Granulocytic sarcoma of the thymus in a nonleukaemic patient

Received: 21 October 1998 / Accepted: 19 May 1999

Abstract We report a case of granulocytic sarcoma arising from the thymus in a 17-year-old nonleukaemic patient. The patient presented with an anterior mediastinal tumour and underwent surgical resection. Histological examination showed a diffuse infiltrate of immature round cells in the thymus. Tumour cells were diffusely peroxidase positive, but naphthol AS-D chloroacetate esterase negative. Immunohistochemical staining revealed expression of CD34 and terminal deoxynucleotidyl transferase (TdT), but not of CD13 and CD33. Ultrastructurally, electron-dense or medium-density granules were present in the cytoplasm. Four months after successful autogenic bone marrow transplantation, pleural and pericardial fluid contained tumour cells with azurophilic granules, which expressed CD13 and CD33, but not CD34 and TdT. The patient died of the disease 18 months after clinical manifestation, but still without developing leukaemia. The granulocytic sarcoma in the present case may have originated from myeloid precursors in the thymus and remained within the extramedullary site despite the differentiation into a more committed myeloid lineage at the relapse.

Key words Granulocytic sarcoma · Thymus

Introduction

Granulocytic sarcoma is a heterogeneous neoplasm with regard to clinical behaviour. It usually occurs in association with acute myelogenous leukaemia (AML), chronic myeloproliferative disorder, and myelodysplastic syndrome [14]. While there is usually evidence of these haematological diseases in either the blood or the bone marrow at the time of diagnosis, in some cases the granulocytic sarcoma may precede them [3, 12, 14]. The common sites of occurrence are skin, lymph node, bone, orbit, and nasal fossa, but any site may be affected [3, 12, 14]. The lesions may also be present as anterior mediastinal masses in patients with symptoms of leukaemia, whereas they occur extremely rarely in nonleukaemic patients [2, 8, 11]: only three cases, which terminated in AML, have been reported in detail in the literature [8, 11].

We report here an additional case of granulocytic sarcoma in the anterior mediastinum, probably originating from the thymus, in a patient who did not have prior haematological disease and who did not subsequently develop leukaemia. Our initial diagnosis of the tumour was lymphoblastic lymphoma, a haematological malignancy that is much more frequent in the thymus, but subsequent differentiation of the tumour cells to more committed cells along the myeloid lineage was observed at the relapse. Thus, both the morphological characteristics of the tumour and the difficulty in diagnosing granulocytic sarcoma are also worth reporting.

Clinical history

A 17-year-old man was admitted to Tokyo Metropolitan Komagome Hospital in September 1992 complaining of shortness of breath. Chest roentgenography showed slight mediastinal enlargement. Computed tomography (CT) of the chest disclosed a huge tumour in the anterior mediastinum, invading both lungs. The clinical diagnosis was invasive thymoma. Surgical excision of the tumour was carried out, but this was not complete because of infiltration of the pleura and the lung. A definite histological diagnosis could not be made because of the primitive morphology of neoplastic round cells and negative reactions for B/T-cell-associated antigens and naphthol AS-D chloroacetate esterase. Peroxidase staining was not performed at that time. A tentative diagnosis of lymphoblastic lymphoma was made. The patient was treated with standard chemotherapy for malignant lympho-

ma and radiation therapy of the mediastinum, followed by autogenic bone marrow transplantation. In October 1993, radiographic evaluation demonstrated regrowth of the residual tumour and massive pleural and pericardial effusion. The cytochemical and immunophenotypic analysis of the tumour cells in the fluid revealed a myeloid phenotype. The patient died of the disease 6 months after the relapse. There was no evidence of the development of AML in the frequent bone marrow and peripheral blood examinations during the follow-up period. An autopsy was not performed.

Pathological findings

The primary mediastinal mass was an elastic hard tumour with an irregular contour, 10.5×5.5×5.0 cm in size. The cut surface was white to grey, and there was no fibrous encapsulation or lobulation. The tumour invaded the right lung, and multiple pleural satellite nodules were found. Microscopically, the thymic lobules were entirely or partially replaced by monomorphous round cells, which also infiltrated into the interlobular septa with hyaline sclerosis (Fig. 1A). There were scattered reactive lymphoid follicles with germinal centres. The tumour cells were medium sized and had a blast-like appearance with a round configuration. The nuclei were round or slightly irregular, with finely dispersed chromatin and

Fig. 3 Representative electron micrograph of a primary tumour cell. The cell contains scattered electron-dense or medium-density granules in the cytoplasm, compatible with myeloid differentiation. Original magnification ×10,000

occasional prominent nucleoli (Fig. 1B). A small number of lymphocytes were present in the tumour, but eosinophils and neutrophils were not observed.

The recurrent tumour cells in the pleural and pericardial fluid had fine dust-like azurophilic granules in the cytoplasm (Fig. 1C).

Specimens of the primary tumour were fixed for 10 h with periodate-lysine-paraformaldehyde (PLP), embedded in OCT compound, frozen in dry ice-hexane, and stored at –80°C. Cytological specimens obtained from the pleural and pericardial fluid at the time of relapse were prepared by standard techniques using cytospin or cell blocks. These sections or formalin-fixed, paraffin-embedded sections were stained by the avidin-biotin-peroxidase complex method for immunohistochemistry. The panel of antibodies used is listed in Table 1. Histochemical stains for naphthol AS-D chloroacetate esterase and peroxidase were also performed (Table 2).

The results of the histochemical and immunophenotypic studies are also summarized in Tables 1 and 2. The primary tumour cells were negative for naphthol AS-D chloroacetate esterase. Stains were positive for peroxidase in the primary and recurrent tumour. The primary tumour cells were positive for CD34 and TdT (Fig. 2A), and negative for CD13 and CD33 (Fig. 2C). In contrast, the cells in the recurrent tumour were positive for CD13 and CD33 (Fig. 2D), and negative for CD34 and TdT (Fig. 2B). In the primary and the recurrent tumour, expression of B-, T-, and NK-cell-associated antigens was not observed. The results of a flow cytometric analysis of the recurrent tumour cells in the pleural fluid were similar to the results of the immunohistochemical test.

Genotypic analysis of the primary tumour by Southern blot hybridization showed clonal rearrangement of the immunoglobulin heavy chain (IgH) gene, but not of the T-cell receptor (TCR)-β or -γ genes.

A retrospective ultrastructural study was carried out for the primary tumour. Electron-dense and medium-density granules were scattered in the cytoplasm, but Auer rods were not observed (Fig. 3).

Discussion

The thymic tumour in the present case was initially misinterpreted as a lymphoma, since neoplastic cells showed the morphology of primitive blast cells with the expression of TdT and clonal rearrangement of the IgH gene. However, we could have made a correct diagnosis of granulocytic sarcoma by a touch preparation had this been available. Positive peroxidase staining and electron microscopic findings displaying primary granules might have led to a correct diagnosis if the possibility of granulocytic sarcoma had been consciously taken into consideration.

The present case illustrates some of the pitfalls involved in the pathological diagnosis of unexpected granulocytic sarcoma in the clinical setting. First, this tumour occurred in a nonleukaemic patient, who did not subsequently develop acute leukaemia. Byrd et al. reported that nearly half (47%) of the patients with primary granulocytic sarcoma were misdiagnosed at the initial presentation [3]: the most frequent incorrect diagnosis was lymphoma, but other types of sarcoma were also frequently assumed. Second, the location of this tumour was also exceptional. It has been recognized that the thymus may be involved in all types of leukaemia. According to Middleton et al., thymic involvement was present in five of ten patients with myeloid leukaemia [13]. However, only three patients with primary involvement of the anterior mediastinum have been documented in detail [8, 11]. Mediastinal germ cell tumours coexisting with haematological malignancies including AML and granulocytic sarcoma have been also reported [5, 15]. The tumour in the present case was distinguished by the absence of germ cell tumour components. In contrast, the thymus is involved more frequently by malignant lymphoma [Hodgkin's disease, precursor T-lymphoblastic lymphoma, primary mediastinal large B-cell lymphoma, and mucosa-associated lymphoid tissue (MALT) lymphoma]. In our case, the tumour cells were similar to

those of lymphoblastic lymphoma in some features, such as the morphology and immunoreactivity for TdT. However, TdT may also be expressed in 14% of AML, and frequently in FAB M0 and M1 [10]. Although clonal rearrangement of the IgH gene was found in the present case, as in 20% of precursor T-lymphoblastic lymphoma/leukaemia [7], approximately 14% of cases of AML also demonstrate clonal IgH gene rearrangement [1]. Third, the primary tumour cells were not stained for naphthol AS-D chloroacetate esterase. Naphthol AS-D chloroacetate esterase stain is useful for demonstrating myeloid lineage of the tumour cells in paraffin-embedded tissue sections, but is not highly sensitive or specific. According to Davey et al., 3 of 15 extramedullary myeloid cell tumours (20%) were negative for naphthol AS-D chloroacetate esterase stain [4]. Enzyme histochemical staining for peroxidase and immunohistochemical staining for myeloperoxidase are more sensitive methods for establishing a correct diagnosis.

In the present case, the tumour regrew at the original site and without entering the bone marrow, excluding the possibility of the development of a second, independent neoplasm. Tumour cells initially lacked myeloid-associated antigens, CD13 and CD33, whereas they later acquired both these markers and lost the initially observed CD34 expression and TdT positivity, which are characteristics of progenitor cells [10], later at the relapse. It is possible that tumour cells may differentiate into cells more committed to the myeloid lineage. Although all the published cases of primary mediastinal granulocytic sarcoma have relapsed, immunophenotypic differences between the primary and recurrent tumour have not been documented [8, 11]. Eosiniphils and other cells of the myeloid series can be regularly seen in the human fetal and neonatal thymus, and in the connective tissue of the septa and around the blood vessels [6]. Furthermore, $CD34^+$, $CD4^-$, $CD8^-$, and surface $CD3^-$ immature thymocytes retain the capacity to differentiate into clonal myeloid lineage when influenced by cytokines from thymic epithelial cells [9]. Along these lines, this immature tumour may have arisen directly from myeloid precursors in the thymus.

In summary, we have reported an unusual case of granulocytic sarcoma of the thymus. Cases diagnosed as thymic lymphoblastic lymphomas should be studied carefully to ascertain the possible presence of granulocytic sarcoma.
