Hydrops-ectopic calcification-“moth-eaten” (HEM) or Greenberg skeletal dysplasia is an autosomal recessive chondrodystrophy with a lethal course, characterized by fetal hydrops, short limbs, and abnormal chondro-osseous calcification. We found elevated levels of cholesta-8,14-dien- 3β -ol in cultured skin fibroblasts of an 18-wk-old fetus with HEM, compatible with a deficiency of the cholesterol biosynthetic enzyme 3β -hydroxysterol Δ^{14} -reductase. Sequence analysis of two candidate genes encoding putative human sterol Δ^{14} -reductases (*TM7SF2* and *LBR*) identified a homozygous 1599–1605TCTTCTA→CTAGAAG substitution in exon 13 of the *LBR* gene encoding the lamin B receptor, which results in a truncated protein. Functional complementation of the HEM cells by transfection with control *LBR* cDNA confirmed that *LBR* encoded the defective sterol Δ^{14} -reductase. Mutations in *LBR* recently have been reported also to cause Pelger-Huët anomaly, an autosomal dominant trait characterized by hypolobulated nuclei and abnormal chromatin structure in granulocytes. The fact that the healthy mother of the fetus showed hypolobulated nuclei in 60% of her granulocytes confirms that classic Pelger-Huët anomaly represents the heterozygous state of 3β -hydroxysterol Δ^{14} -reductase deficiency.

Hydrops-ectopic calcification-“moth-eaten” (HEM) skeletal dysplasia (MIM 215140), also known as “Greenberg dysplasia,” is a rare autosomal recessive chondrodystrophy characterized by early in utero lethality and, therefore, considered to be nonviable (Greenberg et al. 1988; Chitayat et al. 1993; Horn et al. 2000). Affected fetuses typically present with fetal hydrops, short-limbed dwarfism, and a marked disorganization of chondro-osseous calcification and may present with polydactyly (Chitayat et al. 1993) and additional nonskeletal malformations (Horn et al. 2000).

After obtaining informed consent, we conducted bio-

chemical and molecular investigations in cells from a fetus with HEM—detected by fetal ultrasound performed on a 24-year-old woman of Turkish descent—who presented with intrauterine growth retardation at gestational age 17 wk. The fetus showed severe hydrops and short-limb skeletal dysplasia. Amniotic fluid examination showed a 46,XY karyotype, and a tentative diagnosis of thanatophoric dysplasia was made. Intrauterine death occurred at 18 wk, and delivery was induced. Fetal examination showed severe hydrops, extremely shortened edematous limbs, and postaxial polydactyly on both hands. Radiographic examination showed severe platyspondyly, short irregular ribs, a “moth-eaten” aspect of scapular and pelvic bones, and very short tubular bones with angulated diaphyses. Histopathology showed almost complete absence of enchondral ossification, severe disorganization of cartilage (with nodular calcification deposits), and defective or absent joint formation. On the basis of these findings, the fetus was diagnosed with HEM/Greenberg skeletal dysplasia. The consan-

guineous parents ($F \geq 1/16$) were both healthy, and the family history was noncontributory.

Since sterol analysis elsewhere of tissues and cells of six fetuses with HEM obtained from a skeletal dysplasia repository suggested a deficiency of 3β -hydroxysterol Δ^{14} -reductase (R. I. Kelley, unpublished data; Kelley and Herman 2001), we analyzed the sterol content in cultured primary skin fibroblasts obtained from the fetus with HEM. To this end, the cells were cultured in lipoprotein-depleted medium for 4 d, after which the sterols were extracted and analyzed by gas chromatography/mass spectrometry (GC/MS), as described elsewhere (Waterham et al. 2001). This revealed elevated levels of cholesta-8,14-dien- 3β -ol (fig. 1A), a cholesterol precursor that was not detected in fibroblasts from healthy control subjects or in chorionic villi and amniotic fluid cells from fetuses of similar age. In analogy with sterol Δ^{14} -reductase-deficient *erg24* mutants of yeast, which accumulate ergosta-8,14-dien- 3β -ol (Crowley et al. 1996; Silve et al. 1998), this finding pointed to a deficiency of the enzyme 3β -hydroxysterol Δ^{14} -reductase, which catalyzes the reduction of the Δ^{14} double bond in early sterol intermediates (fig. 1B).

Two different genes have been reported to encode human sterol Δ^{14} -reductases: *LBR* (GenBank accession number L25932–L25941) at 1q42 and *TM7SF2* (GenBank accession number AF096303) at 11q13. *LBR* encodes the lamin B receptor, a 70.4-kDa protein of the inner nuclear membrane that contains an N-terminal lamin B/DNA-binding domain of ~ 200 amino acids followed by a C-terminal sterol reductase-like domain of ~ 450 amino acids (Holmer et al. 1998), which exhibits sterol Δ^{14} -reductase activity when expressed in yeast (Silve et al. 1998). *TM7SF2* encodes a sterol reductase of 46.4 kDa located in the endoplasmic reticulum (ER) membrane (Holmer et al. 1998), which exhibits sterol Δ^{14} -reductase activity when overexpressed in COS-7 cells (Roberti et al. 2002). On the basis of the highest sequence similarity of the encoded protein with fungal sterol Δ^{14} -reductases and its localization in the ER membrane (as are most other sterol reductases known to date), the *TM7SF2* gene was considered the best candidate to encode the defective 3β -hydroxysterol Δ^{14} -reductase. However, sequencing, by means of –21M13 and M13rev fluorescent primers (Waterham et al. 2001), of all exons and flanking intron sequences of *TM7SF2* amplified by PCR (*TM7SF2*-specific primer sequences available upon request) did not identify mutations. Subsequent sequencing of PCR-amplified exons and flanking intron sequences of the *LBR* gene (table 1), by means of –21M13 and M13rev fluorescent primers (Waterham et al. 2001), identified a homozygous substitution of seven nucleotides in exon 13 (fig. 2). Homozygosity was confirmed by finding the same mutation in heterozygous form in genomic DNA of the mother; no DNA from the father was available.

Figure 1 Sterol synthesis in cells from a control and the fetus with HEM. *A*, GC/MS sterol analysis in primary skin fibroblasts cultured for 4 d in lipoprotein-depleted medium revealed elevated levels of cholesta-8,14-dien- 3β -ol (*peak 2*) in cells of the fetus with HEM, whereas, in control cells, only cholesterol (*peak 1*) was detected. *B*, The accumulation of cholesta-8,14-dien- 3β -ol in HEM cells points to a deficiency of the enzyme 3β -hydroxysterol Δ^{14} -reductase, which catalyzes the reduction of the C_{14-15} double bond of cholesta-8,14-dien- 3β -ol to produce cholesta-8-en- 3β -ol.

The same homozygous substitution was also observed in *LBR* cDNA (GenBank accession number L25931) prepared from total RNA isolated from the fetus's cells, which indicates that the mutation neither affects transcription nor is part of a nontranscribed pseudogene. The 1599–1605TCTTCTA→CTAGAAG substitution introduces a stop codon (underlined) that leads to the production of a truncated protein lacking the C-terminal 82 amino acids. Since the C-terminus is highly conserved among the various sterol reductases (Holmer et al. 1998; Waterham et al. 1998), it is very likely that no functional sterol Δ^{14} -reductase is produced.

To confirm that *LBR* indeed encodes the defective sterol Δ^{14} -reductase, the patient's fibroblasts were transfected transiently with control *LBR* cDNA by means of retroviral transduction, using the Phoenix retroviral system (Kinsella and Nolan 1996; Michiels et al. 2000). To this end, the coding region of *LBR* cDNA was amplified by PCR from control cDNA using a *Bam*HI-tagged *LBR* cDNA-specific forward primer (5'-TTAAAGGATCCTCGTGTCACCGCCGGAACC-3') and an *LBR* cDNA-specific reverse primer (5'-AAGTACAGACCCTGTCAGTGC-3'). The amplified *LBR* cDNA was cloned first in the pGEM-T vector (Clontech) and sequenced to exclude PCR-introduced errors. Subsequently, the *LBR* cDNA was released from pGEM-T with *Bam*HI and *Not*I and

ligated into the *Bam*HI and *Not*I sites of the pLZRS-IRES-ZEO/pBR plasmid (Michiels et al. 2000). The resulting pLZRS-LBR-IRES-ZEO/pBR plasmid and, as a control, empty pLZRS-IRES-ZEO/pBR plasmid were transfected into amphotrophic Phoenix Φ NX-A packaging cells (gift from Dr. G. P. Nolan) using lipofectamine-plus (Invitrogen), and helper-free recombinant retrovirus was produced as described elsewhere (Michiels et al. 2000). LBR-containing and, as a control, non-LBR-containing viral supernatants (7 ml) were added to patient's fibroblasts, seeded 1 d prior to the experiment at 40% confluence in T75 culture dishes. After 24 h of incubation, the viral supernatants were replaced by lipoprotein-depleted Dulbecco modified Eagle medium. After 4 d of culturing in the lipoprotein-depleted medium, cells were harvested, and sterols were extracted and analyzed by GC/MS, as described elsewhere (Waterham et al. 2001). The levels of cholesta-8,14-dien-3 β -ol were corrected for total protein and recovery of the internal sterol standard epicoprostanol, which was added prior to the sterol extractions. In two independent experiments, we observed a marked reduction of 41% and 49.5% of cholesta-8,14-dien-3 β -ol in the patient's cells that were transduced with the LBR-containing retroviral supernatant, when compared with the identically treated cells transduced with the non-LBR-containing retroviral supernatant.

When this work was near completion, Hoffmann et al. (2002) reported that heterozygous mutations in *LBR* are responsible for Pelger-Huët anomaly (PHA [MIM 169400]). This is a benign autosomal dominant disorder of leukocyte development characterized by hypolobulated nuclei and abnormal chromatin structure in granulocytes of heterozygotes but without evident clinical symptoms (Pelger 1928; Huët 1932). Presumed PHA homozygotes present with ovoid granulocyte nuclei; may have developmental delay; display variable skeletal abnormalities, such as polydactyly and metacarpal short-

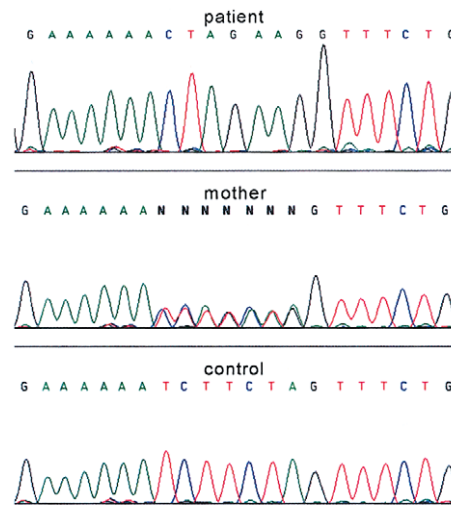

Figure 2 Sequence analysis of the entire *LBR* gene from the fetus with HEM revealed a homozygous 1599–1605TCTTCTA→CTAGAAG substitution in exon 13. The mother was heterozygous for the same mutation.

ening (Aznar and Vaya 1981; Von Siegert et al. 1983; Hoffmann et al. 2002); and may reach adult age (Hoffmann et al. 2002). Moreover, PHA homozygosity leads to short-limbed chondrodysplasia in rabbits (Nachtsheim 1950) and cats (Latimer et al. 1988). These findings combined with ours imply that HEM/Greenberg skeletal dysplasia and homozygous PHA are allelic disorders that display a wide clinical spectrum, with nonviable fetuses with HEM representing the severe end and minor limb defects representing the mild end of the spectrum. It is unfortunate that no sterol analysis to further substantiate this was performed in the single individual with homozygous PHA reported by Hoffmann et al. (2002). However, the mother of the fetus showed hypolobulated

nuclei in 60% of her granulocytes (fig. 3), which demonstrates that classic PHA represents the heterozygous state of 3β -hydroxysterol Δ^{14} -reductase deficiency.

HEM/Greenberg skeletal dysplasia is the sixth inherited disorder of cholesterol biosynthesis for which the molecular basis now has been resolved. Most of these disorders represent previously reported clinical entities of unknown etiology that could be attributed to different enzyme defects in the postsqualene segment of the cholesterol biosynthetic pathway after the finding of abnormally increased levels of intermediate sterol metabolites in patients, followed by the demonstration of disease-causing mutations in genes encoding the implicated enzymes (Kelley and Herman 2001; Porter 2002; Waterham 2002). Apart from autosomal recessive HEM/Greenberg skeletal dysplasia, these include the three autosomal recessive disorders Smith-Lemli-Opitz syndrome (MIM 270400), which is caused by 3β -hydroxysterol Δ^7 -reductase deficiency (Fitzky et al. 1998; Wassif et al. 1998; Waterham et al. 1998); desmosterolosis (MIM 602398), which is caused by 3β -hydroxysterol Δ^{24} -reductase deficiency (Waterham et al. 2001); and lathosterolosis (MIM 607330), which is caused by 3β -hydroxysterol Δ^5 -desaturase deficiency (Brunetti-Pierri et al. 2002). In addition, the molecular basis of two X-linked dominant inherited disorders of cholesterol biosynthesis has been resolved: Conradi-Hünemann-Happle syndrome (MIM 302960) and CHILD syndrome (MIM 308050) are caused by deficiencies of sterol Δ^8 - Δ^7 isomerase (Braverman et al. 1999; Derry et al. 1999) and a sterol C-4 demethylase (Konig et al. 2000), respectively. Patients afflicted with these inborn errors of cholesterol biosynthesis are characterized, in general, by multiple morphogenic and congenital anomalies, including skeletal, internal organ, and/or skin abnormalities (Kelley and Herman 2001; Porter 2002; Waterham 2002).

The occurrence of an abnormal granulocyte chromatin structure in the hetero- and homozygous individuals with PHA and the presence of (severe) skeletal abnormalities in individuals with homozygous HEM/Greenberg skeletal dysplasia indicate that the lamin B receptor has two different physiological functions, namely, preserving chromatin structure by promoting heterochromatin binding to the inner nuclear membrane (Ye and Worman 1994) and functioning as the primary sterol Δ^{14} -reductase in human cholesterol biosynthesis. The latter was somewhat unexpected, since all enzymes involved in the postsqualene cholesterol biosynthesis pathway have been localized to the ER membrane, whereas the lamin B receptor is present (predominantly) in the inner nuclear membrane. In this respect, the gene product of *TM7SF2* a priori seemed a better candidate, since it is localized in the ER membrane (Holmer et al. 1998) and also exhibits sterol Δ^{14} -reductase activity (Roberti et al. 2002). Now that *TM7SF2* is not the primary sterol Δ^{14} -reductase involved

Figure 3 Blood smear of the mother of the present fetus with HEM showing the two characteristics of PHA: granulocytes with the typical pince-nez appearance of the bilobed nuclei and coarse clumping of chromatin.

in human cholesterol synthesis, its physiological function remains to be discovered.
