Tubular carcinoma of the breast and associated intra-epithelial lesions: a comparative study with invasive low-grade ductal carcinomas

Received: 14 February 2005 / Accepted: 2 June 2005 / Published online: 10 August 2005
© Springer-Verlag 2005

Abstract Ductal intra-epithelial lesions of the breast are associated with invasive neoplasms and comprise a large spectrum of histological patterns. We have examined 23 cases of pure tubular carcinomas (TCs) of the breast and 53 cases of invasive ductal low-grade carcinomas to determine the relationship and distribution of intra-epithelial lesions, mainly of ductal in situ carcinoma type, but including also lobular intra-epithelial neoplasia (LIN) in both entities. Eleven cases of TC showed flat epithelial atypia (FEA) (47.8%), and, in 14 and 6 cases, micropapillary and cribriform low-grade ductal carcinoma in situ (DCIS) were present (60.7 and 26.1%, respectively). On the opposite, in ductal grade I invasive carcinomas, the most frequent architectural pattern was low-grade DCIS growing in arcades in 26 cases (49%). While absent in TCs, low-grade DCIS of solid type was found in five (9.4%) cases of ductal invasive carcinomas, where FEA were present in seven (13.2%) cases. LIN lesions were present in four (17.4%) cases of TC, whereas they represented 7.5%, as reported by Carstens et al. (Am J Clin Pathol 58:231–238, 1972), of cases of low-grade carcinomas. These results suggest that invasive pure TC and low-grade ductal carcinomas of the breast are different lesions, and support the fact that TC, of low histopathological grade, is a particular distinct tumoural entity.

Introduction

Tubular carcinoma (TC) of the breast is a distinct low-grade ductal neoplasm characterized by well-differentiated tubular structures, typically one layer thick, and surrounded by abundant stroma (Fig. 1) [5, 11, 15]. It is an uncommon entity, as it represents less than 2% of all breast carcinomas. However, with the advent of mammographic screening, this proportion is increasing [14].

The majority of ductal invasive breast carcinomas are considered to develop from premalignant lesions [1], mostly atypical duct hyperplasia (ADH), and ductal carcinoma in situ (DCIS). In the majority of cases, the grade of the intra-epithelial lesions is highly correlated with the grade of their invasive counterpart.

Different studies have found an association of TC with low-grade DCIS of cribriform and micropapillary type [7, 9], and also with flat epithelial atypia (FEA) [9]. However, to date, there are no studies comparing a larger spectrum of low-grade DCIS lesions and lobular intra-epithelial neoplasia (LIN) found in TCs with those encountered in well-differentiated low-grade invasive ductal carcinomas of the breast of no specific type. This investigation was undertaken to assess the different types and grades of in situ carcinoma lesions accompanying TCs and to compare them with the intra-epithelial lesions associated with grade I, not otherwise specified and not mixed, invasive ductal neoplasms.

Material and methods

The analysed surgical specimens were obtained from the surgical pathology data base of the Department of Pathology of the Erasmus University Hospital, Brussels, Belgium, from 1988 to 2004. Twenty-three cases of TCs were retrieved. Afterwards, the rest of the invasive carcinomas were evaluated, and the ductal grade I neoplasms were selected. Therefore, 53 cases of well-differentiated invasive ductal carcinoma of not otherwise specified (NOS) type were examined. The histological diagnosis was reviewed

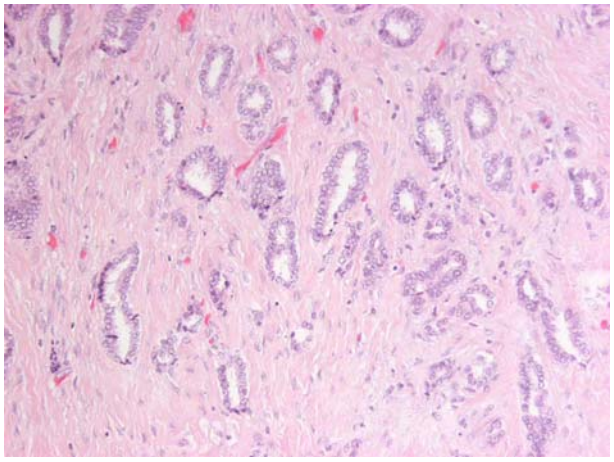

Fig. 1 Tubular carcinoma. Invasive haphazardly distributed round to oval and focally angulated glands in a fibrous stroma (×100)

independently by two pathologists on routine hematoxylin and eosin sections. Strict diagnostic criteria were used to select TCs. Indeed, following the 2003 World Health Organization (WHO) classification of breast tumours [19] and recent refined morphologic criteria [8], the lesions should be composed of at least 70% well-differentiated tubular structures, with the open lumina lined by a single layer of epithelial cells with grade I nuclei and few or no mitoses (Fig. 1). As for the NOS well-differentiated invasive ductal carcinomas, mixed, pleomorphic, osteoclastic giant cells, choriocarcinomatous and melanotic neoplasms were excluded. The histopathological low grade was evaluated according to the semi-quantitative method from Elston and Ellis [5, 6], which takes into account tubular formation, nuclear pleomorphism and mitotic index.

Afterwards, associated intra-epithelial lesions were assessed according to the 2003 WHO classification of breast tumours [19]. Therefore, we divided intra-epithelial breast proliferative lesions into FEA (DIN1a), ADH (DIN1b) and ductal intra-epithelial neoplasia with its different grades (DIN1c, DIN2 and DIN3). Low-grade in situ carcinoma (DIN1c) lesions were subdivided following the 2003 WHO classification into cribriform, solid, micropapillary, papillary and arcade patterns. Cribriform-type lesions were characterized by multiple adjacent ducts distended by a sieve-like proliferation of monotonous, uniform cells with homogeneous, regular and organized lumens. In solid DIN1c lesions no lumens were present. Arcade pattern lesions showed a principally roman bridge architecture, and the ductal spaces within these lesions were not regular, as was the case of cribriform lesions. We also took into consideration the minimum size criterium of 2 mm to establish the diagnosis of DIN1c [18]. Concerning LIN, only low-grade (LIN1) lesions were evidenced in the cases analysed, with no distended acini or necrosis. Histopathological lesions were confirmed by means of immunohistochemistry techniques. For this purpose, high-molecular-weight keratines (Dako, clones 34BE12 and D5/14B4, 1/100 and 1/50 dilutions, respectively, citrate pH 6.00), and E-cadherin (Novocastra, clone 36B5, 1/25 dilution, citrate pH 6.00) antibodies were used. Statistical analyses were made using the Fisher's Exact Test (two-tailed).

Results

The results and patients' characteristics are summarized in Table 1. The mean age of patients was 51.7 (34–73) years for TCs and 54.8 (36–78) years for ductal low-grade carcinomas. Mean tumour size was 9.2 (4–27) and 10.9 (6–19) mm in TC and ductal low-grade neoplasms, respectively.

In 22 of 23 patients with TC no lymph node metastases were found, and the tumour size was less than 2 cm. Therefore, they were staged as T1N0 according to the 2003 WHO classification. The remaining case was represented by a 27-mm tumour with four lymph node metastases. Regarding low-grade ductal carcinomas (LGDCs), the 53 cases analysed corresponded to T1 lesions measuring less than 2 cm. Seven cases showed positive axillary lymph nodes (13.2%).

For practical reasons, we did not take into account atypical hyperplasia lesions (DIN1b) because they are morphologically similar to low-grade ductal in situ carcinoma lesions, and the only valid criterium nowadays for the differential diagnosis is size (2 mm) [18]. These lesions were included within the DCIS group. Eleven cases of TC contained FEA (47.8%) (Fig. 2). These lesions were characterized by cuboidal to columnar cells showing mild atypia and indistinguishable in most cases from TC cells. Apical cytoplasmic eosinophilic snouts were focally prominent. When present, these lesions were often located right next to invasive glands and adjacent to DCIS lesions. In situ carcinoma of micropapillary type was frequently encountered next to TCs (60.9% of cases), whereas their presence in invasive grade I ductal carcinoma was more rare (17% of cases, P=0.0012). The percentage of in situ carcinoma le-

sions with a cribriform pattern was also greater in TCs than in invasive low-grade carcinomas of ductal type (26.1 vs 5.7% of cases, respectively, P=0.0192) (Fig. 3).

Interestingly, FEA, although not so frequent as in TCs, were evidenced in seven cases (13.2%) in association with invasive grade I ductal carcinomas, where the predominant in situ lesions were of arcade pattern (49% of cases) (Fig. 4) in contrast with TCs, in which they were only encountered in two cases (10%) (P=0.0007). Finally, in situ ductal carcinoma of solid type was observed adjacent to grade I ductal invasive neoplasms in five cases (9.4%), while it was absent in TCs (P=0.3146). No higher grade intra-epithelial (DIN2 and DIN3) lesions were observed in TCs, whereas DIN2 was evidenced in two cases of invasive duct carcinoma (3.8%) (P=1).

Lobular intra-epithelial neoplasia lesions were observed in 4 (17.4%) of the 23 TC cases. They were seen in 100% (4 of 4) of cases associated with FEA (DIN1a) lesions and in 50% (2 of 4) accompanying DCIS of micropapillary type. In one case (25%) they were also associated with DCIS of arcade and solid type. From the four cases of LGDC showing LIN (7.5%), two cases were associated with DCIS of arcade and solid type, and in one case, with DCIS of micropapillary type. Interestingly, in one case, LIN was the only intra-epithelial lesion encountered in LGDC.

Discussion

As recently stated by Goldstein et al. [8], there has been a lack of standardized definitions for TCs of the breast. These limitations mostly concern the percentage of tubularity.

These authors have therefore refined the histopathologic criteria and claim neoplasms with at least 70% tubularity, grade I nuclei and rare mitoses to have an excellent prognosis. In this study we have compared a wide spectrum of different intra-epithelial mammary lesions associated with invasive TCs and those encountered in low-grade ductal invasive breast carcinomas of no specific type. Patients with TCs and ductal low-grade carcinomas had similar demographic and neoplasm characteristics, including age and tumour dimensions. For so doing, we have used the last standardized 2003 WHO classification of breast tumours featuring the DIN concept [17–19]. To date, there are a few studies that have analysed the association of some intra-epithelial ductal neoplasia and TCs [7, 9]. These studies mostly concern on one hand, "ductal carcinoma in situ cells with apocrine snouts", a term that corresponds now to FEA, and on the other hand, ductal intra-epithelial neoplasia of micropapillary and, to a lesser degree, cribriform type [11, 12]. However, to the best of our knowledge, the former is the only article comparing TCs and grade I invasive ductal carcinoma associated lesions, which are limited to FEA. Indeed, the authors demonstrated a higher prevalence of these lesions in TCs, which were present in 43.7% of cases, than in invasive grade I carcinomas, where the proportion only attained 3.7% of cases. Our data are in ac-

cordance with those ones (47.8 vs 13.2%, respectively). We should point out that the slightly higher rate of FEA encountered in our 53 grade I invasive carcinomas in relation to previous studies can be explained by the fact that four out of the seven carcinomas displaying these lesions (57%) showed tubular features (Fig. 4), that is to say, neoplastic areas with regular, opened and tubular structures whose proportion was not sufficient to establish a diagnosis of TC (to strictly diagnose TC as such, a minimum 70% proportion of invasive tubular structures, according to recent criteria with grade I nuclei, and few or no mitoses is required [8]). In these cases, as stated above for TC, flat lesions were mostly evidenced next to infiltrative tubular structures.

But no specific comparative analysis seem to have been performed to establish if there is really a difference between TCs and grade I invasive ductal neoplasm intra-epithelial associated lesions if we exclude the study by Goldstein and O'Malley [9], in which FEA are more frequently encountered in TCs than in LGDCs.

Previous studies have shown an overall increased frequency of ductal intra-epithelial lesions concurrent with ductal invasive neoplasms [2], with a good correlation between the histological grade of ductal intra-epithelial neoplasia and the grade of the infiltrative component. Our results also concur with previously reported data stating a close relationship of micropapillary in situ carcinoma and TCs as well as a higher frequency of FEA in these particular tumours. Interestingly, a clear relationship between low-grade DCIS, with an arcade growing pattern, and low-grade invasive ductal carcinoma emerged from this study with respect to TCs. Low-grade DCIS of solid type, although not so frequent, was also distinctively observed in association with low-grade invasive ductal carcinomas. However, the results were not statistically significant (P= 0.3146), perhaps partly due to the small number of cases examined. Another important issue is the higher frequency of LIN in TC, and also their close association with FEA, and in a lesser degree, with low-grade DCIS of micropapillary type. Indeed, FEA lesions and fully established micropapillary DCIS have been reported together in the same surgical specimen in a high proportion of cases [3, 13] as well as in coexistence with LIN. Our results seem to be in accordance with these data and we put them together in the context of TC. The small number of TC cases assessed, however, does not show a statistically significant difference (P=0.2344).

The difference in the lesions observed, together with the results of some genetic studies, give further evidence that TC and invasive grade I ductal carcinoma are different entities. Genetic alterations in TCs have proven to be less frequent than in other breast neoplasms [10, 16, 20]. The nature of these mutations is also different, with a predominance of 16q loss [20]. However, to date, there are no genetic studies comparing the different morphological patterns of (low-, intermediate- or high-grade) DCIS lesions classified within the same differentiation grade. This issue can be interesting, as genetic alterations seem to be different from a quantitative and qualitative point of view when comparing tubular and other (including grade I) ductal carcinomas and, perhaps, genetic abnormalities may vary according to the architectural type of lesion. Unfortunately, the number of genetic studies is scarce and hampered by the paucity of cases analysed.

In summary, our study shows a different profile and distribution of intra-epithelial lesions in TC and ductal low-grade invasive carcinomas. These data, put together with the results of previous histopathologic and genetic studies, support TC of the breast as a clear distinctive entity.

p63, cytokeratin 5, and P-cadherin: three molecular markers to distinguish basal phenotype in breast carcinomas

Received: 30 November 2004 / Accepted: 17 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract Human breast carcinomas represent a heterogeneous group of tumors diverse in behavior, outcome, and response to therapy. However, the current system of pathological classification does not take into account biologic determinants of prognosis. The purpose of this study was to classify and characterize breast carcinomas based on variations in protein expression patterns derived from immunohistochemical analyses on tissue microarrays (TMAs). Therefore, 11 TMAs representing 168 invasive breast carcinomas were constructed. Breast tumors were classified into four different subtypes depending on estrogen receptor (ER) and HER2 expression. Basal-type tumors expressed neither of these proteins and represented 7.6% of our series; basal-like HER2-overexpressing tumors did not express ER and represented 17.7%; luminal-type tumors expressed ER and represented 72.8% of this series (luminal A 56.3%, luminal B 16.5%). Moreover, we characterized each subtype based on P-cadherin (P-CD), p63, cytokeratin (CK) 5, BCL2, and Ki67 expression. Basal-type tumors were mostly grade III, more frequently P-CD-, p63-, and CK5-positive, and had a high proliferation rate. Conversely, luminal-type tumors rarely expressed basal markers and had a low grade and proliferation rate. Basal-like HER2-overexpressing tumors showed a basal-type profile similar with a high grade and up-regulation of P-CD and CK5. With this study, we show that P-CD, p63, and CK5 are important molecular markers that can be used to distinguish a basal phenotype. In addition, we also demonstrate the usefulness of TMAs in breast carcinoma immunoprofiling.

Introduction

Human breast carcinomas represent a heterogeneous group of tumors with a diverse biologic behavior, outcome, and response to therapy. An important challenge to the study and treatment of breast cancer relies on the resolution of molecular heterogeneity that is not apparent by morphological evaluation. Recent cDNA microarray profiling studies on breast tumors have identified distinct subtypes of breast carcinomas that are associated with different clinical outcomes [21, 22]. Sorlie et al. analyzed the expression profiles of 115 sporadic breast tumor samples and categorized them into five main groups: one basal-like, one HER2-overexpressing, two luminal-like (luminal A and luminal B), and one normal breast-tissue-like. When tumors from *BRCA1*-mutated carriers were similarly analyzed, it was found that this genotype strongly predisposes to the basal-like tumor subtype [22, 25]. The so-called basal tumors expressed cytokeratin (CK)5 and CK17 mRNAs, resembling the pattern found in the basal epithelial cells of the normal breast, whereas the luminal phenotype was based on the expression of CK8/18 and CK19 mRNAs similar to those of luminal epithelial cells [2]. The expression of HER1 and P-cadherin (P-CD) was later associated to the basal subtype [15, 16].

Breast cancer treatments evolved and directed target therapies against the estrogen receptor (ER) and HER2 oncogene. However, these therapies would not be expected to be effective against basal breast carcinomas because these tumors express neither of these proteins [15]. The characterization of this subtype assumes a major importance, leading to a more focused investigation on putative

therapeutic targets. Therefore, in the present study, we confirmed by immunohistochemistry (IHC) on tissue microarrays (TMAs) the association of high levels of P-CD and CK5 expression to the basal subtype. Moreover, we show that p63 is also up-regulated in this subgroup and can help distinguish basal breast carcinomas. p63 is a p53 homolog crucial for the maintenance of a stem cell population in several epithelial tissues and is necessary for the normal development of the human mammary gland [9, 13, 14, 26]. According to previous studies from our group, approximately 9% of the invasive ductal carcinomas of the breast are positive for p63 [18].

In this report, the existence of four different subtypes of breast cancer was confirmed by protein expression patterns assessed by IHC on 11 TMAs containing 168 independent breast carcinoma cases. The definition and characterization of the different subtypes were based on the expression of seven molecular markers (ER, HER2, P-CD, p63, CK5, Ki67, and BCL2).

Materials and methods

Patients' selection

One hundred sixty eight tumor samples were obtained from patients treated at the State University of Campinas (UNICAMP), Sao Paulo, Brazil, and at Hospital Sao Joao, Porto, Portugal. Of these, 50 tumors presented clinical features of familial breast cancer according to the Breast Cancer Linkage Consortium [5, 6]: early onset, bilaterality, and multiple cases of breast and ovarian cancer in the family (more than two first-degree relatives involved). The remaining 118 cases were from patients without any clinical familial feature (sporadic). All sporadic cases had ER IHC information available for whole tissue sections. From these, 62 tumors also had previous information for P-CD expression, and 73, for fluorescence in situ hybridization (FISH) analysis.

Tissue microarray construction

Representative areas of different lesions were carefully selected on hematoxylin and eosin (H & E)-stained sections and marked on individual paraffin blocks. Two tissue cores (2 mm in diameter) were obtained from each selected specimen and precisely deposited into a recipient paraffin block using a TMA workstation (TMA builder ab1802, Abcam, Cambridge, UK). Eleven TMA blocks were constructed, each containing 24 tissue cores, arranged in a 4×6 sector. In each TMA block, nonneoplastic breast tissue cores were also included as controls. After construction, 2-μm tissue sections were cut and adhered to Superfrost Plus glass slides. An H & E-stained 4-μm section from each block was reviewed to confirm the presence of morphological representative areas of the original lesions.

Immunohistochemistry

Immunohistochemical staining was performed using the streptavidin–biotin–peroxidase technique (Lab Vision Corporation, Fremont, CA, USA) in each set of 11 glass slides comprising the TMAs. Antigen retrieval was done by incubating TMA sections in an antigen-unmasking solution, pH 6.0 (Vector Laboratories Inc., Burlingame, CA, USA), or in ethylenediaminetetraacetic acid (EDTA), pH 8 (Lab Vision) at 98°C. The antigen retrieval times, antibodies, dilutions, and suppliers are listed in Table 1. After washes in a phosphate buffer solution (PBS), endogenous peroxidase activity was blocked by incubation of the slides in a 3% hydrogen peroxide solution in methanol (Merck, Germany). The slides were incubated with a blocking serum (Lab Vision) for 10 min and then incubated with the specific antibody. Immunostaining was performed overnight at 4°C (P-CD and CK5) or for 1 h at room temperature (HER2, ER, p63, BCL2, and Ki67). After washes, the slides were incubated with biotinylated secondary antibody, followed by streptavidin-conjugated peroxidase (Lab Vision). Diaminobenzidine was used as a chromogen. Tissues were then counterstained with hematoxylin and coverslipped using a permanent mounting solution (Zymed, San Francisco, CA, USA).

Immunoreactivities were classified by estimating the percentage of tumor cells showing characteristic staining. In nonneoplastic breast tissues, p63 showed nuclear positivity in myoepithelial cells. P-CD presented a distinctive membranous and occasionally cytoplasmic immunoreactivity in nonneoplastic myoepithelial cells. CK5 stained the myoepithelial cells of breast lobules and ducts. Two pathologists (F.S. and R.D.) evaluated the IHC staining. Because nonneoplastic mammary secretory cells do not express P-CD, either membranous or cytoplasmic immu-

noreactivity was considered positive when more than 10% of the neoplastic cells expressed this marker [19]. Similarly, we adopted the same cutoff value for nuclear p63 and ER reactivity and for cytoplasmic CK5 and BCL2 reactivity. Four categories were defined for Ki67: 0, 0–5%, 5–25%, and >25% of stained nuclei. To evaluate HER2, the percentage of cells with membranous staining and intensity was assessed. HER2 was evaluated according to the four-category system (0–3+) and considered positive when 3+ was attributed. We compared our HER2 results with previously obtained FISH information. Of 73 tumor cases, 27 were simultaneously positive, and 39 were simultaneously negative. Only seven tumors presented discordant information: five were HER2-positive and FISH-negative, while the remaining two cases were HER2-negative and HER2-positive for the FISH analysis. For those discordant cases, we assumed FISH results.

Statistical analysis

The χ^2 contingency test was used for categorical variables to determine differences between phenotypes. A p value of <0.05 was considered to reflect a significant association. The StatView 5.0 (SAS Institute Inc., Cary, NC, USA) program was used for this analysis.

Results

Tissue microarray analysis and validation data

To validate the use of TMA for immunoprofiling, we compared, from whole tissue sections, available information on protein expression levels of ER and P-CD with those obtained by IHC on TMA. Of 118 breast carcinomas, 88 were simultaneously ER-positive, whereas 25 were simultaneously negative. Only three cases presented divergent information, and four were not interpretable. Overall, the concordance was 97.4%. In the same way, P-CD expression was also validated. Of 62 sporadic tumors, 12 were simultaneously positive and 48 were simultaneously negative, whereas only 2 cases were discordant. For this basal marker, we observed an overall concordance of 96.8%. This high concordance between IHC on whole tissue sections and on TMAs justified the further use of TMAs.

Immunohistochemistry profiles in breast tumors

We performed IHC on each set of 11 TMA slides for ERα, HER2, P-CD, p63, CK5, Ki67, and BCL2. The results are shown in Table 2 and Fig. 1. Cases positive for ER, p63, and Ki67 showed the characteristic nuclear staining, whereas BCL2 and CK5 showed a cytoplasmic pattern on neoplastic cells. HER2- and P-CD-positive tumors showed a membranous staining. We observed that 72.9% of breast carcinomas in our series were ER-positive, whereas 34.5% were HER2-positive (3+). Less than 31.7% of the tumors analyzed presented expression of a basal marker (P-CD, p63, and CK5).

Like Nielsen et al. [15], we also classified each tumor in a practical way based on its ER and HER2 expression. A total of 158 cases were immunohistochemically interpretable to allow sample characterization into one of five groups (Table 3). If a tumor was ER-positive, it would be classified as luminal; however, we distinguish luminals A and B on the basis of HER2 overexpression. If a tumor was ER-positive and HER2-negative (0, 1, or 2+), it would be classified as luminal A (ER+/HER2−); however, if it was ER- and HER2-positive, it would be classified as luminal B (ER+/HER2+). If a tumor was ER-negative and HER2-positive (ER−/HER2+), it would be classified as basal-like HER2-overexpressing, and if it was both ER- and HER2-negative but positive for at least one basal marker (P-CD and/or p63 and/or CK5), it would be classified as basal (ER−/HER2−). If a tumor did not show expression for any of these markers, it would be classified as negative and would not be considered in the remaining analyses. Using this definition, we observed that basal type comprised 7.6% of all tumors, whereas luminals A and B comprised 56.3 and 16.5%, respectively. Basal-like HER2-overexpressing tumors represented 17.7% of the series, and null phenotype, 1.9% (Table 3). When these immunoprofiles were compared in relation to familial and sporadic origin (Table 4), we observed that basal tumors were mostly associated to familial cases (83.3%), whereas luminal and basal-like HER2-overexpressing cases were more frequently sporadic (69.7% of luminal A, 92.3% of luminal B, and 71.4% of basal-like HER2-overexpressing tumors; $p<0.0001$).

The protein expression profiles clearly differed in luminal A, luminal B, basal, and basal-like HER2-overexpressing tumors concerning P-CD, p63, CK5, Ki67, and BCL2 (Table 4). Statistically strong significant differences between the four groups were observed in this study. Basal and basal-like HER2-overexpressing tumors presented a high histological grade (75 and 81.5% grade III, respectively, $p=0.0001$), had a higher proliferative rate, and demonstrated a clearly higher frequency of P-CD (83.3 and 60.9%, $p<0.0001$) and CK5 (66.7 and 37%, $p<0.0001$) expression (Table 4). Luminal pattern was associated with an increasing frequency of tumors expressing BCL2 (69.1% luminal A and 56.5% luminal B, $p=0.0006$) and with a lower expression of basal markers. Actually, less than 20%

of luminal tumors presented a basal marker expression (Table 4). p63 expression was strongly associated to basal tumors (55.5%, p=0.0255).

Finally, we analyzed whether each basal marker was expressed exclusively by the tumors or if its expression was associated with another basal marker (Table 5). We observed that the majority of the luminal tumors (60.3% luminal A and 73.8% luminal B) were simultaneously negative to P-CD, CK5, and p63. This percentage was much lower for basal-like HER2-overexpressing tumors (36.4%) and absent for basal ones. Within basal and basal-like HER2-overexpressing subtypes, p63 was only positive when coexpressed with other basal markers. The same occurred for CK5 within a basal subtype. Simultaneous expression of P-CD, p63, and CK5 was rare in luminal A tumors (4.1%), being completely absent within the luminal B subtype. Interestingly, we observed that 18.2% of basal tumors and 13.7% of basal-like HER2-overexpressing tumors were simultaneously positive for all basal markers (p=0.0016).

Discussion

Gene expression profiling has refined the classification of sporadic breast tumors into distinct subtypes [17, 21, 22, 25]. Basal breast tumors represent one of the most important subtypes since there is no efficient therapy against it, and it is often associated with a poor prognosis [1, 21, 22, 24, 25]. Gene expression profiling approaches have also allowed the observation that familial *BRCA1* mutant tumors segregate strongly with basal-type sporadic cancers, which indicate that basal-type sporadic tumors and familial *BRCA1* tumors can have similar etiologies [23]. *BRCA1* tumors commonly express basal cytokeratins, but not ER, and are of a higher histological grade, indicating a

more rapidly dividing tumor [10, 16]. In the present study, we observed that the majority of basal tumors had a familial clustering, were the most proliferative ones, and were more frequently grade III. Foulkes et al. [10] associated CK5 expression to *BRCA1*-derived tumors. In their study, 40% of CK5-positive tumors were from *BRCA1*-mutated carriers. Palacios et al. [16] have also demonstrated a strong correlation between P-CD- and *BRCA1*-derived tumors. In the present study, we show that P-CD and CK5 were up-regulated in the basal subtype. This evidence suggests that these patients are at a high risk of having *BRCA1* mutations; however, additional studies are needed to investigate this issue further. Basal tumors were also characterized by p63 overexpression. This molecular marker, expressed in the basal cell layer, is thought to play an essential role in the differentiation and growth control in stratified epithelia [13].

Besides the identification of a basal-like subtype, we also distinguish luminal A, luminal B, and basal-like HER2-overexpressing subtypes. For this purpose, we used TMA technology since it allows the screening of a large series of samples at the same time without losing tumor representativity [7, 11, 12, 20].

The basal-like HER2-overexpressing subtype was characterized by a high grade and up-regulation of P-CD and CK5. In fact, Birnbaum et al. [2] have recently suggested that HER2-overexpressing tumors should be included in a bona fide basal-like subclass. Luminal-like tumors were distinguished on the basis of HER2 expression. The luminal A subtype did not express HER2 and was strongly associated with low proliferation and with high levels of BCL2 expression. This is not surprising since it is well known that BCL2 is up-regulated by ER [7]. The luminal B subtype was characterized by HER2 overexpression. These tumors were mostly sporadic and rarely expressed a basal marker.

Finally, we studied whether each basal marker was expressed exclusively by the tumors, or if its expression was associated with another basal marker. p63, P-CD, and CK5 are proteins that are expressed early in epithelial differentiation and may contribute to a committed stem cell and/or progenitor phenotype [3, 4, 9]. In this study, we thus confirmed the existence of heterogeneity among breast tumor cells since we observed different patterns of basal marker expression within luminal A, luminal B, basal-like HER2-overexpressing, and basal subtypes. Luminal A and luminal B subtypes were characterized by tumors that expressed exclusively one or two molecular markers, the majority being simultaneously negative. In contrast, the basal subtype rarely expressed just one basal marker but frequently expressed them simultaneously, which suggests a more undifferentiated profile. These pieces of evidence are in accordance with a hierarchy model of breast cancer oncogenesis that predicts functional heterogeneity among the cells that comprise the tumor [2, 8]. Malignant cells may have been derived from stem cells that were either able to differentiate to a mature estrogen-responsive stage (luminal tumors) or, due to a block in differentiation, stopped earlier in an immature stage (basal tumors). A basal-like HER2-overexpressing profile may represent an intermediary phenotype which failed the terminal differentiation of cells toward the luminal lineage due to a constitutive activation of HER2, an epidermal growth factor receptor (EGFR) family member [2].

With this work, we demonstrated that TMAs are an efficient and reliable platform for subclassifying breast cancers into relevant subtypes, using only a limited number of markers. Moreover, we showed that ER, HER2, P-CD, p63, and CK5 were important to characterize and distinguish basal-like breast tumors.

Immunohistochemical study of androgen receptors in breast carcinoma. Evidence of their frequent expression in lobular carcinoma

Received: 14 March 2005 / Accepted: 16 May 2005 / Published online: 2 August 2005
© Springer-Verlag 2005

Abstract Androgens and androgen receptors (AR) are involved in the pathogenesis of breast cancer. Epidemiological studies have shown a significant association between the risk of breast cancer and androgens. However, the functional role and clinical value of AR expression in breast carcinoma have still not been clearly defined. The present study was set up to investigate the prevalence of ARs in a series of consecutive invasive breast carcinomas (IBCs) and to evaluate the patterns of AR phenotypes in a series of selected invasive lobular carcinomas (ILCs). Among the 250 consecutive IBCs (consisting of 212 ductal and 38 lobular neoplasms), AR immunoreactivity was observed in 151/250 (60.4%) cases, being expressed in 118/212 (56%) ductal and 33/38 (87%) lobular carcinomas (a statistically significant difference, χ^2=11.82). AR expression was frequently associated with ER (65.2%, χ^2=14.33) and PR positivity (66.9%, χ^2=7.36). Most AR positive cases showed a low proliferative index (63.7%) and a low or intermediate histological grade (G1–G2, 63.9%). Among the 80 selected ILCs, AR expression was observed in 64/80 (80%) cases. Our results confirm that ARs are expressed in most breast cancers. Moreover, we demonstrated that AR positivity is particularly marked in lobular neoplasms. In addition, AR positive carcinomas are frequently characterized by a low or intermediate grade, a low proliferative index and ER and/or PR co-expression.

Introduction

In the last two decades the molecular mechanisms related to the hormone dependence of breast tumours have been extensively investigated and the role of estrogen and progesterone receptors (ERs and PRs) in promoting breast cancer has been well documented [28]. It has been demonstrated that these hormone receptors are present in a large proportion of breast cancers, ranging from 50 to 80% of cases [30, 36, 39]. The prognostic value of ER and PR status in breast carcinoma in predicting a good response rate to hormone treatment has been well established [14, 28, 35]. In contrast, the clinical value and functional role of both androgen levels in circulating blood and AR expression in breast carcinomas are less well defined.

Epidemiological evidence of an association between breast cancer risk and androgens has been documented [8, 17, 27]. In particular, it has been observed that high serum testosterone levels can precede the occurrence of breast cancer in both premenopausal [27] and postmenopausal women [3]. However, the role played by androgens in the pathogenesis of breast cancer is not well understood; in particular, the mechanism by which testosterone exerts its proliferative or anti-proliferative effects on breast carcinomatous cells remains unclear [25].

Recent biochemical and immunohistochemical studies indicate that ARs are expressed in a considerable proportion of breast carcinomas, ranging from 35 to 90% of cases [9, 11, 19–22, 32]; in addition, a consistent co-expression of ARs, ERs and PRs has been demonstrated in the same breast cancers [19, 21]. In about 25% of breast cancer metastases, ARs are the sole sex steroid receptors observed

Table 1 Antibodies, methods and dilutions used in the current study

Antigen	Antibody	Autostainer	Dilution	Incubation time (min)	Antigen retrieval (min)
AR	AR27 (Novocastra)	Streptoavidin-DAB (Ventana)	1/20	32	24
ER	6F11 (Ventana)	Streptoavidin-DAB (Ventana)	Ready to use	28	16
PR	16 (Ventana)	Streptoavidin-DAB (Ventana)	Ready to use	24	16
Ki-67	MIB-1 (Dako)	Streptoavidin-DAB (Ventana)	1/100	32	16
E-cadherin	ECH-6 (Ventana)	Streptoavidin-DAB (Ventana)	Ready to use	32	16

AR Androgen receptor, *ER* estrogen receptor, *PR* progesterone receptor, *DAB* diaminobenzidine

in neoplastic cells [22]. ARs have also been detected in the majority of breast carcinomas in situ [28, 31], and their expression appeared to be unrelated to the degree of differentiation in ductal carcinomas in situ (DCIS) [31].

Some studies have focused on the pattern of AR expression in different histological subtypes of breast cancer but the majority of data refer only to ductal carcinomas [7, 28]. A strong, consistent AR positivity has been described both in in situ and in invasive apocrine carcinomas as well as in apocrine metaplasia and the intense expression of ARs was often accompanied by a lack of ER and PR immunoreactivity; AR positivity was therefore proposed as a specific marker of apocrine differentiation [15].In one series of invasive breast carcinomas [21], in which ARs were examined, only 14 lobular carcinomas were included; most of these showed an intense AR immunoreactivity.

The aim of the present study was to conduct an immunohistochemical investigation of the prevalence of ARs in a large series of consecutive breast carcinomas. In addition the patterns of AR phenotypes in a series of selected lobular carcinomas were evaluated. Finally, the AR status was matched with the following clinicopathological parameters: histological type, grade, proliferative index, ER and PR expression and stage of the tumours.

Materials and methods

A total of 330 cases of breast carcinomas were retrieved from the files of the pathology departments at the universities of Bologna, Sassari, Insubria-Varese (Italy) and Falun (Sweden).

This series included two subgroups:

1. Two hundred fifty invasive breast carcinomas (IBCs) consecutively collected during 2003;
2. Eighty selected invasive lobular carcinomas (ILCs).

Among the 250 consecutive IBCs, 28 cases (11.2%) were associated with an extensive carcinoma in situ component, represented by DCIS in 27 cases and lobular neoplasia (LN) in one case. Clinicopathological information about patient age, tumour site, size and local extension was obtained from patient records. The tumour stage was assessed according to the TNM sixth edition recommendations [37].

Formalin-fixed paraffin-embedded sections of tissues obtained from surgical samples were stained routinely with hematoxylin and eosin (H&E). Microscopic slides of all 330 cases were reviewed by two senior pathologists in order to assess histological type, according to the WHO criteria [33], and the grade, applying the Elston–Ellis score system [12]. Lobular carcinomas were graded G2 when classical and G3 when pleomorphic in type [13].Immunohistochemical stains for ARs, ERs, PRs and MIB-1 were applied in all cases; a stain for E-cadherin was applied to all lobular carcinomas (Table 1). Serial, 4-μm-thick, paraffin sections mounted on precoated slides were deparaffinized, hydrated in a graded alcohol series and incubated with primary antibodies using standardized automated procedures (Ventana).

Immunoreactivity was evaluated semiquantitatively as the percentage of positive cells in all the cases. Samples were considered positive for ARs, ERs and PRs when at least 10% of nuclei were immunoreactive, independently of the intensity of the immunostain; For ARs, we considered nuclear labeling in ≥10% neoplastic cells as the cut-off point for positivity, similar to standardized criteria used for other steroid hormone receptors [28]. The MIB-1 labeling index (LI) was calculated as a percentage of positive cells in at least 1,000 tumour cells and was scored as 'high' when the MIB-1 LI was ≥30% and 'low' when the MIB-1 LI was <30%. E-cadherin negativity reinforced the diagnosis of lobular carcinoma.

Table 2 Anatomo-clinical correlation

Series	Histotype	No. of cases	Age (mean)	T1	T2	T3	T4
Consecutive series	IDC	212 (84.8%)	65	116 (54.7%)	51 (24%)	23 (10.8%)	22 (10.3%)
	ILC	38 (15.2%)	64.7	16 (42.1%)	13 (34.2%)	7 (18.4%)	2 (5.2%)
	Total	250		132	64	30	24
Selected series	ILC	80	63.5	41 (51.2%)	28 (35%)	9 (11.2%)	2 (2.5%)

IDC Invasive duct carcinoma, *ILC* invasive lobular carcinoma

Positive controls included normal breast tissue that surrounded the neoplastic lesion (for all antibodies) and normal prostatic tissue (for ARs). Negative controls included the omission of primary antibodies.

All the immunoreactions were separately evaluated by two senior pathologists.

The statistical significance of the results was tested using the chi-square and the Fisher exact tests.

Results

Clinicopathological results

The consecutive series of 250 IBCs included 249 female patients and one male patient. There were 212 invasive ductal carcinomas (IDCs) (84.8%) and 38 invasive lobular carcinoma (ILCs) (15.2%). The age of the patients ranged from 34 to 96 years (mean age 64.9) (Table 2). Among the IDCs, 21 (10%) were well-differentiated (G1), 123 (58%) moderately differentiated (G2) and 68 (32%) poorly differentiated (G3) tumors. Among the ILCs, 27 were G2 (71%) and 11 G3 (29%) neoplasms.

The selected series of 80 ILCs included only female patients whose age ranged from 37 to 86 years (mean age 63.5). Among these cases, 60 (75%) were G2 and 20 (25%) G3 tumors. All relevant clinicopathological data are reported in Tables 2 and 3.

Immunohistochemical results

The immunohistochemical analysis of the consecutive IBCs revealed AR positivity in 151 out of 250 cases (60.4%). The data are reported in Table 3. AR immunoreactivity was observed more frequently in grade 1 and 2 carcinomas (110/172, 63.9%) than in grade 3 carcinomas (41/78, 52.5%). Looking at the tumour stage, ARs were observed in 78/132 (59%) T1 tumors and in 73/128 (61.8%) T2–T3–T4 tumors. AR positivity was observed in 121/190 cases (63.7%) in association with a low MIB-1 LI, whereas half of the cases with a high MIB-1 LI (30/60, 50%) were AR negative. AR immunoreactivity was expressed in 118/212 cases (56%) of IDCs and in 33/38 cases (87%) of ICLs (Table 2). The number of AR positive cells ranged from 10 to 100%, with a mean of 50.2%, in IDCs, and from 30 to 90%, with a mean of 62.4%, in ILCs. The intensity of AR immunoreactivity was generally proportionate to the percentage of positive cells.

There were 216 ER positive cases (86.4%), 141 of which (65.2%) were also AR immunoreactive. Ten ER negative carcinomas (29.4%) showed AR expression. In addition, 109 out of 163 PR positive carcinomas (66.9%) also displayed AR positivity, while 42 out of 87 PR negative carcinomas (48.2%) showed AR immunoreactivity.

Table 3 Grade and immunohistochemistry in 250 consecutive ductal (IDC) and lobular (ILC) carcinomas

	IDC (212 cases)	ILC (38 cases)
G1	21 (10%)	0
G2	124 (58%)	27 (71%)
G3	67 (32%)	11 (29%)
AR+	118 (56%)	33 (87%)
AR−	94 (44%)	5 (13%)
ER+	180 (85%)	36 (95%)
ER−	32 (15%)	2 (5%)
PR+	137 (65%)	26 (68%)
PR−	75 (35%)	12 (32%)
MIB-1+	56 (26%)	4 (11%)
MIB-1−	156 (74%)	34 (89%)

AR Androgen receptor, *ER* estrogen receptor, *PR* progesterone receptor; *G1*, *G2*, *G3* grade of tumour differentiation

Table 4 Number of ductal (IDC) and lobular (ILC) carcinomas among consecutive series of 250 IBCs with androgen receptor (AR) positivity and lack of immunoreactivity for estrogen receptor (ER) and progesterone receptor (PR) according to degree of differentiation (G2, G3)

	ER−/PR−
AR+IDC G2	4/12 (33.3%)
AR+IDC G3	3/18 (16.6%)
AR+ILC G2	3/3 (100%)
AR+ILC G3	2/3 (66.6%)

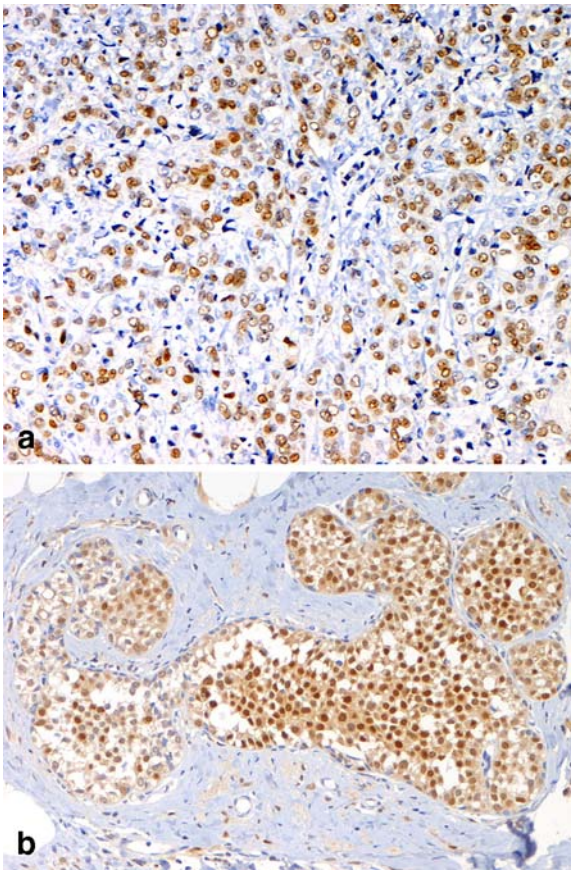

Fig. 1 Lobular carcinoma showing intense AR immunoreactivity both in invasive (**a**) and in situ component (**b**) (DAB-H, 200×)

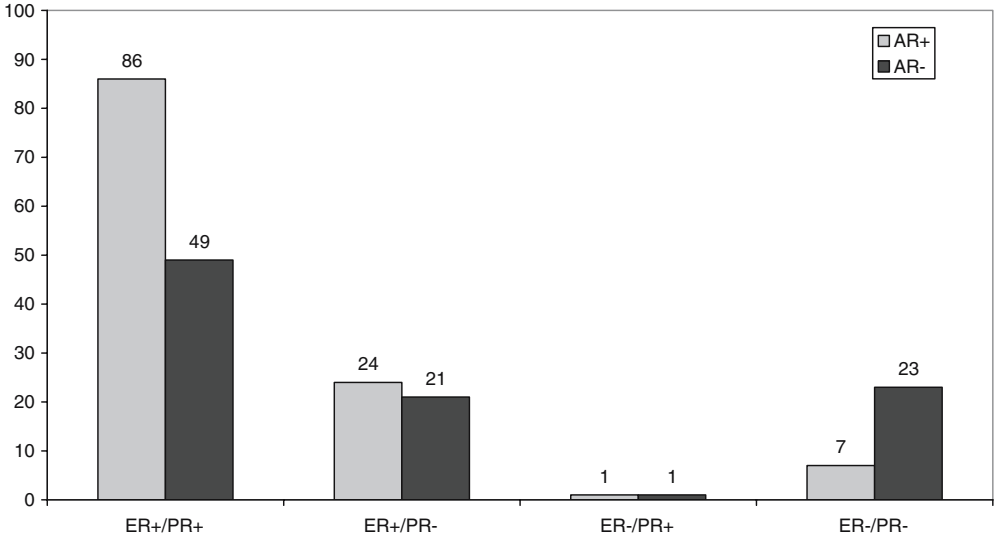

Fig. 2 Comparison of androgen receptor (*AR*) expression and simultaneous estrogen receptor (*ER*) and progesterone receptor (*PR*) immunoreactivity in 212 invasive ductal carcinomas (IDC) consecutively collected

Twelve out of 36 (33.3%) tumors, negative for both ER and PR, were AR-immunoreactive; in these cases, the number of AR positive cells ranged from 15 to 90% with a mean of 60.4%. The distribution of grade in AR+/ER−PR− is shown in Table 4. Twenty-three cases (9.2%) were negative for all hormone receptors tested; all these negative cases were IDCs.

The IDC cases showing a DCIS component revealed AR positivity in both the invasive and in the in situ components in 18 out of 27 (66.6%) cases. In such cases the proportion of AR positive tumor cells in DCIS was usually lower than that observed in invasive areas. Six out of 27 (22.2%) carcinomas expressed ARs in only the invasive component, whereas three cases were negative in both the in situ and in the invasive areas. The only case with lobular neoplasia associated with ILC showed strong AR positivity in both components (Fig. 1a,b).

In the selected series of ILCs, AR immunoreactivity was observed in 64 out of 80 cases (80%). AR expression was present in 51 (85%) cases of classical ILC (G2) and in 12 (65%) pleomorphic ILC (G3). AR immunoreactivity was detected in 34/41 (83%) T1 ILC and in 30/39 (77%) T2–T3–T4 ILC.

ERs and PRs were expressed in 56/64 (87.5%) and 48/64 (75%) of AR positive ILCs, respectively; only one case (1.2%) was negative for AR, ER and PR.

Statistical analysis of all the data showed a significant association between:

1. AR expression and lobular histotype in the series of 250 consecutive IBCs (χ^2=11.82).
2. ER and AR positive status (χ^2=14.33) in the consecutive series.
3. PR and AR positive status (χ^2=7.36) in the consecutive series.

None of the other parameters considered, including grade (χ^2=3.55), stage (χ^2=0.09) and proliferative index

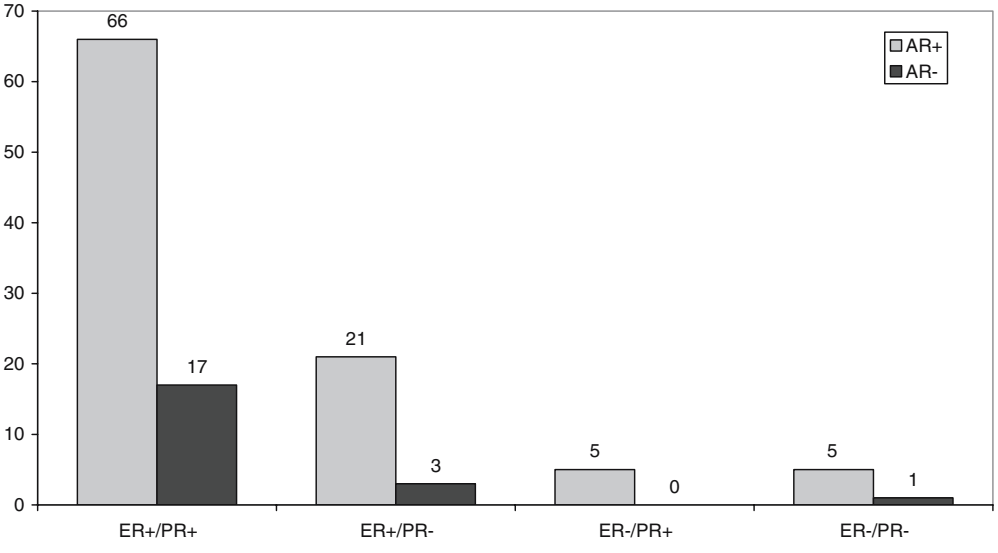

Fig. 3 Comparison of androgen receptor (*AR*) expression and simultaneous estrogen receptor (*ER*) and progesterone receptor (*PR*) immunoreactivity in 118 invasive lobular carcinomas (80 selected and 38 consecutive ILC)

(χ^2=3.02), showed a significant correlation with AR immunoreactivity.

In the series of 80 selected ILCs, no significant association was found between AR expression and other parameters such as hormonal status, proliferative index, grade, stage and age.

Discussion

Numerous studies have demonstrated the role of estrogen (ER) and/or progesterone (PR) receptors as strong predictors of a good response rate to hormone therapy and chemotherapy in the management of patients with breast carcinoma [2, 18]. However, the clinical significance and functional role of androgen levels and of androgen receptor (AR) expression in breast cancer has not been well defined.

There is evidence that androgens can directly stimulate the growth of human breast cancer cell lines [26]. Various studies that were conducted to establish the levels of adrenal and ovarian androgens in breast cancer patients have led to conflicting data [4, 41]. An Italian perspective investigation enrolling a large cohort of premenopausal and postmenopausal women from the province of Varese demonstrated the relationship between invasive breast cancer and preoperative high serum androgen levels in both premenopausal [27] and postmenopausal women [3].

AR is a member of the larger nuclear receptor family that mediates the biological functions of androgens [6]. Some biochemical and immunohistochemical data have indicated the presence of AR in breast cancer tissue. In particular, recent studies show that AR is expressed in a considerable proportion of breast cancers, ranging from 35 to 70% of cases [5, 19, 20, 28, 32]. The results of our study appear support these findings; in fact, we found AR expression in a high percentage (60.4%) of a large series of 250 consecutive IBCs. These data suggest that ARs are involved in the pathogenesis of at least a subset of breast carcinomas.

Moreover, our study showed a strong widespread AR positivity in the majority of lobular carcinomas (87%) and the difference of expression between lobular and ductal carcinomas was statistically significant.

Similar results were obtained in the series of selected lobular carcinomas that showed AR immunoreactivity in 80% of the cases, confirming that a frequent, widespread, intense AR expression seems to be a distinctive feature of invasive lobular carcinomas.

The present immunohistochemical analysis of the hormone status of 250 IBCs indicated a statistically significant positive correlation between AR and ER expression (χ^2= 14.33) as well as a statistically significant co-expression of AR and PR (χ^2=7.36). These data concur fully with those reported in previous studies [11, 19, 21].

Most AR positive carcinomas in our series were associated with a low or intermediate histological grade (G1–G2, 66%) and a low proliferative index (80%); this association reflects that of the majority of ER and PR positive IBCs [29].

Furthermore, our study demonstrated that most ILCs are characterized by a generally low proliferative index and high ER, PR and AR expression. This steroid receptor pattern clearly suggests a hormonal involvement in the pathogenesis of ILCs [10, 23, 24, 38].

An interesting result obtained in our study was the isolated AR positivity found in a subset of ER and PR negative IDCs (7/30 cases) (Fig. 2) and ILCs (5/6 cases) (Fig. 3). This hormonal pattern (ER−, PR−, AR+) did not show any correlation with tumor grade (Table 3), in either ductal or lobular histotypes. This is in contrast with the results reported in recent studies [1, 28] in which AR expression was detected in a subset of G3 ER/PR negative IBCs.

The efficacy of response to endocrine treatment is generally correlated with ER and PR positivity of tumors, but not with AR expression [40]. In this context, it must be recalled that a previous study [16] has shown that medroxyprogesterone acetate (MPA), a synthetic progestin, inhibits the proliferation of ER and PR negative cancer cell lines via androgen receptors. Moreover, in a group of women with metastatic breast cancer, a good response determined by the AR, but not PR levels was seen after a high dose treatment using megestrol acetate, another synthetic progestin [34]. Thus, the detection of AR in a small subset of ER and PR negative tumors, especially in infiltrating lobular carcinomas may indicate new endocrine therapeutic strategies in women who would not fully benefit from conventional, mainly anti-estrogen based, hormonal treatment.

In conclusion, our study confirms that ARs are expressed in most breast cancers. In addition, we demonstrated that AR positivity is a common feature of invasive lobular carcinomas. AR positive tumors are frequently characterized by ER and/or PR co-expression and by a low grade and a low proliferative index.

The potential role and the impact of ARs in breast carcinoma needs further study; however, ARs are a potential new target for hormonal therapies and they may be clinically useful predictors.

Tissue microarray of head and neck squamous carcinoma: validation of the methodology for the study of cutaneous fatty acid-binding protein, vascular endothelial growth factor, involucrin and Ki-67

Received: 20 January 2005 / Accepted: 16 May 2005 / Published online: 13 July 2005

Abstract Tissue microarrays allow the simultaneous analysis of many tumours using small-diameter cores sampled from larger blocks of tissue, but may be limited by tumour heterogeneity. This study considers the validation of tissue microarray for the study of four molecules of interest as prognostic factors in head and neck squamous carcinoma, including a consideration of methods for assessing immunocytochemical scoring of microarrays. Tissue microarray blocks were constructed from 100 cases of head and neck squamous carcinoma, taking four cores from different areas of each tumour. Immunocytochemical labelling was performed for cutaneous fatty acid binding protein, involucrin, vascular endothelial growth factor and Ki-67. The extent and intensity of scoring was determined for each core and the degree of agreement determined for results from the assessment of two, three or four cores for each carcinoma. In a subset of 30 representative cases, the labelling in the tissue microarrays was compared with that in whole-tissue sections of the same carcinomas. An adequate sample of carcinoma was achieved in more than 90% of the 400 cores; unsuccessful results were attributed to uneven core alignment or to poor targeting of the tumour tissue in the donor blocks. The degree of agreement in the assessment of extent and intensity of labelling was moderate to good (weighted kappa, range 0.479–0.902) between whole-tissue sections and microarray sections depending on the antigen and the scoring system. Tissue microarray is a reliable tool to demonstrate cellular and molecular alterations in head and neck squamous carcinomas. We recommend using the mean results from four cores for biological studies, with analysis of categorical data based on quartile groups. Concordance with whole-tissue section data is reassuring, but data from microarrays need to be validated against clinical outcomes.

Introduction

Tissue microarray (TMA) technology has been developed to address the limitations of conventional histopathological techniques and to facilitate genome-scale molecular pathology studies linking novel genes with clinical end points [20, 26]. TMA is a purely mechanical technique, which involves taking tissue cores from multiple donor blocks with precise insertion (arraying) into an empty 'recipient' block [13]. Each core provides two to three high-power microscopic fields for assessment, approximately 0.05% of the area of a section from a conventional wax block of tissue [3, 32]. Potential problems with the use of TMAs in molecular pathological studies include technical aspects of TMA preparation, targeting of tumour tissue and the extent to which TMA cores are representative of a whole tumour because of tissue heterogeneity, particularly in epithelial tumours [1]. Discrepancies between data from arrays and full sections may bias clinicopathological correlations [15], although it is uncertain which method is more appropriate, and this may be a minor concern if the focus of the study is the expression profiles of tumour populations under standardized experimental conditions rather than individual cases [23, 34, 37].

Validation studies have compared TMA discs and whole-tissue sections to consider the number of cores required to adequately represent the expression of the antigen [17,

19]. Sampling typical and representative regions of each tumour is the key step in TMA construction [41], and punching multiple sites from each original block is recommended to compensate for tumour heterogeneity [30]. In breast carcinomas, two 0.6-mm-diameter cores accurately represent 95% of whole-tissue section specimens [3], although one core may be sufficient to derive most of the information on oestrogen receptor expression [20]. A high concordance between whole-tissue sections and TMA sections when using three cores was achieved in immunocytochemical studies on fibroblastic tumours [17].

Head and neck carcinomas are relatively uncommon, although oral carcinomas account for 2.6% of all malignancies worldwide and, like carcinoma of the larynx, are particularly common in Europe and south and west Asia [27]. In England, head and neck carcinomas are most common in the northwest of the country, with a prevalence of 13.7 per 100,000 [2]. Heterogeneous protein expression in head and neck squamous carcinomas has been described [36], but the optimal strategy to describe this phenomenon and its clinical significance are uncertain. Few studies describe the validation of the technical aspects of TMAs in head and neck squamous carcinomas [5, 12], and some studies have validated against clinical outcomes rather than whole-tissue sections data [9, 10].

As part of a study of mechanisms involved in cell proliferation and angiogenesis in head and neck squamous carcinomas, we have constructed TMAs to investigate the expression of a range of molecules. Cutaneous fatty acid binding protein (C-FABP) is one of the family of small intracellular fatty acid-binding proteins that bind growth regulatory ligands and modulate cellular differentiation, growth and metabolic pathways [6, 42]. C-FABP is associated with differentiating keratinocytes and is strongly expressed in cutaneous squamous carcinomas but not in basal cell carcinomas [38]. C-FABP expression is associated with metastatic behaviour and expression of vascular endothelial growth factor (VEGF) in prostatic adenocarcinomas [18]. VEGF is also closely associated with angiogenesis in head and neck squamous carcinomas [31].

This paper describes the validation of TMA data on the immunocytochemical expression in squamous carcinomas of C-FABP, VEGF and Ki-67, as a marker of proliferation, and involucrin, as a marker of squamous differentiation [39]. Issues related to the number of cores that are needed to minimise problems of heterogeneity and the scoring of results are considered.

Materials and methods

Paraffin wax blocks from 100 cases of head and neck squamous carcinomas were retrieved from the archives in the Department of Pathology at the University of Liverpool, UK. The cases were received between 1993 and 2000 and all patients gave consent for the storage and use of their tissue for research as part of the Cancer Tissue Bank Research Centre. The study was approved by the Liverpool Research Ethics Committee. The mean age of the patients at surgery was 60 years (range 32–88) and 91 patients were male. The primary sites of the carcinomas were oral cavity (n=27), pharynx (n=30), and larynx (n=43). Tumour size according to the TNM classification [35] was T1 (n=10), T2 (n=23), T3 (n=12) and T4 (n=55). Ninety-one percent of the carcinomas were keratinizing, with a range of grades: grade I (n=24), grade II (n=36) and grade III (n=40).

Whole-tissue sections from tumour blocks of a subset of 30 cases were compared with the corresponding TMA discs. The cases were selected to include 10 cases of each grade. The clinicopathological data of these cases were very similar to those of the whole series (not shown).

Tissue microarray construction

Haematoxylin and eosin-stained sections of primary tumours were reviewed, and areas of tumour and normal tissue were marked on the slides, avoiding areas of necrosis and keratin pools. Where possible (63% of the cases), two donor blocks of each carcinoma were used, but for the other cases, only one donor block was available. Two tissue cores, each 0.6 mm in diameter, were placed into each of two recipient paraffin blocks using a manual tissue microarrayer (Beecher Instruments, Silver Spring, MD, USA). Normal liver, kidney, intestine and pancreas were used for orientation. Cores were spaced at intervals of 1 mm in the x- and y-axes. Sections (5 μm thick) were placed on precoated adhesive slides, left to dry at 37°C overnight, immersed in molten paraffin and stored in the dark to protect from oxidation. One section from each TMA block was

Table 1 Antibodies used

Antibody	Source	Clone and code	Dilution	Pretreatment	Positive control
C-FABP	Iwaki Glass Corporation, Japan	Polyclonal	1:1,000	None	Normal tongue squamous epithelium
Involucrin	Santa Cruz Biotechnology	Monoclonal involucrin (SY5): sc-21748	1:400	None	Normal squamous epithelium adjacent to carcinoma
VEGF	Santa Cruz Biotechnology	Monoclonal VEGF (C-1): sc-7269	1:100	None	Normal kidney and breast carcinoma
Ki-67	Novocastra	Monoclonal NCL-Ki-67-MM1	1:200	Pressure cooker with EDTA (pH 7.0)	Palatine tonsil

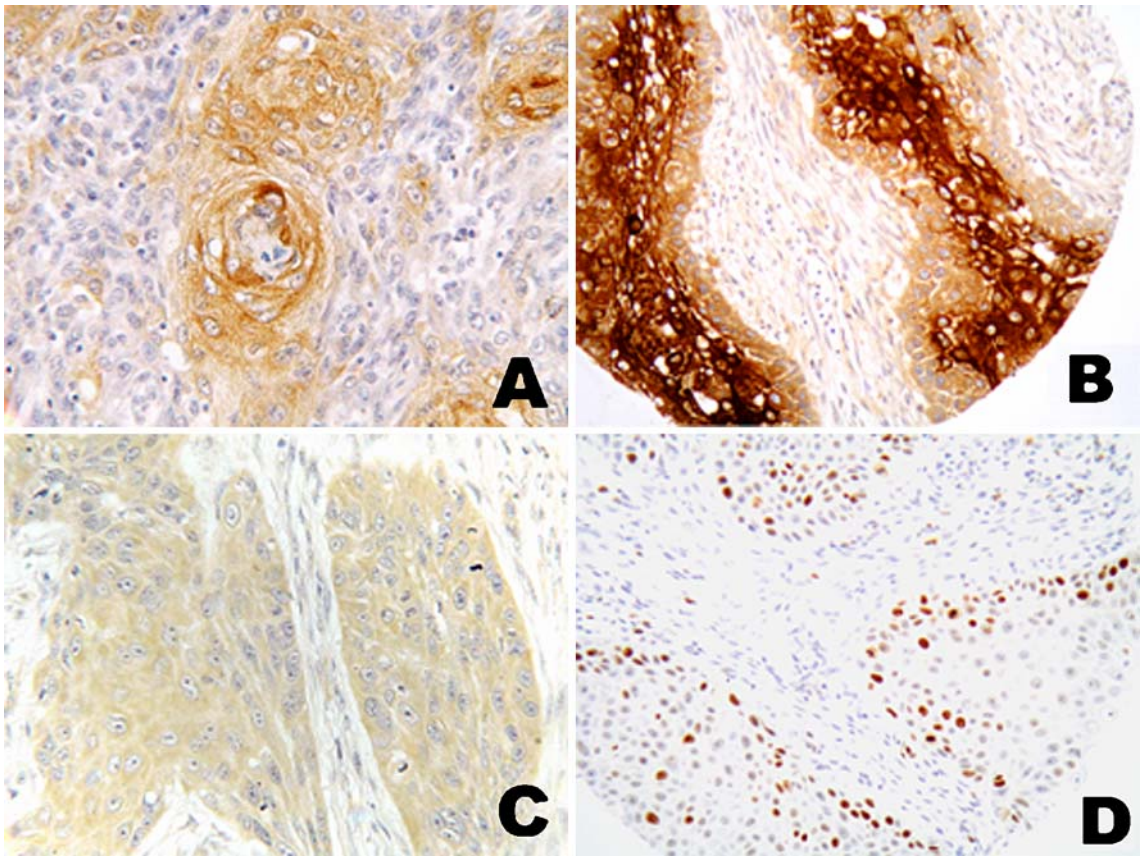

Fig. 1 **a** Cytoplasmic expression of C-FABP is stronger in keratinizing cells. **b** Strong cytoplasmic expression of involucrin is present in most cells in a well-differentiated carcinoma. **c** Cytoplasmic expression of VEGF in carcinoma cells. **d** Nuclear expression with Ki-67 is more frequent in cells at the edges of the islands of carcinoma cells. Immunocytochemical labelling using the primary antibodies stated, with diaminobenzidine as the chromogen and haematoxylin counterstain

stained with haematoxylin and eosin for morphological assessment.

Immunocytochemistry

Immunocytochemistry was performed using antibodies to C-FABP, involucrin, Ki-67 and VEGF (Table 1) and the Dako ChemMate Envision HRP detection Kit (code no. K5007). This is a two-step immunocytochemical staining technique using a polymeric horseradish peroxidase-labelled conjugate. TMA sections on slides previously immersed in molten paraffin were placed in xylene for 1 h. Thereafter, whole-tissue sections and TMA sections were treated identically. Sections were deparaffinized in xylene and rehydrated in industrial methylated spirits, and endogenous peroxidase activity was blocked with H_2O_2/methanol. Sections were pre-treated as indicated (Table 1) and incubated on a Dako autostainer with the primary antibody for 40 min, followed by the labelled polymer for 30 min and ChemMate DAB+ chromogen for 20 min. Slides were washed and counterstained with Mayer's haematoxylin. Negative control slides were prepared by substituting Dako ChemMate antibody diluent for primary antibody. Positive control sections were included (Table 1).

Scoring of immunocytochemistry

A disc was considered unsuccessful for analysis if it was completely absent, it contained no tumour tissue at all (sampling error), or it contained too few tumour cells (<10%) for analysis (uninformative). One observer (W.G.) scored all of the sections on two separate occasions. The percentage of tumour cells that were positive for each antibody was assessed at ×200 magnification, guided by a square lattice, eyepiece graticule. Intensity of labelling was categorized as negative (0), weak (1), moderate (2), and strong (3), where strong intensity was seen at ×40, moderate when staining is evident at ×200 and weak staining is evident only at ×400. Each informative disc from each tumour was scored and the mean values calculated. Ten fields (×200 magnification) were randomly selected from each of the whole-tissue sections and assessed as above.

Statistical analysis

Non-parametric correlation (Spearman's rho coefficient; SPSS Release 12.0.1) was used to compare data from whole-tissue sections and discs and to relate the mean scores obtained from four discs to the scores obtained from individual discs, the mean scores of two discs and the mean scores of three discs.

For categorical analysis, the data on percent labelling were grouped in two ways: an arbitrary 5-point scale where 0–10%=1, 10–25%=2, 25–50%=3, 50–75%=4, and 75–100%=5; and an unbiased, 4-point quartile scale where the groups were separated at the 25th, 50th and 75th centiles. The degree of agreement between data from whole-tissue sections and the mean of four discs was assessed using weighted Cohen's kappa coefficient (SAS for Windows, release 8.02). For descriptive purposes, kappa <0.4 represents poor-to-fair agreement, 0.4–0.6 moderate agreement, 0.6–0.8 substantial agreement, and >0.8 almost perfect agreement [21].

Results

Cutaneous fatty acid binding protein is expressed in the cytoplasm and/or the nuclei of carcinoma cells with stronger and more extensive expression in the more differentiated and keratinized carcinomas (Fig. 1a). Nuclear expression was observed in a small number of cases and was not included in this study. Cytoplasmic expression occurred in 86% of the cases included in TMA. In the validation study, C-FABP was expressed in 29 (96.7%) of 30 TMA cases and in 24 (80%) of 30 whole-tissue sections. Involucrin was expressed in the cytoplasm of carcinoma cells (Fig. 1b) in 94% of all cases and in 100% of the cases

used in the validation study. VEGF expression is cytoplasmic and was seen in 95% of all TMA cases (Fig. 1c). In the validation study, VEGF was expressed in 100% of the TMA sections and in 28 (93.3%) of the whole-tissue sections. Nuclear expression of Ki-67 was present in all cases (Fig. 1d). The median, interquartile ranges, mean and standard deviation of each assessment are shown in Table 2. Table 3 indicates the numbers of cases falling into each scoring category.

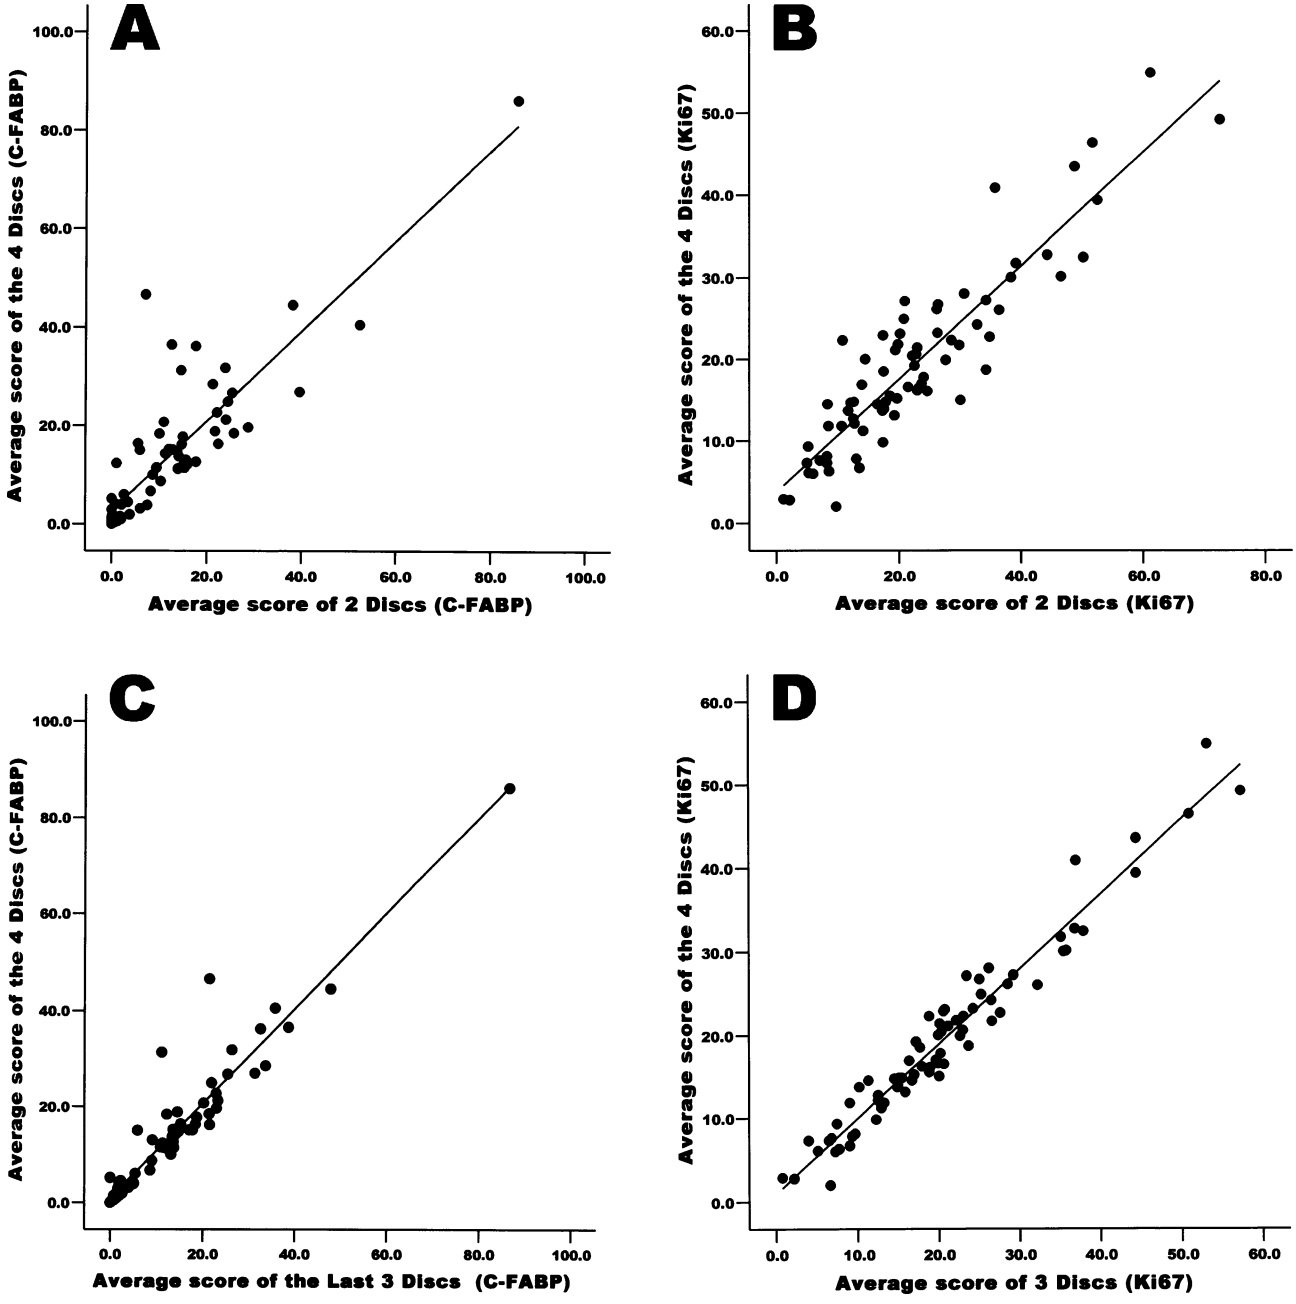

Fig. 2 Scatter plots show a tighter grouping of points when the mean of four discs is plotted against the mean of three discs (*lower plots*) than when plotted against the mean of two discs for both C-FABP and Ki-67 (*upper plots*). The *added lines* are the lines of best fit

Technical validation

Overall, 8.75–9.5% of the discs were unsuccessful. Absent discs on sections were attributable in two instances to absence of the whole core and in seven cases to uneven tissue representation in the cores. Five slides had absent discs due to part of the section being lost during staining. Pressure cooker pretreatment of sections for Ki-67 labelling did not affect the number of lost discs. When two donor blocks were used, the proportion of unsuccessful discs was lower (mean 8.4%) than when one donor block was used (mean 10.1%). Sampling errors were seen throughout the cores in 28 instances, including cores composed mainly of stromal tissue and mucosal glands, or necrotic tissue (one case). Only two cores had uninformative discs (<10% tumour). The 30 cases used in the validation study had 6.6–9.2% unsuccessful cores for individual antibodies.

Overall, 362–365 cores (depending on the antibody) were assessable. Seventy-five percent (range 73–80%) of the cases had four discs available for evaluation. Sixteen percent of the cases had three evaluable discs and 8% of the cases had two evaluable discs. Only two cases had a single

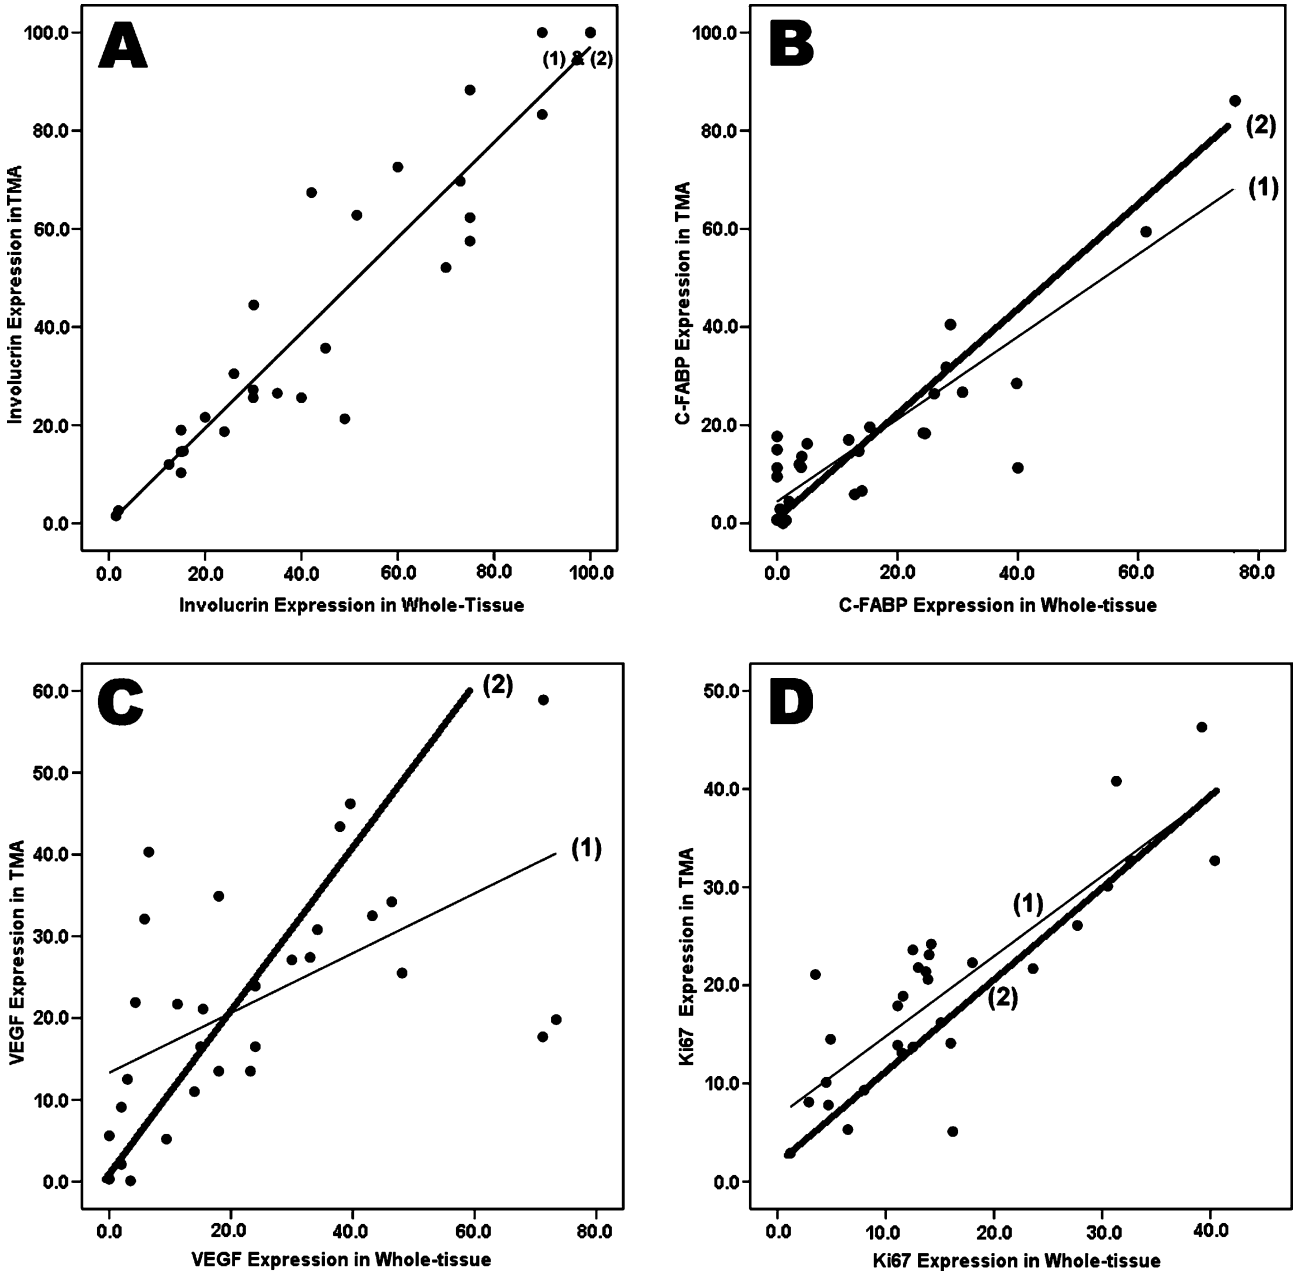

Fig. 3 Comparison of the percent labelled cells on TMA sections and whole-tissue sections for the four antibodies. *Line (1)* indicates line of best fit for the data, whereas *line (2)* is the line of equivalent labelling if both methods gave the same result. For involucrin, the two lines overlap, whereas for the other markers there is a tendency for C-FABP and VEGF to show more extensive labelling in TMA sections and for Ki-67 to be more extensive in whole-tissue sections

Table 6 Weighted kappa scores and Spearman's correlation coefficients for the agreement between values for the scoring of extent (% cells) of labelling of TMA sections and whole-tissue sections

*$p<0.001$

Antibody	Quartile scale		5-Point scale		Correlation coefficient
	k value	95% CI	*k* value	95% CI	
C-FABP	0.5946	0.3861–0.8031	0.6868	0.4828–0.8908	0.724*
Involucrin	0.7495	0.5832–0.9159	0.9211	0.8341–1.0081	0.936*
VEGF	0.4790	0.2388–0.7192	0.6333	0.3929–0.8737	0.635*

successful disc. In the 30 cases used for the validation study, 77, 13 and 10% of the cases had four, three or two discs containing adequate carcinoma for evaluation.

Validation of immunocytochemical scoring

All TMA cases

On continuous data, highly significant ($p>0.001$) correlations were found in all comparisons between four discs and smaller numbers of discs (Table 4). The values of Spearman's correlation coefficient are higher (Table 5), and there is less scatter of data points (Fig. 2) when comparing the means of three discs to the means of four discs than when comparing two discs to four discs.

Selected 30 cases

For percentage positivity, analysis of continuous data shows a highly significant ($p<0.001$) correlation between whole-tissue section and TMA data for each antibody (Fig. 3). For C-FABP and VEGF, the percent labelled cells tends to be greater in TMA sections than in whole-tissue sections. For involucrin, there is no difference between the section types, and for Ki-67, the percent labelled cells tends to be higher in whole-tissue sections. For categorical data (Table 6), the weighted kappa values for most antibodies indicate mod erate or substantial agreement between TMA and whole-tissue section data, with higher kappa scores for the 5-point scale than the quartile scale. For involucrin, the level of agreement was almost perfect on the 5-point scale.

For intensity of staining, categorical data (Table 7) show substantial agreement between TMA sections and whole-tissue sections for C-FABP and Ki-67 (*k* values 0.6005 and 0.6699, respectively). For involucrin, the agreement was almost perfect (*k* value 0.9020), whereas for VEGF, agreement was moderate (*k* value 0.5207).

Table 7 Weighted kappa scores for the agreement between the scoring of intensity of labelling of TMA sections and whole-tissue sections

Antibody	*k* value	95% CI
C-FABP	0.6005	0.3860–0.8149
Involucrin	0.9020	0.7139–1.0900
VEGF	0.5207	0.3080–0.7333
Ki-67	0.6699	0.4571–0.8827

Discussion

This study has demonstrated that for the selected antigens, TMAs can provide a realistic and reliable estimate of the extent of antigen expression in head and neck squamous carcinomas. These results support the findings of other groups who have considered the validity and technical issues of using TMAs to study p53, cyclin D1, retinoblastoma (Rb) and epidermal growth factor receptor (EGFR) [5, 12]. Other papers confirm the prognostic significance of results derived from TMA [9, 10].

The techniques of TMA are well established, and most authors indicate that validation studies to consider technical, biological and statistical issues are necessary to establish the optimal number of cores for each molecular marker and tumour type. Some loss of discs is inevitable due to technical issues of poor core location, sections floating and variations in tumour content of cores at different depths in the recipient block. In our microarrays, 8.75–9.50% of the discs were unsuccessful in producing stained tumour tissue. Discs that were completely absent (1.25–2% of all discs) may be due to poor tissue fixation and processing or poor punching technique leading to tissue loss from the block or to tissue loss during sectioning or staining. Our percentage disc loss is similar to that of Griffin et al. [12] and is lower than the figures reported in most other studies [7, 11, 17, 19, 22, 37, 41], particularly those that have used high-density TMAs [4]. We used a relatively low-density array to facilitate screening of the slides, and this may have helped to reduce disc loss. Others have reported that disc loss was higher when heat-facilitated antigen retrieval was used [37], although this was not our experience.

Uninformative discs with 0–10% tumour tissue result from errors in sampling the donor blocks and comprise the majority of unsuccessful discs (7.5%). This compares favourably with other studies [5, 7, 12, 17, 22, 29, 41] and may reflect the careful comparison with haematoxylin and eosin-stained sections at the time of donor site selection and the avoidance of necrotic areas and keratinous debris. When possible, the use of two donor blocks also reduces the number of unsuccessful discs.

Whether or not TMAs allow adequate representation of the range of antigen expression in a particular tumour is fundamentally no different from considering how many whole-tissue sections might be representative of a tumour, or how to assess an adequate number of fields in one large section [3, 29, 37], and ultimately will reflect whether one is trying to assess the 'average' characteristics of the neoplastic cells or trying to detect more aggressive subclones within a tumour. Heterogeneous protein expression has

been described in squamous carcinomas [36], but studies of TMA in squamous carcinomas, as well as the present study, suggest that this is not a major problem.

Most authors view the whole-tissue section as the 'gold standard' against which microarrays are judged. This approach has its limitations as a single 3-μm-thick tissue section of 3×2 cm represents only 1/19,000 of the volume of a tumour with diameter of 4 cm [33] and may in itself not be representative of the whole tumour. A single TMA disc has an area that is approximately 0.05% of that of a whole-tissue section, although this may underestimate its value when whole-tissue sections contain significant stromal or normal tissue. However, validation against whole-tissue sections provides a pragmatic way forward and some reassurance that microarrays provide data comparable with whole-tissue section analyses. The taking of cores from more than one donor block achieves better representation than more restricted sampling.

Using continuous data, the present study found a good correlation between the results from TMA sections and whole-tissue sections for the extent and intensity of expression of all of the antigens studied. Using categorical data, the kappa statistics indicate substantial or almost perfect agreement between TMA and whole-tissue sections for all antigens. An important issue to be considered is whether the scoring categories should be assigned arbitrarily (e.g., as our 5-point scale) or in an unbiased manner (e.g., using quartile values). Our data indicate that the cut-off points between categories can influence the degree of statistical agreement, particularly where the cut-off values are close to the median or where most data points fall into one category. The 5-point scale used in the present study is similar to that used by many groups and has the merit of being simple to apply and easily transferred to the clinical/diagnostic setting. However, arbitrary cut-off points may obscure potentially interesting biological differences between tumours [14]. Despite these difficulties, our observations are similar to those of other groups for Ki-67 [15, 28, 29] and for VEGF [24], indicating that the technique is robust across tumour and tissue types and different antibodies. Data on intensity of immunocytochemical labelling need to be viewed with some caution due to variations in fixation and tissue processing when cases are collected over a period of several years.

Heterogeneity of antigen expression is difficult to quantify in whole-tissue sections requiring statistically rigorous random selection of microscopic fields for assessment. Depending on the antigen of interest, point counting or 'hot spot' counts may be used, with the potential for bias in the selection of areas for assessment. The relatively unbiased selection of cores for microarrays provides an easy method to define and quantify heterogeneity of expression by comparing the results of one core with those in other cores [24]. Either the mean value or the highest value from a set of cores could be used depending on the biological relevance of the marker being studied.

We have shown that as more discs (one to three) are evaluated, the closer is the level of agreement with the mean of four discs. Others have noted similar findings [3, 7, 8, 16, 17, 25, 29] and that using more than four cores does not improve tissue loss or the degree of agreement [30, 40]. We agree that selecting four cores is optimal to allow for the inevitable loss of informative cores due to technical and sampling issues and to assess tumour heterogeneity [8, 30].

A novel observation is that for some antigens there appears to be a trend for TMA-labelled sections to show slightly more or less extensive labelling than whole-tissue sections. The reason for this is not obvious but may relate to TMA sections having a lower proportion of the section containing tissue-binding sites for antibodies (due to the spaces between the cores) compared with whole-tissue sections or to different rates of oxidation of antigens after cutting sections. This observation followed the realisation that the arbitrary selection of categories for kappa analysis may not be appropriate and indicates that it may not be appropriate to try to validate TMAs against whole-tissue sections. Correlation between microarray data and clinical outcomes may be more relevant [33].

In summary, our results show that the use of three cores will produce a mean value for antigen expression (extent or intensity) similar to that of four cores or whole-tissue sections. We suggest that four cores be taken from each tumour to allow for unavoidable unsuccessful cores due to disc loss or sampling of uninformative tissue. TMA is most valuable for high-throughput analysis of many tumours and, although the use of multiple cores provides some information on tumour heterogeneity, the technique is not ideally suited to the detailed investigation of the microanatomical distribution of antigens within a tumour. This study expands the range of antigens studied by TMA in squamous carcinomas and reinforces the view that TMA is a reliable tool to demonstrate cellular and molecular alterations in these tumours. There are unresolved issues on how TMA data should be expressed, although we would advocate unbiased description of molecular data (using median and quartile values) as a first stage. The nature of the antigens and the genetic mechanisms underlying under- or over-expression may then suggest other options for biologically meaningful categorisation of data.

Acknowledgements This work forms part of the Ph.D. thesis of Dr. Gomaa, who is sponsored by the Ministry of Higher Education, Egypt. The authors would like to express their thanks to Mrs. Wendy Prime for her kind guidance during construction of the TMA and Mr. Andy Dodson for his support while performing the immunocytochemistry.

Immunolocalization and distribution patterns of type IV collagen alpha chains in oral mucosal melanoma

Received: 11 January 2005 / Accepted: 27 April 2005 / Published online: 27 July 2005
© Springer-Verlag 2005

Abstract The basement membrane (BM) is mainly composed of type IV collagen, which is composed of triple combinations of six distinct alpha (α) chains in a tissue-specific manner. The six collagen chain-specific antibodies (α1–α6) were used to examine the BMs of the oral epithelium (OE) and tumor clusters in oral mucosal melanoma (OMM). Eight OMM cases were examined. Results showed that the α1 and α2 chains were constantly detected at the BM of the normal OE as well as at the OE with atypical melanocytic proliferation and in invasive melanoma with nodular nests. The α1 and α2 chains were intermittently detected in in situ OMM, early invasive OMM and advanced invasive OMM with sheet-like nests. Gradual loss of α5 and α6 from the OE with atypical melanocyte through in situ OMM and early invasive OMM was observed. These findings suggest that changes in the immunolocalization and distribution patterns of type IV collagen α chains are associated with the progression of OMM. The distribution pattern of type IV collagen α chain varies depending on the architecture of the nest.

Introduction

The basement membrane (BM) is a specialized form of extracellular matrix (ECM) that not only lines the epithelial sheets and blood vessels but also exists in other cell types that come in contact with the connective tissue. The BM is essential in normal biological functions such as cell adhesion, growth and differentiation [3]. It provides a barrier that limits or regulates the exchanges of macromolecules between connective tissue and other tissue types [10]. It has also been regarded as the site of tumor invasion and metastasis by associating the loss of its components during tumor progression [3]. Type IV collagen is the main component of the BM. Other components are laminin, nidogen/entactin and heparan sulfate proteoglycans.

Type IV collagen molecule is composed of a triple helix structure consisting of three polypeptides called alpha (α) chains [10].

Six α chains have been identified based on their amino acid sequence differences [11]. α1 and α2 are called "classic chains" and are widely distributed in tissues [11]. On the other hand, α3, α4, α5 and α6 are called "novel chains" and are selectively distributed in human tissues [11]. Random combinations of the six (α) chains assemble into triple helical protromers which further associate with other protomers forming multiple networks [4]. The three common and distinct networks are composed of α1, α2 found in human BMs [28]; α3, α4, α5 in the alveolar BM of the lung, glomerulus and some parts of the tubular BM of the kidney [22, 28]; and α5, α6 in the BM of the mammary duct and lobule, epidermis, smooth muscle and prostate gland [5, 21, 29, 30, 32]. Additional distinct type IV collagen network consisting of α1, α2, α5 and α6 have been detected in BMs of bladder, uterus, stomach, small intestine, Bowman's capsule and that of the oral epithelium (OE) [19, 22, 29, 30, 35].

Various studies have been focused on the distribution of these α chains in breast [21], skin [32], prostate [5], lung [20], pancreas [11], colorectal tumors [8, 23] as well as odontogenic [19] and salivary gland tumors [17], but so far the immunolocalization and distribution of type IV colla-

gen α chains in OMM has not been reported. The objectives of the study were to determine the distribution patterns of type IV collagen α chains at the BM of OMM and to determine the variations in the distribution of these α chains in different types of OMM, employing immunohistochemical procedures.

Materials and methods

Paraffin sections

The paraffin sections used were obtained from biopsy and surgical tissues examined at the Department of Oral Pathology and Medicine, Graduate School of Medicine and Dentistry, Okayama University. The study protocol was approved by the Experimental Ethics Review Committee of Our Institution. The cases were categorized using the Western Society of Teachers in Oral Pathology (WESTOP) system of nomenclature [1]. Microscopically, two major patterns have been identified. These are in situ pattern in which the neoplasm is limited to both the epithelium and epithelium-connective tissue interface, and invasive pattern in which the neoplasm is found within the supporting connective tissue only. Invasive OMM with in situ component was also included in the study. Invasive OMM and invasive OMM with in situ component that depicted the invasion of the melanoma cells from the epithelium into the connective tissue were specifically referred to as early invasive OMM, whereas the tumor clusters deeply localized within the connective tissue were referred as advanced invasive OMM. Atypical melanocytic proliferation was designated as part of oral mucosal lesions with equivocal histopathologic features, such as hyperchromatic and angulated nuclei with very infrequent mitotic activity as described previously [1]. A total of eight cases were examined: one case of in situ OMM, one case of invasive OMM and six cases of invasive OMM with in situ component. The specimens were stained using routine hematoxylin and eosin, and malignant melanoma markers such as S-100, HMB-45, Vimentin and Melan-A. Other markers such as Masson-Fontana, CD34, Actin, Leucocyte Common Antigen and Cytokeratins were used for differential diagnoses (data not included).

Table 1 Type IV collagen alpha chain antibodies

Specificity	Clone	Dilution
α1	H11	1:400
α2	H22	1:400
α3	H31	1:100
α4	H43	1:10
α5	H53	1:100
α6	H63	1:20

Immunohistochemistry

Deparaffinized tissue sections of 3-μm thickness were blocked for endogenous peroxidase activity using 3% hydrogen peroxide in methanol for 30 min and then washed in Tris-buffered saline (TBS) three times for 5 min each. Heat pressure antigen retrieval was the pretreatment done by immersing in a citrate buffer with a pH of 3.5 for 5 min at

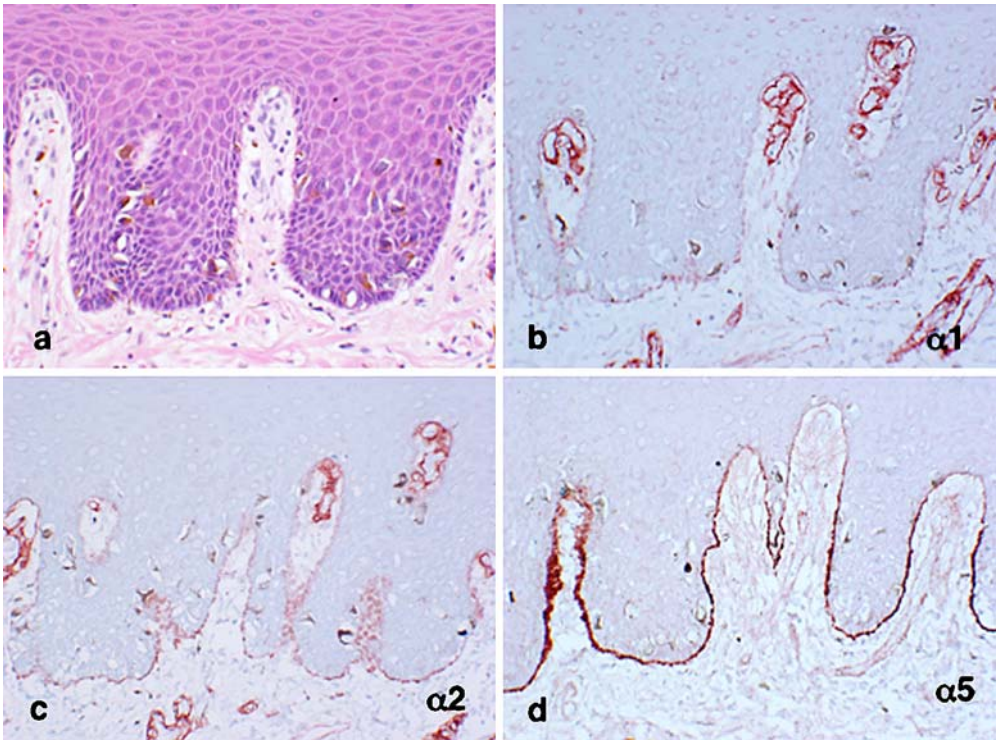

Fig. 1 Oral epithelium with atypical melanocytes. Immunostaining for α1 (**b**) and α2 (**c**) were constant, whereas that for α5 (**d**) chain was intermittent (×400)

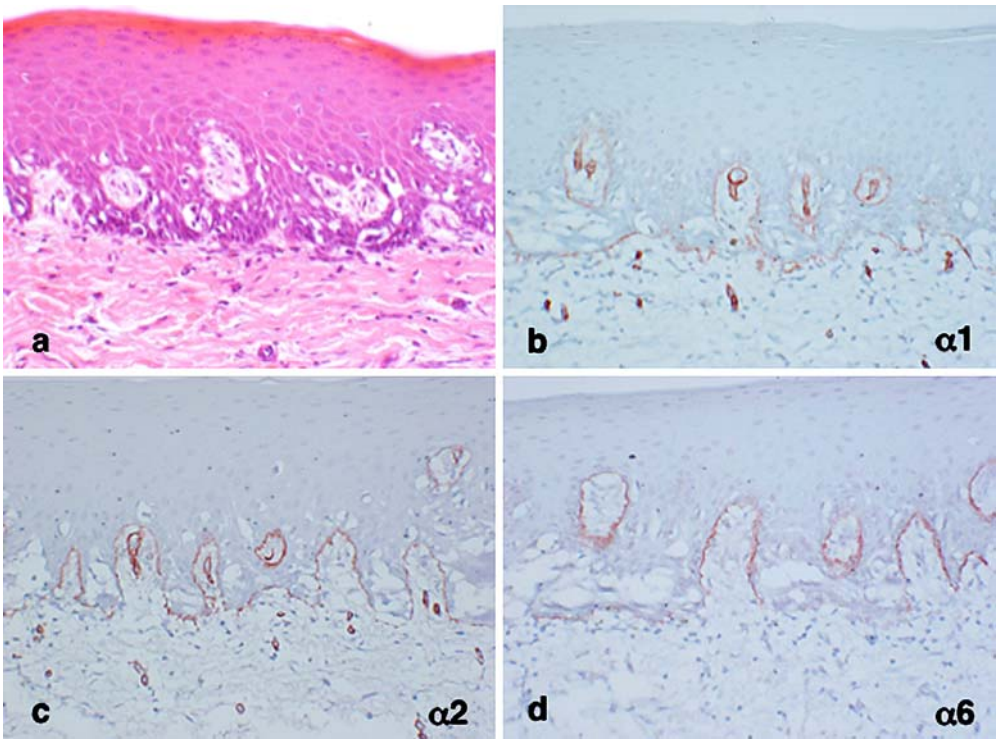

Fig. 2 In situ oral mucosal melanoma. Intermittent immunostainings for α1 (**b**), α2 (**c**), and α6 (**d**) chains at the basement membranes of the oral epithelium (×400)

121°C. The slides were then immersed in 5% normal rat serum blocking solution for 15 min, covered with each of the type IV collagen α chain antibodies and incubated overnight at 4°C. The specificity of rat monoclonal antibodies recognizing type IV collagen α chains was previously reported via ELISA and immunoblotting, and epitopes were determined by multipin-peptide scanning [12, 27]. The clones and dilutions of each type IV collagen α chain-specific antibody are shown in Table 1. Immunoreactions were performed using Vectastain peroxidase ABC Kit (Vector Laboratories, Burlingame, CA, USA). The antigenic sites were disclosed using 3-amino-9-ethylcarbazole (AEC) substrate chromogen (Dako, Carpinteria, CA, USA) and counterstained with Mayer's hematoxylin.

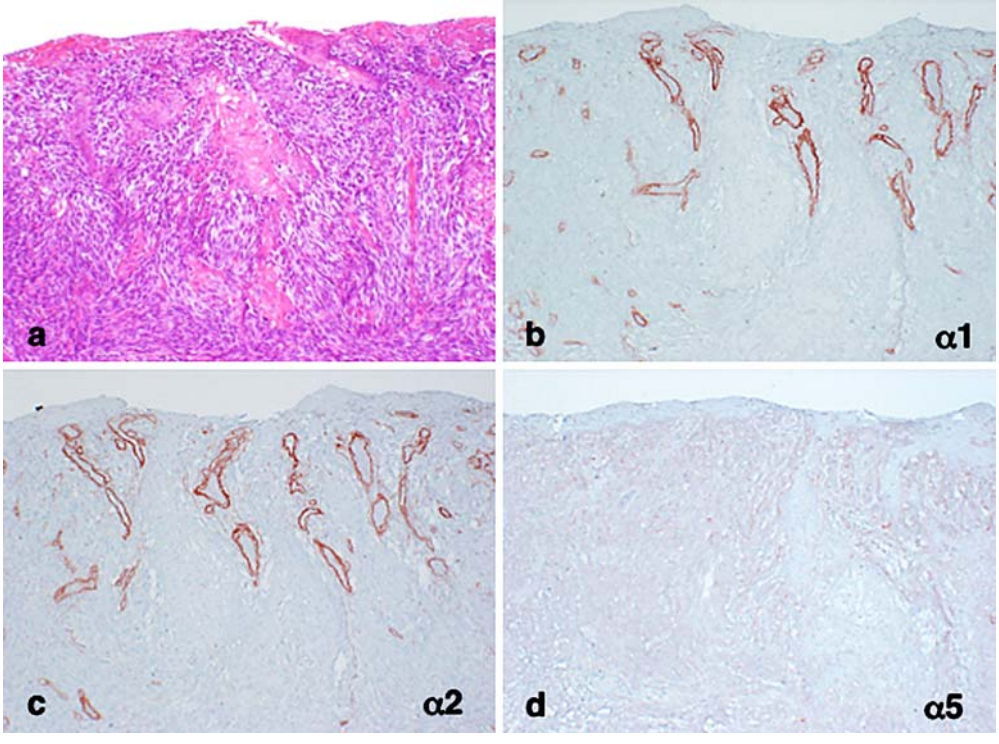

Fig. 3 Early invasive oral mucosal melanoma. Immunostainings for α1 (**b**) and α2 (**c**) chains were intermittent at the basement membrane of the oral epithelium, while that for α5 (**d**) chain was negative (×200)

Results

The BMs of the normal OE as well as those surrounding the melanoma nests were examined for the immunolocalization and distribution of type IV collagen α chains. Qualitative analysis of the BM immunoreactivity was microscopically examined and categorized into three patterns: (1) constant, in which the immunostaining can be seen without a disruption on its continuity; (2) intermittent, in which the pattern is discontinuous; and (3) negative, in which no immunostaining was detected.

α1, α2, α5 and α6 chains were detected at the BM of the normal OE (figure not shown). They were also detected at the BM of the OE with atypical melanocytic proliferation (Fig. 1). Immunostainings for α1 and α2 were both constant (Fig. 1b,c), while those for α5 (Fig. 1d) and α6 (figure not shown) were intermittent although the α5 immunoreaction was more intense compared to α1, α2 and α6 chains. α1, α2, α5 and α6 chains were intermittently detected at the BM of the OE in in situ OMM (Fig. 2). α1 (Fig. 3b) and α2 (Fig. 3c) chains were intermittently detected at the BM of the OE in early invasive OMM, while immunostainings for α5 (Fig. 3d) and α6 (figure not shown) were negative.

Tumor clusters in invasive OMM were surrounded by BMs. α1 (Fig. 4b) and α2 (Fig. 4c) chains were constantly detected at the BM of nests with nodular architecture, while they were intermittently detected at the BM of the nests with sheet-like architecture (Fig. 5b,c). Most of these nests that were constantly positive for α1 and α2 chains were detected at the center of the tumor mass. α5 and α6 chains were both negative in nodular (Fig. 4d) and sheet-like nests (Fig. 5d). In all of the cases, α3 and α4 chains were not detected (figure not shown) at the BMs of the OE and melanoma nests. Table 2 summarizes the results of the immunohistochemistry.

Discussion

In the head and neck region, OMM is an extremely rare neoplasm representing 0.5% of oral malignancies [6]. The most common sites are the hard palate and the gingiva [1], although it may also occur in other areas of the oral cavity. It has a poor prognosis with a 5–20% survival rate [25]. Although researches have been conducted, the classification of OMM is still not settled. Some studies reported similarities between OMM and acral lentiginous melanoma (ALM) with a radial growth phase both clinically and histologically [26, 34]. Others regarded OMM separately from cutaneous melanoma because of the difference in the prognosis [13]. Nevertheless, WESTOP has stated that OMM appeared similar to ALM and less frequently to nodular melanoma when no in situ component was evident [1].

Melanocytes are specialized melanin-producing cells that developed embryonically from the neural crest and migrated to the skin, hair follicle and retina. The presence of melanocytes in these structures is necessary and known, but their existence and function in the oral mucosa are not known for certain [7]. Melanocytes in the oral mucosa may transform into atypical melanocytes and tumor cells. These tumor cells may either be confined within the OE or within the connective tissue, or may be found both in the OE and the connective tissue at the same time.

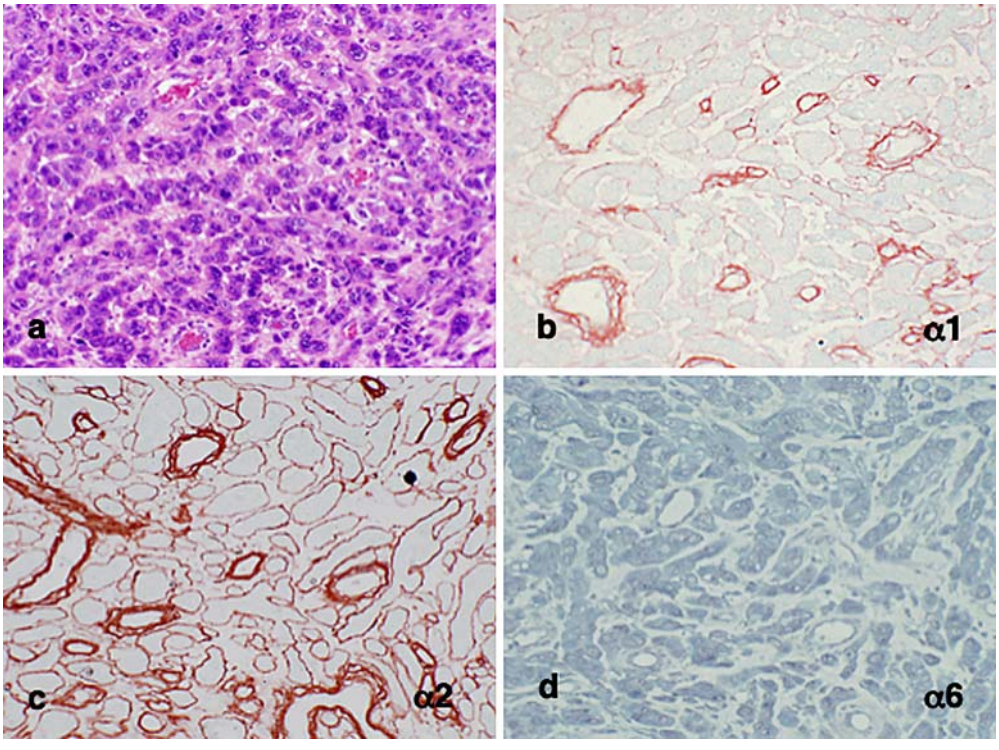

Fig. 4 Advanced invasive melanoma nodular architecture. Immunostainings for α1 (**b**) and α2 (**c**) chains were both constant, while that for α6 (**d**) chain was negative (×400)

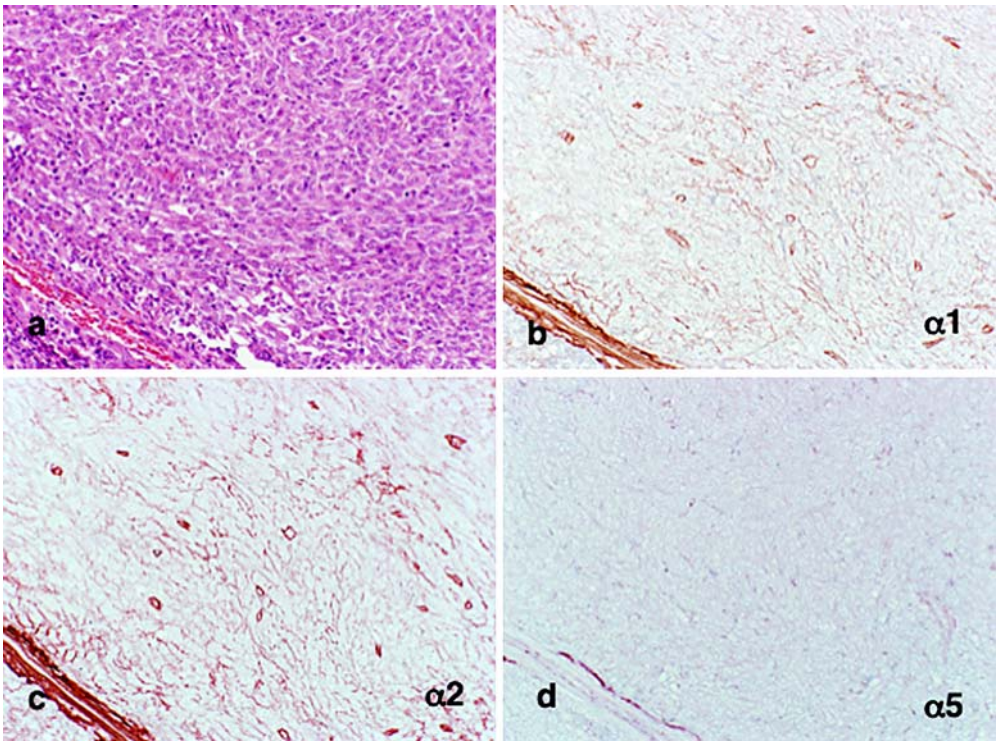

Fig. 5 Advanced invasive melanoma sheet-like architecture. Immunostaining for α1 (**b**) and α2 (**c**) chains were intermittent, while that for α5 (**d**) chain was negative (×400)

Melanoma cells may either be epithelioid or spindle in shape. Both cell types can be found in a single tumor. When these tumor cells invade the connective tissue, they tend to organize and form tumor clusters surrounded by BMs. Various architectures have been described, ranging from sheet-like, organoid, alveolar, neurotropic and desmoplastic [7]. The BM was either produced by the tumor cells or stromal cells or by both [31].

The study illustrated, for the first time, the gradual modifications in the immunolocalization of type IV collagen α chains at the BM of the OE during the carcinogenic progression of OMM. The BM of the OE is composed of the combined supramolecular network of α1, α2 and α5, α6. However, the BM of OE with atypical melanocytes was intermittently stained for α5 and α6 chains, suggesting a possible malignant change. The presence of atypical melanocytes at the BM of the OE might have caused the change in the pattern since no inflammatory reaction was observed. Atypical melanocytic proliferation is used for lesions with equivocal histologic features and is sometimes difficult to differentiate from in situ melanoma. Nevertheless, the condition may exemplify an undetermined to premalignant melanocytic lesion similar to cutaneous atypical mole (dysplastic nevus) as described previously [7]. Atypical melanocytic proliferation in the oral mucosa may represent a precursor lesion to melanoma or an indication of increased risk for developing mucosal melanoma at other sites [7]. Taken together, the changes in the type IV collagen α chains may suggest the possibility of progress to OMM.

Table 2 Summary of the immunolocalization of type IV collagen alpha chains in the basement membranes of normal oral mucosa and melanoma[a]

	α1	α2	α5	α6
Normal oral epithelium	+	+	+	+
With atypical melanocytes	+	+	±	±
In situ OMM	±	±	±	±
Early invasive OMM	±	±	−	−
Advanced invasive OMM (nodular architecture)	+	+	−	−
Advanced invasive OMM (sheet-like architecture)	±	±	−	−

+ Constant, ± intermittent, − negative; *OMM* oral mucosal melanoma
[a]Eight cases as well as their normal margins were studied, including one in situ, one invasive, six invasive with in situ OMM

In situ OMM is characterized by the transformation of atypical melanocytes into melanoma cells. Melanoma cells retain some features of the atypical melanocytes but they possess considerable pleomorphism with large, irregular, hyperchromatic nuclei and prominent nucleoli, and have readily detectable mitotic activity [7]. Our results showed that a more dramatic change was observed in in situ OMM by the interruption of the continuity of each α1, α2, α5 and α6 chains, suggesting the further modification of the α chain component during carcinogenic progression.

Degradation of the oral epithelial BM is necessary for invasion to the surrounding tissues prior to metastasis. The action of proteases particularly matrix metalloproteinases (MMP) family and plasminogen activation system are also involved in the degradation of the BM [24]. It has been shown that MMP-2 and MMP-9, both of which can degrade BM components such as type IV collagen, were highly expressed in melanoma cells or by stromal cells in the case of MMP-9 [9]. Furthermore, plasmin can either directly degrade extracellular macromolecules or activate pro-MMPs [18]. In this study, the degradation of the BM

was accompanied by the change in its type IV collagen α chain specific composition. Initially, the BM of the OE was composed of type IV collagen α1, α2, α5 and α6 chains and followed by intermittency in α5 and α6 chains, although α1 and α2 chains remained constant. Further invasion resulted in the intermittency of α1 and α2 chains and the total loss of α5 and α6 chains, suggesting that α1 and α2 chains were more stable against degradation compared to α5 and α6 chains.

Melanoma cells that invaded the connective tissue synthesized BMs [31]. Our results confirmed previous findings that melanoma cell clusters were surrounded by BMs [31, 33]. Invasive tumor clusters formed two types of architecture. The first architecture was characterized by nodular nests, which included epithelioid cells resembling melanocytes that are highly differentiated. These were constant to α1 and α2 immunostainings. The second architecture was characterized by sheet-like nests consisting of spindle cells that are diffusely arranged and less-differentiated. These were intermittent to α1 and α2 immunostainings. Both architectures were negative to α5 and α6 stainings. The production of ECM, including BM mostly, is advantageous for the melanomas since growth factors can be stored in it [31]. This may be the rationale for the production of BM around tumor clusters. However, the variation in the type IV collagen α chain distribution in relation to metastasis was not considered due to the paucity of cases.

Studies regarding the concepts of vasculogenesis of melanoma have been reported including endothelium-lined tumor vessels, tumor cell-lined matrix and matrix-rich vascular channels [14, 16, 33]. Type IV collagen has the capacity to promote and modulate angiogenic response [2]. Type IV collagen also has an important role in promoting the adhesion and motility of various cell types to include endothelial cells [15]. The BM molecules and interstitial collagen may also provide a scaffold for the neovessels [2]. Altogether, it may be speculated that the presence of BM type IV collagen may enhance the formation of the heterogenous tumor microvasculature in OMM necessary for its progression.

In conclusion, the study suggests that the change in the immunolocalization of type IV collagen α chains is associated with the progression of OMM. BMs are dynamic structures that are not only degraded in the process of invasion but are also deposited around melanoma cell clusters and the distribution pattern varies depending on the architecture of the nest.

Clinicopathological significant and prognostic influence of cadherin-17 expression in gastric cancer

Received: 15 March 2005 / Accepted: 17 May 2005 / Published online: 26 July 2005
© Springer-Verlag 2005

Abstract Cadherin-17 (CDH17), also called liver–intestine cadherin, is a structurally unique member of the cadherin superfamily. Our serial analysis of gene expression demonstrated that CDH17 was one of the most up-regulated genes in advanced gastric carcinomas. CDH17 expression is known to be regulated by Cdx2. In the present study, we examined the expression of CDH17 in primary gastric carcinoma tissues by immunohistochemistry, and analyzed the correlation of CDH17 expression with clinicopathological characteristics and patients prognosis. CDH17 expression was detected in 63/94 (67%) of gastric adenocarcinomas in addition to intestinal metaplasia. The expression of CDH17 tended to be associated with intestinal type carcinoma, and carcinomas with CDH17 expression was significantly more frequent in advanced stage cases (80%) than in early stage (53%). The prognosis of patients with positive CDH17 expression was significantly poorer than that of the negative cases (P=0.0314). However, multivariate analysis revealed that CDH17 was not an independent prognostic factor. Six of seven cases that showed positive expression of Cdx2 simultaneously expressed CDH17 protein. These results suggested that the expression of CDH17 was characteristic of the advanced gastric carcinoma that is associated with poor prognosis.

Introduction

Cadherin-17 (CDH17), which is also called liver–intestine (LI) cadherin or human peptide transporter-1 (HPT-1), is a structurally unique member of the cadherin superfamily [2, 4]. Whereas the so-called classic cadherins, such as E-, N- and P-cadherin, have five cadherin repeats within the extracellular domain, CDH17 consists of seven cadherin repeats. Moreover, CDH17 has only 20 amino acids in the cytoplasmic domain, whereas classic cadherins have a highly conserved cytoplasmic domain consisting of 150–160 amino acids. CDH17 is expressed in mice and humans almost exclusively in epithelial cells of both embryonic and adult small intestine and colon, with no detectable expression in the liver [1, 5]. It has been reported that transcription factor Cdx2 regulates CDH17 gene expression in the gastrointestinal tract [6]. Cdx2 gene is quite broadly expressed during the early stages of embryonic development; however, in later stages of development and in normal adult tissues, expression of the genes is restricted to epithelium of the small intestine and colon [15]. Cdx2 has been reported as a tumor suppressive factor in colon cancer. It has been reported that CDH17 is overexpressed in hepatocellular carcinoma [18], and the expression of CDH17 could be useful as a marker for predicting the outcome of patients with pancreas cancers [17].

We examined the gene expression profiles of gastric cancer by serial analysis of gene expression (SAGE) and found that CDH17 was one of the most up-regulated genes in the advanced cases [20]. Quantitative RT-PCR analysis had confirmed that over 70% of gastric carcinoma overexpressed CDH17 and the expression levels was significantly associated with depth of tumor invasion [20]. Recent

reports indicated that the expression of CDH17 was correlated with lymph node metastasis [8, 9]. Therefore, CDH17 could be a novel prognostic factor of gastric carcinoma. However, no study has demonstrated the prognostic impact of CDH17 in gastric carcinoma. In the present study, we examined the expression of CDH17 protein in primary gastric carcinoma tissues and corresponding non-neoplastic mucosa by immunohistochemistry, and analyzed the correlation of CDH17 expression with clinicopathological characteristics and patient's prognosis. We also compared CDH17 expression with Cdx2 in gastric carcinoma tissue.

Materials and methods

Tissue samples

We used a total of 94 gastric adenocarcinoma cases. Tumor tissues and corresponding non-neoplastic gastric mucosa were obtained by surgery at the Hiroshima University Hospital and its affiliated hospitals. For immunohistochemistry, tissues were fixed in 10% buffered formalin and embedded in paraffin.

Histological classification of gastric cancer was done according to the Lauren classification system [11]. Staging of gastric carcinoma was done according to the Tumor-Node-Metastasis Stage Grouping [16]. Classification of the quantity of stroma was made according to the criteria of the Japanese Classification of Gastric Cancer [7] as follows: scirrhous type (sci), stroma is abundant and fibrous; medullary type (med), stroma is scanty; intermediate type (int), the quantity of stroma is intermediate between sci and med.

Western blotting and immunohistochemistry

To confirm the specificity of the anti-CDH17 antibody, Western blotting was carried out as described [14]. Human gastric carcinoma cell line, HSC39, was used. The cells were lysed in lysis buffer [50 mM Tris–HCL pH 7.4, 125 mM NaCl, 0.1% (v/v) NP-40, 5 mM ethylene diamine tetraacetic acid (EDTA), 50 mM NaF, 50 μg/ml phenylmethylsulfonyl fluoride (PMSF), 10 μg/ml leupeptin, 10 μg/ml soybean trypsin inhibitor, and 1 μg/ml aprotinin]. Protein (50 μg) was subjected to Western blot analysis. Anti-CDH17 polyclonal antibody (C-17, sc-6978; Santa Cruz Biotechnology, USA) at a 1:100 dilution was used in primary reaction. As expected, a single band of 120 kDa was detected (Fig. 1).

Consecutive 4-μm tissue sections were prepared from paraffin blocks and immunostained for CDH17 and Cdx2. Each section was mounted on a MAS-coated glass slide, deparaffinized, and soaked for 15 min at room temperature in 3% H_2O_2/methanol to block endogenous peroxidase. Anti-CDH17 polyclonal antibody at a 1:200 dilution and anti-Cdx2 monoclonal antibody (CDX2-88, BioGenex, USA) at a 1:100 dilution were used as primary antibody and was applied for overnight at 4°C. The primary antibody was visualized using the Histofine Simple Stain MAX-PO (MULTI) kit (Nichirei, Tokyo, Japan) according to the instruction manual. The slide was counterstained with hematoxylin. Negative control staining was done using non-specific IgG in the primary reaction. The stained slides were observed without clinicopathological information. Reproducibility of staining was confirmed by re-immunostaining via the same method in multiple, randomly selected specimens. To determine the definition of CDH17 expression, we counted the number of positive cells that showed immunoreactivity on the cell membrane among tumor cells in the representative ten microscopic fields, and calculated the percentage of positive cells. The definition of staining was as follows: positive, more than 40% of tumor cells showed immunoreactivity; weak, 5–40% of tumor cells showed immunoreactivity; negative, from 0% to less than 5% of tumor cells showed immunoreactivity. To define Cdx2 expression, we counted the number of nuclear stained cells. Definition of staining was as follows: positive, over 40% of tumor cells showed immunoreactivity; negative, from 0% to less than 40% of tumor cells showed immunoreactivity.

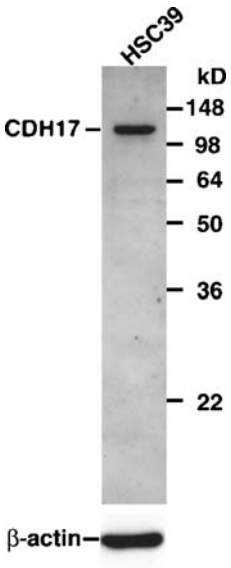

Fig. 1 The specificity of CDH17 antibody. Western blot analysis was performed as described in Materials and methods. A single band of 120 kDa was detected in HSC-39 gastric carcinoma cell lines

Statistical analysis

Statistical analyses were performed with non-parametric test and *P* values were shown. If the P value is less than 0.05, it means that each parameter has a significant correlation with the level of CDH17 expression. Survival rates were calculated via the Kaplan–Meier method. The difference between the survival curves was analyzed by means of log-rank test.

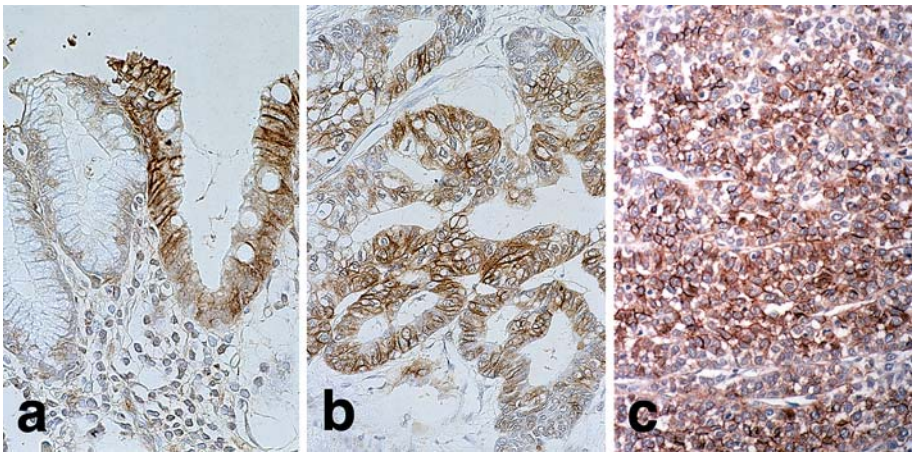

Fig. 2 Expression of CDH17 protein in gastric carcinoma tissues and non-neoplastic mucosa. CDH17 immunohistochemical staining: **a** non-neoplastic mucosa with intestinal metaplasia, **b** intestinal-type carcinoma, **c** diffuse-type carcinoma. CDH17 expression was found in cell membrane and cytoplasm at various levels in gastric carcinoma tissues. In non-neoplastic mucosa, the expression of CDH17 was not recognized in normal foveolar epithelia, while intestinal metaplasia revealed expression of CDH17

Results

Immunohistochemical detection of CDH17 in gastric carcinoma tissues and non-neoplastic mucosa

We immunohistochemically examined the expression and localization of CDH17 protein in 94 cases of gastric carcinoma and non-neoplastic mucosa. Representative stainings of CDH17 are shown in Fig. 2, and the results are summarized in Table 1. CDH17 was expressed in 67% (63/94) of gastric carcinomas at various levels (Fig. 2b, c and Table 1). CDH17 expression was mainly localized in cell membrane and cytoplasm. In non-neoplastic gastric mucosa, CDH17 was also detected in the cell membrane of epithelial cells with intestinal metaplasia (Fig. 2a).

Correlation between CDH17 expression and clinicopathological characteristics of gastric carcinoma

We next analyzed the relationship between the expression of CDH17 and the clinicopathological parameters of gastric carcinoma. As shown in Table 1, the expression of CDH17 tended to be associated with intestinal histology. The incidence of cases with positive expression of CDH17 was significantly higher in medullary type (37/47, 79%),

Table 1 Expression of CDH17 in gastric carcinomas and its correlation with clinicopathological parameters

	Case no.	CDH17 expression[a]		*P* value
		Positive	Weak and negative	
Gastric carcinomas	94	63 (67%)	31 (33%)	
Histology[b]

[a]Grades of CDH17 expression were classified as "positive" and "weak and negative", as described in Materials and methods
[b]Histological classification of gastric carcinoma was done according to the Laure classification system [11]
[c]According to the criteria of the Japanese Classification of Gastric Cancer [7]
[d]Tumor staging of gastric carcinoma was done according to be Tumor-Node-Metastasis Stage Grouping [16]
[e]Correlation was analyzed by non-parametric test and *P* values are shown. *P* values less than 0.05 were regarded as statistically significant

than in scirrhous and intermediate type (26/47, 55%). Positive expression of CDH17 was significantly associated with deep invasion of tumor cells in gastric wall (P=0.01581). The incidence of positive expression of CDH17 tended to be higher in carcinomas with lymph node metastasis. Further more, cases with positive CDH17 expression were significantly more frequent in carcinomas of stages II–IV than stage I (P=0.00683).

Prognosis of gastric carcinoma cases with or without CDH17 expression

We studied the survival rate of gastric carcinoma patients after surgery. If all patients with carcinoma of different stages were included, the cases with positive expression of CDH17 showed worse prognosis than the cases with negative expression of CDH17 (P=0.0314) (Fig. 3). However, we did not find any significant correlation between CDH17 expression and the prognosis of the patients with "stage I and II" carcinoma (P>0.5) or "stage III and IV" carcinoma (P=0.1072). With multivariate survival analysis, the factor that gave the strongest influence was not CDH17 expression, but tumor stage (data not shown). Thus CDH17 expression must be one of the effective factors for gastric cancer prognosis.

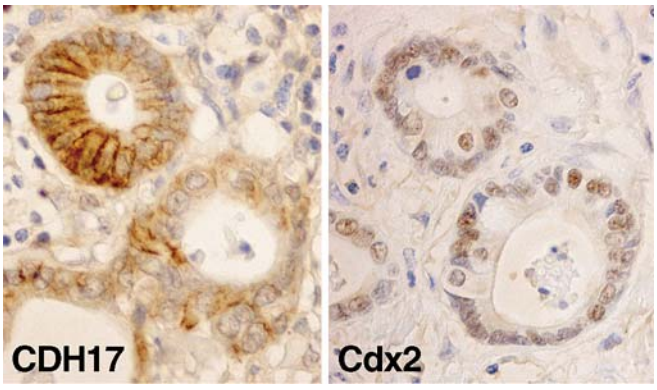

Fig. 4 Relationship of the expression of CDH17 and Cdx2. Synchronous expression of CDH17 and Cdx2 was detected in intestinal type gastric carcinoma

Comparison of the Cdx2 expression with CDH17 expression

We finally compared CDH17 expression with Cdx2 protein expression. Cdx2 immunohistochemical staining was performed in 52 gastric cancer cases extracted from cases that had been investigated with CDH17 immunohistochemical staining. Representative stainings are shown in Fig. 4. Seven

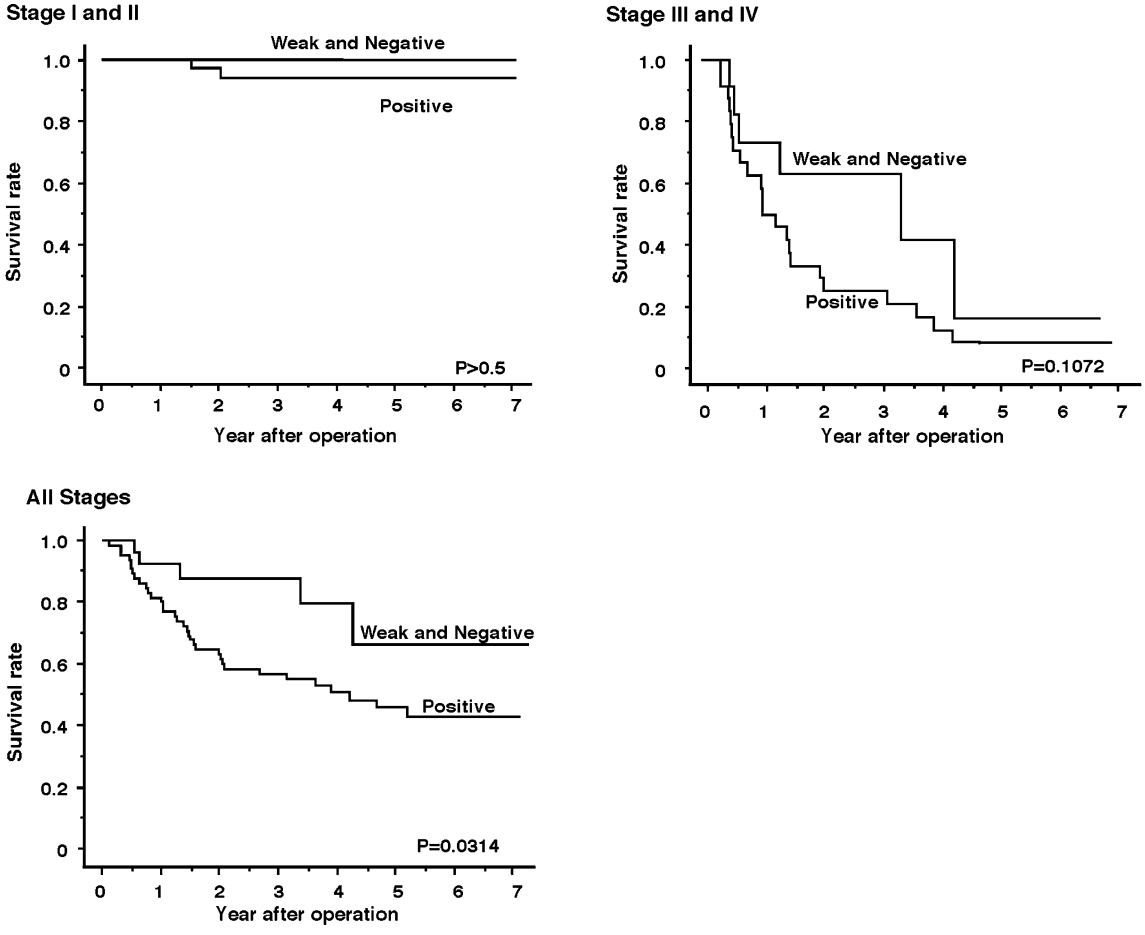

Fig. 3 Comparison of survival rates in patients between CDH17 positive cases, and weak and negative cases. The prognosis of patients with CDH17 positive cases was significantly poorer than that of the patients weak and negative for CDH17, whereas there is no significance between survival rate and CDH17 expression when divided the cases into "stage I and II" and "stage III and IV"

Cdx2 positive cases (7/52, 13%) were found in 52 gastric cancer cases, and all of them were intestinal-type gastric carcinoma. Six of the seven cases (86%) expressed CDH17 simultaneously, and five of these six cases were stage I (data not shown).

Discussion

In the present study, we examined the expression of CDH17 in human gastric carcinoma and compared it with clinicopathological parameters, prognosis and Cdx2 expression. The expression of CDH17 protein was detected in 67% of gastric carcinomas that were correlated with depth of tumor invasion, tumor stage and amount of stromal tissue. It was recently reported that CDH17 mRNA expression is an independent factor associated with lymph node metastasis [8, 9]. Furthermore, our study demonstrated an association between CDH17 expression and poor prognosis. Although CDH17 was not an independent prognostic factor by multivariate analysis, CDH17 expression may be associated with aggressiveness of gastric carcinoma and can be a good marker for high-grade malignancy. On the other hand, in pancreas carcinoma, the survival prognosis was significantly poorer in CDH17 negative tumors compared with CDH17 positive tumors, and CDH17 might participate in the early stage through interaction with galectin-3 [17]. CDH17 may have a distinct organ-specific distribution and the role of CDH17 may be different through distinct intracellular interacting molecules.

Dysregulation of the classical cadherin–catenin adhesion network has been implicated in the progression of gastrointestinal tract cancer [3]. CDH17 is structurally distinct from its E-cadherin counterpart, and there is no direct association with the β-catenin network [10]. According to a previous report, tumor aggressiveness is associated with changes in cadherin expression. For example, P-cadherin, one of the classical cadherins, is highly expressed in well-differentiated adenocarcinoma, and its expression decreased in the advanced stage [19]. E-cadherin expression is also down-regulated in advanced gastric carcinoma cases [12]. LI cadherin is capable of mediating Ca^{2+}-dependent homophilic cell–cell adhesion independent of interactions with the cytoskeleton, indicating that the adhesive function of CDH17 may be complementary to that of E-cadherin. At present, while the role of CDH17 in tumor progression remains unknown, overexpression of CDH17 might be complementary to the co-expressed classical cadherins that are down-regulated in advanced gastric carcinoma.

Cdx2 is one of the transcription factors regulating CDH17 gene expression in normal, metaplastic and neoplastic tissues of the gastrointestinal tract via binding to elements in the 5′-flanking region of the gene [6]. In gastric carcinoma, Cdx2 gene is known to be methylated [21], and therefore epigenetic alteration of CDH17 may be one of the important steps in gastric carcinogenesis. In our study, most of the gastric carcinomas with simultaneous expression of Cdx2 and CDH17 were in the early stage (stage I). All the seven Cdx2 positive cases showed intestinal phenotype and CDH17 positive expression. Moreover, six of seven cases were early stage. Mizoshita et al. [13] examined Cdx2 protein expression with T1 (intramucosal and submucosal invasion) gastric carcinoma cases and the data suggest that Cdx2 is expressed in the very early stage of gastric carcinogenesis in association with the shift from gastric to intestinal phenotypic expression. Because our samples were constructed from all stages of gastric carcinomas, the number of Cdx2 positive cases is lower in our study. Alternatively, CDH17 may regulate not only Cdx2 but also other transcriptional factors.

Our results suggest that CDH17 may participate not only in stomach carcinogenesis, but also in tumor progression which is associated with poor prognosis. CDH17 and Cdx2 may serve as molecular targets for gastric carcinoma treatment.

Detection of JC virus DNA sequences in colorectal cancers in Japan

Received: 13 November 2004 / Accepted: 21 April 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract JC virus (JCV), a ubiquitous polyoma virus that commonly infects humans, was first identified as the etiologic agent for the fetal demyelinating disease, progressive multifocal leukoencephalopathy. Recently, a number of reports have documented detection of JCV in samples derived from several types of neural as well as non-neural human tumors. It has been suggested that oncogenicity of JCV depends on a T antigen having a strict structural homology to the T antigen of simian virus 40. To clarify whether JCV might have a potential role with regard to colorectal cancers, we investigated the presence of its genome in a series of cases along with colorectal adenomas and normal colonic mucosa, targeting T antigen, VP and agnoprotein by nested polymerase chain reaction and Southern blotting and T antigen by immunohistochemistry. While VP and agnoprotein were not found in any of the samples examined, T antigen was detected in 6 of 23 colorectal cancers (26.1%) and 1 of 21 adenomas (4.8%), but none of 20 samples of normal colonic mucosa. No clear and diffuse staining with anti-T-antigen antibodies (1:100) could be detected, and there was no correlation with CD20-positive cells, which might have indicated JCV latent infection of B lymphocytes. Presence of T antigen did not influence clinicopathological variables, including survival. In one colonic cancer case positive for T antigen together with lymph node metastasis, DNA extracted from cancer cells in the lymph node revealed no detection of T antigen. Our results are in the intermediate position between the high T antigen rate (81%) in one report and the lack of it (0%) in another focused on colon cancers. It was concluded that T antigen might be integrated in cancer cells in approximately one fourth of Japanese colon cancer cases without clear and diffuse expression of the protein, suggesting a possible role in oncogenesis which might involve a hit-and-run mechanism.

Introduction

Recently, a number of authors have reported detection of the JC virus (JCV) genome in colorectal cancers [3, 6]. Normally, JCV is thought of as a neurotropic virus which can cause the fatal demyelinating disease, progressive multifocal leukoencephalopathy (PML), and usually occurs in individuals with cell-mediated immunity, including AIDS [24]. However, its genome has also been detected at high rates in neurogenic tumors, such as astrocytomas, oligoastrocytomas, glioblastomas and ependymomas [6, 7, 25], and there is mounting evidence of oncogenic potential for the T antigen viral regulatory protein [16].

JCV, identified as a member of the polyoma virus group, was first isolated from the brain of a patient suffering from PML [23]. It is a non-enveloped DNA virus with icosahedral capsids containing small, circular, double-stranded DNA and has a limited host range, not usually causing productive infections in other species [13]. Its circular genome contains two major regions known as the early region and late transcription units, and the primary transcript from the early region is alternatively spliced to give two mRNAs that encode T antigen (large T antigen) and t antigen (small T antigen). T antigen is a large nuclear phosphoprotein and is an essential factor for viral DNA replication. It binds to the viral origin of replication region (ori) where it promotes the unwinding of the double helix

and recruitment of cellular proteins that are required for DNA synthesis [5, 8, 19]. The late region encodes the capsid structural proteins VP1, VP2 and VP3 due to alternative spliced mRNAs derived from the same primary late transcript and a small regulatory protein known as agnoprotein [13]. It has been reported that JCV binds specifically to certain cell types such as glial cells, tonsillar stromal cells and B lymphocytes but not T lymphocytes [20, 28]. The virus can also infect cells in the kidney, which is a major organ for JCV persistence during latency [4].

After binding to the cell surface, JCV capsids undergo endocytosis and are transported to the nucleus where the viral DNA is uncoated and transcription of the early region begins by a clathrin-dependent mechanism that is blocked by tyrosine-specific protein kinase inhibition [22]. JCV can become integrated into the chromosomal DNA of the cell, especially upon non-permissive infection, the location being random both in terms of sites in the cellular genome and the point in the viral genome where recombination occurs [11, 18]. There are two possible outcomes to infection of a cell by JCV. Permissive cells are able to replicate viral DNA, and the result of JCV entry is lytic infection (PML) with viral amplification. Non-permissive cells do not support viral DNA replication, and the result of viral entry is an abortive infection or cell transformation (oncogenesis).

T antigen is considered to play the most important role in JCV oncogenesis [17] since it interferes with two tumor suppressor proteins, pRb and p53, that regulate cell cycle progression. T antigen binds to pRb and displaces E2F, thereby promoting cell cycle progression and the inappropriate cell proliferation characteristic of oncogenically transformed cells [17]. The release of E2F from Rb normally activates p14ARF expression that leads to stabilization of p53. However, T antigen binds to and inactivates p53 and thus prevents inhibition of the cell cycle, providing an optimal cell environment for viral replication and packaging during JCV lytic infection and facilitating transformation in non-permissive cells [11]. The T antigen also directly binds to β-catenin, increasing protein stability and causing accumulation, the protein then translocating to the nucleus where it enhances expression of genes such as c-myc and cyclin D1, typical of deregulation of the Wnt pathway [10].

The present study was conducted to assess possible involvement of JCV in colon cancer, using a combined immunohistochemical, nested polymerase chain reaction (PCR) and Southern blotting approach, comparing expression of viral components in normal, benign and malignant tissue.

Materials and methods

Cases

Thirty-five cases of surgically resected colorectal adenocarcinomas, 21 endoscopically resected colorectal adenomas (not including high-grade dysplasia, such as non-invasive carcinoma) and 27 cases of normal colonic mucosa biopsies without cancerous lesions were selected from the pathology archives of Toyama Medical and Pharmaceutical University from 1999 to 2000. All patients were immunocompetent and none showed signs or symptoms of PML. All adenocarcinoma cases underwent the TNM system of UICC and Dukes classification. After glyceraldehydes phosphate dehydrogenase (GAPDH) checking, as described below, final entry cases were 64 in total (64/83, 77.1%): 23 adenocarcinomas (23/30, 76.7%; m/f 13:10, 40–85 years), 21 adenomas (21/21, 100%; m/f 18:3, 41–88 years) and 20 samples of normal mucosa (20/27, 74.1%; m/f 7:13, 17–80 years), the last being obtained from non-cancer and non-severe inflammatory disease patients through colonic endoscopy. Clinicopathological details for the colorectal cancer cases are summarized in Table 1. The patients were 13 females and 10 males, with an average age of 66.3 years. Ten cases were complicated by regional lymph node metastasis, and three had distant metastases. All cases were followed up from 0.1 to 5.3 years (mean 3.4 years); three patients died of the disease, and three patients were alive with persistent tumors.

DNA extraction

A dedicated microtome was used to cut the paraffin blocks. Furthermore, the block and blade holder were periodically autoclaved, and a new disposable blade was used for each specimen. The sections were handled with a disposable, one-time use applicator to prevent contamination. Samples from eight to ten sections were employed for DNA extraction using a QIAamp DNA mini kit according to the manufacturer's instructions (Qiagen, Maryland, USA).

Quality of sample DNA

Before JCV genome PCR, we checked the quality of samples by PCR for the housekeeping gene, GAPDH. Extracted DNA was amplified with GAPDH primers (Table 2, 199 bp) in 25-μl reaction mixtures containing 0.12 μl Takara Ex Taq HS (Takara Bio Inc., Siga, Japan) with 2.0 mM $MgCl_2$, 2.5 μl×10 PCR buffer (Takara Bio Inc.), 2.5 μl dNTP mixture (Takara Bio Inc.), 5-μl sample DNA and 0.7 μl (100 μM) of each primer set. The PCR consisted of denaturation pretreatment at 95°C for 7 min and 35 cycles of denaturation at 95°C for 60 s, annealing at 53°C for 60 s and extension at 72°C for 60 s followed by an additional 7 min at 72°C. All reactions were regulated using the Gene Amp 9700 PCR System (Applied Biosystems, Foster City, USA). Ten-microliter aliquots of each PCR product were examined by electrophoresis on 8% polyacrylamide gels. After loading, the gels were stained with ethidium bromide and photographed under ultraviolet light. The positive control was DNA extracted from the paraffin block of colorectal cancer tissue fixed in 10% formalin.

Nested PCR for the JCV genome

PCR amplification was performed using three individual sets of primers for T antigen, agnoprotein and VP. Some of the primers were used in previous reports [3] (Table 2). Reaction mixtures (25 μl) contained 0.125 μl Takara Ex Taq HS with 2.0 mM $MgCl_2$ 2.5 μl×10 PCR buffer, 2.5 μl dNTP mixture, 1 μmol/l of each primer set (primers 1 and 2) and 2 ml of sample DNA. PCR conditions were denatured at 95°C for 10 min, followed by 30 cycles of denaturation at 95°C for 15 s, annealing for 30 s and extension at 72°C for 30 s. The annealing steps were performed at temperatures of 55°C for the T antigen primers, 57°C for the agnoprotein primers and 54°C for the VP primers. As a termination step, the extension time of the last cycle was increased to 7 min. DNA extracted from JCI cells (JCV cultured neuroblastoma cell line), kindly provided by Associate Professor Sawa (Department of

Neuropathology, Graduate School of Medicine, Hokkaido University), served as a positive control. Samples amplified in the absence of template DNA were employed as negative controls. Nested PCR was carried out as for the first PCR cycles, using 0.08% (volume) of the first PCR product with primer 1 and primer 3 in each case.

Southern blotting

The nested PCR products were electrophoresed through 2% agarose gels containing ethidium bromide and photographed under ultraviolet light. After gels were denatured, neutralized and Southern blot transferred onto nylon membranes (Roche Diagnostics GmbH, Mannheim, Germany), hybridization was performed using 10 pmol/ml of digoxygenin-labeled oligonucleotide probe (Table 2) at 48°C for 3 h. After washing the membranes with 2×SSC, 0.1% sodium dodecyl sulfate (SDS) and 0.1×SSC, 0.1% SDS at the same temperature as the hybrid temperature, luminescence was detected with X-ray film (Fuji RX-U, Minamiashigara, Japan) using a DIG luminescent detection kit for nucleic acids (Roche Diagnostics GmbH).

Immunohistochemistry

For the immunohistochemical procedure, 4-μm-thick sections were deparaffinized with xylene and rehydrated through an alcohol gradient. The sections were then immersed in TBS-Tween buffer and autoclaved at 120°C for 15 min. The primary antibodies used were clone PAb416 (1:100 dilution, Oncogene Research Products, San Diego, CA, USA) that reacts with the simian virus 40 (SV40) large T antigen, cross-reacting with JCV T antigen as described in previous reports [3] and CD20 (Dako Cytomation, Inc., Carpinteria, CA, USA) for B lymphocytes to inspect the possibility of JCV latent infection. Incubation was with the primary antibodies for overnight, followed by exposure to DAKO EnVision-labeled polymer (Dako Cytomation, Inc.) for 30 min. Staining was developed by reaction with diaminobenzidine chromogen, and counterstaining for 1 min with haematoylin was then performed.

JCI cells, tightened with fibrin clots, fixed with 10% formalin overnight and embedded in paraffin, were cut at 4 μm thick and used as a positive control for clone Pab416.

Statistical analysis

Differences in clinicopathological factors were evaluated by the chi-square test and Student's *t*-test as appropriate. Survival curves were plotted using the Kaplan–Meier method, and *P* values were calculated using the log-rank test. In all analyses, $P<0.05$ was considered to indicate statistical significance.

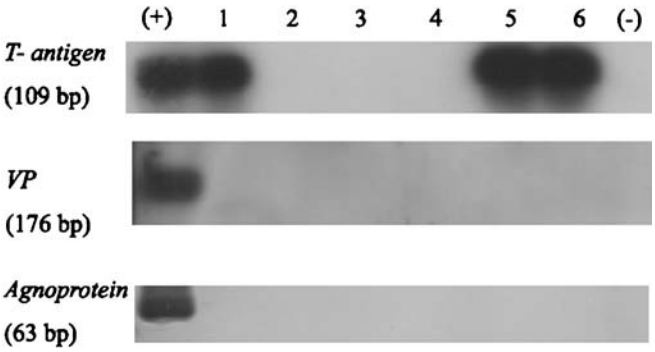

Fig. 1 The *left side* shows the positive control (JCI cells). T antigen, VP and agnoprotein bands are evident in the Southern blot. Cases 1, 5 and 6 of colorectal cancer also show clear single bands for T antigen. VP and agnoprotein bands are only apparent in the positive control. On the *right* is the negative control

Results

Detection of the JCV genome

Figure 1 showed the results of nested PCR/Southern blotting for the T antigen, VP and agnoprotein in some cases (Fig. 1). With regard to T antigen, clear and strong bands were visible in cases 1, 5, 6, 10, 16 and 20 of colorectal cancer (6/23, 26.1%). One adenoma demonstrated the T antigen (1/21, 4.8%) but none of the normal colonic mucosa samples were positive (0/20, 0%). These types of tissue were significantly associated with the presence of T antigen (Table 3; adenoma vs. normal, $P=0.2432$; carcinoma vs. adenoma, $P=0.0425$; carcinoma vs. normal, $P=0.0039$). However, we could not detect VP and agnoprotein in any of the samples, including cancer and adenoma cases and normal mucosa (Table 3). In addition, the one case with lymph node metastasis in six T-antigen-positive cases did not have T antigen present in the metastatic deposits (data not shown).

Correlation between the presence of T antigen and clinicopathological variables and survival in colorectal cancer cases

Since T antigen was only detected in colorectal cancer and adenoma cases, the correlation with clinicopathological variables was investigated. There was no statistically significant links between the presence of T antigen and pT, pN, pM, Dukes classification or histological type (Table 4).

Table 3 Detection rate of T antigen, VP and agnoprotein between colorectal cancer, adenoma and normal mucosa

PCR/Southern blot				
	Number	T antigen	VP	Agnoprotein
Normal mucosa	20	0 (0.0%)	0	0
Adenoma	21	1 (4.8%)	0	0
Adenocarcinoma	23	6 (26.1%)	0	0
		$P=0.0077$	–	–

Table 4 Correlation between clinicopathological variables of colorectal cancer patients and T antigen presence

	T antigen			
	Number	(−)	(+)	
pT				*P*=0.9298

B	7	4	3	
C	8	7	1	
D	2	2	0	
Type				*P*=0.1642
Well	20	16	4	
Moderate	2	1	1	
Mucinous	1	0	1	

Well Well differentiated adenocarcinoma, *Moderate* moderately differentiated adenocarcinoma, *Mucinous* mucinous adenocarcinoma

As for survival, although a good prognosis was evident for T-antigen-positive cases, statistical significance was not attained (Fig. 2).

Immunohistochemistry

Immunohistochemistry demonstrated no positive staining for T antigen in any of the cases. However, the antibody reacted well with the positive control (Fig. 3a), with cy-

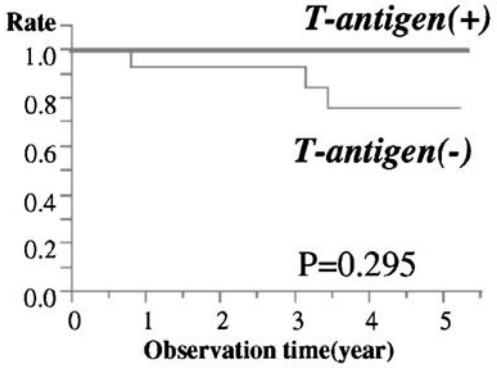

Fig. 2 Survival curves using the Kaplan–Meier method for the T-antigen-positive and negative groups. No statistically significant difference is apparent

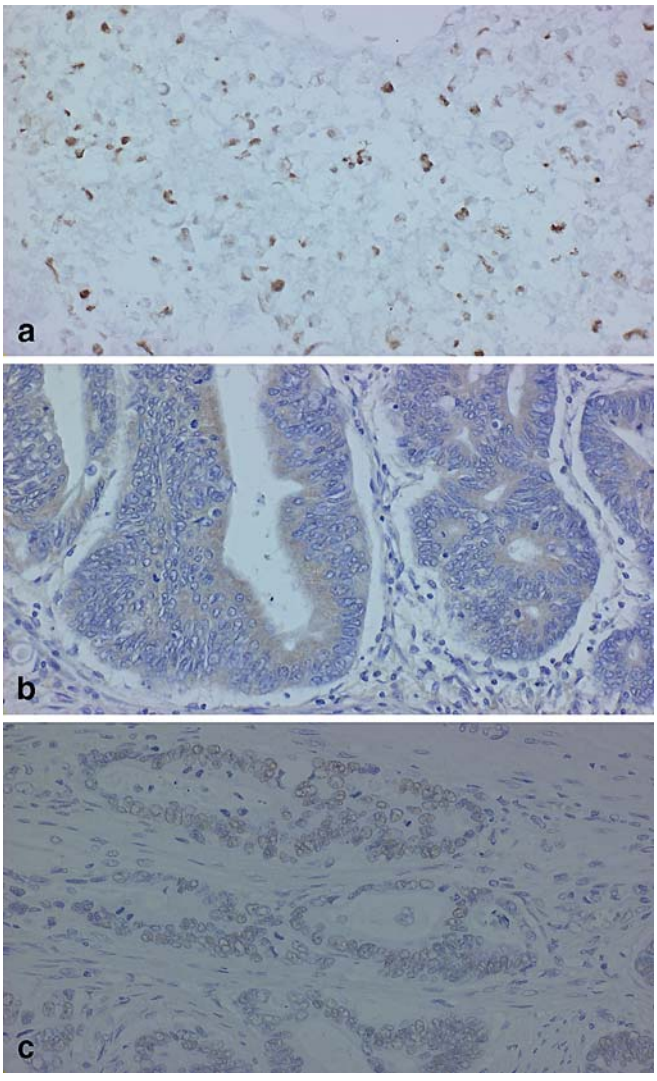

Fig. 3 **a** 10% formalin-fixed and paraffin-embedded JCI cells. About 30% of nuclei of JCI cells bind the PAb146 antibody (1:1,000 titer). **b** A colorectal cancer case reacts for the T antigen(1:100 titer). Cytoplasmic staining is visible weakly. However, this case was judged negative for T antigen (case 15). **c** Another colorectal cancer case reacts for the T antigen (1:100 titer). While a moderate degree of nuclear staining is evident, positive cells were less than 5% and the case was also judged negative (case 23)

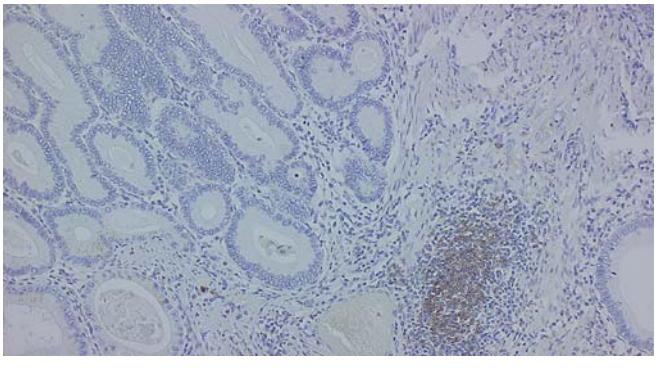

Fig. 4 Aggregates of CD20-positive cells in adenoma tissue

toplasmic staining and limited nuclear staining in less than 10% of cells (Fig. 3b, c).

CD20-positive aggregations consisting of over 30 CD20-positive lymphocytes were counted in each cancer case (Fig. 4). No correlation was evident between the number of CD20-positive aggregations and T antigen presence (Student's *t*-test P=0.64, data not shown).

Discussion

In the present study, JCV T antigen was detected in about 25% of colon cancers, one colon adenoma (5%) and no normal colon samples, whereas agnoprotein and VP were absent in all cases. These results are in contrast to the extremely high rate of 81% in colon cancers reported by Enam et al. [9]. At first, we applied a PCR system for identifying T antigen, agnoprotein and VP in accordance with their approach, although they employed γ32P and we used chemiluminescence. Since obtained bands were actually weak in some cases, the results were not convincing. However, nested PCR succeeded in obtaining clear and strong bands. If JCV integration was a cause of colonic cancer, one could expect to find approximately one virus genome/human genome in cancer tissue [17]. For this reason, weak or faint bands should not be counted as unequivocal positives. Opposite to the results of Enam et al., a recent study reported no evidence of any association of JCV with 233 American cases of invasive colorectal cancer on comparison of matched colorectal tumor/normal tissue samples. They found evidence of the JCV genome only in one normal tissue in spite of usage of a quite sensitive PCR assay [22].

For estimating quality of DNA extracted from paraffin-embedded blocks, it is essential to evaluate PCR products since DNA is easily degraded by formalin fixation. Inoue et al. [14] found fixation in unbuffered 10% formalin to give samples (100% eligible samples) fixed for 1 day, 44% with 2–3 days and only 14% with 4–6 days using PCR amplification with primers producing a 190-bps targeted DNA segment p53 exon 5. Actually, we here first entered over 35 cases of colon carcinomas, but only 23 passed the DNA qualification using primers for the GAPDH housekeeping gene 199 bps in length. However, with fixation in formalin for only 2 days, about 90% of cases complied with the criterion. In the two reports showing completely opposite data (81 vs. 0% in T antigen), where formalin-fixed and paraffin-embedded tissues were employed, there was no mention of the quality of extracted DNA in detail [3, 22]. Another report concerning colonic biopsy samples found a high rate of JCV T antigen detection (81.2%). The assay included treatment with topoisomerase I, which enhanced the sensitivity of JCV T antigen detection [25]. We did not include such topoisomerase I treatment, which may have been a cause of the relatively lower rate for T antigen. However, PCR is a powerful tool for detection of DNA sequences of interest, and problems can arise if there is the possibility of carry-over of amplified DNA into genomic DNA. This is true with screening for virus infection, and therefore, it is necessary to include both positive and negative controls [22]. Even when precautions are taken, contamination may still be a problem. We here performed triplicate experiments for detecting the JCV genome with enough negative controls in each experiment. Results were completely identical in all cases, and no contamination might be evident.

It is essential for evaluating differences to know the background of JCV infection in the general population. JCV is a ubiquitous human polyoma virus which can be detected in raw sewage of urban areas [3]. Infection rates vary among populations and range from 20 to 80% on the basis of urine examination [2]. In one report, 40% of American Caucasians were infected with JCV on inspection of urine samples targeting VP region, but a higher rate was noted for native Americans (from 56 to 69%) [1]. Another report documented a rate of 71% from a similar study [22]. A figure of 40% has been described for Korean people infected with two distinct subtypes of JCV, CY and type 2A [15]. An earlier Japanese study found almost all JCV-infected Japanese to be also subdivided into CY or type 2A, although the infection rate was not determined [12]. Since Japanese and Korean are racially related, a similar incidence of JCV infection might be expected. Enam et al. [9] used 17 Mexican cases out of total 27 cases, and racial variation could clearly be a factor leading to differences.

The detection rates for agnoprotein and VP were lower than that of T antigen in an earlier report [3] and neither could be identified in the present study. JCV may be integrated into the chromosomal DNA of the cell on non-permissive infection, where it occurs at random like SV40 [11, 18]. In laboratory animal studies, when examined by immunohistochemical analysis, JCV-related tumor tissues showed the T antigen in the nuclei of tumor cells. However, attempts to detect VP by immunohistochemistry or virion formation by electron microscopy were unsuccessful [16] in line with our results. The antibody we used has frequently been employed to demonstrate the presence of JCV T antigen [3, 26]. Generally, half-lives of key molecules linked to cell proliferation are very short [27] and hard to detect by immunohistochemistry because these expressions are usually very low, and fixation would be expected to have a major influence. Actually, Shollar et al. [26] employed fresh animal tumor samples for investigating T antigen immunohistochemically. However, immunohistochemistry here precluded the possibility that background JCV latent infection in B lymphocytes could have influenced the detection rate of JCV in colorectal cancer samples.

It remains to be stringently proven that JCV has a causal role in human neoplasia. The incubation period between infection and appearance is long and the initial viral infection is usually subclinical, making it difficult to establish when it may have occurred. Environmental co-factors, such as carcinogens, or host factors, such as immune status, modulate pathogenesis [29] so that Koch's postulates cannot be simply applied in the JCV case. Alternative criteria have been proposed for defining a

causal role for an infection in cancer by zur Hausen [30]: first, epidemiological plausibility and evidence that a virus infection represents a risk factor for the development of a specific tumor; second, regular presence and persistence of the nucleic acid of the respective agent in the specific tumor; third, simulation of cell proliferation upon transfection of the respective genome or parts therefrom in corresponding culture cells; fourth, demonstration that induction of proliferation and the malignant phenotype of specific tumor cells depend on functions exerted by the persisting nucleic acid of the respective agents. Evidence has been described in the present study and earlier reviews [4, 16, 29] that JCV fulfills at least three of these criteria. It seems likely that JCV may perform some role, although possibly limited, in the genesis of colon cancers.

One of our cases positive for T antigen demonstrated lymph node metastasis, but DNA extracted from cancer cells in the lymph node demonstrated no presence of T antigen. A similar phenomenon has been noted in one of cell cultures derived from primitive neuroectodermal tumors (PNETs). After several passages, T-antigen-positive cells lose their expression of T antigen, yet retain their transforming phenotype [16]. It is well established that the adenovirus E1A and E1B gene products can cooperatively transform primary human and rodent cells to a tumorigenic phenotype. Recent studies discovered that oncoproteins E4orf6 and E4orf3 encoded by adenovirus E4 region cooperate with viral E1A proteins to transform primary rat cells in an E1B-like fashion. However, cells transformed by E1A and either E4orf6 or E4orf3 failed to express the viral E4 gene products, and only a subset contained E1A protein. The majority of the cells lack E4- and E1A-specific sequences, indicating that transformation occurs through a hit-and-run mechanism [21]. The same may explain our one case.

In conclusion, T antigen of JCV might be integrated into cancer cells in approximately one fourth of colorectal carcinoma cases, but no clear and diffuse expression of the protein was observed by immunohistochemistry. These results suggested that a hit-and-run mechanism of JCV may be important for the carcinogenesis of human colorectal cancers.

The endothelin/nitric oxide balance determines small-for-size liver injury after reduced-size rat liver transplantation

Received: 5 January 2005 / Accepted: 10 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract Small-for-size (SFS) liver graft injury is probably related to microcirculatory disorders due to an imbalance of vasoconstricting, e.g. endothelin (ET)-1, and vasorelaxing mediators, e.g. nitric oxide (NO). We studied the role of ET-1/NO balance and the effect of an endothelin A receptor (ETAR) antagonist on SFS injury after liver resection and reduced-size liver transplantation (RSLT). One hundred twenty-six Lewis rats were divided into five groups: (I) 70% liver resection, (II) 70% liver resection treated with the ETAR antagonist LU 135252 (1 mg/kg b. w. i.v.), (III) RSLT (30% residual liver volume), (IV) RSLT treated with the ETAR antagonist, (V) sham operation. Liver microcirculation was measured by intravital microscopy. ET-1, ETAR, endothelial NO-synthase (eNOS), activation of Kupffer cells (KCs) and parenchymal injury were studied by immunohistology. Survival and liver function were followed up to 14 days. RSLT led to increased ET-1, ETAR and decreased eNOS protein expression, accompanied by activation of KC, reduced perfusion rate, vasoconstriction and elevated sinusoidal blood flow, as well as hepatocellular damage, impaired liver function and impaired survival. ETAR blockade (groups II + IV) improved the ET-1/NO balance, attenuated microcirculatory disorders and improved hepatocellular apoptosis and liver function. Microcirculatory disorders related to an ET-1/NO imbalance may contribute to SFS liver injury. Maintenance of ET-1/NO balance by blocking ETAR reduces SFS injury by protecting liver microcirculation, thus reducing hepatocellular damage.

Introduction

Reduced-size liver transplantation (RSLT) in adults, e.g. by living donation, is an accepted alternative used to overcome the increasing demand for donor organs [12]. However, after living graft donation and RSLT, a certain minimal residual liver size in the donor and graft size in the recipient are required to allow rapid liver regeneration and maintenance of liver function. Whereas after standard liver resection, 25% of residual normal liver parenchyma is sufficient; more than 40% residual liver parenchyma is necessary after RSLT to allow liver regeneration without profound impairment of liver function [8, 11, 12]. Indeed, to ensure adequate liver function and regeneration after RSLT, it is recommended that the graft weight to recipient body weight ratio (GRBWR) should be close to 1% [8, 11, 12]. If the GRBWR is less than 0.8%, the residual liver function and regeneration will be impaired, leading to a small-for-size (SFS) syndrome [8, 11, 12].

The mechanism of SFS injury is currently under investigation. Irrespective of individual donor and recipient factors, the SFS injury seems to be primarily linked to graft over-perfusion [7]. It has been shown that portal decompression and improvement of hepatic vein drainage of reduced-size liver grafts might improve liver function [4, 12]. We thought that the same effect could be obtained by optimizing the sinusoidal diameter in reduced-size liver grafts by an administration of a selective endothelin A

receptor (ETAR) antagonist. Endothelin (ET)-1 is a potent vasoconstrictor that is synthesized in sinusoidal endothelial cells (SECs) and generates its effects via the endothelin A receptor, largely on hepatic stellate cells (HSCs) [10, 23]. Under physiological conditions, the ET-1 effects are counterbalanced by vasorelaxing agents such as nitric oxide (NO). In the injured liver, ET-1 production is increased, whereas NO release from SEC is reduced, leading to a reduced perfusion rate, reduced sinusoidal diameter and increased leukocyte–endothelial interaction [13, 18]. Here we investigated the potential role of ET-1/NO balance and the effect of ETAR blockade on the SFS injury after liver resection (simulating the donor after living graft donation) and RSLT (simulating the recipient after RSLT).

Materials and methods

Animals and study design

All operations and handling procedures were in accordance with local animal welfare regulations and approved by the veterinary district administration of Muenster. One hundred and twenty-six isogeneic male Lewis rats (238.8± 40.9 g, Charles River, Germany) were divided into five experimental groups. In group I (RES), a two-thirds hepatectomy was performed (Fig. 1). In group II (RES-ETA), a two-thirds hepatectomy was performed just as in group I, but with treatment of the reduced-size liver with Darusentan (LU 135252, Knoll, Ludwigshafen, Germany, 1 mg/kg b.w. i.v.), immediately before liver resection. In group III (RSLT), an RSLT was performed. For this purpose the donor operation comprised a size reduction of the transplant by a two-thirds hepatectomy. The reduced-size liver transplant (30% of the original liver volume) was then orthotopically transplanted with portal venous reperfusion and transplant arterialisation according to the model of Engemann [19]. In group IV (RSLT-ETA), an RSLT was performed just as in group III, but with ETAR blockade of the reduced-size liver transplants, immediately before reperfusion as in group II. In group V (SHAM), the liver was mobilized by dividing the hepatic ligaments. In groups I, III and V, saline solution was given as vehicle.

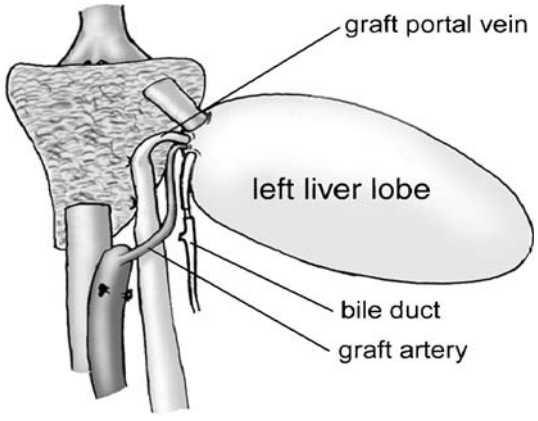

Fig. 1 Surgical technique. RSLT was performed (group III+IV) using a reduced-size liver transplant represented by the left liver lobe (approximately 30% of the original liver volume). The portal vein, supra-, and infrahepatic vena cava were sutured, transplant rearterialisation was carried out using a donor aortic segment and the bile duct was reconstructed by the splint technique according to the model of Engemann [19]

All procedures were carried out under nitrous oxide/isoflurane anaesthesia (N_2O/O_2=2:1+1.5% isoflurane). All animals were assigned to short-term experiments (n=7 per group), in which hepatic microcirculation was assessed by intravital microscopy, or to long-term experiments (resection groups I + II, n=7; transplantation groups III+IV, n=14), in which the rats were kept under observation up to the 14th postoperative day. Preoperatively, the rats were fasted for 24 h, but had free access to water. Postoperatively, animals received water and fed ad libitum.

Liver weight to body weight ratio

In groups I, II and V, the remnant liver weight was determined relative to the liver weight of the remnant liver in untreated Lewis rats (150–250 g, n=10) which had been killed in preliminary experiments. In groups III and IV, the weight of the reduced-size liver graft was determined prior to the recipient operation. Liver weight to body weight ratio (LWBWR) was assessed following the assessment of GRBWR after clinical RSLT using the following formula: liver weight×100/body weight (%) [12]. In this study, an LWBWR of less than 1% was claimed to investigate SFS liver injury.

Serum parameters

Preoperatively, and again 90 min after reperfusion and 1, 2, 7 and 14 days after operation, ammonia (NH_3), bilirubin, albumin and alanine-aminotransferase (ALT) were determined at 25°C by standard enzymatic techniques (micromethod, Ektachem-Kodak, Germany).

Intravital microscopy

Intravital microscopy was performed under constant conditions of anaesthesia and temperature by an adjustable heating system integrated into the table. A polyethylene catheter was inserted into the carotid artery for measurement of arterial blood pressure. Contrast medium was injected via the central venous catheter.

The hepatic microcirculation was studied on the lower surface of the left liver lobe (penetration depth approximately 300 μm) 60 min after liver resection and reperfusion, by intravital fluorescence microscopy [12]. Sodium fluorescein (2 μmol/kg b.w. i.v.; Sigma, Germany) was used to enhance contrast for assessing sinusoidal perfusion, whereas rhodamine 6G (0.2 μmol/kg b.w. i.v., Sigma) was used for vital staining of leukocytes. Microcirculatory parameters were quantified offline by frame-to-frame analysis of video-recorded microscopic images via the

computer-assisted image analysis system AnalySIS (SIS, Muenster, Germany). A final magnification of ×750 was employed for measurement of the microcirculation. Acini (10–12) and post-sinusoidal venules (10–12) were randomly selected and observed for 30 s in each experiment. The following parameters were analysed: sinusoidal perfusion rate [perfused sinusoids/total number of sinusoids observed (%)], sinusoidal diameters [measured in 100 sinusoids per liver both in the periportal and pericentral zones (μm)] and diameters of post-sinusoidal venules (μm); number of sticking leukocytes in sinusoids [stagnant leukocytes not moving during a period of 20 s (n/mm^2)] and sticking leukocytes in post-sinusoidal venules (stagnant leukocytes not moving during a period of 20 s (n/mm^2)]; number of rolling leukocytes in sinusoids [temporarily stagnant leukocytes with adhesion times between 0.2 and 20 s (n/mm^2)] and number of rolling leukocytes in post-sinusoidal venules [leukocytes rolling along the endothelial lining of post-sinusoidal venules (n/mm^2)], as well as the velocity of free-flowing leukocytes in sinusoids and post-sinusoidal venules (μm/s) [21].

Immunohistochemistry

For histological evaluation, all liver specimens were fixed by immersion for at least 2 days in 4% formaldehyde solution and were subsequently dehydrated and embedded in paraffin wax to cut sections at a thickness of 5 μm. Morphologic parameters were recorded by routine histology (hematoxylin and eosin stain). From all sections, photomicrographs were taken off the periportal and pericentral zones of the liver lobule and from the corresponding regions of the control livers in group IV (sham operation). Sections were evaluated for proliferation, atrophy and necrosis of the hepatic parenchyma.

Ultrastructural parameters were recorded by scanning electron microscopy. Liver specimens were cut into 2×2×5 mm blocks, ethanol-dehydrated, freeze-fractured in liquid nitrogen, prepared critical point-dried, ion-sputtered, coated with platinum and viewed with a high-resolution scanning electron microscope (1530 VP, LEO, Germany). Photographs were taken at a magnification of ×20,000.

Immunostaining for activation of Kupffer cells (KCs) (ED-1) and sinusoidal endothelium reactivity detection of the rat endothelial cell antigen (RECA) by His 52 was performed on cryostat sections using the immuno-alkaline phosphatase (APAAP) method, with fuchsin as chromogen. Immunostaining on paraffin sections for ET-1, ETAR, endothelial NO-synthase (eNOS), apoptosis (ssDNA) and nitrotyrosine was performed as follows. After antigen retrieval (Revial, Biocarta, Hamburg, Germany) for 5 min in a domestic pressure cooker as described earlier [15] and after blocking non-specific binding sites with BSA-c basic blocking solution (1:10 in PBS, Aurion, Wageningen, the Netherlands), the sections were immunoreacted with primary antibodies (See Table 1) overnight at 4°C and, after washing in PBS, the sections were treated for 10 min with methanol containing 0.6% H_2O_2 to quench endogenous peroxidase. For fluorescent visualization of bound primary rabbit antibodies, sections were further treated for 1 h at room temperature with DAKO anti-rabbit EnVision-HRP. The HRP label was amplified with FITC-conjugated tyramine at a dilution of 1:300 in PBS in the presence of 0.02% H_20_2 for 10 min. Finally, samples were counterstained for 15 sec with DAPI (5 μg ml^{-1} PBS, Sigma) and mounted with Vectashield (Vector Laboratories, Burlingame, CA, USA). For bright-field microscopy, bound

Table 1 Antibodies and conditions used in this study

Parameter	Primary antibodies	Secondary systems	Analysis
Endothelin-1 (ET-1)	Endothelin-1 (1:50, rabbit polyclonal, DPC Biermann, Bad Nauheim, Germany)	Goat anti-rabbit biotinilated AB (1:20, BiGenex, Hamburg, Germany)	Semi-quantitative score (0–4) [20]
Endothelin A receptor (ETAR)	Endothelin A receptor (1:10, rabbit polyclonal, DPC Biermann)	Goat anti-rabbit biotinilated AB (1:20, BiGenex)	Semi-quantitative score (0–4) [20]
Kupffer cells (KCs)	CD-68 (ED-1) (1:400, mouse monoclonal, Serotec, Oxford, UK)	Goat anti-mouse EnVision-HRP (DAKO Corporation, Hamburg, Germany)	*n* (KC)/100 cells
Apoptosis	ssDNA (1:1,500, rabbit polyclonal, IBL, Gunma, Japan)	Goat anti-rabbit biotinilated AB (1:300, Vector)	*n* (apoptotic HEP)/100 HEP *n* (apoptotic NPC)/100 NPC
Endothelial nitric oxide synthase (eNOS)	eNOS (1 :100, rabbit polyclonal, Transduction Lab., Lexington, KY, USA)	Goat anti-rabbit EnVision-HRP (DAKO)	Semi-quantitative score (0–3)
Nitrotyrosine	Nitrotyrosine (1:20, mouse monoclonal, Zymed, San Francisco, USA)	Goat anti-mouse EnVision-HRP (DAKO)	Semi-quantitative score (0–3)
Rat endothelial cell antigen (RECA)	His 52 (1:40, mouse monoclonal, Serotec)	Goat anti-mouse EnVision-HRP (DAKO)	Semi-quantitative score (0–3)

primary antibodies were detected using DAKO EnVision-HRP and DAB substrate kit (Vector Laboratories), counterstained with Ehrlich hematoxylin for 30 s and mounted with an aqueous mounting medium GelTol (Immunotech, Marseilles, France).

Images shown are representative of at least five independent experiments which gave similar results. The number of KC per 100 hepatocytes (HEPs) was assessed by counting approximately 1,000 HEPs and non-parenchymal cells (NPCs). The apoptosis index, i.e. the proportion of ssDNA decorated nuclei per 100 hepatocellular nuclei, was semi-quantitated by counting approximately 1,000 HEPs and NPCs each. The immunostaining intensity of eNOS, RECA and nitrotyrosine was evaluated by a four-grade score: 0=negative, 1=partially (<25%) weak positive-stained cells, 2=partially (<25%) moderate or diffuse (>75%) weak positive cells, 3=diffuse (>75%) moderate or strong positive cells, 4=diffuse (>75%) strong positive cells. The intensity of cytoplasmic ET-1 and ETAR immunostaining was graded from 0 (no staining) to 3 (maximal intensity of staining). The number of labelled cells was counted and scored semi-quantitatively from 0 to 4 (0=0, 1=1–30, 2=31–60, 3=61–90, 4=>90 stained cells in 1 of 10 observed areas per section; Fig. 5) [20].

Statistics

All data are presented as means±SD. Statistical analysis was performed by the Kruskal–Wallis test using SPSS software. Survival rates were assessed by the Kaplan–Meier method. The log-rank test was used to compare significance. A level of significance of $p<0.05$ was considered as sufficient in all experimental groups.

Results

Survival

After liver resection (group I) six of seven rats survived until their sacrifice at the 14th day (Fig. 2). One rat died on the first postoperative day, showing a macroscopically pale liver. All animals, after liver resection, which were treated with the ETAR antagonist (group II), survived up to the 14th day. After RSLT (group III), the survival rate was significantly reduced compared with that of after liver resection (groups I + II). Three and four rats died on the first or second postoperative day, respectively, displaying pallor and discoloration of the liver in the presence of intact vascular anastomoses. ETAR blockade before RSLT (group IV) led to a survival of 9 of 14 rats. One rat died on the first postoperative day, two rats on the third day and another two on the fourth day (Fig. 2).

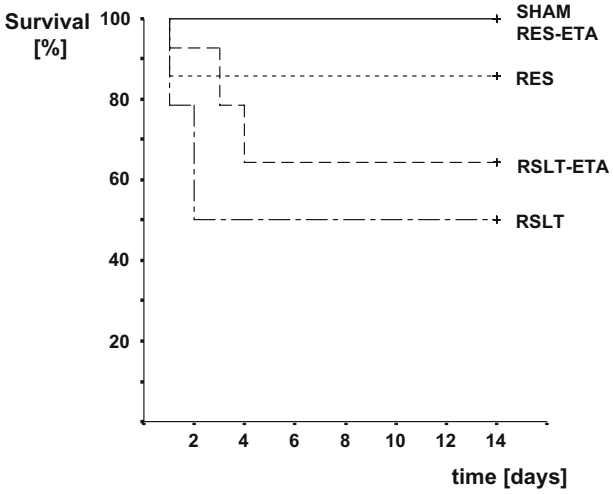

Fig. 2 Survival rates. After RSLT (group III), the survival rate was significantly impaired compared with that of after liver resection (groups I+II), whereas ETAR blockade before RSLT (group IV) led to a survival of 9 of 14 rats. *RES*-Liver resection (group I), *RES-ETA*-liver resection treated by the ETAR antagonist (group II), *RSLT*-reduced-size liver transplantation (group III), *RSLT-ETA*-reduced-size liver transplantation treated by the ETAR antagonist (group IV), *SHAM*-sham operation (group V)

Liver weight body weight ratio

LWBWR was 0.8±0.0% (groups II + III) or 0.8±0.1% (groups I+IV), respectively, and did not differ among groups I–IV, but was significantly lower than in the sham-operation group (Table 2).

Serum parameters

Preoperatively, all serum parameters were within the normal range and did not significantly differ among the groups (Table 3). Liver resection (group I) led to a maximum of ALT release of 912.2±502.1 U/l and an NH_3 level of 199±65.3 μg/dl on the first day, but that was significantly reduced by ETAR blockade (group II). Albumin levels dropped on the first day to 2,285.7±211.6 mg/dl after liver resection (group I) and 1,900±152.8 mg/dl in group II, but normalised by the 14th day. In both groups (I+II), bilirubin levels were within the normal range during the whole postoperative course. RSLT (group III) led to a maximum ALT release of 1,144.1±435.2 U/l on the first day and a maximum NH_3 level of 399.8±141.3 μg/dl 90 min postoperatively, which differed significantly from the liver resection groups (groups I + II). ETAR blockade of reduced-size liver grafts significantly reduced ALT levels at the first, second and seventh day and NH_3 levels 90 min and 1 day after surgery. Albumin levels after RSLT (group III) dropped significantly after surgery compared to the

sham group (group V), but did not differ significantly between both RSLT groups (groups III + IV). Bilirubin levels after RSLT (group III) were significantly increased on the 7th and 14th day and could be reduced by ETAR blockade (group IV).

Intravital microscopy

Arterial blood pressure (mean, 86±12 mm Hg), heart rate (mean, 398±12/min) and body temperature (37.0±0.4°C) showed no significant differences among all groups. Sixty minutes after liver resection (group I), all animals showed microcirculatory disorders with a significantly reduced perfusion rate of 94±1.1%, a reduced periportal sinusoidal diameter of 4.9±0.1 μm and increased numbers of sinusoidal and venular stagnant leukocytes compared to sham-operated animals (group V, Fig. 3). The leukocyte velocity within the liver acini and in the post-sinusoidal veins was increased to 615.7±84.9 μm/s and 1,434.9±176.9 μm/s, respectively, and almost twice as compared to sham-operated animals (group V). ETAR blockade before liver resection (group II) significantly increased the sinusoidal diameter as well as decreased the leukocyte velocity.

RES-Liver resection (group I), *RES-ETA*-liver resection treated by the ETAR antagonist (group II), *RSLT*-reduced-size liver transplantation (group III), *RSLT-ETA*-reduced-size liver transplantation treated by the ETAR antagonist (group IV), *SHAM*-sham operation (group V)

RSLT (group III) led to a significantly decreased perfusion rate of 81.2±1.4%, a sinusoidal diameter of 3.9±0.1 μm and constriction of post-sinusoidal venules, as well as increased counts of sinusoidal and venular stagnant leukocytes, compared to the liver resection (groups I + II) and sham group (group V). The leukocyte velocity within the liver sinusoids and post-sinusoidal veins was increased to 516.5±92.7 and 926.3±239.2 μm/s, respectively. ETAR blockade of reduced-size liver grafts (group IV) significantly reduced microcirculatory disturbances by increasing the perfusion rate, sinusoidal diameter and reducing the sinusoidal leukocyte velocity as well as the numbers of sinusoidal and venular stagnant leukocytes.

Morphology and ultrastructure

After 120 min, all rats which had undergone RES (group I; Fig. 4a,b) and RSLT (group III; Fig. 4e,f) showed a characteristic pattern of damage in the HEPs by cytoplasmic vacuolization and a definite thickening of the endothelium, combined with patchy desquamation of endothelial cells, occasionally resulting in a total loss of endothelium. ETAR blockade in these rats (groups II + IV; Fig. 4c,d,g,h) restored the liver architecture without causing any conspicuous features of cellular damage or destruction in the HEPs and NPCs and preserved the continuity of the endothelium except for some cellular edema and defenestration.

After 14 days, normal liver architecture, without any conspicuous features of cellular damage or destruction among the HEPs and NPCs, was seen in all groups.

Endothelin-1, endothelin A receptor and eNOS

Sham-operated animals (group V) showed no immunoreactivity or only a focal presence of ET-1 (1.0±0.0 pts.) and ETAR (0.3±0.6 pts.) and a strong eNOS protein expression (1.5±0.9 pts.) (Figs. 5i,j and 6). All rats displayed a significantly increased immunoreactivity of ET-1 (3.3±1.2 pts.) and ETAR (2.5±2.1 pts.) 120 min after liver resection (group I), whereas the eNOS protein expression (0.7±1.0 pts.) was reduced (Figs. 5a,b and 6). ETAR blockade before liver resection (group II) significantly

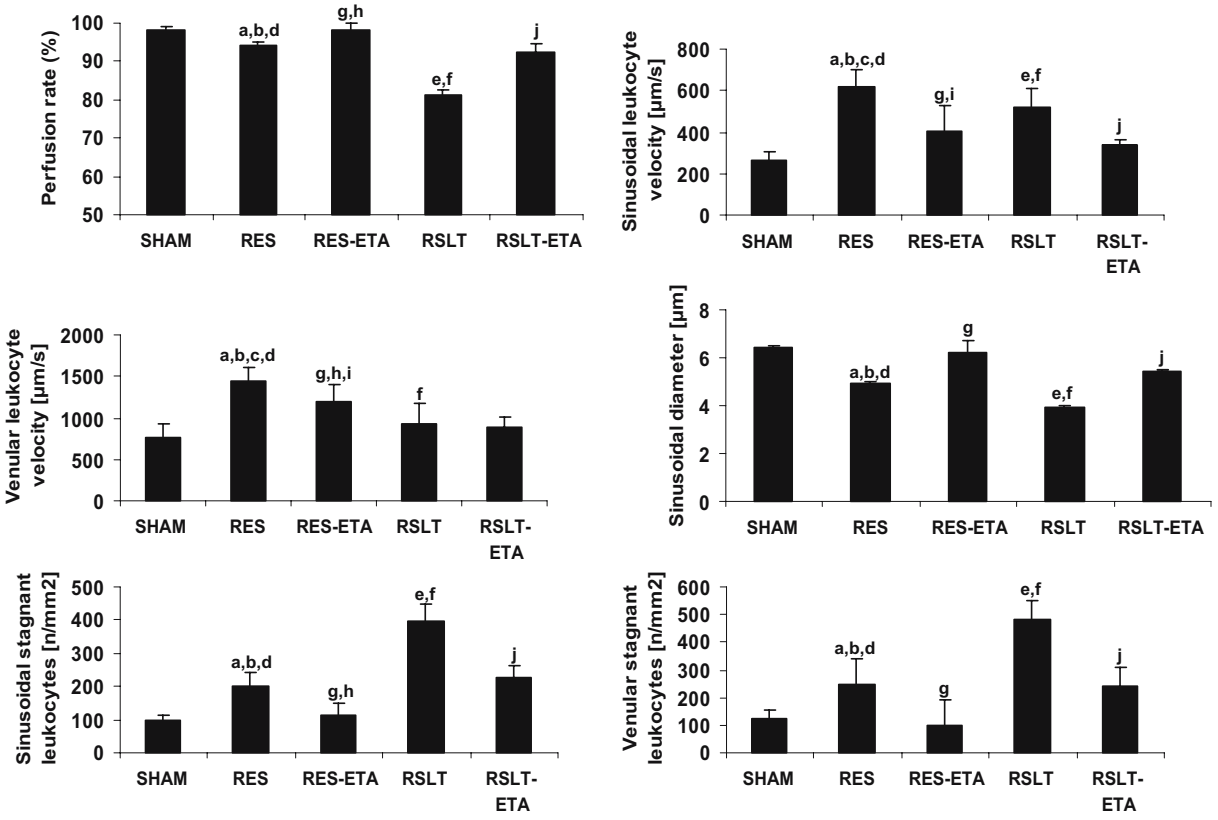

Fig. 3 Results of intravital microscopy. Sixty minutes after surgery, RES and RSLT (groups I+III) had a reduced perfusion rate, vasoconstriction, and elevated leukocyte velocity and leukocyte–endothelial interaction compared to sham-operated animals (group V). ETAR blockade (groups II+IV) reduced these microcirculatory disorders. *RES* Liver resection (group I), *RES-ETA* liver resection treated by the ETAR antagonist (group II), *RSLT* reduced-size liver transplantation (group III), *RSLT-ETA* reduced-size liver transplantation treated by the ETAR antagonist (group IV), *SHAM* sham operation (group V). [a]$p<0.05$ RES (I) vs RES-ETA (II), [b]$p<0.05$, RES (I) vs RSLT (III), [c]$p<0.05$ RES (I) vs RSLT-ETA (IV), [d]$p<0.05$ RES (I) vs SHAM (V), [e]$p<0.05$ RSLT (III) vs RSLT-ETA (IV), [f]$p<0.05$ RSLT (III) vs SHAM (V), [g]$p<0.05$ RES-ETA (II) vs RSLT (III), [h]$p<0.05$ RES-ETA (II) vs RSLT-ETA (IV), [i]$p<0.05$ RES-ETA (II) vs SHAM (V), [j]$p<0.05$ RSLT-ETA (IV) vs SHAM (V)

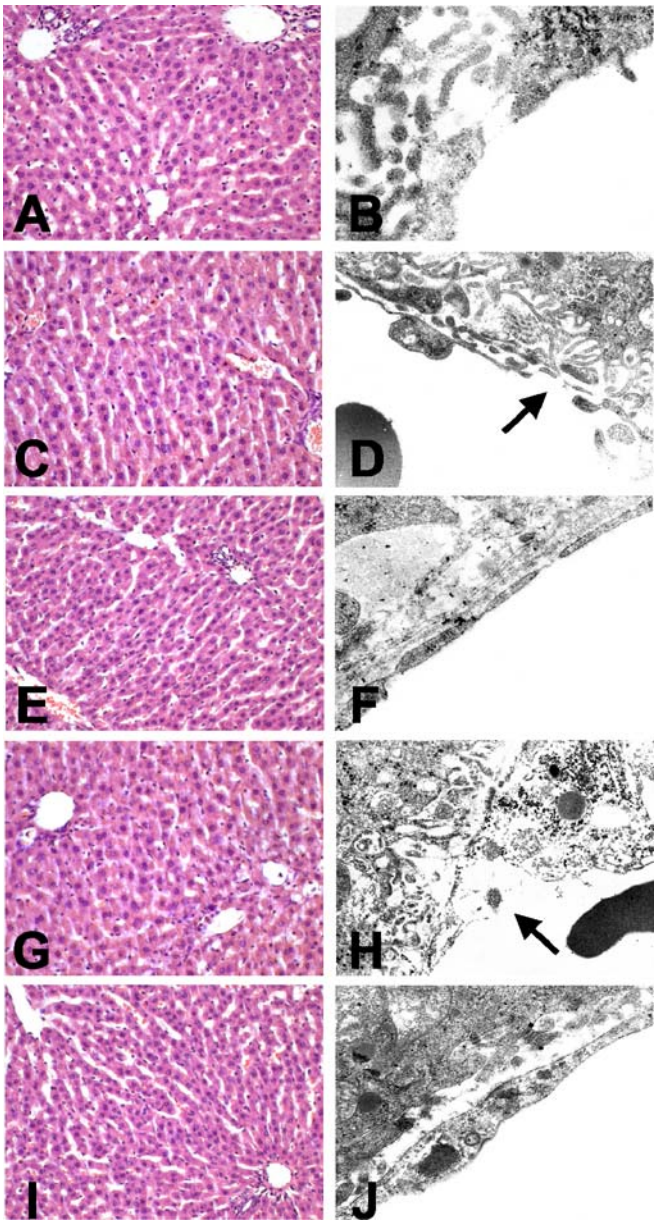

Fig. 4 Morphologic and ultrastructural results. One hundred twenty minutes after RES and RSLT (groups I+III), a characteristic pattern of damage in the hepatocytes, characterised by cytoplasmic vacuolization and definite thickening of the endothelium, combined with patchy desquamation of endothelial cells occurred, occasionally resulting in a total loss of endothelium (*arrow*). ETAR blockade in these groups (II+IV) preserved the continuity of the endothelium with some cellular edema and defenestration (groups II+IV). HE-staining (*left column*) magnification ×120, electron microscopy (*right column*) magnification ×20,000, SHAM (group V, **a**+**b**), RES (group I, **c**+**d**), RES-ETA (group II, **e**+**f**), RSLT (group III, **g**+**h**), RSLT-ETA (group IV, **i**+**j**)

reduced the ET-1 (1.0±0.8 pts.) and ETAR immunoreactivity (1.0±0.0 pts.) and led to moderate eNOS protein expression (3.0±1.0 pts.) (Figs. 5c,d and 6). Just as in the liver resection groups (groups I + II), all animals after RSLT (group III) showed a significantly increased ET-1 (4.0±0.0 pts.) and ETAR protein expression (3.0±2.6 pts.) and decreased eNOS expression (1.1±1.1 pts.) (Figs. 5g,h and 6). Reduced-size liver grafts treated with the ETAR antagonist (group IV) displayed significantly lower ET-1 (3.0±1.7 pts.) and ETAR levels (2.5±1 pts.) as well as moderate eNOS protein expression (2.5±1.2 pts.) (Figs. 5g,h and 6).

After 14 days, the immunoreactivity of ET-1 and ETAR after RES, RSLT and RSLT-ETA and eNOS after RES-ETA and RSLT-ETA were significantly decreased compared to day 0. Furthermore, at this time, differences in the immu-

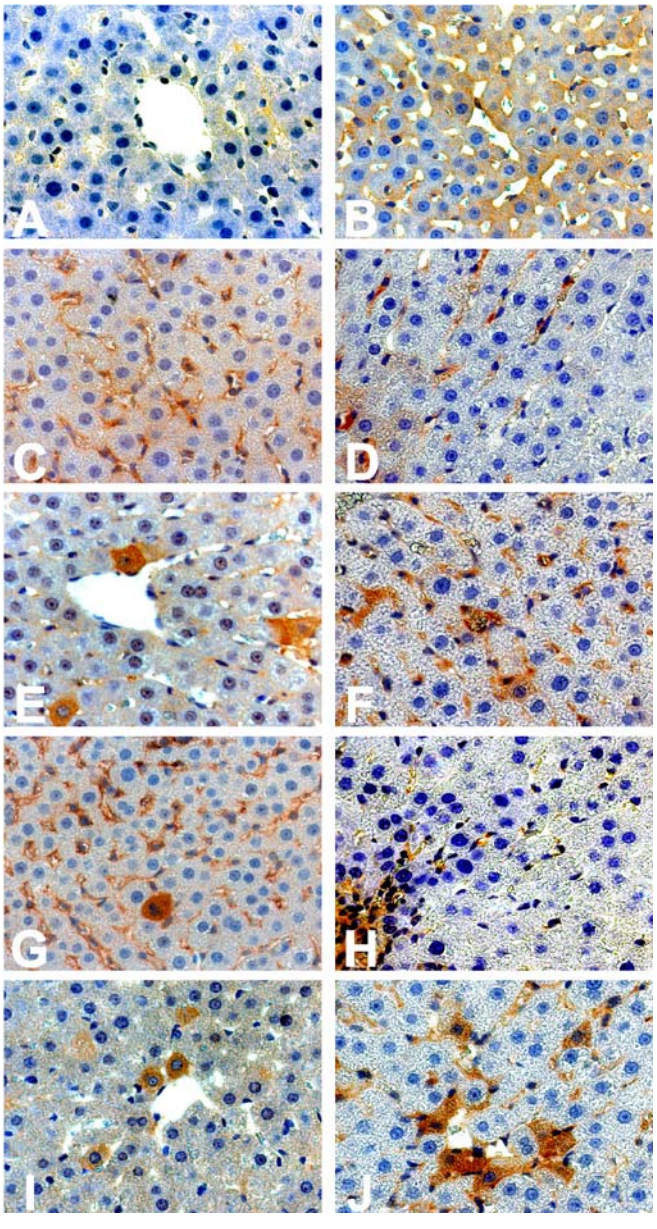

Fig. 5 Intracellular protein expression of ET-1 and eNOS 120 min after surgery. All rats displayed a significantly increased immunoreactivity of ET-1 and ETAR 120 min after RES and RSLT (group I +III), whereas the eNOS protein expression was reduced. ETAR blockade in these groups (II + IV) significantly reduced the ET-1 and ETAR immunoreactivity and led to moderate eNOS protein expression. ET-1 (*left column*), eNOS (*right column*), SHAM (group V, **a**+**b**), RES (group I, **c**+**d**), RES-ETA (group II, **e**+**f**), RSLT (group III, **g**+**h**), RSLT-ETA (group IV, **i**+**j**), magnification ×120

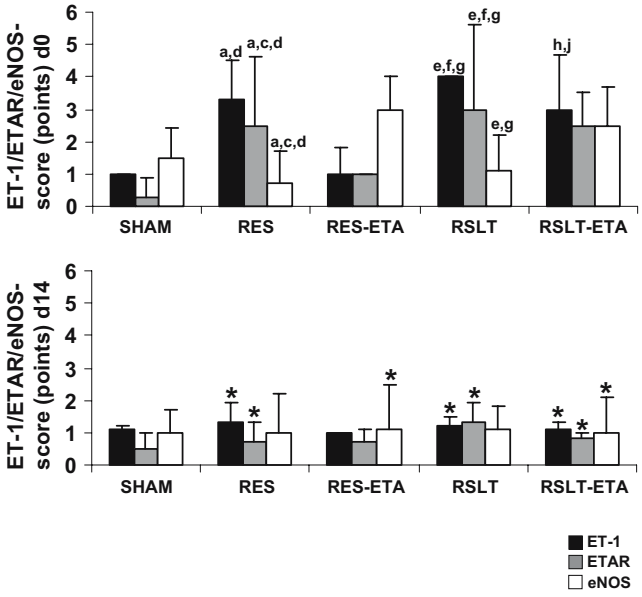

Fig. 6 Semi-quantitative ET-1, ETAR, and eNOS score 120 min and 14 days after surgery (see text for details). [a]$p<0.05$ RES (I) vs RES-ETA (II), [b]$p<0.05$, RES (I) vs RSLT (III), [c]$p<0.05$ RES (I) vs RSLT-ETA (IV), [d]$p<0.05$ RES (I) vs SHAM (V), [e]$p<0.05$ RSLT (III) vs RSLT-ETA (IV), [f]$p<0.05$ RSLT (III) vs SHAM (V), [g]$p<0.05$ RES-ETA (II) vs RSLT (III), [h]$p<0.05$ RES-ETA (II) vs RSLT-ETA (IV), [i]$p<0.05$ RES-ETA (II) vs SHAM (V), [j]$p<0.05$ RSLT-ETA (IV) vs SHAM (V), *$p<0.05$ day 0 vs day 14

noreactivity of ET-1, ETAR and eNOS between all groups were no longer evident (Fig. 6).

Kupffer cells and rat endothelial cell antigen

Sham-operated animals (group V) showed a weakly expression of RECA and numbers of immunostained KC in the sinusoids (Figs. 7a,b and 8). Liver resection (group I, Fig. 7c) and, particularly, RSLT (group III, Fig. 7g) led to an activation of KC up to 9.6±2.4/100 cells and 14.3±3.6/100 cells, respectively, showing a distribution gradient increasing from the periportal tracts towards the central vein (Fig. 8). In addition, these animals showed strong expression of RECA (RES, 3.3±0.5 pts.; RSLT, 3.9±0.3 pts.; Figs. 7d,h and 8). ETAR blockade significantly reduced the number of immunostained KC (RES-ETA, 4.4±3/100 cells; RSLT-ETA, 6.8±2.9/100 cells; Figs. 7e,i and 8) and lowered the expression of RECA after liver resection (group II: 1.4±0.5 pts.; Figs. 7f, and 8) and RSLT (group IV: 1.7±0.5 pts.; Figs. 7j, and 8).

After 14 days, the number of immunostained KC and the expression of RECA were significantly decreased in groups I–IV compared to day 0, and there were no differences between the groups (Fig. 8).

Apoptosis index and nitrotyrosine

After sham operation (group V), no nitrotyrosine and only a few apoptotic cells could be detected (Fig. 9a,b and 10).

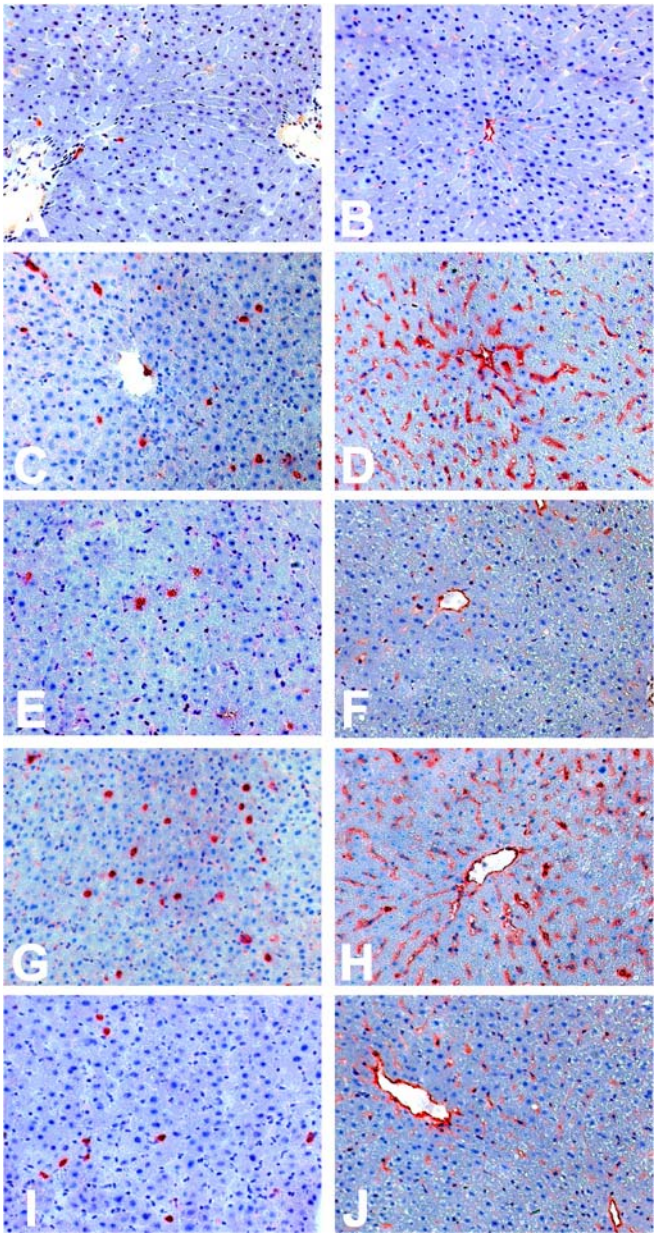

Fig. 7 Kupffer cell and rat endothelial cell antigen staining 120 min after surgery. Sham-operated animals revealed a weak expression of RECA and low number of immunostained KC in the sinusoids, whereas RES and RSLT led to a significant activation of KC and strong expression of RECA. ETAR blockade in these groups reduced the number of immunostained KC and lowered endothelial cell reactivity. Kupffer cell (ED-1)-staining (*left column*), RECA (*right column*), SHAM (group V, **a**+**b**), RES (group I, **c**+**d**), RES-ETA (group II, **e**+**f**), RSLT (group III, **g**+**h**), RSLT-ETA (group IV, **i**+**j**), magnification ×120

After 120 min, the apoptosis index of HEPs and, in particular, of NPCs was significantly increased after RES (group I: 1.7±1.8/100 HEP; 3.8±2.8/100 NPC; Figs. 9c and 10) and RSLT (group III: 3.3±2.5/100 HEP; 4.1±2.3/100 NPC; Figs. 9g and 10). These animals simultaneously showed strong nitrotyrosine immunoreactivity of the endothelial cells in particular (RES, 3.4±0.9 pts.; RSLT, 3.7±0.8 pts.; Figs. 9d,h and 10). ETAR blockade significantly

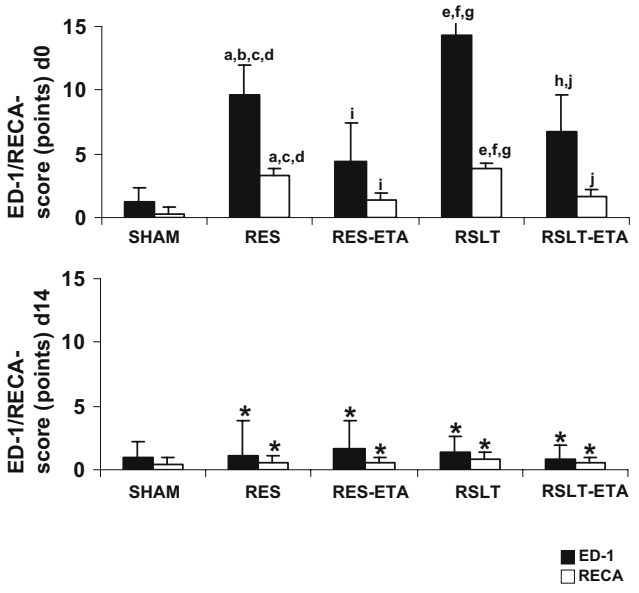

Fig. 8 Semi-quantitative ED-1 and RECA score 120 min and 14 days after surgery (see text for details). [a]$p<0.05$ RES (I) vs RES-ETA (II), [b]$p<0.05$, RES (I) vs RSLT (III), [c]$p<0.05$ RES (I) vs RSLT-ETA (IV), [d]$p<0.05$ RES (I) vs SHAM (V), [e]$p<0.05$ RSLT (III) vs RSLT-ETA (IV), [f]$p<0.05$ RSLT (III) vs SHAM (V), [g]$p<0.05$ RES-ETA (II) vs RSLT (III), [h]$p<0.05$ RES-ETA (II) vs RSLT-ETA (IV), [i]$p<0.05$ RES-ETA (II) vs SHAM (V), [j]$p<0.05$ RSLT-ETA (IV) vs SHAM (V), *$p<0.05$ day 0 vs day 14

reduced the apoptosis index in groups II (1.0±0.8/100 HEP; 1.2±1.1/100 NPC; Figs. 9e and 10) and IV (1.9±1.2/100 HEP; 2.5±2.3/100 NPC; Figs. 9i, 10) as well as reduced nitrotyrosine expression (RES, 1.1±0.7 pts.; RSLT, 1.5±0.8 pts.; Fig. 9f,j).

After 14 days, the apoptotic index of HEP and NPC and nitrotyrosine immunoreactivity were significantly decreased compared to day 0, and there were no differences between the groups (Fig. 10).

Discussion

Microcirculatory disorders correlate with SFS injury after liver resection and RSLT. In this study, rats with a LWBWR of 0.8% displayed characteristic microcirculatory damage with decreased sinusoidal perfusion rates, vasoconstriction and over-proportional sinusoidal blood flow. These microcirculatory changes were accompanied by increased hepatocellular apoptosis, activation of KC and, in particular, damage to SEC with thickening, patchy desquamation and strong expression of RECA leading to impaired liver function and increased mortality. Resection of two-thirds of the liver resection without transplantation—this is a model of the remnant donor liver after living graft donation—led to impaired liver microcirculation and function, but did not affect survival. However, transplantation of a liver graft having the same size—this is a model of the recipient after living graft donation—significantly impairs liver function and survival rate because of the additional ischemia/reperfusion injury [6].

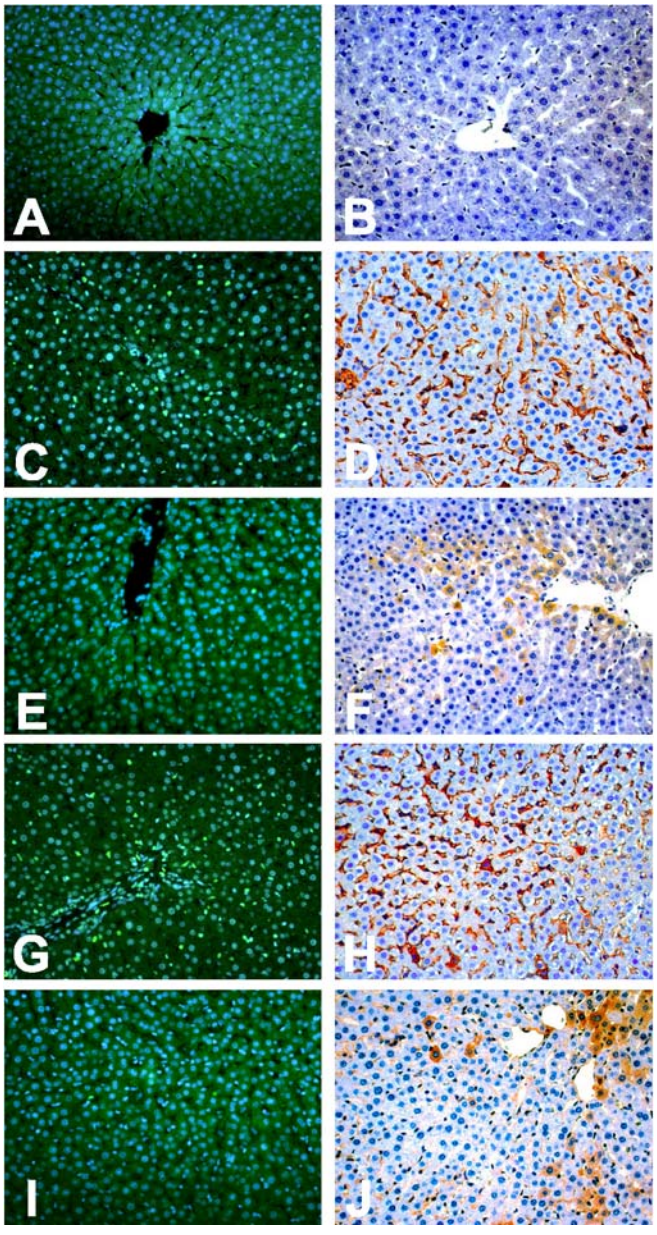

Fig. 9 Apoptosis and nitrotyrosine labelling 120 min after surgery. After sham operation, no nitrotyrosine and only a few apoptotic cells could be detected. The apoptosis index of hepatocytes (HEPs) and non-parenchymal cells (NPCs) and the nitrotyrosine immunoreactivity was significantly increased after RES and RSLT and could be significantly lowered by ETAR blockade. After 14 days, no differences between all groups occurred concerning the apoptosis index and nitrotyrosine immunoreactivity. Apoptosis (*left column*), Nitrotyrosine (*right column*), SHAM (group V, **a**+**b**), RES (group I, **c**+**d**), RES-ETA (group II, **e**+**f**), RSLT (group III, **g**+**h**), RSLT-ETA (group IV, **i**+**j**), magnification ×120

ET-1 and NO seem to play a key role in the pathogenesis of SFS liver injury. NO has vasorelaxing effects and is produced from L-arginine, e.g. by the constitutive eNOS [14]. Whereas under physiological conditions, the sinusoidal diameters are regulated by a balance between ET-1 and NO, liver resection and RSLT lead to a significant increase of ET-1 and ETAR protein expression and, in parallel, to a reduced eNOS expression [15]. It might be postulated that

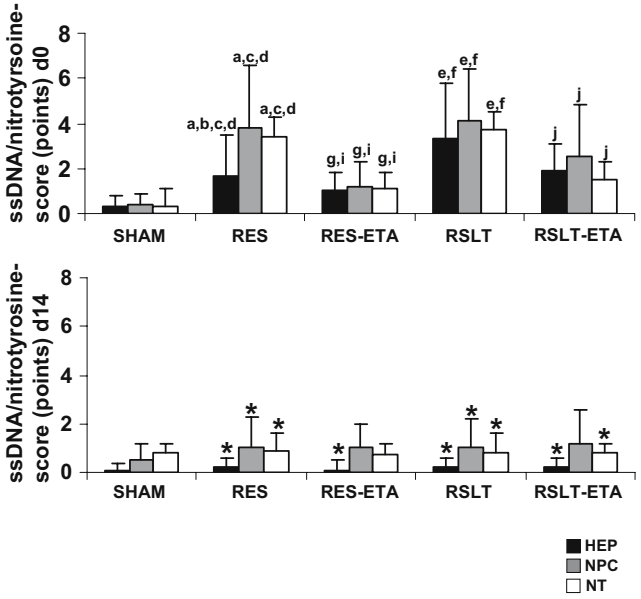

Fig. 10 Apoptosis and nitrotyrosine score 120 min and 14 days after surgery (see text for details). [a]$p<0.05$ RES (I) vs RES-ETA (II), [b]$p<0.05$, RES (I) vs RSLT (III), [c]$p<0.05$ RES (I) vs RSLT-ETA (IV), [d]$p<0.05$ RES (I) vs SHAM (V), [e]$p<0.05$ RSLT (III) vs RSLT-ETA (IV), [f]$p<0.05$ RSLT (III) vs SHAM (V), [g]$p<0.05$ RES-ETA (II) vs RSLT (III), [h]$p<0.05$ RES-ETA (II) vs RSLT-ETA (IV), [i]$p<0.05$ RES-ETA (II) vs SHAM (V), [j]$p<0.05$ RSLT-ETA (IV) vs SHAM (V), *$p<0.05$ day 0 vs day 14

the increased sinusoidal blood flow in the residual livers and the activation of KC would lead to an "endotheliopathy", with increased ET-1 release and up-regulation of ETAR on HSC as well as impaired SEC eNOS activity [10, 14, 16]. KCs are capable of releasing cytokines such as IL-1 or TNF-α, which are known to be potent stimulators of ET-1 release, as well as causing endothelial shear stress and anoxia [2, 9]. The rapid onset of ET-1 and ETAR synthesis, which follows liver damage in this study, is consistent with the kinetics of ET-1 and ETAR–mRNA and protein expression in reperfused pancreas transplants [9, 22]. Increased ET-1 promotes the ETAR-mediated HSC contractility, which is followed by sinusoidal vasoconstriction and the leukocyte–endothelium interaction, as well as the ETBR-mediated constriction of post-sinusoidal venules [19, 21, 22, 24]. Because NO antagonises the effect of ET-1, the reduced production of NO additionally contributes to sinusoidal constriction by HSC and hepatic vascular smooth muscle cells, respectively [14].

Although many vasoactive compounds are likely to play a role in the imbalance of vasoconstrictors and vasodilators leading to an "endotheliopathy" after SFS injury, ET-1 and NO cause the highest magnitude of sinusoidal constriction and relaxation, respectively. To reduce the transient ET-1-mediated sinusoidal constriction and over-perfusion relative to the small size of the remnant liver, a selective ETAR antagonist seemed to be a promising treatment for the acute phase after reperfusion. Selective ETB- and mixed ETA/B-receptor antagonists were rejected because of the absence of any hepatoprotective effect and their narrow therapeutic margin, respectively [3, 24]. ETAR antagonists have been shown to ameliorate toxin- and ischemia-reperfusion-induced hepatic injury as well as portal hypertension and to reduce liver fibrosis [1, 5, 9, 17]. The rationale for administration of the ETAR antagonist immediately before liver resection (group II) or reperfusion (group IV) was the concept that the first few minutes of microcirculatory disturbances seem to be crucially important for the manifestation of SFS liver injury. In view of the transient SFS injury that decreases with progressive regeneration of the liver and the rapid metabolism of the rat, we considered that a single dose of the ETAR antagonist Darusentan—with a half life of 24 h—would be sufficient in this study.

ETAR blockade balanced out the ET-1 and NO levels after liver resection and RSLT with significantly reduced ET-1 and ETAR protein expression and elevated eNOS protein expression, resulting in increased sinusoidal diameter and reduced flow velocity. The reduced number of KC in the treatment groups (groups II + IV) might have additionally contributed to the reduced ET-1 levels by a decreased release of pro-inflammatory mediators [9, 10]. The improved microcirculatory parameters were also reflected in reduced hepatocellular damage, especially SEC apoptosis, and improved serum parameters. However, ETAR blockade did not significantly improve survival after RSLT in this study, probably because the single dose was not sufficient to bridge-over the transient SFS injury that decreases as liver regeneration progresses. Further investigations will be necessary to ascertain whether repeated administration of the ETAR antagonist might significantly improve survival after RSLT.

In summary, it seems possible that the microcirculatory disorders related to ET-1/NO imbalance may have contributed to SFS liver injury. This study has furnished evidence to show that ETAR blockade attenuates microcirculatory disorders and their morphologic sequelae by correcting the ET-1/NO balance and displayed its potential clinical application for the prevention of SFS liver injury in recipients after RSLT, as well as in donors after living graft donation.

Two adult cases of congenital atresia of the left coronary ostium—comparison of a sudden death case with a long-term survival case

Received: 24 February 2005 / Accepted: 16 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract We present two extremely rare autopsy cases with atresia of the left coronary ostium. Case 1 was a 34-year-old man who died of sudden cardiac causes with localized acute subendocardial infarction and Case 2 was an 82-year-old woman who died from non-cardiac causes. In both cases, a string-like small left main trunk that was located in its normal position was found; however, the orifice of the left coronary artery was absent in both cases. The collateral artery (CA), whose caliber was smaller than that of the proximal left descending artery (LAD), arose from the right coronary sinus and was anastomosed with the distal LAD. However, it was only in Case 1 that the CA showed an acute angle of take-off from the aorta, subsequently coursing between the root of the aorta and the pulmonary trunk, with possible mechanical compression by these two arteries. These two cases suggest that atresia of the left coronary ostium is developmentally and anatomically different from single coronary artery or left coronary artery arising from the opposite sinus of valsalva. Atresia of the left coronary ostium is considered to be an important differential diagnosis as a cause of sudden death, not only in the pediatric population but also in adults. The caliber and/or other anatomical features of the CA may predominantly dictate the clinical course of patients with atresia of the left coronary ostium.

Introduction

Congenital atresia of the left coronary ostium is a very rare anomaly of the coronary artery. In a recent publication, the incidence in a continuous series of 1,950 angiograms was 0.67% [1]. Many of the patients whose cases have been previously reported were symptomatic, demonstrating angina, acute myocardial infarction, dyspnea, syncope, and sudden death [8]. Nevertheless, in many of the patients with atresia of the left main coronary ostium, one or more collateral arteries (CA) from the right coronary artery to the left coronary artery were present [8], and the amount of blood flow in the left coronary artery was probably inadequate in almost all of the cases. Here we show the detailed anatomical and pathological findings of two considerably rare adult cases of atresia of the left coronary ostium. One case was found following sudden cardiac death, while the other case was found following non-cardiac death of an aged woman. We compare the anatomical features of the coronary arteries of these two cases with those of other coronary artery anomalies which possibly have identical hemodynamics. In addition, we attempt to compare the anatomical and pathological findings between these two cases with a view to discussing the factors that gave rise to their different outcomes.

Case histories

Case 1 was a 34-year-old man (office worker) who was found dead in the bedroom of his home by one of his office colleagues. He was a single man who had been absent from work for 3 days due to his poor physical condition. He had spoken with the same colleague 2 days before his death. At that time, he had said that he had a cold, but he had not complained of any symptoms that suggested the presence of heart disease. He did not have any apparent medical history, but had not received a medical check-up for at least the past 10 years. He had no problems with his usual daily activities, and he had no history of playing sports of any kind. At autopsy, no traumatic injuries were found on

his body, and alcohol and toxicological examination were negative.

Case 2 was an 82-year-old woman (housewife) who was dead in a severely burned home. Since the level of carbon monoxide in her blood was found to be 70%, the direct cause of death was determined to have been the fire. No other traumatic injuries were found on her body, and alcohol and toxicological examinations were negative. Based on investigations at the scene, we assumed that the cause of the fire had been mismanagement of a wood-burning stove. On the other hand, the woman had a history of mild hypertension and angina pectoris of about 10 years' duration, and oral calcium antagonists had been regularly administered. Since more serious complications had not appeared during those 10 years, and since her age was relatively high, further investigations by invasive procedures had not been performed. She was physically active, and she had no trouble with her daily life. On an electrocardiogram that had been taken the previous year, slight ST segment depression was found on the lead AVF, and a negative T-wave was found on leads I and V4.

Materials and methods

The heart was excised and dissected free from the great vessels. Heart weight, including epicardial coronary arteries and epicardial fat, was measured to the nearest gram. The right and left ventricles were cut at 1-cm intervals parallel to the level of the papillary muscle from the apex. The heart was then opened along the direction of blood flow, and any abnormality in the myocardium, endocardium, or valves was noted. After being fixed with 20% buffered formaldehyde, sections at the level of the papillary muscle and the apex were thoroughly examined histologically. The bilateral atria were also sectioned. The major epicardial coronary arteries, left main trunk, left anterior descending artery (LAD), left circumflex artery, right coronary artery, and their major branches were cut transversely at 5-mm intervals and decalcified as required.

Results

Case 1

The deceased was 170 cm tall and weighed 59 kg. The heart weighed 530 g. On examination of the epicardial coronary arteries, the left main trunk could be discerned as having a string-like appearance and superficially it looked as if it arose from the aorta, but the orifice of the left main trunk was not opened in the left coronary sinus. The LAD and left circumflex artery ended blindly and were located at their normal position with a normal caliber. The CA arose from the right coronary sinus, and the orifice was independent from the right coronary artery. The take-off of the CA demonstrated an acute angle, and the CA finally terminated in the distal LAD after coursing between the root of the aorta and the pulmonary trunk (Fig. 1a, b). While passing between the two large arteries, the surface of the CA was covered by a thin layer of atrial muscle. Horizontal sections of both ventricles showed concentric hypertrophy of the left ventricle and discoloration with softening of the subendocardium of the lateral wall of the left ventricle. No discoloration was found in other regions of the left ventricle or the right ventricle (Fig. 1c). The thickness of the wall was 2.0 cm in the case of the anterior and posterior walls, 2.3 cm in the lateral wall, 1.8 cm in the ventricular septum, and 0.3 cm in the right ventricle. Valvular deformity was not found in any of the valves. As for important gross findings of other organs, polycystic kidney was noted.

On microscopic examination, the heart muscle in the area that was discolored on gross examination revealed focal coagulative necrosis with localized infiltration of neutrophils, these being the findings of acute myocardial infarction (Fig. 2a). The left main trunk demonstrated an arterial appearance, but was completely occluded by non-atherosclerotic intimal hyperplasia. The caliber of the CA was smaller than that of the left-sided coronary artery where it was anastomosed with the CA. The right coronary

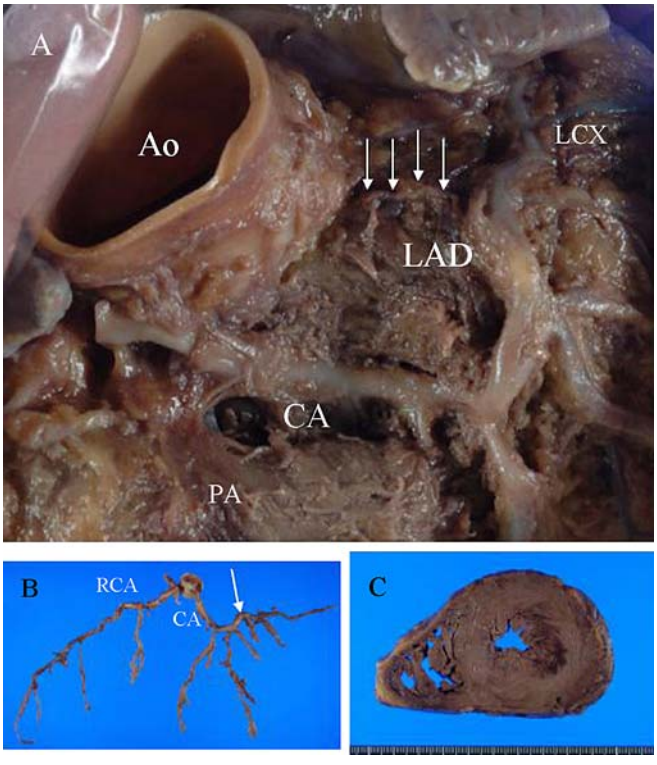

Fig. 1 Gross findings of the heart in Case 1. **a** Gross anatomy of the coronary artery. The pulmonary artery (*PA*) is strongly pulled forward. A string-like left main trunk is indicated by *arrows*. The collateral artery (*CA*) shows an acute angle of take-off from the aorta (*Ao*) and courses between the Ao and the PA. *LAD* Left descending artery, *LCX* left circumflex artery. **b** Coronary artery tree. The left main trunk is already extirpated. Instead, bifurcation of the left descending artery and left circumflex artery is indicated by an *arrow*. The collateral artery (*CA*) is anastomosed with the distal left descending artery. The right coronary artery (*RCA*) is well developed. **c** Horizontal section of the ventricles in Case 1. Discoloration is evident in the subendocardial layer of the lateral wall of the left ventricle

artery was well developed, and atherosclerosis was not found in any artery (Fig. 2b, c).

Case 2

The subject's heart weighed 334 g. The left main trunk showed almost the same appearance as that in Case 1 (Fig. 3a), and the orifice of the left coronary artery was absent (Fig. 3b). A relatively large CA arose from the right coronary sinus with an independent orifice, and then anastomosed with the LAD (Fig. 3a). The CA did not course between the aorta and the pulmonary trunk, but ran through the anterior aspect of the pulmonary trunk before reaching the LAD (Fig. 3c). The right coronary artery was dominant. Serial sectioning of almost the entire epicardial coronary artery revealed diffuse and marked atherosclerosis of both the LAD and the CA. The cut surface of the horizontal sections of both ventricles showed mild symmetric hypertrophy; however, no old or fresh ischemic foci were visible. The thickness of the wall was 1.4 cm in the case of the anterior, lateral, and posterior walls, 1.5 cm in the ventricular septum, and 0.2 cm in the right ventricle. No deformity was found in any of the valves. As for other important findings, severe benign nephrosclerosis, and fusiform atherosclerotic aneurysm of the distal aortic arch (ca. 5 cm) was found.

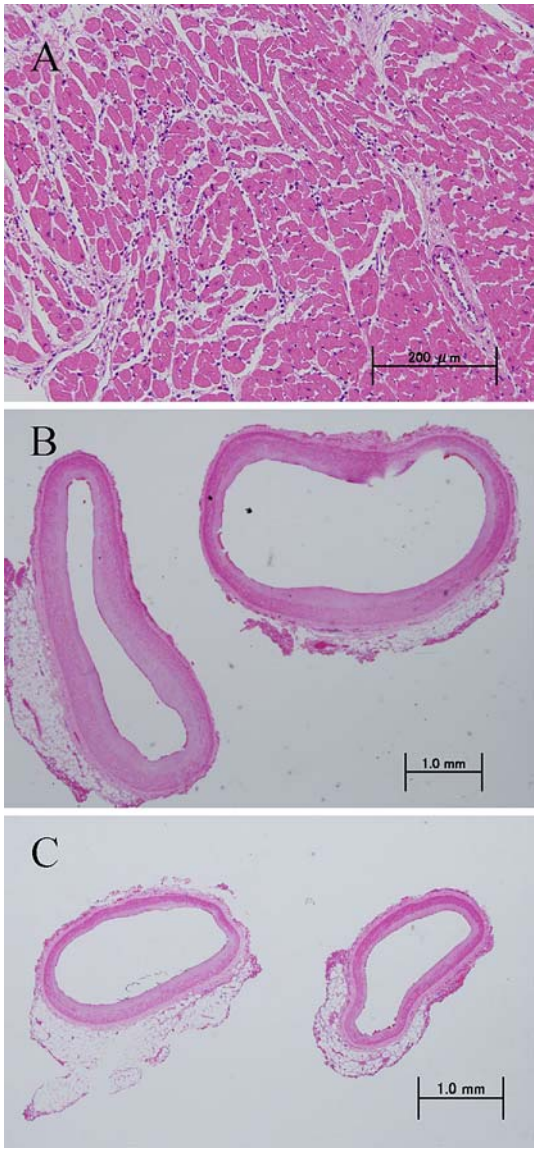

Fig. 2 Histological findings of the heart in Case 1. **a** Histological appearance of the left lateral wall. Eosinophilic degeneration of myocytes with loss of nucleus and infiltration of granulocytes. These findings show evidence of acute myocardial infarction (hematoxylin and eosin stain, 400×). Histological appearance of the **b** left descending artery and **c** collateral artery. The caliber of the collateral artery is thinner than that in the left descending artery (hematoxylin and eosin stain, 4×)

On microscopic examination, small scars whose diameter was not greater than 1.0 cm were found at the posterior papillary muscle (Fig. 4a) and the basal third of the septum. Acute ischemic foci were not visible in either of the ventricles. In the left ventricle, diffuse and severe interstitial fibrosis and focal hypertrophy of myocytes was seen. The left main trunk demonstrated an arterial appearance, but was completely occluded by non-atherosclerotic intimal hyperplasia, as in Case 1 (Fig. 4b). The caliber of the CA was smaller than that of the LAD, where it was anastomosed with the CA, as in Case 1. However, the LAD and CA showed marked stenosis (>95%) due to the progression of atherosclerosis (Fig. 4c). The right coronary artery was well developed and focal mild atherosclerosis was found (Fig. 4d).

Discussion

Referring to previous literature, atresia of the left coronary ostium seems to be synonymous with atresia of the left main trunk [2–9]. In the current report, the left coronary orifice of both cases was absent, but the left main trunk was anatomically present in a rudimentary form. Histologically, two different sets of findings of the left main trunk in the case of atresia of the left coronary ostium have been reported. In one case reported by Leivo and Laurila [7], the left main trunk showed a fibrous string-like structure without any vascular component, whereas in another case reported by Goormaghtigh et al. [6], the left main trunk had a vascular structure but showed severe narrowing of the lumen [9]. In the present two cases, the arterial structure was found in the left main trunks of both cases; however, the lumens were severely obstructed by non-atherosclerotic intimal hyperplasia. We consider that atresia of the left coronary ostium may be a more appropriate anatomical diagnosis for such cases rather than atresia of the left main coronary artery. Moreover, this diagnostic term can be used whether the left main trunk is present in a rudimentary form or is completely absent, since the presence or absence of the left main trunk should be of no clinical significance when the ostium is absent.

Atresia of the left coronary ostium has recently been considered as a different entity from single coronary artery [9] or anomalous orifice of the left coronary artery [2, 11].

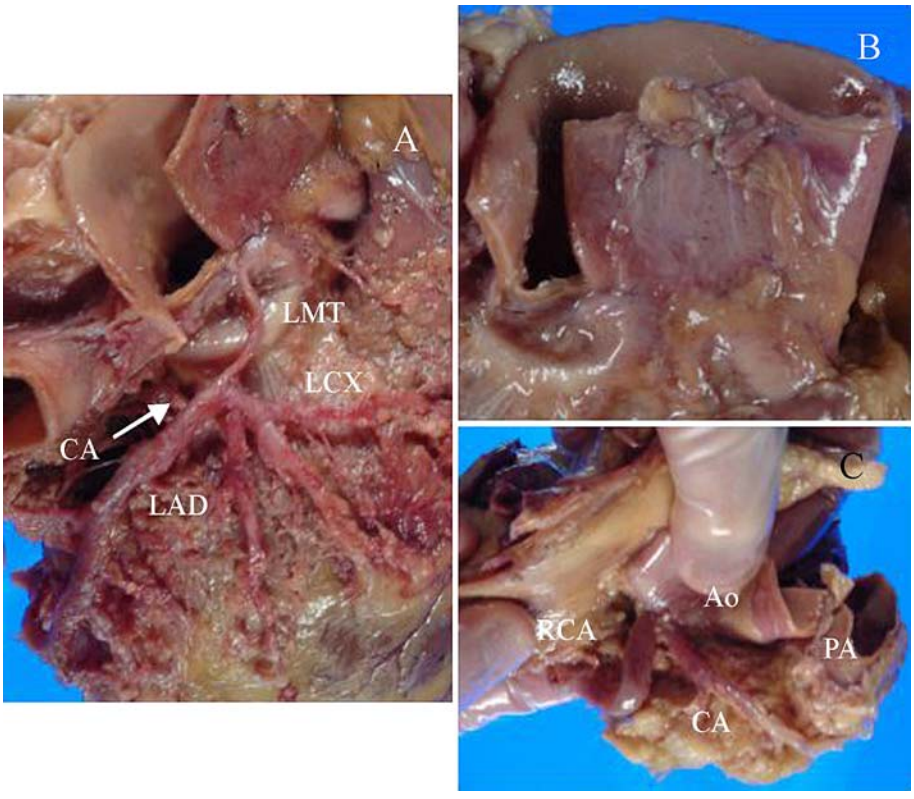

Fig. 3 Gross findings of the heart in Case 2. **a** Gross anatomy of the left coronary artery. A string-like left main trunk (*LMT*) can be seen. Other arteries have a normal caliber. *CA* Collateral artery, *LAD* left descending artery, *LCX* left circumflex artery. **b** After removal of the coronary tree, the orifice of the left main trunk (*LMT*) is not evident. **c** Proximal region of the collateral artery (*CA*). The CA courses in the anterior aspect of the pulmonary artery (*PA*). *RCA* Right coronary artery, *Ao* aorta

In the former cases, the myocardial blood supply is derived from coronary arteries of the opposite side, which run a normal course and ramify extensively [3]. On the other hand, in the latter cases, the left coronary artery arises from the right aortic sinus, whereas the right coronary artery originates normally and runs a normal course [10]. In atresia of the left coronary ostium, the blood flows from the right to the left coronary artery via one or more collateral arteries whose caliber is smaller than that of the target left-sided vessels, as in the present cases. Therefore, the flow is

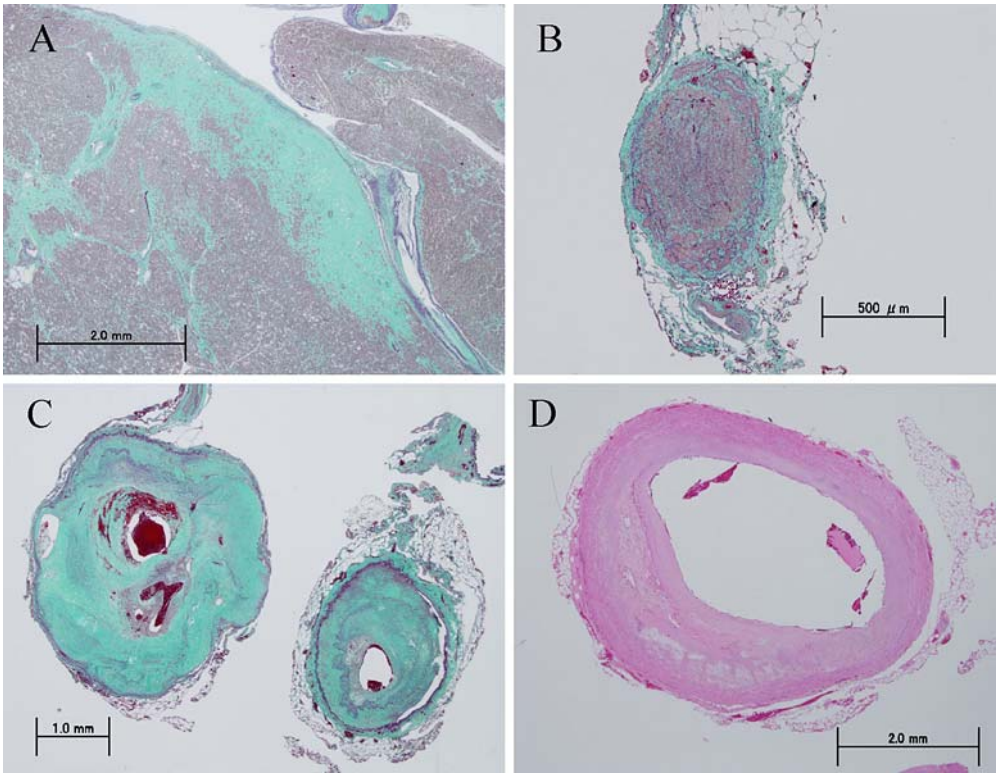

Fig. 4 Histological findings of the hearts in Case 2. **a** Histological appearance of the posterior papillary muscle of the left ventricle. A small scar can be seen in the subendocardial region (Elastica–Masson stain, 4×). **b** Histological appearance of the left main trunk. No significant lumen can be seen. Internal elastic lamina and medial smooth muscle is evident (Elastica–Masson stain, 4×). **c** Histological appearance of the collateral artery. Severe atherosclerosis with stenosis is evident. (Elastica–Masson stain, 4×). **d** Histological appearance of the right coronary artery. The artery shows a large caliber with mild atherosclerosis (hematoxylin and eosin stain, 4×)

in part centripetal, because it flows retrogradely (from the periphery to the center). Under normal conditions, such as with a single coronary artery, or anomalous orifice of the left coronary artery, the blood flow is always centrifugal, flowing from bigger to small arteries [5]. Embriologically, segmental atresia of the left main trunk may suggest that regression of the left main trunk has taken place after elongation of the coronary artery anlage has started, and the mechanism may be different from cases where the left coronary artery arises from the right aortic sinus, which may reflect displacement of the left main trunk anlage during rotation of the trunchus arteriosus [7].

In the case of atresia of the left coronary ostium, many patients die in infancy or childhood after a relatively short interval of cardiac symptoms; however, manifestation of the symptoms that occur with ischemia is not necessarily limited to childhood [7]. Referring to our two cases, the caliber of each of the CAs may have been relatively large, and therefore the timing of the appearance of the symptoms might have been delayed. Nevertheless, atherosclerosis was severe in the CA and the LAD of Case 2, where the cause of death was non-cardiac and where the patient would seem to have been older than any of the previously reported patients with atresia of the left coronary ostium [7], although the mild angina experienced by Case 2 may have been caused by progression of the atherosclerosis of the CA and LAD, rather than by the anomaly of the coronary artery.

One of the striking features of the CA of Case 1 in comparison to Case 2 was the course of the CA. In Case 1, the CA coursed between the aortic and pulmonary root and was sandwiched between these two large vessels. Dymond et al. speculated that mechanical compression of the CA by two large arteries was an accelerating factor of myocardial ischemia in atresia of the left coronary ostium since it diminished the blood flow within the CA [4]. Chronic or transient mechanical compression of the CA could cause a delay in the delivery of blood to the left-sided artery, having blood arrive during systole rather than diastole [3, 4]. Mechanical compression of the CA may become more severe following exercise or emotional stress which are already known to be important risk factors of sudden death in cases where the left main coronary artery originates from the right aortic sinus [2, 11]. We believe that the course of the CA may be one of the important factors for the long survival of Case 2, even though atresia of the left coronary ostium and severe atherosclerosis were present.

An acute angle of take-off from the coronary artery, as in Case 1, and a slit-like appearance of the orifice have also been considered to be risk factors for diminishing the blood flow in the coronary artery based on mechanisms similar to mechanical compression of the CA [3, 4]. Our Case 1 would seem to suggest that the angle of take-off of the CA is also a possible anatomical abnormality in atresia of the left coronary ostium. The presence of a significant anatomical correlation between the angle of take-off and the course of CA has not yet been fully established; however, the CA of Case 1 headed for the LAD more linearly between the aorta and the pulmonary trunk after deriving from the aorta, whereas the CA of Case 2, whose angle of take-off was not acute, ran in a semicircle through the anterior aspect of the right ventricular outflow tract before reaching the LAD.

In summary, atresia of the left coronary ostium should be a developmentally and anatomically different entity from the single coronary artery or a left coronary artery which arises from the right coronary sinus. In the present cases, although a developed CA may delay the appearance of clinical symptoms in atresia of the left coronary ostium, the gradual progression of an insufficient blood supply in the CA due to mechanical or pathological obstruction will eventually cause the development of ischemic complications in the heart and sudden death, even if the patients can survive ordinary life until adulthood. Our Case 2 was considered to be an extremely rare case where the patient had experienced long-term survival due to the overlap of various fortunate factors, which may have comprised some anatomical features, especially with regard to the course of the CA, together with that individual's own personal lifestyle.

Monocyte chemotactic S19 ribosomal protein dimer in atherosclerotic vascular lesion

Received: 17 September 2004 / Accepted: 27 April 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract To elucidate the molecular mechanism inducing monocyte/macrophage infiltration in the atherosclerotic lesion, we measured the monocyte chemotactic capacity in the extracts of aortic lesions. Five out of seven extracts exhibited significant chemotactic activities. Immunohistochemical examination with an anti-CD68 monoclonal antibody demonstrated that the five positive lesions possessed obvious monocyte/macrophage infiltrations at the intima, whereas the two negative lesions did so at significantly lower intensities. We subjected the chemotactic extracts to immunological analyses to identify the monocyte chemoattractant in them. The monocyte chemotactic capacities of all positive extracts were removed with anti-S19 ribosomal protein (RP S19) antibody beads and antimonocyte chemoattractant protein-1 (MCP-1) antibody beads. In three of the five extracts, the anti-RP S19 antibody beads were more effective than the anti-MCP-1 antibody beads for removal, while in the remaining two extracts, the opposite was observed. A combined immunoabsorption with these beads depleted the monocyte chemotactic capacity of a representative sample of each group. Consistently, the chemotactic capacity of an apparently RP S19 dimer-predominant extract was strongly inhibited by the presence of a C5a receptor antagonist. These results suggest that the RP S19 dimer and MCP-1 play a major role in the monocyte/macrophage infiltration of the atherosclerotic vascular lesion.

Introduction

S19 ribosomal protein (RP S19), a component of the small subunit of ribosome, is intermolecularly cross-linked by a transglutaminase-catalyzed reaction during the apoptotic process [5, 10], and acquires the monocyte-selective leukocyte chemotactic capacity [10]. The RP S19 dimer is then extracellularly released and plays an essential role in the phagocytic clearance of apoptotic cells that have liberated the dimer by recruiting circulating monocytes to the extravascular apoptotic lesion [21]. The phagocytic clearance of the apoptotic cells would then be followed by an acquired immune response to the apoptotic cells when the apoptotic cells possessed not-self antigens [15].

We initially discovered the RP S19 dimer in the extract of synovial lesion of rheumatoid arthritis as the major monocyte chemotactic factor in it [10]. The RP S19 dimer has a dual effect to the chemotactic C5a receptor of phagocytic leukocytes: an agonist effect on the monocyte receptor and an antagonist effect on the polymorphonuclear (PMN) leukocyte receptor [12, 14, 17]. Thus the RP S19 dimer induces monocyte predominant infiltration in vivo. Therefore, the RP S19 dimer is assumed to be a chemical mediator of monocyte predominant infiltration in chronic inflammation, such as rheumatoid arthritis.

Monocyte/macrophage predominant infiltration is also observed in atherosclerotic lesion, which is usually clas-

sified into metabolic disorders. In this lesion, macrophages phagocytically clear lipoprotein complexes exuded and deposited, and become foam cells. It was immunohistochemically demonstrated that the majority of the lipid-engulfed macrophages originated from circulating monocytes [1, 20]. Regarding the molecular mechanism that causes monocyte-predominant infiltration, the presence of monocyte chemoattractant protein-1 (MCP-1) in the atherosclerotic lesion was immunohistochemically demonstrated [18, 22]. On the other hand, the presence of apoptotic cells in the atherosclerotic lesion has been histochemically shown [6, 13], suggesting the presence of RP S19 dimer as a monocyte chemoattracting factor in this lesion.

In the current study, we examined whether the RP S19 dimer is really present in the atherosclerotic lesion with the active monocyte chemoattracting capacity by analyzing the extract of the clinical lesion. Furthermore, we functionally evaluated the contribution of MCP-1 and the RP S19 dimer in the monocyte/macrophage recruitment to the atheromatous lesion.

To perform these studies, we needed antibodies against RP S19 with high affinity and high specificity. Because the amino acid sequence of RP S19 is conserved among mammalian species [19], it was not easy to prepare the antibodies against human RP S19. We used a synthetic peptide fragment of RP S19 with 14 amino acid residues, which were conjugated to a carrier protein, to produce anti-RP S19 antibodies in a rabbit.

Materials and methods

Animal

A New Zealand White male rabbit (2.5 kg body weight) was used to produce antibodies.

Reagents and other compounds

RPMI 1640 medium and Hank's balanced salt solution (HBSS) were purchased from Nissui Pharmaceutical (Tokyo, Japan). We obtained fetal bovine serum (FBS) from Gibco BRC (Paisley, Scotland) and Mono–Poly Resolving MediumR from Flow Laboratory (Hertsfordshire, UK). An anti-CD68 monoclonal antibody, KP-1, an anti-MCP-1 monoclonal antibody, and an immunoperoxidase staining kit, Envision/horseradish peroxidase (HRP) were obtained from DAKO (Carpinteria, CA, USA). We also acquired HRP-labeled antirabbit IgG (H+L) goat IgG from Bio-Rad Japan (Tokyo, Japan), and a recombinant MCP-1 from Pepro Tech (London, UK). All other chemicals were obtained from Nacalai Tesque (Kyoto, Japan) or from Wako Pure Chemicals (Osaka, Japan), unless otherwise specified. NMePhe-Lys-Pro-dCha-dCha-dArg was synthesized as described previously [7].

Preparation of RP S19 dimer

A recombinant RP S19 was prepared in an *E. coli* transgene expression system as described previously [11]. RP S19 was dimerized via treatment with type II transglutaminase, after which the RP S19 dimer was separated by immunoaffinity column chromatography with anti-isopeptide bond monoclonal antibody beads as described previously [9].

Preparations of rabbit anti-RP S19 IgG antibodies

A peptide having 15 amino acid residues, Arg-Lys-Leu-Thr-Pro-Gln-Gly-Gln-Arg-Asp-Leu-Asp-Arg-Ile-Cys, with the same sequence as a part of RP S19 from Arg121 to Ile134, except for the C-terminal Cys, was synthesized. This peptide was covalently coupled at the C-terminal Cys residue to keyhole limpet hemocyanin (KLH) with *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester as described previously [3]. Antiserum to the RP S19 peptide–KLH was grown in a rabbit via multiple intradermal injections of the peptide–KLH emulsified with Freund's complete adjuvant (at first sensitization) or with incomplete adjuvant (at the booster injections) four times at weekly intervals. During the initial sensitization and booster injections, 500 and 250 μg of the peptide–carrier conjugate, respectively, were administered. One week after the fourth inoculation, the antiserum was obtained from the rabbit. Next, we analyzed the binding capacities of the antiserum to the peptide–carrier antigen, to the carrier protein, and to RP S19. The IgG fraction was prepared from the antiserum by an affinity column chromatography with a protein G column in the usual way. The purified IgG was used as anti-RP S19 rabbit IgG for the antibody beads preparation.

Enzyme-linked immunosorbent assay

The surface of the 96-well microchamber was coated with a protein solution of the RP S19 peptide–KLH, KLH, or recombinant RP S19 at a concentration of 5 μg/ml. After blocking with phosphate-buffered saline containing 0.5% gelatin and 0.05% Tween 20, the adsorbed proteins were reacted with serially diluted anti-RP S19 peptide–KLH antiserum or preimmune serum. The antigen–first antibody complex on the surface was then reacted with the HRP-labeled antirabbit IgG goat IgG, and the HRP on the surface was reacted with an *o*-phenylenediamine solution (Wako Pure Chemicals). After a 10-min incubation, the enzyme reaction was stopped with 2 M H_2SO_4, and the absorbance at 490 nm was measured using a microplate reader (Ultra Microplate Reader, Bio-Tek Instruments, Winooski, VT, USA).

Preparation of antibody beads

The anti-RP S19 rabbit IgG as well as the anti-MCP-1 monoclonal antibody were covalently coupled by succinylation to NHS-activated Sepharose 4 Fast Flow (Amersham Pharmacia Biotech, Piscataway, NJ, USA) in a 0.2 M $NaHCO_3$ buffer containing 0.5 M NaCl (pH 8.3). The remaining uncoupled *N*-hydroxisuccinimide ester groups on the gel beads were blocked with monoethanolamine as previously described [3]. Control rabbit IgG beads were prepared in the same process. These IgG beads were used for the immunoabsorption experiments.

Immunoabsorption with antibody beads

For immunoabsorption experiments with the anti-RP S19 rabbit IgG beads, with the anti-MCP-1 monoclonal antibody beads, or with the normal rabbit IgG beads, we used the batch-wise method as previously described [17]. Briefly, the sample was mixed with one-fourth volume of the antibody beads and incubated for 60 min at 4°C with continuous shaking. After centrifugation at 10,000×*g* for 20 min at 4°C, the supernatant was recovered and the monocyte polarization capacity remaining in it was measured as described below.

Morphologic polarization assay to measure leukocyte chemoattracting capacity

Mononuclear cells and PMNs were isolated from heparinized human venous blood of healthy donors according to the method of Fernandez et al. [4] as described previously [8]. The mononuclear cell fraction contained monocytes at a ratio of about 20%, and the PMN fraction was composed of over 95% PMNs. Mononuclear cells and PMNs were suspended at a cell density of 1×10^6 cells/ml in RPMI 1640 containing 10% FBS, and in HBSS containing 2% bovine serum albumin, respectively, for the morphologic polarization assay.

The morphologic polarization assay was performed according to the method of Cianciolo and Snyderman [2], as described previously [8]. Briefly, the mononuclear cell suspension was incubated with each sample for 10 min at 37°C in a polypropylene tube. Immediately after the incubation, 1 ml of cold parafolmaldehyde (8% w/v) buffered with 100 mM phosphate (pH 7.2) was added to fix the cells. The fixed cells were washed twice with phosphate-buffered saline and were stained cytochemically for nonspecific esterase with α-naphthylacetate as the substrate for 50 min at 37°C to identify monocytes in the mononuclear cells. The number of polarized and nonpolarized cells of monocytes was counted to at least 100 using an inverted microscope (IMT-2, Olympus Optical Co., Tokyo, Japan). The activity of the sample was expressed as the percentage of the monocyte number with polarized morphology against the total number of monocytes counted. When the effect of the C5a receptor antagonist was examined, the indicator monocytes were pretreated with various concentrations of the antagonist for 10 min at 37°C just before the chemoattractant was added.

Preparation of intimal extract

Small pieces of aortic tissue with atheromatous lesion were obtained from patients undergoing aorta replacement therapy, and those of apparently normal tissue were obtained during autopsy, with the permission of IRB of Kumamoto University Hospital. Shortly after, a part of the aortic tissue was resected and used for the histological examination, and the remainder was used for the preparation of intimal extract.

The intima was separated from the aortic tissue with a sterilized razor blade, weighted, dissected, and stored at −80°C until use. After thawing, the dissected intima was mixed with a cold extraction buffer at a volume of 2.5 ml per g weight of the intimal tissue, homogenized using a polytron homogenizer for 1 min on ice, and extracted for 4 h at 4°C. The extraction buffer used was 10 mM phosphate buffer (pH 7.4) containing 500 mM NaCl, 5 mM EDTA, 20 mM pepstatin A, 0.5 mM *N*-ethylmaleimide, and 1 mM diisopropylfluorophosphate. The supernatant of the extract was obtained by centrifugation at 10,000×*g* for 10 min at 4°C, and used for the experiments.

Immunohistochemistry

For histological examination, aorta specimens were fixed in 10% formalin. Paraffin sections of 4-μm thickness were prepared in the usual way. A section was stained with hematoxylin and eosin; other sections were used for the indirect immunoperoxidase staining.

In immunoperoxidase staining, sections were treated with drops of the anti-CD68 monoclonal antibody solution or of normal mouse IgG solution overnight at 4°C. Mouse IgG was visualized with dextrose-conjugated horseradish peroxidase-labeled antimouse IgG rabbit IgG and diaminobenzidine by using the immunoperoxidase staining kit, Envision/HRP, according to the manufacturer's instructions. The microscopical pictures were prepared using an automatic microscope, Provis AX (Olympus, Tokyo, Japan) and a digital camera, Penguin 600CL (Pixera, Los Gatos, CA, USA).

Results

Monocyte chemotactic capacities of intimal extracts of aortic atherosclerotic lesion

To assess the leukocyte chemotactic capacity in the intimal extracts of atherosclerotic lesions, we used the morphologic polarization assay. Because the incubation period required in the polarization assay (10 min) is much shorter than that in the multiwell chamber assay (90 min), the odds

for undesirable secondary chemical reactions during the incubation period in crude samples must be substantially less in the former.

The chemotaxis assay was performed at various concentrations for each sample, because the dose–response curve in the chemotaxis assay usually forms a bell shape with an optimal concentration of the assay sample. Because all of the samples exhibited the strongest chemoattracting activity at 100-fold dilution (see Fig. 6 as representatives), the polarized ratios of monocytes responded to the 100-fold diluted samples are comparatively shown in Fig. 1. When compared to the chemoattracting capacity of the extracts of apparently normal intima, five out of seven atherosclerotic intimal extracts showed significant chemoattractant capacities to monocytes.

We also examined the chemoattracting capacity of the intimal extracts to PMNs. The capacities were low and the optimum concentrations were varied, from undiluted to 100-fold diluted concentrations, among the intimal extracts (data not shown). Therefore, in the following sections, we only describe the study on monocyte chemoattraction in the atherosclerotic intima.

Immunohistochemical observation of monocyte/macrophage infiltration with anti-CD68 monoclonal antibody

The intensity of monocyte/macrophage infiltration at the atherosclerotic lesion was immunohistochemically observed by using the anti-CD68 monoclonal antibody, KP-1, to detect the infiltrated monocytes/macrophages. The immunoperoxidase method with this antibody visualized two different types of substances. One type was morphologically identified as infiltrating monocytes/macrophages by their size, their shapes, from round to spindle, and their nuclei that had been counterstained. The other type seemed to be degenerated foam cells or their fragments, because their sizes were big, the border was unclear, and many of them did not possess a nucleus. Because a negative control staining with normal mouse IgG as the first antibody instead of the anti-CD68 monoclonal antibody demonstrated no immunopositive signal (data not shown), we neglected the possibility that the immunoreactivity of the latter substance was a nonspecific reaction.

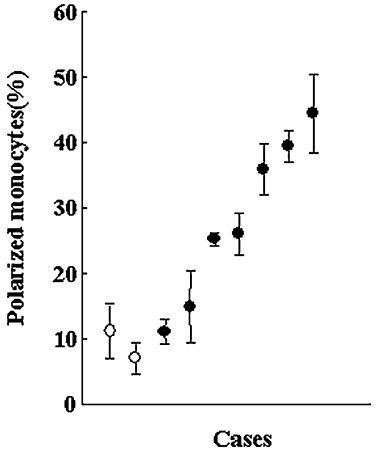

Fig. 1 Monocyte chemotactic capacities of atherosclerotic intimal extracts. Aortic tissues with atheromatous lesion were obtained from seven patients (*closed circles*) during the aorta replacement therapy, and apparently normal tissues (*open circles*) were obtained from two autopsy cases. Their intimas were homogenized and extracted. Monocyte chemoattracting capacities of the intimal extracts were measured using the morphological polarization assay at various concentrations. Because the optimal concentration of the intimal extracts according to the chemoattracting capacity was observed at the 100-fold dilution (see Fig. 6 as representatives), only the polarized ratios at this dilution are shown. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

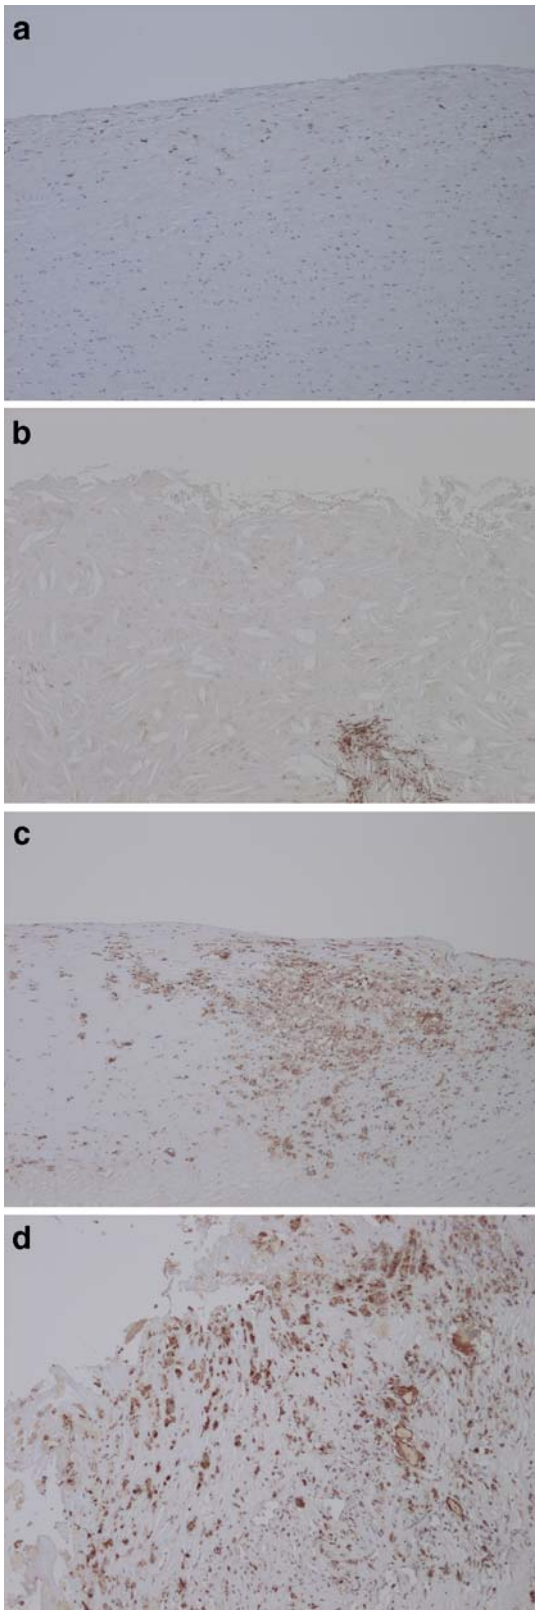
Histological specimens of the two lesions whose extracts exhibited negligible monocyte chemotactic capacity demonstrated severe atheromatous change of the intima containing abundant lipid crystals. However, the cell numbers of infiltrating monocytes/macrophages were very limited, although the immunopositive cell fragments were observed to some extent, as shown in Fig. 2b. In these cases, the biological response seemed very weak compared to the intensities of the intimal alteration.



In a striking contrast, the specimens of the five lesions whose extracts exhibited significant monocyte attracting capacities all demonstrated obvious monocyte/macrophage infiltration, as shown in Fig. 2c. The specimen whose extract exhibited the strongest monocyte attraction capacity demonstrated a severe monocyte/macrophage infiltration, as shown in Fig. 2d. A macroscopically normal aortic tissue, which had been obtained from a 70-year-old man and used as a normal sample for the chemotaxis assay, demonstrated a minor alteration of endothelial cells and a sparse subendothelial monocyte/macrophage infiltration with a weak atheromatous change as seen in Fig. 2a. These changes were similarly seen in the other normal control sample. This would be an age-related phenomenon.

The intensities of intimal monocyte/macrophage infiltration observed via immunohistochemical means fairly corresponded to the functionally measured monocyte chemoattracting capacities of the intimal extracts obtained. This consistency strongly suggested that the monocyte chemoattractant(s) in the chemotactic intimal extracts would be the chemical mediator working to induce the monocyte/macrophage infiltration at the intimal lesion.

Immunoreactivity of anti-RP S19 peptide–KLH antiserum

We initially examined the binding capacity of the anti-RP S19 peptide–KLH antiserum to RP S19 by using a simple enzyme-linked immunosorbent assay (ELISA) method. The surface of the 96-well microchamber was coated with the recombinant human RP S19, RP S19 peptide–KLH, or carrier KLH, and the relative binding affinities of the antiserum to them were examined with serially diluted antiserum.

As shown in Fig. 3, the relative binding affinities of the antiserum to RP S19 peptide–KLH, RP S19, and KLH

◀ **Fig. 2** Immunohistochemical examination of atherosclerotic lesions with anti-CD 68 monoclonal antibody. Usual paraffin sections of formalin-fixed aortic tissues were stained by an indirect immunoperoxidase method with anti-CD 68 monoclonal antibody, KP-1, and dextrose-conjugated horseradish peroxidase-labeled antimouse IgG rabbit antibodies. The microscopical pictures were prepared using an automatic microscope and a digital camera. **a** A macroscopically normal aorta used in the experiments shown in Fig. 1. **b** A monocyte chemotactic capacity-negative aorta. **c** A monocyte chemotactic capacity-positive aorta. **d** The aorta with the strongest monocyte chemotactic capacity

were observed, in this order. Because a significant immunoperoxidase activity in the interaction between RP S19 and the antiserum was observed even when the antiserum was diluted 243,000-fold, we recognized that the binding affinity of the anti-RP S19 peptide antibodies to RP S19 was high enough to be used in the immunoabsorption experiment with the antibody beads. ELISA with the preimmune serum exhibited a weak peroxidase activity only to KLH when the serum was used at a 1,000-fold dilution (data not shown).

Specific absorptions of monocyte chemoattractant with two kinds of antibody beads

In the immunologic analysis of monocyte chemoattractants, we next examined the absorption capacities and the specificities of the anti-RP S19 antibody beads and the anti-MCP-1 antibody beads. As shown in Fig. 4a, the anti-RP S19 antibody beads removed the chemoattracting capacity of the RP S19 dimer but not that of MCP-1. Inversely, the anti-MCP-1 antibody beads removed the capacity of MCP-1 but not that of the RP S19 dimer (Fig. 4b).

C5a is the complement-derived leukocyte chemotactic factor, attracting monocytes as well as PMNs. C5a and the RP S19 dimer share the C5a receptor, although the latter functions as an antagonist to the C5a receptor on PMNs [12, 14, 16]. Concerning receptor sharing, we thought it would be necessary to neglect the cross-immunoreaction

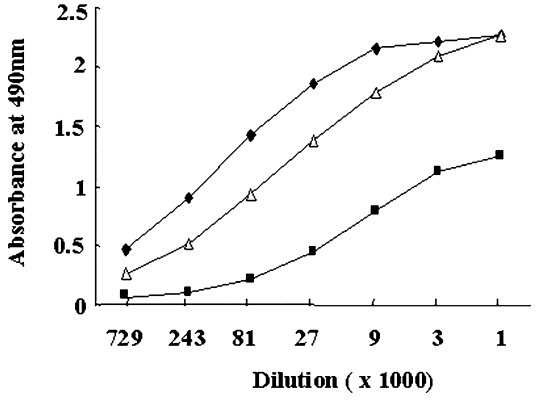


Fig. 3 Relative binding affinity of anti-RP S19 peptide antiserum to RP S19. The surface of the 96-well microchamber was coated with the RP S19 peptide–KLH (antigen, *closed diamonds*), with KLH (antigen carrier, *closed squares*), or with the recombinant RP S19 (*open triangles*). The protein-coated surface was reacted with serially diluted antiserum, and the amounts of rabbit IgG bound to these peptides were respectively measured by the immunoperoxidase method. The relative peroxidase activity is expressed as the absorbance unit at a wavelength of 490 nm on the *y*-axis

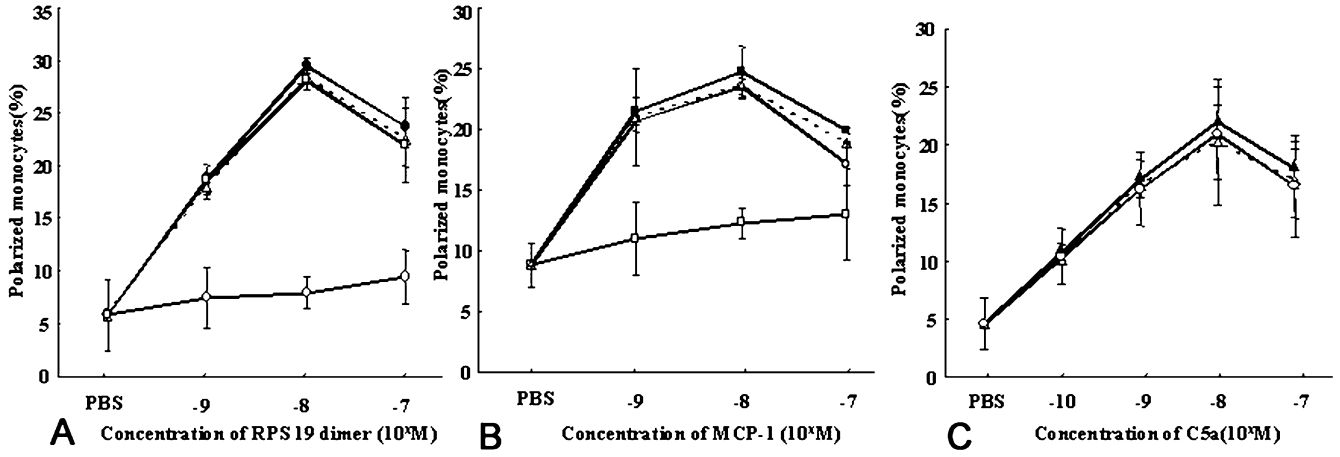

Fig. 4 Chemoattractant-specific immunoabsorption with anti-S19 ribosomal protein (RP S19) antibody beads, or with anti-monocyte chemoattractant protein-1 (MCP-1) antibody beads. Fifty microliters of 10^{-7} M RP S19 dimer (**a**), 10^{-7} M MCP-1 (**b**), or 10^{-7} M C5a (**c**) was treated with 10 μl of anti-RP S19 IgG beads (*open circles*), of anti-MCP-1 IgG beads (*open squares*), or of normal rabbit IgG beads (*open triangles*) for 60 min at 4°C; the supernatants were recovered. The remaining monocyte polarization capacities in the supernatants were measured with serially diluted samples. The *closed symbols* denote the polarization activities of the original samples before treatment with the antibody beads. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

of C5a to the anti-RP S19 antibody beads. As shown in Fig. 4c, the anti-RP S19 antibody beads did not absorb the recombinant human C5a. We also confirmed that the anti-MCP-1 antibody beads did not absorb C5a (data not shown).

The control IgG beads did not affect the capacities of these chemoattractant except for exhibiting a dilution effect of the beads added. From the theoretical point of view, we should use the normal rabbit IgG beads and mouse monoclonal IgG beads in the negative control experiments for the absorption experiments with the anti-RP S19 rabbit IgG beads and with the anti-MCP-1 IgG beads, respectively. However, we only used the normal rabbit IgG beads, not the mouse monoclonal IgG beads, because we have never observed any difference between these two IgG beads when they were used in the negative control experiment.

These results indicated the chemoattractant-specific absorption capacities of the antibody beads without any cross-reactivity among these chemoattractants and the antibody beads.

Immunoabsorptions of monocyte chemotactic capacities of intimal extracts with antibody beads

We then subjected five intimal extracts that had exhibited the significant monocyte chemotactic capacities to the immunoabsorption experiments. In all of the cases, dec-

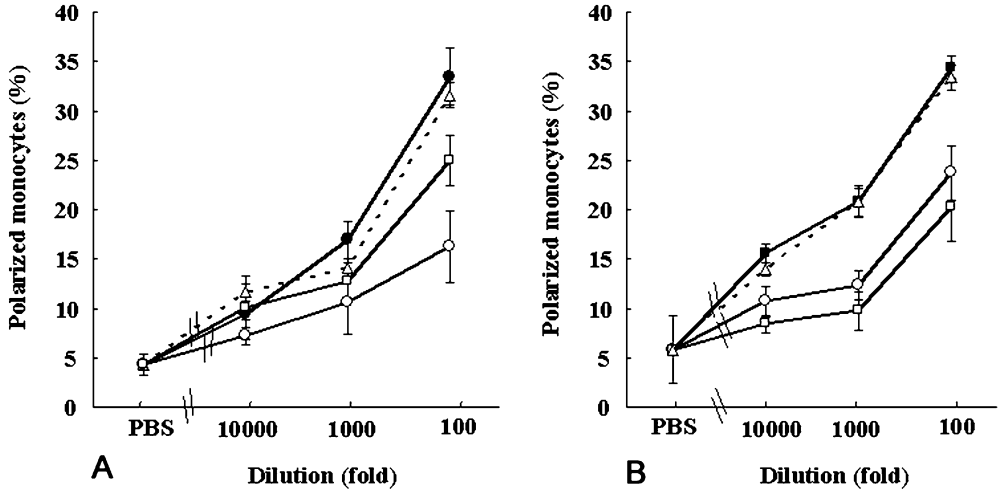

Fig. 5 Immunoabsorption of monocyte polarization capacities of two representative intimal extracts (**a**, **b**) with antibody beads. Eighty microliters of two chemoattractive extracts (*closed circles* or *closed squares*) was treated with 20 μl of the anti-RP S19 IgG beads (*open circles*), of the anti-MCP-1 IgG beads (*open squares*), or of the normal IgG beads (*open triangles*), and the supernatants were recovered. The remaining monocyte polarization capacities in the supernatants were measured with serially diluted supernatants from 100- to 10,000-fold. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

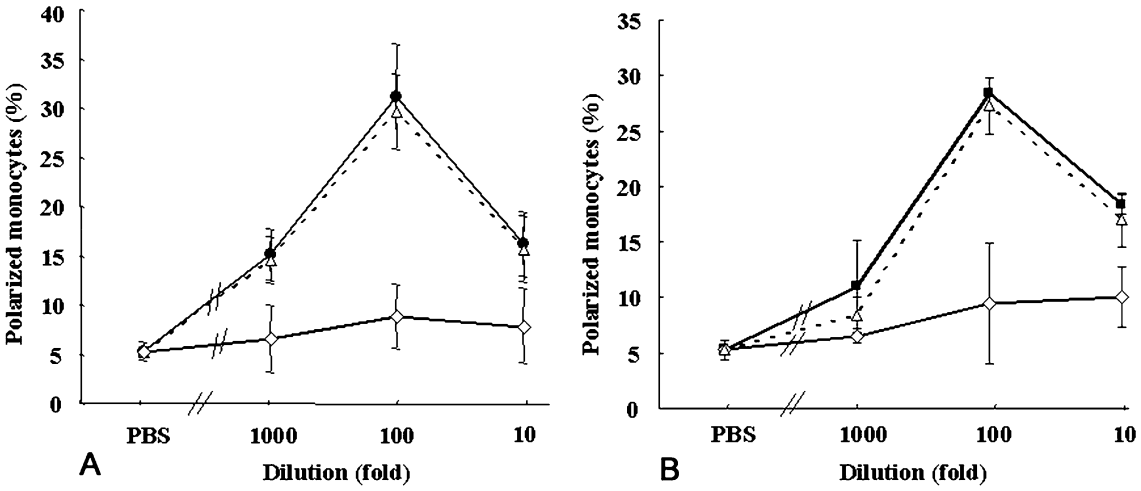

Fig. 6 Combination immunoabsorption of monocyte polarization capacities of two intimal extracts (**a**, **b**) with mixture of antibody beads. The anti-RP S19 IgG beads and the anti-MCP-1 IgG beads were mixed at an equal volume. The same experiment as in Fig. 4 was performed except for using the antibody beads mixture (*open diamonds*). In the control experiment, the normal IgG beads were used (*open triangles*). The remaining polarization capacities were measure with serially diluted supernatants from 10- to 1,000-fold. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

rements of the chemotactic capacities after the treatment with anti-RP S19 antibody beads and with anti-MCP-1 antibody beads were observed. In three cases out of five, stronger effects of the anti-RP S19 antibody beads on absorption were observed than those of the anti-MCP-1 antibody beads. In the remaining two cases, inverse phenomena were observed. A representative result of each case is respectively shown in Fig. 5.

We then subjected these representative samples to a combination of immunoabsorption experiments. In this experiment, we used a mixture of an equal volume of the anti-RP S19 antibody beads and the anti-MCP-1 antibody beads for the absorption experiment in the same way as when using the single kinds of immunobeads. As shown in Fig. 6, the combination beads absorbed almost all of the chemotactic capacities of these extracts.

Inhibition of monocyte chemotactic capacities of intimal extracts with C5a receptor antagonist

The RP S19 dimer and MCP-1 induce the chemotactic response of monocytes via the C5a receptor and the C–C chemokine receptor 2, respectively. An authentic C5a re-

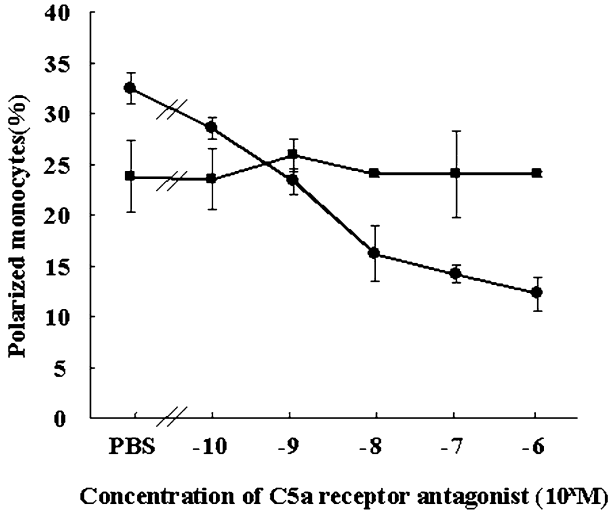

Fig. 7 RP S19 dimer-selective inhibition with C5a receptor antagonist. The indicator monocytes were pretreated with various concentrations of an authentic C5a receptor antagonist (NMePhe-Lys-Pro-dCha-dCha-dArg) for 10 min at 37°C, and used for the polarization assay with the RP S19 dimer (*closed circles*) or with MCP-1 (*closed squares*) as the chemoattractant at a final concentration of 10^{-8} M. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

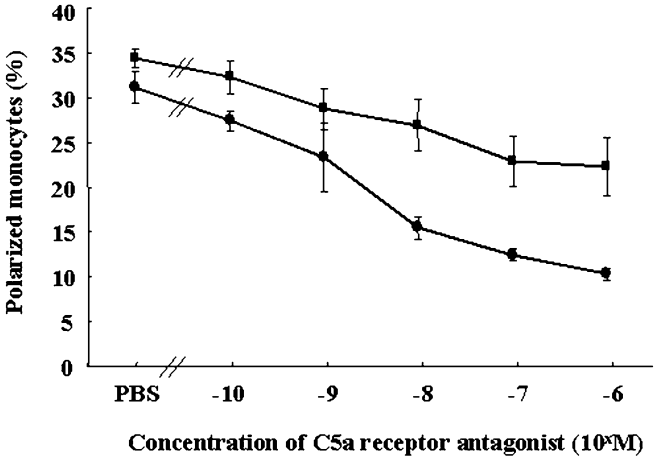

Fig. 8 Inhibition of monocyte chemotactic activity of intimal extracts with C5a receptor antagonist. The RP S19 dimer-predominant (*closed circles*) and the MCP-1-predominant (*closed squares*) intimal extracts, which had been used for the experiments shown in Fig. 4, were subjected to the experiments with the C5a receptor antagonist in the same way as in Fig. 6. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

ceptor antagonist, NMePhe-Lys-Pro-dCha-dArg, must be useful in confirming the presence of the RP S19 dimer in the monocyte chemotactic intimal extracts, whereas an available antagonist of the C–C chemokine receptor 2 is not present.

Before the experiment with the intimal extract, we confirmed the inhibition capacity and the specificity of the receptor antagonist using the RP S19 dimer and MCP-1. As shown in Fig. 7, the C5a receptor antagonist inhibited the chemotactic response of monocytes to the RP S19 dimer in a dose-dependent manner but not to MCP-1.

In the next experiment, we selected a representative sample of the RP S19 dimer predominant extracts or of the MCP-1 predominant extracts. As shown in Fig. 8, the chemotactic response was inhibited by the pretreatment of the indicator monocytes in both cases. The intensity of the inhibition was stronger in the case of the RP S19 dimer predominant extract.

In the final experiment, we confirmed that the monocyte chemoattracting capacity suppressed by the C5a receptor antagonist in the intimal extracts was attributable to the RP S19 dimer. We initially treated the MCP-1-predominant extracts with the anti-RP S19 antibody beads, and we then examined the sensitivity of the remaining chemotactic activity to the C5a receptor antagonist. As shown in Fig. 9, the remaining chemotactic activities in the two cases were resistant to the C5a receptor antagonist. These results indicated that the chemotactic activities that were removed by the anti-RP S19 antibody bead treatment and inhibited by the C5a receptor antagonist treatment were attributable to the single monocyte chemotactic factor—the RP S19 dimer.

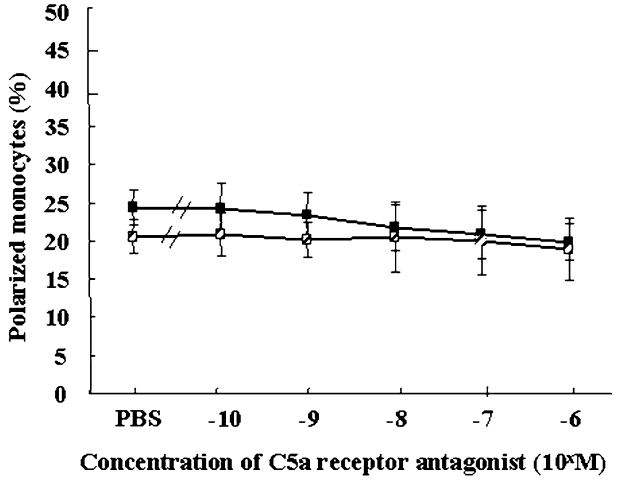

Fig. 9 Insensitivity to C5a receptor antagonist of monocyte chemotactic activity in intimal extracts after absorption with anti-RP S19 antibody beads. The two MCP-1 predominant intimal extracts were initially treated with the anti-RP S19 antibody beads in the same way as in Fig. 5, and the supernatants (*closed squares* and *slashed squares*) were subjected to the polarization assay using the indicator monocytes pretreated with the C5a receptor antagonist in the same way as in Fig. 8. The experiments were carried out in triplicate samples. The polarized ratio (percent) of monocytes is expressed as mean±SD

Discussion

In the present study, we used the anti-RP S19 peptide rabbit antibodies and the anti-MCP-1 monoclonal antibody. Although the latter was an authorized antibody, the former was only prepared for this study. To support the immunochemical identification of the RP S19 dimer, we performed the experiments with the C5a receptor antagonist. By combining the immunochemical data with the results using the C5a receptor antagonist, we were able to conclude that the monocyte chemoattractant capacity that was removed by the anti-RP S19 antibody beads in the intimal extracts was attributable to the RP S19 dimer.

Therefore, the totality of the results described above indicated that the monocyte chemotactic intimal extracts of atherosclerotic lesion contained both the RP S19 dimer and MCP-1, and that these chemoattractant molecules encompassed the whole monocyte chemotactic capacity in the intimal extracts. The contributions of these molecules to the whole monocyte chemotactic capacity varied among the intimal extracts. From the present functional and immunochemical analyses of the intimal extract, we assume that the RP S19 dimer and MCP-1 would recruit circulating monocytes to the atherosclerotic lesion as the major monocyte chemoattractant factors.

The aortic tissue specimens used as normal control samples were obtained from two fresh autopsy cases, whereas the atherosclerotic lesions were obtained during surgical operation. This development ensued because a specimen of a normal region of the aorta could not be resected in the operation due to technical and ethical reasons. We did not macroscopically notice any abnormality in the control specimens; however, histological observation demonstrated minor degenerative changes in endothelial cells with very weak atheromatous sign. The subendothelial monocyte infiltration was already observed immunohistochemically, even though the infiltration was sparse. Extracts of the control intima exhibited weak monocyte chemoattraction capacities. Therefore, there is a possibility that the normal control samples used in the present study might be at an early phase of atherosclerosis.

In the present study, two atherosclerotic lesions possessed very low biological responses in terms of the monocyte/macrophage infiltration despite the presence of severe atheromatous changes with the atheromatous plaque. This is consistent with previous reports that the monocyte/macrophage recruitment, concomitant with the MCP-1 production, was observed most prominently in the developing lesions such as the intimal thickening and the fatty streak, but less prominently in the mature lesion such as the atheromatous plaque [18, 22].

MCP-1-producing cells were immunohistochemically identified to be endothelial cells and subendothelial monocytes/macrophages in human and rabbit atherosclerotic lesions [18, 22]. On the other hand, we are unable to identify the cells producing the RP S19 dimer in this lesion by immunohistochemical means at this time. It is because the anti-RP S19 antibodies are not capable of distinguishing between the monomer form and the dimer form of RP

S19, and because the RP S19 monomer is ubiquitously present as a component of the ribosome. We only speculate that the cells' ongoing apoptosis produces and releases the RP S19 dimer according to our previous in vitro studies [5, 10]. Therefore, we tried to histologically compare the apoptotic cell number between the RP S19 dimer predominant specimens and the MCP-1 predominant specimens with the terminal deoxynucleotidyltransferase-mediated dUTP- digoxigenin nicked end labeling (TUNEL), which we had previously used to detect cultured apoptotic cells [8]. However, the TUNEL method demonstrated the presence of the highest positive cell number in the control specimens, which were obtained at autopsy, and many of the positive cells were morphologically nonapoptotic. We do not know whether the DNA fragmentation would start rapidly after the resection of the tissue or in the postmortem period. For this reason, we could not compare the apoptotic cell number among the specimens.

Co-deposition of amyloidogenic immunoglobulin light and heavy chains in localized pulmonary amyloidosis

Received: 16 January 2005 / Accepted: 27 April 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract Localized pulmonary amyloidosis is a rare condition whose pathogenesis is insufficiently understood. In the present study, we report a case of localized pulmonary amyloidosis associated with lung-restricted lymphoplasmacytoid lymphoma, monoclonal for immunoglobulin (Ig) G lambda (λ). Biochemical microtechniques have been applied for extraction, purification, and characterization of amyloid proteins. Surprisingly, chemical analysis of these proteins revealed a not-previously-described case of combined deposits containing Ig fragments of gamma heavy chain (variable domain) and λ light chain (constant domain). In view of the absence of circulating monoclonal Ig, this case supports the hypothesis that localized amyloid is formed by local plasmacytoid cells.

Introduction

Localized pulmonary amyloidosis is a rare condition usually characterized by a local deposition of immunoglobulin (Ig) light chain-derived amyloid. In addition to the cases with a benign course [9, 10], some studies have demonstrated the coexistence of nodular pulmonary amyloidosis with low-grade pulmonary lymphomas: marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT) [18, 35], small-cell non-Hodgkin's lymphoma [4], and lymphoplasmacytoid lymphoma [11]. Clinically, in these cases of localized pulmonary amyloidosis, the lymphomas were restricted to the lung alone, at least in the early stages when amyloid disease was discovered. Nodular pulmonary Ig light chain deposits having amyloid and nonamyloid features were revealed in one HIV-infected patient [32]. Two cases of localized pulmonary nonamyloid light chain deposition (LCDD) accompanied by low-grade lymphoplasmacytic lymphoma limited to the lung have been recently described [17, 27].

The pathogenesis of localized, organ-restricted amyloidosis is not fully understood. In localized pulmonary amyloidosis, the presence of lymphocytes and plasma cells in the vicinity of amyloid deposits, as well as within them, has been described as an invariable feature of the lesion [1–3, 10]. It has been proposed that the localized amyloid deposits arise from a local monoclonal proliferation of immunocytes [25]. Other authors, however, demonstrated that in most cases of localized pulmonary amyloidosis, these plasma cells are polyclonal rather than monoclonal and are therefore unlikely to be the source of monoclonal Ig [9, 10]. Thus, according to the alternative hypothesis, the Ig light chain precursor protein in localized amyloidosis is syn-

thesized by circulating plasma cells, with targeting of the amyloid formation to a specific organ. This hypothesis was supported by the findings of circulating monoclonal Ig in several patients with localized pulmonary amyloidosis [9, 10, 22]. Whether or not the affinity to a specific organ depends on the primary structure of the amyloidogenic protein, and how, is a question also being raised. However, only a few reported data are based on a direct chemical analysis of amyloid deposits localized in the lung [21]. In this respect, a detailed chemical analysis of such amyloid deposits, together with careful clonal evaluation of the adjacent immunocytes, will aid in understanding the mechanisms of organ-specific amyloid deposition [8].

In the present study, we report a case of localized pulmonary amyloidosis associated with lung-restricted lymphoplasmacytoid lymphoma, monoclonal for IgG lambda (IgG-λ). Surprisingly, chemical analysis of the amyloid proteins revealed a not-previously-described case of amyloid deposits containing fragments of IgG heavy chain (variable region) and λ light chain (constant region), in contrast to the expected λ light chain variable region fragments. In view of the absence of circulating monoclonal Ig, this case supports the hypothesis that in localized amyloidosis, the amyloid is formed entirely by the local plasma cells.

Patient and methods

Patient

A 69-year-old man with a past history of pneumonia 5 years ago was followed by chest x-ray every 6 months, which showed a small mass in the left upper lobe. Following a recurrent pneumonia recently, the chest x-ray and computed tomography (CT) scan showed large consolidation and mass involving the whole left upper lobe. Fluorodeoxyglucose positron emission tomography (FDG-PET) scan showed marked uptake of the same area. Bronchoscopy revealed irregular mucosa, whereas the Congo-red-stained biopsy material was positive for amyloid. There were no clinical or laboratory findings indicating amyloid involvement of other organs such as heart, liver, kidneys, peripheral nerves, intestine, or skin. Due to the unresolved consolidation in the left upper lobe, the patient underwent thoractomy and left upper lobe resection. Bone marrow biopsy showed normal differentiation of the hematopoietic cell lines. Mild increase in plasma cells was noted with polyclonal stain for both kappa (κ) and λ light chains. Using protein electrophoresis and immunofixation electrophoresis, no monoclonal protein was detected on the patient's serum and urine. The patient recovered from surgery and is alive and well.

Pathological studies

Formalin-fixed, paraffin-embedded tissue specimens obtained following lobectomy were subjected to histological and immunohistochemical examination. Sections were stained with hematoxylin and eosin (H & E) and Congo red according to standard methods. Immunostaining was performed with rabbit antihuman antibodies to κ and λ light chains, as well as to IgG, IgM, and IgA heavy chains (Dako, Carpenteria, CA, USA), and visualized by the immunoperoxidase method according to the established protocols. Immunophenotyping of B (CD20) and T (CD3) cells was performed on paraffin sections with a standard avidin–biotin–peroxidase complex (ABC) method.

Isolation of amyloid material

For the biochemical characterization of amyloid proteins, the part of the excised lung tissue was immediately frozen and stored at −70°C until used. Extraction of amyloid proteins was performed by the microtechnique described earlier [13]. Briefly, tissue specimen (about 50 mg wet weight) was homogenized with phosphate-buffered saline (PBS) pH 7.4, followed by centrifugation at 14,000×*g* for 10 min. The obtained pellet was repeatedly homogenized in PBS, and the mixture was centrifuged. The resulting pellet was again washed with deionized water and extracted with aqueous 20% acetonitrile containing 0.1% trifluoroacetic acid (TFA) solution. The extracted material was lyophilized.

Sodium dodecyl sulfate polyacrylamide gel electrophoresis

Electrophoresis was performed in a Novex gel running apparatus (Novex, San Diego, CA, USA) using the precast 20–25% polyacrylamide LongLife microgels, ten wells (Gradipore, Frenchs Forest, NSW, Australia). The extracted material was dissolved in sodium dodecyl sulfate–polycrylamide gel electrophoresis (SDS-PAGE) sample buffer (10 μg/μl) applied to gel (5–8 μl per well). Rainbow-colored molecular mass markers ranging in M_r from 3 to 45 kDa (Amersham, Buckinghamshire, England, UK) were used. Samples were run with Tris SDS HEPES Long Life Running Buffer (Gradipore).

Western blotting

Samples were run by SDS-PAGE and electrotransferred onto nitrocellulose (Schleicher and Schuell, Dassel, Germany) with a Gradipore LongLife Transfer Buffer. The immunostaining was performed by using rabbit antibodies to human Ig κ and λ light chains (Dako) as described earlier [12, 16]. Proteins were visualized using SuperSignal West Pico Chemiluminescent Substrate (Pierce, Rockford, IL, USA).

Micropreparative purification of amyloid proteins

For concentration and micropreparative purification of amyloid proteins, the extracted sample (10 μg/μl) was applied to nine wells of the microgel and run by SDS-PAGE together with the molecular mass markers applied to the remaining well. The electrophoresed proteins were electrotransferred onto Sequi-Blot polyvinylidene difluoride (PVDF) membranes (Bio-Rad, Hercules, CA, USA) with a Gradipore LongLife Transfer Buffer and stained with Coomassie blue R-250. The protein bands of interest were excised, and the bands with the same M_r from different lanes were pooled and eluted with TFA/acetonitrile/water (3:4:3) as described [14]. The eluted material containing protein and Coomassie blue stain was dried (in Speed Vac apparatus). To separate the proteins from the stain, the obtained material was rerun on SDS-PAGE and blotted onto PVDF. One lane of the blot was stained to locate the position of the unstained proteins, which were subsequently recovered from PVDF as indicated above.

N-terminal amino acid sequence analysis (Edman degradation)

The electrophoresed proteins were electrotransferred onto Sequi-Blot PVDF membranes and stained with Coomassie blue R-250. Protein bands were excised and subjected to amino acid sequence analysis as described [16].

Results

The excised left upper lobe specimen (490 g, 6×13×21 cm) was covered by the focal irregular pleura (Fig. 1). The cutting showed extensive exchange of the lung parenchyma by a firm gray tumoral mass. Histopathological examination of the excised lung tissue demonstrated a large infiltrate of small round lymphoid cell with focal plasmacytoid differentiation (Fig. 2a). In and around this lymphoid infiltrate, large amounts of eosinophilic amorphous material were seen. These were Congo-red-positive and showed apple green birefringence under polarized light (Fig. 2b). Immunohistochemical staining of the lymphocyte cells using a panel of antibodies to Ig heavy and light chains showed cytoplasmatic staining with antibodies to γ heavy chains (Fig. 3a) and λ light chains (Fig. 3b). Lymphocytic cells were positive for CD20. Ki-67 proliferative index was positive in 15% of cells. The obtained morphological and immunohistochemical data were typical of a lymphoid neoplasm, whereas the presence of small round lymphocytes expressing CD20 and showing plasmacytoid differentiation was indicative of lymphoplasmacytoid lymphoma. The low proliferative index (ki-67) supports the diagnosis of low-grade lymphoma. Together with clinical and laboratory data, the histopathological findings were consistent with a localized pulmonary lymphoplasmacytoid lymphoma, monoclonal for IgG-λ, with heavy amyloid deposition.

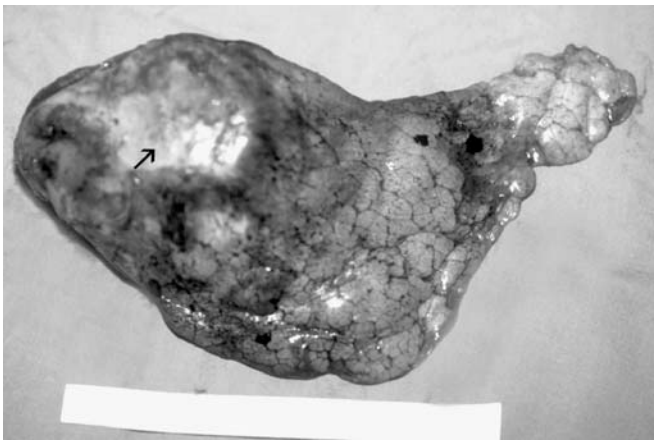

Fig. 1 Macroscopic examination of left upper lobectomy specimen demonstrates irregular mass (indicated by *arrow*) adjacent to pleural surface

For biochemical examination of the amyloid deposits, proteins were extracted from the excised lung tissue specimen according to the procedure described above. By this

procedure, tissue sample was first homogenized and washed with PBS to remove soluble tissue components. Because the disruption of cells is a necessary condition for the removal of soluble cytoplasmatic proteins, including monoclonal Ig of lymphoplasmacytoid cells and mature plasma cells, the samples of the obtained washed tissue homogenate were stained with H & E and examined microscopically. Both the tissue smears and the paraffin block material showed no presence of intact cells. The obtained tissue homogenate was then extracted with acetonitrile/TFA solution. The electrophoretic analysis of the extracted material demonstrated multiple protein bands from about 5 to more than 45 kDa. Inasmuch as the major amyloid components represent the relatively small molecular mass proteins ranging from 3 to less than 30 kDa, the following proteins detected within this molecular weight (MW) range were of major interest: the 12- and 18-kDa protein bands strongly stained with Coomassie blue and two weaker bands with MWs of about 5 and 8 kDa (Fig. 4, track 2). Because the immunohistochemical findings indicated the presence of lymphoid cells monoclonal for IgG-λ, the lung tissue of the patient was presumed to contain amyloid deposits of the AL-λ type. However, in Western blotting, the 8-, 12- and 18-kDa bands revealed no specific immunoreactivity with antibodies to Ig κ and λ light chains; only the 5-kDa protein band showed specific immunostaining for Ig λ light chains. Therefore, for elucidation of the chemical nature of these proteins, they were further analyzed by automated Edman degradation. For this purpose, proteins were concentrated and purified by the micropreparative SDS-PAGE procedure described above (Fig. 4, tracks 3–6). N-terminal amino acid sequence analysis of the purified 5-kDa protein band allowed identification of an Ig λ light chain constant region fragment; this band showed ATLV*LISDF sequence (from position 153 to 163), where the missing amino acid marked with * (blank cycle) was consistent with the presence of cysteine. Analysis of the 12- and 18-kDa bands revealed VQMTRDKT sequences matching a fragment of IgG heavy chain variable region (starting at position 87) [5].

Discussion

In the present case of localized pulmonary amyloidosis, the deposited amyloid proteins were composed of Ig fragments derived from both the IgG heavy chain variable region and the Ig light chain λ constant region. This case is unusual, first, because heavy chain amyloidosis is a rare condition, not yet described in localized pulmonary amyloidosis [7, 20, 23, 30, 33, 36]. Second, to the best of our knowledge, there are no reports on co-deposition of amyloidogenic Ig heavy and light chains in the same patient (Table 1), although it is possible that some of the smaller-molecular-weight proteins that are found in almost every immunocyte-related amyloid material and are not routinely examined contained proteins derived from either light or heavy Ig chains. Deposition of light and heavy chain fragments found in the same patient may probably be explained by the aberrant biosynthesis of these Ig chains in the monoclonal population of B cells, as it was demonstrated in a case of nonamyloidogenic, monoclonal light and heavy chain deposition disease [2]. On the other hand, the abnormal biclonality of B lymphocytes has been observed in several patients with plasma cell disorders [1, 28, 29], monoclonal gammopathy of unknown significance (MGUS) [19] and combined amyloid and LCDD [3, 26]. Therefore, it is also possible that in some cases, the co-deposited light and heavy chain fragments might originate from different clones. The third uncommon feature of our case is that amyloid deposits contained protein originating from constant, but not variable, Ig light chain domain. In fact, it is commonly accepted that the fragments of variable domains of monoclonal Ig light chains play a major role in fibril formation. In this respect, our findings support some recent studies suggesting that the presence of constant region fragments in amyloid deposits may be more common than formerly held and their role in fibril formation was underestimated [6, 16, 24, 31, 34].

The biochemical micromethods of extraction and characterization of amyloid fibrils applied here were used by us previously and were found to be helpful when revealing rare amyloid types or when the immunohistochemical findings were either unexpected or questionable [13, 15, 16]. In the present case, these techniques aided in achieving a precise diagnosis of the disorder. The lung-restricted amyloid proteins presently identified appear to share the same isotypic Ig determinants as those found in monoclonal lymphoid cell population within amyloid deposits (IgG-λ). In light of the absence of circulating monoclonal Ig protein, these data support the view that organ-restricted amyloid formation may occur as a result of a local monoclonal proliferation of immunocytes.

Chromosomal alterations in early stages of malignant mesotheliomas

Received: 17 February 2005 / Accepted: 30 April 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract In a case of a 67-year-old man with two different early stages of a predominantly epithelioid mesothelioma ("mesothelioma in situ", "early-stage mesothelioma"), chromosomal imbalances were determined by comparative genomic hybridisation (CGH), a molecular cytogenetic technique to detect chromosomal gains and losses in tumour cells. In the case of the mesothelioma in situ cells, nine different chromosomal alterations could be detected (losses on 3p, 5q, 6q, 8p, 9p, 15q, 22q, Y; gain on 7q), whereas the early-stage mesothelioma showed the same defects except for the gain on 7q. The simultaneous losses of 6q, 9p and 22q, as well as other chromosomal regions, correlate well with the most common defects previously found in 90 cases of more-advanced-stage mesotheliomas using CGH. These data demonstrate that initial chromosomal defects in early stages of mesotheliomas can be detected by conventional CGH in combination with laser microdissection. The molecular cytogenetic findings support the histological diagnosis of a pleural mesothelioma. The surprisingly high number and extent of genomic alterations found in the examined case probably reflects the genomic instability in the tumour cells and indicates a "genetic chaos" even in earlier stages of malignant mesotheliomas.

Introduction

Malignant mesothelioma (MM) is an asbestos-associated tumour of the serous membranes. Pleural manifestation of a diffuse MM is much more common than peritoneal mesothelioma, mesothelioma of the pericardium or the tunica vaginalis testis. Tumour manifestation is mainly in the sixth decade of life. Pleural mesothelioma is a tumour with a poor prognosis. MMs are relatively resistant to radiotherapy and chemotherapy [13]. MMs have a broad histomorphological spectrum that includes predominantly epithelioid, predominantly sarcomatoid and biphasic subtypes as well as some rare subtypes, which are associated with different survival times [4]. The long latency (20≥40 years from initial exposure) suggests that multiple somatic genetic events are involved, which is supported by the detection of numerous chromosomal aberrations in late-stage mesotheliomas. Advanced stages of mesotheliomas have been examined by Bjorkqvist and co-workers and by our group using the comparative genomic hybridisation (CGH) method [1, 8, 10]. Chromosomal defects of two different earlier stages of an MM were analysed in this report using conventional CGH in combination with laser-assisted microdissection, a method to isolate tumour cell populations free of surrounding normal tissue by an ultraviolet (UV) laser. The interesting biological question behind this study is whether even in early tumour stages there are gross genomic alterations (e.g. loss or gain of chromosome arms). The initial defects were studied in early-stage mesotheliomas and compared to the alterations in manifest mesotheliomas.

Clinical history

A 67-year-old quarry worker with recurrent pleural effusions showed signs of a malignant epithelial tumour in a cytological sample. Tissue samples of the right costal pleura and the right pulmonary lobe were taken. The visceral pleura showed focal structures of an epithelioid neoplasia with pseudo-polypoid histology. Two histologically

different early tumour stages of an MM could be detected in the pleural tissue (mesothelioma in situ, early-stage mesothelioma).

Materials and methods

We have investigated two samples of pleural MM in early stages of tumour development in a 67-year-old patient by immunohistochemistry and CGH in combination with laser microdissection. CGH is a well-established method to screen tumour tissues for chromosomal alterations [3, 5, 7]. A mesothelioma in situ is characterised either by a monolayer of atypically proliferating mesothelial cells (cytokeratin 5/6, pancytokeratin, calretinin positive) with beginning branching to the pleural cavity or by a multilayered solid atypical mesothelial proliferation with branching and/or formation of stromal papillae, but without invasive growth. Similar lesions have been described in a paper by the Australian group of Whitaker and co-workers in 1992 [19]. In contrast, early mesothelioma is defined by beginning infiltrative growth into the adjacent pleural connective tissue as stage pT1 according to the tumour–node–metastasis (TNM) classification [15].

Immunohistochemistry for calretinin, human epithelial antigen, cytokeratin 5/6, epithelial membrane antigen, thyroid transcription factor 1, MiB1 and keratin

Immunohistochemistry was performed on archival formalin-fixed and paraffin-embedded tissue sections using a streptavidin-biotin peroxidase complex technique (LSAB2 System, DAKO, Hamburg, Germany). To distinguish between a secondary pleural carcinosis of adenocarcinoma and epithelioid mesothelioma, periodic acid-Schiff (PAS) staining and an immunohistochemical marker panel including cytokeratin (MNF116, CK5/6), calretinin, human epithelial antigen (HEA) , epithelial membrane antigen (EMA), thyroid transcription factor 1 (TTF-1) and MiB1 (proliferation marker) were used. All used antibodies were acquired from DAKO.

Laser microdissection

Laser microdissection was used to isolate pure tumour cell populations without surrounding normal tissue [16, 17]. Prior to laser microdissection, four sequential 3-μm sections were cut from archival tissue blocks using a microtome with a disposable blade. Three tissue sections were mounted onto 2-μm-thick sterile polyester membranes [Molecular Machines & Industries AG (MMI), Glattbrugg, Switzerland] followed by deparaffination (1 hr at 65°C, 2×10 min xylene at room temperature), rehydration (100, 96 and 70% ethanol; 1 min each) and staining with 1% methylene green/eosin. The fourth tissue section was stained with hematoxylin and eosin (H&E) for a better detection of the tumour cell populations. Dissection of the few mesothelioma cells (100–300 cells) was carried out with a microscopic UV laser system (MMI). The UV laser microdissection system (UV CUT) consists of an inverted research microscope (Axiovert S100, Carl Zeiss, Jena, Germany) with motorised scanning stage, a UV laser unit (connected through the epifluorescence entrance of the microscope), a digital camera and a Pentium computer with control software. The microscopic image of the tissue is displayed on the computer monitor, and the area of interest is marked on the screen. The computer-controlled laser cuts around the area of interest and the dissectate is removed by an adherent lid of a special reaction tube. The selected microdissected areas (tumour and normal DNA) were documented with a digital camera and then transferred to a reaction tube. Handling and digestion of the isolated cells have been described before [6, 16].

Degenerate oligonucleotide-primed polymerase chain reaction

After digestion of the tumour cells, a whole genome amplification was performed by degenerate oligonucleotide-primed polymerase chain reaction (DOP-PCR) to obtain sufficient DNA quantities for subsequent CGH studies [18]. DOP-PCR was performed according to a modified standard protocol [11, 16]. Tests confirmed that amplification of DNA by DOP-PCR did not generate amplification imbalances visible by chromosomal CGH (G. Johnen and M. Jaworska, unpublished data).

Comparative genomic hybridisation analysis

For CGH analysis, we used a slightly modified standard protocol [9, 14]. Reference DNA (extracted from blood lymphocytes of a healthy male donor or normal microdissected tissue of the patient) and tumour DNA were both amplified by DOP-PCR. Reference and tumour DNA were labelled with tetramethylrhodamine isothiocyanate (TRITC) and fluorescein isothiocyanate (FITC), respectively, by random primed labelling. The two DNA samples were simultaneously hybridised to normal metaphase chromosomes (Abbott, Wiesbaden, Germany) in the presence of high concentrations of unlabelled Cot-1 DNA (30 μg), which blocks repetitive DNA sequences. After hybridisation, the fluorescence ratio was measured along the axis of each chromosome using fluorescence microscopy and digital image processing. Fluorescence images were evaluated with the program Quips (Applied Imaging, Sandhausen, Germany). For each tumour sample, 10–11 metaphases were analysed and the results were averaged. A 95% confidence interval and the average profile for each chromosome were calculated. As positive control, we used a tumour cell line with known defects (MPE 600, Abbott), and tissue from a healthy person without a tumour served as a negative control. The DNA of both controls was amplified by DOP-PCR.

Results

Histochemistry and immunohistochemical profile

The immunohistochemical examinations give valuable information for the diagnosis of a malignant pleural mesothelioma and its differential diagnosis (pleural metastases of other primary neoplasia). Benign reactive mesothelial hyperplasia shows monolayered enlarged, partially cuboid and columnar mesothelial cells without atypical mitoses and without papillary structures. In mesothelioma in situ, there is a beginning formation of pseudo-papillary branching (Fig. 1a, upper left), partly with stromal connective tissue, but without infiltration into the connective tissue. Cell proliferation in reactive mesothelial hyperplasia is usually very low in contrast to mesothelioma in situ. Cells of early-stage mesothelioma show invasive growth, as illustrated in Fig. 1b. An infiltration of lung tissue or chest wall as well as pericardium and mediastinal tissues is a sign of more advanced stages. As described in the paper by Whitaker and co-workers [19], we have also immunohistochemically demonstrated a positive membraneous staining for the EMA in mesothelioma in situ (Fig. 1c), and early mesotheliomas in contrast to negative staining results in reactive mesothelial hyperplasia. Adenocarcinomas show a more cytoplasmic-located positive EMA staining in most cases. MiB1 expression is markedly increased in mesothelioma in situ cells in contrast to reactive mesothelial hyperplasia (Fig. 1d)

Co-expression of the mesothelial markers keratin 5/6 and calretinin in the tumour cells with simultaneous negative staining of HEA and PAS leads to the diagnosis of a predominantly epithelioid pleural mesothelioma. The tumour cells did not express the marker for adenocarcinomas of the lung and the thyroid, TTF-1.

Comparative genomic hybridisation results

Detailed results of the CGH analysis are depicted in Fig. 2 and Table 1. In the case of mesothelioma in situ cells, nine different chromosomal aberrations could be detected (losses on 3p21, 5q, 6q, 8p, 9p13–21, 15q11.2–13, 22q, Y and a gain on 7q22), whereas in the early-stage mesothelioma, eight defects could be found (losses on 3p21, 5q, 6q, 8p, 9p13–21, 15q12–14, 22q, Y). The chromosomal losses

Chromosomal losses are represented as *red bars* on the *left side* of each chromosome ideogram; gains are represented as *green bars* on the *right side*. Only the fluorescence ratio profiles of chromosomes with detectable defects are shown. For each sample, 11 metaphases were analysed and averaged

found in this study were also detected in more-advanced-stage mesotheliomas in former studies [10]. Especially the simultaneous loss of 6q, 9p and 22q was often found in advanced-stage mesotheliomas. To validate the chromosomal defects found by using normal DNA extracted from blood lymphocytes from a healthy male donor, CGH was also performed with normal DNA from the fat tissue of the tumour patient. In the case of early-stage mesothelioma, CGH with normal DNA from the patient showed basically the same defects (losses on 3p21, 5q, 6q, 8p, 9p13-21, 15q11.2-14, 22q, Y). In the case of mesothelioma in situ cells, two more gains on chromosomes 4q (4q21, 4q28) and 5p could be detected with normal DNA from the tumour patient.

Table 1 Detailed CGH results in comparison to common defects in advanced-stage MMs

Case	Losses	Gains	∑ Defects
Mesothelioma in situ	3p21, 5q, **6q**, 8p, **9p**13–21, **15q**11.2–13, **22q**, Y	**7q**22	9
Early-stage mesothelioma	3p21, 5q, **6q**, 8p, **9p**13–21, **15q**12–14, **22q**, Y	none	8
Advanced-stage MM	1p, 4pq, **6q**, **9p**, 13q, 14q, **22q**	1q, **7pq**, 15q	6.2 (average)

Chromosomal aberrations that are in good agreement with common defects found in advanced-stage MMs are printed in bold-type

Discussion

The diagnosis of an early-stage epithelioid MM in the presented case is based on conventional light microscopical examination in combination with immunohistochemical findings. While the cytogenetic analysis is in agreement with the MM diagnosis, it was somewhat unexpected that the chromosomal defect patterns in both tumour stages were almost identical and very similar to those frequently found in late-stage MMs [1, 10]. Within the large pleural surfaces, it is not possible to determine the exact region of development of the first neoplastic lesion by means of macroscopical examination. It may be that mesothelial cells undergo a multifocal neoplastic transformation or a discontinuous synchronous growth by spread via effusion, which is usually the first clinical manifestation of the neo-

plasia. Our CGH results favour the second hypothesis with nearly identical chromosomal defects in different manifestations of one tumour. We can not clearly state the significance of the gain on chromosome 7q22. Most probably, this lesion accumulated in the primary lesion after the postulated multifocal tumour cell dissemination with implantation and early invasive growth at another site. On the other hand, it can not be completely excluded that this lesion in the early mesothelioma or the missing of this lesion in the mesothelioma in situ is an artefact during the process of formalin fixation, amplification and the complex process of CGH.

Most cancers show abnormalities in chromosome number and structure (aneuploidy). It has been postulated that chromosomal instability is the cause of aneuploidy and necessary to drive the development of cancer by increased mutation rates. A question is whether this genomic instability is an early event in carcinogenesis or just a side-effect of late-stage cancer [12]. If it is a late event, it would be more likely that normal mutation rates are sufficient and cancer cells accumulate genomic defects in the form of point mutations and other small lesions first. Nevertheless, it is not unlikely that even in cases with an early appearance of chromosomal imbalances, some smaller defects might have occurred initially, e.g. mutations in genes that control and maintain chromosome segregation. To find an answer to the question what kind of alterations can be found in different early stages of pleural MM cells, we used conventional chromosomal CGH in combination with laser microdissection and DOP-PCR amplification. Though the resolution of CGH is not very high (defects in the range of 10–20 Mb can be detected), we found a high number of chromosomal defects. We did not see any signs of DOP-PCR-generated amplification bias between chromosomal regions in the control experiments. These large defects (e.g. losses of chromosome arms 5q, 6q, 8p and 22q) do not rule out the presence of additional smaller defects. The high number of aberrations detected in early stages of MMs would be in accordance with the notion that chromosomal instability contributes to early events in cancer development. A recent publication supports the possibility that at least some cancers start with an early development of aneuploidy [2]. It has to be noted, however, that, considering the age of our patient, “early stage” is a relative term. The development of the MM might have started decades ago, and it is known that MM can progress rapidly at their late stages. Therefore, the examination of more cases, preferably of younger patients, is absolutely necessary. Because most of these very rare cases are discovered by chance, a prospective screening study with former asbestos workers would be a promising approach. The results of the present case report will be a basis for further studies of early stages of MMs with classical CGH and high-resolution methods like array CGH. CGH analysis on cytological specimen may in some cases also be possible if there is a high number of neoplastic and a low number of inflammatory cells. Otherwise, there is a high probability of dilution artefacts with finding too few chromosomal imbalances. The presented method of laser microdissection of fixed and paraffin-embedded tissue provides a pure DNA of only the cells of interest. At the present time, it is too early to draw clinical and therapeutical consequences from the results, but if further CGH results on larger collectives of preneoplastic and early neoplastic mesothelial lesions provide information that helps classify the dignity, the method could gain a clinical relevance in mesothelioma diagnosis.

Complex multilocular cystic lesion of rete testis, accompanied by smooth muscle hyperplasia, mimicking intratesticular Leydig cell neoplasm

Received: 30 March 2005 / Accepted: 23 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract Non-neoplastic smooth muscle cell proliferation occurs under a variety of circumstances in many body organs. These abnormalities have been described as hypertrophy, hyperplasia or hamartomatous proliferations. In the male genital system, the excessive growth of smooth muscle in spermatic cord or paratesticular tissue is rare. In previously described cases, these lesions presented as masses but lacked the microscopic features of a neoplasm. We describe a complex multilocular cystic lesion composed of cystic transformation of the rete testis associated with smooth muscle proliferation mimicking intratesticular Leydig cell neoplasm. The lesion consists of three separate components: (1) cystic dilatation of the rete testis; (2) diffuse, interstitial smooth muscle proliferation with intraseptal expansion; and (3) extensive stroma with myxoid areas and scattered interstitial Leydig cells. These morphological findings, supported by a wide immunohistochemical panel, are consistent with cystic dilatation of the rete testis associated with smooth muscle hyperplasia, most probably of myoid origin. To the best of our knowledge, no similar complex lesion of the rete testis has yet been reported.

Introduction

Non-neoplastic smooth muscle proliferation occurs under a variety of circumstances in many body organs, including the skin, breast, oral cavity, trachea and lungs, vascular system, gastrointestinal tract, kidney and bladder [7, 11]. Excessive smooth muscle proliferation occurring in the spermatic cord or rete testis has received relatively little attention.

Intratesticular leiomyoma was first described by Honore and Sullivan [5], who suggested that the tumor arose from myoid cells of the tunica propria of the seminiferous tubules. Barton et al. [2] later reviewed 16 cases of smooth muscle cell hyperplasia of the testicular adnexa clinically mimicking neoplasm. Out of the 16, 14 were located either in the epididymis or the spermatic cord or both, and two others involved the tunica vaginalis and the tunica albuginea. Microscopic examination in all cases showed an increase in smooth muscle fascicles arranged in a periductal, perivascular or interstitial pattern and lacking the cohesion and well-circumscribed proliferation typical of leiomyoma. No significant inflammation or mitotic activity was seen in any case. Another myxoid gonadal stromal tumor with epithelial differentiation was described by Weidner [10]. Tumor cells, in that case, were immunoreactive for vimentin and S-100 protein, but negative for cytokeratin and desmin and appeared to show bidirectional differentiation, mimicking both peritubular myoid spindle cells and epithelial-like cells.

Cystic testicular dysplasia is a rare disorder affecting the testis of infants and children typically within the first decade of life [6, 8]. In a case of cystic dysplasia of the rete testis, reported in a 22-year-old man, the lesion consisted of a grossly visible, 3.5 cm, multilobulated cystic mass in the upper pole of the left testis. Microscopic examination revealed cystic dilatation of rete channels with a normal branching configuration, lined predominantly by flat cells, although occasional cuboidal cells could be observed. There was no atypia [8].

In the following report, we present a complex multilocular cystic lesion consistent with cystic dilatation of the rete

testis associated with smooth muscle hyperplasia. To the best of our knowledge, no similar complex lesion of the rete testis has yet been described.

Case report

A 26-year-old, previously healthy man presented with a 4.5-cm cystic, probably intraparenchymal, lesion of the testis, detected by manual and ultrasonographic examination. The patient underwent simple orchiectomy without complications or further complaints.

Materials and methods

The surgical specimen, consisting of testis and paratesticular structures, was received in 10% buffered formalin and processed for histological evaluation. Sections were stained with hematoxylin and eosin, phosphotungstic acid–hematoxylin (PTAH), Alcian Blue, PAS and mucicarmine, and immunohistochemical stains included Cam-5.2, AE-3, MNF-116, CK-7, CK-20, CA-125, CEA, EMA, CD-31, EMA, α_1-antitrypsin, CK-20, GFAP, NSE, S-100, MELAN-A, chromogranin, ACTH, β-HCG, α-inhibin, Calretinin, α-fetoprotein and CD-34.

Immunostaining incorporated the streptavidin–biotin–peroxidase method after overnight incubation at 4°C. A microwave antigen retrieval method was used with all antibodies. Slides were immersed in 200 ml of microwave buffer and heated in 800-W microwave oven using a high setting for 5 min. Fifty milliliters of deionized water was added to replace evaporated water from heating, and slides were microwaved for an additional 5 min before automated immunostaining in the Ventana Nexes (Ventana Corp.). Internal and external control tissues with established reactivity were stained concomitantly.

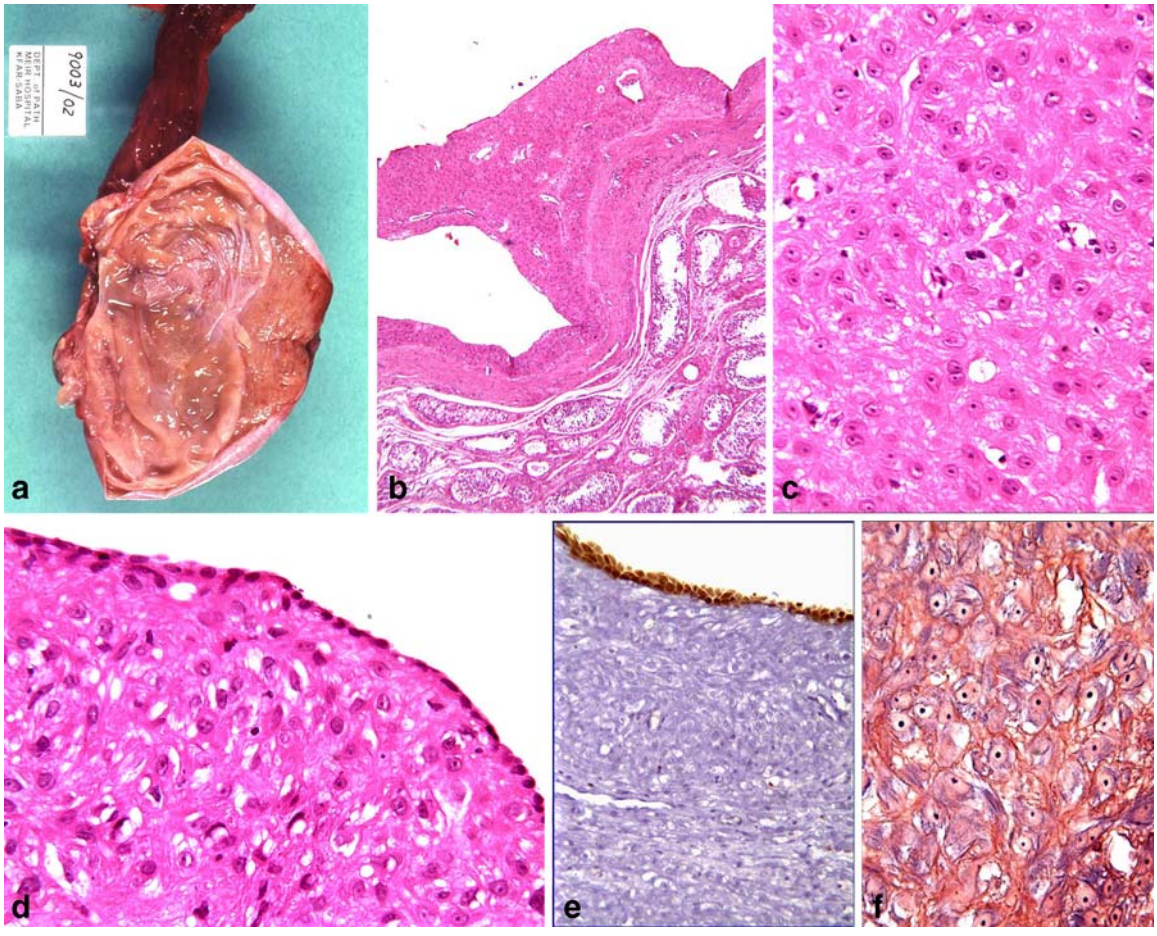

Fig. 1 **a** Macroscopic view of the specimen with multilocular "intratesticular" cystic mass. **b** H&E stain, original magnification ×100. Septal formation composed of large "tumoral" cells and cuboidal epithelial lining. Note distinct border between mass and surrounding testicular parenchyma. **c** H&E stain, original magnification ×400. Center of the mass showing monomorphous large epithelioid cells with centered round nucleus containing prominent nucleolus (Leydig-like cells). Note only one typical mitotic figure (*arrow*). **d**, **e** H&E and Calretinin stains, original magnification ×400. Cystic septa lined by normal mesothelial cells, highlighted by Calretinin immunohistochemical stain. No reactivity for Calretinin is present in large epithelioid cells. **f** PTAH stain, original magnification ×400. Intracellular fibers (*arrow*) are seen in a few epithelioid cells

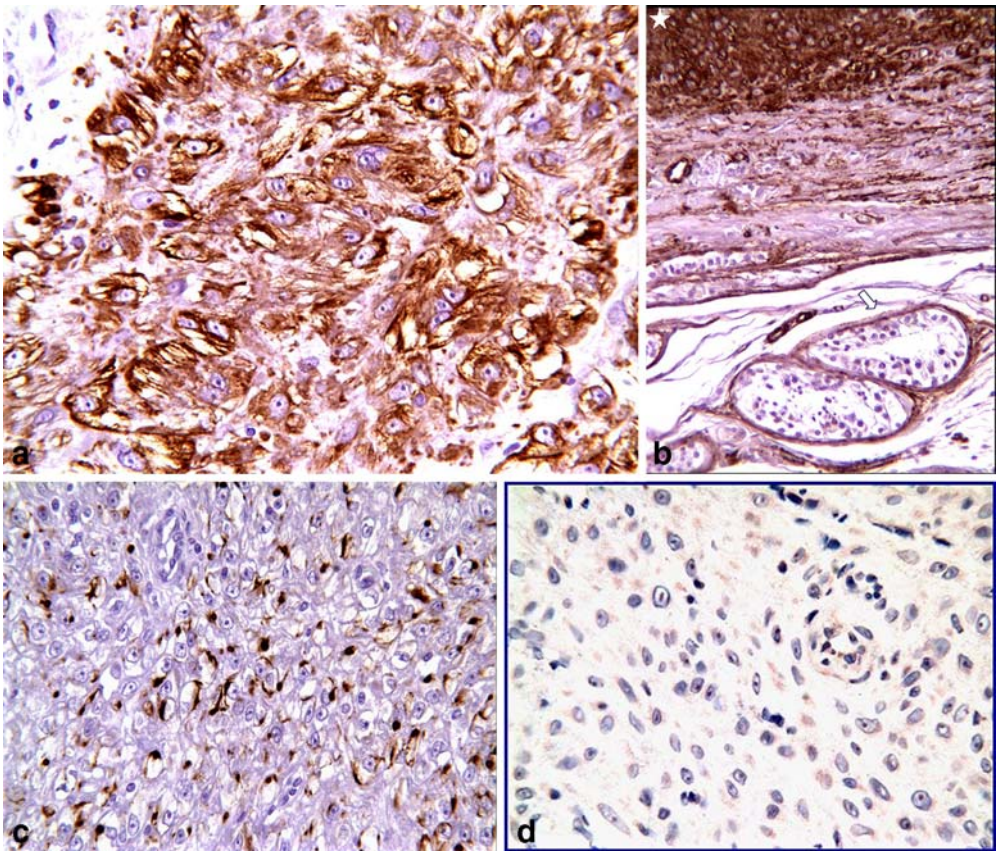

Fig. 2 **a** Desmin stain, original magnification ×400. Diffuse strong cytoplasmic positivity in the large epithelioid cells. **b** α-Smooth muscle actin stain, original magnification ×100. Diffuse strong cytoplasmic positivity in the large epithelioid cells (*asterisk*) and only focal positivity in the periacinar myoid cells in the surrounding normal testicular parenchyma (*arrow*). **c** Cam 5.2 stain, original magnification ×400. Diffuse perinuclear pattern of stain in the large epithelioid cells. **d** α-Inhibin stain, original magnification ×400. No reactivity is seen in large epithelioid cells, but single residual Leydig cells are positive

Results

Macroscopical examination showed a multilocular cystic lesion, 4.5 cm in diameter, separated from residual testicular tissue by a fibrous septum (Fig. 1a). The spermatic cord and adjacent structures were of normal appearance.

Histological examination revealed a complex cystic lesion composed of three different components. The first component consisted of a cystic dilatation of rete testicular channels lined by normal-looking flat cells (Fig. 1b–d). Immunohistochemical stains of these cells were positive for Calretinin, Cam-5.2, MNF-116, AE-3 and CK-7 (Fig. 1e) and non-reactive for CK-20, CA-125, CEA and EMA. This staining pattern supports a mesothelial origin for these cells. The second component consisted of a diffuse proliferation of large eosinophilic epithelioid cells with an interstitial pattern of growth and intraseptal expansion. No cytological atypia was observed, and only rare typical mitotic figures were identified (Fig. 1c, d). PTAH staining highlighted the intracellular myofibrillar bundles (Fig. 1f). These cells also showed diffuse cytoplasmic positivity for α-smooth muscle actin (SMA) and desmin and a perinuclear ("dot-like") pattern of staining for MNF-116, AE-3 and CAM-5.2 (Fig. 2a–c). They were negative for Alcian Blue, mucicarmine and PAS and non-reactive for Calretinin (Fig. 1e), α-inhibin (Fig. 2d), α-fetoprotein, CD-34, CD-31, CA-125, CEA, EMA, α_1-antitrypsin, CK-20, GFAP, NSE, S-100, Melan-A, chromogranin, ACTH and β-HCG [4, 9]. This staining pattern supports a smooth muscle, most probably myoid, origin for these epithelioid cells. Finally, the third component was composed of extensive stroma with myxoid areas and sparse interstitial Leydig cells (Table 1).

Table 1 Comparison of immunophenotypes of the three lesion components

Lesion component	Immunohistochemical stains						
	Cal	MNF-116	AE-3	CAM-5.2	α-Inhibin	SMA	Desmin
Cystic mesothelial lining	pos	pos	pos	pos (cyt)	neg	neg	neg
Large epithelioid cell component	neg	pos (perinuclear pattern)	pos (perinuclear pattern)	pos (perinuclear pattern)	neg	pos (cyt)	pos (cyt)
Residual Leydig cells (in lesion and normal testis)	pos	neg	neg	neg	pos	neg	neg

pos Positive; *neg* negative; *cyt* cytoplasmic; *Cal* Calretinin; *SMA* α-smooth muscle actin

Discussion

Smooth muscle hyperplasia of the rete testis is uncommon even in a consultant practice in genitourinary pathology. A large proportion of palpable masses in this location prove to be malignant, notably liposarcomas, leiomyosarcomas, malignant fibrous histiocytomas and, less often, mesotheliomas and metastatic carcinomas [11]. Determining the type of non-neoplastic smooth muscle cell growth occurring in the rete testis may be difficult. In previous studies, a total of 20 cases of benign smooth muscle proliferation of the rete testis have been described [2, 6]. In addition to epididymal lesions and cysts, most of the benign lesions are adenomatoid tumors, nodular periorchitis (fibrous pseudotumor), leiomyomas and lipomas [2]. Extratesticular lesions closely adherent to the tunica albuginea may not be ultrasonographically distinguishable from intratesticular lesions in some cases. These cases are usually composed of a non-neoplastic excess of smooth muscle bundles growing around and/or between normal paratesticular structures, rather than forming a well-defined tumor nodule.

While a chapter on spermatic cord and testicular adnexa in a recently published urologic pathology textbook [2] reviews and briefly discusses three types of hamartomas arising from smooth muscle, rete testis and fibrous tissue, and a recent case report and review of epididymal leiomyomas describes two lesions as diffuse smooth muscle cell proliferation in and around epididymal structures, a careful literature search indicates that these unique lesions have never really been the object of any focused study or investigation [2, 4–7, 9, 11]. Until now, only one case of rete testis containing smooth muscle proliferation with an extensive stromal myxoid component has been described [5].

Histological examination of our surgical specimen in comparison with previously described cases revealed a complex cystic lesion of the rete testis associated with smooth muscle proliferation, ultrasonographically and macroscopically mimicking intratesticular Leydig cell tumor. The major component of this lesion was the cystic dilatation of rete testis, which has been called cystic transformation of the rete testis and can occur at any age [6, 8]. The second major component was a diffuse smooth muscle proliferation, most probably of myoid cell origin, with intraseptal expansion, which has also been described as a separate entity: “myoid gonadal stromal tumor with epithelial differentiation” [10]. The third component consisted of extensive stroma with myxoid areas and scattered interstitial Leydig cells. This component has also been observed separately as mentioned above [2].

Unlike the cases described in previous studies, our morphological and histochemical findings are consistent with cystic transformation of the rete testis associated with smooth muscle hyperplasia, most probably of myoid origin. To the best of our knowledge, no similar complex cystic lesion of the rete testis has yet been reported with complete immunophenotypic characterization. The wide immunohistochemical panel applied enabled a precise determination of the histogenetic origin of individual cellular components of the lesion [1, 3]. Based on the three admixed components, the diagnostic options for this entity include: (1) epithelioid leiomyoma of myoid origin (leiomyoblastoma) associated with cystic transformation of the rete testis or (2) cystic hamartoma of rete testis associated with smooth muscle cell hyperplasia. In any case, this is an extremely rare, complex, benign lesion located in the testicular adnexa and simulating intratesticular neoplasia. A detailed description and characterization of this unique entity may help in difficult differential diagnoses between benign and malignant testicular lesions.

Primary clear cell sarcoma of the ileum: an uncommon and misleading site

Received: 27 February 2005 / Accepted: 23 May 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract A clear cell sarcoma, arising primarily in the ileum of a 35-year-old man, is reported. Histologically, the neoplasm infiltrated the full thickness of the intestinal wall. It consisted of strands and sheets of round to spindle-shaped cells with clear to eosinophilic cytoplasm, vesicular nuclei and prominent nucleoli. Vascular invasion was present at diagnosis. Tumour cells expressed S-100 protein, melan-A and tyrosinase. They were negative for HMB45, CD117, cytokeratins, epithelial membrane antigen, smooth muscle actin, desmin, CD31, CD34, chromogranin and synaptophysin. Reverse transcription–polymerase chain reaction analysis performed on paraffin-embedded tissue showed EWS–ATF1 fusion transcripts representative of the t(12;22) (q13;q12) clear cell sarcoma reciprocal translocation. The patient, who developed liver metastases 2 months after diagnosis, died of disease at 15 months. This case demonstrates that the gastrointestinal tract is a potential site for primary clear cell sarcoma of soft tissues, and, furthermore, that cytogenetics and/or molecular techniques play a central role in the diagnosis.

Introduction

Clear cell sarcoma (also known as malignant melanoma of soft tissues) is a rare tumour that typically occurs in the tendon sheaths and aponeuroses of distal extremities of adolescents and young adults [3, 6, 10, 11]. Involvement of the gastrointestinal tract is exceedingly rare and, frequently, a source of diagnostic problems. Six cases of digestive tract clear cell sarcoma were heretofore reported in the literature, most of them very recently [1, 4, 5, 7, 13, 15], including one in the ileum [4]. A second ileal case is described below. It occurred in a 35-year-old man and caused the death of the patient 15 months after diagnosis.

Clinical history

A 35-year-old, HIV-negative man without any previous significant medical history was admitted in March 2003 for a 15-kg weight loss over a few months and symptoms of intestinal obstruction (i.e. colic pain, vomiting) without fever. CT scans showed a segmental thickening of the ileum, situated 80 cm above the ileo–caecal valve. Preoperative diagnoses included Meckel diverticulum, polyps and a malignant neoplasm. At laparotomy, a single circumferential, stenotic lesion of the ileum was found. There was neither other detectable tumour in the abdominal cavity nor any liver metastases. The ileal mass was resected along with 20 cm of ileum and one regional mesenteric lymph node. A pathologic diagnosis of unclassified non-epithelial malignant neoplasm was rendered. The mesenteric lymph node was devoid of tumour deposits, but the ascitic fluid, sampled at the time of surgery, contained clusters of malignant cells. A lymphoma, a GIST, a neuroendocrine neoplasm were excluded on the basis of immunohistochemical results. A melanoma (primary or metastatic) was strongly suspected owing to tumour cell reactivity for S-100 protein.

Careful examination of the patient, including extensive examination of skin, eyes, nasosinusal cavities, throat, testes and soft tissues failed to detect any other potential primary tumour. The metastatic work-up was negative, as was the PET scan. A colonoscopy showed several polyps in the ascending and sigmoid colon, which turned out to be adenomatous polyps with low-grade dysplasia at microscopic examination.

Two months post-operatively, several metastases were detected in the liver, along with multiple peritoneal implants and a malignant ascitis. The tumour regressed dramatically after six courses of a platinum-based chemotherapy, but a second look, performed in November 2003, showed that the malignant process extended microscopically to the whole peritoneal subserosa and to the omentum. Lymph node and liver biopsy specimens, taken during the second surgical procedure, were tumour-free. From then on, and despite various treatments, the tumour gradually progressed in the abdomen, leading to several episodes of intestinal obstruction. Patient's death occurred 15 months after disease onset, as a result of *Candida albicans* septicemia. No autopsy was performed.

Materials and methods

Tumour samples were fixed in 4% buffered formalin, embedded in paraffin and stained with hematoxylin and eosin and Fontana–Masson stains. Additional sections were studied with the following antibodies: S-100 protein (Dakopatts, Glostrup, Denmark, pre-diluted), melan-A (Dako, diluted 1:50), HMB45 (Dako, diluted 1:50), tyrosinase (Ludwig Institute, Lausanne, Switzerland, diluted 1:50, gift from Dr. D. Rimoldi), cytokeratins (clone C-11, diluted 1:40 and clone AE1/AE3, diluted 1:200, Novocastra Laboratories Inc., Newcastle upon Tyne, UK), CD31 (Dako, diluted 1:40), CD34 (Immunotech Beckam Coulter, Inc., Fullerton, CA, USA, diluted 1:160), CD45 (Dako, diluted 1:50), CD3 (Novocastra, pre-diluted), CD20 (clone L26, Dako, pre-diluted), CD56 (clone 1B6, Novocastra, diluted 1:50), smooth muscle actin (clone 1A4, Sigma Aldrich, St Louis, MI, USA, diluted 1:20,000), myeloperoxidase (Dako, diluted 1:2,000), synaptophysin (Dako, diluted 1:25), chromogranin-A (Dako, diluted 1:1,000), somatostatin (Bachem Peninsula Laboratories, Inc., San Carlos, CA, USA, diluted 1:800), serotonin (clone 5HT-H209, Dako, diluted 1:50) and CD117 (c-kit, Dako, polyclonal diluted 1:200). Immunostaining was performed according to the avidin biotin complex (ABC) method. Tissue sections were submitted to microwave oven heating prior to staining, except for CD117 staining. All steps were performed at room temperature, and diaminobenzidine was used as chromogen. Appropriate positive and negative controls were employed throughout.

Reverse transcription–polymerase chain reaction (RT-PCR) was used to detect the presence of EWS–ATF1 transcripts in paraffin-embedded tumour samples. RNA extraction and RT-PCR reaction were performed as previously described [9]. Briefly, PCR amplification was performed in duplicate using a 96-well plate (Applied Biosystems, Foster City, CA, USA) with a 50 μl final reaction mixture containing 300 nM each primer; 200 nM probe ATF1 or 50 nM probe beta2-microglobulin; 200 μM of an equal concentration of dATP, dCTP, dGTP, dTTP, dUTP; MgCl2 4 mM; 1.25 U Taq polymerase and 0.25 U Amperase UNG in a 1X Real-Time PCR Buffer containing a passive reference (Rox fluorochrome). Thermal cycling conditions were 2 min at 50°C for amperase activation, 10 min at 95°C for Taq polymerase activation, then 50 cycles of two PCR steps consisting of 15 s at 95°C and 60°C for 1 min. All reactions were performed in the ABI Prism 5700 Sequence Detection System (Applied Biosystems).

Primers and probe sequences were chosen with Primer Express software (Applied Biosystems). Primers were purchased from Eurobio (Les Ulis, France) and probes and QPCR Core kit containing Real-Time PCR Buffer, dNTP, MgCl2, amperase UNG and Taq polymerase were purchased from Eurogentec (Herstal, Belgium). Probes and primer sequences were as follows: forward primer EWS, 5′-CAT GAG CAG AGG TGG GCG-3′; reverse primer ATF1, 5′-CCC CGT GTA TCT TCA GAA GAT AAG TC-3′; probe ATF1, 5′-6-FAM-AGG AGG ACG CGG TGG AAT GGG-TAMRA-3′; forward primer beta2-microglobulin, 5′-TGA CTT TGT CAC AGC CCA AGA TA-3′; reverse primer beta 2-microglobulin, 5′-AAT CCA AAT GCG GCA TCT TC-3′; probe beta 2-microglobulin, 5′-6-FAM-TGA TGC TGC TTA CAT GTC TCG ATC CCA-TAMRA-3′.

Results

A 20-cm segment of ileum was resected, centered by a well-defined firm, circumferential mass, measuring 1.8 cm in maximal diameter. Cut section showed a whitish neoplasm that ulcerated the overlying mucosa and infiltrated the whole thickness of the intestinal wall, extending into the subserosa (Fig. 1.). The tumour cells, arranged in sheets and nests separated by fibrous septa of varying thickness, were polygonal, with a clear to eosinophilic cytoplasm. Tumour cell nuclei were oval, often vesicular with a single central prominent nucleolus (Fig. 2.). Neither multinucleate giant cells nor melanin pigment were observed. Mitoses were numerous (up to 32 mitoses per ten high-power fields; one high-power field, 0.174 mm^2). There was no necrosis, but vascular invasion was present. The mesenteric lymph node sampled was devoid of metastatic deposits. The peritoneal and omental biopsies taken in November 2003 showed the same neoplastic proliferation, although tumour cells were very scarce, embedded in an abundant collagenous matrix. These tumour cells could easily be overlooked in some samples.

Immunohistochemically, the tumour cells were diffusely positive for S-100 protein (Fig. 3.) and, focally, for tyrosinase and melan-A. They were negative for HMB45, keratins, EMA, smooth muscle actin, desmin, chromogranin-A, synaptophysin, CD117, CD31, CD34, CD45, CD20, CD3 and myeloperoxidase. Ultrastructurally, the tumour

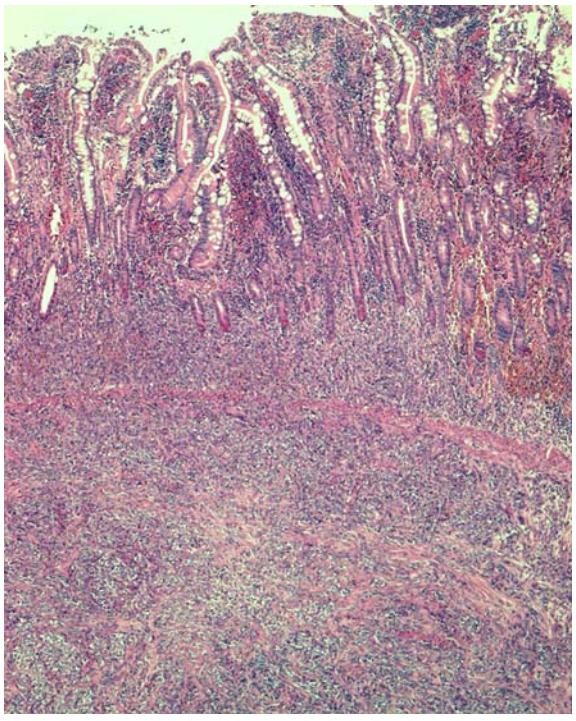

Fig. 1 Diffuse infiltration of the mucosa and submucosa of the ileum by tumour cells. Hematoxylin and eosin stain ×50

cells showed rounded to oval nuclei with smooth or indented contours, open chromatin and one or two prominent nucleoli. The cytoplasm was moderately abundant and contained few organelles as well as immature melanosomes. EWS–ATF1 fusion transcripts representative of the t(12;22) (q13;q12) clear cell sarcoma translocation were detected using real-time RT-PCR (Fig. 4.). The fusion occurred between the exon 8 of EWS gene and the exon 4 of the ATF-1 gene. SYT-SSX1/2 fusion transcripts, representative of the t(X;18) synovial sarcoma translocation, were not detected.

Discussion

Described in 1965 by FM Enzinger [6], clear cell sarcoma of tendons and aponeuroses is a peculiar type of sarcoma which shows features of melanocytic differentiation. Clinically, it presents as a slow-growing tumour (median size, 2–5 cm) that mainly affects young adults (20–40 years). These tumours may be present for years before coming to clinical attention. The distal extremities, particularly the feet, ankles, knees, wrists and hands are the most common sites of tumour development [3, 6, 10, 11]. The lesions are almost always deep seated and intimately associated with tendons, aponeuroses and fascia.

Clear cell sarcoma is infrequent outside the limbs. Heretofore, six cases of clear cell sarcoma of the digestive tract have been reported [1, 4, 5, 7, 13, 15]. The salient clinicopathologic features of those cases, and the case under discussion, are summarized in Table 1. Males seem to be predominantly affected, in contrast to soft tissue lesions, which are divided equally between the sexes. Median age is 37 years (mean, 40 years), and median tumour size is 4 cm. Clear cell sarcoma of soft tissue has a poor prognosis, despite various treatment regimens [3, 6, 10, 11]. The tumour tends to metastasize to lungs but also to regional lymph nodes and bone. The 5-year survival rate is about 50–60%. Long term follow-up is mandatory because metastases can develop late in the course of the disease (10 years or more after diagnosis). Of the seven patients with a clear cell sarcoma of the gastrointestinal tract, two had metastatic disease at the time of diagnosis [13, 15], and an additional four developed liver metastases 2 (current case) to 24 [4] months post-operatively. Only two patients were disease-free at last follow-up, 11 [1] and 18 [5] months after diagnosis. Follow-up of patients 4 and 6 of Table 1 have been updated recently (see Acknowledgements).

In the digestive tract, clear cell sarcoma has the same histology and immunoprofile as in the soft tissues. The tumour presents as bundles or nests of pale staining to eosinophilic spindle cells separated by dense fibrous tissue septa. Tumour cells have prominent vesicular nuclei with

mostly a large, central, single nucleolus. Multinucleate giant tumour cells, a relatively common feature of clear cell sarcoma of soft tissues, seem to be rarer in the gastrointestinal tract (one of seven cases). Intracellular melanin accumulation is reported in half of the cases.

The tumour cells in clear cell sarcoma of soft tissues usually express melanocytic makers, including S-100 protein,

HMB45, melan-A and the melanoma isoform of microphthalmia transcription factor (MITF-M) [2]. In the gastrointestinal tract, clear cell sarcoma cells consistently expressed vimentin and S-100 protein. HMB45 was expressed in three of seven cases only, and melan-A in two of four cases with available data. They were consistently negative for EMA, cytokeratins, muscle-specific actin, smooth muscle actin, desmin, CD34, chromogranin, synaptophysin, CD45 and CD117. Melanosomes at varying stages of development were visible ultrastructurally in all (6/6) cases with available data.

The diagnosis of clear cell sarcoma is a challenging one, especially if the tumour occurs in an unexpected site such as the gastrointestinal tract. In our case, the diagnosis was considered only at the time of the peritoneal tumour regrowth 8 months after the primary tumour had been removed. A metastatic melanoma was initially suspected, but an extensive work-up failed to find any primary elsewhere. The other differential diagnoses, successively contemplated and ruled out on the basis of tumour immunoprofile, included a poorly-differentiated neuroendocrine carcinoma (tumour cells were negative for keratins, EMA, chromogranin and synaptophysin), a malignant gastrointestinal stromal tumour (negativity for CD117 and CD34), a clear cell myomelanocytic tumour/PEComa (negativity for smooth muscle actin, strong positivity for S-100 protein), a paraganglioma (negativity for chromogranin and synaptophysin, diffuse positivity for S-100 protein), some sort of germ cell neoplasia (negativity for epithelial markers and placental alkaline phosphatase), a synovial sarcoma (negativity for epithelial markers, absence of detectable SYT-SSX fusion transcripts), a leiomyosarcoma (negativity for muscle markers) and a lymphoma (negativity for lymphoid markers). Although initially considered as improbable, the other diagnostic hypotheses that could not be definitely ruled out included epithelioid malignant peripheral nerve sheath tumour, sclerosing epithelioid fibrosarcoma and clear cell sarcoma. Ruling out the diagnosis of malignant peripheral nerve sheath tumour was effectively difficult on account of the negativity of the HMB45 marker. Nevertheless, the focal positivity of the melan-A marker was a helpful indication of the melanocytic differentiation of the tumour. The detection of EWS–ATF1 fusion transcripts by RT-PCR finally demonstrated that this lesion was a clear cell sarcoma. The lack of primary tumour elsewhere strongly suggests that this tumour arose primarily in the ileum and was not a metastatic deposit from a soft tissue tumour, as has sometimes been reported [12].

The relationship between clear cell sarcoma and melanoma has been controversial for a long time. Both neoplasms show morphologic features of melanocytic differentiation (melanin pigment), as well as immunohistochemical and ultrastructural features (melanosomes), and some authors refer to clear cell sarcoma as malignant melanoma of soft parts [3, 5]. Clear cell sarcoma differs, however, from cutaneous melanoma in several respects: it is almost always deep-seated, associated with tendons, tendon sheaths and aponeuroses, seldom involves the epidermis and behaves differently, metastasizing predominantly to the lungs. In addition, clear cell sarcoma bears the t(12;22) (q13;q12) translocation which is specific for this tumour type and had never been identified in cutaneous melanoma [2, 8]. This translocation, present in 75 to 90% of cases, fuses the activating transcription factor 1 (ATF1) gene on chromosome 12 with the EWS gene on chromosome 22 [2, 8].

Based on these differences, clear cell sarcoma was considered heretofore as a clinicopathologic entity distinct from melanoma. However, recent gene expression profiling data would suggest that this is not really the case. While examining a series of sarcomas including clear cell sarcomas, Segal et al. [14] found that clear cell sarcomas do not 'cluster' with other soft tissue sarcomas and may rather represent a distinct genomic subtype of melanoma. In addition to genes of melanocytic differentiation, this tumour was also shown to express fibroblast growth factor receptor 1 (FGFR1), a tyrosine kinase receptor involved in angiogenesis and tumour cell growth and migration, suggesting that the use of tyrosine kinase inhibitors might have some value in the treatment of patients with uncontrolled disease.

In conclusion, this case shows that clear cell sarcoma of soft tissues may occur as a primary neoplasm of the gastrointestinal tract. It also underlines the pivotal role of molecular techniques in the diagnostic approach when dealing with 'unusual' locations.

Composite follicular lymphoma and nodular lymphocyte predominance Hodgkin's disease

Received: 17 April 2005 / Accepted: 17 May 2005 / Published online: 28 June 2005
© Springer-Verlag 2005

Dear Editor:

Composite lymphoma (CL) is a lymphoid neoplasm in which two (or more) distinct lymphoma subtypes involve the same lymph node or extranodal site [9]. This condition is relatively rare and raises interesting questions about the pathogenesis as well as the relationship that might exist between the various neoplastic components. Recently, we observed the case of a 29-year-old male who developed a distinctive CL consisting of follicular lymphoma (FL) and nodular lymphocyte predominance Hodgkin's disease (NLPHD) within the same lymph node.

The patient was admitted in our hospital because of a slow-growing lymphadenopathy localized in the left inguinal area. This lymphadenopathy spontaneously appeared and progressively increased in size to reach a diameter of almost 4 cm. There was no history of fever or deterioration in the patient's general condition. Clinical examination did not reveal any other abnormality and peripheral blood analysis was within normal limits. Serum investigations for human immunodeficiency virus, hepatitis B and C viruses, Epstein–Barr virus (EBV), cytomegalovirus, and syphilis were negative. In contrast, the patient demonstrated acquired immunity for toxoplasmosis and hepatitis A virus. A surgical excision of the abnormal lymph node was performed for diagnostic purposes.

Microscopically, the nodal architecture was effaced by numerous uniformly sized follicles (Fig. 1). These follicles were closely packed together and lacked mantle zones. They were mostly composed of small centrocytes mixed up with few centroblasts. Tangible body macrophages as well as mitotic figures were almost completely absent. In a small area of the lymph node, we noted several large lymphoid nodules composed of small lymphocytes mixed up with some large atypical cells (Fig. 2). The latter featured the characteristics of "pop corn" cells, indicative of NLPHD (Fig. 3). Both lymphomatous proliferations were relatively well delineated from each other. On immunohistochemical analysis, the lymphoid cells inside the follicles were found to express CD20, CD79a, and CD10. These cells also expressed the bcl-2 and bcl-6 proteins. Small clusters of CD20- and CD10-positive cells were found in the interfollicular areas. "Pop corn" cells showed immunoreactivity with antibodies directed against CD45, CD20, CD79a, and bcl-6 protein. Although some of these cells were weakly CD30-positive, they did not express CD10, CD15, or bcl-2 protein. "Pop corn" cells were found between CD20-, CD79a-, bcl-2 protein-, and CD10-positive centrocytes, CD23-positive follicular dendritic cells, and CD57-positive T lymphocytes. These CD57-positive T lymphocytes often formed rosettes around the "pop corn" cells (Fig. 4). Polymerase chain reaction (PCR) analysis of DNA extracted from the paraffin embedded sections demonstrated a bcl-2 gene rearrangement resulting from a t(14;18) chromosomal translocation in the major breakpoint region. However, no clonal rearrangement of the genes coding for the immunoglobulin (Ig) heavy (IgH) chain or EBV genomic sequences could be evidenced, using the same method of molecular investigation.

Based on these data, a diagnosis of CL consisting of FL and NLPHD was made. Additional investigations revealed the involvement of several lymph nodes located in the left inguinal area, the retroperitoneal and mesenteric regions, and the right axillary area, respectively. No infiltration of

the bone marrow could be demonstrated. Six courses of R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy were therefore given. The patient is in complete remission, 3 months after the end of therapy.

On rare occasions, CLs consisting of FL and classic Hodgkin's disease (HD) have been reported in the literature [4, 6–8, 10–12, 15, 16]. Using laser capture microdissection, PCR analysis, and sequencing of IgH gene rearrangements, a clonal relationship between the FL and HD has been demonstrated in some of these cases [4, 10, 12]. Interestingly, RS cells often express the bcl-2 protein or carry the t(14;18) translocation in these CLs [11, 12, 16]. To our knowledge, however, there has been no case report documenting the occurrence of FL and NLPHD within a single lymph node. Progression of NLPHD to diffuse large B cell lymphoma is a relatively well-known phenomenon [8], but the association with other B-cell lymphoproliferative disorders, in contrast with classic HD [5], is definitely unusual. Therefore, the present observation raises interesting questions about the relationship that might exist between FL and NLPHD. Unfortunately, we could not perform further molecular investigations in order to determine whether a clonal link between the "pop corn" cells and the FL cells does exist in our patient. Thus, we can only offer speculations on this issue. Nevertheless, two main possibilities may be considered, as follows.

At first, the NLPHD and FL components are totally unrelated and their occurrence together within the same lymph node simply represents a coincidental occurrence. In this regard, the absence of clonal relationship between the neoplastic components in some CL, like those involving HD and mantle cell lymphoma for instance [5], may support such a model of pathogenesis.

Second, both NLPHD and FL originate from a common precursor B cell, that is, the same abnormal B cell gives rise to the two neoplastic disorders through distinct maturation pathways in the germinal center (GC). In such a situation, the timing of t(14;18) translocation is of paramount im-

portance because this chromosomal anomaly is classically not involved in the pathogenesis of NLPHD [1]. Also, it was generally acknowledged that t(14;18) translocation takes place at the pre-B ontogenetic stage, during the initial phase of the IgH V region recombination process [13, 14]. However, recent studies have demonstrated that this chromosomal anomaly may arise at a later stage of B cell development, during receptor revision in the GC [13, 14]. Therefore, the possibility that a common precursor B cell first gives rise to NLPHD and thereafter to FL may be not so unreasonable. Moreover, the numerous similarities that exist between "pop corn" cells in NLPHD and GC B cells at the centroblastic stage of differentiation and the knowledge that FL cells may correspond to late centroblast or centrocyte GC B cells also are consistent with such a hypothesis [12, 14].

Due to differences in terms of prognosis, our case should be distinguished from FL showing progression to CD30-positive large cell lymphoma and from FL featuring numerous RS-like cells [2, 3]. In our patient, the phenotype of the "pop corn" cells as well as the presence of numerous CD57-positive T lymphocytes, notably around these cells, make such a progression unlikely and rather favor a diagnosis of CL featuring FL and NLPHD components. Interestingly, numerous small B lymphocytes in the large follicles harboring the "pop corn" cells were bcl-2 protein- and CD10-positive centrocytes, a finding that can be interpreted as colonization of these follicles by FL cells.

Whatever the precise pathogenesis may be, this intriguing observation further expands the spectrum of CL.

Pseudoangiomatous spindle cell lipoma with "true" angiomatous features

Received: 10 April 2005 / Accepted: 7 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Keywords Pseudoangiomatous · Sex steroid receptor · Spindle cell lipoma · CD31 · F-VIII

Sir,

The pseudoangiomatous variant of spindle cell lipoma (PASCL) is a rare tumor of which only six cases were reported to date [4, 7]. The tumor differs from common spindle cell lipoma [2] by distinctive irregular branching spaces and pseudopapillary projections into these spaces. The spaces were labeled as pseudovascular because their lining cells lacked immunohistochemical reactivity for endothelial markers. Recently, I have seen a further case of this rare lesion. Clinical and morphological features of the tumor were similar to those reported previously, but immunohistochemical results indicated that distinctive spaces in this tumor were true vascular. In addition, the tumor expressed sex steroid receptors, which had not been described in spindle cell lipoma until now.

A 74-year-old male patient presented with superficial subcutaneous lesion in the nuchal region. The tumor grew slowly for 8 years. The clinician suggested an enlarged lymph node, and performed a marginal tumor excision. The lesion was ovoid and well circumscribed, and measured 2 cm in maximum diameter. Histologically, the tumor showed patterns of spindle cell lipoma with mixture of mature fat and short spindle cells, and with abundant small capillary vessels (Fig. 1). The nuclei of spindle cells were regular and bland appearing, but very few of them showed slight pleomorphism similar to that observed in pleomorphic lipoma. Mitotic figures and significant atypia were not found. The intercellular space was slightly mucoid and contained very rare refractile, wavy collagen bundles. Scattered mast cells were identified. A prominent feature of the lesion was the presence of branching cleft-like spaces and villiform tumor tissue projections into these spaces. The spaces and the surface of tissue projections were lined by flat cells, which in hematoxylin and eosin stained sections suggested an endothelial nature of the spaces.

Immunohistochemically, CD34 (QBEnd/10, 1:800, Neomarkers, Westinghouse) was strongly positive in the spindle stromal cells, endothelium of the vessels, and in surface cells of the villous projections and clefted spaces (Fig. 2a). Endothelial markers F-VIII (F8/86, MW, 1:100; Dako, Carpenteria, CA, USA) and CD31 (JC70A, 1:50, MW; Dako) stained endothelium of the vessels and in addition they were positive in many surface cells of villous projections and tissue clefts (Fig. 2b, c). Alpha smooth muscle actin (1A4, 1:1,000; Dako) stained pericytes and rare cells on the surface of the villous projections. Actin was also focally positive in rare spindle cells that were immediately beneath the surface cells (Fig. 2d), thus resembling an "organoid" pericytic positivity. Calponin reactivity (CALP, 1:1,000, MW; Dako) was limited to the smooth muscle cells in larger vessels and to very rare spindle cells, and was negative in pericytes of small vessels. Estrogen receptor (ER) (ER1D5, Immunotech), progesterone receptor (PR) (1A6, Immunotech), and androgen receptor (AR) (AR441, Dako) were positive in 50, 70, and 40% of the tumor cells, respectively (Fig. 2e). S100 protein (S1/61/69, 1:50; Novocastra, Newcastle) reactivity highlighted the adipocytes. EMA, cytokeratin AE1–AE3, and CD10 gave negative results.

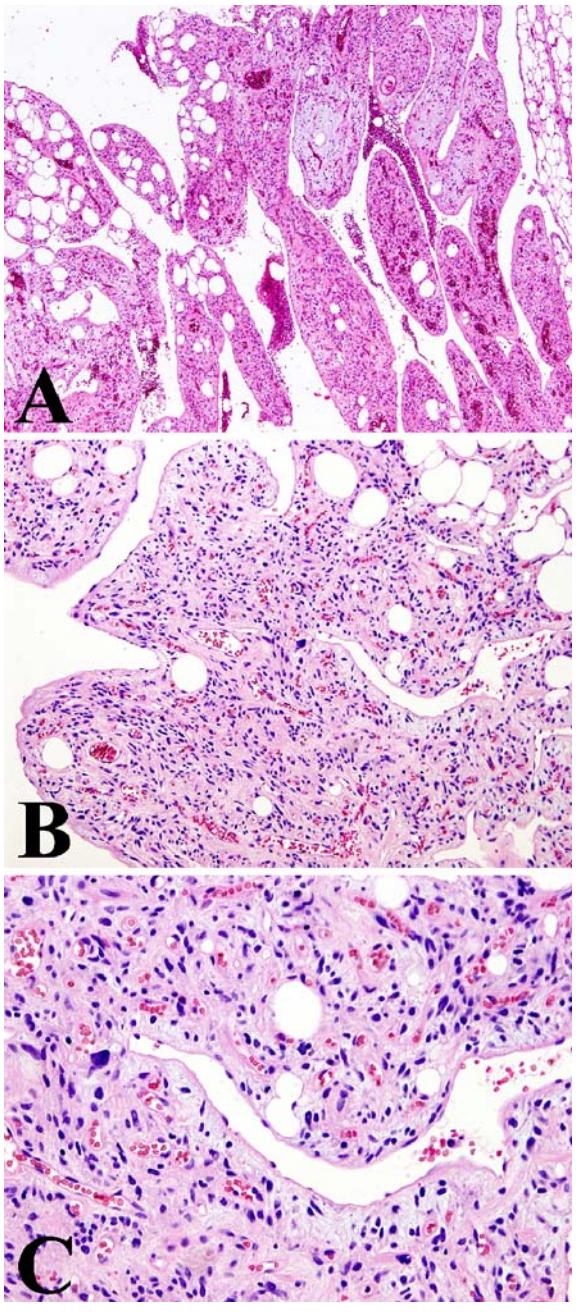

Fig. 1 **a** Low-power view of a villous architecture of the tumor. **b** Medium-power view shows an arrangement of spindle cells and adipocytes in the villous projection. **c** Rare nuclear pseudoatypia of stromal cells and flat cells on the surface of the villous projection are shown

The present tumor shows histological features of PASCL as described by Hawley et al. [4] in 1994. Like common spindle cell lipoma, PASL occurs mostly in the shoulder and neck regions of adult males. Thus, in this case, the patient's gender, age, and location are in keeping with previous observations of PASCL (and of spindle cell lipoma in general) [2, 4, 7].

Our case differs from previously published ones [4, 7] in that immunohistochemical results suggested the true vascular nature of the distinctive spaces inside the tumor. These spaces are lined by flattened and relatively inconspicuous cells. In both previous studies the lining cells were negative for endothelial markers CD31, CD34, F-VIII, *Ulex europaeus* I, and type IV collagen, and therefore the spaces were not regarded as true vascular (hence the adjective *pseudoangiomatous* in the name of the lesion). In contrast, a majority of the lining cells in the present case showed strong positivity for endothelial markers F-VIII, CD31, and CD34. In addition, some actin+ cells resembling pericytes were seen focally beneath the lining cells. The finding of unquestionable endothelial features and possible pericytic nature of rare associated actin+ spindle cells indicates that the spaces represent dilated vessels, and that at least the present case should be labeled as angiomatous spindle cell lipoma. The difference between the present and the previously reported findings is difficult to explain. I suppose that the antibodies and techniques used in both previous studies [4, 7] 10 and 11 years ago, respectively, were less sensitive (e.g., CD34 in the original study was negative in the spindle cells in all cases, which contrasts with almost consistent CD34 positivity in spindle cell lipomas reported in recent years) [8]. The exact cause of dilatation of small vessels in the present tumor remains unknown. It can be hypothesized that such dilatation is a consequence of microcirculation disturbance within a lesion containing abundant abnormal vessels. Of interest, all reported cases of PASCL appear to contain higher number of vessels [4, 7] in comparison with common spindle cell lipomas [2]. Some space-lining cells in the present lesion were positive for actin and CD34, and lacked reactivity for endothelial markers. One can speculate that these spaces may represent immature vascular channels with "incomplete" endothelial cell differentiation and with myoid features of some lining cells, since they resemble similar primitive channels and tissue clefts already described in connective tissue of the skin and mammary stroma [1, 3, 5]. Perhaps such "hidden" channels can distend and their lining cells can differentiate toward more mature (CD31- and F-VIII-positive) endothelial cells. However, a study on additional cases is certainly needed for a more exact characterization of the spaces in PASCL.

Expression of ER, PR, and AR, as seen in our case, was not previously described in spindle cell lipoma. However, to the best of my knowledge, sex steroid receptors were not studied in these tumors as well as in lipomatous tumors in general. The presence of ER, PR, and AR was described in normal adipose tissue (although in quantity lower than in mullerian-derived tissues) [6], and this observation can explain the positivity for these receptors also in some lipomatous tumors.

In sum, a further case of PASCL was reported. The lesion showed clinical and histological features similar to those described previously. In contrast, however, immunohistochemical results indicated that the distinctive intratumoral spaces (having pseudovascular features in the previous reports) in fact possessed a true vascular nature. In addition, a hitherto undescribed positivity for sex steroid hormone receptors was found in the tumor.

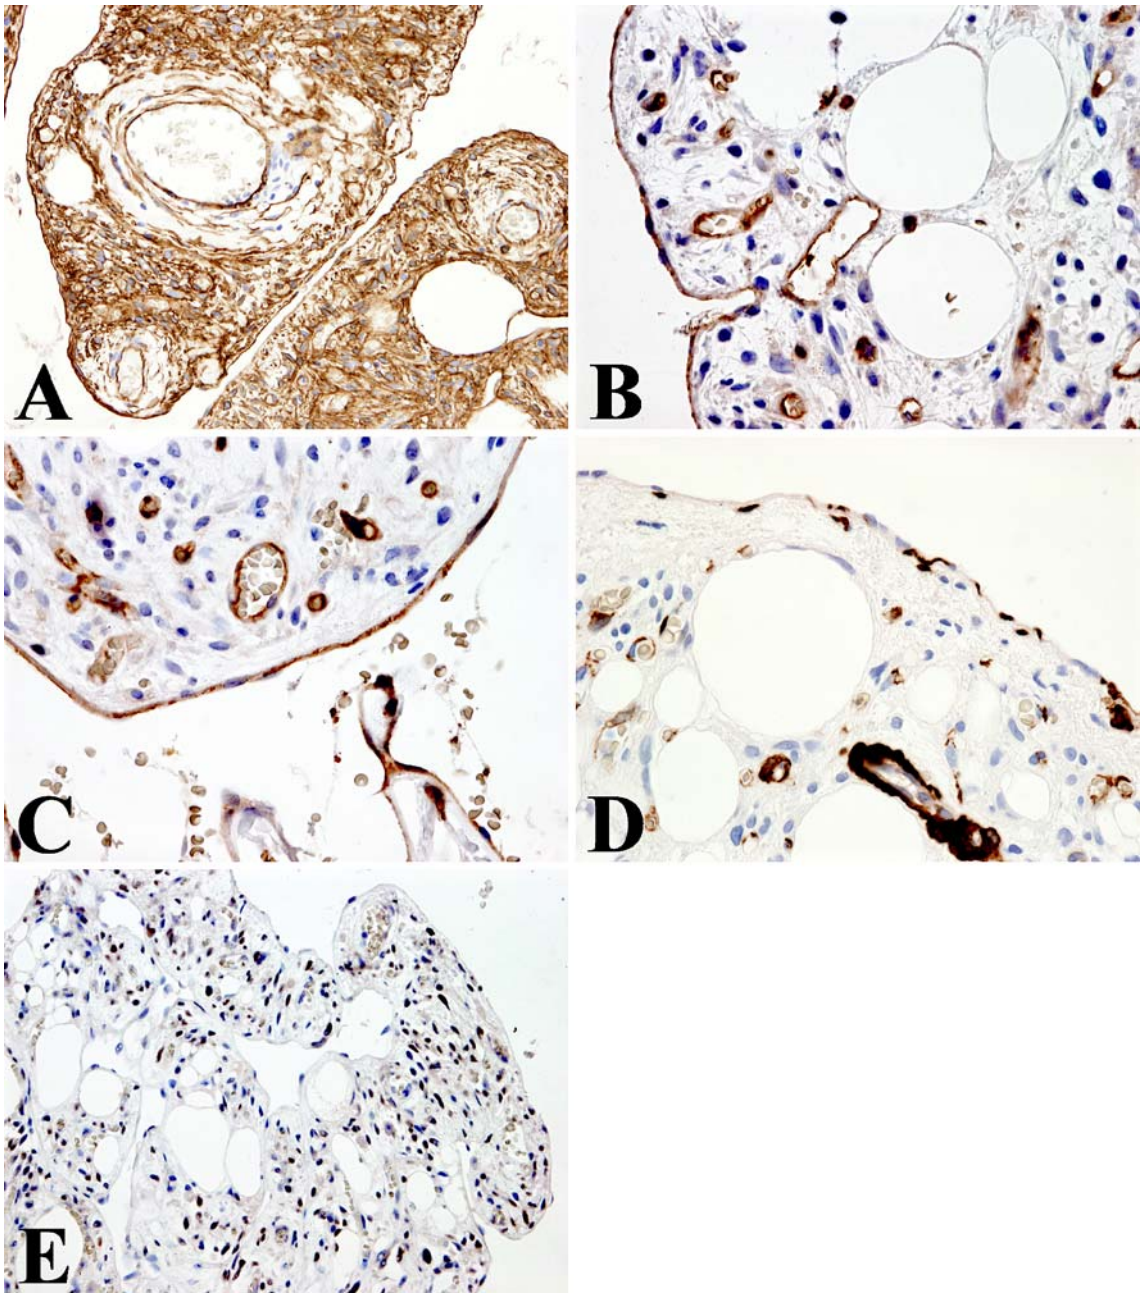

Fig. 2 Immunohistochemical results. **a** Diffuse CD34 positivity. Immunoreactivity for **b** F-VIII and **c** CD31. In addition to the endothelium of small vessels, both antibodies also strongly stain surface cells of the villous projections. **d** Pericytic-like actin positivity of some cells near the surface of the projection, and a typical pericytic positivity of small vessels. **e** Estrogen receptor is positive in numerous stromal cells

EDITORIAL

Anna Kádár · Zsuzsa Schaff · Tibor Kerényi

In memoriam: Professor Harry Jellinek, M.D. (1924–2005)

Received: 29 April 2005 / Accepted: 29 April 2005 / Published online: 3 September 2005
© Springer-Verlag 2005

Dr. Harry Jellinek, emeritus professor of the Semmelweis University, former director of the 2nd Department of Pathology (1968–1993), died on 6 January 2005 after a prolonged illness, which was little noticed by his environment. He celebrated his 80th birthday in September 2004 at the plenary session of the annual meeting of the Hungarian Society of Pathologists. It was attended by many of his colleagues, students and friends from home and abroad, and Professor Jellinek himself delivered a well-acclaimed lecture.

Professor Harry Jellinek was born in Rimaszombat (Slovakia) on 25 November 1924. He obtained his M.D. degree "summa cum laude" from the Budapest University in 1950. In 1952, he joined the 2nd Department of Pathology of Semmelweis University (Budapest, Hungary) as an assistant to Professor L. Haranghy (head of the department, 1952–1967). Later he served as head of the 2nd Department of Pathology for 25 years (1968–1993). He remained active in the department until his death.

Dr. Jellinek obtained his Ph.D. degree (1959) and later D.Sc. degree (1965) based on his studies on the pathomorphology, regeneration and alterations of the arteries. His continuous interest in research stayed within the arterial structure and permeability changes associated with atherosclerosis.

Throughout his career Dr. Jellinek distinguished himself as an outstanding teacher, academician, investigator and an expert in the practice of pathology. One of his main goals when he was appointed as the deputy dean of medicine was to improve and modernize the medical education of the undergraduate, postgraduate, graduate and faculty levels. He himself was an enthusiastic teacher. His lectures in pathology were always interesting, stressing the clinicopathologic approach to diseases. These activities laid the foundation in Hungary for research in pathology of the arteries and earned an international reputation for the Hungarian pathologist. His close to 300 publications with his co-workers cover a wide spectrum of angiopathology; his university handbooks went through many editions, and he was the editor, co-editor or author/co-author of several books in English.

Dr. Jellinek was well aware that productive research requires not only collaborations but financial support, both lacking in Hungary at that time. Given the possibilities of the period and making use of his foreign-language skills, he developed contacts with the German-speaking and later with the English-speaking scientific communities.

Dr. Jellinek forged formal collaboration agreements between Semmelweis University and other universities (Heidelberg, 1981; Freiburg, 1982; Padova, 1984 and the Freie Universität Berlin, 1988). In appreciation of these achievements, Professor Jellinek was appointed Honorary Consul of the Semmelweis Medical University of Budapest in 1995 and earned the distinction of Honorary Senator of the University of Freiburg (Germany) in 2004.

Generations of Hungarian pathologists were able to benefit from the knowledge and guidance of Professor Jellinek. His attitude towards pathology made it possible for his students and colleagues to gain insight into the

beauty of diagnostic pathology. A number of his former co-workers and students have become directors of institutes and clinics or professors and head physicians in several reputable Hungarian and foreign institutions.

Striving for acknowledgement and promotion of his fellow pathologists, Professor Jellinek attempted to augment his efforts at the university level by other activities and avenues: as a director of the National Institute of Pathology (1984–2001) and as the president of the Hungarian College of Pathologists (1984–1992) and of the Hungarian Society of Pathologists (1981–1994).

Dr. Jellinek was a member, or an honorary member, of several foreign scientific societies; he was the founder of the Hungarian Division of the International Academy of Pathology (IAP) and its chairman since its foundation (1972) until 1995, the deputy chairman of the European Society of Pathology (1971–1979) and the European vice president of the IAP (1974–1980). In acknowledgement of his many fruitful activities for the IAP, Professor Jellinek received a letter of recognition from the then president of the IAP (1996).

Dr. Jellinek's outstanding achievements in pathology and in education were acknowledged by several prestigious national and international awards, such as the Jozsef Baló Prize (Hungarian Society of Pathology), Linser Prize (German Society of Arteriosclerosis) and Ratschow Preis und Medal (Freiburg University, Germany). The most honorable was the last, i.e. that of the Hungarian Republic Decoration of the Civil Servants Cross awarded to Professor Jellinek in 2004 by the President of the Hungarian Republic.

The above summary of Dr. Jellinek's life would be incomplete without even a brief reference to the person himself. His commitment to science and higher education, selfless devotion, his charming personality, legendary hospitality, and a limitless benevolence towards his colleagues and co-workers do explain the respect and affection for, and the long-lasting friendships with, Professor Jellinek.

Professor Jellinek's departure appears to have come too early for all of us. The Medical Faculty of the Semmelweis University, all Hungarian pathologists, and in a broader sense the world community of pathologists his, former students and colleagues, together with his family, wife and children, mourn the loss of the scholar, the committed mentor, the outstanding pathologist and the gentle humane "Boss".

Acknowledgements We are indebted to Professor M. Daria Haust of The University of Western Ontario, London, Canada for her input into this account as an old friend of Professor Harry Jellinek, and as a supporter of Pathology and Atherosclerosis Research of Hungary.

Molecular pathology of well-differentiated thyroid carcinomas

Received: 28 July 2005 / Accepted: 15 August 2005 / Published online: 28 September 2005
© Springer-Verlag 2005

Abstract The newly discovered molecular features of well-differentiated thyroid carcinomas derived from follicular cells are reviewed, within the frame of the 2004 WHO classification of thyroid tumours, under the following headings: "Follicular carcinoma", "Papillary carcinoma", "Follicular variant of papillary carcinoma" and "Hürthle cell tumours". A particular emphasis is put on the meaning of *PAX8–PPARγ* rearrangements, *RAS* and *BRAF* mutations, and deletions and mutations of mitochondrial genes and of nuclear genes encoding for mitochondrial enzymes, for thyroid tumorigenesis.

Keywords Thyroid · Follicular carcinoma · Papillary carcinoma · Follicular variant of papillary carcinoma · Hürthle cell tumours · *RET/PTC* rearrangements · *BRAF* mutations · *RAS* mutations

Introduction

The last 5 years has witnessed some major advances in the molecular characterisation of the well-differentiated carcinomas of the thyroid derived from follicular cells. The most important findings were the following:

(a) Detection of *PAX8–PPARγ* rearrangements in follicular carcinomas [28], follicular adenomas [32, 42] and follicular variant of papillary carcinoma [6].
(b) Identification of point mutations and large deletions of mitochondrial DNA (mtDNA) [34] and of mutations of *GRIM-19*, a nuclear gene involved in the mitochondrial respiratory chain (MRC) and cell death [33], which appear to be specific for oncocytic (Hürthle cell) tumours regardless of their histotype (follicular adenoma, follicular carcinoma or papillary carcinoma).
(c) Detection of an extremely high prevalence of *BRAF* mutations in papillary thyroid carcinoma (PTC) [12, 27, 59], namely in PTCs displaying a conventional (papillary or mixed follicular–papillary) growth pattern [65, 67].

In the present article, we have summarised the pathogenic, diagnostic and prognostic meaning of the aforementioned molecular features, together with the available evidence on some other genetic alterations, using as a classificative frame the recently published WHO book on endocrine tumours [14].

For the sake of simplicity, four tumour types will be addressed: follicular carcinoma, papillary carcinoma, follicular variant of papillary carcinoma and oncocytic (Hürthle cell) tumours.

Follicular carcinoma

The most distinctive molecular features of follicular carcinoma are the prominence of aneuploidy and the high prevalence of *RAS* mutations and *PAX8–PPARγ* rearrangements (as the result of a 2;3 translocation).

Aneuploidy is thought to indicate chromosomal instability (CIN) [53] and is frequently observed both in follicular adenomas, namely in those displaying a foetal/embryonal growth pattern, and in follicular carcinomas [4, 7].

Follicular adenomas with a foetal/embryonal growth pattern and follicular carcinomas, besides being aneuploid,

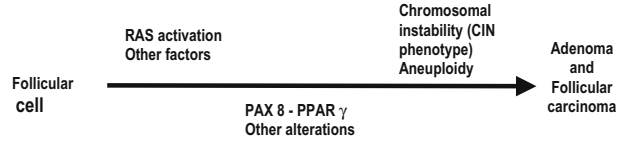
present, in about 60% of the cases, a DNA content which falls within the triploid range [7]. We have found evidence indicating that this DNA pattern is probably attained after a preliminary state of tetraploidisation, which is followed by a consistent loss of some chromosomes [4].

Giaretti et al. [20–22] showed that activating mutations of K-*RAS* were involved in the control of chromosome stability in aneuploidy in colorectal tumours. Fagin [18] advanced that a similar mechanism, also involving *RAS*, might cause aneuploidy in follicular thyroid tumours. This possibility has been recently supported by the finding of a significant relationship between H-*RAS* 81T→C polymorphism, together with increased amount of p21 (which is the active form of *RAS*), and the occurrence of aneuploidy in follicular adenomas and follicular carcinomas (P. Castro et al., unpublished data).

The available evidence suggests there are at least two main pathways for thyroid follicular carcinogenesis: one, characterised by gross aneuploidy and a foetal-like growth pattern, displaying prominent chromosomal gains, and the other, occurring in lesions with a "common" follicular growth pattern and a diploid or near-diploid DNA content, displaying frequent chromosomal losses [4].



The aneuploid pattern and the various molecular alterations detected in follicular adenomas and follicular carcinomas support the assumption that the development of such tumours is the end product of multiple oncogenic steps, thus justifying their usual appearance as single (unicentric) neoplasms.

RAS mutations are frequently detected in follicular adenomas and follicular carcinomas and do not provide any useful information from the diagnostic standpoint [40]. In most cases, N-*RAS* and, less often, H-*RAS* are mutated in codon 61 (and less often in codons 12 and 13) [23, 45]. In some studies, it was advanced that *RAS* mutations carried a guarded prognosis, but such results have not been confirmed in most series, namely when the analyses were restricted to well-differentiated carcinomas, with the exclusion of poorly differentiated and undifferentiated carcinomas [23, 44].

In 2000, Kroll et al. [28] reported the frequent occurrence in follicular carcinomas of the *PAX8–PPARγ* rearrangement, thus creating a sort of mirror image for follicular tumours of the well-known *RET/PTC* and *TRK* rearrangements of papillary carcinomas [19].

Initially, it was claimed that the *PAX8–PPARγ* translocation was exclusively detected in follicular carcinoma and thus could be considered as a sign of malignancy [28]. This concept was disproved in several studies that showed the presence of the translocation in a number of follicular adenomas [10, 15, 32, 42].

The most important molecular features of follicular cell tumorigenesis (follicular adenoma and follicular carcinoma) are summarised in the following scheme:

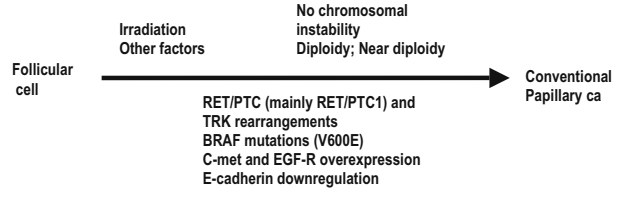
Regardless of the advances at the molecular level, the diagnosis of follicular carcinomas rests on the identification of signs of invasion, namely of vascular invasion at the tumour capsule [14, 49]. Besides the classic categories of minimally invasive and widely invasive follicular carcinoma, it is crucial to identify the vascular invasive tumours and, whenever possible, to quantify the type and number of vessels invaded [14, 49].

Papillary carcinoma

At variance with follicular carcinoma, almost every PTC is diploid or quasi-diploid [24, 25]. Furthermore, PTCs display microsatellite stability [56]. Taking these facts together with the tendency of PTC to occur as multicentric neoplasms, which are clonally independent from each other [37, 54], it is tempting to advance that PTC tumorigenesis reflects the end product of (very) few oncogenic steps.

The major role played by *RET/PTC* and *TRK* rearrangements in the etiopathogenesis of PTC has been known for a while (for a thorough review, see Santoro et al. [51]). The prevalence of the different types of *RET/PTC* rearrangements is not the same in the different variants of PTC—e.g. *RET/PTC1* is particularly prevalent in conventional PTC and in some prominent papillary PTC variants, whereas *RET/PTC3* is more prevalent in the follicular/solid variant of PTC [41]. The overall prevalence of *RET/PTC* rearrangement varies greatly from series to series, depending on geographic factors and radiation exposure [41, 51]. Three other genetic and/or epigenetic alterations play a role in PTC pathogenesis: activating mutation of *RAS* genes, despite its much lower frequency than in follicular tumours [40, 44, 59], c-met overexpression [52] and downregulation of E-cadherin in PTC [47, 57].

Recently, another major player in PTC etiopathogenesis has been reported: the *BRAF* gene. The results on record show that, after melanoma, PTC is the human cancer displaying the highest prevalence of *BRAF* mutations, which occur almost always in the same hot spot (V600E) [12, 27, 59]. This mutation consists in a transversion from thymine to adenine in position 1799, leading to the substitution of a valine by a glutamate in codon 600. The V600E mutation is quasi-restricted to PTC with a conventional (papillary or mixed follicular–papillary) growth pattern and is particularly prevalent in PTCs with a prominent papillary structure, as is the case for tall cell variant and Warthin-like PTC [65, 67]. The prevalence of the *BRAF* mutation is also strongly associated with age, being rarely detected in young patients both in the post-Chernobyl setting and in sporadic cases occurring in western Europe [30].



The finding of a high prevalence of *BRAF* mutations, together with the involvement of *RAS* mutations and *RET/PTC* rearrangements in the majority of PTCs, points to the crucial role played by alterations at the RET/RAS/BRAF/MAPK signal transduction pathway in the etiopathogenesis of PTC. The three mutation groups (*RET*, *RAS* and *BRAF*) appear to be functionally similar and mutually exclusive [27, 59]. Despite the large amount of new molecular data,

the etiology of PTC remains to be fully clarified (for example, there is evidence to support that *RET/PTC* rearrangements are among the earliest initiating events in PTC, but one still ignores the timing of *BRAF* mutations in PTC oncogenesis) [30].

The prognostic significance of $BRAF^{V600E}$ mutation remains controversial. Some groups claimed mutated cases carry a worse prognosis [39], whereas in our hands, mutated *BRAF* PTCs do not display worse pathologic features than wild-type *BRAF* PTC [65]. As a matter of fact, PTCs with $BRAF^{V600E}$ mutation were less often multicentric and less vascular invasive than non-mutated PTCs [65]. Large series with longer follow-up are necessary to clarify the putative prognostic meaning of the $BRAF^{V600E}$ mutation in PTC.

At variance with *RET/PTC*, which is not detected in poorly differentiated and undifferentiated carcinomas [51, 57, 64], $BRAF^{V600E}$ mutation is detected in about one third of poorly differentiated carcinomas and undifferentiated (anaplastic) carcinomas, mainly in those tumours that appear to have arisen from pre-existing PTCs [43, 58].

The most important molecular features of PTC tumorigenesis are summarised in the following scheme:

Despite all these molecular data, the diagnosis of PTC still depends on the identification of the typical nuclei: large, irregular, clear, grooved, occasionally displaying pseudoinclusions. The differential diagnosis is particularly difficult in the field of encapsulated follicular patterned lesions that may correspond to follicular adenoma, follicular carcinoma or follicular variant of PTC (FVPTC; see below) [31].

Follicular variant of papillary carcinoma

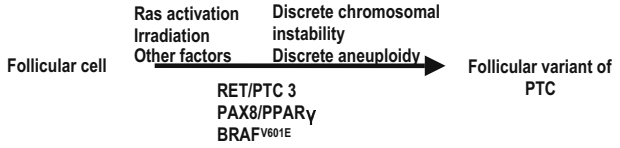
In contrast to the high prevalence of the V600E mutation in conventional PTC, a distinct *BRAF* mutation (K601E) has been detected in 9% of cases of FVPTC [67]. The $BRAF^{K601E}$ mutation has also been detected in two follicular adenomas of the thyroid [30, 59], but one cannot exclude the possibility that such $BRAF^{K601E}$ mutated lesions might represent misdiagnosed cases of FVPTC. Leaving this controversy aside, we think we have obtained enough evidence, after having searched for *BRAF* mutations in several hundreds of thyroid tumours and tumour-like lesions, to conclude that the $BRAF^{K601E}$ mutation is typical of FVPTC although much less frequent (about 7%) than the $BRAF^{V600E}$ in conventional PTC (46–75%) [65].

The 1802A–G transition leading to the substitution of a lysine by a glutamate in codon 601 ($BRAF^{K601E}$) that is detected in the FVPTC mimics the $BRAF^{V600E}$ mutation found in conventional PTC. Both types of mutation affect the activation segment of the protein, particularly the two adjacent residues (V600 and K601) that are localised between two major phosphoregulatory residues (T599 and S602) [11]. It was shown that the two mutations have high kinase activity in vitro [13, 68] and that the $BRAF^{V600E}$ has about 2.5× the kinase activity of $BRAF^{K601E}$ [68]. $BRAF^{V600E}$ and $BRAF^{K601E}$ mutations incorporate a negatively charged amino acid (glutamate) into the activation segment of *BRAF*; it was advanced that such glutamate may mimic the activating phosphorylation of T599 and/or S602 [13]. With so many similarities, the apparent specificity of the mutations vis-à-vis the PTC histotypes remains unexplained. Interestingly, in a microfollicular/solid variant of PTC, we have recently described [66], there was an in-frame triplet deletion of *BRAF* leading, again, to the replacement of a valine and a lysine by a glutamate in the same *BRAF* activation segment (*BRAF VK600-601E*) [66].

Besides the type of *BRAF* mutation, there are other molecular features of FVPTC that differ from those of conventional PTC. Some of those features resemble the molecular alterations that are thought to be characteristic of follicular carcinoma.

E-cadherin immunoexpression in FVPTC resembles that of follicular carcinoma (and normal thyroid) rather than that of conventional PTC [47, 55]. The same holds true regarding some cytogenetic alterations, namely gains at chromosome arms 2q, 4q, 5q, 6q, 8q and 13q and deletions at 1p, 9q, 16q, 17q, 19q and 22q and the 2;3 translocation [5, 48, 69, P. Castro et al., unpublished data].

The frequency of *RAS* mutations is much higher in FVPTC than in conventional PTC [70], thus contributing to approach the FVPTC to follicular carcinoma. We have recently confirmed the results of Zhu et al. with regard to the high prevalence of *RAS* mutations in FVPTC (P. Castro et al., unpublished data). We have found, furthermore, similar prevalence of *RAS* mutations [in most cases, in codon 61 of N-*RAS*] in follicular adenoma (33%), follicular carcinoma (22%) and FVPTC (25%) (P. Castro et al., unpublished data).



Finally, Roque et al. described in 2001, using conventional cytogenetics, the t(2;3)(q12;p25) in one case of FVPTC [48], and Wreesmann et al. [69], using immunohistochemistry, demonstrated in 2004 the overexpression of PPARγ in three cases; in one of these cases, the presence of rearranged *PPARγ* was detected by Southern blot [69]. After having detected in a small preliminary study the presence of the *PAX8–PPARγ* rearrangement in some cases of FVPTC [6], we confirmed such findings in a large series: the *PAX8–PPARγ* rearrangement was detected in 38% of the cases of FVPTC, in 33% of follicular adenomas, in 45% of follicular carcinomas and in no case of conventional PTC (P. Castro et al., unpublished data).

At variance with the rarity of the coexistence of *RAS* mutations and *PAX8–PPARγ* rearrangement in follicular tumours reported by Nikiforova et al. [44], we detected both alterations in 13% of the cases of FVPTC, as well as in 14% of follicular carcinomas and in 8% of follicular adenomas (P. Castro et al., unpublished data). The presence of both alterations was significantly associated with the younger

age of the patients, favouring the concept that such coexistence may lead to more rapidly growing tumours.

Taken together, all the aforementioned data support the conclusion that FVPTC shows genetic differences from conventional PTC and suggest that at least a subset of FVPTC shares some of the molecular features of follicular carcinomas.

The most important molecular features of FVPTC are summarised in the following scheme:

FVPTC cases, like most conventional PTCs, are slowly growing neoplasms that tend to give rise to lymph node metastases [3, 8, 50]. In 1985, Carcangiu et al. [3] pointed out that, differently from conventional PTC, some FVPTC cases were prone to give rise to lung metastases. It was observed, moreover, that the growth pattern of the encapsulated form of FVPTC mimicked that of follicular carcinomas, pushing borders and signs of capsular and/or vascular invasion [4, 8, 50]. Baloch and LiVolsi [2] showed that these encapsulated FVPTCs may give rise to blood-borne metastases in the absence of lymph node metastases.

We still ignore the putative prognostic meaning of the molecular alterations detected in FVPTC (*BRAF*^{K601E} mutation, *RAS* mutations and *PAX8–PPARγ* rearrangements). It remains also to be seen if the subset of FVPTC displaying genetic alterations of the follicular carcinoma-type encompasses cases particularly prone to give rise to lung and/or bone metastases.

Oncocytic (Hürthle cell) tumours

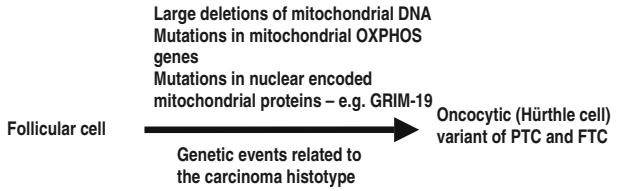
Tumours with oncocytic (Hürthle cell) features may be benign (oncocytic variant of follicular adenoma) or malignant (oncocytic variant of papillary carcinoma and oncocytic variant of follicular carcinoma). Medullary and poorly differentiated carcinomas may also display oncocytic features [14, 35, 46, 60].

It is also well established that oncocytes (Hürthle cells) occur frequently in non-neoplastic conditions such as Hashimoto thyroiditis, nodular goiters and atrophic glands of old individuals [35, 60]. The same holds true for oncocytic transformation in tumours and non-neoplastic conditions of other organs such as the salivary glands, parathyroids, pituitary and kidneys.

Hürthle cells are stuffed with mitochondria with morphologic, functional and genetic abnormalities [35, 60, 61]. The accumulation of the mitochondria may be due to a primary alteration of the mitochondrial DNA (mtDNA) or of the nuclear DNA (nDNA) that encodes mitochondrial enzymes [33, 34, 38]. The most typical mtDNA alteration in oncocytic cells is the presence of a large deletion (about 5 kb, which corresponds to one third of the total DNA in each mitochondrial chromosome) [38]. This large deletion is usually designated by "common deletion" and has been detected in oncocytic cells of Hashimoto thyroiditis and all sorts of oncocytic tumours of the thyroid, as well as in Warthin tumour of the salivary glands [29, 34, 38]. Point mutations in the mitochondrial genes encoding for enzymes of the complexes I, III, IV and V of the mitochondrial respiratory chain (MRC) have also been reported in oncocytic tumours of the thyroid [34]. The mitochondria containing deleted and/or mutated mtDNA proliferate more than "normal" mitochondria, thus leading to a progressive increase in the percentage of abnormal mitochondria [35]. The mechanism of tumour formation under these circumstances is not yet well understood; however, several possibilities have been advanced: (a) The mitochondrial abnormalities block the apoptotic process, increasing the survival of the cells [29]. (b) The deficient mitochondrial function is sensed as a hypoxic stimulus leading to increased levels of the inducible form of the hypoxia inducible factor-1 (HIF-1), which triggers some pro-angiogenesis pathways (and also proliferation?). (For a review on these two possibilities, see Ref. [16].)

Regardless of the mechanism(s) involved in the process, a deficient mitochondrial function leads to an increased number of mitochondria through the stimulation of mitochondrial proliferation [16, 34–36, 60].

The oncocytic variant of PTC has papillary carcinomas that have *RET/PTC* rearrangements and *BRAF* mutations with similar frequency as the non-oncocytic PTC [9, 65, 67]. With regard to the oncocytic variant of follicular tumours, it remains controversial whether or not such Hürthle cell tumours have similar prevalences of *RAS* mutations and *PAX8–PPARγ* rearrangements as their non-Hürthle cell counterparts [62, 63].



The molecular features of the oncocytic tumours of the thyroid are thus associated for one side with the mitochondrial abnormalities that are their hallmarks and, for the other, with the oncogenic alterations that are associated with the carcinoma histotype (e.g. *RET/PTC* rearrangements and *BRAF* mutations in PTC) [9, 33, 67].

The presence of abundant (and abnormal) mitochondria in the cytoplasm of the neoplastic cells may be seen throughout the entire tumour ("primary" oxyphilia, indicating that the carcinogenic hit has occurred in cells with abnormalities of the mtDNA or mitochondrial abnormalities resulting from the nDNA encoding mitochondrial enzymes) or just in some parts of the tumour ("secondary" oxyphilia, indicating that the mitochondrial abnormalities have occurred after tumour development) [1, 34, 35].

The familial forms of benign and malignant Hürthle cell tumours [26] may be due to a germline mutation in *GRIM-19*, a dual-function nuclear gene involved in mitochondrial metabolism and cell death. Downregulation of *GRIM-19* has been shown to confer a growth advantage on cells and to reduce the likelihood that they will enter apoptosis [1]. The detection of a *RET/PTC1* rearrangement in one case of the oncocytic variant of PTC in which there was also a *GRIM-19* mutation suggests that the latter mutation may serve as a predisposing alteration for the occurrence of

tumours with cell oxyphilia; other alterations such as *RET/PTC* rearrangement or *BRAF* mutation may be necessary for the acquisition of the malignant phenotype (for a thorough review, see Ref. [33]).

The most important molecular features of oncocytic (Hürthle cell) tumours are summarised in the following scheme:

The criteria used in the diagnosis of the oncocytic variants of papillary carcinoma and follicular carcinoma are those used in the diagnosis of conventional tumours, i.e. mainly the nuclear characteristics in PTC and the signs of capsular and/or vascular invasion in follicular carcinoma. In other words, the presence of oncocytic cells should not interfere with the diagnostic criteria in any of the thyroid tumour settings. The prognosis of patients with the oncocytic variant of PTC is similar to that of patients with conventional PTC (and the same holds true regarding follicular carcinomas) provided the age of the patients and the staging of the tumours are comparable [17, 60]. From a clinical standpoint, the only negative aspect of oncocytic carcinomas of the thyroid is their lesser ability to trap iodine, thus rendering them less responsive to radioactive iodine [35, 60].

Classification of types of intraductal papillary-mucinous neoplasm of the pancreas: a consensus study

Received: 17 May 2005 / Accepted: 24 June 2005 / Published online: 9 August 2005
© Springer-Verlag 2005

Abstract Now that more than two decades have passed since the first reports of intraductal papillary-mucinous neoplasms (IPMNs), it has become clear that IPMN consists of a spectrum of neoplasms with both morphological and immunohistochemical variations. At a meeting of international experts on pancreatic precursor lesions held in 2003, it was agreed that a consensus classification of IPMN subtypes should be established to enable a more detailed analysis of the clinicopathological significance of the variations. Based on our experience and on information from the literature, we selected representative histological examples of IPMNs and defined a consensus nomenclature and criteria for classifying variants as distinctive IPMN subtypes including gastric type, intestinal type, pancreato-

biliary type, and oncocytic type. These definitions can be used for further analyses of the clinicopathological significance of the variations of IPMN.

Keywords Pancreatic tumor · Intraductal papillary-mucinous neoplasm · Classification · MUC

Introduction

The first cases of intraductal papillary-mucinous neoplasm (IPMN) were reported in the 1970s and 1980s [17, 23]. In the 1990s, the term IPMN was coined, and the tumor was established as a special entity among the pancreatic neoplasms [25]. It was also found that IPMN is related to invasive pancreatic adenocarcinoma because one third of IPMNs have an associated invasive adenocarcinoma and some patients with a noninvasive IPMN subsequently develop either invasive colloid (mucinous noncystic) carcinoma or invasive ductal adenocarcinoma [5, 9, 10]. During the more than two decades that have passed since its first description, a number of reports have been published, and it has become clear that IPMNs include a spectrum of neoplasms with both morphological and immunohistochemical variations. These variations include neoplasms with tall columnar cells arranged in relatively short papillae without significant atypia, those with villous projections lined by cells with significant atypia, those with complex branching papillae containing cells with marked atypia, and those with oncocytic cells with complex papillae [2, 4, 8, 22, 30]. Several authors have proposed classification systems for the spectrum of morphologies seen in IPMNs [4, 8, 22, 30]. One such system divides IPMNs into clear-, dark-, and compact-cell types according to the density of the cytoplasm, shapes of the epithelial cells, and expression patterns of glycoproteins contained in mucin (MUCs), while another system separates IPMNs into intestinal, pancreatobiliary, and oncocytic subtypes primarily based on their architecture and cytology [4, 22, 30].

At a meeting of international experts on pancreatic precursor lesions held at the Johns Hopkins Hospital from August 18 to 19, 2003, a basic definition of an IPMN that is employed in the current study (Table 1) was worked out, and it was agreed that a consensus classification of IPMN subtypes should be established to make it easier to compare studies from different institutions and to improve patient care [14]. The purpose of this report is to establish consensus criteria for the classification of IPMN subtypes based on histological features and immunohistochemical reactivities with antibodies to specific types of mucin (MUCs).

Table 1 Definition of intraductal papillary-mucinous neoplasm of the pancreas [14]

Intraductal papillary mucinous neoplasm is a grossly visible, noninvasive, mucin-producing, predominantly papillary or rarely flat epithelial neoplasm arising from the main pancreatic duct or branch ducts, with varying degrees of duct dilatation. IPMNs usually produce a lesion greater than 1 cm in diameter and include a variety of cell types with a spectrum of cytologic and architectural atypia.

Materials and methods

Review of slides

Representative slides of candidate subtypes of IPMNs were selected from the pathology files of Tohoku University Hospital. They were chosen so as to represent a broad spectrum of the morphological variations of IPMN, based on discussions at the Baltimore meeting and including information from the literature and personal communications. The slide set consisted of ten cases. Each case consisted of four slides, one stained with hematoxylin and eosin and one each labeled for MUC1, MUC2, and MUC5AC. The slides were reviewed by the authors independently and subsequently discussed at an international meeting in Sendai, Japan (July 2004). The goal of this meeting was to establish an international consensus on the classification of IPMNs.

Immunohistochemistry

The primary antibodies employed were a monoclonal antibody to MUC1-core (clone Ma552, Novocastra Laboratories Ltd., Newcastle upon Tyne, UK, 1:100), a monoclonal antibody to MUC2 (clone Ccp58, Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA, 1:600), and a monoclonal antibody to MUC5AC (clone CLH2, Chemicon International Inc., Temecula, CA, USA, 1:1000). Paraffin sections cut at 4 μm were dewaxed with xylene and hydrated with serial immersing in 100, 90, 70, and 50% ethanol solutions and distilled water. Antigen retrieval was performed by incubating slides in boiled citric acid buffer (0.18 mM citric acid, 0.82 mM sodium citrate) for 15 min in a microwave oven. Indirect immunohistochemical labeling was performed as follows: The slides were incubated with PBS containing 0.3% hydrogen peroxide for 30 min to block the endogenous peroxidase activity. After washing with PBS, the slides were incubated with the primary antibody diluted in PBS containing 10% rabbit serum at 4°C overnight. After washing with PBS, the slides were incubated with the biotinylated rabbit anti-mouse IgG antibody solution (Nichirei, Tokyo, Japan) for 30 min at room temperature. The slides were then washed with PBS and incubated with streptavidin-horseradish peroxidase solution (Nichirei) for 30 min at room temperature. After washing with PBS, the slides were incubated with 3, 3′-diaminobenzidine tetrahydrochloride (DAB) diluted in PBS containing 0.05% hydrogen peroxide at a final concentration in 0.2 mg/ml. The slides were washed with running tap water and counterstained with hematoxylin.

Table 2 Consensus nomenclature and criteria for classification of features of four types of intraductal papillary-mucinous neoplasm of the pancreas

Type	Mimicker	Criteria	Atypia	MUC1	MUC2	MUC5AC
Gastric	Gastric foveolae	Thick finger-like papillae, eosinophilic > basophilic cytoplasm, basally located nuclei. This type may have abundant flat areas	Mild/ low-grade	−	−	+
Intestinal	Intestinal villous neoplasm	Villous papillae, basophilic > eosinophilic cytoplasm, enlarged oval and hyperchromatic nuclei with pseudostratification. This type may show low papillae consisting of cells with amphophilic cytoplasm	Moderate or severe/ high-grade	−	+	+
Pancreatobiliary	Cholangiopapillary neoplasm	Thin branching complex papillae, moderate amphophilic cytoplasm, enlarged hyperchromatic nuclei	Severe/ high-grade	+	−	+
Oncocytic	Oncocytic neoplasm	Thick branching complex papillae with intracellular and intraepithelial lumina, abundant eosinophilic (oncocytic) cytoplasm, large round nuclei with prominent nucleoli	Severe/ high-grade	+	−	+

Results

All participants agreed that the IPMN cases provided covered representative histological variations of IPMN and that they can be subclassified into four types. In the following, the consensus criteria for the classification of IPMN subtypes based on morphological features and the immunohistochemical reactivity for MUCs (Table 2) are presented.

The gastric-type IPMN consisted of cells resembling gastric foveolae and usually showed low-grade atypia corresponding to a diagnosis of intraductal papillary-mucin-

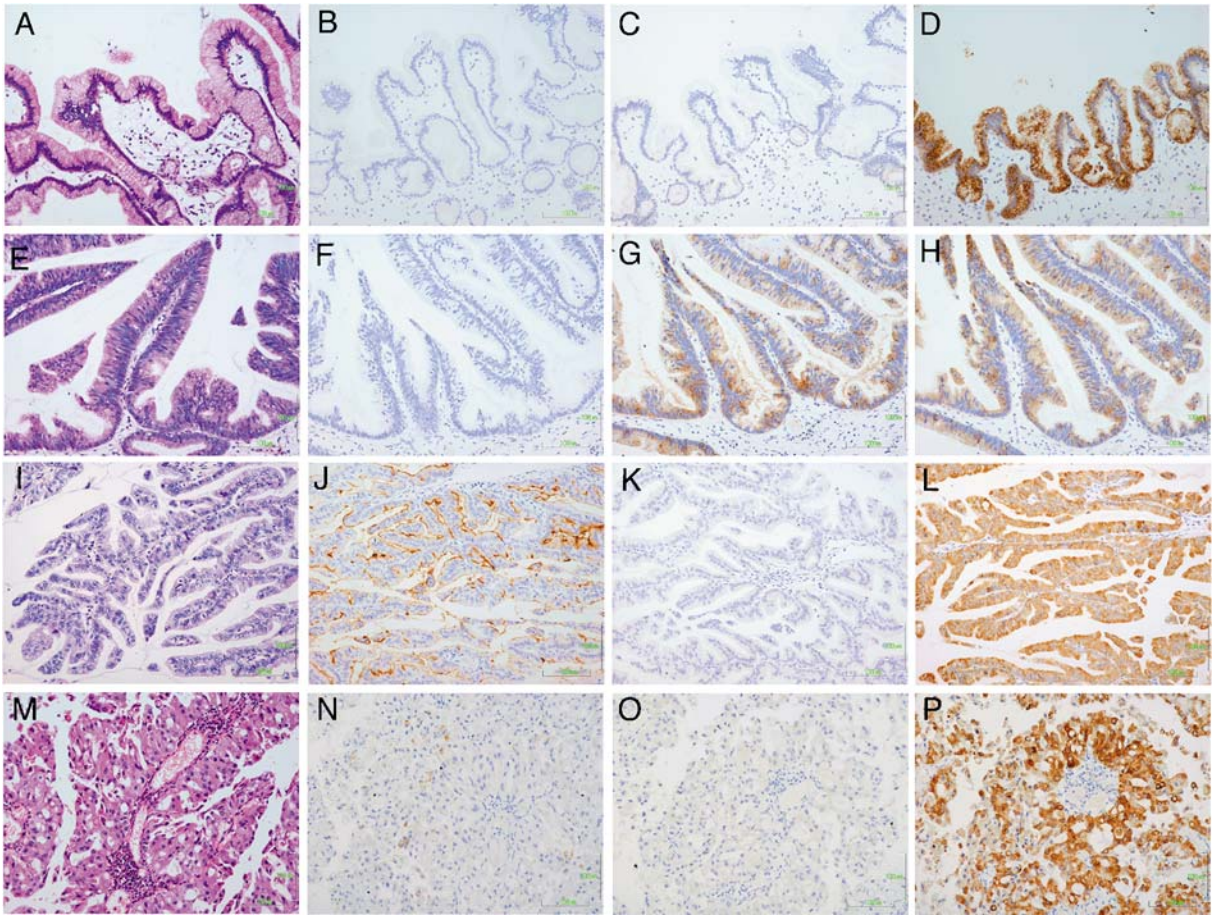

Fig. 1 Representative images of the subtypes of intraductal papillary-mucinous neoplasm of the pancreas. **a–d** The gastric type; **e–h** the intestinal type; **i–l** the pancreatobiliary type; **m–p** the oncocytic type. Hematoxylin and eosin staining (**a**, **e**, **i**, **m**) and immunohistochemical stainings of MUC1 (**b**, **f**, **j**, **n**), MUC2 (**c**, **g**, **k**, **o**), and MUC5AC (**d**, **h**, **l**, **p**)

ous adenoma (Fig. 1a). They expressed MUC5AC but were negative for MUC1 and for MUC2 (Fig. 1b–d). The gastric-type IPMN corresponded to the previously reported null type or the clear-cell type of IPMN [6, 22, 30]. The gastric-type IPMN often presented as a small cystic lesion involving branch ducts of the pancreas. This type of IPMN sometimes merged with other subtypes of IPMNs (Fig. 2c,d).

The intestinal-type IPMN resembled intestinal villous neoplasms with tall columnar epithelial cells that usually showed moderate- or severe/high-grade atypia corresponding to borderline or in situ carcinoma (Fig. 1e). It corresponded to the previously reported dark-cell type of IPMN [22, 30]. The intestinal-type IPMN usually showed large cystic lesions involving the main duct and several branch ducts. Occasionally, there were small papillae with goblet-cell-like appearance with low-grade atypia (Fig. 2a,b). The neoplastic cells consistently expressed MUC2 and MUC 5AC but were negative for MUC1 (Fig. 1f–h).

The pancreatobiliary type of IPMN consisted of cells resembling cholangiopapillary neoplasms and showed complex, thin, branching papillae with severe/high-grade atypia corresponding to carcinoma in situ (Fig. 1i). The lesion was at least focally positive for MUC1 and consistently expressed MUC5AC but not MUC2 (Fig. 1j–l).

The oncocytic type of IPMN consisted of cells with abundant, intensely eosinophilic cytoplasm and showed complex thick papillae with intraepithelial lumina and severe/high-grade atypia corresponding to carcinoma in situ (Fig. 1m). The oncocytic type of IPMN corresponded to the previously reported compact-cell type IPMN [22]. This IPMN subtype expressed MUC5AC consistently and MUC1 focally but was negative for MUC2 (Fig. 1n–p).

While it was the consensus of the group that the classification of IPMNs into these well-defined subtypes will help standardize the reporting of IPMNs, it was recognized that IPMNs often are composed of a combination of more than one cell type. The group therefore proposed that each IPMN should be subclassified by the dominant component and that any other significant subtypes present should be documented. In case of an invasive carcinoma associated with IPMN, the subtypes of the intraductal component should be evaluated and noted, especially in areas associated with the invasive component.

Examples of mixed areas combining the gastric type and the intestinal type (**c**) and the gastric type and the pancreatobiliary type (**d**). Images show immunohistochemical stainings of MUC2 (**c**) and MUC1 (**d**)

Discussion

The diagnostic term IPMN encompasses a spectrum of intraductal mucin-producing neoplasms composed of a variety of cell types showing distinctive architectural and histochemical features [19, 25]. An international panel of experts was assembled to establish a nomenclature for classifying the subtypes of IPMNs. Based on the experience of the panel, information from the literature, and a review of a selected series of IPMNs, consensus criteria for the classification of subtypes of IPMNs were agreed upon. These definitions should facilitate further analyses of the clinicopathological significance of the variations of IPMN.

The panel of experts agreed unanimously that four types of IPMN can be distinguished among the series of cases that had been studied. These IPMN types were classified as gastric, intestinal, pancreatobiliary, or oncocytic type.

According to the currently available data, the gastric-type IPMN usually presents as relatively small cystic lesions in peripheral branch ducts with low-grade atypia, mostly corresponding to intraductal papillary-mucinous adenoma, while the other subtypes of IPMN usually present as large lesions involving the main duct and connecting branch ducts with marked atypia, mostly corresponding to intraductal papillary-mucinous neoplasm in the borderline category or intraductal papillary-mucinous carcinoma [4, 28]. These latter types of IPMN are often associated with an invasive adenocarcinoma [10, 18, 28].

We present this subclassification of IPMN to aid in the comparison of studies from different institutions. One interpretation of our findings is that the types of IPMN described here may simply be a manifestation of a spectrum in the differentiation and progression of a single lineage of IPMN and that these morphologies may, in part, reflect the degree of dysplasia. IPMN may be a progressive neoplastic lesion, in which a small cystic lesion with low-grade atypia may progress to large multicystic ductal lesions with severe atypia and complex histological architecture and, eventually, to invasive cancer. Areas with gastric-type epithelium can be associated with the other subtypes, implying that the gastric type might be a common precursor of the other types [6], although we feel that such a conclusion is premature. Whether the IPMN types we defined are truly distinctive lineages or variations of a single progressive neoplastic lineage should be further clarified by clinicopathological and molecular studies based on the definitions provided. One study on 51 pancreata with IPMNs that compared the various subtypes of IPMN and aberrations of tumor suppressor genes, includ-

ing CDKN2A, TP53, SMAD4, and DUSP6, revealed no significant association [11]. It is hoped that such studies will lead to an understanding of the mechanisms by which IPMNs develop and progress.

Pancreatic intraductal neoplasms consisting mainly of tubular glands of pyloric-gland type have been reported and designated as "intraductal tubular adenoma" [7, 15]. We did not include examples with predominantly tubular growth in the current study. However, because focal tubule formation is often observed in IPMNs, especially those of the gastric type or the pancreatobiliary type, the authors would assume that tubular growth may occur in IPMNs and that neoplasms with a predominantly tubular pattern may correspond to intraductal tubular adenoma, pyloric-gland type. The coexistence of papillae and tubules in both IPMNs and intraductal tubular adenoma suggests that they may be closely related, albeit distinctive, morphological features.

MUCs are useful markers for evaluating subtypes of IPMN [13, 20–22, 29, 30]. MUC1 is a component of the membrane-bound type of mucin and is usually detected in intralobular ductal lumina in the normal pancreas [1]. MUC1 is expressed in invasive ductal adenocarcinoma of the pancreas, often showing extensive positivity [24]. Among the IPMN subtypes, the pancreatobiliary type usually shows positivity for MUC1, which parallels its association with invasive ductal adenocarcinoma of the conventional tubular type [6]. The oncocytic type expresses MUC1 focally, and while it has been reported to be associated with invasive oncocytic carcinoma, its association with invasive ductal carcinoma is unknown [2]. MUC2 consists of secreted mucin usually observed in intestinal glands and is considered to be a marker of intestinal differentiation [12]. The intestinal type of IPMN, of both villous and goblet-cell features, strongly expresses MUC2 [6, 13, 21, 22, 24, 30]. The intestinal differentiation of this subtype of IPMN was supported by the demonstration that they also express CDX2, a homeobox gene involved in intestinal development [6]. MUC5AC is expressed by mucous surface cells of the stomach. MUC 5AC is not detected in the normal pancreas but is consistently detected by immunohistochemistry in all types of IPMN [13, 30]. It is also known that pancreatic intraepithelial neoplasia (PanIN), precursor lesions associated with invasive ductal adenocarcinoma, also consistently express MUC5AC [16, 21]. PanINs are usually negative for MUC2 but often express MUC1, especially in high-grade atypical lesions [5]. The differential diagnosis between PanIN and IPMN was discussed in detail in a previous publication [14].

The prognosis of patients with an IPMN has been shown to depend on the presence or absence of an associated invasive carcinoma and, if an invasive carcinoma is present, on the histological type of the associated invasive carcinoma [26]. Invasive carcinomas associated with IPMN largely consist of two distinct types, invasive carcinoma mimicking usual invasive ductal adenocarcinoma and invasive colloid (mucinous noncystic) carcinoma [5, 21]. Patients with an IPMN associated with an invasive colloid (mucinous noncystic) carcinoma usually have a better prognosis than do those with an associated invasive ductal adenocarcinoma [3, 5].

The classification proposed is based primarily on morphological features. The immunolabeling for MUCs may serve as a confirmatory marker for the classification. We believe our definitions may contribute to an understanding of the biologic behavior of IPMN and to better clinical management. For example, it would be valuable to determine whether a particular type of noninvasive IPMN is associated with a particular type of invasive adenocarcinoma. It will be also of interest to clarify the relationship of the intraductal tubular neoplasm of the pancreas [27] with the types of IPMN described herein.

Pancreatic fibrosis associated with age and ductal papillary hyperplasia

Received: 17 May 2005 / Accepted: 15 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract Little is known about the frequency, type and pathogenesis of fibrotic changes that may occur in the pancreas of persons without any clinically apparent or macroscopically visible pancreatic disease. We screened pancreas specimens for the presence and pattern of fibrosis, determined the relationship between fibrosis, age, and duct lesions, and studied the fibrogenic mechanisms. In 89 postmortem specimens from persons without any known pancreatic disease (age range 20–86 years), fibrosis was recorded and graded and the patients were divided into two age classes (younger or older than 60 years). In addition, we analyzed the association between ductal papillary hyperplasia [i.e., pancreatic intraepithelial neoplasia type 1B (PanIN-1B)] and fibrotic foci in the pancreatic tissue to determine the potential impact of obliterating duct lesions on pancreatic fibrosis. Finally, we studied the occurrence in the pancreas of myofibroblasts, identified on the basis of their α-SMA and desmin positivity, and determined their relationship to the fibrotic foci. Thirty-eight (44%) of 89 pancreata showed scattered foci of lobular fibrosis affecting peripheral lobuli. Fibrotic changes were significantly more common in individuals older than 60 years. Fibrotic foci were commonly associated ($p<0.05$) with ductal papillary hyperplasia in ducts draining fibrotic lobuli. Myofibroblasts were detected in the fibrotic foci. The "normal" pancreas develops a specific type of focally accentuated fibrosis that is highly age related. This patchy lobular fibrosis in the elderly (PLFE) was closely associated with PanIN-1B lesions in the ducts, suggesting that the narrowing of a duct due to papillary hyperplasia of the epithelium may hamper secretion and cause fibrosis of the drained lobule. The presence of myofibroblasts in association with the fibrotic foci indicates an ongoing fibrogenic process.

Introduction

Fibrotic changes are the hallmark of chronic pancreatitis (CP) [3, 15, 16], but may also be observed in the "normal pancreas," i.e., the pancreas of persons without any known or macroscopically visible pancreatic disease. The first indications of an association between fibrosis and age came from a study by Pitchumoni et al. [22]. The patients examined were divided into two groups, alcoholics and nonalcoholics. Diffuse fibrosis was found in the alcoholics, which contrasted with the patchy type of fibrosis seen in the aged nonalcoholics, but the authors did not analyze the pathomechanisms of fibrosis in the aged nonalcoholics and no clear typing of the fibrotic changes was attempted. Fibrotic changes were also described by Stamm [27] and Shimizu et al. [25] in normal pancreatic specimens, but only in Stamm's study were they related to age. Both authors observed an association between fibrosis and ductal papillary hyperplasia. In another study that used photometric measurements to determine the collagen content of histologic sections from the pancreas of patients with CP or subjects with pancreatic disease, no information was given on the distribution of fibrotic foci or the relationship between fibrosis and age [29].

The aim of our study was to gain insights into the pathogenesis of pancreatitic fibrosis that is not associated with the clinical symptoms of CP. We therefore examined the type and extent of pancreatic fibrosis in humans without any known pancreatic disease and related the data to age. In addition, we focused on changes in the ducts draining the fibrotic lobules. These duct changes have become known as "ductal papillary hyperplasia" [18] and were recently classified among the precursor lesions of pancreatic ductal adenocarcinoma as pancreatic intraepithelial neoplasia type 1B (PanIN-1B) [8]. We show here that the fibrosis in the normal pancreas has a patchy distribution with a lobular pattern and a clear relationship to age and to duct

narrowing due to epithelial hyperplasia. Finally, we studied the occurrence of myofibroblasts, identified by their α-SMA and desmin positivity, and identified these cells in association with fibrotic foci.

Materials and methods

Tissue

Paraffin-embedded postmortem specimens were obtained from 89 patients. All cases derived from persons without clinically recognized or macroscopically evident pancreatic disease and were fixed in 10% buffered formalin. The specimens came from three different institutions, the Departments of Pathology of the University of Kiel, Germany, the Kaiser-Franz-Josef-Hospital, Vienna, Austria, and the Semmelweiss University, Budapest, Hungary. All patients had died of nonpancreatic disease, most frequently of cardiovascular, neoplastic, or respiratory disease.

The persons were between 20 and 86 years old. They were divided into two groups based on age, one from 20 to 59 years old (n=39, mean age 46.8 years, 8 women and 31 men), the other 60 years or older (n=50, mean age 72.4 years, 11 women and 39 men). From each pancreatic specimen, eight paraffin-embedded sections deriving from different regions in the pancreas were examined as described by Lüttges et al. [21]: two blocks were taken from the upper part of the head, including the main pancreatic duct (region A), and two further blocks from the lower part of the head with the accessory duct (region B). Two blocks each were taken from the body (region C) and the tail (region D). Three-micrometer-thick sections were stained with hematoxylin and eosin (H & E).

In addition, we examined 59 cases of alcoholic chronic pancreatitis (ACP) to compare the extent and pattern of pancreatic fibrosis in the normal pancreata with that in ACP patients. In these cases, two to three paraffin-embedded tissue blocks from pancreatic resection specimens of 44 men and 15 women with ACP, mean age 47.6 years, age range 31 to 86 (42 Whipple resections, 17 left-sided pancreatic resections), were available. The patients suffered from symptoms of CP (intractable pain, pseudocyst, jaundice).

Histological evaluation

The extent and intensity of pancreatic fibrosis were determined using a scoring system based on the pattern of fibrosis [focal vs diffuse, perilobular (interlobular) vs intralobular] [3]. Intralobular and perilobular fibrosis were scored on a scale from 1 to 6, with 1 (focal, weak), 2 (focal, moderate), 3 (focal, strong), 4 (diffuse, weak), 5 (diffuse, moderate), or 6 (diffuse, strong). In addition, the number of PanIN-1B lesions and their association with fibrotic foci were recorded in each pancreas. We assigned to each case only one PanIN-1B lesion, regardless of how many PanIN-1B lesions were found in an individual pancreas. A spatial association between a PanIN-1B lesion and fibrotic changes was assumed when a PanIN-1B lesion was found in close vicinity to or in direct connection with a fibrotic focus. Only one fibrotic focus connected with a PanIN-1B lesion was assigned to each case.

Immunohistology

Myofibroblasts were identified in the "normal pancreas" by immunohistological labeling with alpha smooth muscle actin (α-SMA, DAKO, Glostrup, Denmark, 1:20) and desmin (DAKO, 1:20).

Statistics

The χ^2 test (SPSS for Windows, version 10.1) was used to compare (1) the number of 20- to 59-year-old subjects with pancreatic fibrosis with that of the 60- to 86-year-old subjects showing the same change in the pancreas and (2) the number of subjects with fibrotic foci and associated PanIN-1B lesion with the number of subjects who had PanIN-1B lesions that lay between normal lobuli.

Results

Persons whose age ranged from 20 to 59 only rarely exhibited pancreatic fibrosis. In most cases, the lobular arrangement of the parenchyma was preserved and the ducts it contained were surrounded by a fibrotic band (Fig. 1). In a few cases (6/39, 15.4%) there were single foci of perilobular and intralobular fibrosis (Fig. 2 and Table 1). The person with the lowest age presenting a fibrotic focus was 40 years old. In contrast, normal pancreata from 60- to 86-year-old subjects commonly showed focal lobular fibrosis, usually affecting peripheral lobes and often containing remnants of acini, small ducts, some islets and small lymphocytic aggregates (Fig. 2). Some ducts contained eosin-

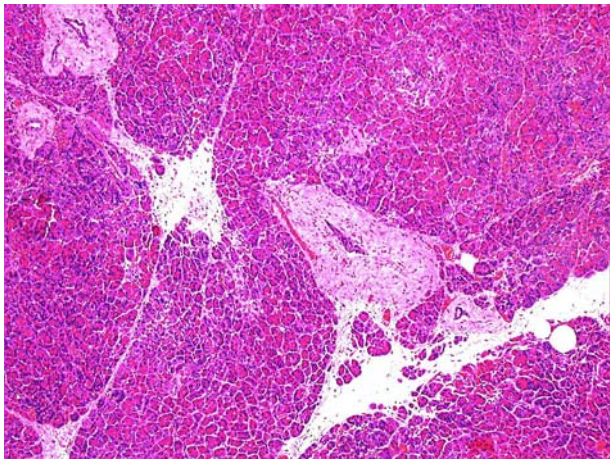

Fig. 1 Normal pancreatic tissue from an individual older than 60 years. H & E

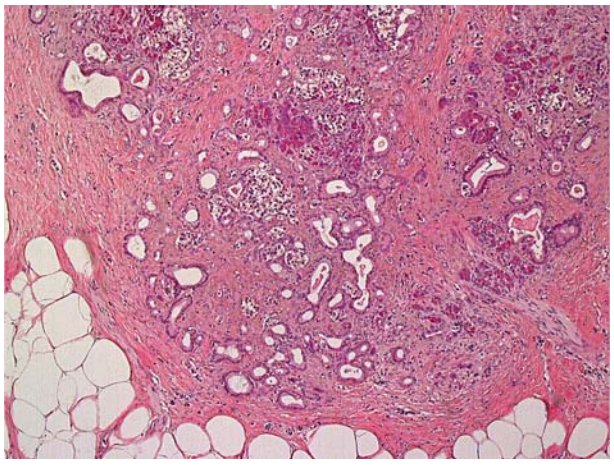

Fig. 2 Pancreatic tissue from an individual older than 60 years showing lobular fibrosis. H & E

ophilic secretions. Islet amyloidosis was detected in two pancreata and was not associated with fibrosis. The fibrotic changes were found in 32 (64.0%) of 50 cases (Table 1). The average fibrosis score was 0.9 for intralobular fibrosis and 0.7 for perilobular fibrosis. The number of fibrotic foci that were observed in the eight sections obtained from one pancreatic specimen ranged from one to seven, with an average of three. The fibrotic foci were randomly distributed in the pancreas. The number of pancreata affected by fibrosis and the grade of fibrosis in the individual pancreata increased with age, as demonstrated in Table 1 ($p<0.001$). Fibrosis was much more intense in ACP cases than in the "normal" pancreata. Whereas in the "normal" pancreata intra- or perilobular fibrosis never exceeded grade 3 (Table 1), it reached grade 5 and 6 in almost 70% of the resection specimens from patients with ACP. Moreover, a comparison of the patterns of fibrosis revealed that in ACP perilobular fibrosis was much more prominent than in the normal pancreas.

Pancreatic duct lesions of PanIN type 1A and 1B were found in a frequency similar to that previously reported [4, 21, 27]. Here we recorded only the PanIN-1B lesions and their spatial association with fibrotic foci in the pancreas. Persons whose age ranged from 20 to 59 only rarely exhibited PanIN-1B lesions (4/39, 10.3%) and there was only one case in which a PanIN-1B lesion was associated with fibrosis (Table 2). In contrast, normal pancreata from

Table 1 Grade of fibrosis in persons without any clinically known pancreatic disease, related to two age classes (50 subjects older and 39 subjects younger than 60 years)

Grade	Age 20–59		Age 60–84

0	34/39	33/39	22/50	18/50
1	5/39	5/39	24/50	25/50
2	–	1/39	3/50	3/50
3	–	–	1/50	4/50
4–6	–	–	–	–

Table 2 Spatial association of PanIN-1B (ductal papillary hyperplasia) with fibrosis in persons without any known pancreatic disease, related to two age classes (older and younger than 60 years)

Age	No. of examined cases	No. of cases with PanIN-1B	No. of cases with PanIN-1B and associated focal fibrosis
20–59	39	4/39	1/4
60–84	50	31/50	25/31

60- to 86-year-old subjects commonly showed PanIN-1B lesions (31/50, 62.0%). In these persons, the PanIN-1B lesions were more common in or near to fibrotic lobuli (25/31, 80.6%) (Fig. 3, Table 2) than in pancreatic lobuli unaffected by fibrosis. Table 3 shows the total number of fibrotic foci, of PanIN-1B lesions, and of fibrotic foci associated with PanIN-1B lesions identified in the eight sections (covering four different pancreatic regions) available from each patient. The association between PanIN-1B and fibrosis was statistically significant ($p<0.002$). The PanIN-1B lesions found in ACP were randomly distributed in the tissue and did not show any increased association with foci of fibrosis.

Most fibrotic foci that were found in "normal" pancreata showed myofibroblasts, which were recognizable by their expression of α-SMA (Fig. 4), and occasionally also desmin. The myofibroblasts were often seen in a perilobular position. In the pancreata without fibrosis, some scattered myofibroblasts were often detected around large ducts.

Discussion

Textbooks on anatomy and histology mention that the pancreas is surrounded by a thin, fibrous capsule and that the pancreatic ducts are surrounded by thin cords of connective tissue [11, 13], but mention nothing about pancreatic fibrosis developing in elderly patients. This is because so far only few studies have described fibrosis in pancre-

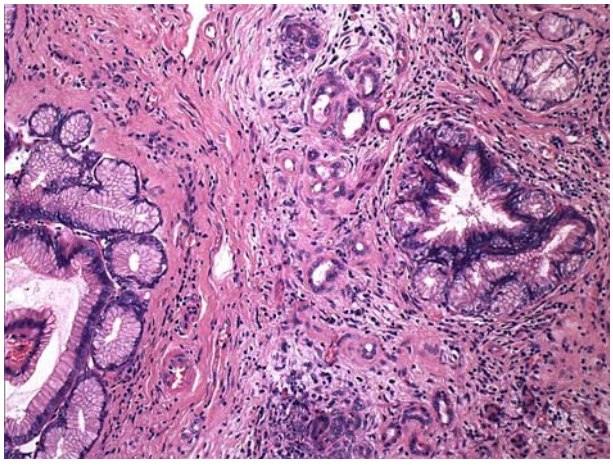

Fig. 3 Pancreatic tissue from an individual older than 60 years showing ductal papillary hyperplasia (PanIN-1B lesion) in association with fibrosis. H & E

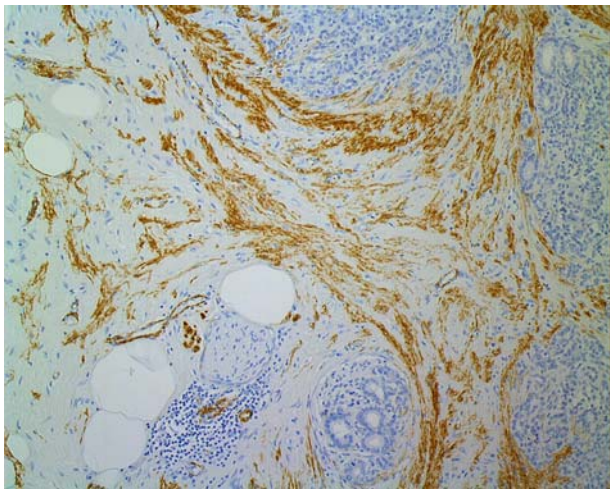

Fig. 4 Pancreatic fibrosis in an individual older than 60 years associated with myofibroblasts showing α-SMA immunoreactivity. ×50

ata that were regarded as normal, i.e., that were not affected by any clinically obvious disease known to lead to fibrotic changes in the pancreas. Pitchumoni et al. [22], Shimizu et al. [25], and Stamm [27] reported age-related fibrotic changes in the normal pancreas, without typing or grading the fibrosis or discussing its pathogenesis. One study quantified fibrosis in the normal pancreas, compared to that in CP [29] and two other studies focused on ectatic changes in the pancreatic duct system and noted in these areas periductal fibrosis that increased with age [2, 23].

We examined 89 postmortem specimens and determined the distribution of fibrosis, graded it, and related it to two age classes (younger or older than 60 years). We found an age-dependent development of fibrosis in the pancreas of persons who had no clinically apparent pancreatic disease and whose pancreas showed no macroscopic changes. Our evaluation of sections from eight different regions of the pancreatic head, body, and tail revealed fibrotic foci with increasing frequency in persons older than 60 years. Before the age of 60, these fibrotic foci were very rare. Fibrotic foci occurred in the periphery of the glands and involved one or two lobuli where the acinar cells were replaced by connective tissue. The resulting pattern of fibrosis may be described as a predominantly intralobular fibrosis since the fibrotic changes appeared to start within the lobule and not in the perilobular space, as has been suggested for ACP [3, 15], and was also seen in our series of pancreatic specimens from patients with ACP. Furthermore, because most pancreata contained more than one fibrotic focus, the pattern of fibrosis was that of multifocal intralobular fibrosis which we termed "patchy lobular fibrosis in the elderly" (PLFE).

In the subjects whose pancreatic specimens were analyzed there was no evidence of CP. This implies that the development of PLFE is most likely not mediated by a process triggered by any of the known factors that may cause CP [17]. That PLFE was age-related and usually in-

volved single peripheral lobuli suggested a causative factor that is focally active and needs time to exert its effect. From tumors such as ductal adenocarcinomas affecting the head of the pancreas and obstructing the main pancreatic duct it is known that this obstruction may lead to a replacement of the acinar tissue by fibrosis, a change called obstructive CP. The experimental model of this disease is the duct ligation procedure, which results in similar alterations in the pancreas upstream of the ligation [9, 10, 30]. As the fibrotic changes resembled obstructive CP as seen in experimental duct ligation, we searched for obliterating changes in the ducts draining the lobules affected by fibrosis. Narrowing of the duct lumen can be caused by papillary proliferations of hypertrophic duct epithelium, formerly described as "ductal papillary hyperplasia" [6, 14, 18, 19, 26]. This change in the duct epithelium has recently been classified among the precursor lesions of pancreatic ductal adenocarcinoma as pancreatic intraepithelial neoplasia type 1B (PanIN-1B) [8]. It occurs not only in association with pancreatic cancer, but also in the nonneoplastic pancreas [4, 14, 20, 21, 27]. When we analyzed this duct lesion in our pancreatic specimens, we found a close association between PanIN-1B lesions and lobular fibrotic foci. This suggests that PanIN-1B lesions may cause partial obstruction of the respective duct and thus a decrease in the flow of pancreatic fluid, promoting apoptosis of acinar cells, followed by their replacement by fibrosis.

Myofibroblasts (that are also regarded activated pancreatic stellate cells) are known to play a pivotal role in fibrogenesis in the pancreas (for a review see [15]) and have been described in the human pancreas [5]. We therefore studied the occurrence of myofibroblasts, identified by their α-SMA and desmin immunoreactivity [5], in the normal pancreata and found them in association with many of the fibrotic foci. This implies that there is an ongoing process of fibrogenesis in these areas, probably triggered by the hampered flow of secretions in the narrowed draining ducts. Experimental work has shown that the cytokines platelet-derived growth factor B and transforming growth factor β cause activation and proliferation of the resident fibroblasts, inducing them to transform into myofibroblast cells, which are capable of producing extracellular matrix [7, 15, 24]. Our data indicate that PanIN-1B lesions in the normal pancreas of elderly persons may provoke such damage to acinar cells due to decreased flow of pancreatic fluid in the ducts, followed by phagocytosis of acinar cells. Afterwards these cells appear to be replaced by connective tissue synthesized by myofibroblasts.

In summary, our study shows that focal lobular fibrosis in the normal pancreas commonly occurs in subjects who are older than 60 and is most likely caused by duct-obstructing PanIN-1B lesions. It will be interesting to clarify whether the peripheral PanIN-1B lesions are also connected with the peripheral cystic changes in the pancreas described by Kimura et al. [12] and the intraductal papillary mucinous neoplasms that occur in the periphery of the pancreas, show gastric foveolar type epithelium and stain for MUC5AC [1, 28].

Expression of small intestinal and colonic phenotypes in complete intestinal metaplasia of the human stomach

Received: 9 February 2005 / Accepted: 26 June 2005 / Published online: 9 August 2005
© Springer-Verlag 2005

Abstract The incomplete intestinal metaplasia (IM) that is reported to be a risk factor for gastric carcinogenesis in man usually features sulfomucin production and thus is considered of colonic type. To cast light on the underlying mechanisms, we here examined the proportions of colonic and small intestinal phenotypes in IM by immunohistochemistry and real-time reverse transcription–polymerase chain reaction at the single isolated gland level. Carbonic anhydrase 1 (CA1) is a specific marker of colonic epithelial cells, whereas sucrase is specific to absorptive cells of the small intestine. Totals of 139 (23.5%) and 452 (76.5%) IM glands were judged to be CA1 positive and CA1 negative, respectively, in resected pyloric mucosa from cancer patients. The average score for MUC5AC in CA1-positive IMs was significantly lower than in CA1-negative counterpart tissue ($P<0.0001$), whereas the opposite was the case for sucrase ($P<0.0001$). High iron diamine–Alcian blue staining revealed CA1 expression to coincide with type I complete IM. The expression of CA1 mRNA strongly correlated with that of sucrase–isomaltase, and inversely with that of MUC5AC in isolated IM glands. In conclusion, CA1 could be colocalized with small intestinal proteins such as sucrase, but only rarely with the gastric mucin, MUC5AC. Its expression warrants further study, with the focus on stimulation and/or suppression mechanisms by gastric and intestinal transcription factors.

Introduction

Intestinal metaplasia (IM) has been extensively studied as a possible premalignant condition in the human stomach [2, 24, 36, 52, 55]. However, many questions remain regarding its pathogenesis as well as the actual relationship to gastric cancers. Several classifications of IM have been suggested by pathologists. Kawachi et al. [16] first proposed division into complete and incomplete types on the basis of morphology. Jass and Filipe [14] described three grades of IM with classical mucin staining. These classifications are generally accepted, but are only based on intestinal properties and do not take into account the gastric properties that are still preserved in association [45]. We have therefore previously proposed a new IM classification based upon the cell differentiation status using both gastric and intestinal epithelial cell markers, such as MUC5AC, MUC6, MUC2, and villin [13, 45, 49]. Division is into two major types: a gastric-and-intestinal-mixed type (GI-IM) and a solely intestinal type (I-IM). Thus, it is important to analyze not only intestinal phenotypic expression but also the contribution of gastric elements within IM glands.

Several studies have provided evidence that type III intestinal metaplasia (incomplete sulphomucin-secreting intestinal metaplasia) may be a risk factor for gastric carcinogenesis [10, 12], although this remains controversial [6]. Classification based upon mucin secretion patterns as well as morphology has allowed division into a “small intestine type” and a “colonic type” [32, 46], although this has hitherto not been confirmed with small intestinal and colonic specific markers. With regard to the distribution of intestinal epithelial cell markers such as villin and MUC2 in the normal human alimentary tract, most are present in both the colon and the small intestine. However, carbonic anhydrase 1 (CA1) is found only in epithelial cells located on the luminal side of colonic mucosa, and not in the small

intestine [29, 35]. Conversely, sucrase is detectable on the luminal surfaces of mature small intestinal absorptive cells, but only rarely in colon [51]. Therefore, regarding intestinal phenotypic expression, CA1 can be used to indicate the colonic phenotype, whereas sucrase is representative of a small intestinal phenotype. The clinicopathologic significance of colonic and small intestinal phenotypes has yet to be clarified in detail for IM. Indeed, to our knowledge, there have been no reports of expression of CA1 in IM.

Most studies for gene expression for IM have been performed using whole tissue [7, 19]. However, it is impossible to avoid contamination of epithelial cell elements with stromal or inflammatory cells using this approach. We have previously established a novel "gland isolation technique" for the isolation of pyloric and IM glands and performance of relative quantitative real-time reverse transcription–polymerase chain reaction (RT-PCR) analysis of gastric and intestinal transcription factors as well as differentiation marker genes [49]. This technique made it possible to analyze gene expression separately in each isolated gland without contamination [20]. In isolated GI-IM glands, we confirmed the expression of both gastric and intestinal transcription factors as well as differentiation markers [49].

In the present study, we evaluated the transcription of CA1, sucrase–isomaltase, and MUC5AC by relative quantitative real-time RT-PCR in individual isolated glands and analyzed the interrelationships among the markers. We also examined the expression of these markers in IMs by immunohistochemistry, with reference to histological and phenotypic classification using other epithelial cell markers.

Materials and methods

Human tissue

A total of 15 stomachs, resected because of gastric cancer at Aichi Cancer Center Hospital, were investigated. This study using human tissue was conducted with approval from the Ethical Review Board of Aichi Cancer Center and after obtaining informed consent from the patients. Non-neoplastic pyloric mucosa distant from carcinomas, at least 10 cm from the tumor margins, was collected and used for RNA analysis after gland isolation as previously described [49]. After surgery, samples were fixed in 10% buffered formalin and embedded in paraffin. Serial sections were cut at 4 μm, one being stained with hematoxylin and eosin (H&E) for routine histological and others for immunohistochemical assessments as previously described [23]. Fresh normal mucosal samples of gastrointestinal tract (antrum of the stomach, jejunum, sigmoid colon) and specimens from each IM region in the pyloric mucosa with chronic gastritis were also obtained with informed consent from other patients and stored at −80°C as previously described [19].

Mucin histochemistry and immunohistochemistry

For mucin histochemistry, Alcian blue (AB) (pH 2.5) staining was performed as described [49]. Immunohistochemical staining was carried out with antibodies against the following antigens: CA1 (Chemicon International, Temecula, CA, USA), Cdx2 (BioGenex, CA, USA), MUC5AC (Novocastra Laboratories, Newcastle upon Tyne, UK), MUC2 (Novocastra), and villin (BD Transduction Laboratories, Lexington, KY, USA). The polyclonal rabbit anti-sucrase antibody was kindly provided by Dr. Kazuyuki Hirano, Department of Pharmaceutics, Gifu Pharmaceutical University, Gifu, Japan. The precise procedures for immunohistochemical techniques were as previously described [21–23, 49–51]. Two independent pathologists (T. T. and K. I.) judged the histology, mucin histochemistry, and immunohistochemical staining of epithelial cell markers, including Cdx2. Reactivity for CA1, MUC5AC, and sucrase was scored according to the rate of mucous cells above the proliferative cell zone in each gland of the pyloric areas on a 3-point scale: score 0, no positive mucous cells; score 1, 0%<positive cells≤35%; score 2, 35%<positive cells≤70%; score 3, 70%<positive cells. Results for CA1 or MUC5AC were considered positive with a score 1 or more. Using the scoring criteria, we evaluated 850 glands, 259 pyloric and 591 IM, in the pyloric region of 10 CA1-positive surgically resected IM cases. Similarly, 444 IM glands were judged for high iron diamine (HID)-AB staining patterns and classified into three subtypes as detailed by Jass and Filipe [14]. The data were analyzed by the Mann–Whitney's U test or the Fisher's exact test for differences between the groups. P values <0.05 were considered statistically significant.

Double immunohistochemical staining of CA1 and sucrase

Double staining of CA1 and sucrase was achieved basically as we previously described [28, 44]. Sections were deparaffinized, hydrated with ethanol, and autoclaved at 121°C in water for 10 min. They were then incubated with goat polyclonal anti-CA1 antibodies at 4°C overnight. Sections were then exposed to biotin-labeled anti-goat IgG and avidin–biotin peroxidase complex (Vector), and binding sites were visualized with DAB as the chromogen. Then, the antibody complex was removed with autoclaving, and the slides were thoroughly washed with Tris-buffered saline (TBS), then incubated with rabbit polyclonal anti-sucrase antibody at 4°C overnight, followed by alkaline phosphatase-labeled chicken anti-rabbit IgG (Chemicon). Color was developed using the DAKO fast red substrate system (DakoCytomation, Glostrup, Denmark) in the presence of levamisole (Sigma Chemical Co., St. Louis, MO, USA), and sections were counter-stained with hematoxylin. By the double staining, CA1-positive cells were stained brown, and sucrase-positive cells red.

Gland isolation

Gland isolation was performed as previously described [20, 49]. Remaining portions of resected epithelium were injected with calcium- and magnesium-free Hanks' balanced salt solution containing 30 mM ethylenediaminetetraacetic acid (EDTA-HBSS) submucosally, incubated in EDTA-HBSS, and shaken for 15 min at 37°C. Then the mucosa was scraped off with a scalpel. Isolated glands were washed in phosphate buffered saline, fixed in 70% ethanol for a few hours, dehydrated with 95% ethanol, and stored at −20°C until use.

Mucin cytochemistry and classification of isolated glands

The phenotypic classification of isolated glands was performed with AB staining as described earlier, based on the presence of goblet cells and pyloric glands, instead of with detailed immunohistochemical analyses to avoid degradation of RNA [45, 49]. Glands exhibiting AB-positive goblet cells in the upper part and an AB-negative bottom region (pyloric gland) were judged as GI-IM. Examples with many AB-positive goblet cells throughout and loss of AB-negative pyloric glands were classified as I-IM. Typical glands as shown in Fig. 6 were used in this study, and transient types were discarded to avoid confusion. This simple method for the classification of isolated glands were found to fit well with histological and immunohistochemical analyses [49].

Total RNA isolation from normal gastrointestinal whole tissues and isolated glands

Total RNAs from frozen tissues were extracted with TRIzol total RNA isolation reagent (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions [19, 22, 47]. For the stomach, neighboring tissues were evaluated for their histology either of the presence or absence of IM irrespective of the presence of gastric component. Individual ethanol-fixed isolated classified glands were transferred to 0.5-ml microfuge tubes under an inverted microscope and subjected to total RNA isolation as described [48, 49]. A total of 12 isolated classified glands were analyzed separately.

Relative quantitative analysis for isolated glands

First strand cDNAs were synthesized as previously reported [48, 49] using the Thermoscript RT-PCR System (Invitrogen) according to the manufacturer's instructions. Relative quantitative PCR for CA1, sucrase–isomaltase, and MUC5AC was performed with the LightCycler system (Roche Diagnostics, Mannheim, Germany), using β-actin as an internal control [49]. The 5′ and 3′ primer sequences are listed in Table 1. PCR was performed basically as described [48, 49] using a SYBR Green PCR Core Reagents kit (Perkin-Elmer Applied Biosystems, Foster City, CA, USA). Quantification was performed as earlier established using β-actin as an internal control. The values for corrected crossing points were calculated by subtraction of the crossing points of the gene of interest from that of β-actin, then used for statistical analyses applying the Mann–Whitney *U* test as earlier described [48, 49]. Specificity of the PCR reaction was confirmed using the melting program provided with the LightCycler software. To further confirm that there was no obvious primer dimer formation or amplification of any extra bands, samples were electrophoresed in 2.5% agarose gels and visualized with ethidium bromide after the LightCycler reaction. Total RNA samples without RT provided a control for PCR amplification (data not shown). The sample correlation coefficient was used for comparisons. A correlation between two factors with relative quantitative real-time RT-PCR was evaluated using Spearman's nonparametric correlation coefficient by rank. *P* values <0.05 were considered statistically significant.

Results

The expression of CA1, sucrase, and MUC5AC in normal gastrointestinal mucosa, and in pyloric mucosa having IM glands, associated with chronic gastritis.

Figure 1 shows double staining of CA1 and sucrase in normal colon (Fig. 1a), jejunum (Fig. 1b), and pyloric mucosa (Fig. 1c). Expression of CA1 was detected in cy-

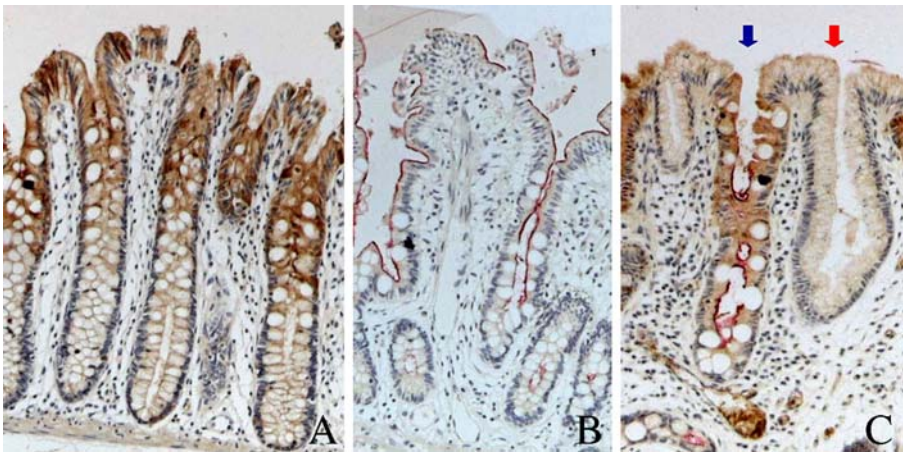

Fig. 1 Double staining of CA1 and sucrase in normal colon, jejunum, and stomach with IM. **a** Expression of CA1 is clearly evident in epithelial cells located on the luminal side of colonic mucosa, but not in the jejunum. **b** Sucrase, on the other hand, is present on the luminal surfaces of mature small intestinal absorptive cells, but not in the colon. **c** In the pyloric region with chronic gastritis, gastric foveolar cells of pyloric glands have neither CA1 nor sucrase expression (*red arrow*), whereas IM glands demonstrate both CA1 cytoplasmic staining and sucrase expression at their luminal surfaces (*blue arrow*). Original magnification, ×200. *CA1*, carbonic anhydrase 1; *IM*, intestinal metaplasia

toplasm of colon epithelial cells, especially on the luminal side of colonic mucosa, but not in the jejunum. Sucrase, on the other hand, was present on the luminal surfaces of mature small intestinal absorptive cells, but not in the colon. Neither CA1 nor sucrase expression was detected in the gastric foveolar cells of pyloric glands (Fig. 1c, red arrow). However, in the pyloric region with chronic gastritis, some IM glands had both CA1 cytoplasmic staining and sucrase expression at their luminal surfaces (Fig. 1c, blue arrow). Erythrocytes in blood vessels beneath the glands cross-reacted with the anti-CA1 antibody (Fig. 1c). Figure 2 shows results of RT-PCR analyses of CA1, sucrase–isomaltase, and MUC5AC in the normal alimentary tract including the colon, jejunum, and antrum of the stomach, with or without IM. Products of β-actin detected as a 142-bp band were used as an internal and sample quality control. CA1 RT-PCR products were detected as a 187-bp band in the colon, but not the antrum or jejunum, whereas RT-PCR products of sucrase–isomaltase were detected as a 193-bp band in the jejunum, but not the antrum or colon, compatible with the immunohistochemistry results. MUC5AC RT-PCR products were detected as a 192-bp band in the normal antrum of stomach, but not in the colon or jejunum. In pyloric mucosa having IM glands, PCR products of all of the abovementioned epithelial cell markers proved detectable (Fig. 2).

The expression of MUC5AC and sucrase in both CA1-positive and CA1-negative IM glands

Next, we evaluated the expression of gastrointestinal differentiation markers in IM at the gland level in serial sections. Figure 3 illustrates immunoreactivitiy of MUC5AC, CA1, sucrase, MUC2, villin, and Cdx2 in IM glands. Elevated MUC5AC expression was observed in CA1-negative mucous cells of GI-IM glands (Fig. 3b and c, red arrow), compared with the CA1-positive I-IM (Fig. 3b and c, blue arrow). The expression of sucrase was more strongly detected on the luminal surfaces of CA1-positive IM gland cells than in CA1-negative IM glands (Fig. 3d). MUC2, villin, and Cdx2 expression was observed in intestinal metaplastic cells irrespective of CA1 expression (Fig. 3e–g, respectively).

To quantitatively clarify the relation of CA1, MUC5AC, and sucrase, 850 glands, comprising 259 pyloric and 591 IM glands, were immunohistochemically evaluated in the pyloric regions of 10 CA1 positive surgically resected cases among a total of 15 cases. In the pyloric glands, all mucous cells demonstrated MUC5AC staining, whereas neither CA1 nor sucrase-positive cells were observed. Among 591 IM glands, totals of 139 (23.5%) and 452 (76.5%) were judged to be CA1 positive and CA1 negative, respectively. The average score for MUC5AC in CA1-positive IM was lower than that in CA1-negative IM with statistical significance ($P<0.0001$) (Fig. 4a). On the other

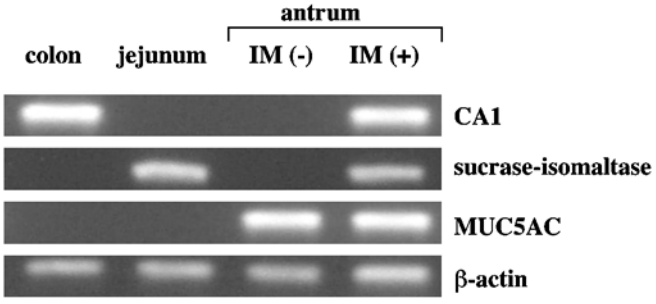

Fig. 2 CA1, sucrase–isomaltase, MUC5AC, and β-actin mRNA expression in colon, jejunum, and antrum of the stomach, with or without IM. CA1 is expressed only in colon, and sucrase–isomaltase only in jejunum. Antral mucosa possesses MUC5AC mRNA and ectopically expresses CA1 and sucrase–isomaltase with occurrence of IM. Products of β-actin detected as a 142-bp band were used as an internal control. *CA1*, carbonic anhydrase 1; *IM*, intestinal metaplasia

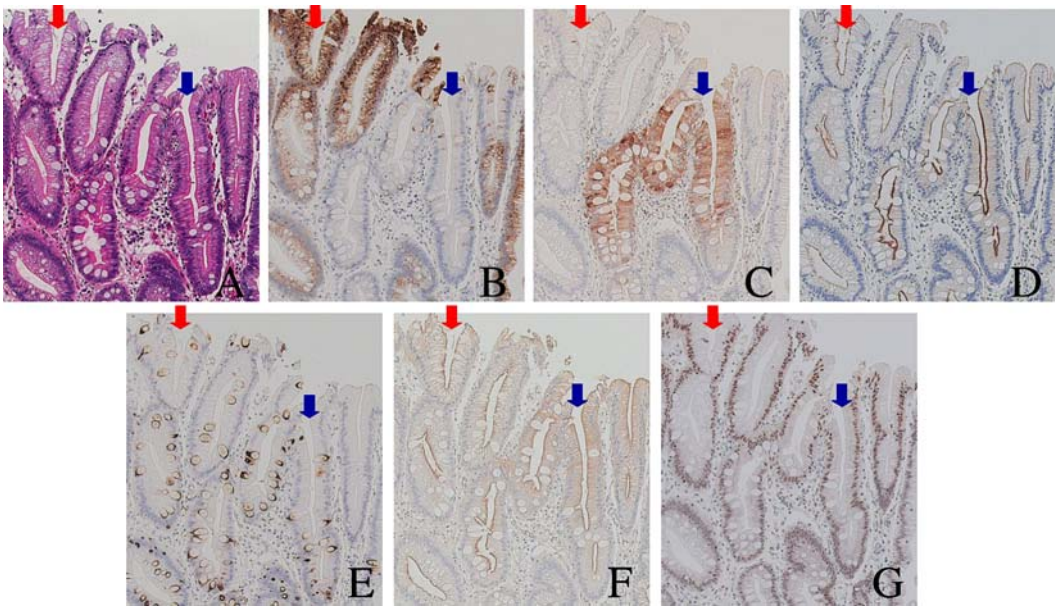

Fig. 3 Histology of IM and expression of gastric and intestinal markers. **a** H&E staining; **b** MUC5AC is apparent in the cytoplasm of CA1-negative (*red arrow*) IM glands, with little expression detected in CA1-positive (*blue arrow*) IM glands; **c** CA1 cytoplasmic staining is observed in the mucous cells of some IM glands (*blue arrow*), but not in others (*red arrow*); **d** Sucrase is apparent at the luminal surfaces of IM glands; **e** MUC2 is detectable in the cytoplasm of IM glands; **f** Villin is positive at the luminal surfaces of IM glands; **g** Cdx2 nuclear staining is apparent in IM glands. Original magnification, ×200. *CA1*, carbonic anhydrase 1; *IM*, intestinal metaplasia

hand, the average score for sucrase in CA1-positive IM was significantly higher than that in CA1-negative tissue (P<0.0001) (Fig. 4b). Considering sucrase expression, many of IM glands (80.4%=475/591) possessed sucrase on the luminal surface. Sucrase-negative IM glands in turn had high level of MUC5AC, 115 IM glands showing score 3 of MUC5AC and only 1 gland having score 2. Thus, sucrase preferred to express more strongly in I-IM than in GI-IM.

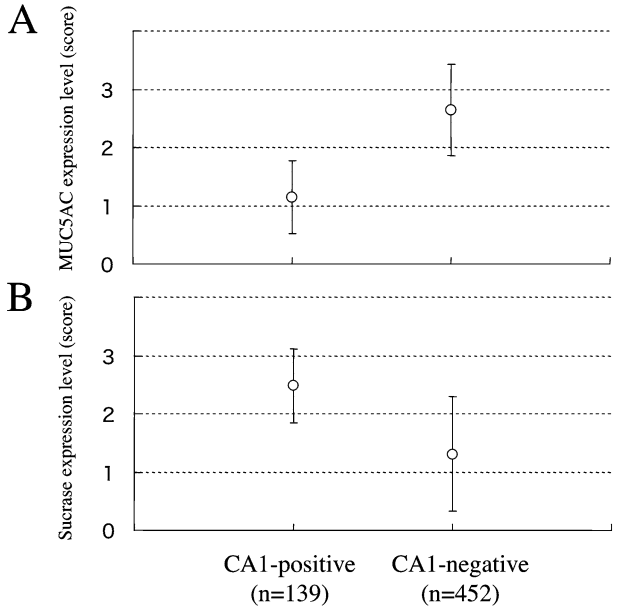

Fig. 4 Relations among MUC5AC, sucrase, and CA1 expression in IM glands by immunohistochemistry. **a** The scores for MUC5AC expression in CA1-positive and CA1-negative IMs are 1.15±0.63 and 2.64±0.78 (average±SD) (P<0.0001). **b** The scores for sucrase expression in CA1-positive and CA1-negative IMs are 2.48±0.63 and 1.31±0.98 (P<0.0001). *CA1*, carbonic anhydrase 1; *IM*, intestinal metaplasia

Comparison of HID-AB staining based IM subtypes with CA1/MUC5AC expression

Inasmuch as HID-AB staining has been widely used for classification of IM in terms of small intestinal sialomucin and colonic sulfomucin expression, we compared the localization of these mucins and the presence of CA1 and MUC5AC proteins. A total of 444 IM glands were evaluated for mucin expression and were classified into 256 type I glands having no mucins in columnar cells but with goblet cells, 104 type II glands with blue-stained columnar cells possessing sialomucins, and 84 type III glands with brown-stained columnar cells producing sulphomucins. Then, serial sections were assessed for expression of a colonic marker, CA1, and also a gastric marker, MUC5AC, for each subtype (Fig. 5 and Table 2). The number of glands with CA1 expression proved higher in type I complete IM compared to types II and III incomplete IM (P<0.005). Furthermore, there turned out to be no differences between the types II and III in terms of CA1 expression, and no correlation with colonic sulfomucin expression was apparent. Considering the gastric marker, type I glands possess less MUC5AC core protein than types II and III (P<0.0001), the last demonstrating the most MUC5AC-positive glands (79.8 and 90.5%, respectively), although this was not statistically significant (P=0.066).

Relative mRNA expression of CA1, sucrase–isomaltase, and MUC5AC in isolated GI-IM and I-IM glands by real-time RT-PCR

To determine the reliability of the data from the immunohistochemical analyses, we evaluated the relative mRNA levels for CA1, sucrase–isomaltase, and MUC5AC by real-time PCR in the isolated IM glands. Twelve isolated IM glands were stained with AB and phenotypically divided into seven GI-IMs and five I-IMs, as shown in Fig. 6. RNA extraction was performed separately for each gland, and real-time RT-PCR analysis of CA1, sucrase–isomaltase, and MUC5AC was carried out at the single gland level. Average (±SE) normalized cycle numbers for MUC5AC, sucrase–isomaltase, and CA1 in GI-IM and I-IM are described in Table 3. The level of MUC5AC mRNA was drastically lower in I-IM compared to GI-IM ($P<0.005$). Inversely, expression of sucrase–isomaltase and CA1 mRNAs was increased from GI-IM to I-IM ($P<0.05$ and $P<0.005$, respectively). Figure 7a shows the relation between CA1 and MUC5AC in the 12 isolated IM glands. The relative MUC5AC mRNA expression was inversely correlated with that of CA1 ($P<0.05$). Figure 7b shows the positive link between CA1 and sucrase–isomaltase in the isolated IM glands ($P<0.05$).

Discussion

The present data provide clear evidence that CA1 expression correlates with sucrase expression in IM glands of pyloric mucosa, and inversely with MUC5AC expression, as assessed by immunohistochemistry and relative quantitative real-time RT-PCR. Some MUC5AC expression was observed in the cytoplasm of CA1-negative mucous cells in areas of IM, and the data from real-time RT-PCR at the single isolated gland level support the results of immunohistochemical analysis. We have previously suggested that intestinalization of gastric mucosa may represent a kind of homeotic transformation [45, 49]. Cdx2, an intestinal homeobox gene, is an important factor for the development of IM [7, 19], its gastric expression alone being sufficient to induce intestinal metaplasia in mice [25, 33]. Cdx2 mRNAs are widely present in the human intestinal

Table 2 Correlation of HID-AB staining and expression of CA1 and MUC5AC

	HID-AB

and colonic mucosa, but not in the gastric mucosa [19]. However, the balance of gastric and intestinal specific transcription factors may be the determinant of phenotypes of IM glands, as well as the normal alimentary tract [49]. Intestinal metaplastic cells having CA1 expression exhibit Cdx2 nuclear staining, in line with the finding by Drummond et al. [4] that Cdx2 plays an important role in the intestine-specific expression of CA1. In vitro in HeLa cells, Cdx2 exerts a positive regulatory effect by binding to a motif 87-bp upstream of the CA1 TATA box [5]. Intestinal metaplastic cells having sucrase expression also exhibit Cdx2 nuclear staining, and Suh et al. [37] have shown that intestine-specific transcription of sucrase–isomaltase, a gene that is expressed exclusively in differentiated enterocytes, is dependent on binding of Cdx2 to an evolutionarily conserved promoter element.

Several subtypes of GI-IM and I-IM can be observed in the stomachs of patients suffering from chronic gastritis [13, 26, 45, 49], and these may be considered not as independent entities, but rather as a sequence of pathological states with gradual change from stomach to intestinal character [45]. In fact, experimentally, shift from GI-IM to I-IM can be observed on sequential observation in X-ray-treated rats [54] and *Helicobacter pylori*-infected gerbils [27]. In the present study, we demonstrated decrease of MUC5AC mRNAs and increase of sucrase–isomaltase mRNAs according to the shift from isolated GI-IM to isolated I-IM by relative quantitative real-time RT-PCR at the single gland level, compatible with our previous report [49]. CA1 mRNAs also increased in line with this shift. In the pyloric mucosa, GI-IM predominates over I-IM [13, 28]. In our previous study, a total of 2,004 glandular ducts were divided phenotypically into 569 (28.4%) pyloric, 1,290 (64.4%) GI-IM, and 145 (7.2%) I-IM glands, respectively, in pyloric areas with chronic gastritis

Table 3 List of IM glands for relative quantitative RT-PCR analysis

[28]. Thus, from our present and previous data, we consider that CA1-positive IM glands may be more prone to alteration from GI-IM to I-IM compared with their CA1-negative counterparts in the pyloric region.

IM has been classified according to HID-AB staining [14], type I being considered to be virtually identical to the morphology of small intestine consisting of mucin-producing goblet cells and absorptive cells without mucin expression. Glands of types II and III are lined by goblet and columnar cells showing mild architectural distortion, respectively, with sialomucins/neutral mucins and sulphomucins in their columnar cells. Reis et al. [30] and Silva et al. [34] have analyzed expression of mucin patterns including MUC1, MUC2, MUC5AC, and MUC6 in IM glands and revealed the type I complete form to have little expression of MUC 1, MUC5AC, and MUC6 in any epithelial components, but strong expression of MUC2 in the goblet cells. In contrast, the incomplete forms of types II and III were found to express gastric markers, MUC1, MUC5AC, and MUC6, together with intestinal MUC2. Our data suggest that expression of CA1, a colonic marker, is not correlated with sulfomucin expression in type III IM, but rather is inversely related to incomplete IM expressing gastric mucins. Furthermore, CA1 was found to be more frequent in type I complete IM. On the other hand, small intestinal markers like sucrase may colocalize with gastric protein, MUC5AC, as noted with the gastric-and-intestinal-mixed phenotype.

IM is widely thought to be a precancerous lesion for differentiated type gastric cancers [1–3, 24, 36, 52, 55]. The hypothesis is based on morphological similarities between cancers and IM and on the results of comparisons of carcinomas and surrounding mucosa. However, previous studies on clonality of gastric cancers and phenotypic expression of each intestinal metaplastic or stomach cancer cells have pointed to several contradictions [8, 11, 15, 17, 23, 31, 40–44]. In addition, using microsatellite instability analysis, Tamura et al. [38] have provided evidence that the majority of differentiated adenocarcinomas of the stomach may develop through a de novo pathway. Endoh et al. [9] also made it clear that the genetic background of differentiated type tumors may differ among cellular phenotypes. In the present study, CA1 expression was observed in approximately one fourth of IM glands in the pyloric region by immunohistochemistry. We have previously shown that early stage gastric cancers, independent of the histological type, mainly consist of gastric phenotypic cancer cells, and a shift from gastric to intestinal phenotypic expression is observed with progression in experimental animal models [23, 39, 40, 41, 51, 53]. More than half of early differentiated gastric cancers have MUC5AC expression in humans [23]. However, the expression of CA1 inversely correlates with that of MUC5AC in IMs, suggesting that IM is important not as a precancerous lesion but rather as a paracancerous phenomenon [8, 18, 43]. Needless to say, many questions remain regarding the pathogenesis of IM as well as the actual relationship to gastric cancers.

In short, expression of gastric and colonic markers may be regulated in different manners, although both can be colocalized with a small intestinal marker. Although the regulatory mechanisms remain unclear, further study of stimulation and/or suppression by gastric and intestinal transcription factors appears warranted [49].

Acknowledgements This study was supported in part by a Grant-in-Aid for the Third-term Comprehensive 10-year Strategy for Cancer Control and a Grant-in-Aid for Cancer Research from the Ministry of Health, Labour and Welfare, Japan, and a Grant-in-Aid from the Ministry of Education, Culture, Sports, Science and Technology of Japan. The authors thank Dr. Malcolm A. Moore for revision of the scientific English language and Ms. Hisayo Ban for expert technical assistance. The anti-sucrase antibody was a generous gift from Dr. Kazuyuki Hirano, Department of Pharmaceutics, Gifu Pharmaceutical University, Gifu, Japan.

Intratumoral heterogeneous expression of p53 correlates with p53 mutation, Ki-67, and cyclin A expression in endometrioid-type endometrial adenocarcinomas

Abstract To further elucidate the significance of p53 mutation in endometrial carcinoma, we investigated it in endometrioid-type endometrial carcinomas showing intratumoral heterogeneous p53 expression. In addition, we also examined the correlation of p53 mutation and cyclin A expression, because we previously reported a topological correlation between the expression of p53 and cyclin A. The p53 mutation in exons 5–8 in 54 cases of endometrial carcinoma showing immunohistochemical expression of p53 was examined using microdissected tissue DNAs. Of the 54 p53-positive endometrial carcinomas, 23 (43%) had p53 mutation with a tendency in histologically higher grade tumors. Ten of the 54 showed a heterogeneous p53 expression, and in 9 of the 10 cases, p53 mutation was present only in p53-positive sites, which were often found in histologically less differentiated areas with elevated Ki-67 in the same tumor. Cyclin A expression was topologically observed in p53-positive areas; however, it was noted in both tumors with (12/23, 52%) and without (18/31, 58%) p53 mutation. These results suggest that p53 mutation is a late event and plays an important role in the acquisition of malignant potentials in endometrioid-type endometrial adenocarcinomas. Unexpectedly, accumulation of the p53 protein itself may be important in cyclin A overexpression.

Introduction

Endometrial carcinoma is one of the most common malignancies in the female genital tract [15] and accounts for approximately 25% of all cancer-related deaths from gynecological malignancies in developed countries [2]. Recent studies revealed that several genetic and epigenetic changes including alterations to the tumor suppressor p53 gene have occurred in endometrial carcinomas [16]. Endometrial carcinomas are now classified into two histological subtypes, endometrioid type and nonendometrioid-type carcinomas [15], and the molecular genetic changes differ between the two types [3, 13, 16]. In the representative nonendometrioid-type carcinoma, i.e., serous papillary adenocarcinoma, p53 mutation is reportedly present in approximately 90% of cases as well as frequently found in its putative precursor, endometrial intraepithelial carcinoma, suggesting that p53 mutation is an early event. In contrast, the significance of p53 gene abnormalities in endometrioid-type adenocarcinomas has been less elucidated. Previous studies showed that p53 gene mutation or overexpression is present in 10–20% of cases and mostly in histologically high-grade tumors [3, 13, 16]. Our previous studies demonstrated that p53 protein expression is inversely correlated with the expression of estrogen receptors in endometrioid-type adenocarcinomas [17]. It is therefore hypothesized that p53 abnormalities may be involved in tumor progression via transformation into higher grade tumors with loss of hormone dependence.

Our previous studies also showed that p53 expression is topologically correlated with overexpression of cyclin A. Cell growth is known to be controlled by interactions of cell cycle-related molecules, such as cyclins and cyclin-dependent kinases (cdks) [21, 22], and abnormalities of these molecules have been reported in various human malignancies [4–6]. In endometrial carcinomas, we reported

that various cyclins and cdks are overexpressed [24, 25], and that overexpression of cyclin A was more frequently found in histologically high-grade tumors and could be an independent prognostic factor for patient survival [23]. Thus, coexpression of p53 protein and cyclin A in endometrial carcinomas suggests that p53 mutation affects cyclin A expression, resulting in a transformation into a more aggressive phenotype via the acquisition of higher proliferative activity.

To address the above hypotheses, we analyzed the presence or absence of p53 gene mutations in endometrial carcinomas, especially of endometrioid type, showing immunoreactivity for p53 protein. Then, we examined the correlation of p53 mutation with histological grade and the expression of cyclin A and the proliferation marker Ki-67. Cases showing heterogeneity of p53 protein expression in the same tumor may be suitable model for an analysis on the functional role of p53 mutation in tumor progression. In these tumors, we examined the possible genetic heterogeneity of p53 mutation using the respective tissues obtained by microdissection and also analyzed the topological correlation with the expression of cyclin A and Ki-67.

Materials and methods

Case selection and DNA extraction

One hundred and thirty-five cases of endometrioid-type endometrial carcinoma were collected from our pathology files for the screening of immunohistochemical expression of p53 using formalin-fixed, paraffin-embedded tissue sections. Clinicopathological characteristics of the patients used for the screening were summarized in Table 1. Consequently, 54 (40%) of the 135 endometrial carcinomas were shown to be positive for p53 protein and were subject to the current study. The age of the 54 patients ranged from 30 to 76 years. Clinicopathological feature of the 54 patients were was also summarized in Table 1. Each tissue sample was used with the approval of the Ethics Committee of Shinshu University after obtaining written consent from the patients.

DNA extraction was performed as previously described [30]. In brief, four or five 8-μm-thick tissue sections of endometrial carcinoma which showed positive staining for p53 were prepared from the paraffin-embedded blocks. The sections were deparaffinized in xylene and rehydrated through graded alcohol. Tumor tissues corresponding to the p53 area were scraped with a razor from consecutive tissue sections avoiding areas of normal tissue using hematoxylin/eosin-stained slides as a template under the observation using stereomicroscope. In cases which showed a heterogeneous p53 immunostaining pattern, i.e., tumors that contained both p53-positive and p53-negative sites irrespective of the positive ratio, and the p53-positive sites are clearly demarcated by the negative sites, which can avoid the contamination of both sites during microdissection, the tissue DNA was scraped from both sites using a microdissection technique. For DNA extraction, the tissues were digested for 16–24 h at 55°C in a digestion buffer (2 mg/ml proteinase K and 0.5% Tween 20), then treated with phenol–chloroform.

Mutational analysis

Because 98% of p53 gene mutations in human cancers have been found in exons 5–8 [8], we also focused on these exons. The polymerase chain reaction–single strand conformational polymorphism (PCR-SSCP) method was used to detect the presence and pattern of p53 gene mutation, as described previously [10]. The oligonucleotide primers were designed based on a published sequence as follows [19]:

Exon 5	5′GGAATTCCTCTTCCTGCAGTAC3′
	5′GGAATTCGCCCCAGCTGCTCACCATCG3′
Exon 6	5′GGAATTCGATGGTGAGCAGCTGG3′
	5′GGAATCAGTTGCAAACCAGACCTCAGG3′
Exon 7	5′GGAATTCTCCTAGGTTGGCTCTGAC3′
	5′GGAATTCCAAGTGGCTCCTGACCTGGA3′
Exon 8	5′GGAATTCCCTATCCTGAGTAGTGGTAA3′
	5′GGAATTCCTGCTTGCTTACCTCG3′

Each exon was amplified by PCR using 0.5 μg of template DNA, sense and anti-sense primers, and an Ampli Taq Gold PCR kit (Applied Biosystems, Foster city, CA, USA). A total of 50 μl of reaction mixture was made according to the manufacturer's instructions, and PCR was commenced at 94°C for 3 min, followed by 35 cycles consisting of 94°C for 30 s, 55°C for 30 s, and 72°C for 1 min, with a final extension for 5 min. The PCR products was denatured at 80°C for 5 min, and 1.5 μl of the products was applied to a 5% polyacrylamide neutral gel containing 5% glycerol. The samples were run at 600 V for 7 h with fan cooling to both sides of the gel plate. After the electrophoresis, the gel was stained with SYBR Green II (Molecular Probes, Inc.,

Table 1 Summary of clinicopathological characteristics of the patients and the results of p53 mutation

	Stage		Grade			Total
	I+II	III+IV	1	2	3

[a]Significantly different from that of stage I+II

Eugene, OR, USA) for 30 min, and the stained bands were analyzed with a FMBIO II Multi-View system (Hitachi, Tokyo, Japan).

When the SSCP band was suggestive of abnormality, the remaining PCR products was purified using an UltraClean PCR Clean-up kit (MO BIO Laboratories, Solana Beach, CA, USA) and subjected to direct sequencing. The direct sequencing was performed using purified products and the same sets of primers in a capillary automatic sequencer (ABI PRISM 3100 Genetic Analyzer, Applied Biosystems) at Shinshu University. Sequence data were analyzed using the Basic Local Alignment Search Tool (BLAST) software located at the National Center for Biotechnology Information (NCBI) web site: http://www.ncbi.nlm.nih.gov.

Immunohistochemistry

Immunostaining was performed using specific antibodies against p53 (DO-1, Immunotech, Marseille, France), Ki-67 (Immunotech), and cyclin A (BF683, Santa Cruz Biotechnology, Santa Cruz, CA, USA). Indirect immunohistochemical staining was performed by the avidin–biotin–peroxidase complex method using a Histofine SAB-PO detector kit (Nichirei, Tokyo, Japan) with microwave pretreatment as described previously [23].

The specific staining of each antibody was identified in the nucleus with/without cytoplasm. Immunoreactivity was evaluated as the percentage of nuclear-positive cells in 500 arbitrarily selected cells in five high power fields and described as a positivity index (PI). With regard to the expression of p53 and cyclin A, when the PI of a tumor was more than 1%, the case was regarded as an "overexpression" or "positive" case, because the PI of these molecules in normal endometrial glandular cells was less than 1% [23]. Cases with a PI of 1–5% were defined as focally positive (+), those with a PI of 6–50% as regionally positive (++), and those with a PI of >50% as diffusely positive (+++).

Statistical analysis

The difference in the p53 mutation ratio among the degree of p53 immunostaining, clinical stages and histological grades was examined using Mann–Whitney's *U* test (Sidak method). The difference in the PI of each immunostaining among the degree of p53 immunostaining, clinical stages, and histological grades was examined with the Kruskal–Wallis test. $p<0.05$ was considered significant.

Results

p53 expression and p53 gene mutation

Of the 54 cases positive for p53 protein, the immunostaining was focal in 14, regional in 18, and diffuse in 22 cases. Those 54 cases were subjected to a PCR-SSCP analysis of the p53 gene, and 26 showed SSCP abnormality (Fig. 1). Direct sequencing was then performed in the 26 cases with abnormal SSCP, and a total of 23 (43%) of the 54 cases were revealed to have p53 mutation. The 23 cases had a total of 26 mutation sites. The number of cases mutated in exon 5, 6, 7, and 8 was 4, 5, 14 and 3, respectively (Table 2, Fig. 2). The 26 mutations consisted of 22 missense and 4 silent mutations.

According to the immunostaining, p53 mutation was present in 8 (57%) of the 14 cases with focal staining, 4 (21%) of the 19 with regional staining, and 11 (50%) of the 22 with diffuse immunostaining (Fig. 3). There was no significant difference of the positive ratio among staining intensities. According to FIGO stage, the 23 cases with p53 mutation consisted of 15 stage I+II and 8 stage III+IV tumors (Table 1). There was no significant difference between the two stage groups. With regard to histological grade, nine were of grade 1, six were of grade 2, and eight were of grade 3 (Table 1). The grade 3 patients had the highest mutation ratio (30%) compared to other grades; however, the difference was not significant.

Correlation among the expression of p53, cyclin A, and Ki-67

Of the 54 cases with p53 expression, 30 (56%) showed cyclin A overexpression (Fig. 3). According to the p53 immunostaining, cyclin A positivity was present in 3 (21%) of the 14 with focal p53 staining, 10 (56%) of the 18 with regional staining, and 17 (77%) of the 22 with diffuse staining, with a significant difference of the positive ratio among three groups ($p<0.0001$). Topologically, the cyclin A-positive cells were frequently observed in p53-positive

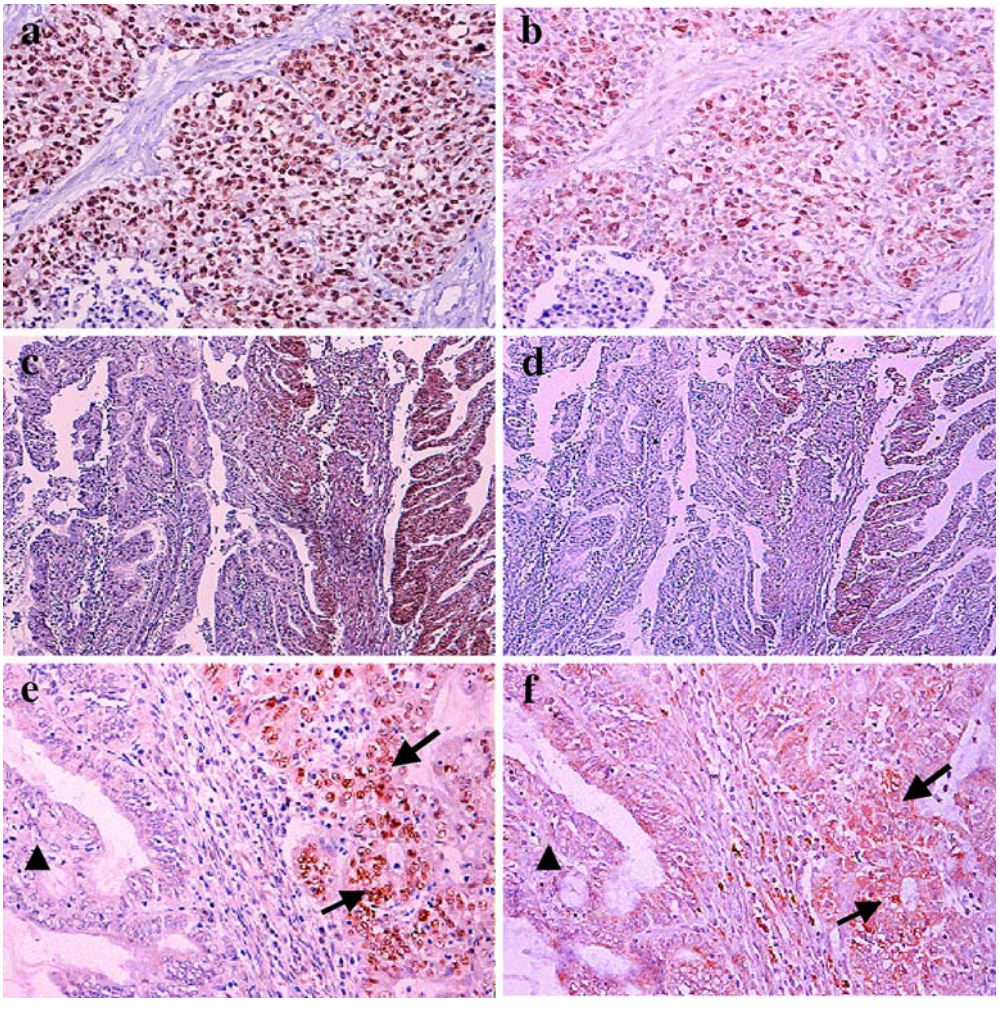

Fig. 3 Result of immunostaining for p53 (**a**, **c**, **e**) and cyclin A (**b**, **d**, **f**). **a** and **b**, **c** and **d**, **e** and **f** are serial sections. The distribution of cyclin A-positive cells (**b**) is similar with that of p53-positive cells (**a**) (×100). The p53-positive cells (**c**, case No. 6 in Table 2) and cyclin A-positive cells (**d**) were intermingled with negative cells. However, the cyclin A-positive sites correlated with the p53-positive sites. p53 mutation was detected in DNA samples obtained from the areas with p53-positive staining (**c**, *right side*) (×40). The p53-positive sites (**e**, *arrow*) locates adjacent to the negative sites (**e**, *arrowhead*) in case No. 24 in Table 2. The nuclear cyclin A-positive sites (**f**, *arrows*) are observed in the p53-positive sites, and cyclin A-negative sites (**f**, *arrowheads*) are negative for p53. p53 mutation was detected in DNA samples obtained from the areas with p53-positive staining (**e**, *right side*) (×100)

with no apparent p53 mutation. The PI for Ki-67 did not differ significantly according to the p53 mutation status (data not shown).

p53 mutation and expression of cyclin A and Ki-67 in cases with heterogeneity in p53 expression

Of the 54 p53-positive cases, 10 showed a heterogeneous pattern of p53 immunostaining and were available for p53 mutational analysis using microdissection for both p53-positive and negative areas in the same tumor (Fig. 1e). There was no apparent tendency in the topological distribution of p53-positive sites in tissue sections. In nine of the ten cases, DNA obtained from p53-positive cells had p53 mutation, whereas that from p53-negative cells had no p53 mutation (Table 2). In the remaining one case, neither of the tumor cells had mutations.

In addition, in four cases (No. 16, 19, 21, and 24), the histological grade of the p53-mutated tumor cells was higher than that of cells with wild-type p53. In the remaining five cases, there was no apparent difference in histological grade between p53-positive and negative cells.

Mutational analysis for the tumor cells invading the adjacent tissue or metastatic to lymph nodes was conducted in two cases (No. 23, 24). In case No. 23, the tumor cells invading the cervical stroma had the same p53 mutation as the tumor cells in p53-positive sites of the primary lesion. In case No. 24, all of the three metastatic nodes showed tumor cells with the same p53 mutation as the primary tumor cells.

With regard to the expression of cyclin A, p53-mutated cells were positive for cyclin A, and vice versa, in five of the nine cases, and both were negative in the remaining four cases. Regarding Ki-67 expression, the PI for Ki-67 was increased in the p53-mutated tumor cells as compared with cells with wild-type p53 in eight of the nine cases, and similar in the remaining case.

Discussion

Our study showed that 54 (40%) of the 135 endometrioid-type endometrial carcinomas were immunohistochemically positive for p53 protein, and that p53 gene mutation was present in 23 (43%) of the 54 cases found to be immunopositive for p53 protein by the PCR-SSCP method followed by direct sequencing. This is consistent with previous studies reporting that the percentage of tumors with p53 mutation among endometrial carcinomas positive for p53 immunostaining ranged 30–60% [1, 9, 27]. It had been believed that the positive p53 immunostaining represents the presence of p53 mutation [12, 20]; however, recent studies demonstrated that p53 immunoreactivity originates from both the mutated and wild-type p53 gene [1, 9, 27]. With regard to the mutation site and amino acid change, the present study showed that the mutations had occurred most frequently in exon 7, and 85% of them were missense mutations. This is also in agreement with previous reports [1, 10, 26].

The most interesting result from our study is the heterogeneous distribution of p53-mutated epithelia in the same tumor of endometrioid-type adenocarcinomas. Ten out of the 54 cases showed both p53-positive and negative areas in the primary lesion, and were available for the analysis of the mutational status of the two sites using a microdissection technique. The results indicated that, in nine of the ten cases, the gene mutation was identified in the p53-positive carcinoma cells, but not in the p53-negative cells. In eight of the nine cases, the PI for Ki-67 was increased in p53-mutated tumor cells compared to those without p53 mutation. In four of the nine cases, p53-mutated carcinoma cells showed a histology of less differentiation than those without the mutation. In a case of stage II carcinoma, the cells invading the cervical stroma had the same p53 mutation as those in the primary lesion. In another stage III case with lymph node metastasis, the tumor cells in all of the three metastatic nodes showed the same p53 mutation as demonstrated in the primary lesion. All of these findings suggest that p53 gene mutation occurred after the development of well-differentiated, endometrioid-type adenocarcinoma, and then the p53-mutated, less-differentiated tumor cell subpopulation acquired higher proliferative activity and metastatic potential. Previous studies reported that the p53 mutation was present more frequently in advanced staged and/or high grade tumors of endometrioid-type carcinomas, presenting the concept that p53 mutation is a late event in this tumor [3, 13, 16]. The current study supports this idea, and it is likely that p53 mutation plays an important role in the transformation of the tumor cells into the invasive phenotype. To our knowledge, this is the first report on a heterogeneous pattern of p53 immunostaining actually associated with p53 genetic heterogeneity in endometrial endometrioid-type adenocarcinoma.

The present study demonstrated that the distribution of cyclin A-positive cells is correlated well with that of p53 expression, especially in tumors showing a heterogeneous p53 staining pattern. This was consistent with our previous reports [23, 24], and suggested possible molecular correlations between p53 protein accumulation and cyclin A expression. Yamamoto et al. reported that wild-type p53 protein can bind the promoter region of the cyclin A gene and suppress the transcription of cyclin A mRNA in leukemic cell lines [29]. This prompted us to analyze the p53 gene mutation with relevance to cyclin A expression. Contrary to expectation, the results indicated that cyclin A positivity was present not only in 52% of p53-mutated carcinomas but also in 58% of carcinomas without p53 mutation. These findings suggest that the accumulation of the p53 protein itself, either mutated or of wild- type, may be important in overexpression of cyclin A. There may be some unknown sites in p53 protein that are involved in the expression of cyclin A protein. Recently, cyclin A-docking sites have been identified on the C-terminus of p53 protein [18]. In addition, because inasmuch as (since) the amount of wild-type p53 protein is reportedly controlled by mul-

tiple double minute two 2 (MDM2) protein which is a ubiquitin ligase acting to degenerate the p53 protein [7, 14], accumulation of wild-type p53 protein may be considered in relevance to insufficient MDM2 functions [7, 14]. It has been reported that expression of MDM2 is reduced in p53-positive areas without p53 mutation in lung adenocarcinoma [11]. Such an inverse relationship between the expression of p53 and MDM2 has also been reported in endometrial carcinomas [28]. Accordingly, the abnormal MDM2 expression may be in part involved in the accumulation of wild-type p53 protein.

In summary, the present study demonstrated that p53 mutation occurs as a late event in endometrial endometrioid-type adenocarcinoma, and may be important to the change of morphology and cell behavior. In addition, overexpression of cyclin A is associated with the accumulation of p53 protein along with higher proliferative activity. Further studies are needed to clarify the molecular interaction between p53 and cyclin A in endometrial carcinomas.

Clear cell mesothelioma presenting as an incarcerated abdominal hernia

Received: 4 April 2005 / Accepted: 7 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract A clear cell mesothelioma presenting as an incarcerated ventral abdominal hernia in a 67-year-old man who had no history of asbestos exposure is described. The cause of the cytoplasmic clearing was the presence of large amounts of glycogen. Although uncommon, this variant of mesothelioma is important to recognize because it can be easily confused with other clear cell tumors involving the serosal membranes. Significant recent advances in the immunohistochemistry of epithelioid mesothelioma are briefly reviewed because immunohistochemical studies can be helpful in establishing the correct diagnosis.

Keywords Clear cell mesothelioma · Hernia · Immunohistochemistry · D2-40 · Podoplanin

Introduction

An important characteristic of tumors arising from the serosal membranes is their ability to grow in a wide variety of histologic patterns. Based on their light microscopic features, mesotheliomas have been subdivided into epithelioid (also referred to as epithelial), sarcomatoid, mixed epithelioid and sarcomatoid (biphasic), and desmoplastic types. Although epithelioid mesotheliomas more often present a tubulopapillary or solid pattern, on occasion, they may present other unusual histologic patterns, including adenomatoid, deciduoid, small cell, signet ring, rhabdoid, and pleomorphic. Mesotheliomas presenting a clear cell morphology are rare and only a few individual case reports have been published [6, 9, 24]. The purpose of this article is to report a case of a clear cell mesothelioma that was unusual in that it originated in the peritoneum and presented as an incarcerated ventral abdominal hernia. Pathologists need to be aware that mesotheliomas can present this uncommon morphology and, therefore, should be included in the differential diagnosis of those tumors that can display similar morphologic features and can metastasize to the serosal membranes.

Clinical history

A 67-year-old black man sought medical attention for an incarcerated ventral abdominal hernia that had developed a year earlier. He had a history of diverticulitis, and prostate cancer which had been treated with a radical prostatectomy and radiation therapy 7 years previously. The patient also had a history of smoking, but not of asbestos exposure. He underwent hernial repair and resection of the hernial sac. Pathology examination of the resected specimen revealed a malignant epithelial clear cell tumor. A CT scan was performed and showed extensive omental "caking" and ascites.

Material and methods

Tissue samples of the resected specimen were fixed in 10% buffered formalin and processed for light microscopy. Sections were stained with hematoxylin-and-eosin, Mayers's mucicarmine, and periodic acid-Schiff (PAS) with and without diastase digestion. Immunohistochemical studies were performed using the avidin–biotin–peroxidase complex (ABC) method in a Dako Autostainer (Carpinteria, CA). The primary antibodies used are listed in Table 1. Immunoperoxidase staining was done using the LSAB2 peroxidase kit (Dako). To enhance the immunostaining, a heat epitope retrieval procedure was performed using a Black-and-Decker vegetable steamer (Shelton, CT) as previously described [19]. The antigen–antibody reaction was visualized using either 3-amino-9-ethylcarbazole or 3′,3-diaminobenzidine tetrahydrochloride as chromogen. To evaluate the specificity of the antibody, known positive and negative tissues were used as controls. For electron

Table 1 Antibodies used in this study

Marker	Source	Type	Dilution	Antigen retrieval

microscopy studies, portions of the tumor from the paraffin blocks were deparaffinized with xylene, postfixed in 1% osmium tetroxide in S-collidine buffer, and embedded in Epon epoxy resin. Ultrathin sections were stained with uranyl acetate and lead citrate.

Results

Histologically, the tumor appeared to be made of solid clusters of uniform, polygonal cells with strikingly clear cytoplasm (Fig. 1a). Periodic acid-Schiff stain demonstrated the presence of large amounts of glycogen (Fig. 1b). Mayer's mucicarmine stain was negative for mucin. Immunohistochemical studies showed strong reactivity for calretinin, keratin 5/6, WT1 protein, D2-40, and podoplanin (Fig. 1c–f). All of the other investigated markers were negative. Ultrastructural examination of paraffin-embedded material demonstrated the presence of numerous, long branching microvilli on the apical surface of the cells.

Discussion

Tumors composed entirely or partially of cells with optically clear cytoplasm have been documented in virtually every organ, including the serosal membranes. Mesotheliomas with clear cell morphology are uncommon and only a few cases have been reported under a variety of descriptive terms, including clear cell mesothelioma [9, 24], glycogen-rich mesothelioma [23], lipid-rich mesothelioma [7], and foamy cell mesothelioma [6]. In the present case, the cytoplasmic clearing was caused by the accumulation of large amounts of glycogen, but this change has also been attributed to other factors, such as the presence of large amounts of lipid [7], or numerous cytoplasmic vesicles [24].

The clinical presentation of abdominal mesotheliomas is usually that of abdominal pain, weight loss, and abdominal distention caused by ascites. About 5–10% of the patients may develop hernias, most often inguinal or umbilical, as a result of the increase in abdominal pressure caused by the ascites [1, 18]. In many of these patients, the diagnosis of mesothelioma is established only after they seek medical attention due to discomfort resulting from the accumulation of ascites fluid in the hernial sac. Although, in most instances, the resected hernial sac only contains ascites fluid, on rare occasions, it can be involved by either an extension of or a metastasis from a peritoneal mesothelioma that has spread into the preestablished hernial sac [2, 3, 10, 11, 27]. The present case is unusual not only in that the abdominal ventral hernia was the presenting symptom of the mesothelioma, but also because of the unusual clear cell morphology of the tumor.

The diagnosis of epithelioid mesothelioma with clear cell morphology can be difficult, especially on biopsy specimens where areas showing more conventional mesothelioma features are not included. In the present case, this diagnosis was confirmed by immunohistochemical studies, in which strong reactivity was demonstrated for calretinin, keratin 5/6, and WT1 protein, and negative staining for CEA, MOC-31, and B72.3, an immunohistochemical pattern that is considered characteristic of mesothelioma [19]. It was further confirmed by the demonstration of strong positivity for D2-40 and podoplanin, two novel markers that, according to recent investigations [9, 22], could assist in the diagnosis of mesothelioma. Even though the tissue specimen used for electron microscopy was poorly preserved, this procedure clearly demonstrated the presence of ultrastructural features supporting the diagnosis of mesothelioma.

D2-40 is a recently developed monoclonal antibody that reacts with a 40-kDa surface sialoglycoprotein known as the M2A antigen that was originally detected in fetal germ cells and germ cell tumors [16]. Subsequent investigations have demonstrated that because this antibody reacts selectively with lymphatic endothelium, it could be very helpful in both the diagnosis of lymphatic-derived tumors,

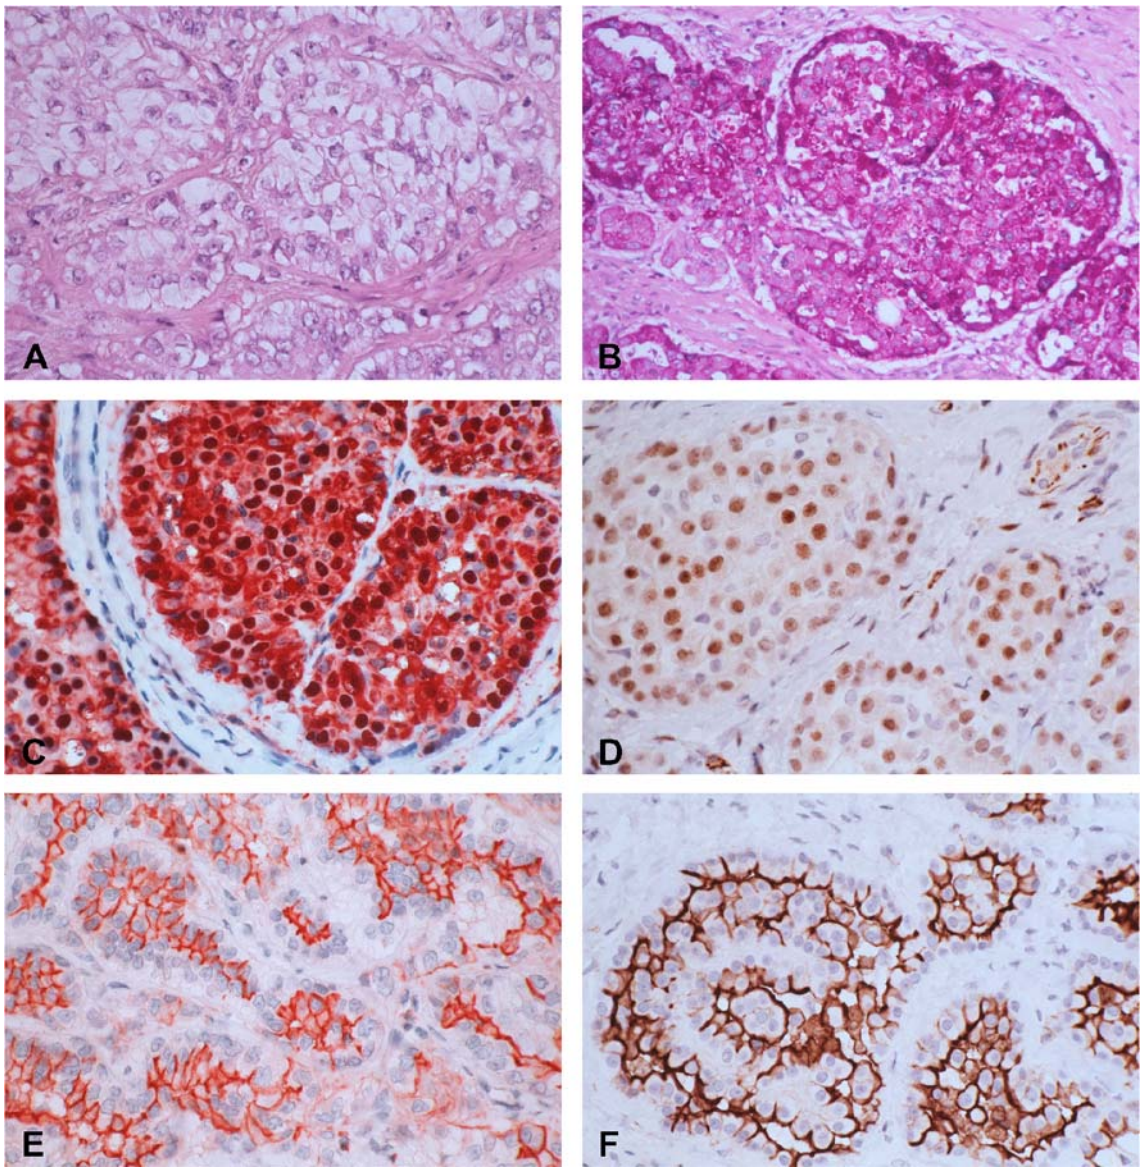

Fig. 1 **a** General appearance of the tumor demonstrating that it is composed exclusively of clear cells (H&E, ×200). **b** PAS stained section showing that the clearing seen on the H&E stained section is caused by the accumulation of large amounts of intracytoplasmic glycogen. **c** Immunohistochemical preparation showing strong nuclear and cytoplasmic reactivity for calretinin. **d** Immunohistochemical preparation demonstrating nuclear reactivity for WT1 protein. **e** Immunostain with the D2-40 antibody showing strong reactivity along the apical cell membrane. **f** Immunohistochemical preparation showing membranous positivity for podoplanin

and in determining lymphatic invasion by tumors [12, 13]. Recent investigations [8, 21] have also shown that, because this antibody usually reacts with epithelioid mesotheliomas, but not with carcinomas, it could be useful in discriminating between these malignancies. Chu et al.'s study [8] on the value of D2-40 as a mesothelioma marker reported strong membranous reactivity in all 33 (100%) epithelioid mesotheliomas and in the epithelioid component of 15 (94%) of 16 biphasic mesotheliomas. Focal, weak, membranous positivity was observed in 17 (65%) of 26 serous carcinomas, but no membranous staining was seen in any of the other carcinomas investigated. A minority of the renal cell carcinomas (5/34), breast carcinomas (3/16), and lung adenocarcinomas (2/31), however, showed weak, cytoplasmic staining. In two separate investigations using different cohorts of mesothelioma and carcinoma cases, I observed D2-40 membranous positivity in 25 (86%) of 29 and in 37 (93%) of 40 epithelioid mesotheliomas, respectively [21, 22]. Among the different types of carcinomas investigated, only about 15% of the serous carcinomas exhibited focal membranous reactivity with this antibody. None of the other carcinomas, including those of the kidney, lung, and prostate, stained with the D2-40 antibody. These findings indicate that D2-40 is one of the most specific and sensitive markers currently available for the diagnosis of epithelioid mesothelioma.

Podoplanin is a 38-kDa mucoprotein first identified in rat glomerular epithelial cells (podocytes) which was found

to be linked to the flattening of the epithelial foot processes in puromycin induced nephrosis [4]. Podoplanin, like D2-40, was found to be expressed in the lymphatic endothelium, but not in the blood vasculature. Subsequent investigations have reported podoplanin positivity in lymphangiomas, Kaposi's sarcomas, and in a subgroup of angiosarcomas [5]. Recently, Kimura and Kimura [15] reported podoplanin expression in five (100%) of five epithelioid mesotheliomas, but in none of 93 adenocarcinomas of various origins, and suggested that podoplanin could serve as a useful immunohistochemical marker for distinguishing between these malignancies. In two comparative studies, I found that podoplanin had a similar sensitivity and specificity in the diagnosis of mesotheliomas to that of D2-40 [21, 22].

The differential diagnosis of clear cell mesothelioma includes a wide variety of carcinomas with similar morphologic features. In my experience, the tumors that are most likely to be confused with clear cell mesotheliomas are renal cell carcinomas, and both adenocarcinomas and squamous cell carcinomas of the lung with clear cell morphology. Because of the high sensitivity and specificity of D2-40 and podoplanin for epithelioid mesotheliomas, immunostaining for either of these two markers can be used in combination with the renal cell carcinoma marker (RCC Ma) to distinguish between epithelioid mesotheliomas and renal cell carcinomas, or thyroid transcription factor-1 (TTF-1) to discriminate between epithelioid mesotheliomas and lung adenocarcinomas. RCC Ma is a recently commercially available monoclonal antibody that was generated using the microsomal fraction of human renal cortical tissue as immunogen and which reacts with a 200-kDa glycoprotein present in normal tubule epithelial cells. This antibody has proved to be highly specific for renal cell carcinomas and it has been reported to react with 75–85% of the clear cell carcinomas of the kidney [17, 20]. Because calretinin and keratin 5/6 are not expressed in carcinomas of the kidney, these markers may also be useful in distinguishing these tumors from epithelioid mesotheliomas. It should be mentioned, however, that because they are expressed in both epithelioid mesotheliomas and squamous cell carcinomas, neither calretinin nor keratin 5/6 is useful in discriminating between these malignancies. This differential diagnosis, however, can be facilitated by the use of p63 immunostaining because this marker is strongly and almost invariably expressed in squamous carcinomas [14, 26, 28], but not in epithelioid mesotheliomas [14, 25].

Malignant mesothelioma with a pronounced myxoid stroma: a clinical and pathological evaluation of 19 cases

Received: 21 May 2005 / Accepted: 19 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract Mesothelioma with a pronounced myxoid stroma has been identified as a morphological pattern that might portend a better prognosis. Reports on this type of cases are few. Its clinical and pathological features are not defined. In this study, we identified 19 such cases from a series of 234 pleural mesotheliomas and performed a comprehensive clinical and pathological analysis. The inclusion criteria were mesotheliomas with at least 50% of the tumor exhibiting a pronounced myxoid stroma that occupied more than 50% of the tumor volume (designated as myxoid mesothelioma). There were ten males and nine females, with a median age of 58 years. Forty seven percent of the patients had probable or definite asbestos exposure. Patients presented at various stages [International Mesothelioma Interest Group (IMIG) stage II, 4; stage III, 9; and stage IV, 6]. Most (16/19) patients were treated by extrapleural pneumonectomy with adjuvant radiation or chemotherapy or both. Overall, the median survival rate was 36 months (median follow-up time, 17 months), and the 2-year survival rate was 79%. Histologically, the tumor cell component was entirely epithelioid without significant cytologic atypia. The myxoid material stained positive for Alcian blue, and the staining diminished after treatment with hyaluronidase in 12 of 12 cases. The tumor cells showed a typical mesothelial immunophenotype. Ultrastructurally, all six tumors examined had typical mesothelial-type surface microvilli and a moderately electron-dense extracellular amorphous material that often formed a haze enmeshing the surface microvilli. Hyaluronic acid-type, fern-like crystals were noted in all cases. These findings show that myxoid mesotheliomas represent a group of epithelioid mesotheliomas that have retained the secretory activity of normal mesothelium. Patients may present at different stages, but survival appears to be superior to that of epithelioid mesotheliomas in general. Our study emphasizes the need for better attention to histologic subtypes, particularly in the context of prognostically or therapeutically oriented investigations of this lethal disease.

Introduction

Malignant mesotheliomas exhibit a broad histologic spectrum. Recognition of the various histologic types not only facilitates accurate diagnosis, it may also identify clinically and/or pathologically significant subsets [18]. For example, recent studies of lymphohistiocytoid mesotheliomas have demonstrated them to have a prognosis similar to sarcomatoid mesotheliomas [20], and an analysis of deciduoid mesothelioma has clarified the clinical features and anatomic distribution of this variant [19]. Malignant mesotheliomas with a pronounced myxoid stroma (myxoid mesothelioma) have been reported, but only in small series [3, 13] or single case reports [5]. This histologic pattern has

been suggested to be associated with a better outcome [3, 13]. Its clinical and pathological characteristics, however, are still to be defined.

Materials and methods

Patient data

All pleural mesothelioma cases treated at Memorial Sloan-Kettering Cancer Center between 1993 and 2001 were retrieved from the pathology database. The pathology materials were reviewed to identify mesotheliomas with extensive myxoid changes. Only those cases with hematoxylin and eosin (H & E) slides or tissue blocks available were included in the study. Clinical data were retrieved from a computer-based disease management data system. Clinicopathological staging was based on the surgical and pathological findings using the tumor-node-metastasis (TNM)-based IMIG staging system[15].

Histologic review

At least three H & E sections were reviewed in each case. Study cases designated as "myxoid mesothelioma" were defined as having at least 50% of the tumor containing a pronounced myxoid stroma that occupied more than 50% of the tumor volume in those regions.

Immunohistochemical and histochemical studies

Immunohistochemical stains were performed on 4-μ-thick, formalin-fixed, and paraffin-embedded sections using the streptavidin–biotin–peroxidase complex method. A panel of ten antibodies was applied, including AE1/AE3 (monoclonal, 1:1,000, Boehringer-Mannheim, Indianapolis, IN), CAM5.2 (monoclonal, 1:1,000, Becton Dickinson, Franklin Lakes, NJ), 34BE12 (monoclonal, 1:50, Enzo, Farmingdale, NY), Vimentin (monoclonal, Ventana, Tucson, AZ), calretinin (polyclonal, Chemicon International, Temecula, CA), WT-1 (monoclonal, 1:40, DAKO), Ber-EP4 (monoclonal, 1:1,000, DAKO), LeuM1 (CD15) (monoclonal, 1:1,000, Becton Dickinson), CEA (monoclonal, Ventana), and Ki-67 (monoclonal, 1:500, clone MIB1, Immunotech, Westbrook, ME). Antigen retrieval was performed for all antibodies (citrate buffer, microwaving at pH 7.2–7.5) Appropriate positive and negative controls were used for each antibody. Histochemical stains for Alcian blue with and without hyaluronidase pretreatment were also performed on all available cases.

Ultrastructural studies

All tissue samples were fixed in 2% glutaraldehyde, post-fixed in 1% osmium tetroxide, and embedded in epoxy resin using standard techniques. In each study case with epoxy resin blocks available, thick sections were cut and stained with toluidine blue to select suitable tissue samples. Ultrathin sections from two selected blocks were stained

with uranyl acetate and lead citrate, and examined with a Zeiss 906 transmission electron microscope.

Statistical analysis

Survival analyses were based on the patients' status at last follow-up. Survival curves were generated using the method of Kaplan and Meier [9].

Results

Patient data

A total of 234 pleural mesothelioma cases were identified from the database that had tissue slides or blocks available for review. Histologic review of the pathological material revealed 19 cases with a pronounced myxoid stroma fulfilling the inclusion criteria (8% of the 234 patients).

Clinical characteristics are summarized in Table 1. There were nine females and ten males. The age range was 40–75 years, with a median of 58 years and a mean of 59.8 years. Fourteen of the 19 patients involved the right pleura, and five involved the left pleura (right to left ratio, 2.8:1). A history of asbestos exposure was confirmed in six (32%) patients and suggested in three (16%). No asbestos exposure was identified in nine patients. In one patient, this information was not available. Sixteen patients underwent an extrapleural pneumonectomy, seven followed by radiation therapy, one by chemotherapy alone, one by combined chemotherapy and radiation, and one patient had neoadjuvant chemotherapy followed by surgery and postoperative chemotherapy. One patient had pleurodesis only, one had chemotherapy only, and one, whose medical condition prevented any surgical or cytotoxic treatment, received only supportive care. In these three cases, the biopsy specimens were available for review. Six patients presented with IMIG stage IV disease, nine patients presented with stage III, and four patients presented with stage II. Follow-up time ranged from 1 to 75 months (median 15 months). At last follow-up, six patients had died of disease at 4–65 months after initial diagnosis (median survival time, 21 months), three died of other causes (two died of myocardial infarction within 1 month of surgical intervention, and one died of sepsis 36 months after diagnosis), five were alive with disease at 9–26 months (median, 17 months), and five had no evidence of residual mesothelioma at 3–75 months (median, 12 months). The two patients who died of myocardial infarction within 1 month of surgery were excluded from survival analysis. With those two patients excluded, the overall median survival was 36 months (median follow up time, 17 months); the estimated 2-year overall survival rate was 79% (95% CI, 0.601–1.00), and the 3-year overall survival rate was 35% (95% CI 0.127–0.972) (Fig. 1).

Histologic review

As defined by the inclusion criteria, all study cases had voluminous myxoid stroma. At low power, this stroma constituted the dominant component of the tumor and imparted a bluish hue to the H & E stained sections under the light microscope. It might form pools with scattered cells floating within, or it might be intermixed with a prominent fibrous component (Fig. 2). An amorphous or granular quality and a bluish tinge were appreciated in this stroma at higher magnification (Fig. 3a). The malignant mesothelial cells were always of epithelioid type and without significant cytologic atypia. They had an eosinophilic cytoplasm. Although enlarged nuclei with prominent nucleoli could be seen, mitoses were not common. These cells formed cords or irregular tubules or clusters, sparsely embedded in the stroma (Fig. 3b). The tumors showed focal areas where the cellularity was high; however, even in

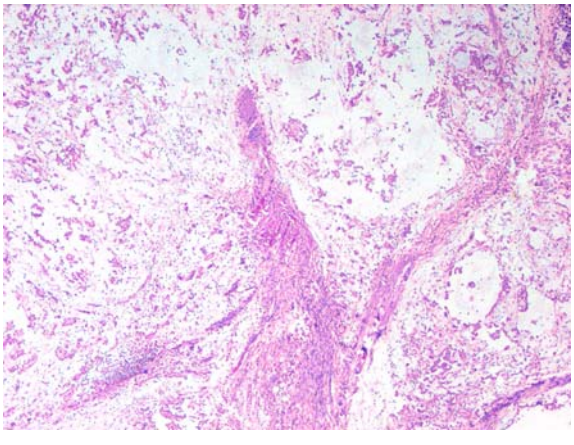

Fig. 2 Low-power view of a myxoid mesothelioma showing pools of myxoid material containing free-floating cell clusters, admixed with fibrous tissue. Note the presence of a bluish tinge imparted by this myxoid stroma

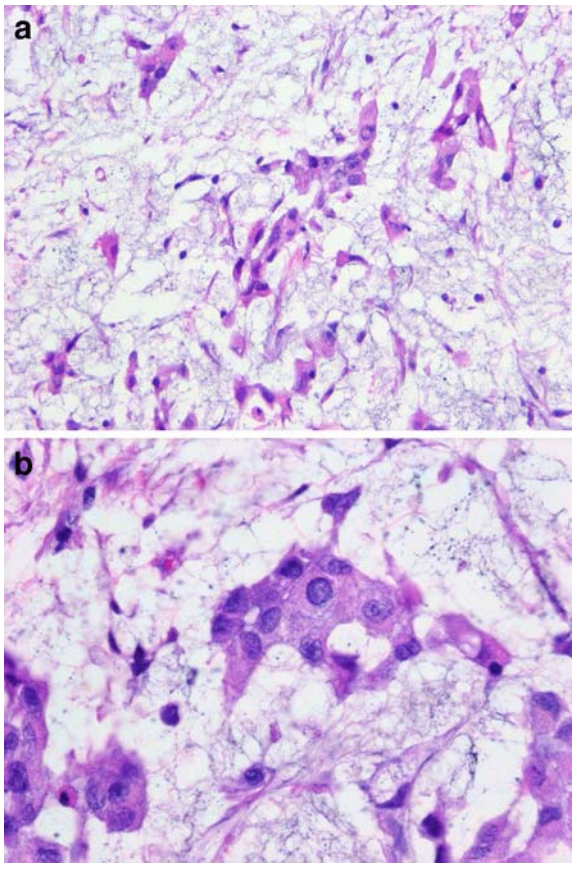

Fig. 3 Higher power view of a myxoid mesothelioma showing a granular quality of the myxoid stroma (**a**) and the tumor cells with eosinophilic cytoplasm and somewhat irregular nuclei. No mitosis is present (**b**)

these areas, the myxoid nature of the associated stroma could still be appreciated. No necrosis was identified in any of the cases. None of the cases showed sarcomatoid features.

Immunohistochemical and histochemical studies

Immunohistochemical studies were performed on 12 cases whose tissue blocks were available. All tumors tested were positive for calretinin (diffuse and strong in 12/12 cases) (Fig. 4a), WT-1 (diffuse and strong in 8/12, focal and weak in 4/12), AE1/AE3 (12/12), cam 5.2 (12/12), and 34BE12 (diffusely positive in 10/12, focally positive in 2/12). All tumors were negative for monoclonal CEA, Leu-M1 (CD15), and Ber-EP4. Nine tumors were diffusely positive for vimentin, one was focally positive, and one was negative. Ki-67 staining showed a proliferation index of less than 5% in seven cases and 10–30% in five (Fig. 4b).

Histochemically, the myxoid stroma in all 12 cases was diffusely positive with Alcian blue at pH 2.5 (Fig. 5a). The positivity was neutralized in every case by pretreatment with hyaluronidase (Fig. 5b).

Ultrastructural studies

Electron microscopy was performed in six cases. All six demonstrated conspicuous long and slender mesothelial-type surface microvilli. Well-formed cell junctions were present in all six cases, and a distinct basement membrane was seen in two. Duplication of the basement membrane was not observed. The cells often contained prominent intermediate filaments, focally forming tonofilaments. In all six cases, an extracellular, mildly to moderately electron-dense amorphous or slightly granular material was noted. This material was denser or more evident immediately adjacent to the tumor cells (Fig. 6a), and often formed a haze in which the surface microvilli were meshed (Fig. 6b). This diffuse haze coating the microvilli lacked the branching filaments seen in the glycocalyceal material associated with intestinal-type microvilli, and it did not form glycocalyceal body-like granules. However, electron-dense, branched fern-like material, similar in appearance to hyaluronic acid crystals, was present in all cases. These "crystals" were often seen in the extracellular spaces adjacent to surface microvilli (Fig. 6c).

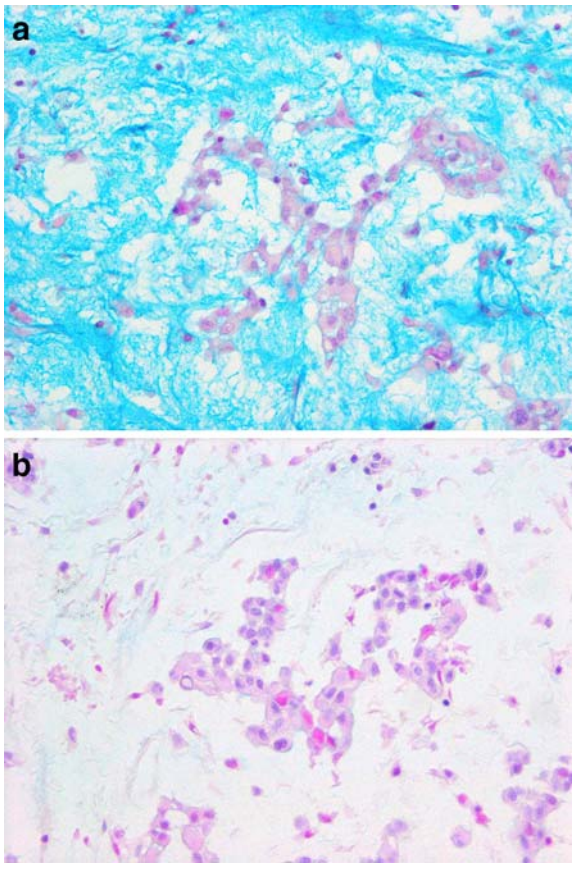

Fig. 5 Histochemically, the myxoid stroma is diffusely positive with Alcian blue at pH 2.5 (**a**). The positivity is neutralized by pretreatment with hyaluronidase (**b**)

Discussion

Histologic subtypes have long been recognized as prognostically significant in malignant mesothelioma [2]. The conventional classification separates mesotheliomas into three major types, the epithelioid type (also referred to as epithelial type), the sarcomatous (or sarcomatoid) type, and the biphasic (mixed) type. The epithelioid type has been shown to have a clear survival advantage over the other two types [1, 2]. More recently, additional subtypes in the epithelioid category have been described. Some have been shown to be associated with a longer survival such as the tubulo-papillary variant [8]; others were thought to be important both in the differential diagnosis with other morphological mimics and in carrying possible prognostic implications such as the deciduoid variant [19, 20].

The occasional presence of a pronounced myxoid stroma in some epithelioid mesotheliomas has been noted. Butchart et al. in 1976 identified three cases, from a series of 29 malignant mesotheliomas, that were characterized histologically by "abundant oedematous mucoid stroma with loosely arranged tumor cells" [3]. These three cases had a more favorable clinical outcome. Later, Mark et al. [13] reported that a prominent myxoid stroma and the formation of tubules and micropapillae were the morphological patterns shared by tumors in six patients with a

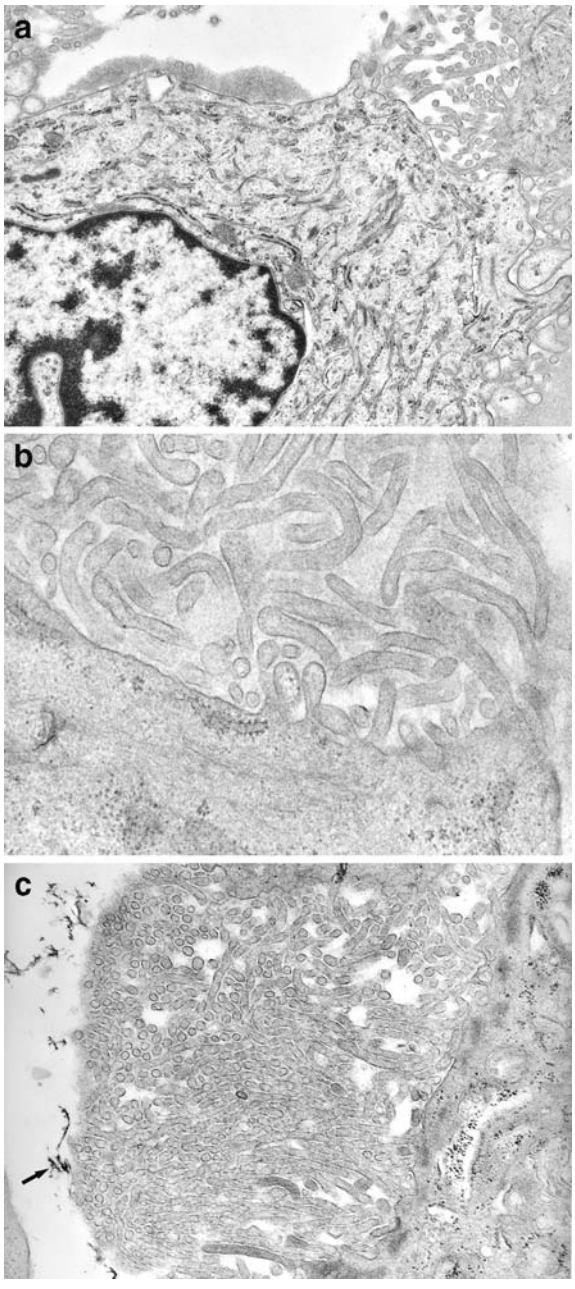

Fig. 6 Ultrastructural features of mesothelioma with a pronounced myxoid stroma. An extracellular moderately electron-dense amorphous material is present, more condensed on the cell surfaces (**a**, magnification ×27,670) and enmeshes the mesothelial-type surface microvilli (**b**, magnification ×66,836). Note the presence of electron-dense, fern-like crystalline material adjacent to the surface microvilli (**c**, magnification ×40,083. *Arrow* indicates crystalline material)

prolonged symptom-free interval or extended survival after biopsy, again suggesting a correlation between this morphological pattern and a relatively favorable prognosis. More recently, Diaz et al. [5] reported a well-differentiated papillary mesothelioma of the pelvic peritoneum that contained extensive areas of myxoid stroma, resulting in a morphology that might be misinterpreted as a soft tissue neoplasm with myxoid stroma or pseudomyxoma perito-

nei. Overall, however, information about this morphological pattern is scarce in literature. The purpose of this study was, therefore, to perform a systematic clinical and pathological assessment of a series of myxoid methotheliomas that we collected from our files.

Our study demonstrates that myxoid mesotheliomas are not rare, as they represented 8% of our series of 234 cases. When compared to a series of consecutive cases that was also treated at our institution [18], patients with myxoid mesotheliomas seem to have less of a male dominance (male to female ratio, 10:9 vs 5:1 in the general group [18]). They, however, share other epidemiological features with mesothelioma patients in general. These features include median age at diagnosis (57 vs 62 years in pleural mesothelioma in general [18]) and history of asbestos exposure (probable or definite exposure in 47 vs 62% in pleural mesothelioma in general [18]). The right-side predominance noted in myxoid mesotheliomas has also been reported in pleural mesotheliomas in general (right to left ratio, 2.8:1 vs 1.6:1 in mesotheliomas of all types [21]) and is thus not a feature unique to myxoid mesothelioma. The explanations suggested for the right-side predominance in pleural mesotheliomas include differences in asbestos fiber deposition between the two lungs, the larger pleural surface area of the right lung, or differences in lymphatic drainage [21].

Overall, patients with myxoid mesotheliomas seem to have a somewhat more favorable outcome than patients with other types of mesothelioma or mesothelioma patients in general. With disease stage varying from IMIG stages II–IV, and the majority of cases being treated with radical extrapleural pneumonectomy with or without adjuvant radiation or chemotherapy, these patients had a median overall survival rate of 36 months, and an estimated 2-year overall survival rate of 79%. When compared to data obtained from our own institution [16, 17], this survival rate is superior to the 15.1-month median survival time in patients with epithelioid meostheliomas [17] and is comparable to the 33.8-month median survival seen in early stage (stages I and II) cases that are treated similarly (i.e., mostly with radical surgery) [16]. Although limited by the small case number and lack of proper controls for stage and treatment modalities, our findings seem to at least suggest a survival advantage in patients with myxoid mesotheliomas and are in agreement with the few reports available in literature [3, 13].

The fact that myxoid mesotheliomas produce a voluminous myxoid stroma that, as demonstrated by our histochemical staining, is mainly composed of hyaluronidase-sensitive material suggests perfect tumor recapitulation of the secretory activity of its normal counterpart. Indeed, normal mesothelial cells secrete glycosaminoglycans, particularly hyaluronic acid, which act as a lubricant, facilitating the motion of the viscera within their respective cavities. Therefore, it is not surprising that these tumors are always associated with epithelioid morphology without significant atypia. Consequently, the tumor cells show a typical mesothelial immunophenotype and ultrastructural characteristics, as has been well demonstrated by this study.

Indeed, the immunohistochemical staining pattern of these tumors is classic for mesothelioma. They show positive staining for keratins, vimentin, and mesothelial markers, and negative staining for the various glycoproteins (monoclonal CEA, Leu-M1, and Ber-EP4). Ki-67 has been reported to show a significant correlation with survival in patients with mesotheliomas [10]. In our study, more than half of the cases had minimal (<5%) nuclear labeling for Ki-67, and the remaining had a labeling index of less than 30%, thus demonstrating an overall low proliferation rate. However, owing to the small sample size, a meaningful comparison of outcome between those with less than 5% Ki-67 labeling and those with more is not possible.

The ultrastructural findings of epithelioid mesotheliomas are characteristic, owing mainly to the presence of abundant long and slender surface microvilli. As expected, all tumors in this series examined ultrastructurally showed typical mesothelial-type microvilli along with other commonly seen features such as well-formed cell junctions, basement membrane, and intermediate filaments. The myxoid stroma corresponds to an extracellular, mildly to moderately electron-dense amorphous or slightly granular material. This material tends to condense around cell surfaces and enmesh the surface microvilli, and is associated with the formation of electron-dense, fern-like bodies, which are considered to represent crystalline forms of hyaluronic acid [4]. This material needs to be distinguished from the glycocalyx material seen in some adenocarcinomas. The latter usually has a filamentous and hairy quality. In contrast to fern-like crystals, it is often associated with spherical glycocalyceal bodies coating the microvilli. The associated microvilli have a filamentous core that extends into the cell cytoplasm as a rootlet. Although glycocalyceal material is most apparent on the apical surface of intestinal epithelial cells and their neoplastic equivalents, it may also be present in tumors of other organ epithelia such as pulmonary adenocarcinoma, pancreatic ductal adenocarcinoma, and urothelial carcinoma [12]. It is therefore important for electron microscopists to distinguish the hyaluronic-acid-type mucous material of myxoid mesothelioma from the glycocalyceal material of adenocarcinomas.

The presence of a voluminous hyaluronidase-sensitive stroma in this group of tumors seems to be a different phenomenon from the intracellular mucin seen in the so-called “mucin-positive mesothelioma” reported by others [4, 7, 11]. In the latter group of tumors, it is believed that the mucin is also of hyaluronic acid type, as demonstrated by its sensitivity to digestion with hyaluronidase [7], and by the presence of electron-dense intracytoplasmic “fern-like” hyaluronic acid crystals [4]. The mucin in the latter group, however, is confined to the cells, and the tumors do not have a voluminous myxoid stroma [4, 7, 11]. The aberrant immunophenotypes, including positive immunoreactivity with a number of adenocarcinoma markers (most notably CEA and Leu M1) reported in mucin-positive mesotheliomas [7, 14], have not been observed in myxoid mesotheliomas. Available data are insufficient for an accurate comparison of these two groups of tumors with regard to their clinical and biological characteristics.

Myxoid stroma is a feature common to many types of tumors, and therefore may cause diagnostic confusion [5, 6], particularly when dealing with cytologic materials or small biopsies. Entities that can be confused for myxoid mesothelioma include mucinous adenocarcinomas, myxoid chondrosarcoma, and chordoma. In myxoid mesotheliomas, the typical mesothelial appearance of the tumor cells should enable correct distinction from other myxoid entities. When in doubt, a multimodality diagnostic approach including immunohistochemical and ultrastructural studies is suggested.

In summary, myxoid mesotheliomas are a group of epithelioid mesothelioma that has retained the secretory activity of normal mesothelium. The tumor cells exhibit immunohistochemical and ultrastructural features characteristic of epithelioid mesothelioma. Patients with myxoid mesothelioma may present at different stages of the disease; however, they seem to have a better overall survival when compared to patients with epithelioid mesotheliomas in general. Obviously, additional studies are needed to confirm the survival advantage. Our study calls for attention to histologic subtypes of malignant mesothelioma, particularly in the context of prognostically and therapeutically oriented investigations of this lethal disease.

Dedifferentiated liposarcoma with rhabdomyoblastic differentiation

Received: 5 April 2005 / Accepted: 30 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract Dedifferentiated areas of dedifferentiated liposarcoma (DDL) usually show malignant fibrous histiocytoma (MFH)- or fibrosarcoma-like features and lack any histologic signs of specific differentiation. However, some reports have demonstrated specific differentiation in these areas, with histologic features resembling those of rhabdomyosarcoma, leiomyosarcoma, and osteosarcoma. We report here a pathologic and genetic analysis of three cases of DDLs with rhabdomyosarcomatous areas. MFH- or fibrosarcoma-like areas of one primary DDL and two recurrent DDLs contained various amounts of rhabdomyoblasts, which were immunoreactive for desmin, myoglobin, muscle actin (HHF-35), and myogenin. An ultrastructural examination demonstrated rhabdomyoblasts with abundant cytoplasm containing thin and thick filaments and Z-bands. By real-time PCR, amplification of *mdm2* and *cdk4* was confirmed in both well-differentiated and dedifferentiated areas with rhabdomyoblasts of all cases. To our knowledge, only seven cases of DDLs with rhabdomyosarcomatous components have been reported, and furthermore, the genetic profiles of the rhabdomyosarcomatous components in DDLs have not been investigated. This study demonstrates that DDLs with rhabdomyosarcomatous areas have genetic alterations that are common to well-differentiated/dedifferentiated liposarcomas.

Introduction

Dedifferentiated liposarcoma (DDL), which was first introduced by Evans [3] in 1979, belongs to the same category as well-differentiated liposarcoma (WDL). DDL occurs most commonly in the retroperitoneum in middle-aged adults. Other locations include the extremity, the spermatic cord, and, less frequently, the head, neck, and trunk. No sex predilection is observed. About 90% of DDLs arise de novo, while 10% occur in recurrences [18].

Dedifferentiated areas of DDL usually consisted of nonspecific, undifferentiated sarcoma, such as malignant fibrous histiocytoma (MFH) and fibrosarcoma, although 10% of DDLs are known to show some specific differentiation including rhabdomyosarcoma, leiomyosarcoma, osteosarcoma, and angiosarcoma [4, 5]. In addition, dedifferentiated areas may show inflammatory MFH-like features, whorl structures, and palisaded myofibroblastoma-like structures. Among these, rhabdomyoblastic differentiation is one of the most uncommon forms of heterologous differentiation in DDLs [5]. Only seven cases of DDLs with rhabdomyoblastic differentiation have been reported in the literature so far to our knowledge [4, 5, 7, 14, 17].

Recently, it was demonstrated that WDLs and DDLs share common molecular cytogenetic abnormalities, that is, the ring or large-marker chromosome [9, 10, 13] and amplification of human homologue of the murine double-minute type 2 (*mdm2*) and cyclin-dependent kinase 4 (*cdk4*) gene [1, 2, 6, 11, 12, 15]. Alterations in *mdm2* and *cdk4* are recognized as major events in the tumorigenesis of liposarcomas. Overexpression of *mdm2* appears to act as an alternative to direct p53 mutation for inactivation of the p53-mediated pathway for cell growth suppression. Overexpression of *cdk4* interferes with the retinoblastoma (pRb)-mediated pathway through phosphorylation of pRb and inactivation of its cell growth-suppressive effect [20].

In the present study, we report three additional DDLs with rhabdomyoblastic differentiation and demonstrate for the first time the amplification of *mdm2* and *cdk4* genes in the dedifferentiated areas with heterologous elements.

Case histories

Case 1

A large retroperitoneal mass was detected in a 57-year-old man during a health checkup. The retroperitoneal tumor, which was 16×9 cm in size, and an abdominal tumor, which was found simultaneously and was 18.5×13.5 cm in size, were resected surgically. Macroscopically, the retroperitoneal tumor was hard and gray, and the abdominal tumor was soft and yellowish. They were diagnosed as DDL. Four years later, an 18×10 cm retroperitoneal tumor was found and removed again and diagnosed as DDL with rhabdomyosarcomatous components (Fig. 1a).

Case 2

A retroperitoneal mass was removed from a 53-year-old man. The tumor was diagnosed as WDL. Seven years later, a 17×17 cm abdominal mass involving the descending colon and the tail of the pancreas was resected and diagnosed as DDL. Three years after the second operation, a 6.8×6.8 cm abdominal mass was removed. The third tumor was diagnosed as WDL. One year after the third operation, a multinodular abdominal mass that involved the stomach, small intestine, and colon was resected. The fourth tumor was diagnosed as DDL with rhabdomyosarcomatous components. One year after the fourth operation,

a retroperitoneal tumor was resected and was diagnosed as DDL.

Case 3

A 35×24 cm retroperitoneal tumor was removed from a 69-year-old man. Macroscopically, the tumor was lipomatous in most parts and contained an 8-cm firm tan-gray mass. It was diagnosed as DDL with rhabdomyosarcomatous components. The patient died of sepsis 4 months after the operation. An autopsy was not allowed.

Materials and methods

Light microscopy

Primary and recurrent tumors of all cases were analyzed. The specimens were fixed in 10% formalin and were processed for paraffin embedding. In addition to hematoxylin-eosin (HE) stain, Masson-trichrome stain and reticulin preparation were applied.

Immunohistochemistry

Sections from all cases were immunostained with the following 14 antibodies. Antibodies were directed against myoglobin (lot 127; 1:500, DakoCytomation, Carpinteria, CA, USA), desmin (clone 33; 1:50, DakoCytomation), muscle actin (clone HHF35; 1:50, DakoCytomation), myogenin (clone F5d; 1:25, DakoCytomation), smooth muscle actin (clone 1A4; 1:50, DakoCytomation), vimentin (clone V9; 1:200, DakoCytomation), CD34 (clone My10; 1:30, BD Transduction Laboratory, San Jose, CA, USA), CD56 (clone 1B6; 1:50, Novocastra, Newcastle, English), CD99 (clone O13; 1:100, SIGNET Lab, Dedham, MA, USA), S100 protein (lot 017; 1:300, DakoCytomation), epithelial membrane antigen (clone E29; 1:100, DakoCytomation), cytokeratin (clone CAM 5.2; 1:1, BD Transduction Laboratory), and Ki-67 (clone MIB-1; 1:100, DakoCytomation). Ventana autostainer (Ventana HX system, Benchmark, Tucson, AZ, USA) was employed for the detection of the primary antibodies with diaminobenzidine as the chromogen.

Electron microscopy

Small specimens of case 3 sampled from formalin-fixed material were processed for ultrastructural study. A few 1-mm cubes were fixed in 1% glutaraldehyde in 0.1 M cacodylate buffer, postfixed in 2% osmium tetroxide, and dehydrated through graded alcohols for Epon embedding. Subsequently, the sections were prepared for electron microscopy in a standard routine.

Real-time PCR

DNA samples taken from rhabdomyosarcomatous components and WDL areas were a target for this analysis. Normal intra-abdominal fat tissues from 28 surgical materials of colonic and ovarian cancers were used as the control. All DNA samples were prepared from formalin-fixed, paraffin-embedded sections. Total DNA was isolated with DNeasy Kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. Real-time PCR was performed using

LightCycler 1.2 System (Roche Diagnostics GmbH, Mannheim, Germany). Primers and probes for target genes (*mdm2* and *cdk4*) listed in Table 1 were designed and made by Nihon Gene Research Laboratories Inc., Sendai, Japan, on the basis of the sequences registered with GenBank (*mdm2*: AF527840; *cdk4*: NM000075). Human beta-globin LightCycler (Nihon Gene Research Laboratories Inc.) was selected as the reference gene. Real-time PCR was

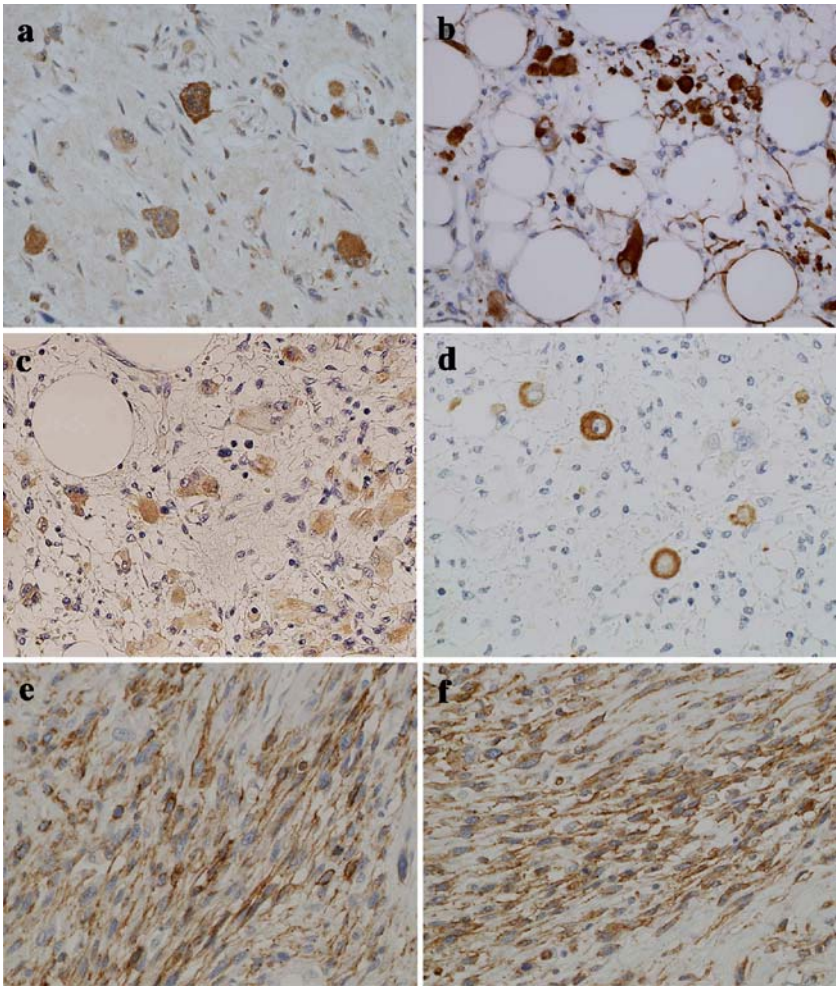

Fig. 2 Immunohistochemical findings of dedifferentiated liposarcoma with rhabdomyoblastic differentiation. Rhabdomyoblasts are immunoreactive for myoglobin (**a**), desmin (**b**), muscle actin (**c**), and cytokeratin (**d**). Spindle cells are positive for CD56 (**e**) and CD99 (**f**)

performed with 20-μl final mixture containing 50 pmol sample DNA, 10 pmol of each primer, 2 pmol of fluorescence probe, 4 pmol of LCRed probe, 2.4 μl $MgCl_2$, and 10 μl LightCycler Fast Start DNA Master Hybridization Probes (Roche Applied Science, Penzberg, Germany) according to the protocol shown in Table 2. The gene copy numbers of *mdm2* and *cdk4* were calculated from a standard curve that was constructed using a plasmid (Nihon Gene Research Laboratories Inc.), the gene number of which is already known. The level of amplification for the target gene was calculated as a ratio of the copy number of the target gene (*mdm2*, *cdk4*) to that of the reference gene (beta-globin). The cut-off value for assessment of the gene amplification level was determined based on that of normal fat tissues by creating a 99th percentile confidence interval, and individual measurements were considered as being amplified when they were beyond the above limit.

Results

Microscopic findings

In one case (case 2), the initial tumor was diagnosed as WDL and the recurrent tumors had dedifferentiated areas. In two cases (cases 1 and 3), the initial tumors were diagnosed as DDL. In all cases, WDL areas showed an atypical lipomatous neoplasm that contained lipoblasts, atypical mesenchymal cells, and mature lipomatous cells (Fig. 1b). In two cases (cases 1 and 2), dedifferentiated areas showed MFH-like features (Fig. 1c), and in one case (case 3), the dedifferentiated area showed fibrosarcoma-like structures (Fig. 1d). In two cases (cases 1 and 3), the border of WDL and DDL was clear, and many rhabdomyoblasts were diffusely seen in the DDL area, being located among bizarre and spindle cells (Fig. 1e,f). In case 2, the tumor had a well-demarcated DDL area, but the area did not contain rhabdomyoblasts. Alternatively, the tumor had a few rhabdomyoblasts scattered among spindle cells in the WDL area (Fig. 1g). The rhabdomyoblasts had atypical nuclei with prominent nucleoli (Fig. 1h) and eosinophilic cytoplasm, which contained filamentous structures.

Immunohistochemical findings

Immunohistochemical results of the cases were summarized in Table 3. The rhabdomyoblasts were immunoreactive for myoglobin (Fig. 2a), desmin (Fig. 2b), muscle actin (HHF-35) (Fig. 2c), myogenin, vimentin, CD56, and CD99 in all cases. A small number of rhabdomyoblasts were also positive for cytokeratin (CAM 5.2) in two cases (Fig. 2d). In one case, S-100 protein was expressed in rhabdomyoblasts.

The dedifferentiated components without rhabdomyoblasts were diffusely immunoreactive for vimentin, CD56 (Fig. 2e), and CD99 (Fig. 2f) in all cases. Desmin was focally expressed in cases 1 and 3. A few spindle cells in case 3 were also positive for smooth muscle actin. Myoglobin, muscle actin (HHF-35), myogenin, S-100 protein, and cytokeratin were not detected in any of these areas.

Electron microscopic findings

Ultrastructurally, rhabdomyoblastic cells had an atypical nucleus and abundant cytoplasm containing thin and thick filaments (Fig. 3a). Z-bands were focally found in the cytoplasm (Fig. 3b). Their ovoid nuclei, irregular in shape, contained euchromatin and a prominent nucleolus.

Real-time PCR

Copy number ratios for the *mdm2*, *cdk4*, and beta-globin were calculated in normal fat tissues. The mean of the copy number ratio was 1.12 for *mdm2* (range 0.12–1.67) and 1.05 for *cdk4* (range 0.52–1.58). The cut-off value (99th percentile) was 1.34 for *mdm2* and 1.20 for *cdk4*. Amplification was found in all samples of well-differentiated areas and dedifferentiated areas of liposarcomas, and the level of amplification was very high. The result of the

WDL Well-differentiated liposarcoma, *DDL* dedifferentiated liposarcoma

amplification status of the cases of liposarcomas is shown in Table 4. Amplification levels between WDL areas and dedifferentiated areas were not statistically significant (Mann–Whitney *U*-test).

Discussion

According to Henrichs et al. [5], DDLs with rhabdomyosarcomatous components account only for 1.3% of the DDLs, and to our knowledge, there have been only seven cases reported in the English literature so far [4, 5, 7, 14, 17]. The clinicopathological summary of ten cases combining seven reported cases and our three is presented in Table 5. They range from 47 to 72 years (mean age 57.4) in age and show a predilection for occurrence in men (men/women 8:2), whereas no sexual predominance is noted in DDL. All cases were located in the retroperitoneum or mesenteries. In the primary tumors, seven cases were diagnosed as WDLs, and the dedifferentiated areas with rhabdomyoblasts appeared in the recurrent tumors. The primary tumors of the remaining three cases were diagnosed as DDLs. The histology of the dedifferentiated areas was MFH in six cases, fibrosarcoma in two cases, and MFH and fibrosarcoma in two cases. Each case contained various amounts of rhabdomyoblasts, and, in addition, one case contained a leiomyosarcomatous component [17]. Follow-up data were available in nine cases. Eight cases underwent recurrences and metastasis [4] (Table 5). Taken together, the DDLs with rhabdomyosarcomatous components likely behave in a malignant fashion equivalent to the usual DDLs.

In our cases 1 and 2, the rhabdomyosarcomatous areas were not noted in the primary tumors; however, these areas were found in the recurrent tumors. In cases 1 and 3, the distribution of rhabdomyoblasts was diffuse in most of the dedifferentiated areas, but in case 2, a few rhabdomyoblasts appeared amongst some spindle cells in the well-differentiated area. The transition between the well-differentiated and dedifferentiated zones has been classified into three types [5]. In most cases, an abrupt transition is noted in such a manner that the two zones are starkly juxtaposed to one another, like in our cases 1 and 3. Less frequently, there is a gradual transition located between the two zones. The least common pattern is that of intricate commingling of dedifferentiated elements among the well-differentiated elements, giving the impression of mosaicism. The rhabdomyoblasts in case 2 were intermixed with well-differentiated areas, thus making it quite unusual in terms of the distribution of dedifferentiated components.

DDL with rhabdomyoblastic differentiation should be differentiated from malignant mesenchymoma, pleomorphic rhabdomyosarcoma, malignant Triton tumor, and malignant mixed mullarian tumor. It was previously proposed that malignant mesenchymoma is a non-epithelial malignant tumor showing two or more unrelated, differentiated tissue types in addition to the fibrosarcomatous elements [16]. In 1991, Newman and Fletcher [8] attempted to refine the criteria for this entity by excluding a variety of morphologic patterns that show no specific differentiation, such as fibrosarcoma, hemangiopericytoma, myxofibrosarcoma, and pleomorphic MFH. In addition, they reported a group of the malignant mesenchymoma with a low-grade behavior, in which six cases that contained liposarcoma and rhabdomyosarcoma were included. Since the concept of malignant mesenchymoma is now becoming less accepted,

some authors suggest the label "malignant mesenchymoma" be deleted from classification schemes, and sarcomas displaying two or more lines of differentiation would best be diagnosed by identifying the lines of differentiation, their approximate amounts, and the grade of the most aggressive component [19]. Some cases that were diagnosed as malignant mesenchymoma may be actually dedifferentiated liposarcoma with specific differentiation.

Pleomorphic rhabdomyosarcoma is a high-grade malignant tumor that may cause an early metastasis. It is important to find a well-differentiated liposarcomatous element, and to distinguish liposarcoma from non-neoplastic fat tissues is important for the differential diagnosis for these tumors.

Recently, amplification of *mdm2* and *cdk4* was reported in WDL and DDL, and these abnormalities were helpful when a histological diagnosis was difficult [2, 6]. WDLs and DDLs belong to the same category as liposarcomas and are characterized by ring or large-marker chromosomes [9, 10, 13]. Hostein et al. [6] showed the amplification of *mdm2* and *cdk4* in WDL and DDL by FISH and quantitative PCR. In the present study, we confirmed the amplification of *mdm2* and *cdk4* in dedifferentiated components with rhabdomyoblasts, as well as the conventional well-differentiated areas by real-time PCR. This result indicates that, regardless of the differences in histologic patterns, the dedifferentiated areas with rhabdomyosarcomatous components, which have rarely been documented in DDLs, have the same genetic alterations as the WDL areas.

In conclusion, we have reported three cases of DDL with rhabdomyosarcomatous differentiation. The dedifferentiated areas with rhabdomyoblastic differentiation showed the amplification of *mdm2* and *cdk4*, which is known to be common to WDLs and DDLs.

Loss of *p16^{INK4A}* expression is associated with allelic imbalance/loss of heterozygosity of chromosome 9p21 in microdissected synovial sarcomas

Received: 24 March 2005 / Accepted: 30 May 2005 / Published online: 5 August 2005
© Springer-Verlag 2005

Abstract Deletions of the short arm of chromosome 9 have been observed in many tumours and cell lines. This chromosomal region is frequently targeted during malignant transformation because it contains at least two known tumour suppressor genes: *p16^{INK4}* and *p15^{INK4B}*. *p16^{INK4A}* acts as a negative cell cycle regulator by inhibiting G_1 cyclin-dependent kinases that phosphorylate the retinoblastoma protein and therefore block the progression of the cell cycle from G_1 to S phase. The role of *p16^{INK4A}* in the development of synovial sarcoma has not been comprehensively investigated. Ten samples of synovial sarcomas were examined for allelic imbalance/loss of heterozygosity (AI/LOH) of the 9p region and p16 protein expression. DNA was isolated from microdissected sections of normal and tumour cells, amplified by polymerase chain reaction and analysed for AI/LOH by using six microsatellite markers that map to the 9p region. Immunohistochemistry for p16 expression was done. AI/LOH with at least one microsatellite marker on 9p21 was detected in six of ten samples. The most frequent allelic deletions were observed within the coding sequence of *p16^{INK4A}*. Loss of p16 immunoreactivity was detected in eight samples, six of which showed evidence of alterations at 9p21 region. These findings suggest a possible role of loss of *p16^{INK4A}* in the development of synovial sarcoma.

Introduction

Synovial sarcoma is a soft tissue tumour of unknown histogenesis, occurring most frequently in adolescents and young adults. Most synovial sarcomas are characterised by a recurrent non-random chromosomal translocation, t(X;18)(p11.2;q11.2) [8].

Alterations affecting cell cycle regulators acting at the G_1–S checkpoint represent one of the most frequent targets in molecular tumourigenesis [6, 25] and have been implicated in the pathogenesis and progression of sarcomas [7]. Nonetheless, little is known about the role of cell cycle regulator proteins in the tumourigenesis of synovial sarcomas.

Chromosomal loss of 9p21 has been implicated in the genesis of several different tumours and cell lines [12, 14]. This chromosomal region contains at least two known tumour suppressor genes, *p16^{INK4A}* [12, 24] and *p15^{INK4B}* [11, 14]. Both encode nuclear proteins that have been shown to block cell cycle progression at the G_1–S transition by their ability to interfere with the catalytic activity of cyclin D/CDK4 complexes [24]. Active cyclin D/CDK4 complexes are necessary for the phosphorylation of Rb protein and the subsequent release of critical transcription factors such as E2F, that are required for progression into S phase.

The aim of the study was to assess the frequency of allelic imbalance at different loci of chromosome 9 and to correlate it with loss of p16 immunoexpression in synovial sarcoma.

Materials and methods

Tissue samples

Ten cases of formalin-fixed paraffin-embedded synovial sarcoma were analysed for allelic imbalance/loss of heterozygosity (AI/LOH) of chromosome 9 and examined for

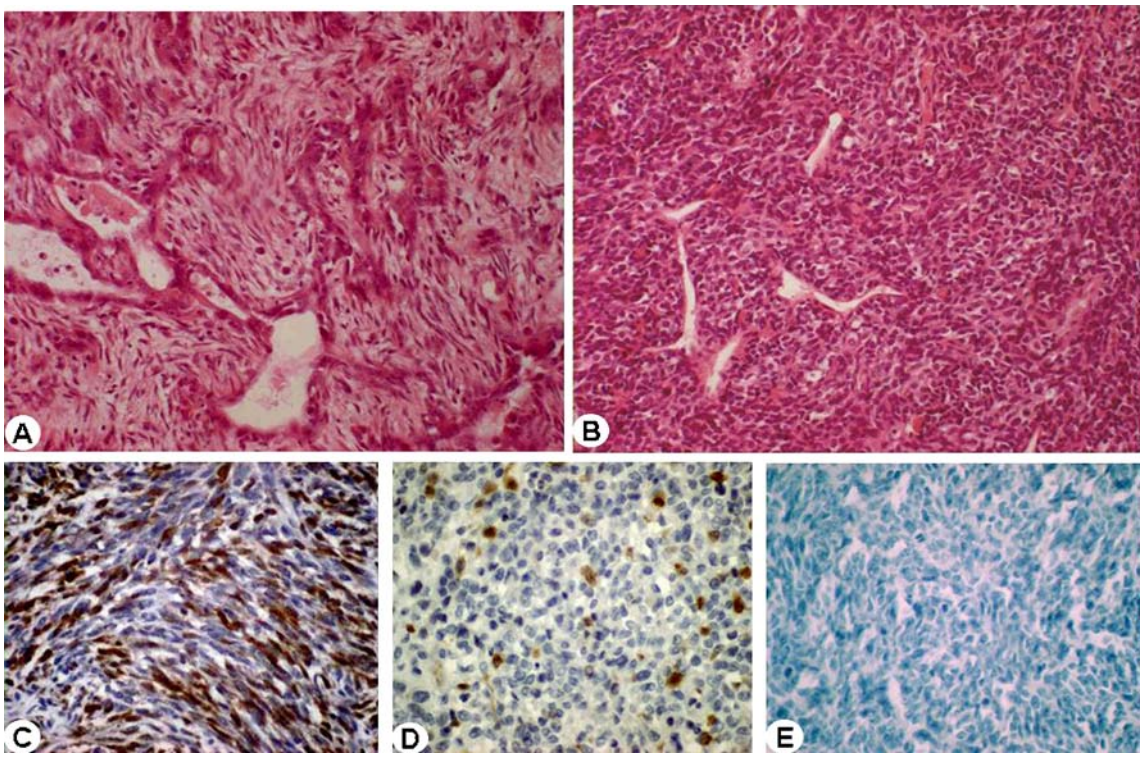

Fig. 1 Haematoxylin and eosin stain: **a** synovial sarcoma with a biphasic morphology, **b** spindle cell sarcoma (original magnification ×200). Positive p16 immunostaining (**c**). Heterogeneous staining (**d**). Negative p16 immunostaining (**e**). Original magnification ×400

p16 immunoreactivity. The diagnosis in each case was based on histologic and immunohistochemical features and was reviewed by the Dublin Soft Tissue Tumour Panel. The cases were graded according to the Fédération Nationale des Centres de Lutte Contre le Cancer (FNCLCC) scoring system [10, 28].

A single case had a biphasic morphology (Fig. 1a) and nine cases were of spindle type (Fig. 1b). Four cases were grade 2 sarcomas and six cases were grade 3 sarcomas. A summary of histologic type and tumour grade is outlined in Table 1.

Table 1 A summary of tumour grade and p16 immunostaining

Case no.	Morphology	Grade	Percentage of cells expressing p16
1	Spindle	High grade	30 (heterogeneous)
2	Spindle	High grade	100 (+)
3	Spindle	High grade	0 (−)
4	Spindle	High grade	0 (−)
5	Biphasic	Intermediate grade	0 (−)
6	Spindle	Intermediate grade	0 (−)
7	Spindle	Intermediate grade	100 (+)
8	Spindle	High grade	5 (−)
9	Spindle	High grade	0 (−)
10	Spindle	Intermediate grade	5 (−)

Immunohistochemistry

Four-micrometer-thick sections were cut and dried overnight at 55°C. Deparaffinization, rehydration and antigen retrieval was performed by using 1× Trilogy (Cell Marque, Hot Springs, AR, USA). The endogenous peroxidase activity was blocked by immersing the sections in 0.9% hydrogen peroxidase for 10 min at room temperature. The sections were incubated at room temperature for 30 min with 200 μl of primary p16 monoclonal antibody (16^{INK4A} Ab-7, clone 16P07, NewMarkers, Fremont, CA, USA), 1/100 dilution. The epitope for this antibody is aa1-32. Antibody detection was then done using Vectastain Elite Universal ABC kit (Vector Labs, Burlingame, CA, USA). Diaminobenzidine with haematoxylin counterstaining was used to develop the colour. Cervical tissue with high-grade dysplasia was used as a positive control. The antibody was omitted for negative control.

Sections were examined for nuclear staining and immunoreactivities were classified into three categories, defined as follows: negative (−), less than 20% of cells were immunoreactive; heterogeneous, 20 to 80% were immunoreactive; positive (+), greater than 80% were immunoreactive. Samples showing either negative or heterogeneous staining were considered abnormal, whereas those with positive staining were interpreted as normal [30].

DNA microdissection

Ten cases were microdissected (Table 1). For each sample, normal and tumour tissue were first identified on routinely stained sections under light microscopy. Two parallel 8-μm-thick sections were dewaxed in xylene, rehydrated through various alcohol grades, rinsed well in distilled water and finally stained with haematoxylin.

Using the original sections as a template, neoplastic and non-neoplastic tissues were microdissected under a stereomicroscope. Non-neoplastic tissue submitted as resection margins was first identified on haematoxylin and eosin sections and then microdissected from haematoxylin sections by a pathologist. The DNA obtained from non-neoplastic tissue was considered as normal DNA. Multiple areas of the tumour were sampled.

Genomic DNA extraction

DNA was isolated from microdissected tumour and normal cells using 60 μl of proteinase K solution [20 mg/ml proteinase K (Roche Diagnostics, Mannheim, Germany) in 50 mM Tris–HCl (pH 7.4), 0.1 mM EDTA, 1% Tween] at 55°C for 72 h. After digestion the proteinase K was inactivated by heating to 94°C for 10 min. The samples were then ready for polymerase chain reaction (PCR) amplifications.

PCR amplifications

Six fluorescent Cy5 end-labelled microsatellite markers were used. Four markers map to 9p21: D9S916, D9S1814, D9S974 and D9S942. The latter two are within the coding sequence of $p16^{INK4A}$. D9S916 is telomeric to $p16^{INK4A}$ and 15^{INK4B}, whereas D9S1814 is centromeric to $p15^{INK4B}$. D9S171 is on 9p13 (proximal to $p16^{INK4A}$ and $p15^{INK4B}$). D9S230 is on 9p24.

PCR amplifications were performed in a final volume of 20 μl and consisted of 1× PCR buffer, 200 μM deoxynucleotide triphosphate, 1.25 mM $MgCl_2$ (Promega, Madison, WI), 2 pmol of forward and reverse primers (TAGN, Newcastle, UK) and 1 μl of sample DNA digest. After denaturation at 95°C for 5 min, 2 μl of Taq (1 U/μl) (Promega) were added at 80°C. A touchdown PCR was then done consisting of two cycles of 95°C for 1 min, 1 min at an initial annealing temperature (Table 2) and extension at 72°C for 1 min. Subsequent steps consisted of two cycles each with annealing temperature reduced by 2°C until 30 cycles were done at the final annealing temperature. A final extension step at 72°C for 10 min completed the reactions. After PCR, 5 μl PCR products mixed with loading dye were electrophoresed through 12% polyacrylamide minigels. The DNA fragments were visualised by ethidium bromide staining under ultraviolet light.

AI/LOH assay

The PCR products were diluted in distilled water and were then mixed with Cy5.5-labelled DNA size ladder and denatured at 94°C for 10 min. Normal and tumour samples were loaded side by side on a Microcel in the OpenGene System (Visible Genetics, Toronto, Ontario, Canada). Run parameters of the OpenGene System were 1,300 V for 30 min at a plate temperature of 54°C. Data were processed and analysed using the GeneObjects Fragment Analysis Tool (Visible Genetics). For each heterozygous locus, the area under each peak representing each allele in the microsatellite pair was obtained using the GeneObjects Fragment Analysis Tool. The area of the first allele was divided by the area of the second allele in each of the normal and tumour DNA samples. A ratio of ratios between the normal and tumour PCR products was calculated to give an overall allele ratio. The cut-off allele ration value for chromosomal loss was 0.74 as was published from studies from our laboratory [2, 18–20]. This figure was obtained from evaluating normal tissue from 13 patients by triplicate PCR. It was calculated that 99.5% of the cases have an allele ratio of greater than 0.74. Furthermore, the distinction be-

tween AI and LOH was made using a cut-off value of 0.30. This was in accordance with a previously published study that compared radioactive and fluorescence-based AI/LOH methods and demonstrated that the value 0.30 separated AI from LOH [26].

Therefore, the value 0.74 was used to separate AI from retention of heterozygosity and the value 0.30 was used to separate AI from LOH. Microsatellite instability (MSI) was defined as the presence of novel alleles or extra peaks in the tumour DNA sample not seen in the normal DNA. The PCR amplification and AI/LOH analysis were done twice to ensure consistency in the results.

Results

Immunohistochemical analysis

The results for p16 immunostaining are presented in Table 1. Two of ten cases showed diffuse positive nuclear staining (+) (Fig. 1c). One case showed heterogeneity in the staining pattern and was regarded as abnormal expression of p16 (Fig. 1d) and seven cases were negative (−) (Fig. 1e).

AI/LOH analysis

A summary of AI/LOH of chromosome 9p and allele ratios are given in (Fig. 2).

Of the ten samples that were analysed for AI/LOH, the average informative rate per marker was 70% (range from 60% to 80%).

Six of ten samples exhibited AI/LOH at one or more loci in the 9p region (Fig. 3). AI/LOH loss was most frequent at D9S942 locus (75% of informative cases), followed by D9S974 (62.5% of informative cases). These two microsatellite markers are located within the coding sequence of $p16^{INK4A}$. D9S916 revealed allelic loss in 50% of informative cases. Both D9S1814 and D9S171 showed AI/

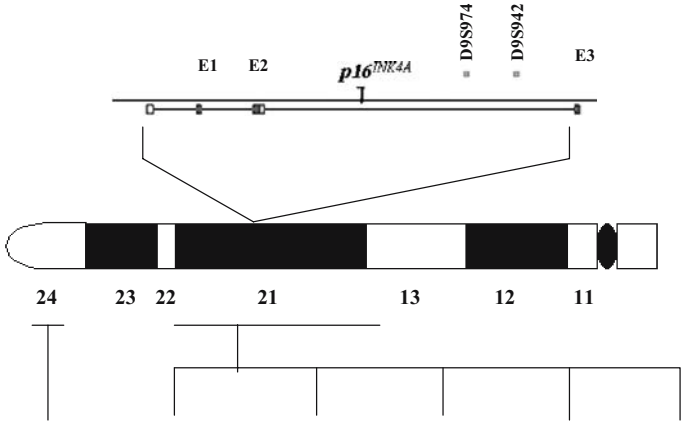

Fig. 2 Microsatellite map of AI/LOH on chromosome 9. The approximate position of each microsatellite marker from 9pter is displayed in the *marker box*. The location of $p16^{INK4A}$, D9S974 and D9S942 is presented according to NCBI map Viewer. The allele ratio is displayed in the corresponding box. *Filled circle* indicates AI/LOH, *open circle* indicates retention of heterozygosity, and *strike through circle* indicates homozygosity (uninformative)

LOH in 33.3% of informative cases. D9S230 locus on 9p24 revealed AI/LOH in 16.7% of informative cases.

Only a single case revealed evidence of MSI at D9S974 locus. AI/LOH was observed in intermediate and high-grade tumours.

Correlation between p16 protein expression and AI/LOH results

All cases with AI/LOH at 9p (cases 3, 4, 5, 6, 8 and 10) were negative for p16 immunostaining. One case showed no evidence of allelic alteration (case 1) but was heterogeneous for p16 immunostaining. This case was uninformative for four microsatellite markers including D9S942.

Two cases (cases 2 and 7) were diffusely positive for p16 immunostaining. Neither of these cases showed allelic alteration with any markers studied. The two cases were informative with retention of heterozygosity for D9S974 and D9S942 markers that are present within the coding sequence of $p16^{INK4A}$.

Discussion

Alterations of chromosomal band 9p21 have been reported in different types of human tumours and cell lines [12, 14]. Moving from the centromere to the telomere, this complex region encodes the tumour suppressor genes $p15^{INK4B}$ [11, 14], $p16^{INK4A}$ [12, 24] and the housekeeping gene methylthioadenosine phosphorylase (*MTAP*) [15]. $p16^{INK4A}$ encodes two proteins p16 and $p14^{ARF}$. p16 is a nuclear protein that blocks cellular proliferation at the G_1–S phase. It binds to the cyclin-dependent kinases CDK4 and CDK6 and inhibits phosphorylation of Rb and subsequent release of critical transcription factors such as E2F that are required for progression from G_1 into S phase [24, 25]. $p14^{ARF}$-protein blocks Mdm2-induced degradation of p53 [17]. Consequently, alteration of $p16^{INK4A}$ impairs both the Rb and p53 tumour suppressor pathways. $p15^{INK4B}$ encodes a nuclear protein, which, in addition to being an inhibitor of CDK4 and CDK6, has also been implicated in the TGF-β pathway leading to cell growth arrest [11]. Inactivation of $p16^{INK4A}$ has been described as the consequence of homozygous deletion, rearrangement, hypermethylation or point mutation [3, 4, 13].

In this study, we examined LOH of chromosome 9p using PCR-based microsatellite analysis in ten cases of microdissected synovial sarcoma. We detected AI/LOH of 9p in 60% of synovial sarcoma cases. AI/LOH at 9p21 region was a consistent finding in these cases. AI/LOH was most frequent at D9S942 locus (75% of informative cases), followed by D9S974 (62.5% of informative cases). These two microsatellite markers are located within the coding sequence of $p16^{INK4A}$. AI/LOH at D9S171 locus on 9p13 band adjacent to 9p21 was observed in 33.3% and at D9S230 locus on 9p24 was identified in 16.7% of informative cases. These findings may point to the existence of tumour suppressor genes at these two loci as was previously suggested for D9S171 [23]. Alternatively, be-

cause alterations at these two loci were associated with alterations on 9p21, they may reflect chromosomal instability secondary to deletions at 9p21.

Immunohistochemistry revealed normal expression of p16 in two of ten samples (cases 2 and 7). These two samples showed no evidence of allelic deletion with any marker examined including the two microsatellite markers that are present within the coding sequence of $p16^{INK4A}$ (D9S974 and D9S942). Loss of p16 expression was identified in eight of ten samples examined. Six of these samples showed AI/LOH at 9p21. In two cases (1 and 9), loss of p16 immunoreactivity was not associated with alterations at 9p21. There are three possible explanations: (1) Technical flaw in LOH study. (2) p16 immunoreactivity is a reflection of other genetic or epigenetic changes including DNA methylation and posttranslational modification that are not detectable by LOH. (3) The two cases were homozygous for either D9S942 or D9S974 marker and therefore were not informative. In this study, the most frequent allelic alterations were observed at these two markers. Given the uniformity of the result, the last explanation seems most likely.

Alterations of $p16^{INK4A}$ have not been comprehensively studied in synovial sarcoma. Antonescu et al. [1] examined the expression of different cell cycle regulators in synovial sarcoma by immunohistochemistry. The authors reported that aberrant expression of different molecules that are involved in regulating the cell cycle was a common event in synovial sarcoma. However, p16 protein was not among the cell cycle regulators examined.

Golouh et al. investigated the role of altered p16 and nm23 mRNA expression as prognostic factors in synovial sarcoma. The authors reported that whereas increased level of nm23 mRNA is associated with poor survival, there was no correlation between survival rate and p16 mRNA expression [9].

$p16^{INK4A}$ has been investigated in mesenchymal neoplasms, but with varying conclusions. Some studies have reported that $p16^{INK4A}$ alterations are infrequent in soft tissue sarcomas [5, 21, 22, 29], whereas others have shown that alteration of $p16^{INK4A}$ is a common event in soft tissue sarcomas. Furthermore, it has been shown that $p16^{INK4A}$ knockout mice frequently develop sarcomas [27]. Orlow et al. reported that coincident homozygous deletion of $p16^{INK4A}$ and $p15^{INK4B}$ occurs frequently in soft tissue sarcomas [16]. Cohen and Geradts reported that aberrant expression of p16 is one of the most common molecular derangements in sarcomagenesis [5]. Similarly, Yoo et al. identified altered expression of p16 protein in 94% of sarcoma cases [30].

The discrepancy in these reports can be explained by methodological factors; for example, the low frequency of genetic alteration of $p16^{INK4A}$ may be due to contamination with normal cells. Microdissection allows one to enrich for tumour cells and, thereby, more accurately analyse tumour samples. Similarly, the discordance in immunohistochemical studies can be explained by the use of different commercially available antibodies, technical variability in immunohistochemistry or differences in the criteria for interpreting the results. Alternatively, these differences can be explained by differences in tumour type, histologic grade or clinical stage of the cases studied.

Although the number of cases in this study is low, it is clear from AI/LOH and immunohistochemical findings that alterations of $p16^{INK4A}$ are common findings in synovial sarcomas. Additional studies are required to determine whether genetic alterations of $p16^{INK4A}$ are an important step in the pathogenesis of synovial sarcomas or whether they represent an epiphenomenon common in this tumour. Identifying various molecular changes in this type of sarcoma is a key to our improved understanding of the biological behaviour of this disease.

Rhabdomyoma of the head and neck: morphology and differential diagnosis

Received: 16 March 2005 / Accepted: 23 June 2005 / Published online: 18 August 2005
© Springer-Verlag 2005

Abstract Rhabdomyomas of the head and neck are exceptionally rare benign mesenchymal tumors. Although histology is very characteristic, several differential diagnoses have to be considered. We investigated five patients with extracardiac rhabdomyoma of the head and neck (median age 65.9 years), four of them presenting with adult rhabdomyoma (AR) and one with fetal rhabdomyoma (FR). We analyzed the histological findings, with special regard to separation from hibernoma (two patients) and granular cell tumor (GCT; six patients, median age 31 years). Both FR and AR showed polygonal eosinophilic cells with peripherally or centrally localized nuclei and cross striations, while in hibernoma, multivacuolated cells with centrally localized nuclei were detected. In GCT, polygonal eosinophilic cells with granular periodic-acid-Schiff-positive cytoplasm were found; in one case, atypical GCT with increased pleomorphism and mitotic rate was observed. Pseudoepitheliomatous hyperplasia occurred both in FR and GCT. Immunohistochemically, rhabdomyomas were strongly positive for myogenic markers (desmin, actin, and myoglobin) but negative for S-100, while hibernoma and GCT strongly expressed S-100. Concerning the differential diagnosis of rhabdomyoma, GCT has to be especially considered since this tumor can undergo malignant transformation.

Introduction

Rhabdomyoma is a benign mesenchymal tumor with skeletal muscle differentiation. Topographically, cardiac and extracardiac types can be distinguished. The cardiac rhabdomyoma almost exclusively occurs in the hearts of young children and is often associated with congenital abnormalities like tuberous sclerosis. Extracardiac rhabdomyomas consist of four clinically and morphologically different types, i.e., the adult, the fetal, and the genital type, and rhabdomyomatous mesenchymal hamartoma [6, 19].

Adult rhabdomyoma (AR) predominantly occurs in elderly persons (median age about 60 years) with a male predilection (3:1 male to female ratio). The head and neck area is by far the most common site. AR grows most frequently as a solitary mass (about 70%), but may be multinodular with discrete nodules in the same area (about 25%) or, rarely, even multicentric (about 5%) [6, 19]. Due to high local recurrence rate (up to 42%), complete excision is recommended [6, 15, 18–21]. By contrast, malignant transformation has not been described. Etiology and pathogenesis of AR are poorly understood. Due to its typical localization in the neck, it has been suggested that this tumor arises from the branchial musculature [6, 19]. Concerning the cytogenetic characteristics, Gibas and Miettinen [8] reported on a case of a pharyngeal recurrent AR, with a reciprocal translocation of chromosomes 15 and 17 and abnormalities of chromosome 10 supporting a neoplastic rather than hamartomatous nature.

Fetal rhabdomyoma (FR) is even rarer than AR. Two forms exist: the myxoid type, which typically affects young boys, and the intermediate type, which is more common in adults. Both forms are predominantly in the head and neck area, with a favorite site in the submucosa and subcutis. While the myxoid type is histologically mainly composed of primitive oval or spindle-shaped cells in a myxoid stroma, the intermediate type generally consists of differentiated muscle fibers with frequent cross striations. However, transitional forms also exist [6, 19].

In the present study, we examined five patients with rhabdomyomas of the head and neck area (four cases with

[a]Data of this patient have already been published as a case report [9]

AR and one case with FR), with special regard to the histological findings. Since granular cell tumor (GCT) and hibernoma are described as most relevant differential diagnoses, we included tissue specimens of the respective diseases in this study.

Materials and methods

The records from the Soft Tissue Registry of the Institute of Pathology in Jena were searched for cases coded as rhabdomyoma, hibernoma, and GCT of the head and neck area from 1995 to the present. The patients' characteristics are summarized in Table 1. In brief, we found five cases of extracardiac rhabdomyoma (four patients with AR and one patient with FR; female to male ratio, 2:3; median age 65.9 years); two patients suffered from hibernoma (among a total number of 31 hibernomas; female is equal to male; median age 56 years), and six patients presented with GCT (among a total number of 52 GCTs). One case presented as atypical GCT. The female to male ratio was 1:1, and the median age of the patients was 31 years. From all cases, available slides were reviewed. Immunohistochemical staining was performed according to previous protocols [11]. The primary antibodies applied for the immunohistochemical analysis are summarized in Table 2.

Table 2 Data on the antibodies used for this study

	Marker[a]	Dilution
1	Desmin (clone D33)	1:400
2	Muscle-specific actin (clone HHF-35)	1:500
3	Myoglobin (polyclonal rabbit antihuman)	1:400
4	Myogenin F5D	1:300
5	S-100 (polyclonal rabbit antihuman)	1:20,000
6	Ki-67 (clone KiS5)	1:300

[a]Antibodies 1–3, 5, and 6 were manufactured by DAKO (DAKO, Hamburg, Germany), while antibody 4 was manufactured by Pharmingen (Pharmingen, San Diego, CA, USA)

Results

Rhabdomyoma

Light microscopy revealed nonencapsulated tumors, which were composed of tightly packed polygonal cells. The cells were most frequently eosinophilic and contained a granular cytoplasm. Sometimes, cross striations were seen. Besides, vacuolated cells with centrally stellate-shaped eosinophilic cytoplasm were found that were regarded as the so-called spider cells (Fig. 1). The nuclei were localized either centrally or peripherally with some multinucleated cells. Immunohistochemistry with antibodies against muscle-specific actin, desmin, myoglobin (Fig. 2), and myogenin demonstrated strong immunostaining, confirming the diagnosis of AR.

In one case (patient no. 5), the cells showed less cytoplasm and were sometimes spindle-shaped. They obtained intracytoplasmic cross striations. Furthermore, glycogen content of cytoplasm can be confirmed by periodic acid-Schiff (PAS) staining. Nuclei were mainly peripherally

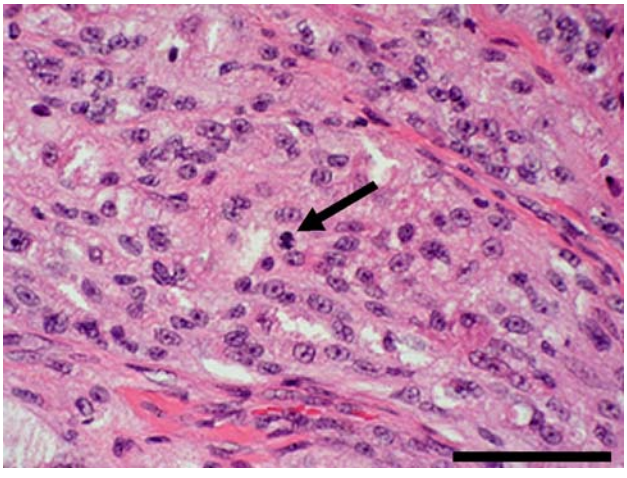

Fig. 11 Same patient as in Figs. 9 and 10 with a detailed view of nuclear pleomorphism. Note prominent nucleoli, mitosis (*arrow*), and granular eosinophilic cytoplasm of the cells (hematoxylin and eosin, original magnification ×400, *bar*=50 μm)

localized. Interestingly, the epithelium in the neighborhood of this tumor showed acanthosis, as well as parakeratosis and some nuclear pleomorphisms, without invasion of the stroma as a sign of pseudoepitheliomatous hyperplasia (Fig. 3). The myogenic nature of the cells was confirmed by immunohistochemical analysis, leading to the diagnosis of an FR (Fig. 4).

Hibernoma

Histologically, the tumors consisted of tightly packed round or oval cells. These cells showed a variable degree of vacuolization, with a few, but distinct, univacuolated cells (Fig. 5). The cytoplasm of multivacuolated cells varied from pale staining to eosinophilic and granular. In particular, nuclei were almost always localized centrally. Sometimes, they contained prominent nucleoli.

Immunohistochemically, cells displayed strong cytoplasmic positivity for S-100 (Fig. 6).

Granular cell tumor

Microscopically, the tumors were nodular but ill-defined. They were composed of polygonal, sometimes spindle-shaped cells, which throughout showed a granular eosinophilic cytoplasm (Fig. 7). Commonly, the intracytoplasmic granules can be stained by PAS reaction. The cells were tightly packed in some tumors, while in others, they were arranged as clusters dispersed between collagen fibers. The nuclei were peripherally localized and showed a dense chromatin; nucleoli were rarely seen. Particularly, two cases (patient nos. 9 and 10) showed remarkable pseudoepitheliomatous hyperplasia of the epithelial lining (Fig. 7). Strong immunoreactivity was obtained with anti-S-100

(Fig. 8) A further case (patient no. 12) focally displayed enhanced nucleocytoplasmic ratio, prominent nucleoli, and an enhanced mitotic rate [3–4 mitoses/10 high-power fields (HPF)], indicating atypical GCT (Figs. 9, 10, and 11).

Discussion

Extracardiac rhabdomyomas of the head and neck area include adult rhabdomyoma (AR) and the less common fetal rhabdomyomas (FR). Both lesions are fairly rare, with only about 150 published reports, mostly in the form of case studies. We present five patients with extracardiac rhabdomyomas of the head and neck region and discuss the relevant differential diagnoses with special regard to soft tissue tumors.

The histological findings of AR are very characteristic, and, in addition, reveal expression of myogenic markers, including desmin, muscle-specific actin, myoglobin, MyoD1, and myogenin[4, 6, 10, 19]. The typical morphology of this tumor should argue against the view that problems in diagnosis might occur at all. However, one needs to be familiar with this rare entity to exclude other diseases. Numerous diseases have been mentioned with the differential diagnosis of AR such as hibernoma, GCT, oncocytoma, paraganglioma, reticulohistiocytoma, lymphoma, rhabdomyosarcoma, and crystal-storing histiocytosis. Among these, GCT and hibernoma are the most relevant soft tissue lesions and, therefore, are especially considered (synopsis is given in Table 3).

Hibernoma is an unusual tumor which mimicks the differentiation of brown fat [2, 13]. In the largest series from Furlong et al. [7], 170 patients were examined. In contrast to the previous opinion that this tumor is mostly localized in areas of residual brown fat, namely, the neck, axilla, and back, Furlong et al. [7] found tumors more often localized in the lower and upper extremity (32 and 22%, respectively) than in the head and neck region (14%). These data are in line with the findings of our report. Of a total number of 31 hibernomas in the Soft Tissue Registry of the Institute of Pathology (Jena), we only found two cases located in the head and neck area (i.e., 6.5%).

In contrast to AR, patients are younger (median age about 40 years), and there is no obvious sex predilection. Since hibernoma cells might show a dense eosinophilic cytoplasm composed of numerous small vacuoles, they can appear granularly shaped. As they additionally can obtain prominent nucleoli, distinction between hibernoma and AR might be difficult. However, less vacuolated or even univacuolated adipocytes are generally found in hibernoma but not in AR. Furthermore, the adipocytic origin of hibernoma can be confirmed immunohistochemically by S-100. However, focal positivity for this marker has also been described in AR [10]. In these cases, distinction can be clarified by using additional myogenic markers. Recently, positivity of desmin was described in spindle cell lipomas [17]. Since a spindle cell variant of hibernoma has been described [7], and similarities of the origin of both hibernoma and spindle cell lipoma are discussed [7, 17], the use of desmin alone might not be sufficient for a clear separation from rhabdomyoma. We therefore recommend a panel of myogenic markers consisting of at least two further muscle-specific antibodies such as muscle-specific actin and/or myoglobin and, in particular, myogenin.

Granular cell tumor, formerly called Abrikossoff's tumor [1] or granular cell myoblastoma [14], has a well-known predilection for the head and neck area, especially for the tongue [14, 16]. The prevailing theory supports that GCT is a true neoplasm, which is of neural origin, and is most probably derived from the Schwann cell. In particular, the consistent positivity for S-100 separates this tumor from neoplasms of histiocytic, fibroblastic, or smooth-muscle derivation [5, 13, 16]. In contrast to AR, FR, and hibernoma, GCT can undergo malignant transformation [2, 3].

Table 3 Synopsis of histological differential diagnosis between adult rhabdomyoma, hibernoma, and granular cell tumor

Tumor	Cells/cytoplasm	Nuclei	Nucleoli	IHC
AR	Polygonal cells, eosinophilic granular cytoplasm, cross striations, spider cells	Peripherally > centrally; vesicular chromatin	Yes	⊕ desmin, muscle-specific actin, myoglobin, and myogenin; ∅ S-100[a]
FR	Small eosinophilic cells, sometimes with cross striations	Peripherally > centrally	Rarely	⊕ desmin, muscle-specific actin, myoglobin, and myogenin; ∅ S-100
Hibernoma	Oval to round cells, variable degrees of vacuolization, eosinophilic granular cytoplasm	Centrally > peripherally; vesicular chromatin	Yes	⊕ S-100; ∅ muscle-specific actin, myoglobin, and myogenin
GCT	Cells variably shaped, eosinophilic granular cytoplasm	Peripherally; dense chromatin	Rarely	⊕ S-100; ∅ desmin, muscle-specific actin, myoglobin, and myogenin
Atypical GCT	Pleomorphic cells, eosinophilic granular cytoplasm, and multinucleated cells occur	Peripherally; vesicular chromatin; increased mitotic rate	Yes	⊕ S-100[b] ∅ desmin, muscle-specific actin, myoglobin, and myogenin

[a]Positivity in a few cases is reported [10]
[b]Negativity is reported [3, 12]

Fetal rhabdomyoma may not easily be separated from GCT. Histologically, both tumors are composed of relatively small eosinophilic cells with peripherally localized nuclei. Pseudoepitheliomatous hyperplasia has been described as a typical feature of GCT [13, 14]. However, as presented in this study, this can also be found in the vicinity of FR and is thus not helpful for exclusion. Immunohistochemistry, using a panel of S-100 and myogenic markers, may help to confirm the diagnosis of either FR or GCT. Particularly, in the case of atypical or malignant GCT, negativity for S-100 has been found [19, 20]. By contrast, expression of myogenic markers has not been demonstrated in GCT so far [3, 12, 16].

In summary, although the histological findings of AR and FR are very characteristic, one needs to be familiar with these rarities. Among the soft tissue tumors, hibernoma and GCT should be especially excluded. In contrast to hibernoma, which is not frequent in the head and neck area, and which is always of a benign nature, GCT should be particularly considered since this tumor can undergo malignant transformation.

Fusion of the *HMGA2* and *NFIB* genes in lipoma

Received: 20 May 2005 / Accepted: 21 June 2005 / Published online: 17 August 2005
© Springer-Verlag 2005

Abstract The major cytogenetic subgroup of lipomas is characterized by aberrations of chromosome segment 12q13–15, which recombines with a large number of other chromosomal regions. The gene *HMGA2* is the main target in these aberrations. For some recurrent rearrangements, chimeric transcripts, including the 5′ part of *HMGA2*, have been described. The 3′ partners identified are *LPP*, *LHFP*, *CMKOR1*, and *EBF*. In addition, subsets of other benign solid tumors show aberrations of 12q13–15. Among pleomorphic adenomas of the salivary glands, where the preferred recombination partner with 12q13–15 is 9p22–24, an *HMGA2*/*NFIB* fusion gene has been reported. In the present study, two cases of lipoma with rearrangements of 9p22–24 and 12q15 were analyzed by reverse transcription polymerase chain reaction to find out if *HMGA2*/*NFIB* was also present in lipoma. An in-frame fusion transcript, combining the four first exons of *HMGA2* with exon 8 of *NFIB*, was detected in one case. It was identical to a transcript that was previously described in salivary gland adenoma and contained a stop codon shortly 3′ of the fusion point. The finding of the same fusion gene in different tumors is not unique. For example, *HMGA2*/*LPP* has been reported in lipoma, pulmonary chondroid hamartoma, and soft tissue chondroma. Since similar 9;12 translocations have been described also in rare cases of hamartoma and uterine leiomyoma, the occurrence of *HMGA2*/*NFIB* could be postulated in these tumors as well.

Introduction

Several benign solid tumor entities are characterized cytogenetically by rearrangements of the chromosome segment 12q13–15 (e.g., [3, 7–9, 11, 17]). The fraction of tumors displaying aberrations of this segment ranges from about 60% among lipomas and chondroid hamartomas of the lung, to 30–35% of uterine leiomyomas and hemangiopericytomas and 20–25% of pleomorphic adenomas of the salivary glands and chondromas [13]. Typically, 12q13–15 recombines with a large variety of other chromosome bands through translocations, insertions, and inversions. Although almost any band may be involved, there are some cytogenetically identical changes that have been detected in several cases. These recurrent aberrations may vary from one tumor type to another. Among lipomas, the preferred rearrangement t(3;12) (q27–28;q13–15) is present in every fifth tumor, with the involvement of 12q14–15 [14].

The gene *HMGA2* (previously *HMGIC*), located in 12q14–15, is the central molecular target of these chromosomal aberrations and plays an essential role in the tumorigenesis of these lesions [1, 4]. The break points related to structural chromosome aberrations may be located within the gene or at megabase distances outside of the gene, and the effects may be dysregulation of gene expression, truncation of the gene, or formation of a fusion gene encoding a chimeric transcript. Among lipomas, *HMGA2* has been reported to form fusion genes with *CMKOR1* (in 2q35–37), *LPP* (in 3q27–28), *EBF* (in 5q33), and *LHFP* (in 13q12) [2, 15, 18, 19]. The *HMGA2*/*LPP* chimera has also been described in chondroid hamartomas [20] and in one case of soft tissue chondroma [3].

Among pleomorphic adenomas of the salivary gland, the major cytogenetic subgroup is characterized by aberrations of 8q12, whereas a minor subgroup shows rearrangements of 12q13–15. The dominating aberration is t(3;8), but both 8q12 and 12q13–15 have been found to recombine with

9p22–24 in several cases. In two tumors, the recombination between 9p and 12q segments is demonstrated to result in the formation of an *HMGA2*/*NFIB* fusion gene [5].

In the present study, two cases of lipoma with a recombination between 9p and 12q were investigated by reverse transcription polymerase chain reaction (RT-PCR) to find out whether an *HMGA2*/*NFIB* chimera may be present also in this tumor type.

Materials and methods

Two cases of lipoma with rearrangements affecting 9p22–24 and 12q15, as determined by G-band karyotyping, were available for RT-PCR analyses (Table 1).

Culturing, harvesting, and chromosome banding of the tumor cells were as previously described [9, 10]. In brief, the tumor tissue was disaggregated mechanically and then enzymatically by 3–5 h of treatment with collagenase II. The resulting cell suspension was rinsed with a medium to remove released fats and was distributed to glass chamber slides and flasks. The RPMI 1640 medium with HEPES buffer, supplemented with 17% fetal bovine serum, L-glutamine, penicillin, and streptomycin, was then added to the cell suspension. The G-banding of the chromosomes was obtained using Wright's stain solution. Karyotypic descriptions were in accordance to "ISCN (1995). An International System for Human Cytogenetic Nomenclature" [12].

Total ribonucleic acid (RNA) from frozen lipoma tissues kept at −80°C was isolated using the RNeasy Lipid Tissue Mini Kit (Qiagen) according to the manufacturer's instructions. From 5 μg of total RNA, complementary deoxyribonucleic acid (cDNA) was synthesized by reverse transcription in a 20-μl reaction, containing 50 mM Tris–HCl (pH 8.3), 75 mM KCl, 3 mM $MgCl_2$, 10 mM dithiothreitol, 1 mM of each dNTP, 0.5 pM random hexamers, 28 U of RNase inhibitor (RNA guard; Amersham), and 400 U of Moloney Murine Leukemia Virus reverse transcriptase (Invitrogen). The reaction mix was incubated at 37°C for 1 h, followed by 5 min at 65°C. From each case, 1 μl of cDNA was amplified by PCR. *ABL1*-specific primers were used as quality control [16].

All RT-PCR reactions were carried out in final volumes of 50 μl containing 20 mM Tris–HCl (pH 8.3), 50 mM KCl, 1.25 mM $MgCl_2$, 0.2 mM of each dNTP, 1 U of PlatinumTaq polymerase (Invitrogen), 0.5 μM of each of the forward and reverse primers for *HMGA2* and *NFIB* (Table 2), and 1 μl of single-stranded cDNA as a template. In a second PCR with inner primers, 2 μl of the PCR product was reamplified. The PCR was run on a PCT-200 DNA Engine (MJ Research). After an initial denaturation for 5 min at 95°C, 30 amplification cycles were performed, each consisting of denaturation for 1 min at 95°C, annealing for 1 min at 60°C, and extension for 1 min at 72°C. The PCR was completed by a final extension at 72°C for 5 min.

HMG876 F	CAGCGCCTCAGAAGAGAGGACG
HMG902 F	GCCCCAGGAAGCAGCAGCAAG
HMG1037 R	CCATTTCCTAGGTCTGCCTCTTGGC
HMG1144 R	AGGTAGAAATCGAACGTTGCGCC

[a]Primer orientation, where F denotes forward and R denotes reverse

The PCR products were analyzed on a 1.3% agarose gel, purified using the Qiagen gel extraction kit, and directly sequenced using the ABI Prism BigDye terminator version 1.1 cycle sequencing kit (Applied Biosystems) on the Applied Biosystems Model 3100-Avant DNA sequencing system. Primers used for sequencing are listed in Table 2. For computer analyses of sequence data, the BLAST software http://www.ncbi.nlm.nih.gov/BLAST/) was used.

Results

G-banding revealed that case 1 had chromosome 12 material inserted into chromosome 9 as the sole anomaly in one clone, whereas the dominating clone had an additional copy of the derivative chromosome 9 (Table 1). All three samples of the lobulated tumor of case 2 had a balanced translocation between chromosomes 9 and 12. The break points in chromosome 9 were interpreted as 9p24 and 9p22, respectively, whereas both cases had a break in 12q15.

RT-PCR products obtained with forward primers for *HMGA2* (HMG846 and HMG876) and reverse primers for *NFIB* (NF41475-006 and NF41475-005) revealed the presence of an *HMGA2*/*NFIB* gene fusion in case 2. The size of the *HMGA2*/*NFIB* product was approximately 400 bp. Its reciprocal counterpart, *NFIB*/*HMGA2*, was not detected.

Table 1 Clinical and cytogenetic data

[b]The karyotype of case 2 has been published [9]

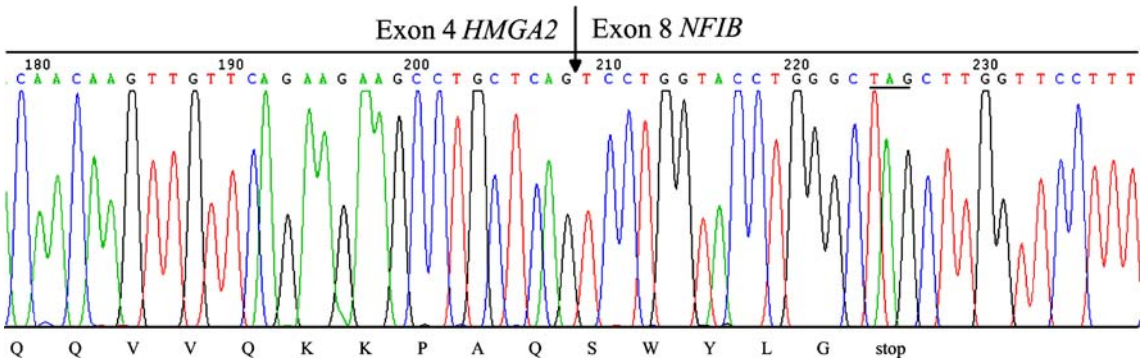

Fig. 1 Sequencing of the PCR product from case 2 showing the in-frame fusion transcript between *HMGA2* and *NFIB*. The fusion point is indicated by an arrow, and the stop codon is underlined

The amplified products were analyzed by direct sequencing (Fig. 1). Computer analyses of the sequence data, using the BLAST software, showed that the fusion of *HMGA2*/*NFIB* chimeric sequences was in frame and contained the first four exons of *HMGA2* located 5′ to exon 8, the last coding exon of *NFIB*. The sixth codon of *NFIB* was a stop codon.

Expression of *NFIB* was detected in both cases, using the forward primer NF41475-001 with reverse primers NF41475-006 and NF41475-005 (Table 2). In addition, *HMGA2* was expressed in both cases, as shown by the forward primer HMG902 combined with reverse primers HMG1037 and HMG1144, to detect transcripts from exons 1–3 and 1–5, respectively.

Discussion

In one of the two presently investigated lipomas, it was possible to demonstrate the presence of an *HMGA2*/*NFIB* fusion gene. Sequencing revealed that the resulting chimeric transcript was identical to that described previously in a case of salivary gland pleomorphic adenoma [5] (i.e., a combination of the four first exons of *HMGA2* with exon 8 of *NFIB*). Although the fusion gene was in frame, the presence of a stop codon shortly 3′ after the fusion point was compatible with the suggestion that the important outcome of the aberration was the deregulation of the expression of the DNA-binding 5′ element of *HMGA2* [1, 4, 5].

t(9;12)(p22–24;q13–15) has been reported not only in pleomorphic adenoma and lipoma but also in uterine leiomyoma and pulmonary chondroid hamartoma [6–8]. Aberrations involving 9p22–24, including t(9;12), are more common among adenomas and appear in about 9% of reported cases with chromosome aberrations, compared to <2% in the three other tumor types [13]. The fraction of tumors with t(9;12) differs less and ranges from below 1.5% among adenomas to less than 0.5% among leiomyomas. These four benign tumor types all include a cytogenetic subgroup characterized by rearrangements involving 12q13–15. Among these tumors, t(9;12)(p22–24;q13–15) has been observed in about 1% of lipomas and hamartomas, 4% of leiomyomas, and 10% of adenomas (Table 3). Several other aberrations, including 12q13–15, are shared by two or more tumor types, but the frequencies may differ distinctly. Apart from the intrachromosomal rearrangements of chromosome 12, which are common among all four tumor types, only two segments, 9p22–24 and 14q22–24, have been involved in all of them, whereas several other rearrangements are shared by only two tumor types. With respect to the low-resolution power of chromosome banding, similar cytogenetic rearrangements need not necessarily have the same consequences at the molecular level. However, the present findings, as well as previous findings of the presence of *HMGA2*/*LPP* fusion genes in lipoma, hamartoma, and chondroma, demonstrate that at least some of these shared cytogenetic aberrations are actually identical also at the molecular level. Since one and the same fusion gene may be associated with distinctly different tumor phenotypes, it seems reasonable to suggest that the aberrant gene might affect cell proliferation in an unspecific way, rather than being a determinant of tumor cell differentiation. The differences in frequencies of certain rearrangements among tumor types could then reflect the probability of a certain aberration to occur in a certain cell type. The mechanisms behind this remain unknown.

The present study provides yet another example of genetic aberrations that are shared by different tumor types. Based on these observations and available cytogenetic data, it seems reasonable to suggest that there are more

Table 3 Frequencies of the most common chromosome segments recombining with 12q13–15 in lipomas, pleomorphic adenomas, lung hamartomas, and uterine leiomyomas

Segment	Lipoma (%)	Adenoma (%)	Hamartoma (%)	Leiomyoma (%)
1p32–34	8	0	0	<1
2p22–24	5	0	1	0
2q35–37	6	0	0	3
3q27–29	20	0	8	0
5q33	6	2	0	0
9p22–24	1	10	1	4
10q22	2	0	0	4
13q12–14	4	0	3	0
14q22–24	1	2	18	61

shared aberrations to be found among benign solid tumors. More specifically, an *HMGA2*/*NFIB* fusion gene might be expected to occur also among leiomyomas and hamartomas.

Transforming growth factor-β1 mediated up-regulation of lysyl oxidase in the kidneys of hereditary nephrotic mouse with chronic renal fibrosis

Received: 7 March 2005 / Accepted: 16 May 2005 / Published online: 5 August 2005

Abstract Lysyl oxidase (LOX), an extracellular emzyme, plays a key role in the post-translational modification of collagens and elastin, catalyzing inter- and intra-crosslinking reactions. Because the crosslinked extracellular matrices (ECMs) are highly resistant to degradative enzymes, it is considered that the over-expression of LOX may cause severe fibrotic degeneration. In the present study, we addressed the role of LOX-mediated crosslinking in chronic renal tubulointerstitial fibrosis using an animal model of hereditary nephrotic syndrome, the Institute of Cancer Research (ICR)-derived glomerulonephritis (ICGN) mouse. Ribonuclease protection assay (RPA) revealed that LOX mRNA expression was up-regulated in the kidneys of ICGN mice as compared with control ICR mice. High-level expression of LOX and transforming growth factor (TGF)-β1 (an up-regulator of LOX) mRNA was detected in tubular epithelial cells of ICGN mouse kidneys by in situ hybridization. Type-I and -III collagens, major substrates for LOX, were accumulated in tubulointerstitium of ICGN mouse kidneys. The present findings imply that TGF-β1 up-regulates the production of LOX in tubular epithelial cells of ICGN mouse kidneys, and the excessive LOX acts on interstitial collagens and catalyzes crosslinking reactions. As a result, the highly crosslinked collagens induce an irreversible progression of chronic renal tubulointerstitial fibrosis in the kidneys of ICGN mice.

Introduction

The Institute of Cancer Research (ICR)-derived glomerulonephritis (ICGN) mouse, an inbred strain of mouse with a hereditary nephrotic syndrome of unknown etiology, is considered to be a good model for human idiopathic nephrotic syndrome. ICGN mice are categorized into two groups, heterozygous and homozygous, based on outward appearance and clinical and histopathological findings [25–27, 29, 30]. Aged homozygous ICGN mice, more than 26 weeks old, have severe glomerulonephritis, showing serious proteinuria, hypoproteinemia, hypoalbuminemia, hyperlipidemia, anemia, systemic edema and glomerular and tubulointerstitial chronic fibrosis characterized by the hyper-accumulation of extracellular matrix (ECM) components. Among these pathological events, it is considered that hypertrophy of glomerular basement membrane is the earliest event of renal failure in the kidneys of ICGN mice, but detailed mechanism of this event is still unknown [30]. On the other hand, during renal failure progression, tubulointerstitial fibrosis develops in the kidney of ICGN mice. We consider that the ICGN mouse is a good model for a spontaneous progressive chronic renal tubulointerstitial fibrosis [11]. Previously, we reported the excessive accumulation of both interstitial components (type I and III collagens, fibronectin and tenascin) and basement membrane (type IV collagen and laminin), in glomeruli and the tubulointerstitial area of ICGN mice as compared with ICR mice, which were used as healthy normal controls [39–42]. However, the mechanisms responsible for the excessive accumulation of ECM components in the kidneys of ICGN mice have not been fully elucidated.

Crosslinking of ECM molecules is an initial and important step for the matrix maturation and stabilization mediated by extracellular enzymes, including lysyl oxidases (LOXs) and transglutaminases [1, 23]. The abnormality of this step disrupts the balance of ECM synthesis and degradation, and causes many kinds of fibrogenic diseases [5, 12, 13, 17, 22]. Among these extracellular enzymes, LOX performs the post-translational modification of ECMs, and catalyzes the crosslinking reaction for interstitial collagens and elastin molecules [21]. The catalytic activity of LOX is critical not only in adult and developing normal connective tissues [20, 24], but also in many organs with fibrotic degeneration including hepatic and pulmonary fibrosis and many cancer tissues [22, 33, 38]. In many cases of such pathological fibrotic processes, increased expression of LOX was noted. The excessively high activity of LOX to catalyze the crosslinking reaction in the ECMs results in abnormally high stability of the crosslinked ECMs against degradative enzymes, and thus ECM metabolism is disrupted. More interestingly, a recent study showed that lysyl oxidase activates the transcriptional activity of collagen III α1 promoter [10]. In many pathological fibrotic situations, the expression of LOX and its enzymatic activity are controlled by transforming growth factor (TGF)-β1 [9, 14, 36], which is the most potent fibrogenic cytokine [2, 4, 18, 44]. Moreover, decreased activities of matrix metalloproteinase (MMP)-1, -2 and -9, which are the major matrix degradative enzymes in normal kidneys [16], were demonstrated in ICGN mouse kidneys with renal fibrosis [40].

Based on these observations, we hypothesized that abnormally expressed LOX inhibits the degradation of the ECM in the kidneys of ICGN mice, and examined the changes in the expression levels and localization of LOX mRNA, major LOX substrates (type I and III collagens) and an LOX up-regulator (TGF-β1) to determine the progression mechanism of the chronic renal tubulointerstitial fibrosis in the kidneys of ICGN mice.

Materials and methods

Animals, tissue preparation and blood biochemistry

As previously reported [28–30], ICGN mice were prepared by mating homozygous males (*nep*/*nep*) with heterozygous females (*nep*/−) at the laboratory of the National Institute of Infectious Diseases (NIID; Tokyo, Japan). Aged male homozygous ICGN mice (26 weeks old) and age- and sex-matched ICR mice, which were purchased from Clea Japan (Tokyo, Japan) and used as normal healthy controls, were housed in autoclaved metal cages and given a standard cubed diet (MF; Oriental Yeast, Tokyo, Japan) and tap water ad libitum in an air-conditioned room (23±1°C), under controlled lighting conditions (12/12 h light/dark). All animals received humane treatment as outlined in the Guide for the Care and Use of Animals (The University of Tokyo Animal Care Committee). Under light ether anesthesia, blood was collected from the cervical vein for analyses of clinical biochemistry. The animals were killed under deep ether anesthesia, and then the kidneys were rapidly removed. One kidney was used for biochemical analyses for LOX and TGF-β1. The other kidney was fixed with 4% (w/v) formaldehyde in 0.5 M phosphate buffer, pH 7.4 (Wako, Osaka, Japan), dehydrated through a graded ethanol series, and embedded in paraffin (Histosec; Merck, Darmstadt, Germany) according to routine histopathological methods. To evaluate the nephrotic state and loss of renal function, serum samples were separated by centrifugation (3,000 *g* for 15 min), and then serum albumin (sAlb), serum creatinine (sCr), blood urea nitrogen (BUN) and serum total cholesterol (sTC) levels were measured with an automatic clinical analyzer (Dri-Chem 3500U; Fuji Film, Tokyo, Japan). All procedures were performed according to the manufacturers' recommendation.

Cell culture

Primary normal human renal proximal tubule epithelial cells (RPTECs) were purchased from Clonetics (Walkersville, MD, USA). RPTECs were grown in renal epithelial cell growth medium (REBM; Clonetics) containing 10 ng/ml of human epidermal growth factor (Clonetics), 5 μg/ml of insulin (Clonetics), 500 ng/ml of hydrocortisone (Clonetics), 500 ng/ml of epinephrine (Clonetics), 6.5 ng/ml of triiodothyronine (Clonetics), 10 μg/ml of transferring (Clonetics), 0.1% (v/v) GA-1000 (Clonetics) and 0.5% (v/v) fetal bovine serum (FBS; Sigma Aldrich, St. Louis, MO, USA) at 37°C in a 5% CO_2 air incubator (Sanyo, Osaka, Japan). Then RPTECs (at passage 2) were preincubated in REBM containing 0.5% (v/v) FBS, 100 U/ml penicillin (Sigma) and 100 mg/ml streptomycin (Sigma) for 24 h at 37°C. After removal of the culture medium, the cells were incubated in REBM medium containing 0.5% (w/v) bovine serum albumin (BSA; Sigma) with 1 or 5 ng/ml of human recombinant TGF-β1 (rTGF-β1; R&D systems, Oxon, UK), an activated form of TGF-β1, for 24 h at 37°C. As a vehicle control, the cells were incubated in REBM medium containing only 0.5% (w/v) BSA.

Extraction of total RNA, synthesis of cRNA probes and non-RI labeling

Total RNA was extracted from fresh kidney samples and RPTECs using an RNeasy mini kit (Qiagen, Chatsworth, CA, USA), and then treated with an RNase-free DNase kit (Qiagen).

To generate templates for cRNA probes, partial sequences of murine TGF-β1 (mTGF-β1), murine LOX (mLOX) and human LOX (hLOX) were amplified from mouse and human cDNA libraries by polymerase chain reaction (PCR). Primer pairs were as follows—mTGF-β1 forward: 5′-TGACG TCACT GGAGT TGTAC GG-3′ and reverse: 5′-AGACA GAAGT TGGCA TGGTA GCC-3′, product size: 375 bp; mLOX-372 forward: 5′-GGTGC

CCGAC CCCTA CTACA TCC-3′ and reverse: 5′-GCAAA GCGCC TGTGG TACCC ATAGT C-3′, product size: 372 bp; mLOX-571 forward: 5′-TGGCC AGTTC AGCAT ATAGG G-3′ and reverse: 5′-TATGT CCAAA CACCA GGTAC GG-3′, product size: 571 bp; and hLOX-583 forward: 5′-TGGCC AGTAC AGCAT ACAGG G-3′ and reverse: 5′-TATTT TTTCC CACTT CAGAA C-3′, product size: 583 bp.

Templates for mTGF-β1 and mLOX-372 cRNA probes, which were used for in situ hybridization, were synthesized using a Lig'n scribe kit (Ambion, Austin, TX, USA). Briefly, PCR products were ligated with the T7 phage RNA polymerase promoter. To generate templates for antisense cRNA probes, PCR was performed by using a T7 promoter-specific primer and target gene-specific 5′ (upstream end) primer. To generate templates for sense cRNA probes used as a negative control, a 3′ (down-stream end) primer was used instead of the 5′ primer in the PCR. For in situ hybridization, both the antisense and sense probe templates were transcribed in vitro and labeled with digoxigenin (DIG) using a DIG-RNA labeling kit (Roche Diagnostics, Rotkreuz, Switzerland). All procedures were performed according to the manufacturer's instructions.

For the quantitative ribonuclease protection assay (RPA), mLOX-571 and hLOX-583 were TA-cloned using pGEM-T easy vector system I (Promega, Madison, WI, USA). The accuracy of the PCR was confirmed by sequencing. Templates for the mLOX-571 and hLOX-583 cRNA probes and a commercial murine β-actin (mβ-actin: 245 bp) and human β-actin (hβ-actin: 245 bp) cRNA probe (Wako) were transcribed and labeled with DIG using a DIG-RNA labeling kit. Sizes of transcribed probes were as follows: mLOX-571, 630 bp; hLOX-583, 642 bp; mβ-actin, 334; hβ-actin, 334 bp. All procedures were performed according to the manufacturer's instructions.

Quantitative RPA for LOX and β-actin mRNAs

RPA was performed using an RNase protection kit (Roche) according to the manufacturer's directions. Briefly, 40 μg of total RNA prepared from kidney tissue or REPTCs, or yeast tRNA (as a negative control) was hybridized with 1 ng each of DIG-labeled mLOX-571 and mβ-actin cRNA probe mixture or hLOX-585 and hβ-actin cRNA probe mixture for 18 h at 45°C. Then, each sample was treated with RNase-T1 (Roche) for 30 min at 30°C to digest the non-hybridized, single-strand RNA. Each digested sample was electrophoresed in a 6% (w/v) denatured polyacrylamide gel, and capillary blotted on a Hybond-N^+ membrane (Amersham Pharmacia Biotech, Piscataway, NJ, USA). After ultraviolet fixation with a UVC 500 UV crosslinker (Amersham Pharmacia), each membrane was incubated with alkaline phosphatase (AP)-conjugated sheep anti-DIG antibody (diluted 1:10000 with blocking solution) for 1 h at RT (22–25°C). After washing, chemiluminescence was visualized using the CDP-star system (Amersham Pharmacia), and then chemiluminescence was recorded with a digital luminoimage analyzer (LAS-1000; Fuji Film). The intensity of chemiluminescence was quantified using Image-Gauge software (Fuji Film) on a Machintosh computer.

Assay of the catalytic activity of LOX

The catalytic activity of LOX was measured with a fluorometric assay according to the method described by Palamakumbura and Trackman [31]. Briefly, fresh kidney was washed in 0.1 M sodium phosphate buffer (pH 7.4), minced using surgical scissors, and homogenized for 10 min at 4°C. After centrifugation at 3,000 *g* for 5 min to remove debris, the supernatant was collected, and the protein concentration of the supernatant was determined with a Bradford assay kit (Bio-Rad Laboratories, Melville, NY, USA) according to the manufacturer's directions. Then, 100 μl of supernatant was mixed with 400 μl of reaction buffer [1.2 M urea (Wako), 50 mM sodium borate (pH 8.2; Wako) with 1 unit/ml horseradish peroxidase (Sigma), 10 μM Amplex Red (Molecular Probes Europe, PoortGebouw, the Netherlands), and 10 μM 1,5-diaminopentane (Wako)] and incubated for 30 min at 37°C. For inhibitory control, the reaction mixture containing a specific inhibitor of lysyl oxidase activity [500 μM β-aminopropionitrile (BAPN) Sigma] was used. After incubation, each mixture was placed on ice to stop the reaction, and the fluorescence intensity (excitation wavelength 560 nm, emission wavelength 590 nm) was measured by using a fluorescence spectrophotometer (VersaFluor; Bio-Rad Laboratories). The difference in fluorescence intensity between samples with and without BAPN was calculated to assess the LOX activity, and each result was normalized with each protein concentration.

Enzyme-linked immunosorbent assay for TGF-β1

Kidney tissue levels of TGF-β1 were determined by enzyme-linked immunosorbent assay (ELISA). Briefly, kidney was homogenized in the lysis buffer [20 mM Tris–HCl, pH 7.4, containing 2 M NaCl, 0.1% (v/v) Tween 80, 1 mM phenylmethylsulfonyl fluoride (PMSF) and 1 mM ethylenediaminetetraacetic acid (EDTA); Sigma]. Each lysate was centrifuged at 19,000 *g* for 20 min at 4°C, and the supernatant was collected. Levels of active form TGF-β1 were measured using a TGF-β1 Emax immunoassay kit (Promega), according to the manufacturer's direction. The optical density at 450 nm was measured with a microplate reader (Model 450; Bio-Rad), and the amount of active TGF-β1 in each kidney sample was expressed in pg/mg of total protein.

Immunohistochemistry

Type I and III collagens in the kidney sections were detected by a conventional indirect immunofluorescence method. Briefly, 2-μm-thick paraffin sections were depar-

affinized, rehydrated and washed with phosphate-buffered saline (PBS; pH 7.4). They were preincubated with normal goat serum [diluted 1:100 with PBS containing 5% BSA (w/v); PBS–BSA] for 20 min at room temperature, and then incubated with each diluted primary antibody for 18 h at 4°C. Primary antibodies used were as follows: rabbit anti-mouse type I collagen antibody (diluted 1:200 PBS–BSA; Calbiochem, La Jolla, CA, USA) and rabbit anti-mouse type III collagen antibody (diluted 1:200 with PBS–BSA; LSL, Nagoya, Japan). After being washed with PBS, the sections were incubated with Alexa Fluor 488-conjugated goat anti-rabbit IgG (diluted 1:300 with PBS–BSA; Molecular Probes) for 90 min at RT, and counterstained with 20 μg/ml of propidium iodide solution (PI; Sigma) for 30 s. After a wash with PBS, they were mounted with glycerol and examined with a confocal laser scanning microscope (Fluoview FV300; Olympus, Tokyo, Japan).

The active form of TGF-β1 protein in the kidney sections was detected by a conventional indirect immunoperoxidase method. Briefly, after rehydration, the paraffin sections (2 μm thick) were pretreated with 0.3% (v/v) H_2O_2 in absolute methanol for 10 min at room temperature, washed with PBS–BSA and incubated with rabbit anti-human active TGF-β1 antibody (diluted 1:100 with PBS–BSA; Promega) for 2 h at room temperature, and then incubated with biotinylated secondary antibody (goat anti-rabbit IgG, antibody, diluted 1:300 with PBS–BSA; Vector, Burlingame, CA, USA) for 1 h at room temperature. They were incubated with avidin biotin complex (ABC kit; Vector), colorized with the 3,3′-diaminobenzidine tetrahydrochloride (DAB) liquid system (Dako, Glostrup, Denmark), and counterstained with Mayer's hematoxylin. After dehydration, they were mounted in Eukitt (Kindler, Freiburg, Germany), and examined with a light microscope.

In situ hybridization for LOX and TGFβ1 mRNAs

LOX and TGF-β1 mRNAs in kidney sections were detected by the in situ hybridization method. Briefly, 4-μm-thick paraffin sections were mounted on silane-precoated slide glasses (Matsunami Glass, Tokyo, Japan), deparaffinized and rehydrated. After a wash with PBS, they were treated with 0.2 N HCl for 10 min at room temperature, washed with PBS and digested with 1 μg/ml proteinase-K (Sigma) in PBS for 25 min at 37°C. They were post-fixed with 4% (w/v) paraformaldehyde (PFA)–PBS, immersed with 2 mg/ml glycine–PBS, washed in PBS and prehybridized with hybridization cocktails 50% formamide (Amresco, Solon, OH, USA) for 1 h at 25°C. They were then hybridized with the antisense DIG-mTGF-β1 or -mLOX-372 cRNA probe for 18 h at 45°C. As a negative control, each serial section was hybridized with each DIG labeled sense cRNA probe. Each probe was diluted with hybridization cocktails 50% formamide at a concentration of 1 μg/ml. After a thorough washing with 2×SSC for 2 hr, with 0.5×SSC for 2 h and with 0.2×SSC for 1 h at 45°C, they were equilibrated with 100 mM Tris–HCl, pH 7.5, containing 150 mM NaCl (THS), blocked with commercial blocking reagent (Roche) for 1 h at RT, and then incubated with AP-conjugated sheep anti-DIG antibody (diluted 1:500 with blocking solution; Roche) for 18 h at 4°C. After a wash with THS, they were equilibrated with 100 mM Tris–HCl (pH 9.5), 100 mM NaCl and 100 mM $MgCl_2$ (THSM) and incubated with THSM containing 0.4 mM nitroblue tetrazolium chloride (Sigma), 0.4 mM 5-bromo-4-chloro-3-indolylphosphate-4-toluidine salt (Roche) and 1 mM levamisole (Roche) at 4°C. The appropriate reaction was verified by microscopy. Finally, they were washed with PBS, mounted with Histofine (Nichirei, Tokyo, Japan), and examined with a microscope. The specificity of the in situ hybridization signal was confirmed by parallel incubation with antisense and sense cRNA probes. As further negative controls, serial sections were hybridized without any probes or processed without the anti-DIG antibody. All negative controls yielded completely negative results.

Statistical analysis

Results are shown as mean±SE. The experiments were repeated independently at least twice, and every experiment was performed in triplicate. Differences in mean values were analyzed with unpaired Student's *t* test and ANOVA using Stat-View 4.5 program m (Abacus Concepts, Berkely, CA) on a Machintosh computer. Differences at $P<0.05$ were considered significant.

Results

Clinical blood biochemistry

Aged (26 weeks old) ICGN mice manifested clinical abnormalities such as exercise intolerance, pale ears and weight loss. Blood biochemical parameters showed that ICGN mice had hypoalbuminemia (mean values of sAlb in ICR and ICGN mice were 3.41±0.15 and 1.92±0.13 g/dl, respectively, a 0.56-fold decrease compared with age-matched ICR mice; $P<0.001$). Marked increases were observed in sCr (0.14±0.03 and 0.62±0.05 g/dl, respectively, 4.43-fold; $P<0.01$) and BUN (40.6±2.0 and 130.0±6.2 g/dl, respectively, 3.20-fold; $P<0.001$) in ICGN mice, indicating a loss of renal function. Increased sTC (107.4±5.9 and 233±19.4 g/dl, respectively, 2.17-fold; $P<0.01$) suggested hypercholesterolemia in ICGN mice. Thus, the aged ICGN mice used in this study were in a nephrotic state.

Expression level and localization of LOX mRNA in the kidneys of ICR and ICGN mice

To compare LOX mRNA expression levels between the kidneys of ICR and ICGN mice, we performed quantitative RPA for LOX mRNA. LOX mRNA expression was increased about 3.46-fold in the homogenated samples of

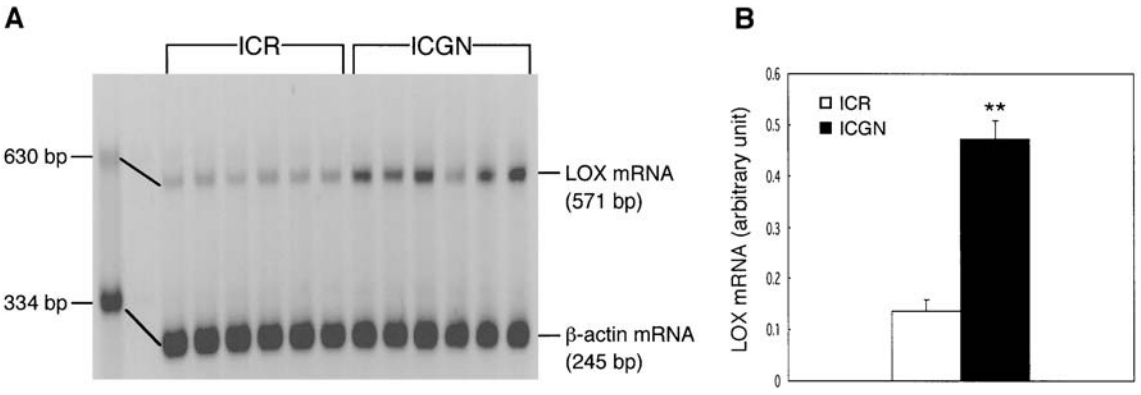

Fig. 1 Lysyl oxidase (LOX) mRNA expression levels were measured by ribonuclease protection assay (RPA) in the kidneys of ICR and ICGN mice (**a**, *lane 1*: full-length probes, *lane 2*: tRNA as negative control, *lanes 3–8*: ICR mice, *lanes 9–14*: ICGN mice). LOX mRNA chemiluminescence signals were normalized to signals of β-actin mRNA and expressed as arbitrary units (**b**). *Empty* and *filled columns* represent the data for ICR and ICGN mice, respectively. $^{**}P<0.01$, compared to control ICR mice

ICGN mouse kidneys as compared with those of ICR mouse kidneys (Fig. 1a,b).

Moreover, we performed in situ hybridization on paraffin-embedded kidney sections to visualize the localization of LOX mRNA. In the kidney sections of ICR mice, trace or low levels of LOX mRNA were detected in the vascular endothelial cells (Fig. 2a). However, in the kidney sections of ICGN mice, a strong reaction for LOX mRNA was observed in the tubular epithelial cells (Fig. 2b). These findings indicated that the synthesis of LOX was up-regulated in the tubular epithelial cells of ICGN mouse kidneys.

Enzymatic activity of LOX in the kidneys of ICR and ICGN mice

To assess the catalytic activity of LOX, whose production was up-regulated in ICGN mouse kidneys as described above, we performed the fluorometric assay based on measurements of hydrogen peroxide, which is a product of the oxidative deamination of alkyl monoamines and diamines (see the following reaction formula). The enzymatic activity of LOX was significantly stronger (2.63-fold) in the kidneys of ICGN mice than those of control ICR mice (Fig. 3).

$$RCH_2NH_2 + O_2 + H_2O \rightarrow RCHO + NH_3 + H_2O_2$$

Expression of TGF-β1 in the kidneys of ICR and ICGN mice

To reveal the factor which up-regulates the expression of LOX in tubular epithelial cells of ICGN mouse kidneys with fibrosis, we compared the expression levels of the active TGF-β1, a candidate up-regulator of LOX, in the kidneys of ICR and ICGN mice using the ELISA method. The levels of active form TGF-β1 protein was increased 8.71-fold in the kidneys of ICGN mice compared to those of normal ICR mice (Fig. 4a). Moreover, the results of in situ hybridization for TGF-β1 mRNA revealed that renal tubular epithelial cells of ICGN mice, but not ICR mice, produced high levels of TGF-β1 mRNA (Fig. 4b and c, respectively), and immunohistochemical staining for the active form of TGF-β1 protein demonstrated that the excessively produced TGF-β1 dominantly localized in the renal tubular epithelial cells (Fig. 4d,e).

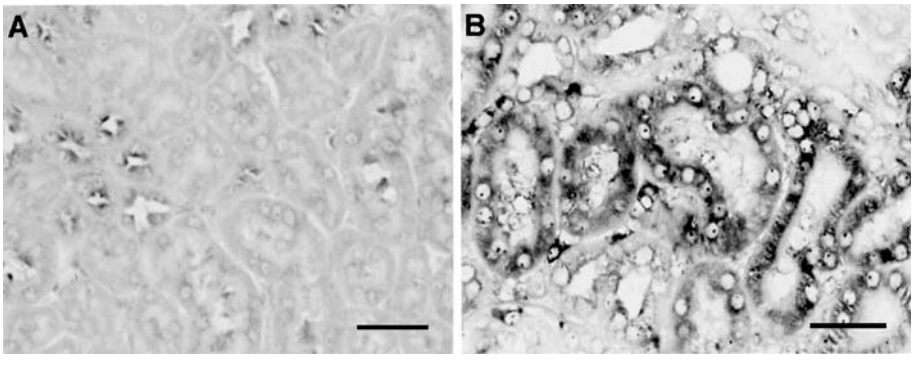

Fig. 2 Representative photographs for in situ hybridization for LOX mRNA in the kidney sections of ICR and ICGN mice (**a** and **b**, respectively). *Scale bar* 20 μm

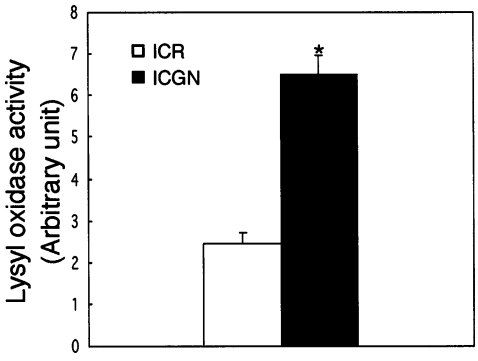

Fig. 3 LOX enzyme activity was biochemically compared by fluorometric assay in the kidneys of ICR and ICGN mice. The difference in fluorescence intensity between samples incubated with and without 500 μM β-aminopropionitrile (BAPN) was calculated, and then the result was normalized to each protein concentration. *Empty* and *filled columns* represent the data for ICR and ICGN mouse kidneys, respectively (n=6 per group). *P<0.05, compared to control ICR mice

Effect of TGF-β1 on LOX mRNA in vitro

To demonstrate the direct relationship between the up-regulated production of the active form of TGF-β1 protein and the expression of LOX mRNA in renal tubular epithelial cells, we examined the effect of TGF-β1 on LOX mRNA levels in cultured RPTECs. Quantitative RPA showed that TGF-β1 (1 or 5 ng/ml rTGF-β1) significantly up-regulated the expression of LOX mRNA in RPTECs (Fig. 5a,b).

Localization of type I and III collagens

In the kidneys of normal ICR mice, trace of type I or III collagen was detected immunohistochemically in tubulointerstitial and tubuloepithelial areas (Fig. 6a and c, respectively). On the other hand, abnormally high levels of type I and III collagens were observed in the tubulointerstitial area of ICGN mouse kidneys (Fig. 6b and d, respectively).

Discussion

It is believed that excessive accumulation of ECM components in fibrotic organs is a consequence of two parallel processes: hyper-increased synthesis and decreased degradation [7]. In normal kidneys, matrix proteases [matrix metallo-proteinases (MMPs), serine proteinases, lysosomal

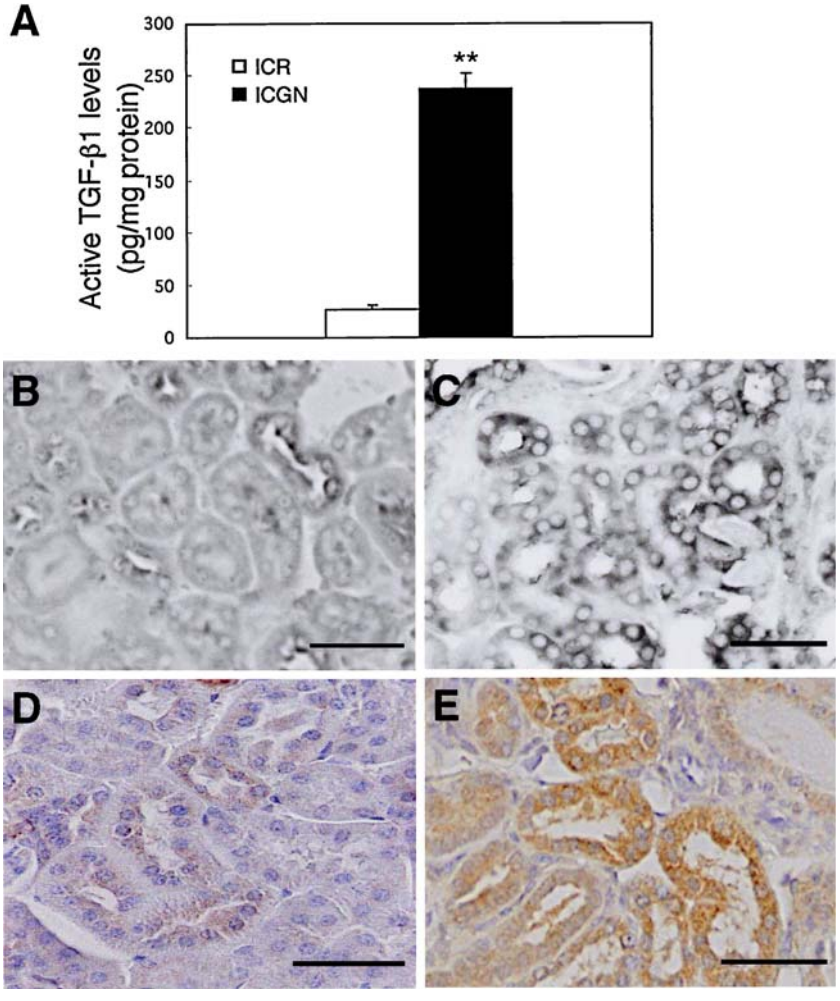

Fig. 4 Active form TGF-β1 protein levels in the kidneys of ICR and ICGN mice measured by ELISA are shown in **a**. Fig. 5 Effect of active form of TGF-β1 protein on expression levels of LOX mRNA in normal human renal proximal tubule epithelial cells (RPTECs) were determined by RPA (**a**, *lane 1*: full-length probes, *lane 2*: tRNA as negative control, *lanes 3–5*: 0 ng/ml of rTGF-β1, *lanes 6–8*: 1 ng/ml of rTGF-β1, *lanes 9–11*: 5 ng/ml of rTGF-β1). Each signal for LOX mRNA chemiluminescence was normalized to signals of β-actin mRNA, and expressed as arbitrary units (**b**). $^{**}P<0.01$, compared to vehicle control

cysteine proteinases and so on] are produced and activated via physiologically sophisticated controls [16]. In ICGN mouse kidneys with fibrosis, however, increased production of ECM and decreased protease activities (MMP-1, -2 and -9 activities) were noted [40]. When interstitial collagens were crosslinked by LOX, they showed greater resistance against MMPs, which led to a severe disruption of the balance between the synthesis and degradation of ECMs. [43]. Based on these findings, we hypothesized that the type I and III collagens accumulated in ICGN mouse kidneys were overly crosslinked by LOX. In various organs with fibrosis, the earliest process in the development of fibrotic degeneration is the cell differentiation to fibrogenic cells, activated myofibroblasts [34, 35]. During fibrotic degeneration, LOX is produced by the activated myofibroblasts [19, 33, 37]. Previously, we demonstrated that many activated myofibroblasts localized in the renal tubulointerstitium of ICGN mouse kidneys with fibrosis [11]. In the present study, we showed that levels of LOX mRNA were increased in kidneys of ICGN mice compared with those of ICR mice. However, in situ hybridization indicated that the LOX was mainly produced by renal tubular epithelial cells, not myofibroblasts, in the fibrotic kidneys of aged ICGN mice. Such a tubular epithelial cell-specific hyper-induction of LOX mRNA expression was consistent with a previous report on rat kidneys with adriamycin-induced nephropathy [6]. On the other hand, trace levels of LOX mRNA expressed in the glomeruli of ICGN mouse kidneys, but it seemed to be the same expression level with those of ICR mice (data not shown). Because the development of glomerular lesion is earlier than tubulointerstitial fibrotic degeneration in the ICGN

mouse kidneys [11, 30], tubulointerstitial fibrosis is mainly progressing in the kidneys of older ICGN mice (26 weeks old) used in this study. Thus, it seems appropriate that LOX is produced by tubular areas in the kidneys of 26-week-old ICGN mice. The roles and involvement of LOX and other collagen crosslinking enzymes, such as trasnsglutaminases, in the formation of earlier glomerular lesion remain unclear. Moreover, we also confirmed the augmentation of enzymatic activity of LOX in ICGN mouse kidneys. These findings indicate that the excessively produced LOX is biologically active in the kidneys of ICGN mice.

To identify the kinds of factor(s) causing the hyperproduction of LOX in the kidneys of ICGN mice, we focused on TGF-β1, which is known as a fibrogenic cytokine and an up-regulator of LOX biosynthesis [3, 36], and examined the changes in the production and localization of TGF-β1 in mouse kidneys during fibrotic degeneration. Abnormal hyper-expression of TGF-β1 has been reported in many animal models of renal fibrosis, and the sources of TGF-β1 in fibrotic kidneys have been discussed. For example, in diabetic animals with renal fibrosis, both glomerular epithelial cells and renal tubulointerstitial cells produce TGF-β1 [15, 32]. In unilateral ureteral obstruction model animals, increased expression of TGF-β1 mRNA was observed in tubular epithelial cells [8]. In the kidneys of ICGN mice, levels of active form of TGF-β1 were significantly increased, and the tubular epithelial cells dominantly produced TGF-β1. The TGF-β1 protein was activated and localized in renal tubular epithelial cell area. Previously, we investigated the mechanism of myofibroblastic differentiation in the kidneys of ICGN mice and demonstrated that abnormal over-expression of Smad4 protein in tubulointerstitial cells causes hyper-sensitivity to TGF-β1, and that such hyper-sensitivity induces the differentiation of tubulointerstitial cells to fibrogenic activated myofibroblasts [11]. However, the tubulointerstitial cells did not produce high levels of TGF-β1 by themselves. These previous findings were consistent with the present observation of TGF-β1 mRNA localization in ICGN mouse kidneys. Moreover, to confirm the relationship between the increased production of TGF-β1 and up-regulation of LOX expression in tubular epithelial cells, we performed an experiment in vitro. Stimulation with the active form TGF-β1 dose-dependently up-regulated the LOX mRNA expression in REPTCs. Interestingly, Shanley et al. [36] reported that TGF-β1 could increase the enzymatic activity of LOX. So, we consider that tubular epithelial cells of ICGN mouse kidneys with fibrosis excessively produce TGF-β1, and then TGF-β1 is activated, and that activated TGF-β1 stimulates the tubular epithelial cells in an autocrine and/or paracrine manner and up-regulates LOX production and enzymatic activity in the kidneys of ICGN mice. Moreover, in the kidneys of ICGN mice, hyperdeposition of interstitial type I and III collagens in the tubulointerstitial area was confirmed immunohistochemically. However, excessive accumulation of elastin, another substrate for LOX, was not observed in ICGN mouse kidneys (data not shown). As we demonstrated previously [11], the interstitial collagens were mainly produced by activated myofibroblasts located in the renal tubulointerstitial area of ICGN mouse kidneys. Moreover, Giampuzzi et al. [10] showed that LOX can activate the transcription activity of type III collagen promoter. This phenomenon is very interesting and may involve the excessive production of type III collagen in the tubulointerstitium of ICGN mouse kidneys. Therefore, it is suggested that the LOX excessively produced by tubular epithelial cells of ICGN mouse kidneys is secreted into the tubulointerstitial area from the basolateral side of these cells and catalyzes the crosslink reaction of type I and III collagens located in this area.

We conclude that the fibrotic process occurs in the kidneys of ICGN mice, as outlined in Fig. 7. The excessive level of TGF-β1 produced by tubular epithelial cells acts on the TGF-β1-sensitive tubulointerstitial cells (paracrine manner) and the tubulointerstitial cells are transformed to myofibroblasts [11]. Simultaneously, activated TGF-β1 stimulates tubular epithelial cells (autocrine and/or paracrine manner) and up-regulates the production of LOX in the cells. The up-regulated LOX catalyzes the crosslinking formation on the type I and III collagens, which are produced by the activated myofibroblasts located in the tubulointerstitial space. The crosslinked interstitial collagens resist degradation by proteolytic enzymes, and accumulate around the renal tubules. Thus, we propose a relationship between the TGF-β1-mediated up-regulation of LOX production and the progression of chronic renal fibrosis. To emphasize the relationship between LOX and the progression of chronic renal fibrosis and formulate an anti-fibrotic therapeutic approach, we need to examine the effect of LOX down-regulation in vivo, and we are de-

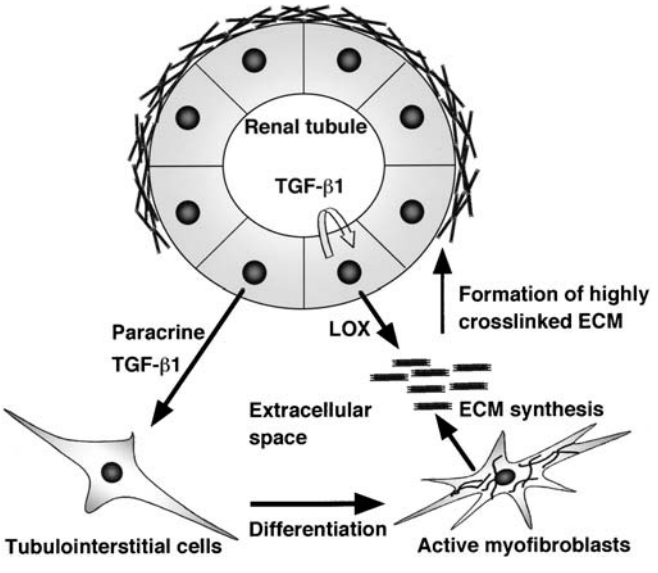

Fig. 7 Schematic illustration of the molecular mechanism of LOX-mediated hyper-crosslinking of collagens in the ICGN mouse kidneys. TGF-β1 excessively produced by renal tubular epithelial cells induces the differentiation of tubulointerestitial cells to fibrogenic activated myofibroblasts. TGF-β1 also promotes hyper synthesis of LOX in the tubular epithelial cells. The activated myofibroblasts produce much collagen and other ECM components, and the secreted LOX acts on the collagens to form hyper-crosslinked collagens, which resists degradative enzymes

veloping a novel renal-specific, long-term gene down-regulation system. Further research on the regulatory mechanism of TGF-β1, which directly affects the production, degradation and maturation of ECM, is necessary to fully understand the pathogenic mechanism of chronic renal tubulointerstitial fibrosis. Moreover, it is also important to identify other factor(s) influencing the balance of ECM metabolism. The ICGN mouse should be a useful model with which to identify novel pathogenic factor(s) and elucidate the molecular regulatory mechanism of chronic renal fibrosis.

Molecular cytogenetic characterization of an ins(4;X) occurring as the sole abnormality in an aggressive, poorly differentiated soft tissue sarcoma

Received: 14 March 2005 / Accepted: 29 June 2005 / Published online: 26 August 2005
© Springer-Verlag 2005

Abstract Cytogenetic and fluorescence in situ hybridization (FISH) analysis of an aggressive undifferentiated soft tissue sarcoma diagnosed as primitive neuroectodermal tumor (PNET) revealed an insertion ins(4;X)(q31–32;p11p22) as the sole aberration. To identify the molecular genetic consequences, contigs of bacterial artificial chromosomes (BACs) covering Xp11–p22 and 4q31–32 were constructed. The breakpoint in Xp22 was considered unlikely to be of pathogenetic significance, as it was very close to the Xp telomere, a region devoid of known or predicted genes. The breakpoint in Xp11 was mapped within a BAC clone containing *BCOR*, encoding a BCL6 (B-cell lymphoma 6)-interacting protein that may influence apoptosis, as the only known gene. FISH analysis with three overlapping clones on normal chromosomes 4 disclosed that the insertion of Xp11 material in der(4) was accompanied by a deletion of chromosome 4 material. Only a predicted gene (XM_094074) was shown to be partially included in the deletion. This gene displays a high similarity with the gene encoding the embryonic blastocoelar extracellular matrix (ECM) protein in sea urchin, which is involved in the migration of the primary mesenchyme cells during embryogenesis. Our results suggest that BCOR and/or an ECM-like protein could be involved in the pathogenesis of a subgroup of PNET or PNET-like sarcomas.

Introduction

Cytogenetic analyses of soft tissue tumors have disclosed several chromosomal translocations, often seen as the sole karyotypic aberration, that are strongly associated with the morphology of the tumor cells [10]. At the molecular level, these translocations often result in the creation of fusion genes, which seem to be equally strongly associated with histologic tumor type. Cytogenetic or molecular genetic information may thus provide diagnostically valuable information. This is especially true for poorly differentiated sarcomas occurring in children and adolescents, where it sometimes may be difficult to differentiate between, for example, synovial sarcoma, rhabdomyosarcoma, and primitive neuroectodermal tumor (PNET) on the basis of morphologic, ultrastructural, and immunohistochemical features alone. It is, however, vital to reach a correct diagnosis, as the different tumor types carry different prognoses and require different treatment strategies.

In the present study, we report the detailed molecular cytogenetic characterization of a previously unreported recombination between chromosomes X and 4, seen as the only cytogenetic aberration in short-term cultured cells from an aggressive undifferentiated soft tissue sarcoma occurring in an 18-year-old boy.

Clinical history

A previously healthy 18-year-old boy had for 3 months noticed increasing pain from a growing mass in his right elbow. A radiograph showed a 6-cm periosteal reaction of the proximal ulnar bone with possible cortical resorption, and MRI displayed a 10×7×3-cm tumor in the proximal ulnar diaphysis and infiltration of adjacent soft tissues. There were no signs of engagement of the bone marrow or of metastasis to the lymph nodes in the axilla. A pulmonary CT showed multiple nodules up to 0.5 cm in diameter in both lungs, but there were no signs of metastases to the mediastinal lymph nodes. A total-body radionuclear bone scan revealed increased activity only in the right elbow. A fine-needle aspiration biopsy (FNA) showed round-to-oval, often dissociated cells, a high mitotic index, and focal areas of necrosis. The tumor cells stained positive for CD99 and vimentin. Electron microscopy showed that the tumor cells displayed sparse, often extended cytoplasm, abundant mitochondria, and small organelles containing glycogen and fat. Based on these findings, the patient was diagnosed with a primitive neuroectodermal tumor (PNET). Neoadjuvant chemotherapy was initiated with vincristin (1.5 mg/m^2), doxorubicin (30 mg/m^2), ifosfamide (1,000 mg/m^2), and cisplatinum (90 mg/m^2) according to the Scandinavian Sarcoma Group protocol IX for soft tissue sarcomas. The chemotherapy was administered without significant subjective toxicity. After four cycles of treatment, a pulmonary CT showed only a minimal mass remaining in the right apical lobe, and MRI of the extremity revealed a marked regression of the primary tumor. The patient underwent surgery with en bloc resection with surgically wide margins of the primary tumor. Both lungs were explored, and the solitary remaining mass in the upper right lobe was excised. Histological examination of the primary tumor showed large areas of fibrosis and small foci of necrosis, probably due to the preoperative chemotherapy. A few small, scattered areas of viable tumor cells were found. Immunostaining showed focal positivity for CD99, while keratins and EMA were both negative. The response to the preoperative chemotherapy was classified as poor (Huvos grade III). No viable tumor cells were found in the resected lung metastasis. Treatment was then continued with one more cycle of chemotherapy, after which stem cell mobilization was intended, followed by myeloablative treatment with high-dose busulphan-melphalan. However, the patient refused further chemotherapy. Instead, the patient received total lung irradiation, with 15 Gy to both lungs (1.25 Gy per daily fraction with 6 MV photon energy).

On a pulmonary CT in October 1999, 17 months after diagnosis, metastases to the lungs were suspected, but the patient refused further examination until January 2000, when metastasectomy of all evident pulmonary metastases was performed. In sections from the lung metastases, the morphology of the tumor tissue was better preserved than in the primary tumor, and diffusely infiltrating tumor cells, having sparse-to-moderate cytoplasm and rounded-to-oval nuclei with finely granular, clumped chromatin, somewhat irregular nuclear membrane, and inconspicuous nucleoli, were seen. Numerous mitoses were seen, as well as small foci of apoptotic cells (Fig. 1). In addition, there were areas where cellular pleomorphism was more marked, with larger cells and more prominent anisokaryosis, irregular cell membranes and coarser nuclear chromatin (Fig. 2). Rosettes, perivascular pseudorosettes, or cytoplasmic glycogen were not seen. Tumor cells were negative for CD99, keratins, and EMA.

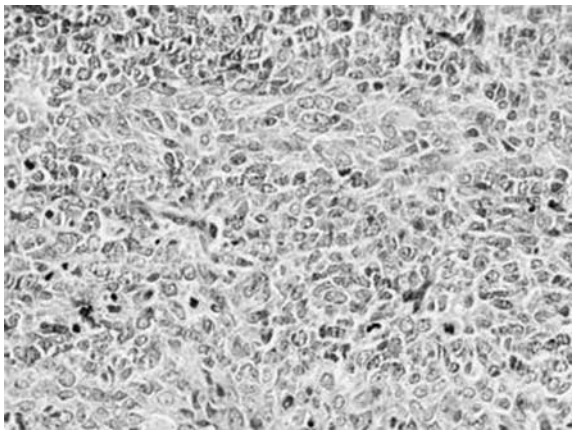

Fig. 1 Histologic section from lung metastasis showing diffusely infiltrating, relatively uniform, or moderately pleomorphic tumor cells with an admixture of apoptotic cells (H & E, ×50)

At this time, the patient refused chemotherapy. New lung metastases were detected 3 months later, and after an additional 2 months, four cycles of high-dose ifosfamide (2,000 mg/m^2) were given. No signs of tumor response were seen, and the patient was subsequently treated from September 2000–May 2001 with oral trofosfamide-etoposide. Radiotherapy to the mediastinum (30 Gy in ten fractions) and apical thoracic cavity (20 Gy in five fractions) was given, but in November 2001, the patient died of respiratory insufficiency due to massive intrathoracic tumor growth.

Materials and methods

Cell culturing, harvesting, and G-banding were performed as previously reported [8]. The karyotype was described according to the International System for Human Cytogenetic Nomenclature [7].

The following bacterial artificial chromosome (BAC) clones were used as probes for fluorescence in situ hybridization (FISH) analysis in order to reveal the exact location of the breakpoints on the X chromosome (the first ten clones) and chromosome 4 (the remaining 15 clones): RP11-552J9 (accession no. AL450023); RP11-344N17 (AL606490); RP11-552E4 (AL683817); RP11-38O23 (AL356464); RP11-386N14 (AL133545); RP11-291H16 (clone placed on cytogenetic map using the STS marker RH63518); RP11-429N5 (genomic survey sequence gi|11995676|gb| AZ254511.2); RP11-495K15 (genomic survey sequence gi|11500710|gb|AZ303207.2); RP11-87M18 (AL606516); RP11-215A12 (AC084716); RP11-196J14 (AC024032); RP11-83A24 (AC097376); RP11-364L4 (AC097658); RP11-58H15 (AC104685); RP11-481K16 (AC139713); RP11-10M9 (AC018535); RP11-424A19 (genomic survey sequence gi|21955327|gb|BH861015.1); RP11-780M14 (AC104090); RP11-673E1 (AC093890); RP11-291L15 (AC098588); RP11-543H9 (AC096757); RP11-552I10 (AC093863); RP11-667D12 (AC093887); RP11-461L13 (AC080078); RP11-458C23 (genomic survey sequence gi|5009527|gb|AQ582417.1). For each chromosome, the BACs are listed according to their map position, starting with the most proximal one. Their location was defined according to the UCSC database (University of California Santa Cruz, http://genome.ucsc.edu/index.html, May 2004 release). The clones belong to the RPCI library (http://www.chori.org/bacpac/) and were obtained from Resources for Molecular Cytogenetics (http://www.biologia.uniba.it/rmc/). Whole chromosome painting (WCP) probes for the X chromosome and chromosome 4 were obtained from Vysis (Downers Grove, IL, USA) and Cambio (Cambridge, UK). Probes were directly labeled with Cy3-dUTP (Amersham Biosciences, Little Chalfont, UK) and Fluor-X-dCTP (Amersham Biosciences) and indirectly labeled with biotin-dUTP (Roche, Penzberg, Germany) and detected with streptavidin-diethylaminocoumarin (Roche and Molecular Probes, Leiden, The Netherlands). The labeling of all the clones was performed by use of Amersham's Mega Prime kit (Amersham Biosciences). FISH was carried out as described elsewhere [5]. The hybridizations were analyzed with the aid of the Chromofluor System (Applied Imaging, Newcastle, UK). The BLAST software (http://www.ncbi.nlm.nih.gov/BLAST/) was used for computer analysis of nucleotide and protein sequence data, in order to look for candidate genes potentially involved in the breakpoints of the chromosome rearrangement.

In order to exclude cryptic rearrangement of the *EWSR1* gene, metaphase-FISH was performed with BACs flanking

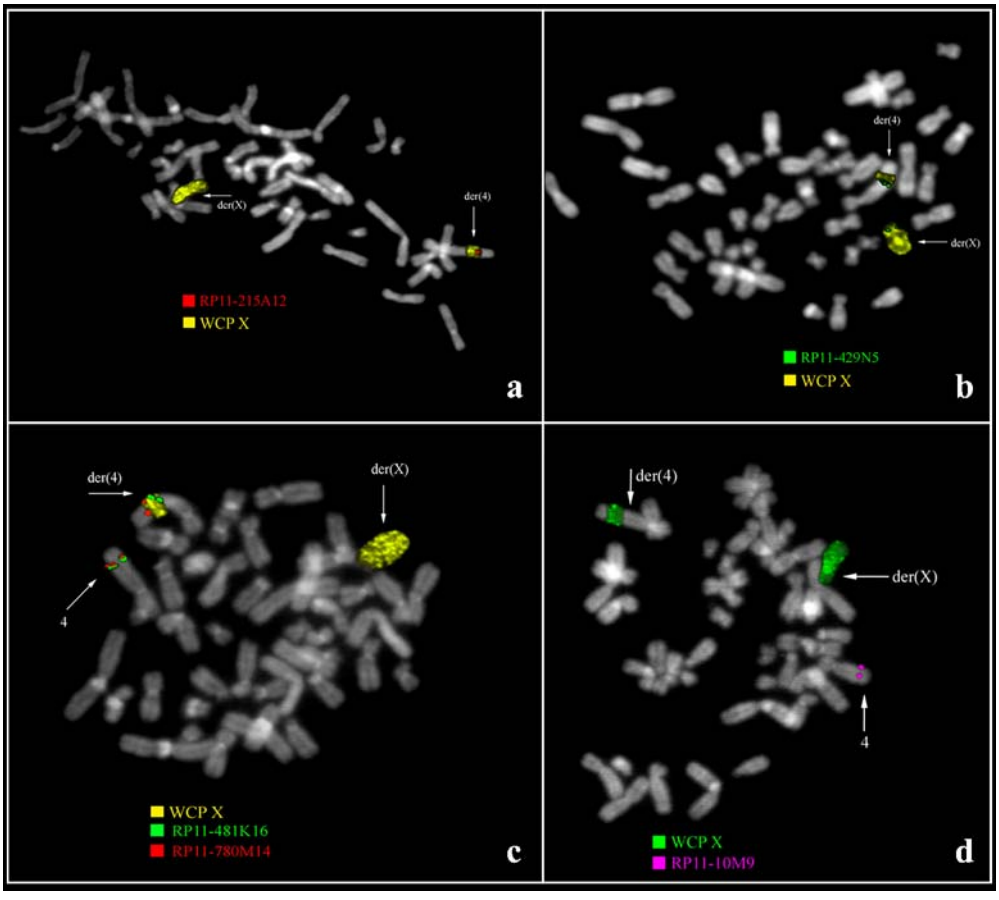

Fig. 3 Results of FISH experiments. The WCP probe for the X chromosome was cohybridized with the following probes: subtelomeric BAC specific for Xp (RP11-215A12) (**a**); BAC RP11-429N5, containing the breakpoint on the X chromosome (**b**); and RP11-481K16 (**c**), RP11-780M14 (**c**), and RP11-10M9 (**d**), covering the region containing the putative breakpoint on the chromosome 4

the *EWSR1* locus (data not shown). The presence of a cryptic *SS18/SSX* fusion gene was excluded through RT-PCR analysis as described [12].

Results

G-banding analysis of metaphase spreads from short-term cultured cells from a fine-needle aspiration biopsy obtained before treatment, as well as from the excised primary tumor obtained after chemotherapy, revealed the following karyotype: 46,Y,t(X;4)(p11;q31)/46,XY. Cytogenetic analysis of peripheral blood lymphocytes showed a normal male chromosome complement. RT-PCR did not reveal any *SS18/SSX* fusion transcript, and FISH for *EWSR1*-rearrangement was negative (data not shown). Preliminary FISH experiments using the WCP probes for X and 4 showed that the chromosomal rearrangement was an inser-

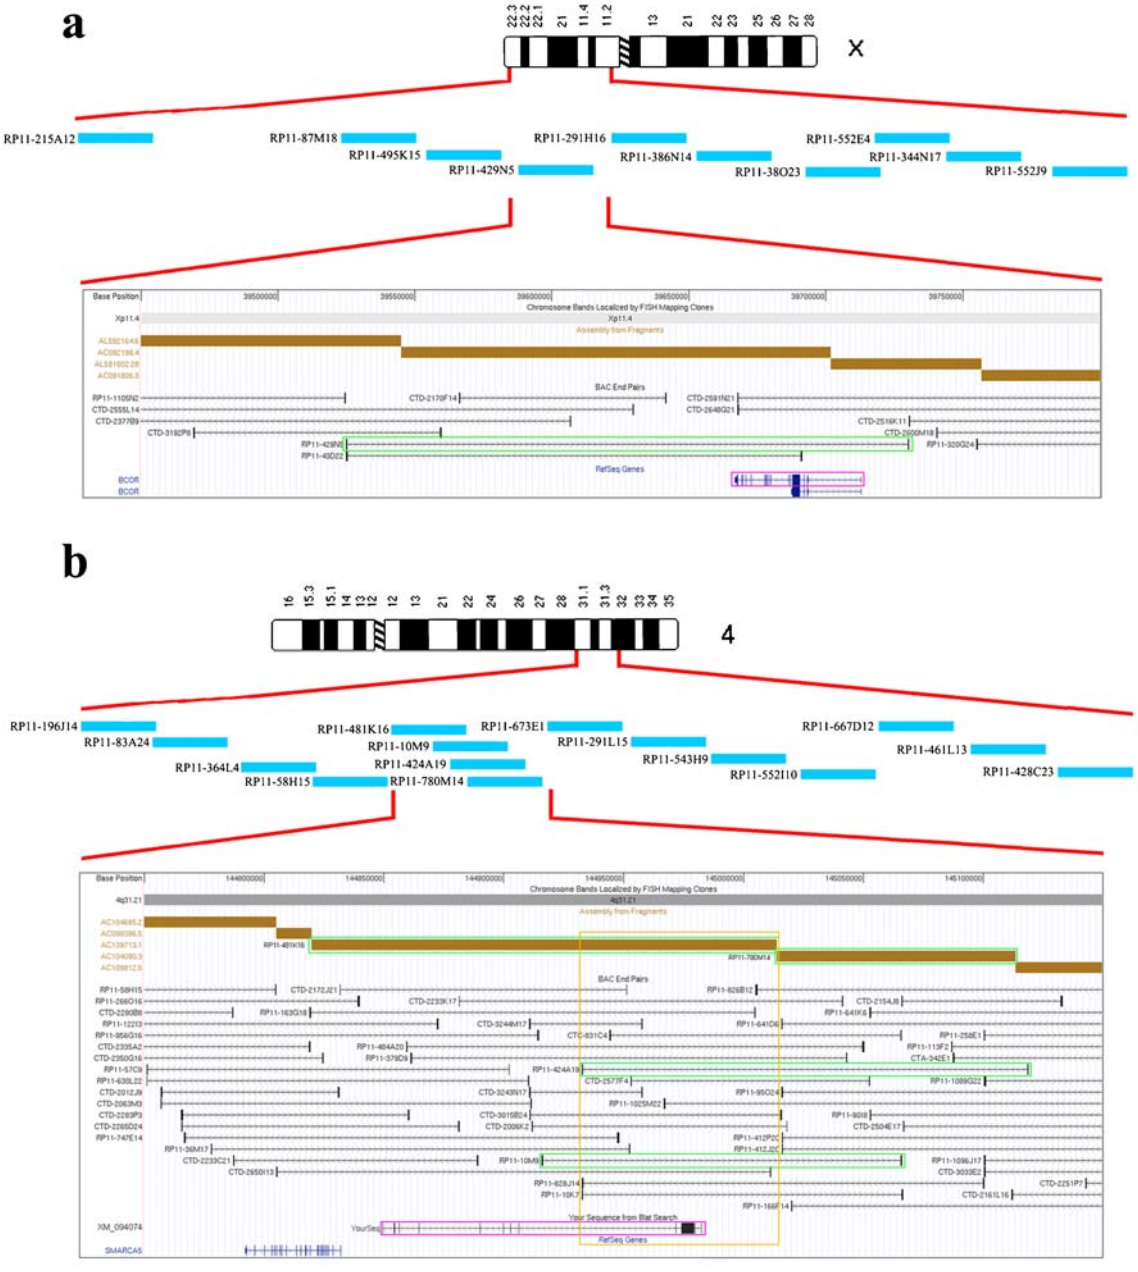

Fig. 4 Location of the clones used in FISH experiments. BACs included in the studied regions (*red intervals* starting from chromosomes) were represented as *light blue boxes*. Regions containing the breakpoints (*red intervals* starting from BACs) were enlarged, and UCSC database web pages were reported (University of California Santa Cruz, http://genome.ucsc.edu/index.html, May 2004 release). The clone RP11-429N5, containing the breakpoint on the X chromosome, was surrounded by *green frame*, and the sole gene included in this area (*BCOR*) was enclosed in a *purple rectangle* (**a**). The BACs covering the breakpoint region on the chromosome 4, RP11-481K16, RP11-10M9, RP11-424A19, RP11-780M14, were displayed surrounded by *green borders*, and the predicted gene (XM_094074) included in this region was enclosed in a *purple frame*. The deleted area was bounded by a *yellow rectangle* (**b**)

tion of Xp into 4q, rather than a translocation. Further FISH analysis revealed that the part of the X chromosome inserted into chromosome 4 spanned from Xp11 to Xpter because the signal for the Xp subtelomeric probe RP11-215A12 was seen on the der(4) (Fig. 3a). Based on these findings, the revised abnormal karyotype was 46,Y, ins(4;X)(q31–32;p11p22).

Contigs of BACs spanning chromosome bands Xp11–Xp21.1 and 4q31–4q32.1 were constructed as described in Materials and methods. The salient findings were as follows: FISH with the X-chromosome-specific clone RP11-429N5 gave a split signal on the derivative chromosomes X and 4 (Fig. 3b). Hence, the breakpoint on X could be mapped to sub-band Xp11.4, between the base positions identified by the ends of the BAC clone. None of the BACs selected for chromosome 4 resulted in a split signal, but the clones RP11-481K16 and RP11-780M14, which are adjacent on normal chromosomes 4, were separated on the der(4) because of the insertion of Xp-material (Fig. 3c). Moreover, FISH with the clone RP11-424A19, which partially overlaps both these clones, resulted in a single signal on the der(4), on the same, telomeric side of the insertion as RP11-780M14. Based on these results, the breakpoint could be mapped to the region between the centromeric end of RP11-424A19 and the telomeric end of RP11-481K16. The fact that we did not observe any splitting of signals using these clones suggested that a segment of that region was deleted. Indeed, FISH analysis with the clone RP11-10M9 did not give any detectable signal on the der(4) (Fig. 3d).

Discussion

In the present study, we report the molecular cytogenetic characterization of an aggressive undifferentiated soft tissue sarcoma diagnosed as PNET. The sole cytogenetic change detected at G-banding analysis, interpreted as a t(X;4), could after FISH analysis be shown to represent an insertion of Xp-material into the long arm of chromosome 4: ins(4;X)(q31–32;p11p22). Neither an ins(4;X) nor a t(X;4) with these or similar breakpoints has previously been reported in soft tissue tumors [10]. However, since this insertion was the sole cytogenetic abnormality, it is reasonable to assume that it was pathogenetically important, and we thus decided to investigate its molecular genetic consequences in more detail.

The X chromosome had two breakpoints, both of which potentially could have harbored genes of importance for tumor development. However, the breakpoint in Xp22 could be shown to be distal to the subtelomeric region recognized by BAC RP11-215A12, making it highly unlikely that the Xp22 breakpoint was of pathogenetic significance. The breakpoint in Xp11 was defined by BAC clone RP11-429N5, showing split signals on the derivative chromosomes X and 4. In the UCSC (May 2004 release) and Ensembl (http://www.ensembl.org/; April 2004 release) databases, there is only one known gene, *BCOR*, mapped to the region covered by this clone (Fig. 4a). *BCOR* encodes a BCL6 (B-cell lymphoma 6)-interacting corepressor that may influence apoptosis. Aberrant expression of *BCL6* due to chromosomal translocations is seen in a subset of non-Hodgkin's lymphoma [6], and BCOR binds AF9, which is a common *MLL* fusion gene partner in acute myeloid leukemia, suppressing AF9 transcriptional activity [13]. *BCOR* mutations have also been implicated in two human syndromes (oculofaciocardiodental syndrome and Lenz microphthalmia), and knock-out experiments performed on the zebrafish ortholog of *BCOR* showed developmental perturbations consistent with the human syndromes, confirming that BCOR is a key transcriptional regulator during early embryogenesis [11]. Based on this previous information, and the fact that there are no other known or predicted genes in the region covered by RP11-429N5, *BCOR* comes forth as a good candidate target gene on the X chromosome.

Regarding the characterization of the breakpoint on chromosome 4, the results suggested that the insertion was accompanied by a deletion of chromosome 4 material. We investigated this region in order to check for putative target genes. No known gene was found, but a gene predicted by Genescan (accession XM_094074.7) was partially included in the deleted region (Fig. 4b). The protein encoded by this predicted gene belongs to a family of proteins conserved from invertebrates to man, whose only member already studied is the embryonic blastocoelar extracellular matrix protein 3 (ECM3, 47% identity with the human protein) of sea urchin (*Lytechinus variegatus*), a protein that is involved in the migration of the primary mesenchyme cells during sea urchin embryogenesis [4]. Furthermore, the ECM3 protein has a large N-terminal NG2-like domain that is related to NG2, a mammalian chondroitin sulfate proteoglycan core protein, which can induce the spreading and migration of other cell types and has been found overexpressed in many human melanomas [1–3]. In addition, the BLASTP analysis of the predicted protein disclosed a 29% identity with the protein encoded by the human *FRAS1* gene that belongs to a family of proteins related to the ECM protein in sea urchin [9].

Unfortunately, lack of material precluded any attempt to investigate the involvement of any of the candidate target genes at the molecular level. However, our results strongly suggest that a subset of undifferentiated, PNET-like soft tissue sarcomas develop through aberrant expression of the *BCOR* gene on chromosome X and/or a gene encoding an ECM-like protein on chromosome 4, and rearrangements of these genes should be searched for in PNET or undifferentiated sarcomas that do not express any of the known fusion genes associated with PNET, synovial sarcoma, or alveolar rhabdomyosarcoma.

The petrified heart in sepsis

Received: 13 February 2005 / Accepted: 25 May 2005 / Published online: 13 July 2005
© Springer-Verlag 2005

Abstract We report the case of a 33-year-old transsexual man who developed severe sepsis after an accidental intravenous injection of urine (3–5 ml) instead of methadone. He died unexpectedly 28 days after the onset of sepsis. On postmortem examination, the outstanding findings were restricted to the heart with an unusual macroscopic presentation. On histological examination extensive calcifications of the heart muscle, particularly of the left ventricle were found. The pattern of calcifications on the right ventricle was also striking. In contrast, the entire cardial conduction system was unaffected. Furthermore, there were no calcium deposits in other organs and tissues. The advanced widespread cardial calcifications in the present case can be attributed to endotoxin-related myocarditis in severe long-term sepsis. The only treatment would have been an urgent heart transplantation. Without prior knowledge of such a condition, it is impossible for clinicians to correctly recognize, diagnose and treat or prevent in due time such a complication.

Introduction

The "classic" cardiovascular signs seen with severe sepsis due to gram-negative bacteremia were first described by Waisbren in 1951 [8]. In a study with fully resuscitated young patients with septic shock, Parker at al. [5] demonstrated significant reductions in both stroke volume and ejection fraction compared with non-septic control patients from the intensive care unit. This myocardial depression was not due to myocardial ischemia, as coronary blood flow and coronary sinus lactate levels were normal in patients with septic shock. In most sepsis-related deaths, a histologic examination of heart samples usually does not reveal any pathologic findings. Sometimes single foci of infectious myocarditis can be found, making the pathological confirmation of the diagnosis easier. The myocardial damage with widespread calcifications in association with severe long-term sepsis is an extremely rare phenomenon despite the high incidence of severe sepsis. In the English literature, only a single report was found regarding cardiovascular signs and severe sepsis: that of Rossi and Santos, who described a myocardial damage with giant cell inflammation and calcifications in a young male. Unfortunately, the authors neglected to provide exact descriptions of the extent and the distribution of calcifications. However, Rossi and Santos attributed their findings to a sepsis-related microvascular myocardial damage [7].

Case report

A 33-year-old transsexual man was admitted to the university hospital 4 h after an accidental injection of urine (3–5 ml), instead of methadone, into a femoral vein. The non-sterile, "clean" urine was kept for a long period of time in a refrigerator, in order to pass monitoring tests at a narcotics out-patient clinic. The misadventure was detected immediately after the injection. Some hours passed before the patient suffered two cerebral seizures, and consequently developed fever and somnolence.

On admission the physical examination revealed an exsiccated and disoriented patient. His temperature was 40°C, pulse 140/min, and respiration 24/min. Blood pressure was 90 mmHg systolic and 40 mmHg diastolic. Laboratory findings were as follows: white blood cell count 1.43 g/l, platelet count 102 g/l, C-reactive protein 3.8 mg/ml (normal range, below 0.5), hemoglobin 12.3 g/dl, creatinine 2.1 mg/dl (normal range, 0.5–1.1 mg/dl). Serum calcium concentrations and phosphate activities were normal. The blood culture was positive for gram-negative bacteria. X-rays of the chest showed a normal-sized heart and inconspicuous lungs. The patient was placed on intensive cardiopulmonary support, and subsequently developed acute renal failure. Some days later, the patient developed an acute liver dysfunction (bilirubin 20 mg/dl) and a respiratory distress syndrome. The day following admission, an increased level of troponine T (0.29 ng/ml, normal range: <0.03 ng/ml) was measured. On the third day the troponin T concentration increased further to 3.54 ng/ml. However, the echo- and electrocardiographic examination revealed no functional or structural abnormalities. The troponin T level had slowly decreased during the first 10 days but did not reach the normal range (1.02 ng/ml). The patient's condition gradually improved and his release from hospital had been planned. However, on the 26th hospital day, 2 days before his death the patient required catecholamines. The echocardiographic examination performed on this day showed an increased density of the entire septal myocardium. His death was attributed to pulmonary embolism and/or an abscess in the septal myocardium.

One week before the incidental injection of methadone a rupture of the right silicon breast implant was diagnosed. The intended surgical replacement of the implant required an examination of the patient (cardiac auscultation, electrocardiography, laboratory tests), which revealed no pathological findings.

Fig. 1 Gross appearance of the heart. Note green discoloration of the endothelium and of the heart muscle

Fig. 2 The anterior wall of the left ventricle showing sharply demarcated, green areas with whitish foci

Autopsy findings

On postmortem examination, the significant findings were restricted to the heart, which weighed 380 g. The endocardium, in particular of the left ventricle, showed multiple, sharply demarcated areas of green discoloration (Fig. 1). The muscle in corresponding areas was very hard. The cut surface of the myocardium was green, dry and sandy, appearing almost crystalline (Fig. 2). Almost the entire septum and left papillar muscles were affected. In the subepicardial areas of the right ventricular free wall green, hard narrow-banded streaks were noted. The atria were not affected. The coronary arteries were widely patent and the cardiac valves were normal. There was no evidence of myocardial infarction.

The histological examination of the heart samples displayed widespread intra- and extracellular calcium deposits, multiple small foci of ossification, interstitial perimysial fibrosis and myocytolytic myocytes associated with inflammatory cells such as lymphocytes, granulocytes, macrophages and monocytes (Fig. 3). The von Kossa stain confirmed calcium deposits in the hematoxyphilic material (Figs. 4, 5). Many mononuclear cells reacted with antibody against CD45RO, demonstrating that the lymphocytes of the inflammatory infiltrate were predominantly

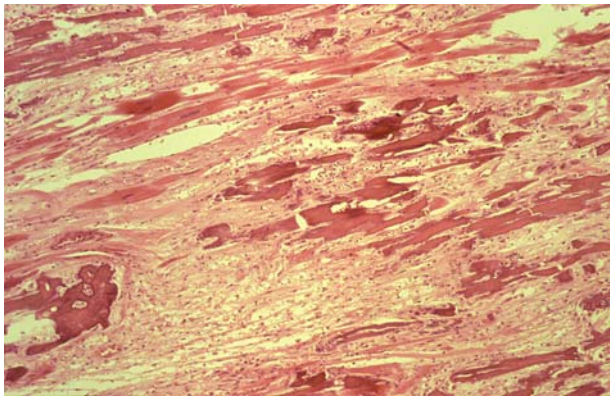

Fig. 3 Typical myocardial lesion showing fibrosis, infammatory infiltration and widespread calcifications. Only a few myocardiocytes are apparently not affected (H&E, ×100)

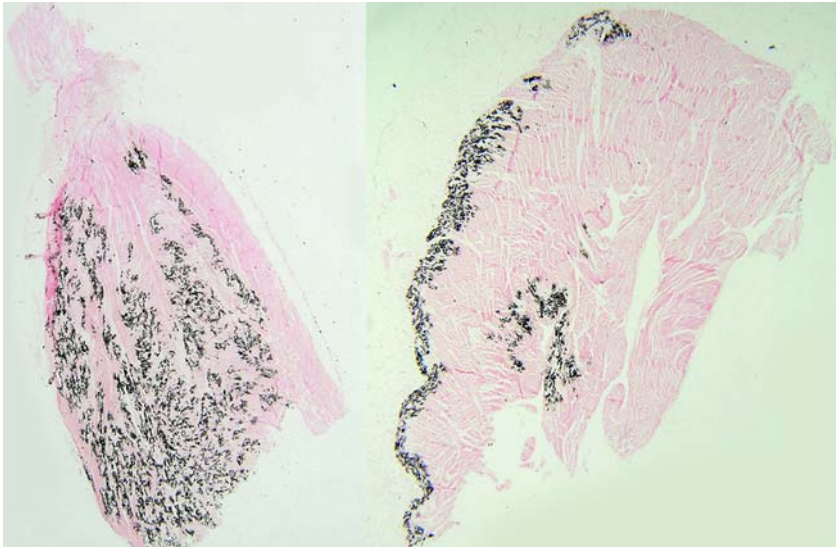

Fig. 4 Right ventricular wall with narrow-banded streaky calcifications in the outer and partially in the subendocardial layer as well as homogeneously calcified myocardial septum (von Kossa stain, whole-mount sections)

T cells. Foci of almost completely calcified embedded myocardiocytes were found in areas of apparently unaffected heart muscle of the left, but not of the right ventricle. Here, signs of inflammation, such as mononuclear cell infiltration or non-calcified fibrotic lesions, were not evident. The myocytolytic cells displayed more intense desmin expression compared to unchanged or only partially calcified myocardiocytes. In contrast, the sinus node, the atrioventricular node and the His bundle were free from inflammation and calcification. Giant cells or granulomas were absent. There were no calcium deposits noted in the other organs, including the kidneys. On postmortem examination of the femoral blood, the patient was negative for HIV.

Discussion

The fact that intensive care unit patients without coronary artery disease have an unexpectedly high percentage of elevated levels of troponin T and I has led to the suggestion of the existence of myocardial cell injury in sepsis and systemic inflammatory response syndrome. Typically, left ventricular myocardial dysfunction is detectable within the first 24 h of the development of septic shock and is completely reversible in survivors within 7–10 days [6]. The pathogenesis of depressed myocardial dysfunction is incompletely understood; however, global ischemia does not seem to be the major mechanism mediating cardiac dysfunction during sepsis. Hematogenic inflammatory foci could explain the altered cardial function only in a small group of patients. Currently, there is a consensus that myocardial dysfunction seems to result from myocardial depressant factors. Candidate mediators for myocardial depressant factor include NO as well as a series of other factors (such as endotoxin, cytokines, platelet-activating factor, reactive oxygen molecules) [2]. Thus, it should be first clarified, whether the unusual myocardial insult in our patient is a result of an endotoxin-induced myocarditis or of a common infectious myocarditis.

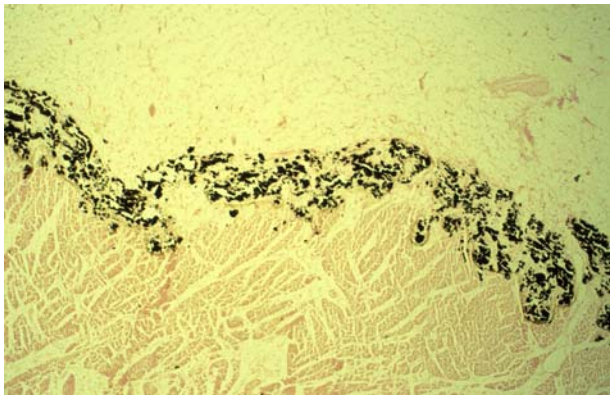

Fig. 5 Right ventricular free wall (von Kossa stain, ×25)

The macroscopic appearance of the heart with its subepicardial narrow-banded deposition of calcium in the right ventricular free wall and the homogenous involvement of the left ventricle, except for structures of the conduction system, has not been described in association with a "classic" infectious myocarditis. Furthermore, the multiple foci of intracellular granular calcifications without concomitant inflammatory signs are not typical for infectious myocarditis. The unusual pattern of the cardiac damage could be explained by regional differences of the myocardium in blood flow, blood volume, metabolism and sensitivity to an ischemic injury, once endotoxin entered the circulation directly in a high dosage [1, 4]. For example, the coronary flow is reported to be lower in the right, rather than in the left ventricle. The regional blood flow is also distributed more randomly and heterogeneously in the right ventricle [3]. Moreover, in an in vivo study, Wong et al. [9] proved spatial and temporary heterogeneity of myocardial responses in endotoxin-induced myocarditis after intravenous application of endotoxin. They also found a gene expression of nitric oxide synthase type 2 in neutrophils, endothelial cell and myocardiocytes located predominantly in the epicardium and endocardium.

The examination of the patient 1 week before the accidental injection of urine showed a healthy man with a normal cardiac function, making a previous cardiac illness appear improbable. The normal echo- and electrocardiographic findings, in association with a dramatic increase in troponin T during the first 3 days, suggest the onset of myocardial inflammation simultaneously with the onset of the sepsis. The subsequent calcifications would explain the rapidly progressing heart failure and the echocardiographic appearance of the septum. Thus, an application of endotoxin in a high dosage directly into the blood circulation followed by an immediate distribution to the heart muscle and subsequent cardiac involvement following blood flow and metabolism patterns, would explain the phenomenon of cardiac inflammation and calcification in the affected myocardial sectors of our case.

In our patient the clinicians diagnosed an increase in the myocardial septal density by echocardiography. However, unaware of such a rare complication of sepsis, they mistook the calcifications for an abscess formation.

The only possible treatment of an almost entirely calcified heart in our young patient would have been a high-urgency heart transplant. Thus, it is important to know about the existence of this unusual condition and to recognize it in due time.

Reactive nodular fibrous pseudotumor involving the pelvic and abdominal cavity: a case report and review of literature

Received: 24 April 2005 / Accepted: 10 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract There are several entities that can present with multiple nodular lesions within the peritoneal cavity, such as "disseminated peritoneal leiomyomatosis," "peritoneal fibrosis," "calcifying fibrous pseudotumor," and the recently described lesion of "reactive nodular fibrous pseudotumor of the gastrointestinal tract and mesentery." Here we present one such lesion in a 28-year-old woman with a history of dysmenorrhea and ergotamine use for migraine attacks. Intraoperative exploration of our patient disclosed numerous nodules located throughout the pelvic and abdominal peritoneum. Histopathologically, these lesions were fibrocollagenous nodules composed of sparse wavy spindle cells within hyalinized "keloid-like" collagen surrounded by an inflammatory infiltrate. Some of the nodules were associated with small foci of endometriosis. We believe this lesion is best described by the term "reactive nodular fibrous pseudotumor" and that endometriosis and the use of ergotamine derivatives may be contributing factors.

Keywords Reactive nodular fibrous pseudotumor · Peritonitis · Endometriosis · Ergotamine · Disseminated peritoneal leiomyomatosis

Introduction

An incidental finding of multiple nodular lesions within the peritoneal cavity can be alarming. There are several entities that can present with this appearance, and it is reassuring to know that some are benign and indolent. Here we present one such lesion in a young woman, which we believe is of a reactive nature and best described by the term "reactive nodular fibrous pseudotumor" used by Yantiss et al. [9].

Clinical history

A 28-year-old woman presented with a gradual onset of abdominal pain that had been present for 3 months. Preoperative examination revealed bilateral cystic lesions in the ovaries, which were thought to be consistent with endometrioma on pelvic ultrasonography. Her previous medical history was significant for severe dysmenorrhea that accompanied every cycle ever since her teens and migraine attacks for which she has occasionally been using ergotamine as well as paroxetine and betahystine derivatives.

Intraoperative exploration disclosed numerous firm, tan-to-white, circumscribed nodules ranging from a few millimeters to 6 cm in diameter. These nodules were present on the surface of the ovaries and appendix, the bowel mesentery, the abdominal peritoneal wall, and the omentum. Frozen section analysis was performed and reported as being consistent with disseminated peritoneal leiomyomatosis (DPL). Debulking of the nodules followed.

Materials and methods

Specimens were fixed in 10% formalin, sectioned, and stained with routine hematoxylin and eosin (H&E). Immunohistochemistry was carried out against cytokeratin (CK- 1/100 Novacastra, Newcastle, UK), smooth muscle actin (1/1000, Neomarkers, Fremont, CA), S100 (1/1000 Neomarkers), CD34 (1/1000 Neomarkers), vimentin (1/5000 Neomarkers), desmin (1/150 Neomarkers), H-caldesmon (1/250 Neomarkers), estrogen receptor (1/100 Neomarkers), and progesterone receptor (1/450 Neomarkers) using the avidin–biotin peroxidase method.

Fig. 1 Macroscopy of the surgical specimen demonstrating numerous tan-to-white nodules of varying sizes within fibroadipose tissue

Results

The surgical specimen consisted of an omental segment, the appendix, and cystectomy specimen from the ovaries and several independent adipose tissue fragments containing circumscribed, lobulated, rubbery-to-hard, white-to-tan nodules ranging from 0.6 to 6 cm (Fig. 1). The cut surface of the nodular lesions was solid and homogeneous. The typical whorled cut surface of a leiomyoma could not be discerned. Similar nodular masses were removed from the ovary and surrounded the tip of the appendectomy specimen.

Histopathological examination largely demonstrated fibrocollagenous nodules composed of sparse wavy spindle cells within hyalinized keloid-like collagen (Fig. 2). Interestingly some of these nodules contained a somewhat-more-cellular peripheral zone composed of active fibroblasts. Most of the nodules were surrounded by an inflammatory infiltrate with abundant mononuclear lymphoid cells and scattered foreign-body giant cells. In addition to these changes, the omentum displayed signs of peritonitis. The

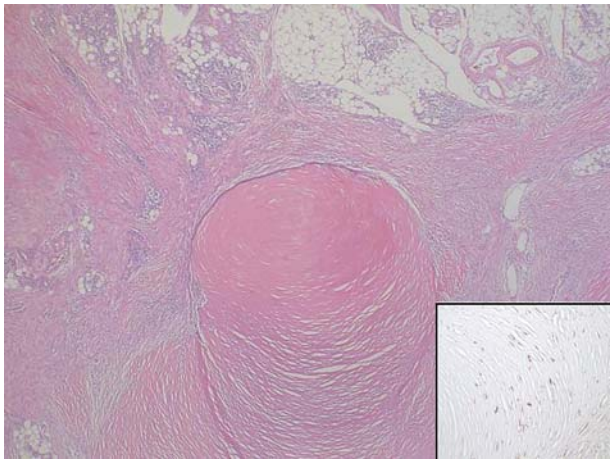

Fig. 2 Fibrous nodule with keloid-like central collagen composed of sparse spindle cells surrounded by a mononuclear inflammatory infiltrate at the very edge (H & E stain). *Inset* shows cytokeratin positivity

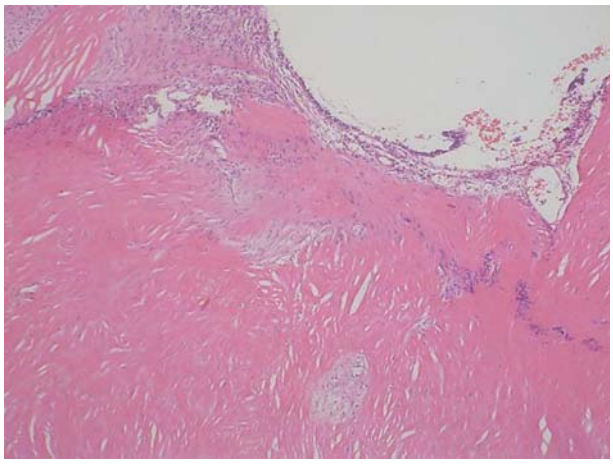

Fig. 3 Foci of endometriosis (*top left*), neighboring one of the fibrous nodules (H & E stain)

cystectomy specimen from the ovary showed endometriosis, and sparse foci of endometriosis were identified within the nodular mass removed from the contralateral ovary (Fig. 3). A nodular fibrous lesion surrounded the appendix, encased its tip, and infiltrated the appendiceal wall, almost to the mucosa in one of the sections (Fig. 4).

Immunohistochemically, the sparse spindle cells composing these nodules were positive with vimentin, CD34, CK (Fig. 2, inset), and smooth muscle actin and, focally, with estrogen and progesterone receptors. They were negative for S100, desmin, and H-caldesmon.

Discussion

The lesion presented, with its low cellularity, prominent hyalinization and lack of atypia and mitoses, and accompanying peritonitis, which we believe is of a reactive nature. Its macroscopical appearance is similar to the benign entity of disseminated peritoneal leiomyomatosis, which is commonly associated with an altered hormonal milieu such

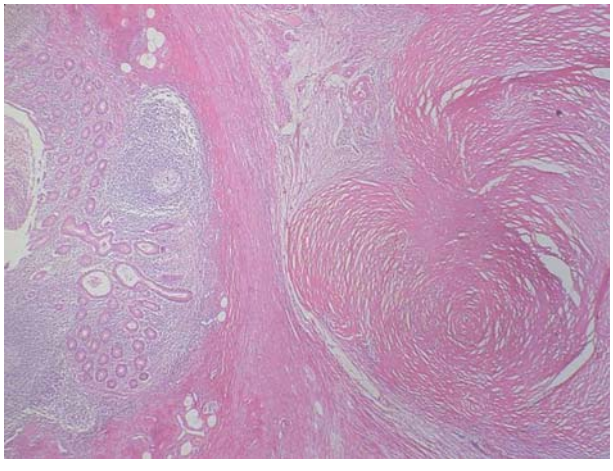

Fig. 4 Fibrous nodules within the appendix wall, close to the mucosa (H & E stain)

as pregnancy [10]. The microscopic characteristics and the size of the nodules in our case argue against DPL but do not exclude it, considering that there are reports of DPL with larger nodules and that leiomyomas can show extreme hyalinization.

If not for the mass lesions, our findings would have been consistent with sclerosing peritonitis, which is a reactive fibrous proliferation resulting in diffuse fibrous thickening of the peritoneum [4]. This lesion can be seen in patients with ascites, cirrhosis, peritoneal dialysis, familial Mediterranean fever, peritoneovenous shunts, and endometriosis [4] and is thought to be associated with chronic irritation of the peritoneum. It is also reported to occur in association with luteinized thecomas, which was not the case with our patient [2]. Nodular lesions referred to as "peritoneal fibrous nodules" by Clement are also characterized by spindle cells believed to derive from the metaplasia of multipotential subserosal cells and are associated with pelvic inflammatory disease and surgical procedures [3]. Desmoid tumor, a myofibroblastic neoplasm of the abdominal wall, also enters the differential diagnosis; however, these lesions are usually ill defined and not nodular, and the accompanying inflammatory infiltrate is not that prominent.

One other similar lesion is the recently described entity of "reactive nodular fibrous pseudotumor (RNFP) of the gastrointestinal tract and mesentery." This entity was first described in a series by Yantiss et al. [9], which was followed by two other case reports by Zardawi et al. [11] and Chatelain et al. [1] and a series of eight cases by Daum et al. [5]. This lesion, like those in our case, is characterized by nodular fibrous pseudotumors composed of scattered fibroblastic spindle cells with a hyalinized collagenous background. The lesions are believed to be reactive and are associated with previous surgery. Immunohistochemically the spindle cells can express vimentin, smooth muscle actin, CD117, and CK. The spindle cells have recently been suggested to be derived from multipotential subserosal cells based on their CK expression [5].

"Calcifying fibrous pseudotumor," a benign soft tissue lesion that is also known to present in similar locations, can also be considered in the differential diagnosis [7]. It is also characterized by a hypocellular spindle cell proliferation (displaying CD34 positivity) within dense collagen, accompanied by dystrophic calcification. Our case could be a noncalcifying variant of this entity or one that has not calcified just yet.

We believe the macroscopic and histopathologic features of our case most closely resemble the RNFP. Indeed, involvement of the mesentery, appendix, and the rest of the gastrointestinal tract represented only a small component of the lesion, and thus it is conceivable that RNFP is not limited to the mesentery. All the differential diagnostic lesions we have discussed are similar in nature and represent reactive fibrous proliferations, most probably in response to various conditions that irritate the peritoneum, and seem to be derived from multipotential subserosal cells. Our case likely represents a variant of the RNFP with more extensive involvement of the peritoneal cavity.

Our patient does not have any of the predisposing conditions described for the cases of RNFP such as previous surgery or inflammatory disorders. However, she did have accompanying endometriosis, which considering her long history of dysmenorrhea probably has been present for quite some time and is a predisposing factor for the other similar entities that we have discussed. It is known that endometriotic foci can be associated with severe fibrosis and end-stage endometriotic lesions can be predominantly composed of fibromuscular tissue rather than endometriotic tissue [6]. Her previous history is also significant for migraine therapy with ergotamine. Ergot derivatives are known to induce fibrosis, most commonly retroperitoneal fibrosis, but are also associated with pleuropulmonary and pericardial fibrosis and cardiac valve damage [8]. The association of our findings with ergotamine use is therefore also a possibility, either on its own or as a contributory factor.

We have described a case characterized by numerous fibrocollagenous nodules, involving the peritoneum of the abdominal and pelvic cavities. Similar lesions have previously been described with names such as "peritoneal fibrous nodules," "calcifying fibrous pseudotumor," and "reactive nodular fibrous pseudotumor of the gastrointestinal tract and mesentery," all of which seem to represent reactive lesions possibly derived from multipotential subserosal cells. Although initially described involving the gastrointestinal tract, we believe the term "reactive nodular fibrous pseudotumor" best characterizes our case, a reactive lesion possibly secondary to endometriosis and/or ergotamine use.

Well-differentiated papillary villoglandular adenocarcinoma of the uterine cervix with a focal high-grade component: is there a need for reassessment?

Received: 10 March 2005 / Accepted: 10 June 2005 / Published online: 9 August 2005
© Springer-Verlag 2005

Abstract Well-differentiated villoglandular adenocarcinoma of the uterine cervix is characterized by an exophytic growth pattern with variably sized papillae that are lined by stratified columnar cells with no more than moderate cytologic atypia. Based on the favorable outcomes in most of the previously reported cases, it has been suggested that some patients with this subtype may be managed conservatively. The case described herein is an otherwise prototypical well-differentiated villoglandular adenocarcinoma but which was associated with a 4.9-mm focus of poorly differentiated carcinoma at its invasive edge. A review of the literature revealed a variety of findings that suggests a need to reassess the potential morphologic and biologic spectrum of this group of tumors. Five of the approximately 89 reported cases were associated with a higher-grade component of the same or a different histologic subtype. At least one patient with apparently stage 1A1 disease was found to have a positive lymph node. Another patient with stage 1B1 disease but no stromal invasion died of her disease following multiple recurrences. Finally, the frequency of lymphovascular invasion and/or lymph node involvement in recent series far exceeds what was found in the two original series. Our case suggests that well-differentiated villoglandular adenocarcinoma is not a diagnosis that should be unequivocally rendered on a small biopsy since other components may be present and the patients may be undertreated. We urge caution when conservative management (cone biopsy alone when margins are negative and there is no lymphovascular invasion) is offered to patients with this tumor since knowledge about its true biologic spectrum appears to still be in evolution.

Introduction

Although cases fitting its basic description had undoubtedly been described previously, well-differentiated villoglandular adenocarcinoma of the uterine cervix (WDVGA) attained widespread acceptance as a distinct clinicopathologic entity following a report of 13 cases by Young and Scully [15] in 1989. Compared to other types of cervical adenocarcinoma, WDVGA is most prevalent at a younger age group, with an average age of 33–37 years in two series [8, 15]. Characteristic morphologic features include an exophytic surface villoglandular papillary component that is usually thin but which may be broad, stromal cores in papillae, and a lining by endocervical, endometrioid, or intestinal-type cells showing no more than mild to moderate cytologic atypia [2–5, 7–10, 12–15]. The underlying etiopathogenesis of this tumor remains to be elucidated. A disproportionately high proportion of patients in whom this tumor was diagnosed were noted to have previously been taking oral contraceptives [8], although the precise nature of this association is currently unclear. Human papillomavirus (HPV), especially type 16, also appears to be directly involved in the pathogenesis of WDVGA [1]. WDVGA generally has an excellent prognosis, and conservative management for selected patients has been suggested [1, 2]. We describe herein a case of WDVGA, which may have important implications both for pathologists making this diagnosis and clinicians managing patients with this tumor.

Clinical history

A 47-year-old gravida 2 para 2 underwent an endometrial biopsy for persistent menorrhagia. Her past medical history was significant for use of oral contraceptives for approximately a 5-year period in her third decade. The biopsy showed an adenocarcinoma with a prominent villoglandular pattern (see below for description). However, due to the prominent endocervical type differentiation, we raised the possibility of a cervical primary tumor. The patient subsequently underwent a radical hysterectomy with bilateral salpingo-oophorectomy and pelvic/periaortic lymphadenectomies. The patient has no evidence of tumor recurrence or metastases 4.5 months after her surgery.

Pathologic findings

Within the uppermost portion of the endocervix and focally extending into the lower uterine segment, a tan-gray, mucoid, and friable mass which measured 3.5×3.0 cm was identified. The microscopic appearance of 95% of the tumor and the biopsy were identical: thin, slender papillae with stromal cores lined by endocervical-type epithelium with moderate nuclear stratification and only mild cytologic atypia (Figs. 1, 2). Some cells showed overt mucinous differentiation, whereas others showed abundant eosinophilic cytoplasmic as typically seen in endocervical adenocarcinoma of the usual type (Fig. 3). Mitotic figures were sparse (three mitoses/10 high-power fields), and stromal invasion was a maximum of 20% of the cervical wall thickness in these regions (2 mm/10 mm). However, in one section, the tumor had a distinctly different appearance: this focus measured 4.9 mm in diameter and was at the advancing edge of invasion in this region (Fig. 4). Effectively, this area showed the highest area of stromal invasion (60% of the cervical wall thickness). This focus was characterized by highly pleomorphic tumoral cells showing a high nuclear/cytoplasmic ratio, nucleomegaly, and multinucleation (Fig. 5). Scattered cells in this nodule also showed cytoplasmic mucin. Mitotic activity was high (26/10 high-power field). Papillary formations were not present. Within this area was a 0.4-mm solid aggregate of cells, which, upon closer inspection, were composed of cells distended by cytoplasmic mucin, resulting in a signet-ring-like appearance (Fig. 6). No lymphovascular or perineural invasion was present, and the lymph nodes showed no tumor involvement. Overall, the tumor was assigned an International Federation of Gynecology and Obstetrics (FIGO) stage of 1B1.

Discussion

In the two original series of WDVGA, none of a total of 37 patients experienced any disease progression following their primary treatments, with follow-up ranging from 7 months to 14 years [8, 15]. For comparison, recent data from the Surveillance, Epidemiology, and End Results program (1976–1995) indicated that the 5-year survival rates for American whites <50 years old with cervical adenocarcinoma ranged from 82.5 to 88% [11]. These two series included six patients who were treated by cone biopsy alone [8, 15]. This favorable prognosis, in conjunction with the young ages of the patients in which these tumors are typically diagnosed, caused the authors of both series to suggest that carefully chosen patients wishing to preserve their fertility may be managed by cone biopsy alone [8, 15]. Young and Scully [15] outlined strict criteria that defined the clinicopathologic circumstances under which conservative management may be considered: (1) the tumor has to be superficial; (2) margins of the excision are negative for tumor; (3) there is no vascular space invasion; and (4) close follow-up examination is feasible. Since those two original reports, at least 52 additional cases have been reported, some with a variety of clinicopathologic findings that suggest a need to reassess the potential

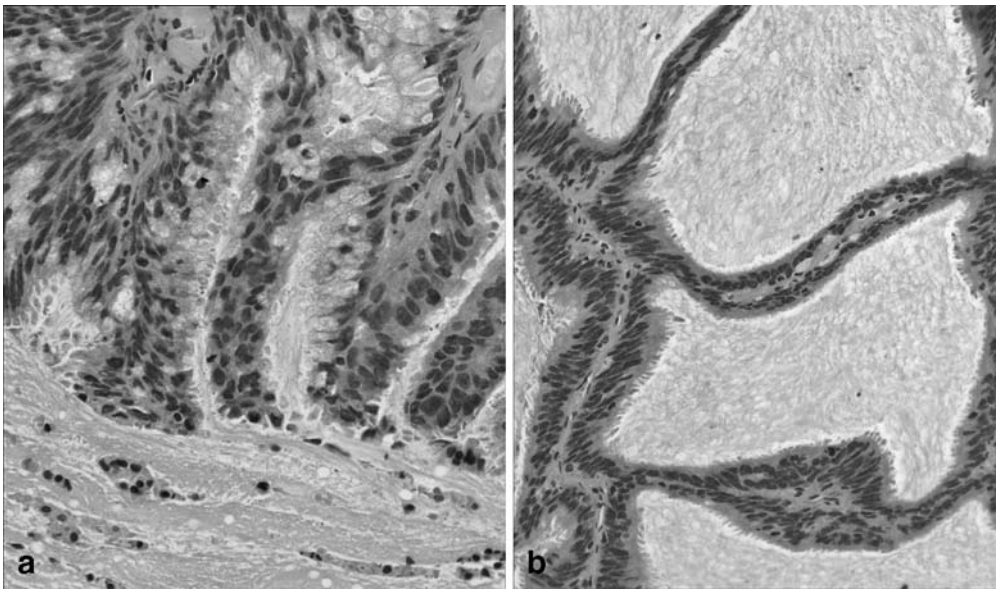

Fig. 3 Higher-power view of Fig. 1 (**a**, *left panel*) and Fig. 2 (**b**, *right panel*). In some areas of the tumor, the cells showed overt mucinous differentiation (**a**), whereas others showed abundant eosinophilic cytoplasmic as typically seen in endocervical adenocarcinoma of the usual type (**b**) (hematoxylin and eosin, original magnification, 200×)

morphologic and biologic spectrum of this group of tumors. It should be noted that the vast majority of these reported patients, irrespective of these findings, have had a favorable outcome. However, whether this is because the tumors are well differentiated and/or that approximately 94% of the tumors [5] are present at stage I (perhaps related to their being exophytic masses that are most likely detected on screening modalities or cause symptomatology) is unclear.

The current case as well as 5 of the other 89 reported cases revealed in the resection specimens histologic findings that were distinct from the main WDVGA. These cases suggest that WDVGA is not a diagnosis that should be unequivocally rendered on a small biopsy since other components may be present and the patients may be undermanaged [14]. Stanley-Christian et al. [12] described a patient in which the biopsy showed WDVGA, but the hysterectomy specimen showed moderately differentiated endocervical adenocarcinoma. Similarly, Bouman et al. [2] described a patient in which the biopsy showed WDVGA, but the hysterectomy specimen showed, in addition to the WDVGA, an infiltrating moderately differentiated papillary adenocarcinoma. Those authors also described a case in which the hysterectomy specimen showed a "well-differentiated infiltrating component with a rather abundant squamous component" [2]. WDVGA was found in coexistence with an invasive squamous cell carcinoma in a cone biopsy in another case [3]. Finally, Kaku et al. [9], in one of their series of seven cases, described a patient with a tumor, 90% of which was a WDVGA and the residual of which was a small cell nonkeratinizing squamous cell carcinoma. Interestingly, another case of a predominantly papillary serous adenocarcinoma of the cervix, which was admixed with a minor component of WDVGA, has also been described [6]. In our opinion, these cases, in addition to the present case, in which a high-grade component was

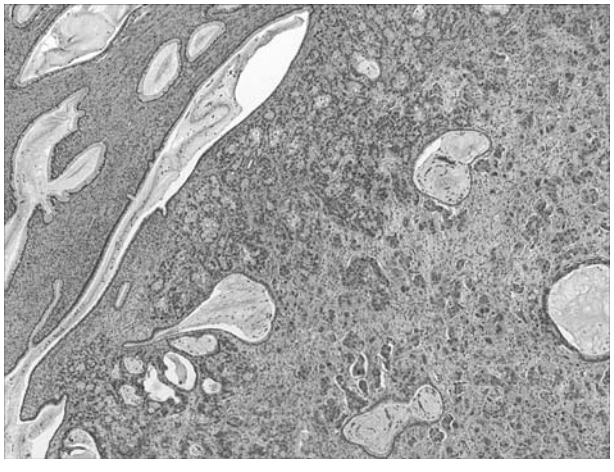

Fig. 4 The high-grade component was at the advancing edge of invasion and was not present in the biopsy. Note the benign glands in the area beneath the invasive edge (hematoxylin and eosin, original magnification, 100×)

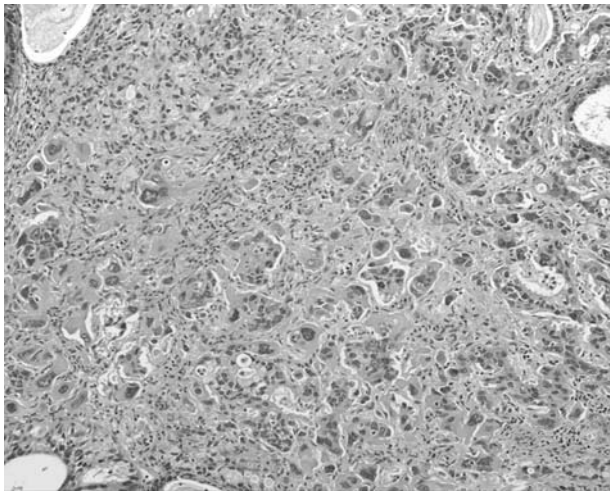

Fig. 5 The high-grade component is shown. Mitotic activity and cytologic pleomorphism is evident (hematoxylin and eosin, original magnification, 160×)

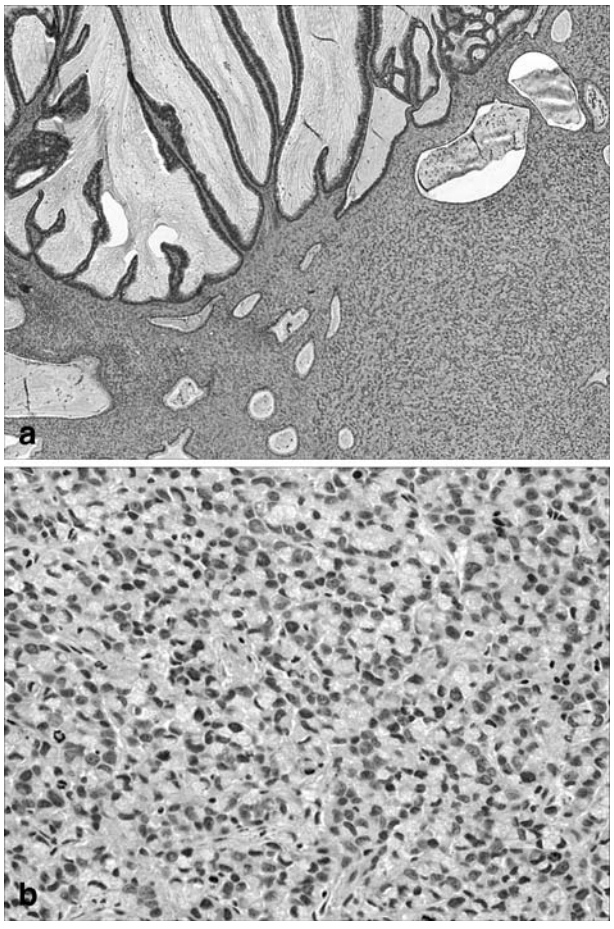

Fig. 6 A nodule of cells with a signet-ring-like appearance was also present within the high-grade nodule (hematoxylin and eosin, original magnification, 100×; *inset*, 200×)

identified at the base (advancing, invasive edge) of an otherwise prototypical WDVGA, bolster the aforementioned argument that WDVGA is not a diagnosis that should be rendered without equivocation on a small biopsy since other components may be present and the patients may be undermanaged. Young and Clement [14] have also expressed some concern about the potential undertreatment of these patients, and those authors have suggested that WDVGA should only be suggested on small biopsy material. Our case strongly bolsters that argument.

In the two original series on WDVGA, lymphovascular or lymph node involvement was not seen in all 37 cases [8, 15]. Recent reports [9, 10, 13], however, suggest a frequency of lymphovascular invasion and lymph node involvement which is not inconsequential. In the series of Khunamornpong et al. [10], lymphovascular invasion was present in 3 (20%) of 15 cases, 2 of which showed lymph node involvement. Kaku et al. [9] reported lymphovascular invasion in two (29%) of seven cases, both of which were associated with lymph node metastases and one of which was eventually fatal. In the recent report of Utsugi et al. [13], lymphovascular invasion was seen in 4 (31%) of 13 cases, one of which also had abundant lymph node metastases.

Parenthetically, it is perhaps prudent to reassess whether conservative management should be considered for WDVGA any more often that it is considered for other well-differentiated adenocarcinomas with the same histopathological parameters. As noted above, the vast majority of the reported cases of WDVGA have had favorable outcomes, although whether this is related to the early stage in which these tumors often present or the intrinsic biologic properties of these tumors is unclear. Using the criteria outlined above as a justification for conservative management, at least one patient with obturator lymph node metastases would have been missed [5]. Additionally, Dede et al. [4] recently described another patient with stage 1B1 WDVGA who was initially managed with a radical hysterectomy. There was no lymphovascular invasion and apparently no stromal invasion ("no invasion focus of atypical small gland in the wall of the cervix was noticed"). This patient would experience multiple pelvic recurrences over the ensuing 5 years and eventually died of her disease [4]. This is another patient who could have been managed with conservative treatment alone based on the above criteria.

The principal differential consideration for WDVGA is endocervical adenocarcinoma of the usual (i.e. endocervical) type, especially since the latter may show a prominent papillary pattern. Young and Clement [14] have recently reemphasized that tumors being designated WDVGA should have "no more than mild to moderate nuclear atypicality and scattered mitotic figures." Whether some of the cases being reported as WDVGA are better considered as other lesions is a matter of opinion. For example, in a recent report, the mean mitotic account in areas of typical WDVGA was reported as 43/10 high-power fields [13]. We concur with Young and Clement [14] that the term WDVGA should only be used for pure lesions, and the descriptive term used in the heading of the current case is being used only for the purposes of this report.

In summary, we have described herein an otherwise prototypical WDVGA but which was associated with a 4.9-mm focus of poorly differentiated carcinoma at its invasive edge. Our case, and others in the literature, suggests that WDVGA is not a diagnosis that should be unequivocally rendered on a small biopsy since other components may be present and the patients may be managed too conservatively. Additionally, the possibility of the coexistence of a high-grade component in WDVGA highlights the importance of adequate tumor sampling in these cases. Finally, caution is urged when conservative management is offered to patients with this tumor since knowledge about its true biologic spectrum appears to still be in evolution.

Pyothorax-associated lymphoma: an unusual case with both T- and B-cell genotypes

Received: 13 March 2005 / Accepted: 19 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Abstract Pyothorax-associated lymphoma (PAL) is a B-cell lymphoma which develops in the pleural cavity of patients with an over-20-year history of pyothorax. Aberrant expression of surface antigens is occassional in PAL, although genotype is not fully investigated. We report here a PAL with dual genotype, i.e., simultaneous immunoglobin (Ig) and T-cell receptor (TcR) gene rearrangement. An 82-year-old woman with pain on the left side of the chest was admitted. She had been suffering from pyothorax after artificial pneumothorax for treatment of tuberculosis of the pulmonary when she was 18 years old. The mass that was confined to the left pleural cavity affected by pyothorax was biopsied and histologically diagnosed as diffuse large cell lymphoma. The tumor cells were positive for CD20, CD16, and TIA-1 but negative for CD79a, CD45RO, CD43, CD3, and CD56. Surface antigen expression was further investigated in cultured cells, showing that the cultured cells did not express representative B-cell markers, except for CD20, as well as T-cell markers, but were positive for CD16, CD30, and CD103. Southern blotting revealed the monoclonally rearranged bands of both Ig heavy chain and TcR gene. The patients died of tumors 14 months after admission. Aberrant genotype and immunophenotype of PAL cells is discussed in reviewing the pertinent literature.

Keywords Pyothorax-associated lymphoma · Epstein–Barr virus · Immunophenotype · Immunogenotype

Introduction

Malignant lymphoma frequently develops in the pleural cavity of patients with an over-20-year history of pyothorax [5]. The term pyothorax-associated lymphoma (PAL) has been proposed by Dr. Aozasa for this type of tumor, and it is now listed as a distinct disease entity in the recent World Health Organization Classification of tumors [2]. Recent large-scale study on PAL showed that patients have an over-20-year history of pyothorax resulting from artificial pneumothorax for treatment of pulmonary tuberculosis or tuberculosis pleuritis and frequently present with chest and/or back pain and fever [7]. PAL histologically shows a diffuse proliferation of large-size B cells [diffuse large B-cell lymphoma (DLBCL)] with a strong association with Epstein–Barr virus (EBV) infection. PAL is unique not only in its clinical presentation but also in its gene expression profile, i.e., distinct from DLBCL of nodal origin [8].

Lymphomatous presentation in the pleural cavity fall into two subtypes; PAL showing mass formation in the pleural cavities and is human herpes virus 8 (HHV-8)-negative, and primary effusion lymphoma (PEL) showing pleural effusion without identifiable mass formation and is HHV-8-positive. Both types of lymphomas are usually EBV-positive. PEL is also a neoplasm of large B cells, usually occurring in the setting of immunodeficiency caused by human immunodeficiency virus (HIV) infection. Most PEL patients are young-to-middle-aged homosexual males.

Expression pattern of cell surface marker in PAL is unique. Typically, lymphoma cells are positive for CD79a and CD20. A number of cases may express at least one T-cell marker (CD2, CD3, CD4, and/or CD7), most frequently with B/T phenotype aberrant dual B/T phenotype in clinical cases [8]. Simultaneous expression of CD2 and CD20 in the cell lines derived from PAL were also

reported [3, 9]. We describe here a first case of PAL showing dual lineage at the genetic level.

Case report

An 82-year-old woman was admitted to Osaka General Medical Center with pain on the left side of the chest. She had suffered from pulmonary tuberculosis in the left lung and received an artificial pneumothorax when she was 18 years old. Computed tomographic (CT) scan revealed the mass to be confined to the left pleural cavity affected by pyothorax. Aspiration biopsy was performed, and it was diagnosed as malignant lymphoma, with no other specifications. Radiographic examination including abdominal CT, brain magnetic resonance imaging, and Gallium scintigraphy, together with bone marrow biopsy, did not reveal any metastatic lesions, whereas bone scintigraphy demonstrated increased uptake in the eighth to tenth left ribs, which was regarded as the secondary involvement of PAL because of the absence of osteoclastic and/or osteoplastic changes as revealed by CT scan. In addition, the previous study shows that lymphomas usually develop in the pleural tissue but not the bone tissue.

The patient was treated with two courses of chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisolone) combined with 50 Gy of radiation therapy. Because the combined therapy was not effective, additional radiation therapy of 40 Gy was added. However, metastatic tumors appeared in the right lung. She suffered from nausea. Then endoscopic examination of upper digestive tracts was performed, revealing well-differentiated adenocarcinoma in the stomach. The patient died 14 months after admission. Autopsy was not performed.

Methods

Small specimens obtained from the PAL lesions by aspiration biopsy were subjected to immunohistochemistry as well as primary cultures. Culture (5×10^6 cells/ml) was started in RPMI 1640 supplemented with 20% heat-inactivated FCS at 37°C in 5% CO_2 in air. Growing cells were collected and subjected to morphological analysis, immunohistochemistry, in situ hybridization for detection of EBER-1 transcript of EBV, flow cytometric analysis, and rearrangement of immunoglobulin heavy chain (IgH) and T-cell receptor gene (TcR).

Immunohistochemistry and in situ hybridization using histologic specimen

Immunophenotyping of the proliferating cells with B-, T-, and NK-cell differentiation antigens and EBV antigens was performed on the paraffin-embedded sections from the original tumor specimens using avidin–biotin–peroxidase complex method. The antibodies used were anti-CD20 (Kyowa Medex, Tokyo, Japan), CD79a, CD3 epsilon, CD45RO (UCHL-1), latent membrane protein (LMP)-1 (CS1-4), EB nuclear antigen (EBNA)-2 (PE2) (Dakopatts, Glostrup, Denmark), CD43 (MT-1)(Bioscience, Emmenbrucke, Switzerland), and CD56 (Novocastra, Newcastle, UK).

RNA in situ hybridization using EBER-1 probe was performed as previously described, with some modification. Briefly, 30-base oligonucleotide probes which were sense and anti-sense for a portion of the EBER-1 gene, a region of the EBV genome that is actively transcribed in latently infected cells, were synthesized using a DNA synthesizer. As a positive control, the Raji cell line was used. As negative controls, the hybridizing mixture containing sense probe or antisense probe after RNase treatment was used.

Flow cytometric analysis using cultured cells

The cultured cells were analyzed by two-color immunofluorescence with a flow cytometer (EPICS XL, Beckman Coulter, Hialeah, FL, USA). Antibodies conjugated with fluorescein isothiocyanate (FITC) or phycoerythrin (PE) (Becton Dickinson, Franklin Lakes, NJ,USA) were used: they included anti-CD2, CD3, CD4, CD5, CD7, CD8, CD10, CD11c, CD15, CD16, CD19, CD20, CD21, CD23, CD24, CD25, CD30, CD34, CD38, CD56, CD103, surface

Immunoglobulin heavy chain and T-cell receptor gene rearrangement analysis using cultures cell

Rearrangement of the IgH and TcR Cb1 and Jb1 genes was analyzed by Southern blotting. Ten micrograms of DNA were digested with appropriate restriction enzyme, electrophoresed in 0.7% agarose gels, and Southern blotted. The filters were hybridized with JH probe, CTb, and Jb1 probe, respectively. Hybridizations were visualized by a Fluorescein Gene Image System (Amersham, Buckinghamshire, UK) according to the manufacturer's instruction.

Results

The biopsy specimen contained a monomorphous proliferation of large lymphoid cells and massive necrotic areas (Fig. 1a). The large lymphoid cells had a round to oval nucleus, in which one to two nucleoli were evident. Mitotic figures were frequent. Immunohistochemical study (ABC method) on the paraffin sections revealed that the tumor cells were weakly positive for CD20 and CD16 but negative for CD79a, CD45RO (UCHL-1), CD43 (MT-1), CD3 epsilon, and CD56. Staining with TIA-1 antibody revealed numerous cytotoxic granules. In situ hybridization using EBER-1 probe revealed positive signals in the nucleus of tumor cells.

Biopsy samples contained inflammatory cells and necrotic areas. (Fig. 1a). Therefore, phenotyping was performed on the cultured PAL cells together with biopsy materials. At the culture, large round cells similar to the original tumors, with occasional bizarre forms, proliferated as clusters (Fig. 1b). Flow cytometric analysis revealed that the cultured cells did not express representative B-cell markers except for CD20 as well as T-cell markers, but positive for CD16, CD30, and CD103 (Table 1). Surface Ig expression was not detected. Southern blotting with the use of JH DNA probe and TcRJb1 probe demonstrated the monoclonally rearranged bands of IgH and TcR gene (Fig. 2).

In situ hybridization using EBER1 probe revealed positive signals in the nuclei of numerous cells (data not shown). LMP-1 and EBNA-2 expression was not detected in these cells by immunohistochemistry (data not shown).

Discussion

Previous gene rearrangement analysis on leukemia and lymphoma cases expressing dual-lineage antigens demon-

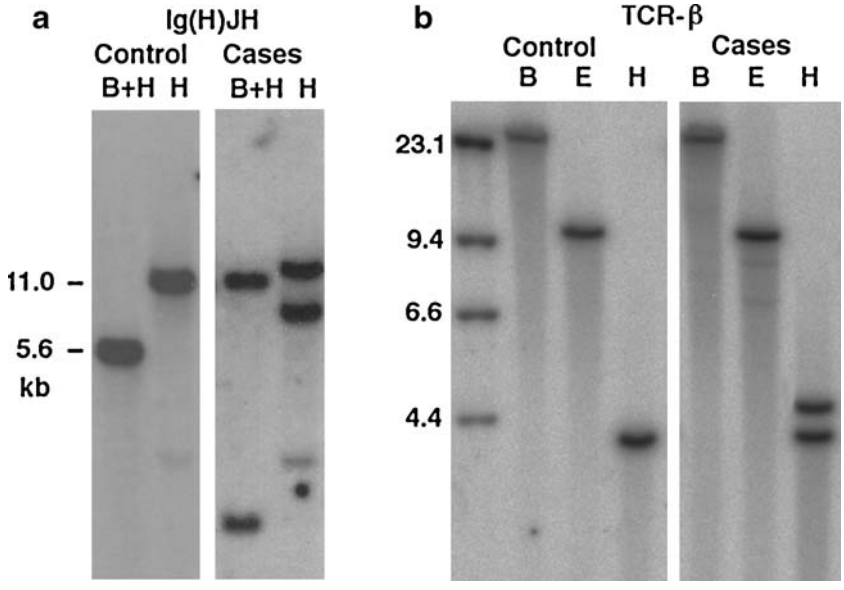

Fig. 2 Southern blot analysis of **a** IgH and **b** TcRJb1. Ten micrograms of DNA were digested with *Bam*HI+*Hin*dIII (*B*+*H*) and *Hin*dIII (*H*) or *Bam*HI (*B*) *Eco*RI (*E*), and *Hin*dIII (*H*), electrophoresed in 0.7% agarose gel, transferred to the nylon membrane, and hybridized with JH DNA probe or TcRJb1 DNA probe. Monoclonally rearranged bands for IgH and TcR were demonstrated in cultured cells

strated either B-cell or T-cell receptor rearrangement, germline configuration of both genes (null cell), or much less frequently, simultaneous Ig and TcR gene rearrangement (dual genotypes). Dual genotype has been described in up to 30% of cases of precursor lymphoid neoplasms, but this phenomenon occurs rarely in lymphomas with a mature phenotype [10]. Previously proposed explanation for dual-lineage antigen expression by leukemia/lymphoma cells are (1) derepression of masked genetic expression during neoplastic transformation, (2) transformation of stem cells committed to different pathways, and (3) neoplastic expansion of a population of normal cells that express both markers. Our previous study on hypermutation of IgH gene indicated that PAL is derived from B lymphocytes at the differentiation stage of the post germinal center [6]. Therefore, derepression of masked genetic expression during neoplastic transformation is likely in the present case.

Hollingsworth et al. [4] reported three lymphoma cases with dual phenotype arising in immunocompromised hosts and suggested that lymphomas arising in such a setting might more frequently show a deregulated differentiation than those arising in immunocompetent hosts. PAL develops mostly in patients with chronic pyothorax that resulted from lung tuberculosis. There might be some immune-deficient condition at the time of lung tuberculosis, but any findings indicative of presence of immune deficiency are not found in patients with pyothorax and PAL. Alternatively, PAL develops in the specific circumstance, i.e., an over-20-year history of chronic inflammation, where reactive oxygen species and cytokines are abundantly produced [7].

Expression pattern of cell surface markers in PAL is unique. CD79a is usually detected in a wider range of B-cell maturation than CD20. Therefore, lack of CD79a expression in the present PAL cells expressing CD20 is conspicuous. The tumor cells express CD20 but lack CD79a, whereas the opposite may be found in immature B-cell proliferations. A number of cases may express at least one T-cell marker (CD2, CD3, CD4, and/or CD7), most frequently with B/T phenotype [2]. Simultaneous expression of CD2 and CD20 in the cell lines derived from PAL was reported [3, 9]. The present case showed the dual rearrangement of both IgH and TcR genes and unusual immunophenotypes. Al Saati et al. [1] also reported a similar case with dual rearrangement, although they did not diagnose the case as PAL and sufficient clinical and pathologic data were not provided. Another interesting point in the present case is that the tumor cells expressed CD16 and contained cytotoxic granules in the cytoplasm. The CD16 is a 50- to 80-kDa glycoprotein that is expressed in two different isoforms. The transmembrane form is found on NK cells, macrophages, and mast cells. The transmembrane form plays a role in signal transduction, activation, and antibody-dependent cellular cytotoxicity. Taken together, dual rearrangement of both IgH and TcR gene and aberrant antigen expression are not uncommon in PAL.

Gastrointestinal autonomic nerve tumor secreting catecholamines

Received: 14 April 2005 / Accepted: 2 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Dear Editors:
Gastrointestinal autonomic nerve tumors (GANTs) form a subset of gastrointestinal stromal tumors (GISTs) [4]. In contrast to classical GISTs, GANTs have ultrastructurally a distinct neuroendocrine phenotype [1, 4]. The nature of these ultrastructural neuroendocrine granules remains enigmatic. With the exception of a single GANT, which was described as secreting vascular endothelial growth factor and endostatin [3], there are no published reports that these tumors secrete polypeptide hormones, growth factors, or biogenic amines.

In the present paper, we report a GANT found to secrete catecholamines. We are submitting this case for publication to indicate that GANTs can be functionally active.

A 49-year-old man visited his primary care physician complaining of lower quadrant pain that began following a minor work-related injury of the abdomen. During the initial examination, an abdominal mass was palpated, and a subsequent computerized tomographic examination revealed a 15-cm lower abdominal mass. He was obese and had been treated for elevated blood pressure, which fluctuated between 150/105 and 163/93 mm Hg, even though he was taking antihypertensive drugs. Because of the suspicion that the tumor might be secreting catecholamines, several laboratory tests were performed, and the following abnormalities were found: urinary 5-hydroxyindolacetic acid (5-HIAA) was elevated 13.7 mg/24 h (normal, <6 mg/24 h), homovalinic acid 10.7 mg/24 (normal, <8 mg/24 h), fractionated metanephrine 281 μg/24 h (normal,<180 μg/24 h; hypertensive range, >400 μg/24 h), normetanephrine 610 μg/24 h (normal, 451 μg/24 h), and total metanephrines 891 μg/24 h (normal, 680 μg/24 h). The tumor was located in the mesentery of the small intestine and was resected in toto with a segment of the small intestine. The patient recovered completely.

The tumor was multilobular and solid and measured 15×14×13 cm (Fig. 1a). Histologically, it was composed of elongated spindle cells showing moderate nuclear pleomorphism and hyperchomasia (Fig. 1b). There was an average of eight mitotic figures per ten high-power fields. Immunohistochemical stains showed that the tumor was positive for CD117, CD 34, and vimentin (Fig. 1c). Other immunohistochemical tests, including the staining with antibodies to S100, smooth muscle actin, desmin, cytokeratins, chromogranin, and synaptophysin gave negative results. Electron microscopy revealed that many cells have elongated or rounded-up filopodia-like processes containing neurosecretory granules (Fig. 1d). There were also prominent interdigitating cytoplasmic processes and rudimentary intercellular junctions. There was no evidence of smooth muscle or Schwann cell differentiation. On the basis of these morphologic data, the diagnosis of a malignant GANT was rendered. On the basis of the size (more than 10 cm in diameter) and the number of mitoses, the tumor was designated as high risk, as defined at the National Institutes of Health Consensus Conference [2]. The patient was treated with Gleevac, which he tolerated well. Within 18 months, he had recurrent tumor in the abdominal cavity, which was resected at another hospital. Two and half years after surgery, he is still alive and apparently free of tumor.

According to the best of our knowledge, this is the first GANT reported to secrete catecholamines. This secretory activity was discovered by accident because we thought that the tumor might be a catecholamine secreting paraganglioma/pheochromocytoma. The huge size of the tumor also played an important role; even if the tumor cells were

only weakly secretory, a large number of such cells probably contributed to the rise of catecholamines in the body. A future preoperative search for catecholamines performed prospectively on patients, suspected of having GISTs, might be warranted. Such a study could discover more secretory GANTs and thus help us define their true secretory potential.

Chromophobe renal cell carcinoma with extensive rhabdomyosarcomatous component

Received: 15 April 2005 / Accepted: 10 June 2005 / Published online: 14 July 2005
© Springer-Verlag 2005

Keywords Chromophobe cell carcinoma · Rhabdomyosarcoma · Sarcomatoid carcinoma · Kidney

Sir,

Sarcomatoid changes may occur in all subtypes of renal cell carcinoma [1], especially in chromophobe cell carcinoma [3, 6], and are invariably associated with a poorer prognosis. It is likely that the sarcomatoid component arises from a metaplastic transformation of carcinomatous cells that may acquire a spindle cell morphology with a growth pattern, usually resembling that observed in malignant fibrous histiocytomatous, fibrosarcoma or unclassified high-grade spindle cell sarcoma [1, 2]. Although a focal rhabdomyosarcomatous differentiation has been rarely reported [2], we are not aware of any published renal cell carcinoma composed predominantly of a rhabdomyosarcomatous component. We report a rare case of chromophobe renal cell carcinoma with a dominating rhabdomyosarcomatous component accounting for 70% of the entire tumour. A 61-year-old man presented with abdominal and left flank pain. Ultrasonography and computerized tomography examination revealed a tumour mass in the left kidney. Radical nephrectomy with abdominal lymph node dissection was performed. Grossly, a tumour mass measuring 16 cm in its greatest dimension and whitish in colour was located in the upper pole of the kidney. Histologically, tumour was mainly composed of spindle- and large round-shaped cells with deep eosinophilic cytoplasm, frequently containing cross-striations consistent with rhabdomyoblasts (Fig. 1a). This rhabdomyosarcomatous component represented about 70% of the entire tumour. Immunohistochemical analyses, which revealed a strong and diffuse immunoreactivity for vimentin, desmin, myogenin (MyF4) and sarcomeric actin in these cells, confirmed their skeletal muscle differentiation (Fig. 1b). Focally, rhabdomyoblasts were closely intermingling with residual nests of chromophobe renal cell carcinoma (Fig. 1c), which were better highlighted by pancytokeratin immunostaining (Fig. 1d). Carcinomatous cells were also reactive to cytokeratin 7 and EMA.

The remaining tumour was composed of pure chromophobe cell carcinoma (10%) and high-grade spindle cell sarcoma NOS. (20%). The latter component was immunoreactive for vimentin and, focally, for pancytokeratins. Diffuse areas of necrosis and numerous mitotic figures were observed throughout the tumour. Perirenal and renal sinus adipose tissue was infiltrated by tumour, and iliar lymph nodes were metastatic (pTNM, T3 N1 Mx).

Differential diagnosis mainly revolved around primary renal rhabdomyosarcoma. Even if the possibility of the existence of this entity in adults cannot be completely excluded [4, 5], we suspect that at least some of the reported cases may represent renal cell carcinoma undergoing extensive rhabdomyosarcomatous differentiation. Accordingly, we recommend that an extensive tumour sampling be performed to rule out the existence of small carcinomatous areas in an otherwise typical rhabdomyosarcoma. However, we admit that a precise distinction between a

primary renal rhabdomyosarcoma and a sarcomatoid carcinoma with extensive rhabdomyosarcomatous differentiation appears to be rather academic, as both tumours share a high-stage disease at presentation and a poor prognosis.

BOOKREVIEW

H. Kalthoff

Apoptosis methods and protocols edited by Hugh J. M. Brady, Humana Press, Totowa, New Jersey 2004

Published online: 13 July 2005
© Springer-Verlag 2005

Major insights as well as enormous progress in understanding the role and mechanisms of apoptosis, programmed cell death, could be achieved within the last 15 years. Since apoptosis is assumed to have not only influence on cancer development within mammalian organisms, a large number of research groups focuses on this physiological process in a different context. As a matter of fact, apoptosis plays a central role in the physiology of all multi-cellular organisms studied so far. Disturbances in apoptosis, e.g. inhibition, underlie several pathological states such as cancer or auto-immunological diseases. On the other hand, excessive apoptosis may result, for example, in neurodegenerative disorders or ischemic damage.

The impact of apoptosis is still not fully determined during the above-mentioned timeframe since it proved to be of complex functions. It still requires further intense investigation to fully understand the mechanisms of regulation of apoptosis to gain tools to achieve a better control of apoptosis. Thousands of research articles about apoptosis and the surrounding mechanisms are published every year, but standard protocols to analyze apoptotic cell death are still largely missing from laboratory methods and text books.

This book offers a comprehensive overview about numerous methods to study the complex mechanisms of apoptosis. The particular chapters have been written by experts in this field and represent the achieved experiences in years of the research.

Chapters are clearly structured and therefore provide an easy access to the provided information. Each chapter starts with a short but clear introduction, giving enough background information not only for researchers working with apoptosis but also for less-experienced students and/or technical assistants. Methods to be applied are introduced with listing of the required materials like buffers, chemicals and the laboratory equipment. The very clearly written and sufficiently explained methods are supplemented by practical comments like (a) stability of chemicals or (b) some useful controls as well as (c) figures analyzing the typical results achieved. With these clear and complex instructions, a very supportive tool is provided to perform the desired experiments. Furthermore, a support for evaluation and critical examination of the gathered data is given.

In conclusion, the presented book shows the qualities to be regarded as standard manual for apoptosis research within the near future. It can be fully recommended for all scientists and for those establishing standard operation procedures to support research in this area of cutting edge technologies.

ANNOUNCEMENTS

15–16 June 2006
Thyroid Pathology for the Practicing Pathologist
15 rue de l'Ecole de Médecine, Paris,France

A 2-day course will take place in Paris again under the auspices of the French Division of the I.A.P.

This course will be given in English by Prof.M.Sobrinho-Simões (Porto) and Prof.R.Heimann (Brussels).

It will consist of lectures alternating with slide reviews and a slide seminar over a multihead microscope. The cases of this seminar will be sent (on CD)before the meeting.

The audience will be limited to 22 participants.
Course fees: 390 euros (320 euros for members of any I.A.P. division).
The fees include registration,hand-out, CD of the slide seminar and coffee breaks.

For further information please contact

Newsletter of the European Society of Pathology

Dear Members,

In this newsletter you have the Presidential Address from the new President of the Society given at the Closing Ceremony at the 20th European Congress of Pathology which was a very successful congress with a huge program of very high quality, scientifically as well as socially, attended by more than 2000 participants.

The Minutes of the General Assembly, which took place at Palais des Congrès, Paris, September 7th 2005, are published in details along with the list of members of the new Executive Committee.

Notice that a new contract with Springer has been approved. This implies that the EUOPATH NEWS will appear once a month in 2006. All ESP members are invited to use the possibility to publish information in the newsletter and also on the website of the society.

For futher information look at the ESP home page: http://129.240.38.9/espl

Sincerely yours,
Grete Krag Jacobsen

Presidential Address

Dear Members,

I am proud and honoured to have been elected President of our Society. The European Society of Pathology is now 42 years old and has been developing continuously since its foundation in 1963. I am a member since 1975 and the last 25 years I have been actively involved in several administrative and/or scientific positions.

I always enjoyed the cooperative and friendly, family-like atmosphere that characterizes our Society. In the Xth ECP in Athens (Sept.1985) I was appointed to serve as the Secretary General of the local Organising Committee. By that time, I could never imagine that 20 years later you would elect me to serve our Society as its President. I am thanking you all for this great honour from the bottom of my heart.

In starting my 2 year term as President, I would like to thank all the Officers (A. Cardesa, G. Bussolati, R.R.W.Simpson and H.van Krieken) and all the Members of the Executive Committee (Fr. Capron, F. Carneiro, Ch.De Wolf-Peeters, R. Golouh, Gr. Krag Jacobsen, V.P. Lehto, M. Wells and D. Yilmazbayhan) for everything they have done for the benefit of ESP. Then, it is my privilege to welcome the new President-Elect, Fr. Bosman, ex-Member of the Executive Committee and Chairman of the Eurocell Path, and the new Members of the Executive Committee (N. Gale, Th. Kirchner, M. Marichal and F. Schmitt). I am wishing to the new comers all the best and I am sure that all together we will try to contribute for the further development of ESP.

Furthermore, I am extending my sincere thanks to each and everyone of the 17 Past Presidents, who have all served our ESP extremely well and led it to its present high standards. Due to their skills and initiatives, a lot of progress has been achieved, however, much more remains to be done. Among them, the only other woman was the late A. Piringer-Kuchinka, who served as President from 1975 to 1977 and has been a great personality in the family of European Pathologists. Therefore, as a matter of respect, I am dedicating my two-year Presidency in her memory.

My vision for the next two years is focused on the following:

1. Development of the European Institute for Continuing Medical Education in Pathology (EICME-Path).

The EICME-Path must be further developed and the best way is to make the Presidents' office responsible, while having a running Committee, chaired by the President-Elect, to devise ways and means, like the Examination Committee of UEMS. Additionally, the President, along with the Past-President, would be responsible to motivate the working groups for the expansion of Continuing Education, independently of the Intercongresses' Meetings and the ESP Congresses. I believe that this would be an immense contribution, especially to the Eastern European Countries.

The European School of Pathology with its extensions to different European cities, as well as the Eurocell Path are increasingly well regarded at a time when University investment in Academic Pathology is falling in some European Countries. The Society should strengthen its Academic Meetings as well as the main Congresses. The existing Montebello, IUCP and other well-known Postgraduate Courses in the UK are not enough for the number of young European Pathologists and/or residents. Therefore, the motivation of the working groups with didactic lectures, symposia, panel discussions and slide seminars will be very beneficial for small groups in remote Universities or State Hospitals in Eastern Europe and in the Balkans

1a. Courses for technicians

I strongly believe that the task of our Institute should be also extended towards

the continuing education of the technicians from Eastern European Countries and from Balkans. Senior Technicians should be invited to Postgraduate ESP Courses in order to see how these might be done. To my knowledge, the UK has well established University based courses in which after basic training, the technicians learn how to proceed with special techniques.

2. Links between the ESP and the UEMS.

The links between the ESP and the UEMS should be encouraged, so that the regulation of Pathology moves along with its science. The cross-border training should be advanced and if the local situation of the Country permits, on a reciprocal basis. The latter would be beneficial for both sides and will lead to the creation of common research projects. Furthermore, this training will increase the personal skills of young residents, who might try to obtain the UEMS examination, as a way of demonstrating competence and mobility in the profession.

3. Links with Forensic Societies.

I think that science is moving on fast and we should build more links with Forensic Societies. To my knowledge, there are some places lacking appropriate facilities and human resources, therefore I believe that collaboration with ESP might be sensible. Our Laboratories should offer cooperation in such forensic labs.

4. Virchows Archiv.

All Senior European Pathologists should be encouraged to contribute with editorials and/or reviews, as well as young researchers of our Specialty should be motivated by their Directors to send manuscripts, in order to maintain the quality and further increase the Impact Factor of our official Journal for the next ten years.

Last, but not least, I would like to congratulate heartly the President of the 20th ECP P. Bedossa and his brilliant Stuff for the great success (at all levels) of this major scientific event. Furthermore, the highest number of registrations ever achieved (up to 2200!!) gives us the strength to try hard to recruit new members among them.

Ending my address I am asking you, the members of our Society, to support all these initiatives and I am thanking you for the honour to elect me as President of our Society.

I am looking forward to seeing you not only in Ioannina (May 2006), but also in our 21st ECP in Istanbul (September 2007).

Prof. Dr. Niki J. Agnantis,
President of ESP

Minutes of the General Assembly, European Society of Pathology; Hall Bleu, Palais des Congrès, Paris, France; September 7th 2005, from 12.00 to 13.30hrs.

1. Welcome.

The President, Prof. Antonio Cardesa welcomed approximately 170 ESP members.

2. Approval of agenda.

Item 8 to be considered after item 5. Approved.

3. Approval of Minutes from the Extraordinary General Assembly in Paris, 7th February 2004.

These had previously been published, and copies were circulated at the start of the meeting. These were approved as a true and accurate record, and signed by the President and Secretary.

4. Report of the President.

Between 1964 and 2003, the ESP had evolved to meet great changes, and the scientific structures were satisfactory for the time being. In contrast, the administrative aspects of the ESP remained as they were in 1964, and it was agreed that major changes were needed.

In 2003, a ballot of members approved by more than 70% the decision of the Executive Committee to elect Prof. Niki Agnantis as President-elect. This was ratified by the General Assembly in Paris on 7th February 2004, which also elected Dr. Roderick Simpson to complete the term of Secretary of Prof. Jahn Nesland, who had resigned.

New Statutes were approved, and have since been accepted under Belgian law. Under the new statutes, the ESP is officially a non-profit society, with appropriate legal and financial protection. New rules for election of officers were drawn up by Prof. Michael Wells and have subsequently been approved by the Executive Committee at its meeting in Barcelona in November 2004. The meeting in Porto in April 2005 made recommendations for new officers in accordance with the new rules.

As agreed at the General Assembly in 2004, a Constitutional Sub-Committee was set up to update the By-Laws. These have been published in the 2005 Members' handbook, and will be presented in Item 5.

The biennial congresses of the ESP continue to be successful. This is especially so with the current Paris one which has more than 2000 participants, making the ESP congresses the second largest in the World. The President expressed his great thanks on behalf of the ESP to Prof. Pierre Bedossa and the French Society of Pathology.

A successful Intercontinental Congress was held in 2004 in Iguaçu, Brazil involving the ESP, Sociedad Latinamericana de Patología (SLAP) and Sociedade Brasileira Patologia. In future intercontinental congresses, it is hoped to involve additional continents.

The Inter-Congress meeting in Ioannina, Greece in May 2006 is well advanced, and progress will be reported in Item 14.

As there are now more and larger congresses, the Executive Committee has decided that a Congress Coordinator will be needed.

The Advisory Council provides a link between the ESP and the national societies of pathology, and the President expressed his thanks to the chairman, Prof. Günter Klöppel.

The Newsletter and website are in the process of being updated, and the President expressed his appreciation to the respective editors, Drs. Grete Jacobsen and Bjørn Risberg.

The European School of Pathology continues to thrive under the direction of Prof. Gianni Bussolati. In addition to courses in Turin, Italy, they are also given in Kraków, Poland, Kraiova, Romania and Ankara, Turkey. Similar courses are also sponsored by the ESP in Ioannina, Greece under the direction of Prof. Niki Agnantis.

Eurocellpath under the chairmanship of Prof. Fred Bosman has run excellent courses in Girona, Spain in 2004 and in Montebello, Norway in 2005.

The Working Groups remain the backbone of the ESP, and are doing extremely well, particularly in linking applied and basic research.

The official journal of the ESP is Virchows Archiv and its impact factor has considerably increased over the last few years. The new editor-in-chief is Prof. Heinz Höfler. A new contract has been negotiated, which is economically beneficial for the ESP. See Item 6.

It is considered that the ESP needs a strategically located permanent address. See Item 7.

The President thanked the immediate Past President, Gianni Bussolati and the departing members of the Executive Committee for their support and contribution to the Society.

The President noted that his term will finish at the end of this congress, and he expressed his best wishes to Prof. Niki Agnantis who will lead the Society to its next congress in Istanbul. He thanked all members of the ESP who will ensure that the Society continues to thrive.

Finally, the President announced with regret the death of Prof. Julius Plank, Martín, Slovakia in January 2004. The General Assembly stood silently in respect.

5. Statutes and By-Laws.

New statutes were approved by the General Assembly in Paris in 2004. A Sub-Committee chaired by Prof. Mia Marichal was set up to update the By-Laws, in particular the rules for election of officers and regulations of the Working Groups. The President expressed his thanks to the Committee comprising Profs. Michael Wells, Manuel Sobrinho-Simões, Frédérique Capron and Urbain Van Haelst.

The President added that By-Laws were relatively easy to change if necessary.

The General Assembly approved the new By-Laws unanimously.

6. Contract with Virchows Archiv.

The President reported a good interaction between the Executive Committee, the Editor-in-Chief and with Springer, and that an offer beneficial to the ESP had been made. Under the new contract, the ESP receives 50% of the net profit of the journal. On present figures, this is likely to be about €50,000. The Executive Committee (in particular, the Treasurer) support this proposal.

The Editor-in-Chief believed that the new contract was advantageous for both the ESP and Virchows Archiv. In addition, there were other benefits for the ESP. Prof. Höfler added that he believed that there was still room to increase the Impact Factor of the Journal.

The General Assembly approved the new contract with Springer unanimously.

7. Permanent office for the European Society of Pathology.

The ESP is a society registered in Belgium, at present at Prof. Mia Marichal's private address. Therefore, it needs a permanent address, as well as an office, a store for documents, and possibly a meeting room. The Executive Committee had discussed this extensively at four recent meetings, where it was felt essential that the office should be in Belgium, probably in Brussels. The Treasurer reported that the ESP could afford to spend up to €250,000. It was also felt necessary that the ESP should employ a managing assistant, probably on a part-time basis.

The President asked the General Assembly to approve the principle and allow the Executive Committee to develop the details. Open questions remain on the exact location and size of any property, whether to buy or not (based on a sum of approximately €250,000) and on the level of expertise of the society employee.

The General Assembly agreed unanimously:

a). that the ESP should have a registered permanent address in Belgium.
b). to mandate the Executive Committee to buy a property up to a maximum value of approximately €250,000.
c). to the employment of one appropriate person.

8. Report of the Treasurer.

a). Prof. Han van Krieken presented his report, which will be published in detail on the website.
b). The Treasurer thanked Christine van Haelst for her help in the transition. He noted that at present, the financial year ends on Aug 1st, which leaves too little time to collate the figures and contact the financial committee. He requested a change to 1st January, and the General Assembly approved this unanimously.
c). Total assets in 2005 are €435,684-06 (2003 - €383,686-44). A considerable sum had been changed from long term investments to interest-bearing bank accounts. The income from 2003-05 was €214,584-25 (2001-03 - €159,247) mostly from subscriptions, investments and profits from the Ljubljana congress. It will not be possible to recoup the loan of €10,000 to the Intercontinental Congress in Iguaçu. Overall expenses were €159,286-63, the largest part being the €90,320-15 paid to Virchows Archiv. There was a substantial increase in Executive Committee expenses, due to there being several meetings. The total surplus of income over expenditure was €55, 297-62.
d). The General Assembly is required to approve new members. Rather than reading out all their names, it was agreed that publication of the list of members in the Handbook was sufficient.

The General Assembly unanimously approved the Treasurer's report.

9. Report of the Chairman of the Advisory Council.

Prof. Günter Klöppel presented his report. The Advisory Council met on Saturday, 3rd September. 19 of 29 possible members attended. Amongst items discussed were:

a). It was emphasised that the AC is the link between the national societies of pathology and the Executive Committee. Under the new By-Laws, each member must be approved by his/her national society, and the representative should preferably be the secretary or president.
b). A request that each national society should have a member in each Working Group.
c). The AC should advise in the planning of the congresses, such as in Istanbul.
d). The AC would be a good forum to receive information about pathology from most countries of Europe.
e). The ESP newsletter and website should be used as a link between the national societies and the ESP.
f). Pathologists should be involved in the planning of EORTC trials.
g). A request was made by the Czech representative for the European School of Pathology to hold courses in the Czech Republic.
h). The next meeting of the Advisory Council will be held in May 2006 in Ioannina.

The General Assembly approved this report unanimously.

10. Rules for election of new officers, additional members of the Executive Committee.

New rules had been drawn up by committee led by Prof. Michael Wells. These are published on pages 21-22 of the Members' Handbook and were read out by the President.

The General Assembly approved them unanimously.

11. New Officers and members of the Executive Committee.

In accordance with the new rules for election, the following candidates for officers were proposed by the Executive Committee. No other nominations were received.

President-elect:	Fred Bosman.
Secretary:	Roderick Simpson.

Both were approved by the General Assembly, and thus duly elected.

The Executive Committee proposed as members of the Executive Committee: Nina Gale, Thomas Kirchner, Mia Marichal, Fernando Schmitt. They were approved by the General Assembly and thus duly elected.

The President noted that there were several other good potential candidates for the Executive Committee, who should not be discouraged from putting themselves forward for consideration in the future.

12. Honorary memberships.

The President proposed two outstanding members of ESP for Honorary Membership:

a). Antonio Llombart-Bosch for his great contribution to pathology and the ESP as Past President, President of the Advisory Council and for his general wisdom.

b). Paul Kleihaus for being an outstanding morphologist, cancer researcher and for coordinating the publication of the new series of WHO tumour "blue" books.

13. 21st ESP Congress, Istanbul 2007. Report of the Chairman of the Organising Committee.

Prof. Sitki Tuzlali presented the outline for the Congress scheduled for September 2007. The opening ceremony will take place on 8th September, the General Assembly on the 12th and the Congress will close on 13th September.

The site will be the Istanbul Convention and Exhibition Centre, which has 21 rooms, the largest having 2000 seats. There will be 4 keynote lectures plus many slide seminars, symposia, short courses, free paper and poster sessions. The programme would be formulated in consultation with the Advisory Council and Working Groups. There will be an active social programme, and opportunities for tourism afterwards. The second announcement will appear in Autumn 2006.

The Congress website is: www.ecp2007istanbul.org

Prof. Tuzlali invited all to attend what will be an excellent congress in an unique city.

14. ESP Inter-Congress, Ioannina, May 2006. Report of the Congress President.

Niki Agnantis presented the programme. It will be based primarily around the Working Groups and associated societies, and there will be a guest lecturer. It will last 2½ days, and will be preceded by the annual meeting of the Greek Society of Pathology. There will be an active social programme, including excursions, as well as an opportunity to visit an interesting area of Greece. The site will be the Hotel du Lac, and there are plenty of hotels of different costs. There are flights from Athens and other cities, as well as travel by sea and overland.

The congress website is: www.triaenatours.gr

15. Approval of the site of the 3rd Intercontinental Congress 2008.

The Executive Committee in 2004 approved Barcelona as the site of next Intercontinental Congress scheduled for May 2008, and to be organised by Prof. JA Bombí.

The General Assembly unanimously approved this proposal.

16. Approval of the site of the 22nd ESP congress 2009.

In 2004, the Executive Committee approved Florence as the site for the congress scheduled for September 2009, and to be organised by Prof. Marco Santucci.

The General Assembly unanimously approved this proposal.

17. Frequency of General Assemblies.

The Executive Committee believes that biennial General Assemblies are unlikely to be sufficient to deal with the increased complexity of the Society. As the Statutes state that "the General Assembly meets at each biennial congress", any additional meetings will have to be Extraordinary General Assemblies (EGAs). The President asked this General Assembly for a free hand to be given to the Executive Committee to call EGAs if required. The first would be held in Ioannina during the Intercongress meeting in May 2006.

This was approved unanimously.

18. Any other business.

The Congress Awards were presented by Prof. Pierre Bedossa. He acknowledged that due to many excellent papers, it had been a very difficult task, but the following were chosen.

a). Best oral presentation (prize of €1500): Chromosomal instability predicts the malignant phenotype in sporadic insulinomas. Speel EJM, Jonkers YMH, Claessen SMH, Perren A, Schmid S, Komminoth P, Verhofstad AA, Hofland LJ, de Krijger RR, Slootweg PJ, Ramaekers FCS - Maastricht, Nijmegen, Rotterdam (Netherlands), Zürich, Baden (Switzerland).

b). Best poster presentation (prize of €1000): Head and neck squamous cell carcinomas: epidermal growth factor receptor (EGFR) protein expression and EGFR gene copy numbers. Mrhalová M, Plzak J, Betka J, Kodet R - Czech Republic.

c). George Tiniakos award for the best presentation in gastrointestinal, liver and pancreas pathology (prize of €1000): Endocrine precursor lesions are associated with duodenal gastrinomas in patients suffering from multiple endocrine neoplasia type 1. Anlauf AM, Perren A, Meyer C, Schmid S, Saremaslani P, Kruse MI, Weihe E, Komminoth P, Heitz PU, Klöppel G - Kiel, Marburg (Germany), Zürich (Switzerland).

19. Date and place of next meeting.

An Extraordinary General Assembly will take place in Ioannina, Greece in May 2006.

The next (regular) General Assembly will take place in Istanbul on 12th September 2007.

Signed:

Professor Antonio Cardesa, President of the ESP.

Dr. Roderick HW Simpson, Secretary of the ESP.
26th September 2005.

Erratum

Please notice that in the Abstracts from the 20th European Congress of Pathology in Paris printed in the August 2005 issue of Virchows Archiv vol 447, number 2, page 436, the authors of P 644 are missing and should be : P644. Repair of bone defects by anionic collagen matrices. **Lenaldo B Rocha (1), Randall L Adam (2), Neucimar J Leite (3), Konradin Metze (2), and Marcos A Rossi (1).** 1. Department of Pathology, Faculty of Medicine of Riberão Preto, University of São Paulo, Brazil. 2. Department of Pathology, Faculty of Medicin, and 3. Institute of Computing, State of University of Campinas Brazil.

The European Society of Pathology

Dear Colleague,

It will surely not have escaped your attention that *Virchows Archiv* is now the Official Journal of the European Society of Pathology.

But did you realise what benefits membership in the society offer you?

- A subscription to the journal *Virchows Archiv* at no extra charge – this is automatically sent to every member every month.
- Access to the journal online (take a look at http://link.springer.de). If you are already a member of ESP but have not yet registered for your free electronic access, you will find the necessary form to complete online here too.
- A discount of 20% on most titles published by Springer. To take advantage of this, simply send your order directly to the publisher, with details of your membership.
- Attendance at the Society's conferences at a reduced fee.

If you have not yet joined the European Society of Pathology, why not do so now?
Simply complete and return the form enclosed.

We look forward to welcoming you as a member.

Yours sincerely

N. Agnantis	H. van Krieken	H. Höfler
President European Society of Pathology	Treasurer European Society of Pathology	Managing Editor Virchows Archiv

Application for Membership of the EUROPEAN SOCIETY OF PATHOLOGY

This application can also be downloaded from our website:
http://www.Europathology.org

Please complete the following form (block capitals please) and return it to the Office of the Treasurer

FAMILY NAME: .....

First Name(s): .....

Male ❑ Female ❑

Place and date of birth: .....

Title/Present Position: Prof. ❑ Dr. ❑ Resident ❑

Other: .....

Please clearly indicate which one of the following addresses should be used for subsequent correspondence, mailings, and listing in the Members Handbook:

Gianni Bussolati

Of GISTs and EGISTs, ICCs and ICs

Received: 25 August 2005 / Accepted: 25 August 2005 / Published online: 21 September 2005
© Springer-Verlag 2005

Interest in the structural and biological features of cells originally described by Cajal in muscle layer of the gastrointestinal tract has recently been enhanced by demonstration of their histogenetic link with gastrointestinal stromal tumors (GISTs) and sensibility of the latter to STI-571 (imatinib mesylate) treatment. Since tumor growth is dependent from the tyrosine-kinase c-KIT product (CD117), its demonstration by immunohistochemistry has acquired diagnostic interest and is a prerequisite for the related treatment.

Immunohistochemical staining with anti-CD117 antibodies is not specific for Cajal's interstitial cells (ICCs), nor for GISTs. However, such staining is highly sensitive, being reportedly positive in the vast majority of GISTs [6], displaying diffuse or membranous and a perinuclear dot-like pattern of distribution. Another marker of interest is CD34 (positive in approximately 80% of cases), while staining for contractile proteins, such as actin and desmin, is uncommon and focal. Mutations of *c-KIT* and *PD-GFRA* genes have also been described in GISTs and carry diagnostic and therapeutic impact.

Besides the gastrointestinal tract, similar tumors, defined as extra-gastrointestinal stromal tumors (EGISTs) [13], have been described in locations such as urinary bladder, gallbladder, omentum, and mesentery [3, 5].

Most recently, rare cases of spindle cell tumors morphologically and immunohistochemically similar to GISTs have been described in the pancreas. The first observation of a single case of a pancreatic tumor histologically reminiscent of GIST, composed of spindle-shaped cells and immunohistochemically positive for vimentin, CD34 and c-KIT protein was made in 2004 by Yamaura et al. [14]. A similar case was described, in the same year, by Neto et al. [7]. Such observations were soon followed by the description of two similar cases by Pauser et al. [9]. In April 2005, Daum et al. [2] reported on a GIST of the pancreas, defined on the base of morphological, of immunohistochemical and, for the first time, of genetic data (mutation of *c-KIT* gene by deletion of six base pairs in exon 11).

Interestingly, Yamaura et al. [14] noted the presence, in the normal pancreas surrounding the tumor, of c-KIT positive cells, surrounding the intercalated ducts and the acini, and suggested that such cells might be the origin to the stromal tumor they described. These authors relied only on the relatively unspecific immunohistochemical staining for CD117 and did not go as far as defining the presence of interstitial cells (ICs) in the pancreas. This was recently achieved by Popescu et al. [12] on the base of cultural, electron-microscopical as well as immunohistochemical data. In striking similarity, Ortiz-Hidalgo et al. [8] reported a c-KIT positive stromal tumor in the gallbladder and linked such finding to the presence of numerous c-KIT expressing ICs in the gallbladder wall.

These reports just underline how much normal histology and pathological observations are mutually interconnected. Several examples of pathological observation of lesions to be regarded as an "experiment of nature" suggest properly addressed histological investigation, and vice versa.

The relatively recent burst in discoveries of ICs in several tissues outside the gastrointestinal tract such as the fallopian tubes and the myometrium, the portal vein and the stroma of the breast and of the pancreas [1, 4, 10, 11] led new light to the histology and physiology of these fascinating and still mysterious cells, which might have additional significance besides a "pacemaker" activity. We can easily predict that an origin from ICs will soon be acknowledged for a number of extra-gastrointestinal spindle cell tumors, which are presently hidden under uncommitted definitions.

In the past, tumors now unanimously recognized as GISTs were variously defined as leiomyomas, leiomyoblastoma, schwannomas, or other rather vague definitions. The possible responsiveness to appropriate treatment of tumors to be included under the generic definition of EGISTs would add impact to the biologic interest of their histogenetic definition.

Ancillary techniques in bone marrow pathology: molecular diagnostics on bone marrow trephine biopsies

Received: 18 May 2005 / Accepted: 11 July 2005 / Published online: 18 October 2005
© Springer-Verlag 2005

Abstract Pathologic examination of trephine bone marrow (BM) biopsies plays a central role in the diagnosis and staging of haematological neoplasms and other disorders affecting haematopoiesis. Haematopathology has been profoundly influenced by the advent of molecular genetic techniques suitable for paraffin-embedded tissues, and certain applications, such as the determination of B- and T-cell clonality, belong to its standard diagnostic repertoire. Many of these molecular tests can be performed successfully with nucleic acids extracted from BM trephine biopsies, if some technical aspects specific to this template source such as various fixation and decalcification procedures are taken into consideration. The current indications for molecular BM diagnostics range from the confirmation of lymphoma involvement with gene rearrangement analysis, demonstration of tumor-specific translocations in lymphoid and chronic myeloproliferative disorders along to the detection of microorganisms or marrow involvement by soft tissue sarcomas. The availability of quantitative polymerase chain reaction techniques for the investigation of allelic imbalances and gene expression levels in paraffin-embedded material also open new avenues for research and advanced diagnostics. The molecular detection of minimal residual disease in haematological neoplasms, especially in the context of new treatment strategies, will provide future challenges. This article summarizes the current state of the art in molecular diagnostics applied to paraffin-embedded BM biopsies.

Introduction

Examination of the bone marrow (BM) is of central importance for the diagnosis and staging of haematological disorders. Conventional aspiration cytology, flow cytometric immunophenotyping, cytogenetics and the histopathological examination of trephine BM biopsies, usually obtained from the posterior iliac crest, are currently the standard examination techniques [4, 15, 80]. Traditional indications for a trephine biopsy include all disorders in which marrow aspiration alone is considered unreliable or insufficient, such as staging of malignant lymphoma, chronic myeloproliferative disorders, metastatic disease and any disorder accompanied by marrow fibrosis [21, 68]. However, in many centres, trephine biopsy is considered an integral part of BM examination and is taken in most instances when an aspirate is performed, irrespective of the indication. Traditionally, the examination of BM biopsies was limited to conventional histological and histochemical stains, such as hematoxylin and eosin, Giemsa, NASD-chloroacetate-esterase, as well as iron and reticulin stains. The availability of a broad range of antibodies suitable for paraffin sections as well as the development of molecular techniques applicable to fixed tissues have significantly broadened the possibilities for the examination of trephine biopsy samples. Although an excellent morphology undoubtedly remains the mainstay and basis for the diagnosis of haematological disorders, the thoughtful application of these ancillary methods can improve diagnostic accuracy, can help to obtain a better subclassification of neoplastic disorders and may increase sensitivity for the detection of residual disease. This review focuses on the methodical

possibilities and limits as well as the diagnostic applications of molecular in vitro techniques for the examination of BM trephines. The role of immunohistochemistry in BM diagnostics is addressed in a separate paper.

Relevance of BM fixation and processing for molecular studies

The presence of bone trabecules and the necessity for preservation of the subtle cytological features of haematopoietic cells poses special problems with regard to specimen fixation, decalcification and processing. To obtain optimal morphology, a variety of fixatives, including buffered formalin, Bouin's, mercury-containing solutions such as Zenker's fixative and B5 or a combination of formalin and glutaraldehyde (Schäfer's solution), are used, followed by brief acid-based or EDTA decalcification [62]. However, several of these fixatives have a detrimental influence on the immunoreactivity and/or the preservation of nucleic acids and therefore limit the application of ancillary techniques [74, 77]. In addition to paraffin embedding, plastic embedding of biopsies is still used. Extraction of DNA and even RNA suitable for molecular studies such as polymerase chain reaction (PCR)-based determination of B-cell clonality or detection of fusion transcripts is possible from plastic-embedded BM samples [6, 27]. However, due to the decreasing role of plastic embedding, the techniques described in this review are based on the use of conventional formalin-fixed, EDTA-decalcified, paraffin-embedded BM specimens, but can be equally applied to non-decalcified material such as BM clot preparations. Samples briefly decalcified with acid-based agents can also be used for DNA-based PCR assays [8, 30]. Fixation in buffered neutral formalin for 24 h followed by EDTA decalcification renders both satisfactory morphology as well as good antigen, DNA and even RNA preservation and therefore can be regarded as a good compromise between optimal morphological detail and the availability of the full spectrum of ancillary techniques. Although decalcification with EDTA is more time-consuming than treatment with acid-based agents, application of an ultrasonication bath allows decalcification within 8 to 12 h.

Similar to conventional paraffin tissues, DNA and RNA extracted from BM biopsies is significantly degraded, and the prevalent fragment size for DNA is below 500 bp. Decalcification procedures, prolonged fixation in comparison to surgical specimens and additives such as glutaraldehyde may further reduce the yield of amplifiable DNA. Nevertheless, we and others have demonstrated that DNA from trephine biopsies can be used for a broad range of PCR assays, and amplification products of more than 500 bp can be achieved [6, 43, 59, 64, 81, 83]. A large number of extraction protocols have been published for paraffin-embedded tissues. In our experience, such standard protocols can also be applied to BM trephines, as long as column-based kits designed for fresh tissue are used with caution, since they may lead to the exclusion of small DNA and RNA fragments. Common to all these procedures, proper digestion with Proteinase K (best performed at elevated temperature overnight) is mandatory to release the maximum amount of DNA from the tissue, whereas purification of DNA extracts is not necessary on a routine basis. Irrespective of the procedure used, control amplification of single copy gene fragment(s) of adequate size—usually in the range of 250–400 bp—is mandatory to check DNA quality, since some tests such as clonality analyses may render false positive results with highly degraded DNA. Control PCRs for amplificates of increasing size in a multiplex format, such as designed by the BIOMED-2 group, may help to get a better estimate of DNA quality [79].

If available, archival, air-dried BM smears can be used as an additional source for DNA and RNA of excellent quality, since they have not been subjected to cross-linking fixatives. Air-dried slides, which are received at many pathology laboratories in addition to trephine biopsies, can even be used for Southern blot analysis, which requires high molecular weight DNA [34].

Although the majority of applications of molecular diagnostics on BM biopsies still use DNA as template source, recent studies have described RNA-based analyses from paraffin-embedded BM samples for a variety of purposes, especially in combination with quantitative techniques such as real-time reverse transcriptase (RT)-PCR (Table 1). The negative effects of fixation, embedding and extraction procedures on RNA integrity, which is less resistant than DNA, have been elucidated [51]. Parameters such as tissue fixation (i.e. type of fixation reagent, duration of fixation) and RNA extraction (i.e. concentration of Proteinase K, duration of sample digestion) have different effects on RNA integrity [40, 41, 55, 73]. However, the mechanisms which lead to cross-linkage between RNA and proteins and to the addition of monomethylol ($-CH_2OH$) groups to all four bases by formalin is largely unknown [51]. The decalcification procedure applied on BM trephines also exhibits a negative effect on RNA integrity [7]. Preferably, the fixed BM trephine should be decalcified in a solution displaying a neutral pH such as EDTA, because an acidic environment augments the process of RNA fragmentation. The degree of RNA fragmentation is variable within different tissues, but the average length of RNA from archival tissues such as BM trephines can be estimated rarely to exceed 200 bp. PCR products which are 100 bp in size or less are amplified more efficiently and thus highly recommended [32, 46, 73].

Indications for molecular examination of BM biopsies

Determination of clonality in the diagnosis of lymphoproliferative disorders

The differential diagnosis of lymphoid infiltrates in the BM is one of the most frequent problems in haematopathology. Although the majority of lymphoid infiltrates can safely be diagnosed as either reactive or neoplastic based on the

extent of involvement, distribution, cytology and immunophenotype, a significant minority of cases cannot be classified with certainty [43, 78]. For some low-grade lymphoma entities such as follicular and marginal zone B-cell lymphoma, the detection of an aberrant immunophenotype may be difficult or impossible in small BM infiltrates. Even flow cytometric immunophenotyping as complementary technique may fail to detect a proportion of cases with BM infiltration, mainly due to sampling error in the presence of focal fibrosis [36, 75]. However, the presence of limited vs disseminated disease—as characterized by the presence of BM involvement—is of crucial importance as prognostic information and for therapeutic decision making.

Detection of B-cell clonality

A variety of approaches have been used for the molecular detection of B-cell clonality in BM specimens. For paraffin-embedded tissues in general, the use of consensus primers against the framework 3 (FR3) or framework 2 (FR2) regions of the immunoglobulin (Ig) heavy chain variable genes in conjunction with primers against the joining region (JH or FR4) [2, 18, 20, 56, 79] is the most frequently chosen approach and will pick up clonality in 50–90% of B-cell non-Hodgkin's lymphoma (B-NHL) cases with a significant BM infiltrate, depending on the type of lymphoma and the method used for the analysis of amplicons [8, 9, 14, 27, 61, 63, 81]. Whereas B-cell chronic lymphocytic leukemia (B-CLL) and mantle cell lymphoma show a clonal product in nearly 100% of cases with these primer sets; other entities, especially follicular lymphoma, will show much lower clonality rates. This is due to point mutations and other events during ongoing somatic hypermutation, which alter or abolish primer binding sites. This relatively high false negative rate has to be kept in mind when evaluating molecular results in the setting of suspicious lymphoid BM infiltrates. Acute lymphoid leukemias may show false negative results due to incomplete VDJ rearrangements [79].

Other primer combinations, such as the recently published BIOMED-2 primer sets, which give a much higher pick-up rate of more than 90% irrespective of lymphoma type, have not been tested sufficiently on BM samples to allow for definitive conclusions [79]. However, primer sets rendering amplicons in excess of 300 base pairs such as the family-specific framework 1 (FR1) region primers should be used with caution on fixed BM samples, because poor DNA quality may result in detection of pseudoclonality due to preferential amplification of rare B cells. The same problem may occur, if semi-nested or nested protocols are used which can give oligoclonal or pseudoclonal results with poor template quality [37, 43]. To avoid false positive results, stringent control of DNA quality and reproducibility of PCR results are mandatory. Repetition of the same PCR reaction with different template concentrations, or repeat extractions, are ways to confirm clonal results [25, 38].

To increase the sensitivity for the detection of small clonal populations in nodular lymphoid infiltrates, we have successfully used microdissection to enrich the target cell population [43–45]. Although this increases the pick-up rate through reduction of the polyclonal background population, it also increases the risk of pseudoclonality due to the small amount of template, and only clearly reproducible bands of identical size should be regarded as evidence for clonality [43, 85]. Since the most frequent diagnostic question is the presence of BM involvement by a malignant lymphoma diagnosed at another site, DNA from the primary tumor can be used for comparative purposes, and clonal products of the same size and sequence will confirm the presence of BM infiltration. However, one has to keep in mind that lymphoid infiltrates in the marrow may be the result of another clonal process, rather than dissemination of an extramedullary lymphoma. This is especially the case in so-called discordant lymphoma, where a BM infiltrate composed of small lymphocytes is found in the setting of nodal or extranodal large cell lymphoma. In a recent study, we were able to show that one third of the cases of discordant lymphoma actually represented two different clonal processes, rather than morphological progression of the same clone (Fig. 1) [45].

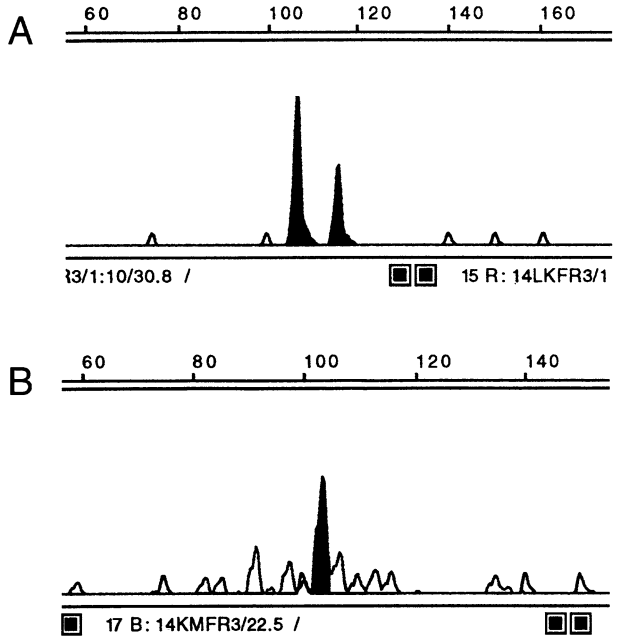

Fig. 1 Genescan analysis of immunoglobulin heavy chain gene PCR products with framework 3 (*FR3*) primers in a patient with diffuse large B-cell lymphoma and so-called discordant bone marrow involvement by small lymphocytes. **a** Lymph node biopsy. **b** Microdissected lymphoid infiltrates from the BM trephine. Genescan analysis shows two clonal products of different size. A distinct clonal origin was confirmed by sequencing

Another application of microdissection in BM biopsies is the clonal analysis of two neoplastic processes with divergent phenotype, such as composite NHL or combinations of Hodgkin's and non-Hodgkin's lymphoma [28, 29, 45]. In addition to nodular infiltrates necessitating discrimination from reactive lymphoid aggregates, some lymphoma subtypes with occasionally very subtle patterns of infiltration such as splenic marginal zone lymphoma or intravascular large B-cell lymphoma may require molecular studies for diagnostic confirmation [22].

There are very few data available concerning the sensitivity of molecular techniques in BM trephines, but it can be assumed from mixing experiments and other data that the sensitivity is the range of 2–10% clonal cells with conventional consensus primers, if sensitive detection methods such as the Genescan technique with fluorescently labelled primers, heteroduplex analysis or high resolution polyacrylamide gels are used. BM trephines may be more representative samples for molecular studies than simultaneously obtained aspirates, since the aspirate is frequently significantly diluted by peripheral blood lymphocytes, a phenomenon similarly observed in flow cytometric immunophenotyping [14, 36].

The detection rate can be increased by addition of primers for common translocations, namely the t(14;18)(q32;q21) involving the bcl-2 locus in follicular lymphoma and the t(11;14)(q13;q32) involving the bcl-1/CCND1 locus in mantle cell lymphoma. However, extremely sensitive tests such as nested PCR, which can pick up rare cells carrying the translocation, should be avoided in the diagnostic setting. A detection of the t(14;18) without morphological correlate is not sufficient for a diagnosis of malignancy on its own, since rare benign B cells carrying this translocation are a frequent finding in elderly patients [52, 53]. Positive results, especially for bcl-2 rearrangements, obtained in BM samples should always be compared to the primary diagnostic tissue by appropriate techniques such as sequencing to confirm the clonal identity of the detected translocation.

Alternative methods for detection of B-cell clonality such as the use of primers against the kappa light chains can be employed analogously to the common Ig heavy chain assays [33]. More recently, a promising technique for BM biopsies based on the quantitative detection of kappa and lambda mRNA transcript ratio has been described [48].

Detection of T-cell clonality

Since BM involvement by T-cell NHL (T-NHL) is distinctly less frequent compared to B-cell lymphoma, only a limited number of studies have dealt with the molecular detection of T-cell clonality in BM trephines [30, 35, 44, 81, 82]. Nevertheless, molecular studies may provide significant help in certain diagnostic settings. The higher number of reactive T-cells in normal BM, the frequent difficulty to identify an abnormal immunophenotype in T-cell neoplasms and the subtle pattern of infiltration characteristic for certain T-NHL such as T-cell proliferations of large granular lymphocytes (T-LGL) or hepatosplenic T-cell lymphoma are potential reasons to study T-cell clonality in BM trephines [30, 82]. The most frequently used strategy for detection of T-cell clonality in paraffin-embedded tissues are various primer combinations directed at the T-cell receptor gamma locus (TCRγ), less commonly against the TCRβ genes, since the latter locus is more complex and requires a large number of primers [2, 57, 79]. The vast majority of T-cell neoplasms of both α/β, as well as γ/δ, phenotype show TCRγ rearrangements. Since somatic hypermutation of rearranged TCR genes does not occur, mispriming is less of a problem than in B-cell lymphomas. However, due to the restricted repertoire of germline genes, pseudoclonality due to diverse rearrangements of identical length may cause false positive results, especially with a limited number of target cells. Therefore, analysis of PCR products by either Genescan or heteroduplex analysis is mandatory, and each reaction should be run at least in duplicate [79].

General issues of clonality determination

One needs to point out that demonstration of B- or T-cell clonality in the BM should not be equated with malignancy. Leaving the technical problem of pseudoclonality aside, true lymphocyte clones may be detected in a variety of fairly common benign or premalignant disorders, such as monoclonal gammopathy of unknown significance (MGUS), in patients with subclinical clonal B-cell populations with a B-

CLL phenotype or occasionally in patients with nodular lymphoid infiltrates [26, 43]. This underlines that a diagnosis of malignancy should only be made if appropriate clinical, morphological and phenotypical findings are present.

The identification of a clonal population in the presence of a morphologically suspicious lymphoid infiltrate with standard molecular techniques has to be discerned from the detection of minimal (residual) disease for staging or follow-up purposes. The presence of minimal numbers of clonal cells in morphologically negative BM samples of lymphoma patients, identified through highly sensitive techniques such as nested PCR or with clone-specific primer sets, usually does not carry the same impact on patient management as overt BM involvement, but may help to identify patients at higher risk for relapse or progression. For a more detailed review of the topic of minimal residual disease, especially in the context of new treatment options and the technical issues involved such as tumor-specific primers and quantitative PCR, the extensive haematological literature should be consulted [11, 17, 23].

Practical issues of DNA studies in trephine BM biopsies

DNA is extracted either from serial paraffin sections or microdissected tissue fragments with xylene followed by a graded alcohol series. The resulting pellet is digested overnight with Proteinase K in an adequate amount (25–200 μl) of buffer at 55°C and continuous shaking. If the supernatant is clear, Proteinase K is inactivated by boiling, and the resulting crude extract is used directly as template for PCR. Since quantitation of DNA by photometric measurement is of limited usefulness, it can be helpful to perform two PCR reactions in parallel, using two different DNA concentrations (e.g. 1–2 μl undiluted and diluted 1:10). As mentioned above, DNA extracted from trephine BM biopsies may show increased degradation, and it is crucial to check amplification efficiency with a control primer set. The size of the control product should be larger than the fragment size achieved with primer sets routinely used for clonality determination, e.g. at least 250–270 bp. Most diagnostic DNA PCR assays in our laboratory are carried out as single-step PCR with 40 cycles of amplification. For clonality determination, AmpliTaq Gold (Perkin Elmer) has shown better amplification efficiency. Separation of fluorescently labelled PCR products for clonality determination is performed in our laboratories by automated fragment length analysis using an ABI 3130 capillary sequencer (Applied Biosystems, Foster City, CA). Alternatively, polyacrylamide gels (with or without heteroduplex analysis) may be used, but agarose gel electrophoresis alone is clearly insufficient for product analysis. Currently used primer sets are listed in Table 2. Although the clonality pick-up rate in NHL varies with different primer sets, a fairly good concordance between different laboratories has been reached in multi-centre trials, if stringent quality controls are performed and more than one primer set is used [12].

Quantitation of gene expression

In addition to using the ratio of Ig light chain mRNAs as a surrogate marker for B-cell clonality [48], the recent advent of real-time RT-PCR for the precise quantitation of mRNA transcripts holds significant promise for BM diagnostics.

Table 2 Sequences of primers commonly used in our laboratories

Primer	Sequence 5′–3′	Product size
B-cell clonality		
FR3, forward	ACACGGCYSTGTATTACTGT[a]	~70–130 bp[b]

MBR Major breakpoint region of bcl-2 in follicular lymphoma
[a]These primers contain sites with multiple ("degenerate") nucleotides to allow annealing to different VH (or TCR J) genes
[b]Gives the approximate size range for a product derived from a normal polyclonal population
[c]Alternatively, a mix of multiple JH primers (JH 1-2-4-5 and JH3 and JH6) can be employed

By using microdissected cells from paraffin sections including decalcified BM biopsies, we could show that determination of cyclin D1 levels with real-time PCR, using intron-spanning primers (exon 1/2) amplifying a 70-bp mRNA fragment and a corresponding specific TaqMan probe (Perkin Elmer) is an excellent tool for the differential diagnosis of small B-cell neoplasms [71]. Mantle cell lymphomas could be reliably discerned from other lymphoma subtypes by virtue of their constantly high cyclin D1 levels caused by the t(11;14)(q13;q32) translocation (Fig. 2). Hairy cell leukemia, which shows up-regulation of cyclin D1 by another, so far unknown mechanism, showed cyclin D1 levels intermediate between mantle cell lymphoma and other B-NHL. In multiple myeloma, real time RT-PCR was able to discriminate three groups with high, intermediate and low to negative cyclin D1 levels. All cases with high mRNA levels showed the presence of a t(11;14) by fluorescence in situ hybridization (FISH), whereas most cases with intermediate values contained a trisomy 11, pointing to a role of gene dosage for cyclin D1 levels. Cases with low to negative cyclin D1 did not show alterations of the CCND1 (cyclin D1) locus on 11q13 by FISH [72]. This example demonstrates the enormous potential of quantitative gene expression analysis in archival tissues. However, the pitfalls as well as the biological and technical limitations of these techniques have to be kept in mind if they are applied for diagnostic purposes [32, 49, 51, 73, 74]. The problem of normalization has not been solved satisfactorily to date, since many so-called "housekeeping" genes can show some variation in expression levels depending on cell type and conditions. In addition, the normalization against multiple housekeeping genes recommended by some investigators may be impractical in the diagnostic setting with sometimes very limited archival material. Furthermore, quantitative RT-PCR assays may show variable sensitivity to fixation-mediated degradation or alterations of secondary RNA structure, which necessitates stringent controls for comparisons among different mRNA species. Nevertheless, the investigation of differential expression ratios using the delta/delta Ct method is feasible in paraffin-embedded BM biopsies if results are rigorously controlled, and the expression levels of the target genes are within the linear range of the standard curve.

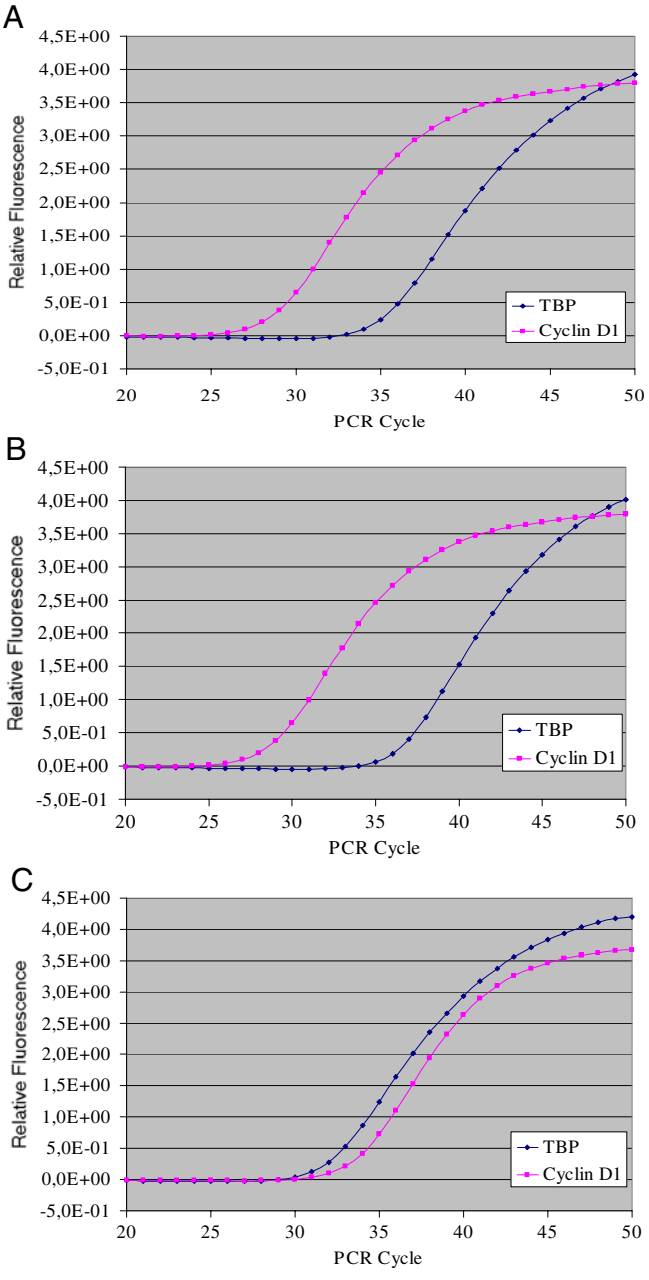

Fig. 2 Amplification plots of cyclin D1 and housekeeping gene TBP of microdissected tumor cells from a patient with mantle cell lymphoma. **a** Lymph node biopsy. **b** BM biopsy involved by lymphoma. **c** Reactive control lymph node. Whereas the curves for cyclin D1 and TBP are almost superimposed in the control tissue, both lymph node and BM biopsy show an identical left shift of the cyclin D1 curve with significantly lowered Ct, indicating significant overexpression of cyclin D1 mRNA

Molecular diagnostics in myeloproliferative disorders

The rapidly expanding knowledge of the molecular alterations in myeloproliferative diseases and their importance for patient management have resulted in an increasing amount of work aimed at identifying these genetic alterations in trephine biopsy samples. A model disease where molecular studies are of significant practical relevance is chronic myelogenous leukemia (CML), which is characterized by the hallmark Philadelphia chromosome caused by the t(9;22) translocation resulting in a breakpoint cluster region–Abelson (BCR–ABL) fusion. Already more than 10 years ago, up to two-decade-old archival tissues were demonstrated to be suitable for detection of BCR–ABL hybrid genes and fusion transcripts [3]. In accordance with these data, the successful detection of BCR–ABL transcripts also has been shown in other reports [40, 41]. Predominantly, these studies were conducted to confirm that these molecular techniques are applicable to archival tissues, i.e. proof of principle. The transfer of these techniques to the daily routine, however, represents a challenging step.

Histomorphological evaluation of the patients' BM trephine in synopsis with clinical data usually enables the diagnosis of CML. In CML, the initial diagnostic workup is often accompanied by application of metaphase cytogenetics or FISH analysis performed on BM aspirates, i.e. fresh specimens. In more than 95% of typical CML as well as in up to 30% of adult and 5% of childhood acute lymphoblastic leukemia (ALL), a reciprocal chromosomal translocation t(9;22), can be detected [13, 19]. This translocation exhibits an underlying molecular anatomy with either a major BCR (M-BCR), a minor BCR (m-BCR) or rarely a micro BCR (μ-BCR). In CML, the M-BCR typically encodes for the fusion transcript b2a2 or b3a2, whereas in ALL, the m-BCR mainly encodes for e1a2 [19]. In some cases of chronic neutrophilic leukemia, e19a2 fusion transcripts were detected as the result of a breakpoint in the μ-BCR [19]. Although several rare types of fusion transcripts have been described (e.g. b2a3, e1a3) [47], the most frequently detected types are indeed b2a2, b3a2 and e1a2 (Fig. 3). However, there is no complete concordance between the type of BCR–ABL fusion transcript and the disease type, either CML or ALL. Rare cases of typical CML can exhibit transcripts derived from the m-BCR [66]; conversely, some ALL cases contain M-BCR fusions [31]. The fusion transcripts of the M-BCR and m-BCR encode for chimeric proteins, the $p210^{BCR–ABL}$ and the $p190^{BCR–ABL}$ protein, respectively. This causes aberrant expression and constitutive activation of the ABL tyrosine kinase with uncontrolled proliferation of the affected neoplastic cells [19]. In cases of ALL, the detection of BCR–ABL fusion transcripts is associated with an aggressive course and poor survival [13].

Although CML and ALL typically can be diagnosed by histomorphological evaluation and in ALL additional immunohistochemistry, pathologists may be confronted with the need to investigate the BCR–ABL rearrangement in patients presenting with myeloproliferative disorders in case of (1) small BM biopsies with haematopoiesis that is not representative (2) leukemic infiltrates without available metaphase cytogenetics and (3) the existence of cryptic translocations that cannot be detected by conventional cytogenetics [10]. In addition, the embedded BM trephine may be the only available material when cytogenetics has not been conducted initially. Especially since the introduction of a specific tyrosine kinase inhibitor against the BCR–ABL protein (imatinib mesylate, formerly STI 571), which has shown marked activity in patients with CML and Ph1+ ALL, the detection of a BCR–ABL transcript and its type should accompany both initial diagnosis and the monitoring of tyrosine kinase inhibitor-based therapies [13, 24].

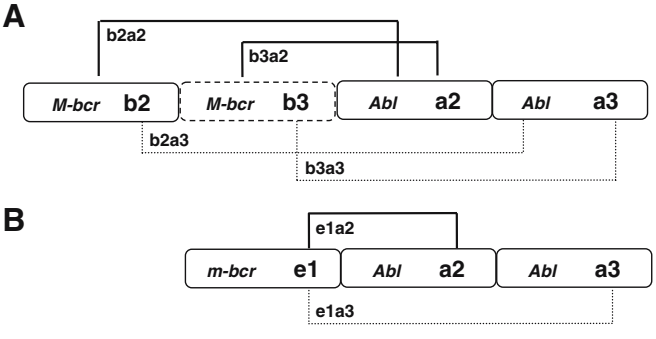

Fig. 3 Schematic illustration of the BCR and ABL hybrid genes fused in the M-BCR (**a**) and m-BCR (**b**). *Drawn lines* in the M-BCR (b2a2, b3a2) and m-BCR (e1a2) represent the most common fusion transcripts derived from the BCR–ABL hybrid genes. *Dotted lines* indicate rare but optional detectable fusion transcripts (b2a3, b3a3, e1a3)

Given the considerable extent of RNA degradation in paraffin-embedded tissues, the detection of BCR–ABL transcripts is more efficient when the product amplified by RT-PCR is less than 100 bp. In addition, for the specific detection of a particular BCR–ABL transcript, one primer should be placed directly into the fusion region. Primers suitable for RT-PCR for amplification of either b2a2 or b3a2 fusion transcripts have been previously described [16]. Although not particularly designed for the application in archival tissues, the accuracy of these assays has been successfully reproduced in our hands in archival BM trephines of patients with proven Ph-chromosome positive CML and ALL.

RT-PCR assays should be able to detect the three most common BCR–ABL transcripts. For the daily routine in a diagnostic molecular pathology laboratory, at least three RT-PCR reactions per case (+RT in duplicate, single −RT reaction as the case-specific control) per given BCR–ABL fusion type as well as adequate positive control reactions for all types have to be performed, giving a total of at least 12 RT-PCR reactions for one case. However, rare BCR–ABL fusion transcripts will not be detectable by such an approach. Multiplex RT-PCR approaches could reduce time and costs by enabling the detection of several potential BCR–ABL fusion types in a single reaction. A variety of multiplex RT-PCR assays including commercially available kits have been described by different laboratories [54, 67, 84]. However, their usefulness is restricted to fresh, unfixed samples such as peripheral blood or BM mononuclear cells because of the large amplicons generated by these assays. Unfortunately, a multiplex PCR approach often leads to a reduced sensitivity due to primer interference along with suboptimal PCR reaction conditions [60]. We have recently described a simple, robust and reliable multiplex RT-PCR, the usefulness of which for daily routine has been extensively demonstrated (Fig. 4) [7]. In addition, the detection of rare transcripts such as e1a3 is enabled by using the same forward primers and placing an additional reverse primer in ABL exon a3 (see Table 2). However, for diagnostic purposes it is highly recommended to initially establish BCR–ABL fusion type-specific RT-PCR assays separately and only consecutively design a multiplex RT-PCR along with optimization of reaction conditions.

The quantification of BCR–ABL fusion transcripts in peripheral blood mononuclear cells (PBMC) and BM aspirates of patients with CML and ALL using real-time RT-PCR has been shown to be important for monitoring the response to therapeutical intervention such as BM transplantation, peripheral blood stem cell tranplantation

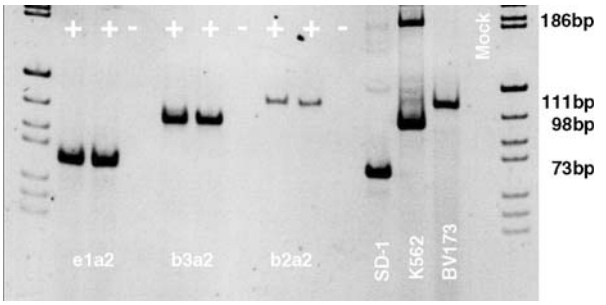

Fig. 4 Representative gel-electropheresis demonstrating BCR–ABL positivity in bone marrow trephines of patients with Ph+ CML (b3a2, b2a2) and Ph+ ALL (e1a2). Each case was analysed in duplicate by a multiplex RT-PCR along with a negative control. BCR–ABL positive cell lines (SD-1, K562, BV173) serve as positive control. Note that these primer design and primer mix respect the inevitable fragmentation of RNA in archival tissues by generating PCR products that are as small as required for an efficient RT-PCR approach. The two PCR products obtained in the K562 cell line derived from the exon-specific binding of the forward primers (b3–a2=98 bp, b2–[b3]–a2=186 bp, respectively). DNA marker, pBR322/Bsu RI. Note that it is digitally inverted

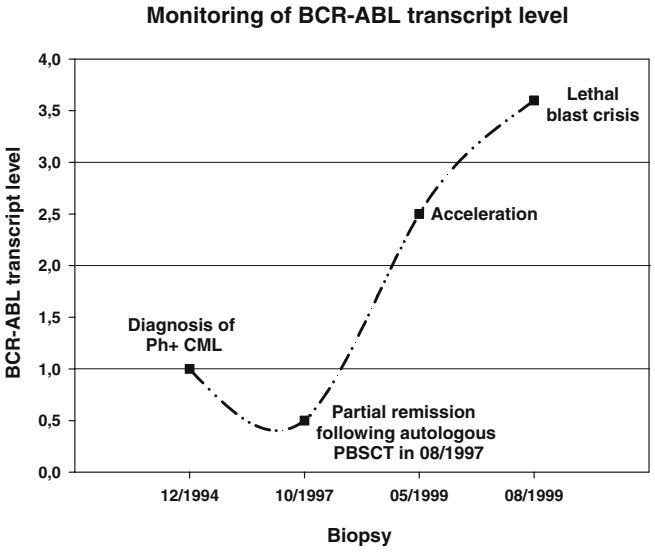

Fig. 5 Retrospective monitoring of BCR–ABL transcript levels in archival bone marrow trephines of a patient with Ph+ CML initially diagnosed in 1994. Declining levels could be correlated to a histopathologically demonstrable partial remission in 10/1997 after an autologous PBSCT in 08/1997. The phase of acceleration diagnosed in 05/1998 was accompanied with a 3.0-fold increase of BCR–ABL transcripts. The patient died in the blast crisis 3 months later after another increase of the BCR–ABL transcript level

(PBSCT), interferons and tyrosine kinase inhibitors [19]. Furthermore, the levels of BCR–ABL transcripts prior, during and after therapeutic intervention seem to predict the clinical outcome of the patients, and thus qualitative and quantitative detection of these transcripts from PBMC became a standard in clinical studies [65]. To transfer our knowledge from qualitative detection to quantitative monitoring of BCR–ABL transcripts, we investigated whether archival BM trephines of patients with proven CML are suitable for determination of the BCR–ABL transcript level at a given time point of the disease [6]. Retrospectively, we retrieved sequential BM trephines that have been taken from ten patients during the course of the disease, including more than 10-year-old plastic-embedded specimens. We were able to demonstrate that monitoring of BCR–ABL transcript levels in both plastic- and paraffin-embedded BM trephines is feasible in an accurate and sensitive manner. Moreover, the intra-individual BCR–ABL transcript level could be properly correlated with the histomorphological features at a given time point during the course of the disease. One representative time course of a CML is shown to demonstrate the BCR–ABL transcript levels in good correlation with therapeutic interventions and histopathological findings (Fig. 5).

Although the detection of BCR–ABL fusion transcripts currently is the most relevant molecular diagnostic assay in myeloproliferative disorders, several other applications have been described in the last years, e.g. suppressor gene methylation in myelodysplastic syndromes and expression of aberrant transcripts in chronic myeloproliferative disorders based on DNA and RNA extracted from paraffin-embedded trephines. Using either laser capture microdissection of immunostained BM sections or special PCR techniques for enrichment of the mutated allele, several groups demonstrated the occurrence of the activating c-kit mutation D816V in mast cells and lymphoid aggregates of patients with systemic mastocytosis [70, 76].

Another potential application of molecular diagnostics on BM trephines is the detection of the recently described activating point mutation V617F in the JAK2 gene, which is found in a high percentage of chronic myeloproliferative disorders other than CML [5, 39, 42, 50].

Other applications of molecular tests in BM pathology

Several other applications for molecular testing on BM biopsies have been described, and many assays performed on aspirates can be adapted to trephine biopsies. For example, the detection of tumor-specific fusion transcripts can also be applied to recurrent translocations of soft tissue tumors involving the BM, such as the t(11;22)(q24;q12) EWS/FLI-1 and t(21;22)(q22;q12) EWS/ERG translocations of Ewing sarcoma. In the future, minimal residual disease quantitation by real-time RT-PCR will play an increasing role for monitoring these patients under therapy [86]. In non-neoplastic disorders, detection of infectious agents such as *Mycobacteria* spp., especially in immunosuppressed patients, can be facilitated by molecular testing [1, 69].

Conclusions

In conjunction with other techniques such as immunohistochemistry and FISH [58, 72], the application of molecular genetics to paraffin-embedded BM trephines has significantly expanded the scope of histopathologic bone marrow examination. Some tests, such as PCR-based determination

of clonality, can help to resolve common diagnostic problems such as the nature of nodular lymphoid BM infiltrates in the setting of NHL. If the technical aspects of BM fixation and processing are observed and common pitfalls such as poor template quality avoided, the success rates for molecular studies in BM trephines are equal to other routinely fixed, archival tissues. The combination of excellent morphological detail and preservation of marrow architecture with the phenotypical and genetic information obtained from ancillary techniques makes the BM trephine biopsy a valuable resource for modern diagnostics and research in haematopathology.

Acknowledgements We thank Mrs. Birgit Geist for her excellent technical support. This study was supported in part by the Deutsche Forschungsgemeinschaft (DFG), grant FE 597/1 to FF, LQ-M and MK.

Immunohistochemistry in bone marrow pathology: a useful adjunct for morphologic diagnosis

Received: 13 June 2005 / Accepted: 23 August 2005 / Published online: 18 October 2005
© Springer-Verlag 2005

Abstract Pathomorphological examination of trephine biopsies of the bone marrow (BM) represents a standard method for the diagnosis and staging of hematologic neoplasms and other disorders involving the BM. The increasing knowledge about the genetic basis and biology of hematologic neoplasms, as well as the recently proposed WHO classification system, provide the framework for an accurate diagnosis. Although conventional morphology remains the gold standard for paraffin-embedded BM trephines, immunohistochemical stainings have become an integral part of the diagnostic workup. Antibodies suitable for paraffin sections are generally applicable to BM trephines, but modifications of staining protocols may be necessary due to the alternative fixatives and decalcification procedures used for BM biopsies. The indications for immunostainings range from confirmation and classification of lymphoma involvement, subclassification of acute leukemias, and estimating blast counts in myelodysplastic and myeloproliferative syndromes to characterization of BM involvement in nonhematologic neoplasms. Although subtyping of NHL in the BM is more difficult from the point of morphology, classification of the entities that frequently involve the BM, especially the small B-cell lymphomas, can easily be achieved with the help of immunohistochemistry. In this review, we try to summarize the current state of the art in BM immunohistochemistry for the diagnosis of hematologic disorders. Moreover, diagnostic algorithms and useful antibody panels are proposed for a rational and cost-effective approach.

Introduction

Morphological examination of trephine biopsies of the bone marrow (BM) is a standard method for diagnosis and staging of patients with malignant lymphoma (ML), plasma cell dyscrasias, chronic myeloproliferative syndrome (MPS) and myelodysplastic syndrome (MDS), acute leukemia, and metastatic tumors. Occasionally, the diagnosis of nonneoplastic conditions such as infectious diseases or, to a lesser extent, anemias also require examination of a BM trephine [10]. In addition, determination of BM cellularity following BM transplantation or administration of chemotherapeutic agents is most reliably established by trephine biopsies. Ideally, trephine biopsy, aspirate smears, and flow cytometry should be viewed as integral parts of a combined diagnostic approach. In some instances, e.g., myelofibrosis, the trephine biopsy will be the only specimen available for examination. Due to both technical and historical reasons, the use of immunohistochemistry for BM diagnostics has lagged behind other applications. On one hand, the availability of antibodies suitable for paraffin was limited for a long time, and flow cytometry was (and for many indications it still is) the primary technique for immunophenotyping of hematologic neoplasms. On the other hand, the aim of alternative fixation, decalcification, and embedding techniques at optimizing morphology frequently proved detrimental for the preservation of antigens. However, recent years have seen an exponential increase in antibodies suitable for paraffin-embedded tissues, plus improvements in antigen retrieval, leading to a rapid integration of immunohistochemistry into BM diagnostics. Of note, the necessity for immunohistochemical studies on trephine biopsies is greater in countries like

Germany, where the biopsy is signed out by the pathologist, whereas flow cytometry and, frequently, also cytology is seen by the hematologist, making an integrated diagnostic approach more difficult.

Since diagnosis and staging of ML are among the most frequent clinical indications for trephine biopsies, this review provides a detailed description of the morphological and immunophenotypical criteria for making the diagnosis of ML in the BM.

The role of immunohistochemistry in the classification of myeloproliferative disorders, MDSs, acute leukemias, and nonneoplastic BM changes comprises the second part of this review.

Technical issues of BM immunohistochemistry

A variety of fixatives and decalcification procedures are routinely used for BM trephines in different parts of the world. Many, but not all of them, are well suited for immunohistochemical stains. In our opinion, fixation in buffered formalin, decalcification in EDTA, and embedding in paraffin is a good compromise, because it not only provides good morphology and excellent conditions for immunohistochemistry but also allows DNA- and RNA-based molecular studies. Acceleration of the decalcifying process can be achieved by using ultrasound energization, which reduces the decalcification time to approximately 6–12 h. (Medite, Burgdorf, Germany) [106, 119]. In addition, formalin fixation allows routine processing of BM sections on automated immunostainers, which improves reproducibility and reliability of immunostaining [21, 32, 42, 161]. However, certain recommendations should be considered for obtaining optimal staining results. The fixation time should not exceed 24 h, since staining intensity decreases with prolonged fixation time. In our experience, staining results are not significantly affected by the duration of EDTA decalcification. Nevertheless, staining protocols and especially antigen retrieval used for other paraffin tissues such as lymph nodes may have to be adjusted for BM trephines to avoid inadequate staining or tissue damage due to overly strong antigen retrieval.

Schaefer's fixative (0.4% glutaraldehyde/10% formalin), a fixative solution widely used in Germany, and methacrylate embedding are two techniques that offer some advantages over conventional formalin fixation, such as excellent morphological detail and the ability to perform numerous histochemical reactions, but both techniques severely limit immunohistochemical studies [18, 60, 133]. Fixation with B5 or Zenker fixative for up to 2.5 h, frequently used in the USA, renders good staining results, but prolonged fixation of the specimen may abolish immunoreactivity. An important drawback of these fixatives, despite the good morphology achieved, is that molecular analysis, in general, cannot be performed.

Currently, a wide array of antibodies is available for BM diagnostics. Table 1 shows a list of primary antibodies used in our institution. Obviously, this selection represents the personal choice of the authors and is by no means complete. Of note, some standard antibodies for lymphoma subtyping such as CD15, CD43, or CD68 (KP1) show broad reactivity with myeloid cells and, therefore, are less suited for BM trephines than for lymph nodes. The choice of antibodies and the amount of stains necessary depend on the type of the disease and the clinical question. For instance, the primary classification of neoplasms in the BM usually requires a larger panel of antibodies, whereas confirmation of BM infiltration by lymphoma diagnosed at another site, assessment of treatment response, or detection of minimal residual disease or relapse is usually possible with a few selected stains.

Malignant lymphoma

Peripheral B-cell lymphomas

Non-Hodgkin lymphomas (NHL) composed of small B lymphocytes comprise the majority of lymphoma infiltrates in the BM. Bone marrow involvement is seen in virtually 100% of B-cell chronic lymphocytic leukemia (B-CLL)/small lymphocytic lymphoma (SLL), in almost all cases of lymphoplasmacytic lymphoma (LPL) and hairy cell leukemia (HCL), in 55–93% of mantle cell lymphoma (MCL), in 50–60% of follicular lymphoma (FL), and invariably, in splenic marginal zone B-cell lymphoma (SMZL). The only notable exception within these groups is nodal and extranodal marginal zone B-cell lymphoma, which involves the marrow in approximately 10–30% of cases [34, 37, 51, 57, 82, 83, 95, 103, 120, 121, 135, 149, 164]. Distinction of the most common types of B-NHL in the trephine biopsy can be difficult on morphological grounds alone due to overlapping cytological features and distribution patterns, and therefore, requires integration of immunophenotypic and occasionally molecular data for primary diagnosis. Nevertheless, the morphology of an infiltrate gives important clues for subclassification and should guide the selection of antibodies. The pattern of BM involvement is one of the most important hints for diagnosis. Five main patterns of BM infiltration by NHLs are recognized, namely, paratrabecular, randomly focal intertrabecular, interstitial, diffuse, and sinusoidal/intravascular [37, 72, 82, 135]. In some cases, multiple or mixed patterns are present in the same specimen. Although most infiltrates are easily recognizable in standard stains, sparse interstitial and sinusoidal involvement can be practically undetectable by conventional morphology and requires immunohistochemistry to highlight the neoplastic population.

Immunohistochemical classification of small B-cell lymphomas in the BM

A practical approach to the primary diagnosis of small B-cell lymphomas involving the BM is based on (1) infiltration pattern and cytology and (2) immunohistochemistry with a limited panel of antibodies based on morphological findings. This strategy, which is directed at reducing

Table 1 Primary antibodies employed for BM diagnostics in our institution

Antigen	Clone	Company	Main cellular expression
CD1a	MTB-1	Novocastra	T cell (thymic)
CD2	AB75	Novocastra	T cell (thymic, NK)
CD3	F7.2.38	DAKO	T cell (mature)
CD4	IF6	Ventana	T cell (helper)
CD5	4C7	Novocastra	T cell (mature)
CD7	272	Novocastra	T cell (thymic)
CD8	C8/144B	DAKO	T cell (cytotoxic)
CD10	56C6	Novocastra	LPC, GC B cell
CD15	MMA	BD	Granulocytes, monocytes
CD20	L26	DAKO	Pan B cell (except PC)
CD21	1F8	DAKO	B cell (subset), FDC
CD23	IB12	Novocastra	B cell (subset), FDC, LC
CD30	BerH2	DAKO	Activated B/T cell, HC
CD31	JC/70A	DAKO	EC, Platelets
CD34	QB-END/10	BMA	Hemopoietic SC, EC
CD43	MT1	Novocastra	T cell, myeloid cells
CD45 LCA	X16/99	Novocastra	Panleukocyte
CD56	IB6	Novocastra	T cell (NK, MM)
CD61	Y2/51	DAKO	Platelets, Megakaryocytes, EC
CD68	PGM-1	DAKO	Monocytes, LC, Macrophages
CD68	KP1	DAKO	Monocytes, Macrophages, myeloid cells
CD79a	HM57	DAKO	B cell, PC
CD117	c-kit	DAKO	SC, mast cells, Melanoc
CD138	MI15(4)	DAKO	Plasma cells
ALK 1	ALK1(2)	DAKO	Anaplastic lymphoma kinase (ALCL)
BCL-2	124(3)	DAKO	Lymphocytes (subset)
BCL-6	P1F6	Novocastra	GC, activated B cells
Cyclin D1	SP4	DC Systems	Cell cycle (MCL, MM)
DBA.44	DBA.44	DAKO	Hairy cells, B cell
Granzyme B	GrB-7	DAKO	T cell (cytotoxic)
Glycophorin C	Ret40f	DAKO	Erythroblasts, erythrocytes
Lysozyme	Polyclonal	DAKO	Monocytes
Mast cell tryptase	AA1	DAKO	Mast cells
MUM-1	MUM-1p	DAKO	PC, post-GC B cells
Myeloperoxidase	MPO-7	DAKO	Myeloid cells
PAX5	Polyclonal	BD	HC, B-cell transcription factor
p27	F8	Santa Cruz	Cell cycle
TDT	polyclonal	Zytomed	Immature B/T cells
TIA-1	2G9	Immunotech	T cell (cytotoxic)
VS38c	VS38c	DAKO	Plasma cells
kappa	R10-21-F3	DAKO	Light chain
lambda	N10/2	DAKO	Light chain
IgG	7701	BioGenex	Immunoglobulin class G
IgA	NIF2	BioGenex	Immunoglobulin class A
IgM	R1/69	DAKO	Immunoglobulin class M
IgD	Polyclonal	DAKO	Immunoglobulin class D

The most frequently used antibodies are highlighted
Abbreviations: *NK* Natural killer, *LPC* lymphoid progenitor cells, *GC* germinal center cells, *PC* plasma cells, *FDC* follicular dendritic cells, *LC* Langerhans cells, *HC* Hodgkin cells, *EC* endothelial cells, *SC* stem cells, *MM* multiple myeloma, *ALCL* anaplastic large-cell lymphoma, *MCL* mantle cell lymphoma

unnecessary stains and misinterpretations, is outlined in a flow chart (Fig. 1).

In cases with nodular or interstitial centrally located lymphoid infiltrates composed of small cells, the differential diagnoses mainly encompass B-CLL/SLL, MCL, and

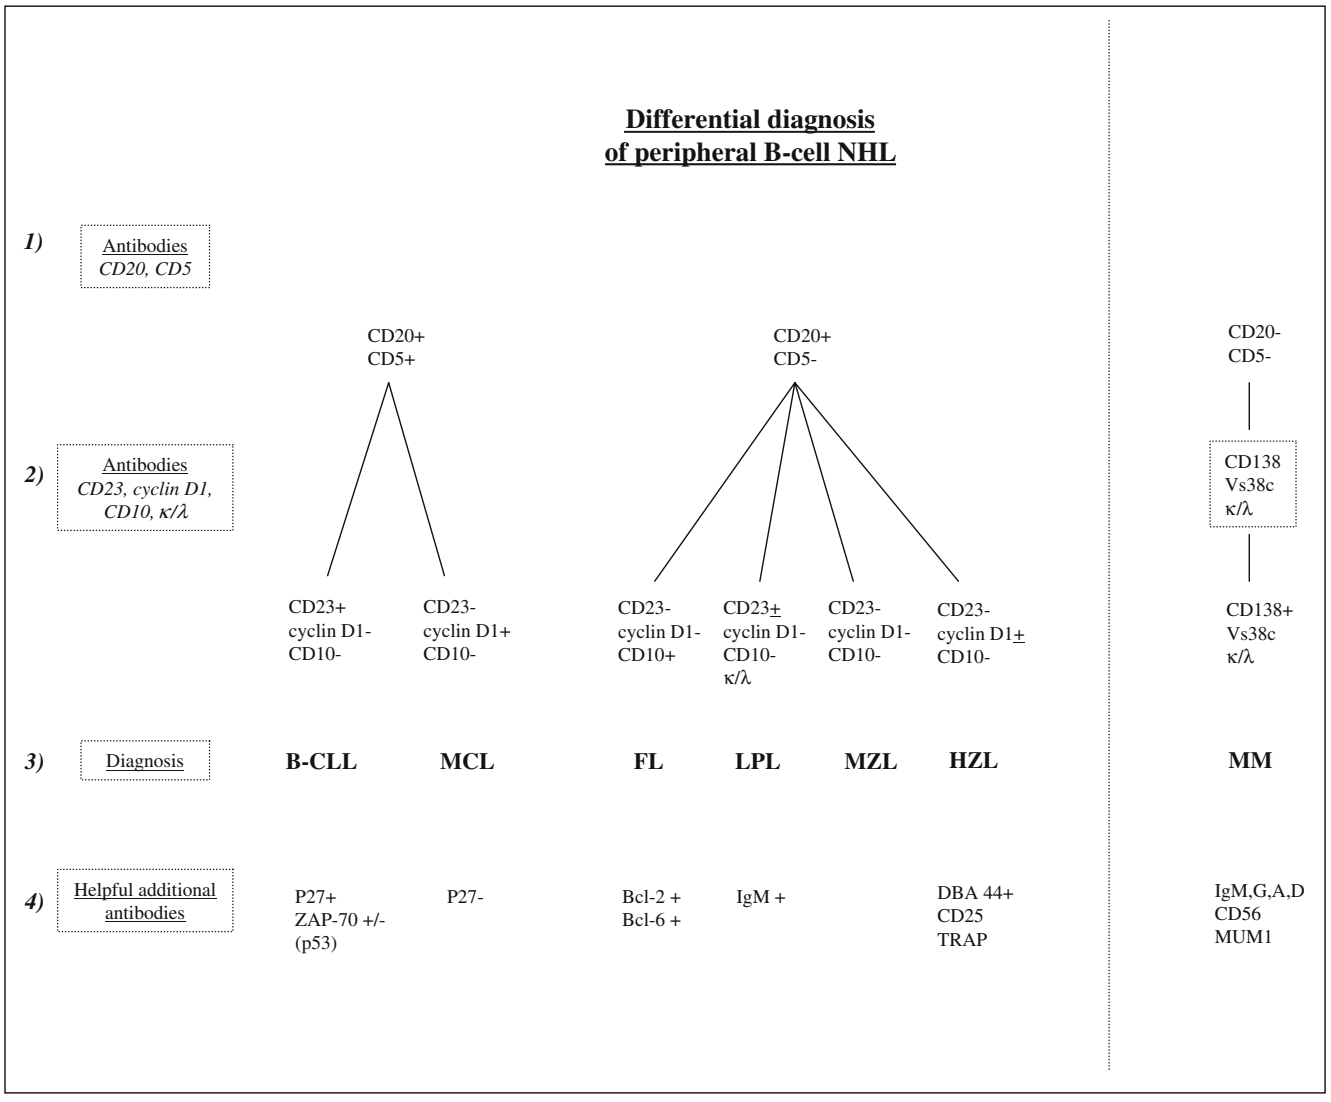

Fig. 1 Flow chart for the differential diagnosis of mature B-cell non-Hodgkin's lymphoma. If a low-grade B-cell NHL or an MM is suspected, we recommend a "first-line" staining with two basic antibodies, CD20 and CD5 (*1*). In cases of CD20-positive infiltrates, an array of antibodies consisting of CD23, cyclin D1, CD10, and possibly light chains, kappa, and lambda is required for further analysis (*2*). In most cases, these stains will lead to identification of the most frequent B-cell NHL, affecting the BM (*3*). Additional stainings for each entity, including optional prognostic markers such as ZAP-70 or p53 as shown at the baseline (*4*), conclude the immunohistochemical analysis of mature B-cell NHL. If MM is suspected, or the "first-line" immunostaining results lead to a CD20- and CD5-negative cell population; CD138, Vs38c, and light chains should be added in a second step for the diagnosis of MM. Further stains with antibodies against IgM, G, A, D, CD56, and MUM1 may help in ambiguous cases. Note the exception of cyclin D1- and CD20-positive lymhoplasmacytic MM as shown in Fig. 3D,E

MZL. In these cases, CD20 or CD5 are the most informative markers. The simultaneous expression of CD5 and CD20 helps to narrow down the differential diagnosis to mainly B-CLL and MCL, since both lymphomas express CD5 in more than 90% of cases [22, 45, 145, 157]. The choice of further antibodies depends on the main differential diagnoses and the need for additional prognostic information. Of practical importance in patients with B-NHL is the downregulation of CD20 antigen expression occasionally observed after treatment with anti CD20 antibodies (rituximab) [81]. In doubtful cases with nodular lymphoid aggregates after therapy, other B-cell antigens such as CD79a can serve to discriminate residual B-cell infiltrates from CD3+ reactive T-cell infiltrates.

B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma

B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma is one of the most frequently encountered B-cell neoplasms in BM trephines. The phenotype of B-CLL is characterized by coexpression of CD5, CD20, and CD23, and these three markers are usually sufficient for diagnosis (Fig. 2A,B). Of note, the staining intensity of CD20 is almost

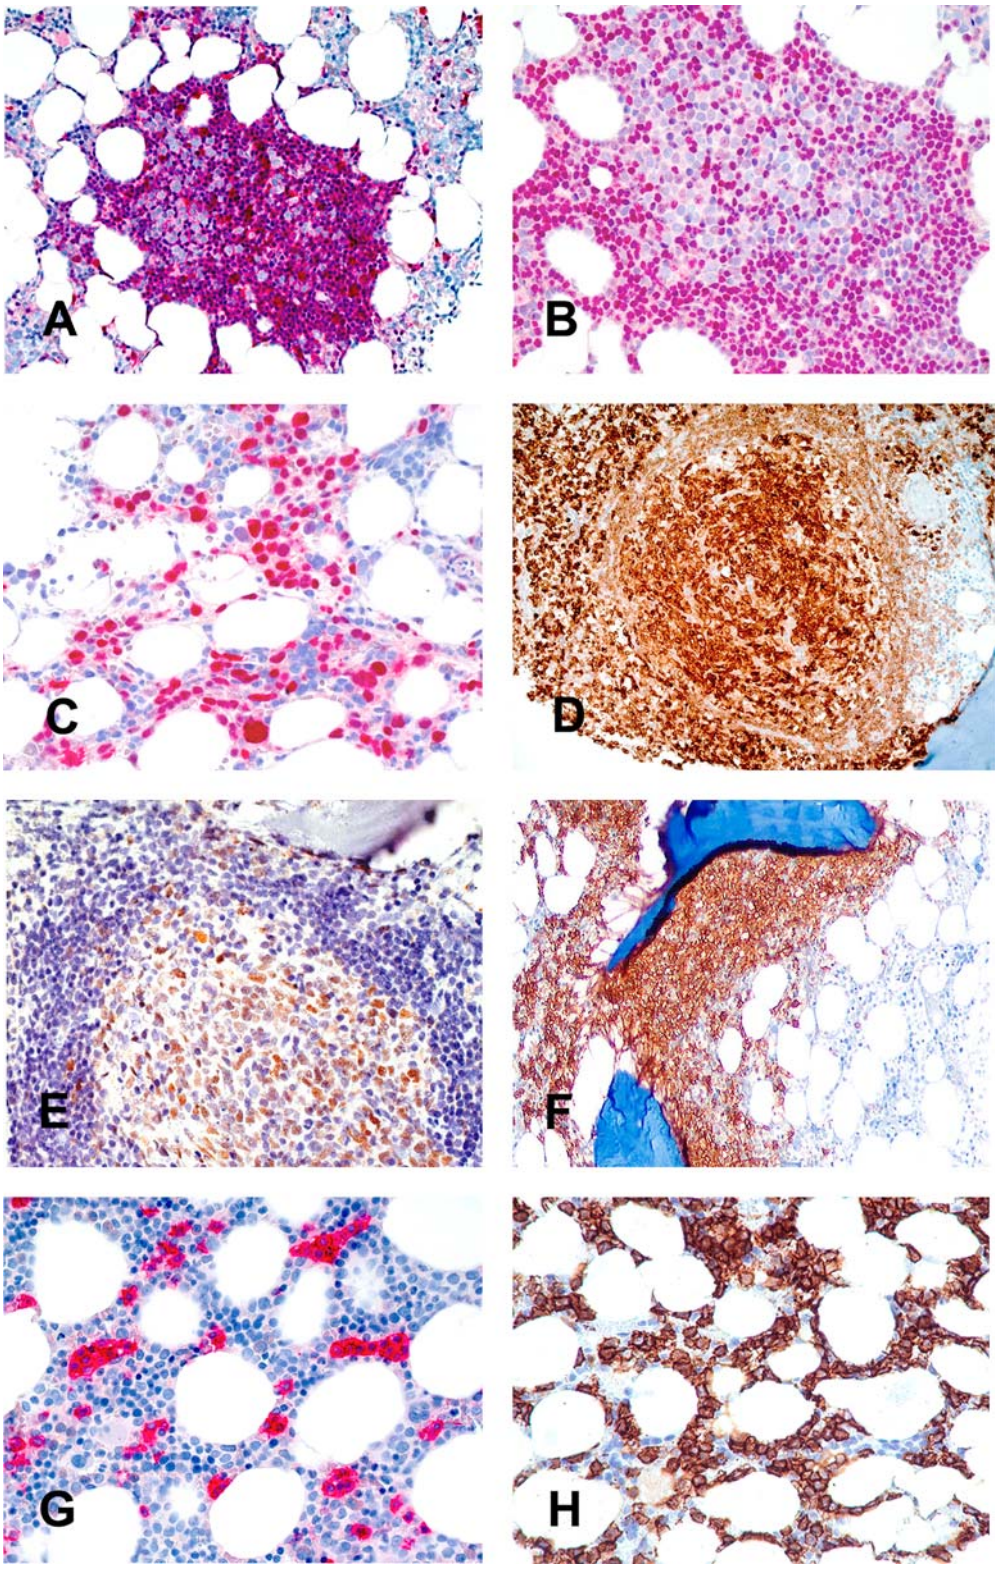

Fig. 2 Immunostainings of small B-cell NHL in the BM. **A** CD5 staining of a characteristic nodular B-CLL infiltrate. The neoplastic cells exhibit a relatively faint staining, whereas the "reactive" intermingled T cells show a strong immunostaining with CD5. Of note is the sharp border between unaffected BM cells and the neoplastic infiltrate (×200 ABC-AP). **B** $P27^{Kip1}$ staining of the same B-CLL case, with a strong immunoreactivity of the small lymphocytes. The intermingled "paraimmunoblasts" are negative for p27 (×300, ABC-AP). **C** Cyclin D1 reactivity of a MCL, pleomorphic variant. Note the interstitial infiltration pattern in this case (×400 ABC-AP). **D**, **E** These microphotographs represent an exceptional case of an FL with true neoplastic germinal centers. The tumor cells are positive for Bcl-2 (**D**) and Bcl-6 (**E**) (×200 ABC-POX, ×300 ABC-AP). Microphotograph (**F**) shows the more common peritrabecular infiltration pattern of an FL (CD20+) (×300, ABC-POX). **G** SMZL with characteristic intrasinusoidal infiltration stained for CD20. This pattern of infiltration is easily overlooked in routine stains (×200, ABC-AP). **H** HCL with characteristically strong membranous CD20 staining. (×400 ABC-POX)

always weaker than in other B-NHL [117]. The expression of CD23 in most cases is helpful, especially to rule out the diagnosis of MCL [90]. The coexpression of CD20 and CD5 is a universal finding in B-CLL. Still, there are cases of small infiltrates with large numbers of reactive T cells where comparison of CD3 and CD5 staining may be necessary to determine the presence or absence of CD5 coexpression by the B-cell population. A feature that can be very helpful is the double intensity of positivity of CD5. Reactive T cells are strongly positive for CD5, whereas the neoplastic B lymphocytes show a weaker reactivity (Fig. 2A).

In the last few years, the systematic analysis of gene expression profiling have led to the discovery of new diagnostic and prognostic markers. One of these markers is the zeta-chain-associated protein 70 (ZAP-70), which is normally expressed in T cells and was found to be highly expressed in a subgroup of B-CLL cases [165]. This finding was confirmed by flow cytometry, where the expression of ZAP-70 was found in almost 100% of patients with nonmutated immunoglobulin heavy chain (IgH) genes and only in 10% of patients with mutated IgH genes. The mutational status of the IgH gene is a strong predictor of survival in B-CLL [136]. Of interest, ZAP-70 is not only a surrogate marker for the mutational status but also seems to have independent predictive value and may provide a cheaper and easier way to obtain prognostic information [27, 136, 165]. ZAP-70 can also be detected by paraffin section immunohistochemistry, thus potentially making it an excellent prognostic marker for routine diagnostics. P53 protein and CD38 represent two other prognostic markers which can be assessed by immunostaining [102, 136]. Whether immunohistochemical demonstration of ZAP-70 and CD38 in BM biopsies renders equal prognostic information as their determination by flow cytometry remains to be shown. Worth mentioning in this context is the so-called secretory B-CLL with a detectable monoclonal paraprotein in the serum and cytoplasmic light chain expression, which is found in approximately 5% of otherwise typical cases. These cases also express CD5 and CD23, distinguishing them from LPL (see below).

B-prolymphocytic leukemia

B-prolymphocytic leukemia (B-PLL) is a rare disease defined mainly by clinical and laboratory features and shows high lymphocyte counts in the peripheral blood with more than 55% prolymphocytes, splenomegaly, and BM infiltration. The neoplastic cells are larger than lymphocytes of classical B-CLL. They typically lack CD23 and show CD5 only in a minority of cases. Cases of B-PLL carrying a t(11;14)(q13;q32) translocation as described in the earlier literature will nowadays be regarded as leukemic MCL by most investigators [128]. Further investigations will have to demonstrate whether the remaining cases of B-PLL represent a true entity or just variants of other leukemic B-NHLs.

Mantle cell lymphoma

The main differential diagnosis of CLL/SLL in the BM is MCL. MCL is characterized by the t(11;14)(q13;q32) translocation, resulting in aberrant expression of cyclin D1, which is the hallmark of the diagnosis [19, 25, 115]. MCL have a very characteristic phenotype, cyclin D1+, CD20+, CD5+, CD10−, and CD23−. Nevertheless, in the past, the inconsistency of the cyclin D1 staining in BM biopsies often precluded an accurate diagnosis. This problem seems to have been overcome with the introduction of the new monoclonal rabbit antibody against cyclin D1 (clone SP4, DC System, Germany), which gives a reliable and strong staining. Another useful marker for the diagnosis of MCL is the anti-$p27^{Kip1}$ antibody [147]. The lack of $p27^{Kip1}$ protein expression is a characteristic feature of MCL, which is not found in other small B-cell NHL. The lack of p27 staining in a small B-cell infiltrate in the BM is highly suspicious of the diagnosis of MCL [86, 123, 132]. A word of caution, since T cells are strongly positive for p27, the parallel assessment of the number of reactive T cells within the neoplastic infiltrate is important to avoid misinterpretation of staining results. As mentioned above, CD23 is very helpful in distinguishing MCL from B-CLL, although one has to keep in mind that rare cases of bona fide MCL have been reported to express CD23. Another potential problem in the differential diagnosis of MCL is the more aggressive blastic and pleomorphic variants. Aggressive MCLs show a spectrum of cytological appearances ranging from lymphoblast-like cells to large pleomorphic cells mimicking large-cell lymphomas (Fig. 2C). Similar to the classic variant of MCL, the blastic variant shows focal infiltration in the BM, a useful feature in the differential diagnosis of lymphoblastic leukemia/lymphoma that tends to infiltrate in a diffuse pattern. Immunohistochemically, blastic variants of MCL can be separated from lymphoblastic leukemia/lymphoma by their strong staining for CD20 and cyclin D1 and the lack of terminal desoxyribonucleotidyl transferase (TdT) and/or CD3. P53 overexpression and high proliferation rate in MCL are associated with the cytologically more aggressive blastic and pleomorphic variants of MCL and a worse outcome [25, 64, 66, 71, 73, 114, 123, 146].

Follicular lymphoma

Follicular lymphoma shows a characteristic infiltration pattern in the BM with peritrabecular rather than centrally located infiltrates with significant lesional fibrosis. This allows a definite diagnosis of FL by morphology in many instances. Immunostainings are useful in the presence of extensive diffuse infiltrates and in minimal paratrabecular lesions, which are hard to spot in routine stains. The phenotype of FL in the BM is virtually identical to its nodal counterpart. The tumor cells express antigens of germinal center cells, including CD10, Bcl-6, and Bcl-2. Rare cases express CD43, and even less commonly, CD5 [44]. CD10 also marks BM stromal cells and immature B cells and may be difficult to interpret in small infiltrates. A meshwork of follicular dendritic cells can be demonstrated in larger infiltrates with stains against CD21 and CD23. Rare cases of FL show centrally located neoplastic follicles with mantle zones, imitating reactive follicles [151]. In these cases, demonstration of bcl-2 positivity in the follicle centers is necessary to confirm malignancy even in patients with known FL, since most true BM follicles are of a reactive nature (Fig. 2D–F). Similar to FL in lymph nodes, BM infiltrates of FL frequently contain high numbers of intermingled “reactive” T cells within the neoplastic in-

filtrate, which should not discourage from a diagnosis of lymphoma, if the other diagnostic criteria are met.

In contrast to nodal FL, grading of FL in the BM has not been studied systematically to date. However, many cases of FL grade 3a/3b and even diffuse large-cell lymphoma show a predominance of small lymphoid cells in the BM, frequently with typical paratrabecular infiltration, also referred to as discordant BM infiltration. This phenomenon seems to be associated with a better clinical outcome than concordant infiltration by large-cell lymphoma. Discordant BM infiltration should not be confused with those cases where the large B-cell component is obscured by small reactive T cells. In these cases, immunostaining highlights the presence of malignant large B cells immersed in a sea of reactive T lymphocytes [88]. Approximately one to two thirds of patients with FL transform into large B-cell lymphoma during the course of their illness [38, 104, 105, 168].

Lymphoplasmacytic lymphoma

Lymphoplasmacytic lymphoma is a rare disease, infiltrating the BM in approximately 80% of patients at presentation and virtually all patients during the clinical course, usually with an interstitial and diffuse pattern [4, 69]. LPL in the WHO classification is a diagnosis of exclusion and is, in most cases, associated with the clinical syndrome of Waldenstrom's macroglobulinemia. Immunohistochemically, CD20 and CD79a are strongly positive, with an occasionally observed coexpression of CD43 in 20% of the cases [3, 92]. Immunoglobulin heavy (typically IgM, sometimes IgG, and rarely IgA) and light chains are virtually always demonstrable as cytoplasmic staining in paraffin sections [22, 45, 69, 70, 145, 157]. By definition, CD5 is negative. Most cases of the so-called lymphoplasmacytoid variant of immunocytoma recognized in the Kiel classification, which frequently expressed CD5, are regarded as variants of B-CLL/SLL with cytoplasmic immunoglobulin in the new WHO classification. The plasmacytoid differentiation of LPL can be easily confused with other ML showing lymphoplasmacytic or plasmacytic differentiation such as MZL, B-CLL, and multiple myeloma (MM) with lymphoplasmacytic morphology. The lymphoplasmacytic or small-cell variant of MM is frequently CD20+, adding to the potential for misdiagnosis (see below).

Nodal and extranodal (MALT-type) marginal zone B-cell lymphoma

Marginal zone B-cell lymphoma has to be considered in the differential diagnosis of CD20+ and CD5− nodular BM infiltrates [26, 51, 70]. The incidence of BM involvement in extranodal MZL is lower (~20%) than in other low-grade B-NHL, albeit recent studies described BM infiltration in up to 44% of cases [51, 83, 94, 120, 124, 149]. For nodal MZL, the available data are sparse and contradictory, with the incidence of BM infiltration ranging from 35 to 77% [11, 17, 83]. The tumor cells of both nodal and extranodal MZL express CD20, CD79a, and, in a subset of cases, CD43 [24, 92]. They are usually CD5- and CD23-negative, although rare CD5-positive MZL have been reported, potentially complicating the differential diagnosis with MCL and CLL/SLL [11, 12, 51].

Splenic marginal zone lymphoma

In contrast to nodal and extranodal MZL, BM involvement in SMZL is frequent and often shows a characteristic distribution pattern which is of great help in establishing the diagnosis. A significant percentage of SMZL show circulating B cells with small cytoplasmic projections, reflected in their previous designation as splenic lymphoma with villous lymphocytes [8, 57]. Although different patterns of infiltration can occur, the presence of intrasinusoidal tumor cells is highly characteristic for this entity. Intrasinusoidal spread may be found in the absence of obvious lymphoid nodules and can be so subtle that it is frequently overlooked in conventional stains [56, 57, 91]. Therefore, immunostainings are mandatory if SMZL is suspected (Fig. 2G). The neoplastic cells show positivity for CD20, CD79a, PAX5, Bcl-2, and express surface IgM and IgD. They are consistently negative for CD23, CD10, Bcl-6, cyclin D1, and CD43 [41, 56, 57, 108, 155]. The clinical course of SMZL is relatively indolent. A recent study documented clinical progression in 13% of cases, histologically accompanied by an increased number of blasts in the BM. Transformation usually correlates with a higher proliferation index and p53 overexpression [24, 41, 98].

An important diagnostic pitfall is persistent polyclonal B lymphocytosis with binucleated lymphocytes, a benign lymphoproliferation almost exclusively observed in female smokers, which shows an increase in intravascular B cells in the BM closely resembling the highly characteristic intrasinusoidal infiltration pattern by SMZL. Correlation with clinicopathologic findings, careful cytologic examination, and even molecular analysis may be required to avoid overdiagnosis of ML in these cases [39, 52, 154].

Hairy cell leukemia

Hairy cell leukemia involves the BM in almost all patients at the time of diagnosis. The morphology is highly characteristic, showing a patchy infiltration of widely spaced cells with oval nuclei and ample, clear cytoplasm, with progressive replacement of normal hematopoetic cells and increased reticulin fibers [137, 150]. HCL shows very strong staining for CD20, and staining of the cytoplasmic processes of the neoplastic cells may give them a "hairy" appearance (Fig. 2H). In contrast to other small-cell NHL, the combined positivity of DBA44 and tartrate-resistant acid phosphatase (TRAP) is highly suggestive for HCL. Another useful HCL marker is CD25, the interleukin (IL)-2 receptor. Very recently, Falini and coworkers described a promising new HCL-specific antibody against annexin 1

(ANXA1) suitable for paraffin [50, 163]. SMZL represents the main differential diagnosis for HCL. SMZL may also express DBA44 and TRAP, albeit the staining intensity in SMZL is generally weak [68, 78, 127, 131]. In contrast to SMZL, a significant subset of HCL shows staining for cyclin D1 in variable intensity accompanied by a reduction in p27 staining, which should not pose any problem with the differential diagnosis of MCL [86]. An important role of immunohistochemistry in HCL is the detection and quantification of residual disease. With the availability of highly efficient drugs such as 2-CDA, complete remission is frequently obtained, and histological and immunohistochemical criteria for response evaluation in the BM trephine have been defined [67].

Immunosecretory disorders: monoclonal gammopathy of undetermined significance and multiple myeloma

Immunosecretory disorders such as monoclonal gammopathy of undetermined significance (MGUS), MM, and Waldenstrom's macroglobulinemia represent a frequent indication for BM trephine examination. MM is the second most frequent B-cell tumor in Western countries and accounts for approximately 10% of all hematologic neoplasms [74, 139]. In most cases with significant infiltration, MM is a straightforward diagnosis. BM infiltration in MM is highly variable and can range from randomly distributed sheets or clusters of abnormal plasma cells to large nodules or complete obliteration of the marrow space. Immunohistochemistry is of importance for the diagnostic workup of MM in several settings, namely, (1) discrimination from MGUS, (2) identification of small numbers of tumor cells after therapy, (3) distinction from other neoplasms in morphologically unusual cases, and (4) for the identification of prognostic markers. Given the close biological relatedness of MGUS and MM, a distinction of these two disorders is somehow arbitrary in the presence of a non-tumor-forming plasmacytosis without cytologic atypia, but the presence of a clear-cut light chain restriction with a kappa/lambda ratio of more than 16:1 or the reverse and more than 10% plasma cells are suspicious for a diagnosis of MM (Fig. 3A–C) [54]. Since well-differentiated plasmacytomas can be cytologically indistinguishable from normal plasma cells, the finding of plasma cells in sheets or clusters without association with vascular structures is another important criterion for the diagnosis of MM. Immunophenotypically, neoplastic plasma cells lack in most cases the pan-B-cell antigen CD 20, whereas CD38, CD79a, the collagen-1 binding proteoglycan, syndecan (CD138), and VS38c are usually strongly expressed. The latter two markers are well suited for plasma cell enumeration in trephine biopsies. The neural adhesion molecule CD56 is abnormally expressed in approximately 75% of cases of MM and is frequently associated with lytic bone lesions. In contrast, CD56 is absent both from polyclonal plasma cells and other mature B-NHL with plasmacytic differentiation [46, 65, 87]. Together with CD138, CD56 is thought to be important for plasma-cell anchoring in the BM. Immunoglobulin heavy chains are frequently expressed, with IgG more common than IgA. IgM expression is rare in MM and usually indicates LPL. Occasionally, MM expresses aberrant antigens such as CD10 or even myeloid markers, but their importance in terms of prognosis remains unclear [47, 107]. Although currently not specified in the WHO classification, the lymphoplasmacytic or small-cell variant of MM mentioned above has some specific features such as more frequent secretion of rare Ig isotypes (IgE and IgM), common CD20 positivity, and a high frequency of the t(11;14) translocation associated with strong nuclear cyclin D1 protein expression (Fig. 3D,E). These cases represent a potential diagnostic pitfall because MCL may be suspected based on morphological and phenotypical findings. Prognostically, this MM variant seems to have a better prognosis, possibly due to a paradoxically low proliferation rate [9, 53, 122, 126, 142, 166]. Another subset of MM shows weaker, heterogeneous cyclin D1 expression frequently associated with trisomy 11.

High-grade B-cell lymphomas

Diffuse large B-cell lymphoma

Diffuse large B-cell lymphoma has a relatively low incidence of BM involvement at time of diagnosis (20%) [2, 35, 82, 109, 111, 116, 156]. Apart from discordant involvement (see above), large-cell BM infiltrates in DLBCL are highly variable, ranging from minimal small foci rarely observed intrasinusoidal involvement to subtotal replacement of the BM [111]. In cases of a minimal infiltration, immunostainings facilitate the search for tumor cells, which express CD20 and CD79a in most cases, and in up to 50% CD10, Bcl-2, and Bcl-6. Primary DLBCL expressing CD5 have to be distinguished from the blastic variant of MCL as well as Richter's transformation of B-CLL/SLL [167]. Whereas cyclin D1 positivity helps to distinguish blastic MCL, separation of secondary de novo DLBCL from clonally related Richter's transformation in patients with B-CLL may be impossible by immunohistochemistry. AML M6 is another, albeit rather infrequent differential diagnosis of DLBCL. Stainings for gylocphorin A or hemoglobin A are helpful in these cases, but immature erythroblasts can fail to show immunoreactivity for glycophorin A, whereas myeloid markers such as CD117 and MPO are variably expressed [59, 96].

Bone marrow involvement by the T-cell/histiocyte-rich variant of DLBCL requires special attention, since it resembles BM involvement by Hodgkin's lymphoma (HL) morphologically, due to its high number of reactive T cells and histiocytes and the resemblance of the rare neoplastic cells to L&H or Reed–Sternberg (RS) cells [30]. The tumor cells are usually CD20- and epithelial membrane antigen (EMA)-positive but lack CD30 and CD15. Nodular lymphocyte-predominant HL (nodular paragranuloma)

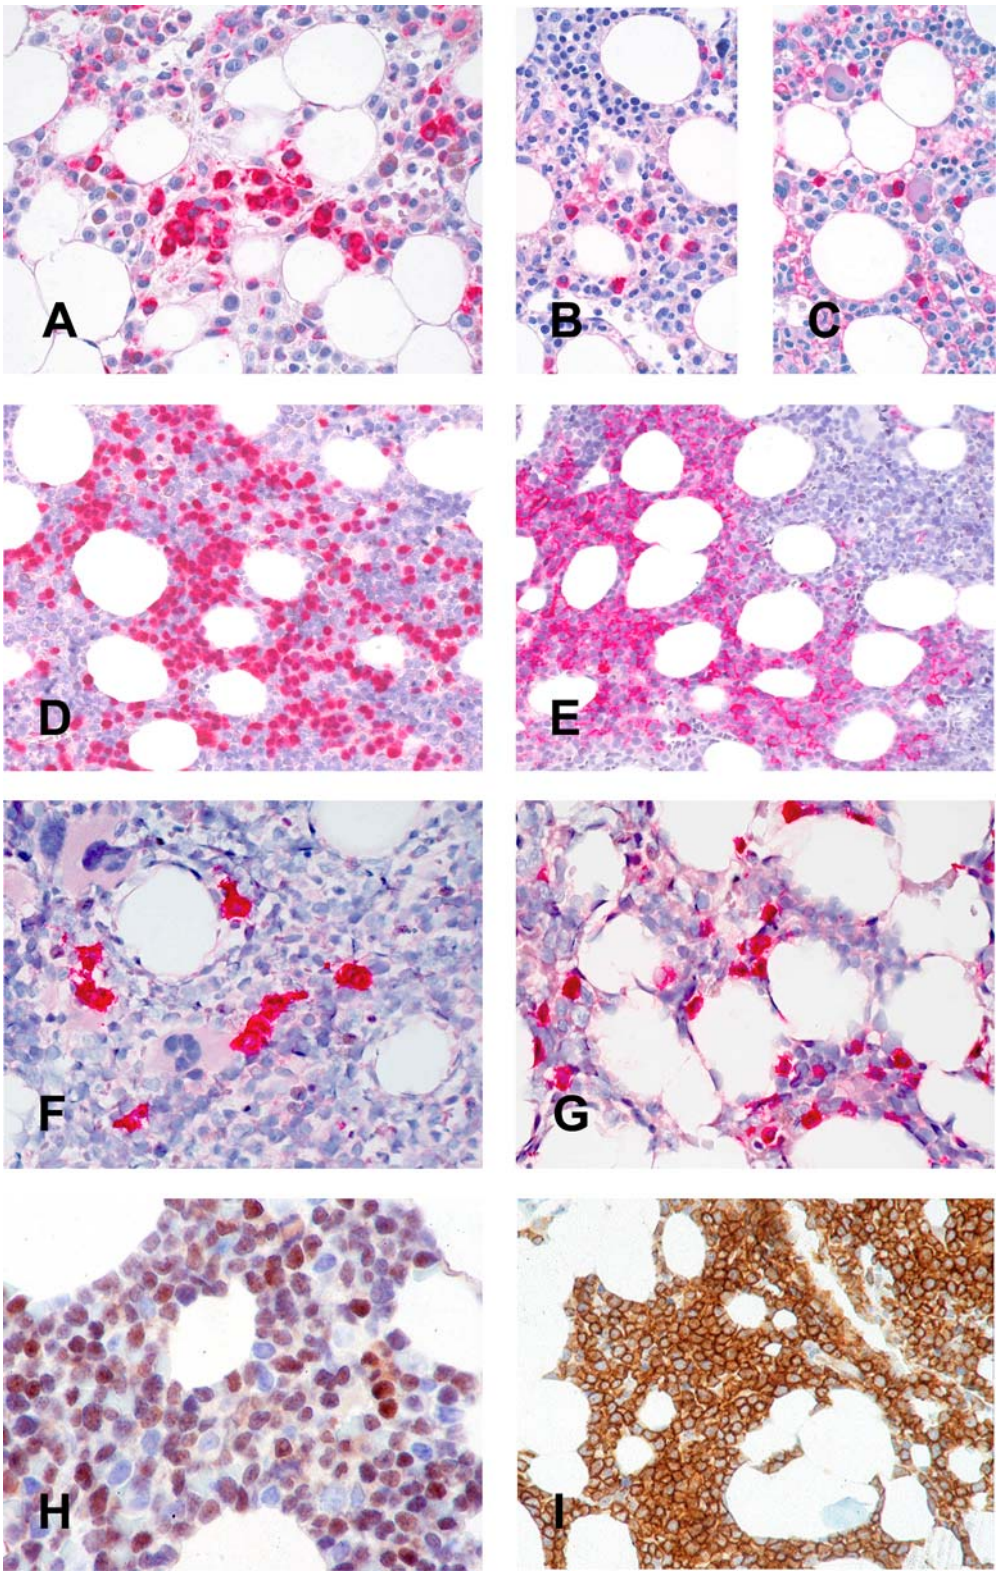

Fig. 3 Immunostainings of immunosecretory disorders, T-cell NHL, and acute lymphoblastic leukemia/lymphoblastic lymphoma. **A**–**C** Microphotographs showing a case with marked reactive BM plasmacytosis without evidence of light chain restriction. Staining for Vs38c (**A**) demonstrate the mainly perivascularly located clusters of plasma cells. There is a polyclonal distribution of immunoglobulin light-chains kappa (**B**) and lambda (**C**) (×300, ×200 ABC-AP). **D**, **E** t(11;14) positive MM with characteristic lymphoplasmacytic morphology. Note the strong cyclin D1 staining intensity with the recently introduced antibody (clone SP4, DC System, Germany) in **D**. The tumor cells in this MM subtype are regularly CD20-positive (**E**) (×300 ABC-AP). **F** BM involvement by ALCL with scattered strongly CD30-positive tumor cells. (×300 ABC-AP). **G** T-LGL with a morphologically inconspicuous interstitial infiltrate of CD8-positive T lymphocytes (×300 ABC-AP). **H**, **I** T-ALL/T-LBL. TdT shows strong homogeneous nuclear reactivity (**H**; ×400 ABC-POX). The tumor cells express the pan-T-cell marker CD7 (**I**) (×400 ABC-POX)

shows an immunophenotype similar to T-cell/histiocyte-rich DLBCL, but BM involvement, especially at primary presentation, is rare [84].

Burkitt's lymphoma

Burkitt's lymphoma (BL) involves the BM in up to 60% of cases. The pattern is nearly always diffuse or interstitial, and the extent of involvement varies from occasional

scattered lymphoma cells to complete replacement of the marrow [23, 144]. Areas of necrosis are observed frequently. Immunohistochemically, BL cells have a germinal center cell phenotype with expression of CD20, CD79a, CD10, Bcl-6, and CD43 but with constant absence of bcl-2. The proliferative activity, assessed with MIB1, should be virtually 100%. In contrast to lymphoblastic lymphoma (LBL)/acute lymphoblastic leukemia (ALL), BL lacks TdT [16, 20, 33].

Peripheral T-cell non-Hodgkin lymphoma

General considerations

The histopathology of BM involvement by T-cell non-Hodgkin lymphoma (T-NHL) has recently been reviewed comprehensively by Dogan and Morice [43]. T-NHL are rare diseases accounting for approximately 15% of all lymphoproliferative disorders in the Western world, with peripheral T-cell lymphoma (PTCL) unspecified, angioimmunoblastic T-cell lymphoma (AITL), cutaneous T-cell lymphomas, and anaplastic large-cell lymphoma (ALCL) representing the most common entities [129]. The frequency and the histology of BM involvement vary greatly between the different entities. Diagnosis of BM infiltration is hampered by frequent secondary changes in the BM microenvironment induced directly or indirectly by the lymphoma cells [49]. Some PTCL such as AITL show a vaguely nodular or interstitial infiltration pattern, whereas others, like large granular lymphocyte leukemia and hepatosplenic T-cell lymphoma (HSTCL), are characterized by a predominantly intrasinusoidal involvement [29, 31, 58, 61, 63, 99]. Immunophenotyping reveals an aberrant T-cell phenotype with considerable variations, mostly with the absence of one or more pan T-cell antigens. In T-cell NHL, in general, immunostainings are helpful in identifying the frequently subtle infiltrates and should be performed whenever possible.

Anaplastic large-cell lymphoma

Bone marrow involvement in ALCL is seen in about one quarter of the systemic cases but, as a rule, is absent in the cutaneous form. Most systemic cases have translocations involving the ALCL kinase-1 (ALK-1) gene, resulting in nuclear and/or cytoplasmic staining for ALK-1 protein [93, 143]. BM infiltration is usually interstitial and often too subtle to be recognized in routinely stained sections. This is particularly the case for the small-cell variant of ALCL, in which the neoplastic cells can easily be confused with immature megakaryocytes [14, 55]. For this reason, immunostainings for CD30 and/or ALK-1 are mandatory to identify a minimal infiltration in BM biopsies (Fig. 3F). The great majority of ALCL express one or more T-cell antigens; however, some cases may have an apparent "null cell" phenotype but, nevertheless, show evidence for T-cell lineage at the genetic level [55, 143]. Classic HL is the main differential diagnosis of ALCL, although this issue will rarely be raised in a BM biopsy.

Angioimmunoblastic T-cell lymphoma

Bone marrow involvement is seen in the majority of the cases (50–80%) and often mimics the features seen in peripheral lymph nodes [61, 62]. The infiltration pattern may be focal (paratrabecular) or diffuse and is characterized by a patchy polymorphic infiltrate often accompanied by a proliferation of arborizing vessels and fibrosis. Immunophenotypically, the phenotype of the neoplastic cells is very difficult to define, similar to the situation in involved lymph nodes. AITL cells express CD3 and CD4, whereas cytotoxic markers are negative. Interestingly, the recently described CD10 reactivity of the neoplastic cells observable in peripheral lymph nodes is often absent in the tumor cells infiltrating the BM [6, 7]. The frequent presence of large, Epstein–Barr virus (EBV)-positive B cells in AITL, which occasionally can show the morphology of Hodgkin and RS cells, may lead to confusion with either large B-cell lymphoma or HL. Another important differential diagnosis of BM involvement by AITL are reactive infiltrates with granulomas.

T-cell granular lymphocytic leukemia and hepatosplenic T-cell lymphoma

T-cell granular lymphocytic leukemia (T-LGL) is an indolent lymphoproliferative disorder, characterized by a distinct clonal cytotoxic T-cell population in the peripheral blood, which is easily identified by flow cytometric immunophenotyping. However, in BM trephines, the neoplastic cells of T-LGL cannot be reliably identified by morphological assessment alone. Immunostainings with antibodies against CD3, CD8, TIA-1, and granzyme B reveal the neoplastic infiltrate present as small interstitial infiltrates or typically in marrow sinusoids (Fig. 3G).

An important differential diagnosis is a reactive increase in cytotoxic T cells, which usually lacks the relatively distinct intrasinusoidal and intravascular pattern observed in T-LGL [110]. Like T-LGL, HSTCL shows an intrasinusoidal and subtle interstitial infiltration pattern, which is difficult to recognize by morphology alone. HSTCL is usually positive for CD3 and TIA-1 and frequently expresses CD56, whereas CD4, CD8, granzyme B, and perforin are negative [15, 36, 162].

Hodgkin's lymphoma

The incidence of BM involvement in HL ranged between 5 and 30% according to older studies, but was found in only 5.2% of patients in a recent large series of HL [77]. The lowest incidence was reported in lymphocyte-predominant HL (<5–10%), and the highest incidence was reported in HL with lymphocyte depletion (50–75%). Of note, BM

infiltration is frequent in HIV-associated HL and may be the site of primary diagnosis [80]. The infiltration pattern may be diffuse or focal, occasionally occupying the entire trephine volume. The infiltrate consists of a polymorphous inflammatory background with histiocytes, eosinophils, lymphocytes, and plasma cells with an accompanying dense collagen fibrosis. Diagnostic RS cells and variants are rare and difficult to identify even if immunohistochemistry for CD15 and CD30 is employed. However, the presence of a polymorphous lymphohistiocytic infiltrate with fibrosis, without diagnostic cells, can be regarded as sufficient evidence for BM infiltration if a diagnosis of classical HL has been established at a nodal site. ALCL, PTCL, T-cell-rich B-cell lymphoma, mast cell diseases, granulomatous or histiocyte disorders, or even metastatic carcinoma are among the differential diagnoses. If encountered as primary diagnosis in the BM, an extended panel of antibodies, including CD20, PAX5, OCT2, BOB1, CD3, granzyme B, EMA, ALK-1, and pancytokeratin may be necessary. In contrast, the neoplastic cells in nodular lymphocyte-predominant HL are characteristically positive for CD20, raising the differential diagnosis of T-cell/histiocyte-rich DLBCL.

Lymphoblastic lymphoma/acute lymphoblastic leukemia

In BM biopsies, lymphoblasts are relatively uniform in appearance with round to oval nuclei. Nucleoli are generally inconspicuous, and the chromatin is typically finely dispersed. The infiltration pattern is almost always interstitial or diffuse. Characterization of LBL/ALL is best performed using flow cytometry and cytogenetics, but a number of markers suitable for trephines have become available recently. The most constant and reliable marker for LBL/ALL of both lineages is TdT, which is expressed in almost all cases of ALL (Fig. 3H). TdT usually shows strong nuclear staining of virtually all cells. TdT expression also occurs in a significant subset of acute myeloid leukemia (AML) but is usually less intense and not as uniform as in ALL/LBL. In most cases of ALL/LBL, assignment to either B- or T-cell lineage is possible. The most reliable marker for B-LBL/ALL is the B-cell transcription factor PAX5 followed by CD10 and CD79a, whereas CD20 is variably expressed [152]. Of note, CD79a is not absolutely lineage-specific in this context and may be present both in rare cases of T-ALL and in AML [5]. T-LBL/ALL can usually be confirmed by staining for a variety of T-cell antigens, including CD1a, CD3, CD4, CD5, CD7, and CD8, with CD7 being the earliest T-cell marker to appear (Fig. 3I). Coexpression of CD4 and CD8 can be found frequently and is diagnostic for T-LBL/ALL. The number and sequence of T-cell antigens present may be used for stratification according to maturation stage. Both B- and T-ALL/LBL can show an expression of CD34 and, less frequently, CD117. In rare biphenotypic acute leukemias, an aberrant coexpression of myeloid markers is observed [13, 89, 118, 153]. The differential diagnosis of ALL/LBL includes such diverse entities as AML, BL, blastoid MCL, reactive BM with increased CD10+ hematogones, and even nonhematopoietic tumors such as Ewing sarcoma or rhabdomyosarcoma. Of practical importance is the immunoreactivity of LBL for CD99 (MIC-2), which may lead to confusion with Ewing sarcoma [100, 169].

Myeloid disorders

Myelodysplastic syndromes/acute myeloid leukemias

The diagnosis of MDS rests largely on clinicopathologic and morphological (cytological) findings complemented by cytogenetics. However, immunohistochemistry provides a useful tool for accurate classification of MDS in BM trephines. The identification of abnormally located precursors for a diagnosis of refractory anemia with excess of blasts (RAEB) type 1 or 2 is easily achieved with antibodies against the hematopoietic stem cell antigen CD34 (Fig. 4A) [76, 112]. Several studies investigated CD117 (c-kit) as an additional marker for the characterization of blasts in MDS. However, in our experience, the application of CD117 is problematic, since this marker is also expressed on immature erythroid cells [79, 101, 112]. For the differentiation between hypoplastic MDS and aplastic anemia, CD34 staining can be helpful to identify small numbers of immature precursors, which are a strong indicator for hypoplastic MDS [113].

In AML, a panel of antibodies, including CD34, TdT, myeloperoxidase, CD68 (KP-1 and PG-M1), glycophorin A, CD61, CD20, CD79a, CD3, and CD1a, is a useful adjunct for the differentiation between AML and ALL and for a tentative subgrouping of AML according to the French–American–British Group (FAB) criteria as illustrated by Pileri and coworkers [118]. CD34, TdT, and lymphoid markers are necessary for discrimination of AML M0 (Fig. 4B,C) and ALL (B/T). AML M2 and M4 can be separated by the use of two CD68 clones: PG-M1 is restricted to AML with monocytic/monoblastic differentiation (M4 and M5), whereas KP-1 is additionally positive in myeloblasts (M2). The sometimes difficult distinction between promyelocytic leukemia (AML M3) and a reactive increase in promyelocytes can be resolved by staining for CD117, which is aberrantly expressed in malignant promyelocytes of AML M3 [28, 125]. CD61 and glycophorin A are helpful markers for the identification of acute megakaryoblastic leukemia (M7) or acute erythroid leukemia (M6) (Fig. 4D,E).

The very recently described mutations in the nucleophosmin (NPM) gene, leading to abnormal cytoplasmatic protein expression in karyotypically normal AML, can be demonstrated with anti-NPM antibodies. Nevertheless, the importance of this observation in terms of prognosis has to be elucidated [1, 48].

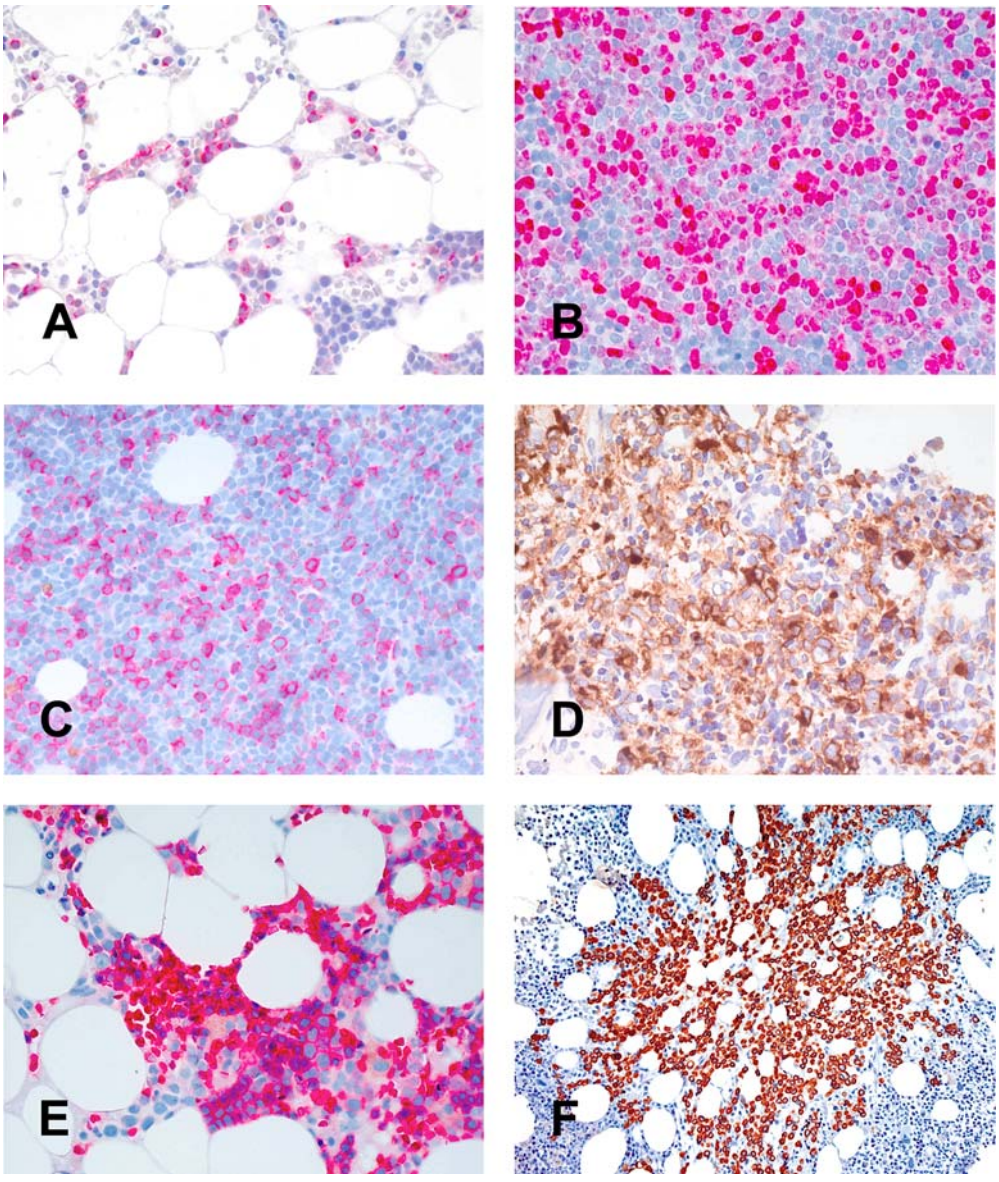

Fig. 4 Immunostainings of acute myeloid leukemias, myelodysplastic syndromes, and metastatic bone marrow disease. **A** Hypocellular MDS (RAEB-1 WHO). CD34 highlights the small interstitial aggregates of myeloblasts. The corresponding aspirate contained 9% blasts (×300 ABC-AP). **B**, **C** AML M0 (FAB) TdT (**A**) and CD34 staining (**B**) of a "packed marrow." Note the heterogeneous expression of TdT in the AML blasts in contrast to ALL (×300 ABC-AP). **D** AML M7 (acute megakaryoblastic leukemia) CD61 shows a strong cytoplasmic and membrane staining of cells of the megakaryocytic lineage. Note the mixture of small mononuclear megakaryoblasts and more differentiated cells (×300 ABC-POX). **E** Marked erythroid hyperplasia in a patient with a secondary erythrocytosis stained for glycophorin C. Maturation from erythroblasts to normoblasts is easily recognized (×300 ABC-AP). **F** BM infiltration by a lobular breast carcinoma. The infiltration by neoplastic epithelial cells is highlighted by pancytokeratin staining (×200 ABC-POX)

Chronic myeloproliferative syndromes

The diagnosis of chronic myeloproliferative syndromes such as chronic myeloid leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET), and idiopathic myelofibrosis (IMF) is generally based on a synopsis of clinical, morphological, and molecular data. However, immunostainings, including glycophorin A or C, hemoglobin, MPO, or CD61, are undoubtedly helpful for assessing the distribution and quantities of the different cell types and to identify morphologically abnormal forms such as micromegakaryocytes. In addition, CD34 is useful for determining the number of blasts present in the BM if an accelerated phase or acute transformation is suspected. Interestingly, mature megakaryocytes of MPS frequently show an aberrant cytoplasmatic CD34 expression, which can aid in the distinction from reactive processes.

Systemic mastocytosis

The BM is one of the major sites of involvement of systemic mastocytosis. The most common form of systemic mast cell disease is indolent systemic mastocytosis usually associated with cutaneous lesions. Due to the generally pronounced concomitant fibrosis in mast cell infiltrates, a BM trephine should always be performed. Although mast cells usually are easily demonstrated with 3-hydroxy-4′-nitro-2-naphthanilide chloroacetate (NASD) esterase or Giemsa stains, neoplastic mast cells may be poorly granulated, and occasionally, immunostains are required for their identification. They stain strongly for CD117 and mast cell tryptase [159, 160]. In addition, mast cells in systemic mastocytosis have been reported to aberrantly express CD2 and CD25 [141].

Metastatic disease

Bone marrow trephines generally exhibit the highest yield for detecting metastatic disease because neoplastic cells are frequently inaspirable due to concomitant fibrosis. Although metastatic solid tumors are rarely confused with hematopoetic neoplasms, immunostainings may be required for identification of the putative primary site. A diagnostic challenge, especially if minor involvement is suspected, are infiltrates of small blue round cell tumors, e.g., Ewing's sarcoma, or small-cell carcinoma. The primary antibody panel for these cases should at least contain anticytokeratin, CD99, CD56, and TdT.

The role of immunohistochemistry in reactive BM changes

In healthy adults, the mature lymphocyte compartment in the BM comprises less than 10% of nucleated cells and consist mainly of T lymphocytes (CD 3+ and CD5+) and, to a lesser extent, B lymphocytes (CD20+) [148]. However, lymphoid aggregates are commonly seen especially in the elderly or in patients with autoimmune disease. Distinction between benign nodular lymphoid aggregates and infiltrates of ML remains a difficult problem in BM histology and has been the subject of a number of studies [72, 85, 130, 134]. Benign nodules tend to have well-defined borders, are distributed at random in the marrow spaces, and have a more polymorphic cellular composition. True germinal centers can be seen occasionally. Although intralesional fibrosis, a typical feature of neoplastic infiltrates, is usually absent or mild in reactive lymphoid nodules, this feature lacks specificity. Immunohistochemically, benign lymphoid infiltrates show a polytypic staining pattern with a mixed population of B and T cells, with the latter predominating. An analysis of a light chain restriction is useful in cases with increased plasma cells. As outlined above, identification of an aberrant immunophenotype such as CD5 coexpression allows identification of early nodular involvement by B-CLL or MCL, but this feature is not present in other subtypes of B-NHL. Although most cases will be resolved by morphological and immunohistochemical studies, ambiguous cases may require molecular analysis [85]. Another important reactive condition, which may require immunostaining for its identification as mentioned above, are increased numbers of hematogones. Hematogones are immature B-cell precursors at various stages of maturation and may cause diagnostic problems when present in great numbers such as in regenerative marrow postchemotherapy or in children. In contrast to LBL/ALL, they show a range of maturation with variable expression of TdT, CD34, CD10, CD20, and/or CD79 and lack clonal antigen receptor gene rearrangements. Usually, mature forms already lacking TdT expression predominate [140].

Immunohistochemistry may also aid in the identification of infectious agents especially in immunosuppressed hosts. One of the agents worth mentioning in this context is human Parvovirus B19, which causes aplastic crisis and also the failure of nonerythroid lineages. Although B19 infections exhibit a typical morphology, with giant erythroblasts containing viral inclusions and arrest of erythroid maturation, immunostainings using a monoclonal antibody against the virus capsid protein (R92F6) can facilitate the detection [97].

Acute hemophagocytic syndrome is an important and distinctive manifestation of acute viral/bacterial infections (i.e., EBV, Parvovirus B19, hepatitis virus, and mycobacteria) especially in immunocompromised patients. The BM is characterized by an overall hematopoietic hypocellularity, variable reticulin fibrosis, and pronounced histiocytic hyperplasia, which can be highlighted by immunostainings with CD68. Highly characteristic are ingested mature and immature BM cells in the cytoplasm of histiocytes, giving them a "sack-like" appearance. The differential diagnosis includes acute monocytic leukemia and a paraneoplastic hemophagocytic syndrome in patients with peripheral T-cell NHL [75, 138, 158].

Bone marrow granulomas are encountered in both infectious and noninfectious conditions. They consist of cohesive clusters of histiocytes, lymphocytes, and occasionally, eosinophils. Immunohistochemistry can aid in the identification of microorganisms and in differentiating granulomas in the setting of ML, mastoocytosis, or reactive disorders [40].

Conclusion

Immunohistochemistry is a powerful auxiliary technique for the diagnosis of hematologic disorders in BM trephine biopsies. If standard fixation and decalcification procedures are employed, primary antibodies suitable for paraffin-embedded tissues can be applied to BM trephines without restrictions. An accurate characterization and primary classification of lymphoid neoplasms is possible in the majority of cases and expands the diagnostic scope of BM histology. Moreover, diagnostic algorithms provide a rational, fast, and cost-effective diagnostic approach.

Can renal oncocytoma be differentiated from its renal mimics? The utility of anti-mitochondrial, caveolin 1, CD63 and cytokeratin 14 antibodies in the differential diagnosis

Received: 17 February 2005 / Accepted: 14 July 2005 / Published online: 17 August 2005
© Springer-Verlag 2005

Abstract Among the epithelial renal tumours with eosinophilic cytoplasm, the main differential diagnostic problem arises between renal oncocytomas (ROs) and eosinophilic variants of chromophobe renal cell carcinomas (RCCs). We investigated the possible role of anti-mitochondrial (AMA), anti-caveolin 1 (CAV1), anti-CD63 (CD63) and anti-cytokeratin 14 (CK14) antibodies in the differential diagnosis of eosinophilic epithelial tumours and applied the Muller and Mowry modification of Hale's colloidal iron stain (HCI). Thirty-five ROs and 77 eosinophilic RCCs (27 chromophobe, 28 clear cell and 22 papillary RCCs) were included in this study. Apical and/or polar CD63 immunostaining (94%) and diffuse AMA (91%) and CAV1 (88%) immunostainings were the characteristics of ROs, whereas diffuse CD63 immunostaining (96%) and diffuse-peripheral AMA (96%) and CAV1 (92%) immunostainings were characteristic immunohistochemical features of eosinophilic chromophobe RCCs. We showed CK14 antibody not to be useful in the differential diagnosis of the eosinophilic epithelial renal tumours. The staining localisations with AMA, CAV1 and CD63 antibodies were significantly different between tumour groups. AMA had 96% sensitivity and 94% specificity, whereas CAV1 had 92% sensitivity and 97% specificity in diagnosing chromophobe RCCs. With HCI staining, ROs, showing apical and/or polar staining, could be differentiated from chromophobe RCCs, showing diffuse cytoplasmic staining. HCI had fairly low (69%) sensitivity and 100% specificity, whereas CD63 had 95% sensitivity and 100% specificity to diagnose ROs. We recommend using CD63 as the best marker of choice for distinguishing ROs from eosinophilic chromophobe RCCs when standard diagnostic criteria are not helpful.

Introduction

Epithelial renal tumours with eosinophilic cells include renal oncocytomas (ROs), eosinophilic variants of chromophobe and clear cell and papillary renal cell carcinomas (RCCs). The main problem in the differential diagnosis arises between ROs and eosinophilic variants of chromophobe RCC. RO is a benign neoplasm, while chromophobe RCC is a malignant tumour [1, 3, 12, 39, 49, 50]. ROs should be separated from eosinophilic variants of RCCs. Some ROs and eosinophilic variants of RCCs have several common macroscopic and microscopic features such as cellular pleomorphism and focal perinephritic adipose tissue invasion as well as microvascular invasion [4, 35, 37].

Nowadays, more renal tumours are detected incidentally due to the improvement in radiological modalities, and more are sampled preoperatively [38, 41, 45]. The differential diagnosis between ROs and eosinophilic variants of RCCs, which is sometimes difficult in resection materials, becomes more problematic in core biopsies [1, 24].

In recent years, although many markers such as cytokeratin (CK) 7, CK14 and CK20, epithelial membrane antigen (EMA), CD10 and parvalbumin have been studied for the differential diagnosis between chromophobe RCCs and ROs, the results are still unsatisfactory [1, 5, 23–25, 30, 31, 58]. However, diffuse staining with Hale's colloidal iron (HCI) stain and ultrastructural demonstration of chromophobe-type micro-vesicles in the cytoplasm of the tumoural cells are still accepted as the most important criteria for the diagnosis of chromophobe RCCs [2, 10, 24, 28, 47, 49, 50, 58].

Ultrastructural and immunohistochemical studies showed that the cytoplasmic distribution pattern of mitochondria in the eosinophilic epithelial renal tumours could be different from each other [19, 51, 53, 57]. For this reason, we used anti-mitochondrial antibody (AMA) to identify the mitochondrial distribution pattern of ROs and subtypes of RCCs.

Recently, the increased expression of CAV1 has been reported in ROs [11]. CAV1 is the major functional and structural protein component of vesicular invaginations of the plasma membrane called caveolae [26, 42]. Three proteins (caveolin 1, caveolin 2, caveolin 3) were identified in the caveolin family. CAV1 plays a key role in the membrane traffic, signal transduction and carcinogenesis [22, 26, 42, 56]. Caveolins are found in many cells, but mainly in mesenchymal tissues [26, 42].

Chu and Weiss presented CK14 as a marker of ROs [14]. However, contradictory results have been reported [24]. CK14 expression is also described in squamous cell carcinoma, thymoma, pleomorphic adenoma, Hürthle cell lesions of the thyroid and Warthin's tumour [13, 15].

CD63 is a lysosomal membrane glycoprotein translocated to plasma membrane after platelet activation [32, 43]. Anti-CD63 antibody (CD63) reacts with nevi, melanomas and alveolar soft part sarcoma [21, 29, 33, 36, 54]. CD63 has not been investigated in eosinophilic epithelial renal tumours previously, but its immunoreactivity has been reported in epithelioid angiomyolipomas of the kidney [17, 46].

HCI stain detects polyanionic acid mucopolysaccharides in tissues [52]. It has some technical difficulties, and its interpretation may be challenging. For this reason, modifications of this staining technique have been studied in the past. The Muller and Mowry modification of HCI is accepted to have the superior results due to the maintenance of pH at 1.1 to 1.3 [6, 52, 55].

The purpose of this study is to perform a detailed histopathological examination on ROs and eosinophilic variant of chromophobe RCCs on resection specimens and to investigate the possible role of AMA, CAV1, CK14 and CD63 in the differential diagnosis between them. We also applied the Muller and Mowry modification of HCI staining to compare its usefulness with those of the immunohistochemical markers.

Materials and methods

Tissue samples

A total of 112 resected eosinophilic epithelial renal tumours (35 ROs, 27 eosinophilic variants of chromophobe, 28 eosinophilic variants of clear cell and 22 eosinophilic variants of papillary RCCs) which were diagnosed in the Department of Pathology, Istanbul Faculty of Medicine, Istanbul University, were included in this study. All cases were classified according to the standard diagnostic criteria and HCI staining results [18, 34]. We reviewed our archive files for patients' age and gender information, as well as the gross pathologic features (size, presence of macroscopic necrosis, haemorrhage and scar formation) of the tumours.

Histopathological methods

The archive slides were reviewed, and a detailed histopathological examination was done in ROs and eosinophilic variants of chromophobe RCCs. We re-examined the H & E stained slides for cellular, nuclear, cytoplasmic, stromal and vascular network features of the tumours.

Immunohistochemistry

One paraffin block having the most representative tumoural area was selected for the immunohistochemical studies of each tumour. Routine immunohistochemical staining was performed on formalin-fixed, paraffin-embedded tissues using the streptavidin-biotin-complex method (Lab Vision Corp., Fremont, CA, USA) after pretreatment with heat-induced antigen unmasking by incubating the sections in 10 Mmol/l citrate buffer solution (pH 6) using a domestic pressure cooker (25 min, 1 atm). The entire procedure was carried out in room temperature. The following primary antibodies were applied: anti-mitochondrial Ab-2 (Monoclonal, mouse anti-human, Clone: MTCO2, 1:100, 60 min, Code: MS-1372-P, NeoMarkers, Fremont, CA, USA), anti-caveolin 1 (Polyclonal, rabbit anti-human, Clone: N-20, 1:50, 60 min, Code: SC-894, Santa Cruz Biotechnology Inc., USA), anti-CD63 (Monoclonal, mouse anti-human, Clone: NKI/C3, 1:100, 60 min, Code: MS-1118-P, NeoMarkers), anti-keratin 14 (Monoclonal, mouse anti-human, Clone: LL002, 1:100, 60 min, Code: MS-115-P, NeoMarkers). Blood vessels and mesenchymal tissue of the intestine and non-neoplastic tissue adjacent to the tumour for CAV1, intradermal naevus for CD63, squamous cell carcinoma for CK14 and proximal renal tubular epithelium for AMA were used as the positive controls. Staining localisations (cytoplasmic diffuse, cytoplasmic diffuse-peripheral, cytoplasmic polar and/or apical, cytoplasmic irregular-disperse) were assessed for each immunohistochemical reaction.

Histochemistry

Representative sections from each tumour were stained with HCI as modified by Muller and Mowry [6, 52, 55]. Non-neoplastic kidney parenchyma adjacent to the tumour was used as internal positive control. The tumours showing a positive blue-purple staining were documented for the staining localisation.

Photography

Photographs were taken by an Olympus BX50 microscope equipped with a Nikon E4500 digital camera (1024×768 pixel, high-resolution mode).

Statistical analysis

Kruskal–Wallis and Mann–Whitney *U* tests were used to evaluate the statistical correlations between the groups and variables. All data were analysed utilising SPSS 10.0 for Windows.

Results

Clinical findings

The main clinical findings are summarized in Table 1. A male predominance was observed in chromophobe, papillary and clear cell RCCs. ROs showed a slight female predominance (male to female ratio 16:19).

Gross pathological findings

The main gross pathological findings are summarized in Table 1. The mean size of the ROs (5.1±3 cm) was found to be significantly lower than that of the eosinophilic variants of clear cell RCCs (7. 9±4.9 cm) (p=0.024). The eosinophilic papillary RCCs were found to be the most necrotic (63%) and haemorrhagic (86%) tumour group. No necrotic area was observed in ROs. Haemorrhage was generally minimal in ROs and eosinophilic chromophobe RCCs. Scar formation was observed in ROs (80%), eosinophilic chromophobe (17%) and clear cell (21%) RCCs.

Histopathological findings

The results of histopathological examination are summarized in Table 2. Two types of eosinophilic cells were observed in varying proportions in ROs and chromophobe RCCs. A delicate vasculature separating tumoural cell groups in solid sheets was seen in 26 eosinophilic variants of chromophobe RCCs (96%). This kind of typical vascular network was totally absent in ROs. We also observed entrapped normal tubules in the central and/or peripheral parts of the tumour in 25 ROs (71%). This feature was totally absent in the eosinophilic chromophobe RCCs. Microscopic necrosis was found in only one RO (2%) which measured 15 cm in diameter.

ROs renal oncocytomas, *RCCs* renal cell carcinomas
[a]Test could not be performed because at least one group was not stained

Immunohistochemical findings

Staining localisation details and statistical results are summarized in Tables 3 and 4.

Anti-mitochondrial antibody

A positive weak cytoplasmic immunostaining was seen in the non-neoplastic kidney tubules. All tumour groups were positive with AMA (Table 3). A diffuse cytoplasmic immunostaining in 32 ROs (91%) (Fig. 1a), a diffuse and peripheral immunostaining in 26 eosinophilic chromophobe RCCs (96%) (Fig. 1b) and an irregular-disperse cytoplasmic immunostaining in 23 eosinophilic clear cell RCCs (82%) were observed. Twelve papillary RCCs showed diffuse cytoplasmic (55%), and ten cases showed irregular-disperse cytoplasmic (45%) immunoreactivity. The difference in the staining patterns of the ROs and the

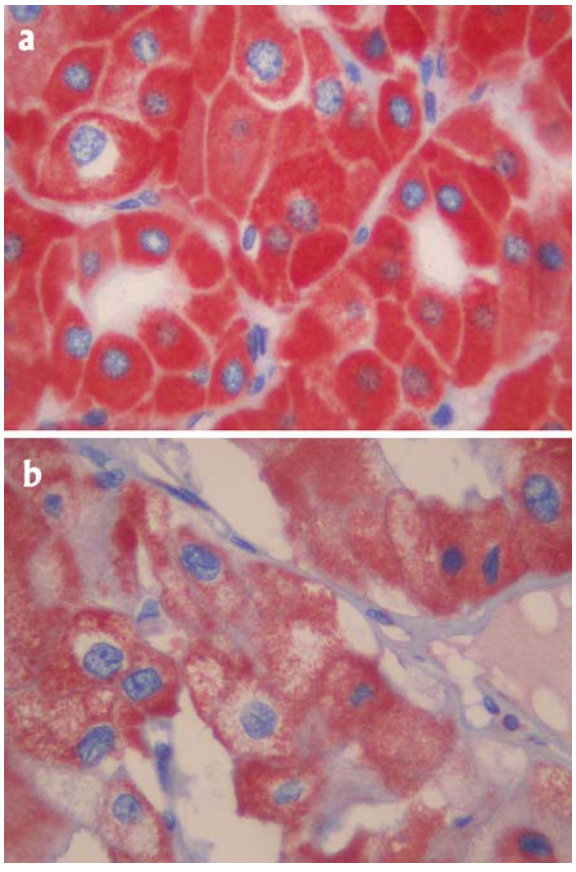

Fig. 1 **a** Diffuse cytoplasmic immunostaining with anti-mitochondrial antibody (AMA) in renal oncocytoma (original magnification ×400). **b** Diffuse and peripheral cytoplasmic immunostaining with AMA in chromophobe renal cell carcinoma (original magnification ×400)

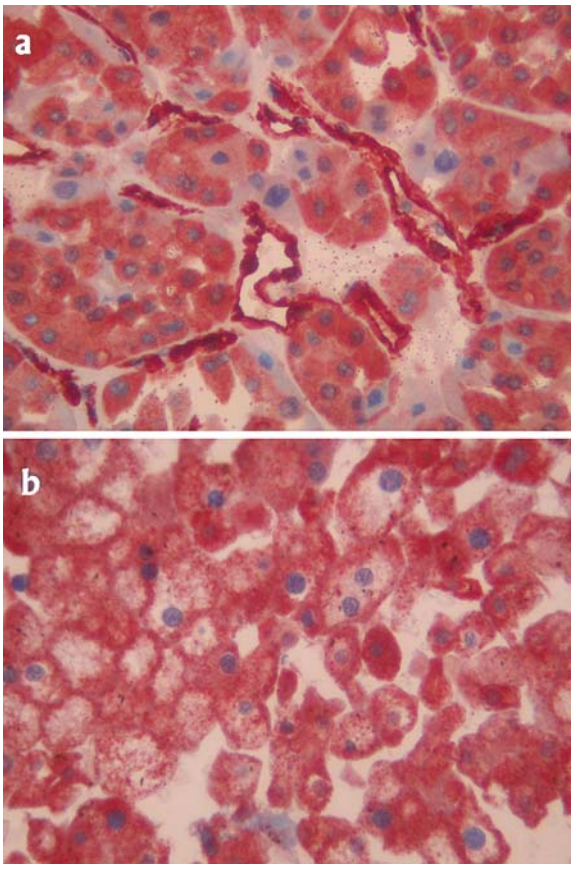

Fig. 2 **a** Diffuse cytoplasmic immunostaining with anti-caveolin 1 antibody (CAV1) in renal oncocytoma and positive cytoplasmic immunostaining in endothelial cells (original magnification ×200). **b** Diffuse and peripheral cytoplasmic immunostaining with CAV1 in chromophobe renal cell carcinoma (original magnification ×400)

subtypes of RCCs was found to be statistically significant (Tables 3, 4).

Anti-caveolin 1 antibody

A weak positive diffuse cytoplasmic staining in the tubular epithelium and a moderate-to-strong staining in the Bowman's parietal cells and visceral epithelium of the glomerulus were seen in the non-neoplastic tissue. Vascular endothelial cells in the non-neoplastic tissues showed strong immunoreaction. Cytoplasm was the main staining area in all tumour groups. In addition to the cytoplasmic staining, focal membranous staining was present in one (3%) RO and four (14%) eosinophilic chromophobe RCCs. A diffuse cytoplasmic staining in 31 ROs (88%) (Fig. 2a), a diffuse and peripheral cytoplasmic staining in 25 eosinophilic variants of chromophobe RCCs (93%) (Fig. 2b) and an irregular-disperse staining in 20 eosinophilic variants of clear RCCs (71%) were observed. Thirteen eosinophilic papillary RCCs (59%) showed a diffuse cytoplasmic staining predominantly and nine (41%) cases showed an irregular-disperse cytoplasmic staining. The difference in the staining patterns of the ROs and the subtypes of RCCs was found to be statistically significant (Tables 3, 4).

Anti-CD63 antibody

Non-neoplastic tubular epithelium showed focal apical and weak staining. All of the ROs (35/35) and all of the eosinophilic chromophobe RCCs, 19 (68%) eosinophilic variants of clear cell RCCs and 14 (64%) eosinophilic variants of papillary RCCs were positive for CD63 (Table 3). Positive staining in the apical part of the cytoplasm and/or in one pole was observed in 33 ROs (94%) (Fig. 3a). Diffuse cytoplasmic staining was seen in 26 (96%) eosinophilic variants of chromophobe RCCs (Fig. 3b). Fifteen (54%) eosinophilic variants of clear cell RCCs showed an irregular-disperse staining. Seven (32%) eosinophilic variants of papillary RCCs showed apical cytoplasmic, and six cases (27%) showed irregular-disperse staining. The differences between ROs and eosinophilic variants of chromophobe, clear cell and papillary RCCs were found to be statistically significant (Tables 3, 4).

Anti-cytokeratin 14 antibody

A non-specific weak staining was observed in the tubular epithelium of the non-neoplastic kidney tissue. All the eosinophilic clear cell RCCs were negative for CK14. Only

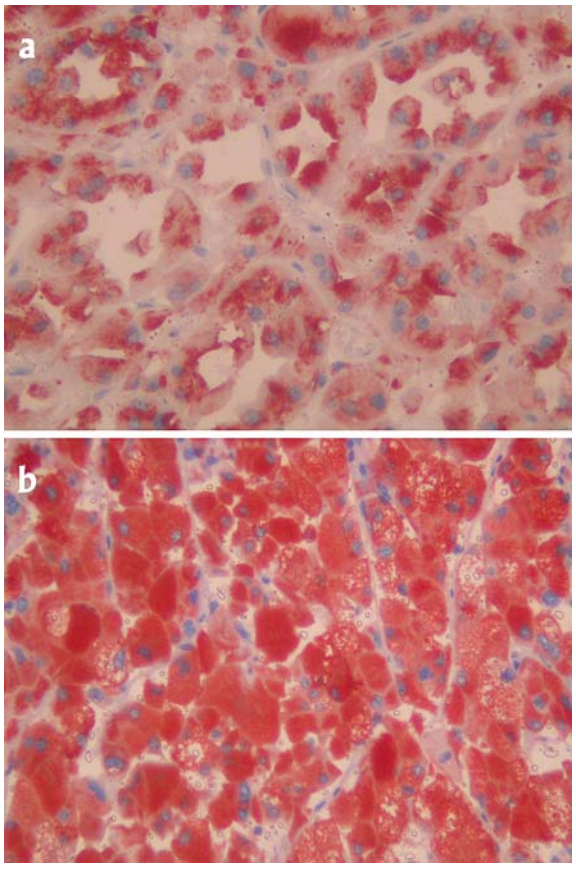

Fig. 3 **a** Apical and/or polar cytoplasmic immunostaining with anti-CD63 antibody (CD63) in renal oncocytoma (original magnification ×200). **b** Diffuse cytoplasmic immunostaining with CD63 in chromophobe renal cell carcinoma (original magnification ×200)

nine (26%) of the ROs, five (18,5%) of the eosinophilic variants of chromophobe RCCs and three (14%) of the eosinophilic variants of papillary RCCs were immunopositive with mild staining intensity and small stained area. No significant difference was found between the groups (Tables 3, 4).

Histochemical findings

Focal weak cytoplasmic HCI staining in the apical part of renal tubular cells was observed. Areas of haemorrhage showed strongly positive staining. Twenty-five (71%) of the ROs, all of the eosinophilic variants of chromophobe RCCs (100%) and six (21.4%) of the eosinophilic variants of clear cell RCCs showed positive reaction for HCI (Table 3). Eosinophilic variants of papillary RCCs did not show any positivity related to the tumour cells. Only frequent areas of haemorrhage at the apical part of the cell cytoplasm and the histiocytes in the cores of the papilla showed strong-to-moderate positivity. Apical cytoplasmic staining associated with weak-to-moderate staining intensity was observed focally in 24 (68%) ROs (Fig. 4a), whereas all of the eosinophilic variants of chromophobe RCCs showed diffuse cytoplasmic staining (Fig. 4b). In five (17.9%) of the eosinophilic variants of clear cell RCCs, irregular-disperse and weak positivity was observed and was associated with a small percentage of stained cells. The staining intensity was mild or very mild (almost negative) in eosinophilic cells without clearing.

According to the staining results, HCI distinguished ROs significantly from eosinophilic variants of chromophobe RCCs and from eosinophilic variants of clear cell RCCs by their different staining localisations (Tables 3, 4).

Sensitivity and specificity of anti-mitochondrial, anti-caveolin 1, anti-CD63 and Hale's colloidal iron stain

We differentiated chromophobe RCCs from ROs by way of diffuse-peripheral AMA staining, with a sensitivity of 96% and a specificity of 94%. The differentiation of chromophobe RCC by way of diffuse-peripheral CAV1 staining was done with a sensitivity of 92% and a specificity of 97%.

CD63 immunohistochemistry distinguished ROs, with apical and/or polar staining, from eosinophilic chromophobe RCCs with 95% sensitivity and 100% specificity.

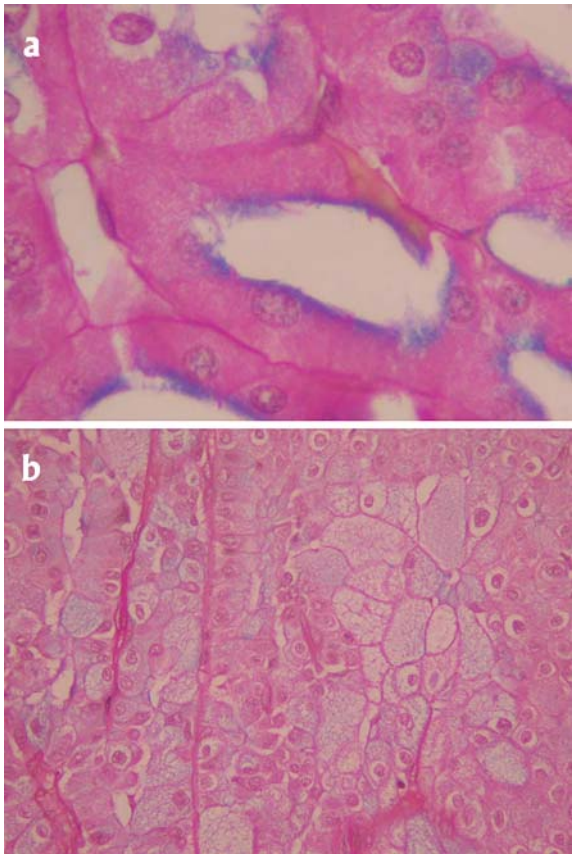

Fig. 4 **a** Apical cytoplasmic staining with Hale's colloidal iron (HCI) in RO (original magnification ×400). **b** Diffuse reticular cytoplasmic staining with HCI in chromophobe renal cell carcinoma (original magnification ×200)

The sensitivity and specificity of apical and/or polar HCI staining for diagnosing ROs from eosinophilic variants of chromophobe RCCs were 69% and 100%, respectively. The sensitivity of apical and/or polar CD63 staining in the HCI false-negative group (11 of 35 ROs) for diagnosing ROs was 82%.

Discussion

Histopathological examination should be the first and the most important step in the diagnostic approach to eosinophilic epithelial renal tumours. Based on our histopathological examination results, entrapped normal-appearing tubules and absence of delicate vascular network are important factors for differentiating ROs from eosinophilic variant of chromophobe RCCs in routine sections, but the interpretation of these two parameters could be difficult in their absence in core biopsies. Thus, additional criteria are required.

It has been shown in some previous ultrastructural studies that the distribution of mitochondria varies among eosinophilic epithelial renal tumour groups [19, 51, 53]. Our results showed that AMA immunostaining could be used to distinguish ROs from eosinophilic variants of chromophobe RCCs. ROs showed predominantly diffuse immunostaining, whereas the eosinophilic variants of chromophobe RCCs showed both peripheral and diffuse immunostaining. The distinctive peripheral immunostaining could be explained by the peripheral distribution of the mitochondria within the cells. In fact, the peripheral immunostaining is related to the cells exhibiting perinuclear clearing and peripheral eosinophilia seen in H & E stained slides. The absence or scarcity of the perinuclear clearing in chromophobe RCCs causes the major limitation of AMA immunostaining, which has a 96% sensitivity and 94% specificity in distinguishing them from ROs. Furthermore, this limitation could be more pronounced in core biopsies. Although the difference between the AMA staining patterns of the ROs and the eosinophilic variants of papillary RCCs was found to be statistically significant, the presence of diffuse cytoplasmic immunostaining in papillary RCCs causes the second limitation of AMA in the differential diagnosis of ROs.

Carrion et al. have recently investigated the CAV1 expression in adult renal tumours including ROs and reported an increased expression of CAV1 in ROs and a decreased expression level among RCC subtypes [11]. They have suggested that ROs could be differentiated from malignant renal tumours by their high CAV1 expression levels [11]. In contrast to their result, we observed increased expression levels of CAV1 in all eosinophilic variants of RCCs. According to our study results, the dominant diffuse immunostaining for ROs and the diffuse and peripheral immunostaining for chromophobe RCCs made the differentiation possible. Our results showed that CAV1 immunostaining localisations could be used to differentiate ROs from eosinophilic variants of RCCs. In addition to the diffuse cytoplasmic CAV1 immunostaining in the eosinophilic variants of chromophobe RCCs, the peripheral cytoplasmic CAV1 immunostaining was also observed in our study. It is this staining localisation that proved useful in differentiating them from ROs. It is interesting to note that the distribution of CAV1 and AMA immunostainings were nearly identical in the tumour groups. With these findings, we suggest that CAV1, which has a 92% sensitivity and a 97% specificity for differentiating chromophobe RCCs from ROs, reacts as a mitochondrial marker and that it has the same diagnostic benefits and limitations of AMA in the differentiation of eosinophilic epithelial renal tumours. These findings could also explain why Carrion et al. [11] observed a decreased expression in the non-eosinophilic variants of RCCs where mitochondria were scanty. The data supporting our results are few, but the accumulation of CAV1 in the modified mitochondria of airway epithelial cells has been reported before and this finding could suggest one of the possible mechanisms of CAV1 for regulating intracellular traffic between mitochondria and cell membrane [27, 40].

Based on our study results, CK14 immunohistochemistry cannot be used in the differential diagnosis of eosinophilic epithelial renal tumours due to small number of tumours showing positive immunoreactivity associated with a mild staining intensity and small stained area. Chu and Weiss studied and reviewed keratin expression in human tissues and neoplasms, and they observed CK14 positivity in many oncocytic tumours [13–15]. They have found that CK14 immunoreactivity could distinguish ROs from its renal mimics [14]. In contrast, Langner et al. have recently reported diffuse weak cytoplasmic staining, and they regarded this reaction as non-specific since they observed a similar reaction with nuclear antigens and other cytokeratins. For this reason, they used the biotin-free EnVision+System, and no immunostaining was observed. They suggested that this staining pattern was due to the presence of endogenous mitochondrial biotin in ROs [24].

We suggest that CD63 can be used in the differential diagnosis of eosinophilic epithelial renal tumours. ROs, by their dominantly apical and/or polar immunostaining, could be differentiated from eosinophilic variants of chromophobe RCCs showing cytoplasmic diffuse immunostaining. Papillary RCCs with an apical and/or polar immunostaining determine the limitation of CD63 in differentiating ROs from eosinophilic variants of papillary RCCs; however, a statistically significant difference was found regarding their cytoplasmic immunostaining localisations. Disperse-irregular cytoplasmic immunostaining of clear cell RCCs could be useful in the differential diagnosis of ROs and clear cell RCCs.

The typical HCI staining is believed to be due to the intracytoplasmic micro-vesicles in chromophobe RCCs [8, 10]. Although ROs were previously found to be negative for HCI, Skinnider and Jones reported the ultrastructural presence of micro-vesicles in ROs showing focal cytoplasmic distribution [44]. However, focal cytoplasmic HCI stainings such as apical, perinuclear and perimembranous localisations have been shown in various studies [16, 44, 52]. In our case, apical and/or polar cytoplasm was the

dominant (68%) HCI staining localisation of ROs. Similarly, Cochand-Priollet et al. reported an apical HCI staining in 89% of ROs [16]. We did not observe any perinuclear HCI staining and perimembranous staining as reported in other previous reports [16, 44, 52].

As mentioned before, HCI staining is related to the presence of micro-vesicles, and it detects polyanionic acid mucopolysaccharide context of these micro-vesicles [8, 9]. The nature of micro-vesicles is still unknown. The correlation of micro-vesicles with endoplasmic reticulum, lysosomes and mitochondria has been questioned, and the mitochondrial origin is mostly suspected [2, 48, 49]. It is noteworthy that CD63 staining localisations were similar to those seen in HCI staining. Our observation may suggest the lysosomal nature of micro-vesicles or a cross-reaction between the mucopolysaccharide content of micro-vesicles and anti-CD63 antibody, which is targeted to lysosomal membrane glycoprotein [32, 43]. However, it is known that acid mucopolysaccharides are degraded in lysosomal vacuoles [20].

In the present study, diffuse cytoplasmic staining of HCI and CD63 is found to be useful in distinguishing chromophobe RCCs from ROs showing an apical and/or polar staining. All apically stained ROs with HCI were also stained apically with CD63. Only nine HCI-negative ROs were CD63-positive with respect to apical staining. Similarly, Skinnider and Jones reported that three HCI-negative ROs contained ultrastructurally intracytoplasmic micro-vesicles [44]. In our opinion, anti-CD63 antibody might detect a small amount of micro-vesicles which were not detected by HCI stain. This could be related to HCI staining, which is known to have some technical difficulties arising from unbalanced pH level in the study solution [52, 55]. Due to the technical problems, a negative HCI result is not reliable, and as it is shown in our study, anti-CD63 antibody sensitivity (95%) is higher than HCI sensitivity (69%). The sensitivity of apical and/or polar CD63 staining in the HCI false-negative group for diagnosing ROs was 82%. Therefore, we recommend CD63 immunochemistry in HCI-negative cases in the differential diagnosis of ROs.

In spite of their high sensitivity and specificity rates, AMA (96 and 94%, respectively) and CAV1 (92 and 97%, respectively), which react as a mitochondrial marker, are not the first markers of choice due to their limitations in the differential diagnosis between ROs and chromophobe RCCs. HCI, with a 69% sensitivity and a 100% specificity, still plays an important role in the absence of some technical problems, but it lacks sensitivity. We advocate that the diagnostic dilemmas arising from these two entities will decrease in many cases by using CD63 alone, which was found to be the marker of choice with a high sensitivity (95%) and specificity (100%).

Acknowledgements This work was supported by the Research Fund of Istanbul University (Project number: T-332/03112003). The authors would also to thank Dr. N. Büyükbabani (Department of Pathology, Istanbul Faculty of Medicine, Istanbul University) for his observations about CD63.

Quantification of clonal hematopoiesis in polycythemia vera

Received: 23 June 2005 / Accepted: 3 July 2005 / Published online: 19 August 2005
© Springer-Verlag 2005

Abstract Polycythemia vera (PV) is believed to represent a clonal trilineage myeloaccumulative hematopoietic disorder. This study was undertaken to estimate for the first time the proportion not only of the neoplastic clone but also of clonal and residual nonneoplastic $CD34^+$ progenitor cells. Chromosomal abnormalities, including trisomy 8 or 9, are phenomena associated in about 20% of PV patients. Therefore, we screened peripheral blood (PB) mononuclear cells of PV patients in the chronic phase of the disease and looked for chromosomal abnormalities performing comparative genomic hybridization. Two of the ten patients revealed cytogenetic changes, including trisomy 8 or 9. To quantify the proportion of cytogenetic abnormal cells in these patients, we applied fluorescence in situ hybridization (FISH) technique on immunomagnetically enriched cell fractions. Ninety percent of the mononuclear cells and up to 79% of PB-derived $CD34^+$ progenitor cells presented three signals for chromosome 8 or 9. The diagnostic value of FISH to detect trisomies in trephine biopsies was then tested in all patients under study. Although the probability to detect FISH signals in a certain section plane is reduced, constantly 10–15% of the cells revealed three signals. Concerning the $CD34^+$ progenitor cell pool, a distinct nonclonal population exists in these patients. Our data underline the stem cell character of PV and additionally quantify the proportion of clonal $CD34^+$ progenitor cells for the first time. The finding of a distinct, not aberrant, $CD34^+$ progenitor cell population in chronic phase PV may offer perspectives in treatment of the disease. Finally, FISH analysis of bone marrow biopsies can be helpful to consolidate diagnosis of early PV.

Introduction

Polycythemia vera (PV) is believed to be a clonal disorder arising in a multipotent hematopoietic progenitor cell that causes the accumulation of morphologically normal red cells, white cells, platelets, and their precursors in the absence of a definable stimulus [26]. However, the molecular basis of PV remains elusive. The hallmark of the disease is trilineage hematopoietic proliferation (panmyelosis) dominated by erythropoiesis [26]. Therefore, most investigations on the pathogenesis of PV have focused on the red cell lineage. Indeed, a peculiarity of PV patients is the reduced serum erythropoietin (Epo) level [6]. The results concerning functional aspects of the erythropoiesis in PV, however, are contradictory. PV erythroid progenitor cells are able to proliferate in vitro in the absence of Epo, but this does not define the limits of the abnormal clone since not all PV erythroid progenitor cells exhibit Epo independence [7]. The existence of several hematologic subpopulations in PV may therefore be speculated, and a quiescent significant proportion of nonneoplastic cells in blood and bone marrow of PV patients cannot be excluded. In several recently published studies, the hypersensitivity of PV progenitors to several growth factors was explained by a point mutation of Janus kinase 2 gene (JAK2), leading to a constitutive activation of this downstream transductor of growth-factor-induced signaling [2, 14, 21]. This point mutation, however, was also seen in other chronic myeloproliferative disorders and, therefore, is not specific for PV.

Although there is no pathognomonic chromosomal abnormality defining PV, consistent, acquired cytogenetic changes, including del(20q), del(13q), trisomies 8 and 9 as well as duplication of 1q, have been observed at diagnosis

[1, 5, 24, 29]. Analysis of genomic abnormalities in individual cells of PV hematopoiesis, therefore, might elucidate the proportion of the neoplastic clone in this disease. In addition, fluorescence in situ hybridization (FISH) analysis on bone marrow trephine biopsies can be helpful for the diagnosis of early PV.

Materials and methods

Patients

Following informed consent, bone marrow trephine biopsies and peripheral blood (PB) derived samples from ten patients with histopathologically determined chronic phase PV (seven males and three females) were gained for diagnostic or therapeutical purpose (phlebotomy). The age of the patients ranged from 42 to 86 years (mean 64). According to the relevant clinical records, the duration of the disease ranged from 0.5 to 10 months. No additional myelosuppressive regimens were administered. The diagnosis of PV was ascertained according to the criteria of the WHO classification. At initial diagnosis, all patients presented hemoglobin values of >18.5 g/dl (in men) and >16.5 g/dl (in women), a thrombocytosis of $>400\times10^9$/l, and low Epo levels. Ten trephine biopsies from patients with lymphoproliferative disorders (without bone marrow involvement) and ten healthy blood donors served as controls.

Blood cell preparation

For FISH analysis, blood samples underwent centrifugation over Ficoll-Paque (Pharmacia, Uppsala, Sweden) to obtain a mononuclear cell concentrate. Selection of $CD34^+$ progenitor cells was performed by immunoaffinity selection, employing an immunomagnetic separation kit (Miltenyi Biotec, Bergisch Gladbach, Germany) as described before [30]. The purified cells were washed three times in phosphate-buffered saline (PBS), swollen in 75 mmol/l KCl at 37°C for 45 min, and then resuspended in ice-cold acetic methanol (1:3) fixative. The nuclei were then washed twice and stored in fixative at −20°C before FISH analysis.

Fixed nuclei were dried onto glass slides and sequentially incubated in solutions of ribonuclease A (Sigma, Dreisenhofen, Germany) at 37°C for 60 min, saline sodium citrate (SSC) for 5 min, pepsin (100 μg/ml, pH 2.0, 37°C; Sigma) for 10 min, PBS (room temperature) for 10 min, and 2× SSC (37°C) for 30 min. The slides were then dehydrated through ethanol solutions (70, 90, and 100%) and dried before denaturing in formamide (70% in 2× SSC and sodium phosphate buffer, 50 mmol/l, pH 7.0; Fluka) under coverslips on a hot plate at 73°C for 1 min. The slides were washed in 2× SSC, dehydrated through the ethanol solutions, and dried.

Preparation of the bone marrow biopsies

Bone marrow biopsies were transferred in buffered fixative (pH 7.4) containing 0.5% glutaraldehyde and decalcificated overnight in ethylenediaminetetraacetic acid (EDTA; 10% w/v in Tris pH 7.4). For phenotypic evaluation, 4-μm paraffin-embedded sections of trephine biopsies were dewaxed through xylene, air-dried, microwave-heated in appropriate buffer (100 mM Tris/50 mM EDTA, pH 7.0) for 12 min, cooled, and rinsed twice in Tris–HCl/0.05% Tween 20 buffer (pH 7.6) at 4°C. Subsequently, immunostaining with CD34 (QBEND10, Dako, Hamburg, Germany) or glycophorin C (Dako) monoclonal antibodies was performed by the alkaline phosphatase–antialkaline phosphatase method. Bromochloroindolylphosphate and nitro blue tetrazolium (Sigma) were used as chromogenic substances. Following preparation for FISH was performed as described before [31]. Briefly, samples were dehydrated through graded ethanol solutions, air-dried, and permeabilized by microwave treatment, followed by enzymatic digestion (proteinase K, Sigma). After this procedure, slides were quickly dehydrated and air-dried.

Fluorescence in situ hybridization

Fluorophore-labeled alpha-satellite DNA probes specific for the centromere of chromosomes 8 or 9 (Abbott-Vysis, Bergisch Gladbach, Germany) from all patients under study as well as the controls were placed on the coverslips. In case of the trephine biopsies, slides were incubated at 94°C for 3 min on a hot plate. After denaturation, the slides were quickly brought to 37°C, sealed with rubber cement, and then placed in a humified box for 16 h at 42°C. Coverslips were removed, and slides were placed in 0.4× SSC at 73°C for 2 min, immersed in 2× SSC/0.01% NP40 at room temperature for 1 min, and then air-dried before mounting in 0.125 μg of 4′-6′-diamidine-2-phenylindole dihydrochloride (DAPI)/ml antifade (DAPI II, Vysis). Slides were evaluated with an Aristoplan microscope (Leitz, Wetzlar, Germany), equipped with an optimized triple-bandpass filter, and imaged by digital camera (Photometrics, SenSys, Tucson, AZ, USA) and appropriate software (IPLab Spectrum P, Vienna, VA, USA).

Specimens were evaluated using fluorescence microscopy by two observers independently of each other. The percentage of nuclei bearing one, two, or three signals for each probe was determined from counts of 200 nuclei concerning the mononuclear cells and the immunomagnetic enriched $CD34^+$ progenitor cells and all cells bearing signals concerning the bone marrow slides.

Comparative genomic hybridization

DNA of mononuclear cells was extracted by standard methods. Samples of DNA were subsequently labeled using

digoxigenin-11-dUTP (normal DNA) or biotin-16-dUTP (test DNA) by nick-translation, according to the supplier's protocol (Roche, Mannheim, Germany). Comparative genomic hybridization (CGH) probes were prepared by co-precipitating gender-matched digoxigenin-1-dUTP normal DNA (1 μg), biotin-16-dUTP test DNA (1 μg), cot-1-DNA (100 μg, Gibco Life Technologies, Paisley, Scotland, UK), and salmon sperm DNA (11 μg, Roche) using 0.1- and 2.5-fold volumes, respectively, of sodium acetate and ethanol at −80°C followed by centrifugation at 4°C. The DNA pellets were dried, dissolved in 10 μl of hybridization buffer (50% v/v formamide, Fluka; 10% w/v dextran sulfate, Sigma, in 4× SSC), denaturized at 73°C for 5 min, and preannealed at 37°C for 60 to 120 min. CGH target metaphase slides, prepared using acetic acid methanol (1:3) fixed phytohemagglutinin-stimulated normal male lymphocytes, were denaturized in formamide (70% v/v in 2× SSC) at 75°C. The CGH probe was applied to the CGH target slide, sealed under a coverslip and the slide incubated at 37°C for 72 h. Posthybridization washes consisted of 0.3% v/v NP40 (Merck) in 0.4× SSC at 74°C for 2 min followed by 0.1% v/v NP40 in 2× SSC at room temperature for 1 min. For the signal detection, probes were incubated with 30 μl fluorescein isothiocyanate (FITC) conjugated avidin and TRIC-conjugated anti-digoxigenin for 30 min and 37°C (both from Oncor, Gaithersburg, MD, USA). The slides were then mounted under a DAPI-containing medium (Vector Laboratories) and subsequently analyzed using a Power Macintosh G3 and the Quips Genetics Workstation (IPLab Spectrum Imaging Software). Fluorescence and DAPI images were captured from as many as 19 meta-

phases per slide for the generation of composite CGH profiles. Chromosome classification was validated by two authors. Deletions and amplifications were suspected when the slide average green/red fluorescence ratio for a given chromosomal region lay outside the range 0.7 to 1.2. Telomer regions, X and Y chromosomes, were excluded from analysis.

Results

Comparative genomic hybridization analysis of peripheral blood mononuclear cells

PB mononuclear cells from ten PV patients and the controls were tested for chromosomal aberrations. Evaluation of 15 to 19 metaphases per slide for fluorescence and DAPI images and generation of composite CGH profiles revealed abnormal pictures in CGH analysis in two of ten patients (cases 1 and 2) and in none of the controls. Both cases presented complex chromosomal aberrations, including gain of material from the centromere region and the q arm of chromosome 9 (Fig. 1a; case 1) or gain of material from the whole of chromosome 8 (Fig. 1b; case 2). Concerning the other eight patients, no chromosomal aberrations were observable. The CGH data were then compared with FISH analysis for centromere region of chromosomes 8 and 9.

Fluorescence in situ hybridization analysis of peripheral blood mononuclear cells

FISH analysis from the PB mononuclear cells from the same ten patients and the controls were undertaken to prove CGH results. As summarized in Table 1, PB mononuclear cells of both CGH-positive cases revealed 91% (case 1) and 86% (case 2) triple FISH signals for centromeres 9 and 8, respectively (Fig. 2a). Concerning the CGH-negative patients and the healthy controls, no triple but 90 to 95% double signals were observed. These findings underline the excellent specificity and good sensitivity of the tests. When analyzing the CD34$^+$ progenitor cells of the above-mentioned cases, the fraction of triple FISH signals was diminished with 79% (case 1) and 62% (case 2), compared to the findings in mononuclear cells (Fig 2b). The CGH-

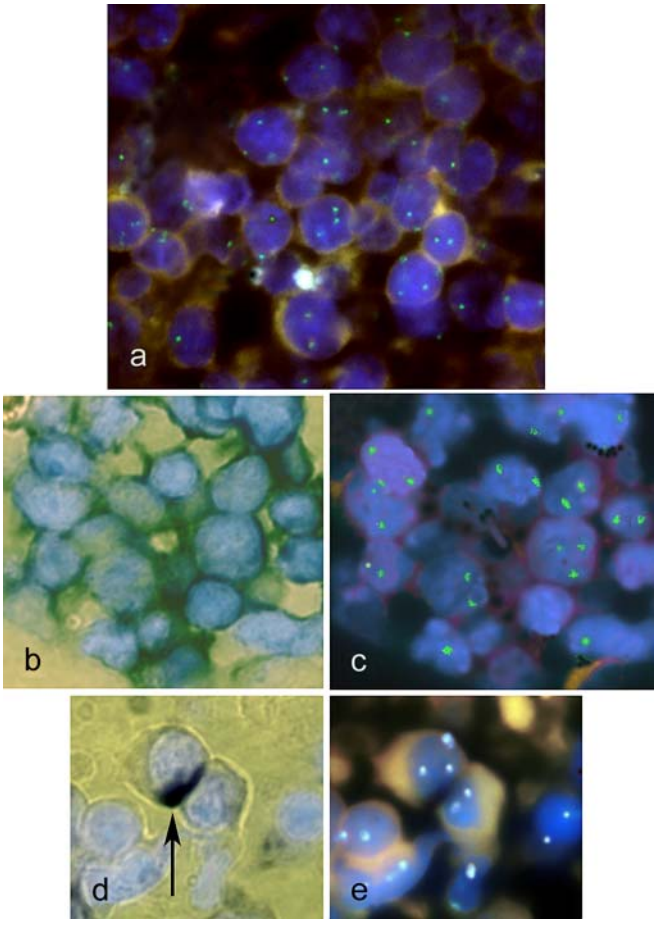

Fig. 3 Representative areas from bone marrow trephine biopsies. **a** and **e** FISH assays for centromere 8 (case 2). **d** Same area of case 2 with one CD34$^+$progenitor cell (*arrow*), CD34 immunostaining. **c** FISH assay for centromere 9 (case 1) of a selected erythrone. **b** Same area of case 1 with strong glycophorin C immunostaining of the erythropoietic precursor cells

negative cases presented the same distribution of FISH signals for $CD34^+$ progenitor cells as for mononuclear cells.

Fluorescence in situ hybridization analysis of bone marrow trephine biopsies

Of the above-mentioned ten patients and the controls, FISH analysis from 4-μm-thick bone marrow slides were performed to test the probability for triple signals in individual hematopoietic cells. Corresponding to the results of the mononuclear cell fractions, none of the CGH-negative cases presented FISH data indicating trisomy 8 or 9. However, in cases 1 and 2, a small but distinct cellular subgroup (12 and 18%; Fig. 3a) bared three signals for chromosome 9 or 8, respectively. In addition, the proportion of two signals per cell was higher in this group, compared with the CGH-negative fraction.

In a second approach, immunohistochemistry was followed by FISH analysis (Fig. 3b–e). Assisted by photographic documentation of the same area of the biopsy in different types of light, phenotype and genotype of individual cells were ascertained. In this experiment, three signals in glycophorin-C-positive erythropoietic cells as well as in $CD34^+$ progenitor cells could be demonstrated. Again, in the CGH-positive cases, $CD34^+$ progenitor cells presented lower levels of triple signaling (6–8%), compared to the overall hematopoiesis (12–18%), and, con cerning the erythropoiesis as well, slightly reduced levels of triple signaling were found (Table 1).

Discussion

When clinical features are suggestive for PV, assays for Epo and erythroid colony-forming cells, bone marrow trephine biopsies, and clonality assays can strongly support the diagnosis [9, 18, 26]. Analysis of X chromosome inactivation patterns, however, is reserved to female patients and may lead to false positive results because some normal elderly women present X chromosome inactivation patterns indistinguishable from those seen in patients with clonal myeloproliferative disorders [8, 10, 11]. Acquired karyotypic abnormalities, being direct markers of clonally transformed cells, are potentially more reliable for diagnostic purposes, but only 34% of PV patients have an abnormal karyotype revealed by conventional cytogenetic techniques [3, 13]. Among them, trisomies 8 and 9 or deletion of chromosome 20 represent the most frequent aberrations [5, 24, 29]. Although not specific for PV, cytogenetic conversion in one case treated with interferon alpha and clinical remission of the disease [23] indicates that the neoplastic cell fraction comprises the karyotypic abnormal cell clone. In this situation, analysis of frequent chromosomal aberrations might help to quantify the neoplastic clone proportion in PV hematopoiesis, even if above-mentioned aberrations in PV are characterized as secondary genetic changes [20].

CGH technique is a cytogenetic screening method with moderate sensitivity and excellent specificity (25% abnormal cells are necessary for correct diagnosis); it requires interphase cells and, therefore, can be applied on viable cells as well as fixed material [17, 22]. The diagnostic utility of this method applied to PV blood granulocytes has already been tested [28]. FISH analysis requires preknowledge of the abnormality to select the appropriate probes. Combined with immunohistochemical analysis, FISH technology allows the identification of single neoplastic cells and, therefore, the proper affiliation to a certain cell fraction. Altogether, this methodological approach is able to answer the question whether and to which extent clonal hematopoiesis in PV dominates residual reactive hematopoiesis and whether there are differences between the certain cell lineages.

The two cases presenting gain of material in CGH concerning chromosome 8 or 9 offered three signals in most PB mononuclear cells performing FISH. This finding as well as the result of 90–95% cells baring two signals in the CGH-negative patients indicates the high sensitivity of FISH. Further, the lack of triple signals in the CGH-negative cases demonstrates the high specificity of this method.

In detail, our data demonstrate a proportion of 86–91% clonal PB-derived mononuclear cells in contrast to 62–79% PB-derived $CD34^+$ cells. In this context, it is necessary to mention that the possibility that $CD34^+$ endothelial cells were taken into account, despite the different morphology of both cell types, cannot be ruled out. However, this difference might also be due to the fact that nonneoplastic primitive $CD34^+$ progenitor cells survive by being quiescent and not proliferating. Probably depending on an ill-defined effect already described in chronic myelogeneous leukemia (CML) [4], the microenvironment in the bone marrow seems to support neoplastic hematopoiesis, thus leading to a dominance of the clonally transformed cell fraction in the more differentiated hematopoietic cell pool of PV. Our data for the first time prove considerable contribution of $CD34^+$ progenitor cells in the neoplastic cell clone in PV. In view of the fact that until now many investigations on PV were undertaken on granulocytes [25, 27], these results indicate that further investigations on molecular pathogenesis of this disease should focus on this $CD34^+$ progenitor cell fraction. The detailed quantification of the $CD34^+$ progenitor cell fraction might further offer important data for potential further therapy strategies in PV.

To analyze the value of FISH technique for diagnosis of early PV examination of bone marrow, biopsies from CGH-tested patients was undertaken to find out whether chromosomal aberrations, especially gain of chromosomal material in the centromere region 8 or 9, could be detected. In this context, it is noteworthy to emphasize that the probability to identify three signals per cell is much lower in the 4-μm-thick sections than in cell smears. The excellent specificity of the test and the finding of 10% genotypic aberrant cells in all CGH-positive cases demonstrate that FISH indeed may facilitate PV diagnosis in chromosomal aberrant cases. Our results further indicate

the affiliation of the erythropoiesis and the $CD34^+$ progenitor cell pool to the neoplastic cell fraction.

A point mutation of JAK2 leading to a constitutive activation was recently described for a certain proportion of PV patients as well as for other Philadelphia chromosome negative chronic myeloproliferative disorders [2, 14, 15, 19, 21]. However, according to the most recently published results, the incidence of JAK2 mutations reveals a significant range of about 65 to 97% in PV. Taking this genomic aberration into account, more detailed information about the distribution of the neoplastic cell clone as well as the dynamics following cytoreductive therapy will now be available and will give more insights in the biology of PV and further provides a means for molecularly targeted therapeutic strategies [12, 16].

MMP-21 is upregulated at early stages of melanoma progression but disappears with more aggressive phenotype

Abstract The expression of matrix metalloproteinases (MMPs) is frequently altered during malignant transformation. We examined the profile of three recently cloned MMPs, MMP-21, MMP-26, and MMP-28, in melanomas in vivo and in culture. Immunohistochemistry for MMPs-21, -26, -28, and -13 in melanoma specimens (27 non-metastatic, 26 with nodal micrometastases, and 10 in situ melanomas) from 63 patients was performed. MMP-21 was expressed in melanoma cells in 29/53 cases, being more frequent in melanoma samples without micrometastases. Six out of ten in situ melanomas were positive, while five nevus samples were negative. MMP-26 and -28 were not generally expressed in melanoma cells. MMP-13 was detected in melanoma cells in 36/53 samples. MMP-21 was not found in sentinel nodes with metastases, while MMP-13 was seen in all of them. MMP-21 messenger RNA was variably expressed in all five melanoma cell lines investigated using reverse transcriptase–polymerase chain reaction. Our results suggest that expression of MMP-21 may serve as a marker of malignant transformation of melanocytes and does not associate with the presence of micrometastases.

Introduction

Cutaneous melanoma is a tumor with significant metastatic potential, the incidence of which has increased significantly over the last two decades. The prognosis of melanoma has historically been based on histological criteria, mainly tumor thickness [7] and the level of invasion [9]. Other prognostic factors include mitotic rate, increased nuclear volume, satellite deposits, and hemangiolymphatic invasion [31]. These criteria have been further supplemented by tumor ulceration and sentinel lymphadenectomy to gain a new, more accurate staging system. According to the recent staging recommendations by the American Joint Committee on Cancer (AJCC), tumor status in melanoma is based on thickness, ulceration, and the number of metastatic lymph nodes [5]. Lymphatic mapping and sentinel lymphadenectomy were created as minimally invasive techniques to provide regional lymph node staging information for patients at high risk for metastatic melanoma. Sentinel lymph node status has become the most significant prognostic factor for patients with melanoma [27].

The invasion of melanomas from the epidermis to the dermis requires degradation of several basement membrane (BM) components. Matrix metalloproteinases (MMPs), a family of 23 human structurally related zinc-dependent endopeptidases, are collectively capable of degrading all extracellular matrix and BM proteins [23]. However, MMPs also regulate angiogenesis and apoptosis as well as cleave growth factors, cytokines, chemokines, and their receptors

and therefore regulate growth factor response and inflammation [10]. We and others have previously shown that several MMPs are overexpressed in melanoma cells in vitro and in vivo [4, 12]. MMP-2 and MT1-MMP have a prominent role in melanoma progression [12, 16]. Induction of MMP-1 and -13 messenger RNA (mRNA) expressions is a late event in melanocytic tumor progression and correlates with the level of invasion [4], while MMP-9 is involved in the early steps of metastasis formation [11]. Furthermore, MMP-1 and MMP-2 have been shown to be prognostic markers in melanoma [24, 30]. Synthetic MMP inhibitors and adenoviral therapy using them have been demonstrated to inhibit the metastatic spread and growth of melanoma in mice [3, 8]. Analogously, new therapies designed to interfere with specific MMP actions may be useful in the treatment of melanoma.

We have recently studied the role of several novel MMPs, such as MMP-19, -26 (matrilysin-2), and -28 (epilysin), in skin cancer [13, 28]. Unlike most classical MMPs, they seem to be downregulated in poorly-differentiated tumors. Furthermore, our group has recently cloned a novel MMP, MMP-21, from placental complementary DNA (cDNA) library [2]. It is expressed in a variety of normal, malignant, and fetal epithelial tissues and might play a role in human embryogenesis and tumor progression [1]. Its physiologic activators or substrates are not yet known. The objective of this study was to examine the expression profiles of three recently cloned MMPs, MMP-21, MMP-26, and MMP-28, in melanomas in vivo and in culture, correlating the findings with lymph node status as determined by sentinel node biopsies. MMP-13 was studied based on previous reports on its expression and prognostic significance in melanoma.

Materials and methods

Tissue samples

The melanoma specimens were routinely formalin-fixed, paraffin-embedded histological material from 63 cases (10 in situ melanomas and 53 invasive melanomas), of which all invasive melanoma patients had undergone lymphatic mapping and sentinel node biopsies at the Helsinki University Central Hospital, during the years 2001 to 2003 (Table 1). Five additional benign nevi and seven sentinel node positive and 12 sentinel node negative lymph nodes obtained from these 63 patients were also analyzed. The study was approved by the corresponding Hospital Ethical Committee. Lymph node micrometastases were detected by hematoxylin–eosin, MART-1, and tyrosinase immunostainings. There were 21 females and 32 males in the invasive melanoma study group, and their average age at diagnosis was 65 years (range 36–87) (Table 1). Invasion levels of the melanomas were determined by Clark's classification [9], and node classification was performed according to Balch et al. [5]. Tumor thickness was measured according to Breslow [7]. The samples included 2 Clark's grade II, 14 grade III, 34 grade IV and 2 grade V malignant melanomas. Mean Clark value was 3.7 and mean Breslow was value 3.1. Twenty-seven samples were from nonmetastatic melanoma, and 26 were from melanomas with nodal micrometastasis (Table 1).

Immunohistochemistry

Immunohistochemical stainings were performed using the Streptavidin–biotin–peroxidase complex technique (DAKO StreptABComplex/HRP Duet, Mouse/Rabbit, Glostrup, Denmark). The following antibodies were used: MMP-13 (1:10, Clone VIIIA2, Labvision Corporation, Fremont, CA, USA), MMP-21 (1:300, RP3MMP-21, Triple Point Biologics, Forest Grove, OR, USA) [1], MMP-26 (1:150, kindly provided by Keiichi Isaka, Tokyo Medical University, Tokyo, Japan) [14], and MMP-28 (1:800, kindly provided by Dr. Jouko Lohi) [18]. Pretreatment included incubation in a +95°C water bath for MMP-13 and MMP-26 and microwaving in citrate buffer for MMP-28. Aminoethylcarbazole (AEC) was used as chromogenic substrate, and tissues were counterstained with hematoxylin. The slides were analyzed by two investigators (SV, US-K) experienced in dermatopathology, and positive immunostaining was scored semiquantitatively (0=under 10 positive cells, 1=10–100 positive cells, 2=over 100 positive cells) (Table 1).

Cell cultures

Melanoma cell lines Bowes, G361, WM852, WM164, and WM165 were cultivated in Dulbecco's modified Eagle's medium/F-12 (D-MEM/F-12) (Gibco BRL, Gaithersburg, MD, USA), containing 10% heat-activated fetal bovine serum (FBS), 2 mM L-glutamine, 100 IU ml^{-1} penicillin, 50 mg ml^{-1} streptomycin, 0.1 μg ml^{-1} cholera toxin, and 3 ng ml^{-1} fibroblast growth factor-2 (FGF-2) at 37°C in humified atmosphere of 5% CO_2 and 95% air. The medium was changed twice a week.

Polymerase chain reaction and RNA analysis

Total cellular RNA from cultured cells was extracted using Rneasy Miniprep-kit (Qiagen, Chasworth, CA, USA) according to manufacturer's instructions. RNA was then reverse-transcribed to cDNA with Taqman Reverse Transcription reagents (Applied Biosystems) with random hexamers and used in a 1:5 dilution as a template for reverse transcriptase–polymerase chain reaction (RT-PCR). As primers, we used T21F (forward nucleotides) and T21R (reverse nucleotides) for human MMP-21 (Sigma Genosys, Cambridge, UK) [1]. TaqMan PCR primers and probes for human MMP-26 were purchased as a ready-to-use 20× reaction mix, and the sequences are property of the vendor (Applied Biosystems). MMP-28 primers (Sigma Genosys) and probes (PE Biosystems, Warrington, UK), described in more detail in our previous work [28], were designed using

Immunohistochemical positivity for MMPs was evaluated under bright-field microscopy
The number of AEC positive cells was assessed as follows: 0= under 10 positive cells, 1=10–100 positive cells, 2=over 100 positive cells
Nd Not determined

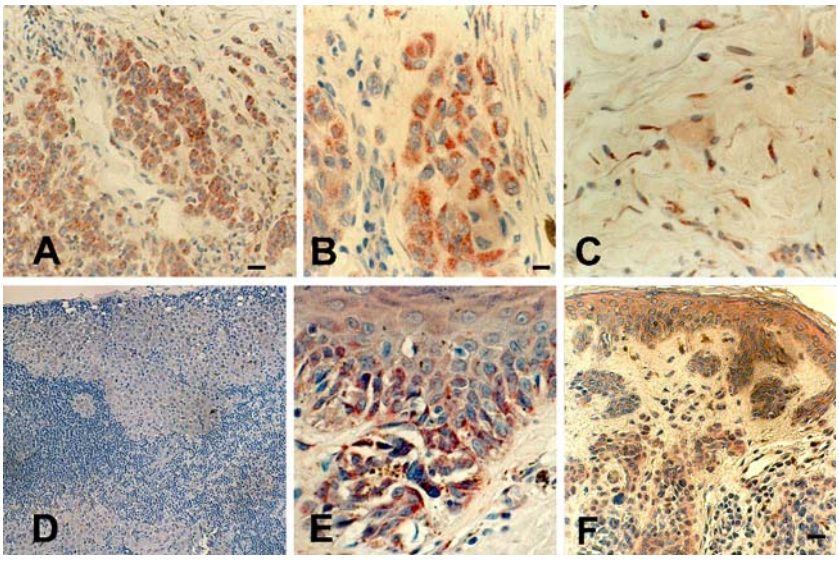

Fig. 1 MMP-21 in melanoma. **a** MMP-21 protein is expressed in melanoma cells of a node negative tumor. **b** Higher magnification of MMP-21 positive melanoma cells. **c** MMP-21 protein was also detected in a subset of melanomas in fibroblasts surrounding melanoma islands. **d** No staining for MMP-21 is detected in a positive sentinel node. **e** MMP-21 was also detected in melanoma cells of in situ melanomas. **f** Nevus samples did not express MMP-21. *Scale bars*: 50 μm (**a** and **f**), 12.5 μm (**b**, **c**, and **e**), 125 μm (**d**)

computer program Primer Express (PE Biosystems). Human glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an endogenous control. The PCR for MMPs-21, -26, and -28 was performed by conventional PCR in separate reactions. The primers were used in a final concentration of 200 nM each (T21F, T21R, GAPDH forward, and GAPDH reverse), 400 μM of each nucleotide, 0.5 μl Advantage-2, 5.5 mM $MgCl_2$, and 3 μl of cDNA-template in a 75-μl reaction. The PCR was started with an initial denaturation of 3 min at 94°C, followed by a total of 40 cycles of 30-s denaturation at 94°C and 30 s of annealing at 60°C, and 30 s of elongation at 72°C followed by 10-min final elongation at 72°C. Finally, PCR products were analyzed in 2.5% agarose gel and stained with 5 ng/ml of ethidium bromide and visualized under ultraviolet light.

Statistical analysis

Chi-square test was performed to compare the number of MMP-21 and -13 positive and negative samples in sentinel node negative and positive patients. The medians of Breslow values of MMP-21 positive and negative melanoma patients as well as the medians of numeric ratings of positivity for MMP-21 and -13 in the sentinel node positive vs negative groups were compared using unpaired two-tailed *t* test. *P* value under 0.05 was considered as significant.

Results

Immunohistochemistry MMP-21 protein was expressed in invasive melanoma cells in 29/53 of the cases (Fig. 1a,b) and in 6/10 in situ melanomas (Fig. 1e). Its expression was more frequent in melanoma samples without nodal invasion (Table 1): 18/27 of the cases without micrometastases and 11/26 with micrometastases in invasive melanoma were positive for MMP-21. No correlation of MMP-21 expression to the presence of ulceration was detected (Table 1). MMP-21 was also expressed by fibroblasts surrounding the melanoma islands in some samples but not by keratinocytes or endothelial cells (Fig. 1c). None of the 19 metastatic or nonmetastatic sentinel nodes examined expressed MMP-21 (Fig. 1d). Five compound nevi samples were immunostained for MMP-21, and they were all negative (Fig. 1f).

Twenty-one melanoma samples and five nevus samples were immunostained for MMP-26. They all turned out to be negative except for fibroblasts surrounding the tumor in a few specimens (Fig. 2a) and for occasional basal keratinocytes bordering ulcerations (data not shown).

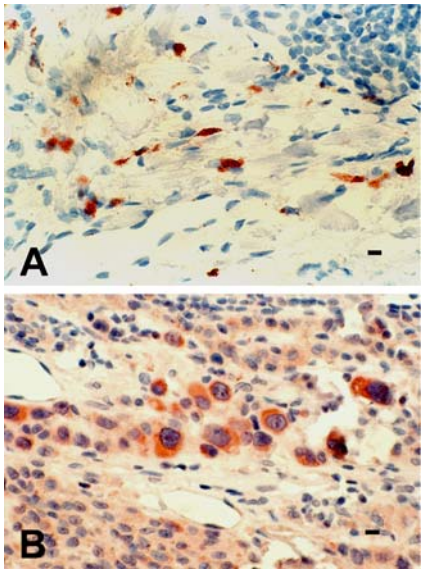

Fig. 2 MMP-26 and MMP-28 in melanoma. **a** MMP-26 was not detected in melanoma cells but occasionally in fibroblasts surrounding the tumor. **b** Staining for MMP-28 in melanoma cells. *Scale bars*: 25 μm (**a** and **b**)

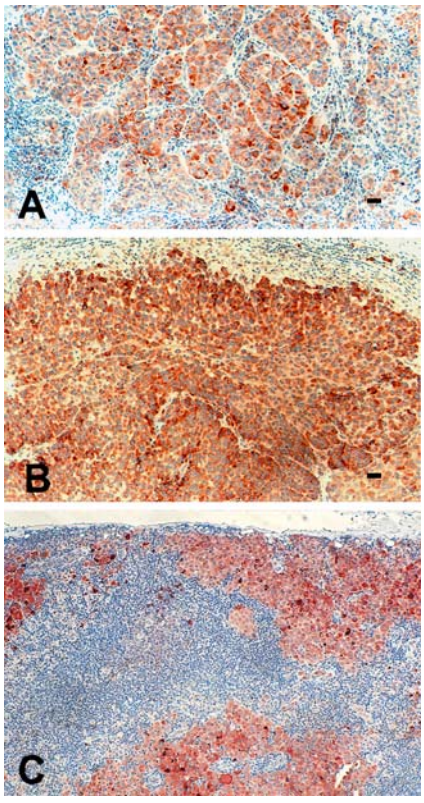

Fig. 3 MMP-13 in melanoma cells. **a**, **b** Immunostaining for MMP-13 in melanomas without (**a**) and with (**b**) micrometastasis. **c** Staining for MMP-13 in a positive sentinel node. *Scale bars*: 50 μm (**a** and **b**), 125 μm (**c**)

Thirty-six invasive melanomas and ten in situ melanomas were immunostained for MMP-28, and expression in melanoma cells was found in only five of them (Fig. 2b). Micrometastases were detected in 2/5 MMP-28 positive melanoma samples. All of the seven positive melanoma metastases were immunostained with MMP-28, and two of them showed a small number of positive melanoma cells. All five compound nevi were devoid of MMP-28 protein. Keratinocytes, endothelial, or macrophages did not express MMP-28.

MMP-13 was detected in melanoma cells in 39/53 samples in invasive melanoma (Fig. 3a,b). Nineteen out of twenty-seven of the cases without micrometastases and 20/26 with micrometastases were positive for MMP-13. There were no statistically significant differences between MMP-21 and MMP-13 positive and negative groups when their Breslow values were compared, respectively. All metastatic sentinel lymph nodes expressed MMP-13 (Fig. 3c), whereas none of the 12 nonmetastatic sentinel lymph nodes expressed MMP-13.

Cell cultures To study whether melanoma cells are able to express any of the three novel MMPs in culture, five melanoma cell lines were studied. MMP-21 was clearly expressed by RT-PCR in Bowes and ML852 melanoma lines, while lower levels were apparent in WM164, WM165, and G361 cells (data not shown). MMP-26 mRNA was detected only at low levels in ML852 and WM165 cells (data not shown). A very low level of MMP-28 was detected in WM165 cells, while all other cell lines turned out negative (data not shown).

Discussion

To our knowledge, this is the first report examining the correlation of expression of several MMPs to sentinel node status of melanoma patients and particularly the expression of MMPs-21, -26, and -28 in melanoma in vivo. Here, we demonstrate that MMP-21 can be expressed by melanoma cells in tissue and in vitro. Expression was more frequent in nonmetastatic melanoma samples, suggesting that MMP-21 is upregulated at early stages of melanoma progression. This is further supported by our negative findings in metastatic sentinel nodes. MMP-21 was present already in in situ melanomas but not in nevus cells. Thus, MMP-21 could possibly serve as a marker of malignant transformation in melanocytes. However, a larger sample set of various stages of melanoma would be required to finally confirm this. Furthermore, our immunohistochemical approach cannot differentiate between latent and active MMP-21 which would require conventional or in situ zymography but would lead to difficulties in determining the cells of origin of MMP-21 on tissue level.

Human MMP-21 is expressed in developing but not in normal adult skin [1]. Furthermore, its expression has previously been associated with aggressive dedifferentiated subtypes of squamous cell cancer, but it is not upregulated by mere keratinocyte hyperproliferation or wound repair [1]. MMP-21 is upregulated at least in keratinocytes by transforming growth factor beta 1 (TGF-β1) [1]. Interestingly, TGF-β1 is also known to modulate melanoma growth and survival [6] and may thus be a potential candidate to upregulate MMP-21 in melanomas in vivo as well. Based on its promoter analysis, MMP-21 is a direct target of beta-catenin transactivation [19]. Indeed, alterations of beta-catenin pathway have been reported in melanoma [15].

MMP-26 (endometase or matrilysin-2) is a rather novel MMP originally found in normal placenta and endometrium [17, 26, 29] but is also widely expressed in malignant tumors, such as endometrial, prostate, breast, and oral squamous cell cancers, and tumor cell lines [14, 21, 32]. We did not detect MMP-26 in melanoma cells in vivo. However, in vitro, two metastatic melanoma cell lines (WM165, ML852) expressed MMP-26. This discrepancy is often seen in the context of MMPs, which are generally expressed by cancer cell lines in vitro, but are not detected necessarily in corresponding tissue in vivo. While this study was in progress, Li et al. [17] reported the expression of MMP-26 by several melanoma cell lines in culture using immunohistochemistry and its correlation with estrogen dependency. We also detected MMP-26 occasionally in fibroblasts surrounding melanoma cell islands. This is in agreement with a recent report demonstrating MMP-

26 in corneal fibroblasts [20] and may be related to contribution of host-derived proteases to tumor progression.

Epilysin (MMP-28) was first cloned from human keratinocyte and testis cDNA libraries [18] and a lung cDNA library [22]. MMP-28 is expressed in various carcinomas, including ovarian, colon, and pancreatic adenocarcinoma [22], and also by proliferative keratinocytes during wound repair [18, 28]. Since 41/46 melanomas were negative in vivo for MMP-28 and the cell lines in culture turned out almost negative by RT-PCR, we conclude that this protease does not play an important role in the biology of melanoma. Our results on negative MMP-26 and -28 expressions in G631 melanoma cells agree with those recently published by Nuttall et al. [25].

Our earlier investigations suggest that MMP-13 expression is induced during melanoma progression [4]. This agrees with the current results showing that MMP-13 is generally present in metastatic melanoma cells of positive sentinel nodes. High expression of MMP-13, unlike that of MMP-1, in melanomas does not, however, correlate with survival parameters but is associated with the presence of visceral metastases [24].

In conclusion, our results show that upregulation of MMP-21 may serve as a marker of malignant transformation of melanocytes and is associated with initial stages of tumorigenesis rather than with micrometastases and poor outcome. While MMPs-26 and -28 are not generally expressed in melanomas in vivo, the presence of MMP-13 positive cells may correlate to more aggressive disease.

Acknowledgements We thank Dr. Jouko Lohi, University of Helsinki, for MMP-28 and Prof. Keichi Isaka, Tokyo Medical University, for MMP-26 reagents and Mr. Sakari Maatta and Ms. Alli Tallqvist for skillful technical assistance.

Claudin expression in Barrett's esophagus and adenocarcinoma

Received: 26 May 2005 / Accepted: 18 July 2005 / Published online: 30 August 2005
© Springer-Verlag 2005

Abstract Claudins (CLDNs) are key molecules in cell adhesion, polarity, and control of paracellular solute transport. Several studies suggested that changes in claudin pattern have a role in cancer development. This study aimed to detect alterations in CLDN 1, 2, 3, 4, and 7 expression patterns in Barrett's esophagus (BE) and adenocarcinoma (ACC) compared with that in foveolar epithelium (FOV), normal squamous epithelium (SQ), and squamous cell carcinoma (SQCC). One hundred twenty five surgically or endoscopically removed, paraffin-embedded cases were studied by immunohistochemistry and analyzed statistically. BE, ACC, and FOV were dissected from 30 paraffin-embedded samples for further mRNA expression analysis. CLDN 7 was the dominating type in all epithelia and carcinomas, but its expression did not differ in normal and altered tissues. CLDN 1 expression was significantly increased in SQCC compared with that in SQ. CLDNs 3 and 4 were significantly elevated both in BE and ACC compared with that in FOV. CLDN 2 expression increased significantly in ACCs compared with that in BE. This is the first report proving similarities and differences regarding claudin expression pattern in BE and ACC compared with that in FOV and SQ. Our data prove a close link in CLDN pattern between BE and ACC, adding further evidence that BE is an alteration preceding esophageal ACC.

Introduction

The incidence of adenocarcinoma (ACC) of the esophagus has shown a rapid increase in the past few decades with a rate of 5–10% per year in the industrialized Western world [3, 5, 18, 25]. Since these tumors have poor prognosis, early detection and treatment are of special importance [25]. It has been proven that ACC of the distal esophagus almost always originates from epithelium that has undergone glandular metaplasia, the so-called Barrett's esophagus (BE) [10, 25].

A number of studies have characterized the biology and carcinogenetic pathways in BE using immunohistochemical and molecular biological methods [2, 9, 17, 18, 32, 36, 39–41], and there are also data related to cancer progression and survival [17].

The definition of BE has changed in the past 50 years from the macroscopically defined lesion to the present criteria [25]. It is now accepted by most authors that BE denotes a precancerous lesion where the normal squamous epithelial lining of the distal esophagus is replaced by specialized intestinal metaplasia (SIM) [25]. ACC develops in BE through a multistep sequence of molecular alterations [18], the understanding of which might allow improvement of diagnosis and better management of the disease [2]. It has been shown that altered cadherin and

catenin complexes correlate with disease progression and differentiation in the BE–dysplasia–ACC sequence [2].

Cell adhesion plays an important role in cancer development and progression [12, 15, 27]. Claudins (CLDNs), the recently identified multigene transmembrane protein family, are thought to be the major constituents of tight junctions (TJ), the most apical components of cell sealing complexes responsible for cell–cell adhesion, cell polarity, and control of paracellular ion transport [7, 22, 33]. Several recent studies have detected changes in claudin expression during carcinogenesis, as in cervical neoplasia [35], breast [16, 38], ovarian [11], pancreatic [23, 26], colorectal [24, 31], prostate [21], and other cancers. TJ proteins have even been suggested as potential antibody targets for pancarcinoma therapy [27].

The aim of the present study was to characterize the expression pattern and changes of different claudins in BE and ACC as well as to draw comparison with the foveolar epithelium (FOV; cardiac type) and with normal and neoplastic squamous epithelia. Based on our previous studies on other tissues and tumors [35, 38], it is likely that certain claudin patterns characterize the different types of glandular/columnar epithelia. Specific changes in claudin expression are anticipated during tumorous transformation. Progression through the metaplasia–carcinoma sequence may well be reflected in the changes in cell–cell contacts influenced and characterized by the TJ proteins.

Materials and methods

Tissue blocks of 125 cases were taken from surgically removed tissues and biopsies including esophageal squamous cell carcinoma (SQCC) (25 cases), BE (25 cases), and ACC (25 cases), with the permission of the Regional Ethical Committee of the Semmelweis University of Budapest (#172/2003). Twenty-five cases of normal esophageal squamous epithelia (SQ) from the distal third of the esophagus obtained from individuals who died unrelated to esophageal or gastrointestinal diseases were used for comparison. The interval between death and tissue fixation was 6 to 12 h. Further 25 biopsy specimens were also included in the study, diagnosed as FOV of the cardiac type without intestinal metaplasia, sampled by endoscopy due to macroscopic alterations. Thirty paraffin-embedded samples were chosen for further molecular biological analysis and dissected for specialized intestinal metaplastic areas of BE, ACC, and FOV components (10–10 cases from each group) then followed by total RNA isolation and mRNA expression analysis.

The age range of the SQCC cases was 48–75 years (mean 60.6), 46–63 years for the ACC (mean 52.0), 58–67 years for the BE (mean 63.2 years), and 16–75 years for the control cases (mean 55.4), respectively. The male/female ratio was equal in every group involved in the study.

The removed tissues were fixed in 4% buffered formalin for 24 h, dehydrated, and embedded in paraffin. The 3–4 μm thick sections were stained by hematoxylin–eosin (HE) and alcian blue–PAS reaction.

Paraffin sections were used for immunohistochemistry studies. The anti-CLDNs 2 and 4 antibodies were monoclonal, anti-CLDNs 1, 3 and 7 antibodies were polyclonal purified from rabbit antiserum (Zymed, San Francisco, CA, USA). First, the slides were treated for 30 min in a target retrieval solution (Dako, Glostrup, Denmark) in a microwave oven, followed by incubation with the primary antibody at a 1:80 dilution at room temperature for 1 h. For visualization, a standard avidin–biotin peroxidase technique (ABC system, Dako) was used with diaminobenzidine as chromogen. The sections were counterstained with hematoxylin. For each CLDN, a negative control with omission of the primary antibody was included. Colon carcinoma and endometrial tissue samples previously shown to express different CLDNs [28] served as positive controls. The reactions were carried out in a Ventana ES automatic immunostainer (Ventana Medical Systems Inc., Tucson, AZ, USA) using the reagents provided by the manufacturer.

The number of positive cells was calculated as follows: 10 randomly selected areas per slide were analyzed using ×20 objective with 100 cells counted in each field. The scoring standardized for each group was as follows: 5=80 to 100%, 4=60 to 80%, 3=40 to 60%, 2=20 to 40%, 1=5 to 20% and 0≤5% of the cells showed positive reactions.

For *statistical analysis*, the Mann–Whitney *U* test was used to compare the expression of individual CLDNs in the different groups.

Real-time RT-PCR for CLDN 2, CLDN 3, CLDN 4, and GAPDH mRNA detection

Tissue specimens

The sample set consisted of ten formalin-fixed, paraffin-embedded ACCs, ten cases of BE and ten foveolar glandular epithelial tissues.

RNA isolation

Total RNA from formalin-fixed paraffin, embedded-tissues was isolated with High Pure RNA Paraffin Kit (Roche, Indianapolis, IN, USA). Depending on the size of the dissected area, two to eight 5-μm-thick sections were cut from each tissue block. Samples from the Barrett's and foveolar epithelia were microdissected to select the areas of SIM of BE and the columnar epithelial cells without goblet cells. Proteinase K digestion time was 16 h for each sample. All purifications were performed in accordance with the manufacturer's protocol. After total RNA isolation, samples were kept at −80°C until use. Total RNA integrity was verified as described previously [28].

Reverse transcription of RNA

Total RNA (500 ng) was reverse transcribed for 50 min at 42°C in 30 μl with MulV reverse transcriptase (Applied

Biosystems, Foster City, CA, USA) in the presence of RNAse inhibitor (Applied Biosystems), using Random Hexamers (Applied Biosystems).

Real-time quantitative RT-PCR

Real-time PCR reaction was performed with 2 μl cDNA template in a total volume of 25 μl, using the ABI Prism 7000 sequence detection system (Applied Biosystems). Each PCR was conducted in 25 μl volume of SYBR Green Supermix (Bio-Rad, Hercules, CA, USA, 1708851). Primer sequences were as follows: CLDN 2 (GI: 9966780), forward 5′-CTCCCTGGCCTGCATTATCTC-3′ (273–293), reverse 5′-ACCTGCTACCGCCACTCTGT-3′ (344–363); CLDN 3 (GI: 21536298), forward 5′-CTGCTCTGCTGCTCGTGTCC-3′ (732–751), reverse 5′-TTAGACGTAGTCCTTGCGGTCGTAG-3′ (836–860); CLDN 4 (GI: 14790131), forward 5′-GGCTGCTTTGCTGCAACTGTC-3′ (741–761), reverse 5′-GAGCCGTGGCACCTTACACG-3′ (829–848) [36]; GAPDH (GI: 7669491), forward 5′-CATTGACCTCAACTACATGG-3′ (186–205), reverse 5′-GAAGATGGTGATGGGATTTC-3′ (287–306) and β-actin (GI:15928802) forward 5′-CCTGGCACCCAGCACAAT-3′ (1031–1048), reverse 5′-GGGCCGGACTCGTCATAC-3′ (1157–1174).

PCR was done in duplicates in 96-well plates, for 2 min at 95°C for initial denaturing, then 40 cycles at 95°C for 20 s, at 63°C for 30 s and 72°C for 1 min. Data analysis and statistical evaluation were performed by REST (expression software tool, http://www.wzw.tum.de/gene-quantification)

Results

Immunohistochemistry

Normal stratified squamous epithelium (Fig. 1a–d) CLDNs 1, 4, and 7 gave a membranous reaction in the suprabasal layer of the epithelium showing a honeycomb appearance. The strongest, most extended reaction was seen with CLDN 7 (Fig. 1d). CLDN 2 reacted in a granular pattern, outlining the cell membrane and sometimes found localized intracytoplasmatically. No CLDN 3 could be detected. The number of cells reacting with the individual CLDN antibodies was variable (Fig. 3). The highest number of positive cells was seen with CLDN 7, followed, in order, by CLDNs 4, 2, and 1 (Fig. 3; Table 1).

Squamous cell carcinoma (Fig. 1e–h) The pattern and staining intensity in SQCC did not change in comparison with that in SQ. The "honeycomb" membraneous staining of the cancer cells for CLDNs 1, 4, and 7 (Fig. 1f–h) was similar to that of the normal cells. The number of positive cells, however, increased significantly in case of CLDN 1 (Fig. 3; Table 1); it was higher, though not significant for CLDN 4, and was equally high for CLDN 7 (Fig. 3; Table 1).

Foveolar epithelium (Fig. 2a–f) The strongest reactions were detected for CLDNs 1 and 7, while CLDNs 2 and 3 were negative. CLDN 4 was positive in only a low percentage of the cells (Figs. 2e and 3).

Barrett's esophagus (Fig. 2g–l) A significant increase in staining intensity and number of positive cells was seen for CLDNs 3 and 4 (Fig. 2j–k), as compared with the FOV (Fig. 3; Table 1). Strong reactions were detected for CLDNs 1 and 7 (Fig. 2h,l) too, but the number of positive cells did not significantly differ from that observed in the FOV, where it was already highly expressed. CLDN 2 reaction was detected in a small percentage of the cells (Fig. 3).

Adenocarcinoma (Fig. 2m–s) In the ACCs, the pattern of CLDN expression was similar to that in BE for CLDNs 3 and 4 (Fig. 2p–r), with a significant increase in CLDN expression noticeable when compared with that in the FOV (Fig. 3; Table 1). Interestingly, CLDN 2 showed a considerable increase (Fig. 2o; Table 1), which was significantly higher in comparison with both BE and FOV.

Both similarities and differences could be noted when comparing CLDN expression in the squamous and foveolar epithelia, BE and carcinomas (Fig. 3; Table 1). CLDN 7 was the dominating type in all epithelia and carcinomas studied in the esophagus, without significant changes in the normal and altered epithelia and tumors. In SQCC, CLDN 1 showed considerable increase as compared with that in SQ. CLDNs 3 and 4 were the prominently elevated types both in BE and ACC when compared with that in FOV. CLDN 2 increased significantly in the ACCs as compared with that in BE.

mRNA expression of CLDNs 2, 3, and 4 detected by real-time RT-PCR The CLDNs which showed significant, characteristic differences at the protein level between BE and ACCs were further studied. mRNA expression analysis of representative and dissected samples comparing FOV with BE and ACC showed that mRNA expression of certain CLDNs reflected parallel changes that were found with the protein production of these dissected tissue components. Increased CLDN 3 and 4 expressions were detected at the mRNA level both in BE and in ACC, in contrast to FOV. Real-time RT-PCR analysis revealed CLDN 2 mRNA expression to be higher in ACC than in FOV, coinciding with the immunohistochemical results. The significantly increased CLDN 2 mRNA expression, however, was not found to be parallel with the slightly increased protein expression noted in BE as compared with that in FOV (Figs. 4 and 5; Table 2).

Discussion

Our study has shown that besides CLDNs 1 and 7, CLDNs 3 and 4 are the main characteristic types of claudins both in BE and in ACC. The expressions of CLDNs 3 and 4 in BE and ACC differ considerably from both the unaltered squamous and foveolar epithelium. These findings associate the SIM of the BE and ACC, clearly distinguishing them from FOV, showing no sign of intestinal metaplasia. The presented data demonstrate that BE differs from FOV even in such a basic characteristic feature as the molecular composition of the main sealing complex—the TJs.

Several studies have described the specific molecular changes that are likely to progress to carcinoma in the esophagus, as changes in protein expression [2], genomic, and chromosomal alterations [39, 41], etc. The best predictor, however, is still the histologic identification of dysplasia [25].

Previously, three types of glandular epithelia were accepted as being a characteristic of BE [25]. More recently, however, the SIM located in the distal esophagus was found to be associated with increased risk to develop ACC [25] and was established as a precancerous lesion. The detection of CLDNs 3 and 4 further helps the definition of "specialized intestinal" epithelium. The increased CLDN 3 and 4 expressions in BE and ACC in contrast to FOV could be demonstrated both at protein and mRNA levels. These data implicate that the expression of these adhesion molecules is regulated at the mRNA transcription level. BE and ACC can therefore be grouped together based on the claudin expression changes, which might further strengthen the link between these two entities in the carcinogenesis sequence.

Other cell adhesion molecules have also been studied in esophageal carcinomas and BE, in relation to prognosis and tumor behavior. Downregulation of CD44s and CD44v4 was described to result in a significantly poorer prognosis for patients with esophageal ACC; expression of CD44v4 proved to be an independent factor in prognosis [4]. Overexpression of alpha-6 integrin was found in 87% of esophageal ACC cases investigated [37] further; cDNA microarray experiments revealed that the expression of alpha-3 and alpha-6 integrins was upregulated in the tumor tissue. This result, however, did not correlate with the clinicopathological features [13].

The transmembrane protein family of claudins is the main component of TJs responsible for maintaining cell polarity, cellular arrangement, adhesion, and paracellular fluid transport. At least two transmembrane CLDN molecules (generally more) characterize each cell and tissue type [7]. This is partly due to the different function of the epithelium: "leaky" or more resistant type [42]. The heterogeneous claudin types are copolymerized to form individual TJs [7]. Homophylic and heterophylic interactions with other claudins as well as with other TJ-related proteins, as occludin, JAM, and ZO1, define the characteristics and function of TJs [19, 34]. The epithelia in different organs and even within the same organ differ qualitatively in their overall ability to regulate paracellular solute and ion movement, and this difference is defined by the quality and complexity of the TJs [34]. Disruption of the TJs due to the change in correlation between the individual CLDNs might lead to the reduction of TJ function [34].

Glandular epithelia have been proven to show a characteristic pattern of CLDNs, including breast [16, 38], pancreas [26], prostate [21], etc., which might be conserved during carcinogenesis, at least qualitatively. Several reports, however, detected increased expression of TJ proteins in carcinomas as in bile duct [20], or pancreatic

p significance, *U* upregulated, *NS* not significant, *CLDN* claudin, *GAPDH* glyceraldehyde-3-phosphate dehydrogenase, *FOV* foveolar epithelium, *BE* Barrett's esophagus, *ACC* adenocarcinoma

cancers [26]. CLDN 4 protein was significantly higher in BE and esophageal ACCs than in the foveolar glandular or squamous epithelia in our study too.

The increased expressions of CLDNs 3 and 4 are of specific interest since these CLDNs have been known as receptors for the cytotoxic *Clostridium perfringens* enterotoxin (CPE) [14]. CPE treatment might cause cell death by increasing membrane permeability, and, more recently, CLDN 4 has been suggested as a future target for adjuvant therapy in tumors expressing this TJ protein, namely cancers of the breast [16], prostate [21], pancreas [23, 26], ovary [11], and bile ducts [20]. From this point of view, our findings that both BE and ACC highly express CLDN 4 might be of further specific interest.

In addition to CLDNs 3 and 4, significant increase in CLDN 2 expression was detected in ACCs as compared with that in BE and FOV in our study at the protein expression level. This, however, was not shown regarding mRNA expression when comparing BE and ACC. Recent observations have suggested that optimal CLDN 2 expression in the gut is required for regulation of the intestinal barrier function and plays a role in enterocyte differentiation [6]. The significant increase in CLDN 2 expression in the esophageal adenocarcinomas in our study might suggest a sign of perturbation during carcinogenesis, being the type of claudin associated with intestinal differentiation. CLDN 2 is considered to form ion-selective channels in TJs of epithelial cells [1, 8, 30], functions as a measure of integrity of TJs [34], and is inversely proportional to transepithelial resistance. Therefore, in the present study, the increase of this protein in esophageal ACCs might suggest a "functional decrease" of TJ integrity.

The increased CLDN 2 expression in ACC at protein level might further help to define the multistep process of esophageal carcinogenesis. Moreover, our data exhibit the characteristic upregulation of CLDNs 3 and 4 in both BE and ACC and add evidence to the link between these two entities, possibly also advocating the use of these two TJ proteins as differentiation markers.

A subset of high-grade pulmonary neuroendocrine carcinomas shows up-regulation of matrix metalloproteinase-7 associated with nuclear β-catenin immunoreactivity, independent of EGFR and HER-2 gene amplification or expression

Received: 18 May 2005 / Accepted: 4 July 2005 / Published online: 13 September 2005

Abstract Nuclear translocation of β-catenin has been correlated with epidermal growth factor receptor (EGFR) overexpression/activation in nonsmall cell lung cancer. Less is known on β-catenin transactivation in high-grade pulmonary neuroendocrine tumors and on the status of β-catenin activating EGFR and human epidermal growth factor receptor 2 (HER-2) or β-catenin target genes cyclin D1 and matrix metalloproteinase-7 (MMP-7). β-catenin immunoreactivity was evaluated in 51 large-cell neuroendocrine carcinomas (LCNEC) and 45 small-cell lung carcinomas (SCLC). Nineteen cases were assessed for *β-catenin* gene exon 3 mutations, expression of MMP-7, and expression/gene amplification of EGFR, HER-2, and cyclin D1. β-catenin was expressed in all 96 high-grade neuroendocrine tumors, the vast majority (94%) showing >50% immunopositive cells. A disarrayed immunoreactivity, however, was commonly encountered consisting in variably altered membrane-associated patterns of staining along with progressive accumulation of cytoplasmic immunoreactivity. In LCNEC, but not in SCLC, the disarrayed patterns correlated with EGFR and HER-2 protein expression. β-catenin nuclear accumulation was found in nine tumors, including seven LCNEC and two SCLC, and was always associated with disarrayed immunoreactivity and increased MMP-7, but not cyclin D1 expression. These cases, however, did not show *β-catenin* gene mutations or EGFR and HER-2 gene amplification or expression. No association was found between nuclear β-catenin and any clinicopathological variable including patients' survival. The subcellular compartmentalization of β-catenin is profoundly altered in high-grade pulmonary neuroendocrine tumors. A minor subset of these tumors shows β-catenin nuclear accumulation in association with increased expression of MMP-7, but not of cyclin D1, independent of EGFR and HER-2 gene amplification or expression.

Introduction

A family of closely related structural cytoplasmic proteins, namely, α-, β-, γ-catenin, tightly connects the transmembrane glycoprotein E-cadherin to the underlying

cytoskeleton network [13, 58] to form a highly effective Ca^{2+}-dependent epithelial cell-cell homophylic adhesion complex at the adherens junctions [17, 53], essential for maintaining normal tissue architecture and morphogenesis [16]. In particular, β-catenin interacts directly with the intracellular domain of E-cadherin, connecting it to the actin cytoskeleton via another actin-binding protein, α-catenin, which in turn binds to vinculin, α-actinin, and zonula occludens-1 [33]. At variance with this spatially segregated and stable pool at the cell membrane, freely-soluble cytoplasmic β-catenin is usually phosphorylated by binding to axin/conductin, glycogen synthase kinase-3β (GSK-3β), and the adenomatous polyposis coli protein (APC) [18, 45, 51] and rapidly degraded via the ubiquitin/proteasome pathway [1]. This mechanism prevents an inappropriate cytoplasmic accumulation of stabilized, hypophosphorylated β-catenin that, after translocation to the nucleus, might be responsible for several biological effects, including increased expression of target genes, such as cyclin D1 [54] and matrix metalloproteinase-7 (MMP-7)/matrilysin [6, 10], augmentation of ligand-dependent activity of androgen receptor [60], or enhancement of vitamin D receptor activity [36]. In general, nuclear accumulation of hypophosphorylated β-catenin may derive from inhibition of the GSK-3β-dependent β-catenin phosphorylation via activation of Wnt/Wingless signal transduction cascade, loss-of-function mutations of *APC*, *AXIN* or *CTNNB1* (encoding for β-catenin), or overexpression/activation of growth factors, such as epidermal growth factor receptor (EGFR), causing β-catenin to dissociate from the membrane E-cadherin complex [27, 28]. Therefore, it is not surprising that dysregulation of β-catenin by a variety of different molecular mechanisms may play major role in several human diseases, including certain types of cancer [43].

Dysregulation of the E-cadherin/β-catenin-dependent adhesion complex has been associated with the development and progression of endocrine-related tumors, whereby either down-regulation or an altered subcellular compartmentalization of these proteins has been documented [2, 8, 15, 20, 23–25, 41, 49, 50, 52, 55]. In particular, nuclear accumulation of β-catenin has been reported in carcinoids of the gastrointestinal tract [25, 49] and of the pancreas [49] and in pituitary adenomas [48], whereas mutations in exon 3 of the *CTNNB1* gene, encoding serine/threonine-rich phosphorylation site for GSK-3β, or *APC* gene, are consistently uncommon [15, 43, 48–50]. Nuclear accumulation of β-catenin has been detected in a subset of pulmonary high-grade neuroendocrine carcinomas [9, 41, 47] in the absence of loss-of-function mutations or polymorphisms of either *CTNNB1* or *APC* [9]. However, insights into target gene expression resulting from β-catenin transactivation activity or mechanisms underlying β-catenin nuclear accumulation in pulmonary neuroendocrine tumor cells are still lacking.

Herein, we demonstrate that nuclear redistribution of β-catenin in a subset of pulmonary high-grade pulmonary neuroendocrine tumors is associated with up-regulation of MMP-7, but not of cyclin D1, and it is independent of EGFR and human epidermal growth factor receptor 2 (HER-2) gene amplification or expression.

Materials and methods

Patients

Ninety-six consecutive patients (82 men and 14 women) with stage I–III high-grade neuroendocrine tumors of the lung, including 51 large-cell neuroendocrine carcinomas (LCNEC) and 45 small-cell carcinomas (SCLC), that were radically resected at the participating Institutions between 1985 and 2004, have been evaluated. Relevant clinicopathological data of the entire cohort of patients is summarized in Table 1. All patients had been studied by total body CT scan and had undergone extensive mediastinal lymph node dissection (median value, nine excised lymph nodes per patient) to ensure accurate staging. The diagnosis of neuroendocrine tumor was based on either morphological features [56] or on previously refined immunohistochemical criteria (i.e., immunoreactivity for synaptophysin, chromogranin A, and a variety of respiratory tract-related

hormones, including gastrin-related peptide, calcitonin, adrenocorticotropic hormone, serotonin and alpha-subunit of human chorionic gonadotropin) [38, 41].

Accurate follow-up information was available for 86 patients: 45 (47%) patients had recurrent disease and 36 (37%) died of disease. Follow-up time was 29±39 months (median 12) for LCNEC and 20±21 months (median 15) for SCLC patients. No patient presented with symptoms due to hormone hyperproduction. Detailed information on cigarette smoking history was unavailable at the time of the present study, although most patients were known to be heavy smokers. Ten LCNEC and 17 SCLC patients underwent neoadjuvant combination chemotherapy using the CAVE protocol (cyclophosphamide, doxorubicin, vincristine and etoposide).

Immunohistochemistry

Paraffin-embedded tumor samples were investigated using the antibodies listed in Table 2, according to staining protocols previously reported [38]. Samples of normal lung from 10 patients with nonmalignant lung diseases and 10 pulmonary neuroendocrine tumorlets were used as control groups. Tumorlets and normal neuroendocrine cells were highlighted by chromogranin A immunostaining as previously detailed [39]. All immunostains were evaluated in a blinded fashion. Immunoreactivity for β-catenin, EGFR, and Her-2 was assessed as reported [12, 37, 41]. Proliferative activity of neuroendocrine tumors was assessed by Ki-67 immunolabeling [40]. For all other markers, the percentage of immunoreactive tumor cells was evaluated scanning at least 2,000 neoplastic cells in randomly selected fields. Tumors were scored as negative if staining was either absent or identified in less than 5% of tumor cells. In particular, nuclear immunoreactivity was defined as the nuclear accumulation of immunostaining product in at least 5% tumor cells, independent of the distribution of any additional staining. The specificity of immunoreactions was assessed substituting the primary antibody with a nonrelated isotypic mouse immunoglobulin or normal rabbit serum.

Dual-color FISH

Commercially available dual-color fluorescence in situ hybridization (FISH) assays [LSI EGFR/CEP7 (code 32-191053) and LSI Cyclin D1 11q13/CEP11 (code 32-191039), both from Abbott-Vysis Inc., IL, USA] were employed using 4-μm-thick paraffin-embedded sections according to the manufacturer's instructions to evaluate the status of the EGFR and cyclin D1 genes, respectively. Briefly, the locus-specific identifier EGFR or cyclin D1 DNA probe is a 300 kb SpectrumOrange (Abbott-Vysis, Inc.) fluorescent DNA probe specific for the EGFR (7p12) or cyclin D1 (11q13) gene locus. The chromosome 7 or 11 enumeration DNA probe is a SpectrumGreen (Abbott-Vysis, Inc.) labeled DNA probe specific for the alpha satellite DNA sequence at the centromeric region of chromosome 7 (7p11.1-q11.1) or 11 (11p11.11-q11), respectively. At least 100 neoplastic cells were evaluated for gene amplification as previously described [37]. Digital images were obtained using a Leica DMRB epifluorescence microscope equipped with a Leica digital camera DC250 (Leica Imaging Systems Ltd., Cambridge, UK). FITC, Cy3, and DAPI fluorescent signals were detected using specific filters. The images were recorded, pseudo-colored, and merged using the QFluoro software (Leica).

DNA extraction and mutational analysis

Tumor cells from nuclearly immunoreactive high-grade neuroendocrine neoplasms were microdissected from 5-μm-thick sections of formalin-fixed paraffin-embedded tissue, and DNA was extracted by digesting the tissues in lysis buffer [100 mM Tris–HCl (pH 8.0), 500 mM KCl, 0.01% Tween 20, and 200 μg/ml proteinase K]. Exon 3 of β-catenin was amplified by polymerase chain reaction (PCR) using the following primer pair: forward, 59-GAA CCA GAC AG AAA AGC GGC TG-39 and reverse, 59-ACT CAT ACA GGA CTT GGG AGG-39 (nucleotides 257–278 and 410–390 respectively; GenBank NM001904). Each PCR reaction was performed in a 20-μl reaction mixture containing 0.5 units of Taq polymerase, 0.25 μM of each primer, 0.2 μM deoxynucleotide triphosphates, 2.5 mM $MgCl_2$, and PCR buffer containing 100 mM Tris–HCl (pH 8.0), 500 mM KCl, and 0.01% Tween 20. Reaction conditions were as follows: 94°C for 5 min and then 35 cycles of 94°C for 1 min, 55°C for 1 min, 72°C for 1 min followed by a final extension of 70°C for 10 min. Products were purified and then sequenced in both directions using Big Dye Terminator Cycle Sequencing kit (Applied Biosystems, Foster City, CA, USA). The sequence reactions were run and analyzed on an ABI 3,100 Genetic Analyzer (Applied Biosystems).

Statistical analysis

Associations of categorical or ordinal variables were evaluated by the Fisher exact test or the Mantel–Haenszel chi-square test for trends (with 1 DF), respectively. Survival curves were assessed according to the Kaplan–Meier method and compared with log-rank. All estimates were performed using the SAS statistical software package (SAS Institute, Inc., Cary, NC, USA). All p values were based on two-sided testing and were considered significant when ≤0.05.

Results

Disarrayed β-catenin immunoreactivity is common in LCNEC and SCLC and is associated with EGFR and HER2 expression in LCNEC

Normal cells from bronchial mucosa and lung tissue from both neoplastic and nonneoplastic patient groups, as well as scattered bronchial neuroendocrine cells and all neuroendocrine tumorlets, showed exclusively a membrane-associated immunoreactivity for β-catenin, characterized by linear decoration of the entire cell membrane without any cytoplasmic or nuclear immunostaining.

β-catenin was expressed in all the 96 high-grade neuroendocrine tumors, with 20 to 100% immunoreactive tumor cells in LCNEC and 50 to 100% in SCLC (Table 3). The two tumor groups did not differ significantly with regard to the β-catenin labeling index, and the vast majority showed more than 50% immunoreactive cells. Only four (8%) LCNEC and one (2%) SCLC showed 50% or less immunoreactive cells.

Significant differences were instead observed in the staining patterns of these two tumor groups that persisted even after adjustment for confounding factors such as age, gender, and tumor size (Table 3). Indeed, a disarrayed β-catenin immunoreactivity was seen in both groups, consisting in a variably retained membrane-associated pattern along with progressive increase of cytoplasmic staining. A membrane-linear/cytoplasmic pattern prevailed in LCNEC, showing preservation of the membrane-linear signal along with variable degrees of cytoplasmic staining. Conversely, a membrane-disrupted pattern was more prevalent in SCLC exhibiting irregularly wrinkled staining of the cell membrane along with more prominent cytoplasmic staining.

In LCNEC, an inverse relationship was found between β-catenin labeling index and pT class (p=0.014) and as a trend with more advanced tumor stage (p=0.091) or size (p=0.087), but not with the other demographic (age, gender) or clinicopathological (recurrence rate, survival) variables under evaluation. As far as the β-catenin immunostaining pattern is concerned, a nonmembrane-linear staining was associated with complete and intense membrane immunoreactivity for EGFR (p=0.017) and as a trend with HER-2 expression tumors (p=0.080). At variance, LCNEC with cyclin D1-immunoreactive tumor cells showed a retained membrane-linear signal (p=0.009). No other significant associations between the immunostaining pattern of β-catenin and any other parameter were observed.

In SCLC, reduced expression of β-catenin was associated with tumor recurrence (p=0.043), death for tumor (p=0.015), and Ki-67 labeling index ≥50% (p=0.004), but not with age, gender, tumor stage, and EGFR and HER-2 or cyclin D1 expression. No relationship was found between β-catenin immunostaining patterns and the different clinicopathological variables investigated.

Table 3 Prevalence of β-catenin immunoreactivity according to histology

Variable	Category	LCNEC	SCLC	p
β-catenin labeling index	Mean±SD	90.4±18.9	94.4±10.9	NS
	Median	100	100	
	Range	20–100	50–100	
β-catenin pattern	Membrane linear	10 (91%)	1 (9%)	<0.0001*
	Membrane cytoplasmic	12 (86%)	2 (14%)	
	Membrane disrupted	29 (41%)	42 (59%)	

NS not significant
*These differences remained significant even after adjusting for confounding factors such as patients' age and gender and tumor size

β-catenin nuclear immunoreactivity is detected only in a subset of LCNEC and SCLC

Nuclear accumulation was observed in a subset of high-grade neuroendocrine tumors, including 7/51 (14%) LCNEC and 2/45 (4%) SCLC, where positive tumor cells ranged from 10 to 95% (mean±SD, 45±26%; median 45), with either diffuse (three cases) or patchy (six cases) distribution pattern within individual tumors, the latter being characterized by irregular clustering of positive tumor cells (Fig. 1). Nuclear immunostaining was always associated with a disarrayed, nonmembrane/linear immunoreactivity for β-catenin, including either membrane-linear/cytoplasmic or membrane-disrupted pattern. Specifically, four of seven LCNEC and the two SCLC with nuclear staining presented a simultaneous membrane-linear/cytoplasmic pattern, whereas the remaining three LCNEC were associated with a membrane-disrupted pattern ($p<0.001$). Nuclear immunoreactivity for β-catenin was also associated as a trend with either absent (one LCNEC) or variably misplaced E-cadherin immunoreactivity, the latter consisting in wrinkled staining of the cell membrane along with prominent cytoplasmic accumulation (six LCNEC and two SCLC) ($p=0.053$).

No association was found between nuclear accumulation of β-catenin and any parameters.

β-catenin nuclear accumulation correlates with increased MMP-7 but is independent of EGFR/HER-2 or cyclin D1 expression/activation or gene amplification

The nine tumors showing nuclear immunoreactivity for β-catenin were compared for immunohistochemical expression of target genes such as MMP-7 and cyclin D1 and growth factor membrane receptors responsible for nuclear accumulation of β-catenin upon activation using a control group of 10 randomly selected, consecutive, nuclear-unreactive high-grade neuroendocrine carcinomas, including LCNEC and SCLC, randomly chosen among those exhibiting the same β-catenin membrane/cytoplasmic pattern of immunoreactivity. We found matrilysin (MMP-7) immunoreactivity in four of nine tumors (three LCNEC and one SCLC) showing nuclear staining of β-catenin vs none of the 10 control tumors ($p=0.070$), with a mean percentage (±sd) of immunoreactive cells being 18.8% (±8.5; median 17.5%, range 10–30) ($p=0.033$). Conversely,

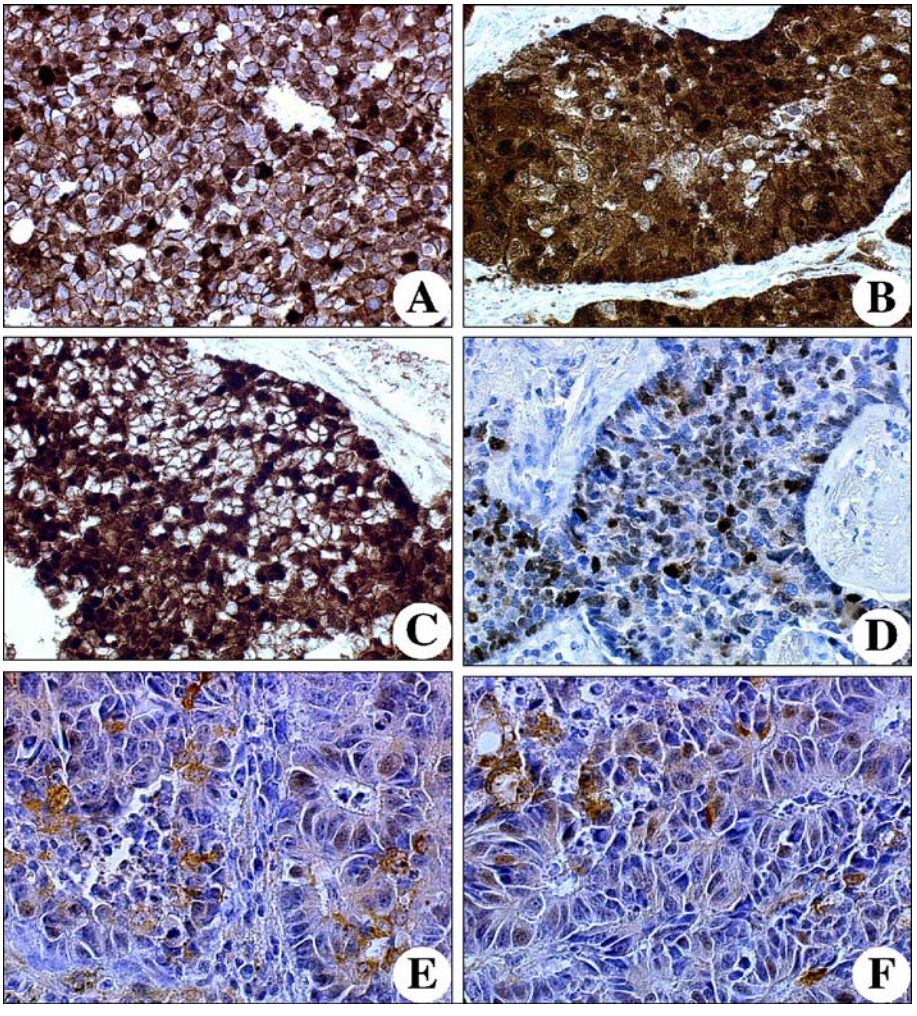

Fig. 1 Representative immunoreactivity patterns for β-catenin (**a**–**c**), cyclin D1 (**d**), and matrix metalloproteinase-7 (**e**, **f**) in high-grade neuroendocrine tumors of the lung. A membrane-linear pattern for β-catenin with scattered nuclearly immunoreactive tumor cells is shown in two different cases of LCNEC along with variable degrees of cytoplasmic staining (**a**, **b**), whereas a more evident cytoplasmic pattern with some membrane disruption and consistent nuclear immunoreactivity is seen in another case of LCNEC (**c**). Nuclear accumulation of cyclin D1 by tumor cells is virtually confined to LCNEC although it is not differentially expressed by β-catenin nuclearly immunoreactive tumors (**d**). The cytoplasmic immunolabeling pattern for matrix metalloproteinase-7 is shown in two different cases of β-catenin nuclearly accumulating LCNEC (**e**, **f**)

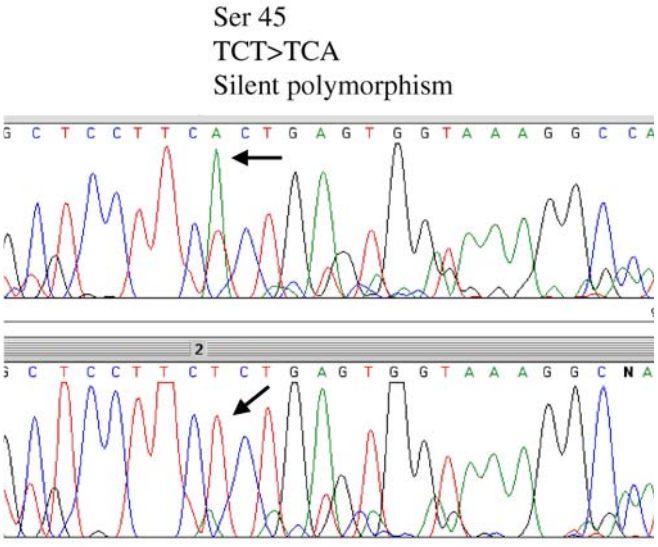

Fig. 2 Sequence analysis of β-catenin exon 3 in a case of LCNEC showing a silent polymorphism at the codon Ser 45 with TCT→TCA transversion

no differences were found between the two tumor groups for all the other markers evaluated, including phosphorylated and unphosphorylated EGFR or HER-2, p38 and p42/44 MAPK, amphiregulin, TGF-α, and EGF. Finally, FISH analysis did not show any gene amplification for HER-1/EGFR or HER-2/Neu genes in either tumor group, and direct sequencing of exon 3 of the *CTNNB1* gene encoding β-catenin did not show any mutation, apart from a silent polymorphism in one LCNEC (Fig. 2). Cyclin D1 immunoreactivity was confined to LCNEC (mean±sd, 13± 18%; median 5), but was not differentially expressed between the two tumor groups, and FISH analysis did not reveal any specific gene amplification.

Discussion

In this study, we demonstrate that (1) disarrayed β-catenin immunoreactivity is common in high-grade neuroendocrine tumors, whereas normal and hyperplastic (tumorlets) bronchial-associated neuroendocrine cells express only membrane-bound β-catenin; (2) nuclear β-catenin immunoreactivity is present in a minor subset of high-grade neuroendocrine tumors, where it correlates with matrilysin, but not with cyclin D1 expression. Nuclear immunoreactivity is independent of either mutations in exon 3 of β-catenin or expression/activation or gene amplification of members of the HER membrane receptor gene family.

The genotypic and phenotypic relationships between LCNEC and SCLC are still a matter of debate. Similarities have been suggested by experiments with gene expression profiling [19] or morphometry [30], whereas comparative genomic hybridization [57] and immunohistochemistry [7, 14] have suggested that the opposite is true. Our data are based upon the largest series of LCNEC and SCLC analyzed to date for β-catenin immunoreactivity and suggest that this protein is likely to play a different role in these tumors. Overall, the expression of β-catenin is highly conserved in high-grade pulmonary neuroendocrine tumors, inasmuch as their labeling indexes do not differ significantly. However, what is dramatically subverted is the subcellular distribution of β-catenin, as argued by the differential distribution between LCNEC and SCLC of the diverse immunoreactivity patterns. In fact, a retained membrane-linear decoration prevails in the former along with variable cytoplasmic accentuation of immunostaining, whereas a more disarrayed pattern is common to the latter with irregularly wrinkled membrane immunoreactivity and a more accentuated cytoplasmic reinforcement of immunostaining. The close positive relationship between β-catenin and E-cadherin immunoreactivity patterns we have recently documented in LCNEC, but not in SCLC [41], was confirmed in the current investigation (data not shown), indicating that the majority of β-catenin molecules is tightly connected to E-cadherin, not only when localized at the cell membrane but also when they are displaced into the cytoplasm. This colocalization is partially lost only when β-catenin is translocated into the nucleus, as E-cadherin has never been found in the nuclei of pulmonary neuroendocrine tumors [9, 41].

In LCNEC, down-regulation of β-catenin correlates with pathological indicators of tumor growth, such as pT and tumor stage or size, and in SCLC with tumor recurrence rate, cancer-related deaths, and increased proliferative activity, indicating a critical role of reduced β-catenin for impaired cell-cell adhesion responsible for local tumor development and progression. Moreover, in LCNEC, a nonmembrane-linear immunoreactivity pattern is associated with the expression/overexpression of two important members of HER family in lung cancer, namely, EGFR and HER-2, but not with cyclin D1, one of the target genes transactivated by nuclear β-catenin [54]. This indicates on one hand that overexpression/activation of these growth factors may favor the cytoplasmic accumulation of β-catenin, causing it to dissociate from the membrane E-cadherin complex [27, 28], on the other hand that modulation of cyclin D1 expression, a protein reportedly overexpressed in LCNEC [3, 14], is independent of either β-catenin nuclear activation or cyclin D1 gene amplification. As a matter of fact, in such tumors, cyclin D1 immunoreactivity is significantly associated with a distinct membrane-linear signal of tumor cells and the absence of cyclin D1 gene amplification.

The nuclear accumulation of β-catenin in a minor subset of high-grade neuroendocrine tumors is always associated with disarrayed distribution of the E-cadherin/β-catenin complex, evoking a profoundly altered function of this cell-to-cell adhesion complex in such subset of tumors. Moreover, we first get new insights into the gene activation occurring in nuclearly immunoreactive high-grade pulmonary neuroendocrine tumors, reporting that matrilysin (MMP-7), but not cyclin D1 immunoreactivity, is significantly increased in this subset of tumors as compared with the nuclearly unreactive control arm. This overlap between MMP-7 and β-catenin nuclear immunoreactivity

we documented in a subset of high-grade pulmonary neuroendocrine carcinomas has also been reported in other human cancers, including colorectal [35], endometrial [29], esophageal [46], and pancreatic [26] carcinomas, at variance with breast [32] or liver [44] cancer where β-catenin nuclear accumulation does not correlate with MMP-7 immunoreactivity. These findings emphasize once again the complex multifunctional role of β-catenin in the activation process of reporter genes in human cancers where diverse mechanisms are likely to be responsible for the final tumor development. Our findings of 9% high-grade pulmonary neuroendocrine carcinomas being nuclearly immunoreactive for β-catenin, of an inverse relationship between membrane/linear and nuclear localization, and of the absence of mutations in exon 3 of the *CTNNB1* gene, are also in keeping with recent data obtained on nonsmall cell lung cancer [22, 42]. This suggests that common carcinogenetic events may cause different subtypes of lung cancer to develop, and that the destruction mechanisms of the E-cadherin/β-catenin system may be functional in neuroendocrine tumors of the lung.

In addition to Wnt pathway, it has been proposed that β-catenin nuclear accumulation may also result from EGFR activation in A431 squamous carcinoma cell line [28], but this mechanism is unlikely to play a role in our series of high-grade pulmonary neuroendocrine tumors, because either EGFR and HER-2 expression or up-/down-stream signals of the corresponding pathways, such as p38 and p42/44 MAPK, amphiregulin, TGF-α, and EGF, do not differ between the two tumor control arms under evaluation. On the contrary, we found that EGFR or HER-2 expression is associated with a nonmembrane-linear immunoreactivity pattern of β-catenin in LCNEC, but not in SCLC, indicating that the same receptor(s) may account for subcellular redistribution of the protein with detachment from cell membrane and cytoplasmic accumulation. This mechanism is different from that proposed in human esophageal squamous cell carcinoma lines where EGF activation signaling pathway plays an active role in MMP-7 production of tumor cells [59]. FISH analysis of *EGFR* or *HER-2* gene copy number status excludes that gene amplification may account for the nuclear accumulation of β-catenin in high-grade pulmonary neuroendocrine tumors. Our results on direct sequencing of exon 3 of the *CTNNB1* gene confirm previous studies failing to detect any mutation in the β-catenin gene in pulmonary endocrine tumors [9], at variance with the reported occurrence of such mutations in gastrointestinal carcinoids [15]. On the other hand, loss-of-function mutations or deletions of key regulators of the Wnt pathway, such as APC gene, have not been detected in neuroendocrine tumors of the lung [9], and mutations or deletions of other important regulatory genes, such as GSK-3β, are unlikely to be found in tumors probably because its overall ablation is incompatible with cell viability [43].

Matrilysin has been found in neuroendocrine carcinomas of the lung up to 20% of tumors with a prevalence of LCNEC over SCLC [4], and our findings of 4/19 (21%) immunoreactive tumors (three LCNEC and one SCLC) for MMP-7 are in full agreement with these results. Although the expression of several matrix metalloproteinases has been linked to the invasive phenotype of lung cancer [4], we failed to find any relationship between matrilysin expression and indicators of tumor aggressiveness probably because of the little number of cases being reactive rather than to the lack of biopathological meaning in these neuroendocrine tumors of the lung that are known to be highly aggressive tumors. The same explanation could hold true for the lack of any correlation between β-catenin nuclear occurrence and indicators of tumor growth or progression. Besides its function in the degradation of extracellular matrix, it has also been reported that MMP-7 is able to mediate E-cadherin ectodomain shedding in either injured lung epithelium [31] or human cancer cells [11, 34], resulting in a soluble E-cadherin fragment that in turn inhibits the E-cadherin/β-catenin system functions via a paracrine mechanism and accelerates cell migration required for either epithelial repair or tumor invasiveness. Moreover, the levels of MMP-7—an enzyme able to efficiently bind to cell surface and produce homotypic loose cell aggregates [21]—may also be regulated in human cancers by the degree of E-cadherin-mediated cell-cell connections [5], making the functional relationships among these molecules complex and intriguing. Therefore, further studies on a larger number of β-catenin nuclearly immunoreactive high-grade neuroendocrine tumors of the lung are warranted to elucidate these challenging aspects.

Mucinous tubular and spindle cell carcinoma: a report of 15 cases and a review of the literature

Received: 31 January 2005 / Revised: 25 May 2005 / Accepted: 29 June 2005 / Published online: 18 October 2005
© Springer-Verlag 2005

Abstract Mucinous tubular and spindle cell carcinomas are low-grade renal epithelial neoplasms, which were first recognized as a specific entity in the World Health Organization 2004 classification. Forty-five documented cases have been reported. We present 15 additional cases that were incidentally discovered in ten women and five men, with a mean age of 53 years. The tumor is characteristically made up of large eosinophilic regular spindle cells separated by a myxoid stroma with intercellular alcian-blue-positive clear droplets. In peripheral areas, elongated tubules and papillae covered by cubic cells are found. Until this entity had been defined, pathologists used to classify these tumors as variants of solid papillary carcinomas with compressed and elongated papillae, metanephric adenomas, and sarcomatoid carcinomas. In the literature, cytogenetic data indicate various chromosomal losses and gains, but no loss of 3p or trisomy 7 and/or trisomy 17. In two cases, we demonstrate chromosomal loss involving chromosomes 1, 4, 6, 11, 8, 13, 14, 15, 18, and 22. In our 15 cases, immunohistochemistry favored a distal tubule origin (EMA$^+$, AE1/AE3$^+$, CK7$^+$, CK19$^+$, E-cadherin$^+$, AMACR$^+$, and CD10$^-$). Prognosis was favorable in our cases, while in the literature, two metastatic cases were reported. Further investigations are required to determine the frequency and true prognosis of these tumors, which are easily identifiable morphologically.

Introduction

A novel entity among low-grade renal epithelial neoplasms has recently been identified under the denomination "mucinous tubular and spindle cell carcinoma", which was adopted at the World Health Organization consensus conference on the classification of renal neoplasms in December 2002 [11]. The histological profile of this tumor is well-established, and pathologists easily recognize it on routine hematoxylin–eosin staining (HES) [1]. We report our clinical, histological, and immunohistochemical experiences with 15 such cases.

Materials and methods

Case selection

Fifteen cases of renal tumors, which were originally seen by one of the authors (A.V.) in consultations between 1995 and 2003 and were initially considered as a "compact variant of papillary carcinoma without papillae", corresponded to the new entity. One of the cases had been previously reported [2]. Macroscopic descriptions and follow-up were obtained by communications with referring pathologists.

Aquaporin 3	Polyclonal, 1/100 (Alomone Laboratories)
Ulex	Monoclonal, UEA-1, 1/100 (Vector, Burlingame, CA, USA)
AMACR	Monoclonal, clone RP134, 1/100 (Dako)
Vimentin	Monoclonal, clone Vim3B4, 1/20 (Dako)
Smooth muscle actin	Monoclonal, clone 1A4, 1/500 (Dako)

Immunohistochemistry

Immunohistochemistry stains were performed on paraffin-embedded tissues, with antibodies representing different parts of the nephron (Fig. 1a), to determine the histogenesis of these tumors. We analyzed antibodies for the proximal tubule (RCC, CD10, CD15, and aquaporin 1), the loop of Henle (EMA, Tamm–Horsfall, and CD15), the distal tubule (EMA, Tamm–Horsfall, CD15, AE1/AE3, CK19, E-cadherin, and aquaporin 2), and the collecting duct (EMA, AE1/AE3, CK19, E-cadherin, Ulex, and aquaporin 3). Racemase (AMACR), vimentin, and smooth muscle actin were also explored. Immunohistochemical data are summarized in Table 1.

Results

Clinical data

Clinicopathological data are summarized in Table 2.

Patients' age ranged from 21 to 81 years (mean, 53 years), with a male/female ratio of 1:2. All tumors were solitary, and all had been treated with total nephrectomy. Clinical follow-up, which ranged from 1 to 6 years (mean, 3 years), was available for ten patients. One patient died with lymph node metastasis, but she had also been treated for breast carcinoma. No autopsy was performed, and the origin of lymph node metastasis remained undetermined.

Rough features

The rough aspects of these tumors were highly stereotypical and differed from the usual macroscopic aspects seen in renal carcinomas. The tumors were well-defined and had a firm, smooth consistency. They consistently

displayed a whitish aspect with grayish sectors. Necroses and hemorrhages were rare (Fig. 2). Their diameter varied between 3 and 11 cm (mean diameter, 6 cm).

Microscopic findings

On microscopic examination, a predominant pattern of regular spindle cells arranged in sheets (Fig. 3) and some peripheral areas with cuboidal regular cells arranged in cord tubules and papillae (Fig. 4) consistently existed. Spindle cell areas consisted of monotonous sheets of fairly uniform cells with large eosinophilic cytoplasms. The tubular papillary pattern was made up of cuboidal cells with eosinophilic cytoplasm. Tumor cells always displayed a low nuclear grade (Fig. 5), while the interstitium appeared clear. Numerous small intercellular droplets locally formed an abundant myxoid stroma. The stroma reacted characteristically with alcian blue (Fig. 6). Clusters of foamy cells were present in papillae and also among fusiform cells. No vascular or sinus invasion or lymph node metastases were observed.

Immunohistochemistry

In all our cases, immunophenotype was epithelial, with an expression of a panel of epithelial markers in most cells: EMA, AE1/AE3, CK7, and CK19 (Fig. 7). E-cadherin expression was observed in 90% of cases, and AMACR (racemase) was strongly expressed in 100% of them. RCC was expressed in 45% of cases.

A few cases displayed an expression of vimentin, CD10, CD15, aquaporin 1, aquaporin 3, Tamm–Horsfall protein, or Ulex.

Table 3 and Fig. 1b summarize immunohistochemical findings in 45 cases from the literature and in our personal series of 15 cases.

Cytogenetic analysis

Two cases were selected for cytogenetic analysis. For one tumor, comparative genomic hybridization showed chromosomal losses involving chromosomes 1, 4, 6, 8, 13, 14, 15, and 18. For the second tumor, the karyotype was hypodiploid (42, XX), with chromosomal losses involving chromosomes 1, 6, 11, 14, and 22 and with a gain on chromosome 15.

Discussion

Low-grade mucinous tubular and spindle cell carcinomas can easily be identified and separated from other primitive renal malignancies. Since 1998, single cases and small series have been reported [3–5, 7–10, 13]. They are preferentially observed in adults, with female predominance. These tumors constitute firm, compact, whitish, well-defined masses [9]. Microscopically, they have the same typical features as those described in our series, including an interconnecting tubular and spindled architecture within myxoid stromas and low-grade nuclei.

As seen in Table 2, our results are similar to those found in the literature, except for vimentin staining, which was expressed in only a few of our cases in contrast to half of the cases in the literature.

For the first time, we have explored two additional markers AMACR and aquaporin 3. Our study demonstrates the

positivity of AMACR in 100% of cases and the expression of aquaporin 3 in a few cases.

Immunohistochemical data do not enable the elucidation of the exact histogenenesis of these tumors. Epithelial markers, especially CK7, CK19, EMA, E-cadherin, and AMACR, have been shown to be positive in 80–100% of cases both in the literature and in our series. Although these markers are not specific to the distal tubule, their positivity lends support to the hypothesis of a distal tubule origin. The rest of the markers, which are more specific to the proximal tubules (CD10 and aquaporin 1), the loop of Henle (Tamm–Horsfall, CD15, and Ulex), and the collecting duct (aquaporin 3), are expressed in only a few cases. As in our series, Weber et al. [13] eliminated the hypothesis of proximal tubular origin, as they found only 1 of 21 cases to be weakly marked by CD10. However, they described positivity for RCC but excluded a proximal origin, as RCC remains a new marker that does not seem to be very reliable. They also found very weak Tamm–Horsfall protein staining, which tends to refute the hypothesis of a loop-of-Henle origin, which had previously fueled controversy [10]. Moreover, AMACR expression rendered a distal tubular origin more likely [12]. Rakozy et al. [9] observed a weak expression of vimentin in the periphery in two of five cases. These results complemented our series, with positivity in 2 of 14 cases (14%).

Cytogenetic studies demonstrate that mucinous tubular and spindle cell carcinoma seems to have very high genomic instability [13]. In the cases explored in the literature and in two personal cases, karyotyping, comparative genomic hybridization, and fluorescent in situ hybridization demonstrate complex genomic aberrations, with losses (on chromosomes 1, 4, 6, 8, 13, and 14) and gains (on chromosomes 7, 11, 16, and 17). Although these abnormalities are varied and nonspecific, loss of chromosome 3p, trisomy 7, and/or trisomy 17 has never been encountered. This is a strong argument for the hypothesis that mucinous tubular and spindle cell carcinoma is a distinctively new entity [6].

Differential diagnosis with other renal tumors presented a problem prior to the definition of this entity.

Pathologists might tend to classify this tumor as a variant of solid papillary carcinoma with compressed and elongated papillae, metanephric adenoma, collecting duct carcinoma, or fusiform sarcomatoid carcinoma [11].

The most accurate diagnosis would be that of a solid variant of type 1 papillary carcinoma. Macroscopically, papillary carcinomas are quite different—often not very firm, but necrotic; not whitish, but yellowish. However, a solid variant has been described. Papillary carcinomas have a predominantly tubulopapillary pattern, but compression of elongated tubules and papillae can create a fusiform pattern. The hypothesis that there exists a continuum between the fusiform areas observed in mucinous tubular and spindle cell carcinomas and tubulopapillary structures is reinforced by the presence of lipophage nests within tumor cells. However, mucinous stroma is never observed in papillary carcinomas. Moreover, genomic profile without trisomy 7 and/or trisomy 17 has eliminated the diagnosis of solid papillary carcinoma. Metanephric adenoma has a different pattern: cells are small, cuboidal, and embryonic in appearance, with a very scant cytoplasm and a hyperchromatic oval nucleus. There is no myxoid stroma, but psammoma bodies may be present. Immunohistochemical profile is not discriminative: keratins and vimentin can be expressed by both tumors. However, negativity for CK7 is usually found in metanephric adenomas. Collecting duct carcinomas may have a papillary compact growth pattern, but they have larger eosinophilic cells with marked atypia. The stroma is often fibrous with necrosis. Ulex, the emblematic marker of collecting duct carcinomas, is expressed only in rare cases. The diagnosis of sarcomatoid carcinoma can be evoked. In some areas, sarcomatoid carcinomas display monotonous fusiform cells without atypia, but in other areas, they are obviously high-grade tumors with marked nuclear atypia and numerous mitoses.

In our series, prognosis seems to be favorable based on low histological grade, with a follow-up of between 1 and 6 years. In the literature, two cases with lymph node metastasis have been reported [4, 13]. In conclusion, we feel that the true frequency of this entity is probably underestimated. It is essential to report new cases to determine the frequency and prognosis of low-grade mucinous tubular carcinomas.

Classification of parietal pleural invasion at adhesion sites with surgical specimens of lung cancer and implications for prognosis

Received: 8 February 2005 / Accepted: 15 June 2005 / Published online: 21 September 2005
© Springer-Verlag 2005

Abstract Parietal pleural invasion of non-small cell lung cancer (NSCLC) is a factor for poor prognosis, and a tumor of any size that invades the parietal pleura is classified as T3. However, with microscopic invasion beyond elastic fibers of the visceral pleura but no penetration to the parietal pleura at tight adhesion sites (we term this p1–3), classification as to the T factor is unclear. Among 1,179 consecutive patients with NSCLCs who underwent curative surgery between 1980 and 2002, 20 were in this category. Here, a comparison was made with subgroups of p stages IB, II, and IIIA with regard to histology, pleural invasion, and survival rates. To maximize the power of assessing prognostic potential, we set the significance level at 0.10, one-sided. The p1–3 condition sites of the 20 cases were the parietal pleura for 17 cases and the pericardium, diaphragm, and chest wall for one each of the remainder. The 5-year survival rate for these p1–3 patients was 71.6%. Significant differences were observed between p1–3 and IIIA groups. Although the 5-year survival rates did not significantly differ between p1–3 and T3N0 or unequivocal T3 subgroups, the prognosis of p1–3 patients was rather better than that of T3 and identical to T2. It was demonstrated that p1–3 status is not a factor warranting T3 classification for NSCLCs. Considering the prognosis, pathologic p1–3 tumors should be managed as a T2 disease for the present.

Introduction

Pleural invasion of lung cancers is recognized as an important poor prognostic factor [1–3]. Visceral pleural invasion has been adopted as a specific parameter in the current Tumor–Node–Metastasis (TNM) classification of the International Union Against Cancer (UICC) staging system [4, 5]: a lung cancer tumor of any size that invades the visceral pleura is classified as T2, and it is classified as T3 when it directly invades the chest wall including the parietal pleura, diaphragm, mediastinal pleura, or parietal pericardium [4, 5] (Fig. 1).

The UICC TNM classification includes little detail on histological pleural invasion in its definitions. In contrast, the Japan Lung Cancer Society (JLCS) classifies visceral pleural invasion based upon histological examinations as follows: p0, tumor with no pleural involvement beyond its elastic layer; p1, tumor extension beyond the elastic layer of the visceral pleura but with no exposure on the pleural surface; p2, tumor exposure on the pleural surface but no involvement of adjacent anatomic structures; and p3, tumor that involves adjacent anatomic structures [6] (Fig. 1). The Society classifies a p2 tumor of any size as T2 and a p1 tumor of 3 cm or less as T1.

However, there is no clear definition as to the T factor when a tumor shows invasion extending beyond the visceral pleura but with no clear adjacent parietal pleural invasion despite tight adhesion between visceral and parietal pleurae histologically (we term this p1–3; Figs. 1, 2). From a practical matter, this pathologic issue poses a potential staging problem in spite of a small subset of the total number of patients with this status. The current TNM classification does not take this condition into account [4, 5].

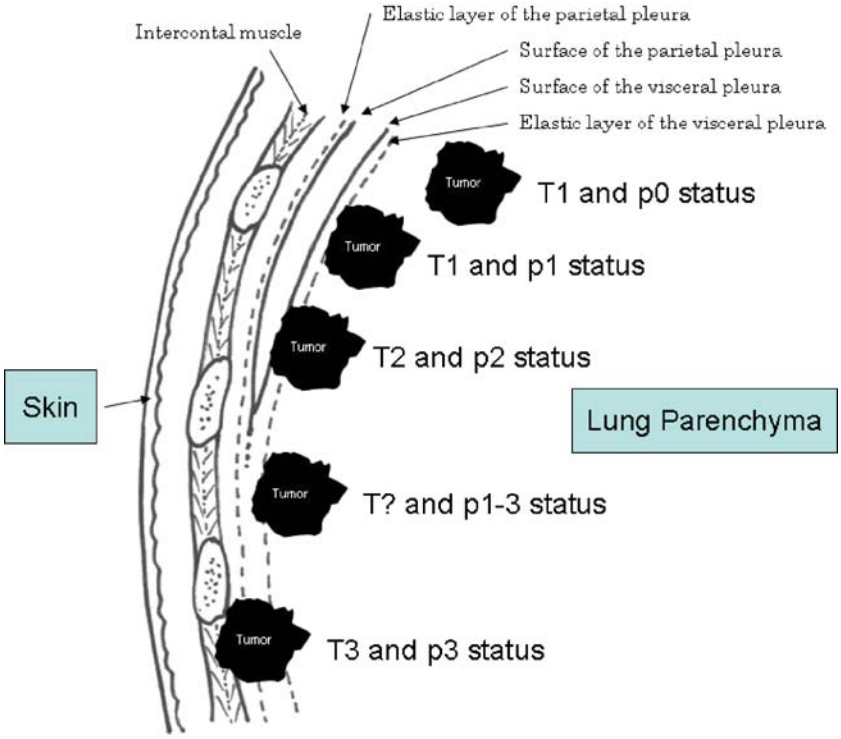

Fig. 1 Schematic illustration of the T factor and the histological pleural invasion grades. The current TNM classifications of the UICC staging system are as follows: T1 disease is defined as a tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura; T2 disease involves tumors more than 3 cm in greatest dimension and/or invasion of the visceral pleura; and T3 disease is a tumor of any size that directly invades the chest wall, including the parietal pleura. On the other hand, the JLCS classifications of visceral pleural invasion based upon histological examinations are as follows: p0, tumor with no pleural involvement beyond its elastic layer; p1, a tumor that extends beyond the elastic layer of the visceral pleura but with no exposure on the pleural surface; p2, a tumor with exposure on the visceral pleural surface but no involvement of adjacent anatomic structures; and p3, a tumor that involves adjacent anatomic structures. However, there is no clear definition as to the p factor when a tumor extends beyond the visceral pleura but has no clear adjacent parietal pleural invasion in cases with tight adhesion between visceral and parietal pleurae histologically (we term this condition p1–3)

Since unequivocal parietal pleural invasion is diagnosed as T3, the question arises as to whether invasion beyond the visceral pleura at tight adhesion sites (excluding interlobar invasion) should also be considered in the same way. To clarify this point, a series of resected non-small cell lung cancers (NSCLCs) with invasion histologically demonstrated beyond the visceral pleura at adhesion sites were studied here.

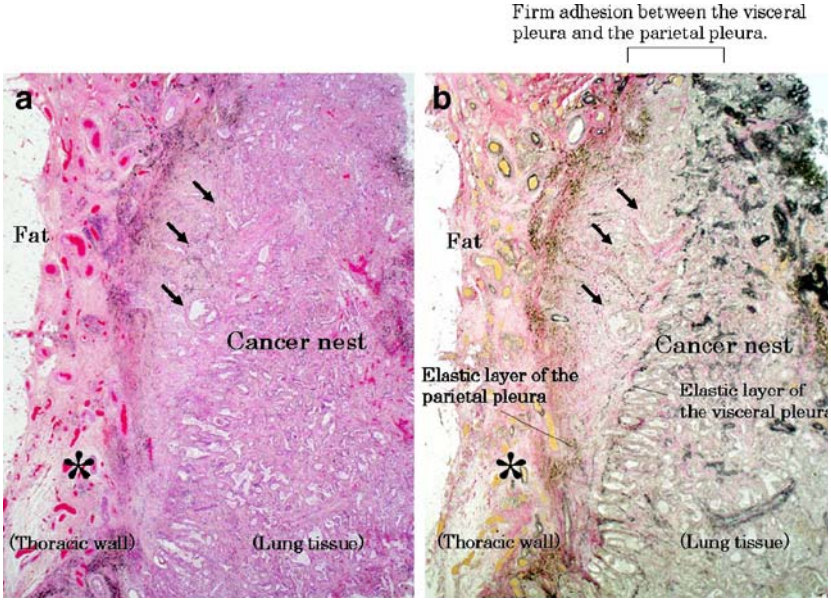

Fig. 2 Histologic features of a p1–3 case. Note cancer invasion extending beyond the visceral pleura with firm adhesion between visceral and parietal pleurae (*arrows*). However, destruction of parietal elastic fibers and chest wall invasion are not apparent. (**a** Hematoxylin and eosin stain, ×4; **b** elastica van Gieson stain, ×4; *asterisks* indicate the endothoracic fascia.)

Materials and methods

Between 1980 and 2002, 1,179 consecutive patients with NSCLCs underwent curative surgical resection at the Cancer Institute Hospital. Staging definitions for T (primary tumor), N (regional lymph nodes), and M (distant metastasis) components were according to the International Staging System for Lung Cancer [4, 5]. Twenty lung cancer patients (1.7%) with p1–3 pleural invasion were included. These patients were studied clinically and pathologically in comparison with cases having stage IB (T2N0), IIA (T1N1), IIB (T2N1 or T3N0), or IIIA (N2 disease) treated during the same period.

Histologically, pleural invasion was evaluated by elastic fiber staining and subdivided into four pleural invasion grades according to the JLCS criteria [6], as follows: p0, tumor with no pleural involvement beyond its elastic layer; p1, tumor that extends beyond the elastic layer of the visceral pleura but is not exposed on the pleural surface; p2, tumor that is exposed on the pleural surface but does not involve adjacent anatomic structures; and p3, tumor that involves adjacent anatomic structures with destruction of parietal pleural elastic fibers (Fig. 1). Briefly, p0 and p1 diseases belong to T1, p2 to T2, and p3 to T3 disease. Further, the p1–3 status was identified as follows: invasion extending beyond the visceral pleura but showing unclear parietal pleural invasion (excluding interlobar invasion) in cases with firm adhesion between the tumor and parietal pleura (Fig. 2). In this condition, parietal pleural invasion was hard to evaluate due to destruction of parietal pleural elastic fibers as a result of inflammatory process. When the elastic layer of the visceral pleura was not sufficiently well developed, we turned the existence of fat layer to account as an auxiliary pointer for parietal pleura.

N3	1	0

[a]All cases were diagnosed as p1–3 on postoperative pathological examination

The 20 patients with p1–3 were 19 men and one woman with an age distribution of 44–80 years. The tumors comprised nine adenocarcinomas, seven squamous cell carcinomas, and four large cell carcinomas (Table 1). There were 14 N0, one N1, and five N2 cases (Table 2). Lobectomy and parietal resection with a sufficient safety margin was performed for 18 patients, bilobectomy for one, and pneumonectomy for the remaining one. Parietal resection included the parietal pleura in 17 cases, and the pericardium, diaphragm, and chest wall in one case each. En bloc mediastinal lymph node dissection was performed for all patients, and lymph nodes were carefully examined for pathological staging. Five suffered relapses and died of lung cancer (one with locoregional recurrence, two with distant metastases, and two for which precise data were not available). One patient died of pneumonia. Fourteen patients are alive and disease-free 5 years after surgery.

Survival curves were plotted using the Kaplan–Meier method, and p values were calculated using the log-rank test, $p<0.1$ being considered statistically significant. To maximize the power to detect a potential of p1–3 as a prognostic marker, we set the significance level at 0.10, one-sided, in accordance with common statistical practice and the proposal by Makuch and Simon [7].

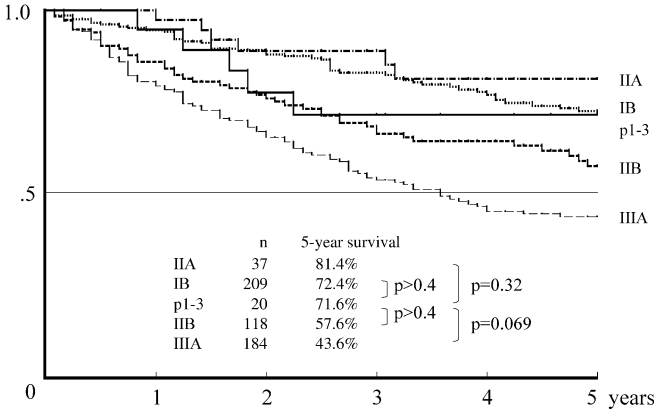

Fig. 3 The 5-year survival rates for patients with p1–3 or stage IB, IIA, IIB, or IIIA disease

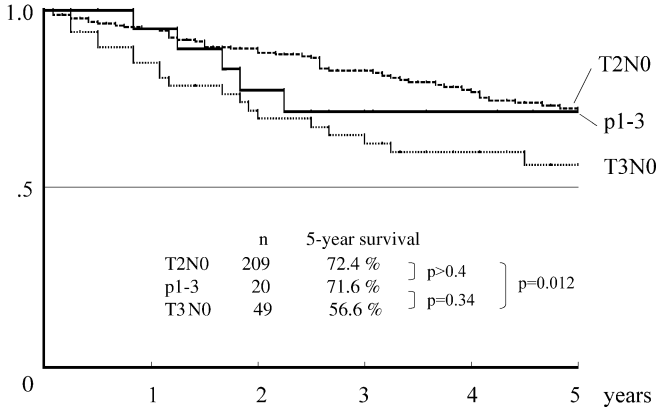

Fig. 4 The 5-year survival rates for patients of the p1–3, T2N0, and T3N0 subgroups

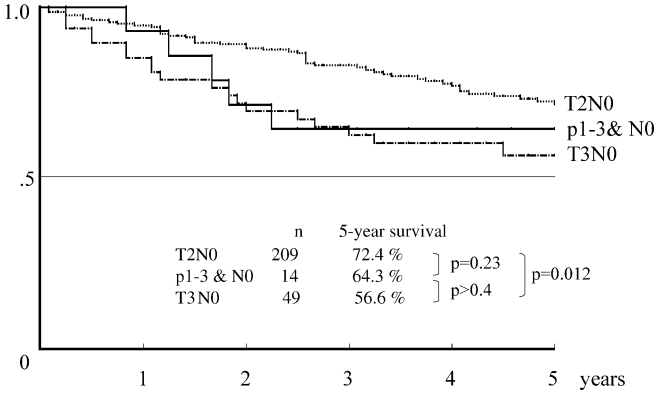

Fig. 6 The 5-year survival rates for patients of the p1–3 and N0, T2N0, and T3N0 groups

The operative technique was as follows: the chest cavity of each patient was entered posterolaterally. Within the pleural cavity, the limits of chest wall invasion and the state of the mediastinal lymph nodes were explored to ascertain operability. To define the disease-free margins of resection for the parietal pleura, diaphragm, rib and pericardium, the tumor was palpated and the boundaries were grossly assessed. Thus, a free margin was estimated, and en bloc resection of the chest wall with lungs was performed. When obvious chest wall invasion was not found but tight adhesion between visceral and parietal pleurae near the tumors was apparent, extrapleural resection was performed. Areas suspected of neoplastic involvement at the margin were sent for immediate histologic analysis of frozen sections.

Results

First, the p1–3 group was compared with those with stage IB (n=209), IIA (n=37), IIB (n=118), and IIIA (n=184) diseases regarding survival. The 5-year survival rates were 71.6, 72.4, 81.4, 57.6, and 43.6%, respectively, with significant intergroup differences for IB and IIIA, IIA and IIIA, IIB and IIA (p<0.05), and p1–3 and IIIA (p=0.069) (Fig. 3).

Then, 5-year survival rates were compared between p1–3 and stage IB (T2N0), and IIB (T3N0 and T2N1) subgroups with regard to status of pleural invasion and lymph node metastasis. When disease was subclassified into T2N0 (n=209), T3N0 (n=49) and p1–3, the values were 72.4, 56.6, and 71.6%, respectively. Those for T3N0 and T2N1 were 56.6 and 58%, respectively. No significant differences in prognosis were evident between p1–3 patients and T3N0 or T2N1 subgroups (Fig. 4). Among the N0 and pm0 (no intrapulmonary metastasis) patients, the 5-year survival rates for p0 (n=401), p1 (n=74), p2 (n=39), p3 (n=51), and p1–3 groups were 87.2, 74.4, 54.6, 50.4, and 71.6%, respectively, being statistically significant between p0 and p1–3 (p=0.006) and p0 and p1 subgroups (p=0.003) (Fig. 5). Although no significant difference in survival rates was found between p1–3 and p2 or p3 subgroups, the 5-year survival rate of the p3 subgroup was poorer than those of p1–3 (Fig. 4). The 5-year survival rates of patients with T2N0 (n=209), T3N0 (n=49), and p1–3 with N0 (n=14) were 72.4, 56.6, and 64.3%, respectively, the differences between p1–3 and T2N0 or T3N0 subgroups not being statistically significant (p values were

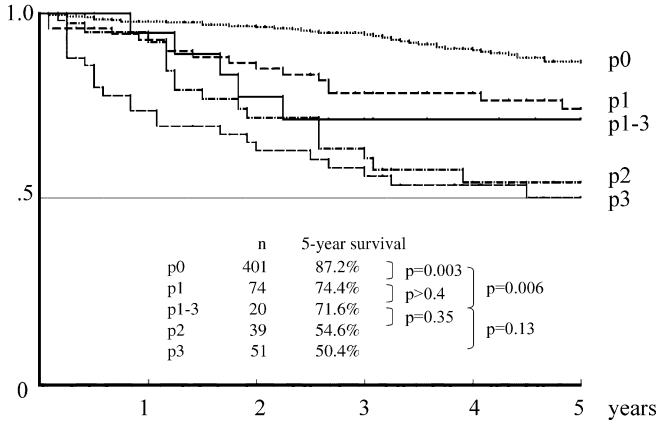

Fig. 5 The 5-year survival rates for patients with different p factor grades

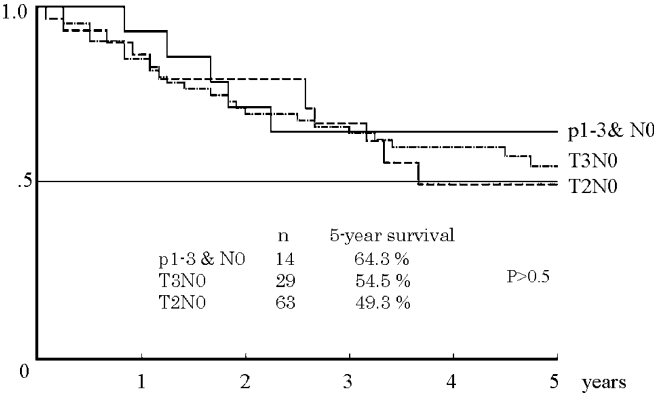

Fig. 7 The 5-year survival rates for patients of the p1–3 and N0, T2N0, and T3N0 groups of cases undergoing pulmonary with chest wall resection

0.23 and >0.4; Fig. 6). Moreover, the 5-year survival rates of patients with T2N0 (n=63), T3N0 (n=29), and p1–3 with N0 (n=14), a series of cases undergoing pulmonary resection with chest wall resection, were 49.3, 54.5, and 64.3%, respectively, the differences not being statistically significant (p values >0.5; Fig. 7).

Among five cases with N2 disease in the p1–3 group, two remain alive without evidence of disease, one alive with disease, and two died of other diseases, which suggest a relatively good prognosis.

Although chest wall invasion was assessed preoperatively in three cases (15%), no patient had symptoms of chest pain (Table 2).

Postoperative radiotherapy was carried out for two (10%) patients in the p1–3 group. Preoperative systemic chemotherapy was also administered in only one case, but none received such drugs postoperatively.

Discussion

It was reported that elastic fiber stains provide prognostically important information for diagnosis of pleural invasion [8, 9]. However, it is difficult to determine the accurate pleural invasion factor histologically when a cancer shows the p1–3 status, extending beyond elastic fibers of visceral pleura but not reaching those of the parietal pleura at tight adhesion sites. We therefore performed the present comparative study, which indicated that classification as a T2 disease may be most appropriate. Thus, the outcome was better than that of patients with T3 invasion, although without statistical significance because of the small numbers. The outcome of five cases with N2 disease indicates that complete resection is a more influential positive factor for prognosis than the degree of pleural invasion [10]. Our results therefore agree with the currently prevailing notion that long-term survival is related to the extent of nodal involvement and completeness of resection in lung cancer with chest wall invasion [11–13].

Preoperative diagnosis of chest wall invasion is still a matter of debate [5]. Modalities such as chest X-rays, ultrasounds, CT, and magnetic resonance imaging lack specificity and sensitivity, except in the presence of extensive bone destruction [14, 15]. In our series, invasion beyond visceral pleura was not evident in CT scans of 17 patients (85%), and this approach may be inaccurate for assessing the p1–3 status.

Visceral pleural invasion, which is frequently associated with extensive N2 involvement of lung cancer, is a factor of poor prognosis [3, 16]. In our p1–3 group, nodal involvement was very few, and the presence of lymph node metastases did not reduce survival time. We did not use N factor in the current study for survival analysis because there was no significant difference in preoperative and postoperative N status in our series (Table 2).

A number of investigators have reported that patients with chest wall invasion show different prognoses depending on the site, i.e., whether it be the parietal pleura, intercostal muscle layer, or ribs [17, 18]. When a lung cancer invades beyond the parietal pleura (T3 status), en bloc resection of both lung and chest wall resection should be performed. As a surgical procedure, Akay et al. have argued that an extrapleural resection provides adequate tumor clearance of firm adhesion between the tumor and only the parietal pleura of the chest wall [19]. However, in a series reported by Albertucci et al., the rate of local recurrence was significantly lower in patients undergoing en bloc chest wall resection than their counterparts receiving extrapleural resection [20]. When comparing the stages and p factors, we found similar survival times between the p1–3 group and stage IB and p1 subgroups (Figs. 2, 3, 4). We conclude, therefore, that extrapleural resection is appropriate for NSCLCs with p1–3 status.

In conclusion, our results indicate that p1–3 patients should be managed as having a T2 disease for the present, and that in such cases, complete tumor removal improves the long-term survival. Because of the small number of patients available for this analysis, additional studies are warranted for validation of p1–3 status as a T2 disease for NSCLCs.

Unusual sarcomatoid neoplasm of the lung suggesting a myofibrosarcoma

Received: 15 April 2005 / Accepted: 7 July 2005 / Published online: 13 September 2005
© Springer-Verlag 2005

Abstract Myofibrosarcoma is a rare neoplasm that occurs mainly in the head and neck region and extremities of middle-aged patients. It often appears as a low-grade sarcoma and rarely metastasizes. We report the case of a 47-year-old male patient with a malignant mesenchymal pulmonary tumor affecting almost the entire lower left lobe. Clinically suggestive for a lung carcinoma, the tumor showed typical features of a myofibrosarcoma. A major spindle cell component was observed being positive for smooth-muscle actin, calponin, and vimentin, while stainings for desmin, h-caldesmon, alkaline phosphatase (ALK), and extensively studied cytokeratins were negative. Striking was a strong infiltrate with neutrophilic and eosinophilic granulocytes. DNA cytometry revealed aneuploidy with a peak in the near triploid range. Comparative genomic hybridization demonstrated multiple DNA gains and losses correlating with an aggressive clinical course. Shortly after resection of the primary tumor, the patient showed multiple distant metastases in the contralateral lung, the mediastinal lymph nodes, the left adrenal gland, and the pectoral and deltoid muscle, which responded well to chemotherapy. The case report will discuss the evidence for the final diagnosis of a primary pulmonary myofibrosarcoma and the differential diagnosis of sarcomatoid tumors of the lung.

Introduction

The concept of myofibroblastic sarcoma, also known as myofibrosarcoma, has been the subject of controversial discussions [7, 16, 20]. The cell type of a myofibroblast was described only 30 years ago, primarily based on ultrastructural criteria, i.e., the coexistence of features of fibroblasts and smooth muscle cells as well as the finding of so-called fibronexus [7, 9, 14, 16, 22]. Meanwhile, myofibroblasts are regarded as distinct cell types, and a variety of myofibroblastic tumors has been defined. The myofibrosarcoma, which has now also been generally accepted as an entity by the World Health Organization (WHO) [8, 15, 16], is diagnosed by its histomorphological appearance and its immunohistochemical phenotype with expression of smooth-muscle actin and/or desmin [16, 17].

Myofibrosarcoma is a rare neoplasm, which is possibly underdiagnosed due to a lack of consensus on diagnostic criteria and pathological variability. Our knowledge about this entity comes from various case reports and two larger studies, describing 15 and 18 cases, respectively [16, 17]. Mostly, the tumor is located in the head and neck region (tongue, neck, and face) or in the extremities [4, 8, 15, 16, 17]. Montgomery et al. described 15 cases, 5 of which

involved the head and neck region, 5 the extremities, 3 the trunk, and 1 each the abdominal cavity and the breast [17]. Mentzel et al. reported 18 cases, 5 of which arose in the oral cavity, 7 in the extremities, 4 in the abdominal/pelvic cavity, and 2 in the trunk [16]. Intraosseous tumors have also been observed [24]. The lung has not yet been described as a site of primary myofibrosarcoma. The tumor occurs predominantly in adults rather than children; the patients' age ranged from 33 to 73 years (median 52 years) in the study of Montgomery et al. and from 19 to 72 years (median 42 years) in the study of Mentzel et al. It showed a slight male predominance [8, 16, 17].

Most tumors present as low-grade sarcomas and exhibit a rather benign behavior, with a local recurrence rate of 27% [8]. They rarely metastasize; however, both Mentzel and Montgomery each described one case with distant metastases in their studies [8, 16, 17]. Although the general term "low-grade myofibrosarcoma" is often used [15], intermediate-grade tumors have also been described when grading the tumor according to the French Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) system [8, 11]. These are associated with a worse outcome [8, 12, 17].

Clinical history

The 47-year-old male patient presented with clinical signs of pneumonia and was hospitalized for diagnostics and therapy. The patient had been smoking for 30 years, and the family anamnesis for cancer or lung disease was blank. Computer tomography (CT) demonstrated a solid mass of 103×89 mm in the lower lobe of the left lung with a poststenotic pneumonia, impression, but not infiltration of the diaphragm and no significant effusion. Three small lesions, with diameters up to 20 mm, were demonstrated in the upper left and the lower right lobe. Positron electron tomography (PET) demonstrated a metabolically active tumor with a necrotic center; the smaller lesions described in the CT were not detected by PET. The scintigraphy of the bone revealed no uptake. Taken together, there was strong evidence for a large primary lung tumor, with metastatic dissemination into both lungs.

The resection of the lower left lobe was executed shortly after the detection of the tumor. Preoperative biopsies had only shown necrotic material or chronic and florid inflammation and had not led to a tumor diagnosis. The postoperative course was uneventful, and the patient can be dismissed into ambulant aftercare. One month after the primary surgery, the control CT revealed a new tumor nodule 4 mm in size in the upper left lobe and progression of the contralateral foci, the largest now being 26 mm in diameter. New findings were multiple mediastinal lymph nodes of up to 12 mm and a node in the left adrenal gland with a size of 17×12 mm.

The patient was hospitalized again 3 weeks later with new foci, this time in the left deltoid and pectoral muscle and the left axilla, all being around 20 mm in diameter. One lesion was sampled, showing the same histomorphology as the primary. Assessment of the renal function revealed a decreased creatinine clearance of 48 ml/min. Therefore, as systemic chemotherapy, a combination of dimetyl-triazeno-imidasole-carboxamide (DTIC) and doxorubicin was chosen instead of an ifosfamide-containing regimen. Within the following 6 weeks, the patient received three cycles of DTIC 300 mg/m^2 (d1-3) and doxorubicine 75 mg/m^2 (d1). Chemotherapy was well tolerated, but fever due to neutropenia occurred after the second cycle and was successfully treated with piperacillin–tazobactam. Clinical observation after the third cycle of chemotherapy showed regression of the subcutaneous lesions. Likewise, abdominal ultrasound at this time showed regression of the adrenal gland metastasis, confirming partial remission.

Materials and methods

The pneumonectomy specimen was fixed in 4% buffered formalin. After fixation, the larger bronchi were opened lengthwise, and the parenchyma was laminated into slices of 5 mm. Thirty specimens, representative of the tumor, including bronchial and vascular invasion sites, tumor center, and tumor margin, were paraffin-embedded for routine histology and immunohistochemistry. Hematoxylin and eosin (H & E) staining was performed on 5-μm sections according to standard procedures.

Immunohistochemistry was carried out using antibodies for BerEP 4, pancytokeratin, CK7, CK18, EMA, TTF-1, surfactant A, calretinin, vimentin, desmin, alpha-smooth-muscle actin (BioGenex) and myosin, h-caldesmon (Bio Genex), calponin, alkaline phosphatase (ALK), factor VIII, CD34, MIB-1, CD117, melan A, S-100, synaptophysin, chromogranin, CD56, CD3, CD20, CD30, and CD68. Antibodies and detection system were purchased from DAKO if not otherwise indicated and were applied according to the manufacturer's recommendations.

For static DNA cytometry, a tumor slide of 15 μm was deparaffinized and digested with trypsin. After Feulgen staining was carried out using Merck reagents, the DNA content of 308 selected tumor cells was measured on a Leica microscope and analyzed using AutoCyte software (AutoCyte, Burlington, NC, USA) [2]. For calibration, 28 normal fibroblasts from cell cultures were used.

Comparative genomic hybridization (CGH) was performed as previously described [19]. Digital image analysis with karyotyping and calculation of the CGH ratio was performed using the computer program Karyomed, available through Karyomedics (http://www.KaryoMedics.de).

Results

The majority of the resected lung lobe was affected by a solid tumor with mainly well-defined margins (Fig. 1a). The tumor cambered but did not penetrate the pleura. Its cut surface was firm, rather homogeneous grayish white, with some areas of gelatinous necrosis, each about 10–20 mm in diameter. The tumor infiltrated large and small bronchi and

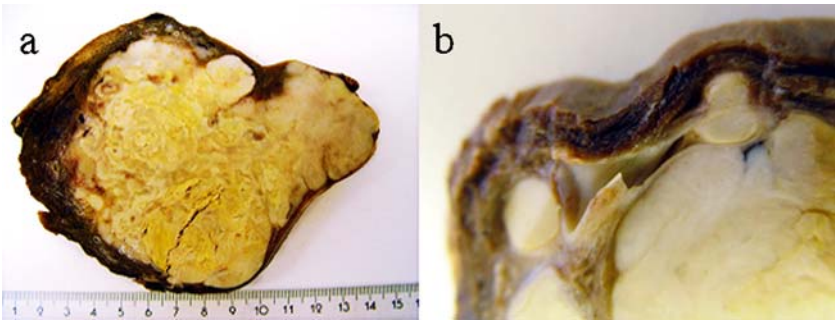

Fig. 1 **a** Cross section through the resected lung lobe showing a large tumor with rather well-defined margins and a nodular, white cut surface. **b** Close-up view of the tumor periphery demonstrating nodular margins and tumor invasion into a large blood vessel

one large blood vessel (Fig. 1b). The rest of the lung showed a slight mucus retention. One separate subpleural, circumscribed tumor nodule of 5-mm size, with a firm white cut surface, was additionally detected.

Histopathological examination demonstrated a spindle cell neoplasm with a strong inflammatory superposition. The tumor showed marked heterogeneity. Fasciculated areas alternated with solid ones. In some parts, an almost netlike vascularization was found. Focally, a pale eosinophilic extracellular matrix was present, which passed into hyalinized areas. Several central areas of about 10–20 mm diameter were necrotic, constituting less than 50% of the entire tumor (score 1 according to FNCLCC grading [11, 15]). In large parts, the picture was dominated by neutrophilic and eosinophilic granulocytes; additionally, lymphocytes and plasma cells were present in smaller numbers (Fig. 2a). The tumor infiltrated diffusely into the surrounding lung tissue, filling the alveoli rather than infiltrating the septa; no pushing borders were seen. The tumor cells themselves were basically spindle-shaped and displayed a remarkable heterogeneity. The cytoplasm was blurred and pale eosinophilic. No perinuclear vacuoles could be found. Some tumor cells had medium-sized, cigar-shaped nuclei, others had elongated and undulated nuclei, while others had markedly enlarged, plump, oval, or bizarre nuclei with indentations (score 2; Fig. 2b,c).

Prominent nucleoli were sometimes present. Up to three mitoses per ten high-power fields (HPF) (0.196 mm^2) were counted (score 1); the proliferation index (MIB-1 immunohistochemistry) was approximately 20%.

The tumor cells were immunohistochemically positive for smooth-muscle actin (Fig. 2d), calponin, and vimentin. No expression was detectable for desmin, h-caldesmon, pancytokeratin, CK7, CK18, (five samples for each antibody), ALK, BerEP4, EMA, CD117, melan A, S-100, synaptophysin, chromogranin, CD56, calretinin, TTF-1, surfactant A, CD3, CD20, CD30, and CD68 (one sample for each antibody).

The separate subpleural tumor nodule and the subsequently sampled subcutaneous metastasis exhibited a similar histomorphology as the large tumor of the lung. The remote lung tissue showed no pneumonia. The bronchial

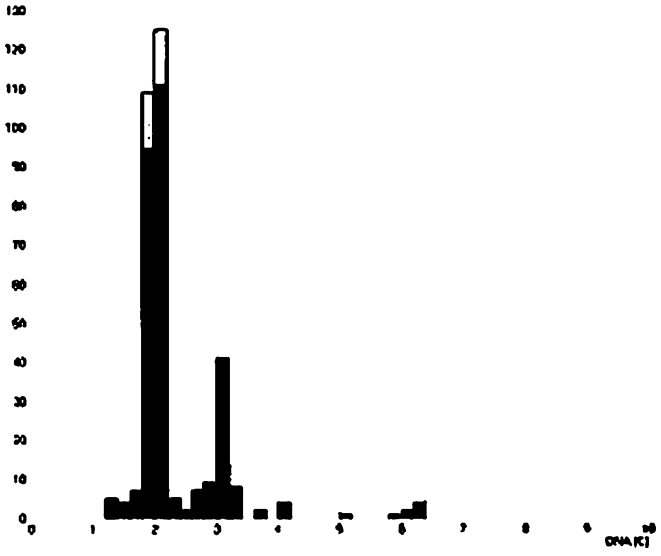

Fig. 3 Histogram of the DNA cytometry measurement demonstrating an aneuploid tumor stemline at 3.1c and a doubling line at 6.2c in addition to peak at 2c, which might be due to normal cell contamination or near diploid tumor cells (*dark*, tumor cells; *light*, reference cells)

epithelium displayed no squamous metaplasia, and, in particular, no dysplasia.

Electron microscopy was carried out on samples from five different tumor sites. However, due to fixation in formalin for some days, the membrane integrity was destroyed, and neither features of epithelia nor of myofibroblasts could clearly be detected. Therefore, electron microscopy was not contributory to the diagnosis.

DNA cytometry demonstrated an aneuploid tumor (Fig. 3) with an abnormal stemline at 3.1c and the appropriate doubling peak at 6.2c.

Comparative genomic hybridization was carried out twice. In a first evaluation of a tumor area with the typical pronounced granulocytic infiltration, no DNA gain or loss could be unequivocally detected. In a second analysis of another tumor area with less inflammation and almost pure spindle cell differentiation, numerous chromosomal imbalances became visible, correlating with the aneuploidy detected by DNA cytometry. Prominent DNA overrepresentations (ratio>1.25) were detected at 1p34.1–p36.2, 11q12, 16p12–p13, 17p12–p13, 17q12–q25, 19p + q, 20q12–q13, and 22q12–q13, while a clear deletion (ratio< 0.75) was seen at 13q13–q34 (Fig. 4).

Based on the histopathological evaluation and the immunohistochemical expression profile, we diagnosed a primary myofibrosarcoma of the lung. According to the FNCL CC grading system, a total score of 4 leads to the diagnosis of an intermediate-grade tumor (grade 2) [11].

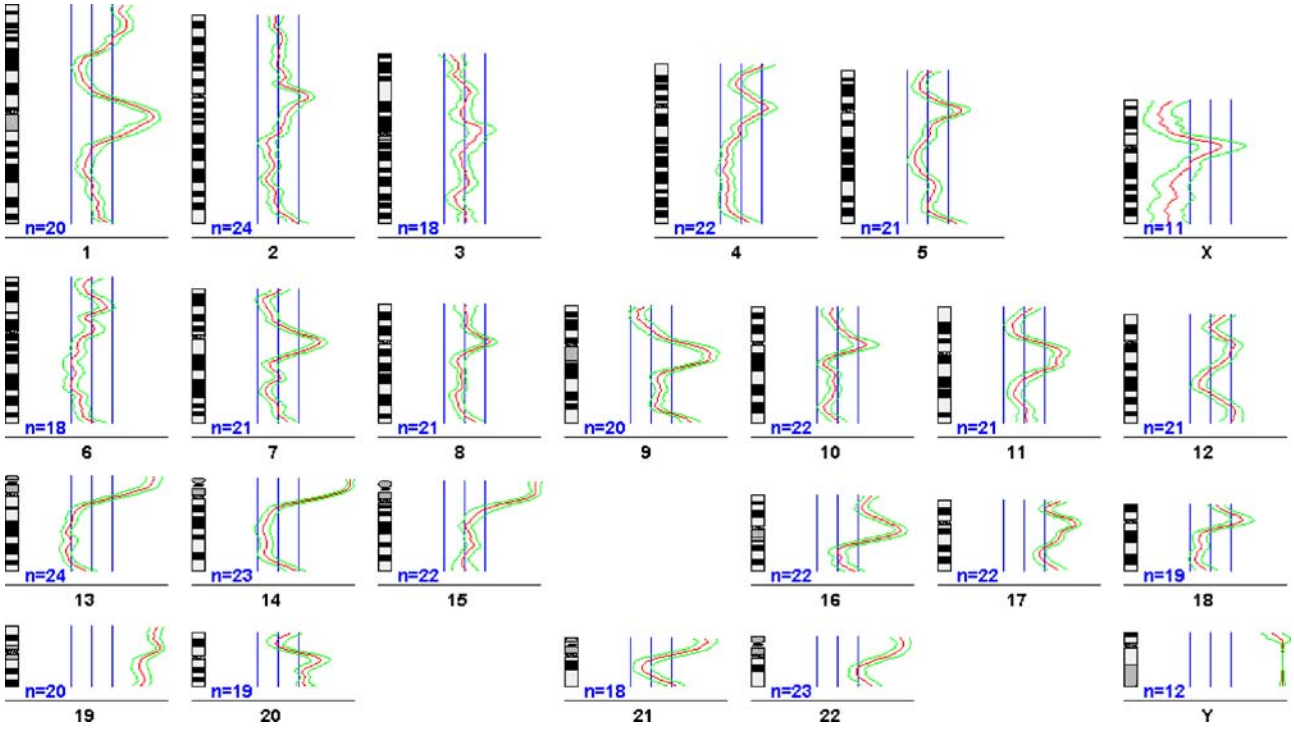

Fig. 4 Results of the CGH demonstrating multiple DNA gains and losses. Deviation of the ratio profile together with its 95% confidence interval to the *left side* from the mean *vertical line* representing the normal ratio 1.0 was scored as deletion, deviation to the *right* was scored as overrepresentation. The *left* and *right* vertical lines represent the ratio values *0.75* and *1.25*, respectively. Pronounced DNA gains and losses, potentially representing high-copy amplifications or multi-copy deletions, were defined by regions in which the ratio profile exceeded the values *1.5* or *0.5*. The tumor DNA of the male patient was hybridized together with female reference DNA, leading to the deviations of ratio profiles of Y and X chromosomes which served as internal control

Discussion

The myofibrosarcoma, or myofibroblastic sarcoma, is a rare tumor that rarely metastasizes. We report the first example of such a tumor occurring in the lung [8, 16, 17].

Our diagnosis was based on the typical light microscopic picture of the tumor cells with blurred cytoplasm and heterogeneous, partly spindle or cigar-shaped, sometimes undulated, sometimes plump nuclei with indentations. The immunohistochemical demonstration of smooth-muscle actin and calponin in the absence of cytokeratins, ALK, and h-caldesmon especially led to the diagnosis of a myofibrosarcoma. Electron microscopy was not contributory due to membrane degradation. A variety of differential diagnoses (DD), however, needs to be considered, i.e., inflammatory myofibroblastic tumor (IMT, also known as inflammatory pseudotumor), sarcomatoid mesothelioma, spindle cell melanoma, lymphoma, leiomyosarcoma, fibrosarcoma, and, in particular, lung carcinoma.

From tumor morphology, particularly the pronounced inflammatory cell infiltrate, IMT was the most imminent DD. This entity typically shows a mixture of histiocytes, lymphocytes, fibroblasts, and, in particular, plasma cells, with the fibroblasts showing expression of ALK [1, 12, 13]. Plasma cells were also present in our case but not as the predominant population. The major distinction, however, was the infiltrative growth pattern, the absence of ALK-positive cells, and finally, the presence of distance metastases in our case. Due to the morphological similarity, it might be hypothesized that the tumor originated as an IMT since Donner described a case in which an IMT progressed into a spindle cell sarcoma after several recurrences and a 12-year course [5]. However, such a long preclinical development was not evident in our case.

Apart from the untypical morphology, melanoma and malignant lymphoma can be excluded by the negative immunostains for protein S-100, melan A, as well as CD3, CD20, and CD30. Similarly, other sarcomatous lesions, especially leiomyosarcoma and fibrosarcoma, were excluded by histology and immunohistochemistry [8, 12, 23]. Sarcomatoid mesothelioma was excluded because of lack of calretinin and cytokeratin expression. Furthermore, the tumor exhibited a predominant intrapulmonary growth pattern, with only secondary involvement of the pleura.

The DD of a synovial sarcoma and spindle cell carcinomas was essentially excluded by the negativity of the tumor cells for cytokeratin expression, which was tested by investigating a panel of cytokeratins on different tissue blocks. High-grade synovial sarcoma may occur in the lung [6]; however, the tumor cells rather have a scanty cytoplasm, and the nuclei, which are tightly seated and often overlapping, are oval, with finely dispersed chromatin [3]. Furthermore, glandular elements typical for biphasic synovial sarcoma were not detectable.

Spindle cell carcinoma is another important and critical DD. Clinical and pathological parameters were suspicious, i.e., the clinical history of long-time cigarette smoking, the pattern of metastasis formation, the good response to chemotherapy, and the association with the bronchial airways. Spindle cell carcinomas have been reported to lose their cytokeratin expression while acquiring mesenchymal markers, like desmin, actin, or vimentin [18]. However, spindle cell carcinomas are described as rather homogeneous with plump cytoplasm and prominent nucleoli [3], which was not evident in the present case.

By cDNA microarray analysis, we had demonstrated that large cell lung carcinomas acquire an expression profile indicative of an epithelial–mesenchymal transition [10]. Large cell cancer may show a prominent inflammatory infiltrate with eosinophilia, which might be related to the expression of granulocyte colony-stimulating factors by the tumor cells [21]. Additionally, the DNA histogram of the present tumor showed a peak at the near triploid range, clearly indicating an aneuploid tumor, with many tumor cells having a chromosome complement in the near trisomic range similar to many nonsmall cell lung carcinomas [19]. Furthermore, the complexity of the chromosomal imbalance pattern detected by CGH, which, when applying more sensitive criteria for scoring DNA gains and losses, suggested even more alterations, including interstitial deletions on chromosome 3p, is also reminiscent of lung cancer. However, no precursor lesions of lung carcinoma, like dysplasia or squamous metaplasia, were detectable. Similarly, not even small areas with clear epithelioid tumor differentiation or cytokeratin expression were seen. Finally, neither DNA measurement nor extensive chromosomal studies have yet been performed on myofibrosarcomas that provide further criteria for establishing or disproving the diagnosis. In summary, the evidence prevailed for the final diagnosis of a primary myofibrosarcoma of the lung.

Hepatocellular carcinoma and nonalcoholic steatohepatitis developing during long-term administration of valproic acid

Received: 25 February 2005 / Accepted: 6 July 2005 / Published online: 17 August 2005
© Springer-Verlag 2005

Abstract We report a case of hepatocellular carcinoma (HCC) arising in nonalcoholic steatohepatitis (NASH). The patient, a 64-year-old man, was incidentally found to have multiple tumors in the liver when admitted for pneumonia. He had been obese, had been receiving a standard dose of valproic acid since clipping surgery for subarachnoid hemorrhage 17 years previously, and had not consumed any alcohol since the surgery. Laboratory data revealed moderate hyperlipidemia and no evidence of diabetes mellitus, hepatitis B or C infection. The patient died of hepatic insufficiency, and an autopsy was performed. A tumor, a maximum of 13 cm in diameter, grossly occupied the entire left lobe and one third of the right lobe of the liver. Histologically, moderately differentiated HCC was found with foci of poorly differentiated HCC. The non-tumorous area showed NASH with moderate bridging fibrosis, without interface hepatitis, hemochromatosis, or copper accumulation. In this patient, obesity, hyperlipidemia, and long-term treatment with valproic acid could have all been associated with induction of NASH. The present case suggests that HCC could develop in non-cirrhotic NASH liver, and that chronic inflammation in itself could be an important risk factor in the development of HCC.

Introduction

Nonalcoholic steatohepatitis (NASH) is part of the spectrum of nonalcoholic fatty liver disease (NAFLD), clinically related with metabolic syndrome [3], and is histologically indistinguishable from alcoholic hepatitis [1]. Although the natural history of NASH has yet to be fully clarified, simple hepatic steatosis is nonprogressive, whereas nearly 20% of NASH cases may slowly progress to cirrhosis [8], and distinctive cases with hepatocellular carcinoma (HCC) arising in NASH have recently been reported [6, 13, 16, 17, 19, 23]. Valproic acid (VPA) is a worldwide antiepileptic drug, which occasionally causes idiosyncratic hepatotoxicity, but the association of VPA with steatohepatitis and HCC has not been determined [1]. This is the first report of HCC arising in moderately fibrosing NASH liver in a patient receiving long-term VPA administration.

Clinical history

A 64-year-old man was admitted to hospital with a diagnosis of pneumonia. CT scans of the lower chest incidentally detected multiple tumors in the liver. The patient had received VPA (800 mg per day, standard dose) since clipping surgery for subarachnoid hemorrhage 17 years previously. He had been a chance drinker but had consumed no alcohol since the surgery 17 years previously. His family history was unremarkable. Laboratory data had irregularly shown slightly elevated liver enzymes. At the time of admission, total cholesterol (261 mg/dl) and triglyceride (175 mg/dl) levels were moderately increased, and the serum levels of α-fetoprotein (18,270 ng/ml) and PIVKA-II (487 AU/ml) were highly elevated. The HbA_{1C} value was within the normal range. Hepatitis B surface

Fig. 1 Macroscopic appearance of the cut surface of the autopsied liver. The main tumor occupies the entire left lobe and approximately one third of the right lobe of the liver. There are also multiple nodules in the right lobe

antigen and anti-hepatitis C virus antibody in the serum were negative. Neither liver biopsy nor chemotherapy was performed. The patient died of hepatic insufficiency 1 year after admission, and an autopsy was performed 2 h after death.

Materials and methods

The autopsy specimens were fixed in 10% formalin and embedded in paraffin. Tissue sections of 4 μm in thickness were stained for hematoxylin and eosin as well as the Azan-Mallory method.

Results

At autopsy; the patient was obese, 82 kg in weight (BMI 34.1 kg/m^2), and 155 cm in height. The skin showed an icteric discoloration. Massive ascitic fluid (6,000 ml) was observed. The liver weighed 1,500 g, and the gross appearance showed that the tumor measured a maximum of 13 cm in diameter. The tumor occupied the entire left lobe and one third of the right lobe of the liver (Fig. 1). Histologic examination revealed that the tumor consisted mainly of moderately differentiated HCC, with a focal pseudoglandular pattern (Fig. 2a). A poorly differentiated HCC component was also observed in some parts of the tumor. HCC cells with marked fatty deposition were also observed focally (Fig. 2b). In the background of the tumor, both micro- and macrovesicular steatosis was apparent, especially in the centrilobular area. Ballooned liver cells with Mallory bodies and infiltrates of neutrophilic cells were commonly observed around the central veins (Fig. 2c). Spotty necrosis was scattered throughout the lobules. Perivenular and pericellular fibroses were also manifested. Bridging fibrosis between the central veins and portal tracts was evident, but regenerative nodules had not formed (Fig. 2d). There was no evidence of interface hepatitis, hemochromatosis, or copper accumulation.

Discussion

This case is interesting as HCC developed in a non-cirrhotic NASH liver, and the patient had received long-term VPA therapy. The liver, in the presence of NASH, may have the potential to progress to cirrhosis and liver

failure, thereby promoting the development of HCC [17]. Although a large number of HCCs have been reported to arise in cryptogenic cirrhosis in patients with risk factors for NAFLD [4], the accurate incidence of HCC in NASH remains undetermined [3]. Half of the patients with cryptogenic cirrhosis have pathological and clinical characteristics consistent with NAFLD and account for 13% of HCC cases [12]. Some cases of cryptogenic cirrhosis have histologic features of burned-out NASH [15]. Cases of HCC that developed in NASH are not uncommon; however, to our knowledge, there have been only 11 well-documented cases reported in the literature [6, 13, 16, 17, 19, 23].

Table 1 summarizes the clinicopathologic features of the cases of HCC developing in NASH, including the present case. The histology of the background liver was cirrhosis in ten cases, and pre-cirrhosis in only one case. The present case is unique in that the tumor developed in a non-cirrhotic liver. More than 80% of patients with HCC have underlying cirrhosis [18], and cirrhosis itself is recognized as a common factor promoting HCC. However, the remaining cases of HCC, approximately 20%, can develop in a non-cirrhotic liver. There is a report of an animal study in which a new inbred mouse strain, fatty liver Shionogi, spontaneously developed fatty liver and HCC in the non-cirrhotic liver [21]. Although it remains uncertain whether cirrhosis is required for the development of HCC, at least, this case indicates that HCC can arise in a non-cirrhotic NASH liver.

Reactive oxygen species (ROS), products due to oxidative stress, activate lipid peroxidation, and TGF-β induction, can stimulate fibrosis [1]. On the other hand, the major products of lipid peroxidation, malondialdehyde, and 4-hydroxynonenal, act as DNA mutagens [11], which might be associated with the initiation of HCC [5]. Because inflammation is a principal source of ROS, chronic inflammation can be a risk factor for various carcinomas [7]. Recently, mice with somatic inactivation of the *nrf1* gene in the liver have been reported to spontaneously develop HCC in a background of non-cirrhotic liver, and oxidative injury had been present before tumor development [22]. These results suggest that ROS overproduced in NASH liver could trigger carcinogenesis as well as fibrosis, and that cirrhosis is not essential for the development of HCC.

Major risk factors for primary NASH are: obesity, type 2 (non-insulin-dependent) diabetes mellitus, and hyperlipidemia [1]. Hyperinsulinemia is an underlying factor in these conditions. NAFLD was found to be present in almost 90% of patients with obesity; approximately 25% of whom had NASH [14]. About 50% of patients treated with VPA, which is speculated to modulate insulin secretion and systemic metabolism, experienced weight gain [2]. The present patient was obese and presented moderate hyperlipidemia, without evidence of diabetes mellitus. Obesity might be influenced by VPA and be indirectly associated with the development of HCC through the induction of NASH.

Causes of secondary NASH include: drugs, nutritional factors, and metabolic or genetic disorders [1]. VPA, a short fatty acid derivative, can cause hepatic microvesicular steatosis, which is related to insulin resistance [1]. VPA also impairs mitochondrial β-oxidation, a frequent mechanism underlying drug-induced steatohepatitis [9]. Derangements of mitochondrial β-oxidation generate an overproduction of ROS, leading to enhanced lipid peroxidation and cytokine production similar to primary (obesity-related) NASH [1]. These pathogenetic factors may act as an enhancement of HCC development. Contrarily, VPA has shown anticancer activity mediating inhibition of histone deacetylases and an induction of carcinoma cell differentiation [10, 20]. However, the antiproliferative effect on carcinoma cells of VPA and the relationship between VPA treatment and HCC development are not evident.

Intravascular large T-cell lymphoma: a case report of CD30-positive and ALK-negative anaplastic type with cytotoxic molecule expression

Received: 15 June 2005 / Accepted: 25 August 2005 / Published online: 28 September 2005
© Springer-Verlag 2005

Abstract We reported a case of intravascular T-cell lymphoma (T-IVL) with anaplastic large cell morphology, the hemophagocytic syndrome, and an aggressive clinical course. Phenotypic analysis of the tumor cells revealed CD2+, CD3−, CD4+, CD5−, CD8−, CD30+, CD56−, T-cell receptor alpha/beta−, ALK−, TIA1+, granzyme B+, and perforin+. No association with Epstein–Barr virus was found by in situ hybridization. A review revealed that 25 cases of T-IVL have been reported in the available literature, only two of which were of CD30+ anaplastic large cell or cytotoxic T-cell type. The findings in the present case may highlight the unique clinicopathologic aspects of a subset of CD30-positive T-IVLs with an ALK-negative cytotoxic phenotype.

Introduction

Intravascular lymphoma (IVL) is a rare malignancy characterized by a proliferation of lymphoma cells only within the blood vessels. This disease was originally described in 1959 as "angioendotheliomatosis proliferans systemisata" when it was regarded as an endothelial neoplasm by Pfeger and Tappeiner [19]. However, in mid-1980s, immunohistochemical investigation and gene rearrangement studies demonstrated the neoplastic cells to be of lymphoid origin [21, 23].

An increasing number of IVL cases have been documented, most of which have provided evidence of derivation from B cells. The recent World Health Organization (WHO) classification defined intravascular B-cell lymphoma (B-IVL) as a rare subtype of extranodal diffuse large B-cell lymphoma [9]. A recent nationwide study of 3,194 Japanese patients with malignant lymphoma classified according to the new WHO classification showed a very low incidence (0.09%, three cases) of B-IVL and none of IVLs of T-cell type (T-IVL) [15]. On the other hand, 25 cases of T-IVL have hitherto been reported in the English literature [3–5, 7, 10–14, 16, 17, 20–23, 25–28, 30]. Among them, only one case was described as CD30+ anaplastic large cell type [12], whereas another CD30− case in a HIV-positive patient showed TIA1+ cytotoxic T-cell phenotype in association with Epstein–Barr virus (EBV) infection [17].

We herein report a case of T-IVL, which was unique in having a constellation of anaplastic large cell morphology, CD30+ALK−TIA1+granzyme B+perforin+ phenotype, the hemophagocytic syndrome (HPS), and an aggressive clinical course.

Case history

A 72-year-old Japanese man presented with a 7-day history of worsening flu-like syndrome. On admission, physical examination revealed hypotension, fever, and breathlessness. Lymphadenopathy or skin nodules were

not found. There were no risk factors for HIV infection in his lifestyle analysis. Two days after admission, the patient rapidly developed multiorgan failure. Laboratory examination revealed pancytopenia with a white blood cell count of 3.6×10^9/l, a hemoglobin level of 10.7 g/dl, and a platelet count of 17×10^9/l. Examination of bone marrow smears revealed many atypical large lymphoid cells and hemophagocytic macrophages, compatible with a clinical diagnosis of malignant lymphoma associated with HPS. The patient died within a week of admission despite CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy. An autopsy was performed, and a systemic gross examination showed no lymphadenopathy, hepatosplenomegaly, or tumor mass formation.

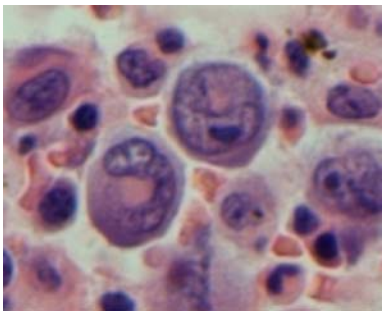

Fig. 2 Bone marrow section with tumor cells showing eccentric horseshoe-like nuclei with an adjacent eosinophilic region. These cells resemble "hallmark" cells in anaplastic large cell lymphoma (hematoxylin and eosin; original magnification ×400)

Materials and methods

Histologic and immunohistochemical staining

Formalin-fixed paraffin-embedded tissue blocks were available from all organs at autopsy. Immunoperoxidase studies were performed on formalin-fixed paraffin sections from autopsy specimens of bone marrow, lung, and lymph nodes using an avidin–biotin peroxidase complex method.

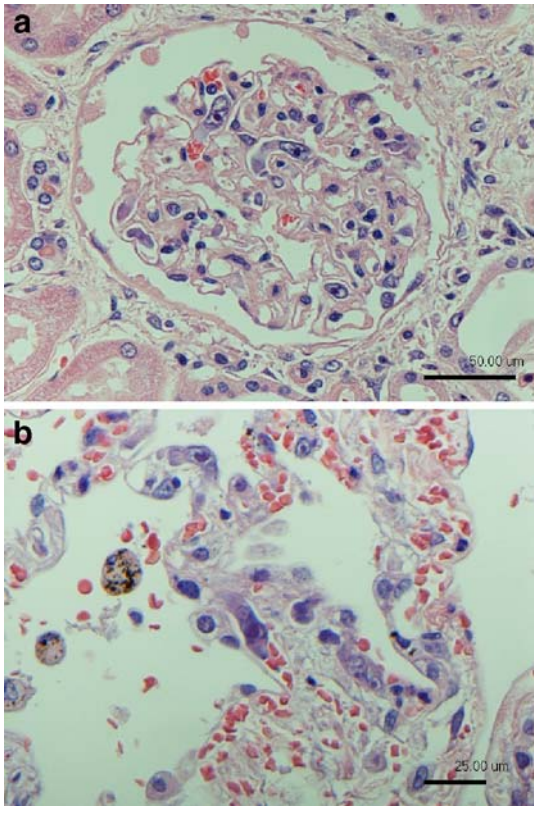

Fig. 1 **a** Autopsy kidney tissue shows single tumor cells in the capillaries of the glomeruli (hematoxylin and eosin; original magnification ×300). **b** Lung section exhibiting single tumor cells in the capillaries of alveolar septa (hematoxylin and eosin; original magnification ×400)

A panel of monoclonal antibodies against CD1a (O10, dilution 1:10; Immunotech), CD2 (AB75, dilution 1:40; Novocastra), CD3 (F7.2.38, dilution 1:25, Dako), CD4 (1F6, dilution 1:40; Novocastra), CD5 (4C7, dilution 1:40; Novocastra), CD8 (C8/144B, dilution 1:25; Dako), CD10 (NCL-CD10, dilution 1:40; Novocastra), CD15 (MMA, dilution 1:80; Becton-Dickinson), CD20 (L26, dilution 1:300; Dako), CD21 (1F8, dilution 1:20; Dako), CD23 (1B12, dilution 1:30; Novocastra), CD27 (137B4, dilution 1:50; Novocastra), CD30 (Ber-H2, dilution 1:15; Dako), CD43 (MT1, dilution 1:40; BioScience), CD45RA (4KB5, dilution 1:80; Dako), CD45RO (UCHL1, dilution 1:80; Dako), CD56 (1B6, dilution 1:50, Novocastra), CD57 (Leu7, dilution 1:50; Becton-Dickinson), CD68 (KP1, dilution 1:50; Dako), CD79a (JCB117, dilution 1:80; Dako), ALK (ALK1, dilution 1:25; Dako), EMA (E29, dilution 1:50; Dako), bcl-2 (124, dilution 1:80; Dako), βF1 (8A3, dilution 1:10; Endogen), granzyme B (GrB-7, dilution 1:80; Monosan), TIA1 (TIA-1, dilution 1:80; Immunotech), and perforin (5B10, dilution 1:20; Novocastra) were applied. For all antibodies except CD4, CD15, CD20, CD43, CD57, CD68, and EMA, the slides were pretreated with a microwave procedure for antigen retrieval.

In situ hybridization study

Assessment of the presence or the absence of EBV small ribonucleic acids (RNAs) by in situ hybridization using EBV-encoded small nuclear early region (EBER) oligonucleotides was performed on formalin-fixed paraffin-embedded sections. Briefly, a Dako hybridization kit was used with a cocktail of fluorescein isothiocyanate (FITC)-labeled EBER oligonucleotides (one oligonucleotide corresponding to EBER1 and one to EBER2, both 30 bases long; Dako A/S code Y017). Hybridization products were detected using a mouse monoclonal anti-FITC (M878) and a Vectastain ABC Kit (Vector, Burlingame, CA). RNase A or DNase I pretreatment was applied as negative controls and EBER-positive Hodgkin lymphoma specimens as positive controls.

Results

Histopathology

Tumor cells were seen within vascular spaces of many extranodal sites, such as the liver, spleen, kidney, lung, and bone marrow. The tumor cells were primarily scattered in the hepatic sinusoids, the splenic sinusoids, and the renal capillaries, especially those of the glomeruli (Fig. 1a). In both lungs, single or small clusters of tumor cells were found mainly in the capillaries of alveolar septa (Fig. 1b). The bone marrow showed small foci of aggregated tumor cells and scattered single tumor cells intermingled with normal trilineage hematopoietic marrow tissue. Hemophagocytic macrophages were indistinct in the bone marrow sections at autopsy; this may have been due to chemotherapy. Some lymph nodes adjacent to trachea also showed infiltration of tumor cells mainly in the sinuses, although the nodal architecture was preserved.

Lymphoma cells were large-sized with irregular nuclei containing one or two conspicuous nucleoli and abundant amphophilic cytoplasm. Some appeared to bear the cytomorphologic features of "hallmark" anaplastic large cell lymphoma (ALCL) cells, having horseshoe/kidney-shaped nuclei often with an eosinophilic region in the adjacent abundant cytoplasm, although they were scattered in distribution (Fig. 2). The involved blood vessels showed no occlusion or fibrin thrombi.

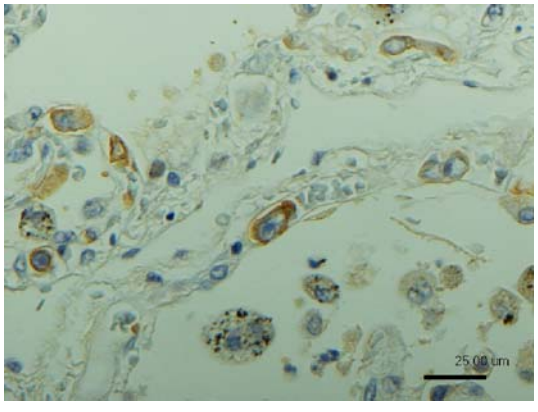

Fig. 3 Tumor cells are positive for CD30 on the cell membrane and in the Golgi region (original magnification ×400)

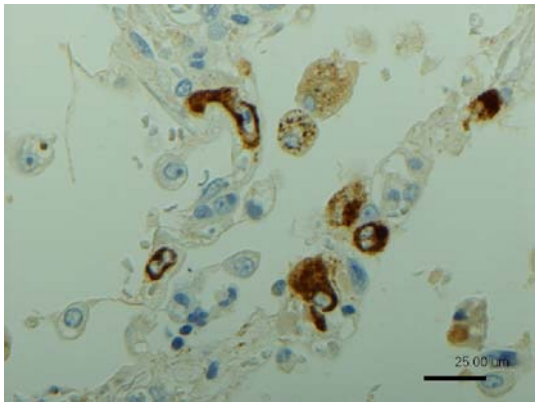

Fig. 4 Tumor cells show strong granular staining for granzyme B (original magnification ×400)

Immunohistochemistry and in situ hybridization

The tumor cells were positive for CD2, CD4, CD30 (Fig. 3), CD43, CD45RO, granzyme B (Fig. 4), TIA-1, and perforin and were negative for CD1a, CD3, CD5, CD8, CD10, CD15, CD20, CD21, CD23, CD27, CD45RA, CD56, CD57, CD68, CD79a, ALK, EMA, Bcl-2, and TCRβF1. No positive signals for nuclear EBV-encoded RNA transcripts were evident on in situ hybridization.

Discussion

In this article, we document a unique CD30-positive case of IVL featuring anaplastic large cell morphology and an ALK-negative T-cytotoxic phenotype, with the HPS and an aggressive clinical course. Based on the cytopathologic features of the tumor cells, the present case could be diagnosed as T-IVL within the ALK-negative ALCLs, a heterogeneous or undefined category in the WHO classification [6] whose diagnostic implications remain controversial among pathologists. The ALCL is a T-cell lymphoma usually with large tumor cells having pleomorphic, often horseshoe-shaped nuclei [6] as seen in the present case. Most cases of ALCL express cytotoxic granule-associated antigens, such as TIA1, granzyme B, and perforin [6], and predominantly show a CD2+, CD3−, and CD4+ T-cell phenotype, again as in the present case [6].

Details for the 25 cases of T-IVL documented in the English literature are listed in Table 1. These include only one case of CD30+ anaplastic large cell type, reported by Ko et al. [12]. That patient was a 55-year-old male who died within 3 months of the diagnosis, having an aggressive clinical profile similar to our case. Another case associated with EBV infection in a HIV-positive patient showed a TIA1+ cytotoxic T-cell phenotype, but was negative for CD30 [17]. In case 3 of Table 1, only a few cells were positive for CD30 and CD8, and the expression of cytotoxic molecules was not investigated, providing no definite evidence of ALCL [21]. Thus, our case may be only the second reported case of CD30+ anaplastic large cell type and also only the second case with a cytotoxic T-cell phenotype. Although Ko et al.'s [12] case, with the expression of CD30 and anaplastic large cell morphology, belongs to ALCL T-IVL, the expression of ALK was not analyzed. Our case is thus the first for which tumor cells could be shown to be ALK-negative but cytotoxic-molecules-positive. However, it is possible that some of the other reported T-IVL cases lacking immunophenotypic evaluation of CD30, ALK, or cytotoxic molecules might also have been intravascular ALCLs or cytotoxic T-IVLs.

One stillborn [28], one renal allograft recipient [10], and two HIV-positive cases with acquired immunodeficiency syndrome [16, 17] are included among the 25 cases of

reported T-IVL (Table 1). The latter three cases were males in their third decade of life [10, 16, 17]. The remaining 21 of the T-IVL cases, as well as the present case, were mainly elderly with a mean age of 58 years, median age of 61 years, and ranging from 17 to 84 years old, with a male predominance (male-to-female ratio of 13:7), no age being given for two cases. The patients generally exhibited an aggressive clinical course, and the longest duration of survival was 18 months after the diagnosis, except in one patient demonstrating complete resolution and two others. Regarding the affecting organs, only one location was involved in 14 cases: the skin in 10 [4, 14, 21–23, 25, 26], the lung in 2 [12, 27], the colon in 1 [30], and the brain in 1 [5]. Multiple organ involvement was observed in seven cases, as well as ours [3, 7, 11, 13, 20, 30]. In a recent study, 38 IVLs, all except one T-IVL being of B-cell type, also were found in elderly patients (median age 70 years, range 34–90; male-to-female ratio 0.9) and resulted in a poor prognosis (3-year overall survival 25±7%) [8]. T-IVL seems to slightly differ from B-IVL regarding occurrence in younger individuals with a male predilection. However, the prognosis is essentially the same. Although the CD30+ ALCL tends to show a relatively better prognosis compared to other high-grade lymphomas, its IVL form may follow a poor clinical course as in our case and as suggested by Ko et al. [12].

The present case was clinically accompanied by HPS, a feature frequently reported in B-IVL patients especially in Asian populations [18, 24, 29]. Allory et al. [1] recently described a high number of reactive T cells of predominantly CD8+/TIA1+ cytotoxic phenotype to possibly play a role in the pathogenesis of HPS in diffuse large B-cell lymphomas. In a separate study in our laboratory, lymphoma-associated HPS was also observed in 20% of peripheral T-cell lymphomas of cytotoxic phenotype during their clinical course [2].

In conclusion, we here have documented a rare case of intravascular T-cell lymphoma with anaplastic large cell morphology and a CD30+ALK−TIA1+granzyme B+perforin+ phenotype, indicating the presence of heterogeneity in T-IVLs. In the WHO classification, the more common B-IVLs have been categorized into a single entity [9]. Accumulation of more cases of rare T-IVLs is now needed to allow subtyping.

Multiple calcifying fibrous tumor of the pleura

Received: 6 June 2005 / Accepted: 19 August 2005 / Published online: 21 September 2005
© Springer-Verlag 2005

Dear Sir,

The article by Mito et al. [4] concerning multiple calcifying fibrous tumor of the pleura (CFTP) is a great contribution to the subject of respiratory pathology, as only eight cases of CFTP have been reported [2–4], and multiple CFTP has been poorly documented. In our opinion, pathologists and surgeons should be made aware of multiple CFTP since it is possible to confuse CFTP macroscopically with disseminated metastatic sarcoma or diffuse malignant mesothelioma during surgery. We would like to add one additional case of multiple CFTP that was pathologically diagnosed on intraoperative frozen section slides.

Case report

A 35-year-old Japanese woman, who had smoked about 20 cigarettes per day for 15 years, consulted our hospital complaining of right chest pain that had occurred for the past 2 years. Occupational exposure to asbestos was probable. Computed tomographic scan of the chest showed remarkable thickening of the parietal pleurae of the right hemithorax. A tentative diagnosis of diffuse malignant mesothelioma was made. Family history and past medical history were unremarkable. Video-assisted thoracoscopic surgery was performed for histological examination. Thoracoscopic examination demonstrated a large arborized nodule, 5 cm in diameter on the diaphragmatic pleura (Fig. 1a), and other miliary dome-shaped nodules at the costal and mediastinal pleurae as well as visceral pleura mainly in the lower lobe (Fig. 1b). There was a small amount of serous pleural effusion. In the pleural fluid, no cytological abnormalities were observed. Pleural plaques were present at the fourth, fifth, and sixth costal pleura. The surgeons thoracoscopically diagnosed eccentric disseminated metastatic sarcoma or diffuse malignant mesothelioma at resection of the largest nodule. Intraoperative frozen section slide showed hyalinized fibrosclerotic nodular lesions with microcalcifications, which highly supported the pathological diagnosis of multiple CFTP. Thoracotomy was performed, and all remaining nodules were extirpated. On postoperative gross examination, all nodules were well circumscribed, solid, or firm with a uniform gray-white fibrous cut appearance without any hemorrhage or necrosis (Fig. 1c). All nodules were pleural-based. Histologically, the nodules were circumscribed, nonencapsulated, and composed chiefly of hypocellular hyalinized fibrosclerotic tissue with scattered cytologically bland spindle cells, scant lymphoplasmacytic infiltrate, and small calcifications. The calcifications had a laminated appearance showing typical psammoma bodies (Fig. 2a). The surface of the nodules was occasionally covered by a single layer of mesothelial cells. Asbestos bodies were not detected in or around the nodules. Immunohistochemical studies showed that most spindle cells were positive for vimentin and factor XIIIa (Fig. 2b) but negative for epithelial membrane antigen (EMA), keratin (AE1/3), desmin, α-smooth muscle actin, S-100, anaplastic lymphoma kinase, and CD34. Taken together, a pathological diagnosis of multiple CFTP was made.

Recognition of this extremely rare miliary type of CFTP is important because of the possibility of confusing it intraoperatively with malignant fibrous neoplasms including desmoplastic mesothelioma or disseminated metastatic sarcoma [2–4]. Desmoplastic mesothelioma shows a storiform collagen pattern, collagen necrosis, bland acellular collagen, and focal cytologic features of malignancy [5]. Moreover, desmoplastic mesothelioma stains for cytokeratins, but our case was negative for AE1/3. In disseminated metastatic fibrous sarcoma with pleural

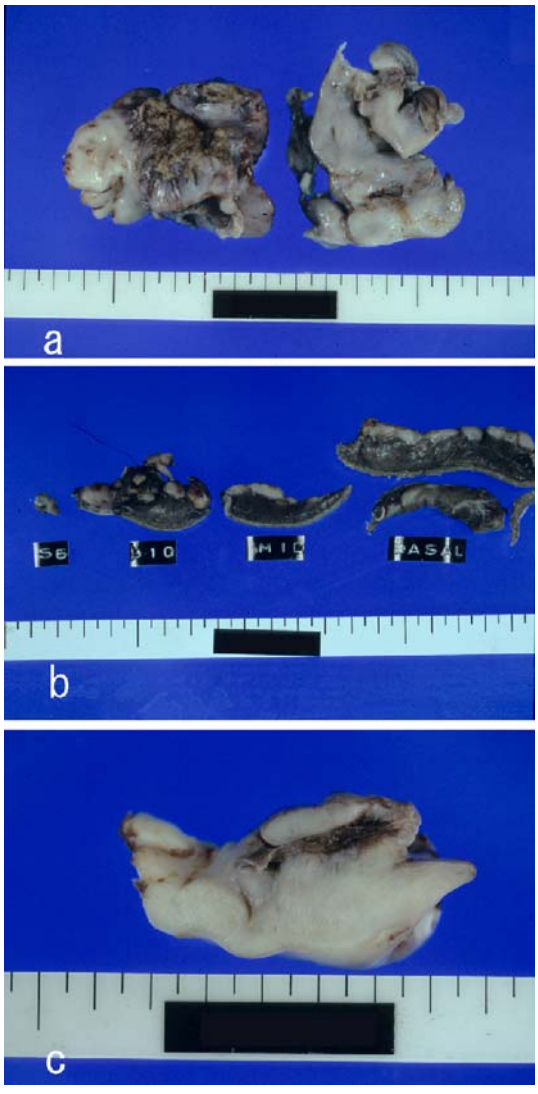

Fig. 1 **a** A large arborized nodule measuring 5 cm in diameter was present on the diaphragmatic pleura. **b** Miliary dome-shaped nodules were also present at the visceral pleura of the right lower lobe. **c** The cut surface of the largest nodule showed a uniform fibrous appearance

calcification, monophasic synovial sarcoma (MSS) should be considered. MSS is usually a localized pleural-based mass [1]. MSS is composed of nearly uniform spindle fibroblast-like cells that are arranged in dense cellular sheets or vague fascicles. Hyalinization and calcification are occasionally seen. In our case, dense cellular areas composed of fibroblast-like cells were absent. Immunohistochemically, cytokeratin and/or EMA is positive in MSS, but this finding was negative in our patient.

In this case, we made a diagnosis of multiple CFTP based on intraoperative frozen section slides. The keys to accurate diagnosis were as follows: (1) recognition of submesothelial origin; (2) hypocellular hyalinized fibrosclerotic tumor with psammoma bodies; and (3) knowledge about multiple CFTP obtained from the article by Mito et al. [4].

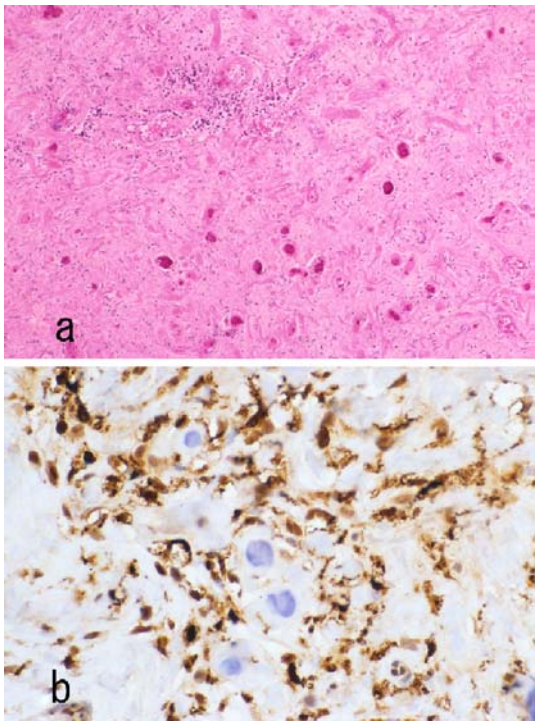

Fig. 2 **a** Histologically, the tumor was predominantly composed of hypocellular hyalinized fibrosclerotic tissue with psammoma bodies and scant lymphoplasmacytic infiltrate (×50). **b** The spindle cells showed positive staining for factor XIIIa immunohistochemically (×100)

15–16 June 2006
Thyroid Pathology for the Practicing Pathologist
15 rue de l'Ecole de Médecine, Paris,France

A 2-day course will take place in Paris again under the auspices of the French Division of the I.A.P.

This course will be given in English by Prof. M. Sobrinho-Simões (Porto) and Prof. R. Heimann (Brussels).

It will consist of lectures alternating with slide reviews and a slide seminar over a multihead microscope. The cases of this seminar will be sent (on CD) before the meeting.

The audience will be limited to 22 participants.
Course fees: 390 euros (320 euros for members of any I.A.P. division). The fees include registration, hand-out, CD of the slide seminar and coffee breaks.
