Evaluating the potential of SSR flanking regions for examining taxonomic relationships in the Vitaceae

Received: 15 December 2000 / Accepted: 12 April 2001

Abstract Three EST-derived microsatellite loci from *Vitis vinifera* were amplified and sequenced across eight species of Vitaceae from four different genera. Phylogenetic analysis of the microsatellite's flanking regions produced informative results in congruence with previous studies. Generic relationships were respected and the data produced sufficient inter-specific variation to distinguish between *Cayratia acris* and *Cayratia saponaria*, two very closely related species. Overall, the sequence alignments showed that priming sites were conserved, whereas microsatellite repeats were present in most cases but structurally variable. The sequence data provided information on the evolutionary patterns of various microsatellite repeats and their correlation to evolutionary relationships among taxa.

Keywords Microsatellites · *Vitis* · Mutation · Flanking regions · ESTs

Introduction

Microsatellites (or simple sequence repeats, SSRs) are considered as being amongst the most-efficient molecular markers. They are abundantly and uniformly distributed throughout the genome, inherited codominantly, are highly reproducible and have simple screening requirements. These properties make SSRs particularly advantageous for applications such as population studies and mapping. The development of increasingly efficient enrichment strategies (Edwards et al. 1996; Cordeiro et al. 1999), the mining of expressed sequence tags (EST) for SSRs (Scott et al. 2000), and the success of cross-species

transferability (Rossetto 2001) have expanded the popularity of these markers. Within the Vitaceae, SSRs have been previously developed for *Vitis vinifera* from genomic DNA libraries (Thomas and Scott 1993) as well as from EST databases (Scott et al. 2000). As previously shown in a number of other taxa, *V. vinifera* SSRs are transferable across cultivars and species (Scott et al. 2000, Rossetto 2001). The success of heterologous PCR amplification usually depends upon the evolutionary distance between the source and target species, with higher genomic homology being likely to translate in greater conservation of SSR flanking regions.

Despite their versatility, SSRs are generally not considered as optimal tools for phylogenetic studies. Empirical studies have shown that, at higher taxonomic levels, SSR alleles identical by size are not necessarily identical by descent (Orti et al. 1997; Doyle et al. 1998). The evolutionary mode of microsatellite repeats is such that new alleles are created following slipped-strand mispairing during DNA replication (Levinson and Gutman 1989; Schlötterer and Tautz 1992; Wierdl et al. 1997). It has been suggested that such events follow stepwise mutation models (single-step, random, or a combination of both: Shriver et al. 1993; Di Rienzo et al. 1994; Estoup et al. 1995; Goldstein and Pollock 1997) rather than the infinite-allele model. Consequently there may be constraints on allelic size-range limiting the genetic distances between distinct taxa and potentially counteracting the effects of genetic drift (Garza et al. 1995). As a result, one of the main problems associated with the use of SSRs for phylogenetic purposes is the absence of a fully validated evolutionary model that can be applied to any type of microsatellite repeat (Goldstein et al. 1995). Since interspecific allelic differences at the one locus are often more complex than simple changes in repeat number, allele frequency and distribution alone are generally inadequate to assess long-term evolutionary divergence.

Phylogenetic reconstructions based on sequence data have the advantage of relying on a large number of characters that follow defined evolutionary patterns (Li 1997). As a result, comparing gene genealogies is be-

coming an increasingly popular phylogenetic approach, even if finding regions containing sufficient information can sometimes be problematic. Phylogenetic resolution between recently diverged taxa can be low because of the lack of informative characters, even when assessing rapidly evolving non-coding regions. For instance, in a recent study of the Vitaceae the combination of sequence information obtained from plastid DNA (*trnL* intron) and nuclear ribosomal DNA (ITS1) was not sufficient to clearly differentiate between closely related taxa such as *Cayratia acris* and *Cayratia saponaria* (Rossetto et al., submitted).

Vitaceae are woody climbers comprising 13 genera and about 700 species worldwide (Mabberley 1995). The family is characterised by leaf-opposed tendrils, which may be modified to form an inflorescence. The majority of the genera have predominantly tropical and subtropical distributions mainly from Africa through Asia and into the Pacific islands. In these latter regions, the Vitaceae often play an important role in rainforest habitats and vine thickets. Originally, only *Vitis* was recognised within Australia by Bentham (1863), but after later revisions this genus is now considered to be absent. Five other genera are represented in the Australian flora, with a total of 30 named species. Despite recent revisions, some uncertainty still exists about the phylogeny of the Australian Vitaceae, particularly *Cissus* for which remarkable morphological polymorphism has been recorded. Recent phylogenetic studies suggest that at least four taxa have been incorrectly included within that genus (Rossetto et al. 2001).

As previous studies have shown that expressed-sequences containing SSR repeats from *V. vinifera* are conserved across a number of taxa (Scott et al. 2000), the present research proposes to investigate the potential of these loci in providing useful phylogenetic information. Such an investigation was made possible by the availability of comparative evolutionary data on intra- and inter-generic relationships in the Vitaceae (Rossetto et al. 2001). The aim of this study was to investigate the potential resolution of SSR flanking-regions in phylogenetic studies, as well as the evolutionary patterns of SSR repeats. A total of eight species and three EST-derived SSR loci were selected and analysed for this purpose.

Materials and methods

Species selection and SSR amplification

Details on the study species, their origin and voucher details are presented in Table 1. Species selection in this study was aimed at representing inter-generic diversity within the Australian Vitaceae. Previous phylogenetic investigations based on plastid and nrDNA found that the genus *Cissus* is not monophyletic but structured into three distinct groups (Rossetto et al. 2001). These groups are represented in this study by *Cissus opaca* (belonging to the genus *Clematicissus*), *Cissus penninervis* (a true *Cissus*) and *Cissus sterculiifolia* (belonging to a new, yet to be named, genus). Thus these three taxa, despite being all *Cissus*, truly represent three different genera. The three *Cayratia* species were selected to represent the genus but also to include two very closely related taxa, *C. acris* and *C. saponaria*. *Tetrastigma nitens* was included as a genus-representative and finally *V. vinifera* was the species from which the SSRs were originally characterised.

Locus selection (scu06vv, scu08vv, scu15vv) was based on preliminary transfer studies across a number of different grape accessions (Scott et al. 2000) and other Vitaceae species (unpublished data). These three loci were chosen because they produced clear amplification products under standard PCR conditions for the majority of the eight test species. They also represent an unbiased sample in repeat length and position within the expressed sequence (scu08vv is located within the 5'UTR, scu06vv within the 3'UTR and scu15vv within the coding sequence).

As this study was aimed at assessing the potential of SSR flanking regions in examining taxonomic relationships, and not at defining phylogenetic relationships within the Vitaceae, sufficient information could be obtained from the species/loci combination selected.

PCR, cloning and sequencing

PCR conditions were as described in Scott et al. (2000), with the only difference being that the annealing temperature was lowered to 48°C for cross-species amplifications. PCRs that produced a homozygous product could be sequenced directly (forward and reverse), but if heterozygous patterns were obtained then cloning was required. At least two separate PCR products or clones were sequenced for each locus/species combination. Cloning was performed using the pGEM-T Easy vector system (specifically designed for cloning PCR products) following standard supplier's protocols (Promega). PCR amplification of ITS1 and the *trnL* (UAA) intron are described in Rossetto et al. (submitted) and the GenBank accession numbers for each sequence is indicated in Table 1. Cycle-sequencing was carried out using the Big-Dye terminator (Perkin Elmer) following standard supplier's protocols on an ABI 3770 automatic sequencer at the Australian Genome Research

Fig. 2 a Strict consensus tree obtained from the combined analysis of the flanking regions from three EST-derived SSR loci. Bootstrap values are indicated on the branches. The position of the SSR repeat mutations are also marked and numbered (see text for details).

b Strict consensus tree obtained from the combined analysis of the *trnL* intron and ITS1. Bootstrap values are indicated on the branches

Facility (Brisbane, Australia). The sequences obtained were aligned using Clustal W (Thompson et al. 1994).

Data analysis

The SSR sequences obtained were evaluated by maximum parsimony. The regions were analysed separately and as a combined data set. Information on parsimony informative indels (insertion/deletions shared by two or more taxa) was added to the sequence data as a presence/absence matrix, which carried equal weight as single base-pair substitutions. Phylogenetic relationships among the eight species were inferred with 1000 random sequence addition and tree bisection-reconnection (TBR) branch swapping, permitting five trees to be held at each step then swapped to completion. Tree searches were conducted via Fitch parsimony (equal-weight unordered characters state, Fitch 1971) using PAUP 4.0b4a (Swofford 2000). Clade robustness was measured by the bootstrap method (Felsenstein 1985) with 500 replicates, and using 1000 random sequence addition and tree bisection-reconnection (TBR) branch swapping, but again permitting only five trees to be held at each step. Fragments that did not amplify (*scu06vv* for *C. opaca* and *scu08vv* for *Cayratia cardiophylla*) were treated as missing data. The same method was used to analyse plastid and nrDNA regions (the GenBank accession numbers for these sequences are shown in Table 1).

Results

Amplification and sequencing were possible for all eight species with *scu15vv*, for all but *C. opaca* with *scu06vv*, and for all but *C. cardiophylla* with *scu08vv* (Fig. 1). The aligned matrices were 188-bp long for *scu06vv* (147 bp without the SSR repeats), 195 bp for *scu09vv* (160 bp without the SSR repeats), and 219 bp for *scu15vv* (189 bp without the SSR repeats). The combined data from the three sets of SSR flanking regions distinguished between all the taxa investigated, with a total of three substitutions (one at *scu08vv* and two at *scu15vv*) and two indels (one each at *scu06vv* and *scu15vv*) differenti-

ating between *C. acris* and *C. saponaria*. The fact that each of the SSR loci could differentiate between these two species is particularly interesting, since no sequence differences were recorded for the *trnL* intron (Rossetto et al. 2001a) and a single indel distinguished these two taxa for ITS1 (Rossetto et al. 2001b).

As expected from the success of PCR amplifications, all priming regions were highly conserved (except for a single transition at locus *scu08vv* in *C. sterculiifolia*). Microsatellite repeats were present within most taxa at all loci, but length and repeat type varied (Fig. 1). At locus *scu06vv* a number of SSR repeats were present (Fig. 1a). The original repeat in *Vitis* was $(AT)_n$ but the same repeat was very small across the other taxa (maximum $(AT)_4$ in *C. cardiophylla*). However, two new repeats were found in most of the other taxa: a perfect $(T)_n$ followed by an imperfect $(TC)_n$ (Fig. 1a). Similarly, at locus *scu08vv* the original $(GGT)_n$ repeat from *V. vinifera* was shorter in most other taxa except for *C. penninervis* and *T. nitens*, for which the repeat was interrupted and compound respectively (Fig. 1b). As for the previous locus a new SSR repeat emerged $(CTT)_n$ but this time within *Cayratia* alone (Fig. 1b). Finally at locus *scu15vv* the original $(GAA)_n$ repeat was conserved across *Cissus*, interrupted for *Cayratia* and absent in *Tetrastigma* (Fig. 1c). The major changes in SSR repeat structure are marked in Fig. 2a.

The Fitch analysis for the combined flanking regions of the SSR sequences resulted in one most-parsimonious tree of 99 steps CI=0.94 and RI=0.91 (Fig. 2a). Strong bootstrap values supported two major clades, one grouping the three *Cayratia* and the one *Tetrastigma* analysed, the other including *C. penninervis*, *C. sterculiifolia* and *V. vinifera* (Fig. 2a). *C. opaca* was outside these two major clades. Within the major clades there was strong bootstrap support for two subclades grouping the two

Cissus and the three *Cayratia* species respectively. A very similar tree could be obtained from the data from locus scu15vv alone (data not shown). The equivalent tree obtained from the combined sequence data from ITS1 and the *trnL* intron is shown in Fig. 2b. This tree was less resolved than the SSR-based one, with only the *Tetrastigma-Cayratia* clade having bootstrap support and the rest of the species forming a polytomy.

Discussion

The combined analysis of the flanking sequences from three EST-derived SSR loci was more phylogenetically informative than the combined analysis of ITS1 and the *trnL* intron. The SSR flanking regions contained a high number of informative substitutions and indels, and such variation proved to be particularly useful for distinguishing between very closely related taxa such as *C. acris* and *C. saponaria*. Overall, the main intra- and intergeneric relationships were successfully resolved (Fig. 2). A previous study on the Vitaceae (Rossetto et al. 2001) found that the genus *Cissus* was not monophyletic. This is supported by the SSR data which clearly distinguishes between *C. opaca* (likely to be a *Clematicissus*; Rossetto et al. 2001) and the other members of the genus tested (Fig. 2a). The close relationship between *Tetrastigma* and *Cayratia* is also clearly corroborated by the SSR data and, as expected, the three *Cayratia* species tested form a well-supported subclade (Fig. 2a). The resolving power of this study is clearly limited by the number of taxa used; nevertheless, the main aim of this investigation was not to define phylogenetic relationships in the Vitaceae but rather to show the potential application of SSR flanking regions to such studies. Clearly, the phylogenetic information obtained from the three loci was accurate enough to respect relationships among taxa and sufficiently informative to distinguish between two very closely related species.

The sequence variation found within the SSR loci was significantly higher than that obtained from the analysis of plastid DNA alone (Rossetto et al. 2001). Plastid DNA is generally less informative than nuclear DNA but has the advantage of being single-copy, non-recombinant and usually uniparentally inherited. Multiple gene families in nuclear DNA, such as the internal transcribed spacer regions (ITSs), are more informative because they are highly variable and undergo concerted evolution (which ensures sequence orthology). However, excess variability, especially among more distantly related taxa, can complicate the alignment of ITS regions thus reducing their overall informativeness. In the present study, the ease of alignment of the SSR loci is likely to have contributed to their greater resolution power when compared to ITS1. Small et al. (1998) found that the variation within a genic region (alcohol dehydrogenase, *Adh*) was phylogenetically more informative than that found within plastid and nrDNA. As for the SSR flanking regions, *Adh* was also easier to align and provided suffi-

cient information to resolve relationships between tetraploid *Gossypium* species (Small et al. 1998). However, special care is required when dealing with nuclear genes, as orthology can be more complex to demonstrate.

Empirical studies on pedigrees have estimated SSR mutational events to be between 10^{-2} to 10^{-3} per locus, per gamete, per generation (Weber and Wong 1993). Because of their different evolutionary constraints, generally it is preferable not to include SSR repeats in phylogenetic analyses. However, comparing SSR repeat structure among a number of related species provides interesting information on their evolutionary patterns. Taylor et al. (1999) summarised two major events in SSR evolution, 'birth' and 'death', both originating from the combination of two mutational events. During the birth of a SSR, a first mutational event produces sufficient length for the second mutational event, slipped-strand mispairing, to occur and produce repeat length variations. Death of a SSR involves a first mutation which interrupts and stabilises a previously perfect repeat, followed by a second mutation which deletes a large portion of that repeat. The alignment matrices in Fig. 1 suggest that both events have occurred within the three loci sequenced. The presence of $(AT)_n$ at scu06vv in *Vitis* alone (mutation 1, Fig. 2a) appears to be an example of the birth of a SSR, as no interruptions are present among related taxa. The remaining SSR repeats in this study represent mainly SSR death events. The $(GGT)_n$ repeat of scu08vv is present in *Cissus* and *Vitis*, with an initial interruption appearing in *C. penninervis* (mutation 2, Fig. 2a). Within *Cayratia* and *Tetrastigma* this repeat sequence has followed different paths, being close to complete deletion in the former (mutation 3, Fig. 2a) and having evolved into a compound $(GGC)_n$ $(GGT)_n$ repeat in the latter (mutation 4, Fig. 2a). Interestingly, the death of the $(GGT)_n$ repeat in *Cayratia* appears to have been balanced by the birth of a new $(CTT)_n$ repeat at a different site (mutation 5 in Fig. 2a). Finally, while the $(GAA)_n$ repeat in locus scu15vv is conserved across all *Cissus* and *Vitis* investigated, an interruption is present in all *Cayratia* (mutation 6, Fig. 2a) and the repeat has disintegrated in *T. nitens* (mutation 7, Fig. 2a). Some evolutionary information can be extracted from these data and this study is in agreement with the concept of SSR interruptions being frequently found within species more recently evolved than the one from which the loci were characterised (Taylor et al. 1999). Such findings suggest the potential existence of a correlation between mutational events within SSR repeats and evolutionary relationships across taxa.

In conclusion, in the Vitaceae the benefits of investigating cross-species amplification of SSR loci are multiple. Firstly, the conservation of loci is conducive to their use in genetic studies across a number of related species. For instance, six loci characterised for *V. vinifera* are currently being used in population studies of *Cissus hypoglauca* and *C. sterculiifolia*. Secondly, the variability recorded within the flanking sequences of a small number of loci is sufficient to distinguish between closely related species and to

examine evolutionary relationships. For such applications, this approach is likely to be more reliable than the analysis of allelic frequencies alone. This strategy can be particularly beneficial to the study of closely related agricultural varieties, especially those with previously characterised SSR libraries and/or EST databases. Finally, the findings suggest that further large-scale studies on mutational events within microsatellite repeats are likely to advance our understanding of SSR evolution.
