**Abstract** Detailed quartet and doublet potential energy surfaces for the  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_3\text{H}_6^+ + \text{H}_2$  and  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_2\text{H}_4^+ + \text{CH}_4$  elimination reactions have been studied using density functional theory with B3LYP functional and ab initio coupled cluster CCSD(T) methods. Several  $\text{H}_2$  elimination and  $\text{CH}_4$  elimination reaction paths have been examined including the IRC following. In particular, the mechanisms involving, respectively, the  $\text{H}_2\text{TiC}_3\text{H}_6^+$  and  $\text{CH}_3\text{TiHC}_2\text{H}_4^+$  intermediates have been studied.

**Keywords**  $\text{Ti}^+ + \text{C}_3\text{H}_8$  reaction · Density functional theory · CCSD(T)

## 1 Introduction

Gas-phase studies of bare transition-metal cations ( $\text{M}^+$ ) with neutral substrates enable elucidation of the elementary reaction steps under well defined conditions, and they have been an active experimental research area [1–8]. This especially concerns activation of the prototypical C–H and C–C bonds by  $\text{M}^+$ . Because of the charged nature of intermediates and products of these activations, various mass spectrometric techniques have been the methods of choice to study such processes [1–8]. The lack of additional effects caused by solvents, other coordinated ligands, counterions, etc. make

the gas-phase transition metal cation/molecule reactions also well suited for computational modeling, provided that the appropriate theoretical methods are used [9]. Previously, we investigated the reaction paths for the early transition metal cation  $\text{Ti}^+$  and ethane using density functional theory (DFT) and single- and multi-reference ab initio methods [10]. The ethane C–H activation by  $\text{Ti}^+$  resulting in the formation of  $\text{TiC}_2\text{H}_4^+ + \text{H}_2$  was calculated to be essentially thermoneutral, while the C–C activation leading to the formation of  $\text{TiCH}_2^+ + \text{CH}_4$  appeared to be a significantly endothermic process with all the computational methods used [10]. In the present work, we extend these theoretical studies to the  $\text{Ti}^+ + \text{propane}$  mechanism. From the mechanistic point of view, the bond activation of propane by a transition metal cation is a more complex process compared to that of ethane because, both primary and secondary C–H bonds can be attacked by  $\text{M}^+$  in propane. Unlike the lower alkanes, the exothermic C–C bond activation channel might be available with the propane substrate [1–3].

There have been reported several experimental studies on the gas-phase reactions of  $\text{Ti}^+$  with propane conducted under low and high pressure conditions [11–15]. Using a flow tube reactor technique, Weisshaar and co-workers [11] observed in the high-pressure multiple-collision environment that the primary products at thermal energies were those of  $\text{H}_2$  elimination,  $\text{TiC}_3\text{H}_6^+ + \text{H}_2$ , with the adduct ions  $\text{TiC}_3\text{H}_8^+$  and  $\text{CH}_4$  elimination products  $\text{TiC}_2\text{H}_4^+ + \text{CH}_4$  found to be relatively small, i.e., 16 and < 1%, respectively. Consistent with the results of Weisshaar [11], the Castleman group [12] also found under high-pressure multiple-collision conditions that the  $\text{H}_2$  elimination is the predominant process at thermal energies (91%). Sunderlin and Armentrout [13] studied the  $\text{Ti}^+ + \text{C}_3\text{H}_8$  reaction by means of a guided-ion beam mass spectrometer under low-pressure single-collision conditions. These researchers observed that at thermal energies the  $\text{H}_2$

elimination products prevailed, with only small amounts of  $\text{CH}_4$  elimination detected [13]. The most recent study of the reaction of  $\text{Ti}^+$  with propane and deuterated propanes at thermal energies was conducted by the Armentrout group [14]. In the low-pressure single-collision environment of the flow tube, the  $\text{TiC}_3\text{H}_6^+ + \text{H}_2$  were again the primary products detected, followed by the  $\text{TiC}_2\text{H}_4^+ + \text{CH}_4$ , with the product distribution determined to be 98 and 2%, respectively. The dehydrogenation and demethanation of  $\text{C}_3\text{H}_8$  by  $\text{Ti}^+$  were found to be mildly exothermic processes, by  $7 \pm 3$  and  $16 \pm 3$  kcal/mol, respectively [14,15]. Note the more exothermic channel in the case of  $\text{CH}_4$  elimination. However, despite the moderate exothermicity of the two elimination channels, the observed reaction efficiency was low, 17% for  $\text{H}_2$  loss and  $< 1\%$  for  $\text{CH}_4$  loss [14].

Following the previous theoretical investigation [10], both density functional theory (DFT) and ab initio calculations have been performed for the  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_3\text{H}_6^+ + \text{H}_2$  and  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_2\text{H}_4^+ + \text{CH}_4$  elimination reactions. The main goal is to find the most preferred reaction paths for the two cases, and possibly, to indicate the factors contributing to the observed low efficiency of these eliminations, especially  $\text{CH}_4$ . The present work adds to the systematic studies of structural and reactivity aspects of Ti chemistry [16]. One finding of the preceding study for  $\text{Ti}^+ + \text{ethane}$  was that the DFT B3LYP optimized structures of the intermediates and transition states along the reaction paths were generally in acceptable agreement with the corresponding multi-reference ab initio structures [10]. To the current knowledge of the authors, there are only few related computational studies of the reactions between the first row transition metal cation and propane aiming at the elucidation of the detailed mechanisms of both the C–H and C–C activation [17–20]. In fact, all of these calculations involved exclusively late transition metals. Holthausen and Koch [17] studied the reaction of  $\text{Fe}^+$  with  $\text{C}_3\text{H}_8$  at the DFT B3LYP level, whereas Yi et al. [18,19] investigated the  $\text{M}^+ + \text{C}_3\text{H}_8$  reactions for  $\text{M} = \text{Ni}$  and  $\text{Co}$  at the same electronic structure level combined with statistical rate theory. The  $\text{Co}^+ + \text{propane}$  reaction was also examined by Fedorov and Gordon [20] using the multi-reference based CASSCF/MRMP2 ab initio methods and effective core potential on the transition metal.

## 2 Computational methods

The potential energy surfaces (PESs) of the two elimination reactions were explored with density functional theory (DFT) [21] using the hybrid B3LYP [22–25] functional. Optimized structures were followed by a force constant matrix calculation/diagonalization to confirm the character of the located stationary points [minimum or transition state (TS)] and to provide zero-point energy (ZPE) corrections. The latter cor-

rections are included in the relative energies discussed below (collected in Tables 1, 2). Each transition state was verified to connect a desired pair of minima by tracing the intrinsic reaction coordinate (IRC) [26–32]. These DFT calculations used the valence triple-zeta plus polarization (TZVP) basis set stored internally in GAMESS [33] and described fully in a previous paper [10]. The relative energies have also been calculated with the supplemented Wachters/Pople's basis sets [10,34,35], denoted as WP, and using both the B3LYP and coupled-cluster singles and doubles methods including perturbative triples [CCSD(T)] [36–41]. For WP, the final Ti basis derived from Wachters primitive set [34] and supplemented with diffuse p, d and polarization f functions had the form (15s11p6d2f)/(10s7p4d2f) and it was used in conjunction with Pople's 6-311+G(2d,2p) basis set for C and H [35].

## 3 Results and discussion

### 3.1 Reactants and products

The structures of the  $\text{C}_3\text{H}_8$  reactant and those of the products of dehydrogenation and demethanation of  $\text{C}_3\text{H}_8$  by  $\text{Ti}^+$ ,  $\text{TiC}_3\text{H}_6^+ + \text{H}_2$  and  $\text{TiC}_2\text{H}_4^+ + \text{CH}_4$ , are shown in Fig. 1. The experimental ground state of  $\text{Ti}^+$  is  $^4\text{F}(4s^13d^2)$  with its lowest doublet state  $^2\text{F}$  derived from the same electronic configuration lying 13.2 kcal/mol higher in energy [42]. The DFT B3LYP estimates of the  $^2\text{F} - ^4\text{F}$  splitting of  $\text{Ti}^+$  [43] of 14.3 (TZVP) and 13.5 (WP) kcal/mol compare satisfactorily with experiment. As discussed previously [10], the CCSD(T) method with WP basis set predicts the correct ordering of the  $^4\text{F}(4s^13d^2)$  and  $^2\text{F}(4s^13d^2)$  states of  $\text{Ti}^+$ , though it underestimates the  $^2\text{F} - ^4\text{F}$  splitting. The geometric and electronic structure of the  $\text{CH}_4$  elimination product  $\text{TiC}_2\text{H}_4^+$  (Fig. 1c) was examined thoroughly in the previous paper as the  $\text{H}_2$  elimination product from the  $\text{Ti}^+ + \text{ethane}$  reaction [10]. Briefly, B3LYP finds the quartet ( $^4\text{B}_1$ ) to be the ground state of  $\text{TiC}_2\text{H}_4^+$  separated from the lowest doublet state ( $^2\text{A}_1$ ) by only 2.0 kcal/mol (WP basis). The CCSD(T)/WP energetic order is reversed, i.e., the doublet  $^2\text{A}_1$  ground-state is 0.2 kcal/mol below the quartet  $^4\text{B}_1$ . In both methods, the two states are nearly degenerate.

The distinct  $\text{H}_2$  elimination paths described below resulted in the following elimination product ( $\text{TiC}_3\text{H}_6^+$ ) isomers:  $\text{TiCH}_3\text{CHCH}_2^+$  ( $\text{Ti}^+$ -propene),  $\text{TiCH}_2\text{CH}_2\text{CH}_2^+$  ( $\text{Ti}^+$ -cyclopropane) and  $\text{TiCHCH}_2\text{CH}_3^+$  (Fig. 1b). The quartet  $\text{TiCH}_3\text{CHCH}_2^+$  ( $\text{Ti}^+$ -propene) is found consistently to be the ground-state  $\text{H}_2$  elimination product, with the doublet  $\text{TiCH}_3\text{CHCH}_2^+$  lying only 2.5 and 1.2 kcal/mol higher at the B3LYP/WP and CCSD(T)/WP levels of theory. The doublet cyclic isomer  $\text{TiCH}_2\text{CH}_2\text{CH}_2^+$  ( $\text{Ti}^+$ -cyclopropane) is the third most stable  $\text{H}_2$  elimination species, placed respectively

Energies are relative to the Ti<sup>+</sup>(<sup>4</sup>F) + C<sub>3</sub>H<sub>8</sub> ground-state reactants and include ZPE corrections

<sup>a</sup> At the B3LYP/TZVP geometries

<sup>b</sup> C-H<sup>(i)</sup> means the primary (*i* = 1) and secondary (*i* = 2) C-H bond

<sup>c</sup> The first two steps are common with *Path 2*

at 3.7 and 3.9 kcal/mol relative to the ground-state. The quartet cyclic structure TiCH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub><sup>+</sup> is not competitive energetically, being 29.2 (B3LYP) and 31.1 (CCSD(T)) kcal/mol less stable than the ground state. Another plausible H<sub>2</sub> elimination species, TiCHCH<sub>2</sub>CH<sub>3</sub><sup>+</sup>, obtained from a 1,1 type H<sub>2</sub> elimination reaction from the relevant insertion intermediate (see below) and with Ti<sup>+</sup> bound only to one C atom (Fig. 1b) are high energy structures: at B3LYP/WP (CCSD(T)/WP) they lie 24.8 (20.2) and 32.8 (28.3) kcal/mol above the ground-state for the doublet and quartet, respectively. Although the latter elimination channel is obviously not accessible at thermal energies, the calculated paths will also be presented for comparison.

### 3.2 Initial complexes

It was mentioned in the Introduction that Ti<sup>+</sup> ··· C<sub>3</sub>H<sub>8</sub> adducts/initial complexes were stabilized and detected under multiple-collision conditions [11]. Due to the presence of two terminal CH<sub>3</sub> groups and a central CH<sub>2</sub> group in propane, several Ti<sup>+</sup> ··· C<sub>3</sub>H<sub>8</sub> adducts of an ion-induced dipole kind are conceivable. A systematic search led to the  $\eta^3$  **1**,  $\eta^4$  **4**

and  $\eta^3$  **9** structures with Ti<sup>+</sup> coordinating to either two or one CH<sub>3</sub> (**4,9**) or to both CH<sub>3</sub> and CH<sub>2</sub> (**1**) as shown in Figs. 3, 4, 6 and 7 for the doublet and quartet, respectively. It is important to note that all of these adducts have been confirmed by an IRC to be involved in the respective elimination reaction paths. Additionally, the unique  $\eta^3$  **5a** quartet adduct (Fig. 6) having all three CH<sub>n</sub> groups of propane engaged (one C-H per group) was confirmed by an IRC to be involved in the H<sub>2</sub> elimination path (see below). For the “low-coordinated”  $\eta^2$  complex **1a** having Ti<sup>+</sup> bound to the central CH<sub>2</sub> (Fig. 2), only the quartet is structurally stable. The doublet structure is a saddle point with a small 30icm<sup>-1</sup> imaginary mode. As for Ti<sup>+</sup> + ethane [10], the quartet Ti<sup>+</sup> ··· C<sub>3</sub>H<sub>8</sub> structures are significantly lower in energy than the doublet analogs (Tables 1, 2). The binding energies (BE) of the lower energy quartet Ti<sup>+</sup> ··· C<sub>3</sub>H<sub>8</sub> complexes are within a 4–5 kcal/mol range. The actual BE values are ca. 20–25 kcal/mol (B3LYP/WP) and 14–18 kcal/mol (CCSD(T)/WP) (Tables 1, 2). The binding energy of  $\eta^2$  **1a**(<sup>4</sup>B<sub>1</sub>) complex is 19.9 and 14.5 kcal/mol at B3LYP/WP and CCSD(T)/WP, respectively. Taking into account the expected overbinding by B3LYP [46,47], the two sets of BEs compare reasonably well.

In analogy with the reactions of M<sup>+</sup> with ethane involving the first-row transition metal M<sup>+</sup> cations (M=Ti,Co,Fe)

**Fig. 1** Structures of **a**  $\text{C}_3\text{H}_8$  reactant, **b** various  $\text{H}_2$  elimination products, and **c**  $\text{CH}_4$  elimination products from the  $\text{Ti}^+ + \text{C}_3\text{H}_8$  reaction (bond lengths in Å). For  $\text{TiC}_2\text{H}_4^+$ , H bend denotes the out-of-plane

bending angle of the H atoms ( $0^\circ$  for the isolated  $\text{C}_2\text{H}_4$ ). Values in parentheses are from experiment (taken from references [44,45])

**Fig. 2** The initial  $\text{Ti}^+ \cdots \text{C}_3\text{H}_8$  complex structures not involved in the elimination paths (bond lengths in Å); magnitude of imaginary frequency ( $\text{cm}^{-1}$ ) for the doublet complex is shown

[10,46,47], for  $\text{Ti}^+ + \text{propane}$ , the relevant  $\text{Ti}^+ \cdots \text{C}_3\text{H}_8$  complex initiates a subsequent  $\text{Ti}^+$  insertion, into a primary ( $\text{C}-\text{H}^{(1)}$ ) or secondary ( $\text{C}-\text{H}^{(2)}$ )  $\text{C}-\text{H}$  bond or  $\text{C}-\text{C}$  bond of propane. Based on the results for  $\text{Ti}^+ + \text{ethane}$  [10], the quartet and doublet PESs for  $\text{C}-\text{H}$  activation in propane are expected to cross early in the reaction coordinate (r.c.). This expectation arises from the significantly higher energy of the quartet  $\text{C}-\text{H}$  insertion intermediates relative to the doublet analogs. Furthermore, since some doublet and quartet  $\text{H}_2/\text{CH}_4$  elimination products from the  $\text{Ti}^+ + \text{C}_3\text{H}_8$  reaction have similar relative energies, the spin crossing between the quartet and doublet PESs can also occur in the vicinity of the exit channel. In this work, the doublet and quartet PESs have been calculated systematically along the respective paths.

The structures involved in the  $\text{H}_2/\text{CH}_4$  elimination reactions are shown in Figs. 3, 4 and 5 (doublet) and Figs. 6, 7 and 8 (quartet). The same labels are used for the corresponding doublet and quartet structures (except for some unique cases). Because there is a substantial degree of similarity between the B3LYP/TZVP geometric parameters of the species involved in the  $\text{Ti}^+$  + ethane [10] and  $\text{Ti}^+$  + propane reactions, the discussion below primarily focuses on the mechanistic and energetic issues for the latter process.

### 3.3 $\text{H}_2$ elimination

The energy profiles for  $\text{H}_2$  elimination paths examined are denoted *Pathi* ( $i = 1 - 4$ ) and drawn in Figs. 9a–d. These profiles are calculated based on the B3LYP energies and each *Pathi* includes the high- and low-spin PESs, essential to predict the lowest energy path. The corresponding CCSD(T) energy profiles have been shown in Figs. 10a–d. The CCSD(T)/WP versus B3LYP/WP relative energies for the various intermediates and transition states involved are compared in Table 1.

#### 3.3.1 *Path1*

*Path1* involves the reaction sequence  $\mathbf{1} \rightarrow \mathbf{TS1-2} \rightarrow \mathbf{2} \rightarrow \mathbf{TS2-3} \rightarrow \mathbf{3} \rightarrow \text{TiCH}_3\text{CHCH}_2^+ + \text{H}_2$  (Figs. 3, 6, 9a). The energy profile of *Path1* bears close resemblance to that for dehydrogenation of ethane by  $\text{Ti}^+$  [10]. There is, especially, double spin crossing along the r.c.: first, between the initial complex and secondary C–H insertion transition state, and second, after passing the  $\text{H}_2$  elimination TS. Both crossings take place below the  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8$  asymptote, at least according to B3LYP (Fig. 9a). At low energies, the first spin crossing could turn the reaction to the lower energy doublet PES, on which the energetically most favorable C–H insertion TS is located. This is on condition that the strongly enough spin-orbit coupling occurs [10]. As explained earlier [10], switching to the low-spin PES enables forming a stable insertion species by singlet coupling a pair of electrons to form Ti–C(Ti–H) bonds. Conserving the high spin does not permit forming strong covalent bonds [10] and the quartet reaction intermediates show significantly longer Ti–C distances compared to the doublet analogs (up to 0.4 Å).

Thus, for *Path1*, the insertion occurs into the C–H<sup>(2)</sup> bond and leads to the doublet intermediate  $\text{HTiC}_3\text{H}_7^+$  **2** via the **TS1-2** transition state (oxidative addition). As the next step on the doublet PES, the molecular complex  $\text{TiCH}_3\text{CHCH}_2^+ \cdots \text{H}_2$  **3** is formed via the four-center 1,2  $\text{H}_2$  elimination transition state **TS2-3**. Because, on the quartet surface, the complex **3** formation step is significantly exothermic (by 22.1 kcal/mol at B3LYP/WP with respect to **2**) and results in the more stable quartet structure compared to the doublet analogue, the second spin crossing occurs in this region. The final step is the

endothermic  $\text{H}_2$  release from **3** (Fig. 9a). The overall  $\text{H}_2$  elimination reaction  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8 \rightarrow \text{TiCH}_3\text{CHCH}_2^+(\text{}^4\text{A}) + \text{H}_2$  is calculated at B3LYP/WP to be mildly exothermic, by 8.1 kcal/mol, in reasonable agreement with experiment ( $7 \pm 3$  kcal/mol) [14]. At this computational level, the rate-limiting doublet transition state **TS1-2** is located slightly below (0.6 kcal/mol) the  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8$  asymptote. CCSD(T)/WP (Fig. 10a) finds the overall reaction to be essentially thermo-neutral ( $\Delta E_0 = 0.9$  kcal/mol), while the barrier for the doublet C–H<sup>(2)</sup> bond insertion is located at this level 7.9 kcal/mol above the ground-state reactant energy. It is well known that DFT underestimates barrier heights, so these results are consistent with that observation. However, the doublet-quartet crossings are predicted by the two methods to occur in the same regions.

#### 3.3.2 *Path2*

*Path2* involves the reaction sequence  $\mathbf{4} \rightarrow \mathbf{TS4-5} \rightarrow \mathbf{5} \rightarrow \mathbf{TS5-6} \rightarrow \mathbf{6} \rightarrow \text{TiCH}_2\text{CH}_2\text{CH}_2^+ + \text{H}_2$  (Figs. 3, 6, 9b), with an early spin crossing analogous to *Path1* (Fig. 9b). CCSD(T), Fig. 10b, exhibits similar spin crossing. The doublet insertion takes place into the primary C–H bond via the **TS4-5** transition state, resulting in the intermediate **5** (Fig. 9b). The subsequent formation of  $\text{H}_2$  proceeds through the four-center 1,3  $\text{H}_2$  elimination **TS5-6** and leads to the dihydrogen complex  $\text{TiCH}_2\text{CH}_2\text{CH}_2^+ \cdots \text{H}_2$  **6**. The latter contains the cyclic product  $\text{TiCH}_2\text{CH}_2\text{CH}_2^+$ , left after releasing  $\text{H}_2$ . The quartet PES remains significantly shifted upward after the spin crossover, ending endothermically (Fig. 9b). The energetically most favorable channel within *Path2*,  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8 \rightarrow \text{TiCH}_2\text{CH}_2\text{CH}_2^+(\text{}^2\text{A}') + \text{H}_2$ , is formally spin-forbidden, with a B3LYP/WP exothermicity of 4.4 kcal/mol, ca. half that of *Path1*. At CCSD(T)/WP (Fig. 10b), this reaction is slightly endothermic, by 4.8 kcal/mol (Table 1). Compared to *Path1*, *Path2* appears also less favorable kinetically because the rate-limiting doublet transition state **TS4-5** involved in the latter is located 4.0 (11.2) kcal/mol above the  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8$  asymptote, based on the B3LYP/WP [CCSD(T)/WP] calculations.

#### 3.3.3 *Path3*

The first two steps of *Path3* including the spin crossing and yielding the C–H<sup>(1)</sup> insertion intermediate  $\text{HTiC}_3\text{H}_7^+$  **5** (Fig. 9c) are common with *Path2*. On the doublet surface, **5** can rearrange to the somewhat less stable isomer **10** (Fig. 3), differing primarily by the Ti–C–C–C dihedral angle (the latter isomer is also involved in *Path4*, see below). Attempts to locate the corresponding isomerization TS failed. The IRC calculation confirmed that starting with **10**, further rearrangement via the H migration transition state **TS10-7** leads to the dihydrido intermediate  $\text{H}_2\text{TiC}_3\text{H}_6^+$  **7** (Fig. 3). Interestingly,

**Fig. 3** Doublet structures relevant to the  $H_2$  elimination of  $C_3H_8$  by  $Ti^+$  and starting with the  $\eta^3$  **1** and  $\eta^4$  **4**  $Ti^+ \cdots C_3H_8$  initial complexes, respectively (bond lengths in Å, bond angles in degrees); for TS's, the associated imaginary frequencies ( $cm^{-1}$ ) are given

**Fig. 4** Doublet structures relevant to the  $\text{H}_2$  elimination of  $\text{C}_3\text{H}_8$  by  $\text{Ti}^+$  and starting with the  $\eta^3$  **9**  $\text{Ti}^+ \cdots \text{C}_3\text{H}_8$  initial complex (bond lengths in Å); for TS's, the associated imaginary frequencies ( $\text{cm}^{-1}$ ) are given

**Fig. 8** Quartet structures relevant to the CH<sub>4</sub> elimination path analogs of the doublet paths described in Fig. 5 (bond lengths in Å, bond angles in degrees); for TS's, the associated imaginary frequencies (cm<sup>-1</sup>) are given

**Fig. 9** The B3LYP energy profiles for the  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_3\text{H}_6^+ + \text{H}_2$  reaction corresponding to **a** *Path1*, **b** *Path2*, **c** *Path3* and **d** *Path4*

this kind of intermediate was postulated by experimentalists [8, 14]. However, for the  $\text{M}^+ + \text{C}_3\text{H}_8$  reactions involving  $\text{M} = \text{Fe}$  and  $\text{Ni}$ , the existence of the dihydrido structure as a minimum on the PES was not supported [17, 18]. At the B3LYP/WP level of theory, the dihydrido species **7** and **TS10-7** directly leading to it both lie below the ground-state reactant energy, by 4.7 and 1.0 kcal/mol, respectively. CCSD(T)/WP (Fig. 10c) locates the two structures somewhat above this asymptote, by 5.7 and 10.4 kcal/mol (Table 1). Towards the exit channel, **7** can transform via **TS7-8** to the dihydrogen

complex  $\text{TiCH}_3\text{CHCH}_2^+ \cdots \text{H}_2$  **8**, from which  $\text{H}_2$  is expelled. Note that **8** shows the  $\text{H}_2$  fragment in the *cis* position with respect to the  $\text{CH}_3$  group, unlike its more stable isomer **3**, involved in *Path1*, having  $\text{H}_2$  unit in the *trans* position.

On the the quartet PES, dihydrido species **7** is highly unstable (Fig. 9c). The IRC calculation revealed that the immediate transition state involved, **TS5a-7**, connects to the  $\text{Ti}^+ \cdots \text{C}_3\text{H}_8$  complex **5a** instead of to the quartet analog of **10**. Consequently, the predicted reaction step from **5a** to **7** requires overcoming a large energetic barrier. Similar to

Fig. 9 continued

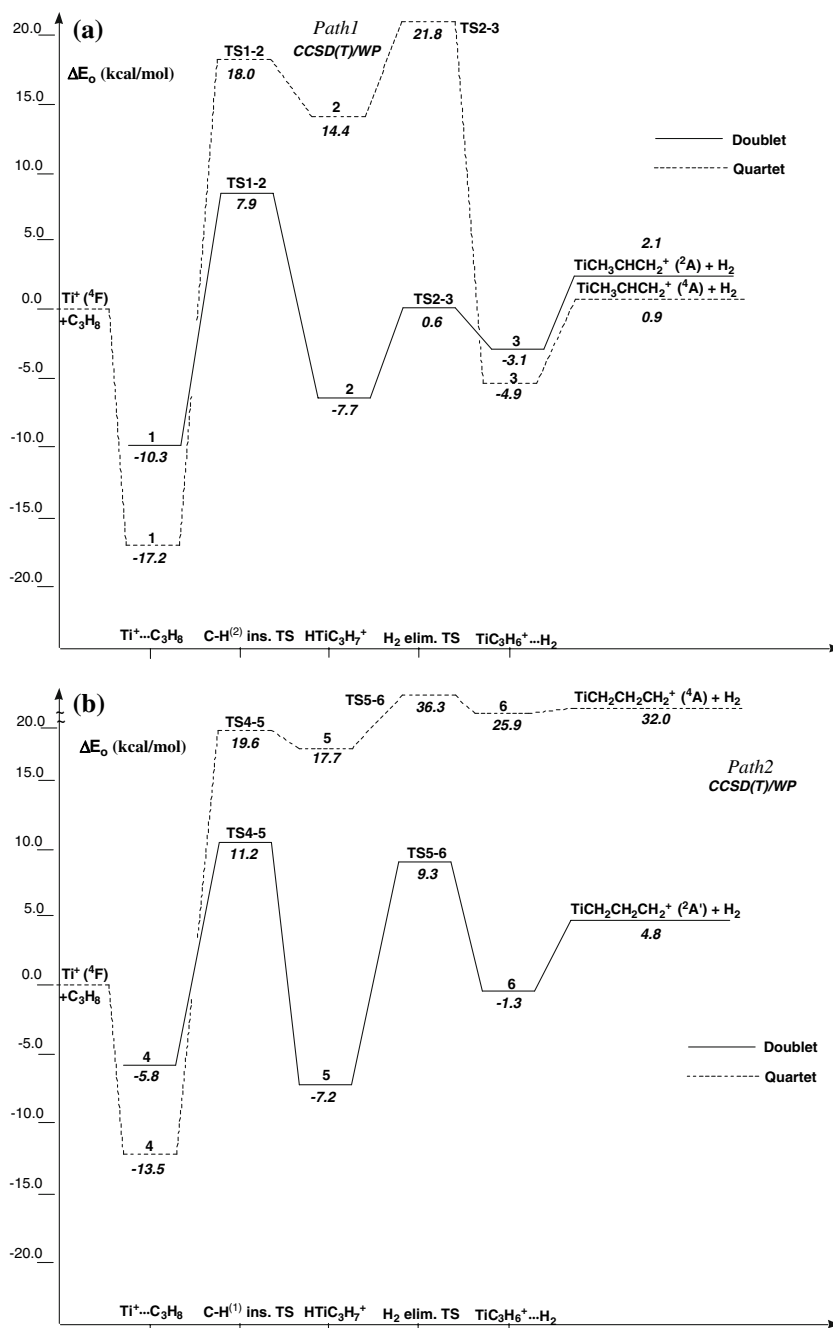

*Path1*, the following step leading to the elimination products precursor  $\text{TiCH}_3\text{CHCH}_2^+ \cdots \text{H}_2$  **8** is appreciably exothermic on the quartet PES (by 47.7 kcal/mol relative to **7** at B3LYP/WP), which crosses the doublet surface after passage of **TS7-8**. The exit channel of *Path3* corresponds to that of *Path1*. *Path3* is consistent with the general stepwise mechanism for  $\text{M}^+ + \text{C}_3\text{H}_8$  reaction originally suggested by experimentalists [8, 14]. At B3LYP/WP, the rate-limiting TS of *Path3* is the same as for *Path2*, whereas with CCSD(T)/WP, the  $\text{H}_2$  elimination **TS7-8** is the highest energy point on the doublet PES lying 13.1 kcal/mol above  $\text{Ti}^+(^4\text{F}) + \text{C}_3\text{H}_8$  (Table 1, Fig. 10c).

### 3.3.4 Path4

*Path4* (Figs. 4, 7, 9d) is similar to *Path2* in that there is a single spin crossing early at r.c. - between the initial  $\eta^3$  adduct **9** and C-H<sup>(1)</sup> insertion transition state **TS9-10**—and that the quartet surface is mostly shifted above the doublet one. The insertion step produces directly the intermediate **10**, involved also in *Path3* (note a different view of doublet structure **10** in Figs. 3, 4). The B3LYP/WP(CCSD(T)/WP) barrier height at the doublet **TS9-10** amounts to 2.2 (10.4) kcal/mol relative to the quartet reactants, which is only 2.9 (2.5) kcal/mol larger than the net energy requirement at the doublet **TS1-2**

**Fig. 10** The CCSD(T) energy profiles for the  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_3\text{H}_6^+ + \text{H}_2$  reaction corresponding to **a** *Path1*, **b** *Path2*, **c** *Path3* and **d** *Path4*

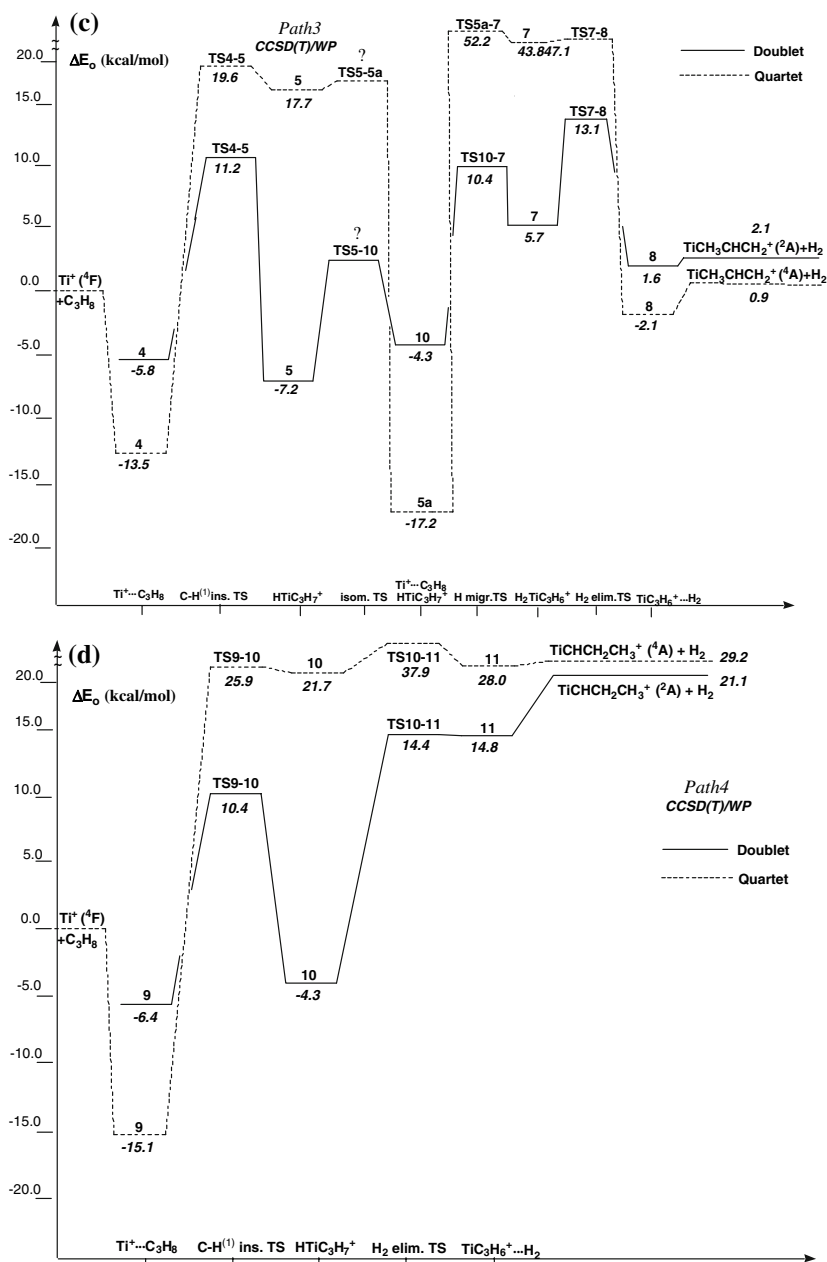

belonging to *Path1* (Table 1). Nevertheless, the remainder of *Path4* proceeding on the lower energy doublet PES is less favorable, ending especially with the endothermic products obtained from **10** by 1,1  $\text{H}_2$  elimination through **TS10-11** (Fig. 9d, Table 1).

It appears from the above comparison, that the three routes *Path $i$*  ( $i = 1 - 3$ ) involve an “early” quartet-doublet spin crossing (we neglect the endothermic *Path4*), with *Path1* and *Path3* found to have the largest exothermicity. The rate-limiting TS located on the doublet PES reachable by the

prior efficient spin crossing is found to be either for C–H insertion or  $\text{H}_2$  elimination, depending on the path and the method. For *Path1*, the associated net barrier which corresponds to the secondary C–H insertion is predicted to be the lowest and ranges from  $-0.6$  (B3LYP/WP) to  $7.9$  (CCSD(T)/WP) kcal/mol. One can thus conclude that the  $\text{H}_2$  elimination *Path1* is expected to be most favoured at low energies. The two methods agree qualitatively, although the CCSD(T) PES is shifted upward by several kcal/mol.

Fig. 10 continued

### 3.4 CH<sub>4</sub> elimination

The CH<sub>4</sub> elimination energy profiles are named *Pathic* ( $i = 1 - 3$ ) and presented in Figs. 11a–c (B3LYP) and Figs. 12a–c (CCSD(T)). Both *Path1c* and *Path2c* involve an initial C–C insertion, whereas *Path3c* involves the initial primary C–H bond insertion shared with *Path2* for H<sub>2</sub> loss. The three paths begin with the  $\eta^4$  **4** adduct formation.

#### 3.4.1 Path1c

*Path1c* involves the reaction sequence  $\mathbf{4} \rightarrow \mathbf{TS4-12} \rightarrow \mathbf{12} \rightarrow \mathbf{TS12-13} \rightarrow \mathbf{13} \rightarrow TiC_2H_4^+ + CH_4$  (Figs. 3, 4, 5, 6, 8, 11a,

12a). After passing the C–C insertion transition state **TS4-12**, the quartet PES crosses for the first time the doublet PES and this apparently occurs above the  $Ti^+ (^4F) + C_3H_8$  asymptote (Figs. 11a, 12a). The lower energy doublet PES in this region leads to the very stable  $CH_3TiC_2H_5^+$  **12** insertion intermediate (the global minimum), lying ca. 30 kcal/mol [17 for CCSD(T)] below the  $Ti^+ (^4F) + C_3H_8$  reactants. The energy profile featuring the C–C insertion product “deep well” resembles that of demethanation of C<sub>2</sub>H<sub>6</sub> by  $Ti^+$  [10]. In the next step on the doublet surface,  $CH_3TiC_2H_5^+$  **12** is transformed to the molecular complex  $TiC_2H_4^+ \cdots CH_4$  **13** via the CH<sub>4</sub> elimination transition state **TS12-13** (Figs. 5, 11a). The latter step on the quartet surface appears to be

**Fig. 11** The B3LYP energy profiles for the  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_2\text{H}_4^+ + \text{CH}_4$  reaction corresponding to **a** *Path1c*, **b** *Path2c* and **c** *Path3c*

significantly exothermic (by 30.5 kcal/mol at B3LYP/WP and 30.2 kcal/mol for CCSD(T) relative to **12**) which results in the more stable quartet structure **13** relative to the doublet counterpart and second spin crossing (Fig. 11a). The endothermic  $\text{CH}_4$  release from **13** ends *Path1c*. Note that according to CCSD(T)/WP (Fig. 12a) this is accompanied by another spin crossing because the doublet products lie at this level 0.2 kcal/mol below the quartet ones (Table 2).

The overall  $\text{CH}_4$  elimination reaction  $\text{Ti}^+({}^4\text{F}) + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_2\text{H}_4^+({}^4\text{B}_1) + \text{CH}_4$  is found at B3LYP/WP to be exothermic by 16.8 kcal/mol, in reasonable agreement with experiment ( $16 \pm 3$  kcal/mol) [14, 15]. At this level of theory, the

rate-limiting C–C insertion quartet transition state **TS4-12** is placed 7.9 kcal/mol above the  $\text{Ti}^+({}^4\text{F}) + \text{C}_3\text{H}_8$  asymptote. The CCSD(T)/WP predicted exothermicity is 5.2 kcal/mol [with the  $\text{TiC}_2\text{H}_4^+({}^2\text{A}_1) + \text{CH}_4$  products], whereas the barrier for the quartet C–C bond insertion is located 20 kcal/mol above the ground-state reactant energy (Table 2).

### 3.4.2 *Path2c*

The first two steps of *Path2c* (Figs. 11b, 12b) are the same as for *Path1c*. Along *Path2c*, the common insertion intermediate  $\text{CH}_3\text{TiC}_2\text{H}_5^+$  **12** rearranges on the doublet PES to

Fig. 11 continued

the  $\text{CH}_3\text{TiHC}_2\text{H}_4^+$  species **14** via an H migration transition state **TS12-14** (Fig. 5). At B3LYP/WP, **14** and **TS12-14** are below the  $\text{Ti}^+(^4\text{F}) + \text{C}_3\text{H}_8$  reference, by 17.0 and 13.8 kcal/mol, respectively. CCSD(T)/WP locates the two structures also below this reference, by 4.5 and 0.5 kcal/mol (Table 2; Fig. 12b). The doublet intermediate **14** can eliminate  $\text{CH}_4$  through the transition state **TS14-13** to yield the molecular complex  $\text{TiC}_2\text{H}_4^+ \cdots \text{CH}_4$  **13**.

On the quartet PES, starting from  $\text{CH}_3\text{TiC}_2\text{H}_5^+$ , the mechanism of  $\text{CH}_4$  elimination is different. In this case a single step is needed to transform the  $\text{CH}_3\text{TiC}_2\text{H}_5^+$  intermediate to the  $\text{CH}_4$  precursor. It begins rather with its isomer **12a** and leads directly to the complex  $\text{TiC}_2\text{H}_4^+ \cdots \text{CH}_4$  **13** via **TS12a-13** as confirmed by the IRC (Figs. 8, 11b). Despite careful searching, we were not able to locate the **12** → **12a** isomerization TS. As anticipated from the *Path1c* profile, the rearrangement from **12a** to **13** is accompanied by the second spin crossing (Fig. 11b). Obviously, the exit channel here looks like that for *Path1c*.

### 3.4.3 Path3c

For *Path3c*, the  $\text{C-H}^{(1)}$  bond insertion step is shared with *Path2* (*Path3*) for  $\text{H}_2$  loss. Starting from the doublet insertion intermediate **5**, the key step of *Path3c* is the  $\text{CH}_3$  group migration via **TS5-14** to form the  $\text{CH}_3\text{TiHC}_2\text{H}_4^+$  intermediate **14**, the latter already encountered along *Path2c* (Fig. 5, Fig. 11c). Therefore, the remainder of *Path3c* on the doublet PES, starting from **14**, corresponds to *Path2c*. Between **5** and **14**, the quartet PES lies some 12–36 kcal/mol (B3LYP/WP) above the  $\text{Ti}^+(^4\text{F}) + \text{C}_3\text{H}_8$  asymptote. Transforming the

quartet **14** to  $\text{TiC}_2\text{H}_4^+ \cdots \text{CH}_4$  via **TS14-13** leads to a second spin crossing in the region of the exit channel (Fig. 11c).

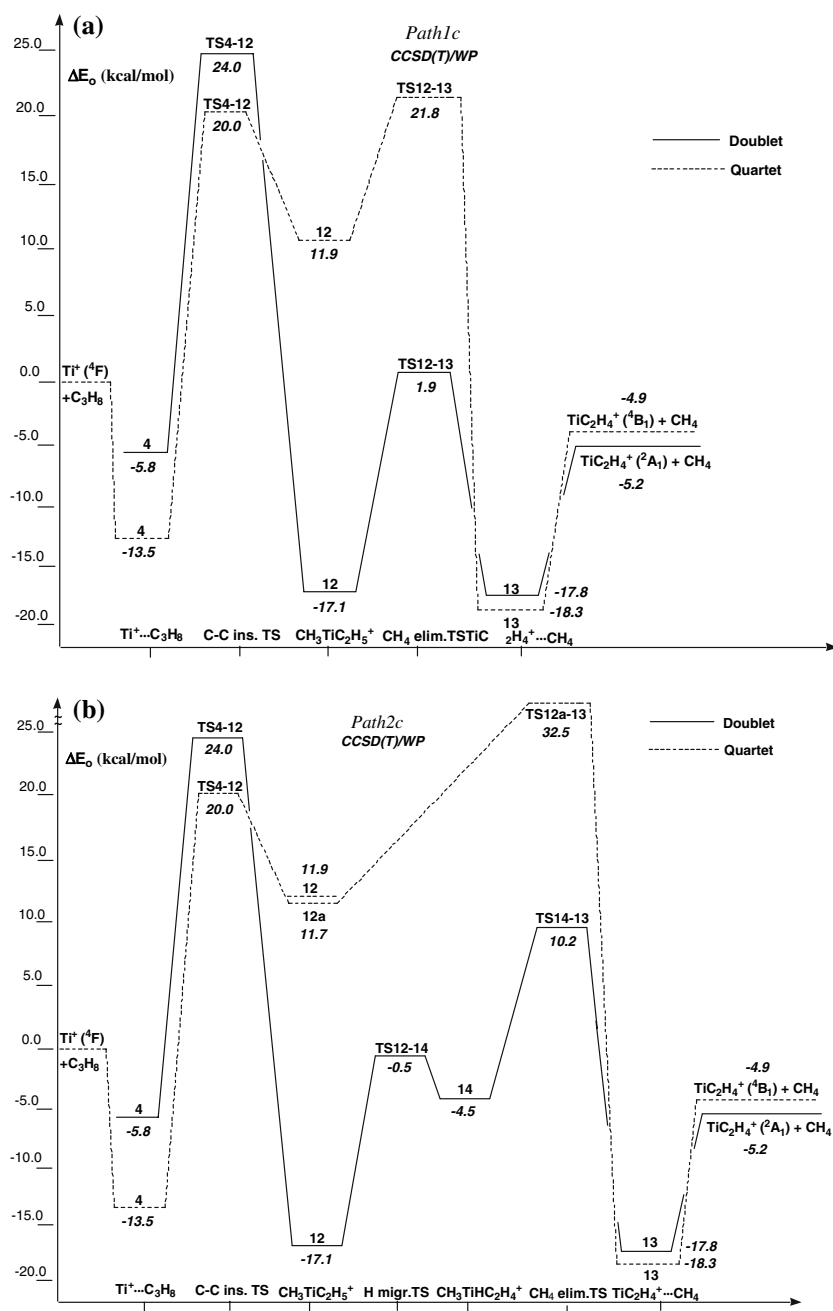

Although, the overall  $\text{CH}_4$  elimination reaction exothermicity of *Path3c* is the same as for *Path1c* and *Path2c*, the three paths differ kinetically. For the last two routes, the rate-limiting TS is that for C–C insertion, located on the quartet PES and lying 7.9 (B3LYP/WP) and 20 kcal/mol [CCSD(T)/WP] above  $\text{Ti}^+(^4\text{F}) + \text{C}_3\text{H}_8$ . For *Path3c*, the rate-limiting TS is located on the doublet PES. According to B3LYP/WP it is for the primary C–H insertion with the net barrier of 4.0 kcal/mol. With CCSD(T)/WP, the doublet TS heights for primary C–H insertion (11.2 kcal/mol) and  $\text{CH}_4$  elimination (10.2 kcal/mol) of *Path3c* are within 1 kcal/mol and are thus both candidates for the rate-limiting TS (Table 2). The three paths feature a second “late” spin crossing in the vicinity of the exit channel; though only for *Path1c* and *Path3c* this is expected to occur below the  $\text{Ti}^+(^4\text{F}) + \text{C}_3\text{H}_8$  asymptote. At low energies, the  $\text{CH}_4$  elimination *Path3c* is thus most likely.

## 4 Conclusions

The following major conclusions can be inferred from the detailed exploration of PES for the reactions of  $\text{H}_2$  and  $\text{CH}_4$  elimination of  $\text{C}_3\text{H}_8$  by  $\text{Ti}^+$ :

(i) The lowest energy path for  $\text{H}_2$  elimination (*Path1*) involves an initial  $\text{Ti}^+$  insertion into a secondary C–H bond on the doublet PES. This step must be preceded by the quartet-doublet spin crossing. An additional “late” spin crossing occurs in the region of the exit channel. At B3LYP/WP, the overall  $\text{Ti}^+(^4\text{F}) + \text{C}_3\text{H}_8 \rightarrow \text{TiCH}_3\text{CHCH}_2^+(^4\text{A}) + \text{H}_2$  reaction is found to be exothermic by 8.1 kcal/mol. The rate-limiting TS, for the secondary C–H insertion, is located at

**Fig. 12** The CCSD(T) energy profiles for the  $\text{Ti}^+ + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_2\text{H}_4^+ + \text{CH}_4$  reaction corresponding to **a** *Path1c*, **b** *Path2c* and **c** *Path3c*

this level 0.6 kcal/mol below the  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8$  reference. CCSD(T)/WP finds the overall elimination reaction to be essentially thermoneutral with the corresponding barrier of the same rate-limiting TS of 7.9 kcal/mol.

(ii) The lowest energy path for  $\text{CH}_4$  elimination (*Path3c*) involves an initial  $\text{Ti}^+$  insertion into primary C–H bond on the doublet PES. This step must be preceded by a spin crossing. Second [and third at CCSD(T)/WP] “late” spin crossings also take place along the path. With B3LYP/WP [CCSD(T)/WP], the overall  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8 \rightarrow \text{TiC}_2\text{H}_4^+(\text{}^4\text{B}_1) + \text{CH}_4$  ( $\text{TiC}_2\text{H}_4^+(\text{}^2\text{A}_1) + \text{CH}_4$ ) reaction exothermicity is calculated as 16.8 (5.2) kcal/mol. The B3LYP/WP rate-limiting TS, for

the primary C–H insertion, is located 4.0 kcal/mol above the  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8$  reference. According to CCSD(T)/WP, the doublet TSs along *Path3c* for primary C–H insertion and  $\text{CH}_4$  elimination with the respective heights of 11.2 and 10.2 kcal/mol are both candidates for the rate-limiting TS.

(iii) The observed [14] at thermal energies low efficiency of the two eliminations, especially  $\text{CH}_4$ , can be caused by multiple spin crossings required along the lowest energy paths. To discuss this effect quantitatively, both the precise location of the spin crossings, especially those lying above the  $\text{Ti}^+(\text{}^4\text{F}) + \text{C}_3\text{H}_8$  asymptote, and Ti spin-orbit coupling matrix element estimate are needed [10].
