### Abstract

The thermodynamics of dissolution in water of a set of substances has been studied calorimetrically. The examined substances were: potassium chloride, (glycyl-glycyl)diketopiperazine, (alanyl-alanyl)diketopiperazine, (leucyl-glycyl)diketopiperazine. They were chosen on the basis of their solubilities, going from a highly soluble electrolyte to the sparingly soluble diketopiperazines. It is shown that, using a commercially available calorimeter, it is possible to perform in a single calorimetric experiment the simultaneous determination of all thermodynamic parameters characterizing dissolution of a substance in a given solvent, i.e. solubility, dissolution enthalpy and dilution enthalpy. The solubility values in water obtained through the proposed method are in good agreement with those reported in the literature and obtained by other techniques. © 1998 Elsevier Science B.V.

*Keywords:* Dilution enthalpy; Dissolution; Dissolution enthalpy; Microcalorimetry; Solubility

### 1. Introduction

A knowledge of the thermodynamic properties of aqueous solutions of simple organic substances is particularly useful because these compounds may be looked upon as simple models for biochemical systems. For instance, the energetics of transfer of cyclic dipeptides (i.e. diketopiperazines) from the crystal into water has been especially studied, since these model solid compounds seem appropriate in an attempt to understand the energetics of protein stability [1–8].

Most of the studies concerning model compounds require the determination of dissolution properties of

sparingly soluble substances. Solubility and heats of solution as a function of temperature provide the key quantities to evaluate changes in free energy, enthalpy and heat capacity. The low solubility of many solids often does not allow the determination of reliable values for this parameter. When a suitable chromophore is present in the molecule, optical techniques such as UV absorbance are appropriate. In the absence of these chromophores, other techniques are required. One such techniques is a dry-weight determination, in which the dried residue from a known volume of saturated solution is weighed [2,9]. Another technique, the differential refractive index determination, is more versatile and yields solubilities over a range of temperatures [5]. On the other hand, enthalpies of dissolution have been measured by flow calorimetry, where a precise weight of a dry sample is dissolved in

a continuous flow of solvent [10,11]. Alternatively, the phase-equilibrium perturbation calorimetry utilizes a titration calorimeter [1,12]. To know the complete energetics of the dissolution process, therefore, a separate determination of the solubility is required.

On the contrary, a calorimetric method reported here allows the simultaneous determination of solubility, dissolution and dilution enthalpies. This method does not require separate techniques to determine the solubility, and is independent of the nature of the examined solute and/or solvent. It allows through a single calorimetric experiment to obtain the complete energetics of the dissolution process. The examined substances were: potassium chloride, (glycyl-glycyl)-diketopiperazine c(Gly-Gly), (alanyl-alanyl)-diketopiperazine c(Ala-Ala), and (leucyl-glycyl)-diketopiperazine c(Leu-Gly). These were chosen on the basis of their solubilities in water, going from a highly soluble electrolyte to the sparingly soluble diketopiperazines. Their different natures and the wide range of solubilities put in evidence the great versatility of the method, whose simplicity must be stressed. The method uses a commercially available batch calorimeter and does not require reference curves for the substance and the solvent employed. That leads to a rapid determination of the free energy of transfer from one solvent to another.

## 2. Experimental

The dissolution process for a pure phase going to an infinitely dilute solution can be divided into two steps: transfer of a molecule from the pure phase to a saturated solution, and transfer of a molecule from the saturated solution to an infinitely dilute solution. Here, the first process is referred to as dissolution and the second as dilution. All experiments were run at  $(298 \pm 0.01)$  K in a Thermal Activity Monitor (TAM), model 2277 from Thermometric (Sweden), equipped with a steel perfusion–titration vessel with an effective volume of about 4 mL. The temperature of the calorimeter was maintained by a water bath to within 0.001 K using a Grant LTD6 temperature control unit. Additions of titrant to the solution into the cell are performed through a syringe controlled by a Hamilton Microlab M. In a typical experiment, the reaction cell was loaded with ca.  $(0.5–1.0) \times 10^{-3}$  L of the saturated

solution and excess solid of the examined substance, and the injection syringe was filled with doubly distilled water. The system was equilibrated under constant stirring until a steady baseline was obtained. The injection volumes were 15, 25 or 50  $\mu\text{L}$ , depending on the heat generated by the dissolution of the substance. The mixing is ensured through a helical stirrer. The reaction required ca. 80 min to return to a steady baseline, and the heat generated as the system returns to equilibrium was measured. A computer controlled the injections and collected the data. Approximately 10–30 injections of the added solvent were made in each experiment, and at least three experiments were performed for each substance. When the solid was completely solubilized, injections of pure solvent to the homogeneous solution were continued while measuring the dilution heats.

Substances were obtained from Bachem (diketopiperazines) and Carlo Erba (potassium chloride): they were ground using a mortar and pestle to ensure maximum surface area. Saturated solutions were prepared in doubly distilled deionized water by adding sufficient substance to ensure an excess of solid.

The basis of the method is the determination of the heat upon the addition of solvent to a saturated solution, until a homogeneous solution is formed. This solution is further diluted to evaluate the dilution heats. From the determination of these heats and from the knowledge of the quantities of solute and solvent into the cell it is possible to evaluate the solubility, dissolution enthalpy, and enthalpic interaction coefficients of the excess enthalpy. In Figs. 1–4, the registered heat for each addition vs. the volume of the added solvent is reported for the four substances examined. In the presence of two phases, namely in the presence of saturated solution and solid and for constant additions of solvent, invariant heats are obtained: that occurs up to the  $i$ th addition. The  $(i+1)$ th addition induces a deviation from the almost invariant value, since only part of the solvent in the addition dissolves the solid, while the other dilutes the resulting saturated solution. From the  $(i+2)$ th addition of solvent, heats generated or absorbed represent only heats of dilution, which can be interpolated by the following function:

$$[a + b(i + n)^x + c(i + n)^y + d(i + n)^z + \dots] \quad (1)$$

Fig. 1. Heat,  $Q$ , in J, for each addition against the volume of the added solvent, in  $\mu\text{L}$ , for potassium chloride at 298 K.

Fig. 2. Heat,  $Q$ , in J, for each addition against the volume of the added solvent, in  $\mu\text{L}$ , for c(Gly-Gly) at 298 K.

where  $n \geq 2$ ,  $x, y, z, \dots$  are whole or fractional numbers, and  $a, b, c, d, \dots$  coefficients having no physical meaning. Through the best fitting of the experimental data, the most probable values of these coefficients can be obtained. The crude experimental data are reported in the Appendix A, describing the heat gen-

erated upon the addition of a given volume of solvent to the solution in the cell. Three experiments are reported for KCl, c(Gly-Gly), c(Ala-Ala) and four for c(Leu-Gly): the mass of solvent and substance initially present in the cell for each experiment is also shown.

Fig. 4. Heat,  $Q$ , in J, for each addition against the volume of the added solvent, in  $\mu\text{L}$ , for c(Leu-Gly) at 298 K.

### 2.1. Solubility and dissolution enthalpy

$Q_{av}$  is the average value of the heat associated with the dissolution of solid, when  $k$  kg of solvent per every addition is added to the biphasic solution in the cell. Up to the  $i$ th addition, all the added solvent are needed

for the dissolution. In the  $(i+1)$ th addition, however, only a fraction  $f$  of the  $k$  kg of solvent dissolves the remaining solute, while the  $(1-f)$ th part dilutes the resulting homogeneous saturated solution. For this addition, the heat associated with the dissolution, namely the heat associated with the formation of

the monophasic system,  $Q_s$ , is given by:

$$Q_s = fQ_{av} \quad (2)$$

where  $0 \leq f \leq 1$ .

Considering that the  $(1-f)$ th part of the  $(i+1)$ th addition dilutes the saturated homogeneous solution, the total heat in this step,  $Q_{i+1}$ , is given by the sum of  $Q_s$  and the heat of dilution,  $Q_{dil(i+1)}$ :

$$Q_{i+1} \equiv Q_s + Q_{dil(i+1)} = fQ_{av} + [a + b(i+1)^x + c(i+1)^y + d(i+1)^z + \dots](1-f) \quad (3)$$

Knowing the coefficients  $a, b, c, d, \dots$ , the parameter  $f$  is obtained through a minimization procedure, taking the value which gives the best agreement between the experimental and calculated heats. The solubility,  $m_{sat}$ , and the final molality in the  $(i+1)$ th step,  $m_{f(i+1)}$ , are given by:

$$m_{sat} = n_T / (k_c + ik + fk) = n_T / [k_c + (i+f)k] \quad (4)$$

and

$$m_{f(i+1)} = n_T / [k_c + (i+1)k] \quad (5)$$

where  $m_{f(i+1)}$  is the final concentration of the homogeneous solution,  $m_{sat}$  the solubility in mol kg<sup>-1</sup> of solvent,  $n_T$  the total number of solute moles,  $k$  the kilograms of solvent for each addition,  $i$  the number of additions before the disappearance of the excess solid,  $(i+1)$  the addition that provokes the solubilization of the excess solid and the dilution of the homogeneous solution, and  $k_c$  the kilograms of solvent initially present in the cell.

The enthalpy relative to the solubilization of one mole of solid up to the formation of the homogeneous saturated solution,  $\Delta H^{0'}$ , is given by:

$$\begin{aligned} \Delta H^{0'} &= (iQ_{av} + fQ_{av}) / (n_T - m_{sat}k_c) \\ &= (i+f)Q_{av} / (n_T - m_{sat}k_c) \end{aligned} \quad (6)$$

where  $\Delta H^{0'}$  is expressed in J mol<sup>-1</sup>.

The enthalpy relative to the dissolution of one mole of solute up to the infinitely dilute solution,  $\Delta H^0$ , is:

$$\begin{aligned} \Delta H^0 &\equiv \Delta H^{0'} - \Phi_L(m_{sat}) \\ &= [(i+f)Q_{av} / (n_T - m_{sat}k_s)] \\ &\quad - [A_1 m_{sat} + A_2 m_{sat}^2 + \dots] \end{aligned} \quad (7)$$

where  $\Phi_L(m_{sat})$ , the apparent molal enthalpy of the saturated solution, is given by the polynomial on the right side of Eq. (7). The value of  $\Delta G^0$  is calculated from the solubility as:

$$\Delta G^0 = -RT \ln X_2 \quad (8)$$

and  $T\Delta S^0$  as:

$$T\Delta S^0 = \Delta H^0 - \Delta G^0 \quad (9)$$

where  $X_2$  is the solubility mole fraction. The absence of any information about the activity coefficients leads to the evaluation of parameters that are thermodynamically not exactly defined.

In Table 1, solubilities, solution enthalpies, free energies and entropies are reported for the four substances examined. The solubility values are compared with those reported in the literature. The good agreement indicates that the proposed method is as reliable as spectrophotometric and gravimetric methods. It must be underlined that when using this procedure, we are dealing with wet substances. Then, differences between the  $\Delta H^{0'}$  values obtained through this method and those reported in the literature could eventually be found and used for the determination of the wetting heat.

According to the treatment of solution properties originally proposed by McMillan and Mayer [14] and specifically applied to those of aqueous solutions of nonelectrolytes by Kozak et al. [15] and some other authors [16–18], an excess thermodynamic property,  $J_T^E$  can be expressed as a function of molalities of pair and higher order coefficients,  $j$ , as follows:

$$J^E = \sum_x \sum_y j_{xy} m_x m_y + \text{higher terms} \quad (10)$$

Virial coefficients of the power series of the excess enthalpies as a function of molalities can be easily derived from the enthalpies of dilution of binary solutions as follows:

$$\begin{aligned} \Delta H_{dil}(m_x^i \rightarrow m_x^f) &= h_{xx}(m^f - m^i) \\ &\quad + h_{xxx}[(m^f)^2 - (m^i)^2] + \dots \end{aligned} \quad (11)$$

where  $m_x^i$  and  $m_x^f$  are the molalities of the  $x$  solute before, and after, the dilution process, respectively. According to the McMillan–Mayer approach [14], the  $h$  coefficients represent the enthalpic contributions to the Gibbs free energy coefficients characterizing the interactions between pairs, triplets or higher order

<sup>e</sup> Ref. [5].

<sup>f</sup> Ref. [8]. In this reference,  $\Delta H^0$  is given at 30°C and a final concentration  $m=0.0088$ .

<sup>g</sup> Ref. [2].

coefficients. They implicitly account also for all variations of solvent–solvent and solute–solvent interactions.

Knowing the enthalpic interaction coefficients, the dilution heat for the ( $i+1$ )th addition can be evaluated also as follows:

$$Q_{\text{dil}(i+1)}(J) = n_{\text{T}}[h_{\text{xx}}(m_{f(i+1)} - m_{\text{sat}}) + h_{\text{xxx}}(m_{f(i+1)}^2 - m_{\text{sat}}^2) + \dots] \quad (12)$$

The enthalpy for the dissolution of one mole of solute up to the infinitely dilute solution is:

$$\begin{aligned} \Delta H^0 &\equiv \Delta H^{0'} - \Phi_L(m_{\text{sat}}) \\ &= [(i+f)Q_{\text{av}}/(n_{\text{T}} - m_{\text{sat}}k_{\text{s}})] \\ &\quad - [h_{\text{xx}}m_{\text{sat}} + h_{\text{xxx}}m_{\text{sat}}^2 + \dots] \end{aligned} \quad (13)$$

Conversely, it is possible to evaluate the unknown enthalpic interaction coefficients through the interpolation of the experimental heats of dilution as a function of the difference in molalities.

As a conclusion, a single calorimetric experiment allows to obtain fast and reliable information on the energetics bound to the dissolution of a solute in a given solvent. The results of such studies allow to

characterize the interaction between the solute functional groups and the solvent, water in particular. When the examined small-molecule model compounds contains the key elements describing the interaction of amino acid residues in a polypeptide chain, thermodynamic parameters can provide quantitative information on the contributions of the various interactions that determine protein conformation.
