNR for the group with sloping hearing losses.

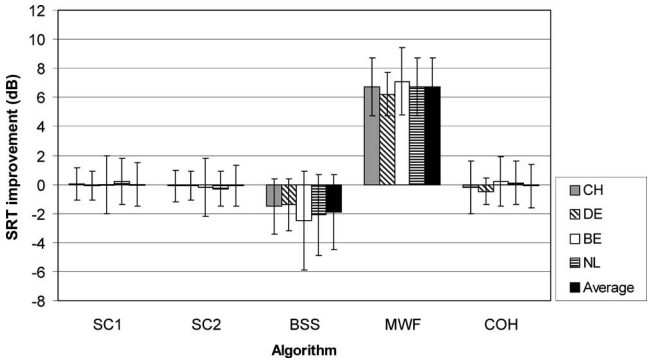

FIG. 1. Mean SRTs (and standard deviations) relative to those for the unprocessed condition in an office-like room with three noise sources. Results are shown for the different test sites averaged over all subject groups.

The main effect of test-retest ($p \leq 0.001$) was significant. The mean difference between test and retest data was 0.8 ± 0.1 dB with lower SRTs for the retest. There were no significant interaction effects between the factor test-retest and any other factors in this analysis ($p > 0.24$). The effect of test-retest is thus independent of algorithm, test site, and subject group.

There was a main effect of algorithm ($p \leq 0.001$), but the factor algorithm did not interact with other factors ($p > 0.23$). The differences between the algorithms are thus similar for test and retest scores, and for all subject groups and test sites. Pairwise comparisons of the SRTs for the five algorithms under test and the unprocessed condition showed that only BSS and MWF differed significantly from the unprocessed condition. The improvement with MWF was 6.6 ± 0.2 dB ($p \leq 0.001$). With BSS the SRT worsened by 1.9 ± 0.3 dB ($p \leq 0.001$).

In what follows, we focus on the SRT changes for the different algorithms relative to the SRT for the unprocessed condition, as the SRT changes or relative scores did not interact with subject group and test site. Figures 1 and 2 show the mean SRT improvements, averaged over subjects and test/retest, for the different test sites and subject groups, respectively. Positive numbers in the figures indicate an improvement.

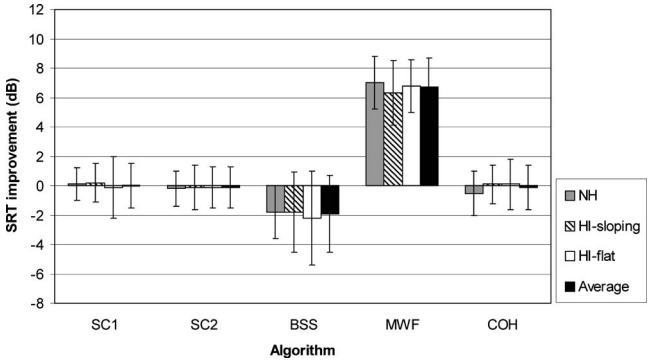

FIG. 2. As Fig. 1, but for the three subject groups averaged over all test sites.

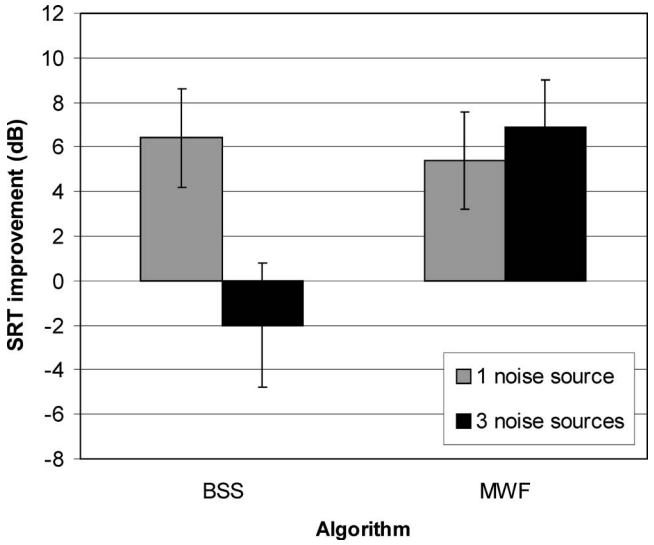

FIG. 3. Comparison of results for two noise scenarios. Mean SRTs (and standard deviations) relative to those for the unprocessed condition in an office-like room are shown. Results are averaged over three subject groups and three test sites.

2. Evaluation of BSS and MWF in two different noise scenarios

At three test sites (BE, NL, and CH), additional measurements were carried out in the office-like room with one noise source for the BSS and MWF. An ANOVA on the SRT improvements with three factors (test-retest, noise scenario, and algorithm) showed no effect of test-retest ($p=0.617$). There was a main effect of noise scenario and algorithm and an interaction between the two ($p \leq 0.001$). As shown in Fig. 3, the performance of the MWF improved significantly from 5.4 (SD=2.2 dB) to 6.9 dB (SD=2.1 dB) when adding more noise sources. The BSS performed well with one interfering noise source (6.4 ± 2.2 dB improvement), but led to worse performance for three uncorrelated noise sources (-2.0 ± 2.8 dB).

3. Comparison of test rooms

At two test sites (BE and DE), the algorithms were also evaluated in a highly reverberant room using three interfering noise sources. The SRTs in the highly reverberant room were on average 6.7 dB higher at BE and 5.2 dB higher at DE than the SRTs in an office-like room. A mixed-model ANOVA on the SRT improvements was carried out with the within-subjects factors test-retest (two levels), room (two levels), and algorithm (five levels). Subject group and test site were between-subjects factors.

The factors subject group and test site were not significant ($p > 0.05$). The main effect of room was not significant ($p=0.697$), but there was a significant interaction between room and algorithm ($p=0.009$). The origin of this interaction effect is shown in Fig. 4. The SRT improvement for the MWF was lower for the reverberant room (5.4 ± 2.2 dB) than for the office-like room (6.7 ± 2.0 dB), while the effects for the other algorithms were comparable across rooms.

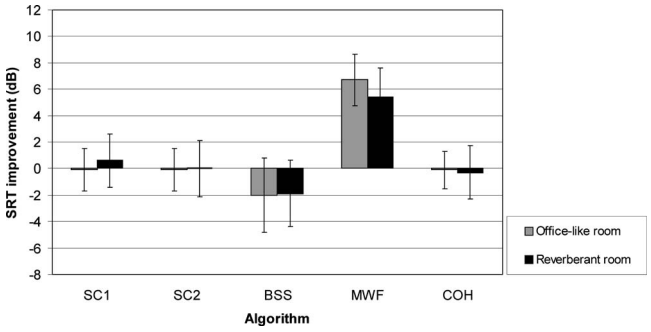

FIG. 4. Comparison of results for two types of rooms. Mean SRTs (and standard deviations) relative to those for the unprocessed condition are shown. Results are averaged over three subject groups and two test sites.

C. LES

Unlike the SRT scores, the LES scores were not normally distributed. Moreover, the distributions were very different for the different SNRs. Therefore, non-parametric tests were used.

1. LES for the unprocessed condition

The LES scores for the unprocessed condition (average of test and retest scores) were analyzed in order to assess whether there were baseline differences in LES scores between subject groups, test sites, and SNRs. The LES scores for the unprocessed condition are depicted in Fig. 5 as a function of SNR for the four test sites (left panel) and three subject groups (right panel). For each SNR, the effect of test site and subject group was evaluated with a non-parametric Kruskal–Wallis test. The effect of test site was significant at all SNRs ($p \leq 0.005$), except at -10 dB. In general, the effect was similar to the effect observed in the SRT scores. The SRTs for the Dutch-speaking subjects were higher than for the German-speaking subjects. Similarly, the Dutch-speaking subjects required more effort than the German-speaking subjects at the same SNR.

The effect of subject group was significant at -5, +5, and +10 dB SNR ($p \leq 0.005$). At these SNRs, Mann–Whitney tests were carried out to investigate the differences between groups. At all three SNRs the HI groups did not differ significantly ($p > 0.4$), but the NH group differed significantly from both HI groups ($p \leq 0.011$). Again, this effect is similar to the SRT scores for the unprocessed condition: HI subjects required a higher SNR to reach 50% intelligibility than NH subjects. Accordingly, at the same SNR, HI subjects required more effort than NH subjects. No difference was observed between the two HI groups for SRT or LES.

2. LES scores relative to the unprocessed condition

We focus on scores relative to those for the unprocessed condition. A positive relative score means that less effort was required than for the unprocessed condition. The effect of subject group and test site on the relative LES scores was assessed with Kruskal–Wallis tests for each algorithm at each SNR. After Bonferroni correction for multiple testing, only one variable (the MWF at -10 dB SNR) showed an effect of

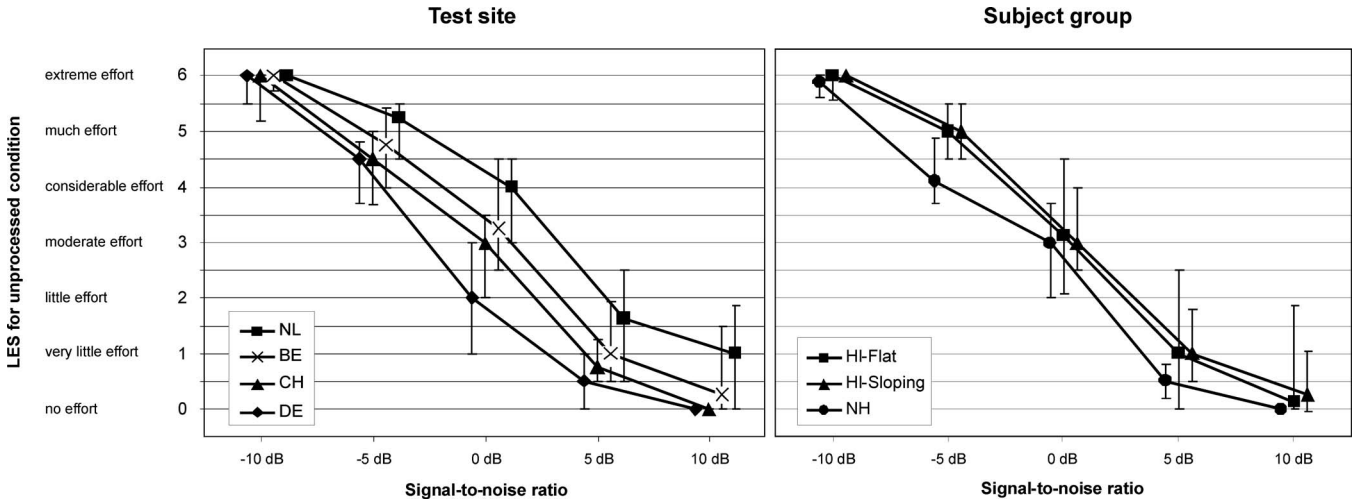

FIG. 5. Median LES for the unprocessed condition for different SNRs. The effects of test site and subject group are shown in the left and right panels, respectively. Error bars represent first and third quartiles.

subject group. The effect of test site, however, was significant for many variables. Therefore, Fig. 6 shows the LES difference scores for each test site, but averaged over subject groups. Because the results were not normally distributed, medians and quartiles are shown. Results are only shown for 0 dB SNR as the largest effects were obtained at this SNR. To assess whether LES scores for the algorithms were different from those for the unprocessed condition, Wilcoxon signed ranks tests were carried out. As 25 comparisons were needed, the significance level was decreased to 0.002 ($p = 0.05/25$). Algorithm scores that were significantly different from those for the unprocessed condition are indicated with an asterisk. The absolute effort scores for the algorithms can be estimated by adding the relative scores to the average effort scores for the unprocessed condition as shown in Fig. 5. As becomes clear from Fig. 6, results differed across test sites. However, general trends were similar. Figure 7 illustrates the effect of SNR on the relative LES scores, averaged over subject group and test site. Overall, the MWF required less effort than the unprocessed condition. This effect was largest at low SNRs, i.e., in the more difficult conditions. BSS was the only algorithm that required significantly more efforts than the unprocessed condition, and this was the case at SNRs from −5 to +10 dB SNR. This effect, however, did not occur at all test sites. The other algorithms did not have a large effect on the effort scores. Only at 0 dB SNR did SC1, SC2, and COH have an overall positive effect on the effort scores.

D. PRs

1. Win count

The PRs were initially analyzed by counting the percentage of wins, which is the percentage of times a given algorithm was preferred over the unprocessed condition. If subjects had no preference, the percentage of wins would be 50%. Figure 8 shows the percentage of wins for the five algorithms for the three tested SNRs. SC1, SC2, MWF, and COH were significantly preferred over the unprocessed condition. For BSS, subjects preferred the unprocessed condition (binomial test, $p \leq 0.001$). The general trends were the same for the three SNRs.

To compare the percentage of wins between the different algorithms, McNemars χ^2 test was applied. To limit the num-

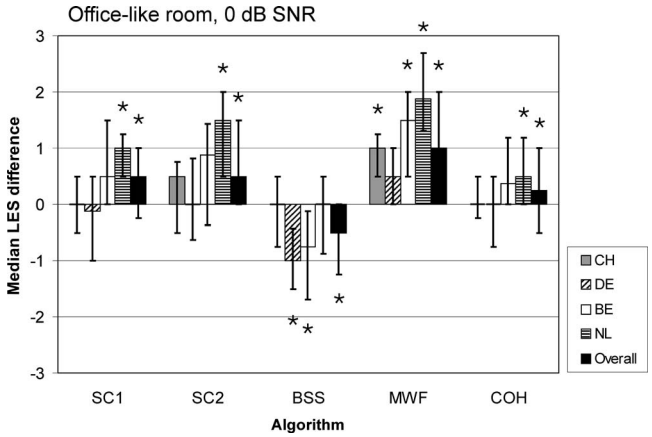

FIG. 6. LES relative to the LES for the unprocessed condition for 0 dB SNR. The error bars show the first and third quartiles. Algorithm scores that are significantly different from those for the unprocessed condition are indicated with an asterisk.

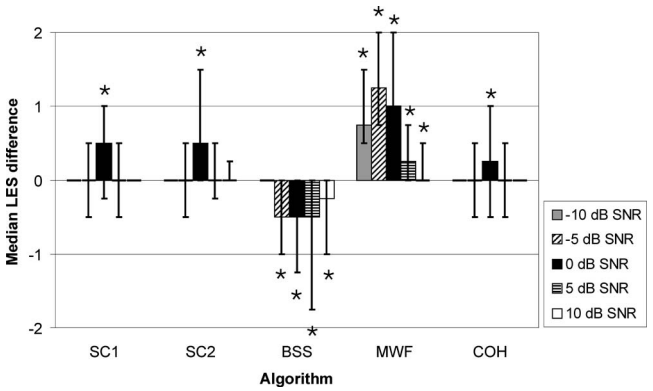

FIG. 7. LES relative to the LES for the unprocessed condition for SNRs from −10 to +10 dB, averaged over all subjects. The error bars show the first and third quartiles. Algorithm scores that are significantly different from those for the unprocessed condition are indicated with an asterisk.

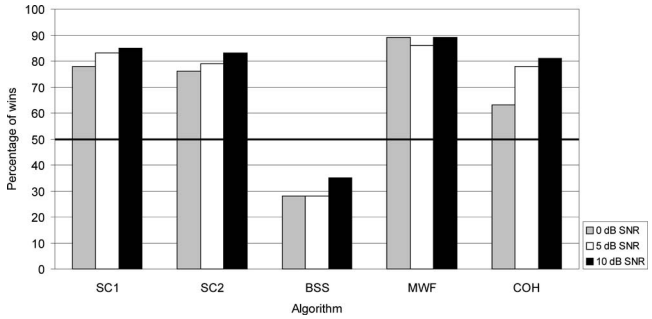

FIG. 8. PR results expressed as the percentage of wins for the algorithms compared to the unprocessed condition at three SNRs.

ber of comparisons, the total of wins across SNRs was used. Except for the differences between SC1 and SC2, and SC2 and COH, all differences were significant ($p \leq 0.001$, with a significance level of $p=0.005$ after Bonferroni correction). The MWF had the highest percentage of wins. However, the difference between MWF and the other algorithms was very small.

2. Degree of preference

The PR scores were not normally distributed, and thus non-parametric statistics were applied. The PR data were rescaled with a LGM. A Kruskal–Wallis test on the rescaled data of each algorithm showed no significant effect of test site ($p > 0.4$). A significant effect of subject group was found only for COH ($p=0.001$). COH was preferred more often than the unprocessed condition by the HI subjects, but not by the NH subjects. Figure 9 shows the effect of algorithm and SNR, averaged over the test sites and subject groups. For the noise scenario with three noise sources, MWF led to the highest preference score. SC1, SC2, and COH were also preferred over the unprocessed condition. BSS had a negative preference score, meaning that the unprocessed condition was more preferred. For each of the algorithms, the effect of SNR was significant (Friedman's ANOVA, $p \leq 0.001$). The degree of preference (positive or negative) was in general lower at 0 dB SNR than at the higher SNRs.

E. Correlations SRT-LES-PR

SRT, LES, and PR scores were obtained for all subjects and in the same test conditions. The correlation between results of the three tests was determined.

1. Relative scores

For PR, only scores relative to the unprocessed condition were available. Consequently, correlations between PR, SRT, and LES scores were calculated for the relative scores. As not all variables were normally distributed, Spearman correlations were calculated. Doing this for each algorithm separately did not result in any significant correlation. This is not surprising, as the variability between subjects (and thus the data range) was smaller for the relative scores than for the absolute scores. Several algorithms did not show any improvement for SRT and LES scores. This restricted range of the variables affects the correlations.

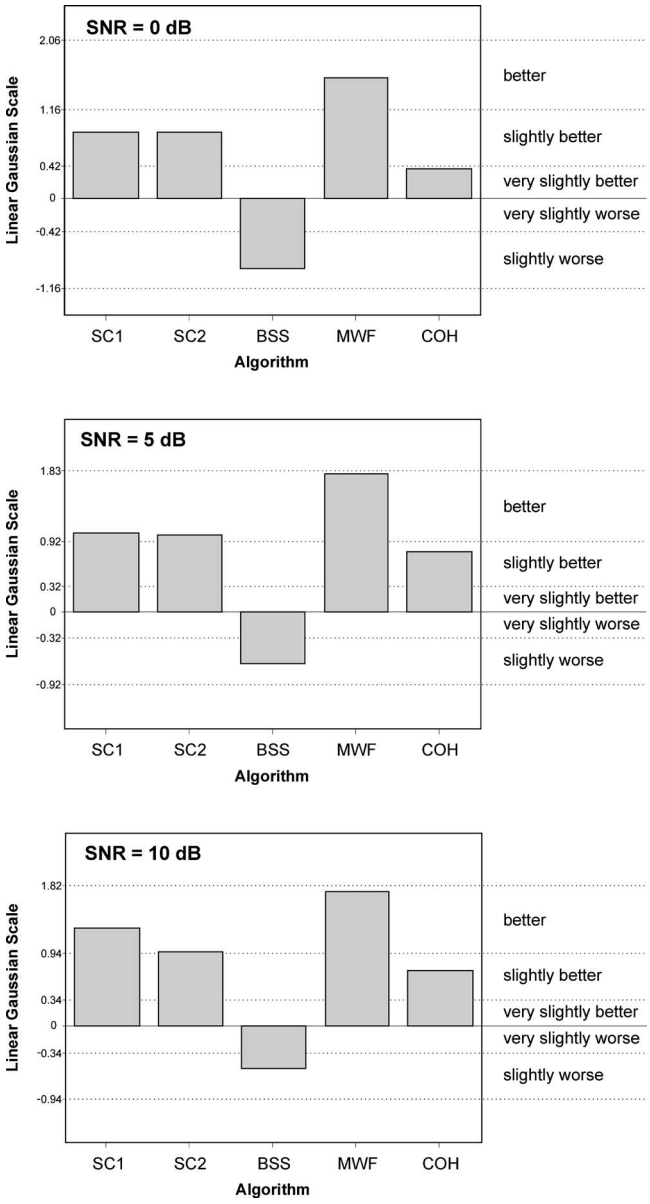

FIG. 9. PR scores for the different SNRs averaged over the test sites and subject groups. The medians (for the rating of the algorithms and the estimated confidence intervals) of the individual (subject) data, transformed with a LGM, are plotted with bars. The offset along the LGM scale is adjusted to zero for the unprocessed condition for every subject individually. Additionally, the categories are indicated.

Correlations were also calculated for all algorithms together, to investigate if subjects rated algorithms in a consistent way over the different tests. The relative SRT scores were significantly correlated ($p \leq 0.001$) with relative LES and PR scores at all tested SNRs. For LES the correlations ranged from 0.192 at 10 dB SNR to 0.418 at −5 dB SNR. For PR the correlations ranged from 0.316 at 10 dB SNR to 0.379 at 0 dB SNR. These results indicate that improvement in speech intelligibility is weakly associated with improvement in listening effort and degree of preference. The average SRT over all algorithms was between 0 and −5 dB SNR for the different groups, so it is not surprising that the highest correlations were obtained at these (low) SNRs. PR and LES relative scores were also significantly correlated ($p \leq 0.001$),

although correlations were low. The Spearman correlations were 0.237, 0.179, and 0.200 at 0, 5, and 10 dB SNR, respectively.

2. Absolute scores

The absolute LES and SRT scores were also compared. Overall correlations (for all algorithms and the unprocessed condition together) ranged from 0.439 to 0.547 ($p \leq 0.001$). The highest correlation was found at −5 dB SNR. Correlations for each algorithm separately were all significant at $p \leq 0.05$ (without correction for multiple comparisons). At −5 dB SNR, Spearman correlations were 0.454, 0.348, 0.442, 0.499, 0.277, and 0.437 for the unprocessed, SC1, SC2, BSS, MWF, and COH conditions, respectively ($p \leq 0.004$). These correlations indicate that lower SRTs (better speech intelligibility) are associated with lower LES scores (less listening effort).

VI. DISCUSSION

A. Effect of test site

One goal of this study was to evaluate how comparable the results were for the different test sites. To ensure comparability of the results across the four test sites, special attention had to be paid to the test protocol. On the one hand, the protocol had to be flexible to allow for inherent variations, e.g., of the specification of the test rooms and the auditory profile of the subjects. On the other hand, the protocol needed to be sufficiently strict to minimize the impact of unknown factors on the test results.

For the absolute SRT scores, a significant effect of test site was observed. The overall SRT in multitalker babble noise for the German-speaking test sites was about 3.6 dB lower than the SRT for the Dutch-speaking test sites. This is not surprising, as each speech material has its own reference psychometric curve with an average SRT and slope. The SRT for the German OLSA sentences in stationary speech-weighted noise for NH subjects is lower than the SRT in the same conditions for the Dutch VU-sentences. This absolute shift in SRT scores can be taken into account by considering the improvements relative to the SRTs for the unprocessed condition. In this study, care was taken to use a uniform procedure for, e.g., calibration of the setup and fitting of the hearing aids. A common evaluation platform was used, test procedures were thoroughly discussed and evaluated through a series of pilot tests, and test instructions were uniform across test sites. Other parameters, such as the specific type of loudspeaker, sound card, speech material, and exact room characteristics such as size and reverberation time, differed between test sites. Variations in these parameters (controlled to a certain extent) did not significantly influence the effects of the algorithms on SRTs.

For PR, there were no significant differences between the test sites. For LES, in contrast, there were differences across the test sites. For the unprocessed condition, the pattern of the LES scores resembled the pattern of the corresponding SRT scores. Lower absolute SRTs corresponded with lower effort scores. For LES scores, the differences between test sites were not completely eliminated by taking the relative scores. General trends, however, were the same across test sites. It was mainly the size of the effects that differed. It is not clear what the cause of these differences was.

B. Effect of subject group

The absolute SRT and LES scores showed differences between subject groups. As expected, HI subjects had higher (worse) absolute SRT and LES scores than NH subjects. Nevertheless, the relative SRT and LES scores were not significantly different between subject groups. For PR, results were also very similar between subject groups. It is reasonable to assume that the noise suppression algorithms succeed in improving the SNR by some decibels, at least for positive SNRs. As they operate on the noisy speech signals before they are delivered to the NH or HI subject, this could result in similar perceptual improvements for all subject groups.

Besides the perceptual evaluation of the algorithms, a physical evaluation was performed (not reported in this paper), where the algorithm effects were evaluated for several different "auditory profiles," i.e., types of hearing impairment. The algorithm performance was quantified by objective performance measures that use established auditory models to account for one or more of the following fundamental effects of hearing impairment: loss of audibility at low input levels, loudness recruitment, reduced frequency resolution, and reduced ability to extract supra-threshold speech cues for speech recognition. The performance measures included (among others) the SII-improvement, which is a standardized and commonly used performance measure for predicting speech intelligibility in non-fluctuating noise (ANSI S3.5-1997, 1997) and the segmental SII-improvement, a modified version where the SII is first calculated for each short-time segment, and these values are then averaged over the duration of the test signal. According to this physical evaluation, the algorithms did show differences in performance for different auditory profiles (Eneman *et al.*, 2008a, 2008b). NH subjects were expected to benefit more from the algorithms than HI subjects. Additionally, a lower benefit was expected for the flat than for the sloping audiogram configurations. The perceptual results, which show no differences between NH and HI listeners, appear inconsistent with the physical evaluation, but there are several possible explanations for this discrepancy. First, in the perceptual study, the groups were defined by audiogram information only. The HI subjects were assigned to the HI-S or HI-F group on the basis of slope of the audiogram between 500 and 4000 Hz, but they might have differed in other ways. Other aspects of the auditory profile might affect the perceptual scores. Second, the SRT (defined as the SNR for 50% intelligibility) and SRT improvement were determined at very different SNRs for the NH and HI subjects. It was postulated that the algorithms would perform worse in terms of SRT improvement at low (negative) SNRs, e.g., the speech-noise detector of MWF would perform worse at low SNRs. The algorithms may decrease the noise level at these low SNRs, but this may be accompanied by a decrease in the speech level as well. Indeed, Eneman *et al.* (2008a, 2008b)

showed that the segmental SII-improvement of the MWF worsened with decreasing SNR below 0 dB. This might explain the decreased algorithm benefit measured for NH subjects compared to the benefit measured for the HI groups, whose SRTs were higher. To conclude, the discrepancy between physical and perceptual results emphasizes once more the importance of perceptual evaluations using NH and HI subjects.

C. Algorithm performance

1. SRT results

In the pseudo-diffuse noise scenario, MWF was the only algorithm that provided a significant SRT improvement relative to the unprocessed condition. Averaged over test sites and subject groups, an improvement of 6.6 dB was obtained with the MWF. The single-channel noise reduction methods, SC1 and SC2, did not significantly affect SRTs. This is noteworthy, since in single-channel noise reduction the competing signal cannot be removed without distorting the desired signal. Single-channel noise reduction is a challenging task, in particular, at the low SNRs at which the SRT is measured. The BSS had a negative effect and increased SRTs relative to those for the unprocessed condition, by on average 1.9 dB. This is not really surprising, as the two-channel BSS algorithm used was designed to separate two distinct point sources only. At three test sites, BSS and MWF were also evaluated using a single point-source masker. The multimicrophone enhancement techniques BSS and MWF were able to take advantage of the spatial diversity of the setup and to improve speech intelligibility in this noise scenario by, on average, 6.4 and 5.4 dB, respectively. Whereas the MWF algorithm performed well in both noise scenarios (with one and three noise sources), the BSS algorithm appears suited for the single point-source masker only.

The additional measurements in the reverberant room showed that the SRT improvements were very similar for the two rooms. Only for MWF was the relative SRT score significantly different for the two rooms. In the reverberant room, the improvement in SRT reduced by 1.3 dB. Nevertheless, even in these very demanding listening circumstances, an improvement of 5.4 dB was obtained.

2. Comparison of SRT, LES, and PR

As a consequence of the adaptive procedure, SRTs and SRT improvements were measured at different SNRs depending on the subjects' hearing status. Additionally, for many subjects, the SRT was at a negative SNR. This is a disadvantage of the speech intelligibility measurements, as it is known that several signal enhancement algorithms perform differently at low and high SNRs. Nonetheless, speech intelligibility improvements are most required in difficult listening situations (e.g., at 50% intelligibility), which occur at different SNRs depending on the hearing loss. Therefore, SRT measurements are considered to be highly relevant in the perceptual evaluation of speech enhancement algorithms. In addition to the SRT measurements, LES and PR can be used to evaluate the algorithm improvements at high input SNRs, as the measurements can be obtained for SNRs up to +10 dB.

For the relative LES scores, there were differences between test sites. However, some general observations could be made. In the pseudo-diffuse noise scenario, the MWF required less effort than the unprocessed condition, especially at the lower SNRs. At the higher SNRs, speech was easy to understand in the unprocessed condition, and thus the MWF did not decrease the listening effort much. At some test sites, the BSS led to a negative effect on listening effort, mainly at the higher SNRs, although variability was large. This was not unexpected since the LES scores (and PR scores) were obtained in a scenario with three uncorrelated noise sources, whereas the two-channel BSS algorithm was designed to separate two distinct point sources.

The LES revealed improvements for algorithms, which did not give improved SRTs, analogous to the results of Marzinzik and Kollmeier (1999) and Walden *et al.* (2000). These researchers showed a significant positive effect of noise reduction algorithms on LES, although no improvement in speech intelligibility was shown by SRT tests. Similarly, in the current study, an improvement in listening effort for SC1, SC2, and COH was found at 0 dB SNR, although no SRT improvement was measured for these algorithms. At the other SNRs, LES did not reveal improved listening effort for these three algorithms.

For the PR results, preference was higher for MWF, SC1, SC2, and COH than for the unprocessed condition, at all three SNRs. So, PR did reveal differences for a number of algorithms. The preference for the algorithms was higher at the high SNRs (+5 and +10 dB) than at 0 dB. The increasing PR scores with increasing SNR for SC1, SC2, and COH are most probably due to less (audible) speech and noise distortion at higher SNRs. Analogous results were obtained in a study of Ricketts and Hornsby (2005). They used a similar paired-comparison approach to determine preference. Although the single-channel noise reduction in a commercial hearing aid did not affect speech intelligibility, there was a strong preference for the noise reduction algorithm using both low-level and high-level noise. Natarajan *et al.* (2005) also reported increased speech quality ratings, while no measurable changes in intelligibility occurred. A study of Alcántara *et al.* (2003), however, showed no preference for a commercial noise reduction algorithm.

The discrepancy between LES and PR has several possible causes. First, different dimensions were rated. LES is based on a rating of the effort in understanding speech in a noisy situation and PR gives an indication of the preference for an algorithm in a noisy situation, which is much broader and includes the general quality of sounds processed using an algorithm. Second, the psychophysical methods used for LES and PR are different. LES makes use of a categorical magnitude rating, whereas PR is based on paired-comparison. In addition to this methodological difference (and as a consequence), the LES scores show clear floor and ceiling effects at the lowest and highest SNRs. Because of these floor and ceiling effects it might be more difficult to

measure differences between the algorithms and the unprocessed condition. This is avoided in the paired-comparison procedure used for the PR test.

VII. CONCLUSIONS

In this multicenter study, five different signal enhancement approaches were evaluated through listening tests with large numbers of NH listeners and hearing aid users with flat and sloping moderate hearing losses. The SRT improvements and PR scores for the different signal processing strategies were comparable across the test sites, despite differences in test material. For LES, slightly different results were obtained across the test sites. Additional investigations are necessary to interpret these differences. For the SRT improvements, LES improvements, and PR scores, outcomes were very similar for the different subject groups. In a pseudo-diffuse noise scenario, MWF was the only algorithm that provided a significant SRT improvement. The BSS algorithm seemed suited only for the single point-source scenario. Unlike the lack of improvement in SRT for SC1, SC2, and COH, the PR did show preference for these algorithms over the unprocessed condition at all tested SNRs and the LES showed decreased listening effort at 0 dB SNR for the same algorithms. This study shows that perceptual evaluations of signal enhancement algorithms can be obtained in a precise, robust, reproducible, and comparable manner across different research groups and subject groups when an appropriate test protocol is used.

Speech production: Papers from a 2008 symposium

The five papers that follow are written versions of papers presented at the Sixth International Conference on Voice Physiology and Biomechanics (ICVPB), held in Tampere, Finland, on 6-9 August 2008. This series of conferences grew out of an earlier set of conferences on Vocal Fold Physiology, these having been held biannually since 1980. (The first of the present series took place in Evanston, Illinois, in May 1997.) The conferences have no proceedings as such, but the organizers endeavor to have authors of papers falling within distinct topical areas publish their work as a group. Four papers from the first conference were published as a group in the January 1999 issue of the Journal (Vol. 105:1). Six papers from the second conference were published as a group in the October 2000 issue (Vol. 108:4). The authors of the present five papers wanted to have them published in the Journal. Each of the papers was reviewed independently and subjected to the same rigorous peer review procedure as are all archival research articles submitted to the Journal. Four associate editors, David Berry, Avraham Hirschberg, Anders Lofqvist, and Douglas O'Shaughnessy handled the peer review processing.

Anders Lofqvist

Pharyngeal articulation in the production of voiced and voiceless fricatives[a)]

Michael I. Proctor,[b)] Christine H. Shadle, and Khalil Iskarous
Haskins Laboratories, 300 George Street, New Haven, Connecticut 06511

(Received 18 December 2008; revised 10 April 2009; accepted 19 April 2009)

A structural magnetic resonance imaging study has revealed that pharyngeal articulation varies considerably with voicing during the production of English fricatives. In a study of four speakers of American English, pharyngeal volume was generally found to be greater during the production of sustained voiced fricatives, compared to voiceless equivalents. Though pharyngeal expansion is expected for voiced stops, it is more surprising for voiced fricatives. For three speakers, all four voiced oral fricatives were produced with a larger pharynx than that used during the production of the voiceless fricative at the same place of articulation. For one speaker, pharyngeal volume during the production of voiceless labial fricatives was found to be greater, and sibilant pharyngeal volume varied with vocalic context as well as voicing. Pharyngeal expansion was primarily achieved through forward displacement of the anterior and lateral walls of the upper pharynx, but some displacement of the rear pharyngeal wall was also observed. These results suggest that the production of voiced fricatives involves the complex interaction of articulatory constraints from three separate goals: the formation of the appropriate oral constriction, the control of airflow through the constriction so as to achieve frication, and the maintenance of glottal oscillation by attending to transglottal pressure. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3299199]

I. INTRODUCTION

It has long been observed that voiced consonants are characterized by supralaryngeal configurations that differ from those used during the production of voiceless equivalents. Westbury (1983), for example, found that voiced stops "always exhibit active volume increases during their closures," but concluded that the precise nature of any such increase is not especially important, since the means by which the pharynx was expanded was found to vary widely. A cinefluorographic study of English stop cognates by Kent and Moll (1969) found that voiced stops were produced with larger supraglottal volumes caused by lengthening and expansion of the oropharynx, which was attributed to "the result of muscular action rather than passive responses of the vocal tract."

Many other studies have addressed pharyngeal behavior in voiced stops (e.g., Ladefoged, 1963; Rothenberg, 1968), but it has not been established which parts of the pharynx are responsible for voiced expansion, and there has been little treatment in the literature of the mechanisms of voicing in the production of fricatives.

At a first level of analysis, the voicing of fricatives is subject to the same physical constraints as any other voiced obstruent: for glottal excitation to occur, there must be sufficient airflow through the glottis. This is initiated by creating a pulmonically driven pressure differential across the glottis, but in order to *sustain* airflow, a mechanism for the reduction of supraglottal air pressure must be created. In the case of stop consonants, three mechanisms can be employed (Rothenberg, 1968, p. 91):

(i) a passive, pressure-actuated expansion of the walls of the supraglottal cavity,
(ii) a muscularly activated enlargement of the supraglottal cavity, and
(iii) (nasal) airflow through an incomplete (velopharyngeal) closure.

The production of fricatives typically involves no nasal airflow but is characterized by the continuous release of air from the supraglottal cavity through an oral constriction, so the same three mechanisms are available for absorption of glottal airflow. Another strategy might be to increase the aperture of the constriction during the production of voiced fricatives. However, if the speaker controls a similar rate of airflow through the fricative constriction for both members of a voiced-voiceless fricative pair, the question to be considered here is the extent to which the first two mechanisms come into play.

In the case of labial fricatives, supraglottal volume can be manipulated by adjusting the lips and cheeks. However, the more posterior the place of constriction, the fewer the options available for manipulating supraglottal volume. Considering also that the production of English fricatives requires precise articulatory control of the lips, tongue tip, and tongue body (Hardcastle, 1976), then it would appear that the pharynx—which is less directly involved in the generation of noise at the fricative constriction than the active articulators—should bear a greater functional load in the achievement of voicing requirements.

[a)]This paper is an expanded version of a talk presented by the second author at the Sixth ICVPB, Tampere, Finland, 6–9 August 2008.
[b)]Author to whom correspondence should be addressed. Electronic mail: proctor@haskins.yale.edu

The central question addressed in this paper is the way in which the pharynx is articulated during voicing; specifically, in the production of a voiced fricative:

- to what extent is pharyngeal volume actively manipulated or allowed to change passively?
- to what extent do competing constraints on the production of fricatives interact with the control of pharyngeal volume for voicing?

A. Supraglottal volume control during voicing

Rothenberg (1968) addressed in detail the ways in which "glottal airflow in a voiced plosive is often absorbed by a muscularly activated enlargement of the supraglottal cavity," arguing that there are three components of pharyngeal volume change, attributable to movements of the (i) anterior, (ii) vertical, and (iii) posterior-lateral boundaries of the pharynx.

Perkell (1965) reported expansion of the pharynx through forward movement of the base of the tongue by up to 50 mm, which Rothenberg (1968) estimated as contributing up to 6 ml of volume. Stetson (1951) described how vertical motion of the larynx-hyoid unit can elongate the pharynx in that dimension, and Perkell (1965) measured net vertical pharyngeal augmentation of the order of 2 mm during the production of voiced plosives. Based on these data, Rothenberg (1968) estimated that vertical displacement might be responsible for pharyngeal volume increases of up to 2 ml. The third mechanism of pharyngeal expansion, attributable largely to the action of the stylopharyngeous muscles, is estimated to contribute an additional 2 ml of volume, although Rothenberg (1968) did not base this figure on any phonetic data. In total, Rothenberg (1968) estimated that the combined action of these three components could expand the pharynx by up to 10 ml during the production of a voiced consonant, a factor of 20% for a pharyngeal volume of 50 ml.

Bell-Berti (1975) examined the activity of four muscle groups responsible for control of pharyngeal cavity size during the production of stops—levator palatini, superior constrictor, middle constrictor and sternohyoid—and found that all three subjects used at least one of the active expansion mode muscles significantly. She concluded that each subject used "a different arrangement of muscle activities to achieve the pharyngeal cavity expansion necessary for the continuation of glottal pulsing during voiced stop consonant occlusion." On the other hand, Magen *et al.* (2003) used magnetic resonance imaging (MRI) and x-ray cineradiography to examine the behavior of the posterior pharyngeal wall in Japanese and English speakers' vowel production, and found very little movement. The authors concluded that "the position of the posterior pharyngeal wall in this region can be eliminated as a variable, and the anterior portion of the pharynx alone can be used to estimate vocal cavities." The study did not include voiced-voiceless consonantal contrasts.

B. Supraglottal volume control in the production of fricatives

Although many of these same mechanisms are available to a speaker during the production of a voiced fricative, the task differs considerably from that of stop production because of the aerodynamic continuancy involved in producing frication. Ohala (1983) proposed that the difficulty of managing the competing aerodynamic requirements of frication and voicing might account for the comparative typological scarcity of voiced fricatives in comparison to the more commonly occurring voiced stops.

There are little phonetic data currently available with which to test such hypotheses and gain further insights into the details of voicing mechanisms in fricatives. In a cineradiographic study of English sibilants, Subtelny *et al.* (1972) found that "pharyngeal dimensions for /s/… were smaller than for /z/" within some vowel contexts, but these fricative pairs were not elicited in identical phonological contexts. Cineradiographic data collected by Perkell (1969) reveal pharyngeal augmentation during the production of /z/ due to advancement of the tongue dorsum 2 mm further than for /s/. A limitation of these studies is that the data are restricted to the midsagittal plane, and cannot be used to calculate pharyngeal volumes, nor to examine articulation in other dimensions.

In an MRI study of English fricatives, Narayanan *et al.* (1995) observed that "the tongue root tended to be more advanced in the case of the voiced fricatives when compared to their unvoiced counterparts …Tongue root advancement resulted in greater areas in the mid- and lower-pharyngeal regions (and) also influenced the epiglottic-vallecular volume to some extent." All fricatives in their study were elicited in a [ə_] context; however, it has been found that schwa is an inconsistently articulated context vowel, and that adjacent vowels can have a large influence on the position of the tongue when producing fricatives (Shadle *et al.*, 2008). This vocalic coarticulation effect is an important factor which must be controlled when considering the pharyngeal variation that can be attributed to consonantal voicing.

II. METHOD

The pharyngeal models considered in this study were constructed from MR images acquired while speakers of American English produced a range of fricative tokens in a scanner.

A. Subjects and corpora

Four monolingual native speakers of Standard American English, two women (W2 and W3) and two men (M1 and M2), were recruited as subjects. All were students of linguistics, aged between 21 and 26 years, who were paid for their participation. Non-naive subjects were deliberately chosen so that stimuli could be presented in the International Phonetic Alphabet (IPA), and the subjects could be instructed about the linguistic requirements of each task.

Each subject was asked to produce each of the English oral fricatives: eight consonants organized as voiced-voiceless pairs distributed over four places of articulation: labiodental [f]-[v], dental [θ]-[ð], alveolar [s]-[z], and post-alveolar [ʃ]-[ʒ]. Each fricative was elicited in three maximally distributed vocalic contexts [i_i], [a_a], and [u_u].

Stimuli were presented in the format [ifi if:i], allowing the subject to practice the token once, before taking a breath and sustaining the target fricative. The vowel immediately before the long fricative was sustained for approximately half a second before the scanner sequence was initiated at the beginning of frication. Subjects were instructed to sustain even frication and to concentrate on maintaining a consistent articulatory posture throughout the production. At the end of each sustained fricative, the final context vowel was repeated after the scanner had stopped to ensure that, as much as possible, the vocalic context had been maintained throughout the production.

Subjects practiced sustaining fricatives before each MRI session by producing the same corpora in an anechoic chamber while they were prompted using the same stimulus presentation software which was deployed in the scanner. High quality acoustic recordings were made during the anechoic sessions to allow for acoustic analysis of the speakers' fricatives.

A Siemens Sonata 1.5 T MRI scanner was used to image the subjects' vocal tracts while they produced all fricative tokens over the course of two 90-min sessions. Subjects lay supine in the scanner, sustaining each fricative in each vocalic context for 36 s. Prompts were presented in IPA, projected onto a screen which could be read by the subject from within the scanner bore. Subjects varied in the number of breaths they took during the sustained frication, from none (M1) to two (M2, depending on the trial); they were instructed to do so with a minimum of oral movement. In the few cases where the quality of an image sequence was compromised by motion blur associated with breathing or other activity, the token was reacquired.

All fricatives elicited during the scanning session were monitored using a FOMRI dual channel noise canceling optical microphone (Optoacoustics Ltd., 2007) integrated into the scanner. Scanner noise was attenuated by approximately 40 dB, allowing for real-time supervision of the subjects' speech. In this way the veracity of each fricative and vowel was monitored during the production of each token, as well as the maintenance of voicing in the long-hold fricatives. Scan sessions were organized such that, as much as possible, multiple tokens of the same fricatives and all tokens of voiced-voiceless fricative pairs were elicited in a single session to reduce alignment errors.

A two-dimensional True-FISP scan sequence (T_r = 200 ms, T_e = 3.3 ms, flip angle = 70°) was chosen as the best compromise between image resolution and scan time. Each token was repeated three times, so that it could be imaged in each of three orientations: sagittally (from ear to ear), axially (from upper trachea to nasal cavity), and obliquely, 45° to the axial planes, providing cross-sectional imaging of the tract in the alveolar region (from lips to velum) (see Proctor *et al.*, 2008 for details of imaging orientations). In each orientation, parallel slices of 4 mm thickness were acquired, spaced at 4.8 mm intervals. Although this interslice spacing was coarser than ideally desired, it was deemed more important to keep the scan time short to ensure that vowel context persisted through the production of each token. The number of slices acquired for each subject and each orientation was varied as needed in order to sample the tract over the region of interest.

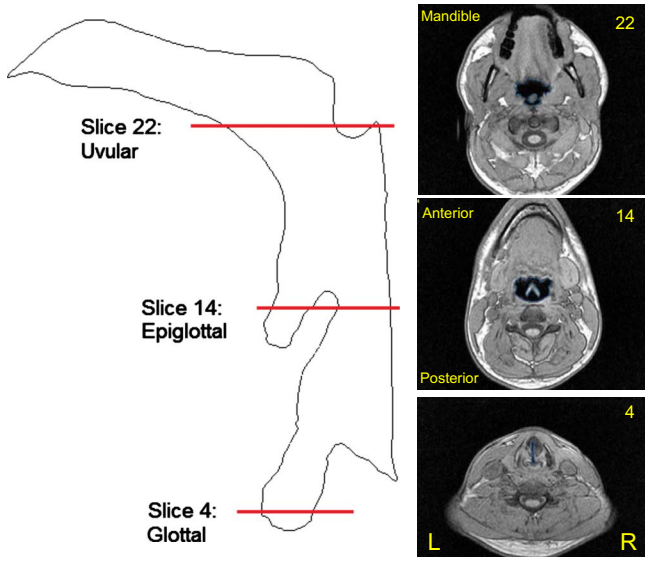

FIG. 1. (Color online) Left: Midsagittal outline of tract from glottis to alveolar constriction, showing location of three axial MRI slices for subject M1—[s] in token [as:a]. Right (bottom to top): Axial slice 4: through glottis; slice 14: midpharynx, showing epiglottis; slice 22: slice above top of oropharynx, showing tip of uvula.

B. Pharyngeal model construction

Initial processing of MR images was performed using 3D-DOCTOR, a vector-based three-dimensional image processing and modeling suite (Able Software Corp., 2007). All subsequent image processing and tract modeling was performed in MATLAB (MathWorks Inc., 2007). Image stacks were assembled from DICOM files in each orientation: sagittal, axial, and oblique. The MR images provided a resolution of 0.47×0.47 mm^2 in the plane of each image slice, with an interslice spacing of 4.8 mm.

For each fricative token, a subset of slices was selected from the axial stack to create a model of the subject's pharynx. A stack of 15–20 slices was required to cover the full extent of each oropharynx, depending on the size, gender, and anatomy of the subject. The bottom slice selected in each stack was the most constricted slice through the glottis above the elliptical sections defining the trachea (Fig. 1, slice 4). The top slice delineating the stack was chosen to be the last slice imaging the oropharynx before any evidence of the uvula was apparent (Fig. 1, slice 21). The sets of images chosen in this way corresponded to a 72–96 mm section of the pharynx.

Three-dimensional models were constructed from the subset of axial images defining the pharynx. Each image slice was segmented by identifying a set of points defining the air-tissue boundary, resulting in a set of curves lying in parallel planes representing the intersection of the tract with the center of each imaging plane. A model of the airway of each oropharynx was constructed from the axial stack of boundaries (Fig. 2). The tract model surface was created by fitting a triangulated mesh to the points defined on the con-

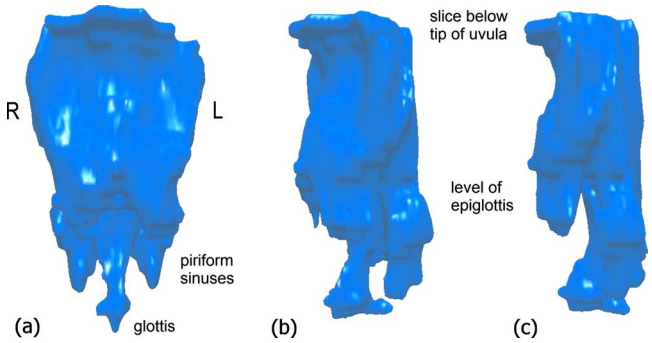

FIG. 2. (Color online) Pharyngeal model constructed from axial MRI slices—subject M1, fricative [z] in token [aza]. (a) Frontal view through mandible. (b) Front-left perspective. (c) Lateral view through left cheek.

stituent boundaries. The surface was triangulated using a DELAUNAY algorithm (de Berg, 1997).

C. Pharyngeal volume estimation

The volume of each pharynx was estimated from the triangulated surface defining the pharyngeal tract boundary. An arbitrary reference point on the tract surface was first chosen. For each triangle on the tract surface, a tetrahedron based on the triangle with an apex at the reference point was constructed, and the volume of the tetrahedron was calculated. All signed tetrahedral volumes defined over the surface with respect to the reference point were then summed to calculate the total volume enclosed by the surface.

III. RESULTS

A. Pharyngeal articulation and voicing

Comparison of the fricative tract models reveals that voiceless fricatives are generally produced with a different pharyngeal configuration to that employed in the production of voiced fricatives at the same place of articulation. Although the region of the tract around the fricative constriction is not shown in these models, no major differences were observed in the primary place of articulation between voiced and voiceless fricative pairs, nor in the size of the constriction.

Articulatory differences between voiced and voiceless fricatives are most apparent in the upper oropharynx, where voiceless tracts typically appear more constricted than their voiced equivalent tracts. Lateral views of the pharynx of subject W3 producing voiced and voiceless fricative pairs are shown in Fig. 3. Frontal views of the same pharyngeal models are shown in Fig. 4.

The vocal tract articulations employed in the production of the voiceless fricatives at all four places of articulation can be seen to be more constricted in the midpharyngeal region. The most constricted section of each of the voiceless pharynges is the region immediately above the epiglottis; in contrast, the voiced tracts maintain a more consistent volume throughout the upper pharynx.

The frontal views of the models (Fig. 4) reveal that the voiceless tracts are also more laterally constricted in the upper pharynx compared to their voiced equivalents, which are noticeably wider in the region below the uvula. For subject

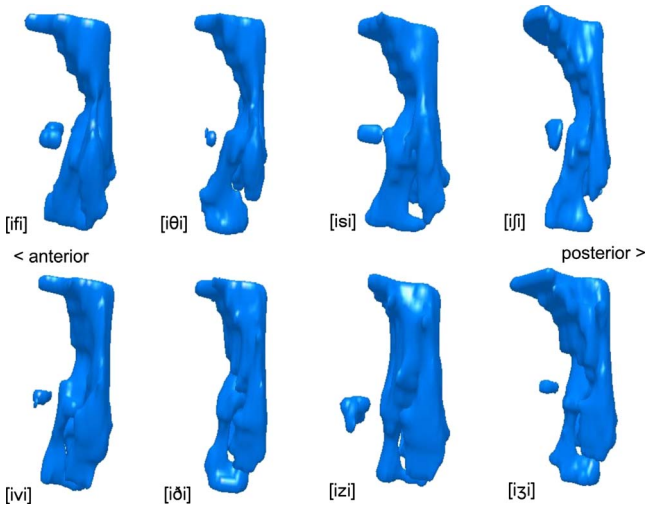

FIG. 3. (Color online) Pharyngeal models of voiceless (top row) and voiced (bottom row) fricatives. Left lateral view. Subject W3, all oral fricatives produced in [i_i] context.

W3, whose pharyngeal models are illustrated here, this effect is particularly noticeable in the sibilant tokens [izi] and [iʒi], which display considerable lateral expansion compared to their voiceless equivalents [isi] and [iʃi]. The issue of whether this expansion is passive or active is addressed in Sec. IV.

These same differences in pharyngeal articulation between voiced and voiceless fricatives are also evident in all tokens produced by subjects M2 and W2, across all four places of articulation. Subject M1 did not show the same consistent pharyngeal expansion for voiced tokens as the other subjects, and his pharyngeal articulation varied considerably with place of articulation. For some tokens, M1's pharynx was more expanded during the production of voiceless fricatives—an effect not observed in any other subject.

B. Pharyngeal volume and voicing

The gross differences in pharyngeal articulation observed in the tract surface models were quantified by calcu-

TABLE I. Mean pharyngeal volume (cm^3) by place of fricative articulation. All four subjects and all three vowel contexts. Percentage difference calculated as $(V_{voiced}-V_{unvoiced})/V_{unvoiced}\times 100$.

Place of articulation	Volume voiced	Volume unvoiced	Difference	
			cm^3	%
Labiodental	26.9	20.2	6.7	33
Dental	22.9	19.5	3.4	18
Alveolar	34.3	23.0	11.4	49
Postalveolar	33.1	23.7	9.3	39
All fricatives	29.3	21.6	7.7	36

TABLE II. Mean pharyngeal volume (cm^3) by subject. All fricatives and all vowel contexts. Percentage difference calculated as $(V_{voiced}-V_{unvoiced})/V_{unvoiced}\times 100$.

Subject	Volume voiced	Volume unvoiced	Difference	
			cm^3	%
M1	50.4	49.7	0.7	1
M2	37.9	18.9	19.0	100
W2	13.1	8.8	4.3	49
W3	15.8	9.0	6.8	76
All subjects	29.3	21.6	7.7	36

lating the volumes of the pharyngeal models for each token (Sec. II C). Differences in volumes of voiced and voiceless tracts were calculated for each pair of fricatives, and averaged over subjects and vowel contexts (Table I). Overall, for this group of speakers, voiced fricatives are produced with a 36% larger mean pharyngeal volume than their voiceless equivalents.

Mean pharyngeal volumes for each subject, averaged over fricative token and vocalic context, are given in Table II. The data show that three of these speakers produced voiced fricatives with a pharyngeal volume at least 49% larger than their voiceless equivalents. For one speaker (M2), the pharynx used to produce voiced fricatives is on average twice as large as the pharynx used to produce voiceless fricatives. Compared to the other subjects, the pharyngeal volume data of subject M1 were anomalous, showing no major difference in mean pharyngeal volume between voiced and voiceless fricatives.

Although mean voiced fricative pharyngeal volumes are consistently larger than voiceless volumes across all places of articulation, the magnitude and direction of these differences vary between subjects. Pharyngeal volumes of fricatives produced by individual subjects at each place of articulation are compared in Figs. 5–8.

The data show that three of the four subjects (M2, W2, and W3) consistently produce voiced fricatives with larger

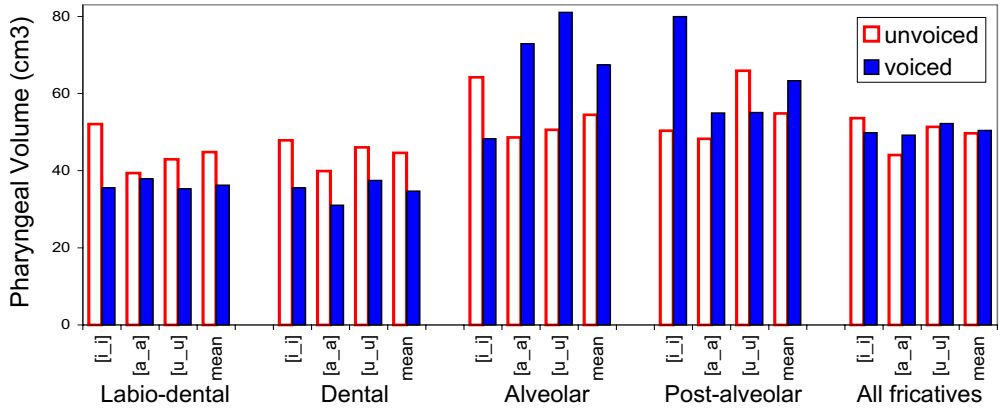

FIG. 5. (Color online) Fricative pharyngeal volumes by place of articulation and vocalic context—subject M1. Solid bars indicate voiced volumes; outlined bars indicate voiceless volumes. Contexts [i_i], [a_a], and [u_u] and mean volumes shown for each pair.

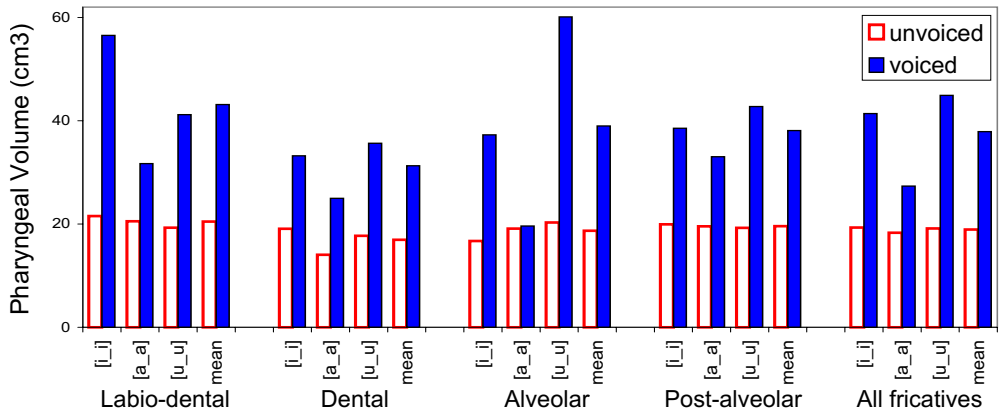

FIG. 6. (Color online) Fricative pharyngeal volumes by place of articulation and vocalic context—subject M2. See Fig. 5 for legend.

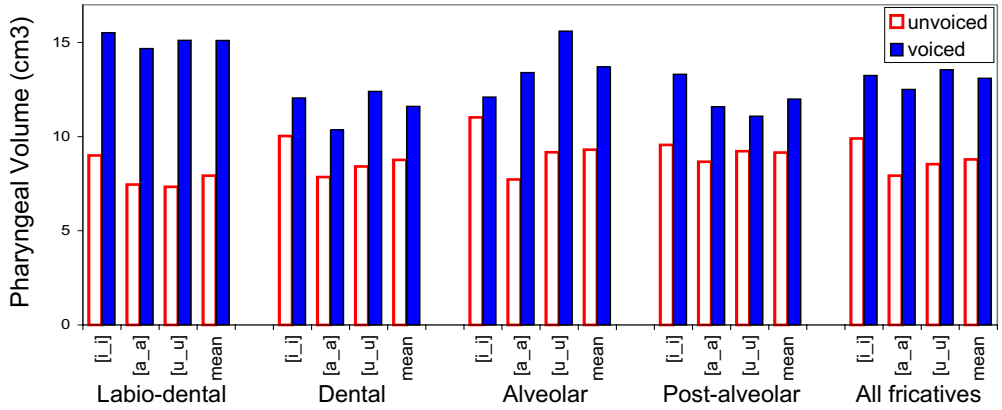

FIG. 7. (Color online) Fricative pharyngeal volumes by place of articulation and vocalic context—subject W2. See Fig. 5 for legend.

pharyngeal volumes than their voiceless equivalents, in all vocalic contexts at all places of articulation (Figs. 6–8). Subject M1 is anomalous in that his voiceless dental and labiodental fricatives, as well as the tokens [isi] and [uʃu], are all produced with a greater pharyngeal volume than that used in the production of their voiced fricative pairs (Fig. 5).

The data in Table II also reveal that the mean volume of the pharynx of the largest male subject (M1) was more than 3.5 times greater than the mean volume of the smallest female subject (W2). To provide a better means of comparison across the population of subjects, the data were normalized with respect to each subject.

Each pharyngeal volume was divided by the largest volume calculated for the same subject, resulting in four sets of relative volumes lying within the range [0–1]. The normalized pharyngeal volumes obtained in this manner were averaged over all subjects and grouped according to vowel context. The mean normalized volume data are illustrated in Fig. 9.

The data in Fig. 9 reveal that the fricative pair for which the voiced-voiceless pharyngeal volume differences are the most robust over all vowel contexts is [f-v]. For labiodental fricative tokens, the minimum differential pharyngeal volume is 49% (for vowel context [i_i]), the maximum differential volume 63% (vowel context [u_u]), and the mean difference across all contexts and speakers is 57%. The sibilants [s-z] also show a mean differential volume difference of 57%, but for this pair of fricatives the difference is less consistent, varying from 23% in the high front context [i_i] to 101% for context [u_u]. Although some of this variation is clearly attributable to the anomalous volume differences found in M1, subjects M2 and W2 also show large differences in the amount of pharyngeal volume change with sibilant voicing in different vowel contexts (compare M2 [isi-izi], [asa-aza], and [usu-uzu]).

C. Articulatory characterization of supraglottal changes during voicing

In order to examine the geometry of the pharynx during the production of voiced and voiceless fricatives in more detail, tissue outlines were extracted from selected MR imaging planes and superimposed to compare vocal tract configurations. Midsagittal images were superimposed to compare tract length, laryngeal position, and overall tract shape, and axial slices were used to examine cross-sectional differences in the epiglottal and pharyngeal regions.

1. Method

For each pair of voiced-voiceless fricative tokens, the two axial image stacks were aligned such that the configuration of the pharynx in each corresponding image slice could be compared across tracts. For each MR image stack, a Sobel edge-detection algorithm (Duda and Hart, 1973) was applied to automatically detect air-tissue boundaries. Contrast and edge-detection thresholds were selected to produce the best tissue outlines for the images of interest.

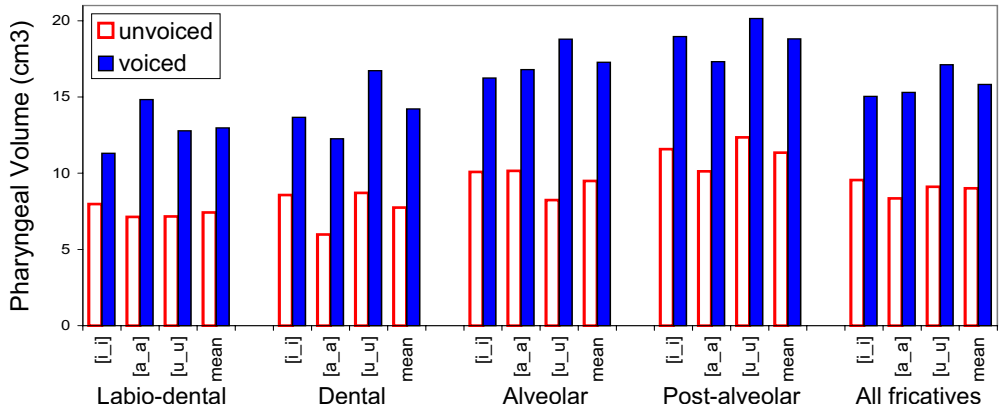

FIG. 8. (Color online) Fricative pharyngeal volumes by place of articulation and vocalic context—subject W3. See Fig. 5 for legend.

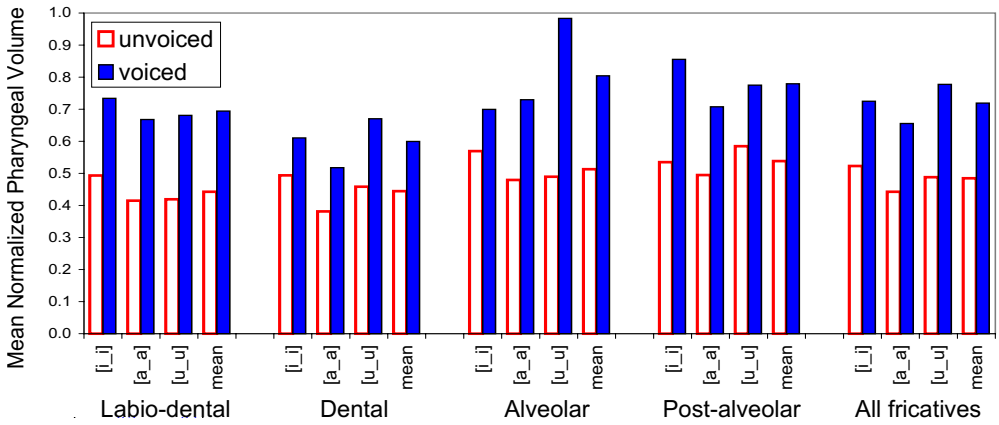

FIG. 9. (Color online) Mean normalized pharyngeal volumes by place of articulation and vowel context, averaged over all subjects. Solid bars indicate voiced volumes; outlined bars indicate voiceless volumes. Contexts [i_i], [a_a], and [u_u] and mean shown for each pair.

Tract boundaries corresponding to voiced and unvoiced tokens were superimposed. Alignment between image stacks was verified by comparing anatomical landmarks—primarily the outline of the subjects' head. In most cases, because the voiced-voiceless fricative pairs were acquired during the same imaging session, the subject's heads remained in perfect alignment, so that the superimposed tracts could be compared directly without any need for translation of the images with respect to each other. An example of a superimposed pair of image stacks generated in this way is shown in Fig. 10.

2. Characterizing pharyngeal differences

Area functions of fricative pairs were calculated from the axial image stacks in order to compare the contributions of different regions of the tract to the voiced-voiceless pharyngeal volume differences. For each slice in the image stack, the areas enclosed by the two tract boundaries were computed. A pair of area functions was constructed in this manner for each superimposed pharyngeal stack. Comparative area functions calculated from tract models of subject W3's productions of [uʃu] and [uʒu] are plotted in Fig. 11. Area functions comparing subject M2's tokens [usu] and [uzu] are shown in Fig. 12.

The area functions in Figs. 11 and 12 reveal that the bulk of the additional volume observed in the voiced pharynges is contributed by expansion of the upper pharynx. The same pattern is observed for all other tokens produced by subjects M2 and W3, and for all tokens produced by subject W2.

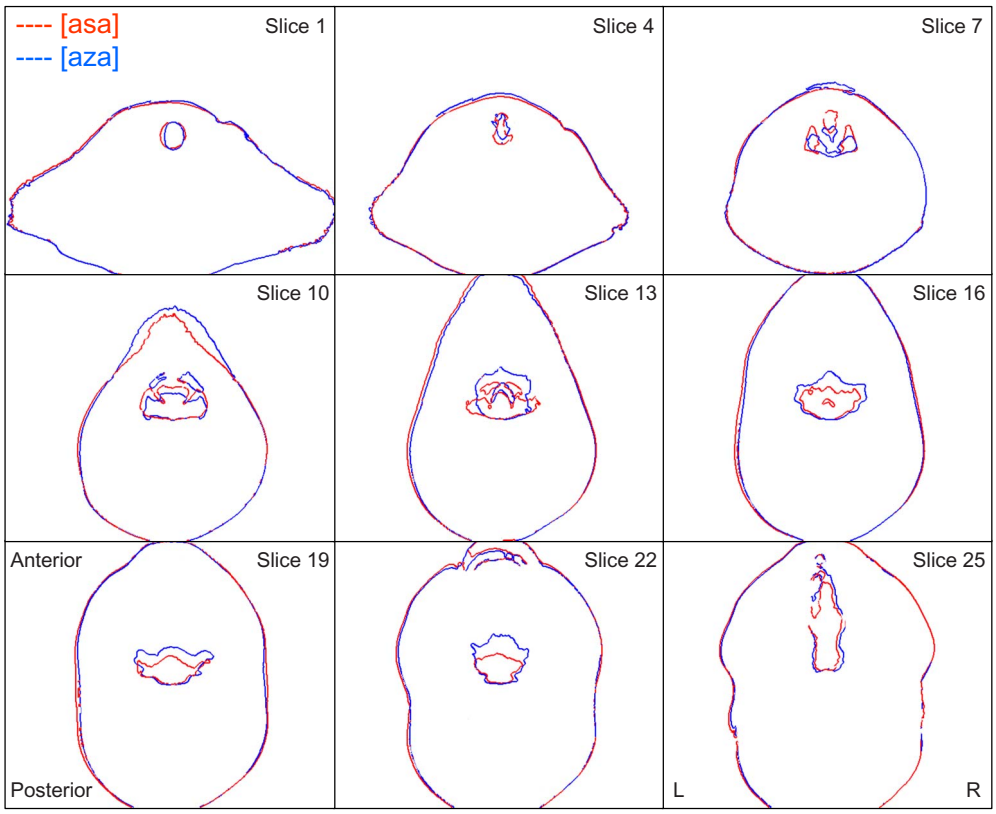

FIG. 10. (Color online) Superimposition of axial slices to compare pharyngeal articulation—subject M1, tokens [asa] vs [aza]. Higher slice numbers correspond to higher positions in tract. Slice 1 (top left): trachea; slice 7: supraglottal slice showing piriform sinuses; slice 13: midpharynx and epiglottis; slice 25 (bottom right): oral cavity beneath hard palate.

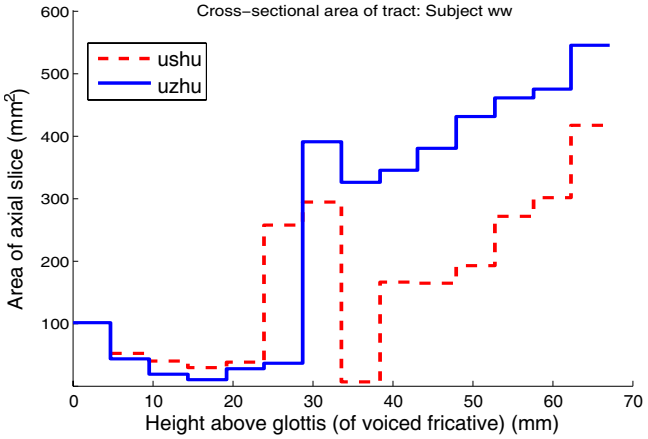

FIG. 11. (Color online) Comparative pharyngeal area function—subject W3, tokens [uʃu] (broken line) vs [uʒu] (solid line).

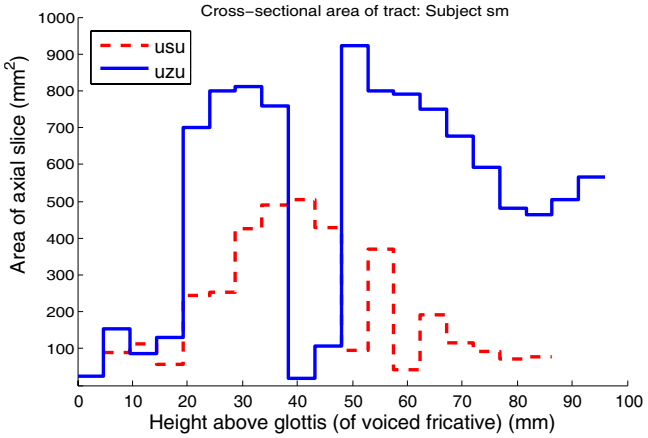

FIG. 12. (Color online) Comparative pharyngeal area function—subject M2, tokens [usu] (broken line) vs [uzu] (solid line).

The comparative area functions of fricatives produced by M1 also show the same pattern, except in those cases where the voiceless pharyngeal volumes are larger; in these cases—tokens [ifi], [ufu], [isi], and [uʃu]—the bulk of the additional volume in the voiceless pharynges is also contributed by expansion of the upper pharynx.

3. Pharyngeal variation throughout the pharynx

To gain further insights into the effect of vocalic context and place of articulation on fricative production, differential area functions were generated to observe the way in which the volume varies between voiced and voiceless productions in different parts of the tract. The data, organized by speaker and place of articulation, are illustrated in Fig. 13. Area functions are aligned by slice number within each subject such that slice 1 corresponds to the lowest position of the glottis for any token by that subject.

The differential area functions in Fig. 13 offer a number of insights into the difference between voiced and voiceless fricative pharyngeal articulation. Negative values indicate regions of the pharynx where the cross-sectional area of the voiced tract is greater than that used in the production of the corresponding voiceless fricative. The general pattern observed in all of these graphs is a function that starts at zero, becomes positive for 1–2 slices, and then trends negative for the remainder of the slices, corresponding to the upper half of the pharynx. Variations of this same general trend are observed for all subjects, including M1, whose upper laryngeal volume differences are anomalous compared to the other subjects. The fact that the differential area function alternates between positive and negative in this way indicates that the minimum pharyngeal areas occur at different heights for the same fricative place, vowel context, and subject.

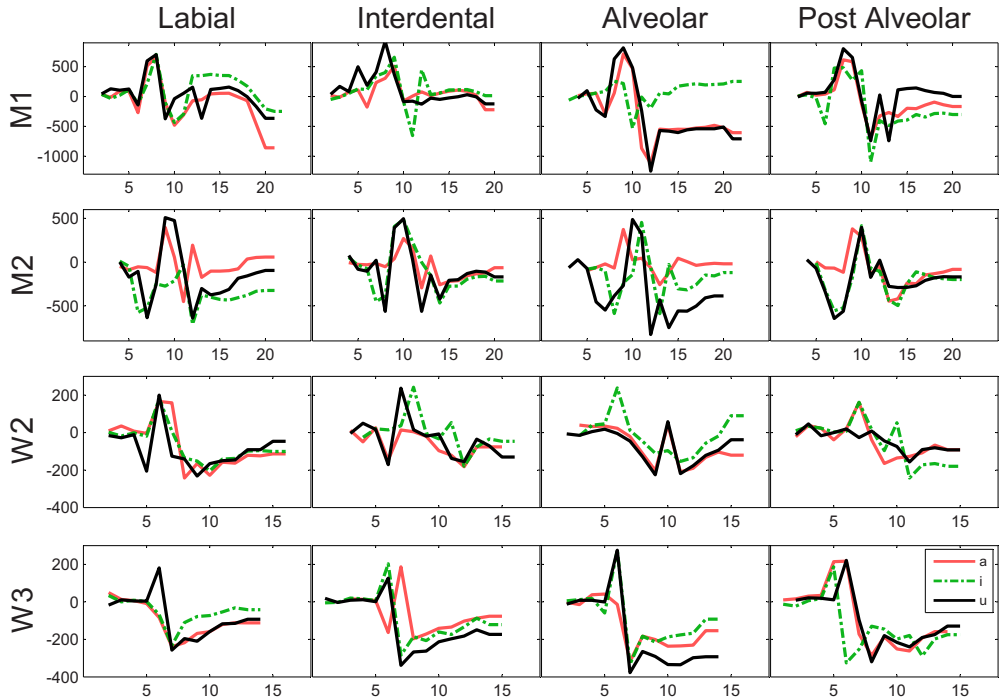

FIG. 13. (Color online) Differential area function ($A_{unvoiced}-A_{voiced}$, mm^2) by subject (row), place of articulation (column), and vocalic context: [i_i] (broken line), [a_a] (light solid line), and [u_u] (dark solid line). *x*-axis: image slice numbers. Higher slice numbers correspond to higher positions in pharynx.

The near-zero values at the beginning of the function correspond to the small volumes observed around the glottis in both voiced and voiceless fricatives. The functions trend rapidly positive and then negative because of differences in the vertical alignment of different parts of the larynx, piriform, and false vocal folds between the voiced and voiceless fricatives being compared, and because of differences in the volumes of these regions of the tract.

4. Laryngeal height

One of the important insights revealed by the area functions derived in Sec. III C 2 is that the glottal slices in the voiced fricative productions are often displaced with respect to the equivalent voiceless fricative productions. In both Figs. 11 and 12, for example, the area function of the voiced tract (solid line) begins one slice before the voiceless tract area function (broken line), indicating that the glottis is lower in the tract during the production of the voiced fricative.

In all 48 fricative pairs (4 subjects $\times$ 4 places of articulation $\times$ 3 vowel contexts), the height of the glottis during the production of the voiced fricative was either level with or up to three slices (14.4 ± 2.4 mm) lower in the tract than the voiceless fricative glottal height. Subject W3 showed the least glottal displacement with voicing, averaging 2.4 mm, and subject M2 the most (9.2 mm). The mean vertical glottal displacement across all 48 fricative pairs was 1.0625 slices or 5.1 ± 2.4 mm. That is, the glottis was on average half a centimeter lower in the voiced tracts than it was during the production of the voiceless fricative equivalents. This suggests that either the larynx is lowered during voicing or raised during the production of voiceless fricatives.

D. Mechanisms of expansion

Another question addressed in this study is whether the increased pharyngeal volume observed in the voiced fricative productions results from a uniform expansion of the upper pharynx or whether the additional volume is attributable to a particular active mechanism of articulation.

A comparison of midsagittal images of voiced-voiceless fricative pairs revealed no major differences in the height or configuration of the uvula, eliminating vertical displacement of the upper oropharynx as a mechanism of expansion for voiced production. For example, the tip of the uvula was located 59 mm below the top of the sphenoidal sinus during subject W3's production of [uvːu] and 58 mm below the sinus during her production of [ufːu]—a fricative pair which differs in volume by 43%, yet shows no evidence of vertical displacement of the uvula. Likewise, for subject M1, the uvular tip was measured to be 71 mm below the sphenoidal sinus during his production of [isːi] and 72 mm below the sinus during his production of [izːi].

In order to gain more insights into the nature of pharyngeal expansion, the voiced and voiceless tracts were compared by measuring the relative displacement of the front, rear, and side pharyngeal walls at different heights.

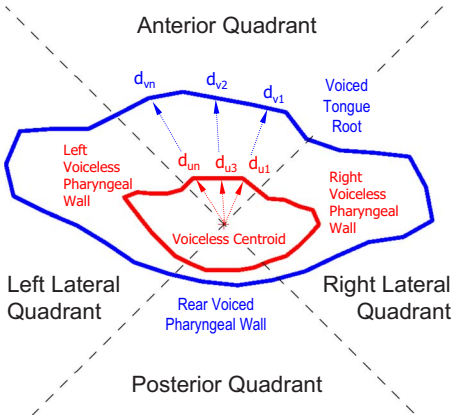

FIG. 14. (Color online) Superimposed voiced (outer) and voiceless (inner) pharyngeal boundaries, showing four quadrants and method of calculation of pharyngeal wall displacements in each quadrant—subject M2 [isi-izi] (slice 17).

In each slice of the pharyngeal stack, the centroid of the voiceless fricative tract was calculated. The image plane was divided into four quadrants by constructing two perpendicular axes intersecting at the centroid and oriented at 45° with respect to the anterior-posterior axis. The tract boundaries of the corresponding voiced fricative were superimposed on each slice, so that the relative articulations of the voiced-voiceless fricative pair could be compared. Because all fricative pairs were acquired during the same scanning session, no image registration was required to perform the superimposition, since each set of boundaries was represented within the same coordinate space.

1. Quantifying gross pharyngeal expansion

For both tract boundaries on each slice, the distance of each point to the voiceless centroid was calculated. By averaging both sets of distances in each quadrant, a mean displacement from the centroid was calculated for both voiced and voiceless tract boundaries. The relative displacement of the voiced tract with respect to the voiceless tract was then calculated as the difference between the mean boundary displacements (Fig. 14).

The method of calculation of the anterior pharyngeal differential distance A, for example, is given by

$$A = \frac{1}{n}\sum_{1}^{n} d_{Vi} - \frac{1}{m}\sum_{1}^{m} d_{Ui}, \tag{1}$$

where n, m = number of points on anterior quadrant of voiced and voiceless boundaries, respectively, and d is defined in Fig. 14. The posterior P, left lateral LL, and right lateral RL differential distances are calculated in the same way in their respective quadrants. The distance metrics calculated in this manner provide an indication of the amount of expansion of the voiced tract with respect to the voiceless tract at different heights in the pharynx.

In the lower pharynx, this pharyngeal expansion metric did not prove to be a reliable means of quantifying changes in articulation between voiced and voiceless fricatives because the morphology of this part of tract is not sufficiently simple. In the lower-midpharyngeal region, for example, the

TABLE III. Mean total differential pharyngeal wall displacement (dVoiced−dVoiceless) (mm), and ratios of anterior wall to total displacement and posterior wall to total displacement by subject—all fricatives and all vowel contexts.

Subject	Total V-U displacement (mm)	Anterior/total	Posterior/total
M1	3.19	0.15	0.15
M2	13.75	0.29	0.11
W2	8.47	0.51	−0.09
W3	11.65	0.29	0.08
Mean	9.27	0.31	0.06

epiglottis introduces a bifurcation, and in the laryngeal region, the tract trifurcates at the piriform sinuses. Another factor which prevents the use of the metric throughout the entire pharynx is the vertical displacement of the laryngeal region due to voicing (Sec. III C 4). This causes dissimilar parts of the pharynx to appear on the same image slice, which cannot be sensibly compared.

For these reasons, a subsection of each pharynx was chosen in which the voiced and voiceless tract morphologies were sufficiently alike to allow for comparison using this method—a section extending from the top slice in the pharynx down to the top of the epiglottis. The mean number of slices in the upper pharyngeal section was 4.85, representing a 23.3 mm section, covering approximately the top third of each pharynx.

In each slice of the upper pharynx, the total displacement of the voiced tract with respect to the voiceless tract was calculated as the sum of displacements in all four quadrants. The total pharyngeal displacement T was defined to be the sum of anterior, left lateral, right lateral, and posterior displacements [Eq. (2)].

$$T = A + LL + RL + P. \tag{2}$$

The gross differential pharyngeal wall displacement calculated using this metric varied considerably across fricative tokens, from a minimum of −9.30 mm (subject M1, tokens [ifi-ivi], reflecting the larger size of the voiceless tract) to a maximum of 31.05 (subject M2, tokens [usu-uzu]). The mean total differential upper pharyngeal wall displacement across all 48 fricative pairs was 9.27 mm (Table III).

2. Directional characterization of pharyngeal expansion

To better characterize the nature of pharyngeal expansion, the percentage contribution of pharyngeal wall displacement in each direction was estimated by calculating the ratio of directional displacement to total displacement T in each quadrant. The left (LL/T) and right (RL/T) displacement ratios were added to provide an indication of total lateral displacement (L/T), which could then be compared to the anterior (A/T) and posterior (P/T) displacement ratios. In each slice, by definition, the sum of anterior, posterior, and lateral displacement ratios is 1.

One pattern of upper pharyngeal expansion which was observed among these fricative pairs is shown in Fig. 15. The

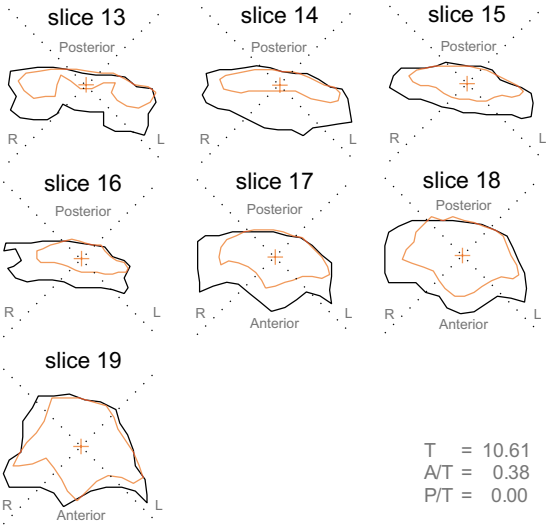

FIG. 15. (Color online) Upper pharyngeal expansion primarily through tongue root and lateral displacement—subject W2, upper eight slices of [ifi] (inner boundary) vs [ivi] (outer boundary). Slice 13: midpharynx, above epiglottis; slice 19: top of oropharynx, below uvula.

seven superimposed tract slices contrast subject W2's production of [ifi] (inner tract boundary) and [ivi] (outer boundary). The rear pharyngeal walls of both fricative productions are revealed to be in close alignment (P/T=0.00), and nearly all of the expansion of the voiced tract results from displacement in the lateral (L/T=0.59) and anterior (A/T=0.38) quadrants, suggesting that the sole mechanism of pharyngeal expansion employed in the production of the voiced fricative, in this case, involves forward displacement of the tongue root.

In a few cases, the expansion of the voiced pharynx was observed to occur more equally in all directions, as in the case of the fricative pair compared in Fig. 16. In this example (W2 [afa-ava]), 14% of displacement occurs in the posterior quadrant, 25% in the anterior quadrant, and the remainder is lateral (L/T=0.64). These data suggest that some volume differences might result from active constriction of the voiceless tract with a sphincterlike mechanism.

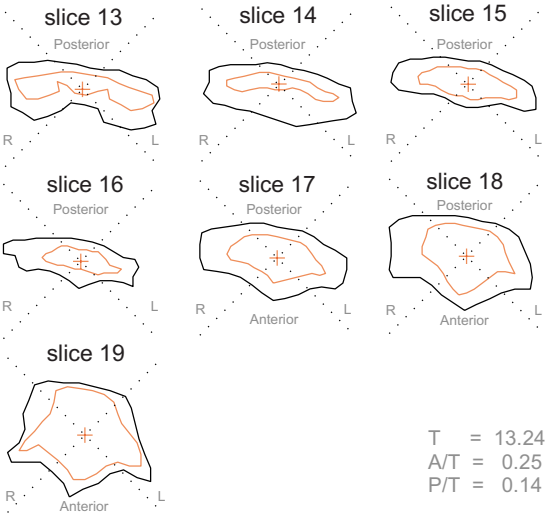

FIG. 16. (Color online) Concentric voiced/voiceless upper pharynges—subject W2, [afa] (inner boundary) vs [ava] (outer boundary). Slice 13: midpharynx, above epiglottis; slice 19: top of oropharynx, below uvula.

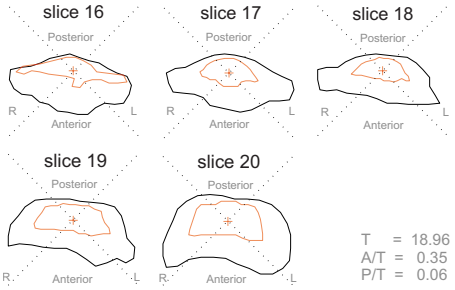

FIG. 17. (Color online) Typical displacement pattern observed in upper pharynx—subject M2, [isi] (inner boundary) vs [izi] (outer boundary). Slice 16: midpharynx, above epiglottis; slice 20: top of oropharynx, below uvula.

The alternative explanation—that the expansion of the voiced tract is passive—does not seem plausible because that would require increased intraoral air pressure in the voiced cases.

The prototypical pattern of pharyngeal expansion observed in this study involves neither a static rear pharyngeal wall (as in Fig. 15) nor a concentric arrangement of the voiced and voiceless tracts (as in Fig. 16), but rather the configuration illustrated in the fricative pair in Fig. 17. Some expansion of the voiced tract may be observed in all directions; however, the majority of the displacement is in the anterior and lateral quadrants, again suggesting that the primary mechanism of voiced pharyngeal expansion seems to involve forward displacement of the tongue root.

The extent to which forward movement of the tongue root dominates the expansion of the rear pharyngeal wall can be quantified by averaging the ratios of anterior and posterior pharyngeal wall to total displacement (Table III). For subject M1, no difference in anterior and posterior displacements was observed, a statistic which reflects the anomalous behavior of this subject in producing some voiceless fricatives with a larger pharynx than their voiced equivalents. However, for the remaining three subjects, the contribution of tongue root displacement to pharyngeal expansion (A/T) outweighs the effect of rear pharyngeal wall expansion (P/T) by a factor of at least 2. Overall, forward displacement accounts for 31% of total voiced expansion in the upper oropharynx.

IV. DISCUSSION

One issue to be considered when assessing the findings of this study is the artificiality of the task. MRI requires subjects to sustain fricatives for an unnaturally long time and to utter them while lying supine in a scanner.

Adopting a supine posture has been demonstrated to have a minor influence on articulation. Engwall (2003) observed slight pharyngeal narrowing in the supine production of Swedish vowels, compared to when prone, most noticeably for the front vowel [i]. In an X-ray microbeam study of two Japanese subjects, Tiede *et al.* (2000) concluded that the supine posture caused nonessential articulators to fall with gravity, while essential articulators are held in position even if against gravity.

Assuming these factors also applied to the subjects in this study, they should not affect the fundamental findings concerning difference between voiced and voiceless articulations, as all fricative tokens were produced under the same conditions. Furthermore Subtelny *et al.* (1972) observed the same direction of change between /s-z/ in a real-time study of subjects using upright posture, and Narayanan *et al.* (1995) observed a similar effect in the tongue root for subjects who were also in a supine position.

The sustained nature of the frication task asked of the subjects should be considered. In a study of Swedish vowels and fricatives, Engwall (2000, 2003) found the effect of sustaining long tokens to be equivalent in some respects to hyperarticulation. Tongue position was found to be more neutral for static holds (as opposed to dynamic), suggesting that the effects of coarticulation should be reduced in long holds.

The data presented in this study provide good evidence that coarticulatory effects persist in the subjects' productions of long-hold fricatives, since there is considerable variation in pharyngeal articulation due to vocalic context (as discussed in more detail in Shadle *et al.*, 2008). Although subjects may have used different strategies to manage airflow throughout the long holds, once more this should have affected both voiced and voiceless productions equally, so the insights into voicing differences remain valid. Factors associated with these different production strategies may explain some of the anomalies observed in the fricatives produced by subject M1, who was remarkable for having the largest lung capacity and perhaps needed to manage his airstream less than the other three subjects.

Given that the finding of a larger pharyngeal volume in voiced fricatives seems to be consistent with other studies, and is unlikely to be an artifact of the unnatural aspects of an MRI study, does Westbury's (1983) explanation for stops work for fricatives? First, Westbury (1983) showed that the vocal tract continued to expand during the closed phase of voiced stops. This does not hold for the voiced fricatives in the current study, as continual expansion would have resulted in blurred MR images. This does not in itself argue against Westbury's (1983) explanation, however; with the incomplete closure afforded by the fricative constriction, continued airflow through the glottis will not result in oral pressure increasing to the point where phonation would cease.

Is it possible, then, that the subjects find an equilibrium at the start of the long-sustained fricative where the air exiting through the constriction just balances the air entering through the phonating glottis, and the pharynx is expanded just enough to keep the pressure drop across the glottis in a range where phonation can continue? This explanation does not work either. The intraoral pressure must be less for voiced than for voiceless fricatives, unless subglottal pressure is sufficient to compensate for the pressure drop across the glottis in the voiced case. While this might be possible for sustained production in a MR scanner, that would be extremely unlikely to occur in normal speech, and thus would not explain Subtelny *et al.*'s (1972) results. With intraoral pressure lower in the voiced case, passive expansion due to air pressure would predict bigger pharyngeal volume in the voiceless case.

If not the result of passive expansion, then perhaps the expanded pharynx is the result of active expansion, held in one position throughout the long-sustained fricative. But it is

hard to come up with a convincing explanation for why this would make it easier, or more possible, to keep both voicing and frication sources going throughout. Instead, it seems possible that in the voiceless fricatives the tongue is actively pulled back in the upper pharynx to create a pressure-regulation mechanism. This could help reduce the airflow through the abducted glottis and would also help explain the anomalous results of subject M1: because of his greater lung capacity and large tract, subject M1 may not need to resort to this type of pressure regulation during long-hold frication as much as the other subjects.

V. CONCLUSIONS

In this study, the pharyngeal articulation of American English fricatives has been examined for four subjects using volumetric MRI data, and differences between voiced and voiceless fricatives have been characterized in three main respects.

The most important finding is that voiced fricatives are generally produced with a larger pharynx than that used during production of voiceless fricatives at the same place of articulation. These volume differences are consistent across all places of articulation and vocalic contexts for three of the four subjects studied. The subject with the largest pharynx differed from the other four by producing labiodental and interdental voiceless fricatives with a larger pharyngeal volume.

The bulk of the additional volume observed in the voiced fricatives was found to result from the expansion of the upper pharyngeal region above the epiglottis, below the uvula. The chief mechanism of expansion of the upper oropharynx was found to be displacement of the tongue dorsum—which was estimated to contribute approximately 31% of the additional volume—and the lateral pharyngeal walls, rather than through displacement of rear pharyngeal walls (6% of additional volume). Although the displacement of the rear wall was found to be smaller than that of the anterior portion of the pharynx, these findings also suggest that the posterior pharyngeal wall cannot simply be regarded as an immovable part of the vocal tract, as has been suggested.

Finally, the larynx was found to be consistently lower during production of voiced fricatives than during production of voiceless fricatives.

Many of the differences between voiced and voiceless fricatives observed in this study were only discovered by examining the geometry of the pharynx in all three dimensions. This demonstrates that midsagittal analysis of the vocal tract alone is insufficient to properly characterize fricative production and voicing.

This study has addressed the broad pharyngeal differences which can be observed in the production of voiced and voiceless fricatives; however, there are many more aspects of fricative production and voicing which remain to be investigated. More phonetic data are required to reconcile the differences in volume observed here with more detailed aspects of mechanisms of voicing and frication, and to account for some of the inconsistencies observed between subjects, and at different places of articulation.

The unsteady drag on the vocal folds is the major source of sound during voiced speech. The drag force is caused by vortex shedding from the vocal folds. The influence of the ventricular folds (i.e., the "false" vocal folds that protrude into the vocal tract a short distance downstream of the glottis) on the drag and the voice source are examined in this paper by means of a theoretical model involving vortex sheets in a two-dimensional geometry. The effect of the ventricular folds on the output acoustic pressure is found to be small when the movement of the vocal folds is prescribed. It is argued that the effect remains small when fluid-structure interactions account for vocal fold movement. These conclusions can be justified mathematically when the characteristic time scale for change in the velocity of the glottal jet is large compared to the time it takes for a vortex disturbance to be convected through the vocal fold and ventricular fold region.

I. INTRODUCTION

The larynx is a complex structure of muscle, cartilage, and epithelium where voiced sounds can be created. The vocal folds consist of a pair of layered structures that partially obstruct the flow produced when the lung pressure is somewhat greater than the pharyngeal pressure. Muscles adjust the positions of the folds to permit flow-structure interaction that drives the vocal folds into oscillation. These oscillations periodically change both the size of the region of air between the folds, known as the glottis, and the resistance to flow through the glottis (van den Berg *et al.*, 1957; Fant, 1960). The resistance to flow is equal and opposite to the drag experienced by the vocal folds, and the resulting fluctuations in the volume velocity of air into the vocal tract generate sound that is heard to emanate from the mouth (Titze, 1994; Stevens, 1998). The sound coming from the laryngeal region can be viewed as having been generated from a fluctuating drag, or pressure expansion waves, superposed on an otherwise uniform pressure wave traveling from the lungs (Zhao *et al.*, 2002; Howe and McGowan, 2007).

Howe and McGowan (2007) presented a theory of the voice source derived using an aeroacoustic analogy and the method of compact Green's functions (Howe, 1975, 1998, 2003). They showed that the major source of sound, the fluctuating drag on the vocal folds, can be calculated with knowledge of the distribution of fluid velocity in regions where vorticity is nonzero, which can be idealized to be a very thin shear layer at the boundary between the glottal jet and the surrounding air in the vocal tract. The calculation of the magnitude of the drag or, equivalently, the source's effect on the output acoustics is localized to be within the shear layer just downstream of the glottal exit because of the shape of the vocal folds. The convolutory solution with a compact Green's function makes explicit the required alignment between the fluid velocity field near the vocal folds and the shape of the vocal folds in order that there be nonzero drag. The effect of the shape of the vocal folds on tissue-air forces is expressed in a factor of the Green's function known as the *Kirchhoff vector*. Because drag is the force of interest, it is the axial component of the Kirchhoff vector that is relevant. Roughly, the axial component of the Kirchhoff vector for the vocal folds is the velocity potential field with unit inflow and outflow in the direction of the vocal tract axis—it depends only on the shape of the tissue boundaries. This potential flow has a stream function, which is here termed the *axial Kirchhoff stream function*. Figure 1(a) shows model vocal folds and Fig. 1(b) shows the axial Kirchhoff streamlines, on which the axial Kirchhoff stream function is constant, below the vocal tract axis of symmetry. At the glottal exit region the gradient of axial Kirchhoff stream function has a large component parallel to the glottal jet velocity; this is a necessary condition for the generation of drag between the tissue and air (e.g., Howe, 1998, 2003).

Howe and McGowan (2007) based their analysis on a relatively simple geometry in order to derive drag on the vocal folds: vocal folds in a uniform duct. The present paper extends that account to tissue structure just downstream of the vocal folds, known as the ventricular folds, or false vocal folds. Like the vocal folds, they protrude into the vocal tract at a distance generally less than 1 cm from the downstream end of the vocal folds (Agarwal *et al.*, 2003). The streamlines of the axial component Kirchhoff vector will certainly

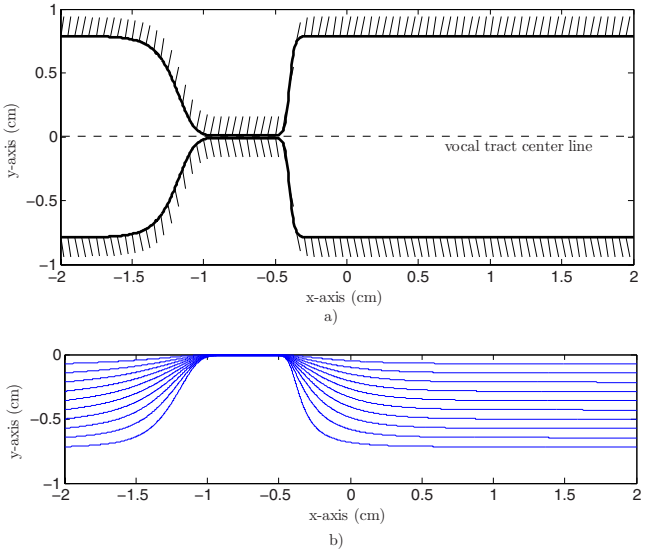

FIG. 1. (Color online) (a) Model vocal folds in the midsagittal plane and (b) axial Kirchhoff stream function streamlines below the axis of symmetry.

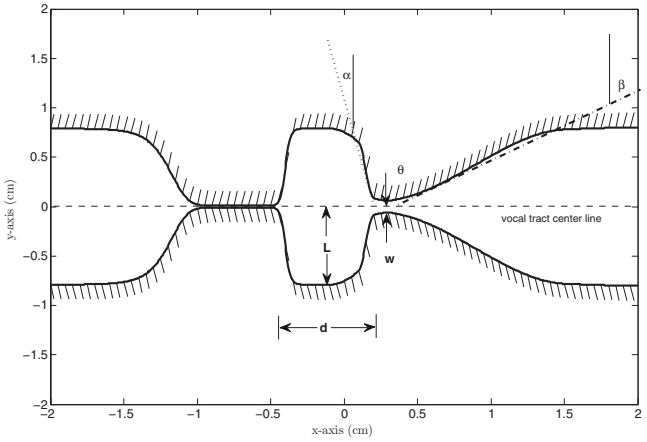

FIG. 2. Model vocal folds and ventricular folds in the midsagittal plane.

be altered near the ventricular folds compared to when they are assumed to be absent. Further, the ventricular folds are proximate enough to the vocal folds that the streamline patterns near the glottal exit can be expected to be altered as well. Either can produce change in the overall force between the tissues and the air near the vocal folds and, thus, affect the radiated acoustic field.

Zhang *et al.* (2002) provided a calculation of the effect of the ventricular folds on the voice source based on computational fluid dynamics (CFD). They found little effect of the ventricular folds on the voice source below 2000 Hz. Routine use of CFD can be very expensive and time-consuming, and, thus, it is difficult to confirm predictions for many possible fundamental frequencies and ventricular fold shapes. The approach of this paper is to generalize the analytic results of Howe and McGowan (2007) to include obstructions close to the vocal folds, which also requires some computational work, but at a much lower effort than full scale CFD.

The movement of the vocal folds will be specified by a simple mathematical model, and the ventricular folds are assumed to be rigid. This kind of analysis is employed when the effects of changes in fluid mechanics are considered without the complications of changes in vibrational patterns caused by fluid-structure interaction (e.g., Zhang *et al.*, 2002). These interactions are a part of the aerodynamic-myoelastic theory of vocal fold vibration. Therefore the results of our study are limited to the determination of the effect of the ventricular folds on the air flow itself, without quantitative consideration on how the ventricular folds influence the vibration of the vocal folds. Section II reviews some of the basic theory from Howe and McGowan (2007) and concludes with an equation for calculation of the drag if structures close to the vocal folds are included. Section III introduces the approximations used in the numerical calculation of the output pressure variation with and without ventricular folds. Section IV presents the results of these calculations, showing that the ventricular folds are expected to have a small effect on the propagated pressure wave from the glottis at frequencies below 2 kHz. In Sec. V it is shown that this is the expected result given the behavior of the axial component of the Kirchhoff vector and the quasi-steady nature of the low-frequency portions of the glottal velocity pulse.

II. THEORETICAL BACKGROUND

The geometries of concern are illustrated in Figs. 1(a) and 2. In Fig. 1(a) the vocal folds form a constriction, the glottis, and in Fig. 2 vocal folds are shown forming a constriction to the left (upstream), and the ventricular folds form a secondary constriction to the right (downstream) in a rigid duct of uniform width $2h$. The figures show a two-dimensional geometry in the x-y plane, with the z direction orthogonal to this plane. The x-axis is the duct centerline and it denotes the axial direction. The coordinate system origin is taken to be about 0.4 cm downstream from the glottis in its rest state. The distance between the downstream end of the vocal folds and ventricular fold constriction is of the order of 1 cm, and, together, these structures occupy less than 4 cm of the vocal tract axis. The source region including both structures can therefore be considered to be acoustically compact for frequencies below about 5 kHz. Only plane wave propagation is assumed to occur in the duct.

Peak air speeds in the glottis during phonation at a conversational level should be less than 4000 cm/s. Assuming that the amount of heat created by viscous action in the vocal tract is small and body temperature does not vary substantially, the flow can be considered to be homentropic. Howe's (1998) formulation of Lighthill's (1952) equation for the production and propagation of sound at low Mach number flow that may be considered homentropic is

$$\left(\frac{1}{c_o^2}\frac{\partial^2}{\partial t^2} - \nabla^2\right)B = \mathrm{div}(\boldsymbol{\omega} \wedge \mathbf{v}), \tag{1}$$

where c_o is the mean speed of sound, which is approximately uniform and constant in low speed flows, and B is the *total enthalpy* defined in homentropic flow by

$$B = \int \frac{dp}{\rho} + \frac{1}{2}v^2, \tag{2}$$

where $v=|\mathbf{v}|$, $\mathbf{v}$ is the fluid velocity, $\boldsymbol{\omega}=\mathrm{curl}\mathbf{v}$, the vorticity, and $\rho\equiv\rho(p)$ is the density.

Let the incident over-pressure from the lungs consist of a step rise in pressure of amplitude p_I impinging on the glottis at $t=0$. Then the corresponding incident total enthalpy wave B_I can be written as

$$B_I = B_I\left(t-\frac{x}{c_o}\right)=\frac{p_I}{\rho_o}H\left(t-\frac{x}{c_o}\right), \tag{3}$$

where H is the Heaviside step function. Put $B=B_I+B_s$, where B_s is the field scattered at the vocal folds, and the ventricular folds if they are present, which has outgoing wave behavior at large distances from the glottis.

Howe and McGowan (2007) derived the following integral representation of the solution to Eqs. (1) and (3):

$$\begin{aligned} B(\mathbf{x},t) = \frac{p_I}{\rho_o}\Bigg\{ & H\left(t-\frac{x}{c_o}\right) \\ & -\frac{\mathrm{sgn}(x)}{\ell([t])}\int_{-\infty}^{[t]}\frac{\partial}{\partial\tau}(H(\tau)\ell(\tau))e^{-\int_\tau^{[t]}2c_o d\xi/\ell(\xi)}d\tau\Bigg\} \\ & -\int[(\boldsymbol{\omega}\wedge\mathbf{v})(\mathbf{y},\tau)]\cdot[\nabla_{\mathbf{y}}G(\mathbf{x},\mathbf{y},t,\tau)]d^3\mathbf{y}d\tau \\ & +\oint_{S(\mathbf{y},\tau)}G(\mathbf{x},\mathbf{y},t,\tau)\left[\frac{\partial\mathbf{v}}{\partial\tau}(\mathbf{y},\tau)\right]\cdot d\mathbf{S}(\mathbf{y})d\tau, \end{aligned} \tag{4}$$

where G is the acoustic Green's function associated with the geometry of either Fig. 1(a) or Fig. 2, $[t]=t-|x|/c_o$ is the acoustic delay time, and viscous terms have been neglected, which is valid for high Reynolds number flows, and thus, for all times except possibly when the vocal folds are nearly closed. $\ell(t)$ is the time-dependent Rayleigh "end correction" of the glottal constriction and ventricular fold constriction, if it exists (Rayleigh, 1945). [Note that unprimed coordinates will be associated with the field coordinate vector $\mathbf{x}$ and primed coordinates with the source coordinate vector $\mathbf{y}$. Thus, $\mathbf{x}=(x,y,z)$ and $\mathbf{y}=(x',y',z')$.]

Let Y be the axial Kirchhoff vector at time t for either the geometry without ventricular folds [Fig. 1(a)] or with ventricular folds (Fig. 2). It is a solution of Laplace's equation satisfying $\partial Y/\partial x_n'=0$ on the surfaces $S(t)$ of the folds and the duct walls, and can be normalized such that

$$Y\sim x'\pm\frac{\ell(t)}{2},\quad x'\to\pm\infty. \tag{5}$$

The end correction is given by

$$\ell(t)=\int_{-\infty}^{\infty}\left(\frac{\partial Y}{\partial x'}(\mathbf{y},t)-1\right)dx', \tag{6}$$

provided the duct cross-sections are the same on both sides of the region containing the vocal folds and ventricular folds, if they exist. The integration is along any path parallel to the duct axis passing through the constriction(s).

The method of compact Green's function was used to derive an approximation to the Green's function appearing in Eq. (4) (Howe and McGowan, 2007). The compact approximation to the Green's function for source positions in the vicinity of the constrictions, $\mathbf{y}\sim h$, is

$$\begin{aligned} G(\mathbf{x},\mathbf{y},t,\tau)\approx & \frac{c_o}{2\mathcal{A}}H([t]-\tau)+\frac{c_o\,\mathrm{sgn}(x)Y(\mathbf{y},\tau)}{\ell([t])\mathcal{A}} \\ & \times H([t]-\tau)e^{-\int_\tau^{[t]}2c_o d\xi/\ell(\xi)},\quad \mathbf{y}\sim O(h), \end{aligned} \tag{7}$$

where $\mathcal{A}=2h\ell_3$ is the cross-sectional area of the duct and ℓ_3 is the length in the z-dimension. The differences between Green's function in a geometry without ventricular folds [Fig. 1(a)] and a geometry with ventricular folds (Fig. 2) are governed by the corresponding differences in the axial component of the Kirchhoff vector Y.

The first term of Eq. (4) is the incident pressure wave, the second term is the initial transient response, the third term is the vortex sound source or drag term, and the fourth term represents the sound created by changes in the volume of the vocal folds. In this paper we are concerned with the evaluation of the vortex sound when ventricular folds are placed just downstream of the vocal folds. The fourth term, which is the monopole strength caused by unsteady volume change, will not be considered further because the absence or presence of the ventricular folds has no effect on this term.

After the step wave of pressure given in Eq. (3) reaches the vocal folds, vorticity is shed from the vocal folds and it is convected downstream in jet shear layers. The strength of the vorticity shed from the vocal folds depends on the relative velocity between the jet and the air outside the jet and, to a first approximation, is proportional to the velocity of the jet. Further, neglecting the effects of viscous dissipation, the circulation of each vortex element of the shed vorticity remains constant as it is convected downstream. The typical approximation is that the shear layer vorticity convects at one-half the local jet velocity that is associated with its circulation. Vortex sound is directly related to the fluctuating drag on the structures in the duct (i.e., forces on structures directed along the axis of the duct).

If the far-field (i.e., typically at a distance from the source region exceeding a duct diameter) is considered and the contribution from the fluctuating volume term (the fourth term on the right) in Eq. (4) is excluded, $B(\mathbf{x},t)\approx p'(x,t)/\rho_0$, where the prime denotes the pressure field without the monopole term. For $x>0$ the acoustic particle velocity of this outgoing wave is equal to $p'(x,t)/\rho_o c_o$. Let

$$U(t)=\lim_{x\to+0}\frac{p'(x,t)}{\rho_o c_o} \tag{8}$$

be the limiting value of this velocity just to the right of the vocal fold region in Fig. 1(a) or the vocal fold and ventricular fold region in Fig. 2. Also, $x\sim+0$ so that $[t]\to t$. In this limit, an equation for $U(t)$ can be derived in the form

$$\frac{d(\ell U)}{dt}+2c_o U+B_\omega=\frac{2p_I}{\rho_0}H(t), \tag{9}$$

with

$$B_\omega = \int [(\boldsymbol{\omega} \wedge \mathbf{v})(\mathbf{y},\tau)] \cdot [\nabla_{\mathbf{y}} G(\mathbf{x},\mathbf{y},t,\tau)] d^3\mathbf{y} d\tau, \qquad (10)$$

where B_ω is the vortex sound term from Eq. (4). Equation (9) is a modification of one found in Howe and McGowan, 2007 [Eq. 6.3] with B_ω left unevaluated so that the effect of geometric changes in the laryngeal region, especially the inclusion of ventricular folds, can be studied. In Howe and McGowan, 2007 B_ω was evaluated in terms of jet velocity using the fact that the jet was narrow compared to the width of the duct and without further obstructions downstream. With the addition of ventricular folds, a numerical procedure is necessary to evaluate this integral.

III. METHOD

A. Vocal folds and ventricular folds

The effect of the ventricular folds on the acoustic output was determined by solving Eqs. (9) and (10) numerically. The geometry of the vocal folds was based on a model for the vocal folds given by Zhao *et al.* (2002). The model for the vocal fold movement had two-dimensional symmetry and was adapted from the original cylindrical geometry (Howe and McGowan, 2007). A further modification was made here so that the folds were narrower in the axial direction and the faces of the vocal folds were steeper, to make them accord with known dimensions. Let $\Delta(x,t)$ be the distance between the vocal folds, so that

$$\Delta(x,t) = \tfrac{1}{2}(D_0 + D_{\min} + (D_0 - D_{\min})\tanh(\hat{s})) + D_{\max}[1 - \tanh(\hat{s})]((\hat{x}+\hat{c})\beta_1(T) - (\hat{x}-\hat{c})\beta_2(T)), \qquad (11)$$

where $T = f_o t - [f_o t]$ is the fractional part of $f_o t$, and where

$$\hat{s} = \hat{b}\left(|\hat{x}| - \frac{1}{|\hat{x}|}\right),$$

$$\hat{x} = \frac{x + 0.8}{D_{\max}},$$

$$\hat{b} = \begin{cases} 1.4 & \text{if } \hat{x} < 0 \\ 6.0 & \text{otherwise,} \end{cases}$$

$$\hat{c} = 0.42,$$

$$\beta_1(T) = \begin{cases} 0 & \text{if } T \le \frac{1}{9} \\ 0.244\left\{1 - \cos\left[\frac{9\pi}{4}\left(T - \frac{1}{9}\right)\right]\right\} & \text{if } \frac{1}{9} < T \le \frac{5}{9} \\ 0.488 & \text{if } \frac{5}{9} < T \le \frac{6}{9} \\ 0.244\left\{1 + \cos\left[3\pi\left(T - \frac{6}{9}\right)\right]\right\} & \text{if } \frac{6}{9} < T \le 1, \end{cases}$$

$$\beta_2(T) = \beta_1\left(T + \tfrac{1}{9}\right),$$

$\Delta_0 = h$, $D_{\min} = 0.02$ cm, and $D_{\max} = 0.2$ cm. With these parameters the minimum glottal width $\Delta_m(t)$ varied from 0.015 to 0.1 cm.

Data provided in Agarwal *et al.*, 2003 were used to guide the choice of the dimensions of the ventricular folds and their position relative to the vocal folds for the numerical experiments. These measures were taken from laminagraphic images while subjects phonated, and those used in this study are illustrated in Fig. 2. The only modification to the dimensions of Agarwal *et al.* (2003) was to make the distance between the ventricular folds smaller than measured. It is possible for human speakers to reduce this distance, and we wanted to maximize the possibility that the ventricular folds could have any effect on the output acoustics. All of the measured values refer to Agarwal *et al.* (2003). The gap between the ventricular folds in measurements was between 0.2 and 0.8 cm, so the distance from a ventricular fold to the vocal tract axis w was measured to be between 0.1 and 0.4 cm. We have taken the distance w to be 0.06 cm in this work, which meant that the height of the lower vocal fold at minimum fold separation was only 0.01 cm higher than the lower ventricular fold when the glottis was maximally open. The measured distance d from the downstream edge of the vocal folds to the false folds ranged from 0.2 to 0.75 cm, and the distance used here was 0.7 cm. The measured maximum width of the channel between the ventricular sinuses ranged from 0.9 to 2.3 cm, and, thus, the maximum distance L from the bottom of one ventricular sinus to the vocal tract axis was between 0.45 and 1.15 cm, while $L = 0.8$ cm here. (The ventricular sinus is the gap downstream of the vocal folds and upstream of the ventricular folds.) The measured interior angle of the lines tangent to the downstream face and upstream face of the ventricular folds θ ranged between 55° and 107°. In this paper we let $\theta = 80°$. The angle α between the tangent of the upstream ventricular fold surface and the perpendicular to the vocal tract axis was measured to be between −18° and 51°, and $\alpha = 15°$ in this paper. Finally the measured angle between the tangent of the downstream ventricular fold surface and the perpendicular to the vocal tract axis β was between 22° and 76°, and $\beta = 65°$ in this work.

B. Numerical method

All vorticity is represented by vortex lines that extend into the z direction. As these vortex lines originate on the vocal folds and are convected downstream, they form two continua that appear as curves in the x-y plane. These continua are vortex sheets in the limit of large Reynolds numbers. The two vortex sheets separate the glottal jet from the surrounding quiescent air in the rest of the duct.

The equation for Green's function, Eq. (7), can be used to simplify Eq. (10), the vortex sound term, in the limit $x \to +0$. In this limit the acoustic time delay is zero, and the time integral in Eq. (10) can be evaluated using an asymptotic approximation, so that the remaining spatial integral is evaluated at time t. Further, integrating in the z direction, Eq. (10) can be written in simplified form

$$B_\omega(\mathbf{x},t) = \frac{1}{4h}\int \left[\omega\left(-v_{y'}\frac{\partial Y}{\partial x'} + v_{x'}\frac{\partial Y}{\partial y'} \right) \right] (\mathbf{y},t))d^2\mathbf{y}, \tag{12}$$

where ω is the signed magnitude of vorticity, and $\mathbf{v}=v_{x'}\hat{\mathbf{i}}+v_{y'}\hat{\mathbf{j}}$ is the vorticity convection velocity.

In this two-dimensional geometry, the axial component of the Kirchhoff vector Y is the real part of a complex potential. The imaginary part is the corresponding axial Kirchhoff stream function ψ, say. Thus, Eq. (12) can be rewritten as

$$B_\omega = -\frac{1}{4h}\int [\omega(\mathbf{v}\cdot\nabla\psi)](\mathbf{y},t)d^2\mathbf{y}. \tag{13}$$

Let $\mathbf{y}_\omega(t)$ be the position of the line vortex ω in the x-y plane. $\mathbf{y}_\omega(t)=\mathbf{y}_s(\tau_w)+\int_{\tau_\omega}^{t}\mathbf{v}dt'$, and τ_w is the time that vortex ω is shed from the vocal fold surface at $\mathbf{y}=\mathbf{y}_s(\tau_\omega)$. Under the conditions of sufficiently low frequency, $\mathbf{y}_\omega$ describes two continuous, one-dimensional curves, within the region of the vocal and ventricular folds—one originating on the upper folds, $y_s'>0$, denoted $\Omega^+=\Omega^+(t)$, and the other from the lower folds, $y_s'<0$, denoted $\Omega^-=\Omega^-(t)$. Let $s_\omega=s_\omega(t)$ be the distance along either vortex sheet from the shedding point at time t, and $s_\omega^\perp=s_\omega^\perp(t)$ be the distance measured from the outward normal to either vortex sheet. In a vortex sheet model,

$$\omega(s_\omega(t),t) = \pm U_\sigma(\tau_\omega)\delta(s_\omega^\perp(t)), \tag{14}$$

where $U_\sigma(t)$ is the asymptotic jet velocity predicted by free streamline theory and $\delta(\cdot)$ is the one-dimensional Dirac delta function. The plus sign in Eq. (14) corresponds to the vorticity shed from the upper vocal fold with $y_s'>0$ and the minus sign to vorticity shed from the lower vocal fold with $y_s'<0$. The magnitude of the convection velocity of the vorticity between the jet and surrounding fluid depends on the strength of the vorticity in terms of jet velocity U_σ, and the direction of convection is approximately the axial direction (x-axis).

$$\mathbf{v}(\mathbf{y},t) = \tfrac{1}{2}U_\sigma(\tau_\omega)\hat{\mathbf{i}}. \tag{15}$$

Further, by symmetry, $\partial\psi/\partial x'((x',y'),t)=-\partial\psi/\partial x'((x',-y'),t)$. These considerations show that the contributions by each vortex sheet to the integral in Eq. (13) are equal, so that it is sufficient to consider the effect of the vortex sheet for $y_s'<0$ in the integral and to double the result. The particle velocity in the jet is related to the particle velocity in the duct by mass conservation

$$U_\sigma(t) = \left(\frac{2h}{\sigma\Delta_m(t)}\right)U(t), \tag{16}$$

where σ is the jet contraction ratio.

Combining Eqs. (14)–(16), Eq. (13) can be rewritten as

$$B_\omega(t) = \frac{h}{2\sigma^2}\int_{\Omega^-}\left(\frac{U(\tau_\omega)}{\Delta_m(\tau_\omega)}\right)^2\frac{\partial\psi}{\partial x'}ds_\omega. \tag{17}$$

It was shown in Howe and McGowan (2007) that the solution of the quasi-steady approximation to Eq. (9) [i.e., Eq. (9) with the time derivative term discarded] produced results very close to the solution of the full equation. Substituting from Eq. (17) into the quasi-steady version of Eq. (9) and solving for $U(t)$ produce

$$U(t) \approx \frac{p_I H(t)}{\rho_0 c_0}\left(1-\frac{\rho_0 h}{4p_I\sigma^2}\int_{\Omega^-}\left(\frac{U(\tau_\omega)}{\Delta_m(\tau_\omega)}\right)^2\frac{\partial\psi}{\partial x'}ds_\omega\right). \tag{18}$$

A time step of $\Delta t=0.000\,01$ s was used and the vortex sheet $\Omega^-(t)$ was approximated by discrete vortices shed at each time step. A fourth-order Runge–Kutta extrapolation was used to advance the positions of these discrete vortices. Then Eq. (18) was used to find the acoustic particle velocity at each time step, with a smoothing window that took a linear weighted average of the current value with the three previous values. The initial condition was $U(+0)=0$. The integral in Eq. (18) was approximated using the trapezoid rule, with the term corresponding to $\tau_\omega=t$ excluded, as it had a negligible effect. The stream function ψ was found at each time step by solving Laplace's equation numerically with uniform inflow and outflow conditions at $x=-2$ cm and $x=2$ cm. A standard second-order finite difference algorithm with a mesh of length 0.005 cm on each side was used for the potential flow solution.

The following were the values of the parameters appearing in this equation (all quantities are in c-g-s): $p_I=8000$, $\rho_0=0.0013$, $h=0.8$, $c_0=34\,800$, and $\ell_3=1$. The contraction ratio σ for vocal folds in high Reynolds number flow can be expected to be between 0.6 and 1.8 (Park and Mongeau, 2007), and its value was kept constant with the value unity. This is consistent with the assumption that the vorticity is convected in the x direction. Equation (11) was used to compute $\Delta_m(t)$ at each time step. The separation point $\mathbf{y}_s(t)$ was set to be the point on the surface of the vocal folds that was closest to the centerline of the duct, with one exception. The exception was when this entailed moving the separation point from the previous time step farther upstream than the distance that was traveled by the previously shed vortex in time Δt, in which case the separation point was set upstream from the previous point by that convection distance. Discontinuities in the vortex sheet were avoided by doing this. When the separation point moved downstream from the previous time step all the previously shed vortices that were upstream were presumed to reattach into the boundary layer.

Initially, numerical experiments were conducted at various fundamental frequencies f_0 and for various ventricular fold shapes. It became apparent that the effect of the ventricular folds on the outgoing acoustic particle velocity was small within the ranges of geometric parameters provided in Agarwal *et al.* (2003). The effect appeared to be largest when the ventricular folds were close together and the fundamental frequency was relatively high. Therefore, only one geometric condition with ventricular folds as previously described and shown in Fig. 2 will be examined below at relatively high f_0s of 325 and 650 Hz.

IV. RESULTS

The acoustic signal downstream to the source region was computed using Eq. (18). The results are presented in terms of transmitted pressure, normalized by the subglottal

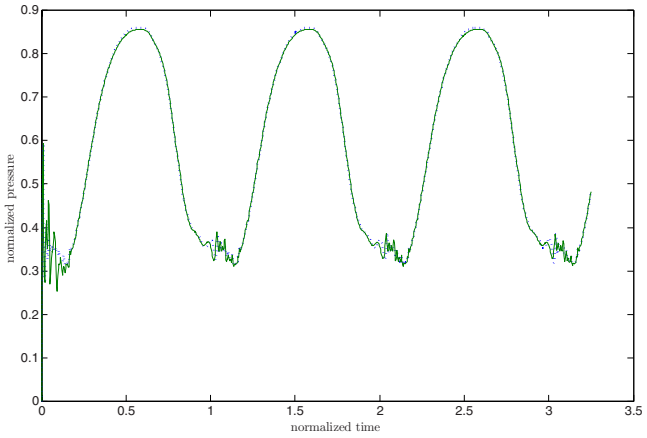

FIG. 3. (Color online) Propagated pressure wave downstream of the source region for when there are only vocal folds (dashed line) and when there are both vocal folds and ventricular folds (solid line) at $f_0=325$ Hz. Pressure is normalized by incident subglottal pressure p_I and time by $1/f_0$.

pressure in Figs. 3 and 4. Figure 3 compares the configuration with only vocal folds (dotted curve) to the configuration with ventricular folds added (solid curve) at $f_0=325$ Hz. The ventricular folds cause only a very slight decrease in peak transmitted pressure. Figure 4 shows the comparison at $f_0=650$ Hz. Again, the effect of the ventricular folds is very small.

Figure 5 shows the differences in the axial Kirchhoff streamlines for the case without ventricular folds [Fig. 5(a)] and the case with ventricular folds [Fig. 5(b)] when the vocal folds are at their most open position [one-half way through the cycle as defined by Eq. (10)]. The vortex sheets one-half through the first cycle are also indicated. Figure 6shows the gradient of ψ projected onto the vortex convection direction (the x direction), at the same phase of the glottal cycle shown in Fig. 5. Figure 6(a) is without ventricular folds and Fig. 6(b) is with ventricular folds.

Equation (18) involves integration along a vortex sheet, so it is important to be aware of its location and shape. Figure 7 shows the vortex sheet in steps of one-sixth of a cycle during the second cycle in the case of $f_0=325$ Hz with ventricular folds. Figure 8 shows the same sequence for $f_0=650$ Hz. The vortex sheet begins to bend over on itself in the first frame of the second glottal cycle in Fig. 7 and in the second frame in Fig. 8. At these times the glottis is in the process of opening, and the faster moving vortices that were shed when the glottis was the most constricted are catching up with the slower moving vortices that were shed when the glottis was the least constricted in the previous cycle. Because Figs. 7 and 8 have the abscissa in time normalized by the vocal fold vibration period, the bending of the vortex sheet occurs at about the same absolute time into the second cycle for both the 325 Hz case and the 650 Hz case. This can be expected because the vortex convection velocities follow very similar patterns. This follows by comparing Figs. 3 and 4 and relating vortex convection velocity to acoustic pressure using Eqs. (8), (14), and (15). The place where this bending occurs is farther upstream for the 650 Hz case because the slower moving vortices shed in the first cycle have not moved as far downstream in the second cycle as in the 325 Hz case.

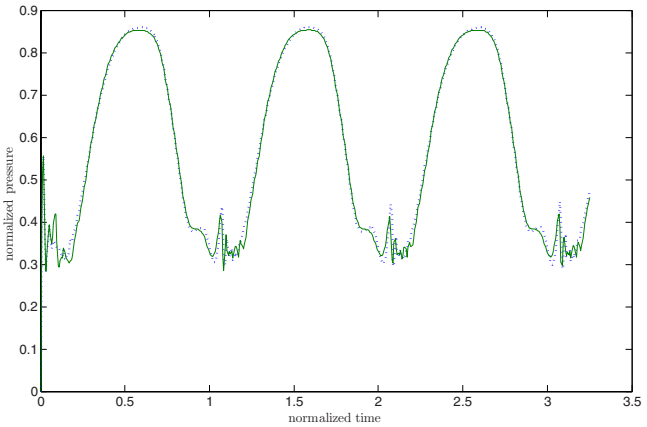

FIG. 4. (Color online) Propagated pressure wave downstream of the source region for when there are only vocal folds (dashed line) and when there are both vocal folds and ventricular folds (solid line) at $f_0=650$ Hz. Pressure is normalized by incident subglottal pressure p_I and time by $1/f_0$.

V. DISCUSSION

The numerical results showing little effect of the ventricular folds on the acoustic output are indicative of two general theorems that follow immediately from Eq. (13). First, in a steady flow, and for vorticity ultimately convected in the horizontal x direction, B_ω depends only on the difference between value of the ψ streamline on which the vorticity arises and the value of the "end" ψ streamline, which is the streamline on which the vortex sheet approaches as $x' \to +\infty$. This follows from the facts that, for a steady flow, both ω and $\mathbf{v}$ are constants in time along the vortex sheet, so that the integral in Eq. (13) has only the x-component of the ψ gradient in the integrand. A second theorem also holds under the same conditions of steady flow and ultimately horizontally convected vorticity: Changes in the shapes of the channel wall will not affect B_ω as long as the value of the streamline on which the vorticity arises and the value of where the vorticity "ends" are unchanged. In the numerical experiments performed in the present work, the streamlines from which vorticity arose (i.e., the streamline at the surface of the vocal fold) and the streamlines where the vorticity becomes parallel to the channel axis were the same with and without the presence of the ventricular folds. Note that these theorems do not depend on the exact path that the vorticity follows, only that the convection ultimately be in the x direction. So the assumption that the vorticity be convected axially is not critical to the conclusion that the ventricular folds do not have a large effect on acoustic output, at least if the vortex sheets do not strike the ventricular folds.

The flows here were not steady. However, these theorems remain approximately true for unsteady flow as long as vorticity traverses the regions of substantial nonzero x-component of the ψ gradient in a short time. Time of traversal is short if the strength of the vorticity entering the region of substantial nonzero x-component of the ψ gradient is nearly equal to the strength of the vorticity exiting this region. In the case of the vocal folds, this time should be short in relation to the inverse of the characteristic frequency

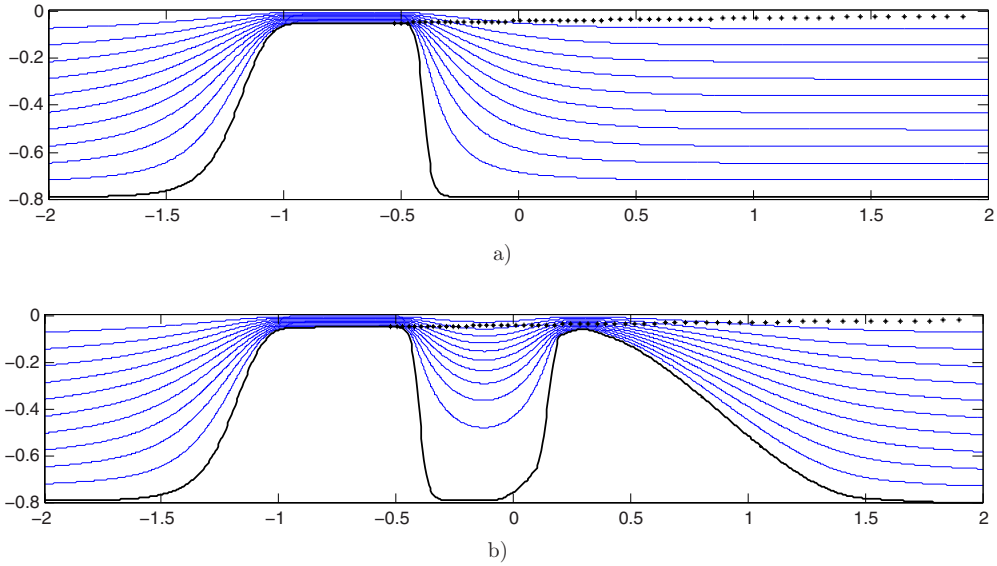

FIG. 5. (Color online) The streamlines of the horizontal component of the Kirchhoff vector and the vortex sheet at 1/2 of the vocal fold cycle, when the vocal folds are maximally open (a) for the case when there are only vocal folds and (b) for the case with ventricular folds.

of the variation in vortex strength. If d is the length scale of the region of substantial nonzero gradient, f_0 is a characteristic frequency for the variation of vortex strength, and V is the vorticity convection velocity in the same region, then the condition that $(f_0 d)/V \ll 1$ is necessary for each region of nonzero x-component of the ψ gradient. In the middle of the glottal cycle shown in Fig. 6(b), there is a region of substantial positive x-component of gradient at the trailing edge of the vocal folds, followed by a region of substantial negative x-component of gradient before the leading edge of the ventricular folds, and a region of substantial positive x-component of gradient after the peak of the ventricular folds. The length scale for these regions together is of the order of 1.0 cm. The vortex convection velocities range from about 1500 to 2600 cm/s, so at 325 and 650 Hz $(f_0 d)/V$ is at most 0.4, and often much smaller.

Another way of interpreting the weak effect on voicing of the ventricular folds is as follows. Vorticity shed from the

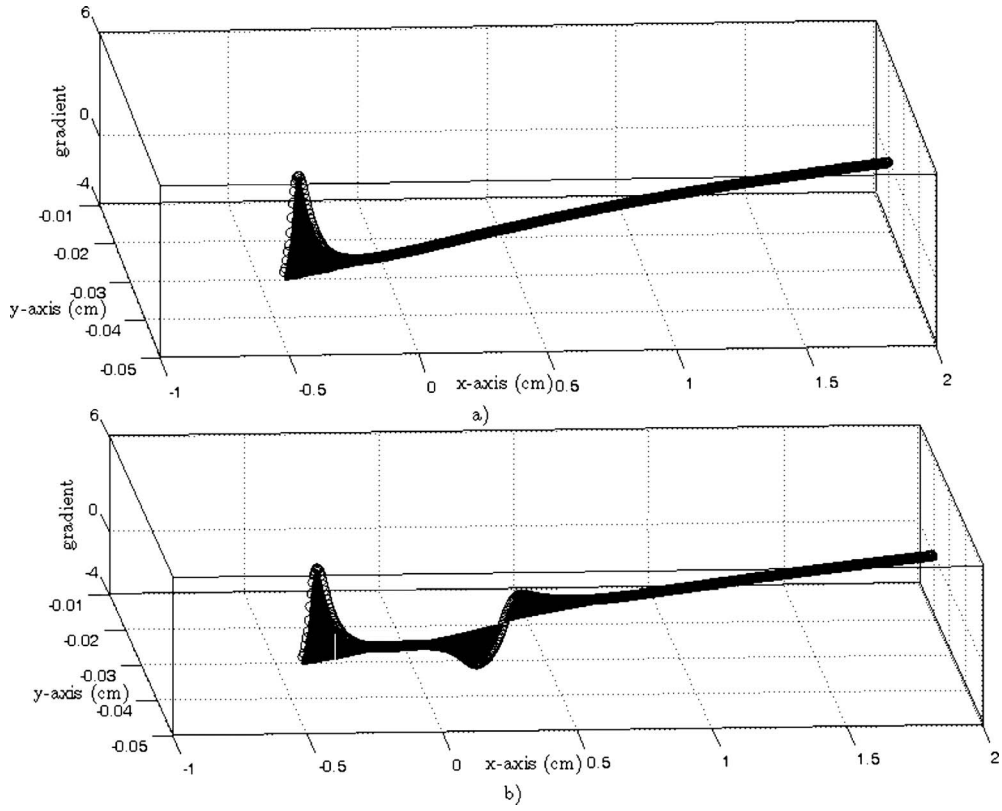

FIG. 6. Gradient of the axial Kirchhoff stream function projected onto the vortex convection direction (x-axis) as a function of position of the elements of the vortex sheet at 1/2 of the vocal fold cycle (a) for the case when there are only vocal folds and (b) for the case with ventricular folds.

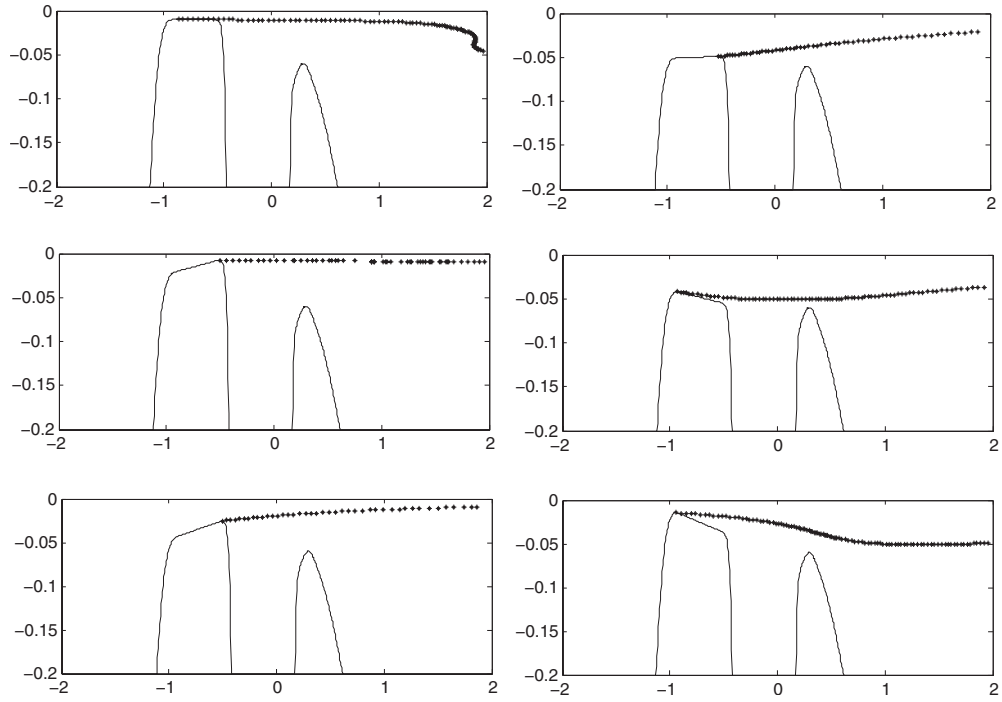

FIG. 7. Vortex sheet at $f_0=325$ Hz shown with outlines of the top of the vocal folds and the ventricular folds at 1/6 intervals of the second glottal cycle. The columns of panels on the left are during the opening phase, sequenced from top to bottom. The columns on the right are during the closing phase, sequenced from top to bottom. The y-axis has been magnified with respect to the x-axis.

vocal folds always passes through the positive x-component of ψ gradient region, creating the fluctuating drag force that is propagated as sound down the vocal tract. The ventricular folds also create their own nonzero regions of x-component of gradient, strongest near the top of the ventricular folds, but with a negative and a positive x-component of gradient regions that tend to cancel one another.

Figures 7 and 8 indicate that the vortex sheets will eventually fold onto themselves. The higher the fundamental frequency, the farther upstream this folding will occur, as indicated by comparing the two figures. The folding is a prelude to transitions to the vortex sheet breaking apart and, eventually, a transition to turbulence. At frequencies somewhat higher than 650 Hz examined here, the vortex sheet could

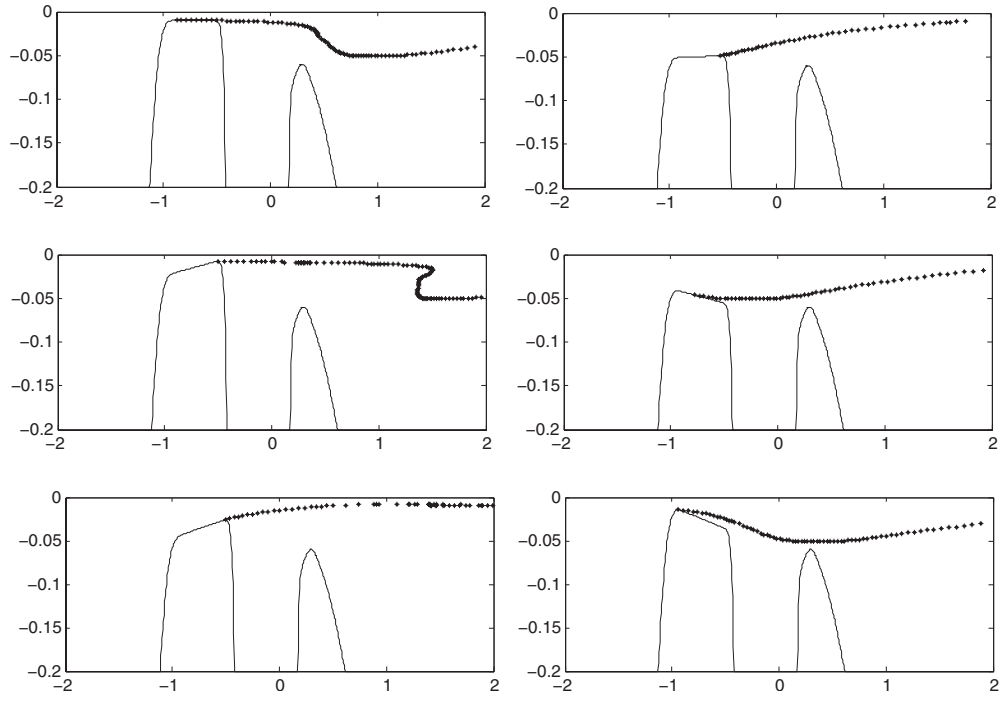

FIG. 8. Vortex sheet at $f_0=650$ Hz shown with outlines of the top of the vocal folds and the ventricular folds at 1/6 intervals of the second glottal cycle. The y-axis has been magnified with respect to the x-axis.

break up before passing above the tip of the ventricular folds. In this case the ventricular folds could have a substantial effect on the output acoustics farther down the vocal tract. The vorticity would interact with the negative x-component of the ψ gradient upstream of the ventricular folds in a coherent manner, but not with the positive gradient downstream. This would promote flow from the glottis because it would act as a negative resistance to flow, thus increasing the peak flow through the glottis. Thus the model is restricted to frequencies for which the vortex sheet does not break up before interacting with both the upstream and downstream sides of the ventricular folds. Further there is some experimental evidence that this kind of breakup can occur for nominally steady jets. Agarwal (2004) experimented with glottal jets and rigid model ventricular folds and found that the presence of the ventricular folds decreased the resistance to flow when the tips of the false folds were separated by distances from one to three times greater than the minimum distance between the vocal folds. This would indicate that the jets remained laminar from the glottis to the channel formed by the tips of the model false folds and became turbulent downstream of this channel. However, the intensity of the inflow turbulence and the level of noise downstream of the test section were not quantified in these experiments.

When vortex sheets' breakup occurs the condition that $(f_0 d)/V$ be small no longer holds, and new effects could be expected to be observed. One such effect is a positive feedback of the vorticity at the ventricular folds enhancing the vortex shedding in the glottis and, hence, the glottal jet. This effect is known as Rossiter buffeting (Howe, 1998) at frequencies greater than 2 kHz. Zhang *et al.* (2002) did attribute the occurrence of a peak in their predicted acoustic spectrum to this phenomenon in their CFD experiment. Whether this requires the breakup of the vortex sheet as described above, or only a time delay in interaction between upstream and downstream portions of the ventricular folds is uncertain at this time. The breaking up of the vortex sheet as described above would certainly enhance the buffeting.

Vortex sheet modeling has been used here on the basis that the distance through a glottal jet shear layer is negligible compared to other length scales, such as glottal channel width. This is a good approximation for the initial portion of the glottal jet. However, the jet shear layer thickens with downstream distance, and, depending on the height of the ventricular folds, a part of the jet will strike the upstream portion of the ventricular folds. This would add to the drag force, which appears to have been the case for false fold tips closer together than were the vocal fold surfaces in Agarwal's (2004) experiments.

VI. CONCLUSION

The ventricular folds do not have a noticeable effect on the voice source according to these results when the movement of the vocal folds is specified. This confirms the CFD results of Zhang *et al.* (2002) at low frequencies. This conclusion is derived from aeroacoustic theory and the use of compact Green's functions so that several fundamental frequencies and geometrical configurations are easily tested. Most importantly, the numerical results can be confirmed by mathematical considerations regarding the integral of the gradient of the axial Kirchhoff stream function. This theoretical understanding is an important one for sources of sound in the vocal tract in general.

In a simulation where the vocal fold motion is not prescribed, but occurs because of interaction with the air, it can be argued that there still will be little effect of the ventricular folds on the oscillation at low frequencies. This is because the vorticity interacting with the negative portion of the gradient of the axial Kirchhoff stream function upstream of the ventricular folds is nearly equal in strength to the vorticity interacting with the positive gradient downstream of the ventricular folds. However, the effect of the ventricular folds on the movement of the vocal folds has not been analyzed here. Further, if the glottal jet strikes the ventricular folds, then their motion would need to be considered.

Similarly, the results presented here may be generalized to fully three-dimensional situations. All that is required is that the changes in vortex strength be small over the regions of nonzero gradients in the axial Kirchhoff stream function that the vorticity traverses.

Biomechanical modeling and bifurcation theory are applied to study phonation onset and register transition. A four-mass body-cover model with a smooth geometry is introduced to reproduce characteristic features of chest and falsetto registers. Sub- and supraglottal resonances are modeled using a wave-reflection model. Simulations for increasing and decreasing subglottal pressure reveal that the phonation onset exhibits amplitude jumps and hysteresis referring to a subcritical Hopf bifurcation. The onset pressure is reduced due to vocal tract resonances. Hysteresis is observed also for the voice breaks at the chest-falsetto transition. Varying the length of the subglottal resonator has only minor effects on this register transition. Contrarily, supraglottal resonances have a strong effect on the pitch, at which the chest-falsetto transition is found. Experiment of glissando singing shows that the supraglottis has indeed an influence on the register transition.

I. INTRODUCTION

Voice registers have been introduced for perceptually distinct types of certain vocal qualities that can be maintained over some ranges of pitch and loudness (Titze, 2000). The perceptive classification can be accompanied by measurements of voice source parameters such as spectral slope or glottal open quotient (Henrich *et al.*, 2005; Salomão and Sundberg, 2008). Characteristic features are vocal breaks at register transitions associated with pitch and amplitude jumps (Roubeau *et al.*, 1987; Švec *et al.*, 1999; Miller *et al.*, 2000). It has been shown by Hirano *et al.* (1970) that the thyroarytenoid (TA) muscle and the cricothyroid (CT) muscle regulate register transitions. Consequently, the perceptive aspects of registers are inherently related to laryngeal features of vocal fold vibrations. In chest phonation the vocal folds are thick and glottal closure is complete, whereas in falsetto only the vocal fold edges vibrate (Vilkman *et al.*, 1995). Despite extensive experimental investigations using acoustic signals (Hollien, 1974; Sundberg and Gauffin, 1979), electromyography (Shipp and McGlone, 1971), electroglottography (Henrich *et al.*, 2005), and videokymography (Švec *et al.*, 2008), many questions regarding register transitions remain open: what determines the pitch of involuntary register transition? What is the role of sub- and supraglottal resonances? Is there hysteresis at register transition?

In order to address these problems, biomechanical modeling can complement experimental studies. Even though some register-like phenomena have been described in two-mass models (Sciamarella and d'Alessandro, 2004; Zaccarelli *et al.*, 2006), an appropriate representation of vibratory modes in chest and falsetto requires more advanced models such as body-cover model of Story and Titze (1995), two-dimensional model of Adachi and Yu (2005), and three-mass model of Tokuda *et al.* (2007). Moreover, a smoothed glottal geometry improves the classical two-mass model of Ishizaka and Flanagan (1972) considerably (Pelorson *et al.*, 1994; Lous *et al.*, 1998).

In this paper, we use a four-mass body-cover polygon model (Tokuda *et al.*, 2008) to study register transitions and the influence of resonators. Sub- and supraglottal resonances are described using the wave-reflection model (Kelly and Lochbaum, 1962; Liljencrants, 1985; Story, 1995; Titze, 2006). Our model simulations reveal hysteresis at the phonation onset and at chest-falsetto transition, which is consistent with experimental data (Berry *et al.*, 1996; Horáček *et al.*, 2004). We find that vocal tract resonances have a pronounced effect on the chest-falsetto transition.

II. FOUR-MASS BODY-COVER POLYGON MODEL

There are complex high-dimensional models of vocal fold vibrations (Alipour *et al.*, 2000; Titze, 2006; Gömmel *et*

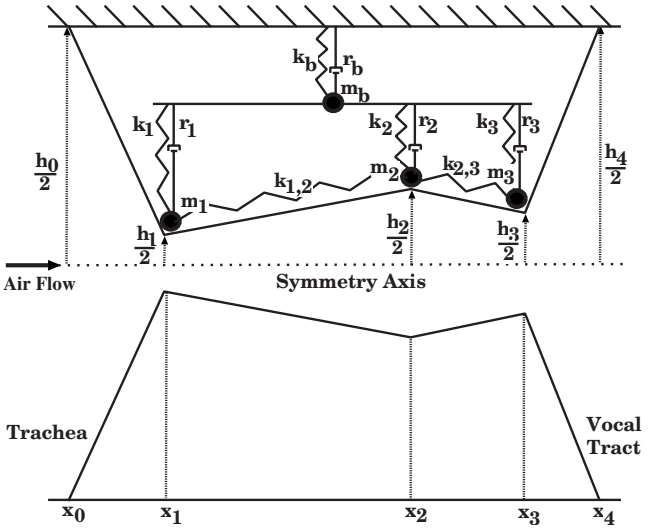

FIG. 1. Schematic illustration of the four-mass polygon model of the vocal folds.

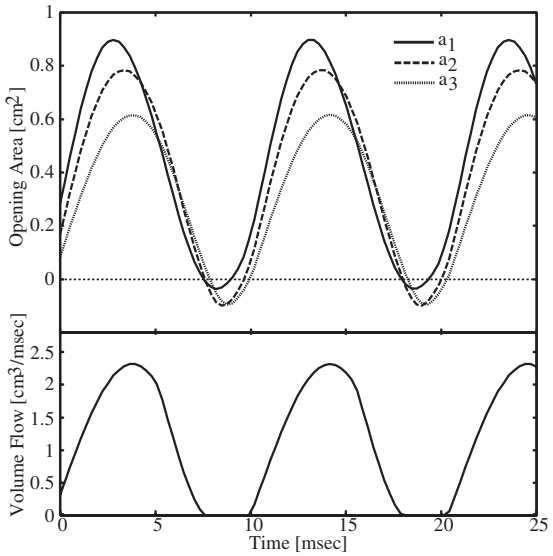

FIG. 2. Chest-like vibration simulated by the default parameter setting. Time series of glottal areas $\{a_i=lh_i:i=1,2,3\}$ (l is glottal length) between the three masses are shown in the upper graph, whereas the corresponding volume flow U is shown in the lower graph.

al., 2008; Zhang, 2009) describing anatomical and physiological details. However, many parameters are not precisely known and a comprehensive bifurcation analysis is difficult (Berry *et al.*, 1994). Consequently, we constructed a low-dimensional model that is consistent with the basic experimental observations.

Our model is based on the body-cover differentiation proposed by Story and Titze (1995), a three-mass representation of the cover (Tokuda *et al.*, 2007), and a smooth vocal fold geometry as in Lous *et al.* (1998). Advantage of dividing the cover layer into the three masses is that they are suitable for representing the coexistence of different vibratory patterns, which may correspond to chest and falsetto registers (Tokuda *et al.*, 2007). The chosen parameter values are similar to the values in these papers and they are consistent with muscle activation rules (Titze and Story, 2002). A detailed discussion of the modeling and a complete set of equations and parameters are given in Appendixes A and B and a recent thesis (Zemke, 2008).

Figure 1 visualizes our four-mass polygon model. The three cover masses allow wave-like vibrations of the whole vocal folds with a complete closure of the glottis in chest-register simulation. For other parameter sets, high-pitched oscillations with diminished closure of the glottis are simulated, which resemble falsetto register. Figure 2 shows chest-like vibrations (fundamental frequency of 96 Hz) for the default parameters listed in Appendix A. The phase shifts in the opening areas shown in the upper graph allow the energy transfer from the air flow to the masses and contribute to a skewing of the glottal pulses of the lower graph.

In order to simulate register transitions, we recall rules for controlling low-dimensional vocal fold models with muscle activation (Smith *et al.*, 1992; Titze and Story, 2002). An active CT muscle decreases the vibrating mass and increases stiffness. We introduce a tension parameter T which mimics the CT muscle (Steinecke and Herzel, 1995). Masses are divided by T and stiffness parameters are multiplied by T and thus the fundamental frequency of the model is roughly proportional to the parameter T. Increasing T from 1 to 7 allows pitch variation from 100 to 600 Hz exhibiting register transitions (detailed simulations in Sec. IV). Figure 3 shows an example of simulating falsetto-like vocal fold oscillations (fundamental frequency of 369 Hz) with the tension parameter $T=3.6$. An almost sinusoidal glottal volume flow with weaker harmonics is observed.

III. MODELING VOCAL TRACT RESONANCES

For male speech, the linear source-filter theory (Fant, 1960) was quite successful (Stevens, 1999). However, as shown already in Ishizaka and Flanagan (1972), source-filter coupling is essential if the fundamental frequency F_0 is comparable to the formant frequencies (Titze, 2008; Titze *et al.*, 2008). Register transition can be regarded as bifurcations of limit cycle oscillations (see Tokuda *et al.*, 2007 for a detailed

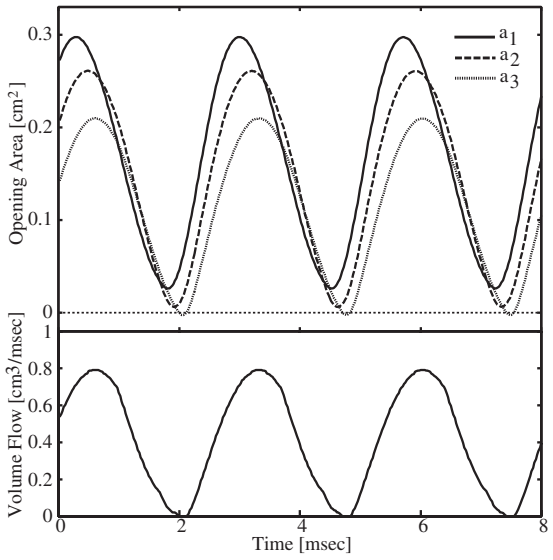

FIG. 3. Falsetto-like vibration simulated with the tension parameter of $T=3.6$.

discussion). It is known that bifurcations, i.e., sudden transitions due to slow parameter variations, might depend strongly on system parameters. Thus, it is possible that even medium effects of the resonances (see Titze *et al.*, 2008 for data on source-filter interactions) can shift register transition drastically. It has been suggested that particular subglottal resonances govern involuntary register transitions (Titze, 2000; Zhang *et al.*, 2006).

In order to study source-filter coupling, we implemented the wave-reflection model (Kelly and Lochbaum, 1962; Liljencrants, 1985; Story, 1995; Titze, 2006). Details of the simulations are given in Appendix B. For simplicity we approximate the resonators by uniform tubes characterized by their length and area. This simplification gives direct insight on how resonance frequencies given by the tube lengths affect the location of register transitions.

IV. SIMULATION RESULTS

A. Simulation of gliding pitch

The analysis of register transitions and source-tract interaction is often studied using glissando singing (Henrich *et al.*, 2005), experimental variation in vocal fold tension (Tokuda *et al.*, 2007), or gliding of the fundamental frequency in biomechanical models (Titze, 2008). In Fig. 4, we compare a glissando of an untrained singer with simulations of a corresponding F_0 glide in our four-mass model coupled to sub- and supraglottal resonators. The singer's glissando in Fig. 4(a) exhibits register transitions with frequency jumps around 3.3 and 7.8 s at slightly different pitches. There is an abrupt phonation onset at 1.2 s and a smoother offset with some irregularities. Glissando is simulated in Fig. 4(b) by varying our tension parameter T from 1 to 5.5 and then back. We find a frequency jump at 6.7 s ($T=3.8, F_0=390$ Hz) and a backward transition at 17 s ($T=3.3, F_0=350$ Hz). These differences between chest-falsetto and falsetto-chest transitions are a landmark of hysteresis (see Tokuda *et al.*, 2007 for a detailed discussion of bifurcations leading to hysteresis). Hysteresis indicates that there are coexisting vibratory regimes ("limit cycles") for a range of parameters. Moreover, hysteresis implies that there are voice breaks instead of *passagi* of trained singers.

In addition to register transitions, occasionally subharmonics are observed, e.g., at 8.7 and 14.1 s. It has been discussed earlier (Berry *et al.*, 1996; Tokuda *et al.*, 2007) that register transitions are often accompanied by nonlinear phenomena such as subharmonics and chaos. The gross features of the experimental and simulated F_0 glides in Fig. 4 are similar. The study of hysteresis at phonation onset/offset requires a more detailed Hopf bifurcation analysis.

B. Bifurcation diagrams of phonation onset

Phonation onset and offset can be studied in the context of Hopf bifurcations (see, e.g., Lucero, 1998; Mergell *et al.*, 2000). Hopf bifurcation theory describes the onset of self-sustained oscillations due to parameter variations. Smooth oscillation onset is associated with a supercritical Hopf bifurcation whereas hysteresis and amplitude jumps indicate a subcritical Hopf bifurcation (see, e.g., Guckenheimer and Holmes, 1983 for details).

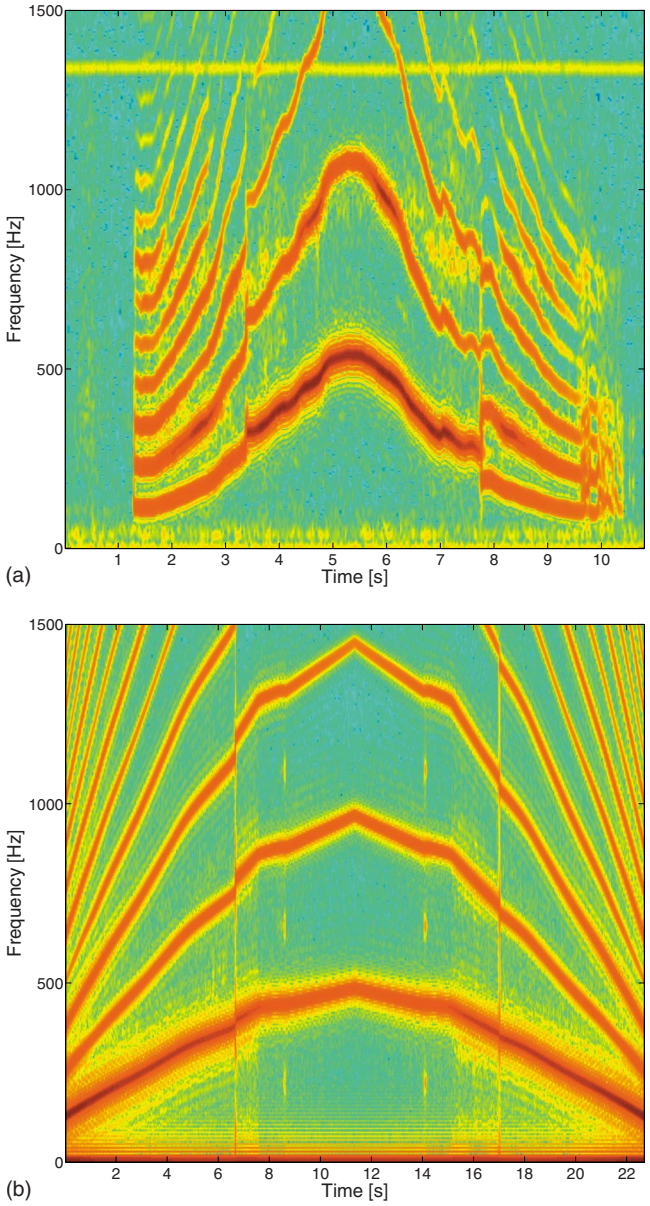

FIG. 4. (Color online) (a) Spectrogram of human voice with a gliding fundamental frequency (F_0). (b) Model simulation of the gliding F_0.

In case of phonation onset, an increasing subglottal pressure indicates vocal fold oscillations at overcritical values. In the simplified two-mass model (Steinecke and Herzel, 1995), no hysteresis was observed. In contrast, excised larynx experiments revealed a clear pressure difference between onset and offset values of about 0.2 kPa (Berry *et al.*, 1996).

Such a hysteretic phonation onset/offset is shown in our model simulations in Fig. 5. Figure 5(a) refers to the model without vocal tract resonators. There are amplitude jumps at 0.52 kPa (onset) and at 0.34 kPa (offset). Differences between increasing and decreasing pressures indicate a subcritical Hopf bifurcation. On the other side, Fig. 5(b) shows that sub- and supercritical bifurcations can occur in the four-mass model, to which sub- and supraglottal resonators are attached. As discussed in Titze (1988), the resonators reduce

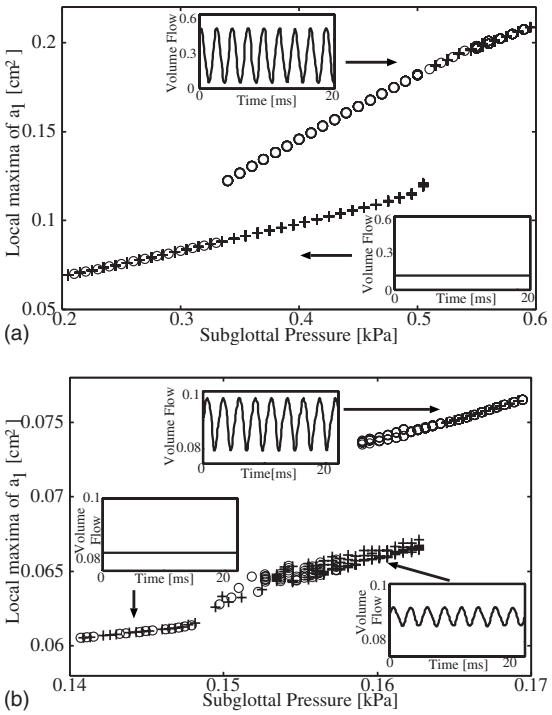

FIG. 5. Phonation onset. No vocal tract is attached to the vocal fold model in (a), but in (b) vocal tract is attached. Tension parameter is set as $T=4$. Local maxima of the opening area of the lower mass ($a_1=lh_1$) are plotted for both increasing (crosses) and decreasing (circles) subglottal pressure. The small graphs inside of each diagram represent the volume flow U (cm^3/ms) corresponding to each branch of the onset curve.

the threshold pressure. The phonation onset around 0.15 kPa seems rather smooth, implying a supercritical Hopf bifurcation. The generated phonation on the middle branch, however, has a relatively small amplitude and becomes unstable around 0.165 kPa, where it jumps to more stable one with larger amplitude on the upper branch. This jump creates hysteresis in the model simulations.

C. Influence of vocal tract on chest-falsetto transition

We induced register transitions in our model by changing the tension parameter T gradually and by measuring the fundamental frequency F_0, the amplitude of the opening area, and the number of the colliding cover masses. We observed a steady increase in F_0 and collision of all three cover masses at low F_0 and collision of only the top mass at high F_0. For simplicity, a binary classification is applied to draw the register transitions of Figs. 6–8 as follows: collision of three cover masses are termed chest, whereas collision of less masses are termed falsetto. If only the upper masses collide, open quotient (OQ), defined as OQ=duration of the open phase of the glottis/pitch period, became large as known from measurement in singers (Henrich *et al.*, 2005). In our bifurcation diagrams, with the tension T as the bifurcation parameter, we plotted the fundamental frequency F_0 on the x-axis instead of T since this allows a direct comparison with glissando spectrograms.

Figures 6 and 7 compare register transitions of the isolated four-mass model with the ones of the complete model including sub- and supraglottal resonances. In both cases, we

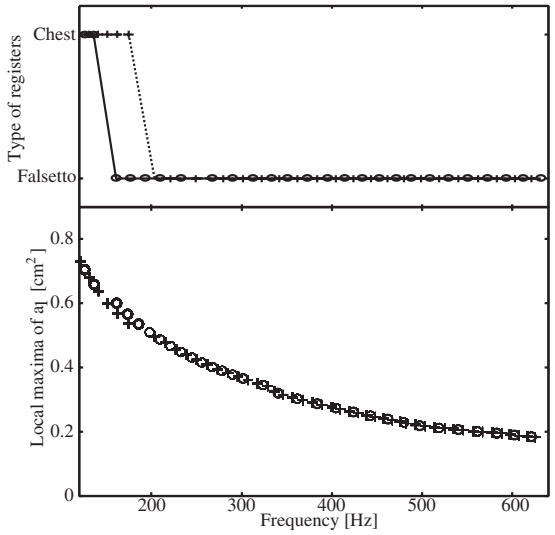

FIG. 6. Register transition of the vocal fold model without vocal tract. Frequency domains for chest and falsetto registers are drawn in the upper graph, whereas the corresponding bifurcation diagrams are drawn in the lower graph. The curves were drawn by both increasing (dotted line with crosses) and decreasing (solid line with circles) tension parameter T. In the bifurcation diagram, local maxima of the opening area of the lower mass ($a_1=lh_1$) were plotted.

find a pronounced hysteresis of about 30–40 Hz but relatively small jumps of the amplitudes. Most notable is the dramatic shift in the transition due to the coupling to vocal tract resonators. This observation reveals that the chest-falsetto transition depends sensitively on source-tract interactions.

In order to substantiate this finding, we varied the length of the sub- and supraglottal tubes. First, we decreased and increased the length of the subglottal tube by 25%. It turned out that there are only minor effects on the register transition. The length changes led to shifts in the transition point by 10–15 Hz (no graphs shown). In contrast, the supraglottal resonance had a profound effect: changing the default length of 17.5 cm to 75% or 125% induced major shifts in the

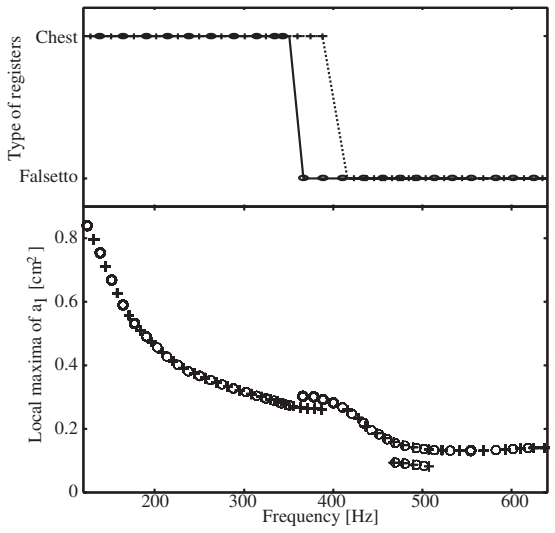

FIG. 7. Register transition of the vocal fold model with vocal tract. The default lengths for sub- and supraglottis are $L_{sub}=24.7$ cm and $L_{sup}=17.5$ cm, respectively.

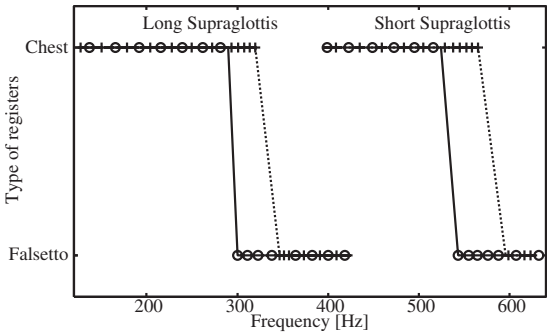

FIG. 8. Dependence of the register transition on the supraglottal length. The right and left graphs show the case of short supraglottis (L_{sup}=13.125 cm) and long supraglottis (L_{sup}=21.875 cm), respectively.

frequencies at which register transitions are observed (see Fig. 8). Note that these vocal tract lengths are within the physiological range. For all considered vocal tract length, subharmonics were observed slightly above the chest-falsetto transition. Hysteresis with a frequency difference of about 30–40 Hz and subharmonics were robust features of our simulation. The pitch of the register transition was, however, strongly affected by the formant frequencies.

V. EXPERIMENT

Our numerical study has shown that the supraglottal resonance has a strong influence on the pitch of the chest-falsetto transition. In order to examine this effect, we have carried out an experimental study of glissando on vowel /i/. This vowel has been chosen, since /i/ is one of the vowels that provide the lowest formant frequency F_1, thereby the F_0-F_1 interaction can be easily observed in the singing experiment. Four subjects were asked to perform F_0 gliding (from low F_0 to high F_0 and then back to low F_0). Two recordings were obtained from each subject. The subjects were all untrained males who have no evidence on laryngeal pathology. Both speech signal and electroglottographic (EGG) signal were simultaneously recorded.

Figure 9 shows an example of the recording data. The first formant F_1 was estimated from the speech signal by the conventional technique based on linear prediction analysis (McCandless, 1974). The spectrogram shows that, as the fundamental frequency F_0 increases and crosses the first formant F_1=250 Hz, the frequency jump is induced at t=4.6 s. The same frequency jump is observed, when the fundamental frequency decreases and crosses the first formant at t=6.5 s. As indicated by the OQ computed from the EGG signal by the method of Henrich *et al.* (2005), these frequency jumps are accompanied by the register change. The regime of falsetto register, characterized by high OQ, is clearly distinguished from the regime of chest register by dashed lines in Fig. 9(b). The timing of the register change coincides with the F_0-F_1 crossings quite well. This implies that the register transition is induced by the source-filter interaction, which is known to become strong when F_0 and F_1 are close to each other (Story *et al.*, 2000; Titze, 2008). Among the four subjects, coincidence of the register transition and the F_0-F_1 crossing has been observed in three subjects, where the other subject showed register transitions with a pitch much higher than the

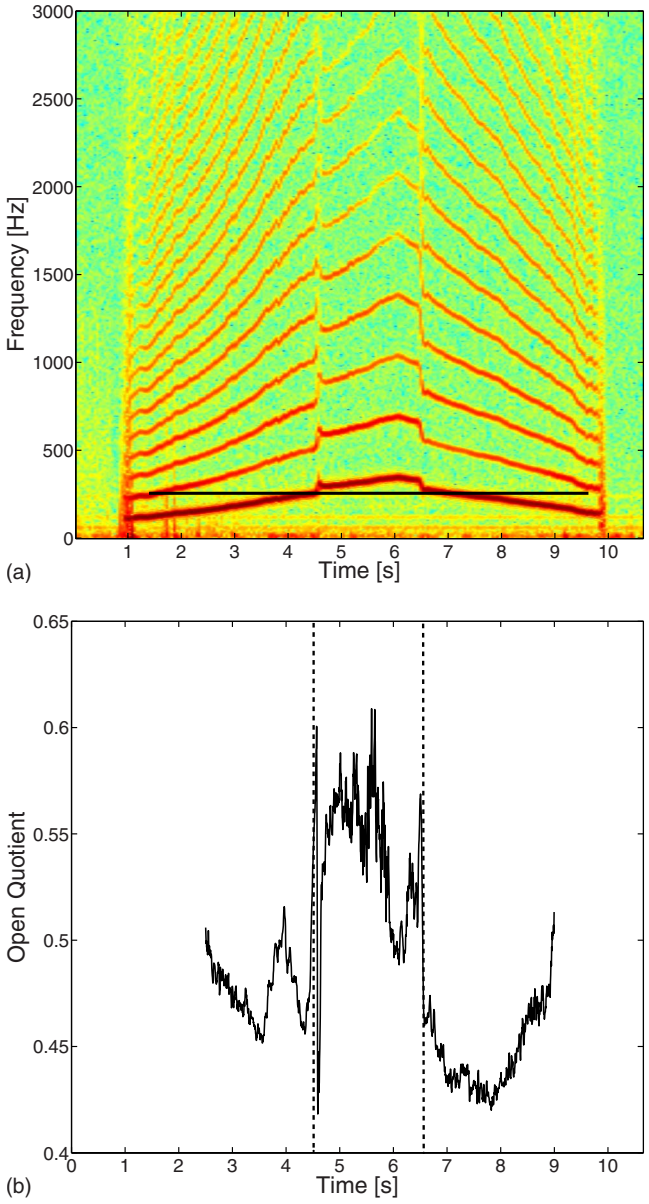

FIG. 9. (Color online) (a) Spectrogram of a male subject on vowel /i/ with a gliding fundamental frequency (F_0). The first formant (F_1) estimated from the speech signal is indicated by a solid line. (b) OQ computed from the EGG signal of (a). A region of high OQ, corresponding to falsetto register, is separated from low OQ regions by dashed lines.

first formant. Our experimental study therefore implies that the supraglottal resonance has indeed a strong influence on the register transitions. This influence of course depends on the individual characteristics of the subject, where well-trained singers should know how to sustain the chest register by avoiding the voice instability. Hence it is reasonable that not all subjects in our experiment showed a clear influence of the resonator on the registers.

To study how the different vowels affect the register transition, we further collected statistical data from the three subjects, who showed the influence of the resonator. Each subject was asked to perform F_0 gliding on both vowels /a/ and /i/, where ten recordings were obtained for each vowel. Average and standard deviations of the fundamental frequency F_0, at which the register transition takes place when

TABLE I. Average and standard deviation of the fundamental frequency F_0, at which the register transition takes place when increasing F_0. For each subject, ten recordings were collected.

Subject	I (Hz)	II (Hz)	III (Hz)
/a/	270 ± 19	271 ± 18	238 ± 20
/i/	240 ± 14	275 ± 13	231 ± 20

increasing F_0, were computed from the ten data sets, as summarized in Table I. Because of the high variability of the register transitions, the standard deviation was estimated to be relatively large. According to Welch's t-test, the mean frequency difference between /a/ and /i/ was statistically significant for subject I with a level of 1%. For the other two subjects, the difference was not significant.

We remark that Titze *et al.* (2008) carried out the same experimental framework in the context of voice instability induced by the source-tract coupling. Their main focus was, however, on the frequency jumps and not much attention has been paid to the register change. They found many frequency jumps induced by the F_0-F_1 crossing accompanied by hysteresis, in particular, for male subjects. Our observation essentially agrees with their study.

VI. SUMMARY AND DISCUSSION

From the nonlinear dynamics point of view, voice registers are distinct types of limit cycle oscillations. In this context, phonation onset refers to a Hopf bifurcation and register transitions are associated with bifurcations of limit cycles. In Tokuda *et al.* (2007), we characterized register transition in excised larynx experiments and simulations by two-dimensional bifurcation diagrams. In that paper, we analyzed a simple three-mass cover model.

Here we introduced a more realistic four-mass polygon model coupled to sub- and supraglottal resonators. This model was used to study bifurcations at phonation onset and the chest-falsetto transition.

In Mergell *et al.* (2000), a smooth phonation onset was quantified using the normal form of a supercritical Hopf bifurcation. This model explained high speed glottographic data in a reasonable way. In excised larynx experiments, however, amplitude jumps and hysteresis were reported at phonation onset (Berry *et al.*, 1996). The present simulation without vocal tract exhibits a subcritical Hopf bifurcation, where the associated hysteresis is in good agreement with the excised larynx experiments. Another simulation with vocal tract showed that the coupling to the resonators lowers the phonation onset threshold. It remains to be tested experimentally under which circumstances the phonation onset can be regarded as super- or subcritical Hopf bifurcation.

It is well known that register transitions in untrained singers are accompanied by vocal breaks (see, e.g., Švec and Pešák, 1994). In our simulations, we find indeed sudden jumps of pitch and amplitudes while varying the tension parameter T smoothly. In computer simulations, the associated phenomenon of hysteresis can be studied more easily than in glissando of singers. It turns out that our model exhibits clear pitch differences between chest-falsetto and falsetto-chest transitions.

In order to analyze the role of sub- and supraglottal resonators on register transition, we varied the length of the tubes by $\pm 25\%$. We find that the length of the subglottal tube has only minor effects on the register transition. Contrarily, the supraglottal resonator influences the pitch of the chest-falsetto transition strongly. To examine this effect, a simple experiment has been carried out based on the glissando singing on vowels /i/ and /a/. We have found a strong correlation between the register transition and the source-filter interaction for most of the subjects. Significant difference in the register transition point between the sung vowels was also detected from one subject despite high variability of the register breaks. These results provide a good indication that the supraglottal resonator has indeed an influence on the register transitions.

We remark that the present experiment is only preliminary and further investigations with more recording trials and with more subjects having various singing backgrounds are indispensable. To further study the influence of the resonators, the following experiments may also be of great interest. (i) The vocal tract anatomy can affect the register shift, i.e., vocal tract length might be correlated with the pitch of register transitions. (ii) Singing into tube (Hatzikirou *et al.*, 2006) should shift register transitions.

We finally note that comparable frequency jumps are also frequent in a variety of animal vocalizations (Wilden *et al.*, 1998; Tembrock, 1996; Riede and Zuberbühler, 2003).

ACKNOWLEDGMENTS

We thank Markus Hess and Frank Müller for the opportunity of acoustic and EGG recordings. We are grateful to Tobias Riede for stimulating discussions. This work was supported by SCOPE (Grant No. 071705001) of Ministry of Internal Affairs and Communications (MIC), Japan.

APPENDIX A: DETAILED FOUR-MASS MODEL

Figure 1 shows a schematic illustration of the four-mass polygon model. Following the body-covered theory (Hirano, 1974; Hirano and Kakita, 1985) this model is composed of a body part m_b and a cover part, which is divided into three masses m_i (lower: $i=1$, middle: $i=2$, and upper: $i=3$). Following the simplifications of (1) neglecting the cubic nonlinearities of the oscillators, (2) neglecting the additional pressure drop at inlet and considering the Bernoulli flow only below the narrowest part of the glottis (Steinecke and Herzel, 1995), and (3) assuming symmetry between the left and the right vocal folds, the model equations read as

$$m_1\ddot{y}_1 + r_1(\dot{y}_1 - \dot{y}_b) + k_1(y_1 - y_b) + \Theta(-h_1)c_1\left(\frac{h_1}{2}\right) + k_{1,2}(y_1 - y_2) = F_1, \tag{A1}$$

$$m_2\ddot{y}_2 + r_2(\dot{y}_2 - \dot{y}_b) + k_2(y_2 - y_b) + \Theta(-h_2)c_2\left(\frac{h_2}{2}\right) + k_{1,2}(y_2 - y_1) + k_{2,3}(y_2 - y_3) = F_2, \tag{A2}$$

$$m_3\ddot{y}_3 + r_3(\dot{y}_3 - \dot{y}_b) + k_3(y_3 - y_b) + \Theta(-h_3)c_3\left(\frac{h_3}{2}\right) + k_{2,3}(y_3 - y_2) = F_3, \tag{A3}$$

$$m_b\ddot{y}_b + r_b\dot{y}_b + k_b y_b + r_1(\dot{y}_b - \dot{y}_1) + k_1(y_b - y_1) + r_2(\dot{y}_b - \dot{y}_2) + k_2(y_b - y_2) + r_3(\dot{y}_b - \dot{y}_3) + k_3(y_b - y_3) = 0. \tag{A4}$$

The dynamical variables y_i represent displacements of the masses m_i, where the corresponding glottal opening is given by $h_i = h_{0i} + 2y_i$ (h_{0i} is prephonatory length; $i = 1,2,3$). The constant parameters r_i, k_i, and c_i represent damping, stiffness, and collision stiffness of the masses m_i, respectively, whereas $k_{i,j}$ represents coupling strength between two masses m_i and m_j. The stiffness is determined as $r_i = 2\zeta_i\sqrt{m_i k_i}$ using the damping ratio ζ_i. The collision function is approximated as $\Theta(\xi) = 0$ ($\xi \le 0$); $\Theta(\xi) = 1$ ($0 < \xi$).

The aerodynamic force, F_i, acting on each mass is derived as follows. First, the vocal fold geometry is described by a pair of four-mass-less plates, as shown in Fig. 1. The flow channel height $h(x,t)$ is a piecewise linear function, composed of $h_{1,0}$ ($x_0 \le x \le x_1$), $h_{2,1}$ ($x_1 \le x \le x_2$), $h_{3,2}$ ($x_2 \le x \le x_3$), and $h_{4,3}$ ($x_3 \le x \le x_4$), which are determined as

$$h_{i,i-1}(x,t) = \frac{h_i(t) - h_{i-1}(t)}{x_i - x_{i-1}}(x - x_{i-1}) + h_{i-1}(t), \tag{A5}$$

where $i = 1,2,3,4$ and h_0 and h_4 are constants. Assuming Bernoulli flow, the pressure distribution $P(x,t)$ below the narrowest part of the glottis, $h_{\min} = \min(h_1, h_2, h_3)$, is described as

$$P_s = P(x,t) + \frac{\varrho}{2}\left(\frac{U}{h(x,t)l}\right)^2 = P_0 + \frac{\varrho}{2}\left(\frac{U}{h_{\min}l}\right)^2, \tag{A6}$$

where ϱ represents the air density ($\varrho = 1.13$ kg/m^3), P_s is the subglottal pressure, P_0 is the supraglottal pressure, and l is the length of the glottis. In the case that no resonators are attached to the vocal folds, the subglottal pressure P_s is considered to be constant ($P_s = 0.8$ kPa), whereas the supraglottal pressure is assumed zero ($P_0 = 0$ kPa). This gives a simple formula for the glottal volume flow velocity as $U = \sqrt{2P_s/\varrho}h_{\min}l\Theta(h_{\min})$. The aerodynamic forces on the plates are induced by the pressure $P(x,t)$ along the flow channel. As m_1, m_2, and m_3 support the plates, an aerodynamic force on point i ($i = 1,2,3$) is found to be

$$F_i(t) = \int_{x_{i-1}}^{x_i} l\frac{x - x_{i-1}}{x_i - x_{i-1}}P(x,t)dx + \int_{x_i}^{x_{i+1}} l\frac{x_{i+1} - x}{x_{i+1} - x_{i-1}}P(x,t)dx. \tag{A7}$$

As shown by Lous *et al.* (1998), this integral can be solved analytically for the pressure distribution $P(x,t)$ described by Eq. (A6).

TABLE II. Default parameters of the four-mass polygon model.

Parameter	Symbol	Nominal value
Cover mass 1	m_1	0.009 g
Cover mass 2	m_2	0.009 g
Cover mass 3	m_3	0.003 g
Body mass	m_b	0.05 g
Stiffness of cover mass 1	k_1	6.0 N/m
Stiffness of cover mass 2	k_2	6.0 N/m
Stiffness of cover mass 3	k_3	2.0 N/m
Stiffness of body mass	k_b	30.0 N/m
Stiffness between cover masses 1 and 2	$k_{1,2}$	1.0 N/m
Stiffness between cover masses 2 and 3	$k_{2,3}$	0.5 N/m
Damping ratio of cover mass 1	ζ_1	0.1
Damping ratio of cover mass 2	ζ_2	0.4
Damping ratio of cover mass 3	ζ_3	0.4
Damping ratio of body mass	ζ_b	0.4
Collision stiffness of cover mass 1	c_1	$3k_1$
Collision stiffness of cover mass 2	c_2	$3k_2$
Collision stiffness of cover mass 3	c_3	$3k_3$
Prephonatory displacement of cover mass 1	h_{01}	0.036 cm
Prephonatory displacement of cover mass 2	h_{02}	0.036 cm
Prephonatory displacement of cover mass 3	h_{03}	0.036 cm
Height at vocal fold entrance	h_0	1.8 cm
Height at vocal fold exit	h_4	1.8 cm
Mass displacement at point 0	x_0	0 cm
Mass displacement at point 1	x_1	0.05 cm
Mass displacement at point 2	x_2	0.2 cm
Mass displacement at point 3	x_3	0.275 cm
Mass displacement at point 4	x_4	0.3 cm
Glottal length	l	1.4 cm

Parameter values used as the default situation of the present study are summarized in Table II. These values have been carefully selected in accordance with the previous studies (Ishizaka and Flanagan, 1972; Story and Titze, 1995; Lous *et al.*, 1998; Titze and Story, 2002). The observed phenomena were in general robust and did not show a strong dependence on the selected parameter values. To simulate the coexistence of the chest and falsetto registers, the damping ratio of the lower mass was set to be relatively small compared with the other masses. The small damping ratio activates the lower mass so that it leads to a large movement of all the cover masses to produce a chest-like register, which can easily coexist with a falsetto-like register.

The tension parameter T is also introduced to control the frequency of the four masses as

$$m_i' = m_i/T, \tag{A8}$$

$$k_i' = k_i \cdot T \quad (i = 1,2,3,b). \tag{A9}$$

The initial values for all simulations were set as $x_1 = 0.02$ cm, $x_2 = 0.015$ cm, $x_3 = 0.01$ cm, $x_b = 0$ cm, and $\dot{x}_1 = \dot{x}_2 = \dot{x}_3 = \dot{x}_b = 0$ cm/s. To integrate the four-mass model equations (A1)–(A4), Euler's method was applied with an integration step of $\Delta t = 11.4/8$ μs. The model equations were simulated also by using the MATLAB ODE solver

(ODE45) and it was confirmed that essentially the same results can be obtained.

To draw the bifurcation diagrams of Figs. 5–7, 20 local maxima of the opening area of the lower mass ($a_1=lh_1$) were plotted after discarding the transients. For the next parameter values, the final state of the preceding simulation was used as the initial condition.

The spectrogram of Fig. 4(b) was computed using the minimum glottal area ($a_{\min}=lh_{\min}$) with the following parameters. Sampling rate of 44 kHz, window length of 8192 sample points, overlap of 496 sample points, and Hanning window.

APPENDIX B: WAVE-REFLECTION MODEL FOR SUB- AND SUPRAGLOTTIS

Sub- and supraglottal resonances were described by using the wave-reflection model (Kelly and Lochbaum, 1962; Liljencrants, 1985; Story, 1995; Titze, 2006), which is a time-domain model of the propagation of one-dimensional planar acoustic waves through a collection of uniform cylindrical tubes. The supraglottal system was modeled as a simple uniform tube (area of 3 cm^2 and length of 17.5 cm), which is divided into 44 cylindrical sections. The area function for the subglottal tract was based on the one proposed by Zañartu *et al.* (2007). The area function is composed of 62 cylindrical sections. For both sub- and supraglottal systems, the section length Δz was set to 17.5/44 cm. This determines the sampling time interval as $\Delta t=\Delta z/c=11.4$ μs, where $c=350$ m/s stands for the sound velocity. The corresponding sampling frequency is 88 kHz.

Attenuation factor for the resonators was approximated as $a_k=1-0.007(\pi/A_k)^{1/2}\Delta z$ (A_k is kth cylinder area). Radiation resistance and radiation inertance at the lip were

$$R_r=\frac{128}{9\pi^2}\frac{\rho c}{A_L},\quad I_r=\frac{8}{3\pi^{3/2}}\frac{\rho}{\sqrt{A_L}}, \tag{B1}$$

respectively, where the lip area A_L was set to be equal to the last section of the supraglottis.

To couple the sub- and supraglottal resonators to the vocal fold model, an interactive source-filter coupling was realized according to Titze (2006, 2008). In this formula, the glottal flow is given by

$$U=\frac{a_g}{k_t}\left\{-\left(\frac{a_g}{A^*}\right)\pm\left[\left(\frac{a_g}{A^*}\right)^2+\frac{2k_t}{\rho c^2}(P_l+2p_s^+-2p_e^-)\right]^{1/2}\right\}, \tag{B2}$$

where $A^*=A_sA_e/(A_s+A_e)$ with A^s and A^e being the subglottal and supraglottal entry areas, respectively. k_t is a transglottal pressure coefficient set as 1.0. P_l stands for the lung pressure, whereas p_s^+ and p_e^- represent the incident partial wave pressures arriving from the subglottis and supraglottis, respectively. In the present study, subglottal and supraglottal entry areas were set to be equal to that of the last section of the subglottal system and that of the initial section of the supraglottal system, respectively. The lung pressure was set as $P_l=1.2$ kPa. Since subglottal pressure P_s is time dependent in this formula, the pressure value was averaged over a long-term simulation to plot P_s in Fig. 5(b).

Three-dimensional nature of the glottal jet[a)]

Michael Triep[b)] and Christoph Brücker

(Received 4 December 2008; revised 17 September 2009; accepted 17 September 2009)

The factors contributing to human voice production are not yet fully understood. Even normal human phonation with a symmetric glottal opening area is still the subject of extensive investigation. Among others, it has already been shown that fluid dynamics has a strong influence on the vocal process. The full characterization of the glottal jet has not been accomplished yet. Time-resolved measurement and visualization of the three-dimensional (3D) flow downstream the human vocal folds are difficult if not impossible to perform *in vivo*. Therefore, it is common to use mechanical and numerical models with a simplified shape and motion profile of the vocal folds. In this article, further results regarding the 3D flow structure obtained in a 3:1 up-scaled dynamic glottis model (cam model) in a water circuit are given, extending earlier work [M. Triep *et al.* (2005). Exp. Fluids **39**, 232–245]. The model mimics the temporal variation in the 3D contour of the glottal gap while water flow reduces the characteristic frequencies by the order of 1/140. The unsteady flow processes downstream of the vocal folds are visualized in slow motion and analyzed in detail via particle imaging techniques. The visualization results show complex 3D flow behavior of lengthwise jet contraction and axis switching. In addition, the time-dependent flow rate during the phonatory oscillation cycle is measured in detail. It is shown that the pressure loss is decreased in the presence of a second constriction downstream of the glottis in form of ventricular folds and it is observed that for this case the jet is stabilized in the divergent phase of the cycle.

I. INTRODUCTION

The detailed knowledge of flow behavior and real flow processes downstream of the human vocal folds is nowadays subject of extensive study. From their investigations fluid dynamic researchers expect to gain full insight into the flow mechanisms that are important to speech production. In order to do so, the glottal jet has to be described accurately; in particular, three aspects are of immense concern: (a) the three-dimensional (3D) nature of the glottal jet, (b) how variable is the jet behavior from cycle-to-cycle, and (c) what effect do ventricular folds have on glottal flow. Commonly, there are three approaches that are followed for glottal flow investigations: *in vivo* study, the use of *ex vivo*/*in vitro* models, and controlled physical models. The latter has the great advantage that voice production investigations can be carried out in a more controllable environment, such that time-resolving measurements and visualizations of the 3D flow are feasible. These are necessary for the detailed study of the supraglottal development of vortical flow structures, their interaction within the vocal tract, and their impact on flow-induced acoustics.

Important references related to experimental studies involving mechanical physical models of the vocal folds are shown chronologically in Table I. These focused on the study of isolated aspects of the glottal flow.

An important step toward the theory of the glottal physics was first established by Van den Berg (1958) with the myoelastic-aerodynamic theory of voice production. Ishizaka and Matsudaira (1972) developed simplified models for the quantification of the pressure loss across a glottal opening at different subglottal pressures. In order to evidence the self-excited oscillations, silicone vocal folds models have been built; however, these restricted the optical accessibility necessary for detailed flow measurements in the close-up region of the glottis. Furthermore, these models were not appropriate to enforce specific oscillation patterns. Therefore, static models in a transparent test section (Pelorson *et al.*, 1994; Alipour *et al.*, 2002; Zhang *et al.*, 2004; Kucinschi *et al.*, 2006; Erath and Plesniak, 2006a) and models with controllable vocal folds motion (Mongeau *et al.*, 1997; Barney *et al.*, 1999; Zhang *et al.*, 2002b; Triep *et al.*, 2005; Kucinschi *et al.*, 2006; Krane *et al.*, 2007) were employed to study open questions regarding the glottal flow structure. Detailed flow investigations were pursued to study the importance of flow asymmetry on the evolving glottal jet in static two-dimensional (2D) vocal folds models and the evolution of vortical structures downstream the vocal tract (Hirschberg, 1992; Pelorson *et al.*, 1994; Erath and Plesniak, 2006b). Different groups reproduced experimentally an opening and closing motion in lateral direction (Zhang *et al.*, 2002b; Deverge *et al.*, 2003). The results show that the characteristics of the unsteady evolution of the glottal jet differs largely from a quasisteady flow approximation with regard to flow asymmetry and flow mechanisms involving vortical struc-

tures, depending on the motion of the shape and the open quotient of the glottis. At the same time the flow asymmetry is expected to manifest differently in 3D than in the 2D case. An approximate 3D glottis contour during a complete phonatory cycle is known from Hirano *et al.* (1987) who observed a convergent to divergent contour change in the glottis. Up to date there exists no method to detect the complete glottal gap *in vivo* with sufficient spatiotemporal resolution, so that efforts in improving the detection of the vocal folds movement are being undertaken, e.g., by Döllinger and Berry (2006).

The lack of a physical model of the vocal folds with a realistic reproduction of the time-varying 3D motion of the glottis led to the glottal cam model in an earlier study (Triep *et al.*, 2005), which allows the study of the spatiotemporal evolution of the three-dimensional glottal jet flow close to the glottis. This model can produce volume flow waveforms comparable to those produced in real speech. The glottal models of Mongeau *et al.* (1997), Barney *et al.* (1999), Zhang *et al.* (2002b), and Krane *et al.* (2007) demonstrated a similar time-dependent volume flow behavior. The influence of ventricular folds (VFs) on translaryngeal airflow resistance has been studied extensively for steady flow in a static model (Agarwal *et al.*, 2004). It is not clear yet whether this influence holds also for the actual time-varying flow rate profile. Recent works focused on self-oscillating models (Bailly *et al.*, 2008) and canine *ex vivo* models (Alipour *et al.*, 2007). Further studies shall consider the influence of a controlled dynamic motion of the vocal folds.

It is known from technical applications in fluid mechanics that free jets from elliptic orifices experience under certain conditions, a switching of axes. This three-dimensional flow effect has already been observed in a self-oscillating rubber model of the vocal folds (Neubauer *et al.*, 2007; Drechsel and Thomson, 2008) and in excised canine larynx models (Khosla *et al.*, 2007; Khosla *et al.*, 2008). The results obtained in these models suggest at first glance qualitatively similar flow structures as observed in the controllable driven glottal cam model (Triep *et al.*, 2005). It is assumed that the interaction of the glottal jet with the walls downstream the vocal folds will have a strong influence upon the glottal flow behavior; to what extent is still an open issue. Thus, it remains an open question whether the glottal jet through excised canine larynges, which do not include a vocal tract, behaves differently. The present article continues the experimental characterization of the three-dimensional nature of the unsteady glottal jet carried out by Triep *et al.* (2005) using the three-dimensional, scaled-up, driven model of the vocal folds in a water circuit. The model allows an accurate reproduction of the spatiotemporal displacements of the vocal folds during the phonatory cycle. The flow is pressure driven and the resulting time-varying flow rate can be determined. The characteristic time scales of the phonatory cycle in the model are enlarged, such that time-resolved (TR) measurements and visualizations of the glottal flow can be carried out conveniently. The glottal cam model includes a vocal tract with optional insertion of modeled VFs leading to a glottal jet evolution which is focus of discussion. In the pre-

FIG. 1. FIG. 2. (Color online) Photograph (left) and midcoronal plane side view of cam model (right, with VFs). The glottis is turned by 90° to the horizontal.

vious work, the sagittal plane jet motion has not been studied in as much detail because the mismatch in the refractive indices between the solid VFs model and the working fluid precluded it. The goal of the present study is to experimentally characterize the gross features of the time-evolving 3D jet flow field. This is done in order to determine whether the observed effect of ventricular folds on the glottal jet, previously studied in static models by Agarwal *et al.* (2003) and more recently also by Bailly *et al.* (2008), would also be observed when the vocal folds move and the 3D jet evolves in time.

The following issues can be addressed with the glottal cam model:

- the 3D characterization of the entire glottal jet including the emerging vortical structures and their interaction in the vocal tract;
- glottal jet evolution, instabilities, and breakdown and its cyclic behavior;
- the character of the flow past the glottis when including VFs in the model;
- detailed flow visualizations of the jet; and
- the shape and integral of the volume velocity waveforms for selected transglottal pressures.

Looking at its capabilities with regard to the flow measurements and the prescription of relevant parameters (pressure head, fundamental frequency, glottal motion profile, glottal orifice shape, and open quotient), the glottal cam model can contribute in the study of the open questions in the glottal jet physics.

Section II briefly describes the driven 3D vocal fold cam model. Thereafter, the experimental setup and the experimental velocimetry and visualization techniques are described. Finally, results of the glottal volume velocity waveform and the unsteady 3D flow field in this model are visualized and discussed for the case without and with model ventricular folds in natural human phonation conditions.

II. THE CAM MODEL AND EXPERIMENTAL SETUP

The cam model has been described in full detail in earlier publications (Brücker *et al.*, 2004; Triep *et al.*, 2005). A short synopsis of the philosophy behind the cam model, the characteristic flow parameters, and the main features of the model are given here. The cam model consists of two counter-rotating 3D shaped driven cams (Fig. 1), each of which is covered with a stretched silicone membrane (Fig. 2). The global parameters of the contour of the model glottis and its motion (see Fig. 3), which are important for the flow evolution, show the most realistic basic features in comparison to other medical observations. Especially the convergent-divergent shape change in the glottal opening during the cycle is replicated similar to that observed by Hirano *et al.* (1987). In addition, the elliptic cross section (see Fig. 1 and glottograms from literature) is very similar. Finally, the waveform is very close to what can be found in literature: (1) for volume velocity waveform, see Sulter and Wit, 1996, and (2) for glottal area waveform, see Koike *et al.*, 1983. Note that the membrane motion generated by the cam model comprises a vertical (streamwise) and transversal (crosswise) component.

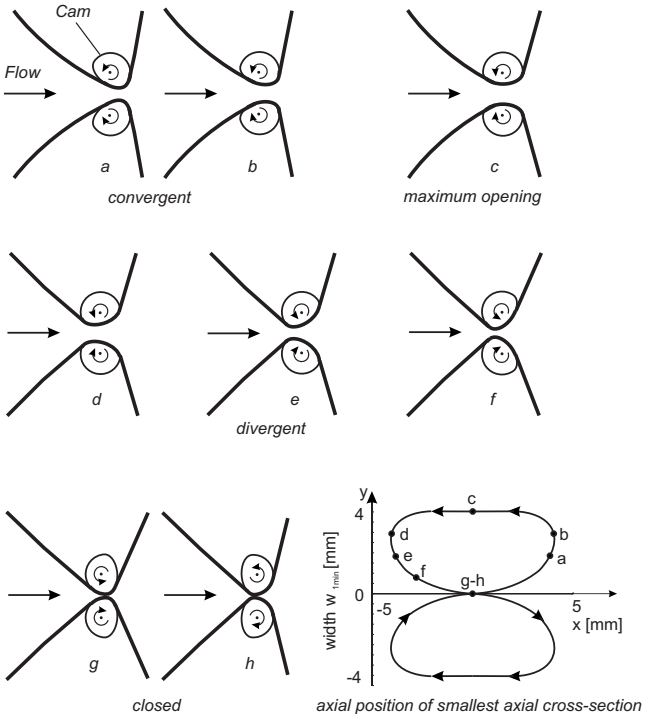

FIG. 3. Variation in the axial cross section of the glottis profile in the midcoronal plane during the glottal cycle and curve of the minimum gap locus over the cycle (bottom, right) [from (a) t/T_0=0.15 until (f) t/T_0 =0.40 in steps of $\Delta t/T_0$=0.05, (g) t/T_0=0.50, and (h) t/T_0=1.0].

Changing the 3D contours (Fig. 1), the rotational speed, or the material of the cams allows to investigate several different phonatory situations. In this paper, similar cams as used in the earlier study which were designed for the reproduction of the natural phonatory oscillation are employed. Besides geometric similarity, the Reynolds (Re) and Strouhal (Sr) numbers are similar for the real situation and in the model experiment. The order of magnitude of the most important characteristic numbers considered here is as follows:

- $\mathrm{Re}_W = u_{\mathrm{mean}} W_{1\,\mathrm{max}} / \nu \approx O(10^3)$ and
- $\mathrm{Sr} = f_0 W_{1\,\mathrm{max}} / u_{\mathrm{mean}} \approx O(10^{-2})$,

where u_{mean} is the typical mean flow velocity in the original glottis during phonation (Pelorson *et al.*, 1994), c is the velocity of sound in air, f_0 is the fundamental frequency of the glottal cycle, $W_{1\,\mathrm{max}}$ is the maximum glottal opening, ν is the kinematic viscosity, and ρ is the density of the fluid. The fundamental frequency $f_0 = 1/T_0$ of the model is in the order of 1 Hz which corresponds to 135 Hz in human voice. Furthermore, the ratio between the dynamic pressures of the model and the human voice leads to a pressure head in the model that is half the value of that prevailing in human voice. The Mach number which is estimated as $\mathrm{Ma} = u_{\mathrm{mean}}/c \approx O(10^{-1})$ is small so that the flow during natural phonation can be considered to be incompressible.

The vocal folds module is placed in the test section of a U-shaped water flow channel arrangement with a column at both ends for imposing the pressure head (Fig. 4). The downstream column includes an overflow with a sharp edge, whereas the inlet column comprises a Styrofoam disk. In general, a free surface of the water column is prone to oscillations resulting from pressure waves at the opening and closing of the glottis. In order to ensure an almost oscillation-free surface, a lightweight Styrofoam disk is placed on the water column. This extension to the previous setup allows a more precise evaluation of the flow velocity waveform measurements. This method of volume flow measurement adds an important advantageous feature of this unique cam model and experimental setup. All components of the channel are made of Perspex, so that optical access is guaranteed for whole plane flow measurements, in particular, in the region close to the glottis and in the Morgagni's ventricle between vocal and VFs. Geometric data of the VFs are according to laminagraphic tracing measurements from Agarwal *et al.*, 2003. Since the refractive index of the Perspex and the working fluid are not matched, the VFs were manufactured of thin material and filled with the working fluid in order to minimize the image distortions.

The glottal cycle in this study has an open quotient of 50% which means that the membranes remain in the closed state for half the period. This is achieved by contouring the cams with a semicircular arc representing the closed phase of 50% of the cycle (Fig. 3). The use of water as the carrier fluid and the upscaling of the glottal model allows us to visualize the flow in slow motion.

The volume flow waveform can be measured accurately by detecting the temporal vertical motion of the disk on the inlet water column reservoir by a microscopic lens/high-speed camera setup and image processing. The flow rate profile is measured for different driving pressure heads in order to study the pressure loss in the near-glottal region. Furthermore, the volume flow waveform is measured for a configuration without and with the VFs for the same initial pressure head condition and driving speed of the cams.

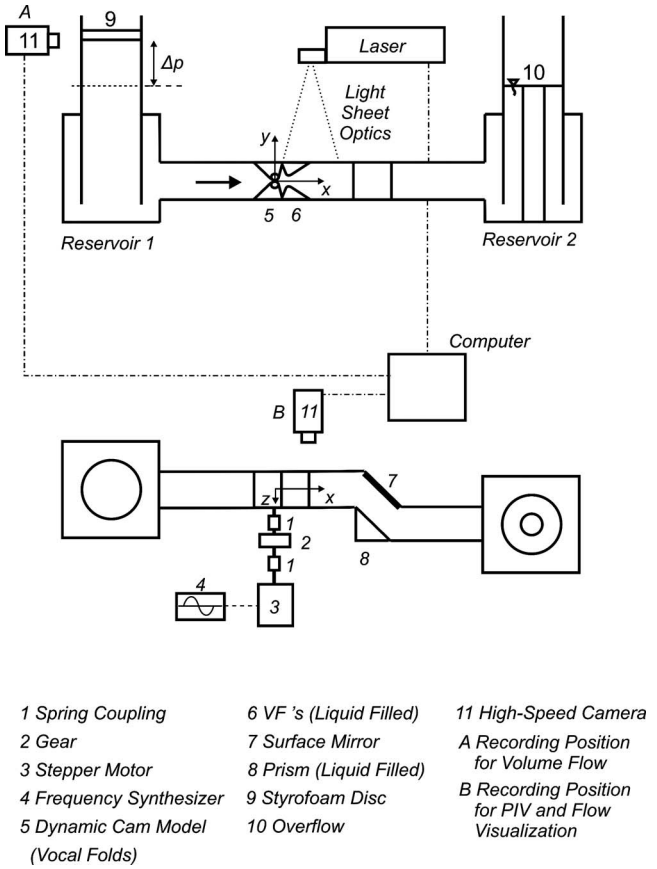

FIG. 4. Front view (top) and top view (bottom) of the experimental setup. The origin of the coordinate system is placed at the center of the glottis; the x-y plane is named coronal plane, the x-z plane is named sagittal plane, and the y-z plane is named transverse plane.

TR flow measurements are carried out downstream of the model glottis by means of high-speed particle-image velocimetry (PIV). The TR-PIV measurements utilize a FASTCAM APX-RS camera (Photron Inc., San Diego, CA, 3000 fps, 1024×1024 pixels) in combination with a Pegasus laser system (New Wave Inc., Fremont, CA). The fluid is seeded with particles with a mean diameter of 20 μm.

In order to provide further important information about the glottal flow in the study of the main issues listed in the Introduction, time-resolved flow visualizations are made. Due to the full optical accessibility into the near-glottal region, the visualization of the glottal flow is accomplished by introducing fluorescent Rhodamine dye homogeneously into the channel downstream of the glottal cam model. In this way, dye-free fluid that passes the glottis becomes visible in the emerging jet (contrast method) which is then recorded in the light sheet with the FASTCAM APX-RS camera. Hereby, we obtain a beneficial view of the overall flow and even of the jet edge instability structures. For all aforementioned measurements, the upstream water column is filled to a level slightly higher than that needed to impose the pressure head

TABLE II. Summary of the experiments.

Type of experiment	Glottal orifice shape	Inclusion of ventricular folds	Open quotient OQ	Physiological pressure head Δp (cm H_2O)	Figure no.
Volume flow	Elliptical	No/yes	0.5	6, 10, 14	5
PIV	Elliptical	No	0.5	6	6
PIV	Elliptical	Yes	0.5	6	7
Visualization	Elliptical	No	0.5	6	11
Visualization	Elliptical	Yes	0.5	6	12
Visualization	Rectangular	Yes	0.5	6	13
PIV	Elliptical	No	0.5	6, 14	14 and 15

across the glottis. For these measurements always the second glottal cycle is observed, and the relative difference in the pressure head for successive measurements is less than 1%. For the purpose of cyclic PIV measurements, an overflow is also introduced in the upstream water column, so that the driving pressure is kept constant for each cycle. The measurements which will be presented in Sec. III are detailed in Table II. The PIV measurements are necessary for the extraction of quantitative data from the flow field while the dye visualizations are rather of qualitative character. Using the method of PIV, the spatial resolution is restricted by the velocity analysis procedure which averages over a small interrogation area that should include at least seven pairs of seeding particles. By contrast the dye visualizations are able to give a very sharp view of the glottal jet edge.

III. RESULTS

A. Volume velocity waveform

The measured results of the volume flow waveform through the glottis model are shown in Fig. 5 for three different pressure heads across the glottis (Δp=6 cm H_2O, Δp=10 cm H_2O, and Δp=14 cm H_2O). All quantities are given as values for real natural phonation. The volume flow waveform is normalized with the friction-free discharge velocity from Torricelli's theorem and the cross-sectional area of the model vocal tract $A_{channel}$.

The shape of the measured flow velocity waveforms look very similar to those found in literature (Cranen and Boves, 1988; White, 1992; Sulter and Wit, 1996). The comparison of the volume flow waveforms for the case without and with model VFs clearly show that the pressure loss is reduced in the presence of VFs, since all curves for this case are always higher than for the cases without. The difference between the integral values is in the order of 10%. The curves show the typical skewing to right, so that the instant within the glottal cycle for maximal volume rate is delayed with respect to the instant of maximal glottal opening (Fig. 1). Note that the glottal area function $A_{glottis}(t)$ in this study is symmetric and the open quotient is 50%, so that the glottis is fully open at 25% of the cycle after glottis opening.

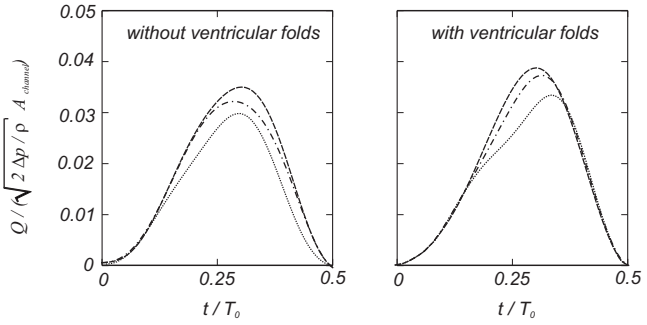

FIG. 5. Measured volume flow rates Q for imposed transglottal pressure heads of Δp=6 cm H_2O (dotted line), Δp=10 cm H_2O (chain dotted line), and Δp=14 cm H_2O (dashed line). The volume flow $Q(t)$ is made dimensionless with the loss-free steady flow rate at the given pressure head.

For the case with VFs, the instant of maximum glottal flow is delayed to later cycle instants for decreasing pressure heads. This tendency is not clearly observed for the case without VFs, where the maximum glottal flow occurs basically at the same instant in the cycle. The effect of strongly abducted VFs on glottal flow, observed by Scherer *et al.* (1983) and Agarwal *et al.* (2004) for steady flows through static geometries, is also observed in the present case, in which the model vocal fold walls move and the flow is time varying. The changes observed in the glottal flow jet, due to the presence of the VFs, will be discussed in more detail in Sec. III B. These changes support the notion that the VFs modify glottal jet entrainment such that the volume flow per unit transglottal pressure is enhanced.

B. Flow evolution

The generation and breakdown of the unsteady jet through the moving glottis is well described in space and time over 1 cycle and characteristic details of the flow are extracted and studied. For a visual representation of the different cross sections of the high-speed PIV measurements and flow visualization, see the coordinate system depicted in Fig. 4. Measurements are carried out in the midcoronal (x-y) plane and in the midsagittal (x-z) plane without and with VFs. Further results from measurements in one exemplary transversal (y-z) plane are also shown.

Figure 6 shows the velocity vector plots in the midcoronal and midsagittal planes of the glottal model without VFs at six characteristic instants of the open phase of the glottal cycle, taken from a single high-speed sequence: t_1/T_0=0.15 (a) in Δt steps of 0.05 up to t_6/T_0=0.40 (f). In the following description the letters (a)–(f) are used when referring to these six instants. The glottal jet front plume and jet edge can be deduced from the velocity vector lengths while considering their actual point of action. In order to better accentuate the

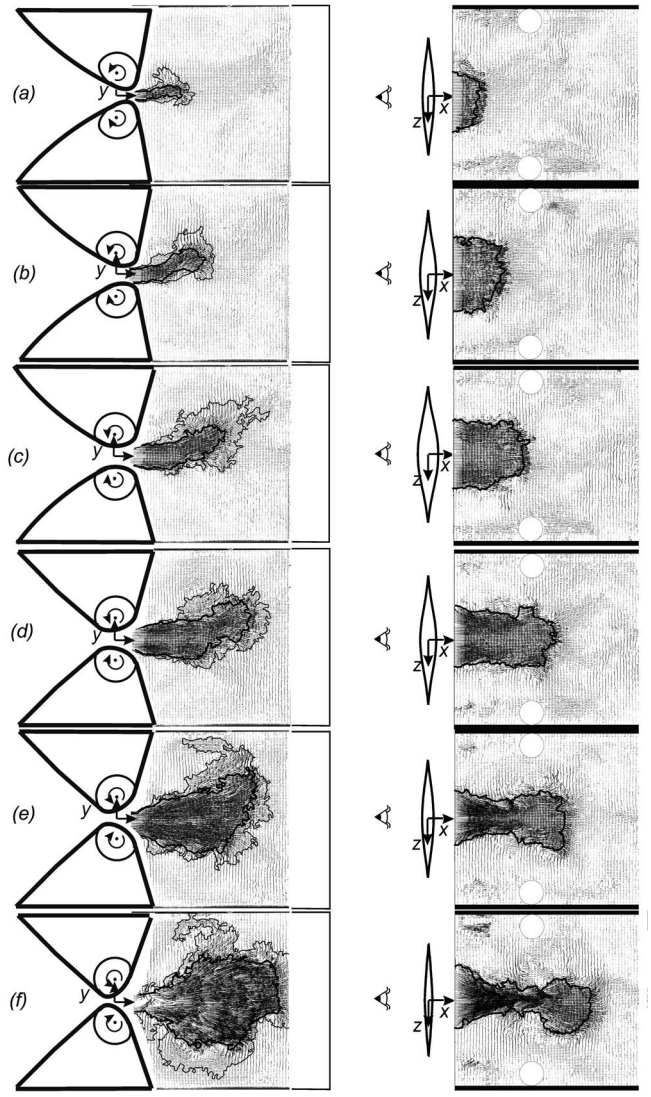

FIG. 6. Flow field at instants (a) $t/T_0=0.15$ to (f) $t/T_0=0.40$ in steps of $\Delta t/T_0=0.05$ after glottis opening (without VFs) in the midcoronal plane (left) and midsagittal plane (right) of the channel for $\Delta p=6$ cm H_2O: velocity vector plots with isocontours of in-plane speed as values in real natural phonation (3.5 m/s—thin solid line and 10 m/s—thick solid line).

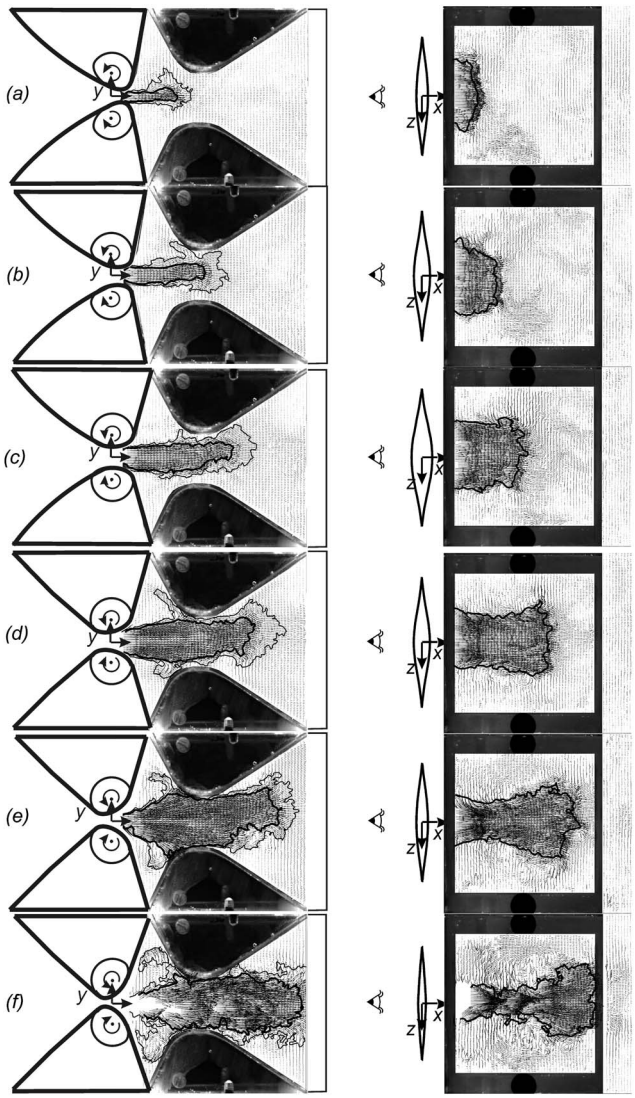

FIG. 7. Flow field with VFs in the midcoronal plane (left) and midsagittal plane (right) of the channel at same instants as in Fig. 6 for $\Delta p=6$ cm H_2O.

jet, the isocontours of the in-plane speeds of 3.5 and 10 m/s are also shown in the midcoronal planes. For the sake of clarity in the midsagittal planes, only the isocontour of 10 m/s is displayed.

After opening of the glottis, the jet exits the glottal gap in this cycle almost aligned with the vocal tract downstream axis. Small deviations are observed in the front plume of the jet. Measurements of several successive glottal cycles show that there are cycles where the jet emerges symmetrically and that this behavior occurs randomly. In this initial stage of the jet evolution, the jet approximately retains the geometrical shape and orientation of the glottal orifice [Figs. 6(a)–6(c)]. The shape of the jet cross section [Fig. 6(c)] remains nearly elliptical as in Fig. 6(a). In the follow-up, both midplane plots clearly reveal the presence of a lengthwise vena contracta. A careful inspection of the jet width in the midsagittal plane shows a somewhat smaller width than at the initial state after glottis opening. This trend continues for the whole phase in which the glottis is open, meaning that the vena contracta effect in this plane becomes more pronounced during the further evolution of the jet [Figs. 6(d)–6(f)]. Maximum volume flow is reached between instants (d) and (e). In this case without VFs, the jet is allowed to spread in crosswise direction in the vocal tract during its emerging and evolving stages: the jet front almost occupies the complete channel height in the midcoronal plane.

Figure 7 shows the flow results in the same midsagittal and midcoronal planes for the case with VFs. This helps to describe the influence of the VFs upon the glottal jet. After opening of the glottis, the jet emerges and is immediately attached in this cycle to the upper wall of the VFs [Figs. 7(a) and 7(b)]. This asymmetry in the flow has been already observed in the previous study by Brücker *et al.* (2004) and later by other groups (Kucinschi *et al.*, 2006; Krane *et al.*, 2007). At maximum glottal opening [Fig. 7(c)], the jet is still attached to the upper wall of the VFs. The lengthwise vena contracta is also clearly observed in both midplane plots for the case with VFs during the closing phase, with a similar

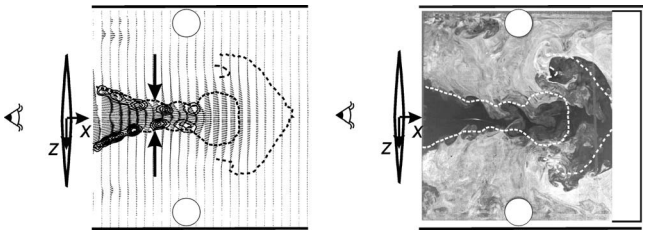

FIG. 8. Flow field at $t/T_0=0.40$ after glottis opening (without VFs) in the midsagittal plane of the channel for $\Delta p=6$ cm H_2O. Left: velocity vector plot with isocontours of in-plane speed as values in real natural phonation of 3.5 and 10 m/s (dashed lines) and isocontours of lengthwise vorticity from 0.02 to 0.2 (solid lines). Right: flow visualization image including isocontours of in-plane speed from left image.

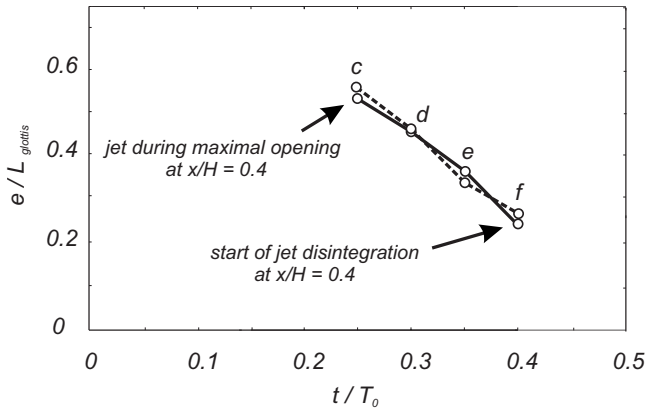

FIG. 9. Temporal change in jet vena contracta width for the case without VFs in the midsagittal plane at $x/H=0.4$ for $\Delta p=6$ cm H_2O from PIV data (dashed line) and flow visualizations (solid line).

temporal evolution in the midsagittal plane as in the case without VFs. Meanwhile, one can see that the jet starts to detach from the downstream facing walls of the VFs [Figs. 7(d) and 7(e)] and enters the vocal tract in axial direction [Fig. 7(f)]. This suggests one of the functions of the second constriction in the channel between the VFs to focus the jet in axial direction. Furthermore, recirculations are formed in the Morgagni's ventricles during the glottal cycle. Analysis of several successive cycles show that the characteristic dynamics of the jet repeat similarly to the previous cycle. However, the side to which the jet first attaches to the VFs after glottis opening seems to occur randomly. The measurements suggest that this is linked to the influence of flow structures left in the vocal tract by the jet breakdown in the previous cycle. Therefore, it is expected to see a stronger influence of the shut-off phase of the jet onto the next cycle for increased open quotients.

For both cases, without and with VFs, instabilities occur already in the early stages of the jet formation in form of staggered shear-layer vortices. The jet flow with its small to moderate velocities in this convergent opening phase of the glottal cycle is accelerated further in the divergent closing phase. In the late stage, a meandering of the jet tail with high velocities is observed, while the jet front—a plumelike structure—travels further unaffected. This finally results in a smoothly shrinking and rupture of the tail at glottis closure, which leaves the jet front plume as an independent bulk of momentum. Further disintegration of the jet plume appears to be of strong dissipative nature. The experiments with VFs show that the VFs prevent a growth of the jet edge instabilities. The jet core is smoothly directed toward the sidewalls of the ventricular walls, where the jet builds up a new boundary layer. It is clear from the experiments without and with the VFs that the second constriction built by the VFs additionally stabilizes the jet.

The obvious difference of the jet cross-section in the different transverse planes demonstrates the 3D nature of the jet flow which is in addition changing over time. First, the flow in the midsagittal plane of the glottal model without VFs is considered. A coefficient of contraction is defined here as the ratio between the contraction width e at the downstream position $x/H=0.4$ and the instantaneous glottal length, L_{glottis}, so that the phenomenon of the lengthwise vena contracta is quantified. For the determination of the contraction width e, consider Fig. 8 (left). This figure shows exemplarily for the case without VFs the velocity field in the midsagittal plane obtained by PIV at instant (f). Note that for the sake of clarity, only each fifth velocity vector in x-direction is shown. In addition, the isocontours of the in-plane speed of 10 m/s (thick dashed line) and partially of 3.5 m/s (thin dashed line) are illustrated. The closed solid isocontour lines designate regions of concentrated crosswise vorticity in levels with values ranging between 0.02 and 0.2 s^{-1}. A convenient way to define the jet edge is to connect the points of maximum vorticity in the shear-layer vortices. Figure 8 (left) demonstrates that the isocontour of the in-plane speed of 10 m/s is appropriate to define the jet edge and by this means to determine the contraction width e of the glottal jet (indicated here by the arrows at position $x/H=0.4$). The coefficient of contraction is plotted in Fig. 9 for the instants (c)–(f) in the glottal cycle. An approximate linearly increasing contraction (decreasing e/L_{glottis}) is observed for the late stage of the glottis motion. For the sake of completeness, the isocontours of speed have been transferred to the corresponding flow visualization image in Fig. 8 (right) affirming that the jet in the PIV measurements and in the flow visualizations with dye shows a similar behavior. As already mentioned, the vena contracta phenomenon is enhanced over the cycle, finally leading to a thin meandering high-speed long-tailed structure in the closing phase. This is diametrically opposite to the observed jet evolution in the midcoronal plane. While at the beginning the jet width in this plane is rather small, it continuously increases in the closing phase, where the downstream glottis contour changes from a parallel to a divergent shape [Figs. 3(c) and 3(d)]. To further investigate this behavior, a measuring plane in the cross-sectional transverse plane is arranged at $(x/H=0.4)$. The PIV measurements were analyzed in the way to discriminate the jet core in the radial cross section from the ambient fluid. Again, isocontours of speed delineate the border of the jet core. These contours are shown in Fig. 10 over successive instants in the cycle. While the cross section has an elliptic contour in the same orientation as the glottal orifice until instant (d), it switches its aspect ratio at the end of the open cycle [Figs. 3(e) and 3(f)]. Note that this behavior results from the imposed motion of the orifice over time and therefore, it can be titled as in-cycle temporal axis switching of

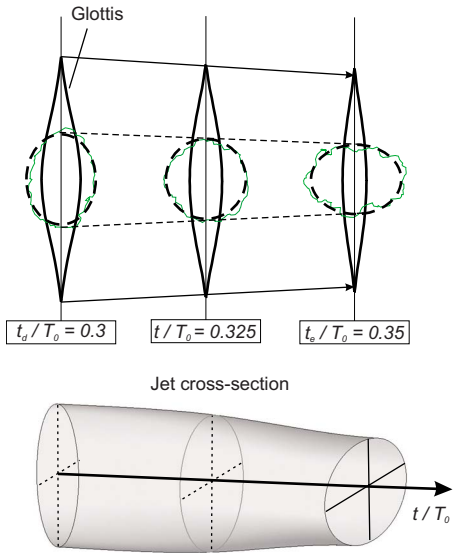

FIG. 10. (Color online) Approximate shape of temporal evolution of the average jet cross section (contour of constant in-plane velocity) in the plane $x/H=0.4$.

the jet. The phenomenon of axis switching in jets through static elliptic orifices has been studied in the past by Hussain and Hussain (1989).

The flow visualizations shown in Fig. 11 (case without VFs) and Fig. 12 (case with VFs) confirm the PIV results. The left column shows the midcoronal plane, and the right column shows the midsagittal plane of the vocal tract. In Fig. 11 the six instants (a)–(f) are presented from top to bottom. In Fig. 12, only the instants (c)–(e) are shown. After jet plume formation, characteristic coherent structures become visible in the jet. It has been observed that these jet structures and their interactions, including vortex pairing, are reproducible from cycle to cycle. Jet axis switching is also evident from the visualizations. The strong lengthwise vena contracta, along with the meandering and decay of the jet, is characteristic in the second half of the open part of the cycle. The small scale structures of the jet edge shear-layer instability are of the order of 1/40 of the channel height and are focus of current studies with measuring techniques with high resolution such as PIV. The coefficients of contraction obtained from these flow visualizations for the instants (c)–(f) in the glottal cycle have been added in the plot in Fig. 9 (solid line). The values show good agreement with the data from the PIV measurements. The existent deviations are first due to different glottal cycles used in the measurements and second due to differences in the spatial resolution of PIV and the flow visualizations. The limited spatial resolution in PIV leads to a frazzle of the isocontours of the in-plane speed. By contrast the dye visualizations give a detailed view of the jet edge instabilities and Kelvin–Helmholtz vortices.

In this section, the flow downstream the dynamic elliptical glottal orifice without and with VFs has been shown to be highly unsteady and of three-dimensional nature. The results show the following: jet axis switching, a strong lengthwise vena contracta which evolves in time, jet edge instabilities, and jet breakdown. Repeated measurements have shown

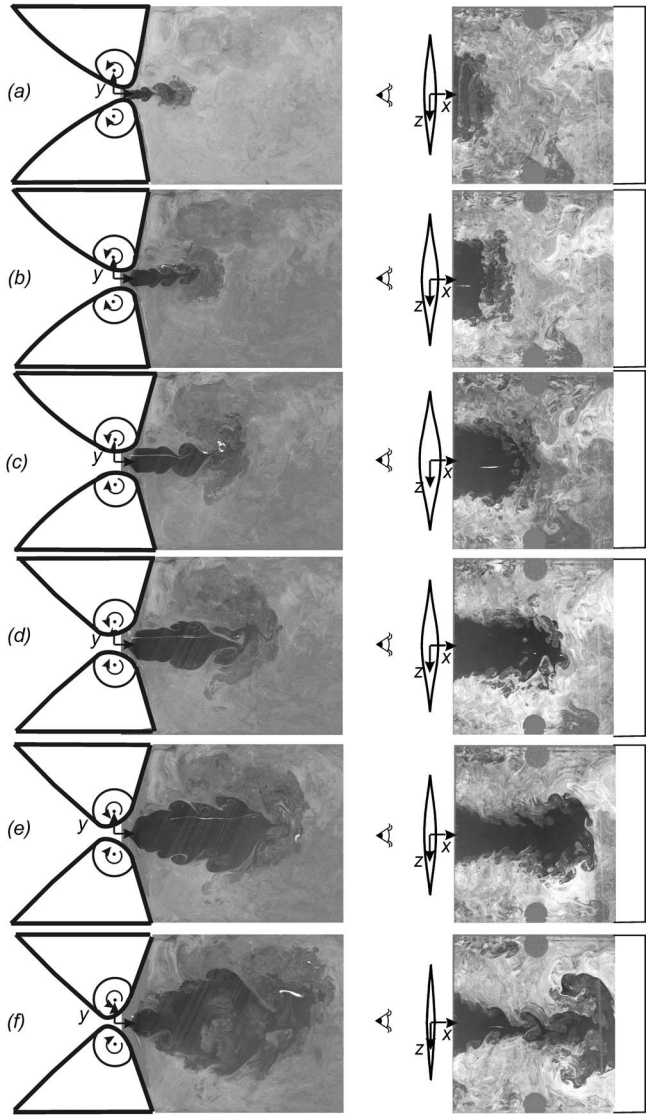

FIG. 11. Visualization of the glottal flow (without VFs) in the midcoronal plane (left) and midsagittal plane (right) of the channel for $\Delta p = 6$ cm H_2O for instants as in Fig. 6.

that the jet behavior is consistent from cycle to cycle, despite some cycle-to-cycle variations mainly at the early stages of the jet formation.

C. Influence of glottal orifice shape and driving pressure head

The character and behavior of the 3D jet past the model glottis depend on the glottal orifice shape. Mainly in the sagittal plane, the flow structures downstream of the cam model are expected to develop according to the 3D contour of the glottal orifice shape. In order to investigate this influence, additional measurements were performed for the jet in the midsagittal plane downstream of a glottal orifice with a rectangular cross section but a similar dynamic behavior of the opening and closing contours, compare Fig. 3. The normalized glottal area time function for the rectangular opening has been chosen to be similar to that of the elliptical opening shown in Fig. 1. The flow in the midsagittal plane for the instants (c)–(e) is shown in Fig. 13 in a view through

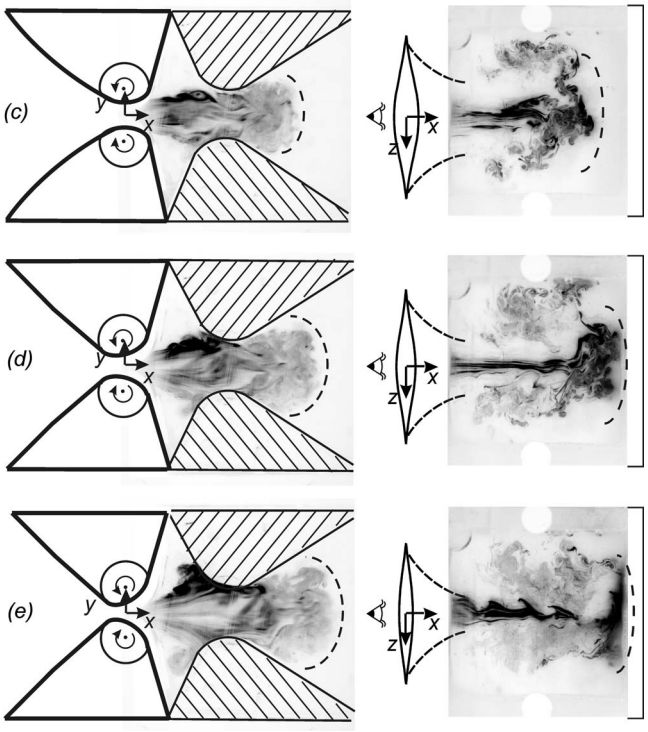

FIG. 12. Visualization of the glottal flow (with VFs) in the midcoronal plane (left) and midsagittal plane (right) of the channel for $\Delta p=6$ cm H_2O for instants as in Fig. 6. The dashed lines indicate the location of the jet front.

the liquid-filled modeled VFs. For the rectangular glottal opening, the contraction of the jet in this plane is constant throughout the open phase of the glottal cycle and is smaller than in the case of the elliptical glottal orifice in Fig. 12. These visualizations evidence that the strong jet contraction in the elliptical glottal orifice case is the effect of the shrinking of the glottis length L_{glottis} during the closing phase.

Next, the influence of the driving pressure head is shown in Fig. 14. The flow in the midsagittal plane (without VFs) for the instant of maximum opening is compared for the pressure heads of $\Delta p=6$ cm H_2O and $\Delta p=14$ cm H_2O. These results are velocity fields phase-averaged over 100 cycles at the same cycle instant. The cyclic variations are exemplarily shown in the instantaneous velocity fields for three different cycles in Fig. 15. These evidence the random tendency (slightly upward, straight or slightly downward) of the plume front of the emerging glottal jet from cycle to cycle. For $\Delta p=14$ cm H_2O, the jet front has traveled almost the double distance further downstream into the vocal tract than for $\Delta p=6$ cm H_2O. In general, the jet shows a similar behavior from cycle to cycle. In the starting acceleration stage of the flow, the low speed jet front is sensitive to any disturbances in the remaining flow in the vocal tract and to smallest inaccuracies in the cams that form the vocal folds. These effects together determine the starting behavior of the jet front. For increased transglottal pressures and in the later stages in its evolution, the jet is stabilized due to the higher velocities.

IV. SUMMARY AND OUTLOOK

The complex unsteady 3D vortex dynamics in the vocal tract was studied in a 3:1 upscaled dynamical model of the human vocal folds (Fig. 2). Volume flow velocity waveform measurements and flow visualizations for normal phonation conditions have been carried out. The modular construction of the setup allowed analyzing the flow in the absence and presence of modeled VFs, which build a second constriction in the test channel. A realistic volume velocity waveform as observed in real speech is obtained for the prescribed transglottal pressure, fundamental frequency, open quotient, and realistic glottal motion. Characteristic details of the evolution and redistribution of vortices could be detected qualitatively and quantitatively.

The experiments reveal a clear picture of the 3D and

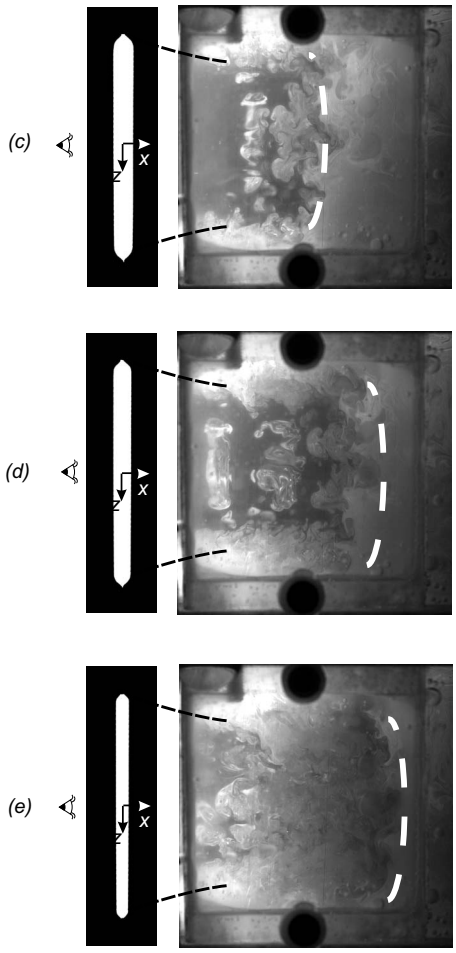

FIG. 13. Visualization of the glottal flow (with VFs) in the midsagittal plane of the channel for $\Delta p=6$ cm H_2O and a rectangular opening shape of the glottis for the instants (c)–(e). The black dashed lines indicate the phase-invariant constant contraction of the jet, while the white dashed lines indicate the location of the jet front.

unsteady nature of the glottal jet in the glottal cam model.

(a) The flow rate measurements in the cam model indicate that the maximum volume flux occurs later than the maximum opening of the glottis. Therefore, convective flow acceleration in the glottis is still present in the closing phase and maximum flow velocities occur later in the cycle while the glottis is in the closing phase. In addition, the measurements demonstrate a reduction in the dynamic transglottal pressure loss in the case of a vocal tract with VFs.

(b) There is a lengthwise vena contracta, which increases with time up to the end of the cycle. Thus the developing jet does not have its maximum width in the lengthwise direction but rather the opposite. This is the consequence of two contributing factors: first, flow through an elliptic orifice in general leads to the so called axis switching of the jet, which is observed in these dynamic experiments, too. Second, with the beginning of glottis closure, the lengthwise scale of the glottal orifice shrinks in the same manner as the width of the glottal gap; therefore, flow is forced to redirect toward the center of the glottal axis. Simultaneously, the cross section of the glottis has changed to the divergent form; thus, the flow can still expand in crosswise direction. These dynamic features of the jet strongly depend on the glottal motion pattern and glottal orifice shape, as the comparison with a rectangular orifice in dynamic mode could show.

(c) No considerable asymmetric lateral or transversal deflection of the glottal jet and no final attachment to one of the side walls of the vocal tract is observed. Instead, the jet exits the glottal gap mainly aligned with the channel axis. Some small deviations could be observed in the regions of the front plume of the jet. This observation holds for the complete buildup and decay of the jet. With increasing pressure head, the jet front is redirected more with the centerline direction of the channel axis. The fluctuations at lower pressure heads seem to result from small inaccuracies of the cams, which may not be perfectly symmetric and which affect the flow only for smaller velocities. The results show the important differences in the flow of a dynamic glottal motion in comparison with the flow results in a static orifice. With the given open quotient of 0.5 and the pressure heads investigated, it seems that the characteristic time scale of buildup and decay of the jet is not long enough to establish any energetic large scale vortices downstream in the vocal tract, which might support the jet deflection. Again, the presence of the VFs further reduces any asymmetric features of the early stage of the jet front and redirects the jet into the axial direction.

(d) The dynamic jet maintains shear-layer instabilities and vortex rollup during the complete cycle of buildup and decay. These vortices interact with the walls on the VFs and may contribute to vortex-induced sound in the acoustic spectrum of the primary sound source generated in the glottis.

(e) Due to the delay of maximum volume flux with respect to maximum glottal opening, one would expect a rather sharp jet breakdown. The measurements on the other hand show a smooth disintegration of the jet at the late stage of glottal closure due to the three-dimensional closure with a smooth closing of the contact line similar to a closing two-slider zipper from both sides of the lateral edges of the glottis.

These results hold for the given conditions in the glottal cam model, prescribed in the form of the pressure head, the fundamental frequency, the glottal motion profile, the glottal orifice shape, and the open quotient. The sensitivity of the flow field to changed parameters, especially to the way the glottal profile and waveform is replicated in the experiments, will be studied in more detail in the near future. Other glottal opening types especially nonsymmetric openings may lead to strongly different flow fields.

The experimental results are used for input and comparison with numerical simulation of our group with exactly the same initial and boundary conditions.

(Received 19 December 2008; revised 17 November 2009; accepted 30 November 2009)

Six aryepiglottic trills with varied laryngeal parameters were recorded using high-speed laryngoscopy to investigate the nature of the oscillatory behavior of the upper margin of the epilaryngeal tube. Image analysis techniques were applied to extract data about the patterns of aryepiglottic fold oscillation, with a focus on the oscillatory frequencies of the folds. The acoustic impact of aryepiglottic trilling is also considered, along with possible interactions between the aryepiglottic vibration and vocal fold vibration during the voiced trill. Overall, aryepiglottic trilling is deemed to be correctly labeled as a trill in phonetic terms, while also acting as a means to alter the quality of voicing to be auditorily harsh. In terms of its characterization, aryepiglottic vibration is considerably irregular, but it shows indications of contributing quasi-harmonic excitation of the vocal tract, particularly noticeable under conditions of glottal voicelessness. Aryepiglottic vibrations appear to be largely independent of glottal vibration in terms of oscillatory frequency but can be increased in frequency by increasing overall laryngeal constriction. There is evidence that aryepiglottic vibration induces an alternating vocal fold vibration pattern. It is concluded that aryepiglottic trilling, like ventricular phonation, should be regarded as a complex, if highly irregular, sound source. © *2010 Acoustical Society of America.* [DOI: 10.1121/1.3299203]

I. INTRODUCTION

There are numerous structures in the vocal tract apart from the vocal folds that can generate phonatory oscillations when subject to appropriate aerodynamic conditions: the esophagic sphincter, ventricular folds, and aryepiglottic folds are some examples (Catford, 1968; Lindestad *et al.*, 2001; Sakakibara *et al.*, 2004). The use of these structures in generating a voice source has been observed for pathological cases, where vocal fold phonation is not possible or done inefficiently (Fröhlich *et al.*, 2000; Schwarz, 2007). The aryepiglottic folds are unique among these structures because they roughly parallel the vocal folds in their ability to produce both articulations and phonatory voicing sources. The aryepiglottic folds contribute a very distinct category of phonation, typically referred to as growl or harsh voice. Singers such as Louis Armstrong, Louis Prima, Koko Taylor, and Tom Waits readily come to mind as famously exploiting aryepiglottic vibration to produce their unique singing styles, illustrating the application of the sound as a voice quality. Esling (1996) and Edmondson and Esling (2006) argued that the aryepiglottic folds play a central role in forming the primary constriction in the pharynx associated with pharyngeal articulations in general. More specifically, these researchers re-attribute the former categories of epiglottal and pharyngeal to the (active) aryepiglottic and the (passive) epiglottal place of articulation, which forms the locus of pharyngeal constriction, achieved supplementarily by retraction of the tongue (and epiglottis) and by raising of the larynx. Their laryngoscopic evidence shows that numerous languages employ the aryepiglottic folds in a variety of ways to produce linguistic contrasts (Carlson *et al.*, 2004; Edmondson *et al.*, 2005; Esling and Edmondson, 2002; Esling *et al.*, 2005). Articulatory possibilities include stop, fricative, approximant, trill, and possibly even tap.[1] The aryepiglottic sphincter is shown to play a role in the production of creaky[2] and harsh voice, which also can exhibit aryepiglottic trilling/vibration. Additionally, languages containing pharyngeal fricatives and approximants can use aryepiglottic vibration as a means of enhancing the distinctiveness of these sounds (Esling, 2005).

The aryepiglottic folds are anatomically situated at the top of the epilaryngeal tube (also referred to as the laryngeal vestibule; see Fig. 1). The tube can be reduced in volume and ultimately form a protective hermetic seal by means of laryngeal constriction (in the sense of Gauffin, 1977; also see Fink, 1975, pp. 85–102). Titze (2008) argued that this tube plays an important role in coupling the glottal source to the rest of the vocal tract, specifically when the epilaryngeal tube is reduced in cross-sectional area through laryngeal constriction (less than or equal to 0.5 cm^2). Two interactions between the vocal folds and the epilaryngeal tube are identified: First, flow pulse skewing can energize glottal harmonics below the first resonance of the vocal tract and, second, vocal

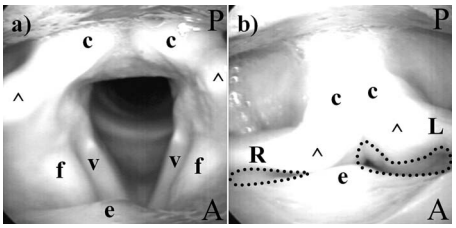

FIG. 1. A superior view of the epilaryngeal tube during the video of a voiced aryepiglottic trill at 100 Hz. Image (a) shows the tube in its unconstricted state (frame 19), and image (b) shows the tube in its constricted state (frame 396). Dotted-line=aryepiglottic aperture, c=corniculate tubercle, ^ =cuneiform tubercle, e=epiglottic tubercle, f=ventricular (false) fold, v =vocal fold, R=right aryepiglottic fold, L=left aryepiglottic fold, A =anterior (front), and P=posterior (back).

fold oscillatory efficiency (the ratio of radiated acoustic power to aerodynamic power) can be enhanced. Using computational models, both of these effects are evinced to be augmented under conditions of reduced epilaryngeal tube area at the expense of destabilizing the oscillation of the vocal folds. Additionally, the epilaryngeal tube also contributes to the resonances of the vocal tract. With respect to the acoustics of the singing voice, Sundberg (1977) claimed that the epilaryngeal tube (or, in his terms, the outlet of the larynx) becomes independent of the vocal tract and produces its own resonance when the cross-sectional area of the epilaryngeal tube is one-sixth the area of the pharynx. Titze and Story (1997) further argued that the epilaryngeal tube is most suitably characterized as a quarter-wave resonator with its first resonance between 2500 and 3000 Hz (also known as the singer's formant). Under voiceless conditions, a turbulent noise source can be produced from an air jet impinging on the posterior surface of the epiglottis and the medial surfaces of the ventricular folds. Stevens (1998, p. 430) estimated that as much as two-thirds of the acoustic energy in glottal fricatives [h] is produced at the surface of the epiglottis. Stevens' (1998) analysis assumes that the pharyngeal airway is not constricted, which presumably means that the epilaryngeal tube is also considered to be unconstricted (i.e., unreduced in cross-sectional area). It is suspected, however, that increased constriction of this tube would also yield an effect on the character of laryngeal-pharyngeal noise sources, which characterize the voiceless pharyngeal fricative /ħ/. For Arabic /ħ/, Butcher and Ahmad (1987) reported high intensity frication noise values with a lower limit between 500 and 1500 Hz and distinct concentrations of noise energy in formant regions associated with the vowel context.

Overall, laryngeal constriction causes the epilaryngeal tube to change the acoustic and aerodynamic properties of the vocal tract. In addition to these effects, the oscillatory capacity of the epilaryngeal tube represents a further degree of complexity of the laryngeal system as a whole. Specifically, it is posited that aryepiglottic trilling can be regarded as a vocal tract source, one that can interact with the glottal source but that is also independent from it. The purpose of this paper is to adduce evidence that supports this characterization and provides an illustration of the oscillatory nature of aryepiglottic trilling in general. The assertion that the aryepiglottic folds are source generators will be supported by comparing aryepiglottic aperture data and kymographic traces with the corresponding acoustic waveforms and electroglottograph (EGG) signals for several aryepiglottic trills with various glottal settings (i.e., pitch and the presence or absence of voicing). The appropriateness of the phonetic label *trill* will also be a central point of discussion, and the decision to use the label is motivated by the data brought forth in this study.

II. HIGH-SPEED LARYNGOSCOPIC DATA

High-speed laryngoscopic videos of six different aryepiglottic trills were studied. All of the trilling sequences were performed by Esling, a 60-year-old male phonetician, who was trained in the Edinburgh tradition of phonetics. Two sets of aryepiglottic trills were performed with an [ə] vocalic target: one voiced and one voiceless. In the voiced set, glottal pitch was targeted at 100 and 200 Hz. In the voiceless set, the subject produced the trills by emulating the voiced configurations required for 100 and 200 Hz while keeping the vocal folds abducted (so that the sound produced would be voiceless). An additional parameter for both voiced and voiceless trills was explored: degree of laryngeal constriction. These are called "tense" trills (cf. Heselwood, 2007), although no claims as to the exact degree of muscular tension are made; rather, the term reflects the subject's own interpretation of his performance, expressing the extra effort or tension in producing these sounds. The performances were facilitated by the use of pre-recorded target sounds, which the subject listened to using headphones during the video recording session.

The system used to capture the trilling sequences was an SL Kamera 500 connected from a rigid oral endoscope to a SpeedCam Lite interface (Weinberger, Erlangen, Germany), which was set to a frame rate of 500 Hz (one frame for every 2 ms) with a resolution of 262×256 pixels. Recording was done at the Sorbonne-Nouvelle Paris III/CNRS-LPP-UMR 7018 research site at l'Hôpital Européen Georges Pompidou, Paris. The average sequence length was 1.945 s (or around 972 frames). Throughout the recording session, the audio signal of the trills was obtained using a head mounted AKG C410 microphone, positioned at 4 cm from the lips, with an angle of 45° from sagittal plane, sampled at 44 100 Hz, 16-bit resolution. The EGG signal was obtained using a Glottal Enterprises EG2-PCX electroglottograph; the surface electrodes were placed externally on each thyroid lamina, which was constant for all trill performances. The audio and video signals were digitized using ANAVOX (custom software; Vannier-Photelec, Antony, France). A time-to-live signal was used to ensure synchronization of the audio with the video signal. The videos were digitized frame by frame in uncompressed format and later stored as uncompressed TIFF files for analysis in MATLAB.

III. AUTOMATED IMAGE ANALYSIS

An automated image analysis technique was employed to analyze the high-speed laryngoscopic videos. This involved assessing the percent of aperture formation for each of the aryepiglottic folds during oscillation. These data are

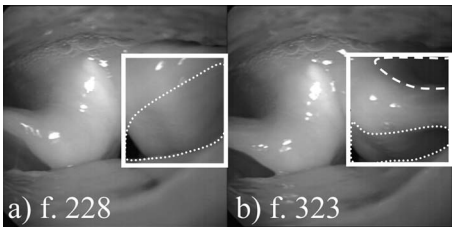

FIG. 2. Non-tense voiceless aryepiglottic trilling. The left fold undergoes extreme displacement, making ROI placement (solid rectangle) over the aperture (dotted-line) difficult. In (a) the left aperture is wide and requires a large ROI in frame 228 of the sequence. The same aperture in (b), however, at frame 323 encloses area over the piriform fossa (dashed-line) in addition to the aryepiglottic aperture.

accompanied by kymographic images and EGG signal for comparison. The following sections discuss this analysis in detail.

A. Aperture area analysis

The aperture analysis involved the identification of regions of interest (ROIs) across the sequence of video frames for both of the aryepiglottic apertures (defined by the subject's right and left aryepiglottic folds; see Fig. 1) and then processing these regions to yield an image that could be measured using MATLAB's image processing functions, e.g., `bwarea()`. Two problematic circumstances arose that required special ROI placement for the left aryepiglottic aperture. For the normal and tense voiceless aryepiglottic trills at 100 Hz, the left aryepiglottic aperture fluctuated so much that it was difficult to select a ROI that maximally excluded non-aperture related areas (primarily the piriform fossa). This is illustrated in Fig. 2(a), where a ROI (solid line; not used in the actual analysis) is placed over an area large enough to enclose an extreme displacement of the left aryepiglottic fold (dotted-line). Later in the trilling sequence [Fig. 2(b)], the same ROI encloses a large portion of the space associated with the piriform fossa (dashed-line), in addition the aryepiglottic aperture itself. Another problem was observed for the voiced aryepiglottic trill at 200 Hz, where the epiglottis occluded the view of the left aryepiglottic aperture entirely, as seen in Fig. 3. In both of these extenuating cases, it was decided that oscillation information for the left aryepiglottic aperture could be still obtained by placing the ROIs over the left piriform fossa instead. Thus, for these cases, the ROIs used in the analysis monitor the position of the posterior surface of the left aryepiglottic fold as it occludes the view of the left piriform fossa. The resultant signal was inverted to match the phase of the actual aperture, which was assumed to be opposite to the signal (i.e., the observed piriform fossa area enlarges when the left aryepiglottic aperture diminishes). The drawback of this approach is that any subtle, minor vibrations (i.e., surface mucosal waves) only visible on the inner portion of the fold are lost; this was deemed an acceptable sacrifice so that at least major pulse information could be collected for the offending fold.

ROI processing is illustrated in Fig. 4; the leftmost image shows frame 236 of the voiced aryepiglottic trill at 100 Hz. In this frame, both the right and left ROIs are outlined. The processing steps used for all ROIs are demonstrated for

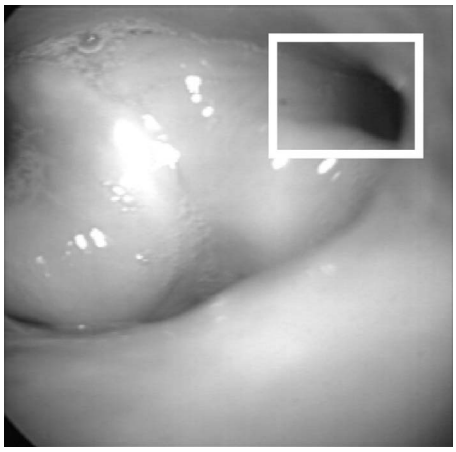

FIG. 3. Frame 166 of the "200 Hz" voiceless aryepiglottic trill. The left aperture is barely visible, but oscillation information was obtained by tracking a ROI (solid rectangle) placed over the left piriform sinus (upper right hand corner) and then inverting the signal. The right aperture is visible as a dark sliver (bottom left hand corner).

the right aperture in the images on the right [Figs. 4(a)–4(c)]. The ROIs were first extracted [Fig. 4(a)] from their corresponding frame and then inverted [Fig. 4(b)]. Before area measurement can be made, the image needs to be in binary representation [Fig. 4(c)]. This step requires a black-white luminance threshold value to be selected. The threshold values were determined automatically (prior to the actual measurement routine) by calculating the average grayscale value for each ROI from its grayscale histogram using the `imhist()` function in MATLAB. An average of all of the mean grayscale values for all ROIs in a given sequence was obtained and converted to a luminance threshold value by dividing by 255 (the number of values in an 8-bit grayscale image). Aperture data are expressed as a percentage of the maximum aperture area value recorded for a particular sequence and fold. Exact values for all parameters of the image analysis are presented in Table I. The overall process was automated using simple MATLAB scripts.

As a complement to the aperture data, kymographic images (e.g., Švec and Schutte, 1996) were created for both the left and right aryepiglottic apertures. A line of pixels (the kymographic line) was selected for each aperture, which was

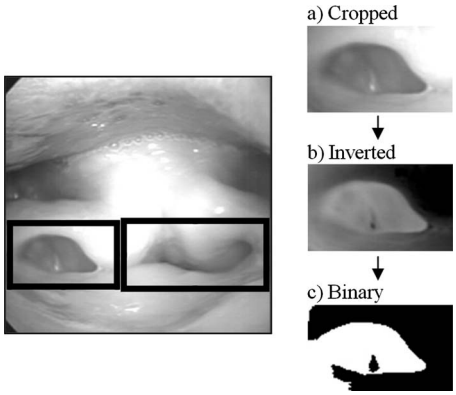

FIG. 4. Illustration of ROI definition over the left (larger rectangle) and right (smaller rectangle) aryepiglottic apertures and image processing sequence to arrive at a binary image that can be measured for aperture area.

different in every video. The lines were selected such that they were perpendicular to the visible section of the fold (at rest) and bisected it. In some cases, due to camera position (as in Fig. 2), only a small portion of the fold was visible. In this case, the line was placed such that it passed through the point on the visible fold that exhibited the greatest displacement. Line length was decided by viewing the entire video and determining the minimal length required to capture as much of the aperture oscillation as possible while excluding non-aperture related image information. This process was complicated by the fact that in several videos the position of the larynx changes slightly through the performance of the aryepiglottic trill, which means that the image of the larynx migrates somewhat. Ultimately, the lines were only used if all of the researchers agreed that they represented the optimal choice given the video data.

The data obtained from the kymographic images were then converted into an oscillatory signal simply by summing the grayscale values for each line in the kymographic image. In the case that a kymographic image included non-aperture data (e.g., an image of the piriform fossa due to migration of the image of the larynx), these areas were masked by setting the pixel values to zero. The kymographic "signal" was then compared to the aperture data using cross-correlation analysis to quantify how similar the two signals were. Successful matching of the signals was defined to be indicated by a normalized zero-lag component of the cross-correlation analysis above 0.7071.[3] None of the signals obtained in this method resulted in a cross-correlation less than 0.7071; values of the analysis are presented in Table I.

The final technique used to analyze the aperture data was peak detection analysis, using a MATLAB script developed by O'Haver (2006), which allowed the average frequency and jitter of the EGG and aperture signals to be calculated. A peak detection analysis window of 50 ms was used for all signals; in the case of the aperture data, this window typically included two to five aryepiglottic pulses. There was a 25 ms overlap interval between analysis windows. The frequency of the signal for each analysis window was determined to be the inverse of the average peak-to-peak (the signal was always positive) interval time; the frequency for the entire signal was the average of all analysis window results. Jitter was calculated by taking the standard deviation of all peak-to-peak durations in the signal.

Sections III A 1–III A 4 present a selection of data from the analysis described above that serve to characterize the nature of aryepiglottic trilling for our subject. Sections III A 1 and III A 2 examine the basic aryepiglottic trill in voiced and voiceless contexts; in both cases a contiguous set of 25 video frames is presented alongside an array of synchronized plots of the aryepiglottic aperture data, the kymographic images, and the audio signal. Section III A 3 documents the tense voiceless aryepiglottic trill. Section III A 4 presents data for all trills including acoustic spectra and Table II, which contains root mean square (rms) intensity values and peak detection analysis values.

1. Voiced aryepiglottic trill

Twenty-five frames of the voiced aryepiglottic trill produced at a glottal frequency of 100 Hz are presented in Fig. 5. The lines used to create the corresponding kymographic images have been superimposed on the first frame. This set corresponds exactly to a time period between 0.800 and 0.850 s in the data plots displayed in Fig. 6. In this time period, two right aryepiglottic fold pulses can be seen; the left fold also exhibits two major pulses, each with an additional minor pulse evident both in the kymographic image and the aperture signal. Throughout the entire trill, the right aryepiglottic fold oscillates semi-periodically; it typically makes complete contact with the surface of the epiglottis. Additional pulses tend to occur when complete contact is not made (e.g., at 0.860, 1.030, and 1.170 s). The gross movements of the left aryepiglottic fold appear to be largely in phase with the right fold during the section shown in the plots and have roughly the same frequency (see Table II); however, very often in this sequence the left fold oscillates with major and minor pulses, particularly between 0.800 and 1.100 s; after this point the pulsing diminishes in magnitude and the alternating major-minor pattern is not discernible. By

TABLE II. Intensity and frequency values for the audio signals of the voiced (vd.) and voiceless (vl.) aryepiglottic trills. rms intensity was obtained for the 200 ms region between the listed analysis frames. Frequency data are averaged across the entire trilling sequence.

	100 Hz		200 Hz		100 Hz tense

observing the videos themselves, the minor pulse of the left aryepiglottic fold appears to be a mucosal wave traveling on the aryepiglottic fold in the cranial (cephalad) direction. Comparison of the EGG signal with the audio and aperture data signals indicates that the aryepiglottic pulse actually corresponds to perturbations of the vibratory pattern of the vocal folds. A double peaked (or plateau-peak type) glottal pulse tends to occur every time the right aryepiglottic aperture is open (e.g., the pulse immediately after 1.000 s). The increase in noise in the acoustic signal at this point indicates that turbulent air is escaping from the glottis, which is open for a prolonged duration during the open phase of the right aryepiglottic pulse. When the right aryepiglottic aperture is closed, the glottis tends to open and close very rapidly. The left aryepiglottic aperture does not appear to have any discernible impact on the vocal folds, although its continually changing size is likely to impact supraglottal pressure.

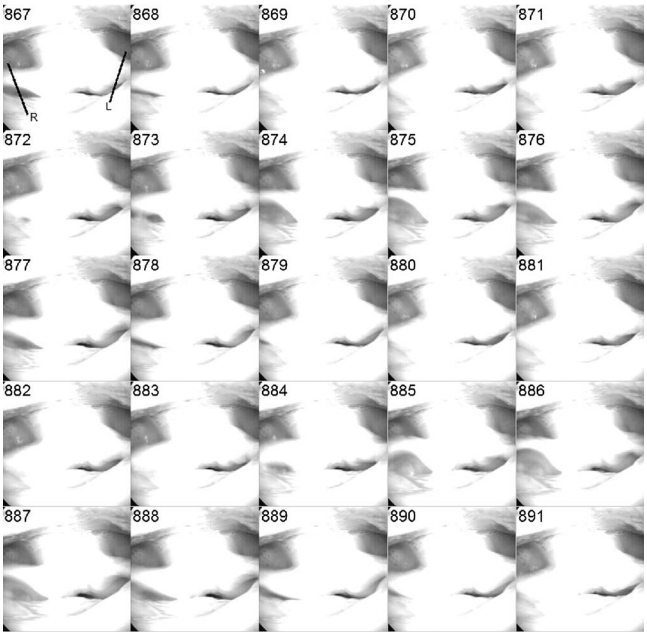

FIG. 5. Twenty-five frames of voiced aryepiglottic trilling (100 Hz glottal pitch, 25 frames, 50 ms). First frame (867) shows right and left lines used to extract kymographic images. Corresponds to Fig. 6 between 0.800 and 0.850 s.

2. Voiceless aryepiglottic trill

The first twenty-five frames and corresponding aperture and kymographic data of the voiceless aryepiglottic trill produced at an emulated 100 Hz can be seen in Figs. 7 and 8 (see Table II for frequency and intensity data). It is crucial to note that there was no actual glottal pulse, which is corroborated by the (essentially) flat EGG signal. Although the audio signal is considerably noisy (indicative of increased airflow due to glottal voicelessness), a distinctive pulse pattern can be seen, which roughly corresponds to the signals in the aperture data. Unlike the voiced aryepiglottic trill at 100 Hz, this trill exhibits massive left aryepiglottic fold displacement, as seen in the video frames (Fig. 7). Particularly interesting is the behavior of the left cuneiform cartilage, which can be seen to oscillate like a rubbery/highly elastic rod.

3. The tense voiceless aryepiglottic trill

An alternative voiceless aryepiglottic trill was performed by our subject; this sequence is considered to be a tense variant of the voiceless trill, although the degree of tension is not strictly quantifiable. Despite the vagary of its characterization, the data in Fig. 9 indicate that this trill merits consideration. It should be noted again that the sound is voiceless, confirmed by the relatively flat EGG signal. The right aryepiglottic pulse pattern shows alternating major pulse and minor pulses: The acoustic effect associated with the major pulse can be clearly seen in the audio signal as a distinctive pressure spike, particularly in the section between 0.450 and 0.700 s. The negative part of this spike appears to coincide with the opening phase of the right aryepiglottic pulse, while the positive part occurs when the aperture is more fully open. Between 0.300 and 0.500 s, the left aryepiglottic fold tends to exhibit the major-minor pattern. The minor pulses must occur for the entire fold (not just the interior surface) because the left aryepiglottic aperture data, in this case, are based on measurements above the piriform fossa. Between 0.500 and 0.700 s, the left aryepiglottic fold begins to exhibit a more steady oscillatory pattern with approximately equal intensity pulses.

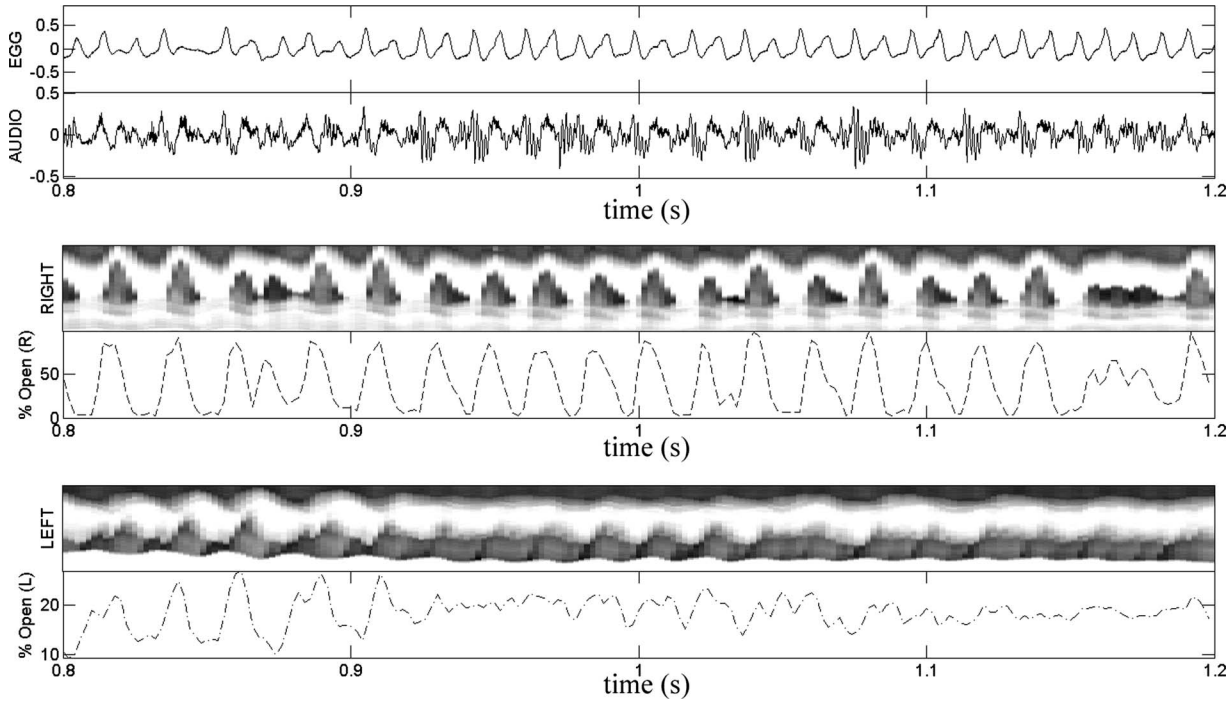

FIG. 6. Voiced aryepiglottic trilling (100 Hz glottal pitch): EGG signal and oscillogram (top), right aryepiglottic fold kymograph and aperture data (middle), and left aryepiglottic kymograph and aperture data (bottom).

4. Aryepiglottic trill frequency data

Figure 10 contains spectra for all six of the trills. All of the spectra were obtained using a fast Fourier transform calculated over a 100 ms section of relative signal stability, using a 20 Hz Gaussian window. As the signals are highly noisy, the lower harmonic content was best visualized by limiting the spectrum display from 0 to 500 Hz. The voiced aryepiglottic trills all have fairly well defined and intense glottal fundamentals, although the higher harmonics are not always clearly defined. The aryepiglottic pulses arguably explain the presence of nearly harmonic energy around the 50 Hz mark (in the 100 and 200 Hz voiced trills), although the noise in the signal and the jitter of the aryepiglottic pulse likely smear the pulse energy over a broader frequency range than the glottal pulse. The voiceless trills show harmonic spikes at values that correspond well with the values measured in the peak detection analysis (see Table II). The tense voiceless aryepiglottic trill is the exception to this where the spectral energy is exceedingly noisy; the peak at 70 Hz might correspond with the measured frequency of the folds, but the stronger peak at ~30 Hz is possibly attributable to the major pulse of the right aryepiglottic fold that characterizes this trill. As mentioned in Sec. III A 3, the fundamental frequency of 73.8 Hz for the right fold during this trill was estimated based on both the major and minor pulses. If the minor pulses are ignored, then the mean frequency for the right fold in the tense trill is 31.2 Hz, which agrees with the spectrum of this sound.

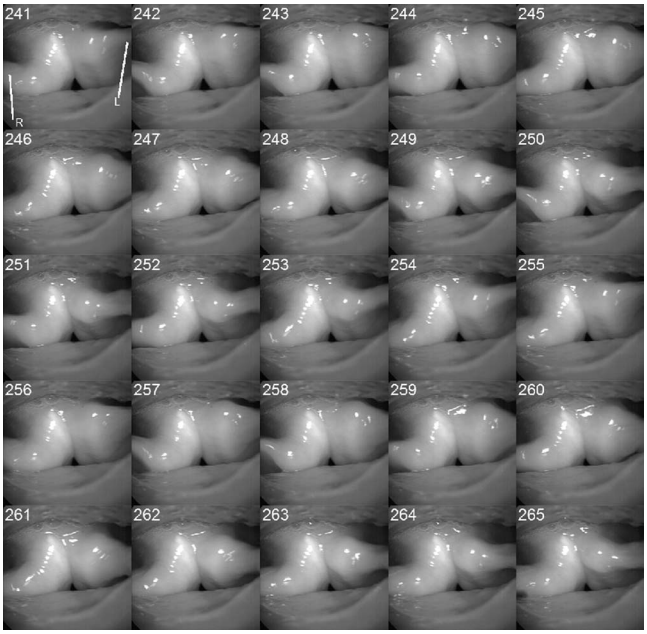

FIG. 7. Twenty-five frames of voiceless aryepiglottic trilling (emulated 100 Hz glottal pitch configuration, 25 frames, 50 ms). First frame (241) shows right and left lines used to extract kymographic images. Corresponds to Fig. 8 between 0.100 and 0.150 s.

Table II provides a listing of all measurements pertaining to the intensity of the overall signal and frequency of the vocal and aryepiglottic fold pulses. In all voiced cases, the average frequency of the glottal pulse (calculated from the EGG signal) corresponds well with the desired target pitches (100 and 200 Hz). In the case of our subject, the right aryepiglottic fold exhibits a frequency range between 55.8 and 92.0 Hz. The subject's left aryepiglottic fold was more difficult to measure (as discussed above in Sec. III A); it ranged between 42.4 and 100.8 Hz. Although not entirely consistent, the tense trills can be said to increase the pulse frequency for both of our subject's aryepiglottic folds by roughly 10–40 Hz.

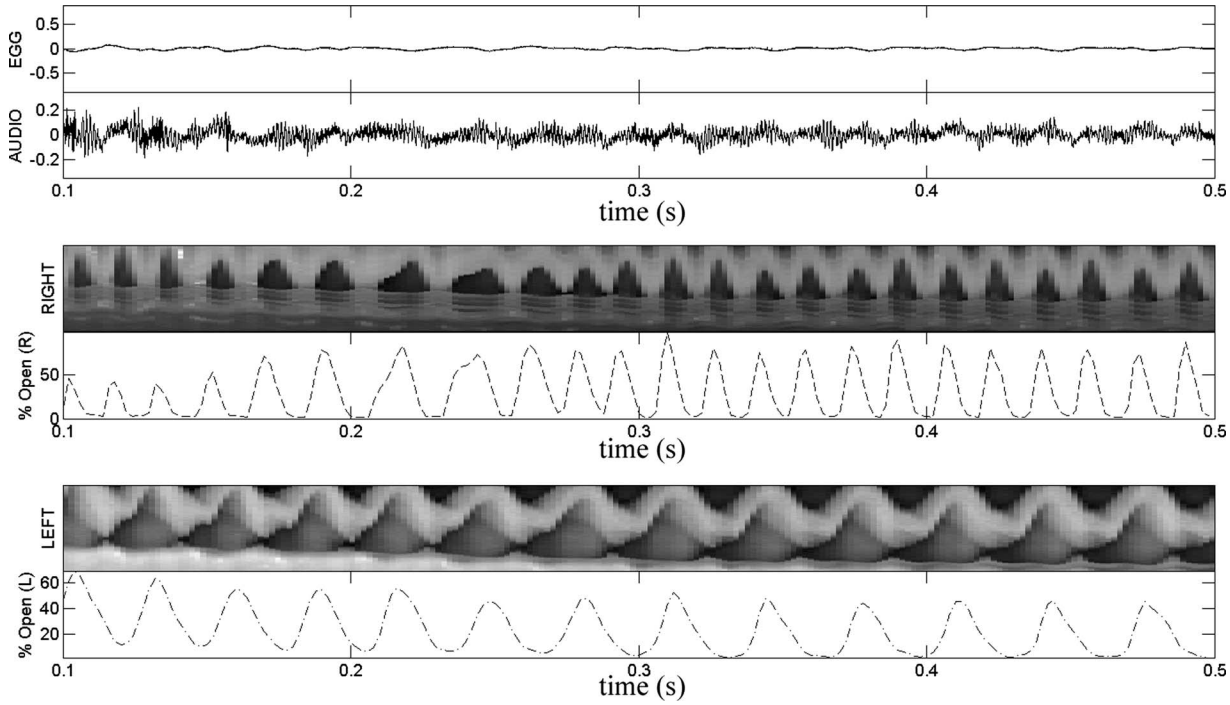

FIG. 8. Voiceless aryepiglottic trilling (emulated 100 Hz glottal pitch configuration): EGG signal and oscillogram (top), right aryepiglottic fold kymograph and aperture data (middle), and left aryepiglottic kymograph and aperture data (bottom).

The rms intensity values for the signals reveal a distinction between the non-tense voiced and voiceless trills: The voiced trills were approximately 8–10 dB more intense than the voiceless ones; however, the tense trills (voiced and voiceless) were of similar intensity. The acoustic spectra (Fig. 10) also show that the voiced trills are generally more intense than the voiceless ones. This difference is likely due to increased turbulent losses during the voiceless trills. The aryepiglottic folds are evidently not as efficient at contouring the pulmonic airstream into a pulsatile flow as the vocal folds are.

IV. DISCUSSION

Even within the performance of a single individual, the variability of aryepiglottic fold trilling behavior is mani-

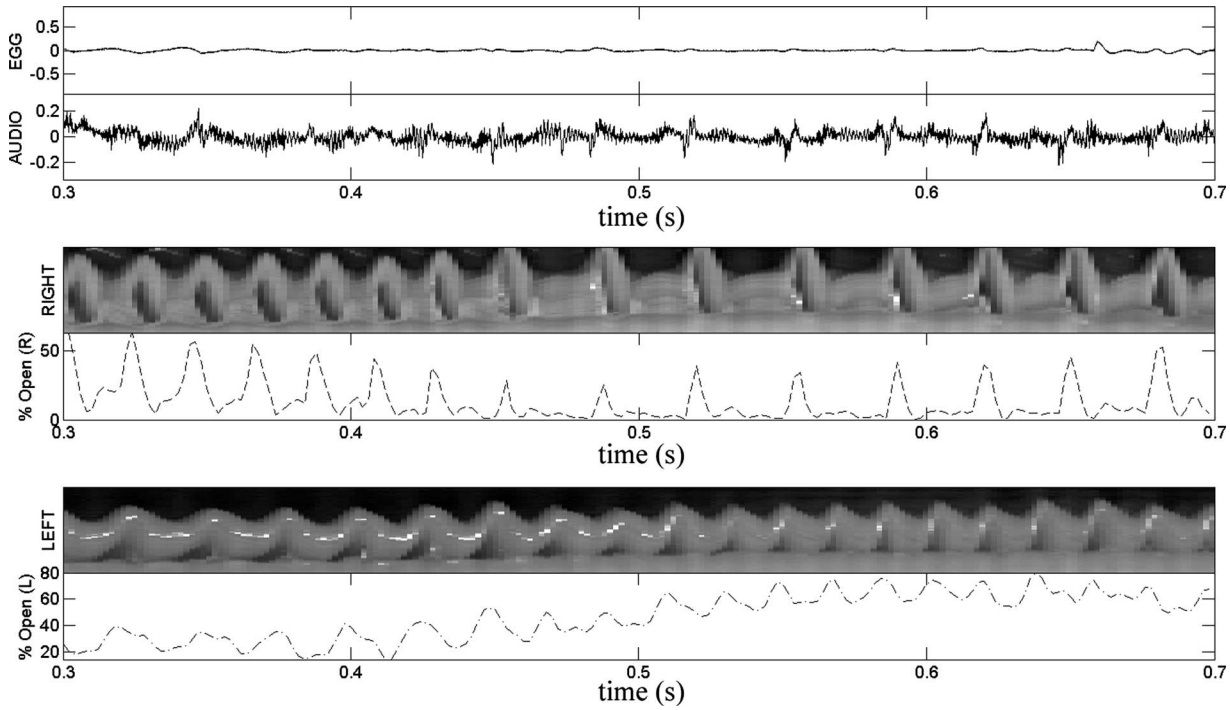

FIG. 9. Tense voiceless aryepiglottic trilling (emulated 100 Hz glottal pitch configuration): EGG signal and oscillogram (top), right aryepiglottic fold kymograph and aperture data (middle), and left aryepiglottic kymograph and aperture data (bottom).

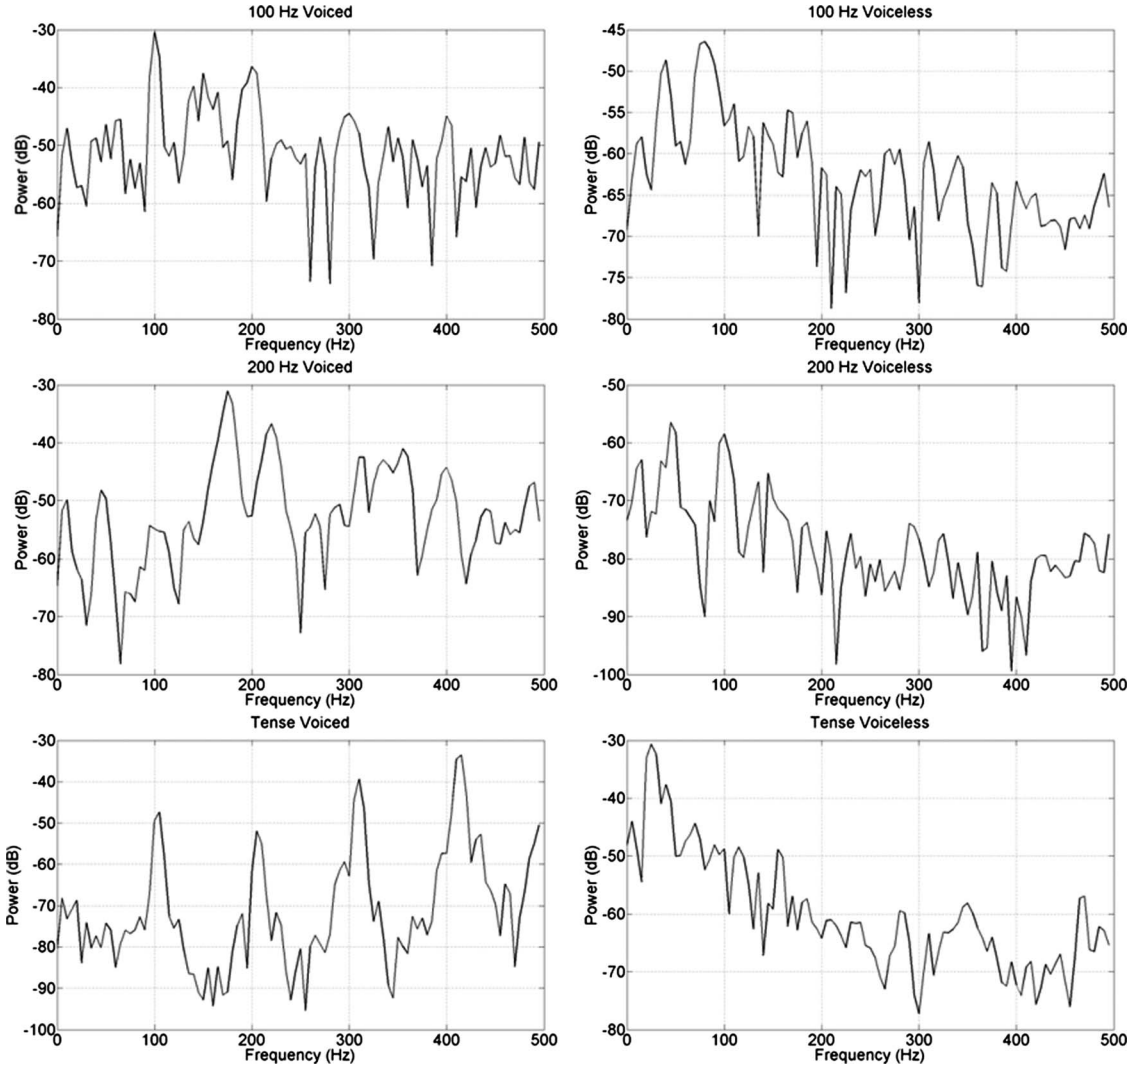

FIG. 10. Spectra of all trills (steady 100 ms interval used). Left columns are voiced trills (100 Hz, ~200 Hz, 100 Hz tense), and right columns are voiceless trills (emulated 100 Hz, 200 Hz, tense).

fested. Three major parameters were employed to study aryepiglottic trilling: the presence or absence of vocal fold vibration, glottal fundamental frequency, and the overall extent of laryngeal constriction. Although the latter parameter is only described qualitatively, it must be possible to vary constriction due to the fact that the aryepiglottic sphincter varies in configuration from being fully open to being fully closed, which is well documented in the languages of the world (e.g., Esling, 1996; Edmondson and Esling, 2006). The 100 Hz set of aryepiglottic trills exhibits similar oscillatory behavior despite one trill being voiced and the other being voiceless. The reader is reminded that the left aryepiglottic fold frequency value measured for the voiceless trill (see Table II) is only indicative of the major pulse, as the actual aperture could not be measured. Thus, it is possible that the value reported is half of its actual value, which depends on the presence of the minor pulses, which can only be observed on the interior of the fold. The 200 Hz set revealed two notable changes in the oscillatory frequency. The voiced trill of this set behaves similarly to its 100 Hz counterpart, with the exception that the left aryepiglottic fold exhibited slower oscillations. The voiceless trill of this set, however, was remarkably different: The right aryepiglottic fold decreases in frequency, while the left aryepiglottic fold considerably increases in frequency. The aperture data from this trill (not presented in this article) show that the left aryepiglottic fold oscillates in a particularly irregular way and with variable intensity; it does, however, consistently make full contact with the base of the epiglottis. It is noteworthy that, despite a doubling of glottal pitch, the aryepiglottic folds themselves do not double in frequency. Finally, the tense trills generally exhibited increased oscillatory frequency for both of the aryepiglottic folds (except for the left fold in the voiceless trill, which dropped in frequency slightly compared to the "non-tense" 100 Hz trills). For the voiced trill of this set, it is speculated, based on the frequency values recorded in Table II, that there is greater coupling between the glottal and aryepiglottal systems. With increased tension, the aryepiglottic folds could be more sensitive to the driving pressure generated by the glottal pulse, which is reflected in the fact that aryepiglottic fold frequencies almost match that of the glottal pulse for this trill.

There are two major theoretical questions of interest for this study. The first is whether the aryepiglottic aperture can

be considered a sound source. Both oscillographic and spectral evidence adduced in this study suggest that the aryepiglottic folds contribute to the harmonic spectrum of the signal. This is particularly evident for the voiceless trills where the EGG evidence indicates that the (near) periodic signal cannot be emanating from the glottis. The high degree of jitter in aryepiglottic fold oscillation, however, makes it difficult to clearly assess the exact harmonic content they are generating, particularly since both folds can oscillate at different frequencies, with major and minor pulsations, and in and out of phase with each other. Furthermore, both folds show open oscillations (where the aryepiglottic fold does not make complete contact with the epiglottis) and close oscillations, where collision with the posterior surface of the epiglottis might also generate acoustic energy. From the aperture analysis data and spectra, the frequency of the aryepiglottic folds was determined to tend toward a range between 50 and 100 Hz in the case of our subject.

While the voiced aryepiglottic trill poses a considerable challenge in determining what the exact contribution of the aryepiglottic fold oscillation to the overall laryngeal sound source is, the voiceless aryepiglottic trill provides some evidence that the folds do indeed contribute a pulsatile excitation to the vocal tract, suggesting that the folds can act as an alternative laryngeal source. For example, when the vocal folds are entirely absent (i.e., due to surgical resection of the vocal folds; Fröhlich *et al.*, 1998; Fröhlich *et al.*, 2000; Schwarz, 2007), the aryepiglottic folds function as the voicing source. The aryepiglottic source, however, appears far less efficient at converting the pulmonic airstream into acoustic energy than the vocal folds: The voiceless aryepiglottic trills were consistently less intense than the voiced trill, and the oscillograms and spectra both indicate that the acoustic signals these trills generate are highly noisy. This could be attributed to the fact that much of the air is escaping non-uniformly through one or both of the aryepiglottic apertures, in addition to the medial opening between the arytenoid cartilages, which is never fully sealed during any of the trills. Undoubtedly this amounts to considerable turbulent loss of aerodynamic power. The exact acoustic and aerodynamic nature of the turbulence generated by the aryepiglottic constriction is crucial to understanding pharyngeal fricatives and requires further study.

Throughout this study, the term trill has been used as a phonetic characterization of the oscillatory behavior of the aryepiglottic folds. This investigation reveals that this label of manner of articulation is appropriate for a number of reasons. While aryepiglottic trilling is unique due to the potential for two structures (the left and right aryepiglottic folds) to vibrate simultaneously and yet with considerably different characters (in terms of frequency, phase, and displacements), they arguably exhibit the same physiological conditions and restrictions of the other trilling structures, such as the tongue tip, uvula, and lips. Anatomically, trilling is claimed to be optimized when the tissue undergoing the trill is well supported by adjacent structures and forms a "funnel-like constriction, with the articulator opening along the direction of the airstream" (Barry, 1997, p. 36). Fundamentally, this configuration takes advantage of the Bernoulli effect when a sufficient airstream is generated (Catford, 2001, p. 173). When the aryepiglottic folds are in their constricted configuration, their opening is indeed in the outward direction of the glottal airstream. The fact that all of the trills in this study were produced with considerable antero-posterior approximation of the epilaryngeal tube and with pharyngeal narrowing reflects the requirement for the aryepiglottic folds to be supported by adjacent structures. No aryepiglottic trilling has been attested, as far as the authors are aware, without these conditions holding (for example, in an entirely unconstricted state as occurs for modal voice). Furthermore, regardless of whether one or both of the folds are oscillating, the end acoustic product is uniformly describable as a trilling sound produced at the aryepiglottic place of articulation.

Aryepiglottic oscillations are also trill-like in the sense that there are no real intrinsic or specialized mechanisms for aryepiglottic pitch control. Vocal fold vibration can be controlled intrinsically with the contraction of the thyroarytenoid muscles and extrinsically relies on the highly specialized cricothyroid mechanism of pitch control. As this study demonstrates, the aryepiglottic folds are considerably limited in terms of their frequency range. The highest frequencies were observed for the tense trills, which indicates that general laryngeal constriction can alter the biomechanical nature of the folds to some degree, perhaps increasing the tension on the folds and resulting in a slightly increased oscillatory frequency (of about 20–40 Hz). Other trills are similar in this regard; they do not permit excessive manipulation of their frequency.

Despite these shared characteristics, the aryepiglottic trill must still be regarded as unique among trills because of its low position in the vocal tract. While it is possible to excite the resonances of the vocal tract using buccal or uvular trills, producing nearly unintelligible speech, aryepiglottic trilling is phonatory in the sense that it can be used as a quality of voicing (described as a category of *harsh voice*), and this function is incorporated into the linguistic systems of several languages, such as !Xóõ (Tuu; Traill, 1986), N|uu (Tuu; Miller *et al.*, 2009), and Jianchuan Bai (Tibeto-Burman; Edmondson and Esling, 2006).

The aryepiglottic trilling documented here might also be compared to the phonation described for various ethnic singing styles of Asia, such as Mongolian throat singing. One of the important conclusions of Lindestad *et al.* (2001) is that a ventricular oscillation half-periodic to the glottal pulse acts to dampen the glottal source on every second glottal pulse. They regarded this mode of phonation as a complex sound source, where the ventricular damping is considered to contribute to a very rich harmonic spectrum that is characteristic of the singing style (which employs overtone enhancement). A similar alternating glottal-damping effect might occur for voiced aryepiglottic trill at 100 Hz (e.g., Fig. 6). In this particular trill, the aryepiglottic occlusion is not complete: Only the right aryepiglottic fold fully closes; the left aryepiglottic aperture, on the other hand, only reduces in area. Thus, the glottal damping in this case is not complete. Rather, once the right aryepiglottic aperture opens, the vocal folds destabilize (exhibiting a double peaked oscillation) and the acoustic signal becomes more noisy. Furthermore, the oscillatory behav-

ior of the aryepiglottic folds is generally more irregular than that of the ventricular folds, which appear to oscillate in sympathy with the vocal folds in Lindestad *et al.*'s (2001) data.

A note must be made about the question of how the acoustic impedances are changed in the vocal tract under aryepiglottic oscillation. As already described, under conditions of static laryngeal constriction, Titze's (2008) *nonlinear source-filter coupling in phonation theory* predicts that the epilaryngeal tube contributes a positive reactance (inertance) to the vocal tract, which can both enhance the efficiency of glottal phonation as well as destabilize it. It is a point for future research to determine how this interaction might change under conditions of aryepiglottic trilling, where the epilaryngeal tube can potentially be separated into two outlet channels (the left and right apertures) that deform over time.

A significant challenge will be the simulation of aryepiglottic trilling in a computational model. One of the purposes of the present research is to contribute to the general understanding of aryepiglottic trilling with the goal of developing a computational simulation of the phenomenon. Much research remains, however, particularly with regard to understanding the acoustic nature of the trill and the aerodynamic conditions under which it occurs. Furthermore, there is little documentation available on the biomechanical properties of the aryepiglottic folds themselves. Computational modeling of the structures would greatly benefit from specific knowledge of their biomechanical characteristics and even their dimensions and mass.

V. CONCLUSION

The purpose of this study has been to understand the oscillatory nature of aryepiglottic trilling. Evidence derived from image analysis of high-speed laryngoscopic videos of six trills with various glottal parameters indicates that the aryepiglottic folds can behave as an acoustic source to the vocal tract under conditions of glottal voicelessness, and perturb the vibration of the vocal folds by triggering alternation in the character of the glottal pulse. On account of this, the voiced aryepiglottic trill should be considered a complex sound source that modulates the quality of voicing and introduces noise as a result of prolonged glottal opening. The voiceless aryepiglottic trills are characterized by being much less intense than the voiced ones, although semi-harmonic excitation of the vocal tract occurs due to the aryepiglottic fold oscillations. Most of the acoustic power for the voiceless trills is converted into noise, which is characteristic of this sound. The aryepiglottic trill is deemed to be appropriately labeled as a trill primarily due its independence of the vocal folds and limited means of pitch control. It was found that increasing the "tension" of the overall laryngeal constriction used in producing the trill could increase the oscillating frequency of the aryepiglottic folds.

Future research must be carried out on other subjects and using linguistic data to determine the strength of these claims. Our next objective will be to analyze aryepiglottic trilling as it occurs in attested words of Iraqi Arabic with the image analysis techniques used for this study. One of the ultimate goals is to create a computational simulation of aryepiglottic trilling. The data collected here will be used as a basis for such a model.

[1]Based on Esling (1996), the International Phonetic Alphabet symbols used to represent these sounds are as follows: stop [ʔ], fricative [ħ], approximant [ʕ], and trills [ʜ ʢ]. The pharyngeal tap [ʡ̆] is also attested.

[2]Lindqvist (1972) also argued that the aryepiglottic sphincter played an essential role in the production of creaky voice.

[3]A value of 1 indicates total positive correlation; in MATLAB this type of normalization is obtained by setting the `xcorr()` option flag to "`coeff`." The limiting value of 0.7071 was selected because it represents the zero-lag component of a cross-correlation analysis of two sine-waves that are exactly 45° out of phase.

How stable are acoustic metrics of contrastive speech rhythm?

(Received 10 December 2008; revised 22 December 2009; accepted 22 December 2009)

Acoustic metrics of contrastive speech rhythm, based on vocalic and intervocalic interval durations, are intended to capture stable typological differences between languages. They should consequently be robust to variation between speakers, sentence materials, and measurers. This paper assesses the impact of these sources of variation on the metrics %V (proportion of utterance comprised of vocalic intervals), VarcoV (rate-normalized standard deviation of vocalic interval duration), and nPVI-V (a measure of the durational variability between successive pairs of vocalic intervals). Five measurers analyzed the same corpus of speech: five sentences read by six speakers of Standard Southern British English. Differences between sentences were responsible for the greatest variation in rhythm scores. Inter-speaker differences were also a source of significant variability. However, there was relatively little variation due to segmentation differences between measurers following an agreed protocol. An automated phone alignment process was also used: Rhythm scores thus derived showed good agreement with the human measurers. A number of recommendations for researchers wishing to exploit contrastive rhythm metrics are offered in conclusion.

I. INTRODUCTION

A. Metrics of contrastive speech rhythm

The study of speech rhythm, once a search for isochronous units of speech (e.g., Lehiste, 1977), has more recently focused on cross-linguistic variation in durational contrast between stressed and unstressed syllables. Dauer (1983) observed that certain phonetic and phonotactic regularities of syllable construction tend to co-occur between languages, at least when one considers the Romance and Germanic languages of Western Europe. Thus, for example, Spanish, French, and Italian have relatively limited clustering of consonants in onsets and codas, with open consonant-vowel syllables being the predominant pattern, whereas English, Dutch, and German allow more complex consonant clusters, with stress tending to occur on heavy syllables, such as those with complex codas. Furthermore, although all of these Western European languages show lengthening of vowels in stressed syllables, Romance languages—Spanish being the most clear-cut example—have attenuated stress-related vowel lengthening compared to the Germanic languages.

Various acoustic metrics have been devised based on these observations (see Table I for definitions of the metrics discussed here), all relying on measurement of the duration of vocalic and consonantal intervals within utterances (e.g., Ramus *et al.*, 1999; Low *et al.*, 2000). Being acoustically based, these intervals take no account of phonological structure, so that coda consonants and immediately following onset consonants are included in the same interval, as are adjacent heterosyllabic vowels (see Ramus *et al.*, 1999, for a discussion of the rationale for this procedure).

These rhythm metrics are intended to capture the stable differences between and within languages in degree of temporal stress contrast, as elucidated by Dauer (1983). Given this assumption, such metrics are best at gauging "contrastive" rhythm, i.e., the balance of strong and weak elements in speech, rather than "dynamic" speech timing, i.e., the temporal arrangement of groups of sounds according to a higher-level structure.

White and Mattys (2007a, 2007b) compared the efficacy of various contrastive rhythm metrics in discriminating between languages held to differ in degree of temporal stress contrast. They also looked for evidence of such differences between varieties of English. In those studies, the most effective metrics were found to be %V (the proportion of total utterance duration made up of vocalic rather than consonantal intervals) and VarcoV (the coefficient of variation of vocalic interval duration, i.e., the standard deviation divided by mean vocalic interval duration, to normalize for articulation rate). Another rate-normalized metric of vocalic interval duration, nPVI-V (Low *et al.*, 2000—see Table I), was also useful and, unsurprisingly, highly correlated with VarcoV, though it manifested somewhat less discriminatory power.

To illustrate the interpretation of contrastive rhythm metrics, Fig. 1 summarizes results for VarcoV and %V from these and related studies (White and Mattys, 2007a, 2007b; White *et al.*, 2009). It is assumed that the high VarcoV scores for English, particularly standard Southern British English (SSBE), and for standard Dutch are a reflection of the strong marking of stress by vowel lengthening in these languages. The lower VarcoV scores for French, Italian, and—in particular—Spanish are assumed to reflect smaller durational

TABLE I. The rhythm metrics considered in the present study.

Metric	Description	Main references
ΔV	Standard deviation of vocalic interval duration.	Ramus *et al.* (1999)
ΔC	Standard deviation of consonantal interval duration.	Ramus *et al.* (1999)
%V	Percent of total utterance duration composed of vocalic intervals.	Ramus *et al.* (1999)
VarcoV	Coefficient of variation of vocalic interval duration (i.e., standard deviation of vocalic interval duration divided by the mean), multiplied by 100.	Dellwo (2006); White and Mattys (2007a, 2007b)
VarcoC	Coefficient of variation of consonantal interval duration (i.e., standard deviation of consonantal interval duration divided by the mean), multiplied by 100.	Dellwo (2006); White and Mattys (2007a, 2007b)
nPVI-V	Normalized pairwise variability index for vocalic intervals. Mean of the differences between successive vocalic intervals divided by their sum, multiplied by 100.	Low *et al.* (2000); Grabe and Low (2002)
rPVI-C	Pairwise variability index for consonantal intervals. Mean of the differences between successive consonantal intervals.	Low *et al.* (2000); Grabe and Low (2002)
nPVI-VC	Normalized pairwise variability index for summed vocalic and consonantal intervals. Mean of the differences between successive vocalic+consonantal intervals divided by their sum, multiplied by 100.	Liss *et al.* (2009)

differences between stressed and unstressed vowels. English and Dutch score low on %V, which is interpreted as indicating the preponderance of consonant clusters compared with the Romance languages. Naturally, %V must also be influenced by patterns of vowel duration, and the shortness of unstressed vowels in Dutch and English is assumed also to contribute to their low %V scores. The influence of vowel duration on both metrics is one factor underpinning the negative correlation between %V and VarcoV, together with the fact that—at least in the languages studied thus far—the trends for vowels and consonants tend to co-occur, as described by Dauer (1983). Thus, the overall picture from such studies is of a gradient variation in temporal stress contrast from low (Castilian Spanish) to high (standard Southern British English).

B. Comparison of contrastive rhythm scores between studies

In recent years, contrastive rhythm metrics have been increasingly applied to address a range of issues: E.g., Carter (2005) looked at the influence of Spanish on the rhythm of Hispanic American English; Patel *et al.* (2006) tested the notion that musical rhythm reflects the rhythm of a culture's native language; and Liss *et al.* (2009) attempted to discriminate between different types of dysarthric speech. One significant problem in interpreting and comparing such results is that absolute rhythm scores can vary widely for the same languages between published studies. For example, in the studies of Ramus (2002), Grabe and Low (2002), and White and Mattys (2007a), nPVI-V ranged from 30 to 42 for Castilian Spanish and from 63 to 73 for standard Southern British English; for rPVI-C, Grabe and Low's (2002) score for Spanish was comparable (58) to Ramus' (2002) score for English (57), despite the strong assumption of much greater consonantal interval variation in English (see Table I for definitions of these metrics).

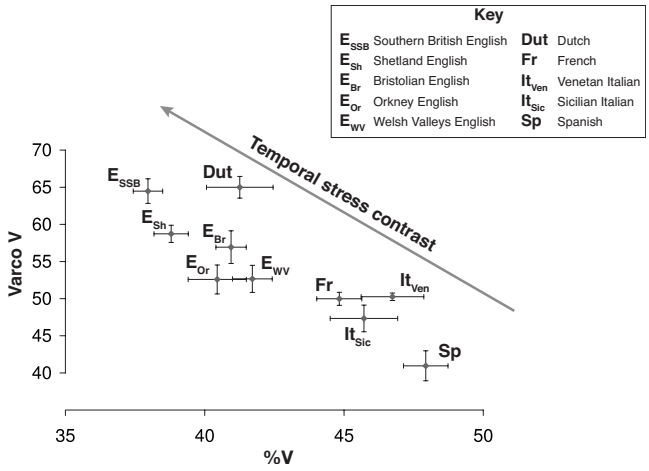

FIG. 1. VarcoV by %V plot showing the scores for Dutch (White and Mattys, 2007a), French (White and Mattys, 2007a), Spanish (White and Mattys, 2007a), two varieties of Italian (White *et al.*, 2009), and several varieties of English (White and Mattys, 2007b).

If contrastive rhythm metrics, as stated above, are intended to capture stable differences between and within languages, such variation in scores represents a significant empirical and theoretical problem. This paper is intended to ascertain whether the variation is merely procedural and can be controlled through improved experimental design, or whether it represents a challenge either to the assumption that languages have stable contrastive rhythmic properties and/or to the assumption that the commonly used rhythm metrics reflect these contrastive rhythmic properties.

There are several obvious potential sources of variation in rhythm scores between studies: The speakers measured, the linguistic materials spoken, and the protocols used for measuring interval duration, together with individual differences between measurers in the application of these protocols. Here we assess the relative variation due to each potential source.

With regard to speakers, there will clearly be variation within any linguistic community in the realization of stress contrasts, as with any segmental or suprasegmental feature, but these differences should be relatively small in comparison with those between languages held to have differing degrees of temporal stress contrast. Variation in articulation

rate is one important factor that might cause significant deviations even within a fairly homogenous accent group, and it is known that certain non-normalized metrics of variation in vowel and consonant interval duration—ΔV, ΔC, rPVI-C—manifest inverse relationships with articulation rate (i.e., higher scores at lower rates—White and Mattys, 2007a). The metrics with most discriminative power—VarcoV, %V, and nPVI-V as discussed above—are robust to variation in rate, however, and so this potential source of between-speaker variation should not be an issue.

Studies also differ in the speech materials used. Given that rhythm metrics are, at least in part, a reflection of phonological structure, variation in rhythm scores is to be expected according to the linguistic materials recorded. In the extreme case, it is possible, for example, to construct English sentences without consonant clusters, so that they mimic the predominant consonant-vowel-consonant-vowel alternation of a Romance language such as Spanish. In this artificial situation, scores for metrics of consonantal interval variation are indeed more similar for English and Spanish than with more natural unconstrained sentences, as are %V scores (Prieto *et al.*, 2009). Of course, while such contrived sentences serve to make a particular point about rhythm metrics, the ideal materials for contrastive rhythm studies should be a representative reflection of the phonological structures of the languages under consideration. The usual—implicit—solution to this problem has been to use a pseudo-random set of naturalistic sentences, although studies such as that of White and Mattys (2007a) have eliminated approximants from the sentence materials in the interest of consistent application of criteria for the identification of segment boundaries.

With regard to measurers, the extraction of interval durations from speech relies mostly on manual inspection of waveforms and spectrograms, and is therefore subject to the vagaries of individual measurers, who may use different criteria or apply common criteria idiosyncratically. The use of experienced phonetically trained measurers and agreement on a set of measurement criteria between studies (see, for example, Turk *et al.*, 2006) are clear first steps toward the maintenance of consistency. Avoidance of awkward segmental junctures—e.g., approximant-vowel or vowel-approximant boundaries—may also help. This study aims to determine the degree of variability in rhythm metric scores between experienced measurers working to a common segmentation protocol.

One potentially useful method of eliminating inter-measurer variability in speech timing research is the use of an automated phone alignment process based on speech recognition algorithms. In studies using read speech, the recognition software is provided with an orthographic or broad phonetic transcription of the sentences, and identifies the boundaries assumed to be present in the signal given this transcription. The practical benefits of such an approach are that a very large amount of speech can be analyzed at little time cost and with consistency of application of segmentation criteria, in contrast with the laborious and error-prone manual approach. Here we examine whether current methods of automated phone alignment—based on statistical properties of the signal rather than phonetically defined criteria—are sufficiently reliable to provide consistency of rhythm scores compared to trained human measurers applying agreed phonetic-based protocols.

C. Purpose of experiment

In this paper, we investigate the robustness of various rhythm metrics to variation in speakers, materials, and measurers, based on an analysis of six speakers of SSBE reading five scripted sentences each. The SSBE sentences were segmented into vocalic and intervocalic intervals by five measurers, all phoneticians trained in the identification of speech segment boundaries. We also used an automatic phone alignment process on the SSBE sentences to derive scores for the same rhythm metrics.
