DCIS, cytokeratins, and the theory of the sick lobe

Abstract We postulate that ductal carcinoma in situ (DCIS), and consequently breast carcinoma in general, is a lobar disease, as the simultaneously or asynchronously appearing, often multiple, in situ tumor foci are localized within a single lobe. Although the whole lobe is sick, carrying some form of genetic instability, the malignant transformation of the epithelial cells may appear localized to a part or different parts of the sick lobe at the same time or with varying time difference. It may be confined to terminal ductal lobular units (TDLUs), to ducts or both. The malignant transformation is often associated with aberrant branching and/or aberrant lobularization within the sick lobe. Involvement of a single individual TDLU or of a group of adjacent TDLUs generates a unifocal lesion. Multifocal lesions appear if distant TDLUs are involved. Diffuse growth pattern in DCIS indicates involvement of the larger ducts. The extent of the involved area in multifocal or diffuse cases varies considerably. Diffuse growth pattern with or without evidence of aberrant arborisation within the sick lobe seems to characterize a subgroup of DCIS with unfavourable prognosis. In this paper, we discuss the anatomical, embryological and pathological background of the theory of the sick lobe and present supporting evidence from modern radiological breast imaging, long-term follow-up studies and from our own series of 108 DCIS cases.

Introduction

Breast carcinoma is a heterogeneous and progressive disease with many variations in morphological appearance, which has always made attempts of classification of breast tumors very difficult. Mammography screening during the last decades has changed the panorama of breast carcinoma, detecting small invasive tumors in asymptomatic women and also detecting malignant lesions in their non-invasive state [3, 16]. Under the circumstances of adequate surgical removal of the lesions, proper histopathologic work-up and systematic mammographic-pathologic correlation, this evolution offers the opportunity of studying breast carcinoma at the earliest stages in its natural history, which in turn may offer a key to better understanding the many variations of breast cancer morphology.

Classical whole organ studies had long ago demonstrated that the vast majority of in situ and invasive breast carcinomas are multifocal/multicentric/diffuse [10, 12]. However, the traditional technique used routinely in most breast pathology laboratories today does not allow repetition of the results of whole organ studies in most cases. The "modern" approach of focusing on histological, immunohistological and molecular analysis of the dominant invasive lesion may lead to underestimation of the importance of the alterations in the tissue adjacent to the dominant mass. In our laboratory, the diagnostic routine is specially adapted to the work-up of quadrantectomy specimens (the method of choice in breast conserving surgery in Scandinavia). This method of two- and three-dimensional large (up to 10×8 cm) histological sections gives the contiguous piece of tissue necessary for proper analysis of the extent and distribution of the lesions belonging to a breast carcinoma and represents an ideal background for detailed and systematic radiopathologic correlation [13, 31, 33]. Based on our 20 years experience and more than 5000 consecutive breast cases documented and analysed this way, we have become more and more convinced that the multiple malignant lesions exhibit a lobar distribution within the breast. Thus, we postulate that ductal carcinoma in situ, and consequently breast carcinoma in general, is a lobar disease, which means that the simultaneously or asynchronously appearing, often multiple, in situ (and invasive) tumor foci belong to a single lobe in one breast [34]. While in situ carcinomas keep their lobar distribution

during their entire development, invasive carcinomas may step out from this frame and grow beyond the borders of the sick lobe, especially in their advance phase.

The diagnosis of breast carcinoma always reflects the actual status of the process of malignant transformation within the sick lobe in the moment of perception. Prolonged time of evolution of the neoplastic process may lead to development of new tumor foci and/or to growth of the already existing foci. Thus, the morphology of breast carcinoma is clearly time-related, which means that the malignant transformation of the cells within the sick lobe may depend on complex genetic-biological timing.

Complex lobar anatomy of the breast

The breast is a glandular organ with lobar morphology [5]. A typical lobe consists of one lactiferous duct opening on the nipple, branching into segmental, subsegmental and terminal ducts and ending up in thousands of lobules. The terminal duct and the corresponding lobule represent the so-called terminal ductal-lobular unit (TDLU), which is considered to be the most important morphologic-functional unit in the breast [32, 36]. Although rare anastomoses between the lobes have been described in one study [22], the breast lobes are considered to be well-defined individual units in the related literature [11, 18]. However, the lobar division of the breast parenchyma is complex, with considerable variation in origin, size and shape of the lobes [5, 11, 18, 31].

A normal lobe of the breast is a complex dynamically evolving and involuting structure during the woman's entire lifetime [31]. There are relatively few TDLUs before puberty [35]. During the reproductive period the numerous TDLUs undergo cyclical changes following the menstrual cycle [17]. The number of the TDLUs is highest during the period of late pregnancy and lactation and is substantially reduced after the menopause [33]. Thus, TDLUs may appear and disappear, the number of them being dependent on the woman's age, constitution and hormonal status. This is probably correct for the smaller ducts, too. The number of the lactiferous ducts and the number of the openings on the nipple is, however, independent of hormonal influences and age. Thus, the number of the breast lobes is constant during the woman's lifetime, but their size and shape and the number of their ducts and lobules varies and depends on anatomical variations, hormonal and age related influences [31]. The actual morphology of the lobe is maintained by the finely regulated equilibrium of development and involution of the ducts (arborisation) and lobules (lobularization).

In one study [11], the breast lobes varied in size, representing between 2% and 23% of the breast volume. Although a malignant transformation may lead to considerable enlargement of the sick lobe, the original size of the lobe may be crucial in determining the extent of the eventually developing disease and the chances for successful breast-conserving surgery. The surgical method of quadrantectomy (segmentectomy) represents an attempt to radically excise the sick lobe and not only the radiologically and/or clinically evident lesion(s). As the lobar morphology of the breast is complex, the surgical intervention is often inaccurate (with local recurrence rate up to 30% in cases without radiotherapy) [24].

Embryological background

The lobes of the breast (the epithelium and the myoepithelium of their ducts and lobules) are of ectodermal origin. During the 21st week of the intrauterine life, buds from the embryonal ectoderm are formed as non-luminated, solid protrusions into the embryonal mesenchyme [2]. All the buds represent an initiation of one potential breast lobe, but some of them probably are abortive. Some of the buds (at least those in the accessory breasts developing along the embryonal mammary line) disappear during intrauterine life. Luminalization begins during the 26th week [2]. The next steps are ramification (branching of the luminated buds, forming smaller and smaller ducts) and lobularization (forming the lobules as groups of blindly ending vesicles on the terminal ducts) [15]. The ramification process is almost completed during intrauterine life, while lobularization mainly characterizes the postpubertal period [33].

Luminalization of the buds, ramification and lobularization represent a complex process related to changes of the expression of different genes and to consequent changes in the phenotype of the epithelial cells. This process can be successfully monitored, determining the cytokeratin (CK) phenotype of the structures of the breast at different stages of intrauterine development. The buds in the initial stage have the same immunophenotype as the basal cells in the embryonal ectoderm and express CK14, vimentin, S-100-beta and p63 [2]. During the period between weeks 21–26 of intrauterine life, expression of CK17, CD10 and alpha-smooth muscle actin appears [2, 15]. Luminarization of the buds is associated with the appearance of cells expressing CK19, while ramification is related to cells not expressing CK19. Lobularization, in turn, seems to be associated with expression of CKs 8 and 18 in the epithelial cells [2, 15]. As demonstrated in several studies, the hyperplastic breast epithelium exhibits "basal cell type" CKs, but DCIS does not [23].

The embryonal development of CK phenotype within the breast lobe may reflect a complex and sensitive genetic regulatory mechanism behind the processes of initialisation, arborisation and lobularization. The similarity of the neoplasia-related and embryonic phenotypic variations may indicate that the malignant transformation is somehow related to lobularization and/or arborisation within the sick lobe, targeting and altering these processes. According to our observations on two- and three-dimensional large histologic sections and to the experience from radiopathologic correlative studies, low-grade DCIS targets most often the process of lobularization while the high-grade DCIS may also alter the process of arborisation.

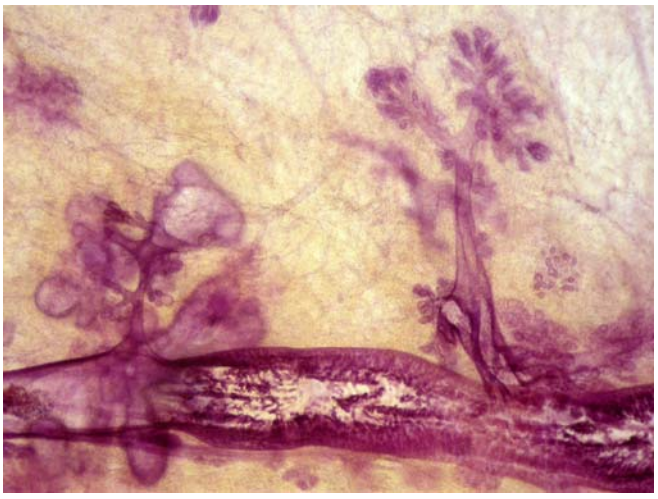

Fig. 1 DCIS involving a segmental duct, but not the related terminal ducts and TDLUs (thick section image, 20×) Note the regular branching into relatively long, narrower ducts

In addition to changes related to the epithelial cells, the embryonal mesenchyme surrounding the mammary buds, and partly the newly formed ducts also exhibits some changes. Overexpression of tenascin C, as demonstrated by immunohistochemistry, is considered to be a sensitive indicator of remodelling of the mesenchyme into a specific periductal stroma [28]. Thus, tenascin C overexpression may represent an indirect indicator of initialisation of a breast lobe during the embryonal period and a sign of arborisation within the lobe. Tenascin C overexpression can also be demonstrated surrounding some duct-like structures in a proportion of cases of (often high-grade) DCIS [14, 28], which may additionally prove the involvement of this type of malignancy in the process of arborisation within the sick lobe. This phenomenon is sometimes designated as "duct neogenesis" [30].

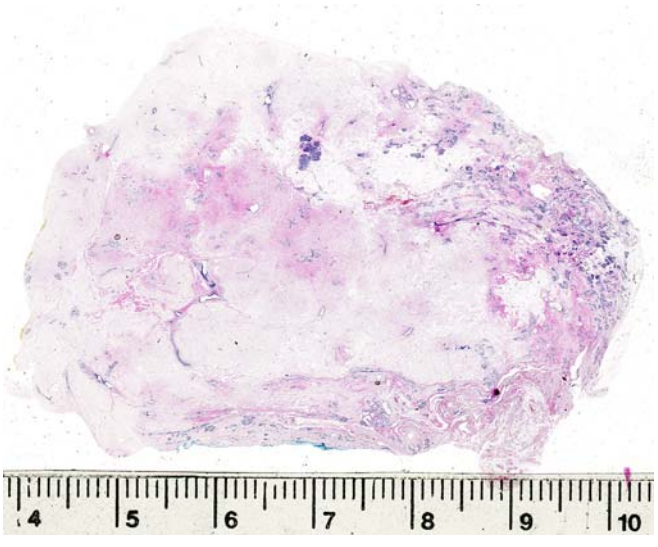

Fig. 2 Unifocal lesion in DCIS. Large histologic section

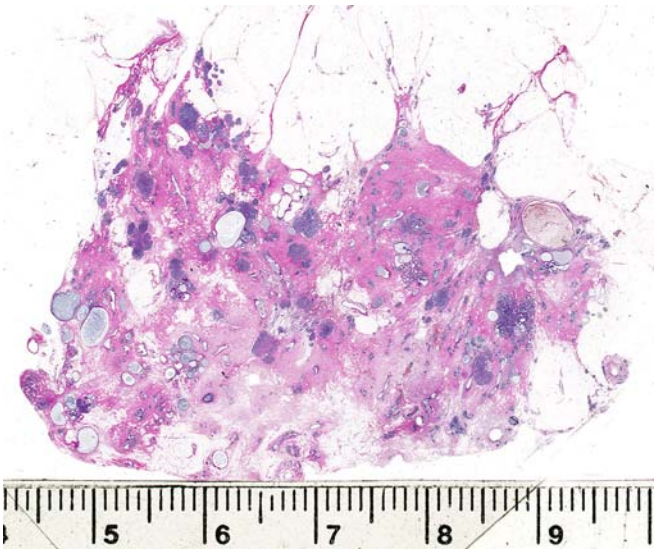

Fig. 3 Multifocal DCIS involving many distant TDLUs, leaving uninvolved tissue in between

Subgross morphology of ductal carcinoma in situ

Our observation based on examination of the large histologic sections and stereomicroscopic analysis of three-dimensional large thick sections, in concordance with the results of previous published similar studies [8, 9] can be briefly summarized in the following. Structures of carcinoma in situ may be demonstrated in TDLUs as well as in ducts. The ductal epithelium may be involved without demonstrable DCIS in the related TDLUs (Fig. 1). The ductal epithelium may be discontinuously involved with "gaps" exhibiting seemingly normal epithelium [9].

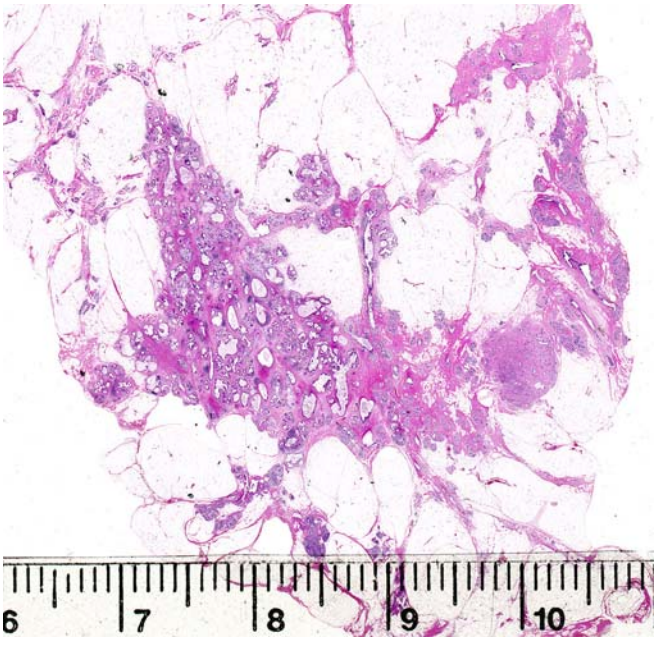

Fig. 4 Diffuse growth pattern in DCIS: the lesion involves the ducts system without well-outlined TDLUs in the left half of the image. The round structure to the right is a fibroadenoma

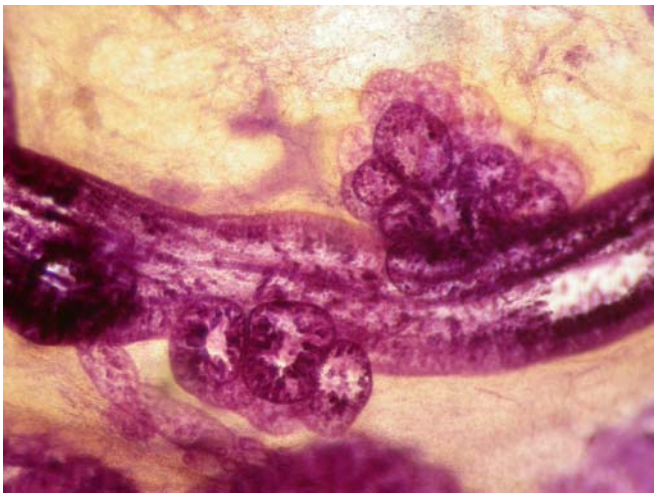

Fig. 5 Aberrant arborisation in DCIS. Note the absence of narrower branches as compared with previous image in Fig. 1 (thick section image, 20×)

The presence of the structures of an in situ carcinoma in a TDLU leads to considerable enlargement and distortion of this structure. The size of the involved individual TDLUs may vary between 1–2 mm to 20 mm or even more. The enlarged TDLU is regularly perceived as a round (spherical) or oval, well outlined structure (Fig. 2). If there are several distant TDLUs containing structures of in situ carcinoma, they are also seen as individual, well-delineated lesions, giving the impression of multifocality of the malignant process (Fig. 3). Involved TDLUs adjacent to each other may form a conglomerate, where the units are no longer separable as individual on radiology or gross examination. In addition to an enlarged single TDLU, this conglomerate is another example of the unifocal lesions. Involvement of the larger ducts may lead to their dilatation, but the long, branching tree of the involved duct system is perceived rather as a diffuse network of tubes than a well-outlined individual structure (Fig. 4). In conclusion, DCIS may manifest as a unifocal, multifocal or diffuse lesion (as well as a combination of multifocal and diffuse lesions) indicating involvement of one individual TDLU or a conglomerate of adjacent TDLUs (unifocal DCIS), simultaneous involvement of several distant TDLUs (multifocal DCIS) or involvement of the larger ducts (diffuse DCIS).

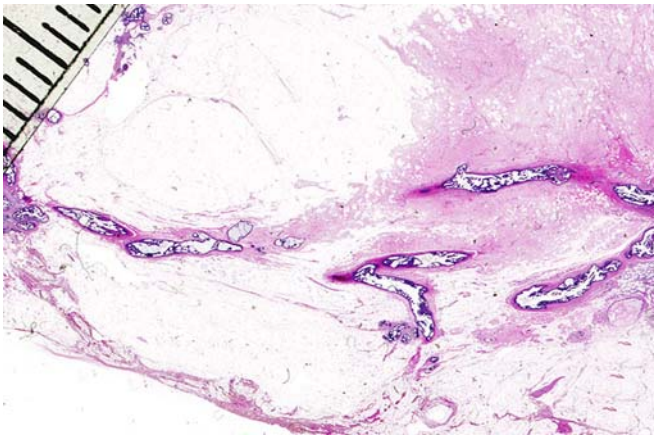

Fig. 6 Duct involvement in DCIS without evidence of altered arborisation. The number of the involved ducts corresponds to normal anatomy and the branching is regular

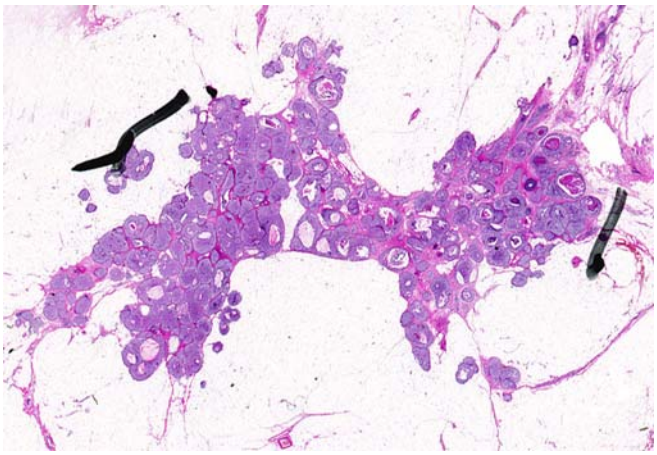

Fig. 7 DCIS with evident disturbance in arborisation as the number of the duct-like structures exceed the anatomically expected number (duct-neogenesis)

While involvement of the TDLUs alters these structures on a relatively uniform way, distending and distorting them similarly, involvement of the ducts may or may not be associated with different changes in ramification of the duct system. In the normal situation, the ducts give raise to smaller and smaller branches, which end up in TDLUs. If this process is altered, the ducts may give abortive branches (Fig. 5) without narrower ducts and TDLUs. In more severe cases, an abnormally large number of duct-like structures are seen in the area of the in situ carcinoma, regularly lacking smaller branches and TDLUs. Already, the tightness of the ducts indicates that they are newly formed, "neogenetic" and cannot represent a part of an anatomically normal lobe (Figs. 6 and 7). As these duct-like structures are often surrounded by a remodelled stroma overexpressing tenascin C (and regularly associated with periductal lymphoid cell infiltration), we assume that this phenomenon corresponds to an aberration in the process of arborisation within the sick lobe.

Theory of the sick lobe

Based on the anatomical, embryological and pathological data discussed above, we postulate that ductal carcinoma in situ, and consequently breast carcinoma in general, is a lobar disease. This means that the simultaneously or asynchronously appearing, often multiple, in situ tumor foci are localised in a single lobe of one breast. We assume that this sick lobe is genetically malconstructed from birth, carrying some kind of genetic instability from its initiation during fetal life. Further accumulation of genetic changes during the decades of the postnatal period may lead to malignant transformation of the epithelial cells in any part of the sick lobe. We believe, that this is a life-long process initiated

during the fetal period of life, which can be influenced or even interrupted by radical excision of the sick lobe and, possibly, with other therapeutic interventions. In addition to malignant transformation at the cellular level, there are two sensitive points in morphogenesis of the sick lobe, which are also regular targets of the neoplastic events: the process of lobularization and the process of arborisation. Altered lobularization is regularly seen in the majority of cases of DCIS, while different alterations in arborisation represent the hallmark of high-grade DCIS.

The biological timing of the malignant transformation of the cells within the sick lobe may be very variable [4, 6, 7]. Simultaneous involvement of most of the epithelial cells within the sick lobe leads to rapid development of extensive, diffuse, usually high-grade, DCIS. The malignant transformation may also be microfocal and localized to one or more individual TDLUs (as in low-grade DCIS, lobular carcinoma in situ or in atypical ductal or lobular hyperplasia). In these cases, the transformation may involve very distant TDLUs within the sick lobe with time difference varying up to several years or decades.

Supporting evidence

Radiological observations on individual extensive DCIS cases support the theory of lobar distribution of multiple and diffuse lesions. Cases with nipple discharge in extensive micropapillary DCIS may manifest such a distribution of the individual filling defects in a lobe filled with contrast on galactography (Fig. 8a and b). The microcalcifications on the mammogram in high-grade DCIS may also exhibit a distribution resembling the anatomy of the duct system of a single lobe. Magnetic resonance images in cases of high-grade DCIS often outline a whole involved breast lobe, including the lactiferous ducts (Fig. 9), [20].

We studied a series of 108 consecutive DCIS cases diagnosed in period 1996–2001 on our department. The so-called “special type DCIS” such as intracystic papillary carcinomas and papillomas with DCIS were excluded, as their growth pattern depends on the morphology of pre-existent lesions. Most of the cases were initially treated with breast conserving surgery and radiotherapy. In 30 cases, based on close or dirty margins (less than 10 mm circumferential margin), the surgical intervention was completed with re-resection or mastectomy. The cases were reviewed by the author and followed up to 31 December 2004. The cases were grouped according to their distribution as unifocal, multifocal and diffuse (as defined above), according to their extent (the area including all the structures corresponding to DCIS within a large histologic section) as extensive (more than 20 mm in largest diameter) and non-extensive. They were also graded as low-grade (low nuclear grade without central necrosis), intermediate (low nuclear grade with central necrosis or intermediate nuclear grade with or without necrosis) and high-grade (high nuclear grade with or without necrosis). The diffuse cases were further divided into a neogenetic group (with evidence of alterations in arborisation of the lobe often

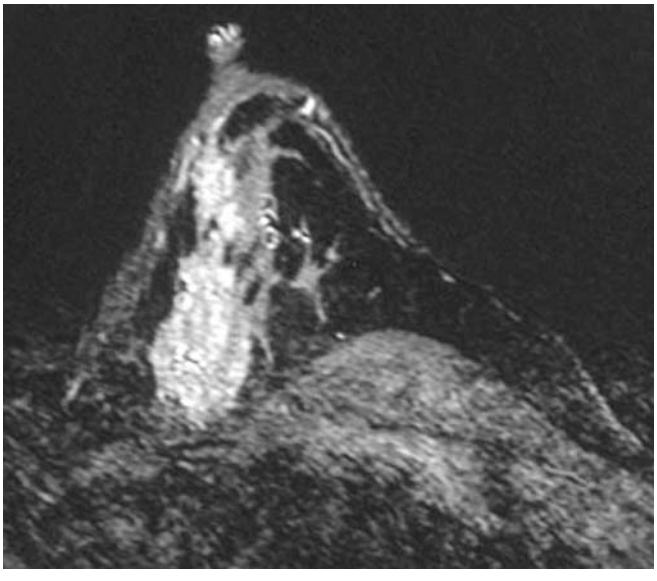

Fig. 9 Lobar distribution of the lesions in a case of high-grade DCIS indicated on a magnetic resonance image

Table 1 Local recurrences by extent and distribution of the lesions in 108 consecutive cases of ductal carcinoma in situ

Extent	Unifocal	Multifocal	Diffuse, non-neogenetic	Diffuse neogenetic	Mixed	Sum
Extensive	0/0	4/24	3/18	4/14	0/2	19% (11/58)
Non-extensive	1/41	0/5	0/3	0/1	0/0	2% (1/50)
Sum	2% (1/41)	14% (4/29)	14% (3/21)	27% (4/15)	0% (0/2)	11% (12/108)

manifesting in tightly packed ductal structures without TDLUs) and a non-neogenetic group. The results are presented in Table 1 and in the diagram in Fig. 10 and indicate that the extensive cases recurred significantly more often compared to non-extensive ones, the diffuse neogenetic subgroup being the prognostically most unfavourable. The same study also demonstrated that low-grade DCIS tends to be multifocal, the cases with intermediate grade tend to be unifocal, while the diffuse cases are mostly of high grade. In fact, the duct-neogenetic subgroup contained exclusively high-grade DCIS cases. One patient with extensive high-grade DCIS without demonstrable invasion, but with evident alterations in arborisation of the duct system developed metastases and died later on of the disease, as was verified on autopsy.

Several long-term follow-up studies have demonstrated that mammographially detected casting-type microcalcification are associated with higher risk of local recurrence of DCIS and with associated invasive carcinoma than the other types of microcalcifications. [21, 26]. As the casting-type microcalcifications most often indicate presence of duct-neogenetic high-grade DCIS, these studies represent an indirect evidence for unfavourable prognosis of this DCIS subtype. Further, small invasive breast carcinomas (less than 15 mm in size) have a more unfavourable outcome in overall survival if associated with casting type microcalcifications [29, 30]. The other types of microcalcifications indicating presence of intermediate or low-grade DCIS, were not associated with increased mortality in the cited studies.

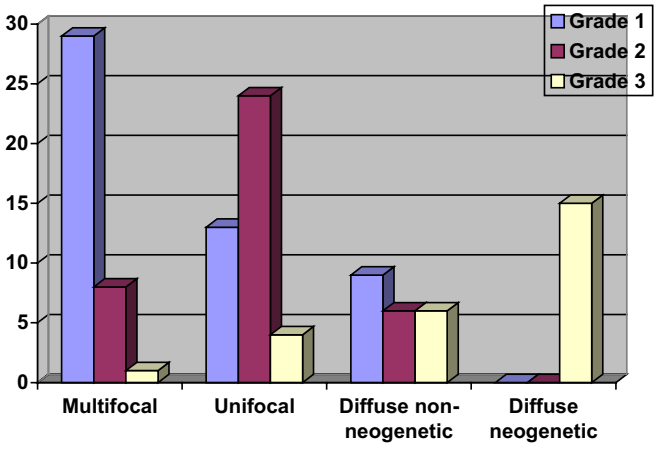

Fig. 10 Grade distribution by growth pattern in 108 consecutive cases of ductal carcinoma in situ

The presented evidence indicates that diffuse involvement of large areas of the sick lobe in DCIS, with altered arborization of the duct system is a characteristics of the unfavourable subgroup of DCIS. Extensive and/or multifocal involvement of the sick lobe with altered lobularization, but with normal arborization is typical of grade I, less often grade II DCIS and is associated with higher local recurrence rate compared to the unifocal cases. The unifocal DCIS cases seem to represent the prognostically most favourable subgroup.

Discussion

Several investigators have previously assessed the extent and the distribution of carcinoma in situ within the breast, however, multicentricity and multifocality in breast carcinoma in situ remains a debated topic in the literature. The reported incidence of multicentricity ranges from 0 to 78%, depending on the used criteria and methods [9, 27]. The group of Holland and Faverly, using the technique of whole organ sectioning and thick section images, demonstrated that ductal carcinoma in situ may exhibit either a continuous or a discontinuous growth; they divided the cases with discontinuous growth into multifocal (less than 4 cm gaps between the foci) and multicentric (larger gaps) and concluded that most of the in situ carcinomas are unicentric (showing a segmental distribution) [9]. Page believe that "multicentricity is a misconception" and that the majority of in situ carcinomas are limited to a single focus with continuous growth pattern, which may be perceived in histological preparations as discontinuous after artificial fragmentation [25]. Andersen et al. divided the cases of ductal carcinoma in situ into microfocal, tumor forming, diffuse and mixed. Their microfocal cases correspond to the low-grade lesions targeting the terminal ductal-lobular units of the sick lobe. The diffuse cases in their series mostly correspond to the diffuse extensive high-grade cases in our concept [1]. Analysing the three-dimensional distribution of in situ and invasive breast carcinomas, Mai et al. concluded that the in situ component is often located in a single duct, the small invasive carcinomas appear adjacent to the in situ and the whole tumor may form a pyramid with the summit towards the nipple [19]. Thus, the suspicion that DCIS and invasive breast carcinoma may have a segmental (lobar) distribution has been expressed previously. The theory of the sick lobe adds the dimension of time to morphological findings and connects the malignant transformation to an anatomically well-defined

structure of the breast lobe and to disturbances in the dynamically maintained processes of arborisation and lobularization within it.

The most widely accepted concept of breast cancer development, the Wellings concept, connects the initiation of the malignant transformation to changes in the TDLUs [36]. According to this concept, breast carcinoma develops from the individual TDLUs with secondary involvement of the ducts by spread of the tumor cells as well as invasion of the tumor cells through the basement membrane. This concept is considered valid in many benign breast lesions, too, with only a small minority of the lesions developing primarily in the ductal system (e.g. papillomas). Although many in situ carcinomas exhibit the distribution corresponding to the terminal units, the continuous "spread" of the in situ cancer along the ducts in a several cm large area, seen not rarely in cases of DCIS, is difficult if not impossible to explain by the origin of the process in a few individual 1–2 mm large units; the signs of migration of the tumor tissue are seldom evident. Studying the three-dimensional morphology of the early stage breast carcinomas, however, evidenced involvement of large areas of the ductal tree in addition to lobular involvement or, at least partially, without lobular involvement. As discussed above, new insight into this process gave the recent anatomical and embryological studies, and first of all, the new radiological imaging methods enabling the definition of a new concept, the theory of the sick lobe, challenging the classical concept of Wellings. The theory of the sick lobe, in contrast to the concept of Wellings, is based on a hypothesis that the malignant transformation may appear in any part(s) of the sick lobe, not only in the TDLUs. The so-called "pagetoid spread" or other forms of tumor spread in DCIS may be explained as malignant transformation of the cells of the ducts distant to the TDLU, rather than spreading of the malignant cells from the involved TDLU. Thus, the biological timing of the malignant transformation, the involved structures of the lobe and the involved morphogenetic processes (lobularization and arborisation) determine the morphology and the natural history of DCIS subtypes.

Consequences/future perspectives

Provided that the theory of the sick lobe is correct, the extent of the disease in breast cancer in situ can no longer be defined as the area including all the detected lesions, but becomes equal to the area delineated by the borders of the sick lobe. Radical interventions have to shift their target from the detected lesion(s) to aiming to excise or otherwise destroy the entire sick lobe. Multicentricity of breast carcinoma may be redefined as the presence of two or more sick lobes within a single breast, the large majority of cases remaining unicentric. Multifocality, in turn, may be defined as presence of more than one individual tumor foci within the sick lobe.

As the sick lobe is formed already during intrauterine life, this theory assumes that prenatal influences of different noxious factors may play a role in predisposing the individual to breast cancer. On the other hand, decades of postnatal life are necessary for the development of breast carcinoma. The surgical intervention itself interrupts this otherwise life-long process only if it leads to excision or destruction of the entire sick lobe. Involvement of different structures and processes into the morphogenesis of breast carcinoma may indicate different pathways of malignant transformation in various categories of breast carcinoma.

Further development of modern imaging methods may play a crucial role in proving or questioning this theory, as methods effectively outlining the sick lobe and the lesions within it at the same time may become routinely used. If proved as correct, in general or in a substantial proportion of cases, the theory of the sick lobe may represent a real challenge in diagnostic breast pathology in the near future.

Thyroid transcription factor 1 expression in cystic lesions of the neck: an immunohistochemical investigation of thyroglossal duct cysts, branchial cleft cysts and metastatic papillary thyroid cancer

Received: 21 December 2004 / Accepted: 6 February 2005 / Published online: 10 June 2005

Abstract Cervical metastases of papillary thyroid cancer (PTC) are of particular diagnostic importance, because they can mimic branchiogenic cysts clinically and histopathologically when undergoing cystic change. Immunohistochemical stains for thyroid transcription factor 1 (TTF-1), which are positive in thyroid cancers, are reported to be valuable in establishing diagnosis. However, TTF-1 may also be expressed in dysontogenetic cysts of the neck. Therefore, immunohistochemical stains for TTF-1 and thyroglobulin (TG) were performed on each of the ten thyroglossal duct cysts, branchial cleft cyst and lymph node metastasis of PTC. Five in ten cases of thyroglossal duct cysts were positive for TTF-1, but all were negative for TG. One of the ten branchial cleft cysts stained for TTF-1, while all cases were negative for TG. All ten cases of lymph node metastases of PTC showed positive for TTF-1, nine of which were positive for TG. Since a positive immunostaining for TTF-1 in cystic lesions of the neck was not only found in metastases of PTC, but also in non-malignant branchiogenic cysts, additional investigations, e.g. an immunostaining for TG, should be added in difficult cases.

Introduction

Thyroid transcription factor 1 (TTF-1) is a DNA-binding protein that plays an important role in the development of the thyroid, lung and brain of the fetus [8]. In the adult it can be detected immunohistochemically in the epithelia of the thyroid, including parafollicular C cells, and the lung as well as in primary tumours and metastases deriving from these tissues [6, 11]. Therefore, immunostaining for TTF-1 is recommended in metastases of unknown primary, in which adenocarcinoma [2] or neuroendocrine tumour of the lung [4], or thyroid carcinoma [1] are considered as a possible origin.

Cervical metastases of papillary thyroid cancer (PTC) are of particular diagnostic importance, because they can mimic branchiogenic cysts clinically and histopathologically when undergoing cystic change [5, 10]. Metastases may be the first item that would draw medical attention, before the tumour in the thyroid is suspected [9]. Immunohistochemical reactions, including TTF-1, are recommended for a thorough diagnosis [11, 12]. So far, however, dysontogenetic cervical cysts have not been tested for their expression of TTF-1.

Thus, we performed immunohistochemical stains of TTF-1 including branchial cleft cysts, thyroglossal duct cysts and metastases of PTC, and added immunoreaction for thyroglobulin (TG).

Materials and methods

From the laboratory file of the Institut für Pathologie, Uniklinikum Mainz, we recruited ten patients each with thyroglossal duct cysts, branchial cleft cyst, with columnar epithelium and cystic lymph node metastasis of PTC

Table 1 Clinical data of the patients

	Patients	Male/ Female	Median age (range)
Thyroglossal duct cysts	10	5/5	57 years (29–75 years)
Branchial cleft cysts	10	4/6	39 years (16–68 years)
Metastases of papillary thyroid cancer	10	6/4	38 years (20–84 years)

(Table 1). The primary tumour was identified within the thyroid of all patients with metastases of PTC. No evidence of malignancy was found in patients with thyroglossal duct- and branchial cleft cysts.

All specimens were fixed in buffered formalin (4%) and embedded in paraffin wax. Immunohistochemistry was carried out using the DAB method after deparaffination. Staining reactions were performed with the antibody against TTF-1, clone 8G7G3/1 (NeoMarkers, California, USA), at a dilution of 1:50 with microwave pre-treatment, using citrate buffer adjusted at pH 6, and the antibody against TG, clone 2H11 (BioGenix, San Ramon, CA, USA), as ready-to-use kit with no pre-treatment.

Results

In thyroglossal duct cysts, a positive immunostaining for TTF-1 was detected in the nuclei of the lining epithelia in five of ten cases. The positivity was found to be focal and less marked than in PTC. It was focused in the basal part of the columnar epithelia (Fig. 1). TG was not detected in the duct epithelia, but in the adjacent thyroid tissue.

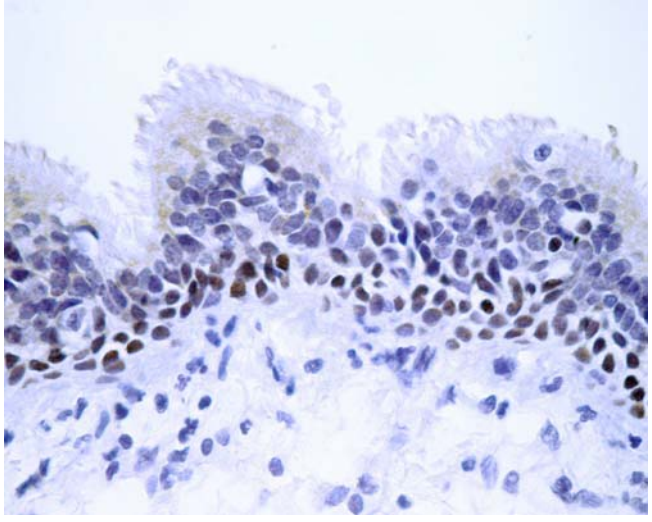

Fig. 1 Weak nuclear staining for thyroid transcription factor 1 (TTF-1) in a thyroglossal duct cyst, accentuated in the basal part of the epithelia

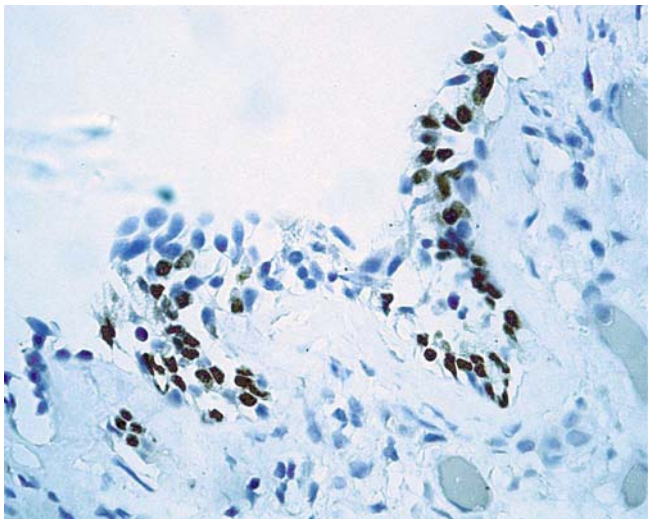

Fig. 2 Focal, but marked nuclear staining of TTF_1 in one of ten branchial cleft cysts

One of the ten branchial cleft cysts revealed a weak but distinct nuclear positivity of TTF-1 (Fig. 2). The other nine cases were negative for TTF-1. All these tissue specimens, including the one that tested positive for TTF-1, were negative for TG.

All ten cases with lymph node metastases of PTC showed an intense nuclear immunostaining for TTF-1 (Fig. 3). Cytoplasmatic staining for TG revealed varying results—ranging from intense and extensive reactions to weak and focal positivity in nine of the ten cases. One case was completely negative.

Discussion

Immunohistochemically, we were able to demonstrate the expression of TTF-1 in five of ten cases of thyroglossal

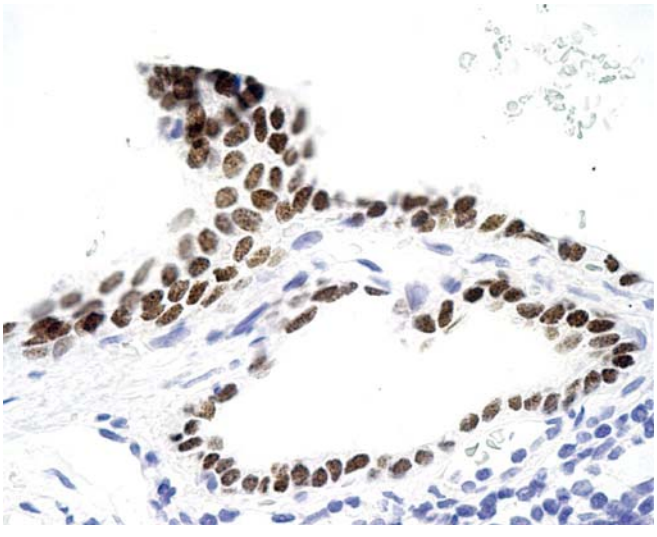

Fig. 3 Strong nuclear staining for TTF_1 in PTC, a constant finding in these lesions

duct cysts and one branchial cleft cyst, as well as in all metastases of PTC investigated. The former, to the authors' knowledge, is the first report of positivity for TTF-1 in these lesions. The latter finding corresponds to results in previous studies, which demonstrated TTF-1 positivity in the adult in normal epithelia and tumours of the thyroid and the lung [6, 11]. Only two tumours unrelated to these organs were also positive for TTF-1: small cell cancer of other-than-lung origin [3] and ependymoma [14]. Thus TTF-1 is a rather specific immunohistochemical marker of lung and thyroid tissue.

Since the thyroglossal duct gives rise to the thyroid gland, its epithelia may already express TTF-1. Therefore, an immunohistochemical positivity for TTF-1 in the thyroglossal duct cyst indicates its relation to the thyroid. A comparable phenomenon is described in tracheobronchial fistulas, where the expression of TTF-1 indicates their origin from the lung [13].

In the branchial cleft cysts, which derive from the branchial clefts and not from the pharyngeal pouch like the thyroid epithelia and C cells [7], there is no developmental relation to the thyroid or the lung. Of these lesions, only one of ten cases stained positively for TTF-1. This may be explained by the respiratory-like metaplasia of the epithelia.

Most of the cases of PTC stained positively for TG. However, we could not demonstrate a positive staining in one case. This may be explained by the relatively inconstant staining for this antibody, which we observed in our reactions and which has also been reported for metastases of thyroid cancer [1]. However, in our study the staining was specific, thereby adding valuable diagnostic information.

The practical implication of our finding is that immunohistochemical reactions for TTF-1 do not reliably distinguish between cystic metastases of PTC and thyroglossal duct cysts or branchial cleft cysts. Therefore, in cases with differential diagnosis of a benign cystic lesion and metastasis of PTC, additional investigations, e.g. an immunostaining for TG, should be performed.

Cyclooxygenase-2 in normal, hyperplastic and neoplastic follicular cells of the human thyroid gland

Received: 5 November 2004 / Accepted: 16 February 2005 / Published online: 10 June 2005
© Springer-Verlag 2005

Abstract This study was undertaken to investigate cyclooxygenase-2 (COX-2) expression in follicular cells of the human thyroid. COX-2 expression was studied immunohistochemically in a total of 174 samples. COX-2 immunoreactivity was confined to the cell cytoplasm with the nuclei remaining unlabelled. COX-2 expression was observed in five cases (17.2%) of normal follicular cells and in one case (16.6%) of solid cell nests. Follicular carcinoma expressed COX-2 more frequently than follicular adenoma (93.4% vs 21.1%) ($p \leq 0.001$). A higher percentage of cases of papillary microcarcinomas up-regulated COX-2 in comparison with all papillary carcinomas ($p \leq 0.05$). However, we could not establish any relationships among COX-2, patients' ages or lymph node metastases in papillary carcinomas. COX-2 expression was found in 12 (92.3%) poorly differentiated carcinomas and in 13 (92.8%) undifferentiated carcinomas. We found that COX-2 is not always useful as a marker of malignancy. Our results suggest that COX-2 plays a role in progression of all thyroid carcinomas, but in papillary carcinomas, seems more important only in the early stages. COX-2 expression in the undifferentiated carcinoma deserves special consideration due to its prognosis and to the fact that selective COX-2 inhibitors were found to enhance tumour response to radiation in some studies.

Introduction

There are two isoforms of cyclooxygenase (COX), COX-1 and COX-2, involved in the synthesis of prostaglandins from arachidonic acid [29]. The COX-1 enzyme is expressed constitutively in most mammalian tissues where, although often undetected, it can be rapidly induced. The COX-2 gene is an early-response gene that is up-regulated by proinflammatory stimuli, growth factors, oncogenes and tumour-promoting phorbol esters [10, 13, 22].

COX-2 seems to play a role in carcinogenesis as well as in carcinoma progression; COX-2 is up-regulated in transformed cells [24], in colorectal cancers [20, 22], ulcerative colitis-associated neoplasia [1], hepatocellular carcinoma [14], oesophageal and gastric carcinomas [25, 34], pulmonary and mammary tumours [22], pancreatic cancer [27], renal cell carcinoma [11], prostate carcinoma [33] and pituitary tumours [30]. COX-2 knockout mice also have a lower incidence of several tumour types including skin papillomas and intestinal polyps [2, 18, 26]. Epidemiological studies have also shown that chronic intake of non-steroidal anti-inflammatory drugs, which function as COX inhibitors, reduces the incidence of gastrointestinal cancer [8, 9, 32].

Enhanced expression of COX-2 in lymphocytic thyroiditis and Hashimoto's thyroiditis suggests an important role of this enzyme in these inflammatory thyroid processes [5, 17]. Thyroid cancer of follicular cells includes several histological types of tumours with various molecular alterations and different clinical behaviours. Papillary carcinoma is the most common malignant tumour of the thyroid and has a relatively indolent clinical course in contrast to the rapidly fatal course of anaplastic (undifferentiated) carcinoma [6]. Poorly differentiated carcinomas fall between well-differentiated (papillary and follicular) carcinomas and undifferentiated carcinomas in terms of

both morphologic appearance and behaviour [6]. Specht et al. [23] reported that COX-2 mRNA level was higher in malignant nodules than in adjacent normal tissue or in benign nodules. Most recently, Ito et al. [12] concluded that the up-regulation of COX-2 may contribute predominantly in the early phase of papillary carcinoma progression while playing a more adjuvant role in follicular carcinoma progression. On the other hand, Siironen et al. [21] showed that COX-2 expression increases with age in papillary thyroid cancer.

In the present study, we examine the expression of COX-2 in a series of normal and hyperplastic follicular cells as well as in well-differentiated (papillary and follicular), poorly differentiated and anaplastic (undifferentiated) carcinomas.

Materials and methods

Tissue specimens

One hundred seventy-four thyroid tissue specimens were obtained from the files of the Department of Pathology, Hospital Clínico Universitario, Santiago de Compostela, Spain. This study was approved by the ethical committee of our institution. Tissue slices had been fixed in 10% formalin and embedded in paraffin wax for histological, immunohistochemical and in situ hybridisation studies. Each case was classified according to the Chan criteria [6]. Specimens were normal thyroid tissue, 29; solid cell nests, 6; Graves' disease, 10; nodular hyperplasia, 15; follicular adenoma, 33; papillary carcinoma, 39 (13 cases of microcarcinomas, 8 cases of classical type, 6 cases of follicular variant, 1 case of solid variant, 4 cases of cribriform-morular variant, 2 cases of Whartin-tumour-like variant and 5 lymph node metastasis); follicular carcinoma, 8; Hürthle cell follicular carcinoma, 7; poorly differentiated carcinoma, 13 (11 cases of insular carcinoma and 2 cases of columnar cell carcinomas); and undifferentiated carcinoma, 14. Of the normal specimens, 16 were from the autopsy specimens, and the other 13 were "normal" tissue taken from non-tumoural areas of the other specimens.

Immunohistochemistry and in situ hybridisation

Immunohistochemical studies were performed on tissue sections 4 μm thick using a COX-2 monoclonal antibody (Cayman Chemical, Ann Arbor, MI, USA, microwaved, 1:50). The reaction was detected using a universal second antibody kit that utilized a peroxidase-conjugated labelled-dextran polymer (Dako EnVision Peroxidase/DAB; Dako, Glostrup, Denmark) in order to avoid misinterpreting endogenous biotin or biotin-like activity in cell cytoplasms [7] or nuclei [3] as positive staining. Paraffin blocks of colorectal cancer known to be positive for COX-2 were used as positive controls. Sections for each negative control were incubated with PBS instead of the primary antibody. Scoring of the immunohistochemical results was performed according to the methods described by Ito et al. [12], with minor modifications. We selected at least five representative fields. Based on the percentages of immunopositive cells, three subdivisions were made as follows: diffusely positive (++), greater than 50% of cells were positive; heterogeneously positive (+), 10–49% of cells were positive; and negative (−), less than 10% of the cells were positive. Equivocal immunointensity was considered to be negative.

As representative cases, in situ hybridisation was performed on 4-μm sections in four cases of normal thyroid tissue, two cases of solid cell nests, one case of Graves' disease, four cases of papillary carcinoma, one case of follicular carcinoma, one case of Hürthle cell follicular carcinoma, two cases of insular carcinoma, one case of columnar cell carcinoma and three cases of undifferentiated carcinoma to confirm immunohistochemical results. Before hybridisation, tissue sections were deparaffinized, rehydrated and washed in TE buffer (Tris 10 mM, EDTA 1 mM). Thereafter, the tissues were treated with proteinase K (4 μg/ml), washed in TE buffer and 2×SSC buffer and dehydrated with 96% and 100% ethanol. Hybridisation was carried out using a 3′FITC-labelled oligoprobe (5′-TCATCAACACTGCCTCAATTCAGTCTCTCATCTGC AATAA-3′) directed against the human COX-2 mRNA. Sections were hybridised at 37°C overnight. After hybridisation, stringent washes were performed in 2×SSC, 1× SSC and 0.5×SSC at room temperature. The oligoprobes were detected using an alkaline phosphatase-labelled anti-FITC antibody (Dako) and visualized with nitroblue tetrazolium (NBT)/BCIP until desired stain intensity was achieved. Sections were counterstained with methylene green and mounted in an aqueous media. We used sections of colon cancer as positive controls for COX-2 mRNA. For negative control, we have substituted the oligoprobe hybridisation mix with hybridisation buffer. Estimation of immunohistochemical and in situ hybridisation scores for each case was performed by different observers (MAGG, JC-T and IA), independently, and determined after discussion when scores were discrepant.

Statistical analysis

χ^2 analysis and Fisher's exact probability test were adopted to examine the relationship between variables. Two results were considered significant when $p<0.05$.

Results

Table 1 summarises the immunohistochemical findings. COX-2 immunoreactivity was confined to the cell cytoplasm with the nuclei remaining unlabelled. Epithelial cells of solid cell nests were negative in five cases and diffusely positive in one case. Although the percentage of immunopositive cells was higher in malignant tumours than in

carcinoma expressed COX-2 more frequently than follicular adenoma ($p \leq 0.001$) (Fig. 1e). Twenty-seven (68.8%) of the papillary carcinomas showed COX-2 immunoexpression (Fig. 1b–d). A higher percentage of cases (92.3%) of papillary microcarcinomas up-regulated COX-2 in contrast to all papillary carcinomas ($p \leq 0.05$) (Table 2). The mean age in the 23 COX-2-positive papillary carcinomas was 49.9±17.3 in comparison with 42.15±19.6 in the COX-2-negative papillary carcinomas. We could not establish any relationship between COX-2 expression and patients' age or lymph node metastases.

COX-2 expression was found in 12 (92.3%) poorly differentiated carcinomas and in 13 (92.8%) undifferentiated carcinomas (Fig. 1f–i). In two cases of undifferentiated carcinoma, residual areas of poorly differentiated carcinoma and mucoepidermoid carcinoma were identified showing less immunointensity for COX-2 than the anaplastic areas (Fig. 1g).

In situ hybridisation analysis showed no staining in solid cell nests. A staining pattern supported the immunohistochemical findings in the other types of samples examined (Fig. 2).

Discussion

In this study, we found that COX-2 expression was frequently up-regulated in thyroid carcinomas as previously reported [12, 17, 21, 23], whereas COX-2 expression was limited in normal follicular cells. Solid cell nests of the thyroid, usually considered as normal embryonic remnants of the ultimobranchial body, were recently proposed as thyroid stem cells [19]; in situ hybridisation was negative in epithelial cells of these structures, and weak immunostaining was found in only one case of our series. COX-2 expression in some normal follicular cells was observed in our study and also observed by Ito et al. [12]. We think that this fact, together with negative expression of COX-2 in 30.8% of papillary carcinomas tested, indicates that COX-2 is not always useful as a marker of malignancy.

At least some follicular carcinomas are believed to arise from preexisting adenomas, although this has not yet been confirmed [6]. In our series, the percentage of COX-2 expression in follicular carcinomas was higher than that reported by Ito et al. [12] (93.3% vs 40.9%), but the percentages were similar in follicular adenomas. We cannot discard the possibility that some follicular adenomas up-regulating COX-2 could in fact be "malignant" tumours that have not yet revealed morphologic criteria of malignancy. Papillary carcinomas frequently over-express COX-2 [12, 17, 21]; but this expression is significantly reduced in tumours related to old age, large size, satellite tumours and the presence of a solid, scirrhous or trabecular growth pattern [12], thus, suggesting that the activation of this enzyme is required in the early phase of papillary carcinoma progression [12]. In our study, a significant higher percentage of papillary microcarcinomas up-regulated COX-2 in comparison with all papillary carcinomas. We think that in papillary carcinomas, COX-2 expression seems more important only in the early stages. At the same time, the higher proportion of COX-2 down-regulation in the entire group of papillary carcinomas could be related to the indolent behaviour of these tumours in comparison with other thyroid carcinomas. Siironen et al. [21] postulate that with the older age group having a much worse prognosis and a higher expression of COX-2, COX-2 confers an adverse prognosis via either invasion or metastasis. An association among age, worse prognosis, and higher grade in thyroid pathology is well recognized in the literature [6].

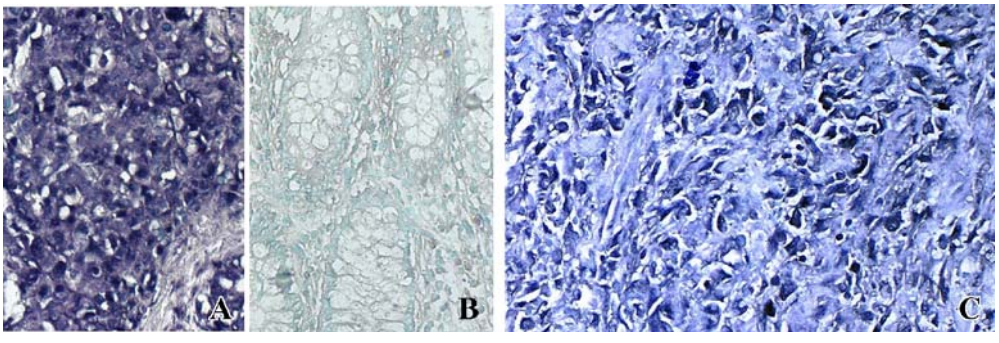

Fig. 2 In situ hybridisation for COX-2. **a** Positive control (carcinoma of the large bowel) (×200). **b** Negative control (normal mucosa of the colon) (×200). **c** Undifferentiated carcinoma of the thyroid showing strong positivity for COX-2 (×200)

In our series, however, we could not establish any relationship between COX-2 expression and patients' ages or lymph node metastases.

The cribriform-morular variant of papillary carcinoma is the sporadic counterpart of the thyroid carcinoma that occurs in patients with familial adenomatous polyposis [3, 4, 6]. *APC* mutations may represent a rare mechanism for COX-2 up-regulation in familial adenomatous polyposis-associated thyroid tumours [18]. However, among our cases of cribriform-morular variant of papillary carcinoma, including one case with germline mutation of the *APC* gene, we found weak but diffuse COX-2 expression in the only case with somatic, but not germline mutation of the *APC* gene [4]. A disturbance of the Wnt signal transduction pathway due to *β-catenin* gene mutations is more significant in the carcinogenesis of the cribriform-morular variant of papillary carcinoma [31].

Solid variant is a rare and poorly characterised variant of papillary thyroid carcinoma [16] whose a less favourable prognosis could correlate with expression of COX-2.

The immunoprofile of the rich lymphoid stroma in Whartin-tumour-like variant of papillary carcinoma is similar to that of chronic lymphocytic thyroiditis [6, 28]. The expression of COX-2 in lymphocytic thyroiditis, Hashimoto's thyroiditis and some thyroid tumours has been proposed as a basis for the relationship between carcinogenesis and autoimmunity [5, 17, 21].

A stepwise increase in immunoreactivity scores for COX-2 staining was found by Nose et al. [17] from follicular adenomas to papillary carcinomas, well-differentiated and poorly differentiated types and follicular carcinomas (with anaplastic carcinoma included in the poorly differentiated papillary carcinoma group). We found a strong COX-2 expression in more than 90% of both follicular carcinomas and poorly differentiated carcinomas. In our series, up-regulation of COX-2 was found in all cells of 93% of undifferentiated carcinomas, and the stain was stronger in undifferentiated areas in the two cases with residual poorly differentiated foci. These findings deserve special consideration due to the ominous prognosis of undifferentiated thyroid carcinoma [6], as well as to the fact that selective COX-2 inhibitors were found to enhance thoracic tumour response to radiation in preclinical studies [15].

Global DNA methylation evaluation: potential complementary marker in differential diagnosis of thyroid neoplasia

Received: 24 December 2004 / Accepted: 3 April 2005 / Published online: 13 May 2005
© Springer-Verlag 2005

Abstract The implications of global DNA hypomethylation were recently reported in several models of tumorigenesis. Little is known about this epigenetic event in thyroid neoplasia. The study aimed to evaluate the status of global DNA methylation in several types of thyroid tumors using a monoclonal antibody specific for 5-methylcytidine (5-mc) and to define the diagnosis potential of this marker. 5-mc immunostaining scores were calculated in 17 papillary thyroid carcinomas (PTC), 6 follicular thyroid carcinomas (FTC), 16 follicular adenomas (FA), 19 nodular goiters (NG) and ten Hürthle cells adenomas (HCA). The expression of galectin-3 was also evaluated. Computerized image analysis showed a significant lower level of 5-mc immunostaining in thyroid carcinoma when compared with benign tumors or adjacent normal thyroid parenchyma ($P<0.0001$). Overall, 5-mc accuracy to distinguish malign from benign thyroid tumors was similar to that of galectin-3 (89% versus 87%, $P>0.05$). The combination of 5-mc with galectin-3 led to an excellent accuracy level of 96%. Among follicular neoplasia 5-mc accuracy to differentiate malign tumors trends to be higher than galectin-3 one (90% versus 66%, $P=0.06$). These data stress the necessity of epigenetic events evaluation among thyroid nodules and propose global DNA methylation assessment as a potential diagnostic tool to combine with other valuable markers.

Introduction

Thyroid nodules represent a very common endocrine pathology, although only a small number are diagnosed as cancers. Over the last few decades, fine-needle aspiration biopsy (FNA) has had the central role in the management of thyroid nodules [21, 22]. Despite good accuracy initially declared [22], classical cytodiagnosis include an important number of indeterminate or non-diagnostic results [2, 11]. Generally, these cases undergo surgery, and up to 70% of them will be shown to be benign [2]. Moreover, a significant number of operated tumors with a certain overall appearance will display opposite patterns over the time for whom inadequate protocols were applied [25, 26, 45]. In consequence, additional tools are mandatory in order to improve the decisional selectivity before and after the surgery.

Several tumoral markers are currently assessed [3, 10, 18]. Over the last few years, a certain homogenous group of studies of histo and cytochemistry promoted galectin-3 as an overall differentiating solution of thyroid nodules [3, 4, 19, 20, 37, 38, 44]. Less enthusiastic researchers, namely those employing semiquantitative or real time RT-PCR, constantly stressed the limits of galectin-3 regarding the follicular neoplasia differentiation [6, 9, 14, 30, 34, 40]. Some studies reported up to 74% false results among follicular thyroid neoplasia [27, 32, 41, 46].

Multiple associations, including galectin-3, HBME-1, MET, fibronectin-1 and cytokeratin-19, have also been in-

vestigated. However, none of these attempts reached very high levels of accuracy [10, 41, 43]. A recent study reported the ability to differentiate malign from benign nodules using microarray technology and molecular profiling [16, 17]. The analysis produced a large list of genes that were significantly differentially expressed between carcinoma and benign thyroid lesions. In all cases, an overlap of gene expression was found between benign and malign tumors in favor of a continuity in tumor progression. Given such variety of gene expression abnormalities, a question arises regarding a "conspirative" trigger event. Consequently, new hypotheses concerning epigenetic-genetic interaction were advanced [15].

Literature data demonstrated recently that global genomic hypomethylation represents an epigenetic difference in cancer susceptibility [35]. Recently, preliminary results were published on the status of global DNA methylation in a small number of thyroid neoplasia [13]. The aim of this study is to verify the possibility of quantifying this phenomenon among thyroid neoplasia and to evaluate its diagnostic potential in distinguishing malign thyroid tumors, isolated or in combination with other valuable markers.

Materials and methods

Tissue samples

We evaluated thyroid neoplasms, including 17 papillary thyroid carcinomas (PTC), six follicular thyroid carcinomas (FTC), 16 follicular adenomas (FA), 19 nodular goiters (NG) and ten Hürthle cells adenomas (HCA). The tumors were classified according to widely accepted histopathologic criteria [29]. Papillary carcinomas were diagnosed based on characteristic cytological features, and architectural (papillary or follicular) patterns. Follicular carcinomas were distinguished from adenomas on the basis of cytological patterns [28] and invasion of the edges of the tumor and/or invasion of blood vessels in or beyond the capsule. Tumors were classified as Hürthle cell neoplasm when the predominant cell subtype (almost 75% of cells) had oncocytic features [29].

Immunohistochemistry (IHC)

All thyroid specimens were fixed in 10% formalin for 24 h. In all cases, immunohistochemical analysis was performed on routinely paraffin-embedded sections. The tissues were sectioned onto positively charged slides (SuperFrost Plus, Menzer-Glaser, Freiburg, Germany) and dewaxed with xylene and alcohol.

Global DNA methylation (5-mc) Antigen retrieval was performed in two steps: 40 min with citrate buffer (pH 3.4) in a water bath at 97°C and 30 min in 3 N HCl for at 37°C. Thereafter, slides were incubated with a hybridoma supernatant containing anti-5-methylcytidine monoclonal antibody at a concentration of 5 μg/ml for 1 h at room temperature on a DAKO TechMate 500 Plus. Arguments in favor of the accessibility of these antibodies have already been published [23, 35, 36].

Galectin-3 (gal-3) Antigen retrieval was performed in 10 mM citrate buffer (pH 6.0). Thereafter, slides were incubated with the primary antibody (NCL-GAL3, IgG2a, 1:200, Novocastra Laboratories, UK) for 40 min at room temperature on a DAKO TechMate 500 Plus.

The EnVision detection system and DAB (diaminobenzidine) chromogen (K4006, DAKO Corporation, Carpinteria, Calif., USA) were used for both antibodies.

Cell immunostaining evaluation

Visual analysis Two independent observers, blinded to clinical data previously established, evaluated galectin-3 immunostaining. Galectin-3 cytoplasmic staining was semiquantitatively scored by a method previously described [1, 5]: (0) no reactivity, (1) faint or weak, (2) moderate positivity, (3) strong positivity.

Computerized image analysis The optical density of the nuclei of epithelial cells stained with anti-5-methylcytidine antibody was measured in 20 microscopic fields belonging to the pathologic portion of the sample and in 20 fields of the normal tissue when possible, in a computerized system (SAMBA Technologies, Lyon, France), connected to a Leica D.M.R. microscope (100× objective). Every tissue was analyzed using the same optical conditions (luminosity). An average staining score was automatically calculated by SAMBA Technologies software.

Statistical analysis

Data are presented as mean±SE. Differences were assessed by Mann-Withney Rank sum test (unpaired) or Wilcoxon test (paired). Significance level was assigned at $P<0.05$. For every marker, ROC curves were calculated (MedCalc Software) in order to evaluate the accuracy of differentiation between benign and malign tumors (area under ROC curve—AUC). AUC values were automatically compared. The output data of every marker ROC analysis included also a cut-off value corresponding to a optimal sensitivity/specificity ratio.

The same statistics were employed in the subgroup of follicular neoplasia (malign and benign).

Results

General group (n=68)

Global DNA methylation Variable nuclear staining was noted in all studied specimens. Visual inspection reported in papillary carcinoma a higher labeling in the periphery of nuclei (compacted heterochromatin) (Fig. 1).

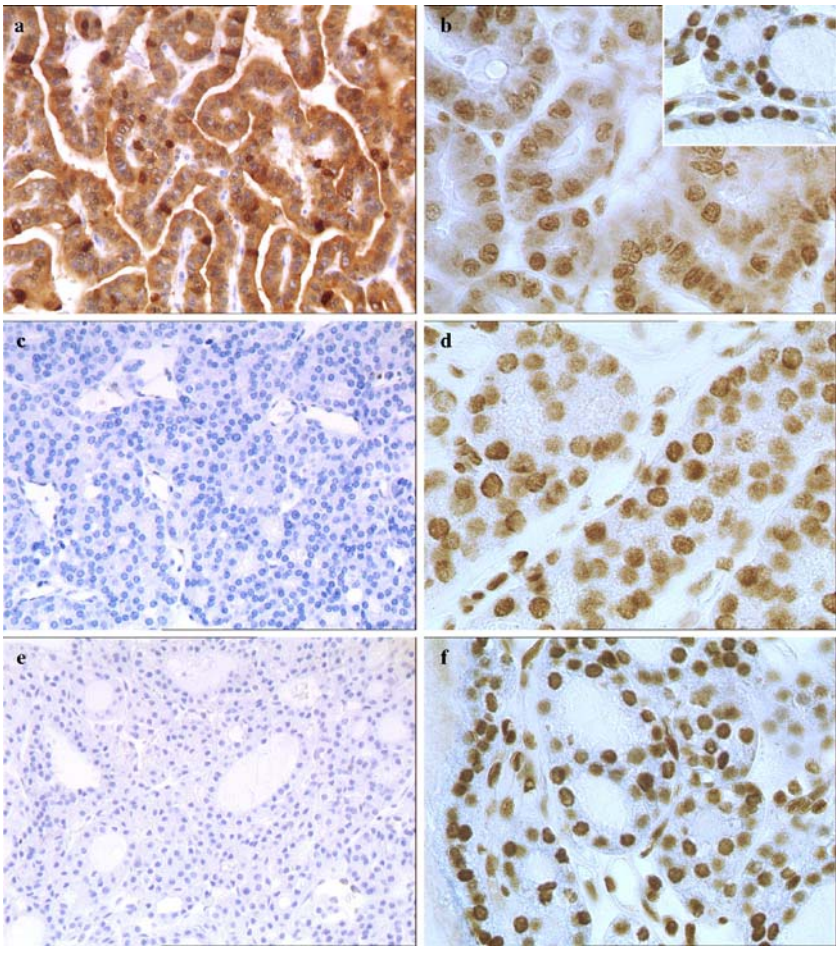

Fig. 1 DNA methylation (*right column*, ×100 magnification) and galectin-3 (*left column*, ×40 magnification) expresion in thyroid neoplasia. **a**, **b** papillary thyroid carcinoma; normal tissue is presented in Fig. 1**b** cartoon. **c**, **d** follicular thyroid carcinoma. **e**, **f** follicular adenoma

Computerized image analysis showed a significantly lower level of 5-mc immunostaining in thyroid carcinoma (PTC and FTC) compared with benign tumors (FA, HCA and NG) ($P<0.0001$, Mann-Witney test) (Fig. 2) or adjacent normal thyroid parenchyma ($P<0.0001$, Wilcoxon test). No difference was found between benign neoplasia and normal thyroid tissue ($P=0.3$). Receiver operator characteristics (ROC) performed to distinguish malign and benign tumors displayed a good accuracy of 89±3% and a optimal cut-off value of 35 with 96% sensitivity and 75% specificity (Table 1).

Galectin-3 Constant strong cytoplasmatic staining was found in PTC, while FTC revealed variable levels (Fig. 2).

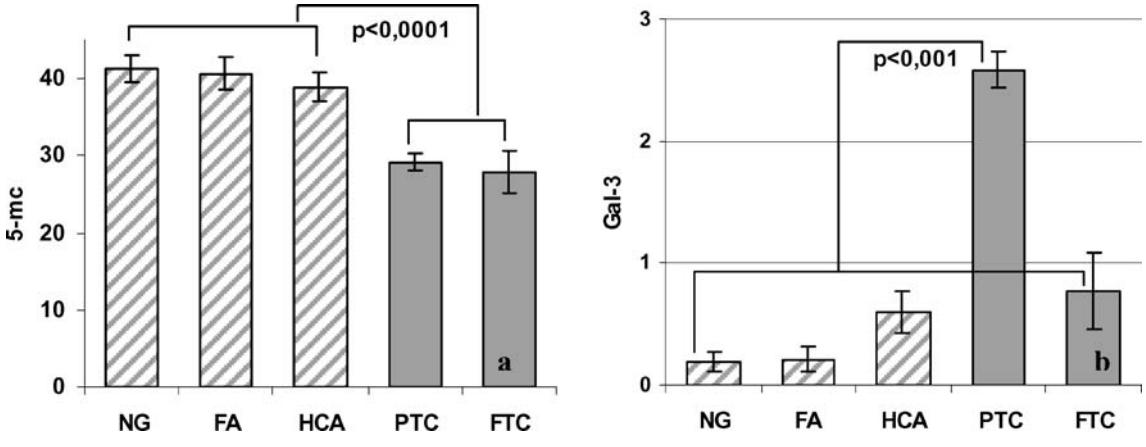

Fig. 2 **a** The mean levels of global DNA methylation assessed immunohistochemically, displayed a significant difference when comparing benign and malign thyroid neoplasia. **b** Gal-3 staining mean level was increased only in PTC. *NG* nodular goiter; *FA* follicular adenoma; *HCA* Hürthle cells adenoma; *PTC* papillary thyroid carcinoma; *FTC* follicular thyroid carcinoma

Table 1 Immunohistochemical results of 5-mc and galectin-3 in thyroid neoplasia

Diagnosis	5-mc* (%)	Gal-3** (%)
Normal thyroid tissue	0/17 (0)	0/17 (0)
Nodular goiter	3/19 (15,7)	2/19 (10,5)
Follicular adenoma	5/16 (31,2)	2/16 (12,5)
Hürthle cell adenoma	3/10 (30)	1/10 (10)
Papillary thyroid carcinoma	16/17 (94)	14/15 (93,3)
Follicular thyroid carcinoma	6/6 (100)	3/6 (50)

*Hypomethylated cases and **galectin-3 positive cases were differentiated according to cut-off values set automaticaly by employing MedCalc software: 5-mc≤35; galectin-3>0.5 (these values corresponding to an optimal specificity/sensibility ratio are orientative)

Gal-3 was found to be absent in almost all FA and NG. ROC curve performed to differentiate benign/malign tumors had an AUC of 87±4%, meaning a good accuracy level (Table 1). On a staining score scale from 0 to 4, an optimal cut-off value was set at 0.5 to differentiate benign and malign tumors with 80% sensitivity and 89% specificity.

A virtual marker was calculated for each specimen by combining gal-3 and 5-mc: GM=5-mc/10—galectin-3. ROC curve of this marker displayed an excellent accuracy level of 96±2%. This value was significantly greater than the accuracy of each marker assessed separately (P<0.001). No difference was found between the two parameters accuracies.

Global DNA methylation and galectin-3 accuracies in detecting papillary thyroid carcinoma presented no significant difference (88% versus 90%, P=0.72).

Follicular neoplasia (n=22)

ROC calculated accuracy of 5-mc IHC assessment trends to be significant grater than gal-3 one (90% versus 66%, P=0.06) in this type of tumors. Moreover, opposite to galectin-3, DNA methylation evaluation preserve its ability to differentiate FA from FTC (P=0.18 versus P=0.0018, Mann-Witney tests).

Discussion

The epigenetics of cancer was recently characterized as a complex dysregulation including global hypomethylation, individual gene hypomethylation and hypermethylation, chromatin modification and altered genomic imprinting [15]. Aberrant methylation and hypomethylation in particular were described in neoplasia as early events [12, 39]. The causes of this hypomethylation are not well known. Functionally, hypomethylation may contribute to chromosomal instability in cancer and, perhaps, to increased expression of selected affected genes [15].

To date, several cancer-associated regional DNA hyper- or hypomethylations have been identified in thyroid tumors [7, 8, 24, 31, 33, 42, 47, 48]. Recently, immunohistochemical techniques were developed in order to assess global methylation of DNA in individual cells [35, 36]. In the present study, we quantified this epigenetic feature in thyroid tumors by employing anti-5-methyl citidine antibodies.

Computerized image analysis allowed us to conclude that benign tumors (follicular or Hürthle cell adenoma, nodular goiter) had a significant higher global DNA methylation level than studied thyroid carcinoma (P<0.001). These results are in line with those previously published concerning 5–methylcytidine level in lung cancers cells [35, 36], breast carcinoma [39] or colorectal adenocarcinomas [23]. A recent study performed on eight cases of thyroid cancer and one multinodular goiter reported similar preliminary results [13].

In contrast to other tissues, benign tumors (stomach, breast) [12, 39], in thyroid follicular lesions the level of global methylation seems to be identical to that from normal thyroid parenchyma. Thus, we supposed that loss of methyl groups in thyroid neoplasia DNA is not such an early event as described in other tumorigenesis models [12, 39].

To better analyze the 5-mc diagnostic qualities, we evaluate this marker in parallel with galectin-3, a well-known, lately promoted marker in thyroid neoplasia differentiation [3]. In our study, the 5-mc diagnostic accuracy in differentiating thyroid tumors proved to be similar to that displayed by galectin-3 IHC assessment. A significant improvement was noticed when combining the evaluation of these two markers (accuracy—96%). In thyroid follicular neoplasia, a category for which galectin-3 differential abilities are controversial, 5-mc evaluation accuracy tends to be significant higher (90% versus 66%, P=0.06). These data propose an extension of global DNA methylation evaluation in thyroid cytologic smears.

In this paper, we stressed the diagnostic potential of global methylation evaluation among thyroid nodules. Our data corroborate a recent hypothesis in which epigenetic alteration contribute to tumor progression. It further suggest that recent microarray analysis revealing several overexpressed genes in thyroid carcinoma [16, 17] should be appended with an extensive approach of epigenetic dysregulation.

Significance of inducible nitric oxide synthase expression in benign and malignant breast epithelium: an immunohistochemical study of 151 cases

Received: 10 December 2004 / Accepted: 4 March 2005 / Published online: 10 June 2005
© Springer-Verlag 2005

Abstract The role of calcium independent inducible nitric oxide synthase (iNOS) in breast carcinoma is controversial, and the implications of iNOS expression on prognosis are not known. In this study, we aimed to investigate the significance of immunohistochemical iNOS expression in 100 invasive ductal carcinomas. In addition, 11 normal breast tissues, 20 cases of usual ductal hyperplasias (UDHs) and 20 fibroadenomas were included. We found that 78% of malignant and 75% of benign cases showed iNOS immunoreactivity. However, the intensity and the quantity of iNOS expression were significantly higher in the cancer group when compared with benign breasts ($P<0.001$), suggesting a role of iNOS in breast carcinogenesis. We were unable to show a correlation between iNOS expression and tumor grade, axillary lymph node status, and estrogen receptor expression. In 50 axilla negative cases having 5–12 years follow-up, disease free survival (DFS) rate was significantly lower in cases showing strong iNOS expression ($P=0.05$). As strong iNOS expression was correlated with short DFS, we concluded that further studies would be necessary to elucidate if iNOS expression might be a useful prognostic marker in breast carcinoma, especially in the axilla negative group.

Keywords Nitric oxide synthase · Benign breast disease · Breast carcinoma · Immunohistochemistry

Part of this study was presented at XXIVth International Congress of the International Academy of Pathology, Amsterdam, The Netherlands on 5–10 October 2002 as a poster presentation.

Introduction

Nitric oxide (NO), a free radical, is involved in several regulatory mechanisms as an intracellular second messenger, but the role of NO in tumor biology is poorly understood. NO seems to have a dose dependent and biphasic effect on tumor growth resulting from its influence on apoptosis and angiogenesis [3]. NO is generated from L-arginine by NO synthase (NOS), which is present in three isoforms, neuronal (nNOS), endothelial (eNOS) and calcium independent inducible (iNOS or NOSII) [3, 7]. iNOS generates a high amount of NO over a prolonged period, whereas the effect of the other two isoforms is smaller with regard to the amount of NO generated and the duration of their effects.

In recent studies, iNOS expression has been reported in human pharynx, esophagus, pancreas, colon, gallbladder, lung, bladder, cervix, ovary, prostate and thyroid carcinomas, cutaneous adnexal tumors, primary malignant mesotheliomas and metastatic malignant melanomas [1, 4, 6, 8, 12–15, 18, 21, 23, 25–27, 29–31, 34, 36–40]. There are also some studies on primary breast carcinomas and benign breast lesions with conflicting results [5, 10, 19, 20, 28, 33, 35]. In a few previous studies, iNOS expression was evaluated with regard to some prognostic clinicopathological parameters (axillary lymph node status, estrogen receptor status, grade) [5, 19, 20, 28, 33], but there is only one previous study on the implication of iNOS expression on survival rate [20].

The aim of this study was to examine iNOS expression immunohistochemically, in a large series of primary breast carcinomas, to determine the possible relationships be-

tween iNOS expression and clinicopathological parameters such as axillary lymph node status, tumor grade, estrogen receptor status and prognosis. In addition, it was aimed to investigate the iNOS expression with a special emphasis on the possible differences within the spectrum of normal to highly proliferative benign breast epithelium.

Materials and methods

Patients

Group 1 (malignant)

Archival sections from operation specimens of 100 patients with invasive ductal carcinoma, diagnosed between 1990 and 2002, and treated with modified radical mastectomy (n=78), lumpectomy/quadranectomy (n=22) and axillary dissection (n=99), were re-evaluated. Axillary lymph node status, tumor grade according to the modified Bloom and Richardson system and estrogen receptor status as determined by immunohistochemistry were recorded. Five to 12 years follow-up information was available for 50 patients. All of the 50 patients with follow-up information were axilla negative breast carcinoma patients evaluated for a previous study. Recurrences, metastases and/or death due to the disease in the follow-up period were considered as a poor prognosis, while no evidence of disease was considered as a good prognosis. DFS and OS rates were also evaluated.

Group 2 (benign)

Archival sections from tissue samples of 40 patients operated on for benign breast disease (20 fibroadenomas and 20 usual ductal hyperplasias (UDHs)) and normal breast tissue from 11 reduction mammoplasty specimens were re-evaluated. UDHs were graded as severe (formation of epithelial bridges across the lumen or filling and distention of the duct), moderate (tufting and the tendency to cross lumens) or mild (three to four cells layers above the basement membrane) [32]. All tissues were fixed in 10% neutrally buffered formalin and embedded in paraffin.

Immunohistochemistry

Sections 5 μm thick were cut from representative blocks and deparaffinized. Without using any pretreatment, sections were washed with PBS. Endogenous peroxidase activity was blocked by incubating with 3% H_2O_2. Histostain-Plus Kit (Zymed Laboratories, San Francisco, Calif., USA) was used as the secondary system. Protein blocking solution in the kit was used as a blocking agent. Sections were then incubated with a primary antibody (Onkogene, Calbiochem, San Diego, Calif., USA; anti-nitric oxide synthase (1131–1144), inducible, rabbit pAB–Cat. No. 482728; dilution:1:1750) against iNOS, without any cross-reactivity with nNOS or eNOS, at room temperature for 2.5 h. Sections were then washed with PBS and incubated with biotinylated secondary antibody for 15 min. After a further step of washing with PBS, sections were incubated with Streptavidin-HRP conjugate for 15 min. After washing in PBS, amino-ethyl carbazole was used as chromogen and finally Mayer's hematoxylin was used for counterstaining. Sections from a known iNOS positive colon carcinoma were used as positive control. Negative controls substituting PBS for the primary antibody were included for each slide run.

The scoring system suggested by Soini et al. was used for iNOS evaluation [30]. Cytoplasmic granular and/or diffuse staining pattern was taken as positive. According to this system, the quantity of iNOS-positive cells was evaluated in the mostly stained area of each tissue subjectively and scored as 0–4 as follows: 0: no positive immunostaining; 1: <25%; 2: 25–50%; 3: 50–75%; 4: >75% of cells showing cytoplasmic positivity. The intensity of staining was estimated visually by dividing the staining reaction in five groups: 0: no positive immunostaining; 1: weak; 2: moderate; 3: strong; 4: very strong staining intensity.

The scoring system suggested by Leake et al. was used for estrogen receptor (ER) evaluation [17]. Only nuclear staining was taken as positive. According to this system, the percentage (quantity) of ER-positive tumor cells was calculated by counting the number of positive cells on a total of 500 cells in the mostly stained area of each tissue and scored as follows:

0: no positive immunostaining; 1: <1%; 2: 1–10%; 3: 11–33%; 4: 34–66%; 5: 67–100% of tumor cells showing nuclear positivity. The intensity of staining was estimated visually by dividing the staining reaction in four groups: 0: no positive immunostaining; 1: weak, 2: moderate, 3: strong staining intensity.

The intensity and quantity scores for each antibody were added together and a total staining score (TSS) was obtained. TSS was then divided into three main groups: no immunostaining (score 0), weak immunostaining (score 1–4) and strong immunostaining (score 5–8).

In evaluation of the immunohistochemical stainings, scoring was performed by two different observers independently and when the scores were inconsistent, a third observer was also asked to score and the results were discussed.

Statistical analysis

SPSS for Windows was used for statistical analysis. Mann-Whitney U, Pearson correlation, Student t-test and Kaplan-Meier survival analysis were performed to detect the associations between clinicopathological parameters and iNOS expression. A P-value of equal to or less than 0.05 was considered as significant.

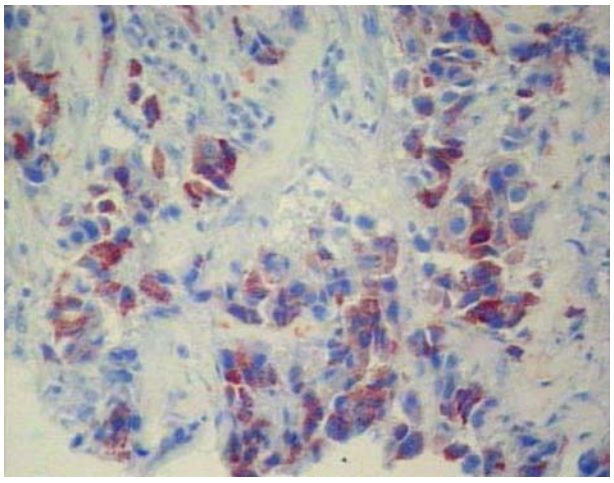

Fig. 1 Strong and widespread iNOS immune staining in a grade II invasive ductal carcinoma; original magnification is ×400

Results

The age of the patients in group 1 ranged from 28 to 76 years, with a mean of 49.4 years. In group 2, ages were 30–68 (mean 46.9), 14–47 (mean 39.3) and 16–63 (mean 35.7) years for UDHs, fibroadenomas and normal breasts, respectively. Thirty-two out of 99 patients had axillary lymph node metastasis at the time of operation; axillary lymph node dissection was not available in one patient. 22 tumors were grade I, 54 were grade II and 24 were grade III. In the second group, UDHs were graded as severe in seven, as moderate in seven and as mild in six patients.

Staining for iNOS was observed in the epithelial component of non-malignant tissues and in tumoral and/or nontumoral epithelial cells in carcinoma cases, either in granular or diffuse cytoplasmic pattern (Fig. 1). Generally, the staining pattern was not homogenous within a single case. Strongly stained cells were observed adjacent to non-stained cells (Figs. 2, 3). Stromal cells did not show immunoreactivity for iNOS.

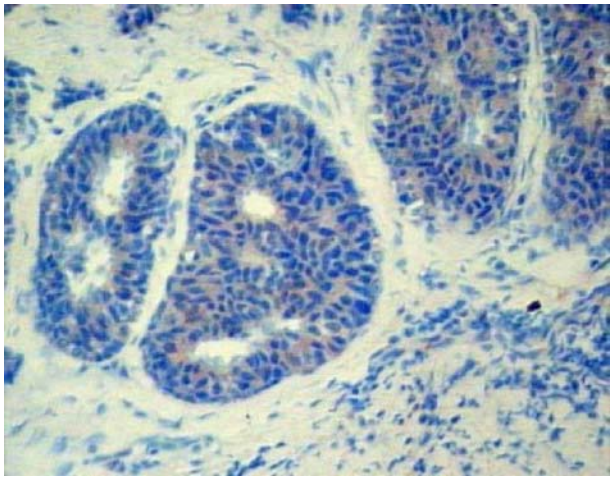

Fig. 2 Mild iNOS immune staining of epithelial cells in UDH; original magnification is ×200

Fig. 3 Focal and strong iNOS immune staining in a fibroadenoma; original magnification is ×100

Positive iNOS immunostaining was detected in 78% of carcinomas (Fig. 1). In the second (benign) group, 13/20 (65%) UDHs, 18/20 (90%) fibroadenomas and 7/11 (63.6%) normal breasts showed iNOS expression (Figs. 2, 3). TSS was significantly higher in the malignant group ($P<0.001$) (Table 1). In UDHs, 6/7 (85.7%) cases with severe, 4/7 (57.1%) cases with moderate and 3/6 (50%) cases with mild hyperplasia showed iNOS positivity. Although the percentage of strongly stained cases increased by the hyperplasia grade, the number of UDH cases was too small to make a statistical analysis between TSS of different hyperplasia grades. (Table 1).

iNOS expression did not show any significant correlation with tumor grade, axillary lymph node status and ER status (Table 2).

In 50 carcinoma patients having 5–12 years follow-up, disease free survival (DFS) and overall survival (OS) rate was 73% and 87%, respectively. Within the follow-up period, 11 cases showed a poor prognosis (four local recurrences, four distant metastasis, three recurrences and metastasis) and four of these patients died of the disease. Thirty-nine cases showed a good prognosis and remained free of the disease. Seventy-three percent of cases with poor prognosis and 41% of cases with good prognosis showed strong iNOS immunoreactivity. OS rates showed no significant difference between tumors showing strong and no/weak iNOS expression, but DFS rate was significantly lower in tumors showing strong iNOS expression ($P=0.05$), suggesting a negative impact of strong iNOS positivity on prognosis in axilla negative cases (Table 3) (Figs. 4, 5).

Discussion

Nitric oxide (NO), a free radical generated from L-arginine by NO synthases, is an important mediator of physiological functions such as vasodilatation, inhibition of platelet aggregation and neurotransmission in low concentrations. Although the role of NO in tumorigenesis and tumor progression is not clearly understood, experimental and

Table 1 iNOS expression in malignant and benign breast lesions and in normal breast

Groups	iNOS expression			Total *n*
	No (TSS:0) n (%)	Weak (TSS:1–4) n (%)	Strong (TSS:5–8) n (%)	
Group 1 (malignant)	22 (22.0)	32 (32.0)	46 (46.0)	100
Group 2 (benign)				
UDH				
Mild	3 (50.0)	2 (33.3)	1 (16.7)	6
Moderate	3 (42.8)	2 (28.6)	2 (28.6)	7
Severe	1 (14.4)	3 (42.8)	3 (42.8)	7
Fibroadenoma	2 (10.0)	16 (80.0)	2 (10.0)	20
Normal breast	4 (36.4)	6 (54.5)	1 (9.1)	11

clinicopathological data suggest that it has biphasic, dose and organ dependent effects. The role of NO in carcinogenesis is probably due to a combination of its dose-dependent and biphasic effects on apoptosis, tumor cell invasiveness and angiogenesis [3]. Although there are at least three different isoforms of NOS generating NO, iNOS gains special attention because it generates higher levels of NO and it has a prolonged activity [7].

In the literature, iNOS expression is observed in malignant cells of different tumors such as bladder, colon, prostate, esophagus, thyroid, pancreas, liver, lung and laryngeal carcinomas; brain tumors, malignant mesotheliomas, malignant melanomas and bone metastases of different tumors [2, 6, 9, 11–14, 18, 24, 30, 31, 36, 37, 39]. In some of these studies, stromal cells such as vascular smooth muscle, macrophages and endothelium have also been shown to be positive for iNOS [10, 13].

According to studies in the literature, 35–61% of breast carcinomas show iNOS expression [5, 19, 28, 33]. To our knowledge there are only three studies, with conflicting results, in which benign breast lesions have been studied and only in one study expression of iNOS in normal breast has been evaluated [19, 28, 33]. In the present study, we observed iNOS positivity in 78% of the cases, in a series of 100 invasive ductal carcinomas. Most of the UDHs, fibroadenomas and normal breasts also showed iNOS expression. Therefore, we suggest that iNOS expression cannot be used for distinguishing malignant epithelial cells from benign ones. However, TSS was remarkably higher in malignant group and this finding suggests a possible role of iNOS in breast carcinogenesis.

iNOS expression was evaluated in two studies on four and eight fibroadenomas in the literature and iNOS expression was not observed [19, 28]. However, in our series consisting of 20 fibroadenomas, iNOS positivity was present in 90% of fibroadenomas. In the literature, there is only one study on iNOS expression in proliferative benign breast lesions [19] in which iNOS expression was not observed in 15 cases. In our study, we found that 65% of 20 UDHs expressed iNOS. Although the percentage of stained cases increased with the hyperplasia grade, the number of UDH cases was too small to make a statistical analysis to show the correlation between iNOS expression and hyperplasia grade. There is only one study about iNOS expression in normal breasts. In this study, Tsugguel et al. showed iNOS expression in most of the epithelial cells in four normal breast tissues [33]. In our study, we also observed iNOS expression in normal breasts. In the previous studies, different polyclonal [19] and monoclonal [28, 33] primary antibodies were used. The discordance between the results concerning iNOS staining in benign breast epithelium may be related to the use of different primary antibody sources and technical procedures in these studies.

There are a few studies on the association of iNOS expression with prognostic parameters in breast carcinomas. The relationship between tumor grade and iNOS expression is controversial. Although NOS activity was more prominent in low-grade tumors in two studies [28, 33],

Table 2 iNOS expression in invasive ductal carcinomas with regard to clinicopathological parameters and prognosis

Parameters	iNOS			*P* value

[b]Prognostic information was available for 50 patients

Table 3 iNOS expression and OS, DFS rates in 50 axilla negative patients

	iNOS		*P* value
	No/weak (TSS:0–4)	Strong (TSS:5–8)	
OS rate	95%	77%	0.25
DFS rate	87%	56%	0.05

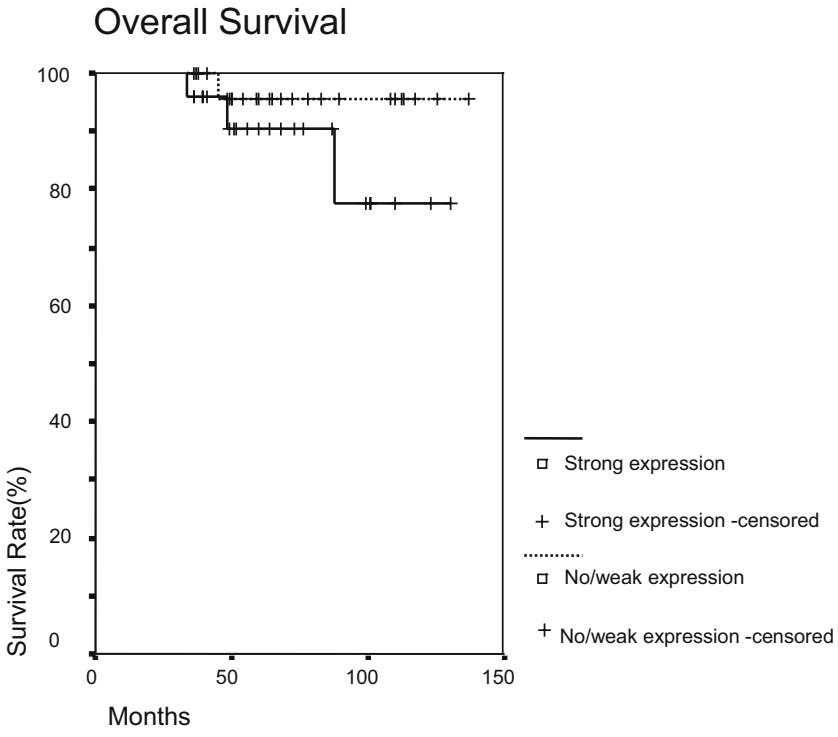

Fig. 4 Overall survival rates of strong and weak iNOS expressing malignant cases

detection of iNOS was positively correlated with decreasing tumor differentiation in another study [20]. There was no correlation in one other study, consistent with our findings [5]. We did not detect any significant correlation between axillary lymph node status and iNOS expression like Reveneau et al.'s study. However, Duenas-Gonzales et al. observed that most of the axilla positive cases were iNOS positive and a trend toward a lower median number of involved nodes was observed in iNOS positive tumors by Loibl et al. [5, 19]. There are only two previous studies investigating the correlation of iNOS expression with ER, and no relation was observed between ER and iNOS expressions either in the present or in previous studies [5, 20].

There are controversial reports about the relationship between iNOS expression in cancer cells from different carcinomas and prognosis. Kong et al., Pukkila et al. and Oka et al. reported that the expression of iNOS shows no prognostic value in pancreatic, pharyngeal and cervical

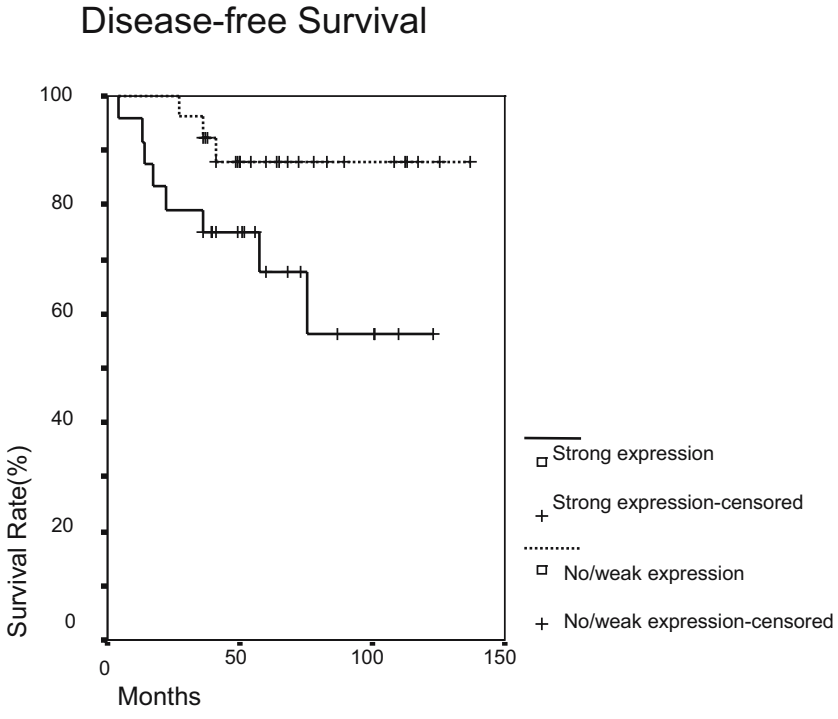

Fig. 5 Disease free survival rates of strong and weak iNOS expressing malignant cases

carcinomas, respectively [15, 23, 26]. On the other hand Ekmekcioglu et al., Raspollini et al., Niu et al., Huang et al., Nozoe et al. and Lagares-Garcia et al. reported that iNOS expression strongly correlated with poor survival and aggressive biological behavior in metastatic melanomas, ovarian serous carcinomas, primary gallbladder carcinomas, supraglottic squamous cell carcinomas and colorectal carcinomas, respectively [6, 9, 16, 21, 22, 27]. Conversely, Ropponen et al. and Puhakka et al. reported that patients with tumors showing high expressions of iNOS and other NOS izozymes had better survival rates in colorectal and non-small cell lung carcinomas [25, 29]. Loibl et al. have studied the impact of iNOS expression on prognosis recently and patients with iNOS positive breast carcinomas were found to have a significantly worse overall survival rate versus those with negative stains [20]. In the present study, in a series of 50 axilla negative invasive ductal breast carcinomas, we observed that patients showing strong iNOS expression had a lower DFS rate than those showing no/weak iNOS expression. This finding suggests that strong iNOS positivity may be a predictor of poor prognosis in axilla negative invasive ductal carcinomas and further studies are needed in this patient group.

In conclusion, iNOS expression can be observed in both benign and malignant mammary epithelium and it cannot be used as an indicator of malignancy. Expression of iNOS is an expected finding in benign epithelium, considering the various physiological functions of nitric oxide [10]. However its stronger expression in carcinomas suggests that it may have a role in pathogenesis of breast carcinoma. Nitric oxide produced by increased iNOS expression may help angiogenesis combined with an increase in tumor blood flow [10, 19]. We believe that strong iNOS expression in the majority of axilla negative breast carcinoma cases with poor prognosis deserves further studies. iNOS expression might prove useful in selection of the cases candidate for more aggressive therapy.

Abstract Immunohistochemical studies of the presence of lactosylceramide (LacCer) in lysosomal storage disorders (LSDs) were done using anti-LacCer monoclonal antibody of the CDw17 type (clone MG-2). No sign of an association between LacCer and the lysosomal system in normal cells was observed, except for histiocytes active in phagocytosis. A comparative study of a group of LSDs showed a general tendency for LacCer to increase in storage cells in Niemann-Pick disease type C (NPC), and types A and B, GM1 gangliosidosis, acid lipase deficiency, glycogen storage disease type II and mucopolysaccharidoses. LacCer accumulated in storage cells despite normal activity of relevant lysosomal degrading enzymes. The accumulation of LacCer displayed variability within storage cell populations, and was mostly expressed in neurons in NPC. An absence of the increase in LacCer in storage cells above control levels was seen in neuronal ceroid lipofuscinoses (neurons and cardiocytes) and in Fabry disease. Gaucher and Krabbe cells showed significantly lower levels, or even the absence, of LacCer compared with control macrophages. Results of immunohistochemistry were corroborated by semiquantitative lipid thin-layer chromatography (TLC). It is suggested that different associations of LacCer with the lysosomal storage process may reflect differences in glycosphingolipid turnover induced by the storage-compromised lysosomal/endosomal system.

Introduction

Lactosylceramide (LacCer) [βGal (1→4) βGlc (1→1′) Cer] belongs to the group of neutral glycosphingolipids (GSLs). Its synthesis starts from glucosylceramide on the cytosolic site of the Golgi apparatus. After translocation into the Golgi lumen, catalyzed presumably by transporters, LacCer synthase (UDP-galactose: glucosylceramide β-1,4-galactosyltransferase) transfers galactose from UDP-Gal to glucosylceramide, generating a β-1,4-glycosidic linkage [9]. In the lumen of the Golgi cisternae LacCer serves as a substrate either for GM3 ganglioside synthesis by sialyltransferase or gives rise to the specific glycolipid series: globo-, isoglobo-, ganglio-, lacto- (at the level of triglycosylceramides), and neolacto- (at the level of tetraglycosylceramides).

From the Golgi complex, LacCer is translocated via transport vesicles or via monomeric transport through the cytosol to various destinations inside the cells [50, 74]. One of the most important targets is the plasma membrane, where LacCer with other GSLs contributes to the creation of specialized microdomains called "rafts" [10, 57]. LacCer is present in both central and peripheral myelins [46, 69], which are derivatives of glial cell membrane. Its localization at the subcellular level has been studied in granulocytes of the neutrophil series, where it represents two-thirds of glycolipids. LacCer was found mainly in secondary granules and at lower levels in primary granules [70]. In rabbit skeletal muscle it has been localized to the sarcoplasmic reticulum [54]. There is evidence that LacCer plays a role as a signal molecule in various cellular processes [2–5, 36, 37, 43, 47, 48, 52, 79, 81]. Some of these functions have been studied in relation to atherogenesis [31].

In addition to granulocytes, LacCer is abundantly present in some blood cells, including platelets, monocytes, a subset of B lymphocytes [23], and in red blood cells [68].

LacCer has been found to be increased in atherosclerotic lesions [34, 53, 60], and in proximal tubular cells in homozygotes for familiar hypercholesterolemia [32, 33].

There are a number of reports describing the relationship between LacCer and the endosomal/lysosomal system. According to studies of the endocytotic pathway using a fluorescent LacCer analogue carried out in living cells, the lipid is transported under normal conditions directly to the Golgi by a specific pathway, whereas in a number of sphingolipid storage disorders the transport is directed to the late endosomal system [35, 61]. Targeting of the lipid is influenced by the amount of intracellular cholesterol [61]. This points to a temporary relationship of LacCer to the endosomal/lysosomal system, which might reflect raft cholesterol dynamics [66] regulated possibly by the NPC1 protein [49].

LacCer is a pivotal intermediate in lysosomal degradation of numerous complex GSLs. There are two lysosomal β-galactosidases, GM1-β-galactosidase and galactocerebroside-β-galactosidase, participating in its degradation and mutually substituting. However, this efficient LacCer degradation depends on the availability of functional sphingolipidhydrolase activator proteins (SAPs) A and B [64].

LacCer has been found to be increased in various tissues of several lysosomal storage disorders (LSDs) (see Discussion), especially in Niemann-Pick type C disease (NPC) [76] and in prosaposin deficiency [6, 27, 30].

We took advantage of having access to a highly specific monoclonal antibody against LacCer to study the association of LacCer with the lysosomal system in controls and in a representative set of LSDs. The results point to marked differences in the association of LacCer with subsets of LSDs. Moreover, data on LacCer in situ distribution provide important complementary information to biochemical lipid studies.

Materials and methods

Materials

Tissues

Samples of unfixed control post-mortem and biopsy tissues (brain, spinal medulla, liver, spleen, palatine tonsil, lymph node, heart, skeletal muscle and appendix) were frozen in liquid nitrogen and stored frozen until use. They were used for comparison with their counterparts from affected individuals with a set of lysosomal storage disorders (Table 1).

Post-mortem samples archived in formaldehyde from the heart and kidney of a Fabry hemizygote with a complex phenotype and of a Fabry heterozygote [29], and from the heart of a patient with Fabry disease cardiac variant [21] were examined for LacCer by TLC immunostaining. Fixed samples of heart and kidney served as controls. Cultured skin fibroblasts from recent patients with prosaposin deficiency (n=1, manuscript in preparation) and NPC (n=2) and from controls (n=4) were used as well.

Table 1 List of archived frozen tissues of LSDs available for studies

LSD	Number of samples	Tissues available
NPA	1	Brain, liver, spleen
NPB	1	Spleen
NPC (juvenile)[a]	2	Brain, liver, spleen, appendix
NPC1 (early onset)[b]	1	Brain, liver, spleen, appendix

Monoclonal antibodies

Three CDw17 clones were tested for LacCer specificity and sensitivity: MEM-74 (purified monoclonal mouse IgM; Exbio, Prague, Czech Republic); Huly-m13 (purified monoclonal mouse IgMκ; Ancell, Bayport, Minn.); MG-2 (monoclonal mouse IgM available as supernatant of hybridoma fluid, produced by conventional techniques [44]).

Lipids used for antibody testing in TLC

Individual glycolipids used as standards (glucosylceramide, galactosylceramide, lactosylceramide, globotriaosylceramide, globoside, sulphatide, GM1, GM2 and GM3

gangliosides) were prepared and characterized in this laboratory or purchased from Sigma (St. Louis, Mo.). Total lipid extracts from different human tissues (liver, spleen, kidney, brain, adrenal glands and erythrocytes) were prepared as described below.

Methods

The majority of samples were used for both immunostaining of cryostat sections and preparation of total lipid extracts used for TLC immunostaining (Table 2).

Preparation of tissue extracts

Selected tissues (Table 2) were weighed, homogenized and extracted successively with mixtures of chloroform/methanol/water (20:10:1, 10:20:1; v/v/v) [55] and finally with chloroform/methanol (1:1; v/v). Formaldehyde-fixed tissues were washed in water overnight before homogenization.

TLC immunostaining

Glycolipids were separated on Polygram Sil G sheets (Macherey-Nagel, Düren, Germany) in a solvent mixture consisting of chloroform/methanol/water (65:25:4; v/v/v). After blocking (1% ovalbumin and 1% polyvinylpyrrolidone in phosphate-buffered saline, PBS, for 1 h at 37°C), the TLC sheets were incubated overnight at 4°C with the tested antibody against LacCer: MG-2 (1:2 dilution with 1% bovine serum albumin, BSA, in PBS) and Huly-m13 (1:100 dilution with 1% BSA in PBS). MEM-74 was not tested in TLC. Repeated usage of MG-2 antibody for TLC

Table 2 LacCer detection in selected tissues in LSDs comparing the results of immunohistochemical in situ staining with those of TLC densitometry

Further details of the storage process are given in the text. The immunohistochemistry (*IH*) results represent a semiquantitative evaluation of staining intensity in situ: − negative, ± just detectable, + discrete, ++ intermediate, +++ strong. The TLC results are presented as densitometric percentage in relation to the mean control values (liver n=5, spleen n=6, brain cortex n=4). *NA* samples not available for analysis, *(v)* admixture of storage cell population of lesser staining intensity (−/±)

[a]Decrease explainable as admixture of cancerous foci, which were devoid of both storage and LacCer [22]

[b]Values of LacCer in splenic samples of Gaucher disease, which were still within the range of controls

[c]Decrease given by less admixture of myelin (hypo- or demyelinization), as confirmed by presence of sulphatides and galactosylceramide on TLC (data not shown)

[d]In the heart sample from the same GSD II patient the value of LacCer was 266% of the mean of control value; The LacCer in the skeletal muscle of the GSD II patient was increased 1.57-fold over the value in the myocardium

immunodetection was possible. The sheets were then washed six times with PBS, blocked for 30 min at 37°C with 1% BSA in PBS, exposed to secondary peroxidase-conjugated goat anti-mouse IgM (Pierce, Rockford, Ill.), diluted 1:200 for 90 min at 37°C, washed again six times with PBS and developed with 4-chloro-1-naphthol. Chromatograms were evaluated densitometrically using a Camag TLC scanner II (Cats3; Camag Scientific, Wilmington, N.C.) in reflection mode.

Immunohistochemistry

Cryostat sections, 5 or 10 μm thick, prepared from unfixed tissues, were allowed to dry and then treated with anhydrous acetone [19] for 20 min at room temperature (no differences from extraction at +4°C or at −20°C), dried for 30 min and fixed with 2–10% phosphate-buffered paraformaldehyde at 4°C for 5 min. After washing with distilled water, the sections were subjected to standard blocking of endogenous peroxidase (1% sodium azide, 0.3% H_2O_2 for 10 min) and a blocking procedure with 5% bovine fetal serum in PBS for 30 min at room temperature. The sections were then incubated for 1 h at 4°C or overnight at 4°C with primary antibody: MG-2 undiluted, Huly-m13 diluted 1:10 or 1:50, or MEM-74 diluted 1:10 or 1:100 (5% bovine fetal serum in PBS was used as the dilution buffer). After washing with PBS, secondary peroxidase-conjugated antibody (goat anti-mouse IgM; Pierce) diluted with 5% bovine fetal serum in PBS 1:100 was used for 1 h at 37°C, followed by PBS and diaminobenzidine (Sigma, St. Louis, Mo.). The sections were counterstained with Harris haematoxylin and mounted in Immu-Mount (Shandon, Pittsburgh, Pa.).

Parallel sections were stained after delipidation with the following total lipid extraction procedure: 50% ethanol (10 min at room temperature) and chloroform/methanol/water (4:8:3; v/v/v) followed by chloroform/methanol (2:1; v/v), both for 30 min at room temperature. Finally, sections were rinsed in 50% ethanol and fully hydrated.

Slides with intact cells (smears, cultured cells) were treated similarly, with or without addition of saponin to primary and secondary antibodies (final concentration 0.02%). For washing, distilled water was substituted by PBS. Cultured cells were prevented from drying.

Cell cultures

Fibroblasts were cultured in Dulbecco's modified Eagle's medium (Sevapharma, Czech Republic) supplemented with 10% bovine foetal serum (PAA Laboratories, Cölbe, Germany). Cells were grown on glass cover slips treated for good cell growth in HCl in 70% ethanol (1:99) and placed in plastic Petri dishes (Sarstedt, Germany or TPP, Switzerland).

Colocalization studies of LacCer in peripheral gut neurons

The colocalization of LacCer in peripheral gut neurons was investigated in cryostat sections of control appendix using a Nikon Eclipse E 800 microscope equipped with a C1 confocal module with EZC1 software supplied by Nikon. Neurites were stained with mouse IgG1 anti-heavy neurofilament protein antibody (NF-01) and mouse IgG1 anti-α-tubulin antibody (TU-01), both from Exbio. Late endosome/lysosome compartment (in both controls and the NPC autopsy sample) was detected using mouse IgG1 antibody against LAMP-2 (clone H4A3; Developmental Studies Hybridoma Bank, University of Iowa). Primary antibodies were visualized using Alexa Fluor 488 goat anti-mouse IgG1 and Alexa Fluor 568 goat anti-mouse IgM secondary antibodies (Molecular Probes, Eugene, Ore.). Primary antibodies were incubated successively for 1 h (anti-LacCer at 4°C and the others at 37°C) while the secondaries were incubated together.

Results

Testing of anti-LacCer antibodies and optimization of the experimental procedure

Immunohistochemistry

Optimal results for in situ detection of LacCer were obtained using cryostat sections of unfixed tissues and MG-2 antibody. This antibody bound the reference control structures (see below) and the binding was entirely removed by lipid pre-extraction. In some instances, e.g., in keratinocytes, there was a slight tendency of the lipid to form discrete in situ aggregates pointing to its relatively loose binding to membranes. Short post-fixation with 2% paraformaldehyde was an optimal treatment for cryostat sections of unfixed tissues. The addition of 0.02% saponin to primary and secondary antibody increased staining intensity and uniformity in *intact cells* (smears, cultured cells). Extensive methodological studies showed that the immunospecificity and sensitivity were completely lost when standard frozen sections were prepared from fixed samples by a routine immersion procedure. Unless otherwise stated, the sections were stained for LacCer and counterstained with Haematoxylin.

TLC immunostaining

LacCer was selectively and sensitively detected with MG-2 antibody (Fig. 1). Binding intensity with Huly-m13, which also cross-reacted with galactosylceramide, was much lower.

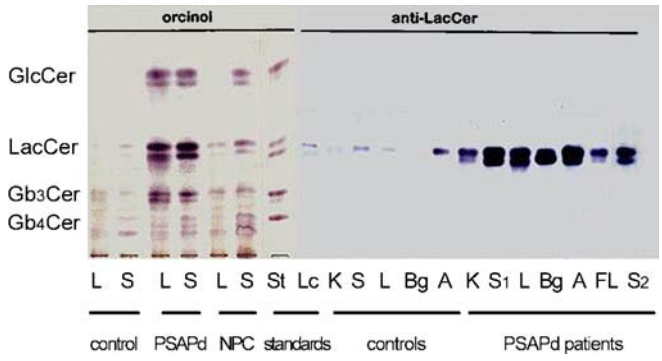

Fig. 1 Verification of anti-LacCer monoclonal antibody (clone MG-2) specificity: TLC immunodetection of LacCer in normal tissues and in tissues of prosaposin deficiency. Aliquots of 5 mg (orcinol) and 0.1 mg (immunodetection) tissue wet weight were applied on Polygram G TLC sheet (Macherey-Nagel, Germany). Solvent system: C:M:W (65:25:4; v/v/v). Abbreviations: L liver; S spleen (in prosaposin deficiency from two patients S_1 and S_2); K kidney; Bg brain grey matter; A adrenal cortex; FL foetal liver; Lc lactosylceramide; St mixture of glycosphingolipid standards; PSAPd prosaposin deficiency; GlcCer glucosylceramide; LacCer lactosylceramide; Gb_3Cer globotriaosylceramide; Gb_4Cer globoside

Inhibition of MG-2 antibody binding was tested with lactose, saccharose and N-acetyllactosamine (50 and 10 mg/ml for 2 h at 37°C for each). Lactose strongly inhibited the immunodetection of LacCer on TLC (Fig. 2), whereas N-acetyllactosamine blocked the LacCer immunostaining only partially (data not shown). Saccharose was without any effect (Fig. 2).

Because MG-2 antibody gave the best results for immunohistochemical analyses as well as for TLC immunodetection, only this antibody has been used in all further experimental work.

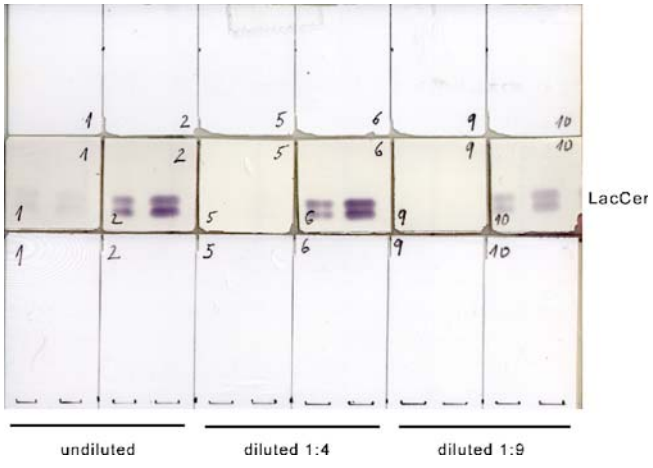

Fig. 2 Inhibition of anti-LacCer monoclonal antibody (clone MG-2) binding by disaccharides. Samples: 125 and 250 ng of LacCer were applied on TLC Polygram sheet. Solvent system: C:M:W (70:30:5; v/v/v). Immunodetection: MG-2 antibody was pre-incubated with 50 mg per ml disaccharide (1, 5, 9=lactose; 2, 6, 10=saccharose). Secondary antibody: goat anti-mouse IgM/Px, (Pierce, USA), dilution 1:500. Visualization: 4-chlor-1-naphtol

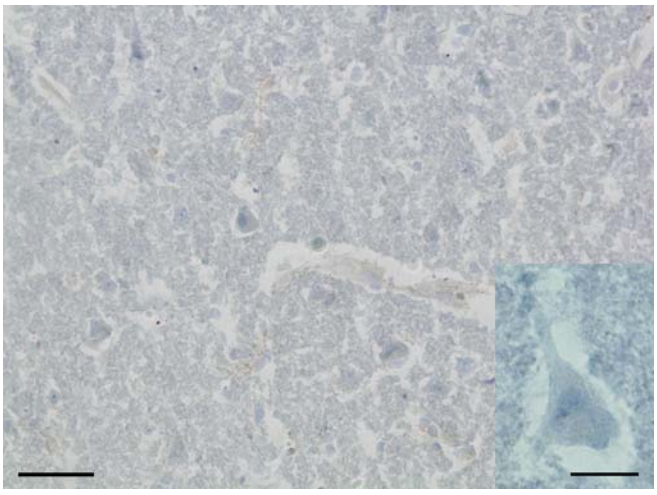

Fig. 3 Cortical neurons in control brain. Absence of detectable LacCer staining (*bar* 100 μm). *Insert* detail of a neuron (*bar* 30 μm)

LacCer in tissues

Nervous system

Controls Neurons of the brain cortex (Fig. 3), thalamus, basal ganglia, brain stem and spinal medulla were consistently LacCer-negative, as were the resting microglia and astrocytes. Occasional perivascular phagocytosing microglia (gitter cells) displayed LacCer positivity. Myelin (both central and peripheral) was stained strongly. Gut neurons in appendix displayed homogeneous LacCer staining of the perikaryon and fibrillar positivity of the neurites in both muscular and submucosal plexi (Fig. 4). Colocalization of LacCer with markers of microtubules and neurofilaments was not observed, although there was a close association with the neurofilaments. There was no sign of colocalization of LacCer with lysosomes (data not shown).

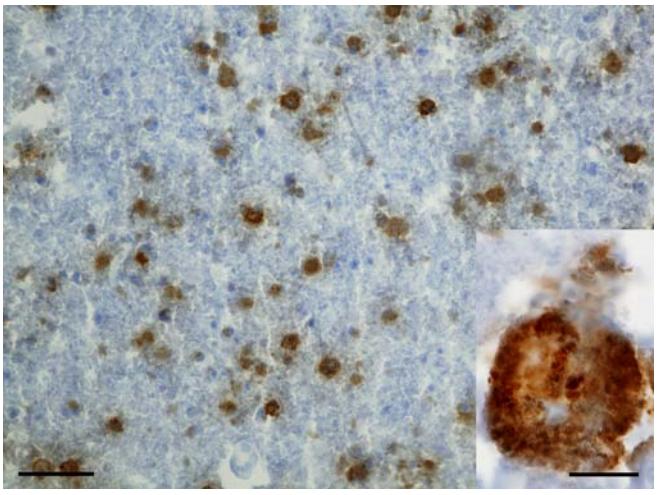

Fig. 7 NPC. Brain. Low magnification (*bar* 200 μm) showing LacCer in a population of cortical neurons displaying a higher degree of variability than in NPA (cf. Fig. 5). *Insert* detail of a storage neuron (*bar* 30 μm)

Neurons in LSDs Storage in cortical neurons was accompanied by strong LacCer staining in the majority of cells in NPC, NPA (Fig. 5), GM1 gangliosidosis, and MPS II and IIIA (Table 2). A small population of storage neurons were LacCer-negative (e.g., in NPA; Fig. 6). In some of the storage neurons LacCer staining was restricted to the cell periphery. In NPC and MPS the areas devoid of LacCer often displayed lipopigment accumulation (Fig. 7).

NPC brain Both the cortical and subcortical regions of NPC brains displayed notable regional heterogeneity of LacCer staining. The less storage distended cortical neurons were strongly positive (Fig. 8). However, the intensively storing ballooned neurons in subcortical areas (basal ganglia, thalamus and spinal medulla) were either devoid of any LacCer staining or displayed slight rim-like LacCer accumulation at the periphery of the neuronal body (Fig. 9). Spheroids of the extensive neuroaxonal dystrophy typically seen in early-onset NPC were LacCer negative.

Peripheral gut neurons in NPC Staining of storage peripheral gut neurons in NPC was either decreased or comparable to that of controls in the perikaryal-neurite complex (Fig. 10), and was not colocalized with lysosomal markers (data not shown). The voluminous submucosal axonal spheroids displayed variable LacCer staining.

Cortical storage neurons in NCL6 Cortical storage neurons in NCL6 were consistently LacCer-negative (Fig. 11

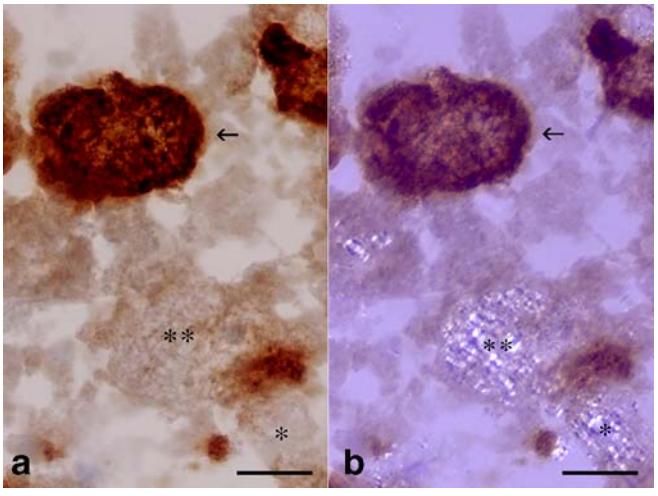

Fig. 6 NPA. Brain. Variability of neuronal LacCer accumulation. LacCer-stained section (**a**) also examined under polarized light (**b**). The LacCer-negative neuron (**a**) displays birefringence of sphingomyelin liquid crystals (**b**) (lipopigment was absent). The corresponding neurons are marked by *asterisks* and *arrows* (*bars* 50 μm)

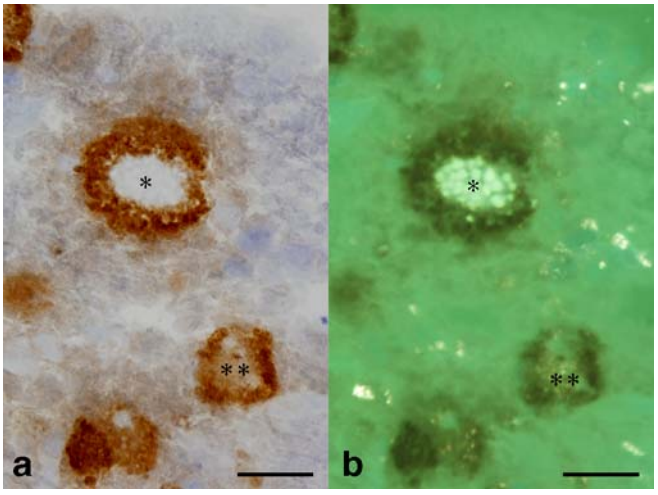

Fig. 8 NPC. Brain. Variability of neuronal LacCer storage. LacCer-stained section (**a**) also examined under UV light (**b**). LacCer least-stained areas (**a**) are rich in autofluorescent lipopigment (**b**). The corresponding areas are marked by *asterisks* (*bars* 50 μm)

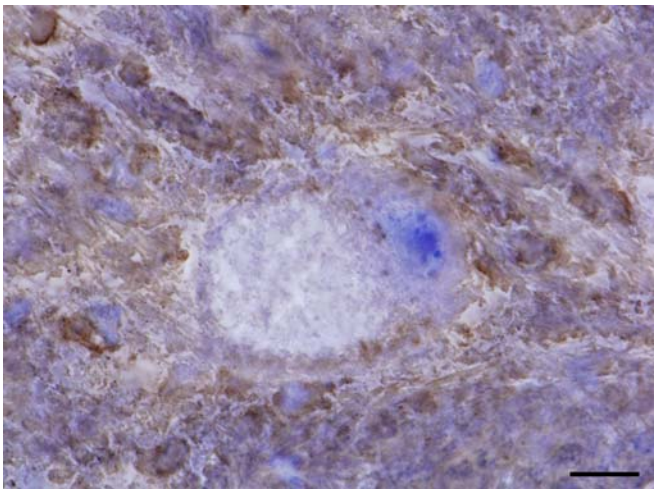

Fig. 9 NPC. Thalamus. Ballooned storage neuron free of detectable LacCer surrounded by positive myelin (*bar* 30 μm)

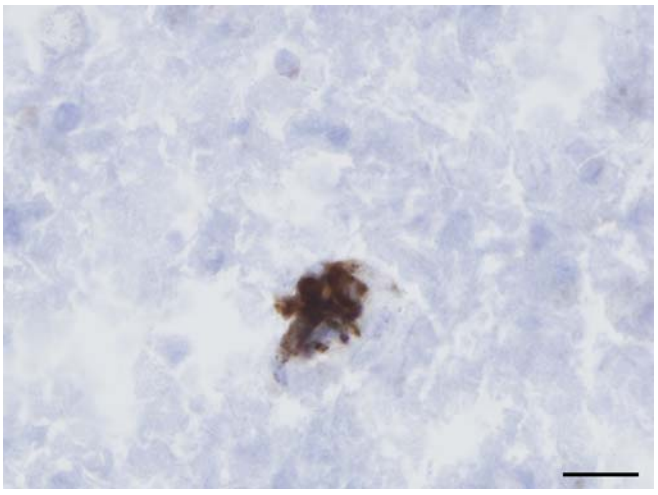

Fig. 11 NCL6. Brain cortex. Strong LacCer staining restricted to the coarse perikaryal lumps of aggregated storage material present in a single neuron. The surrounding storage cells are negative (*bar* 50 μm)

and Table 2), with the only exceptions being infrequent coarse globular or spheroidal perikaryal deposits which were strongly stained (Fig. 11). These deposits corresponded to the transformed storage material described elsewhere [17]. Storage gut neurons in NCL6 displayed decreased perikaryal staining whereas the amount of LacCer in their neurites was similar to that of controls. The cortical population in NCL1 was LacCer-negative with the exception of a small subset of microglia (Table 2). The persisting neurons were negative (Fig. 12).

Hepatocytes

LacCer staining was negative in control hepatocytes. In LSDs LacCer accumulation was seen in the narrow peribiliary zone of hepatocytes in NPC, NCL6 and CESD. It was distinctly expressed in foamy hepatocytes in MPS II and GSD II, whereas heavily storing hepatocytes in NPA were almost LacCer-negative (Table 2).

Macrophages and blood cells

Control macrophages in splenic red pulp, lymph nodes, palatine tonsil, liver and bone marrow displayed strong, coarsely granular cytoplasmic staining for LacCer (Fig. 13). Granulocytes and some lymphocytes and red blood cells in lymphoid organs and in bone marrow were positively stained for LacCer. In bone marrow smears thrombocytes and megakaryocytes belonged to strongly stained elements, the latter (megakaryocytes) being stained to various degrees according to the extent of maturation.

Storage histiocytes were generally strongly stained for LacCer (Fig. 14), irrespective of the type of lysosomal

Fig. 10 Appendiceal myenteric plexus in NPC. Decreased LacCer staining mainly in the storage-enlarged neuronal perikarya (*bar* 50 μm)

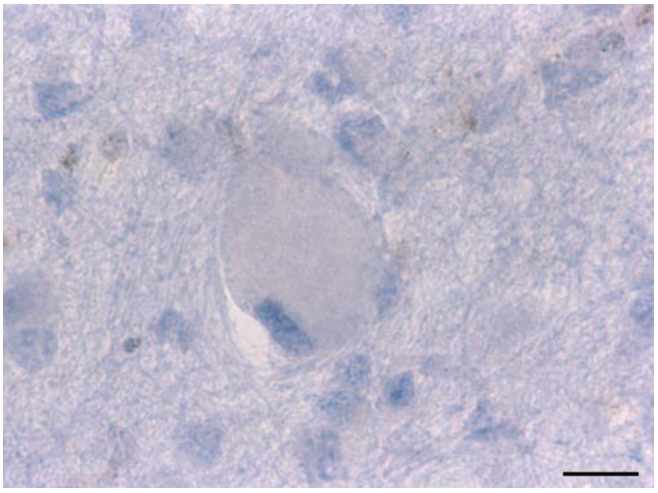

Fig. 12 NCL1. Brain cortex in an advanced stage of the storage process. The persisting ballooned neuron is LacCer-negative similar to the surrounding glial storage cells (*bar* 20 μm)

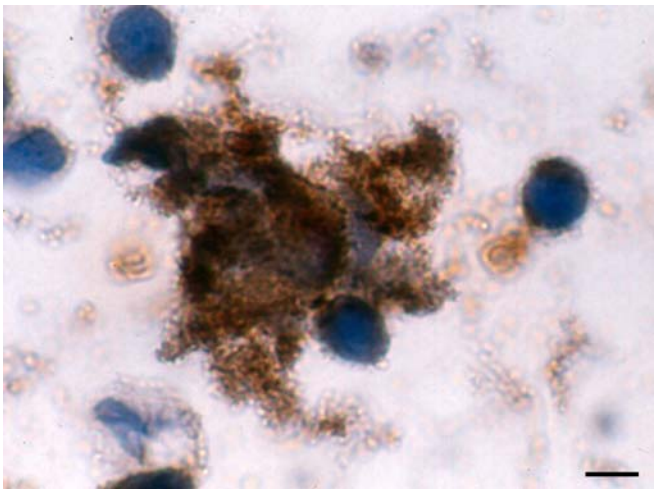

Fig. 13 Control bone marrow with strong staining of LacCer in a normal histiocyte. The histiocyte is active engaged in phagocytosis and has a characteristic stelate appearance (*bar* 20 μm)

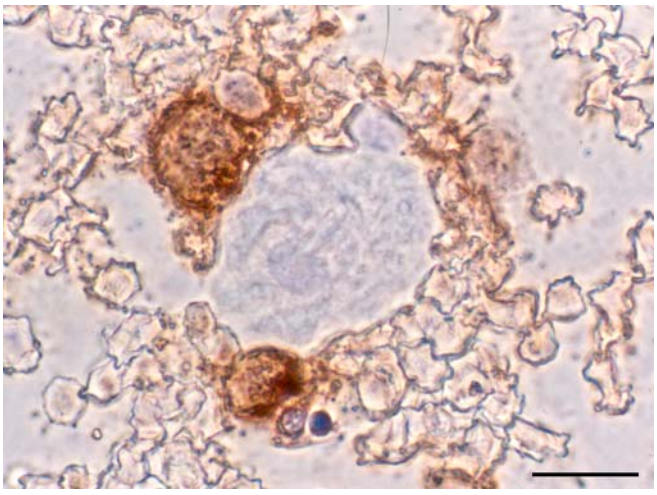

Fig. 15 Bone marrow smear with Gaucher cell showing no detectable LacCer. Note strong staining in the surrounding granulocytes. Phase contrast (*bar* 20 μm)

disorder, differing from the control counterparts by lower degree of uniformity, rounded appearance and larger size (Table 2). The decrease or negativity of LacCer in some of them was associated with deposition of lipopigment.

Krabbe cells and similarly Gaucher cells in the spleen and in bone marrow smears showed a strong decrease or even an absence of immunodetectable LacCer (Figs. 15 and 16a; Table 2). Negative LacCer staining in Gaucher cells sharply contrasted with strongly stained Gaucher-like cells in mantle cell lymphoma (Fig. 16b).

Skeletal muscle

In controls there was discrete mosaic punctuate LacCer staining, which did not correlate with the scarce subsarcolemmal lysosomal population (Fig. 17, insert). Its distribution fits well with localization of LacCer to sarcoplasmic reticulum described for rabbit muscle [54].

In LSDs marked LacCer staining was seen in GSD II obscuring all the sarcoplasmic structures due to massive lysosomal involvement (Fig. 17; Table 2). The relatively numerous discrete autofluorescent lysosomal deposits in NCL6 did not show detectable LacCer, but exhibited the staining pattern seen in control sections (see above).

Heart

Both conductive and contractile cardiocytes in controls were generally LacCer-negative (Fig. 18 insert), with the exception of dispersed LacCer-positive cardiocytes integrated into the fibres and fusiform cells closely associated with them (detailed studies of these cells are in progress).

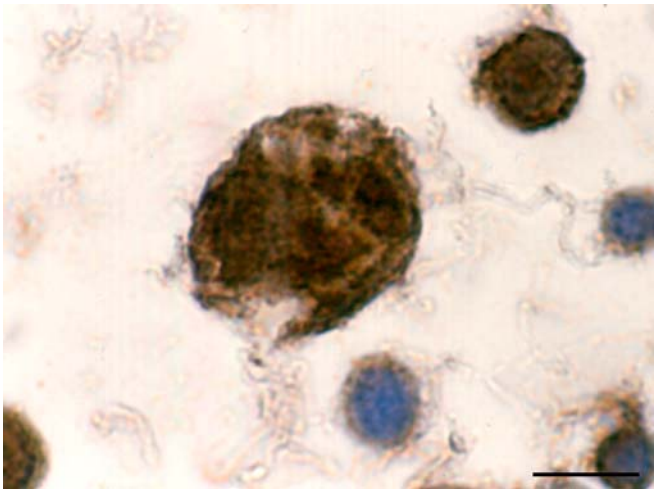

Fig. 14 Bone marrow storage histiocyte in NPC. The strongly stained cytoplasm is rounded and enlarged as compared with that of controls (cf. Fig. 13). The surrounding nonstorage cells display physiological LacCer staining (*bar* 20 μm)

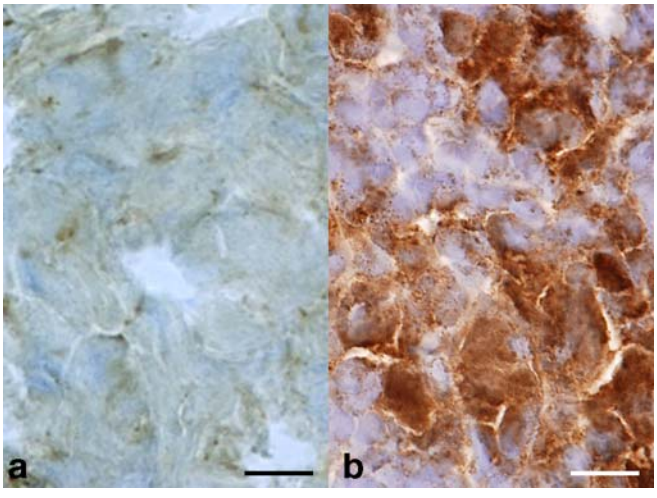

Fig. 16 Gaucher disease. Cryostat section of spleen with numerous Gaucher cells with just detectable cytoplasmic LacCer staining (**a**) contrasting with strong staining of Gaucher-like cells in mantle cell lymphoma (**b**). Slight positivity on membranes of surrounding lymphocytes is apparent (**b**) (*bars* 30 μm)

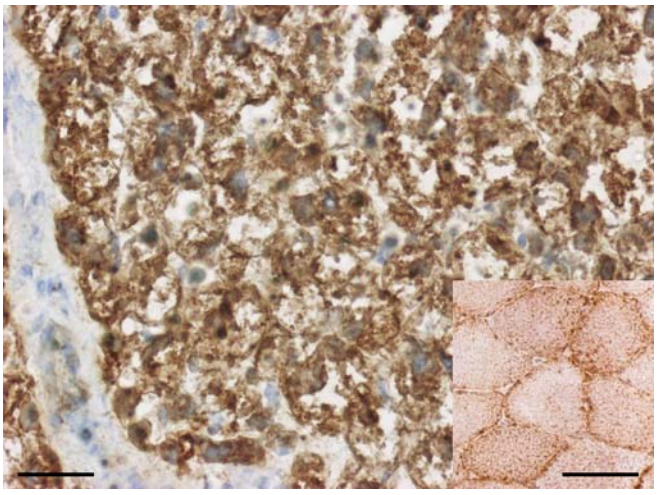

Fig. 17 GSD II. Storage in skeletal muscle with high degree of LacCer accumulation (*bar* 100 μm) contrasting with discrete punctate staining of skeletal muscle in control section (*insert bar* 50 μm)

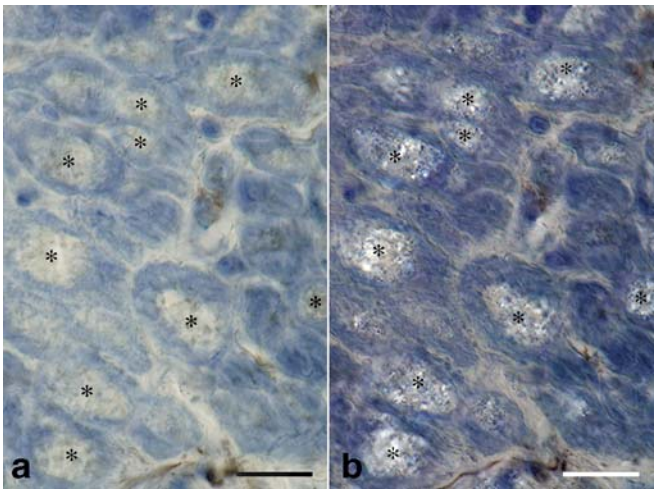

Fig. 19 Fabry disease. Heart auricle. Perinuclear storage lysosomes without detectable LacCer with only minimal lipopigment (**a**), but distended with liquid crystals of globotriaosylceramide with positive birefringence (**b**). Distended lysosomal regions are marked by *asterisks*. Positively stained small nerves are apparent in the interstitium (*bars* 50 μm)

Storage cardiocytes displayed strong LacCer staining in GSD II (Fig. 18; Table 2), which contrasted with the absence of detectable LacCer in lipopigment-loaded cardiocytes in NCL6. Fabry heart auricular cardiocytes displaying lipid and lipopigment storage were completely LacCer-negative (Fig. 19). The dispersed LacCer-positive cardiocytes seen in control sections (see above) did not express storage in either disorder. By TLC (Fig. 20), heart glycolipids in adult Fabry disease (formaldehyde-fixed samples used only for TLC analysis) showed a decrease in immunodetectable LacCer compared with control sections: Fabry hemizygote with complex phenotype 15%, Fabry hemizygote cardiac variant 10%, and Fabry heterozygote 60% of the mean control levels. A comparable decrease was seen in the kidneys of these patients: Fabry hemizygote with complex phenotype 20%, and Fabry heterozygote 17% of the mean of control levels.

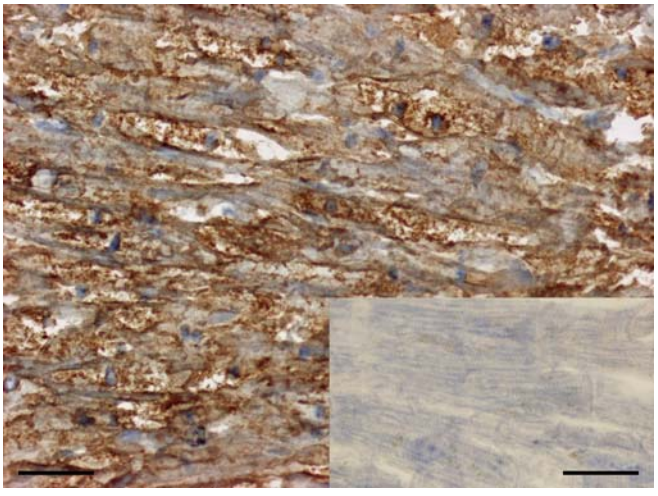

Fig. 18 GSD II. Storage cardiomyocytes strongly stained for LacCer in the expanded perinuclear storage regions (*bar* 100 μm), which contrasts with the absence of staining representing the bulk of control cardiocytes (*insert bar* 50 μm) which showed only the discrete brownish native colour of lipofuscin

Skin

In controls LacCer was found closely associated with the cell membrane of keratinocytes. A decreasing gradient of intensity was observed from the basal layer to several suprabasal layers. The granular and cornified layers were negative (Fig. 21, insert). A discrete, finely granular

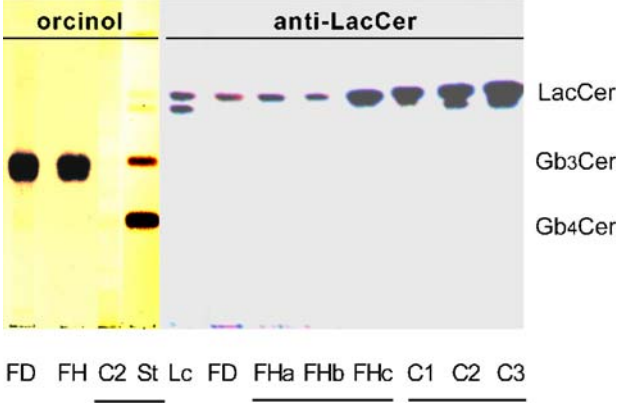

Fig. 20 TLC immunostaining of LacCer in formaldehyde-fixed myocardium from patients with Fabry disease and controls. Aliquots of 4 mg (orcinol) and 0.6 mg (immunodetection) tissue wet weight were applied to a Polygram G TLC sheet. Solvent system: chloroform/methanol/water (65:25:4; v/v/v). Immunodetection with anti-LacCer monoclonal antibody (clone MG-2). *FD* Fabry hemizygote with complex phenotype; *FH* Fabry heterozygote; *FHa*, *FHb*, *FHc* different samples from myocardium of Fabry heterozygote (heterogeneity reflecting either mosaicism in tissues of heterozygotes or different cellular composition of samples); *C1–3* controls; *St* mixture of glycosphingolipid standards; *Lc* lactosylceramide; LacCer lactosylceramide; *Gb3Cer* globotriaosylceramide; *Gb4Cer* globoside

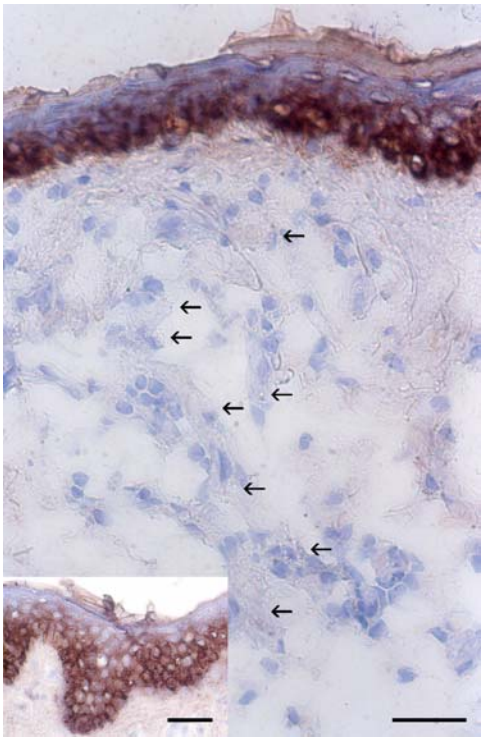

Fig. 21 Skin in Fabry disease (without angiokeratoma). Strong staining for LacCer in keratinocytes (*bar* 100 μm) equal to that of control sections (*insert bar* 50 μm). The storage capillary endothelium shows no staining in (*arrows*)

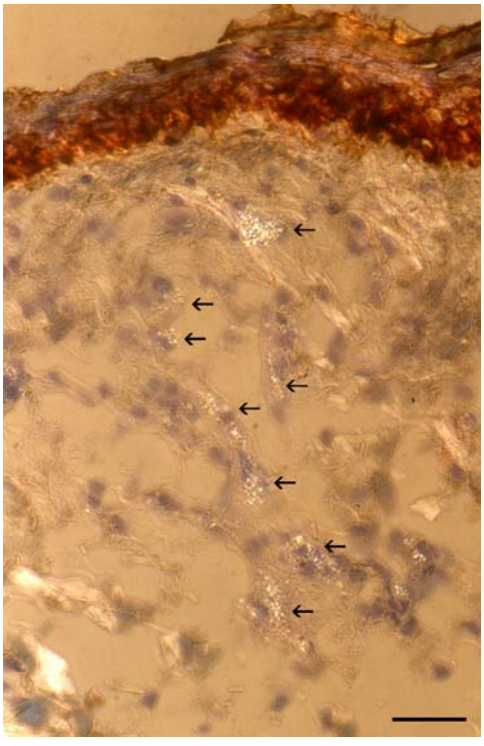

Fig. 22 The same section as in Fig. 21. The stored globotriaosylceramide in dermal capillaries can be visualized in a LacCer-stained section because of its birefringence (*bar* 100 μm). The corresponding structures are marked

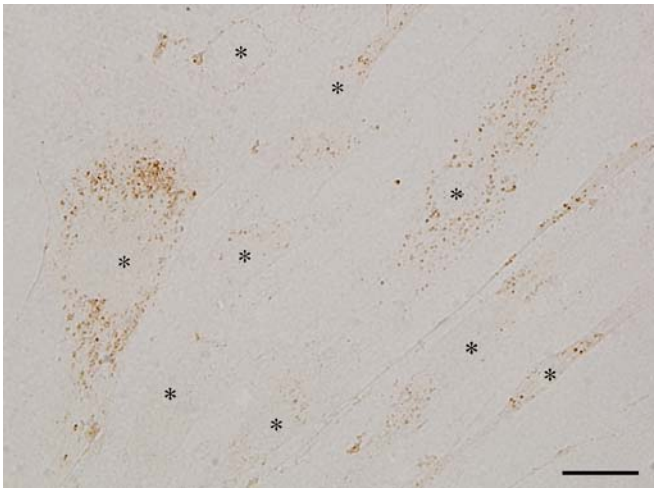

Fig. 23 Cultured fibroblasts (*asterisks*) from a patient with mitochondrial disorder serving as a control. Discrete variable punctate LacCer staining is apparent (*bar* 50 μm)

LacCer reaction in smooth muscle cells (musculus arrector pili) and in ducts of eccrine glands was seen.

The LacCer staining pattern of keratinocytes in Fabry disease was unchanged. Strongly storing eccrine glands in Fabry disease were negative.

Endothelium

In controls the endothelium was generally unstained or displayed just detectable positivity. Mild and variable LacCer staining in LSDs was noted in the spleen sinusoids (NPA, NPB and NPC) and in the capillary endothelium in NPA, GM1 gangliosidosis, NCL1 and NCL6, with the strongest being in the arterial endothelium in GSD II. Dermal capillaries in Fabry disease showed no detectable LacCer despite pronounced lysosomal storage (Figs. 21 and 22).

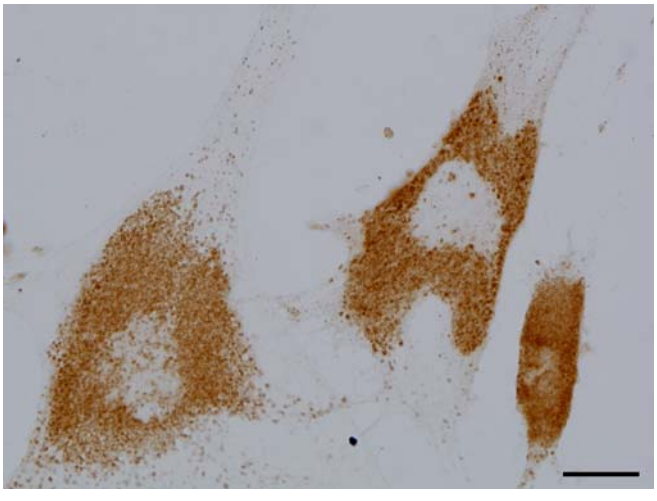

Fig. 24 Prosaposin deficiency. Cultured fibroblasts with strong granular cytoplasmic staining for LacCer (*bar* 50 μm; cf. Fig. 23)

TLC studies with densitometric evaluation of LacCer that were carried out in a majority of cases corroborated the immunohistochemistry results (Table 2).

Tissues in prosaposin deficiency

Tissues in this disorder displayed a large increase in LacCer on TLC. However, in fixed tissues a total loss of immunodetectability of the lipid in situ and an enormous increase in background staining were seen (see above). The cultured fibroblasts exhibited a strong uniform LacCer staining of the mass of storage vacuoles which exceeded by manyfold the staining in both control (cf. Figs. 23 and 24) and NPC fibroblasts.

Discussion

Our results provide evidence of heterogeneity of LacCer expression at both the tissue and cellular levels. The data show that in the lysosomal system of normal human tissues, LacCer is present in immunodetectable amounts in active phagocytes only. The lysosomal storage process, depending on the type of lysosomal disorder, leads to variable induction of LacCer expression.

LSDs associated with increased LacCer

The increase in LacCer in storage cells in GSD II (Figs. 17 and 18) represents the first description of abnormal lipid composition in this lipid-unrelated storage disorder. Our observations that an increase in LacCer occurs in a subset of LSDs (Table 2) corroborates the lipid biochemical studies in the respective entities (e.g., in NPA brain [24] and liver [11], in NPC [20, 40, 59, 76], in GM1 gangliosidosis, albeit inconstantly [1, 41, 72], in human MPS IIIB [25, 26], and in canine MPS I [13]). The association with the storage process leaves no doubt about the close relationship between LacCer and the storage-expanded lysosomes, although its exact position at the subcellular levels could not be specified. Our studies, based on in situ detection, enabled us to unravel the heterogeneity of the increases in LacCer, either within the storage-affected cell population or between different storage-affected cell types. The variability ranged from low in cortical neurons in NPA (Figs. 5 and 6) to high in neurons in NPC (Figs. 7, 8, 9). The remarkable heterogeneity in neurons in NPC suggests a loose association of LacCer with the disorder under the same loss of NPC1 sterol/glycolipid sensing protein function [12]. The variability in LacCer storage sharply contrasts with widespread deposition of GM2 and GM3 gangliosides in neurons in the NPC mouse model [80]. Studies of other glycolipids and cholesterol are therefore planned. The moderate increase in LacCer in the liver in NPC [75] was, in our patients, caused mainly by the sinusoidal macrophage storage pool (Table 2). The LacCer increase in the liver in NPA was also caused mainly by storage macrophages.

LSDs without detectable LacCer induction

By an absence of immunodetectable LacCer in three storage sites (skin, capillary endothelium as shown in Figs. 21 and 22, cardiocytes as shown in Fig. 19, and eccrine glands), Fabry disease differs from the above-mentioned storage disorders. Results of immunohistochemistry were corroborated by studies of lipid extracts of the Fabry heart and kidney, where the amount of LacCer (detected by immunostaining) was always lower than in the controls. The current stored lipid analyses in Fabry disease are mainly concerned with the digalactosylceramide, which has the same mobility on standard TLC analysis using general detection reagents for sugars (e.g., orcinol). Consequently, the absence of immunodetectable LacCer represents a biochemical feature of the storage process in α-galactosidase A deficiency. A satisfactory explanation is not available. Decreased synthesis or partial shunting to GM3–GD3 or other products is theoretically possible. It is doubtful whether the absence of LacCer is solely due to interrupted lysosomal degradation of globotriaosylceramide in that the influx of LacCer may come from other glycolipid series (e.g., lacto- and neolacto-) and from LacCer-rich cell membranes. Moreover, with functioning LacCer-degrading lysosomal enzymes, LacCer is promptly degraded and its immediate amount in lysosomes must be under the limit of in situ immunodetection.

In NCLs of both types examined detectable LacCer was absent. It is noteworthy that the process of transformation of deposits in NCL6 [17] was accompanied by significant LacCer accumulation (Fig. 11), suggesting their different lysosomal processing. Otherwise, secondary lipopigment deposition in NPC neurons and in macrophages was generally associated with either absence of LacCer (Fig. 8) or minimal staining, the only exception being MPS brain neurons, where the LacCer–lipopigment coincidence was frequent, however.

LSDs with progressive decrease in LacCer against control counterparts

The pronounced decrease or absence of LacCer in Gaucher cells (Figs. 15 and 16) is particularly notable as this suggests that Gaucher cells (and Krabbe cells) differ significantly from all other macrophages, with the exception of macrophages modified by high lipopigment load. Lack of LacCer expression in Gaucher disease was seen only in macrophages, i.e. in the storage-affected cell type. The low levels of LacCer in serum in Gaucher disease [15, 78] correlate well with the LacCer deficiency in Gaucher cells.

Results of immunohistochemistry were corroborated by TLC analysis of Gaucher spleen (Table 2). The findings fit well with published data on TLC analyses of Gaucher

spleen lipids showing glucosylceramide as the principal glycolipid [16, 45, 56, 58, 67]. All TLC analyses must consider admixture of LacCer from granulocytes and lymphocytes in spleen samples and the fact that the LacCer pool has been reported to be increased in granulocytes [42].

Our findings suggest significant depletion of the substrate for β-galactosidase, highly active in Gaucher cells [18], which normally provides the main substrate influx for the deficient glucocerebrosidase. The influx is suggested to be based on phagocytosis of glycolipid-rich senescent blood cells by macrophages [7]. The paucity of LacCer might therefore be due to decreased phagocytosis of mature Gaucher cells, provided there is no other significant source of LacCer. A similar situation might exist in Krabbe cells, which in their mature form may be deprived of phagocytosed myelin rich in LacCer precursors. Decreased synthesis with lower availability of LacCer in Gaucher cells does not seem to be a possibility, as GM3 ganglioside, the product of LacCer sialization, has been found to be increased two- to sixfold in Gaucher spleens [56]. This suggests possible recycling of the stored glucosylceramide to the synthetic compartment [63], which is also though to occur in the case of gangliosides [80]. Anyway, loss of LacCer increases the list of features by which Gaucher cells differ from the other storage macrophages [14, 19].

Significance of LacCer levels in LSDs

Decreased degradation because of β-galactosidase deficiency could contribute to LacCer increase. For instance, in MPS I–III (the group deficient in heparan sulphate-degrading enzymes) activity of β-galactosidase is inversely proportional to the degree of storage [73]. However, in GM1 gangliosidosis, which is inherently deficient in one of the critical LacCer-degrading enzymes, the increase in LacCer in the cerebral grey matter (see above) is associated with its normal or even increased degradation rate [8]. In contrast to our finding of a significant increase in LacCer in GSD II (Table 2), β-galactosidase activity has been found to be increased in this disorder [28].

Our conclusion is that the increase in LacCer observed in both lipid and nonlipid (e.g., GSD II) storage disorders, and regardless of the enzymopathic or nonenzymopathic nature of the defect (cf. cortical neurons in NPA with NPC1 protein deficiency, Figs. 5 and 7), can hardly be explained by a decrease in lysosomal degradation. The variable amount of LacCer in a given storage cell population is consistent with this view. The only exception is the deficiency of prosaposin with inactivation of both critical galactosidases [64], leading to massive lysosomal LacCer accumulation (Fig. 24) [30]. Yet, even in this condition one cannot exclude the possibility that a nonenzymopathic mechanism participates in the LacCer increase.

We further suggest that the variable levels of LacCer in LSDs reflect altered homeostatic control of the glycosphingolipid turnover (synthesis, degradation and recycling) that is a consequence of the primary defect. This notion fits well with results of immunohistochemical studies of gangliosides in LSDs [77], as well as with the recently presented hypothesis of deregulation of raft lipids in LSDs [49, 66].

Another lipid—bis(monoacylglyceryl) phosphate (BMP)—similarly reflects lysosomal storage indirectly. BMP has been shown to be increased differently in several storage disorders. In the visceral storage pool it has been found to be highly increased (e.g., in NPA [39, 62] and in NPC [65, 71, 75], but not in Gaucher disease [62] or other LSDs [38]). The lipid has recently been assigned a regulatory function in protein and lipid trafficking through late endosomes [51].

In any event, the varied association of LacCer with LSDs reflects a new aspect of molecular pathology of the lysosomal system worth further study.

Differential activation of mitogen activated protein kinases and nuclear factor-κB in lipopolysaccharide-treated term and preterm amnion cells

Abstract Intrauterine exposure to amniotic sac infection elicits an inflammatory response from the fetus, which is associated with elevated levels of fetal plasma proinflammatory cytokines, i.e. interleukin-6 (IL-6). We have recently demonstrated that the severity of fetal inflammatory response in terms of gestation period is greater in preterm fetuses than in term fetuses. The activation of mitogen activated protein kinases (MAPKs) and nuclear factor kappa B (NF-κB) is known to be associated with up-regulation of proinflammatory cytokine gene expression in many cell types. In the present study, therefore, we studied patterns of MAPK and NF-κB activation following treatment with bacterial lipopolysaccharide (LPS) in amnion cells obtained from placentas of varying gestational ages to assess whether or not MAPKs and NF-κB are differentially regulated during gestation. MAPK phosphorylation was investigated by immunoblot analysis with phosphospecific antibodies. Transient phosphorylations of extracellular signal-regulated kinase (ERK) 1/2 and c-Jun N-terminal kinase (JNK) were observed in LPS-treated amnion cells, with the degree of phosphorylation being more pronounced in preterm cases. The results of NF-κB-dependent reporter gene expression and electrophoretic mobility shift assay (EMSA) of NF-κB were similar to those of ERK 1/2 and JNK activity. To assess whether the results of in vitro observations reflected in vivo results, we further analyzed amniotic fluid and cord blood IL-6 levels in preterm deliveries with placental inflammation. The analysis also revealed a significantly higher level of IL-6 in cases of ≤31 weeks gestation when compared with those of more than 31 weeks ($P<0.001$). All these findings strongly suggest that there is an inverse relationship between gestational age and fetal inflammatory response during human gestation, and that differences in the intensity of MAPK activation and NF-κB-dependent transcription pathways are elements of the major underlying mechanism.

Introduction

Intrauterine infection is emerging as a major cause of preterm deliveries, and exposure to bacterial lipopolysaccharide (LPS) in infected amniotic sac elicits fetal and placental inflammatory responses that are associated with elevation of proinflammatory cytokines in fetal plasma, amniotic fluid, and even in cervical fluids [15, 19, 35]. The severity of the fetal inflammatory response correlates with the levels of proinflammatory cytokines such as IL-1β, IL-6, and IL-8 in fetal plasma, with major perinatal morbidities and also with the severity of placental inflammation [14, 24, 26]. The cytokines subsequently activate matrix metalloproteinases (MMPs) and prostaglandin E_2 (PGE_2), which exert important effects on the degradation of extracellular matrix (ECM) and induce stimulation of preterm labor [4, 5, 1, 21, 32]. We have recently shown that the inflammatory response to intrauterine infection is more severe in preterm than in term fetuses. Preterm cases had a significantly higher incidence of acute funisitis at advanced stages and a higher level of fetal plasma IL-6 [20].

Mitogen activated protein kinases (MAPKs), which include extracellular signal-regulated kinases (ERKs), c-Jun

N-terminal kinases (JNKs), and p38, are members of a family of serine/threonine kinases that participate in signaling pathways initiated by a variety of infectious and inflammatory stimuli. MAPK signal transduction pathways have been well characterized. MAPK kinase kinase activates MAPK kinase (MAPKK), which in turn activates MAPK. The ERK pathway (ERK 1/2) is activated by the dual phosphorylation of MAPKK MEK1 and MEK2. Likewise, MAPKK MKK 4/7 potently activates JNK (SAPK) and MAPKK MKK 3/6 activates p38 [9, 33]. MAPK activation is a hallmark of LPS-induced cellular response [16], and Fig. 1 is a schematic representation of the MAPK signaling pathway.

The transcription factor NF-κB is also known to play a central role in the production of proinflammatory cytokines after exposure to LPS [6, 10]. NF-κB is a homo- or heterodimeric transcription factor, which usually consists of two proteins, a p50 subunit and a p65 subunit (also called RelA) [8]. In unstimulated cells, NF-κB is retained in the cytoplasm by an interaction with inhibitory proteins known as inhibitor of NF-κB (IκB). Many stimuli induce phosphorylation and subsequent proteolytic degradation of IκB via the ubiquitination-proteasome pathway [29, 38]. The release of NF-κB from IκB leads to translocation of NF-κB into the nucleus, where it binds to specific sequences in the promoter regions of many genes involved in immune and inflammatory responses.

Activation of MAPKs and NF-κB by infectious stimuli such as LPS were demonstrated in many cell types [17, 18, 25, 28], and these are also important regulators of various proinflammatory cytokine genes, including IL-1β, IL-6, IL-8, and tumor necrosis factor-alpha (TNF-α) [2, 3, 23]. However, the patterns of MAPKs and NF-κB during inflammation in the human gestational tissues have not been analyzed. We postulated that they would play a central role in the differential regulation of fetal inflammatory response according to gestational age, and therefore conducted the present study to assess patterns of MAPK and NF-κB activations in LPS-treated human placental tissues, especially of amnion. Activation of MAPK and NF-κB following LPS treatment were more pronounced in preterm amnion cells than in their term counterparts in vitro. An additional analysis of amniotic fluid and cord plasma IL-6 levels in preterm births was also conducted to determine whether this inverse relationship reflects fetal inflammatory response in vivo. The levels of amniotic fluid and cord plasma IL-6 were significantly higher during the earlier gestational period, which strongly supports the relevance of our observation in vitro.

Materials and methods

Tissue culture and LPS treatment

Placentas and amniotic membranes were obtained from Caesarean sections at different gestational periods (n=7; 23, 28^{+1}, 34^{+4}, 35, 37^{+3}, 38, and 39^{+1} weeks). Placental villous tissues were minced and meticulously washed with sterile PBS. The tissues were incubated in RPMI 1640 containing antibiotics without serum at 37°C for 30 min to remove residual red blood cells. After washing with RPMI 1640, amnions were cut into pieces of 3 cm^2. Amnion and villous explants were put into six-well plates containing medium supplemented with antibiotics and incubated overnight in CO_2 incubator. On the next day, the tissues were treated with LPS at the concentration of 1 μg/ml for the specified periods of time. The samples were then subjected to immunoblotting analysis and electrophoretic mobility shift assay.

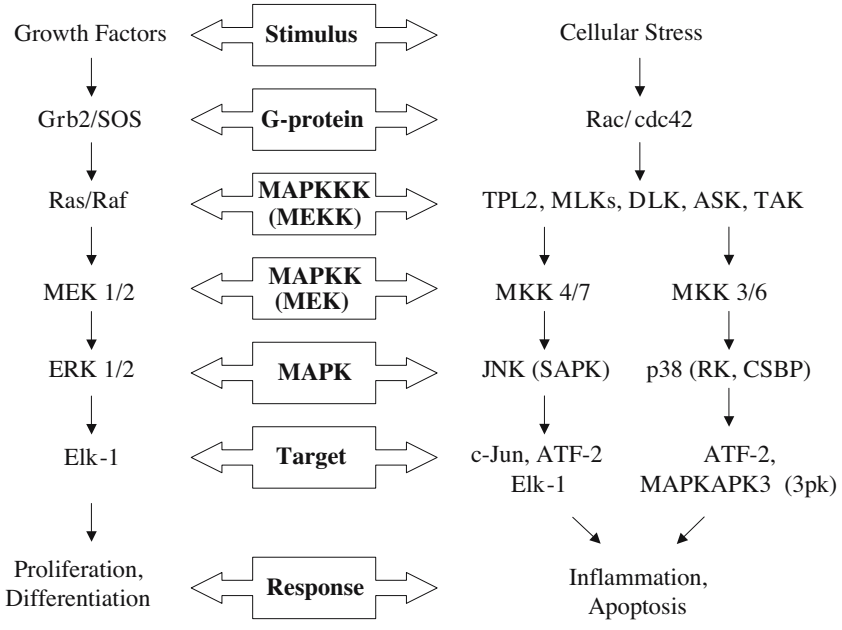

Fig. 1 Schematic drawing of MAPK signaling pathway

Immunoblotting

The cells were lysed in lysis buffer containing 10 mM Tris buffer (pH 7.4), 0.5 mM EDTA (ethylenediaminetetraacetic acid; Sigma Chemical Co., Steinheim, Germany), 0.25 M sucrose, and protease inhibitor with a Dounce homogenizer. The samples were then put on ice for 30 min. Pellets were removed by centrifugation at 6300 *g* for 30 min. The protein concentration was determined with a BCA kit (Pierce, Rockford, Ill., USA). For immunoblotting, a total of 30 or 50 μg protein was subjected to 10% SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto a nitrocellulose membrane. Non-specific binding was blocked by soaking the membrane with 3% non-fat milk in TBS (50 mM Tris, 150 mM NaCl) containing 0.1% Tween 20 (TBS-T) at room temperature for 1 h. p44/42, phospho-p44/42, JNK, phospho-JNK, p38, phospho-p38, p65 and actin were probed with rabbit polyclonal anti-p44/42, phospho-p44/42, JNK, phospho-JNK, p38 and phospho-p38 antibodies (Cell Signaling Technology, Beverly, Mass., USA.) and mouse monoclonal anti-p65 and anti-actin antibodies (Santa Cruz Biotechnology, Inc., Santa Cruz, Calif., USA), respectively. The membrane was incubated with 1:1000 diluted antibodies for 90 min at room temperature and washed 4 times for 15 min each with TBS-T. After washing, the blot was incubated with horseradish peroxidase-conjugated secondary antibodies. Signals were detected using enhanced chemiluminescence reagents (Amersham Life Science, Inc., Arlington Heights, Ill., USA).

Primary amnion cell cultures

Amnion cells were harvested from six additional fetal membranes of varying gestational ages (22^{+4}, 23^{+4}, 33, 37^{+4}, 38^{+3} and 38^{+6} weeks). Two cases (37^{+4} and 38^{+3} weeks) were also used for EMSA. Placentas were obtained from Caesarean section at different gestational periods. All of the cases were free of histologic chorioamnionitis. The institutional review board of Seoul National University Hospital approved the use and collection of the materials and information for research purposes. The amniotic membrane was washed with PBS (sterile phosphate-buffered saline) and initially treated with 0.5% collagenase in PBS for 20 min in a shaking water bath at 37°C, followed by vigorous shaking for 15 min at 15-min intervals over 90 min in 0.25% collagenase at 37°C. Amnion cells were collected using a sieve, centrifuged at 1000 *g* for 5 min, and washed again with PBS. The cells were then subjected to transfection and luciferase assay.

Transfection and luciferase assay

The cells were split in a six-well plate at a density of 4×10^5 cells/well, and cultured overnight in RPMI 1640 containing 10% fetal bovine serum and antibiotics. The cells were transfected with 1 μg of pNFκB-Luc (Stratagene, La Jolla, Calif., USA) using LipoFectamine (Invitrogen, Carlsbad, Calif., USA) and treated with Bacto® LPSs (Difco Laboratories, Inc., Detroit, Mich., USA) at a concentration of 1 μg/ml for 24 h after transfection in the presence or absence of 25 μM of tosyl-phe-chloro-methylketone (TPCK), an inhibitor of NF-κB. After incubation for another 24 h, luminometry was performed using a luminometry kit (Stratagene) according to the manufacturer's instructions. Luciferase activity was normalized to β-galactosidase activity.

Electrophoretic mobility shift assay

Placental villous tissue and amnion were liquid nitrogen-pulverized with a mortar and a pestle. Nuclear extracts were obtained from LPS-treated amnion cells from five placentas (24, 29, 37^{+4}, 38^{+3} and 39^{+1} weeks). After washing twice with hypotonic solution [10 mM 4-(2-hydroxylethyl)-1-piperazineethanesulfonic acid, 1.5 mM $MgCl_2$, 10 mM KCl, 0.1 mM EDTA], the samples were suspended in hypotonic solution containing 0.6% NP-40 and proteinase inhibitors (Completed; Boehringer-Mannheim, Basel, Switzerland) for 5 min on ice and centrifuged at 6300 *g* for 10 min. The supernatant was used as cytoplasmic fractions, and the pellets were dissolved in 20 mM HEPES, 0.4 M NaCl, 1 mM EDTA, 0.6% NP40, 1 mM DTT and proteinase inhibitors for 30 min on ice and centrifuged at 6300 *g* for 30 min. The supernatant was used as nuclear protein and subjected to EMSA. For EMSA, oligonucleotides comprising the consensus sequences for NF-κB (5′-AGTTGAGGGGACTTTCCCA GGC-3′) were end-labeled with [γ-^{32}P]-dATP (Amersham, Piscataway, N.J., USA) using T4 polynucleotide kinase (Promega Corporation, Madison, Wisc., USA). Nuclear extracts (20 μg) were incubated at binding conditions (4% glycerol, 1 mM $MgCl_2$, 0.5 mM EDTA, 0.5 mM DTT, 50 mM Tris-HCl, pH 7.5, 50 μg/ml poly (dI-dC)) for 10 min at room temperature. Radiolabeled probes were then added and the mixture was incubated at room temperature for 20 min. Protein-DNA complexes were analyzed on a 5% non-denaturing polyacrylamide gel. Gels were dried on 3 MM paper and exposed to Kodak X-ray film overnight at -80°C.

Immunoassay of amniotic fluid and cord blood IL-6

The amniotic fluid and cord blood IL-6 was assayed from 265 consecutive, singleton preterm births (≤36 weeks gestation) delivered at the Seoul National University Hospital (Seoul, Korea) between May 1993 and May 2000. All cases were diagnosed with placental inflammation. Many of the patients included in this study had undergone transabdominal amniocentesis either for evaluation of microbiologic status of the amniotic cavity or for assessment of fetal lung maturity. Umbilical cord blood was collected in an EDTA-containing blood collection tube by venipuncture of the umbilical vein at birth. The samples were centrifuged at 700 *g* for 5 min, and supernatants stored in polypropylene tubes at –70°C until assay. The IL-6 in the amniotic fluid and cord plasma was measured using a commercially

available, enzyme-linked immunosorbent assay kit (R & D Systems, Minneapolis, Minn., USA). The sensitivity of the test was less than 0.1 pg/ml and both inter-assay and intra-assay coefficients were less than 10%.

Analysis of major perinatal morbidity

Major perinatal morbidity was defined as the presence of any of the following conditions, as diagnosed according to the definitions previously reported in detail [35]: congenital neonatal sepsis, suspected sepsis, respiratory distress syndrome, congenital pneumonia, bronchopulmonary dysplasia, intraventricular hemorrhage, or necrotizing enterocolitis. Clinical chorioamnionitis was diagnosed when the temperature was elevated to 37.8°C or higher and two or more of the following four criteria were satisfied: uterine tenderness, malodorous vaginal discharge, maternal leukocytosis (>15,000/mm^3) and fetal tachycardia (>160 beats/min) [13].

Statistical analysis

Comparisons of continuous variables were preformed using the Mann-Whitney *U*-test and comparisons of proportions were performed with Fisher's exact test.

Results

Activation of MAPKs in amnion cells

It is well known that LPS treatment leads to activation of three families of MAPKs, ERK 1/2, JNK, and p38, in murine macrophages and human monocytes [17, 28]. To investigate the patterns of MAPK activation in human gestational tissues, placental villous tissues and amnion obtained from caesarean section at different gestational periods were treated with LPS. Four preterm and three term placentas (23, 28^{+1}, 34^{+4}, 35, 37^{+3}, 38, and 39^{+1} weeks) were used to analyze JNK and ERK 1/2 activation. Experiments were performed at least twice. Placental villous and amnion cell extracts were then examined for the active forms of MAPKs by immunoblotting. As shown in Figs. 2 and 3, both JNK and ERK 1/2 were phosphorylated in amnion cells. Although JNK and ERK 1/2 were also phosphorylated in placental tissues by LPS treatment, the response was much weaker than that of amnion (data not shown). Activation of p38 was not found in either placenta or amnion. In amnion obtained at 23 weeks of gestation, there was a 1.51-fold increase in JNK phosphorylation at 15 min after LPS treatment, which quickly declined. In amnion cells at 28^{+1} weeks of gestation, JNK phosphorylation was found at 15 min after stimulation and was sustained for over 1 h with a 3.86-fold increase at peak when compared with control. In amnion cells obtained at 35 weeks, maximal phosphorylation of JNK reached 1.29-fold

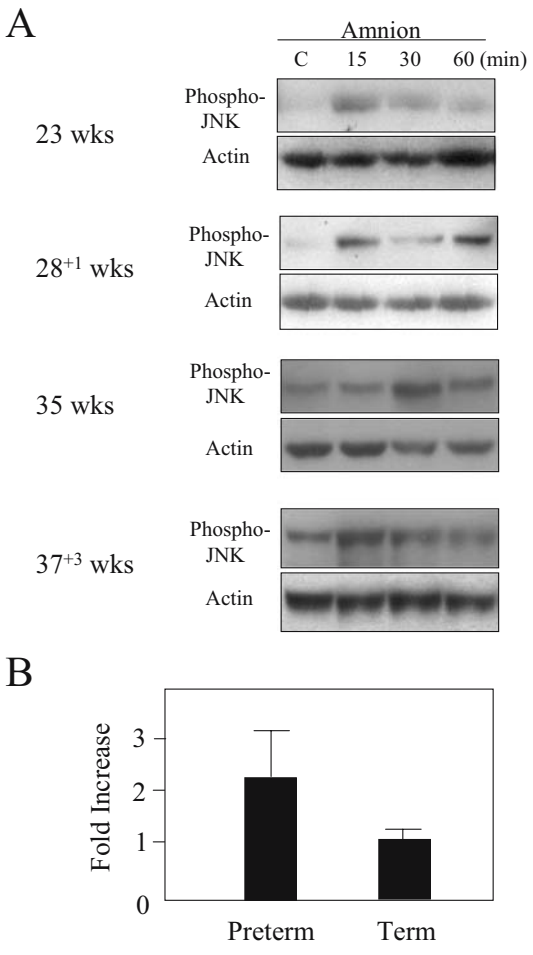

Fig. 2 Patterns of activation of JNK by LPS in amnion cells. (**a**) The amnion cells obtained at different gestational periods were treated with LPS at the concentration of 1 μg/ml for the specified periods of time. After homogenization of amniotic membranes, JNK phosphorylation was determined by immunoblotting with phosphospecific anti-JNK antibody. Aliquots of 50 μg total proteins were electrophoresed in 10% SDS-PAGE, electrotransferred onto a nitrocellulose membrane, and then the signals were detected by chemiluminescence. (**b**) Graph showing densitometric determined JNK activations at 15 min after LPS treatment in preterm (n=3) and term (n=3) amnion cells. The data were quoted as a percentage of control at 0 min

of the control, while LPS treatment had little effect on the levels of phosphorylated JNK in term cases (Fig. 2).

The phosphorylation of ERK 1/2 also increased at 15 min after LPS treatment, with a mean peak level of 1.38-fold in preterm amnion cells (23, 28^{+1}and 34^{+4} weeks; range), and then gradually decreased, showing that LPS causes a transient activation of ERK 1/2 in preterm amnion cells. However, there was only a mean 1.12-fold increase in phosphorylated ERK 1/2 in term amnion cells (Fig. 3).

Activation of NF-κB in term and preterm amnion cells

NF-κB is an obligatory transcription factor in inflammation and innate immunity. Accordingly, luciferase assay of

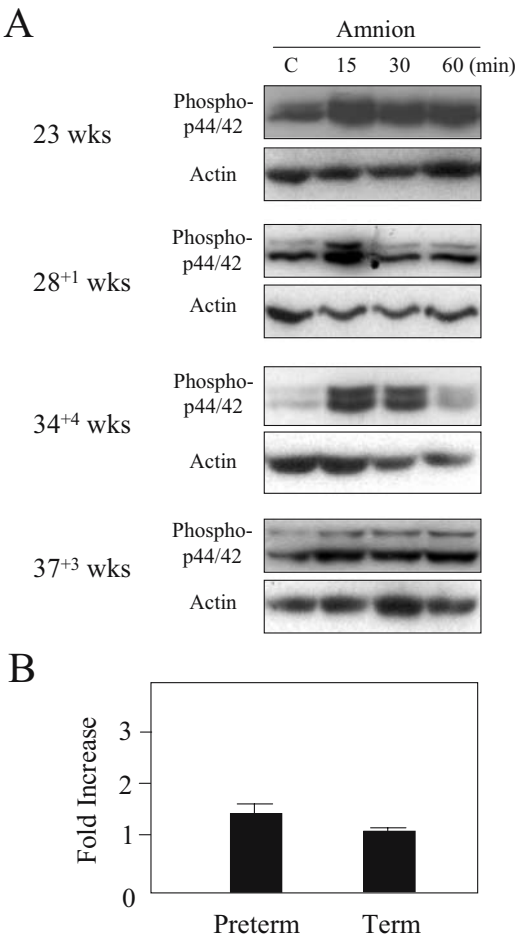

Fig. 3 Patterns of activation of ERK 1/2 by LPS in amnion cells. (**a**) The amnion cells obtained at different gestational periods were treated with LPS at a concentration of 1 μg/ml for the specified periods of time. After homogenization of amniotic membranes, phosphorylation of ERK 1/2 was determined by immunoblotting with phosphospecific anti-p44/p42 antibody. Aliquots of 30 μg total proteins were electrophoresed in 10% SDS-PAGE, electrotransferred onto a nitrocellulose membrane, and then the signals were detected by chemiluminescence. (**b**) Graph showing densitometrically determined ERK 1/2 activations at 15 min after LPS treatment in preterm (n=3) and term (n=3) amnion cells. The data were quoted as a percentage of control at 0 min

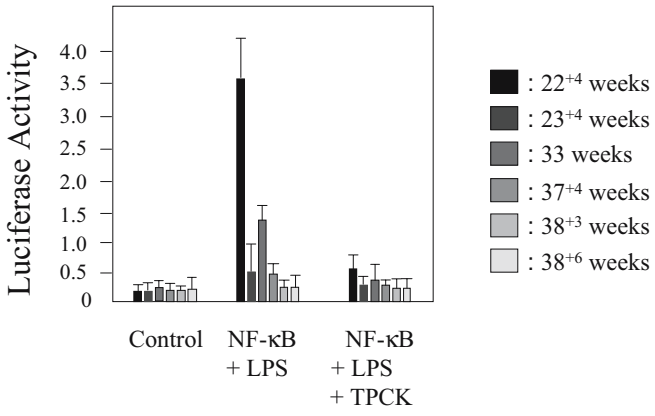

Fig. 4 Reporter gene analysis. Primary amnion cell cultures were transfected with 1 μg of pNFκB-Luc, and treated with LPS at the concentration of 50 ng/ml for 24 h after transfection in the presence or absence of 25 μM TPCK. The results clearly show an inverse relationship between gestational age and luciferase activity and also the inhibition of NF-κB activation by TPCK. The luciferase activity was normalized to β-galactosidase activity and is quoted as a percentage of control. LPS: lipopolysaccharide, TPCK: tosyl-phe-chloro-methylketone

NF-κB dependent gene expression by transient transfection of amnion cells obtained at varying weeks of gestation (n=6; 22^{+4}, 23^{+4}, 33, 37^{+4}, 38^{+3} and 38^{+6} weeks) demonstrated that the magnitude of NF-κB activation after LPS treatment was greater in preterm cases than in term counterparts. The relationship between magnitude of NF-κB activation following LPS treatment and gestational age is shown in Fig. 4. We also examined NF-κB activity by EMSA and western blot analysis using p65 specific antibody in nuclear extracts obtained from LPS-treated amnion cells (24, 29, 37^{+4}, 38^{+3} and 39^{+1} weeks). Competition experiments were carried out to determine the specificity of LPS-induced NF-κB DNA binding activity observed in the oligo NF-κB site. The binding activity was profoundly inhibited by the 50-fold molar excess of an unlabeled NF-κB oligonucleotide, whereas the 50-fold molar excess of an unlabeled oligo AP1 only slightly impaired the binding activity (Fig. 5a). In amnion cells at 24 weeks of gestation, a 2-fold increase in NF-κB activation was observed within 15 min, which gradually decreased at 30 min. The activity after 1 h of LPS exposure was similar to the control activity. At 29 weeks, densitometric analysis of NF-κB activation revealed an approximately 2.6-fold increase after 15 min, which was sustained until 1 h after LPS exposure (Fig. 5b). There was no significant change in NF-κB activation in term amnion cells. These data were consistent with the results of immunoblotting using p65 specific antibody.

Amniotic fluid and cord plasma IL-6 in preterm births

In a separate analysis, IL-6 levels in amniotic fluid and cord blood obtained from preterm deliveries were compared with placental inflammation to assess whether or not the fetal cytokine response during the preterm period is also gestational age-dependent. The level of significance was greatest when the preterm cases with placental inflammation were dichotomized for analysis at the gestational age of 31 weeks (Fig. 6). The amniotic fluid and cord blood IL-6 levels were significantly higher in cases born at or before the gestational age of 31 weeks than in preterm cases born after 31 weeks (amniotic fluid IL-6: median, 16.5 ng/ml; range, 0.1-92.5 ng/ml; versus median, 1.9 ng/ml; range, 0.1-115.2 ng/ml, respectively; cord blood IL-6: median, 68.1 pg/ml; range, 0.6-18107.5 pg/ml; versus median, 7.7 pg/ml; range, 0.0-4897.0 pg/ml, respectively; P<0.001 for all). When the IL-6 concentrations of amniotic fluid and cord plasma in cases with advanced stage of placental inflammation (chorion-decidua grade=3 and umbilical cord

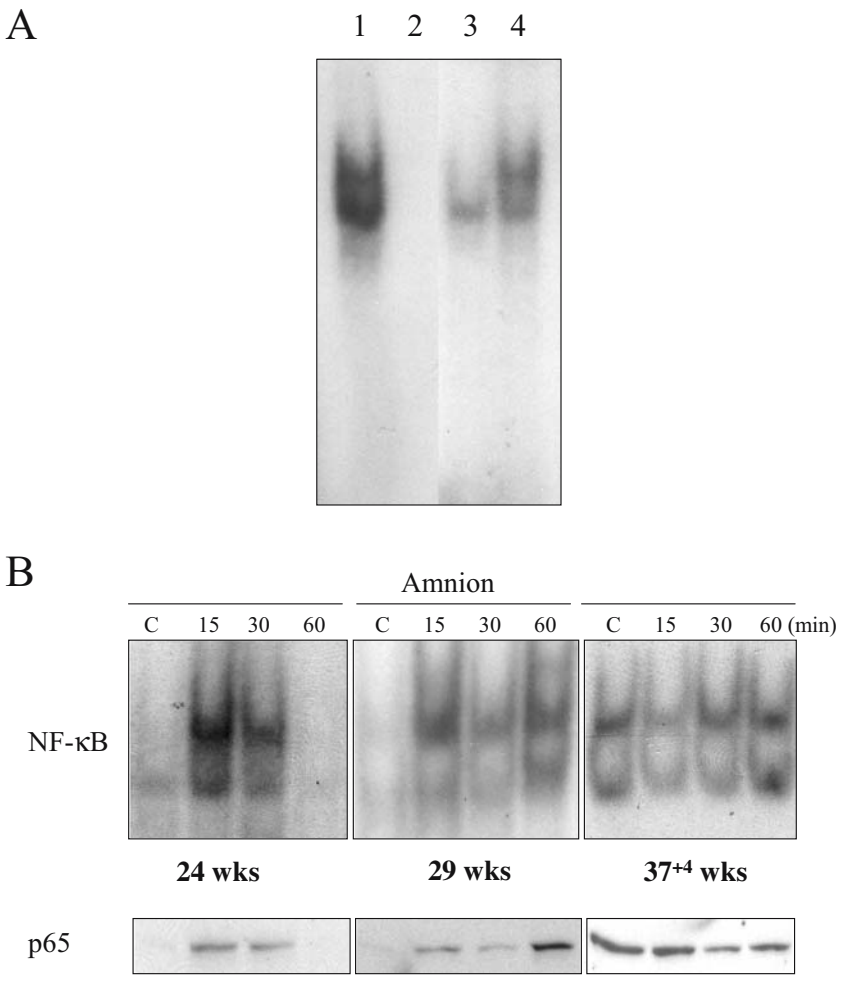

Fig. 5 NF-κB binding activity in response to LPS. Nuclear proteins were prepared and incubated with radiolabeled probes corresponding to the consensus binding site for NF-κB, and their DNA binding activity was determined by electrophoretic mobility shift assay (EMSA). (**a**) Competition experiments. Lane 1: positive control (^{32}P-labeled NF-κB oligonucleotide); lane 2: negative control; lane 3: specific competitor (^{32}P-labeled NF-κB oligonucleotide in the presence of a 50-fold molar excess of unlabeled NF-κB oligonucleotide); lane 4: non-specific competitor (^{32}P-labeled NF-κB oligonucleotide and unlabeled AP-1 oligonucleotide). grade=2; [30]) were compared according to gestational age, the IL-6 concentrations of amniotic fluid and cord plasma were also found to be significantly increased in patients delivered at or before 31 weeks of gestation compared with those delivered after 31 weeks of gestation (amniotic fluid IL-6: median, 18.7 ng/ml; range, 0.2-

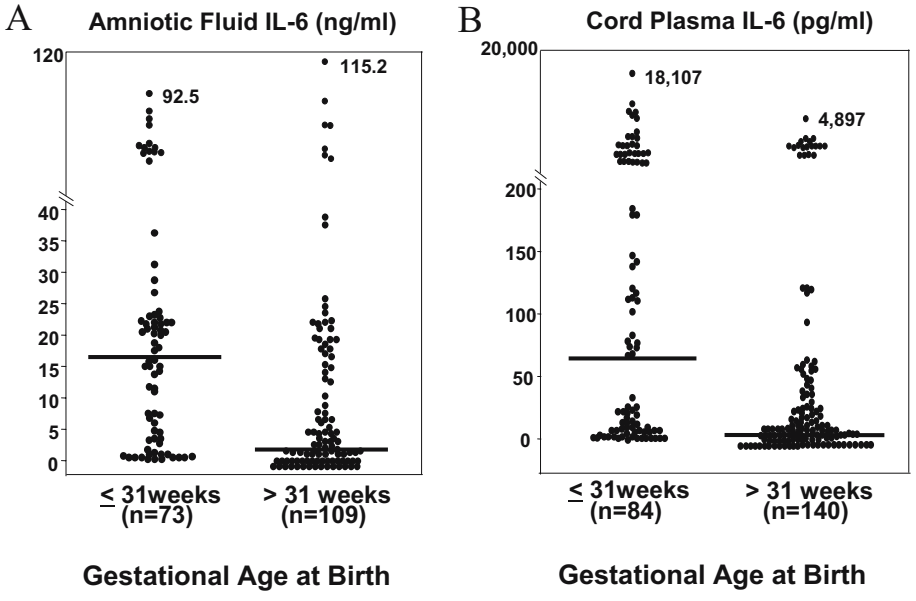

Fig. 6 IL-6 levels in amniotic fluid and cord blood in preterm cases. Amniotic fluid (**A**) and fetal plasma (**B**) IL-6 levels are significantly higher at or before the gestational age of 31 weeks than after the gestational age of 31 weeks (P<0.001). IL-6 levels were measured by specific immunoassay

92.5 ng/ml; versus median, 8.0 ng/ml; range, 0.1-115.2 ng/ml, respectively; P=0.016; cord plasma IL-6: median, 138.5 pg/ml; range, 4.4-7400 pg/ml; versus median, 51.9 pg/ml; range, 0.1-4897.0 pg/ml, respectively; P=0.023). The prevalence of major perinatal morbidity was also significantly higher in cases born at or before the gestational age of 31 weeks (P<0.0001).

Discussion

The intrauterine infection-associated complex of biological reactions occurring in the fetus has been designated as "fetal inflammatory response syndrome" (FIRS) [14]. Increased production of proinflammatory cytokines and fetal plasma cytokines, i.e. IL-6, is an essential component of FIRS, and we have recently shown that preterm fetuses respond more rigorously in terms of IL-6 response to intrauterine infection than their term counterparts [20, 37]. The relationship between the severity of fetal inflammatory response and gestational age led us to speculate that the cause may be the differential activation of signaling cascades activated by amniotic sac infection.

LPS, a surface component of Gram-negative bacteria, binds to cell surface CD14 and activates tyrosine kinases, protein kinase C, MAPKs and NF-κB. As demonstrated in various cell types, LPS can induce activation of ERK 1/2, JNK, and p38. These molecules in turn act as primary regulators of proinflammatory cytokine expression [17, 23, 24]. LPS treatment has been used as an in vitro mimic of bacterial infection in many experimental systems. Although LPS is a potent activator of many cell types including macrophages, microglial cells and embryo cardiomyocytes, these cells often play unique tissue-specific roles and exhibit different sensitivities to LPS. We observed the patterns of MAPK and NF-κB activation in human amnion cells. Although amnion cells do not belong to the fetus per se, they do comprise one of the major sources of proinflammatory cytokines in amniotic sac infection, as well as affording a relevant experimental system for cytokine research [12, 20, 27]. The patterns of JNK and ERK 1/2 activation by LPS in human amnion cells were similar to those reported in other type of cells [17, 18, 25, 28]. LPS increases binding between NF-κB and DNA and cytokine secretion by gestational tissues such as human placenta and amnion. NF-κB also plays a key role in the regulation of the expression and secretion of phospholipase enzymes in gestational tissues [22]. The present study did not address the exact mechanism of the differential activations of MAPK and NF-κB in amnion cells during human gestation. As LPS exerts its effects through CD14 and toll-like receptors [31], we presume that the expression levels of these molecules may be related. Further investigations on these molecules and other components related to innate immunity are necessary to elucidate the nature of the mechanisms underlying our observations.

The results of amniotic fluid IL-6 assay in preterm cases were also consistent with the results of ERK 1/2, JNK, and NF-κB analysis. The biological significance of this differential MAPK and NF-κB activation in amnion cells remains unclear, and further investigation is required to elucidate whether or not this is an organ- or cell type-specific phenomenon. Nevertheless, the results of the present study strongly suggest that critical biological responses potentially related to parturition differ according to gestational age. Elevation of proinflammatory cytokines in the fetus and placental compartments can induce delivery via activation of biological mechanisms that are related to parturition, such as MMPs and prostaglandin, as amnion cells are major sources of MMPs and PGE2 [7, 11, 32]. Such exaggerated cytokine response is also known to be able to induce significant tissue damage [34, 36] and thus may be related to the well-documented correlation between the incidence of major perinatal morbidities and the gestational age of the fetus.

In conclusion, we demonstrated that MAPK (ERK 1/2 and JNK) and NF-κB mediated signaling pathways, which are critical regulatory elements of cytokine gene expressions, are differentially activated by LPS in human amnion during gestation. These findings strongly imply that this differential regulation is the underlying mechanism of the inverse relationship between fetal inflammatory response and gestational period.

Expression of BAFF-R (BR3) in normal and neoplastic lymphoid tissues characterized with a newly developed monoclonal antibody

Received: 10 January 2005 / Accepted: 12 April 2005 / Published online: 14 June 2005
© Springer-Verlag 2005

Abstract BAFF-receptor (BAFF-R) is required for the successful maturation and survival of B-cells. We developed an anti-human BAFF-R monoclonal antibody (mAb), 8A7. The reactivity of 8A7 in normal and neoplastic tissue was examined by performing immunohistochemistry on paraffin-embedded sections. 8A7 reacted with lymphocytes in the mantle and marginal zones, but not with lymphocytes in the interfollicular area. Lymphocytes in the germinal centers were found to be negative or occasionally weakly positive for 8A7. BAFF-R expression was found only in B-cell lymphoma (44/80, positive cases/examined cases): B-lymphoblastic lymphoma 0/3, B-chronic lymphocytic leukemia/small lymphocytic lymphoma 4/4, mantle cell lymphoma 9/11, follicular lymphoma 10/14, diffuse large B-cell lymphoma (DLBCL) 11/25, marginal zone B-cell lymphoma 8/10, lymphoplasmacytic lymphoma 2/2, plasma cell myeloma 0/2, and Burkitt lymphoma 0/9, but not in T/NK cell lymphomas (0/19) or Hodgkin lymphoma (0/10). BAFF-R was expressed in most low-grade B-cell neoplasms and a small number of DLBCL, suggesting that BAFF-R may play an important role in the proliferation of neoplastic lymphoid cells. Thus, the mAb is very useful for further understanding of both healthy B-cell biology and its pathogenic neoplasms.

Introduction

B-cell-activating factor of the tumor necrosis factor (TNF) family (BAFF), also known as BLyS, THANK, TALL-1 and zTNF4, is a fundamental survival factor for B-cells, and BAFF functionality is indispensable for B-cell maturation [13, 18, 27, 28]. BAFF is a trimeric membrane-bound or soluble factor and is expressed by monocytes, macrophages, neutrophils and dendritic cells. Whereas BAFF-deficient mice lack mature B-cells, BAFF-transgenic mice, characterized by overexpression of BAFF, have increased the number of B-cells and develop autoimmunity [3, 4, 9, 12]. In particular, transitional type 2 (T2) B-cells and marginal zone B-cells are expanded in BAFF-transgenic mice. BAFF blockade does not inhibit germinal center (GC) formation or somatic hypermutation of immunoglobulin (Ig) genes, indicating that BAFF is required for the normal maintenance of B-cells, but not for the initiation of the GC reaction, although B-cell maturation and mature functions are severely impaired [35]. Recently, it was reported that BAFF is directly involved in B cell malignancy [2, 7, 22, 23].

Three receptors for BAFF have been established: B-cell maturation antigen (BCMA), transmembrane activator and

calcium-modulator, and cyclophilin ligand interactor (TACI) and the BAFF-receptor (BAFF-R, also called BR3) [3, 14, 32, 33]. All three receptors are expressed on B-cells, while TACI is also expressed on activated T-cells [13]. Whereas TACI and BCMA are found to bind to a proliferation-inducing ligand (APRIL), BAFF-R binds only to BAFF [13, 32]. TACI is known to negatively control B-cell homeostasis and T-cell independent immune responses from evidence obtained from TACI deficient mice [30, 34, 37]. Although BCMA was recently reported to be essential for the survival of plasma cells [1, 24], mice lacking BCMA possess normal-appearing B lymphocyte compartments [27]. Thus, only BAFF-R is clearly a key receptor involved in the successful survival and maturation of B-cells [13]. However, the distribution of BAFF-R in normal and malignant human lymphoid tissue has not been made fully clear.

Only a few reports on BAFF-R in malignant B-cells have appeared to date. Briones et al. examined the BAFF binding activity in 43 cases of non-Hodgkin's lymphoma (NHL) with flow cytometry [2]. Although all cases of NHL express receptors for BAFF, BAFF-R expression was not specifically classified. Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL), mantle cell lymphoma (MCL), follicular center lymphoma, Burkitt lymphoma (BL) and diffuse large cell lymphoma were reported to express BAFF-R mRNA [7, 22], and multiple myeloma (MM) was reported to express cell surface BAFF-R [23].

In this investigation, we established the mouse anti-human BAFF-R monoclonal antibody (mAb) and examined its reactivity in normal and neoplastic lymphoid tissues using immunohistochemistry. We found a high degree of significance in its distribution in normal lymphoid tissue and low-grade B-cell neoplasms as well as in a small part of diffuse large B-cell lymphoma (DLBCL).

Materials and methods

Cell preparation and cell cultures

Human peripheral blood mononuclear cells were isolated from pooled healthy donors by Ficoll-Hypaque density-gradient centrifugation. After the depletion of monocytes by adherence to the plastic surface of the culture dishes, E rosette-negative populations were collected with 5% sheep erythrocytes and Ficoll-Hypaque. Purified B-cells were isolated by depleting the non B-cells using a B-cell isolation kit and auto MACS (Miltenyi Biotec, Auburn, Calif., USA). The resultant B-cell population was <2% $CD14^+$, <1% $CD3^+$, <2% $CD57^+$, and >95% $CD20^+$. All cultures were conducted in RPMI 1640 medium supplemented with 25 mM HEPES (*N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid), 10% fetal calf serum, 2 mM L-glutamine, 1 mM sodium pyruvate, 5.5×10^{-2} mM 2-mercaptoethanol, 100 IU/ml penicillin, and 100 IU/ml streptomycin (all from Invitrogen, Carlsbad, Calif., USA).

Antibodies and reagents

Polyclonal anti-human BAFF-R antibody (C-20), control mouse IgG2a, and FITC-labeled goat antibody to mouse IgG were purchased from Santa Cruz Biotechnology (Santa Cruz, Calif., USA), Sigma-Aldrich (St Louis, Mo., USA), and CALTAG (Burlingame, Calif., USA), respectively.

Establishment of human BAFF-R transfectant

To construct a human BAFF-R expression vector, a cDNA encoding full-length human BAFF-R protein (GenBank No. AF373846) was custom-synthesized (Takara, Shiga, Japan), inserted into pBluescript SK (+) (Stratagene, La Jolla, Calif., USA) at the *Eco*RI and *Bam*HI sites, and finally into the pBCMGSneo expression vector [8] at the *Xho*I and *Not*I sites (pBCMGS-BAFF-R). Murine pre-B-cells (cell line 300-19) were electroporated with pBCMGS-BAFF-R and stable transfectants were selected with G418 treatment. Cells with high-density BAFF-R were cloned with a fluorescence-activated cell sorter (FACS). The vector alone-transfected cells (mock) have been described previously [6].

Generation of anti-human BAFF-R mAb

A BALB/c mouse was immunized with human BAFF-R-expressing transfectant cells 3 times at 10-day intervals. Three days after the final immunization, the splenocytes were fused with NS-1 cells (purchased from Human Science Research Resources Bank), and HAT (hypoxanthine-aminopterin-thymidine) selection and cloning of hybridomas were performed simultaneously using a hybridoma cloning kit (ClonaCell-HY; StemCell Technologies, British Columbia, Canada). Anti-human BAFF-R designated 8A7 (mouse IgG2a, κ) was established.

Immunoblot analysis

PBS-washed cell pellets were resuspended with 0.5% SDS solution and boiled for 5 min. Proteins (5–8 μg) were separated with SDS-PAGE, transferred to an Immobilon-P membrane (Millipore, Billerica, Mass., USA), blocked with 5% skim milk, and immunoblotted with arbitrary Ab and HRP-labeled secondary Ab. The immunoblots were developed by using the enhanced chemiluminescent substrate (SuperSignal West Pico; Pierce Chemical Co., Rockford, Ill., USA) and visualized with a LumiVision analyzer (Taitec Co., Tokyo), as previously described [5].

Flow cytometric analysis

Flow cytometric analysis was performed using FACScalibur and the associated Cell Quest software (both from Becton Dickinson, San Jose, Calif., USA). FITC-labeled

goat antibody to mouse IgG was used as a second Ab. An isotype-matched mouse IgG2a control was used throughout the studies and always reacted with <5% of the cells.

Tissues and immunohistochemistry

Formalin-fixed paraffin-embedded tissues were used in this study. Tonsils resected due to chronic tonsillitis, lymph nodes resected due to non-neoplastic lymphadenopathy, spleens resected because of non-lymphoma and bone marrow clots without malignancy were used for the non-neoplastic lymphoid tissues. Neoplastic lymphoid tissues from 109 cases were used in this study and comprised the following: three cases of B-lymphoblastic lymphoma (B-LBL), four cases of CLL/SLL, 11 cases of MCL, 14 cases of follicular lymphoma (FL), 25 cases of DLBCL, ten cases of marginal zone B-cell lymphoma (MZBCL), two cases of Lymphoplasmacytic lymphoma (LPL), two cases of plasma cell myeloma (PCM), nine cases of BL, three cases of T-lymphoblastic lymphoma, four cases of angioimmunoblastic T-cell lymphoma, five cases of peripheral T-cell lymphoma, unspecified, two cases of adult T-cell lymphoma, one case of systemic anaplastic large cell lymphoma, four cases of NK/T cell lymphoma and ten cases of Hodgkin lymphoma (HL). All cases of CLL/SLL and MCL expressed CD5. Cyclin D1 was immunohistochemically detected in all but one case of MCL. FL consisted of four cases of grade 1, four cases of grade 2 and six cases of grade 3. All cases of FL expressed CD10. DLBCL included three cases with CD5 (+) CD10 (−), three cases with CD5 (−) CD10 (+) and 19 cases with CD5 (−) CD10 (−). HL consisted of three cases of nodular lymphocyte predominance Hodgkin lymphoma (NLP-HL), four cases of mixed cellularity classical Hodgkin lymphoma (MC-CHL) and three cases of nodular sclerosis classical Hodgkin lymphoma (NS-CHL).

The de-paraffinized tissue section was pre-treated in citrate buffer with microwave oven heating. The section was incubated with the primary antibody at 4°C overnight and then the streptavidin-biotin complex method (Dakocytomation, Kyoto, Japan) was used. Neoplasms with >10% positive cells were judged as positive.

Results

Establishment of the anti-human BAFF-R mAb, 8A7

To evaluate the role of the interactions between BAFF and BAFF-R in human B cell responses, we developed an anti-human BAFF-R mAb. For this purpose, we first estab-

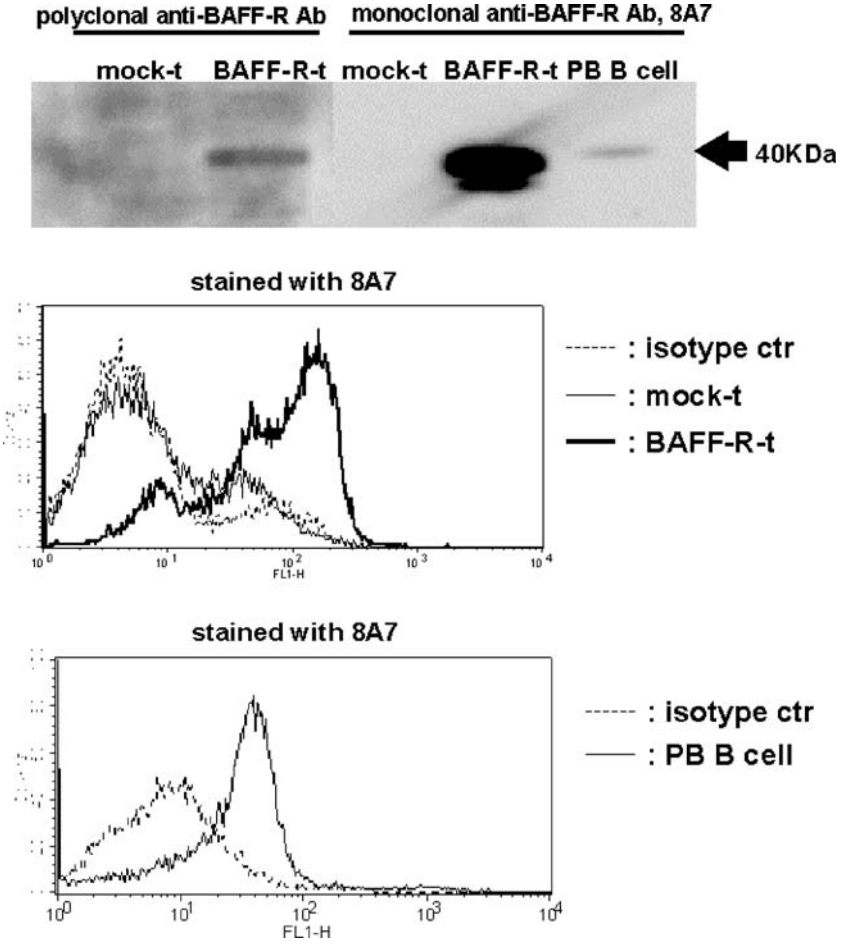

Fig. 1 8A7 mAb detects human BAFF-R. (**a**) Cell lysates prepared from BAFF-R- and mock-transfectants, and peripheral blood B cells, were subjected to immunoblot analysis using anti-human BAFF-R polyclonal Ab or 8A7 mAb. (**b**) Flow cytometric analysis of BAFF-R expression using 8A7 mAb. BAFF-R- and mock-transfectants and peripheral blood B cells were stained with 8A7 mAb or isotype-matched control Ab (IgG2a) followed by FITC-conjugated Ab to mouse IgG. Data shown are representative of three different experiments

lished a transfectant stably expressing human BAFF-R. Stable expression of human BAFF-R on the cDNA transfectant, but not on mock-transfected cells was verified using immunoblot analysis (Fig. 1a). Immunoblot analysis using commercially available polyclonal anti-human BAFF-R Ab revealed that BAFF-R cDNA-transfected cells expressed the BAFF-R molecule. We then immunized a BALB/c mouse with the BAFF-R-transfectant and fused the splenocytes with NS-1 myeloma cells. The hybridomas producing anti-human BAFF-R mAb were screened for specific reactivity to the BAFF-R-transfectant. As shown in Fig. 1a, one obtained mAb, designated 8A7, bound to BAFF-R-transfectant and peripheral blood B cells but not to mock-transfectant. Flow cytometric analysis revealed that the 8A7 mAb reacted with almost all peripheral blood B cells and BAFF-R-transfectant, but not with peripheral blood T-cells, monocytes, or mock-transfectant (Fig. 1b, data not shown).

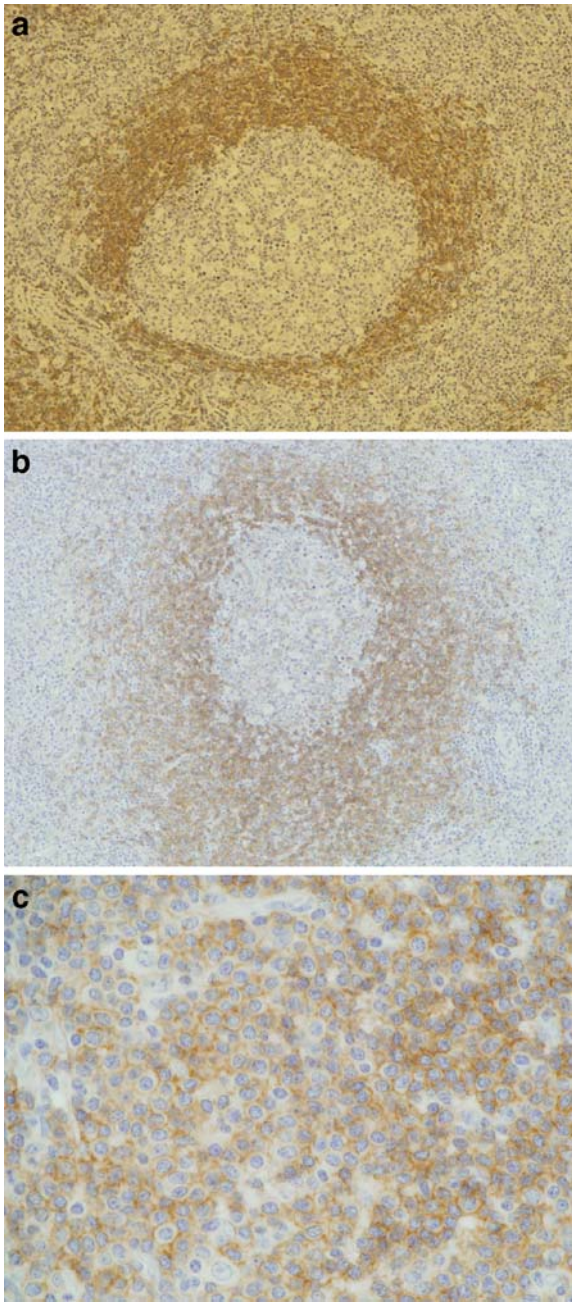

Fig. 2 BAFF-R expression in normal lymphoid tissues according to immunohistochemistry (IHC) on the paraffin-embedded section (strept/ABC method). 8A7 reacts with lymphocytes in the mantle zone of the secondary lymphoid follicles in the lymph node (**a**: IHC, original magnification ×50) and with lymphocytes in the mantle and marginal zones of the splenic white pulp (**b**: IHC, ×50). Marginal B-cells with a clear cytoplasm are positive for 8A7 (**c**: IHC, ×200)

Immunohistochemistry of non-neoplastic lymphoid tissue

8A7 reacted with lymphocytes in the mantle zone of the secondary lymphoid follicles in the tonsil (Fig. 2a) and the non-neoplastic lymph nodes. In the spleen, 8A7 reacted with lymphocytes in the mantle and marginal zones of the white pulp, but not with the interfollicular area (Fig. 2b,c). Lymphocytes in germinal centers (GCs) were found to be negative or occasionally weakly positive for hyperplastic GC. 8A7 failed to stain hematopoietic cells in the bone marrow. Plasma cells were negative for 8A7.

Immunohistochemistry of the neoplastic lymphoid tissue

Expression of BAFF-R in neoplastic lymphoid tissue detected by 8A7 is shown in Table 1 and Fig. 3. BAFF-R expression was only found in B-cell lymphoma (44/80, positive cases/examined cases), but not in T/NK cell lymphoma (0/19) or in Hodgkin lymphoma (0/10).

Discussion

An anti-human BAFF-R mAb, named 8A7, was developed using a transfectant stably expressing human BAFF-R to evaluate the role of interactions between BAFF and BAFF-R in human B-cell responses and malignancy. In this paper, reactivity and distribution in normal and malignant lymphoid tissues was addressed by means of immunohistochemistry with paraffin-embedded tissue.

The distribution of BAFF-R in human lymphoid tissue has not been heretofore reported, except in a recent report by Ng et al. [21]. They stated that the BAFF-R was expressed at a high level on all B-cells and at very low levels on T-cells in human peripheral blood. It is also expressed in tonsil B-cells, but B-cells with a GC phenotype ($CD38^+$, $CD27^+$, $CD39^-$, $CD24^-$ and IgM^-) exhibited lower levels of BAFF-R according to flow cytometry [21]. Intense staining of B-cell follicles and weaker staining of the GCs were observed in the immunohistochemistry using frozen sections [21]. We demonstrated that BAFF-R was strongly expressed on B-cells situated both in the mantle zone and the marginal zones of the secondary lymphoid follicles and weakly expressed on GC B-cells occasionally

Table 1 Reactivity of 8A7 in 109 neoplastic lymphoid tissues according to immunohistochemistry (Positive cases/examined cases). *NLP-HL* nodular lymphocyte predominance Hodgkin lymphoma; *MC-CHL* mixed cellularity classical Hodgkin lymphoma; *NS-CHL* nodular sclerosis classical Hodgkin lymphoma

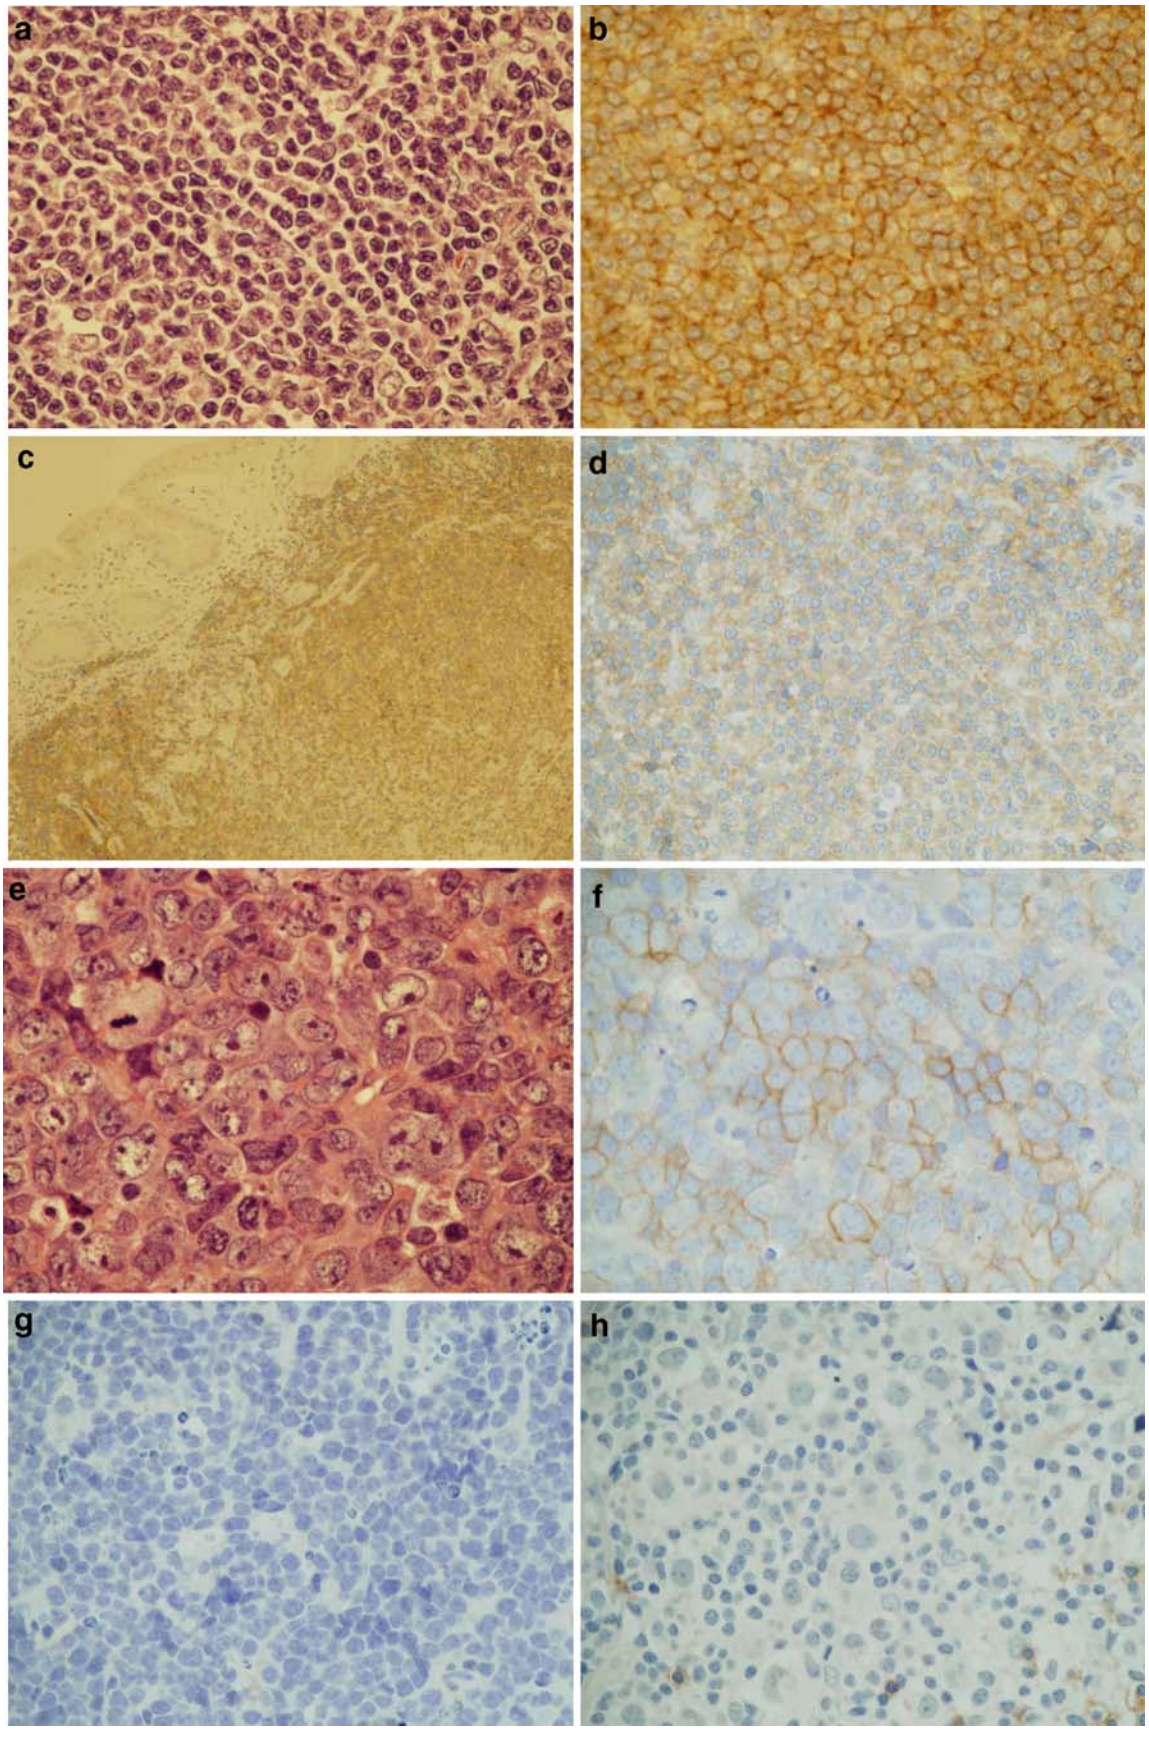
MC-CHL	0/4
NS-CHL	0/3

in the GCs. The intensity of BAFF-R in GC B-cells may vary between each GC. Marginal zone B-cells have somatically hypermutated immunoglobulin (Ig) genes and express CD27 at a level equivalent to memory B-cells [10]. It is widely considered that marginal zone B-cell development and survival are likely to directly or indirectly depend on BAFF [13]. Since the present data indicate that marginal B-cells express BAFF-R, it is likely that BAFF directly contributes to the maturation of marginal zone B-cells. BAFF-R was also expressed strongly on mantle zone B-cells, which are naive B-cells that exhibit unmutated Ig genes and mainly co-express IgM and IgD [11]. On the other hand, GC B-cells that undergo affinity maturation of their antigen receptors and express CD10 and CD38 [25] were observed to be negative or weakly positive for BAFF-R. Thus, BAFF-R is widely distributed on un-stimulated B-cells and antigen-stimulated B-cells during B cell differentiation, except for GC B-cells. This pattern of BAFF-R expression during different stages of B-cell differentiation seemed to be similar to that of Bcl-2 expression. GC B-cells express low levels of BAFF-R and the anti-apoptotic factor Bcl-2, and high levels of the apoptotic factor Fas [17, 39].



Novak et al. reported the cell surface expression of BAFF-R on both CD5 (+) peripheral blood B-cells as well as CD5 (−) peripheral blood B-cells [23]. Mice transgenic for TACI-Ig, and BAFF-deficient mice display a developmental block of B-cell maturation in the periphery, leading to a severe depletion of marginal zone and follicular B2 B-cells, but not of peritoneal CD5 (+) B1 B-cells [4, 13, 29]. Interactions between BAFF and BAFF-R may be needed for CD5 (+) B1 B-cell maturation as much as CD5 (−) B2 B-cell maturation in humans.

The reactivity of anti-BAFF-R mAb against neoplastic lymphoid tissue is of considerable interest. It is likely that BAFF-R expression was only found in B-cell lymphoma, but not in T/NK-cell lymphomas, for reasons related to the fact that BAFF-R expression is normally found only on healthy B-cells [21]. Only a small number of studies reporting BAFF-R expression in malignant B-cells have appeared to date. Seven of seven B-CLL samples, as well as normal B-cells, expressed BAFF-R mRNA [22]. None of the five MM cell-lines but two of the three mononuclear cells of patients with MM expressed cell surface BAFF-R [23]. Six of six NHLs, including CLL/SLL, MCL, FL, BL, and DLBCL, expressed BAFF-R mRNA [7]. In the present study, however, we demonstrated somewhat different results for BAFF-R expression.

Most of the low-grade B-cell neoplasms of B-CLL/SLL, MCL, LPL and MZBCL strongly exhibited BAFF-R. Among them, MCL and MZBCL are believed to be neoplasms derived from mantle zone B-cells and marginal zone B-cells, respectively. The normal counterpart cells of B-CLL/SLL are a neoplasm of CD5 (+) B-cells of the peripheral blood [15, 29]. These normal counterpart cells are all BAFF-R (+) and these B-cell neoplasms seemed to maintain BAFF-R expression. Low-grade B-cell lymphomas may require the interaction of BAFF and BAFF-R for survival and proliferation of the neoplastic B-cells.

Although normal GC B-cells exhibited a negative reaction or an occasionally weakly positive reaction for 8A7, both grade 1 and 2 FLs strongly expressed BAFF-R. FL consists of small-cleaved lymphoma cells with intermingled large sized centroblasts. Grade 1 and 2 FLs include less than 50 centroblasts and 50–150 centroblasts per ten high-power fields, respectively. Both grades 1 and 2 FLs retain a follicular growth pattern supported by a network of follicular dendritic cells (FDCs), and the lymphoma cells express CD20, CD10, Bcl-2 and Bcl-6 [20]. It has recently been shown that FDCs express BAFF [6]. On the other hand, in grade 3 FL, 2/3 in grade 3a and 0/3 in grade 3b were positive for 8A7. This may indicate that lymphoma cells of grade 1 and 2 FLs require the interaction of BAFF and BAFF-R for their survival and growth. Certain lymphoma cells of some grade 3 FL act autonomically in terms of proliferation.

BAFF-R was expressed in a lower number of cases of aggressive B-cell lymphomas. LBL and BL were negative for 8A7. Eleven out of 25 DLBCLs exhibited a positive reaction with anti-BAFF-R mAb, which supports the recent report by He et al. [7]. Among these, the expression of BAFF-R was found in CD5 (+) DLBCL as well as CD5 (+) CLL/SLL and MCL. BAFF-R (+) in many cases of CD5 (+) B-cell neoplasms was independent of their aggressiveness and clinical behavior. These findings may prove to be useful for the continual improvement of understanding of the biology of CD5 (+) B-cells and B-cell neoplasms, especially for CD5 (+) DLBCL, which is reported to have a poorer clinical outcome than CD5 (−) DLBCL [19, 36].

◀ **Fig. 3** BAFF-R expression in neoplastic lymphoid tissues according to immunohistochemistry (IHC) on the paraffin-embedded sections (strept/ABC method). 8A7 is strongly expressed in CD20 (+) CD5 (+) cyclin D1 (+) mantle cell lymphoma (**a**: HE, **b**: IHC, original magnification ×200). 8A7 reacts with the lymphoma cells of gastric MALT lymphoma, but not with the glandular epithelium (**c**: IHC, ×50; **d**: IHC, ×200). 8A7 expressed on some of the lymphoma cells of CD20 (+) CD5 (+) diffuse large B-cell lymphoma (**e**: HE, **f**: IHC, ×200) (**g**: IHC, ×200). Expression of 8A7 is not found in Hodgkin/Reed-Sternberg cells of Hodgkin lymphoma, but in a small number of small lymphocytes (**h**: IHC, ×200) Burkitt lymphoma is negative for 8A7

We analyzed the clinical profiling between BAFF-R (+) and BAFF-R (−) subgroups in all DLBCL examined. When analyzing these between the BAFF-R (+) and BA FF-R (−) subgroups in CD5 (−) CD10 (−) DLBCL, we found a significant difference in LDH. The number of patients with LDH >2-fold of the normal limit in the BAFF-R (+) subgroups was greater than that in the BAFF-R (−) subgroup (detailed data not shown). This may mean that the volume of lymphoma cells in patients with BAFF-R (+) DLBCL is high and may affect the treatment strategy for patients with BAFF-R (+) DLBCL. We found no significant differences in the overall survival curves between the two subgroups due to the small number of patients in this study, and more cases are needed for an accurate estimation. BAFF-R is a possible marker for sub-grouping of DLBCL. On the other hand, two out of three CD5 (+) DLBCL exhibited more than 2-fold the normal limit of LDH, but both cases of CD10 (+) DLBCL exhibited LDH within the normal limit.

The HRS cells of all cases of HL including NLP-HL, MC-CHL and NS-CHL were negative for BAFF-R. This is a marked difference from the finding that more than half of HL cases express the bcl-2 protein, an anti-apoptotic factor [26]. HL is a neoplasm derived from GC B-cells with a hypermutated Ig gene, as disclosed by single cell PCR analysis, and lacks Ig mRNA, which is different from the cases of DLBCL [16, 38]. Since the expression of BAFF-R is regulated by immunoglobulin, it is possible that HL is not able to express BAFF-R [31]. It is, however, odd that the NLP-HL that expresses Ig was also negative for 8A7.

In conclusion, we developed an anti-human BAFF-R mAb and addressed its reactivity and distribution in normal and malignant lymphoid tissues by performing immunohistochemistry with paraffin-embedded tissues. BAFF-R was found to be expressed on B-cells situated in the mantle and marginal zones, but not on B-cells in GC. We demonstrated that BAFF-R was expressed on most low-grade B-cell neoplasms and in some DLBCL.

Numerical and structural centrosome aberrations are an early and stable event in the adenoma–carcinoma sequence of colorectal carcinomas

Received: 7 October 2004 / Accepted: 2 December 2004 / Published online: 1 June 2005

Abstract *Aims:* Numerical and structural centrosome changes have been described for and linked with genetic instability in solid tumors. Here, we specifically address centrosome aberrations in the adenoma–carcinoma sequence of colorectal cancer by detailed evaluation of γ-tubulin staining patterns. *Methods:* Formalin-fixed and paraffin-embedded specimens (normal colonic epithelium n=21; low-grade intraepithelial neoplasia n=27, high-grade intraepithelial neoplasia n=16 and invasive adenocarcinomas n=33) were stained by an anti-γ-tubulin antibody using standard immunofluorescence. Three-dimensional image stacks of the stainings were recorded (Zeiss LSM510 confocal microscope), followed by numerical and structural data analysis (DIAS software package) and statistical evaluation (NCSS-software). *Results:* The mean centrosome signal per cell differed significantly (P<0.0001) between normal colonic epithelium (0.8775) and each low-grade intraepithelial neoplasia (1.787), high-grade intraepithelial neoplasia (2.259) and invasive carcinomas (2.267). Similarly, both the centrosomes' structural entropy (SE) and minimal spanning tree (MST) differed significantly (P< 0.001) between normal (SE=3.956, MST=38.78) and each low- (SE=6.39, MST=26) and high-grade intraepithelial neoplasia (SE=5.75, MST=26.97) and invasive carcinoma (SE=6.86, MST=28.08). *Conclusion:* Numerical and structural centrosome dysregulation is seen as early as in low-grade dysplastic lesions of the adenoma–carcinoma sequence of colorectal carcinomas and may, as such, play an initial role in the carcinogenic process.

Introduction

The formation and organization of centrosomes is essential for proper cell division and the generation of two diploid daughter cells [1, 25]. During interphase, centrosomes are involved in the organization of the cytoplasmatic microtubule network and thereby also influence cell movement and cell polarity. Parallel to the cell cycle, centrosomes duplicate, mature and separate by moving to the opposite poles of the cell, ensuring mitotic-spindle formation and attachment. At mitosis, centrosomes are directly involved in proper chromosome segregation. Changes in either the number and/or location of centrosomes may negatively influence chromosomal segregation and cell ploidy and thereby promote chromosomal instability in malignancy [1, 25].

Indeed, centrosome aberrations have been demonstrated in several types of cancer [2, 3, 4, 18, 22], both in cell lines [7, 23, 27, 32] as well as in solid [8, 17, 19, 26] and hematopathological [5, 21] tumors. In fact, both supernumerary and structurally altered centrosomes have been

described for especially aneuploid cell lines [7] and tumors [18, 19]. Moreover, direct manipulation of centrosome regulation in cell culture models was shown to induce aneuploidy and transformation [32], supporting the concept of a potentially causative role of centrosome aberrations in malignant progression. A recent in situ study of precursor lesions implicated centrosome defects in the carcinogenesis of tumors of the uterine cervix, prostate and breast [24].

In colorectal cancer, concomitant phenotypic and genotypic changes characterize the progression of normal epithelium to adenoma to invasive carcinoma [6, 11, 12, 16]. The genetic alterations accompanying the adenoma–carcinoma sequence are generally divided into two pathways, resulting in either chromosomal unstable, frequently aneuploid tumors (CIN) or microsatellite unstable (MIN), mostly diploid tumors. Specific small genetic alterations, such as point mutations, and/or gains and losses of entire genes have been associated with chromosomal and microsatellite instability [9]. However, whether or not centrosome aberrations and the associated chromosome missegregation are primarily involved in or contribute to the carcinogenesis of colorectal tumors, particularly the CIN-type aneuploid carcinomas, is still unclear.

In the present study, we have therefore investigated centrosome alterations in the adenoma–carcinoma sequence of colorectal cancer by examining numerical and structural changes of the centrosome-specific marker γ-tubulin in situ, using formalin-fixed and paraffin-embedded tissue sections of normal epithelial cells, low-grade intraepithelial neoplasia (LGIN), high-grade intraepithelial neoplasia (HGIN) and invasive adenocarcinoma.

Materials and methods

Tissue specimens

Colorectal specimens (n=76; surgically removed polypectomies and small biopsies), all formalin fixed and paraffin embedded, were selected from the archives of the Pathological Institute of Freiburg. Upon reclassification (GK, MW) according to the World Health Organization 2000 [10] guidelines, these specimens included 27 samples of LGIN, 16 samples of HGIN and 33 samples of adenocarcinomas of the colon. Normal epithelial samples (n=21) were analyzed in some of the above specimens from adjacent tissues.

Immunohistochemistry

Tissue sections (8 μm) were deparaffinized, hydrated using standard measures and subjected to antigen retrieval using Pronase E (0.05%). Subsequently, tissue sections were incubated with a primary mouse anti-γ-tubulin antibody (1:100; clone GTU-88, Sigma), followed by incubation with a fluorescein isothiocyanate (FITC)-labeled goat-anti mouse IgG (1:200; Dianova). Finally, nuclei were counterstained with 4′6′-diamidino-2-phenylindole-2-hydrochloride (DAPI).

Data collection and in-situ parameter analysis

For data collection, five microscopic areas were selected (63 objective, zoom 2), and three-dimensional image stacks, consisting of 16 planes with a distance of 0.5 μm in the z-axis, were acquired with a confocal laser-scanning microscope (Zeiss LSM 510Meta, PlanNeofluar 63×/1.2 water, zoom 2). Excitation of fluorescent dye was at 351 nm for DAPI and 488 nm for FITC-labeled γ-tubulin. Image stacks were converted into a projection image of all recorded slices and were analyzed semi-automatically with respect to the number of cells (DAPI) and γ-tubulin signals by programs based on the DIAS software package [13, 14]. Furthermore, structural image analysis was performed by measuring the structural entropy of γ-tubulin signals, which quantifies the degree of signal perturbation within a given environment (i.e. selected tissue area), as well as the minimum spanning tree (MST) of γ-tubulin signals, which quantifies the shortest connection of all γ-tubulin signals as mean distance within the selected tissue area [15, 31]. The total number of analyzed cells was between 250 and 300 cells per case.

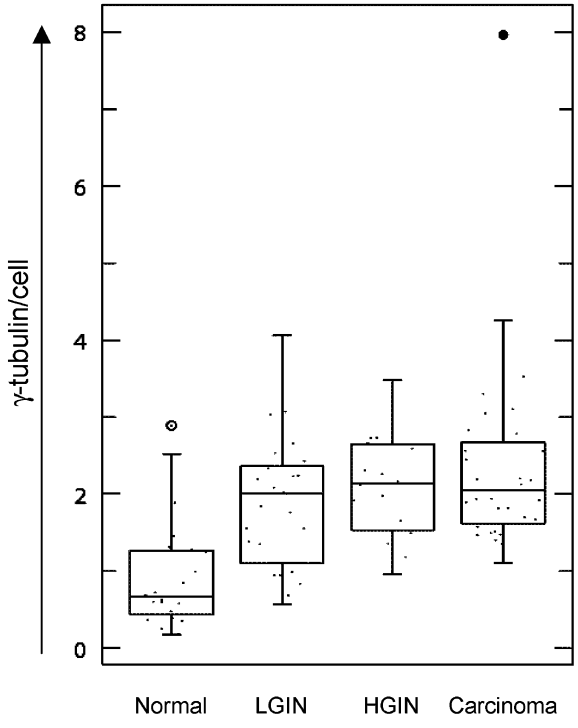

Fig. 1 Summary of the numerical changes of centrosomes along the adenoma–carcinoma sequence of colorectal adenocarcinoma. *Box plots* depict the measured γ-tubulin signals per cell for normal epithelial cells, low- and high-grade intraepithelial neoplasia (LGIN and HGIN) and invasive carcinoma. Each individual sample is indicated by a *dot*, minimum and maximum data points are indicated (*bar*, linked to the box by a line), and one statistical "outsider" (carcinoma) is shown by the *closed circle*

Table 1 Summary of the numerical changes of centrosomes within the adenoma–carcinoma sequence. *DAPI* 4′6′-diamidino-2-phenylindole-2-hydrochloride, *LGIN* low-grade intraepithelial neoplasia, *HGIN* high-grade intraepithelial neoplasia

Histology	γ-Tubulin/ DAPI (per cell)	Fold increase (relative to normal)	Significance (*P*) (relative to normal)
Normal	0.878		
LGIN	1.787	2.035	<0.0001
HGIN	2.259	2.573	<0.0001
Carcinoma	2.267	2.582	<0.0001

Statistical analysis

Statistical analysis was performed on the entire data set collected from all tissue samples using a commercially available software package (NCSS 2000, Number Cruncher Statistical Systems, Kaysville, Utah, USA) and included analysis of variance, the Mann-Whitney U test, the Wilcoxon-Rank test and the Kolmogorov-Smirnov test.

Results

Numerical changes of γ-tubulin staining in the adenoma–carcinoma sequence

In normal colonic epithelial cells (n=21), γ-tubulin staining showed a mean number of 0.88+/−0.6 signals per cell. In LGIN, an increase of γ-tubulin signals to 1.79+/−0.8 per cell was observed. These changes were even more obvious in HGIN, with 2.26+/−0.6 signals per cell, and invasive carcinomas, with 2.28+/−1.2 signals per cell (Fig. 1).

Statistical analysis (summarized in Table 1) of the numerical changes seen in γ-tubulin immunofluorescence stain revealed a significant alteration (P<0.0001) between: (1) normal cells and LGIN, (2) normal cells and HGIN and (3) normal and invasive carcinoma cells. However, the changes of γ-tubulin signals between LGIN and HGIN and invasive carcinoma showed no statistical significance.

Structural changes of γ-tubulin staining in the adenoma–carcinoma sequence

Whilst a regular, apical-orientated distribution of γ-tubulin was seen in normal epithelial cells, a progressively increasing sterical distortion of the γ-tubulin signals was observed in LGIN and HGIN and was most prominent in invasive carcinomas, with a complete loss of orientation (Fig. 2). To quantitatively measure these observations, we performed quantitative and syntactic analysis of: (1) the structural entropy of the γ-tubulin signals and (2) the MST between all γ-tubulin signals within the tissue images.

The structural entropy of the centrosomes within normal epithelium was 3.96+/−1.4 and was raised to 6.39+/−1.6 in LGIN, 5.75+/−1.6 in HGIN and to 6.86+/−2.1 in invasive carcinomas. As seen in the numerical γ-tubulin changes, the structural entropy measurements were also significantly different between normal and neoplastic epithelium (P<

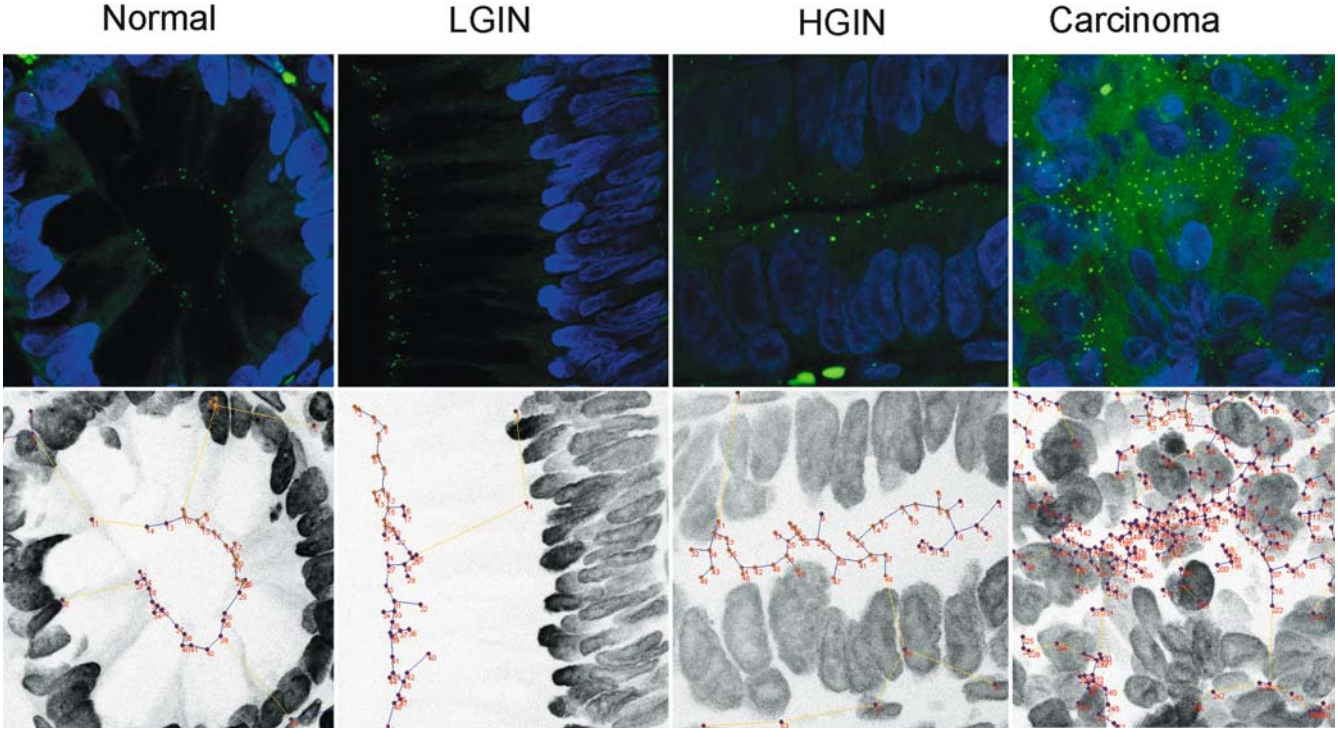

Fig. 2 Changes of centrosomes along the adenoma–carcinoma sequence of colorectal adenocarcinoma. Representative staining of centrosomes by γ-tubulin immunofluorescence (*top row*) and structural analysis of centrosome location by minimal spanning tree (*bottom row*). *Panels from left* normal epithelium, low- and high-grade intra-epithelial neoplasia and far right invasive adenocarcinoma. Magnification: 1260 (63 objective, zoom 2, camera ×10). γ-Tubulin signals are shown in *green*

Table 2 Summary of the structural changes of centrosomes within the adenoma–carcinoma sequence. *MST* minimal spanning tree, *LGIN* low-grade intraepithelial neoplasia, *HGIN* high-grade intraepithelial neoplasia

Histology	Entropy	Significance (relative to normal)	MST	Significance (relative to normal)
Normal	0.0396		38.78	
LGIN	0.0639	<0.001	26.00	<0.001
HGIN	0.0575	<0.001	26.968	<0.001
Carcinoma	0.0686	<0.001	28.08	<0.001

0.001) (Table 2). Together with an elevated number of γ-tubulin signals, this parallel increase of structural entropy may lead to a reduction of the mean distance between γ-tubulin signals, i.e., the MST. Indeed, the measurement of the MST of γ-tubulin signals also revealed significant differences between normal and neoplastic cells ($P<0.001$): the mean MST length in normal mucosa was 38.8+/−13.4 and shortened to 26.0+/−4.0 in LGIN, 27.0+/−3.3 in HGIN and 28.1+/−5.3 in invasive carcinoma.

Discussion

Centrosome dysfunction is closely associated with aneuploidy and chromosomal instability in cell-culture models [32], including colorectal cell lines [7], and has been implicated in a variety of human solid tumors [8, 17, 19, 26] as well as in lymphomas and leukemias [5, 21]. However, the association with and/or involvement of centrosome aberrations at early stages of malignant transformation, such as in dysplastic precursor lesions, have thus far only been addressed in a single study [24].

The present study is, therefore, the first in situ analysis of centrosomes within a large series of normal colonic epithelium, LGIN, HGIN and invasive carcinoma samples of colorectal cancer patients. By visualizing centrosomes with γ-tubulin, a highly conserved component of centrosomes [29, 30], we found not only numerical but also structural aberrations of centrosomes within the adenoma–carcinoma sequence. Moreover, these numerical and structural centrosome changes were already evident at the transition of normal epithelium to LGIN, suggesting that centrosome alterations may represent a very early event in the carcinogenesis of colorectal cancer. In fact, centrosome signals increased twofold from normal to LGIN and threefold from normal to HGIN and invasive carcinoma (Table 1). These observations are in accordance with earlier studies demonstrating that supernumerary centrosomes may occur in pre-invasive lesions of the uterine cervix, prostate and female breast [24], as well as in pre-invasive lesions of the cervix in association with human papilloma virus infections [28].

Centrosome dysfunction may occur not only at the level of numerical changes but also in the failure of structural organization [17, 20, 23]. We, therefore, evaluated whether structural and/or sterical alterations might additionally be involved in centrosomal dysfunction in colorectal carcinogenesis. Indeed, semi-automated image analysis of the structural entropy and MST [13, 14, 15, 31] of γ-tubulin-stained tissues revealed statistically significant changes in centrosome orientation and localization. Concomitantly with the numerical changes, these structural alterations were already present in LGIN.

Finally, the numerical and structural centrosome alterations observed from the transition of normal colonic epithelium to LGIN did not progress further along the adenoma–carcinoma sequence, remaining equally elevated in HGIN and invasive carcinomas.

Together, these results suggest early and stable numerical as well as structural alterations of centrosomes in the carcinogenesis of colorectal cancer. Whether these centrosome alterations are simply a consequence of the well-characterized genetic events of the adenoma–carcinoma sequence [6, 11, 12, 27] or whether they are a primary cause for the progression of a normal epithelium into an (aneuploid) invasive carcinoma remains an open question. However, the early occurrence of centrosome alterations, as seen in our samples of LGIN, may point toward a causative role of centrosome dysfunction in malignant transformation.

In fact, we have obtained further data supporting an early role of centrosome alteration in colorectal carcinogenesis by mRNA expression analysis of STK15, a serine-threonine kinase previously shown to be essential for centrosome function [32]. Similar to the pattern of γ-tubulin staining, STK15 mRNA increased significantly already in LGIN without any further increases in HGIN and carcinoma (Gerlach et al., unpublished observations). Moreover, our preliminary data also suggest that this increase of STK15 mRNA occurs preferentially in the carcinogenesis of chromosomal unstable colorectal tumors, and this appears to also be correlated with the number of γ-tubulin signals/cells. However, further studies have to prove the link of STK15 mRNA and γ-tubulin, i.e., centrosome aberrations, particularly in the development of chromosomal unstable colorectal cancers.

In summary, we have shown that centrosome aberrations are an early event in the adenoma–carcinoma sequence of colorectal adenocarcinomas. These changes are characterized by supernumerary centrosomes and an increasing perturbation in the arrangement of centrosomes within the cells. Both of these alterations may be associated with the induction of aneuploidy in colorectal carcinomas, particularly those that are chromosomally unstable.

Overexpression of carbonic anhydrase-related protein XI promotes proliferation and invasion of gastrointestinal stromal tumors

Received: 5 November 2004 / Accepted: 6 February 2005 / Published online: 8 June 2005
© Springer-Verlag 2005

Abstract Three isoforms of carbonic anhydrase-related protein (CA-RP) are evolutionally well conserved among the CA gene family but lack classical CA activity. Although the biological function of CA-RPs is unknown, overexpression of CA-RP VIII has been reported in certain tumor types. Based on the finding that CA-RPs are commonly expressed in the neuronal cells, we investigated expression of all three CA-RPs in gastrointestinal stromal tumor (GIST). In contrast to no detectable signal of any of the three CA-RPs in intestinal cells of Cajal, immunohistochemical analysis showed distinct cytoplasmic expressions of CA-RPs VIII and XI in 13 (59%) and 20 (91%) of 22 GIST tissue specimens, respectively. The positive signals for both CA-RPs VIII and XI were more intense in the periphery than in the central part of GISTs, whereas no significant signal for CA-RP X expression was observed in any of the GISTs. These expression patterns of CA-RPs were consistently observed by reverse transcription–polymerase chain reaction–Southern blot and immunocytochemistry in the cultured GIST cell line GIST-T1. Ectopic expression of CA-RP XI in GIST-T1 cells induced cell proliferation and invasion in vitro. These findings indicate that CA-RP XI plays a role in the development of GIST.

Introduction

Carbonic anhydrases (CA) are zinc metal enzymes that catalyze the reversible hydration of CO_2 in the reaction $CO_2+H_2O \leftrightarrow HCO_3^-+H^+$ [13]. Among the members of the expanding CA gene family, three isoforms that are evolutionally well-conserved but lack classical CA activity have been reported and designated as CA-related protein (CA-RP): CA-RPs VIII, X, and XI [9]. These three CA-RPs lack one or more histidine residues required to bind the zinc ion, which is essential for CO_2 hydration activity. Recently, CA-RP VIII was reported to bind inositol 1,4,5-triphosphate (IP_3) receptor type I (IP_3R1) and to inhibit IP_3 binding to IP_3R1 by reducing the affinity of the receptor for IP_3 [5]. However, the exact biological function of CA-RPs is still unknown.

We have been working with cDNA cloning and studying expressions of human and murine CA-RPs VIII, X, and XI. Whereas mRNA expressions of CA-RP X and XI are relatively limited to the central nervous system [3, 11, 17], CA-RP VIII is expressed in almost all tissue types [1, 17]. Immunohistochemical analyses showed that all three CA-RPs were expressed in the cytoplasm of neural or glial cells in the central nervous system [16, 17]. Interestingly, CA-RP VIII expression is remarkably increased in colorectal and non-small lung cancer cells as compared with that in their normal counterparts [1, 8]. Furthermore, CA-RP VIII is significantly expressed in the pulmonary epithelial cells in developing lungs [1]. These findings suggest that CA-RPs play some role in the growing process of certain tumor and fetal cells.

Gastrointestinal stromal tumor (GIST) is the most common mesenchymal tumor of the gastrointestinal tract [2]. Most GISTs express a constitutively activated KIT oncoprotein (CD117), a transmembrane tyrosine kinase receptor in which the extracellular portion binds a ligand known as a stem cell factor [4]. A significant proportion of GISTs are also immunopositive for CD34 [2]. These phenotypic markers for GIST are also expressed in the intestinal cells of Cajal (ICCs), intestinal pacemaker cells, which play a neuromotor role in normal gut motility [2]. Accordingly, GIST has been thought to originate from ICC. Being independent of immunoreactivity of KIT and/or CD34, some GISTs express smooth muscle actin or S-100 protein, indicating potential neuromyogenic differentiation of GIST [2]. Our previous study showed the expression of CA-RP VIII and XI in the neural ganglionic cells constituting both myenteric (Auerbach's) and mucosal (Meissner's) plexuses [10]. These findings prompted us to study the expression of CA-RPs in GIST. Along with the results from immunohistochemical studies, we report herein findings obtained in vitro by using cultured GIST cells transformed with the CA-RP XI cDNA.

Materials and methods

Tissue specimens

Surgically resected specimens from 22 patients with GIST (16 primary lesions arisen from the stomach, 2 from the duodenum, and 4 from the small intestine) were used for the immunohistochemical study. Positive KIT expressions were immunohistochemically confirmed in all GIST specimens. No patient had received either preoperative chemotherapy or radiation therapy. To study the expression of CA-RPs in ICC, tissue specimens of the stomach containing hyperplastic ICCs, which were resected from a patient with von Recklinghausen disease, were used. Conforming to the principles of the Declaration of Helsinki, informed consent was obtained from each patient.

GIST cell line

A human GIST cell line, GIST-T1 [15], was used for the transformation study with CA-RP XI. GIST-T1 was originally established from a pleural metastatic lesion in a Japanese patient with gastric GIST, in which heterozygous deletion of 57 bp in the juxtamembrane domain (exon 11) of the c-*kit* gene was identified, resulting in constitutive KIT activation. GIST-T1 cells were strongly positive for KIT and CD34 but not for desmin, S-100 protein, or smooth muscle actin. The cells were cultured in Dulbecco's modified Eagle's medium (Sigma, St. Louis, MO, USA) with 10% fetal bovine serum, 100 U/mL of penicillin G, and 100 μg/mL of streptomycin (Invitrogen, Carlsbad, CA, USA).

Monoclonal antibodies

We previously produced mouse monoclonal antibodies to human CA-RPs VIII, X, and XI that belonged to the IgM subclass [16]. Antibody specificity was evaluated by preabsorption of the positive staining on immunohistochemical analysis using the synthetic peptide, which, as previously reported, had been employed for the immunization of mice to produce the monoclonal antibody [16]. Phenotypic markers for GIST were also immunohistochemically studied: KIT (CD117), by using polyclonal rabbit antihuman c-kit antibody (Dako, Glostrup, Denmark) and CD34 antigens, by using monoclonal mouse anti-HPCA-1 antibody (Becton Dickinson, San Jose, CA, USA).

Immunochemical analyses

Immunohistochemical and cytochemical analyses were performed by means of the streptavidin–biotin peroxidase method without any pretreatment procedures, as previously reported [7, 16]. Briefly, GIST tissues were formalin-fixed and embedded in paraffin. The tissue sections were deparaffinized and incubated with fetal bovine serum. GIST-T1 cells with or without transfection of CA-RP XI were cultured up to approximately 70% confluence on a chamber slide (Nunc, Naperville, IL, USA). The cells on the slide were gently washed with phosphate-buffered saline (PBS) and fixed with 100% acetone for 5 min. The tissue and cultured cell sections were incubated with the monoclonal antibodies to three CA-RPs, KIT, or CD34 at 4°C overnight. After washing with PBS, immunodetection was performed using biotinylated anti-mouse or anti-rabbit immunoglobulin antibody and peroxidase-labeled streptavidin (Dako LSAB kit). Finally, the immunohistochemical reactants were developed with 3, 3′diaminobenzidine. Counterstaining was performed using hematoxylin.

Transfection of CA-RP XI into GIST-T1

A full length of the coding region in the CA-RP XI cDNA was obtained by reverse transcription–polymerase chain reaction (RT-PCR) from a human brain λTriplEx library (Clonetech, Palo Alto, CA, USA) and subcloned into a pCI-neo vector (Promega, Madison, WI, USA) as previously reported [7]. Subsequently, the CA-RP XI cDNA was transfected into GIST-T1 cells by using lipofectamin (Roche, Mannheim, Germany) as previously reported [14]. Transfectants were selected for a 2-week culture in the presence of 800 μg/mL of G418 (Invitrogen) and isolated by a single-cell manipulation technique [14]. Overexpressed mRNA and protein of CA-RP XI were confirmed in the isolated transfectants (GIST-T1-CA11) by RT-PCR–Southern blot and immunocytochemical staining, respectively.

Analyses for mRNA expression of CA-RPs

mRNA expressions of CA-RPs VIII, X and XI in GIST-T1 cells were quantified by real-time PCR and the results were reconfirmed by RT-PCR–Southern blotting. Total RNA was extracted using trizol reagent according to the manufacturer's recommended procedures (Life Technologies, Grand Island, NY, USA). RNA extracts were reverse-transcribed using random hexamers and avian myeloblastosis virus reverse transcriptase by employing a commercial kit (Takara, Kyoto, Japan). For real-time PCR, Assays-on-Demand primers and probes sets were purchased: Hs0018 7850 m1 for CA-RP VIII, Hs00220143 m1 for CA-RP X, and Hs00154213 m1 for CA-RP XI (Applied Biosystems, Tokyo, Japan). Gene-specific PCR products were measured continuously by an ABI PRISM 7000 Sequence Detection System (Applied Biosystems) according to the manufacture's instructions. The relative mRNA expression of three CA-RPs was normalized to the amount of glyceraldehyde phosphate dehydrogenase (GAPDH) in the same cDNA by using the standard curve method described by the manufacturer. For RT-PCR–Southern blotting, the reverse-transcribed cDNAs were amplified by PCR using CA-RP-specific primer pairs. The sequences of the primer pairs were as follows: 5′-TCCTGATGCTAATGGGGAATACC AG-3′ and 5′ CTAAGAGGCTGAGTGGGCCGAAAG-3′ for CA-RP VIII, 5′-AATCAGAGGATGGAAATAGTC TG-3′ and 5′-CTACTTGAGGAGCCATTCATTTA-3′ for CA-RP X, and 5′-GGCAGCAGGTAACATCGGACCAGC-3′ and 5′-GGTTAGAGGTACTGGCCACGTTGAC-3′ for CA-RP XI. The PCR consisted of 30 cycles with denaturation at 94°C for 30 s, annealing at 55°C for 30 s, and elongation at 72°C for 30 s. The PCR-amplified products were electrophoretically separated on a 2.0% agarose gel and transblotted onto a Hybond N+ membrane (Amersham, Tokyo, Japan) according to the previously published method [12]. The membrane was treated with 0.5 N NaOH and processed. DNA probes of three CA-RPs were obtained from poly(A) RNA of the human brain (Clonetech) by RT-PCR with the primer sets described above. The proper cDNA sequence of the probe was reconfirmed by direct sequencing and then used for Southern blotting. The probe DNAs were randomly labeled with digoxigenin using DIG-High Prime (Boehringer, Mannheim, Germany). Hybridization was carried out in Easy Hyb buffer (Roche) at 50°C overnight. After hybridization, the membranes were incubated with an anti-digoxigenin antibody conjugated with alkaline phosphatase buffer (Roche). Alkaline phosphatase reactions were developed on the membranes with CDP-Star

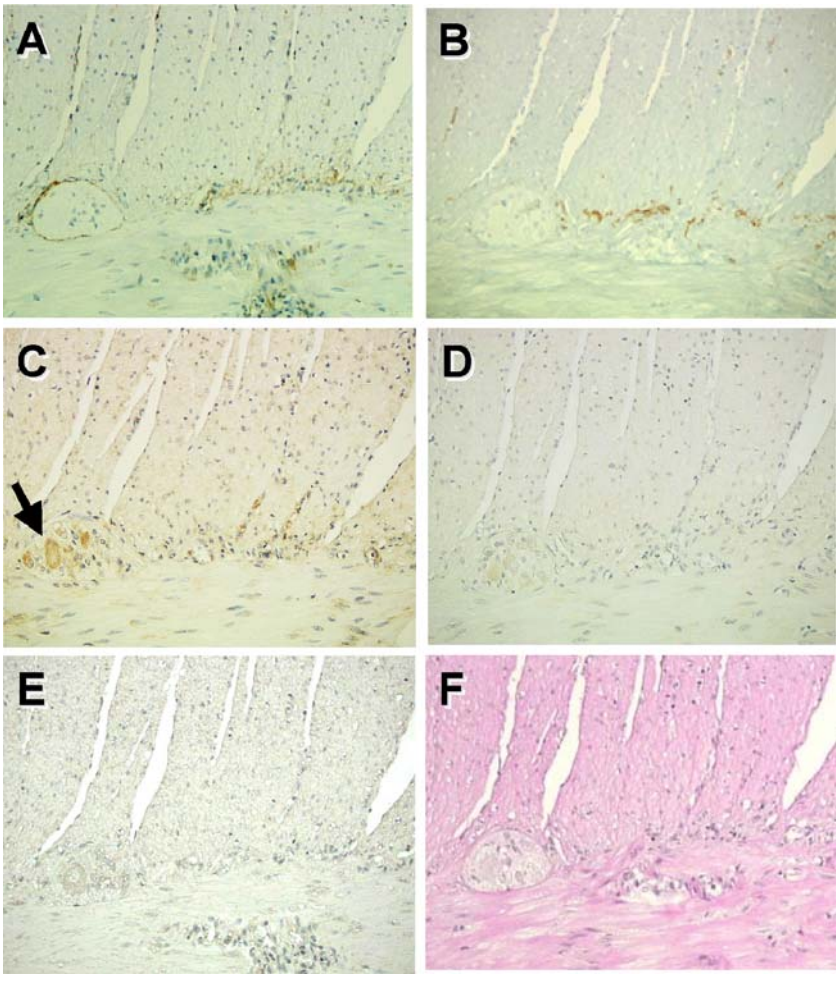

Fig. 1 Immunohistochemical analysis for expressions of CA-RPs, KIT, and CD34 in serial sections of the gastric tissue from a patient with von Recklinghausen disease. Significant signals for expressions of KIT (**a**) and CD34 (**b**) are observed in the myenteric plexus. Distributions of CA-RPs VIII (**c**), X (**d**), and XI (**e**) are completely different from those of KIT and CD34. CA-RPs are expressed in neural cell bodies. Among the expressions of the three CA-RPs, that of CA-RP VIII is most intense (*arrow*; **c**). Hematoxylin-eosin staining (**f**). (Original magnification×80)

Table 1 CA-RP expression in GIST

buffer (Roche) and exposed to X-ray film (Fuji, Tokyo, Japan).

Cell proliferation and invasion assay

Cell proliferation and invasion properties of wild-type GIST-T1 and GIST-T1-CA11 were studied. Proliferation was determined by cell conversion of a tetrazolium salt into a formazan product with a commercial kit (CellTiter 96, Promega). The cells were resuspended at 1×10^5 cells per well in a 96-well plate (Nunc) and cultured for 24, 48, and 72 h. After the addition of 15 μL of a tetrazolium dye solution into the culture wells and incubation for 4 h, 100 μL of a solubilization-stop solution was added. The absorbance at 570 nm was recorded using a 96-well plate reader (Molecular Devices, Sunnyvale, CA, USA).

The property of cell invasiveness was studied by using a blind-well chemotaxis chamber containing an 8-μm pore-size filter with a thin layer of basement membrane Matrigel, which serves as a reconstituted basement membrane in vitro (BioCoat Matrigel invasion chamber, BD Biosciences, Bedford, MA, USA). The cells were resuspended at 1.25×10^5 cells per chamber and cultured for 48 h. The noninvading cells were removed from the upper surface of the filter by scrubbing with a cotton-tipped swab. The cells on the lower surface of the filter were stained with hematoxylin, and then the number of invading cells per high-power field was microscopically counted. Both assays were performed in triplicate.

Statistics

Where appropriate, values are expressed as means±standard deviation. Comparisons were made by Student *t* test, and differences with *P* values of <0.05 were considered significant.

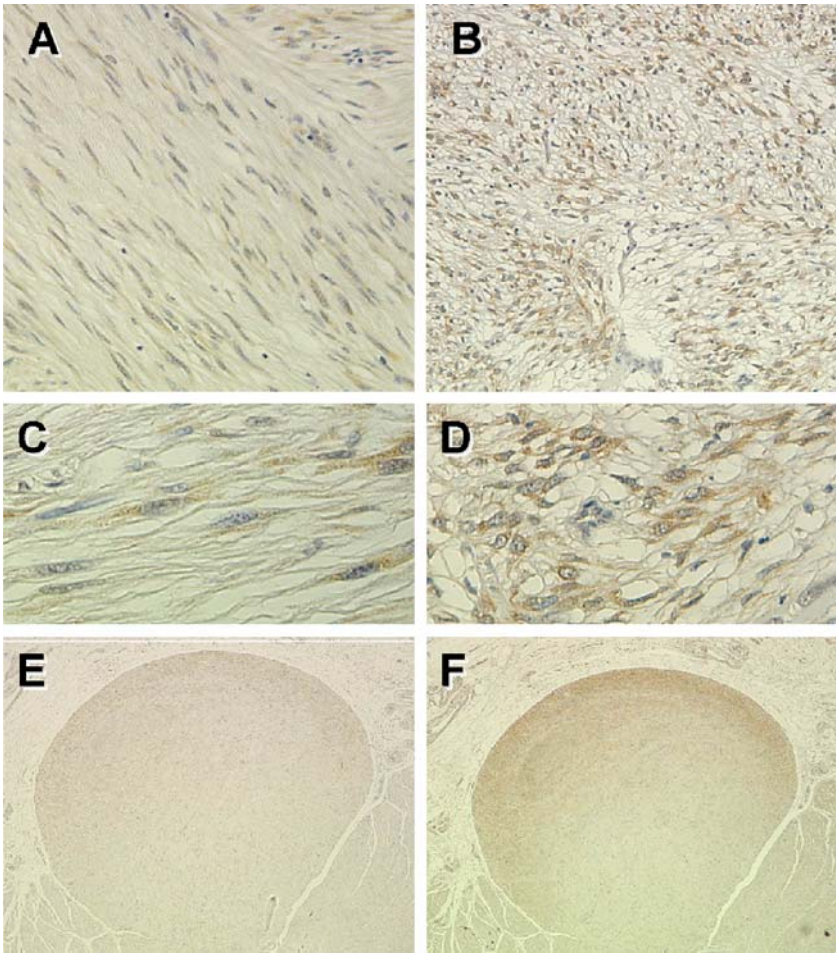

Fig. 2 Immunohistochemical analysis for expressions of CA-RPs VIII and XI in gastrointestinal stromal tumors (*GIST*). Significant signals for CA-RPs VIII (**a**, **c**, and **e**) and XI (**b**, **d**, and **f**) expression are observed in GISTs. Positive signals for both CA-RPs VIII and XI expression are observed in the cytoplasm of GIST cells (**c** and **d**). Expressions of CA-RP VIII and XI are more prominent in the invasive front of the tumor as compared with the central part of the tumor (**e** and **f**)

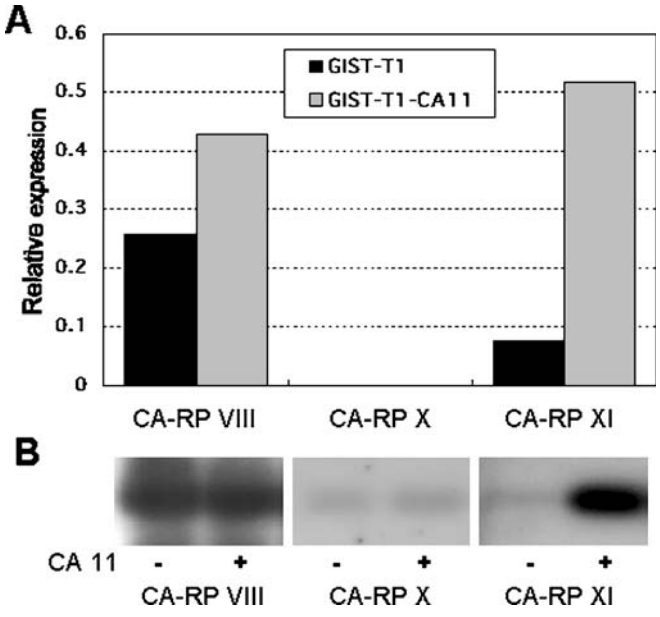

Fig. 3 Quantitative real-time PCR (**a**) and RT-PCR–Southern blot (**b**) for mRNA expression of three CA-RPs in wild-type and CA11-transfected GIST-T1 cells (*GIST-T1-CA11*). Real-time PCR shows 0.076 of relative expression of CA-RP XI mRNA normalized to GAPDH mRNA in GIST-T1 and 0.517 of that in GIST-T1-CA11, yielding 6.803 times increase in CA-RP XI mRNA expression by the CA11-transfection, which is consistent to the finding shown by RT-PCR–Southern blot. Intense signals for CA-RP VIII expression are seen in both GIST-T1 and GIST-T1-CA11 with 1.676 times increase by ectopic expression of CA-RP XI. In contrast, real-time PCR fails to show the standard curve to quantify CA-RP X mRNA expression, and RT-PCR–Southern blot shows very weak signals for CA-RP X in both GIST-T1 and GIST-T1-CA11

Results

CA-RP expression in ICC

Expression of three CA-RPs, KIT (CD117), and CD34 was studied in serial sections of the gastric tissue specimen in a patient with von Recklinghausen disease (Fig. 1). Immunohistochemical analysis revealed significant signals for expressions of KIT (CD117) and CD34 in the myeteric plexus (Fig. 1a, b, respectively). Distributions of all three CA-RPs (Fig. 1c–e) were completely different from those of KIT and CD34; CA-RPs were expressed in neural cell bodies. Among the expressions of the three CA-RPs in the neural cell bodies, that of CA-RP VIII was most intense (Fig. 1c, arrow).

CA-RP expression in GIST

Immunohistochemical analysis showed significant signals for CA-RP VIII and XI expression in 13 (59%) and 20 (91%) of 22 GIST tissue specimens, respectively (Table 1). In contrast, no significant signal for CA-RP X expression was observed in any of the GIST specimens studied herein. Positive signals for both CA-RPs VIII and XI expression were observed in the cytoplasm of GIST cells (Fig. 2a–d). Expressions of CA-RPs VIII and XI are more prominent in the periphery of the tumor as compared with the central part of the tumor (Fig. 2e, f).

CA-RP XI transfection into GIST-T1 cells

GIST-T1 cells were transfected with the CA-RP XI cDNA ligated into the expression vector (GIST-T1-CA11), and mRNA and protein expression of three CA-RPs were studied. Quantitative real-time PCR showed 0.076 of relative expression of CA-RP XI mRNA normalized to GAPDH in wild-type GIST-T1 and 0.517 of that in GIST-T1-CA11, yielding 6.803 times increase in CA-RP XI mRNA expression by the transfection (Fig. 3a). This was confirmed by RT-PCR–Southern blot analysis, showing remarkably increased expression of CA-RP XI mRNA in GIST T1-CA11 as compared to that in GIST-T1 (Fig. 3b). Immunocytochemical analysis also showed an increased expression of CA-RP XI protein in GIST-T1-CA11 as compared to GIST-T1 (Fig. 4). Intense signals for CA-RP XI expression were observed in the cytoplasm of GIST-T1 cell bodies.

Strong signals for mRNA and protein expression of CA-RP VIII were observed in both GIST-T1 and GIST-T1-CA11 (Figs. 3 and 4). Although there was no obvious difference in CA-RP VIII mRNA expression level between GIST-T1 and GIST-T1-CA11 (1.676 times increase by the transfection; Fig. 3a), interestingly, subcellular localization of CA-RP VIII protein was altered. CA-RP VIII was observed in the perinuclear area of GIST-T1, whereas in GIST-T1-CA11, it was seen in the whole cell body (Fig. 4). Real-time PCR failed to show the standard curve to quantify CA-RP X mRNA expression and RT-PCR–Southern blot showed a very weak signal for CA-RP X in both GIST-T1 and GIST-T1-CA11. Immunocytochemical analysis also showed no significant signal for CA-RP X expression in both GIST-T1 and GIST-T1-CA11. These findings indicate a trace level expression of CA-RP X in GIST-T1 and it is not influenced by ectopic expression of CA-RP XI.

Effects of CA-RP XI on proliferative and invasive properties of GIST-T1 cells

Cell proliferation assay showed no significant difference in cell growth between GIST-T1 and GIST-T1-CA11 after 24 h culture (Fig. 5a). After culture for 48 and 72 h, proliferative cell numbers of GIST-T1-CA11 had increased significantly more than that of GIST-T1 ($P<0.002$ and $P<0.005$, respectively). Meanwhile, cell invasion assay showed a significantly increased number of GIST-T1-CA11 (39.7±3.1/high-power field), which invaded through a thin layer of basement membrane Matrigel, as compared to that of GIST-T1 (6.7±4.6/high-power field; $P<0.005$) (Fig. 5b).

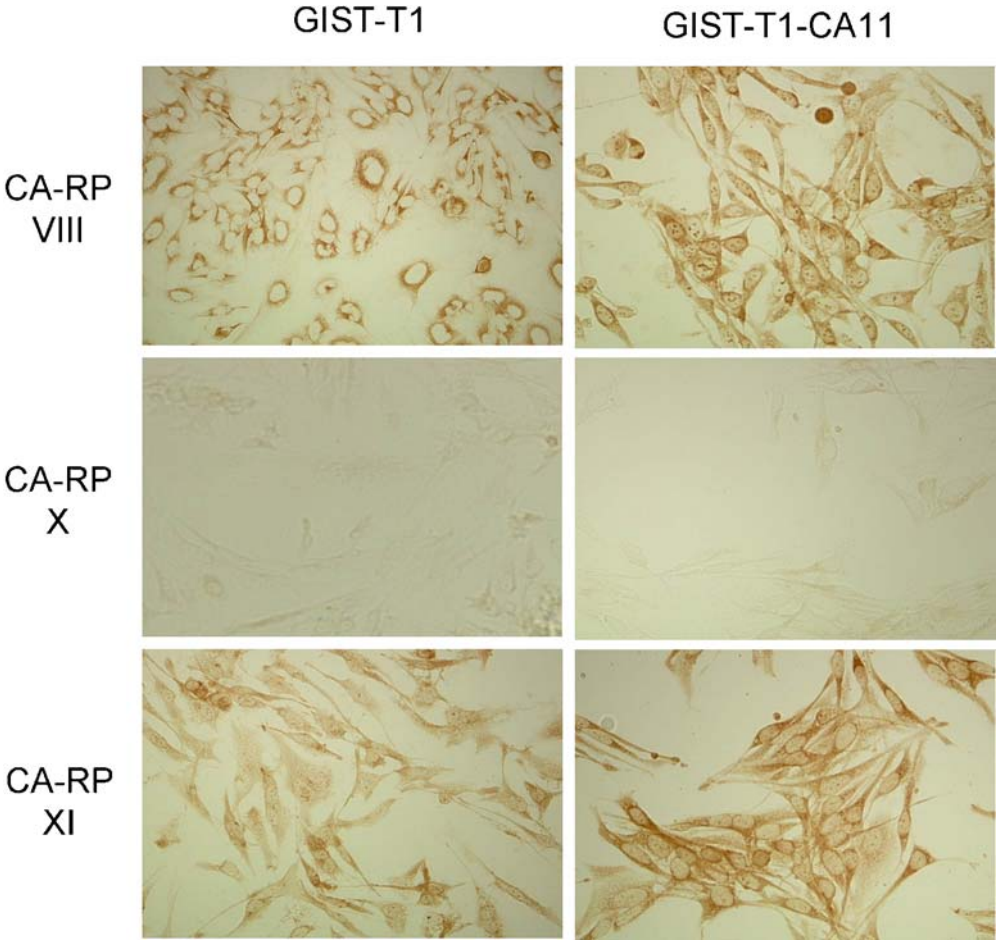

Fig. 4 Immunocytochemical analysis for expressions of three CA-RPs in wild-type and CA11-transfected GIST-T1 cells (*GIST-T1-CA11*). An increased expression of CA-RP XI protein is observed in the cytoplasm of GIST-T1-CA11 as compared to GIST-T1. In contrast, a trace level signal for CA-RP X is seen in both GIST-T1 and GIST-T1-CA11. CA-RP VIII is expressed in the perinuclear area of GIST-T1, whereas in GIST-T1-CA11, it is seen in the whole cell body

Discussion

To date, GIST has been believed to arise from ICC because both cell types express the characteristic phenotypic markers KIT and CD34 [2]. In this study, the distribution of CA-RPs was shown to be completely different from those of ICCs. Furthermore, ICCs exhibited no detectable signal for expression of any of the three CA-RPs, whereas GIST

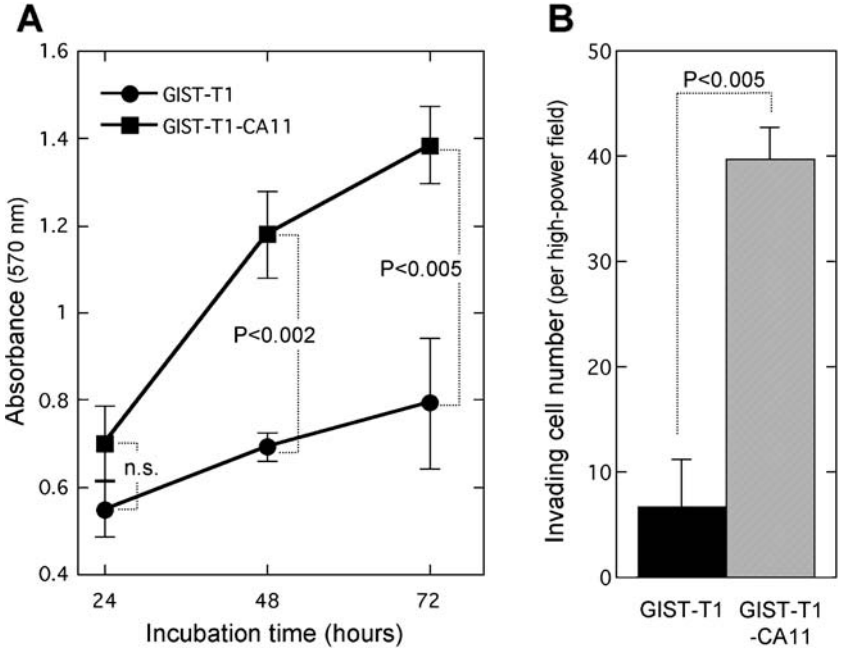

Fig. 5 Proliferation and invasion properties of wild-type and CA11-transfected GIST-T1 cells (GIST-T1-CA11). **a** Cell proliferation assay shows no significant difference in cell numbers between two cell types after 24-h culture. After culture for 48 and 72 h, proliferative cell numbers of GIST-T1-CA11 have increased significantly more than that of GIST-T1 ($P<0.002$ and $P<0.005$, respectively). **b** Cell invasion assay shows a significantly increased number of GIST-T1-CA11 (39.7±3.1/high-power field), which invades through a thin layer of basement membrane Matrigel, as compared to that of GIST-T1 (6.7±4.6/high-power field) ($P<0.005$)

cells significantly expressed CA-RPs VIII and XI in their cytoplasm. We previously reported that CA-RP VIII expression is remarkably up-regulated during carcinogenesis of lung and colorectal epithelial cells [1, 8] and also during fetal development of the pulmonary epithelium [1]. Although the exact biological function of CA-RPs has not yet been elucidated, these findings suggest that CA-RPs VIII and XI play a possible role for GIST development.

Most GISTs (91%, *n*=22) showed CA-RP XI overexpression. In contrast, CA-RP VIII expression was seen in 59% of GISTs, and there was no GIST showing a detectable signal for CA-RP X expression on immunohistochemical studies. These findings suggest that CA-RP XI has a more significant role in the progression of GIST than do the other two CA-RPs. Accordingly, we focused on the effect of CA-RP XI expression in vitro on biological properties of cultured GIST cells GIST-T1. We found that CA-RP XI-overexpressed GIST-T1 cells showed significantly increased capacities of cell proliferation and invasion as compared to wild-type GIST-T1 cells. We obtained similar findings in a previous study using the lung cancer cell line PC-9. CA-RP VIII-overexpressed PC-9 cells grew faster than wild-type PC-9 cells on laminin-coated dishes [7]. Furthermore, in the present study, expression of CA-RPs VIII and XI was much more intense in the marginal area of GISTs than in the central part of the tumor (Fig. 2). CA-RP VIII was also reported to be overexpressed at the invasion front of colorectal and lung cancer tissues [1, 8]. These findings indicate that not only CA-RP VIII but also CA-RP XI function to enhance the proliferation and invasion of certain tumor cells. CA-RP VIII and XI are evolutionally well-conserved isoforms [9]. The difference of CA-RP isotype expression between GIST and colorectal or lung cancer might be due to the different cell origins: that of the colorectal and lung cancers are derived from epithelial cells and that of the GIST arises from ICC, which belongs to the mesenchymal cell types [4].

The molecular mechanism by which CA-RP XI enhances proliferative and invasive properties of GIST cells is still uncertain. Although constitutive KIT activation was shown, GIST-T1 cells showed a low expression level of CA-RP XI. These findings indicate that enhancement of cell growth and invasion by CA-RP XI are not directly related to KIT. Interestingly, it was reported that malignant GIST cells had the gene amplification of chromosome 19q13 [6], on which the CA-RP XI gene has been reported to locate [4]. Although there was no direct evidence of an increased copy number of the CA-RP XI gene, gene amplification might be a possible explanation for the increased expression of CA-RP XI in GIST.

An additional finding obtained in the present study is the subcellular localization of CA-RPs in GIST-T1 cells. Consistent with immunohistochemical findings, CA-RPs VIII and XI were expressed in the cytoplasm of GIST-T1, but CA-RP X was undetectable in any part of the cell. Interestingly, whereas CA-RP VIII appears to be condensed in the perinuclear area in wild-type GIST-T1, CA-RP VIII was dramatically spread throughout the cytoplasm of GIST-T1-CA11 cells. Recently, CA-RP VIII was reported to bind inositol IP_3R1 and to inhibit IP_3 binding to IP_3R1 by reducing the affinity of the receptor for IP_3 [5]. IP_3R1 is known to be expressed on the membrane of the endoplasmic reticulum; thus, the perinuclear localization of CA-RP VIII suggests its colocalization with IP_3R1. This idea leads to further speculation; in GIST-T1-CA11 cells, ectopic CA-RP XI expression could substitute for CA-RP VIII to bind IP_3R1, resulting in the wide distribution of CA-RP VIII in the cytoplasm. To verify these hypotheses, an immunocoprecipitation study using a panel of antibodies reactive with three types of IP_3R and with three CA-RPs is currently underway.

In summary, although ICC showed no expression of any of the three CA-RPs, GIST cells demonstrated strong expression of CA-RPs VIII and XI. Overexpressed CA-RP XI possibly substitutes for CA-RP VIII in the cytoplasm and enhances the proliferation and invasion of GIST cells. Although the regulatory mechanism of CA-RP expression remains uncertain, these findings indicate that CA-RP VIII and XI play respective roles in the development of GIST.

Early atherosclerotic lesions in infancy: role of parental cigarette smoking

Received: 18 October 2004 / Accepted: 6 February 2005 / Published online: 10 June 2005
© Springer-Verlag 2005

Abstract Cigarette smoking is associated with an increased incidence of atherosclerotic diseases. The aim of this study was to examine the progression of the preatherosclerotic lesions previously observed by us in coronary arteries of fetuses of smoker mothers and in infants with smoker parents. We examined the coronary arteries of 34 infants, aged 1–36 months, and the histological and biological [c-*fos*, proliferating cell nuclear antigen (PCNA), and apoptosis] features of the early atherosclerotic lesions. In 17 infants (50%), at least one parent smoked, generally more than five cigarettes a day. In 18 cases (53%), we observed variable thickening of the coronary walls from preatherosclerotic lesions to juvenile atherosclerotic plaques, related to parental smoking habit. This morphological progression of the lesions was accompanied by a sequence of biological changes in the smooth muscle cells of the tunica media. We suggest that the oxidants present in the gas phase of the parental cigarette smoke pass through the endothelium and induce at first the c-*fos* gene activation and subsequently the PCNA positivity, that is, a proliferative process.

Introduction

The atherogenic role of cigarette smoking is well-known. In particular, numerous epidemiological studies have shown that cigarette smoking is a major cause of cardiovascular diseases [3, 24, 32, 42, 44]. Tobacco smoking has been implicated both in the initiation and the progression of atherosclerotic vascular lesions [21, 41, 43, 44], but the precise mechanism by which cigarette smoke induces atherosclerosis is not yet fully established.

Recently, we demonstrated the presence of preatherosclerotic coronary artery lesions in human fetuses and infants of smoker mothers [28–30]. Our findings prompted us to continue the search to appraise whether there is progression of such lesions in infants with smoker parents. In this study, we examined on serial sections the coronary arteries of 34 subjects who died during the first years of life, including 21 cases of sudden infant death syndrome (SIDS). Our purpose was to correlate the possible presence of structural alterations of the vessel walls with one or both parents' smoking habit. In addition, following the protocol previously applied to fetal and infants' coronary arteries [28–30], we investigated the possible presence of some biological markers, namely, high expression of the proliferating cell nuclear antigen (PCNA), activation of the proto-oncogene c-*fos*, and apoptosis, which we previously described in the active atherosclerotic process [25, 26, 29, 30].

Materials and methods

We examined the coronary arteries of 34 infants, 20 males and 14 females, aged from 1 to 36 months. Twenty-one were victims of SIDS and 13 died of other causes (Table 1).

Table 1 Case profiles with morphological and biological results

m Maternal smoking, *p* paternal smoking, *A* preatherosclerotic lesion, *B* juvenile plaque (*B1* initial plaque, *B2* advanced soft plaque), *SIDS* sudden infant death syndrome

Pregnancy in all cases had run a normal course. The mothers, aged between 24 and 34 years, were all healthy and under good socioeconomic conditions. All the subjects considered in this study were breast-fed.

Clinical data collected for each case included any parental cigarette smoking habit (mother's cigarette smoking before and/or during pregnancy, postnatal cigarette smoking of one or both parents, and in all cases, the number of cigarettes smoked daily). In 17 cases (50%), at least one parent smoked, generally more than five cigarettes a day, keeping or even increasing the smoke habit after the child's birth. In the smoker mothers, the smoking habit had started before pregnancy.

Coronary arteries examination According to the protocol followed by Roberts and Jones [37], the hearts were fixed in formalin for at least 1 day. The four major epicardial coronary arteries (left main, left anterior descending, left circumflex, right) were excised transversely to the longitudinal axis into segments approximately 2–4 mm long. Each segment was labeled sequentially either from its aortic ostium or from its origin from the left main coronary artery, dehydrated, embedded in paraffin block, and serially cut. The first serial sections of each block were stained with hematoxylin–eosin, trichromic Heidenhain (Azan) for histological examination, Alcian blue at pH 0.5 and 2.5 for acid mucopolysaccharides analysis, hyaluronidase–

Alcian blue for hyaluronic acids detection, and Weigert for elastic fibers identification. The following sections were submitted to specific immunohistochemical methods for lymphocyte, monocyte, and smooth muscle cell (SMC) typing and for PCNA, c-*fos*, and apoptosis detection.

Cellular typing

Immunophenotyping of the cells present in each lesion was performed using the immunoperoxidase technique with the following primary antibodies (Dako, Carpinteria, CA): anti-α-smooth muscle actin (1A4, Dako) to identify SMCs, anti-CD68 (EBM11, Dako) to identify monocytes, and anti-CD20 (L26, Dako) and anti-CD45RO (UCHL-1, Dako) to identify B- and T-lymphocytes, respectively.

Biological marker immunohistochemistry

Proliferating cell nuclear antigen Sections were air-dried overnight at room temperature and immunostained with the monoclonal antibody PC 10 at a dilution of 1:200, using an immunoperoxidase method (ABC complex) with light hematoxylin counterstaining. Only nuclei with intense immunostaining were considered to be PCNA positive.

c-fos Sections were deparaffinized in xylene and rehydrated. Endogenous peroxidase was blocked by incubating with 3% hydrogen peroxide for 5 min. After washing in phosphate-buffered saline (PBS), the sections were incubated with 10% normal goat serum and then with 1:100 diluted polyclonal anti-c-*fos* antibody (SC-52P, Santa Cruz Biotechnology, Santa Cruz, CA) at room temperature for 1 h. After washing in PBS for 5 min, the sections were incubated for 30 min with the biotinylated goat antirabbit IgG antibody supplied in the kit, then incubated with streptavidin–peroxidase for 30 min, stained with 3-3′-diaminobenzidine tetrahydrochloride (DAB, Sigma, St. Louis, MO) solution (30 mg of DAB and 0.5 ml of 0.3% hydrogen peroxide in 100 ml of 0.05 M Tris–HCl, pH 7.6), and counterstained with Mayer's hematoxylin. The cells with intense brown immunostaining were considered to be c-*fos* positive.

Apoptosis The sections were deparaffinized and incubated with 20 μg/ml proteinase K (Sigma St. Louis, MO 63178). After blocking the endogenous peroxidase with 3% H_2O_2, deoxynucleotidyl transferase (TdT 0.3 U/ml) was used to incorporate digoxigenin-conjugated deoxyuridine (dUTP 0.01 mM/ml) into the ends of DNA fragments. The TdT-mediated dUTP nick end labeling (TUNEL) signal was then detected by an antidigoxigenin antibody conjugated with peroxidase (Apoptag Peroxidase In Situ Apoptosis Detection kit, Oncor, Gaithersburg, MD). Apoptotic nuclei were identified by the presence of dark brown staining. Counterstaining was performed by immersing the slides in methyl green for 10 min.

All the sections obtained from the above immunohistochemical techniques were examined using a ×40 lens. For all the immunohistochemical methods, negative controls were prepared replacing the respective primary antibodies with PBS in the incubation. In these procedures, staining always failed to occur.

Immunohistochemistry evaluation

To evaluate the immunoreactivity for c-*fos*, PCNA, and apoptosis, we applied for each method a rating system based on the examination of all the immunostained sections. Only cells with very intense brown staining were considered to be positive. We have quantified the scoring for each case as − (no positive cell or presence of weakly immunostained cells), + (a number of positive cells 30% or less, low positivity), ++ (a number of positive cells more than 30% and less than 60% or less, moderate positivity), and +++ (a number of positive neurons 60% or more, high positivity).

The scores, referred to bilateral sides of every nucleus, were assigned by two independent and blinded observers, and comparison among the data was performed to evaluate the interobserver reproducibility. In case of discordance among the investigators, the case was reviewed and discussed until the same result was obtained.

Statistical analysis

The statistical value of the results was determined using the analysis of variance test (*F* test). The selected level of significance was $p<0.05$.

Definition of terms

Preatherosclerotic lesions

The earliest morphologically recognizable alterations are characterized by fragmentation of the tunica media with intense infiltration of SMCs, often arranged perpendicularly in columns or tangentially to the axis of the tunica itself. These SMCs infiltrate the intima, which tends to be thickened, also due to initial mucopolysaccharide deposits, mainly composed of type A and C chondroitin sulfates and of hyaluronic acid. Rare monocytes and B-lymphocytes are also present. The endothelium is morphologically intact. The internal elastic membrane appears to be focally fragmented [28, 29].

Juvenile soft atherosclerotic plaques

Such lesions are characterized by wide myointimal thickness with alteration of elastic fibers and of the tunica media. They are defined as "soft plaques" as they have abundant SMCs, associated with moderate infiltration of

monocytes and rare lymphocytes. Amorphous deposits of acid mucopolysaccharides, mainly composed of B chondroitin sulfates, are present, occasionally also in the internal portion of the tunica media. There is evident fragmentation of the elastic fiber system and of the tunica media. The endothelium is morphologically intact. Reduction of the lumen varies from approximately 10–15% to 30–40% [25, 29, 30].

Results

Table 1 shows the relationships between the results obtained from the morphological examination of the coronary arteries of the 34 victims, the parental smoking habit, and the biological markers.

At the histological study, a normal structure was found in 16 cases. In 18 cases (53%), there was a variable thickening of the walls: in 2 cases (cases 1 and 5), the lesions were preatherosclerotic (Fig. 1), mostly located in the anterior descending branch of the left coronary artery, whereas in 16 cases, juvenile soft atherosclerotic plaques of variable entity were observed in all the coronary branches, with a lumen decrease of up to 30–40% (Fig. 2).

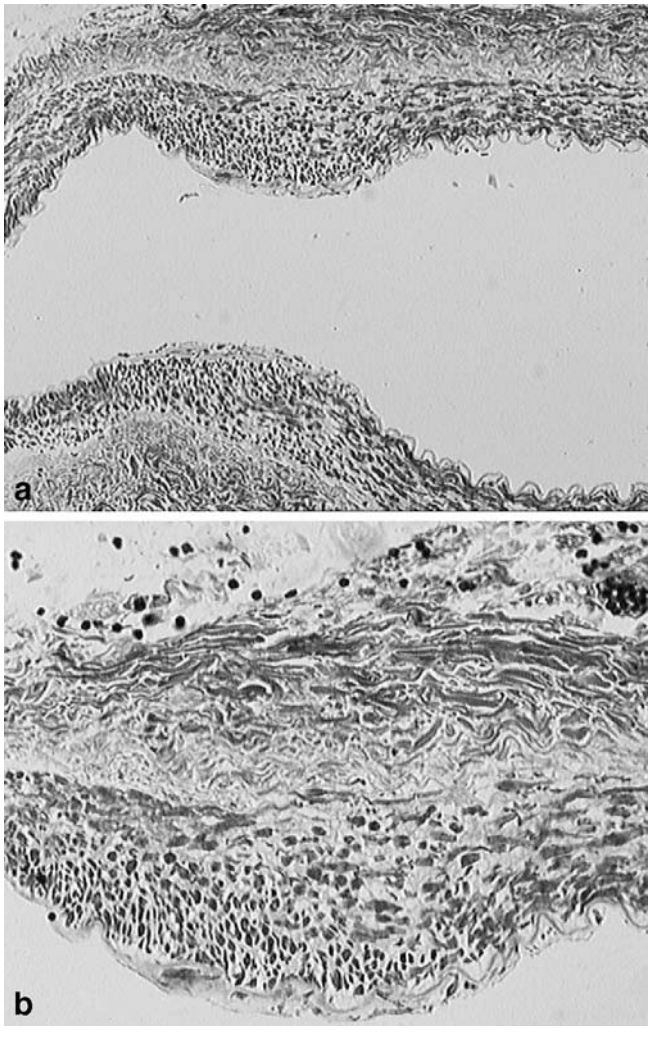

Fig. 1 Preatherosclerotic lesion in an epicardial coronary artery (left anterior descending branch) of an infant aged 2 months (case 5). The focal thickness consists of medial SMCs, perpendicularly oriented. Azan stain, **a** ×100; **b** ×200

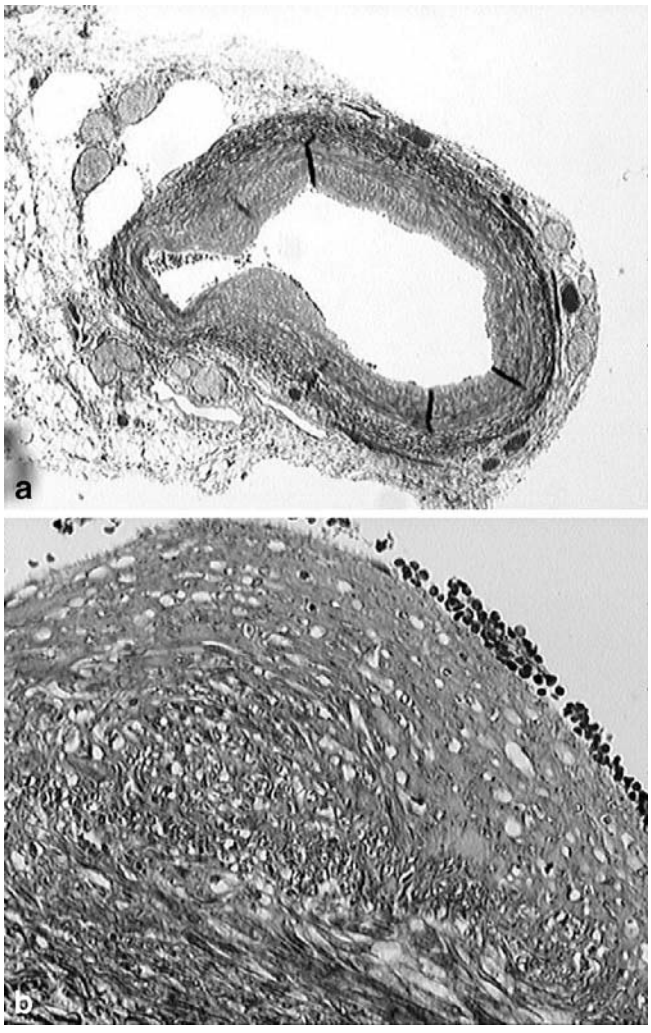

Fig. 2 Juvenile soft atherosclerotic plaque in an epicardial coronary artery (left anterior descending branch) of an infant aged 4 months (case 12). The myo-intimal thickness shows numerous SMCs and increased amounts of mucoid ground substance. Azan stain, **a** ×25; **b** ×200

We found a significant correlation ($p<0.05$) between such atherosclerotic lesions and the parental smoking habit, referred in 17 cases (50%). Only in three cases (20, 21, and 25) arterial lesions were observed in infants with nonsmoker parents, and only in two cases (3 and 24) with a smoker father did the coronary walls show a normal structure.

The preatherosclerotic lesions observed in two infants, aged 1 and 2 months, respectively, with a smoker mother, are characterized by initial alteration of the architecture of the tunica media, which appears focally fragmented and presents columns of SMCs perpendicularly located to the axis of the media itself (preatherosclerotic lesions). Together with rare monocytes and B-lymphocytes, these elements infiltrate the tunica intima, which tends to be

thickened, also due to the initial deposit of mucopolysaccharides. Focal alterations of the elastic fibers system, characterized by detachment and fragmentation of the fibers, were detected.

In infants older than 2 months with smoker parents, a progression of such coronary lesions is generally observed. The lesions are characterized by the formation of initial plaques that gradually increase mainly after the first 6 months, have abundant SMCs, and markedly reduce the coronary lumen, even up to 40% (juvenile soft atherosclerotic plaques).

Our findings demonstrate a correlation between the infants' age and the lesions' histological and biological aspects and progression. In fact, in the first 3 months of age, preatherosclerotic or juvenile plaques (B1) are found, mainly characterized by c-*fos* and apoptosis positivity. In infants 4 months or older, the SMCs are PCNA positive whereas are mostly c-*fos* and apoptosis negative. The percentage of PCNA-positive SMCs increases with age.

The most frequent result of the biological analysis was PCNA positivity observed in a relatively low number of SMCs in 9 of the 18 observed lesions (50%), having the prevalent appearance of juvenile soft plaques. The number of PCNA-positive SMCs was increased in cases 26, 30, and 34, corresponding to subjects aged 12, 18, and 36 months, respectively, whose plaques were advanced.

In six lesions (33%), a moderate number of c-*fos*-positive SMCs, and in four cases (22%), a moderate (++) apoptotic index were observed. Positivity for both the c-*fos* gene and apoptosis was a prevalent feature of infants aged a few months.

Discussion

In our previous works [28, 30], we have reported preatherosclerotic lesions in the coronary arteries of fetuses after the 35th gestational week, demonstrating a significant correlation with the mothers' smoking habit during pregnancy. We then described the early atherosclerotic lesions in infants, particularly if bottle-fed and with smoking parents [29, 30].

In the present study, we showed the progression of these lesions up to the development of juvenile soft atherosclerotic plaques in infants and pinpointed the fundamental atherogenic role of cigarette smoke. In fact, we detected a significant correlation between the atherosclerotic lesions in infant coronaries and the parental cigarette smoking habit. Other atherogenic factors were not identified. All the analyzed infants were the products of uncomplicated pregnancies of healthy mothers under good socioeconomic conditions, and all were breast-fed.

We noticed different morphological aspects of the coronary lesions in relationship to the infant's age and, therefore, to the duration of exposure to the noxious action of cigarette smoke.

The first early alterations of preatherosclerotic type were observed in the first 2 months of life. These lesions are characterized by alterations of the tunica media that become focally fragmented with intense infiltration of SMCs. Such fibrocells seem to lose their polarity and migrate toward the intima in columnar structures, progressively contributing, together with the initial deposition of acid mucopolysaccharides, to the formation of myointimal thickness.

As the lesions progress, myointimal thickening grows and successively soft atherosclerotic plaques appear.

This progression in the morphological appearance of the coronary lesions is accompanied by a sequence of biological changes. In fact, in the atherosclerotic lesions observed in the first months of life, the activation of the c-*fos* gene is evident. The proto-oncogene c-*fos* belongs to the family of "immediate early genes," so defined for their ability to become rapidly activated in the presence of noxious signals in a variety of vascular and nonvascular cells, because they do not require de novo protein synthesis [6, 14, 33].

In some of these primary lesions, immunopositivity of the SMCs for apoptosis was also observed. Many authors have provided morphological and biochemical evidence of apoptotic cell death in both experimental and human advanced atherosclerotic plaques [9, 10, 12, 16].

Cell death by apoptosis occurs during different stages of the evolution of the progression of the atherosclerotic process in a coordinate and highly regulated fashion that requires the expression of certain groups of genes critical for cellular signal transduction and metabolism. Besides, complex interactions between extracellular microenvironmental factors and intrinsic gene products occur before apoptosis begins [10]. In advanced atheroma, cell death may contribute to aneurysm formation and to weakening of the fibrous cap, enhances thrombogenicity of the lesion core, and increases the risk of plaque disruption.

Our observation of apoptotic cells in initial phases of atherosclerosis cannot have similar significance. This finding can be interpreted, as suggested by several authors [13, 19], as a beneficial physiological attempt to prevent the evolution of the atherogenic process and to preserve the wall structure under normal conditions.

Atherosclerotic progression is testified by the biological events in the coronary walls of infants aged more than 4 months. These consist prevalently of a moderate number of PCNA-positive SMCs that are increased in the more advanced lesions observed in older infants. This finding suggests that c-*fos* gene overexpression could promote a proliferative process. In fact, PCNA, principally expressed during the S phase of the cell cycle, is a specific marker of cellular replication [23, 26, 27].

Based on the biological data obtained in this study and on the observation in our previous works [26, 28] of intense overexpression of the proto-oncogene c-*fos* in preatherosclerotic lesions of coronary arteries of fetuses with smoker mothers, we can postulate that the first morphologically detectable signal of human atherosclerosis determined by cigarette smoke is c-*fos* gene alteration in the SMCs of the tunica media. Activation of the c-*fos* gene seems to promote a process of SMCs transformation with loss of

the differentiated state and acquisition of the ability of ameboid movement, then migration toward the intima.

Several authors [5, 7, 20, 40] have reported that in atherosclerosis, there are two types of SMCs, the contractile or quiescent type, characterized by the presence of typical SMCs contractile proteins, such as α-actin and SM myosin, and inability to undergo cytokinesis, and the synthetic or activated type, characterized by the loss of contractile function, a decrease of contractile proteins with a typical switch in actin expression from α- to β-form, an increase in rough endoplasmic reticulum, and increased synthetic and proliferative capacity. The dedifferentiated cells we observed to be involved in intimal thickening correspond to activated type SMCs and also to cells defined by Schürch et al. [39] as "myofibroblasts," having features in common with both SMCs and fibroblasts [8, 31].

Recently, experimental studies [11, 22, 36] have shown that in vascular SMCs, proto-oncogene expression, and in particular, c-*fos* levels, can be stimulated by exogenous and endogenous oxidants. Besides, Ikebuchi et al. [15] demonstrated that in cell cultures, exogenously added O_2 could also cause a rapid increase in intracellular pH and, subsequently, cytoplasmic alkalinization, considered to be an important early signal for the initiation of DNA synthesis.

More than 4,000 individual constituents that have been identified in cigarette smoke include polycyclic aromatic hydrocarbons such as benzopyrene, cadmium, nicotine, and also oxidants [1, 2, 4, 17]. Oxidative stress produced by cigarette smoke has been demonstrated by some authors in experimental studies to contribute to the pathogenesis of atherosclerosis, directly influencing the oxidation of plasmatic low-density lipoproteins (LDLs), which are taken up by macrophages to form foam cells [31, 35, 38, 45, 46].

We suggest, also based on interpretations by others' report on this issue [18, 22, 34, 36], that the oxidants present in the gas phase of cigarette smoke could determine the sequence of biological events in the arterial walls observed in this study. First, the oxidants pass through the endothelium, without causing morphologically identifiable alterations, and induce immediate and intense stimulation of the c-*fos* gene in the SMCs of the media. These cells, so activated, reacquire the primordial characteristic of ameboid movements and leave the media to move through the intima toward the lumen. Subsequently, again, due to the oxidative effect of the cigarette smoke, the c-*fos* gene exerts its mitogenic effect. This is confirmed by the presence of PCNA-positive SMCs in the coronary arteries of older infants.

Therefore, we can maintain that parental cigarette smoking is associated with an increased risk of coronary atherogenesis that begins very precociously in fetal life, as demonstrated in our previous work [28], and, persisting the parents' smoke habit, progresses through definite morphological and biological sequential stages toward true atherosclerotic plaques.

All the findings presented herein underline the severe atherogenic effect of cigarette smoke and the need to prevent cardiovascular diseases already during prenatal life.

Atypical presentations of solitary fibrous tumors of the central nervous system: an analysis of unusual clinicopathological and outcome patterns in three new cases with a review of the literature

Received: 20 October 2004 / Accepted: 28 January 2005 / Published online: 31 May 2005
© Springer-Verlag 2005

Abstract Central nervous system (CNS) solitary fibrous tumors (SFTs) are rare mesenchymal neoplasms recognized less than a decade ago. Approximately 60 cases of SFT have been reported in the central nervous system. We describe three atypical SFTs of the CNS, two intracranial and one within the spine. One intracranial SFT arose from the sella turcica and expanded into the suprasellar areas. It relapsed twice during the 3 years following partial resection, and the MiB1 labeling index steadily increased without obvious malignant transformation. The second SFT arose from the confluence of the sinuses, widely invaded the lateral sinus and adjacent bones, had a low MiB1 index and has not recurred after 5 years. The intraspinal tumor occurred at T5–T7 in a patient with multiple café-au-lait spots, was predominantly myxoid and developed a second similar lesion at S3–S5 14 years later. The MiB1 index was lower in the second tumor. Immunohistochemistry confirmed that all were SFTs. These atypical presentations gave us an opportunity to provide further information about the natural histological course of CNS SFTs.

Introduction

The new World Health Organization classification of tumors of the nervous system [19] includes SFTs among the mesenchymal, non-meningothelial tumors [3, 10, 11, 31]. This category encompasses a wide variety of rare lesions with histological features resembling extracranial soft tissue tumors. SFTs of the meninges were first described by Carneiro and co-workers in 1996 [4]. The identification was based on distinctive immunohistochemical features common to soft tissue SFTs, including immunoreactivity for CD34, CD99, Bcl2 and vimentin but not for early membrane antigen (EMA) or S100 protein. This immunohistochemical profile differs from that encountered in fibrous meningiomas or hemangiopericytomas [4, 8, 32, 34]. Approximately 60 cases of SFT have been reported in the CNS. We present 3 additional cases of SFT, 2 intracranial and 1 within the spine, with emphasis on atypical features and outcomes, including a histological and MiB1 index analysis in sequential recurrences and in multicentric lesions.

[a]Corresponds to the number of immunostained cells over ten high-power fields

Materials and methods

All of the surgical specimens were fixed in 10% buffered formalin and embedded in paraffin. Histological sections were stained with hematoxylin–eosin with or without saffron counterstaining, periodic acid–Schiff and reticulin. Mitoses were counted by examining ten high-power fields (HPF), three times for each tumor, and determining an average number per ten HPF. Immunohistochemical studies were performed using the standard labeled streptavidin–biotin technique or Envision peroxidase method (Dako S.A., Trappes, France), as detailed in previous reports [13, 30]. Primary antibodies, dilutions and sources used in the current study are listed in Table 1.

Results

Clinical findings

Patient 1

A 66-year-old woman presented in 2000 with a history of several months of reduced visual acuity and visual field loss in the left eye. CT and magnetic resonance imaging (MRI) showed a lesion in the pituitary fossa radiologically consistent with a pituitary adenoma. Intraoperative observations revealed an intrasellar tumor with upward expansion. The mass was incompletely resected and recurred twice in the same location within 3 years (2002, 2003) with extension to the optic chiasm, carotid arteries and left cavernous sinus. The patient is alive with residual disease.

Patient 2

This 53-year-old male presented with a 6-month history of fronto-temporal headaches, visual disturbances and poor memory. CT revealed a homogenous right temporal supratentorial 6.5×3×6-cm growth radiologically consistent with a meningioma. MRI demonstrated that the mass arose from the cerebellar tentorium and extended into the supra- and infratentorial spaces. Intraoperatively, a well-circumscribed mass arose at the confluence of the sinuses and widely invaded the lateral sinus and adjacent bone. The lesion was completely resected. The patient is disease free 5 years post-surgery.

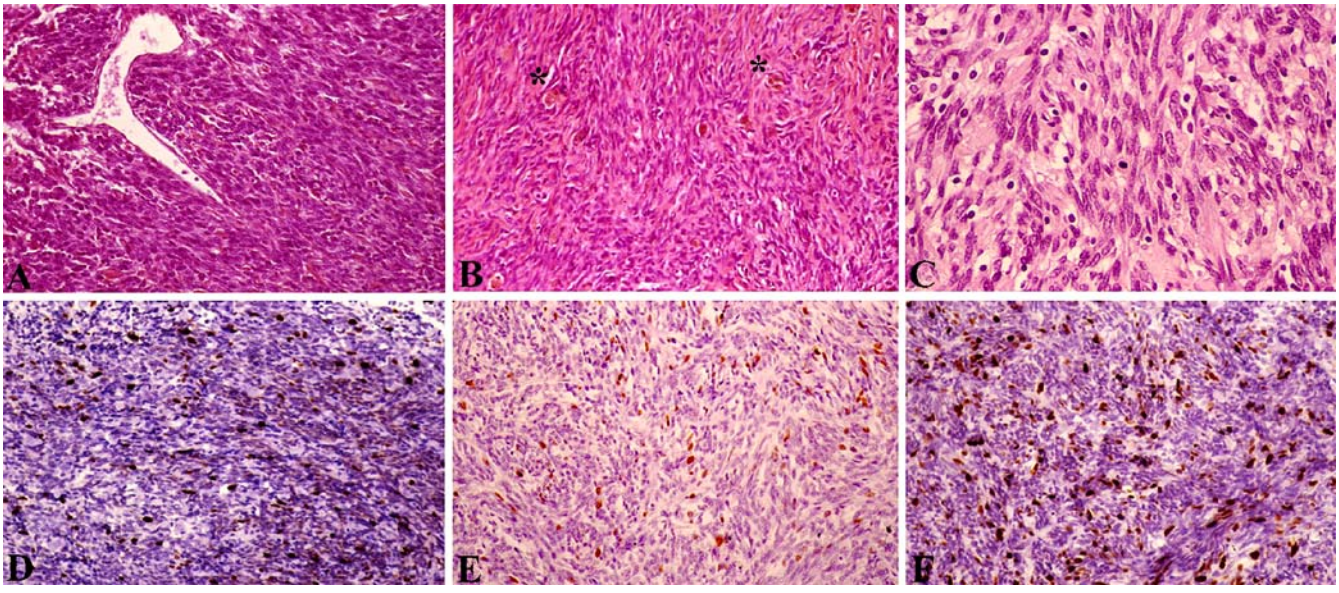

Fig. 1 Patient 1 primary solitary fibrous tumor of the sella turcica. **a** Bland spindle cells, a patternless growth pattern, collagen-rich network and a staghorn vascular pattern [hematoxylin and eosin (H&E) ×200]. **b** First recurrence. Bland spindle cells, patternless growth pattern, abundant collagen-rich matrix and hemosiderin-laden macrophages (*asterisk*) are conspicuous (H&E, ×200). **c** Second recurrence. Hyperchromatic spindle cells, patternless growth pattern and scattered mitoses (H&E, ×200). **d–f** Increasing MiB-1(*Ki-67*) labeling index in consecutive recurrences

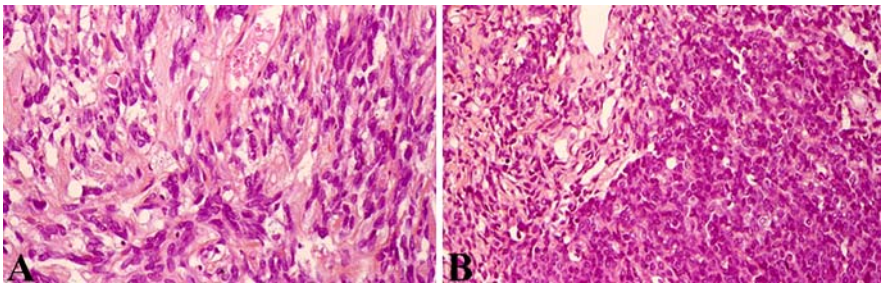

Fig. 2 Patient 2 primary solitary fibrous tumor of the posterior-fossa. **a** Spindle-shaped cells in a patternless growth pattern and collagen-rich matrix [hematoxylin and eosin (H&E), ×200]. **b** Cluster of spindle and oval cells, patternless pattern and collagen-rich matrix (H&E, ×200)

Patient 3

A 27-year-old male presented with recurrent back pain in 1987. He had multiple "café-au-lait" spots without a history of neurofibromatosis type 1 or other anomalies. MRI revealed an intradural extramedullary T5–T7 lesion measuring 2.5×2×2 cm consistent with a schwannoma. Intraoperatively, the tumor extended into the spinal cord and posterior nerve roots and was incompletely resected. The patient complained of nocturnal severe lower back pain 14 years later. MRI revealed an intradural extramedullary tumor of the distal dural sac. Intraoperatively, a tumor consistent with a schwannoma was located between S3 and S5 and the coccygeal nerve roots. The mass was surgically removed.

Histopathology

The primary sellar SFT (patient 1) was hypercellular with spindle-shaped cells arranged in a random pattern with thin bands of collagen between the cells (Fig. 1a) and rare myxoid areas. Increased collagen deposition between the spindle-shaped cells, hemosiderin-laden macrophages (Fig. 1b), resolving hemorrhage (Fig. 1b asterisk) and focal brain invasion were noted in first recurrence. The second recurrence (Fig. 1c) had spindled cells with increased mitotic activity, a collagen-rich background and a complete absence of myxoid changes. The increased proliferative activity in the sequential recurrences roughly correlated with the MiB-1 labeling index, ranging from less than 3% up to 6%, (Fig. 1d–f; Table 1).

The histological appearances of the tumor in the region of the confluence of the sinuses (patient 2) are illustrated in Fig. 2. The lesion was well circumscribed and encapsulated. There was a collagen-rich network between hypocellular and hypercellular areas of spindle- or oval-shaped cells that had bland nuclear features (Fig. 2a) and were typically arranged in a patternless growth pattern. Myxoid changes were noted in about 25% of the tumor. A prominent staghorn vascular pattern (Fig. 2a) and foci of round cells were also identified (Fig. 2b). The MiB1 index was below 0.5% (Table 1).

The spinal cord tumor (patient 3) was well circumscribed, encapsulated and multinodular (Fig. 3a). Loose myxoid areas (approximately 50–70%) (Fig. 3b) predominated over the solid hypo- and hypercellular zones (Fig. 3c). Spindled fibroblast-like cells showed bland features with occasional mitoses. They were arranged in a patternless growth pattern (Fig. 3a–c) with a prominent staghorn vascular pattern (Fig. 3a). The histological appearance of the recurrent tumor at S3–S5 was similar to the primary lesion at T5–T7 (not shown). The MiB1 labeling indices were 5% and 3%, respectively, in the primary and in the recurrent lesions.

None of these lesions exhibited cellular whorl arrangements or psammoma bodies suggestive of a meningioma. The tumors also did not have nuclear pleomorphism or tumor necrosis, which have been associated with aggressive behavior in SFTs.

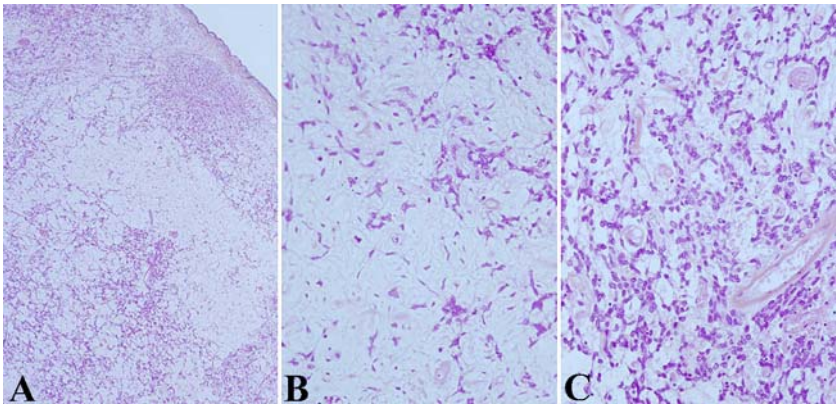

Fig. 3 Patient 3 primary solitary fibrous tumor (SFT) of the spinal cord. **a** Solid, myxoid and staghorn changes are seen as well as the fibrotic capsule at low magnification [hematoxylin and eosin (H&E), ×100]. **b** Detail of predominantly loose hypocellular myxoid changes (H&E, ×200). **c** Detail of hypercellular areas in predominantly myxoid SFT (H&E, ×200)

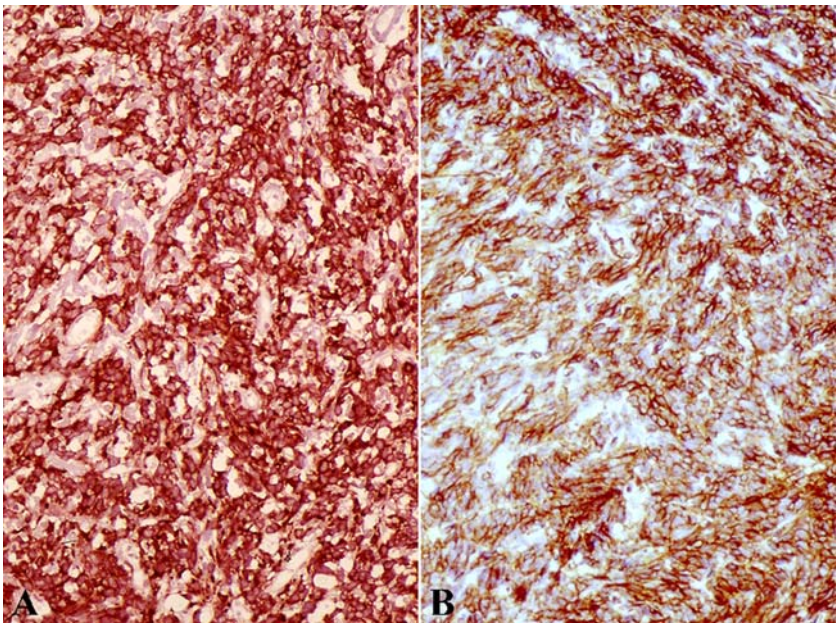

Fig. 4 Representative immunostaining for CD34 (×200) (**a**) and for Bcl-2 (×200) (b)

Immunohistochemistry

The immunophenotype of the spindle-shaped cells is shown in Table 1. The cells displayed strong diffuse cytoplasmic immunoreactivity for CD34 (Fig. 4a), CD99, Bcl-2 (Fig. 4b) and vimentin. Cytokeratins AE1/AE3, CD117 (c-kit), h-caldesmon, calretinin, estrogen receptors, cerb2, EMA, desmin, actin and the S-100 protein were negative. Progesterone receptors expressed diffuse weak staining.

Discussion

CNS SFTs are recently recognized distinctive dural-based neoplasms of the CNS [3, 10, 11, 31]. They are considered as counterparts of similar lesions initially identified in the pleura by Klemperer and Rabin in 1931 [20], which subsequently have been reported in numerous extrapleural sites and soft tissue [15, 26]. In the CNS, they are known to arise from the meningeal coverings [3, 4, 10, 11, 31] without meningothelial differentiation and are classified as mesenchymal nonmeningothelial tumors. Current studies suggest they are derived from vascular mesenchymal cells [8, 14]. Since their recognition in the CNS [4], approximately 60 cases have been recorded in the CNS literature. The actual incidence is unknown, in part because they were long overlooked in the differential diagnosis of solid CNS tumors and classified as fibrous meningiomas. Most SFTs occur in adulthood and show a slight male predominance [6]. A few cases have been described in children [18, 33]. While headaches predominate with intracranial lesions, visual disturbances, poor memory and occasional symptoms have also been reported [6, 23]. Back pain often occurs in intraspinal SFTs [1, 2, 17, 36].

Although MRI has proved the modality of choice for detecting, characterizing and staging most soft tissue tumors, a consensus MRI study regarding CNS SFTs is not yet available. In addition, this entity is still poorly recognized among the imaging community. As a consequence, most SFTs are still radiographically misdiagnosed and/or mistaken for meningiomas or schwannomas. With increased recognition of SFTs, radiological studies are reporting imaging features for solitary fibrous tumors [6, 18, 21, 22]. It appears that meningeal SFTs show a tendency to arise in the posterior fossa (26%) and spine (25%) [6].

SFTs are usually well-circumscribed encapsulated lesions resembling meningiomas, hemangiopericytomas or schwannomas. Histologically, SFTs exhibit spindled cells with scant eosinophilic cytoplasm growing in short fascicles, sheets, storiform patterns or irregular arrangements commonly referred to as a "patternless" pattern. Thin parallel bands of collagen are located between the spindled cells, and a hemangiopericytoma-like staghorn vascular pattern is often present [3, 10–12, 14]. Myxoid changes have been reported in SFTs, particularly in the spinal cord lesions, but pure myxoid variants are extremely rare [1, 2, 17, 36]. Hyperchromatism, nuclear pleomorphism, mitotic figures and tumor necrosis have been infrequently documented in the so-called malignant variants [4, 7, 14]. The unifying characteristic of all SFTs remains the strong reactivity of the spindle cells for CD34, CD99, Bcl-2 and vimentin plus their negative staining for S100 protein, EMA and muscle markers [4, 8, 34, 35]. In this study, staining for CD117 was negative. Ultrastructural studies have shown features consistent with fibroblasts or mesenchymal cells [4, 8].

The treatment of choice is surgical resection. Local recurrences have been reported with incomplete surgical excision [3, 4]. Some cases with malignant potential have also been reported, as well as metastases [7, 18, 28, 37]. Predictors of long-term outcome have not been well defined. The cytogenetics of SFTs is not well developed [9, 12, 14, 24]. A translocation involving chromosome 4q13 has been reported in two cases involving the pleura and peritoneum

[9]. A study on meningeal solitary fibrous tumors reported a loss of chromosome 3, deletions in the region of 3p21, losses in 4p15, 8q22, 10, 11q24, 17q11 and 21 and gains of 18p11, 1p11 and 20q11 [24].

This study includes a case of a spinal cord SFT and pigmented skin abnormalities (patient 3) not previously reported in the literature. Our patient had no history of neurofibromatosis. The primary SFT was resected, and 14 years later the patient developed a new lesion distant from the primary site with identical histological and immunohistochemical features. The decreased MiB1 labeling index in the second tumor is suggestive of a new lesion rather than metastasis from the original resection and may represent a genuine multifocal process. Multicentric CNS SFTs have not been previously reported in the literature. There is a single case report of a double primary localized fibrous tumor of the pleura and the peritoneum [16] and a case report of a multifocal primary intracerebral malignant fibrous-histiocytoma [25]. The importance and the nature of these findings, whether coincidental or part of a new syndrome, await further elucidation.

Only one other SFT has been reported involving the pituitary fossa [5]. In a parallel study of the radiological anatomy of the sella turcica and the histopathology of the pituitary gland in 205 autopsy specimens, Muir and co-workers found three cases of solitary tumors not otherwise specified in the anterior lobe, in the pre-immunohistochemistry era [27]. Our patient's lesion (patient 1) was incompletely excised and experienced several recurrences. Ogawa and co-workers [29] reported a case of a meningeal SFT, which locally relapsed four times and finally metastasized to the lung and invaded in the cerebellum over a period of 26 years. Similar to their experience, our patient expressed a steady increase of cellularity and of the MiB1 labeling index with each occurrence, suggesting a worse prognosis and a potential malignant transformation risk. Cerebral microinvasion was noted in the second occurrence, but this finding has not generally been regarded as a sign of malignant transformation but as an expression of increased local aggressiveness [7]. It is well known that repeated local reoccurrences may result in distant metastases over time [28, 29, 37], stressing the need for careful follow-up.

Our last patient (patient 2) had a well-circumscribed encapsulated intracranial SFT located in the posterior fossa. The lesion widely invaded adjacent structures and the lateral sinuses but had a very low MiB1 index. Since the posterior fossa has been identified as the most common site for intracranial SFTs [6], the imaging and pathological differential diagnosis of lesions in this area should include SFTs. This tumor showed focal round-shaped cells without noticeable features of malignity (Fig. 2b), which were strongly Bcl-2 and vimentin positive but negative for CD34 and CD99. Round-shaped tumor cells have been also recorded by others in cerebral SFTs [8], but this immunophenotype has not drawn much attention and will require further investigation. In summary, our study further shows the unpredictable nature and variability of the natural course of CNS SFTs.

Portal capillary C4d deposits and increased infiltration by macrophages indicate humorally mediated mechanisms in acute cellular liver allograft rejection

Received: 22 November 2004 / Accepted: 1 March 2005 / Published online: 10 June 2005
© Springer-Verlag 2005

Abstract Almost no data exist concerning the role of antibody-mediated mechanisms in human acute cellular liver allograft rejection (ACR). Therefore, the aim of this study was to determine whether ACR is associated with depositions of complement split products and increased infiltration by B-lymphocytes, plasma cells and macrophages. A total of 35 liver biopsy specimens (ACR n=22, controls n=13) were analyzed by immunohistochemical single and double staining. The average numbers of $CD20^+$, $CD38^+$ and $CD68^+$ cells per portal tract were established while the presence of C4d and C3d deposits was evaluated semiquantitatively. Significantly greater numbers of $CD20^+$ (P=0.029) and $CD38^+$ (P=0.014) cells were found in the ACR specimens than in the control specimens. Additionally, 50% of patients diagnosed with ACR showed C4d deposits along portal capillaries, which was associated with a significantly increased portal infiltration by macrophages (P=0.007). Taken together these results support the involvement of humorally mediated mechanisms in some cases of ACR.

Introduction

Evidence for the existence of humorally mediated acute rejection (AHR) of human kidney and heart allografts has increased over the last few years, mainly due to improved immunohistochemical detection of C4d, an enzymatic cleavage product of the complement component C4 [4, 5, 12]. Proteolytic cleavage of C4 results from the classical pathway of activation of complement by immunocomplexes. Its final split product C4d exposes a thioester group which leads to the formation of a covalent bond to the closest protein or carbohydrate near the site of C4 activation and therefore allows immunohistochemical detection. Today AHR is accepted as a separate entity associated with kidney and heart allograft rejection. In line with this, humorally mediated mechanisms are suspected to be responsible for several pathological alterations in organ transplants other than heart and kidney.

So far only a few investigations have been carried out concerning the role of a humoral element of immunity in acute cellular liver allograft rejection (ACR) [19, 20]. In a recent study, we were able to show a significantly increased immigration of B-lymphocytes and plasma cells as well as depositions of C4d along portal capillaries in patients with ACR with a high rejection activity index, which indicates an association of acute liver allograft rejection with humoral immunity [8]. Additionally, IgVh analysis in a patient with ACR has demonstrated that B-cells in the transplanted liver tissue express a restricted V-gene repertoire and have a selected pattern of somatic mutations [15].

Although most investigators have focused on C4d as a marker for AHR of renal allografts, additional markers seem to provide supplementary information [2]. Deposits of C3d, a degradation product of C3, derived from both the classical and the alternative pathway of activation of the complement cascade, have been found to be associated with a worse clinical outcome in patients with renal AHR [9]. The occurrence of macrophages marks more severe renal allograft rejection and differentiates clinical from

subclinical rejection [3, 6]. A correlation between immigration of macrophages into the glomeruli and deposition of C4d on peritubular capillaries has been demonstrated [10].

Therefore our aim was to clarify whether these markers, as well as being useful in diagnosis of renal AHR, also provide additional information in acute rejection of liver allografts.

Materials and methods

Patients and tissues

A total of 35 liver biopsy specimens (n=35) taken between 1993 and 2003 from patients who had undergone liver transplantation due to various indications were selected for this study (Tables 1 and 2). Biopsies were taken 5 days to 3 years after transplantation. Of the 35 biopsies, 22 (9 from female patients, 13 from male patients; age 18–62 years) showed histologically proven ACR, and 13 (7 from female patients, 6 from male patients; age 20–65 years) were without clinical and histopathological signs of ACR and served as a comparison group.

Histopathological evaluation of acute rejection was done according to the Banff schema for grading liver allograft rejection [1]. Nine patients were diagnosed with mild, 12 with moderate and 1 with severe acute rejection. Patients with HCV reinfection were ruled out by selecting only those with a distinct histopathological diagnosis of acute rejection and without any histopathological signs of HCV reinfection.

Immunohistochemistry

Immunohistochemical single staining (CD20, CD38, C4d, C3d, CD68)

Paraffin-embedded sections were deparaffinized, demasked (pressure cooker, citrate buffer, pH 6) and stained with commercially available mouse monoclonal antibodies specific for CD20, CD38 and CD68. For C4d and C3d staining rabbit polyclonal antibody was used.

Primary antibodies were diluted as follows: CD20 (DAKO, Glostrup, Denmark) 1:100; CD38 (Novocastra, Newcastle upon Tyne, UK) 1:100; CD68 (DAKO) 1:50; C4d (Biomedica Austria, Vienna, Austria) 1:10; and C3d (DAKO) 1:800.

In chronically inflamed tissue and in blood, CD38 is expressed on B-lymphocytes (memory cells, germinal center cells) and on plasma cells. As CD138, another plasma cell marker, is also expressed by bile ducts, it was not used in this study. While anti-CD20 antibodies specifically stain B-lymphocytes, anti-CD68 antibodies identify monocytes and macrophages.

C4d and C3d, enzymatic cleavage products of the complement components C4 and C3, both expose a thioester group which enables them to bind covalently to the clos-

est protein or carbohydrate. Thus they are considered to be residues of a humorally mediated immunoresponse.

Staining was done using the labeled streptavidin-biotin method (LSAB Kit+, DAKO). Peroxidase-linked streptavidin binds to biotin, which again is linked to the secondary antibody. DAB (3,3-diaminobenzidine; DAKO) was used as a chromogen for the reaction with peroxidase. Endogenous peroxidase was blocked using H_2O_2. In a final step nuclear counterstaining with hematoxylin was performed according to the method of Mayer. Tonsil tissue treated as described above was used as a positive control; negative controls were obtained by omitting the primary antibody.

Immunohistochemical double staining (C4d/CD68)

For immunohistochemical double staining of C4d and CD68 the ENVISION Doublestain system (DAKO) was used according to the manufacturer's instructions. After epitope demasking (pressure cooker, citrate buffer, pH 6), anti-C4d antibody (polyclonal; Biomedica) and anti-CD68 antibody (DAKO) were successively added. DAB (CD68) and Fast Red (C4d) were used as chromogens. Tonsil tissue served as a positive control; negative controls were obtained by omitting the primary antibody. Double staining was performed on 11 biopsy specimens showing C4d positivity in immunohistochemical single staining.

Immunofluorescence (C4d/CD68)

As immunofluorescence serves as a gold standard in the diagnosis of renal allograft rejection, this technique was used to validate the results derived from immunohistochemical staining. Thus C4d/CD68 double stainings were performed on three biopsy specimens showing C4d positivity in immunohistochemical single staining. After deparaffinizing the sections (1–3 μm), demasking the epitopes (citrate buffer, pH 6) and blocking nonspecific binding sites, primary antibodies were diluted (CD68 1:50; C4d 1:10) and simultaneously added. Avoiding light exposure, slides were incubated simultaneously with secondary antibodies, Cy2-conjugated donkey anti-rabbit (1:100; Dianova, Hamburg, Germany) and Cy3-conjugated donkey anti-mouse antibody (1:200; Dianova). Finally, nuclear counterstaining was performed. While Cy2 fluoresces green (C4d), Cy3 emits a red signal (CD68).

Histopathological evaluation and statistical analysis

Immunostainings were evaluated by two pathologists (V.K., A.D.). The intensity of C4d and C3d staining was graded semiquantitatively, distinguishing diffuse, focal and weak positivity from completely negative specimens. Only diffusely and focally positive findings were considered a significant pathological result.

For the analysis of CD20, CD38 and CD68 staining, immunohistochemically positive cells in five portal tracts per specimen were counted, followed by calculation of the arithmetic mean and the standard deviation.

For further statistical analysis the nonparametric Mann-Whitney and Kolmogorov-Smirnov tests, and for metric parameters the *t*-test for unpaired samples were performed. *P* values less than 0.05 were regarded as statistically significant.

Results

Immunohistochemical single staining

CD20

All examined tissue sections contained $CD20^+$ cells, predominantly localized in the portal tracts. Additionally biopsies from patients with ACR showed small clusters of

$CD20^+$ cells without formation of follicular structures. Furthermore, the evaluated biopsies revealed a noticeable difference in B-cell content of individual portal tracts. While in some portal fields no $CD20^+$ cells were detected, other portal tracts in the same biopsy showed strong infiltration by B-lymphocytes.

Quantitative analysis of $CD20^+$ cells demonstrated a significant increase in B-lymphocytes in biopsies from patients with ACR (mean 32.4, median 33.6, range 1.0–113.0) compared to biopsies from patients without ACR (mean 14.1, median 6.6, range 1.6–38.6; P=0.029).

CD38

$CD38^+$ cells were detected in all biopsy specimens. The mean number of $CD38^+$ cells per portal tract differed significantly between biopsies from patients with ACR (mean 17.0, median 10.1, range 0.4–106.4; Fig. 1) and from those without ACR (mean 3.4, median 2.0, range 0.2–17.0; P=0.014). No significant difference was seen between biopsies from $C4d^+$ and $C4d^-$ ACR patients.

C4d

Out of 22 liver biopsies from patients with ACR, 3 showed diffuse and 8 showed focal C4d positivity according to the semiquantitative grading used for evaluation of the immunohistochemical staining for C4d (Fig. 2). These biopsies were considered as definitely $C4d^+$. While 1 biopsy expressed weak C4d positivity, 10 showed no positivity (11/22; 50%). C4d deposits were seen attached to endothelial cells of portal vessels. As they were not restricted to venous endothelium, but could in some cases also be demonstrated along endothelial cells of portal arteries and portal capillaries, no distinct distribution pattern of the C4d staining was apparent regarding vascular structures in the portal fields. Nevertheless, C4d deposits were not detected attached to hepatic veins or along sinusoidal endothelium.

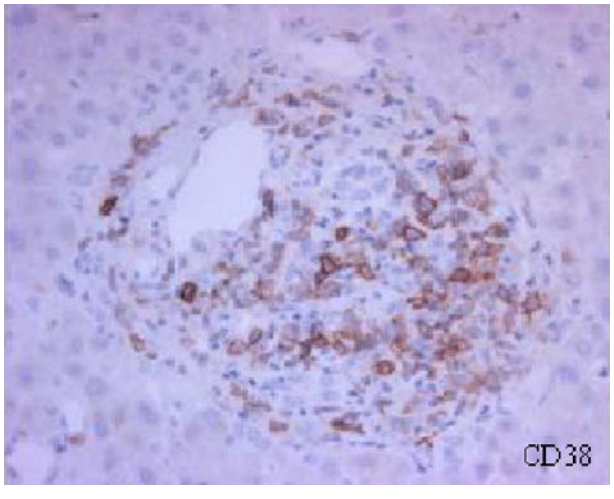

Fig. 1 $CD38^+$ cells in a portal field of a biopsy showing ACR (original magnification ×400)

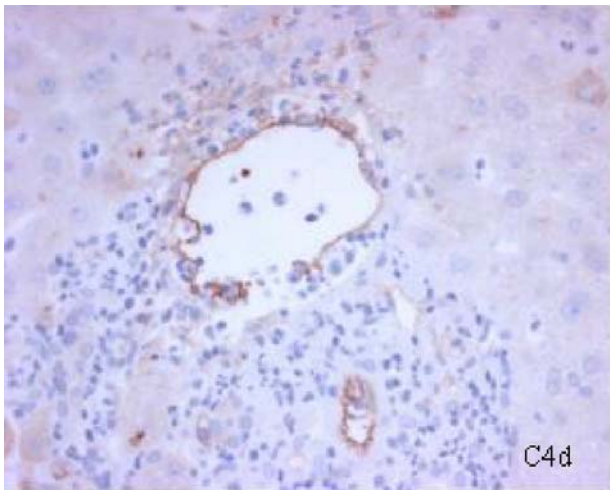

Fig. 2 Immunohistochemical staining of C4d deposits along portal vessels in ACR (original magnification ×400)

None of the control biopsies was considered $C4d^+$ (three biopsies showed only weak positivity and the remaining ten were negative). This represents a significant difference between ACR and control biopsies (P=0.013). No correlation was found between C4d positivity and rejection severity grade. There was also no statistically significant difference in the mean delay between transplantation and biopsy in patients with ACR between those with $C4d^+$ and $C4d^-$ biopsies (33 and 41 days, respectively).

CD68

$CD68^+$ macrophages were detected in all biopsies. The portal tracts of ACR biopsies contained a mean of 66.7 $CD68^+$ cells (median 53.5, range 15.5–164.8) compared to

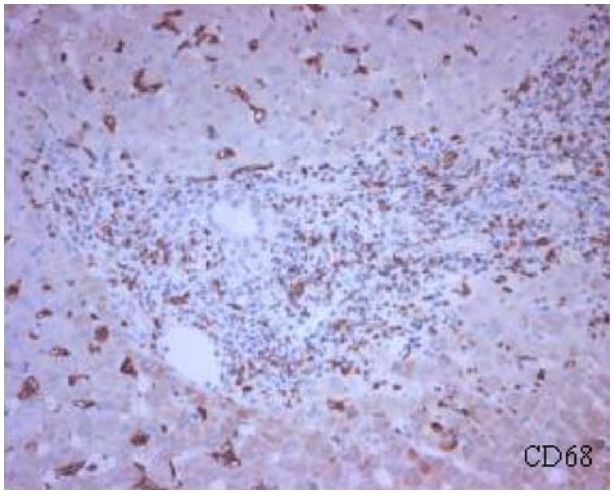

Fig. 3 $CD68^+$ macrophages in the portal tract as well as numerous $CD68^+$ Kupffer cells in the lobules of a rejected allograft (original magnification ×200)

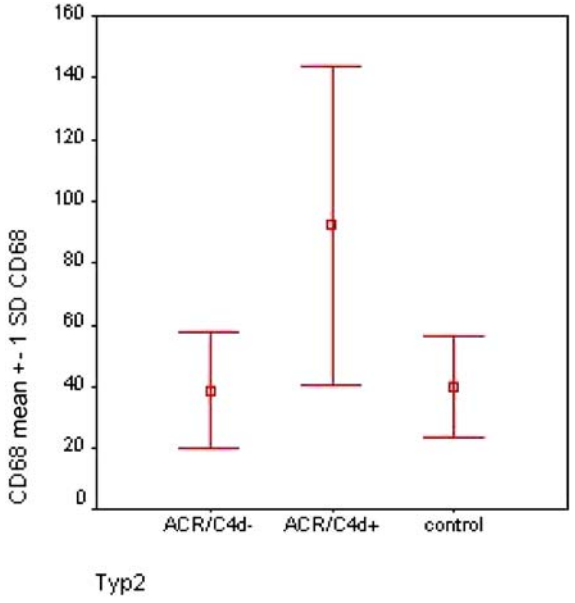

Fig. 4 C4d$^+$ biopsies from patients with ACR (*ACR/C4d*$^+$) showed a significant increase in CD68$^+$ cells per portal tract compared to C4d$^-$ biopsies from patients with ACR (*ACR/C4d*$^-$) and controls (*P*=0.007)

40.0 CD68$^+$ cells (median 41.8, range 13.7–63.4) in control biopsies. There was a highly significant difference in the mean of CD68$^+$ macrophages per portal tract between C4d$^+$ and C4d$^-$ ACR biopsies. In C4d$^+$ biopsies, there were 92.4 CD68$^+$ cells per portal field (median 80, range 27.3–164.8) compared to an average of 38.5 CD68$^+$ cells per portal field (median 39.5, range 15.5–71.3) in C4d$^-$ ACR biopsies (*P*=0.007; Figs. 3 and 4). CD68$^+$ cells were widely distributed across the portal fields.

C3d

C3d deposits were seen in 21 biopsies from patients with ACR (14 with focal positivity, 7 with diffuse positivity), whereas 1 biopsy remained unstained. In the comparison group positive staining was seen in 12 biopsies (9 diffusely positive, 3 focally positive), while 1 biopsy was negative. The number of positive biopsies was therefore not significantly different between patients with ACR and the control group.

Immunohistochemical double staining

C4d/CD68

Double staining was performed on 11 biopsies, which were demonstrated to be C4d$^+$ in immunohistochemical single staining. Results derived from immunohistochemical single staining were confirmed. In some biopsies an attachment of CD68$^+$ cells to C4d$^+$ endothelium could be demonstrated (Fig. 5).

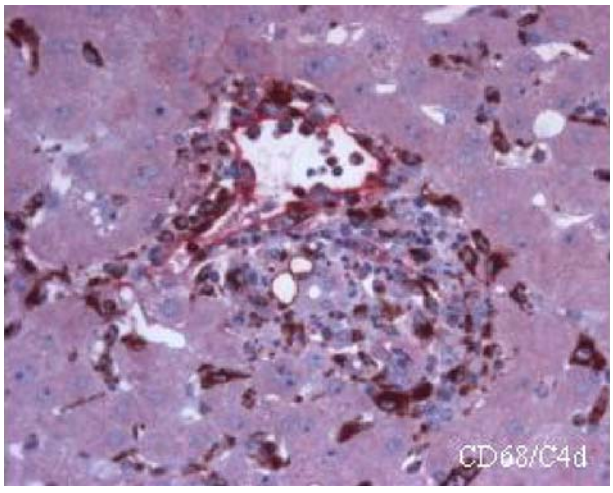

Fig. 5 Immunohistochemical double staining for C4d and CD68. CD68$^+$ cells are apparent in the vicinity of C4d deposits along the venous endothelium (original magnification ×400)

Immunofluorescence

C4d/CD68

Immunofluorescence single and double staining was conducted in three C4d$^+$ biopsy specimens to validate the results obtained by immunohistochemistry (Fig. 6). C4d$^+$/CD68$^+$ signals were detected in all biopsies. While bright focal and diffuse C4d deposits were seen along the portal capillary endothelium, CD68$^+$ cells were disseminated across the portal fields with slight accumulation at sites with strong C4d staining (Fig. 7).

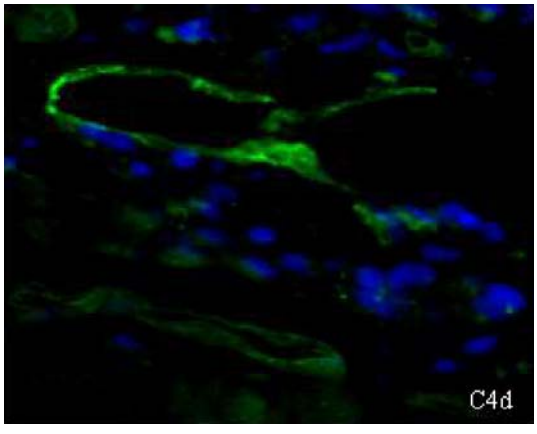

Fig. 6 Immunofluorescence staining of C4d deposits along portal endothelium in a rejected liver allograft (original magnification ×400)

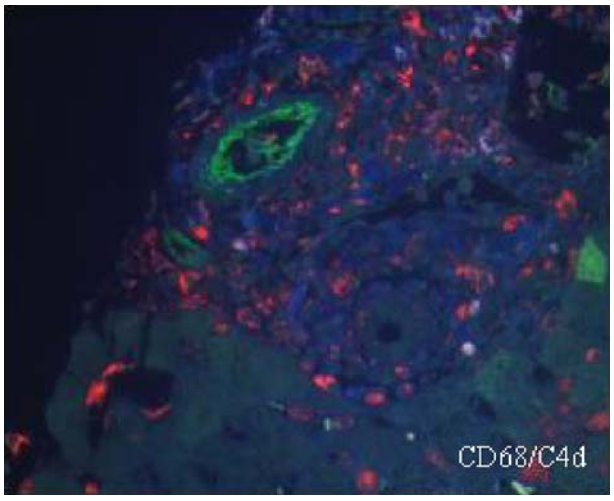

Fig. 7 Immunofluorescence double staining of C4d and CD68. Bright green C4d deposits are apparent along endothelial cells of a portal artery together with diffusely distributed red macrophages (original magnification ×400)

Discussion

Acute liver allograft rejection is considered to be primarily driven by T-lymphocytes. Histopathologically it is reflected by mononuclear infiltration of portal tracts by $CD3^+$ T-cells, and injuries to the bile ducts and venous endothelium [1]. Only few data exist concerning the role of antibody-mediated mechanisms in acute liver allograft rejection, but several studies have demonstrated an association between circulating anti-donor antibodies and rejection and graft loss [7, 11, 19]. Furthermore our group has recently identified C4d deposits along portal capillaries in liver biopsies from patients with ACR [8]. C4d has been shown to be a reliable marker of humoral immunoresponse to renal transplants so that today there is consent about AHR being an independent entity in renal allograft rejection [14].

IgVh analysis in a patient with ACR has demonstrated that B-cells in the transplanted liver tissue express a restricted V-gene repertoire and have a selected pattern of somatic mutations [15], indicating activation and clonal expansion of B-cells in liver tissue. Since no lymphatic follicles can be detected and immunohistochemical double staining of CD20 and Ki-67 does not demonstrate co-localization [8], an antigen-selected migration seems to be responsible for the colonization of portal fields by B-cells in ACR [15].

Although these studies have revealed new insight into the pathogenetic role of humorally mediated mechanisms in ACR, a systematic analysis of a larger population of ACR patients accompanied by validation of immunohistochemistry by immunofluorescence has yet to be carried out.

Immunohistochemical staining revealed a significant increase in $CD20^+$ and $CD38^+$ cells in biopsies from patients with ACR compared to control biopsies. These results are consistent with data recently published by Krukemeyer et al. who found a significantly increased accumulation of B-lymphocytes and plasma cells during acute rejection [8]. No significant difference was seen between $C4d^+$ and $C4d^-$ ACR patients.

However, concerning the histopathological evaluation of the comparison group, one major objection has to be considered. Protocol biopsies from patients who have undergone liver transplantation often reveal histopathological signs of a nonspecific inflammatory reaction despite fulfilling the criteria for ACR. The degree of this inflammation may be mild or moderate, and in some cases even severe. While three biopsies from the comparison group showed no signs of inflammation, ten protocol biopsies were diagnosed with mild inflammation. Statistical analysis of $CD20^+$ and $CD38^+$ cells in biopsies from ACR patients and the comparison group, disregarding biopsies without signs of inflammation, did not indicate significant differences. Therefore the possibility that increased infiltration of B-lymphocytes and plasma cells may be due to nonspecific inflammation rather than the hallmark of humoral immunoresponse in ACR cannot be ruled out completely. Nevertheless, the mere presence of B-lymphocytes and plasma cells challenges the concept of a pure cellular immunoresponse in ACR. Together with the finding that B-cells in acute liver allograft rejection express a restricted V-gene repertoire and have a selected pattern of somatic mutations [15], the results may suggest that antigen-induced selection, subsequent clonal expansion and final immigration of B-cells are part of the pathogenesis of ACR.

C4d deposits were seen along the endothelium of portal capillaries, portal veins and portal arteries in 50% of the biopsies from ACR patients, whereas no such deposits were seen in the protocol biopsies. C4d deposits were restricted to portal structures as they were not detected attached to hepatic veins or along sinusoidal endothelium. The specificity of the immunohistochemical staining was confirmed by immunofluorescence. As C4d is derived from the classical activation pathway of the complement cascade and specifically marks sites of humorally mediated reactions [2, 16, 17], this further supports involvement of a humoral immunoprocess in ACR. Although Krukemeyer et al. demonstrated C4d deposits in severely inflamed portal tracts [8], C4d positivity did not turn out to be correlated with rejection severity grade in this study. There was also no statistically significant difference concerning the mean delay between transplantation and biopsy between $C4d^+$ and $C4d^-$ biopsies from patients with ACR. Moreover no preponderance of late onset ACR was seen among $C4d^+$ biopsies.

Immunohistochemical detection of C3d, another proteolytic cleavage product of the complement cascade, was also performed. Almost all analyzed tissue specimens showed C3d deposits in the portal fields. This corresponds with the finding that normal renal tissue contains less C4d than C3d [2]. Furthermore, C3 shows the highest serum

concentration of all complement proteins and is capable of diffusing into interstitial spaces due to its molecular size [2]. But above all, it is the central link in the complement cascade, activated by the classical as well as the alternative pathway. Via an amplification loop, C3b is able to boost its own production, which reinforces complement-mediated reactions [2]. This may explain the occurrence of $C4d^{-}/C3d^{+}$ biopsies.

As C3d deposits were detected in almost all biopsies from the comparison group, one may question the significance of C3d immunostaining, but exclusive activation of the complement cascade via the alternative pathway triggered by a nonspecific inflammatory reaction could explain C3d deposits in these cases.

Despite the concern that, comparing biopsies from ACR and control patients, an increased infiltration of $CD68^{+}$ cells may again be a nonspecific sign of inflammation, this study showed that increased infiltration of macrophages is associated with C4d positivity in biopsies from patients with ACR. This association was first demonstrated in renal allograft rejection by Magil and Tinckam [10]. In another study investigating humoral rejection in cardiac transplantation macrophages served as a marker for AHR [13]. Accumulation of macrophages marks more severe renal allograft rejection and differentiates clinical from subclinical rejection [3, 6]. Macrophages are known to be activated by the formation of immunocomplexes by IgG and complement components (C5a) [18] and are capable of synthesizing complement factors (C4, C3).

Taken together the results of this study demonstrate an increased infiltration of portal tracts by B-lymphocytes and plasma cells in patients with ACR. Examining a larger population for the first time, C4d deposits were detected in 50% of biopsies from patients with ACR. Furthermore a significant association between the detection of C4d deposits and an increased infiltration of portal fields by macrophages in biopsies from patients with ACR was shown.

Thus we conclude that the frequent occurrence of macrophages, B-lymphocytes and plasma cells in portal tracts together with the presence of C4d deposits along portal capillaries indicate that there is actually more to acute liver allograft rejection than a mere cellular immunoresponse. The results suggest the involvement of humorally mediated mechanisms and innate immunity in some ACR patients. Whether the histopathological findings also mirror differences in the clinical course has yet to be determined.

Recolorization of museum specimens: a modification of Romhanyi's technique based on pyridine/nicotine hemochromogen reactions

Received: 28 February 2005 / Accepted: 12 April 2005 / Published online: 14 June 2005

Abstract Romhanyi's technique for preservation and restoration of color in museum specimens is almost unknown outside Hungary. The technique was based on the use of pyridine, nicotine and sodium dithionite (sodium hydrosulphite) for restoring the natural red color of formalin-fixed gross specimens. We developed a modification of the original technique using a mounting medium containing citrate-phosphate-dextrose (CPD) buffer and glycerin to control pH and osmolality. Specimens recolorized with the modified and improved Romhanyi technique remained stable with a natural red color, and no histological deterioration, for more than 18 years. The technique demonstrates the formation of red colored complexes between nicotine and pyridine and ferro-hemochromes such as hemoglobin, myoglobin and other cytochromes in tissues, giving specimens a natural color. The modified technique enables further improvement for the old process of recolorization of museum specimens. In addition, it opens up new methods for demonstration of nicotine, pyridine and their analogues in biological tissues.

Introduction

Formaldehyde is used universally to fix biological tissues and prevent their decomposition. Although formalin-fixed specimens can be stored for long periods, they appear dull, grey-brown and featureless. During the last century, several methods were attempted to make anatomical and pathological museum specimens look natural, fresh and more appealing to the eye. Numerous museum techniques were developed, the most widely followed one being that of Kaiserling [5, 6]. These used formalin for fixation, with or without alcohol (ethyl and methyl) for restoring the red colour and mixtures of salts and glycerin for preservation of the specimen and its colour [3, 5, 8], but were generally found to be unsatisfactory or unstable over time.

An important technique by Pulvertaft [11], further modified by Wentworth [15, 16], used sodium dithionite (sodium hydrosulphite) to recolourize museum specimens. A less known but more important technique based on the hydrosulphite method was developed by the late Professor Romhanyi in Hungary, using pyridine and nicotine for recolorization of formalin-fixed tissues [12]. The technique (Table 1), obtained from Professor Romhanyi and brought to India by the third author (S.S.), produced specimens that had a near-natural colour and appearance. However, it did not become popular for various reasons. If care was not taken to follow the procedure strictly, the red colour disappeared with time or deteriorated irreversibly to a dirty-brown colour in some of the specimens.

We report modifications made in Romhanyi's technique to improve restoration and preservation of the natural red color of museum specimens. We successfully used combinations of glycerin with salts, with modification of the citrate-phosphate dextrose (CPD) buffer, commonly employed for storage of blood [4]. This paper highlights the stability of the tissues and preservation of their red color for more than 18 years, using the modified technique. The studies also indicate that nitrogenous substances such as pyridine and nicotine may have a long-lasting binding effect on hemoglobin, myoglobin and possibly other cytochromes present in blood and tissues.

Table 1 Romhanyi's technique[a]

Solution I (Fixative)	
Formaldehyde 40% solution	1 l
Common salt	300 g
Distilled water	5 l
Place in solution I for 1 week, rapidly wash in tap water, transfer to solution II	
Solution II (Colour Restorative)	
Formaldehyde 40% solution	1 l
Distilled water	5 l
Sodium dithionite	100 g
Potassium carbonate	30 g
Pyridine	10 ml
Nicotine (5% in distilled water)	10 ml
Change the solution every 2 or 3 days, at least 3 replacements	
Mount in fresh change of solution II	

[a]Personal communication, to Sriramachari

Materials and methods

The compositions of solutions used for the modified Romhanyi technique are given in Table 2. In order to avoid shrinkage or swelling of the tissues, initially a double concentration of CPD is employed, to ensure osmolality even after subsequent dilution with equal quantities of glycerin-distilled water mixture in the mounting medium. Thus, the final pH of approximately 6.3–6.4 in the final mounting medium is best suited for ensuring the optimum hue and saturation. In the recolorized specimen, hemoglobin attains a red colour (bright-red with pyridine and a darker shade of red with nicotine); muscle becomes brownish-red in colour. The quantities of pyridine and nicotine may be varied to get the desired shades in the specimens. It is important to use only laboratory grade reagents and chemicals. Only sodium dithionite ($Na_2S_2O_4$), also called sodium hydrosulphite should be used for this procedure and not sodium thiosulphate or "hypo" ($Na_2S_2O_3$), a fact correctly pointed out by Wentworth [15].

Procedure The specimen is dissected with minimum exposure to tap water, dabbed with cotton-wool to remove surface blood and fluids and placed in solution I for at least 1 week for proper fixation. The specimen is then taken out, trimmed and mounted on appropriate acrylate or Perspex sheet or suspended within a glass frame and placed in a fresh change of solution I for 3–4 days to remove loose fragments of tissue, blood etc. from the surface. Any further contact of the specimen with tap water is to be avoided. The specimen is placed in solution II for 7–10 days, until the entire specimen becomes uniformly recolorized. Solution II should be changed every 3 days, at least twice. Thereafter, the specimen is transferred to the mounting medium (solution III), taking care to deposit a layer of sodium dithionite (solid pieces or coarse powder) at the bottom of the jar, and the jar is "filled to the brim", before permanent sealing. Museum jars made of glass or Perspex may be used. A 1 ml aliquot of 40% formaldehyde or 1 g of camphor introduced into the mounting medium may prevent growth of microorganisms and repel insects. The mounting medium may need to be changed occasionally, if it develops a brownish discoloration due to any excess pyridine or nicotine seeping out of the specimen.

Table 2 Modified Romhanyi's technique for recolorization of museum specimens: composition of solutions

Solution I (Fixative)	
Formaldehyde 40% solution	1 l
Sodium chloride	300 g
Distilled water	5 l
Solution II (Color Restorative)	
CPD (×2 concentration)*	1 l
Distilled water	1 l
Sodium dithionite	100 g
Pyridine	10 ml
Nicotine (5% v/v in distilled water)	10 ml
Solution III (Mounting Medium)	
CPD (×2 concentration)*	1 l
Glycerin	250 ml
Distilled water	750 ml
Sodium dithionite	100 g
***CPD (×2 concentration) - composition adapted from Dacie and Lewis [4]**	
Trisodium citrate	52.60 g
Citric acid	6.60 g
Sodium dihydrogen phosphate	4.44 g
Dextrose anhydrous	51.00 g
Distilled water, make up to	1 l

Results

Color restoration begins immediately and takes 2–3 days for larger specimens. The brilliant red color of the specimens is best viewed with oblique and top illumination (Fig. 1a–c). Good preservation of the tissue, as evidenced by histology, was present even after the lapse of 18 years in a recolorized specimen of myxoma of the heart (Fig. 1d). Old specimens, primarily fixed in buffered formalin, can also be recolourized (Fig. 1c), but the red color may not be as stable and of optimum saturation as in fresh specimens, directly fixed in solution I. Imperfect initial or primary fixation may result in leaching out of hemoglobin from the erythrocytes forming "pools" within the lumen of the blood vessels as illustrated in a poorly fixed intestinal specimen (Fig. 1e). By contrast, the cytomorphological features were well preserved in a specimen of placenta fixed directly in solution I (Fig. 1f).

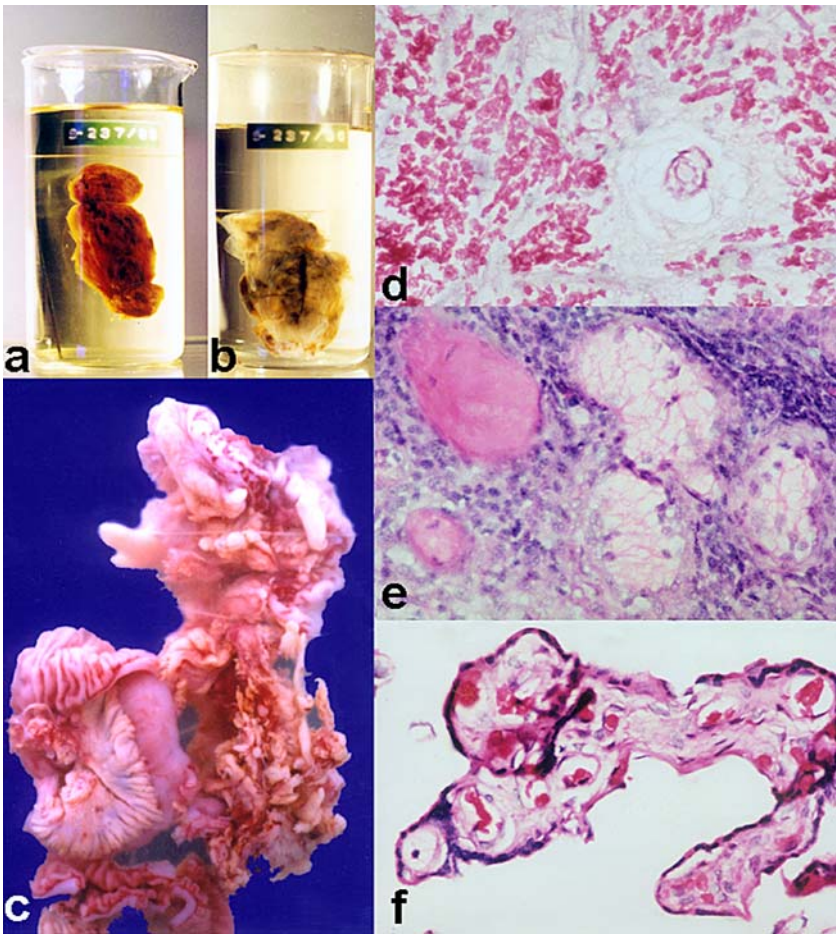

Fig. 1 Dark red color of right ventricular myxoma recolorized with the modified Romhanyi technique is in sharp contrast to the drab gray-brown appearance of its other half in 10% buffered formaldehyde (**a**,**b**). Bright red color is restored with the modified Romhanyi technique in a 2-year-old formalin-fixed specimen of small intestine and mesentery (**c**). Histology shows intact well-preserved erythrocytes and double-layered blood vessel in the recolorized myxoma specimen even after 18 years (**d**). Extracellular hemoglobin within capillaries (**e**) indicates improper primary formalin-fixation of the intestine specimen shown in (**c**). Intact erythrocytes and good staining characteristics are seen in a placental villus fixed directly in solution I prior to color restoration (**f**). [**d**,**e**,**f**: hematoxylin and eosin *385]

Discussion

After some preliminary trials, the authors succeeded in developing an improved method of recolorization that is quite stable over long periods of time. From a perusal of Romhanyi's original publication [12] and his personal communications to the third author (S.S.), the process involved pyridine, nicotine and sodium dithionite as the main constituents. However, in the details of the personal communication, the specimen is first fixed in solution I, containing formaldehyde and common salt, which probably acts as an osmotic factor; and later it is transferred to solution II containing formaldehyde, sodium dithionite, potassium carbonate, pyridine and nicotine (Table 1).

Although Romhanyi's modified technique gave excellent results initially, the rich red colour of the specimen slowly turned reddish brown and after a year or two in many instances there was a gradual seepage of colour into the mounting medium. In some cases, the colour turned a dull brown with development of a dirty brownish-white precipitate that formed a sediment over the surface of the specimen. Probably due to the presence of formalin in the mounting medium, the red colour developed was not rich and brilliant enough. It is well known that even though formaldehyde denatures and fixes tissues, there is with time, a slow disintegration of tissues and leaching out of colour and cell contents, especially evident from tissues rich in fat. To overcome these problems, we omitted formaldehyde and potassium carbonate from solution II (recolourization medium) and solution III (mounting medium). Formalin is necessary only for primary fixation of the specimen and not required after that in the recolorization and mounting solutions. Further, formalin fixation results in better preservation of tissues and many of their histochemical reactions (including the recolourization processes), only if buffered solutions are used for primary fixation and during long-term storage. Therefore, a combination of glycerin and salts (CPD) was introduced in solution III (mounting medium) to maintain pH and osmolality, as advocated for erythrocyte preservation by Dacie [4] and several museum technologies [5]. This was found to be a better combination to obtain a stable rich red color and its retention within the specimen over long periods. Histological examination of our specimens continued to show maintenance of cyto-architecture and intact erythrocytes within hemorrhagic areas (Fig. 1d) even after the lapse of 18 years.

In a series of experiments using pellets of fresh and formalinized erythrocytes and pieces of tissue samples, it was found that sodium chloride in fixative solution I had the effect of pickling the tissues. It prevented tissue lysis and release of cellular components, particularly hemoglo-

bin. However, we found that a cloudy precipitate forms if sodium chloride is mixed with pyridine or nicotine. In Romhanyi's method (see Table 1), after fixing the specimen in solution I with formalin and common salt, the specimen was rapidly and thoroughly washed in tap water, possibly to remove sodium chloride on the surface. Instead in the present modified technique, it was observed that dabbing the surface with cotton wool was better than washing with tap water, as it helped to exclude any microorganisms and deleterious effects of variations in salt composition and pH of tap water from different places.

The most important modification by us was introduction in solutions II and III of double-concentrated CPD initially and later adjusting it supplemented with glycerin and distilled water to finally attain "unit-concentration of CPD". It is well known that CPD is very effective in lengthening the storage and prolonged preservation of blood for transfusion purposes in blood banks. With added glycerin, blood could be stored for a longer term [2, 4]. Citric acid present in CPD may have helped to keep hemoglobin in a reduced (ferrous) state and so enhance the effect of sodium dithionite, as described below. The action of citric acid may be similar to that of ascorbic acid used in McCormick's technique [9]. It was found that CPD, along with glycerin gave better control of tissue shrinkage and swelling and retention of color within the specimen. Glycerin lends a translucency to dull-brown opaque formalin-fixed tissues, prevents bacterial growth, helps to control osmolality and being of high refractive index, it gives a crystal-like sparkle to the mounting medium. Hence although is costly, glycerin has been introduced in the mounting medium.

From Professor Romhanyi's personal communication (S. Sriramachari, personal communication), it would appear that pyridine and nicotine form respective "complex hemochromogens" with hemoglobin and myoglobin in the specimen resulting in red colored compounds. The term "hemochromogen" was later renamed "ferrohemochrome" and was considered to be a complex formed by the combination of heme with a nitrogenous substance such as pyridine, ammonia, glycine or denatured globin [1]. The red colored compound formed on addition of pyridine and nicotine resembles the colour of oxyhemoglobin. Pyridine gives a bright red colour and nicotine a darker shade of red. Similar reactions with myoglobin and possibly cytochromes also present may give rise to various shades of pink and brown in the specimen. The colour changes are more obvious in formalin fixed-tissues and blood samples than in fresh unfixed materials. Hence the direct binding effects of pyridine and nicotine on hemoglobin and other cytochromes may have gone unnoticed by scientists. We postulate that formalin-denatured globin may remain attached to heme in the tissue and form a complex compound called formaldehyde-globin-ferrohemochrome that is kept in a reduced state (ferrous iron form) by sodium dithionite.

Preliminary studies carried out by the first author (unpublished observations) suggest that pyridine and nicotine combine with the globin part of hemoglobin and affect its absorption spectrum in the region of the Soret band and also alter its affinity to oxygen. This is in contrast to the effect of carbon monoxide on hemoglobin to produce a cherry-red compound, carboxyhemoglobin, by displacing oxygen. Coal gas was bubbled into the fixative solution to produce carboxyhemoglobin for recolourizing museum specimens in Pick's technique and its modification by Schultz [3, 5]. Although the pyridine hemochromogen reaction was known as a test for identifying blood stains [1], it was not used in any technique other than Romhanyi's, to restore colour in museum specimens. Piperazine, a possible analogue of pyridine, was used for colour restoration, but the method published in Hungarian, was not known outside Europe [7]. The effect of nicotine on museum specimens and its reaction with hemoglobin and myoglobin were also not known in the literature.

If hemoglobin does become oxidized to a ferric state (ferrihemochrome), then the resultant complex with pyridine and nicotine will no longer be red in color and the tissue develops a dirty white or dull brown color. This reaction is irreversible. Such a change is usually the result of remnant detergents in the jar when a brownish-white powdery precipitate forms in the medium and sediments all over the specimen. Therefore, thorough washing and cleaning procedures are required for all glassware used for preparation of fixative and mounting solutions and even the specimen jars, supports or frames used for final storage of specimens. Good quality glass or Perspex museum jars may be used, but one must ensure that they are scrupulously cleaned. All traces of cleaning detergent should be removed by thorough washing of glassware and museum jars with distilled water. Failure to follow these procedures will result in suboptimal results and irreversible deterioration of colour.

The red colored compounds, pyridine- and nicotine-formaldehyde-ferrohemochromes do not decompose in the specimen as they are denatured and "fixed" by formaldehyde. Being "ferrohemochromes" they can become oxygenated and remain stable even on exposure to air. However their oxidation to a ferric state (ferrihemochromes) must be prevented by all means, using reducing substances, buffering salts, maintaining pH and excluding any oxidizing agents or detergents from the medium. Sealing the museum jar is not absolutely essential; it is done mainly to exclude contamination by microorganisms. Slow oxidation of the colored complex in the presence of air or bleaching on exposure to direct sunlight cannot be totally ruled out. Hence there may be a need to exclude air from the jar by boiling the mounting medium before use, as recommended by Wentworth [16], or degassing the medium under vacuum. Such procedures were, however, not done for our specimens, exposed to indirect sunlight and regular room illumination, but the colour remained stable for over 18 years.

Although Romhanyi's technique produced the most spectacular results, it did not become popular in India, even after distribution of the methodology to various medical

colleges and institutions as a personal communication by the third author (S.S.). Due to non-availability of some of the ingredients, particularly nicotine, and the above-mentioned technical difficulties, the procedure resulted in unstable colors. Therefore, the technique failed to arouse the curiosity of pathologists in general, who were keen on improving teaching methodologies [13], barring a few who could reproduce the technique with some success [10].

It was Kaiserling's lifetime desire and effort to produce near-natural fresh-looking museum specimens that did not deteriorate in color and appearance even after many decades [5]. Although alcohol treatment did not always give uniformly good results, his technique remained the most popular one for want of better methods and continues to be followed despite introduction of the "dry-mounting" technique of plastination [14] in some of the museums. Romhanyi's technique was far superior to all other methods of recolorization. The technique was almost lost in oblivion till the present authors revived it when they realized its importance not only as a unique museum technique but also as one that provided definite evidence regarding hitherto unknown tissue-binding effects of nicotine, pyridine and related compounds. It is hoped that in due course the technique may prove to be useful in the demonstration of deleterious tobacco products in biological tissues at the subcellular levels.

Bizarre parosteal osteochondromatous proliferation with a t(1;17) translocation

Received: 19 January 2005 / Accepted: 30 March 2005 / Published online: 31 May 2005
© Springer-Verlag 2005

Abstract Bizarre parosteal osteochondromatous proliferation (BPOP) is a benign lesion that tends to recur repeatedly. Histologically, BPOP contains three components (cartilage, bone, and spindle cells) in differing amounts. The histological findings of BPOP are similar to those of florid reactive periostitis (FRP) and subungual (Dupuytren's) exostosis. Some authors have postulated that all of these conditions are reactive proliferative lesions representing different phases of reactive processes. Whether BPOP is a reactive proliferative lesion or a neoplastic lesion, however, remains controversial. Recently, a t(1;17)(q32;q21) translocation in BPOP was detected using chromosome banding and fluorescence in situ hybridization (FISH) analyses. Here, we describe a 39-year-old Japanese female with BPOP arising in the proximal phalanx of her third toe. A cytogenetic analysis revealed a t(1;17)(q42;q23) translocation. The breakpoints in this case are located close to those of previously reported cases. These results suggest that t(1;17) is a distinct translocation of BPOP and that BPOP is a neoplastic lesion, rather than a reactive proliferative process.

Introduction

Bizarre parosteal osteochondromatous proliferation (BPOP), also known as Nora's lesion, is a rare tumorous lesion first described by Nora et al. in 1983 [7]. The lesion occurs in young adults and predominantly involves the small tubular bones of the hands and feet [5]. Radiologically, BPOP presents as a mass with distinct margins arising from the cortical surface of the affected bone. Cortical flaring of the adjacent bone or continuity of the central part of the tumor with the underlying osseous medulla, as seen in typical osteochondroma, is not present in BPOP. The histological features of BPOP resemble those of a reactive lesion, including the presence of cartilage, bone, and spindle cells. Although the cartilage is hypercellular and contains double-nucleated cells, neither hyperchromasia nor cytologic atypia are seen in the spindle cells. Mitotic figures are common, but none is atypical. Surgical excision is the treatment of choice. Although local recurrences frequently occur, BPOP is considered to be a benign lesion because it does not metastasize. Whether BPOP is a neoplasm or a reactive proliferative lesion remains uncertain. Recently, Nilsson et al. reported a t(1;17)(q32;q21) translocation in five cases of BPOP, as revealed by chromosome banding and fluorescence in situ hybridization (FISH) analyses [6]. Here, we present an additional case of BPOP with a t(1;17) translocation occurring in the foot of a 41-year-old Japanese woman.

Clinical history

A 39-year-old Japanese female complained of right foot pain after kicking a ball. She underwent a thorough medical examination at a local clinic, but no abnormal findings were found. At the age of 41 years, the pain recurred at the same site, without any traumatic episode, and began to worsen. She consulted a doctor and was referred to our hospital because of a suspected bone tumor. Clinical examination revealed a solid hard mass fixed to the proximal phalanx of the third toe. The mass was tender to palpation,

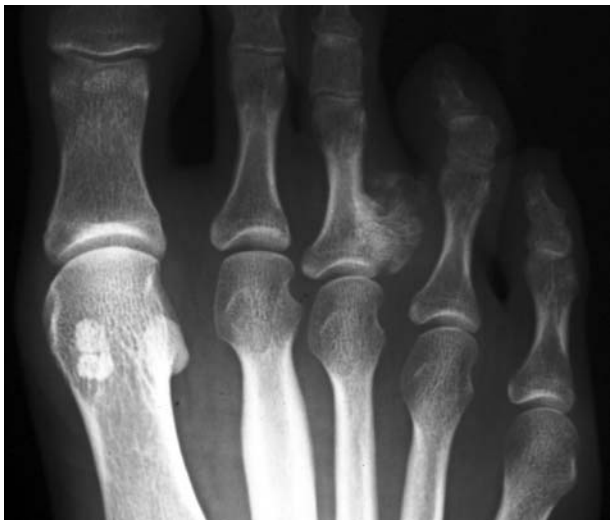

Fig. 1 Plain radiograph showing an oval mass with a distinct margin and heterogeneous patchy opacity adjacent to the lateral aspect of the base of the proximal phalanx of the third toe

but the overlying skin was intact. No neurovascular complications in the third digit were observed. Plain radiographs demonstrated a solid, 1.6×0.9 cm calcified mass with distinct margins arising from the cortical surface on the lateral aspect of the proximal phalanx (Fig. 1). Flaring of the cortex was not visible on an X-ray. Continuity with the osseous medulla was not seen using computed tomography. T1-weighted magnetic resonance imaging (MRI) showed a low-intensity mass adjacent to the proximal phalanx. Fat-suppressed T2-weighted images showed a heterogeneous, high-intensity mass with a well-defined convex border against the surrounding tissue. With regard to the proximal phalanx, neither cortical nor medullary abnormalities were seen. $^{99\ m}$Tc-and ^{201}Tl-scintigraphies demonstrated an abnormal uptake in the right foot lesion, while the uptake in other parts of her body was normal. All laboratory data were within the normal range. An open biopsy was performed, and a diagnosis of bizarre parosteal osteochondromatous proliferation was established. The mass was excised completely, and the patient has remained free of any evidence of local recurrence or metastasis for 3 months after the surgery.

Materials and methods

Histology and immunohistochemistry

The biopsy and excised specimens were fixed in formalin. Paraffin-embedded tissue was examined using standard histopathological techniques. Immunohistochemical staining was performed using antibodies against vimentin (V9; 1/200; DakoCytomation, Glostrup, Denmark), desmin (D33; 1/100; DakoCytomation), smooth-muscle actin (SMA) (1A4; 1/100; DakoCytomation), cytokeratin (AE1/3; 1/100; DakoCytomation), muscle-specific actin (MSA) (HHF35; 1/100; Enzo, New York, USA), epithelial membrane antigen (EMA) (E29; 1/100; DakoCytomation), S-100 protein (polyclonal antibody; 1/2000; DakoCytomation), CD34 (my10; 1/100; DakoCytomation), CD68 (KP1; 1/1000; DakoCytomation), p53 (DO7; 1/50; DakoCytomation), and Ki-67 (MIB-1; 1/100; DakoCytomation).

Cytogenetic and FISH analysis

A fresh fragment of the lesion obtained at the time of surgery was prepared for cytogenetic analysis using collagenase. The specimen was cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum and antibiotics. Slides were stained using a previously described G-banding technique [3].

Multicolor FISH (M-FISH) [8] was performed using the SpectraVysion assay system (Vysis, Downers Grove, Ill., USA). The hybridization of the probe was visualized using fluorescence microscopy.

Results

Histopathological features

The histological evaluation showed a gross appearance consisting of a cancellous bone matrix partially covered by an irregular cartilaginous cap. Microscopically, three components (cartilage, bone, and spindle cells) were observed in differing amounts. The cartilage and bone interface showed irregular endochondral ossification, and the bone

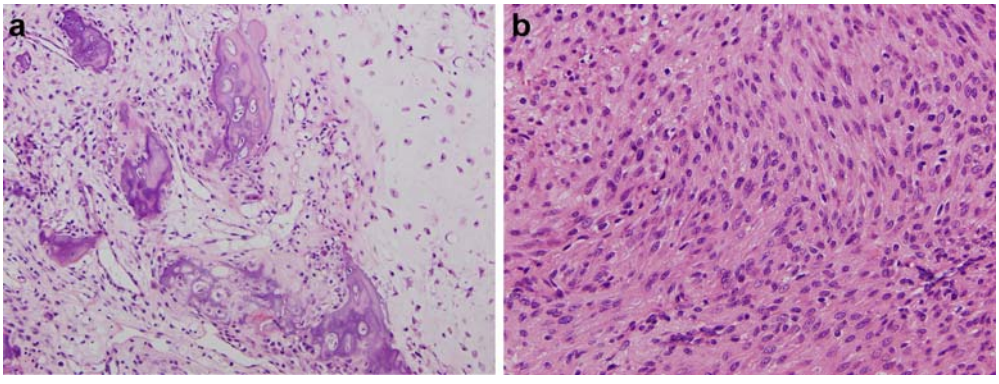

Fig. 2 Microphotographs of the lesion. **a** The cartilage and bone interface shows irregular ossification, and the formed bone trabeculae are characteristically stained blue [Hematoxylin and eosin (HE); original magnification, ×100]. **b** The spindle cells show monotonous proliferation without cytologic atypia (HE; original magnification, ×200)

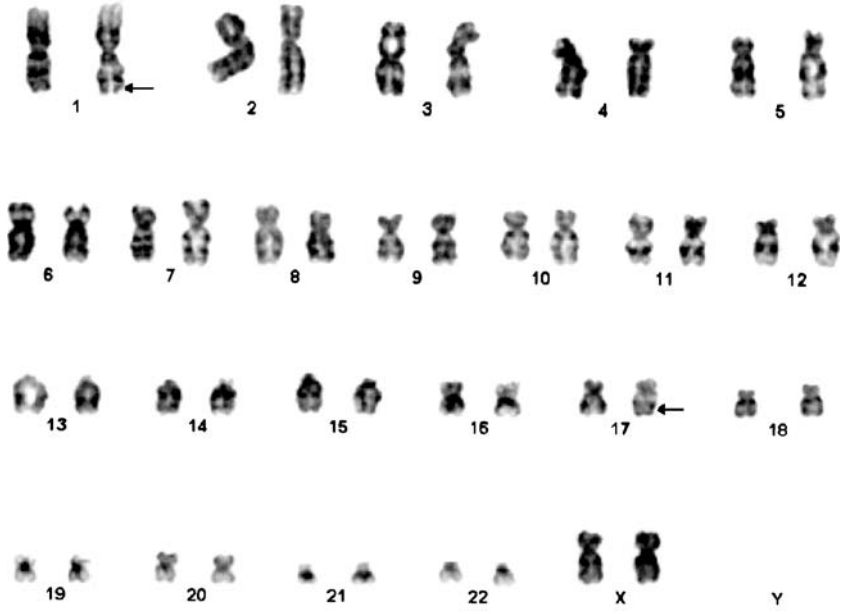

Fig. 3 G-banded karyotype showing a t(1;17)(q42;q23) translocation

trabeculae formed were characteristically stained blue with hematoxylin and eosin (Fig. 2a). The cartilage was partially hypercellular with moderately enlarged nuclei and contained large chondrocytes. The spindle cells were uniform without any cytologic atypia (Fig. 2b) and were loosely arranged between the bony trabeculae. Mitotic figures were occasionally seen, but none was atypical. Immunohistochemical examination showed that the spindle cells were positive for SMA. Desmin was expressed in the spindle cells and some chondrocytes, and vimentin was positive in almost all cell types within the lesion. MSA, cytokeratin, EMA, S-100 protein, CD34, CD68, and p53 tested negative. The MIB-1 labelling index was about 1% in the spindle cells.

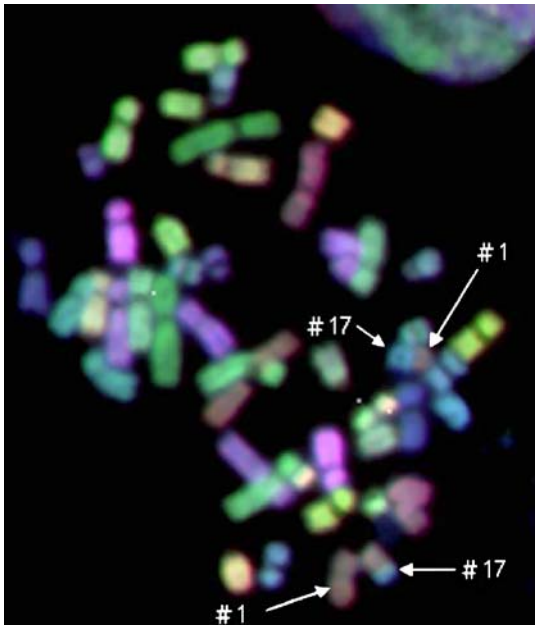

Fig. 4 Multicolor FISH analysis of a metaphase cell showing a t(1;17)(q42;q23) translocation. The colors representing chromosomes 1 and 17 are grey and light blue, respectively

Cytogenetic and FISH analysis

Cytogenetic analysis of the lesion revealed a karyotype with a t(1;17)(q42;q23) translocation (Fig. 3). The reciprocal translocation was further characterized by M-FISH analysis (Fig. 4).

Discussion

Recently, chromosomal aberrations in BPOP were reported by Nilsson et al. [6] and Zambrano et al. [12]. Nilsson et al. reported the cytogenetic findings of five cases of BPOP using G-banding and FISH analyses [6]. They reported the t(1;17)(q32;q21) translocation to be a recurrent and unique aberration in BPOP [6]. On the other hand, Zambrano et al. reported an abnormal clone characterized by additional ring chromosomes derived from chromosome 12 in one case [12]. In our experience, cytogenetic analysis of the lesion revealed a karyotype with a t(1;17)(q42;q23) translocation. Nilsson et al. used 1q32-and 17q21-specific bacterial artificial chromosome (BAC) probes to produce a detailed map of the breakpoints on chromosome 1 and 17 [6], but the BAC probes were unavailable for use in our analysis. The identification of the translocation breakpoints in our analysis might be rather approximate, and the present cytogenetic findings might actually express the same translocation as that reported by Nilsson et al. [6].

BPOP has a tendency to recur repeatedly, but it is regarded as a benign lesion because it does not metastasize [5]. Whether BPOP is a neoplastic lesion or a reactive proliferative lesion remains controversial. Although an antecedent traumatic history, which has been reported in

some cases [12], may support a reactive theory, a traumatic history cannot be documented in most cases. The histological features, primarily the maturation from cartilage to bone, support a reactive process akin to heterotopic ossification [5]. However, the monotonous proliferation of spindle cells, as seen in our case, suggests a neoplastic process, particularly one characterized by a genetic abnormality. If BPOP is a reactive lesion, the remarkable tendency to recur after excision would be difficult to explain. Although chromosomal aberrations have been reported in some soft-tissue lesions considered to be reactive, such as nodular fasciitis and proliferative myositis [1, 4, 9, 10], these were all single case reports that have not yet been corroborated. The t(1;17) translocation in BPOP is a distinctive cytologic abnormality that has been confirmed in at least six cases of BPOP, including the present one [6]. These histological and cytologic features support a neoplastic theory.

Some authors have proposed that several separately described entities, such as florid reactive periostitis (FRP), BPOP, and subungual exostosis, represent different phases of reactive processes initiated by trauma and subperiosteal hemorrhage, with subsequent organization and maturation [11]. The clinical and histological findings of BPOP resemble those of FRP and subungual exostosis. Zambrano et al. [12] and Dal Cin et al. [2] reported a t(X;6) translocation in four cases of subungual exostosis and suggested that subungual exostosis was a neoplastic lesion. Our chromosomal translocation findings in the present BPOP case were different from those found in subungual exostosis, so these two lesions might be distinct clinicopathologic entities with a different molecular pathogenesis. Concerning FRP, no cytogenetic abnormality has been reported.

In summary, we present an additional case of BPOP with a clearly demonstrated t(1;17) translocation. This finding suggests that BPOP is a neoplastic lesion, rather than a reactive proliferative lesion. Additional cases should be studied to determine the consistency of this finding, and further studies may help to elucidate the role of this translocation in the onset of BPOP.

Hemosiderotic fibrohistiocytic lipomatous lesion: clinical correlation with venous stasis

Received: 23 December 2004 / Accepted: 3 February 2005 / Published online: 10 June 2005
© Springer-Verlag 2005

Abstract Hemosiderotic fibrohistiocytic lipomatous lesion (HFLL) is a recently proposed lipomatous entity. HFLL was originally suggested to be a benign reactive lesion arising due to an antecedent trauma. We report two patients with HFLL who also suffered from chronic vein insufficiency due to varicose involving deep veins of the low limbs. Both patients were middle-aged women with solitary, poorly circumscribed subcutaneous lesions on the lower extremities. Histopathological examination revealed typical features of HFLL. We think that the consistent clinical features such as advanced age, female sex predilection, and specific location along with distinctive histopathological features allow the suggestion that impaired blood circulation, to wit, venous stasis is involved in the pathogenesis of HFLL. We hypothesize that the proliferation of spindled fibroblastic and myofibroblastic cells and capillaries, erythrocyte extravasation, and hemosiderin deposition with lipomatous tissue of HFLL may simply represent an exaggerated tissue response to venous stasis in which elevated venous and capillary pressures, oxygen saturation, and edema stimulate the proliferation of the abovementioned elements and lead to erythrocyte extravasation. A similar histopathological pattern is seen in acroangiodermatitis of Mali and vascular transformation of lymph node sinuses, and these conditions are also associated with impaired blood circulation.

Introduction

In 2000, a new entity within the group of adipose tumors was proposed [7]. It was called hemosiderotic fibrohistiocytic lipomatous lesion (HFLL) by the authors who identified 10 patients with this condition among all benign lipomatous lesions at the AFIP files over the preceding 24 years [7]. Its reproducible clinical and histopathological findings suggested that HFLL merits designation as a separate entity. HFLL was found to mainly occur in middle-aged women in the low extremities, especially in the foot/ankle region. Histopathological features included proliferation of bland or slightly pleomorphic spindled cells within well-delineated mature adipose tissue in a background of mixed inflammatory infiltrate and hemosiderin deposition. Immunohistochemically, the spindled cell component was demonstrated to represent a mixture of myofibroblasts, fibroblasts, and histiocytes. HFLL was originally suggested to be a benign reactive lesion arising due to an antecedent trauma [7]. Most recently, however, Folpe and Weiss [4] suggested that HFLL might represent a variant of pleomorphic telangiectatic tumor. We have seen two patients with HFLL who also had varicose involving deep veins of the low limbs. We suggest that impaired blood circulation due to varicose may also be implicated or even dominate in the pathogenesis of HFLL.

Case reports

Both patients were women (48 and 60 years old) suffering from varicose of deep veins of the low extremities with chronic venous insufficiency with known recurrent ulcerations of the skin of the calves. Both clinically presented with a solitary, poorly circumscribed subcutaneous mass located over the extensor surface of the right foot with extension onto the ankle. In the first patient, the lesion had previously been surgically removed twice, but recurred in the same site 3 years and 1 year after surgical interventions, respectively. The history of the second patient was irrelevant. The mode of treatment in both cases was surgical

removal of the lesion. Both patients were without signs of further recurrence or metastasis after the last excision 1 year and 6 months, respectively.

Material and methods

Tissues were fixed in 4% formaldehyde embedded in paraffin. The paraffin blocks were cut into 5-μm-thick sections and stained with hematoxylin and eosin, Giemsa, PAS with and without diastase pretreatment, Fontana, and Prussian blue stains.

Immunohistochemical studies were performed on formalin-fixed paraffin-embedded tissue. Primary antibodies against S-100 protein (polyclonal, 1:4,000, DakoCytomation, Glostrup, Denmark), CD34 (clone QBEnd/10, 1:100, DakoCytomation, Glostrup), CD68 (KP1, 1:200, DakoCytomation, Carpenteria), α-smooth muscle actin (ASMA) (1A4, 1:200, DakoCytomation, Glostrup), muscle-specific actin (MSA) (HHF-35, 1:5,000, DakoCytomation, Carpenteria), calponin (CALP, 1:1,000, DakoCytomation, Carpenteria), desmin (D33, 1:500, DakoCytomation, Glostrup), vimentin (V9, 1:200, DakoCytomation, Glostrup), melanosomes (HMB-45, 1:400, DakoCytomation, Glostrup), antigen Ki-67 (MIB-1, 1:150, Biotex, Westinghouse), epithelial membrane antigen (EMA) (E29, 1:700, DakoCytomation, Glostrup), and lysozyme (polyclonal, 1:200, DakoCytomation, Glostrup) were used. Immunostaining was performed according to standard protocols using an alkaline phosphatase–anti-alkaline phosphatase method or avidin–biotin complex labeled with peroxidase or alkaline phosphatase. Appropriate positive and negative controls were applied.

A polymerase chain reaction (PCR) with primers KSHV-1 (5′-AGCCGAAAGGATTCCACCAT-3′) and KSHV-2 (5′-TCCGTGTTGTCTACGTCCAG-3′) for human herpes virus 8 (HHV8) detection was performed as described elsewhere [12].

Clonality analysis was performed by a previously described method based on digestion of genomic DNA with methylation-sensitive restriction enzymes followed by PCR amplification of the CAG repeat at the human androgen receptor gene (HUMARA) locus at the X chromosome [1]. The primers used were as follows: 2A (5′-TCC AGA ATC TGT TCC AGA GCG TGC-3′) and 2B (5′-ATG GGC TTG GGG AGA ACC ATC CTC-3′) [10]. The amplification program consisted of denaturation for 14 min at 95°C, then five rounds of 2.5 min at 95°C, 1 min at 60°C, 1.5 min at 72°C, followed by 30 cycles of 1 min at 95°C, 1 min at 60°C, and 1.5 min at 72°C. Amplification program was finished by a final extension at 72°C for 10 min. All PCR products were examined by fragment analysis on 8% ReproGel High Resolution (AP Biotech, Uppsala, Sweden) using an ALFexpress automated sequencer and fragment analyzer (AP Biotech). All samples were analyzed in duplicate. Peak intensities of the two alleles were measured for each specimen. A corrected ratio (CR) was first assessed by dividing the ratio (allele 1/allele 2) of the *Hpa*II digested samples by the ratio (allele 1/allele 2) of the non-digested sample. A final clonality ratio was determined by dividing the CR of the lesional DNA by the CR of the nonlesional DNA. Samples were considered as monoclonal if the final ratio was 1.5 or greater [11].

Results

Gross findings

Only the lesion from the first patient, representing the second recurrence, was available for gross pathological examination. It had an overall appearance of adipose tissue, the size of 6×5×4 cm. The cut surface was homogeneously tan with tiny foci of hemorrhage.

Histopathological findings

Both lesions demonstrated mature adipose tissue with foci of proliferation of bland spindled cells around individual homogeneous adipocytes, small blood vessels, and along fibrous septa (Fig. 1a–c). There also were scattered infiltrates composed of small lymphocytes, mast cells, plasma cells with occasional Russell bodies, and rare granulocytes. Occasional normal mitotic figures were seen. The cellular proliferations were invariably associated with erythrocyte extravasations and hemosiderin deposits (as verified by Fontana and iron stains), and small areas of fibrosis. Small and medium-sized blood vessels appeared to be slightly increased in number and occasionally demonstrated a somewhat thickened wall and plump endothelial cells. All these changes were more prominent in the first case. In addition, the biopsy from this patient displayed rare multinucleated cells with prominent nucleoli and slight myxoid degeneration of small nerve twigs. There were no pleomorphic cells, nuclear crowding, lipoblasts, or abnormal mitotic figures.

Immunohistochemical findings

The spindled cells variably coexpressed CD34, calponin, lysozyme, vimentin, and CD68, and were negative for desmin, ASMA, MSA, and EMA. Proliferation index was low. S-100 protein stained adipocytes and nerves. HMB-45 reacted negatively.

Human herpes virus 8 PCR

The PCR failed to detect HHV8 DNA in the lesional tissues.

HUMARA analysis

One case was homozygous in locus HUMARA and was thus unsuitable for analysis of clonality. The analysis of the

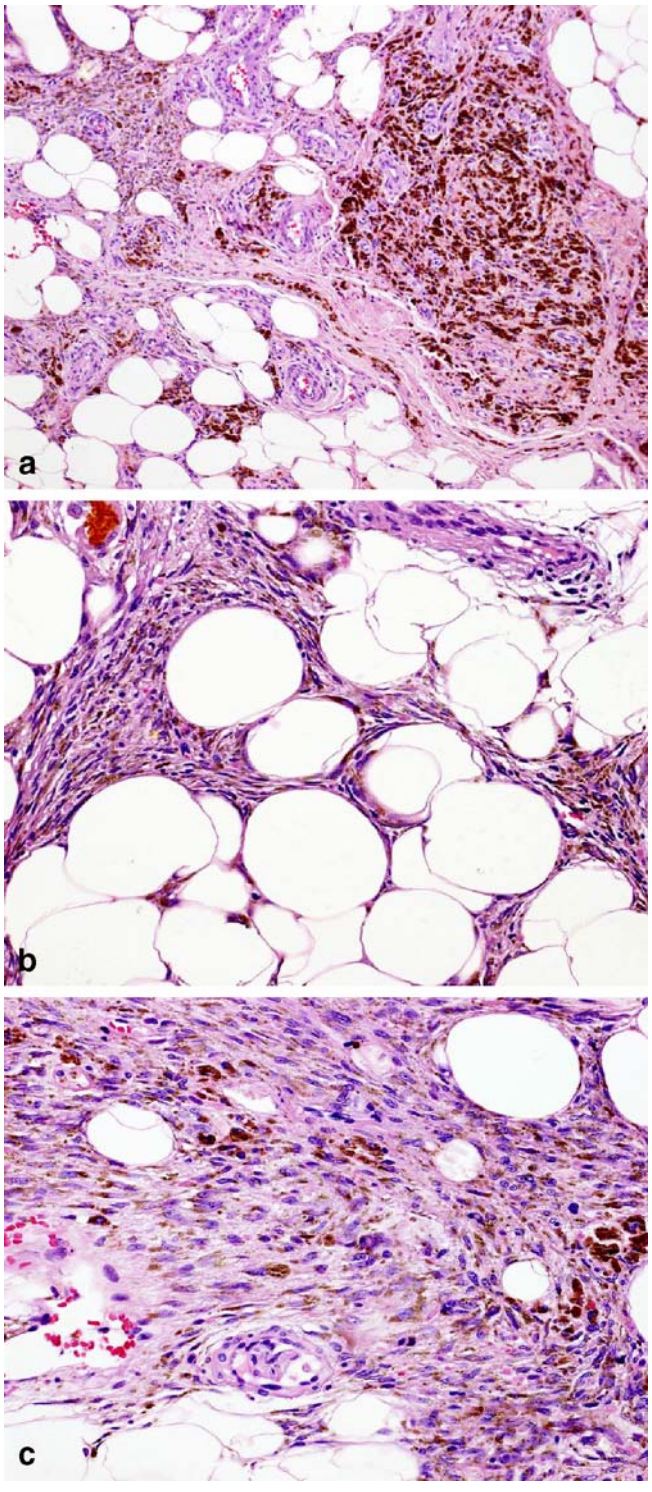

Fig. 1 **a** Mature adipose tissue with hemosiderin deposits, small areas of fibrosis, and proliferation of spindled cells along the fibrous septum and blood vessels. **b** Proliferation of spindled cells around individual lipocytes. **c** A close-up view: plump, relatively uniform spindled cells

HUMARA gene in the other patient showed partial loss of one allele in samples digested with restriction enzyme *Hha*I (*Hpa*II). Signal intensity ratio of nondigested and digested DNA was 1.55.

Discussion

Because a history of an injury (specific injury and/or multiple repeatable traumas) was given by the majority of the patients of the original series, it was suggested that HFLL occurs as a result of these [7]. Not denying this, we think that another factor may play a role in the pathogenesis of this condition. The predilection site of HFLL is the lower extremities, and the lesion usually occurs in middle-aged to old women. This very anatomic area of soft tissue in women is likely to suffer from impaired blood circulation as a result of venous insufficiency. Because this area is prone to traumas anyway, we think that it is not possible to deny the close association of HFLL with an injury. We therefore believe that the consistent clinical features such as advanced age, female sex predilection, and specific location along with distinctive histopathological features may lend credit to the suggestion that impaired blood circulation, to wit, venous stasis is involved in the pathogenesis of HFLL. This possibility was mentioned by Marshall-Taylor and Fanburg-Smith [7] while discussing the differential diagnosis of HFLL and acroangiodermatitis of Mali, but finally discarded by the authors, because none of their patients were known to have vascular insufficiency. In many women, the signs of congestions are, however, often mild and are only subclinically apparent, and still, these patients are prone to injuries, which often results in ulceration of the skin on the calves. Our patients had severe chronic venous insufficiency secondary to varicose of deep veins of the low extremities. Further, the histopathological pattern of HFLL and that of acroangiodermatitis of Mali is basically the same, namely, the proliferation of spindled fibroblastic and myofibroblatsic cells and capillaries, erythrocyte extravasation, and hemosiderin deposition. This pattern simply represents an exaggerated tissue response to venous stasis in which elevated venous and capillary pressures, oxygen saturation, and edema stimulate the proliferation of the abovementioned elements and lead to erythrocyte extravasation. The differences are only in the location: in acroangiodermatitis of Mali, the histopathological changes are confined to the upper dermis, and the main response is seen as the proliferation of capillaries that often assume a lobular pattern [6]. In HFLL, a deeper tissue, mainly fat, is involved. In respect to the skin, similar histopathological features are seen in patients with Stewart–Bluefarb syndrome (unilateral acroangiodermatitis secondary to congenital arteriovenous malformation) [2, 14] and in patients on hemodialysis as a consequence of an arteriovenous fistula [5]. The same pattern (proliferation of endothelial cells, spindle-shaped fibroblasts, erythrocyte extravasation, and hemosiderin deposition) is also seen in "vascular transformation of lymph node sinuses" [9, 13] especially in the nodular spindle cell variant of this lesion [3, 8]. This condition also occurs due to local impaired blood circulation after occlusion of efferent lymphatic vessels and veins by a tumor arising in the adjacent tissue or may be reproduced experimentally [13]. In fact, microscopically vascular sinus transformation of lymph node, acroangiodermatitis of Mali, and HFLL, and

other spindle cell mesenchymal lesions caused by congestion look identical; all these lesions have a similarity to Kaposi's sarcoma. Half of the patients with HFLL in the original series with follow-up had a local recurrence or residual disease within 3 years, requiring reexcision [7]. This was also seen in one of our patients and further supports our hypothesis, because the main underlying pathogenic mechanism, impaired blood circulation, persists and predisposes to recurrence.

In summary, we suggest that impaired blood circulation due to varicose may also be involved in the pathogenesis of HFLL. Further observations would be necessary to support or decline our hypothesis.

Primary signet-ring stromal tumor of the testis

Received: 10 November 2004 / Accepted: 19 January 2005 / Published online: 21 May 2005
© Springer-Verlag 2005

Abstract We present, in a 47-year-old man, the first case of the signet-ring stromal tumor of the testis. The tumor was located beneath the tunica albuginea surrounded by the testicular tubules and rete testis. It was sharply circumscribed by a thin and irregular fibrous capsule. Histologically, it was composed of cells with a widespread signet-ring cell change separated by fibrous stroma. In some places, the signet-ring cells formed vague Indian files, thus resembling metastatic carcinomas with signet-ring cell morphology. Under high magnification, most of the cytoplasm of the tumor cells was seen to be replaced by an empty clear vacuole which pushed the nuclei to the periphery of the cells. Some of the nuclei were indented by the cytoplasmic vacuoles, others were without indentation. Only in a small area did the tumor show cells without a signet-ring cell change. They looked like epithelioid fibroblasts forming abortive and vaguely tubular structures. Mitoses and necroses were absent. Mucicarmine and PAS stains were negative. Immunohistochemically, the tumor was vimentin positive and it was negative with antibodies to cytokeratins, inhibin, prostatic acid phosphatase, prostate-specific antigen, smooth muscle actin, S-100 protein, EMA and calretinin. The signet-ring stromal tumor of the testis is thus similar morphologically and immunohistochemically to the signet-ring stromal tumor of the ovary. The patient was free of recurrence and metastasis 3 years after the excision.

Keywords Testis · Signet-ring cell stromal tumor

Introduction

Signet-ring stromal tumor is a rare type of ovarian tumor and it has never before been described in the testis. Microscopically, this ovarian neoplasm is characterized by a proliferation of stromal spindle-shaped cells merged with rounded cells containing eccentric nuclei and single vacuoles, resembling signet-ring cells [1, 3, 7–10, 12]. The signet-ring cells may either be diffuse or represent only a focal change in an otherwise typical fibroma. We present a case of signet-ring stromal tumor of the testis identical to that of the ovary. To the best of our knowledge, this is the first case of signet-ring stromal tumor of the testis ever to be published.

Materials and methods

Tissue was fixed in 4% formaldehyde and paraffin embedded. Sections (5 μm thick) were stained using routine staining methods.

The case was examined by means of immunohistochemistry on the formaldehyde-fixed, paraffin-embedded material. As a detection system, we employed the avidin–biotin complex or streptavidin–biotin complex labeled with peroxidase or alkaline phosphatase (DakoCytomation). We used microwave antigen pretreatment prior to the application of the primary antibodies. Automated immunostaining employing Lab Vision autostainer was used. Antibodies against cytokeratins (CAM 5.2, Becton-Dickinson), AE1–AE3 (Boehringer), epithelial membrane antigen (EMA; E29, DakoCytomation), S-100 protein (polyclonal, DakoCytomation), neuron specific enolase (NSE; polyclonal, DakoCytomation), prostate specific antigen (polyclonal, DakoCytomation), prostate acid phosphatase (polyclonal, DakoCytomation), glial fibrillary acidic protein (polyclonal, DakoCytomation), CD 34 (QBEnd 10, DakoCytomation), calretinin (DC8, Zymed), vimentin (V9,

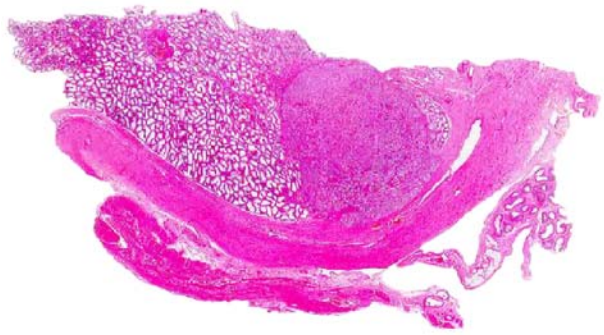

Fig. 1 A low-power view showing that the tumor lies beneath the tunica albuginea surrounded by the testicular tubules and rete testis

DakoCytomation), smooth muscle actin (1A6, DakoCytomation), desmin (D33, DakoCytomation), placental alkaline phosphatase (8B6, DakoCytomation), melanosome (HMB45, DakoCytomation), estrogen and progesterone receptors (Immunotech), androgen receptors (AR 441 DakoCytomation) and Ki67 (MIB1, Immunotech) were used.

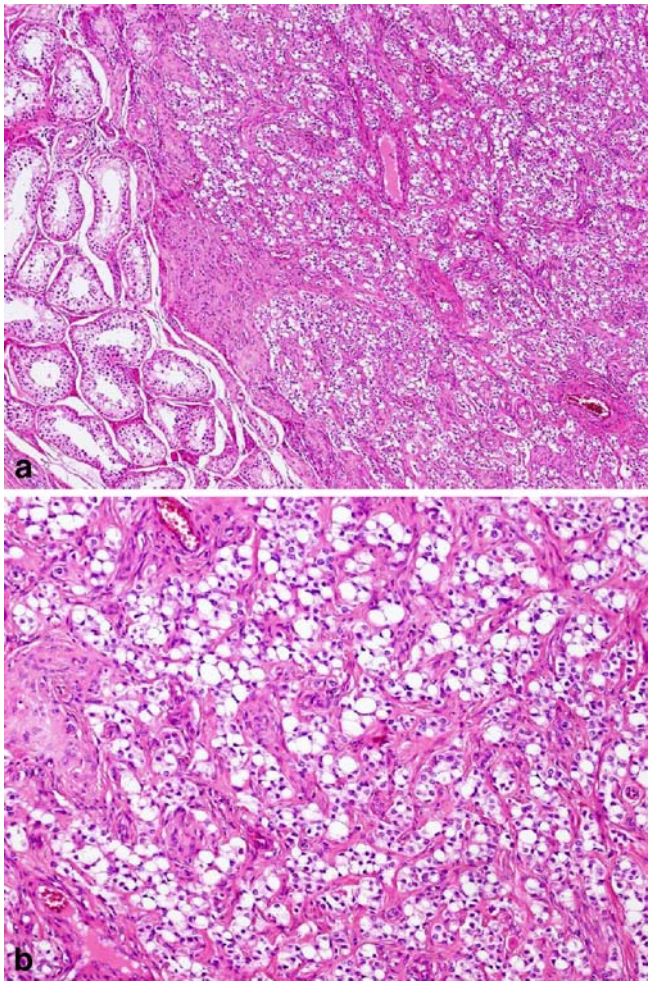

Fig. 2 The tumor is well circumscribed (**a**) and is formed by cells with widespread signet-ring cell change separated by fibrous stroma (**b**)

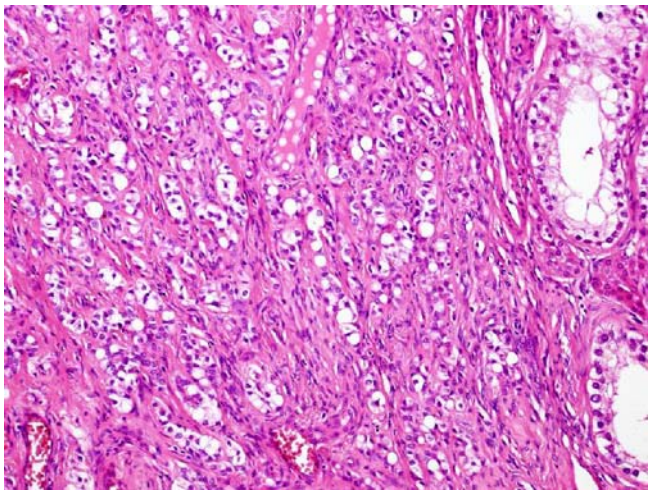

Fig. 3 In some places, the signet-ring cells form vague Indian files, thus having a resemblance to metastatic signet-ring cell carcinomas

Tissue material for ultrastructural examination was not available.

Results

Case report

A 47-year-old patient was found to have a round-shaped tumor 1 cm in largest diameter in the right testis. The tumor was surgically removed. Grossly it was white in color and hard in consistency. The patient is without signs of recurrence and metastasis 3 years after the excision.

The tumor was located beneath the tunica albuginea surrounded by the testicular tubules and rete testis. It was sharply circumscribed by a thin and irregular fibrous capsule (Fig. 1). Histologically, it was composed of irregular and variously shaped trabeculae of cells with a widespread

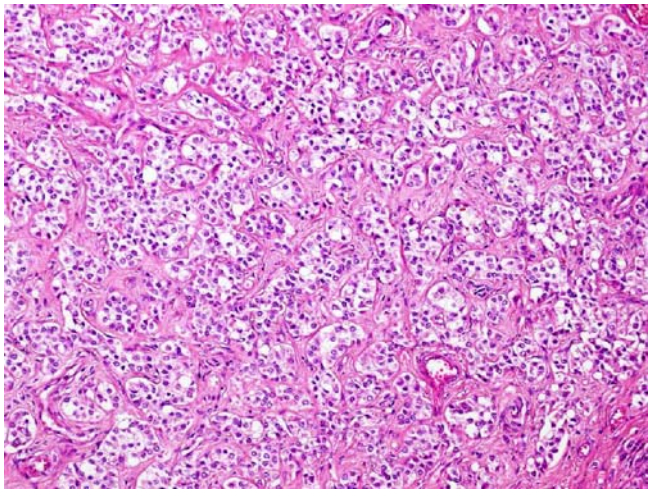

Fig. 4 The tumor cells in this area have the appearance of epithelioid fibroblasts

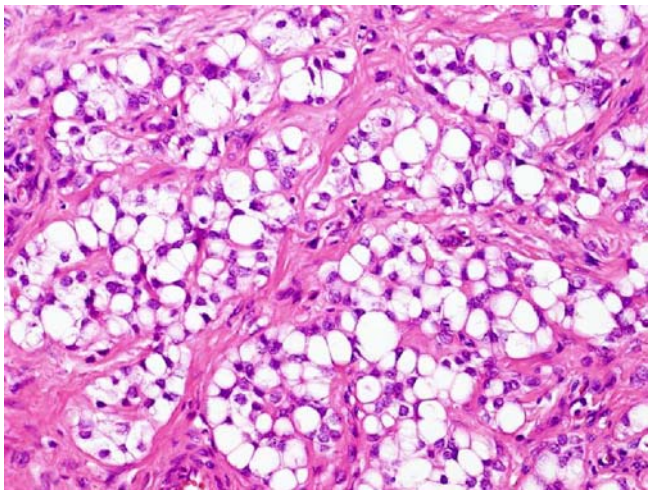

Fig. 5 Under high magnification, most of the cytoplasm is shown to be replaced by an empty clear vacuole that has pushed the nucleus to the periphery of the cell. Some of the nuclei are indented by the cytoplasmic vacuoles, while others are not

signet-ring cell change separated by fibrous stroma (Fig. 2). In some places the signet-ring cells formed vague Indian files, thus resembling metastatic signet-ring cell carcinomas (Fig. 3). Only in a small area were there cells without signet-ring cell change. The tumor cells in this area had the appearance of epithelioid fibroblasts arranged in abortive and vaguely microalveolar structures (Fig. 4). Under high magnification, most of the cytoplasm of the majority of the tumor cells was seen to be replaced by an empty clear vacuole which pushed the nucleus to the periphery of the cell. Some of the nuclei were indented by the cytoplasmic vacuoles, others were without sign of indentation (Fig. 5). Mucicarmine and PAS stains were negative. Mitoses and necroses were absent.

Immunohistochemically, the tumor cells reacted strongly with antibody to vimentin; and all other antibodies—including those against MIB1 and estrogen, progesterone and androgen receptors—reacted negatively.

Discussion

Benign fibrous tumors of the testis are quite unusual. Most of these tumors within this category are paratesticular and they have been considered variants of fibrous pseudotumor [11]. Jones et al. [4] coined the term "fibroma of gonadal stromal origin" for a group of rare testicular tumors in order to delineate these neoplasms from all other types of testicular lesions for which the term "fibroma" was used. However, in none of the cases of testicular fibromas of gonadal stromal origin was the observation of a signet-ring cell change ever published [2, 4].

Our case seems to have many similarities to the rare ovarian neoplasm called "signet-ring stromal tumors of the ovary" (SSTO). SSTO shown a spindle cell fibroblastic component which merges imperceptibly with rounded cells containing eccentric nuclei and large vacuoles resembling signet-ring cells. Ultrastructural examination showed that in some cases of SSTO the vacuoles result from generalized edema of the cytoplasmic matrix, from a swelling of mitochondria or from cytoplasmic pseudoinclusions of an edematous extracellular matrix [3]. Similar to this tumor, our case revealed a fibroblastic component without signet-ring vacuoles, which merged with PAS and mucicarmine negative signet-ring cells [3]. In addition, immunohistochemical vimentin positivity and immunohistochemical negativity with antibodies to cytokeratins, inhibin, smooth muscle actin, S-100 protein, EMA, and calretinin confirm that the immunoprofile of our case was identical to that of SSTO [3, 12]. Absence of mitoses, necroses, immunohistochemical negativity with MIB1 antibody and sharp circumscription of the lesion point to the benign nature of signet-ring stromal tumor of the testis.

There are very few lesions from which signet-ring stromal tumor of the testis should be differentiated. In contrast to the ovary, metastasis of gastric adenocarcinoma (Krukenberg tumor) with signet-ring cell morphology is an extremely rare event in the testis [5, 6]. Sharp circumscription, lack of mitoses, PAS, mucicarmine negativity and immunohistochemical negativity with antibodies to MIB1, EMA and cytokeratins clearly distinguish the visceral metastases with signet-ring cell morphology from the primary signet-ring stromal tumor of the testis. The authors are not aware of any other primary testicular tumor with so widespread a signet-ring cell morphology.

In summary, we describe the first example of the signet-ring stromal tumor of the testis, which had similar features to the SSTO. It is different from any other known primary testicular neoplasm and it can easily be differentiated by morphology and by immunohistochemical means from visceral metastatic carcinomas with signet-ring cell morphology.

Not all "mucinous carcinomas" are equal: time to redefine and reinvestigate the biologic significance of mucin types and patterns in the GI tract

Received: 6 January 2005 / Accepted: 15 February 2005 / Published online: 8 June 2005
© Springer-Verlag 2005

We read with great interest the study by Solcia et al. [14], published in the December 2004 issue of *Virchows Archives*. Their results reaffirm that the muconodular (or colloid) type of mucinous carcinoma is associated with a significantly better prognosis than other types of mucinous carcinomas (or the conventional carcinomas of the respective organs), not only in the breast [8] and pancreas [2], but in the stomach as well. As such, this study adds another major blow to a long-held dogma that mucinous carcinomas of any type are particularly aggressive in the gastrointestinal (GI) tract.

It has long been known that "pure mucinous" carcinomas of the breast, also referred to as colloid carcinomas [7, 9, 10, 13], are associated with an excellent prognosis, even better than that of some in-situ carcinomas of this organ [7]. It is also noted that, interestingly, even a small component of the usual ductal carcinoma negates this survival benefit [4, 8]. The same seems to apply to the pancreas; pancreatic carcinomas composed almost entirely of the colloid pattern have a very good prognosis [2], whereas mixed-mucinous carcinomas are highly aggressive tumors [12].

Why is pure colloid carcinoma indolent, but not mixed-mucinous carcinoma? We believe the answer lies in the pathogenesis of the colloid carcinoma pattern. It has been speculated that in colloid carcinoma, the mucin acts as a containing factor, exerting a function similar to that of the basement membrane in in-situ carcinomas [1, 7]. Indeed, the survival advantage and indolent behavior of colloid carcinomas appear to be most evident when most of the cells are floating within the mucin, without any non-mucinous glands infiltrating into the stroma. What causes the tumor cells to float within the mucin rather than invading the stroma? One characteristic feature of the colloid pattern is that the cells have reversed polarity (as evidenced by both immunohistochemical and ultrastructural studies) [1], in which the secretory pole of the cells is oriented toward the stroma-facing surface of the cells, leading to the accumulation of mucin in the stroma, which in turn acts as a barrier to the spread of the cells. Furthermore, the mucin secreted by these cells appears to be distinctive, with inhibitory properties [1]. MUC2, which is a tumor suppressor, is highly expressed in this type of mucinous carcinoma but not others. Why then is it that even a small component of ordinary carcinoma negates the survival advantage of the colloid pattern? One can speculate that once the cells of a colloid carcinoma acquire the properties that allow them to overcome the mucin and independently invade the stroma, these cells may represent a more aggressive phenotype than even ordinary invasive carcinomas.

Does the colloid (muconodular) pattern have the same implication in the GI tract as in the breast and pancreas? The studies by Solcia et al. [14] and others [3] show that it probably does. But in fact, there were already several questions regarding the significance of mucin production in the GI tract. First, appendiceal mucinous neoplasms that have a predominantly colloid pattern are associated with a protracted clinical course even if they give rise to pseudomyxoma peritonei. There are several observations that support this impression [5, 6]. The invasive (disseminated) component of the cases, referred to as "disseminated peritoneal adenomucinosis" by Ronnett et al. [6] or "low-grade mucinous neoplasm" by Misdraji et al. [5], typically shows a predominant colloid pattern and has a much better prognosis than those with less of a colloid pattern. There is yet

another emerging set of data supporting the supposition that there may be distinct subsets of "mucinous" carcinoma in the GI tract: patients with hereditary nonpolyposis colorectal cancer (HNPCC) syndrome. Recent studies suggest that HNPCC-associated colorectal carcinomas have a better clinical outcome [15] (beyond that which can be explained by the younger age of the patients), and it has been also shown that HNPCC-associated colorectal carcinomas are commonly mucinous [11]. All of this evidence raises the question of whether different types and patterns of mucin production may have different clinical implications in the lower GI tract as well.

To determine the significance of mucin production in different sites, a more uniform approach to the definition of "mucinous carcinoma" is necessary. As discussed above, there is mounting evidence that the muconodular (colloid) pattern ought to be defined strictly as well-delineated lakes of mucin, in which most of the cells are floating unattached to the stroma. If a substantial number of the cells are clinging to the stroma or if the mucin lakes are ill defined, this should not be regarded as the muconodular (colloid) pattern. For a given case, the percentage of the colloid pattern in the tumor ought to be recorded. The goal for investigators, then, would be to determine what percentage of colloid pattern qualifies a case as a "colloid (or a muconodular or low-grade mucinous) carcinoma" so that the significance of this phenomenon can be verified.

Absence of Epstein-Barr virus EBER transcripts in male breast cancer

Received: 16 December 2004 / Accepted: 10 February 2005 / Published online: 31 May 2005
© Springer-Verlag 2005

Sir,

Epstein-Barr virus (EBV) is a ubiquitous human herpesvirus infecting more than 90% of the adult population worldwide. Since its discovery in 1964, EBV DNA has been demonstrated to be associated with several malignancies (e.g. Burkitt lymphoma, Hodgkin lymphoma, lymphomas occurring in immunodeficient individuals, and nasopharyngeal carcinoma) where it is almost always found in the latent state. Recently, it has been proposed that breast carcinomas should also be included in the list of EBV-related neoplasms [4]. Infection with EBV results in the establishment of a life-long carrier state, associated with the expression of a restricted set of viral antigens which encode two non-translated nuclear RNAs (EBER-1 and -2), six nuclear antigens (EBNAs), three integral membrane proteins (LMPs), and a polypeptide (RK-BARF0). Three forms of latent infection, referred to as latency types I–III, have been demonstrated in EBV-carrying B-cell lines and EBV-carrying tumour biopsy samples.

The viral EBER-1 and EBER-2 transcripts persist throughout the EBV infection cycle and accumulate to very high copy numbers in the nucleus, making them ideal candidates for identification of latent EBV infection. Male breast cancer is a rare entity (fewer than 1% of cases of breast cancer), and most of the knowledge about its biology has been extrapolated from its female counterpart. It occurs predominantly in old men (average 60 years of age, 10 years older than female breast cancer patients). The oestrogen receptor is expressed in most cases (80–93%), and it has been associated with an unfavourable outcome. In male breast cancer an eventual association with EBV would have implications for both prevention and therapy.

We studied a sample of 23 invasive male breast carcinomas from southern Portugal for the presence of a latent EBV infection by detecting the EBER transcripts using chromogenic in situ hybridization (CISH). ISH was performed on paraffin-embedded sections using the INFORM EBER assay (Ventana Medical Systems, Frankfurt, Germany) according to the manufacturer's instructions (regarding positive and negative controls, and RNA preservation controls within samples). A nasopharyngeal carcinoma was used as a positive control. The patients' ages ranged from 39 to 87 years (mean 64.3 years). All samples were invasive ductal carcinomas of not otherwise specified (NOS) type. Tumour differentiation was assessed using the Elston and Ellis grading system: 3 (13.1%) samples were classified as grade 1, 13 (56.5%) as grade 2, and 7 (30.4%) as grade 3.

No EBER transcripts were found in our 23 male breast cancers. No EBV-positive lymphocytes were detected. The presence of EBV transcripts has been studied in female breast cancer using immunohistochemistry (IHC), PCR and ISH. In studies using IHC/PCR, EBV DNA was detected in 10–51% [4, 5] of female breast cancers, while in studies using ISH no EBV was detected in female breast cancers [2, 3] and or in male breast cancers [5]. The disparity in the results may have been due to differences in the sensitivity of the probes used for the detection of EBV infection. Herrman and Niedobitek [3] have suggested that EBV DNA detected by PCR in breast carcinoma tissues is likely to be related to the presence of EBV-infected lymphocytes in the tumour stroma, and thus does not indicate infection of the tumour cells by the virus. The study of DNA extracts by PCR is clearly unsatisfactory since it does not indicate the cellular source of any viral genome detected. In recent studies [1, 6] laser capture microdissection combined with real-time quantitative *Bam*HIC PCR has been used in an attempt to overcome this problem, but even with such techniques the results are controversial.

In conclusion, our findings corroborate those of Glaser et al. [2], and do not support an association between an EBV latent infection and the pathogenesis and/or progression of male breast cancer. Although we cannot totally

exclude an association of EBV within particular histological subtypes (e.g. medullary carcinoma/lymphoepithelioma-like carcinoma) that were not represented in our series of male breast cancer, the results of studies of these histological subtypes of breast cancer in females argue against this association [7].

Fatal choking due to amyloid infiltration of the laryngeal plexus

Received: 20 February 2005 / Accepted: 23 March 2005 / Published online: 20 May 2005
© Springer-Verlag 2005

Sir,

We hereby report the case of an elderly patient with undiagnosed amyloidosis, who died by choking after food inhalation—caused by unnoticed extensive amyloid infiltration of the laryngeal plexus.

Amyloidosis is a chronic, potentially fatal disease, caused by amyloid deposits in several areas, with heterogeneous clinical manifestations [3]. Peripheral neuropathy may be part of its syndromic context [5], but, very often, the disease is diagnosed late after onset and the pathogenesis of the underlying symptoms remains elusive [3, 5]. Careful post-mortem examination can unravel some puzzling clinical patterns.

In the case under our observation, we were faced with an 82-year-old woman, admitted to the UCSC Emergency Department after a car accident. At arrival the patient was awake, orientated and with transient postural instability. Past medical history was significant for hypertension and paroxysmal atrial fibrillation. A primary physical survey did not disclose significant abnormalities. A cranial CT scan ruled out fractures, intracranial haemorrhages, space-occupying lesions or oedema. Results of routine laboratory tests (including markers of myocardial necrosis) and electrocardiography were within normal limits, and chest X-ray showed mild ectasia of the aorta and pulmonary emphysema. After admission to the ward, the patient remained asymptomatic for over 48 hours. On the third day, however, shortly after lunch and in the absence of other symptoms, she suddenly experienced suffocation, which quickly evolved into respiratory arrest.

Post-mortem examination was requested because of the absence of any obvious medical diagnosis and because of the recent car accident. At gross dissection, in the absence of significant traumatic pathology, we found left ventricular and atrial hypertrophy and coronary atherosclerosis. CNS examination was also irrelevant, and pulmonary embolism could be ruled out. Eventually, a massive alimentary bolus was found, obstructing the bronchial tree bilaterally. In the context of a morphologically normal larynx, abnormal tissue deposits were noticed surrounding the perilaryngeal plexus, together with bilateral diffuse infiltration of cranial nerves IX–X. Histological examination of haematoxylin/eosin and Congo-red stained tissue led us to recognize the typical extracellular amyloid deposits (Fig. 1). Other deposits were also discovered in sections from ventricles, atria and pericardial nervous network. No further regions were apparently involved. Whether we were in the presence of primary or secondary amyloidosis remained unclear.

In the light of such evidence, *ab ingestis* suffocation by abnormal deglutition reflex was assumed as the ultimate cause of death, caused by perineural amyloid infiltration. By questioning the patient's relatives, we then learned about recurrent cough paroxysms that would shake the elderly patient while she was eating.

The present case illustrates sudden death by suffocation, caused by amyloid infiltration of IX–X cranial nerves.

The course of amyloidosis typically encompasses unpredictable morbidity and mortality, with long-lasting asymptomatic intervals and sudden life-threatening episodes. Unexpected symptoms and localizations are, therefore, part of its classical nosology.

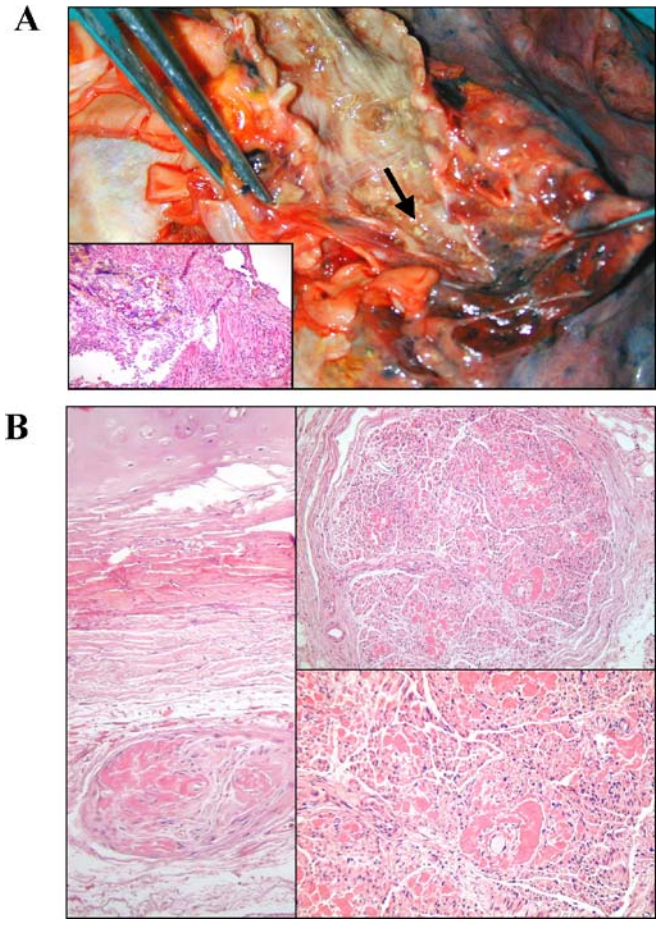

Fig. 1 **a** Macroscopic findings in the lung. Food material in a medium-sized bronchus is confirmed by histology. **b** Peribronchial branches of cranial nerves IX and X with amyloid deposits

Whereas clear-cut motor/sensitive symptoms—the expression of neural region involvement—have a firm place in the clinical descriptions of amyloidosis, the effects of autonomous nervous system involvement have been so far underrated. The same is true for laryngeal localization [1, 2, 4]. Indeed, to the best of our knowledge, sudden death by choking has never, as yet, been reported as a cause of death.

In view of the peculiarly elusive quality of abnormal swallowing symptoms and the uncertainty regarding the real incidence of significant laryngeal amyloid deposits in patients with amyloidosis, this clinical vignette emphasizes that the experienced clinician should regard *ab ingestis* suffocation as one of the most fearful amyloidosis complications. Thus, careful assessment of glottis function should be carried out in any patient with an established diagnosis of amyloidosis.

ANNOUNCEMENTS

22–23 September 2005
Breast Diagnostic Histopathology Update
Hammersmith Hospital (Imperial College), London, UK

A 2-day course designed for pathologists at Consultant and Senior Trainee level. The course is a shorter version of the week long course and is also suitable for those who have previously attended that course and wish to participate in discussing new developments in the field. The course will be based on 30, mostly new, cases derived from the arcives of Hammersmith, Charing Cross, Nottingham City and Cambridge Addenbrook's Hospitals and is slanted to practical diagnostic pathology with special emphasis on areas that pose diagnostic difficulties. The participants will be given ample time to study histological preparations, followed by illustrated discussion of the cases. In addition there will be several talks on specific topics, given by breast pathology specialists followed by discussions. The topics will include issues in the interpretation of breast biopsies, examination of breast biopsies after neo-adjuvant chemotherapy, breast immunohistochemistry, dealing with the gross specimen, fibro-epithelial and spindle cell lesions; papillary, lobular, apocrine and metaplastic lesions, proliferative lesions/carcinoma in situ and sentinel lymph node biopsy. The faculty will include Ian Ellis, Mary Falzon, Andrew Lee, Sarah Pinder and Sami Shousha.

Newsletter of the European Society of Pathology

Dear Members,

In this newsletter you have the Presidential Address before the Paris Congress – excellently reviewing the activities of the society since the last international congress in Ljubljana. Read it before you attend the ESP General Assembly on Wedensday, September 7.

Notice the members nominated as new ordinary members of the Executive Committee 2005–2007.

Some of the Working Groups report on their activities and announce Pre-congress Meetings, do not miss it. And finally the Application form for Membership of the Society is included in case you have colleagues who have still not applied.

We are all looking forward to the 20th European Congress of Pathology.

Sincerely yours,
Grete Krag Jacobsen

Presidential Address

Dear Members,

After the Ljubljana Congress, September 2003, when I assumed the Presidency, it was generally perceived by the membership that the scientific structures of the ESP had undergone a series of important and rapid modernising changes over recent years. They were considered satisfactory for the time being, but it was also felt that the legal and administrative regulations of the ESP had not evolved at a similar pace or so successfully. Therefore, it had become clear that a substantial change of these regulations was very much required. With these priorities so defined, I started working together with the new Executive Committee to achieve the needed changes. Now, almost two years later, the time has arrived to report on the facts and prospects resulting from my term as President.

In October 2003, following the mandate of the General Assembly in Ljubljana, a ballot was conducted to unlock the process of election of the President-elect. By over 70% this approved the decision of the previous Executive Committee to recommend Prof. Niki Agnantis as the next President-elect. An Extraordinary General Assembly took place on 7th February, 2004 in Paris. There, Prof. Agnantis was unanimously elected as President-elect. Roderick Simpson was also elected as Secretary until the Paris Congress 2005, replacing Prof. Jahn Nesland, who had resigned in Ljubljana. Revised Statutes of the ESP were approved in Paris and, after the pertinent adaptation to Belgian law, were officially accepted by the Belgian Ministry of Justice and published in the official Belgian Gazette on 26th November 2004.

Following a recommendation of the Extraordinary General Assembly held in Paris, new rules for election of officers were drawn up by a Constitutional Committee led by Prof. Michael Wells. These were approved by the Executive Committee in Barcelona on 19–20th November 2004.

On 16th April 2005, the Executive Committee met in Porto and, in accordance with the procedure approved in Barcelona, made the following nominations for the term 2005–2007: Fred Bosman as President-elect, Roderick Simpson as Secretary, as well as Mirian Marichal, Nina Gale, Thomas Kirchner and Fernando Schmitt as ordinary members of the Executive Committee. Also in Porto, the Executive Committee asked the Constitutional Committee to finish the new Bylaws, a task that was satisfactorily accomplished in Brussels on 27th May 2005. All these items will be presented for proper approval by the next General Assembly in Paris.

The fifth edition of the Members Handbook "blue book" 2005, will be issued at the Paris Congress by our Treasurer Han van Krieken, and it will contain as its most significant feature the new Statutes and Bylaws. Also, as in previous editions, updated directories of ESP Members, Committees, Bodies, Past Presidents, Honorary Members and Congresses are included. Even though all these data are available at

Important Information

EuroPath News appears in *Virchows Archiv* four times a year, i.e. February, May, August and November. ESP members who want to publish information in *EuroPath News* should send the manuscript by e-mail to the editor (GKJ) *2 months ahead* of publication. Information only for the website should be sent to the editor of the website (BR).

e-mail: grete.krag.jacobsen@rh.hosp.dk
e-mail: brisberg@labmed.vio.no

391296.qxd 11.08.2005 13:44 Uhr Seite 120

our website (www.europathology.org), the "blue book" continues to be a very helpful tool to the ESP membership by providing on the spot precise and unambiguous guidelines. Consequently, we have not hesitated to continue this handy symbol of the ESP identity.

Biennial Congresses are the main and most conspicuous activity of the ESP, and they have become in recent years the second largest attended meeting of pathology in the world. The upcoming 20th Congress, organised by Prof. Pierre Bedossa in Paris, September 3–8, 2005, will have almost one hundred sessions, distributed over five days, more than one thousand posters and free papers, as well as a record figure of attendance of two thousand participants from more than 30 countries, and will certainly mark a new milestone in the history of our successful Congresses. The next scheduled biennial Congresses will take place in Istanbul, Turkey in 2007 and in Florence, Italy in 2009.

Through the imaginative foresight of Manuel Sobrihno-Simoes, the ESP successfully introduced the Intercontinental Congresses, which are currently held every four years. The first of them was hosted in May 2000 on the Island of Madeira, and the second was held in June 2004 in Iguaçu Falls, Brazil, jointly organised with the Latin American and Brazilian Societies of Pathology. The next Intercontinental Congress has been already scheduled for May 2008 in Barcelona. Whereas the main objective of the Biennial Congresses is the exchange of knowledge amongst pathologists in Europe, the Intercontinental Congresses aim to exchange knowledge between our pathologists and those of other continents.

Intercongress Meetings, which mainly focus on the scientific activities of the Working Groups, take place in the years between the main European Congresses of Pathology alternating with the Intercontinental Congresses. The first Intercongress was successfully hosted by Prof. Gianni Bussolati in 2002 in Baveno, Italy. The second Intercongress Meeting has been scheduled for May 2006 in Ioannina, Greece, where an attractive scientific and social programme has already been prepared. It is hoped that a large number of pathologists from throughout Europe will visit this beautiful and largely undiscovered area of Greece for what is expected to be a most valuable scientific meeting. The third Intercongress is planned in 2010.

The increasing complexity of the organisation of all these congresses, which are now every year, requires the appointment of a specific Congress Coordinator. This position was approved by the Executive Committee in Porto in April 2005. Written Guidelines for the Organisation of ESP Congresses are expected to be ready by the end of the current year and will assist the Congress Coordinator as well as the Congress Organisers. It is expected that in this way the trade mark ***ESP CONGRESS*** can be even better. This goal will also mean additional efforts by the Executive Committee, and in particular by the Treasurer and by the Financial Committee, in order to improve and secure the budgets of these congresses.

The Advisory Council acquired great relevance under the previous chairmanship of Prof. Antonio Llombart-Bosch. At present, it continues to be very successfully led by Prof. Günter Klöppel. Its role is to reinforce the links between the ESP and the National Societies thus ensuring a versatile flow of information in both directions. The Advisory Council and the national Societies have greatly contributed to the development of the scientific programme of the Paris Congress.

The newsletter "Europath News", periodically inserted in Virchows Archiv continues to provide a flow of information between the ESP and the membership, as also does the ESP Website. Grete Krag Jacobsen and Bjørn Risberg, their respective editors, continue to adapt the Newsletter and the Website to requests for a more rapid flow of information.

The European School of Pathology (EScoP), established in 1991, is an emblematic body of the ESP and is led by Prof.Gianni Bussolati, acting as a promoter of intensive and practically oriented courses. They are hosted annually in Turin, Italy and in recent years have been progressively extended to Kraków, Poland, Craiova, Romania and Ankara, Turkey. Similar courses are also held in Ioannina in Greece. All of them contribute quite decisively to the continuing improvement in the standards of diagnostic pathology throughout Europe, and have been attended by many hundreds of young pathologists.

Right from the outset, the ESP was eager to promote basic research in Pathology. This crucial aim has been very effectively accomplished, during the past 16 years, through one of the most emblematic bodies of our Society, Euro Cell Path, which is at present led by Prof. Fred Bosman. Founded in 1989, its courses were designed to provide information and standardise practical knowledge in modern cellular and molecular pathology. They are devoted to the most timely topics, efficiently and effectively contributing to the knowledge of numerous young pathologists. These courses are organized yearly, so far always in a different city of Europe. The 14th meeting of Euro Cell Path was held in May 2004 in Girona, Spain, organised by Josep Lloreta, and the 15th in June 2005 in Montebello, Norway was organised by Jahn Nesland.

Due to financial shortages, mainly because of increasing difficulties in attracting European Union funds, EScoP and Euro Cell Path courses need to be rethought. After a recent discussion between EScoP and Euro Cell Path leaders, any possible fusion of the two was felt at present not to be a valid option. The focus of their courses is totally different; the organisational structure and the programme concept of each could not be unified without significant loss for either one or both. However, the present situation of two entirely separate and autonomous bodies, was also viewed as no longer tenable. It was therefore considered as essential that EScoP and Euro Cell Path cross-fertilize, constructing coherent complementary postgraduate education policies within the ESP remit. I am confident that in the near future imaginative and at the same time practical alternatives will progressively develop. The approval of the European Institute for Continuing Medical Education in Pathology, encompassing EScoP and Euro Cell Path, points in the right direction.

The Working Groups have developed as true "European Task Forces of Specialisation in Pathology" and at the same time evolved as a crucial link between applied and basic research by areas of specialty. They are becoming very efficient in assembling by fields of interest previously disconnected pathologists. The number of Working Groups (eleven at present) is progressively increasing, as well as the number of their members and of institutions collaborating with each of them. In this way, the Working Groups are uncovering a large potential for collective stimulation of new ideas, for increasing opportunities of access to larger casuistic and to more sophisticated methodologies, in joint clinical and basic research projects. The Working Groups are therefore emerging as true backbones of the pathology by areas of specialisation. The Meeting of Chairpersons of Working Groups held in Ljubljana for the first time, helps to coordinate activities and administrative structures. Most Working Groups function well or in fact extremely well, but a few groups have encountered occasional difficulties, probably related to uncoordinated rapid growth. It is expected that any problems will solve themselves, as a result of implementing the specific regulations in the new Bylaws.

Very good news is coming from Virchows Archiv. This journal has been central to pathology in Europe for over 150 years, and it is now the Official Journal of the ESP. At its Editorial Board meeting on 18th February 2005 in Frankfurt, general satisfaction was expressed by all participants, (Springer, Editor-in-chief, managing Editors and ESP representatives) at the substantial rise in the impact factor of the Journal in 2004, reflecting the improved scientific vitality of the ESP and of the efforts of the past Editor-in-Chief, Prof. Günter Klöppel and of his successor, Prof. Heinz Höfler. The latter was quite optimistic about possibilities for further improvement. Moreover, it was widely felt that the continuing joint venture between Springer and ESP, offered opportunities for a much closer relationship that was bound to be beneficial for both partners. In this context, negotiations for renewal of the contract started in Frankfurt and were continued at the Executive Committee meeting of last April in Porto. There a net profit

391296.qxd 11.08.2005 13:44 Uhr Seite 121

share of 50% was agreed. This accounts for an initial annual revenue of about 50,000 Euros for the ESP and will considerably improve our financial situation. The new contract will be submitted for approval to the next General Assembly in Paris.

During the last two years, the Executive Committee became increasingly aware of the need to provide the Society with a well equipped and strategically located permanent office, as soon as reasonably possible. The rising organisational complexity of the ESP and its prospects for development in the near future very much require it. Both our Treasurer and Secretary very much endorse this move, as it would greatly facilitate and improve the fulfilment of their tasks. The office should offer facilities for a secretarial assistant and for an accountant, and also a place for meetings of the Executive Committee. Other possible functions are as editorial office of the ESP Journal and, if pertinent, as the centre for our Website. The cities of Brussels and Leyden are the two alternatives under serious consideration. Both offer logistic and financial advantages and disadvantages that need careful comparative evaluation. Renting or buying would be further decisions to make, keeping in mind that the latter seems more attractive in the long run. A proposal, currently under elaboration by the Treasurer and the Financial Committee, will be presented to the General Assembly on 7th September 2005.

At the end of the Paris Congress I will have completed my term as ESP President. Therefore, the time has arrived to express my very best wishes to Niki Agnantis, who will lead the Society towards the Congress of Istanbul, September 2007. I had a very close working relationship with her during the last two years, and I am fully confident in her energy and knowledge of the Society. My best wishes are also extended to Gianni Bussolati, who leaves the position of Past-President, as well as to Günter Klöppel, who continues to chair the Advisory Council, and also to the two continuing officers, Roderick Simpson, Secretary, and Han van Krieken Treasurer. Four members of the Executive Committee will leave after completion of their terms: Fatima Carneiro, Christiane De Wolf-Peters, Rastko Golouh and Grete Krag Jacobsen. Four experienced members will continue for the next two years: Frédérique Capron, Veli-Peka Lehto, Michael Wells and Dilek Yilmazbayhan. All of them have been very kind and extremely collaborative, carrying out time consuming tasks and helping to solve quite complicated issues in the best interest of our Society, and I thank them all both personally and on behalf of all the membership.

Last but not least, I want to express my thanks to you all for your generous support, as well as to my predecessors in office and to the previous and present officers, members of committees and organisers of congresses for their brilliant dedication, tremendous amount of work, and invaluable contributions to the success of the ESP. I am confident that in spite of the momentary political uncertainties in our continent, the vibrant European Society of Pathology that was born, grew and spread throughout Europe even during the difficult times of the Iron Curtain, will continue to thrive even more in the future.

Members nominated as ordinary members of the Executive Committee 2005-2007: Thomas Kirchner, Germany, Nina Gale, Slovenia, Miriam Marichal, Belgium and Fernando Schmitt, Portugal.

Antonio Cardesa
President
Barcelona, June 2005

ESP Working Group on Cytopathology

The Working Group has, in association with the organizers of the 20th European Congress of Pathology, to be held in Paris on 3–8 September 2005, prepared a special programme for participants devoted to cytopathology: A slide seminar, chair by Z.Pohar-Marinsek and Fernando Schmitt with presentation of challenge cases that will be discussed by young cytopathologists supervised for seniors ones, a symposium: How far can we go with cytology? chaired by W. Olszewiski and P. Viehl that will discussed the real possibilities of the cytology in the diagnosis of thyroid, breast, lung, soft tissue and lympho-proliferative diseases, and a short course: Role of bronchoalveolar lavage in pulmonary pathology, chaired by F. Thivolet and H. Popper. This course is a joined activity between the WG on Cytopathology and the WG on Pulmonary Pathology In our business meeting, before our regular administrative meeting we will have a interesting section exploring FNA in gastrointestinal, liver and pancreas pathology, with the participation of some invited guests from US (Andrea Abati and Ricardo Bardales) together with European cytopathologists (L. Skoog, F. Schmitt and V. Sviatoha).

For 2006, the WG will participate in the 2nd Inter-Congress of the ESP that will be held on Ioannina on 25–27 May. The main focus of this meeting is the activities of the ESP Working Groups and our purpose is to organize slide seminars, courses and plenary sections together with the others WGs.

For 2007, the WG was invited for the President of IAC (Matias Jymenez Ayala) to organize together with the Liaison Committee IAC-ESP a Satellite Symposium in the XVI International Congress of Cytology that will be held on Vancouver, Canada on 13–17 May, 2007.

Professor Fernando Schmitt
Chairman Cytopathology WG-ESP

391296.qxd 11.08.2005 13:44 Uhr Seite 122

ESP Working Group on Head and Neck Pathology

At the Annual Spring Meeting of the IAP-Finnish Division, which took place in Kökar Island, Finland from May 12.–15.2005 the following presentations were given by members of the Head and Neck Working Group:

- P Slootweg, Nijmegen: New aspects of odontogenic tumors and fibro-osseous lesions in the WHO classification.
- P Slootweg, Nijmegen: Head and neck squamous cell lesions: Clonal analysis, margins, micrometastasis and arrays as predictors of metastasis.
- R Simpson, Exeter: Salivary gland tumors in the new WHO classification.
- R Simpson, Exeter: Advances in salivary duct carcinoma and new entities of salivary gland neoplasia.
- I Leivo, Helsinki: Slide seminar: "Problems of head and neck".

In association with the 20th European Congress of Pathology in Paris, a one-day Pre-Meeting of the Working Group on Head and Neck Pathology of the ESP and the North American Society of Head and Neck Pathology of the United States and Canadian Academy of Pathology will be organized on **FRIDAY, SEPTEMBER 02, 2005 FROM 08:00 TO 17:30**, **LA PITIÉ-SALPÊTRIÈRE HOSPITAL, BABINSKI BUILDING AUDITORIUM**, **47-83 BOULEVARD DE L'HÔPITAL, PARIS 13ÈME, FRANCE.**

An expert panel will discuss approximately 20 cases which in daily practice resulted in diagnostic difficulty or the differential diagnostic considerations resulted in significantly different prognostic implications. Time for discussion from the audience and between panel members will be sufficient to engender lively exchange of ideas about how to make the diagnosis, special techniques, treatment implications, and future research endeavors.

See for additional information, and registration: http://www.pathology-congress.com/en/ecp.asp

Pieter Slotweg
Chairman of the WG of
Head and Neck Pathology

ESP Working Group on Nephropathology

The activities of the WG have been focused on collecting data about the current state of nephropathology in Europe by means of questionnaires. A database of pathologists and other scientists involved in renal pathology has been completed. The main task in 2005 has been the preparation of the scientific programme for the 20th European Congress of Pathology in Paris. There will be four sessions devoted to nephropathology and transplantation at the Congress: Short Course "Microangiopathies and Vasculitides in Kidney", Slide Seminar "Current Issues in Diagnostic Nephropathology", Short Course "Current Topics in Transplantation Pathology, and Business Meeting "Nephropathology in Europe".

In addition, all pathologists are kindly invited to attend the **Nephropathology Pre-congress Meeting "Updates in Nephropathology and Transplantation"** to be held in Paris, Palais des congres on September 3, 2005, 08.30–17.00, on the opening day of the Congress.the day. There will be four scientific sessions: "Genomics in Renal Pathology", "Berger's IgA Nephropathy and Henoch-Schönlein Purpura", "Current Issues in Kidney Diseases", and Special Workshop "Decoy Cells: Diagnosis and Clinical Significance" (Slide Seminar using virtual microscopy).

The speakers at both the Congress and the Pre-congress Meeting will be internationally recognized experts in the relevant fields. The Pre-congress Meeting will also provide an opportunity for informal contacts. There will be **no Registration Fee** for the scientific programme, Book of Proceedings, coffee breaks and modest lunch at the Pre-congress Meeting.

Dušan Ferluga
Chairman of the WG on Nephropathology

The European Society of Pathology

Dear Colleague,

It will surely not have escaped your attention that *Virchows Archiv* is now the Official Journal of the European Society of Pathology.

But did you realise what benefits membership in the society offer you?

- A subscription to the journal *Virchows Archiv* at no extra charge – this is automatically sent to every member every month.
- Access to the journal online (take a look at http://link.springer.de). If you are already a member of ESP but have not yet registered for your free electronic access, you will find the necessary form to complete online here too.
- A discount of 20% on most titles published by Springer. To take advantage of this, simply send your order directly to the publisher, with details of your membership.
- Attendance at the Society's conferences at a reduced fee.

If you have not yet joined the European Society of Pathology, why not do so now?
Simply complete and return the form enclosed.

We look forward to welcoming you as a member in 2005

Yours sincerely

A. Cardesa
President
European Society of Pathology

H. van Krieken
Treasurer
European Society of Pathology

H. Höfler
Managing Editor
Virchows Archiv

O-1
INFLUENCE OF TGF-B1 IN P-AKT EXPRESSION AND CELL PROLIFERATION-RELATED PROTEINS IN ORAL SQUAMOUS CELL CARCINOMA CULTURED CELLS

SALLES Felipe Torquato
PINTO JR Decio Santos
University of Sao Paulo School of Dentistry, Department of Oral Pathology

TGF-b is a molecule believed to play a crucial role in cellular growth, development and differentiation. Many studies point it out as an important tumor suppressor, and its absence has been related to tumor aggressiveness and invasiveness, especially in oral squamous cell carcinoma, the most frequent malignancy of the oral cavity. In order to evaluate p-Akt expression, as well as cell cycle and apoptosis related proteins, five cell lineages were used: HN6, HN19, HN30, HN31 and HaCat as normal keratinocytes. TGF-b1 (5ng/ml) was applied over cell monolayers during 18h periods and the expressions of p-Akt, cyclin D1, caspase-3 and Bad were evaluated through western-blot and immunofluorescence. The results revealed an increased p-Akt expression in all cell lines, especially HaCat, HN6 and HN30. Cyclin D1 exhibited similar results, except for HN31, where a decrease was noticed. Caspase-3 maintained similar levels in all cell lines, but decreased in HaCat and increased in HN30. Bad levels increased in all cell lines but HaCat. Immunofluorescence revealed cyclin D1 normal nuclear location after treatment, and cytosolic in HN31. These results suggest, according to recent findings, that TGF-b might not always function as a tumor suppressor. Depending on tumor progression stage and its molecular profile, this molecule may exert an adjuvant function in tumor growth. These data may provide evidence for an accurate revaluation of TGF-b role, as well as its use as a tumor marker.

STROMAL VERSICAN OVEREXPRESSION IS AN UNFAVORABLE PROGNOSTIC SIGN IN ORAL SQUAMOUS CELL CARCINOMA

BÖHM Jan *, PUKKILA Matti **, KOSUNEN Ari **, ROPPONEN Kirsi *, VIRTANIEMI Jukka **, KELLOKOSKI Jari **, KUMPULAINEN Eero ***, PIRINEN Risto *, NUUTINEN Juhani **, JOHANSSON Risto ***, KOSMA Veli-Matti.*
Departments of Pathology and Forensic Medicine*, Otorhinolaryngology**, Oncology***, University of Kuopio and Kuopio University Hospital, Kuopio, Finland.

Introduction and purpose: Versican is a large extracellular chondroitine sulphate proteoglycan expressed in several malignant tumors, suggesting involvement in the development and progression of cancer. Versican promotes tumor growth by disturbing cell adhesion. It also stimulates cell proliferation along with angiogenesis. Purpose of the study was to evaluate the prognostic role of versican in oral squamous cell carcinoma (OSCC).
Methods: Versican expression was analyzed immunohistochemically in paraffin embedded specimens of 139 OSCC patients treated in Kuopio University Hospital district between 1979 and 1998. Patients were followed-up until death or June 2002. All relevant clinical data were reviewed for tumor characteristics, primary treatment, follow-up and possible tumor recurrence. The stained stromal part in proportion to whole stromal area around invasive carcinoma nests was assessed on a continuous (0–100%) scale. The most prevailing versican staining intensity was graded into 3 groups: weak = 1, moderate = 2 or strong = 3. Stromal versican staining score (SVSS) was obtained by multiplying the percentage with intensity. The cell proliferation index was determined using immunohistochemical Ki-67 staining.
Results: The median age of the patients was 64 (range 10-88) years. The median SVSS was 100, which was used as a cut-off for statistical analyses. The median disease-free survival (DFS) time was 9.2 months and median disease-specific survival (DSS) was 17 months. Tumor recurrence and cell proliferation index were related to SVSS with borderline significance. Univariate survival analysis showed that lymph node involvement, Karnofsky performance status, SVSS and cell proliferation index were significant prognostic factors for DFS ($p<0.05$ for all). Significant prognostic factors for DSS were the size of the tumor, lymph node involvement, tumor stage and histological grade ($p<0.01$, $p<0.001$, $p<0.001$, $p<0.01$, respectively) along with Karnofsky performance status, SVSS and cell proliferation index ($p<0.05$, $p<0.01$, $p<0.05$, respectively).
In multivariate analysis histological differentiation, stage and SVSS were significant prognostic factors for DSS ($p<0.05$, $p<0.01$, $p<0.05$, respectively).
Conclusion: Our results suggest that the high stromal versican expression is associated with unfavorable outcome of OSCC patients, and may be a useful marker in deciding more aggressive treatment procedures.

SENTINEL NODE BIOPSY AND SUBCLINICAL LYMPH NODE METASTASES IN PATIENTS WITH ORAL SQUAMOUS CELL CARCINOMA ,T1-T2, N0, M0.

THERKILDSEN Marianne Hamilton(1), BILDE Anders(2),von BUCHWALD Christian(2).
Dept. Pathology (1) and Dept. Otolaryngol, Head & Neck Surgery (2), H:S Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark

Introduction
In Denmark (5 million inhabitants) the incidence of malignant tumours of the oral cavity is 310 cases per year the majority being squamous cell carcinomas (SCC).
The presence of clinical lymph node metastasis in head and neck cancer is the single most important prognostic factor reducing survival by 50%. The impact of oral subclinical lymph node metastases including micrometastases is not known.
In oral cancer, clinical and radiological assessments seem unreliable in demonstrating spread to the lymph nodes of the neck.
The sentinel node (SN) concept states that the sentinel node is the first node to which a tumour will metastasize. Furthermore it is believed that the pathological status of SN reflects the histology of the remaining regional lymph nodes.
Purpose
The purpose of the study is to perform sentinel node biopsy in a consecutive material of oral SCC stage T1-T2N0M0 operated at our institution in order to: 1) To establish if the sentinel node biopsy (SNB) procedure is an adequate tool in the detection of metastases thereby reducing the incidence of elective neck dissection in the N0 neck. 2) To gain insight in the frequency of subclinical metastases including micrometastases.
Material and method
The study was initiated September 2004. The SN is identified by means of an isotope. Following resection of the primary tumour, SNB is performed with a subsequent selective neck dissection as part of a learning curve. All sentinel nodes are examined using step serial sectioning cut at 150-øm intervals. The sections are stained with hematoxylin and eosin (H&E) and broadspectrum anticytokeratin antibody AE1/AE3, respectively in order to detect metastases.

Results and conclusion
As of March 2005 18 patients have been included in the study. The number of SN varies between 1 and 4 nodes per patient. Two patients had metastases in the SN leading to upstaging of 11% (2/18) of the patients. The study will continue and further patients will be included with an adequate follow-up to establish the value of the technique.

PROGNOSTIC SIGNIFICANCE OF INTRATUMORAL HETEROGENEITY FOR CATHEPSIN D AND CYCLIN D1 EXPRESSION IN LARYNGEAL SQUAMOUS CELL CARCINOMA.

CORIC Marijana, BATELJA Lovorka, BUMBER Zeljko, DJANIC Davor, SEIWERTH Sven.
Institute of Pathology; ENT Clinic, Medical Faculty University of Zagreb, Croatia

Intratumoral heterogeneity is defined as the parallel existence of different (e.g. diploid and aneuploid) clones within a given tumor. This implies that different tumor parts could express different behavior (e.g. propensity to invade or metastasize, resistance against chemo- or radiotherapy). Current investigations mostly neglect intratumoral heterogeneity in general and completely ignore the possibility of regional intratumoral heterogeneity. The goals of this investigation were to define intratumoral heterogeneity of cyclin D1, cathepsin D and nm23 protein as well as nm23H1 gene in three different tumor regions (tumor center, invasive margin and transformation region), to establish potential prognostic significance of regional factors and to establish potential correlation between the investigated factors and classical prognostic factors (T, N, M, histological grade).
We performed the study on a group of 170 patients with laryngeal cancer undergoing partial or complete laryngectomy. After standard paraffin embedding immunohistochemistry was performed using manufacturers protocols (DAKO, Oncogene Sci.). Immunoreactivity was accessed using semiquantitative score. Follow up of patients was minimum 60 months for survivors. Statistics was performed using Statistica for Windows and RPART statistics.
Results of our study clearly show that the intratumoral heterogeneity is not a random event, but that there is a clear areal distribution of immunoreactivity to cathepsin D and cyclin D1, with the invasive margin expressing the strongest immunoreactivity followed by the tumor center. There is positive correlation for expression of cathepsin D in tumor cells with T (p=0,003), and negative correlation for stromal expression of cathepsin D with T (p=0,006), N (p=0, 01) and histological grade (p=0, 02). Areal expression of cathepsin D and cyclin D1 showed prognostic significance on Kaplan-Meier curves (cathepsin D (p=0,001) cyclin D1 (p=0,008)). Using RPART statistics the expression of cathepsin D in tumor stromal cells of tumor center was demonstrated as being a classificator equal to standard prognostic parameters.
These findings strengthen the concept that areal intratumoral heterogeneity should not be neglected neither in research nor in diagnostic work.

RASSF1A, VHL AND FHIT GENE IN SQUAMOUS CELL CARCINOMA OF LARYNX AND HYPOPHARYNX

M. Volavšek, D. Podpeènik, D. Glavaè, N. Gale
Institute of Pathology, Faculty of Medicine, Ljubljana, SLOVENIA

INTRODUCTION. Loss of heterozygosity (LOH) on short arm of chromosome 3p is frequently found in squamous cell carcinoma of larynx and hypopharynx (LHSCC). It is considered to represent an early step of LHSCC carcinogenesis. This chromosomal region contains three tumor supressor genes, Rassf1, VHL and FHIT.
AIMS. We wanted to determine whether Rassf1, VHL and FHIT changes contribute to LOH on 3p and influence survival of LHSCC patients.
MATERIALS AND METHODS. DNA was isolated from tumor and adjacent normal tissue from 77 LHSCC patients using standard procedure. Non-isotopic LOH analysis was performed with microsatellite markers D3S1007, D3S1038, D3S1233, D3S1285, D3S1300. Presence of mutations in exons 1-6 of Rassf1A gene and exons 1-3 of VHL gene was tested. PCR-non-isotopic conformation analysis was used for mutation analysis. Mutated regions were directly sequenced with ABI Prism Genetic analyser. Molecular analysis results were correlated with disease parameters. Survival analysis was performed.
RESULTS. Most of 77 patients were male (73), aged 36-77 years (58,3 ± 10,17) with laryngeal (56; 72,7%), moderately differentiated cancer (46; 59,7%). LOH at 3p was detected in 47 (61%) cases. There were 17 Rassf1A missense mutations discovered in 16 (20,8%) cases (1 homozygous), located in Rae 3 in 16 and in Rae 5 in one case. We found no pathogenic VHL mutations (3 polymorphisms). Presence of Rassf1A mutations didn't correlate with LOH in general, but there was significant correlation with LOH detected with each individual marker in informative cases(p=0,006 to p=0,020). Molecular analysis results didn't correlate with disease parameters or cancer specific survival.
CONCLUSIONS. Our results confirm LOH at 3p chromosome being a frequent event in LHSCC. Significant correlation between Rassf1A mutations and LOH on sites covered by each individual microsatellite marker is rather surprising, since the markers used cover all three gene sites. According to our results we can exclude possible impact of VHL changes. On the other hand, it is impossible to delineate shares of Rassf1A and FHIT alterations. Regions involved in LOH in individual cases could have spread over both genes. To determine the significance of each gene additional investigations including gene expression profile and methylation status are needed. Nevertheless, our results suggest that Rassf1A and FHIT gene changes contribute significantly to LOH at 3p and are involved in early steps of LHSCC

Introduction: In the larynx, dysplasia is strongly associated with smoking and affects more frequently the vocal cords. The progression from dysplasia to the development of invasive squamous cell carcinoma is well documented. Moreover, it has been noted a positive correlation between the degree of the dysplasia and the probability to develop an invasive carcinoma. Nevertheless, the molecular mechanisms that underlie the different steps of the progression to laryngeal carcinomas are poorly understood.
Aims: To further our understanding on the implications of cell cycle alterations in laryngeal cancer progression and to identify markers with value in predicting the development of invasive carcinoma or recurrence, we evaluated the levels of

proteins involved in cell cycle control in patients diagnosed with laryngeal keratosis or dysplasia.
Material and Methods: Two tissue microarrays were made containing 114 specimens (18 keratosis , 26 LIN I, 42 LIN II and 25 LIN III) obtained from biopsy material. Expression of the following proteins, RB, P63, Cyclin D1, P53, P27, P21, CDK2, CDK1, CDK4, CDK6, P16, Cyclin A, Cyclin E and Survivin were evaluated by immunohistochemistry. Results according to the percentage of positive cells and their distribution along the different epithelial layers were correlated with clinical and pathological characteristics.
Results: Our observations revealed that Cyclin A and P63 protein levels increased as the dysplasia progresses ($p=0.003$ and $p=0.036$ for Cyclin A and P63, respectively). Cases were considered positive when more than 2% and 60% of epithelial cells showed reactivity to cyclin A and P63, respectively. Conversely, CDK6 protein levels decreased and its expression was lost in basal and parabasal layer of the epithelium as the degree of dysplasia increased, distinguishing mainly between LIN II and LIN III ($p=0.017$ and $p=0.0001$, respectively). The correlation with the clinical parameters are being evaluated.
Conclusions: Our results provide information on the molecular profile of cell cycle components in laryngeal dysplasia and identify several cell cycle components as potential markers for dysplasia progression.

COMPUTERIZED IMAGE ANALYSIS ASSESSMENT OF CELL CYCLE RELATED PROTEINS (P16, P21, P27, P53, CYCLIN D1) AND E-CADHERIN IN 289 LARYNGEAL CARCINOMAS – A TISSUE MICROARRAY STUDY

KRAM Andrzej, TERESINSKI Leszek, OKAMOTO Natsumi*, DOMAGALA Wenancjusz.
Dept. of Pathology, Pomeranian Medical University, Szczecin, Poland
* Nara Medical University, Nara, Japan

Introduction: Laryngeal carcinoma is one the most common cancer of the head and neck. Surgery and radiotherapy are generally accepted as the treatment options. The laryngectomy is usually accompanied by lymph nodes surgical excision due to the risk of metastasis. However, there are cases in which the pathologic examination of resected lymph nodes reveals no metastasis. This study was done on laryngeal carcinoma tissue microarrays (TMA) in order to investigate the possible correlation between cell cycle related proteins (p16, p21, p27, p53, cyclin D1) and E-cadherin to the clinical and pathological parameters, with the special emphasis on lymph nodes status. Design: The immnohistochemical stains were done on three TMAs containing 289 laryngeal carcinomas. Tumor location, T- stage, grade and lymph nodes status were examined. Immunohistochemical staining and calculations of positive expression of p16, p21, p27, p53, cyclin D1 and E-cadherin protein with the use of computerised Quantimet 600S Image Analyser (Leica) were performed. Results were related to the clinical (location, T-stage) and pathological (grade and lymph nodes status) parameters of the tumors. Results: The mean age of patients was 54 years, 86.2% cases were male and 13.8% female. The positive expression of p16, p21, p27, p53, cyclin D1 and E-cadherin proteins was shown in 10%, 22%, 15.8%, 45.4%, 29% and 18% of cases respectively. None of the examined proteins was related to location, grade, or lymph node status. However, a significant adverse correlation (chi-square test, $p<0.05$) was found between the p27 protein expression and T-stage. Conclusion: In this study we showed the practical power of TMA technology in rapid immunohistochemical examination of large group of laryngeal carcinomas. Our results indicate that the risk of lymph node metastasis is not related to the expression of cell cycle proteins and E-cadherin. The adverse correlation between p27 protein expression and T-stage was not previously observed.

PROGNOSTIC VALUE OF TUMOR INFILTRATING CD4+T CELL SUBPOPULATIONS IN HEAD AND NECK CANCERS.

BADOUAL Cécile, HANS Stéphane , RODRIGUEZ José, PEYRARD Séverine, KLEIN Christophe, BRUNEVAL Patrick , FRIDMAN Wolf Herman, BRASNU Daniel , TARTOUR Eric

Background : CD4+T cells play a central role in initiating and maintening anticancer immune responses. However, the regulatory CD4+CD25+T cells which express Foxp3 have also been shown to inhibit anti-tumor effector T cells. In face of this heterogeneous CD4+T cell populations, the aim of this study was to determine the prognostic value of different populations of tumor-infiltrating CD4+T cell in head and neck squamous cell carcinoma (HNSCC).
Methods : 84 newly diagnosed untreated patients with primary histologically proven HNSCC were included in this study. Immunofluorescence staining was performed to assess and count the different subpopulations of tumor infiltrating CD4+T cells. CD4+CD69+T cells, regulatory CD4+Foxp3+T cells and the mixed CD4+CD25+T cells comprising both activated and regulatory T cells were analyzed in this study.
Results : In the univariate analysis, CD4+CD69+T cell infiltrating tumors were the only CD4+T cell subpopulations which positively correlated with both locoregional control ($p = 0.0027$) and survival ($p = 0.006$). Levels of regulatory Foxp3+CD4+T cell infiltration have no impact on clinical outcome. Multivariate analysis showed that the only significant prognostic factors independently related to locoregional control were T stage ($p = 0.008$) and CD4+CD69+T cell infiltration ($p = 0.018$) and the same two variables influenced overall survival probability : T stage ($p = 0.02$) and CD4+CD69+T cell infiltration ($p = 0.007$)
Conclusion : High levels of CD4+CD69+T cells tumor infiltration are significantly associated in both univariate and multivariate analysis with a better survival and locoregional control in head and neck cancer patients.

PULMONARY SQUAMOUS CELL CARCINOMA FOLLOWING HEAD AND NECK SQUAMOUS CELL CARCINOMA: METASTASIS OR SECOND PRIMARY?

Tom Geurts(1), Petra Nederlof(2), Michiel van den Brekel(1&3), Laura van ’t Veer(2), Daphne de Jong(2), August Hart(4), Nico van Zandwijk(5), Houke Klomp(6), Alfons Balm(1&3) and, Marie-Louise van Velthuysen(2)
Department of ORL, Academic Medical Center (1), and departments of Pathology (2), Head and Neck Oncology (3), Radiotherapy (4), Pulmonology (5), and Surgery (6) of the Netherlands Cancer Institute / Antoni van Leeuwenhoek Hospital, Amsterdam, The Netherlands.

Purpose: To distinguish a metastasis from a second primary tumor in patients with a history of head and neck squamous cell carcinoma (SCC) and subsequent pulmonary SCC, using clinical, histological and molecular characteristics.
Experimental Design: Of 46 patients with a primary SCC of the Head and Neck followed by a SCC of the lung, clinical data, histology and analysis of loss of heterozygosity (LOH) were used to differentiate metastases from second primary tumors.
Results: Clinical scoring suggested 40 patients with metastases and 6 with second primaries. LOH on different

chromosome arms was observed not to be an independent event. Therefore a novel interpretation strategy based on biological insight was developed and tested. Based on this strategy LOH analysis indicated metastatic disease in 21 cases and second primary SCC in 24 cases. In one case LOH analysis was inconclusive. For 27 patients LOH supported the clinical scoring and in 18 cases it did not. These 18 discordant cases were all considered to be second primary tumors by LOH analysis.
Conclusions: A considerable number of lung lesions (in this study 50%) clinically interpreted as metastases, are suggested to be second primaries by LOH analysis, justifying a surgical approach with curative intent in these cases.

SIMPLE IDENTIFICATION OF ATYPICAL CELLS IN BRUSH BIOPSIES OF ORAL MUCOSA VIA LAMININ-5 IMMUNOCYTOCHEMISTRY

KOSMEHL Hartwig (1), DAHSE Regine (1), BERNDT Alex (2), DRIEMEL Oliver (3), PISTNER Hans (4)
(1) HELIOS Klinikum Erfurt; Institute of Pathology, D-99089 Erfurt, Germany
(2) University of Jena, Institute of Pathology, D-07740 Jena, Germany
(3) University of Regensburg; Clinic of Craniofacial Surgery, D-93042 Regensburg
(4) HELIOS Klinikum Erfurt; Clinic of Craniofacial Surgery, D-99089 Erfurt, Germany

Brush Biopsy is a promising and critically discussed method to detect epithelial oral pre-cancerous and malignant lesions. The gamma2-chain of Laminin-5 (Ln-5) and its proteolytic fragments are an invasive factor in many carcinomas. We studied the impact of Ln-5 immunocytochemistry in cytological analysis of brush biopsies.
Material and Methods: 60 consecutive brush biopsy specimen: normal oral
mucosa (n=10), inflammatory (n=11) and benign (n=22) hyperproliferative lesions, oral carcinomas (n=17) with histopathological diagnosis. Standardised immunocytochemistry. Ln-5 monoclonal antibodies: D4B5 (Chemicon) or 4G1 (DakoCytomation), Detection: ChemMate; Autostainer (DakoCytomation).
Results: 100% specificity was achieved, e. e. no false positive results (atypical or immunostained cells in normal, inflammed or benign hyperproliferative mucosa). Bacteria colonies were stained false positive.
Oral squamous cell carcinoma brush biopsies demonstrated the following immunocytochemical pattern: a) cytoplasmic staining, b) ribbon-like staining between the epithelial cells, c) positive halo around epithelial cells. 4 out of 17 carcinomas could not be diagnosed by conventional cytology (sensitivity of conventional cytology 76%). 3 of the 4 carcinomas not identified by cytology were detected by
Ln-5 immunocytochemistry (sensitivity of conventional cytology + Ln-5 immunocytochemistry 94%).
The positive predictive value of cytology plus immunocytochemistry was 100%; the negative predictive value reached 91% for conventional cytology and 98% for the combination.
Conclusions: 1. The immunocytological Ln-5 staining simplifies the identification of atypical cells in brush biopsies fundamentally. 2. The Ln-5 pattern represents an independent information which confirms cytology. 3. The increased sensitivity of the immunocytologically enhanced brush biopsy recommends oral brush biopsy as an easily interpretable and reliable method.

LYMPHOMAS OF ORAL CAVITY. CLINICAL-PATHOLOGICAL STUDY OF 46 CASES AND REVIEW OF LITERATURE.

ASIOLI Sofia, FOSCHINI Maria P.,*ASIOLI Silvia, MAGRINI Elisabetta, COCCHI Roberto,°PILERI Stefano A.
Department of Anatomic Pathology, University of Bologna and Dept. of Maxillo-Facial Surgery at Bellaria Hospital, Bologna, Italy.
° Chair of Pathology, Institute of Haematology "L. and A. Seràgnoli" , University of Bologna, Bologna, Italy.
*Service of Anatomic Pathology, S. Maria Nuova Hospital, Reggio Emilia, Italy.

Introduction: Although several clinico-pathologic studies on extra-nodal oral cavity lymphomas have been reported, our understanding of these tumours is incomplete. This is mainly because oral lymphomas are quite rare and the opportunity to apply modern techniques to their classification is limited.
Propose: The aim of this study was to determinate both the histotype and phenotype of lymphomas presenting in the oral cavity.
Materials and methods: Cases were classified according to the World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues 2001. Immunohistochemical stains were performed on tissue microarrays (TMA).
Results: Forty-four cases of non-Hodgkin's lymphoma (NHL) and 2 cases of primitive Hodgkin's lymphoma (HL) were observed, with a slight female predominance (21M; 25F). Forty cases of NHL were primitive of the oral cavity, while six cases were secondary lesions. NHL were divided into five groups: 1) diffuse large B-cell lymphoma (DLBCL: 33 cases); 2) follicular lymphoma (FL: 5 cases); 3) extranodal marginal zone B-cell lymphoma (MZL: 3 cases); 4) mantle cell lymphoma (MCL: 1 case); 5) peripheral T-cell lymphomas, not otherwise specified (PTCL, NOS: 2 cases). HL occurred in two males, aged 25 and 65 years respectively. Both cases were diagnosed as nodular sclerosing HL.
The lesions were variably located in different sites of the oral cavity, commonly affected sites being the soft and hard palate and tongue. The most frequent clinical appearance was a sub-mucosal mass (34 cases). Dental waving was present in 5 cases and actinomycotic infection in one. Six cases appeared as slightly raised whitish lesions. Two cases (1 NHL and 1 HL) appeared in HIV infected patients.
Conclusion: The present series shows that malignant lymphomas of the oral cavity more often represent de novo primary growths. The most frequent event is DLBCL affecting elderly patients in the palate or tongue. Although rare, HL should be considered among primary oral cavity lymphomas.

CHONDROSARCOMA OF THE LARYNX

PAGLIARI Angelo Virgilio °, KLINGER Francesco *, KLINGER Marco *
° U.O. ORL - Azienda Ospedaliera di Crema
* Istituto di Chirurgia Plastica e Ricostruttiva
Università degli Studi di Milano - I.C. Humanitas

Introduction Chondrosarcoma is an uncommon malignant neoplasm accounting about 0,5% of all laryngeal primary tumours. The commonly affected laryngeal subsites are thyroid and cricoid cartilage and epiglottis
Methods We report a case of laryngeal chondrosarcoma of the larynx arising from cricoid cartilage with special regard to diagnostic aspects.
Results The patient referred to us for dysphonia, hoarseness and dyspnoea. A laryngoscopy showed a lesion in a area bordered inferiorly by the lower margin of the cricoid

cartilage and superiorly below the free margin of the true vocal cord and a CT scan of the larynx confirmed a heterogeneous calcified mass originated by the cricoid cartilage. Ultrasound-guided fine needle aspiration biopsy was performed and potentially malignant chondroid neoplasm was diagnosed. The snear was composed of metachromatic amorphons myxoid matrix with sparse chondrocyte often binucleated and plurinucleated characterized by plump and slighty irregular nuclei. The patient underwent a partial subglottic laryngectomy with temporary tracheotomy. The lesion was predominantly composed of lobules of well-differentiated hyaline cartilage with rare foci of calcification and chondrocytes showing moderatly hyperchromatic nuclei, plump with slight irregularities. Intermingled with these there were areas more hypercellulated with more marked nuclear irregularities and bi- and pluri-nucleation. Necrosis was not observed and mitoses were rare and limited to hypercellular areas.
Conclusion In the diagnosis of chondrosarcoma the histological distinction between the different degree of malignacy constitutes one challenge for the pathologist. The biological behaviour is characterized by locoregional recurrent in direct correlation with the degree od dedifferentiation. Metastasis in chondrosarcoma is a poor prognostic sign but is very rare.

EVALUATION OF EXPRESSION AND POTENTIAL PROGNOSTIC IMPORTANCE OF METALLOPROTEINASES 1 I 2 (MMP-1 I MMP-2) AND THE INHIBITOR OF METALLOPROTEINASE-3 (TIMP-3) IN CHOSEN ODONTOGENIC NEOPLASMS AND CYSTS.

Jozef Kobos*, Joanna Grodecka**
*Department of Pathology of the Age of Development and Department of Pathology Konopnicka Memorial Hospital Medical University of Lodz, Poland
**Department of Maxillofacial Surgery Medical University of Lodz, Poland

Currently used classification do not allow to predict precisely the biological behavior of odontogenic neoplasms and cysts. Real mechanisms of neoplastic transformation of epithelial and stromal components of odontogenic tumors remain unknown. Recently published data indicate the significance of metalloproteinases and their inhibitors in the phenomenon of local progression of neoplasms.
The aims of the study were evaluation of expression as well as potential prognostic importance of metalloproteinases 1 i 2 (MMP-1 i MMP-2) and the inhibitor of metalloproteinase-3 (TIMP-3) in a group of odontogenic neoplasms and cysts. For our research we used material from 74 patients (18 with ameloblastomas, 14 with other odontogenic tumors and 42 with odontogenic cysts) treated in the Maxillofacial Surgery Clinic of the Medical University of Lodz. For immunohistochemical evaluation Novocastra Company antibodies were applied. The intensity of immunohistochemical reaction was scored semiquantitatively.
Results
Intense expression of MMP-1 was observed in odontogenic cysts with strong inflammatory reaction.
There was no such dependency concerning the expression of MMP-2 and TIMP-3.
The expression of MMP-1 and TIMP-3 was noted in patients with odontogenic neoplasms presenting unfavourable clinical course and the intense expression of MMP-2 was observed in patients with no relapse.
Conclusions
Strong expression of MMP-1 was related to the intensity of inflammatory reaction in odontogenic cysts.
The expression of MMP-2 was related to favourable and the expression of MMP-1 and TIMP-3 to unfavourable clinical course in patients with odontogenic neoplasms.

O-14
EXPRESSION OF P16 IN SINONASAL MALIGNANT MELANOMA

FRANCHI Alessandro, ALOS Llucia, GALE Nina, MASSI Daniela, SANTUCCI Marco, ZIDAR Nina, CARDESA Antonio

Aim: p16 gene is one of the most frequently altered genes observed in various human neoplasms including malignant melanoma. It encodes a negative regulatory protein which prevents cell cycle progression from G1 to S phase by inhibiting the catalytic activity of CDK4 or CDK6/cyclin D complex and subsequently Rb protein phosphorylation. Little is known about the relationship between the clinical feature of the patients with sinonasal malignant melanoma and the expression of tumor suppressor gene products. The purpose of this study is to investigate the expression of p16 in relation with the histopathologic features and the clinical course in patients with malignant melanoma of the sinonasal tract.
Methods: Formalin-fixed, paraffin embedded sections from 34 cases of sinonasal malignant melanoma were immunostained with a monoclonal antibody against p16. The immunostaining was scored semiquantitatively as: negative, focal positivity (1-10% of neoplastic cells), moderate positivity (11-50%) and diffuse positivity (>50%).
Results: Nuclear and cytoplasmic immunoreactivity for p16 was observed in 14 melanomas (42.2%); immunostaining was also present in surface and glandular epithelia. Twenty melanomas (57.8%) showed loss of p16 expression. All cases with spindle or mixed cytology showed loss of p16, while this was present in 50% of tumours with epithelioid appearance (p=0.02). Loss of p16 expression was more frequently seen in melanomas with alveolar architecture (75%) than in tumours with diffuse architecture (61.6%), but this difference was not significant (p=0.68). Of 31 patients with available follow-up, 15 (48.3%) died of disease (follow-up ranging between 2 and 201 months; mean 30.3 months). There was no correlation between p16 expression and presence of lymph node or distant metastases (p=0.38 and 0.67, respectively). In addition, p16 status did not influence overall survival (p=0.2).
Conclusions: Loss of p16 expression is a frequent event in sinonasal malignant melanoma, which may be involved in the development of this tumour. Immunohistochemical analysis of p16 is not helpful in defining the prognosis of patients affected by sinonasal melanoma.

O-15
CHRONIC CALCINEURIN INHIBITOR TOXICITY IS ASSOCIATED WITH HYALINE SCLEROSIS OF THE RENAL VASA RECTA.

Hallgrimur Benediktsson, Min Yi Ngae, Serdar Yilmaz, Kevin McLaughlin and Rodger Loutzenhiser, University of Calgary, Calgary Laboratory Services and Calgary Health Region, Calgary, Alberta, Canada.

Introduction. Calcineurin inhibitor toxicity (CIT) is a common complication in renal allografts, and is associated with functional deterioration of the graft. While acute CIT is not associated with consistent morphologic changes, chronic CIT is characterized by nodular hyaline changes in the efferent arterioles, as well as interstitial fibrosis, tubular atrophy, and glomerulosclerosis, global and/or segmental. Changes have not been described in the post-glomerular vascular bed. We describe hyaline vascular sclerosis occurring in the renal vasa recta (VRHS) in patients with CIT.
Design. We selected 373 renal biopsies from our biopsy database for evaluation of the vasa recta. 143 cases were

excluded due to inadequate medulla sampling.The remaining 230 biopsies were scored semi-quantitatively for VRHS, as well as glomerulosclerosis, arterial fibrointimal thickening, arteriolar hyalinosis, tubular atrophy, cortical and medullary fibrosis. Transplant biopsies included 35 cases with original diagnoses of chronic allograft nephropathy (CAN), 29 with CIT, 23 transplant baseline biopsies, and 34 early post-transplant biopsies with or without acute rejection. Non-transplant cases included diabetic nephropathy (24), IgA nephropathy (33), focal segmental glomerulosclerosis (FSGS) (22), hypertensive nephrosclerosis (10) and various types of glomerulonephritis (20).
Results: Significant VRHS was frequently found in biopsies from patients with chronic CIT (24/29), and was often associated with nodular arteriolar hyalinosis. It was found less often in CAN (11/35), early post-transplant biopsies (6/34), FSGS (8/22), IgA nephropathy (8/33), and diabetic nephropathy (6/24). Mild changes were rarely seen in baseline transplant biopsies (2/23) and in biopsies from various types of glomerulonephritis (3/20). None of 10 biopsies with nephrosclerosis showed VRHS. Marked VRHS was most often seen in association with CIT.
Conclusion: VRHS occurs at significant frequencies in late transplant biopsies, particularly in association with evidence of CIT. It is seen infrequently in native FSGS, IgA nephropathy, and diabetic nephropathy and is not as severe as in transplant biopsies. The pathogenetic mechanism for this lesion is not clear. Increased transmitted blood pressure is a possible mechanism, however toxic drug effects and inflammation may also play a role. VRHS is an under-recognized lesion which may aid in the diagnosis of CIT, and may have significant functional correlates.

O-16
HUMAN IMMUNODEFICIENCY VIRUS ASSOCIATED NEPHROPATHY PATHOGENESIS: DOES VASCULAR ENDOTHELIAL GROWTH FACTOR (VEGF) PLAY A ROLE?

BROCHERIOU Isabelle*, IZZEDINE Hassane §, LAUNAY-VACHER Vincent §, DERAY Gilbert §, CAPRON Frederique*. Departments of *Pathology and §Nephrology, Pitié-Salpêtrière Hospital, Paris, France.

Background: Vascular endothelial growth factor (VEGF) is a major regulator of blood vessel biology and is highly expressed in presumptive and mature podocytes within the glomerulus. It has been suggested that overexpression of this factor may play a role in collapsing focal segmental glomerulosclerosis (cFSGS); however, definitive proof that it plays a pathogenic or developmental role in the Human immunodeficiency virus-associated nephropathy (HIVAN) has remained elusive. The aim of this study was thus to determine if the angiogenic peptide VEGF is required for glomerular ischemia-associated HIVAN.
Methods: Twenty renal biopsies from patients were selected from our tissue bank of frozen renal biopsy material. Five renal biopsies proven of HIVAN cases were studied immunohistochemically for expression of the VEGF. An equal number of, normal adult control kidneys, not HIV-associated cFSGS and other HIV-associated nephritis were tested for the same antibodies.
Results: VEGF protein was localized exclusively in glomeruli, predominantly in podocytes and the level of tubular expression was much lower or inexistant than that found in glomeruli in normal kidney tissue. In glomeruli with segmental or global sclerosis, cells expressing VEGF protein were not present in the sclerotic areas, as well as in epithelial tubular cells. In HIV-related nephritis without cFSGS cells expressing VEGF protein were markedly reduced in number in the glomeruli and tubules. However, in HIVAN, expression of VEGF protein was markedly increased in collapsing glomeruli and in epithelial cells of the microcystic dilated tubules.
Conclusion: Expression of VEGF by glomerular visceral epithelial cells and dilated tubule cells is increased in HIVAN, and this may have an important role in this disease.

ET-1/ETB-RECEPTOR IN COL4A3 KNOCKOUT MICE

Ch. Licht1, O. Gross2, M. Odenthal3, H.-P. Dienes3, D.V. Michalk1, M. Weber2,
J.W.U. Fries3
Department of Pediatrics1 and Pathology3 of the University of Cologne, and
Department of Internal Medicine I, Merheim Medical Center2, Cologne, Germany

Objectives:Tubulointerstitial injury (TI) is a common pathway of chronic renal disease and determines the loss of renal function. Chronic proteinuria causes
TI, but it is still controversial by what mechanism. Purpose of the present study was to find out whether ET-1/ETB-receptor is involved in the TI caused by
proteinuria. We made use of the COL4A3 -/- animal model mimicking Alport syndrome (AS), which is characterized by hematuria and proteinuria leading to progressive renal failure. Untreated COL4A3 -/- mice die from renal failure
after about 70 days. However, treatment with ramipril delays onset and reduces extent of proteinuria thereby increasing the lifespan by more than 100%. - The
model of the ramipril treated COL4A3 -/- mice was used to study the role of the endothelin (ET) - system in the development of the proteinuria caused tubulointerstitial fibrosis.
Methods:COL4A3 wild type and knockout mice were treated with 10 mg/kg/day ramipril in the drinking water starting at 4 wks of age and compared to controls (placebo). Animals were sacrificed following 7.5 and 9.5 wks. Kidneys
were rapidly harvested and either processed for immunohistochemistry or used for extraction of total RNA. TI was characterized by incubation with a-smooth
muscle actin (aSMA) antibody identifying myofibroblasts. Expression of ET-1 and ETB receptor was quantified by real time RT-PCR with b-actin as housekeeping-gene.
Results: Wildtype controls showed normal kidneys and no upregulation of ET-1 or ETB receptor expression. However, untreated COL4A3 -/- mice showed increasing amounts of aSMA positive cells and a with time increasing expression of ET-1 (7.5 wks: 2.05; 9.5 wks: 4.73) but not of ETB receptor (7.5 wks: 0.29; 9.5 wks: 0.13). Ramipril treatment did not affect renal histology in wildtype control animals, nor did it alter expression of ET-1 or ETB receptor. However, ramipril treated COL4A3 -/- mice developed less TI; ET-1 expression was increased (7.5
wks: 2.47; 9.5 wks: 2.98) but did not reach the level of placebo treated COL4A3-/- animals. ETB receptor expression was only slightly different from placebo treated animals (7.5 wks: 0.30; 9.5 wks: 0.59).
Conclusions:
(1) renal ET-1 expression is increased and ETB receptor expression is decreased in chronic proteinuria
(2) the protective effect of ramipril treatment against renal TI is linked to a reduced increase of ET-1 expression.
ET-1/ETB receptor may be important for mediating TI caused by proteinuria.

O-18
AN ADENOVIRUS-PROMOTER-CONSTRUCT TO STUDY RENAL MYOFIBROBLAST FORMATION IN VITRO AND IN VIVO

M Odenthal, J Wallraf, T Roth, C Licht*, HP Dienes and JWU Fries.
Department of Pathology and * Pediatrics, University of Koeln, Koeln, Germany

Objective: Myofibroblastic differentiation in the kidney is characterised by the presence of smooth muscle actin (SMA) in mesangial cells in glomerulosclerosis and in the interstitium following ureteral obstruction. To further study this process, we developed a convenient system in living cells allowing readily detection of early mesangial activation by using different mediators applicable to in vitro and in vivo investigation.
Methods: Human mesangial cells (HMCs, Cambrex Bioproducts)in subculture 6-9 were subjected to different commercially available transfection reagents (Lipofectin, Fugene, Lipofectamine, CaCl2, DEAE-dextran) or electroporation with the nucleofactor (Amaxa) using a CMV-ß Gal reporter plasmid for evaluation of transfection efficency. Also, adenoviral-mediated infection was performed with recombinant reporter expression driven by the CMV or the SMA promoter. Infection efficiency was monitored by GFP reporter fluorescence of CMV reporter infected mesangial cells. Recombinant reporter expression directed by the SMA promoter was quantitatively analysed by the Bioanalyszer (Agilent) during the myofibroblastic transition upon glucose (4 vs. 30mM) and mechanical strain (15, 30, 60 cycles/min)treatment of HMCs for up to 48 hrs. To test the inducibility of this construct in vivo, unilateral renal perfusion after 1.5 nephrectomy or ureteral ligation are used as models.
Results: Adenovirus-mediated transgene transmission and recombinant expression in HMCs was successful in 100% of the cells after 24 hrs. of infection with 10 MOI (multiplicity of infection) of an adenoviral CMV promoter driven reporter construct. From the commercially available transfection mediators only DEAE-dextran yielded positive cells (about 5%). Electroporation failed. In contrast to constitutive expression of CMV driven GFP, fluorescence of the SMA promoter GFP construct could be induced after 24 hrs by mechanical strain and by glucose. Maximal GFP intensity was achieved after glucose stimulation for 7d, lasting for at least 3 weeks after switching to normal feeding medium. In the in vivo models, the adenovirus-promoter construct was detected primarily in the epithelium of the proximal tubules, facilitating studies of epithelial-mesenchymal transition.
Conclusion: Adenovirus-mediated infection is an efficient way to achieve HMC manipulation. Using GFP, the inducibility of any promoter construct can be easily monitored and its in vitro and in vivo applicability tested.

IMMUNOHISTOCHEMICAL EXPRESSION OF ACTIVATED CASPASE-3 AS A MARKER OF APOPTOSIS IN HUMAN LUPUS NEPHRITIS

JERUC Jera, VIZJAK Alenka, FERLUGA Dušan
Institute of Pathology, Medical Faculty, University of Ljubljana, Ljubljana, Slovenia

Introduction. The significance of renal cell apoptosis in human lupus nephritis (LN) is not clear. One of the key events in the process of apoptosis is activation of caspase-3. Recently, antibodies that recognize activated caspase-3 have become commercially available. Studies on various experimental models of apoptosis suggest that activated caspase-3 is a reliable indicator of apoptotic rate, with a favourable comparison against the widely used TUNEL assay.
Aim of the study. We investigated the expression of activated caspase-3 in the glomeruli of LN patients and its relationship to histomorphologic changes, activity (AI) and chronicity (CI) indexes and renal function.
Material and methods. Kidney tissue samples of 36 patients with systemic lupus erythematosus were classified according to the current ISN/RPS 2003 classification of LN. In addition, AI and CI were calculated. Immunohistochemistry was performed by a sensitive peroxidase-streptavidin method on formalin fixed, paraffin-embedded tissue, using monoclonal antibodies against activated caspase-3 (Cell Signaling, MA, USA) and proliferative marker Ki-67.
Results. There were five cases of class II, 11 cases of class III and 20 cases of class IV LN. Among class IV, there were 9 cases of diffuse segmental and 11 cases of diffuse global LN. Active caspase-3 positive cells were identified in the glomeruli of all but three patients (two class II and one class III). The number of glomerular apoptotic cells was significantly higher in class III compared to class II LN ($p<0.005$) and in class IV compared to class III ($p<0.05$). There were more positive cells in global compared to segmental class IV LN, but the difference was not significant. The number of glomerular apoptotic cells correlated with AI, proliferation of glomerular cells and proteinuria ($r = 0.54$, 0.57 and 0.42, $p < 0.05$), but not with CI and renal function.
Discussion and conclusions. Our study shows that the apoptotic rate assessed by activated caspase-3 is higher in severe, active glomerular lesions in human LN. The results suggest that increased apoptosis of glomerular cells may be involved in the progression of human LN. Inhibitors of caspases are highly effective in preventing apoptotic cell death in both in vitro and in vivo models of apoptosis and should therefore be investigated among further therapeutic modalities of human LN.

PLASMA CELL DYSCRASIA AND DIAGNOSTIC INTRACELLULAR CRYSTALS IN THE URINE

LEH Sabine (1), IMMERVOLL Heike (1), LØVØ Mona Grete Skivenesvåg (2), BOSTAD Leif Henry (1)
(1) Department of Pathology and (2) Department of Medicine, Haukeland University Hospital, Bergen, Norway
sabine.leh@helse-bergen.no

Introduction: Crystalloid tubulopathy is a rare but well documented renal complication in plasma cell dyscrasia. The entity is usually diagnosed by histologic and ultrastructural investigation of a kidney biopsy. In our case tubular cells with crystalline inclusions were detected in the urine.
Case report: A 56-year-old man was admitted to the outpatient clinic with hypertension, slight increase of serum creatinine and slight proteinuria. Antihypertensive therapy resulted in nearly complete normalisation of blood pressure, but the serum creatinine value continued to increase over a period of 6 months. A renal ultrasound examination showed slightly reduced kidney size with reduced cortical parenchyma.
Subsequently monoclonal immunoglobulin IgG kappa was detected in serum, and urine analysis revealed monoclonal kappa light chains (16100 mg/l). The bone marrow smear contained 11% plasma cells. There were no osteolytic foci in an X-ray examination of the skeleton. A plasma cell dyscrasia was diagnosed.
The kidney biopsy showed massive intracellular deposition of crystals in proximal tubules. A few tubular lumina contained single needle shaped crystals. In addition benign nephrosclerosis with arterio/arteriolosclerosis and slight to moderate tubular atrophy was found. Ultrastructurally proximal tubular epithelial cells contained numerous partly membrane bound polygonal crystals without identifiable substructure.
Proximal tubular epithelial cells were seen in urine by cytological examination. Alcohol fixed Papanicolau stained cytospin preparations showed many tubular cells with clear polygonal inclusions. The staining pattern of these inclusions in a cell block preparation was identical to that seen in histological sections. The shape of the crystals in cytologic, histologic and ultrastructural preparations was similar.

Conclusion: This case of monoclonal gammopathy and crystalloid tubulopathy exemplifies that tubular cells with crystalline inclusions are easily recognised by urine microscopy. Urine analysis could therefore contribute considerably to establish the diagnosis in this rare entity.

O-21
NCAM POSITIVE INTERSTITIAL CELLS ARE INCREASED IN DIFFERENT FORMS OF GLOMERULONEPHRITIS

MARKOVIC-LIPKOVSKI Jasmina, MÜLLER Claudia, KLEIN Gerd, FLAD Thomas, KLATT Tatjana, BLASCHKE Sabine, WESSELS Johannes, MÜLLER Gerhard
Institute of Pathology, School of Medicine, University of Belgrade, Serbia & Montenegro;
Section for Transplantation Immunology and Immunohematology, ZMF, University Medical Clinic, Tübingen, Germany;
Department of Nephrology and Rheumatology, Center of Internal Medicine, Georg-August University, Göttingen, Germany

In adult human kidneys, NCAM expression is restricted to rare interstitial cells with dendritic morphology, which are neurofilament-negative and predominantly localised in the outer medulla. In this study NCAM expression was analyzed on interstitial cells in different forms of glomerulonephritis (5 IgA nephropathy, 7 focal segmental glomerulosclerosis, 5 membranous glomerulonephritis and 3 rapidly progressive glomerulonephritis) by immunohistochemistry and Western blot analysis. NCAM+ renal interstitial cells were characterized by double immunofluorescent staining using antibodies against alpha smooth muscle actin, vimentin, alpha-5-beta-1 integrin and the potential progenitor cell markers CD34, CD117, CD133, CD24 and cadherin-11.
The number of NCAM+ interstitial cells increased in the initial phases of interstitial fibrosis in different forms of glomerulonephritis such as IgA nephropathy, focal segmental glomerulosclerosis, membranous glomerulonephritis as well as in early phase of rapidly progressive glomerulonephritis. NCAM isoform of 140 kDa was detected in renal tissue of IgA nephropathy. In normal renal tissue NCAM positive cells are very conspicuous, single located and some subpopulation of them co-express the hematopoietic stem cell markers CD34 and CD133. However, in different forms of GN in the areas with slight interstitial interstitial fibrosis, the accumulated NCAM positive interstitial cells do not share CD34 and CD133 and they are also negative for alpha smooth muscle actin.
These data indicate that a rare subpopulation of NCAM+ interstitial cells in normal adult kidneys could represent renal progenitors. The number of NCAM+ interstitial cells is increased in the initial phase of interstitial fibrosis in different forms of glomerulonephritis and these cells are probably involved in this process.

O-22
HANTAVIRUS NEPHROPATHY IN MECKLENBURG-VORPOMMERN (NORTH GERMANY)

STROPAHL Gerhard1, FÜHRER Andreas2, STROPAHL Karsten2, JONAS Ludwig3, NIZZE Horst1
Institute of Pathology1, Clinic of Internal Medicine2, Electron Microscopic Centre3, University of Rostock, Germany

Hantaviruses are regarded as “emerging” viruses that have been detected in the Americas, Asia, and Europe. Their natural hosts are rodents (mice and rats). As zoonotic pathogens they cause human hemorrhagic fever with renal syndrome (HFRS) as well as the hantavirus pulmonary syndrome, each with varying degrees of severity. In Central Europe infections are normally caused by viruses type Dobrava and Puumala leading to a mild or moderate HFRS with prominent renal symptoms (Nephropathia epidemica). Due to differential-diagnostic problems a renal biopsy is carried out in some cases.
In the region of Mecklenburg-Vorpommern 23 cases with infectious diseases by hantaviruses were registered in the last 6 years (17 men, 6 women, age: 14-66 years). In 7 cases the virus type could be differentiated (6x Central European variant of Dobrava, 1x Puumala). 18 patients showed clinical and paraclinical signs of a nephropathy. The remaining 5 cases had only influenza-like symptoms. Mostly hantavirus nephropathy manifested suddenly with high fever, headache, back and/or abdominal pain. The majority of the cases showed proteinuria (> 3 g/d), microhematuria, increased serum creatinine level (> 310 µmol/L), thrombocytopenia (< 100,000/µL). Oliguria and subsequent polyuria were frequent. In 3 of the cases kidney biopsies were performed because of suspected acute or rapidly progressive glomerulonephritis. Histologically in one case only uncharacteristic changes of an acute renal failure with swelling, vacuolization, and single cell necrosis of tubular epithelium were detected. Specimen of the second patient showed fresh spot-shaped interstitial hemorrhages in the renal marrow in addition to the acute tubular kidney damage. Lesions of a moderate acute interstitial nephritis characterized the third case. Electron-microscopically virion particles with spherical or ovoid form (80-120 nm in diameter) were proved in tubular epithelium.
The diagnosis was established either by demonstration of antibody titer elevation or by culturing the virus from the urine. The renal failure was transient and patients recovered spontaneously.
In conclusion, an unclear acute renal failure with a sudden febrile onset, in particular with additional interstitial hemorrhages or an acute interstitial inflammation in the kidney tissue, can indicate a hantavirus nephropathy and should be clarified by serological tests. The suspected diagnosis can be supported by electron-microscopic examinations.

O-23
GLOBAL PROTEOMICS IN CONGENITAL OBSTRUCTIVE NEPHROPATHY

LIAPIS Helen and TOWNSEND Reed. Department of Pathology & Immunology and of Internal Medicine, Washington University, St Louis, MO, USA

Proteomics is a major spin off of the human genome project. We have previously studied congenital obstructive nephropathy in humans and in animal models and performed genomic analysis in human kidneys. In this study we aim to characterize the proteome.
We used three congenitally obstructed kidneys and equivalent controls. Fifty micron thick sections were used for total protein extraction. High throughput proteomics to profile protein changes was performed. Proteins were labeled with Cy dyes and separated by 2-D DIGE. Images were analyzed using DeCyder image analysis software to determine fold differences between obstructed and control kidneys. Selected spots were excised from the gels, trypsinized in situ and analysis was performed by matrix-assisted laser desorption ionization-time-of flight (MALDI-TOF/TOF) or by LC MS/MS mass spectrometry.
A total of 48 proteins were differentially expressed; 35 were positively identified, while 11 were not identified in the protein data bases that are currently available. In segmentally scarred kidneys, there was increased HSP, Albumin, Glyceraldehyde-3-phosphatedehydrogenase (GPH) and Tubulin. In contrast, Lumican, Vimentin, Collagen I and Osteoglycin were markedly increased in globally scarred obstructed kidneys and GPH was decreased. Other proteins

were variably expressed included tropomyosin. Of these, Lumican was previously found increased in experimental ureteral obstruction models by genomic analysis. Albumin is considered a urine marker for progressive kidney disease. Osteoglycin is expressed in the renal interstitium and thought to regulate collagen fibril spacing and to inhibit embryonic renal cell growth in vitro. Tubulin a both cytoplasmic and nuclear protein is currently a drug target in RCC.
Our findings are the first to report on the proteome of congenital obstructive nephropathy, a common cause of ESRD in children. Proteomics is a promising new tool for identification of biomarkers to shed more light in the natural history of this disease and to identify molecular endpoints for therapeutic intervention.

CELL CONTACT AND FAK INFLUENCE VEGF EXPRESSION THROUGH IRS-2

M. NEID(1), K. DATTA(2), D. MUKHOPADHYAY(2), A. TANNAPFEL(1) AND CH. WITTEKIND(1)
(1)Institut für Pathologie des Universitätsklinikums, Liebigstr. 26, 04103 Leipzig, Germany
(2)Biochemistry and Molecular Biology and Cancer Center, Mayo Clinic, Rochester, MN 55905, USA

Introduction: Under hypoxic conditions, tumour cells produce the Vascular Endothelial Growth Factor (VEGF) to induce tumourangiogenesis. We have shown recently that the Insulin Like Growth Factor-1 receptor (IGF-1R) and its downstream molecules Insulin Receptor Substrate-1 (IRS-1) and IRS-2 regulate VEGF expression in different ways. IRS-1 leads to a Hypoxia Inducible Factor-1 (HIF-1) dependent VEGF transcription whereas IRS-2 activates the transcription factor SP1.

Purpose of the study: In this study, we wanted to characterize factors that influence the expression of IGF-1R, IRS-1 and IRS-2, hence having an indirect impact on VEGF transciption. Data in the literature show a crosstalk between IRS-1 and integrin dependent signaling through Fokal Adhesion Kinase (FAK). This suggests an influence of the extra cellular matrix (ECM) on VEGF expression.
Methods: AsPC-1 pancreatic cancer cells were cultured either on plastic or on different extracellular matrices (fibronectin, ECL). VEGF transcription was measured by luciferase assays using either the full length VEGF promoter (2.6kb), containing HIF-1 binding sites, or a 0.35kb promoter construct with SP1 bingin sites only (hypoxia independent). Functional deactivation of FAK was achieved using a dominant negative mutant (dN FAK). Cell confluency experiments were carried out by putting the same amount of AsPC-1 cells, transfected with the VEGF promoter, onto a variably dense matrix of non-transfected AsPC-1. mRNA of IRS-1, IRS-2, IGF-1R were measured by RT real time PCR using a light cycler.
Results: ECM did not influence neither 2.6kb nor 0.35kb VEGF transcription. We observed colony forming of AsPC-1 and found that high cell confluency increased 0.35kb VEGF transcription and decreased 2.6kb VEGF transcription. In highly confluent cells, IRS-1 and IRS-2 were upregulated, but the total amount of IRS-2 exceeds the one of IRS-1. Although ECM did not change VEGF transcription, blocking FAK revealed the same changes in VEGF transcription pattern as in highly confluent cells. Moreover, dN FAK increased the IRS-2 and decreased the IRS-1 mRNA level. No change was observed in IGF−1R mRNA expression.
Conclusion: Extra cellular matrix does not influence VEGF transcription in the pancreatic cancer cell line AsPC-1. Abundant cell contacts increase hypoxia independent VEGF transcription (via SP1) through IRS-2. This is modulated by the integrin kinase FAK.

O-25
DEVELOPMENT OF A RAPID SCREENING APPROACH FOR CANDIDATE GENE SETS IN CANCER

R. Wittig1, R. Salowsky2, S. Blaich1, S. Lyer1, JS. Maa3, O. Müller2, J. Mollenhauer1, and A. Poustka1.
1Molecular Genome Analysis, Deutsches Krebsforschungszentrum (DKFZ), Heidelberg, Germany, 2Agilent Technologies, Waldbronn, Germany, and 3Maxim Biotech, San Francisco, CA, U.S.A.

Background: During the last decade, microarray-based gene expression analysis gave rise to a large number of candidate genes for the diagnostics and therapy of cancer. Bioinformatic approaches delivered gene sets, the expression patterns of which were predictive for certain cancer phenotypes. A synergy between these advances and the development of screening tools for a rapid and reliable screening of marker gene expression represents an important step towards an improved treatment of cancer.
Methods: For the semi-quantitative expression screening of eleven candidate genes for drug resistance in melanoma, we combined multiplex RT-PCR (mRT-PCR) with subsequent microfluidic fragment analysis.
Results: The functionality of this approach was demonstrated by low inter-experimental variations of amplicon quantities after endpoint analysis. Applied to RNA samples derived from drug-sensitive and -resistant melanoma cell lines, mRT-PCR delivered results qualitatively concordant with data obtained from Northern blot- and array-analyses. A preliminary screen of four additional melanoma cell lines points to IL1B, APOD, and CYR61 as interesting candidates for drug-resistance associated genes. First tests using an automated on-chip electrophoresis platform indicate the applicability of this approach for high throughput measurements.
Conclusion: mRT-PCR combined with on-chip electrophoresis reveals a rapid and easy-to-handle method for candidate gene set evaluation from limited amounts of mRNA. Using gene sets indicative for different tumor phenotypes, this procedure may represent an alternative for future cancer diagnostics.

6 Department of Pathology and Urology, University of Michigan, Ann Arbor, MI.
7 University Hospital of Ulm, Ulm, Germany
8 Dana Farber Cancer Institute, Boston MA

Background: The critical clinical question in prostate cancer research is to develop means of distinguishing aggressive from indolent prostate cancer. Expression array technology has lead to the development of discrete molecular signatures but the development of a robust signature to characterize aggressive prostate cancer has yet to be achieved. We

describe a multi-stage approach to develop a model of prostate cancer progression.
Methods: A recent study from our group employed high-throughput immunoblotting using antibodies against 1383 distinct proteins or post-translational modifications in order to interrogate tissue extracts derived from benign prostate, clinically localized prostate cancer, and metastatic prostate cancer. An integrative analysis of this compendium of proteomic alterations and transcriptomic data derived from 8 prostate cancer profiling studies was used to select a smaller set of genes that demonstrated concordance between protein and transcript levels. 41 of these genes could be evaluated on archival tissue samples. Using a prostate cancer progression tissue microarray, the protein products of these genes were tested using quantitative analysis of immunohistochemistry. The best model was validated using prostate cancer expression array data with associated clinical outcomes data.
Results: Linear discriminant analysis determined that the optimal model consisted of 12 proteins. This 12 protein model accurately distinguishes stages of prostate cancer progression. Intriguingly, the transcriptional levels of the 12 genes encoding for these proteins predict PSA-failure in 80 men following surgery for clinically localized prostate cancer (p=0.0015).
Conclusion: This study demonstrates that cross platform models can lead to predictive models with the possible advantage of being more robust through this selection process.

BPC 157 ALTERS CELL GROWTH, DIFFERENTIATION AND SIGNAL TRANSDUCTION IN SHSY5Y HUMAN NEUROBLASTOMA CELL LINE

Sanja Radeljak, Sven Seiwerth, Ljiljana Hlupic and Predrag Sikiriæ, Lab. Of Molecular Pathology Dept. of Pathology and Dept. Of Pharmacology, School of Medicine, University of Zagreb, Salata 12, 10000 Zagreb, Croatia

Neuroblastoma is among the most aggressive cancers in humans predonimantly affecting children. Gastric pentadecapeptide BPC157 (GEPPGKPADDAGLV) is a novel small peptide molecule with various pharmacological effects on different organs in vivo in rat experimental models and it was never tested on human cancer cells. Various pharmacologic inhibitors are implicated in the mitogen-activated protein kinase (MAPK) path. This was supported by the finding that expression of a constitutively activated component of the MAPK path, MAPK kinase (MEK), decreased N-myc levels. Human neuroblastoma cells (NB) were grown in cell culture under standard conditions, treated with BPC157, VEGF and the combinations of these agents during 24-48 h. Changes in cell morphology were observed daily and photomicrographs were taken. After harvesting cells were prepared for flow cytometry and Western blot analysis of MAPK kinase signal transduction pathway.Western blot analysis of MAPK pathway was performed using ERK as primary antibody and phosphorylated (activated) ERK (pERK) as secondary antibody. Morphological changes in NB cells were most striking after 48 h treatment with BPC157 in concentrations of 2 and 10 ng/ml and after combined treatment of cells with BPC157 (10ng) and VEGF (10ng). Decrease in cell density, disapperance of cell clusters and mitosis were most prominent after treatment of cells with 10 ng of BPC 157 and after adding 10ng of BPC 157 to VEGF stimulated cells. Futhermore, cells were fully differentiated into neuronal-like phenotype, with long extensions of neurites, formed cellular network and visible synapses. Flow cytometry analysis showed 20% decrease percentage of cells entering S-phase of cell cycle, after treatment with 2 and 10ng of BPC157. Decrease of 15 % of S-phase cells were observed with combination of VEGF stimulation folowed by BPC157 treatment (10ng). Consistent with these findings, BPC157 acts as an antiproliferative and differentiating agent in neuroblastoma cell culture, affecting the G1-S transition state of cell cycle. Finally, BPC 157 exerts its antimitogenic properties by inhibition of ERK phosphorylation before and after VEGF stimulation, thus it blocks mitogenic signal along the MAPK kinase pathway. Our results indicate that BPC157 is selectively involved in downregulation of ERK phosphorylation. Here, we propose that BPC157, may act as a novel inhibitor of MAPK kinase signaling pathway and it could be of particular clinical interest.

O-28
SOCS-3 IS FREQUENTLY METHYLATED IN HEAD AND NECK SQUAMOUS CELL CARCINOMA AND ITS PRECURSOR LESIONS AND CAUSES GROWTH INHIBITION

Anette Weber; Dept. of Otorhinolaryngology, University of Leipzig
Iris Tischoff; Institute of Pathology, University of Leipzig
Christian Wittekind;Institute of Pathology, University of Leipzig
Andreas Dietz;Dept. of Otorhinolaryngology, University of Leipzig
Andrea Tannapfel;Institute of Pathology, University of Leipzig

The suppressors of cytokine signaling (SOCS) are inhibitors of cytokine signaling that function via the Janus kinase (JAK)/signal transducers and activators of transcription (STAT) pathway. Recently, methylation of SOCS-1 and SOCS-3 has been implicated in the tumorigenesis of liver and lung cancer. This study was performed to elucidate the role of SOCS-1 and SOCS-3 in squamous cell carcinoma of the head and neck (HNSCC) and its precursor lesions. HNSCC of 94 patients and corresponding normal mucosa, lymph node metastases as well as 16 high and 21 low grade squamous cell dysplasias were studied by using methylation-specific PCR (MSP) for the SOCS-1 and SOCS-3 promoter after microdissection. The presence of SOCS-3 mRNA transcripts was confirmed by semiquantitative real-time PCR, and the SOCS-3 protein was analyzed immunohistochemically. SOCS-3 hypermethylation was found in 85/94 HNSCC (90%) and in 10/16 high and 9/21 low grade dysplasias (63% and 43%, respectively). SOCS-1 promoter hypermethylation was detected in 10/94 HNSCC samples (11%) and in 2/16 high grade and 1/21 low grade dysplasias (13% and 5%, respectively). Lymph node metastases exhibited an identical methylation status as the primary tumors. Methylation of the SOCS-3 promoter correlated with downregulation of SOCS-3 transcripts and protein expression in these tumors and various cell lines. In the cell lines tested, SOCS-3 and SOCS-1 transcripts increased upon treatment with the demethylation compound 5-aza-2-deoxycytidine (5-AZA-DC). Overexpression of wild type SOCS-3 in carcinoma cells with methylated SOCS-3 resulted in the induction of apoptosis and growth suppression as well as downregulation of STAT3, bcl-2 as well as bcl-xL. Our data suggest that promoter methylation and subsequent transcript downregulation of SOCS-3 transcripts and, to a much lesser extent, SOCS-1 are involved in the multistep carcinogenesis of HNSCC. Due to its involvement in tumor growth, restoration of SOCS-3 may hold treatment potential for HNSCC.

SOMATIC AND GERMLINE MUTATION IN GRIM-19, A DUAL FUNCTION GENE INVOLVED IN MITOCHONDRIAL METABOLISM AND CELL DEATH, IS LINKED TO MITOCHONDRION-RICH (HÜRTHLE CELL) TUMOURS OF THE THYROID

Sobrinho-Simões M1,2,3, Maximo V1, Botelho T1, Capela J4, Soares P1,2, Lima J1, Magalhães J2,3, Taveira A1,4, Amaro T5, Barbosa A P6, Preto A1, Harach R7, Williams D8.

Oñativia Hospital, Salta, Argentina; 8.Strangeways Research Laboratory, University of Cambridge, Cambridge, United Kingdom.

Oxyphil or Hürthle cell tumours of the thyroid are characterized by their consistent excessive number of mitochondria. A recently discovered gene, GRIM-19, has been found to fulfil two roles within the cell: as a member of the interferon-beta and retinoic acid-induced pathway of cell death, and as part of the mitochondrial Complex I assembly. In addition, a gene predisposing to thyroid tumours with oxyphilia (TCO) has been mapped to chromosome 19p13.2 in one family. A cluster of genes involved in mitochondrial metabolism occurs in this region; one of these is GRIM-19. We have searched for GRIM-19 mutations in a series of 52 thyroid tumours. Somatic missense mutations in GRIM-19 were detected in 3 of 20 sporadic Hürthle cell carcinomas. A germline mutation was detected in a Hürthle cell papillary carcinoma arising in a thyroid with multiple Hürthle cell nodules. No mutations were detected in any of the 20 non-Hürthle cell carcinomas tested, nor in any of 96 blood donor samples. In one of the sporadic Hürthle cell papillary carcinomas positive for GRIM-19 mutation we have also detected a RET/PTC-1 rearrangement. No GRIM-19 mutations were detected in any of the six cases of known familial Hürthle cell tumours tested, so that our results do not support the identification of GRIM-19 as the TCO gene. The GRIM-19 mutations we have detected are the first nuclear gene mutations specific to Hürthle cell tumours to be reported to date; we propose that such mutations can be involved in the genesis of sporadic or familial Hürthle cell tumours through the dual function of GRIM-19 in mitochondrial metabolism and cell death.

COMPARISON OF 3 COMMERCIALLY AVAILABLE IMMUNOHISTOCHEMICAL TESTS FOR EGFR EXPRESSION IN COLORECTAL CANCERS. IS IMMUNOHISTOCHEMITRY (IHC) RELIABLE ?

F. M. Penault-Llorca, A. Cayre,L. Arnould, F. Bibeau, M. Bralet, P. Rochaix, J.C Sabourin

IHC appears to be the required test for the selection of patients for a monoclonal antibody based targeted treatment with C225 (Erbitux®). To validate the usefulness of IHC, confirmation of assays and scoring systems are mandatory. PURPOSE OF THE STUDY :In an attempt to standardize the immunohistochemical detection of EGFR, we have retrospectively evaluated three commercially available EGFR kits or antibodies and analyzed the discrepancies between the tests in terms of percentage of positive cells, intensity, cut off value and fixatives. METHODS: we extracted 230 paraffin embedded samples from a metastatic colorectal cancer trial. For all cases, EGFR expression have been assessed with the FDA approved Dako EGFR pharmaDx kit, the Zymed EGFR kit and the Ventana CONFIRMTM EGFR 3C6 antibody. Different cut off were tested, intensity was scored 0, 1+,2+, 3+ following the suppliers' recommendations.
RESULTS: number of positive cases
Dako Zymed Ventana
Cut off >0% 75 % 86% 93%
Cut off 5% 61% 78% 80%
Cut off 10% 48% 60% 72%
Performances of the tests i)percentage of positive cells: Ventana > Dako ($p<10-7$), Zymed > Dako ($p = 0{,}000002$), Ventana > Zymed ($p=0{,}75$, ns); ii) The intensity of staining was correlated to the percentage of positive cells for Ventana ($p < 10-6$) and Zymed ($p < 10-5$). iii) No interaction with staining was identified for any of the fixative, or with the nature of samples.Each technique has pros: full automation for Dako and Ventana tests, easier interpretation with Ventana's test (counterstaining), lower costs for Zymed kit.
CONCLUSION: our data showed a higher number of positive cases detected by Ventana and Zymed, whatever the cut off value for positivity was. No scoring system showed, to date, its accuracy, and more studies have to be conducted with an evaluation of response to C-225. Whether and how the EGFR status has to be tested for the selection of patients for C225 is still a non-answered question. The proper selection might be through a co-evaluation of other markers involved in EGFR regulation.

IMPACT OF PREOPERATIVE RADIOTHERAPY IN LYMPH NODES STATUS AFTER MESORECTAL EXCISION FOR RECTAL ADENOCARCINOMA

RULLIER Anne (1), LAURENT Christophe (2), CAPDEPONT Maylis (2), VENDRELY Veronique (3), BELLEANNEE Genevieve (1), RULLIER Eric (2)
Departments of (1)Pathology, (2)Surgery and (3)Radiotherapy-CHU Bordeaux-France

The number and status of lymph nodes analyzed is a crucial issue for optimal tumor staging and adjuvant treatment. The impact of preoperative radiotherapy in the number of lymph nodes retrieved in rectal specimen is still controversial. The aim of the study was to define influence of preoperative treatment in the number of both lymph nodes retrieved and positive lymph nodes after rectal excision for cancer.
From January 1994 to December 2004, 495 rectal adenocarcinomas underwent rectal excision. Preoperative radiotherapy (45 Gy in 5 weeks) was given in 332 patients (248 with concomitant chemotherapy) whereas 163 patients were treated by surgery alone. Influence of 11 clinical and pathological variables on nodal status (total number and positive lymph nodes) was assessed by univariate and multivariate analyses.
The mean number of lymph nodes retrieved per specimen was 14.6. The four variables influencing independently the number of lymph nodes were preoperative radiotherapy, tumor size, pathological tumor staging and surgical treatment. The mean number of lymph nodes retrieved after preoperative radiotherapy was smaller than after surgery alone (13 vs 17). Concomitant chemotherapy did not influence the number of lymph nodes retrieved whereas a boost of 10 Gy did influence ($p=0.008$). The mean number of positive lymph nodes was 1.6. The six variables influencing independently the number of positive lymph nodes were preoperative radiotherapy, tumor size, pathological tumor staging, tumor differentiation and vascular invasion. The mean number of positive lymph nodes retrieved after preoperative radiotherapy was smaller than after surgery alone (1.2 vs 2.3). The number of positive lymph nodes correlated with the number of lymph nodes retrieved ($p<0.001$).
Compared to surgery alone, preoperative radiotherapy decreases the number of both lymph nodes retrieved and positive lymph nodes after rectal excision for rectal cancer. However, further studies are needed to assess the optimal lymph nodes number to analyze after preoperative radiotherapy for rectal cancer.

REACTIVATION OF P16INK4A AND RASSF1A GENES AND INHIBITION OF C-MYC AND HTERT EXPRESSION BY AS2O3 IN COLORECTAL CANCER CELLS

Xing CUI1, Toshifumi WAKAI2, Katsuyoshi HATAKEYAMA2 and Seishiro HIRANO1
£¨1Environmental Health Sciences Division, National Institute for Environmental Studies, 2Division of Digestive and General Surgery, Niigata University Graduate School of Medical and Dental Sciences, Japan

Background & Aims
Inactivation of tumor suppressor genes and overexpression of DNA methyltransferase 1 (DNMT1), c-myc, and human telomerase reverse transcriptase£¨hTERT£©have been reported in human colorectal carcinoma (CRC). Arsenic trioxide (As2O3), an effective anticancer agent for the treatment of malignant hematopoetic diseases, has been shown to induce apoptosis and suppression of hTERT in leukemia cells. On the other hand, arsenic has been shown to induce DNA hypomethylation by depletion of methyl donor pool. In the present study, we investigated effects of As2O3 on restoration of some major tumor suppressor genes, p16INK4a, RASSF1A, and inhibition of DNMT1, c-myc, and hTERT in CRC cell lines.
Materials & Methods
HCT116 and SW480 cells were treated with 2-20 mM of As2O3 and/or 2 mM of demethylating agent, 5-aza-2'-deoxycytidine (5-aza-CdR) and/or trichostatin A (TSA), a histone deacetylase inhibitor, for 24, 48 and 72 h. DNA and RNA were extracted from these cells. The methylation status of the CpG island around the promoter regions of p16INK4a and RASSF1A was detected by a methylation-specific polymerase chain reaction (MSP). The mRNA and protein levels of above two genes in addition to c-myc, DNMT1 and hTERT were determined by quantitative real-time RT-PCR, immunohistochemical analysis. DNMT enzyme activity was also estimated in the cells treated with or without As2O3.
Results
CpG methylation of the p16INK4a and RASSF1A genes was correlated to the reduction of mRNA levels in CRC cell lines, and its mRNA expression was indeed restored by low concentrations (2-6 mM) of As2O3 through demethylation, as well as 2 mM of 5-Aza CdR and/or combined with 50 ng of TSA. Immunohistochemical analysis showed that expression of p16INK4a and RASSF1A was significantly enhanced after the treatment with a low concentration of As2O3. In contrast, high concentrations (10-20 mM) of As2O3 damaged cell membranes and markedly suppressed immunoreactivity. With nuclear extracts as the enzyme source and polydeoxyinosine-deoxycytosine as the substrate, As2O3 dose-dependently inhibited DNMT activity. Moreover, a low concentration of As2O3 suppressed expression of DNMT1, c-myc, and hTERT in CRC cells.
Conclusions
In conclusion, a low concentration of As2O3 can reactivate partially/fully silenced tumor suppressor genes through demethylation, and also inhibits expression of proto-oncogene such as c-myc and hTERT.

THE SIGNIFICANCE OF BETA-CATENIN, E-CADHERIN, AND P-CADHERIN EXPRESSIONS IN COLORECTAL ADENOMA-CARCINOMA SEQUENCE: AN IMMUNOHISTOCHEMICAL STUDY USING TISSUE ARRAYS

Berna Savas, Arzu Ensari, Sibel Percinel, Isinsu Kuzu, Ayhan Kuzu, Nazmiye Kursun.
Ankara University, Medical Faculty, Department of Pathology, Department of Surgery and Department of Biostatistics, Turkey

Introduction: Alterations in APC gene are known to be early events in colorectal adenoma-carcinoma sequence, causing activation of Beta-catenin/TCF pathway. Alterations of Beta-catenin together with its binding partner, E-cadherin are commonly observed in colorectal carcinogenesis. Increased nuclear Beta-catenin expression together with downregulation of E-cadherin was observed in the neoplastic progression of adenomas in previous studies.
Aim: To investigate the role of Beta-catenin, E-cadherin and P-cadherin in colorectal adenoma-carcinoma sequence.
Methods: Core tissue biopsies of 4 mm in diameter were prepared from paraffin-embedded tissue blocks of 167 cases, including 95 colorectal adenomas, 10 hyperplasic polyps, 8 serrated adenomas, 28 colorectal carcinomas and 26 normal colon mucosae. Of 95 adenomas, 17 were tubular; 41 were tubulovillous and 37 were villous adenomas. Fourteen adenomas contained microscopic foci of intramucosal carcinoma. Immunohistochemistry was performed using antibodies to Beta-catenin, E-cadherin, P-cadherin. Distribution of positivity was assessed using percentage expression while an arbitrary grading scale was used for staining intensity.
Results: Beta-catenin expression was either cytoplasmic-membranous or nuclear where as both E-cadherin and P-cadherin expressions were confined to cytoplasmic-membranous compartments. Cytoplasmic-membranous expression of Beta-catenin was significantly higher in adenomas including serrated adenomas compared with hyperplastic polyps and normal mucosae ($p<0.001$) while no such difference was observed between adenomas and carcinomas. Nuclear expression of Beta-catenin showed a mean of $8 \pm 14,4$ in TA, $2,97 \pm 7,5$ in TVA and $8,96 \pm 25,7$ in VA while adenomas with intramucosal carcinoma and carcinomas had significantly higher expression ($p<0.001$). Nuclear Beta-catenin expression showed a positive correlation with the grade of dysplasia in adenomas ($p<0.01$). No such difference was observed in E-cadherin, P-cadherin expressions.
Conclusions: The increase of nuclear expression of Beta-catenin correlating with the grade of dysplasia in adenomas and increased Beta-catenin nuclear staining intensity in carcinomas support the previous studies regarding the role of Beta-catenin in colorectal carcinogenesis. The presence of E-cadherin and P-cadherin expressions in adenomas suggests that these molecules are also involved in adenoma formation though not necessarily involved in neoplastic progression.

Cyclooxygenase (COX) is a key enzyme for prostaglandin production and is directly involved in colorectal tumor development mainly via generation of prostaglandin E2 (PGE2). However, prostaglandin production is also directly

dependent on arachidonic acid availability. Cytoplasmic PLA2 (cPLA2) preferentially hydrolyses arachidonic acid that is the limiting substrate for COX mediated prostaglandin production. Because of this key role in prostaglandin production, the role of cPLA2 in intestinal tumorigenesis has been suggested. However, contradictory data are found in the literature.
In this study we evaluated cPLA2 expression in colon carcinomas and determined if cPLA2 expression could contribute to PGE2 production.
cPLA2 and COX-2 protein expression were evaluated in 65 colon carcinomas by immunohistochemistry and in 8 colorectal cancer cell lines by Western Blot. Furthermore, basal PGE2 production and PGE2 production after cPLA2 stimulation by calcium ionophore were evaluated in the cell lines by enzyme immunoassay and correlated to cPLA2 and COX-2 expression. As the presence of microsatellite instability influences COX-2 expression, we also investigated the relationship between cPLA2 expression and microsatellite instability assessed by PCR.
Twenty -five carcinomas had microsatellite instability. A moderate or strong cPLA2 expression in carcinomas was observed in 49 % of all the cases. Within a same tumor cPLA2 expression positively correlated with COX-2 expression (p=0,0003). Although a low COX-2 expression correlated with the presence of microsatellite instability (p=0,0002) there was no association between cPLA2 expression and microsatellite instability (p=0,69). Both cPLA2 and COX-2 protein expression were detected in 4 cell lines and COX-2 protein expression was detected in one additional cell line. In the cell lines, levels of cPLA2 and COX-2 protein expression correlated (p=0.008). Basal PGE2 production was correlated with COX-2 levels (p=0.03) but not with cPLA2 levels (p=0,2). The increase in PGE2 production after a 30 minutes stimulation by calcium ionophore was correlated with cPLA2 levels (p=0.002) but not with COX-2 levels (p=0.06).
Conclusion: A moderate or strong cPLA2 protein expression exists in about half of colon carcinomas, and is often associated with a moderate or strong COX-2 expression. cPLA expression in colon carcinomas seems to be involved in prostaglandin E2 production and could contribute to colon tumor development.

EVALUATION OF REVISED BETHESDA GUIDELINES FOR HEREDITARY NON-POLYPOSIS CANCER IN A CONSECUTIVE SERIES OF 225 COLORECTAL CARCINOMAS

JULIÉ Catherine, MUTI Christine, COULET Florence, TRESALLET Christophe, BROUQUET Antoine, SOUBRIER Florent, BOILEAU Catherine, NORDLINGER Bernard, ROUGIER Philippe, PENNA Christophe, FRANC Brigitte, RADVANYI Hélène. CHU Ambroise Paré, Boulogne; CHU Tenon, Paris, France (AP-HP)

Introduction: Hereditary non-polyposis cancer (HNPCC) is an autosomal dominant cancer predisposition syndrome caused by germline mutations in DNA mismatch repair (MMR) genes. Defective MMR results in microsatellite instability (MSI) phenotype, which has been almost always found in HNPCC tumors, and in only 10-15% of sporadic colorectal tumors. The Bethesda guidelines developed in 1996 to guide who should undergo MSI analysis were recently revised to further aid in the identification of HNPCC kindred for genetic testing. Among the 5 revised criteria, 1 focuses on the histopathological features. Our aim was to evaluate the validity of the revised Bethesda criteria.
Methods: A consecutive series of 225 resected colorectal invasive adenocarcinomas from 214 patients was collected in our institution. All patients were seen by a clinical geneticist and personal and familial cancer history were collected. For all patients, age at diagnosis, location, stage and pathological characteristics of the tumor were collected. All tumors were reviewed by a senior pathologist. Tumors were analysed for MSI status using the five markers of the original NCI microsatellite panel. Germline mutations in the MMR genes pointed by immunohistochemistry were searched for MSI-high (MSI-H) tumor patients.
Results: Eighty-six patients (40%) fulfilled at least one of the 5 Bethesda criteria, but 75 of these Bethesda-positive patients (87%) fulfilled only 1 criteria. Among our 214 patients, 21 (8 Bethesda-positive and 13 Bethesda-negative) had a MSI-H tumor. Five out the 8 Bethesda-positive patients with MSI-H tumor presented a germline mutation of one of the MMR genes (4 hMSH2 mutations, 1 hMLH1 mutation). For the 3 remaining patients, search for mutation is ongoing, but there is some evidence for HNPCC (familial history (2/3), loss of expression for hMSH2 (2/3), rectal location (1/3)). Among the 13 Bethesda-negative patients with MSI-H tumor, 2 presented a germline mutation (1 hMLH1 mutation and 1 hMSH6 mutation).
Conclusion: In our study, the revised Bethesda criteria were not very selective: 40% of our unselected patients were retained using these criteria, only 9% of them had a MSI-H tumor. All the Bethesda-positive patients with MSI-H tumor presented a proven or likely HNPCC. On the other hand, we found 2 HNPCC cases in Bethesda-negative patients, showing that in our series, the revised Bethesda criteria were not sufficient to identify all HNPCC patients.

MICROSATELLITE INSTABLE (MSI+) COLORECTAL CANCERS COMPLICATING INFLAMMATORY BOWEL DISEASE MAY HAVE A DIFFERENT GENETIC PATHWAY FROM MSI+ SPORADIC COLORECTAL CANCERS

SVRCEK Magali (1, 2), DUVAL Alex (2), HAMELIN Richard (2), COSNES Jacques (3), BEAUGERIE Laurent (3), TIRET Emmanuel (4), PARC Rolland (4), FLEJOU Jean-François (1, 2)
Departments of Pathology (1), Gastroenterology (3), Digestive Surgery (4), Saint-Antoine Hospital, AP-HP, University Pierre et Marie Curie ; INSERM U434 (2), CEPH, Paris, France

Twelve to 15% of sporadic colorectal cancers (CRC) display defective DNA mismatch repair (MMR), manifested as microsatellite instability (MSI). In this group of cancers, the MMR deficiency is due to silencing of hMLH1 by methylation of its promoter, resulting in loss of hMLH1 protein expression.
Patients with inflammatory bowel disease (IBD) face an increased risk of CRC in ulcerative colitis (UC) and Crohn's disease (CD), and of small intestinal adenocarcinoma (SIA) in CD. MSI has been found to be a feature of some IBD-associated intestinal cancers, with a frequency still debated.
The aim of this study was to assess the prevalence of MSI in IBD-associated CRC and SIA in a referral hospital. We also compared the expression of MMR proteins and the clinicopathological variables of MSI+ cancers complicating IBD to those of a series of 21 MSI+ sporadic CRC observed in the same centre.
Paraffin embedded tissues from 53 CRC in 37 patients with UC and 17 CRC and 6 SIA in 21 patients with CD were studied. We evaluated MSI by PCR on 5 mononucleotide markers and immunohistochemistry (IHC) of hMLH1, hMSH2 and hMSH6.
15 cancers complicating IBD were suitable only for IHC. 61 were investigated using both techniques.
10/70 CCR (14%) and 0/6 SIA exhibited MSI. These 10 cancers were observed in 6 patients (2 with CD and 4 with

UC) (1 patient with UC had 5 cancers). IHC revealed a loss of expression of one MMR protein in 9/10 MSI+ cases (5 of 6 patients). One case showed loss of hMLH1, 3 cases hMSH2 and 5 cases (1 patient) hMSH6. All MSI+ sporadic CRC showed a loss of expression of hMLH1. MSI+ CRC complicating IBD were seen more frequently in left colon and rectum than sporadic CRC (50% vs 5%, p<0.01). The mean age at diagnosis of cancer was younger in the group of IBD-associated cancers (57 yrs, range 50-65 vs 74 yrs, range 49-91, p<0.01). Tumours in the two groups of patients shared many pathological features, in particular mucinous or partially mucinous differentiation (50% in IBD and 71% in sporadic, respectively), expanding margins (30% and 38%) and Crohn's-like lymphoid infiltrate (30% and 29%).
In conclusion, the prevalence of MSI in IBD related CRC is similar to that observed in sporadic CRC. The immunohistochemical pattern of MMR protein expression suggests that different genetic events may be involved in tumorigenesis of these two groups of cancers. MSI seems to be a rare event in IBD related SIA.

THYMIDILATE SYNTHASE QUANTITATION, VASCULAR ENDOTHELIAL GROWTH FACTOR AND P53 PROTEIN OVEREXPRESSION, AND POINT K-RAS MUTATION IN COLORECTAL CARCINOMA: RELATIONSHIPS WITH TUMOR RECURRENCE AND SURVIVAL

USAJ Slavica, KRTOLICA Koviljka*, BOGDANOVIC Andrija**, CEROVIC Snezana, BRAJUSKOVIC Goran, TARABAR Dino***
Institute of Pathology, Military Medical Academy; *Institute of nuclear science, Vinca, **Clinic of Hematology, School of Medicine, Belgrade University, *** Clinic of Gastroenterology, Military Medical Academy, Serbia and Montenegro

Introduction. Tumor angiogenesis, K-ras mutation and p53 protein overexpression are commonly involved in colorectal tumorigenesis, but their interrelationship and clinicopathological effects remains inconclusive. The expression of thymidilate synthase (TS) determines the response of patients with colorectal carcinoma (CRC) to fluorinated-pyrimidine based chemotherapy, but there are a few reports regarding prognostic value of TS expression on recurrence and overall survival of patients treated with curative surgery alone. The aim of this study was to examine the immunohistochemical expression of vascular endothelial growth factor (VEGF), p53 protein, and TS as wall as the presence of K-ras mutation in CRC tissue, their relationships and their significance in predicting tumor behavior and clinical outcome in CRC patients. Material and methods. Paraffin embedded tumor tissue specimens of 81 curatively resected colorectal carcinomas (Dukes stage A-21, stage B-24, and stage C-36 patients) were studied by immunohistochemical methods for detection of VEGF, TS and p53 protein and by polymerase chain reaction (PCR) for identification of mutations in the 12th and 13th codon of the K-ras gene. Median follow up was 31.4 month (range, 2-66 months). Results. TS, VEGF expression, nuclear p53 protein overexpression and K-ras mutation were found in 44.4%, 66.7%, 58.0% and 40.7% of CRC tissue, respectively. In high TS expressing group there were significantly more frequent VEGF and p53 protein overexpression as wall as the presence of K-ras mutation than in low TS group (86.1%, 77.8% and 63.9% versus 51.1%, 42.2% and 22.2% respectively, p value < 0.01)). Survival analysis showed that high value of TS, VEGF and p53 protein expression as wall as the presence of K-ras mutation in tumor tissue significantly correlated with early recurrence and poor overall survival (p ¡Ü 0.01) of CRC patients. Conclusions. The investigated molecular markers may be useful for prediction of outcome and recurrence rate in curatively treated CRC patients. In conjunction with clinical and pathological staging, they may provide a stronger indication of clinical outcome than staging alone and help better selection of therapeutic options in CRC patients.

Raman spectroscopy is a vibrational spectroscopic technique that can be used to probe molecular changes associated with tissue malignancy and prognosis. A previous study conducted on 52 tissues (26 normal mucosa and 26 tumors) human fresh colonic samples has shown the potential of Raman spectroscopy to discriminate between normal and tumor tissues on frozen sections. The aim of this work was to investigate the effect of formalin-fixation and deparaffination on human colonic tissues by near-infrared Raman microspectroscopy. Raman spectral images were recorded from paraffin-embedded, deparaffined, and frozen normal (n=3) and tumor (n=3) tissue sections. A mathematical routine involving vector algebra was developed to substract the paraffin contribution in each spectrum (virtual deparaffination). Multivariate statistical analysis was performed to identify the molecular composition (lipids, proteins, and collagen) in normal and malignant tissues. The comparison between the information obtained from frozen, paraffined, and deparaffined sections showed i) some significant spectral changes in protein content due to formalin-fixation, ii) the absence of lipid as expected after paraffin inclusion process iii) less information from protein and collagen spectra after deparaffination. Unsupervised hierarchical cluster analysis was used to classify the data obtained from frozen, paraffined, and deparaffined sections. This analysis permitted to classify tissues into two groups, normal and adenocarcinomas whatever the tissue preparation. In conclusion this study demonstrates that Raman spectroscopy can be applied on fixed tissues as well as on fresh tissues.

ACCUMULATION OF LEPTIN AND ADIPONECTIN WITH INCREASED EXPRESSION OF ADIPONECTIN RECEPTORS IN THE LIVER OF PATIENTS WITH NON-ALCOHOLIC FATTY LIVER DISEASE

CERVERA Pascale, LEMOINE Maud, WENDUM Dominique, CHARLOTTE Frédéric, KIM Minji, BASTARD Jean-Philippe, POUPON Raoul, HOUSSET Chantal, FLEJOU Jean-François, CAPEAU Jacqueline, SERFATY Lawrence.

Fat-secreted adipokines leptin and adiponectin are possibly involved in the pathogenesis of non-alcoholic fatty liver

disease . While a profibrogenic action of leptin and an antiinflammatory action of adiponectin are suggested by animal experimental studies, it is not known whether hepatic levels of leptin, adiponectin or adiponectin receptors are modified in patients with non-alcoholic steatohepatitis (NASH).
To address this question, we investigated 49 patients with biopsy-proven NASH (age 50±13, sex ratio 1, BMI 29.2±4.4), 14 with steatosis only (age 49±13, sex ratio 1.2, BMI 26.9±4.3) and 6 controls without steatosis who underwent liver surgery (age 63±8, sex ratio 2, BMI 24.4±1.5). In all subjects, insulino-resistance index, serum leptin and adiponectin levels were measured, intrahepatic leptin and adiponectin immunoreactivity was analyzed by immunohistochemistry, and hepatic expression of adiponectin receptors RI and RII was quantified by real-time RT-PCR.
Results : Patients with NASH, steatosis and controls were significantly different for insulino-resistance index (6.3±5.4 vs 3.1±2.4 vs 0.5±0.4, p=0.01) and serum adiponectin/leptin ratio (0.97±1 vs 1.6±1.4 vs 3.8±4.7, P=0.001). Liver adiponectin immunoreactivity was higher in patients with NASH than in patients with steatosis or controls (mean score 1.55±1.06 vs 0.93±0.3 vs 1±0 respectively, p<0.05), whereas leptin immunoreactivity was similar in the 3 groups. There was no relationship between serum concentrations and hepatic contents of leptin or adiponectin. Among patients, the amount of adiponectine immunoreactivity was positively related to the degree of steatosis and necrosis (p<0.0001 and p=0.02). The amount of leptin immunoreactivity was related only to the degree of steatosis (p=0.02). Leptin or adiponectin mRNAs were undetectable by RT-PCR in the liver both of patients and controls. Adiponectin RII mRNA levels were significantly higher in patients with NASH than in patients with steatosis and controls (4.9±2.6 vs 3.5±1.9 vs 2.2±1 respectively, p=0.01).
Conclusion : In patients with non-alcoholic fatty liver disease, 1) adiponectin and leptin accumulate within the liver, in the absence of significant local synthesis, 2) NASH is associated with higher amounts of hepatic adiponectin and its receptor RII as compared to patients with steatosis or to controls, 3) the amount of hepatic adiponectin, is related to the degree of steatosis and of necrosis.

O-40
A COMPARISON OF STELLATE CELL ACTIVATION AND TGF-Â EXPRESSION IN PATIENTS WITH HEPATITIS C AND WITH COMBINED HEPATITIS C/ DIABETES MELLITUS

M Rivera- NYPH-Weill Cornell Medical Center, New York, NY
F Ahmed- NYPH-Weill Cornell Medical Center, New York, NY
E Hyjek- NYPH-Weill Cornell Medical Center, New York, NY
LM Petrovic- NYPH-Weill Cornell Medical Center, New York, NY

Backround: Hepatits C virus (HCV) infection is a major cause of chronic liver disease.Hepatic stellate cell activation, manifested by the expression of smooth muscle actin (SMA) and TGF-â arekey factors in liver fibrogenesis.
Aim: The aim of this study was to assess and compare the degree of stellate cell activation in liver biopsies of patients with HCV alone and in patients with HCV/DM.The pattern of TGF-â expression was examined in selected cases.
Design: 69 liver biopsies were evaluated: HCV (n=39), and HCV/DM (n=30).All biopsies were immunostained for SMA, and 26 (13 from each group) randomly selected cases for TGF- â.A grading scale was applied (range: 0-3) reflecting the percentage of stellate cell activation which occurred in each zone of the hepatic acinus. A similar scale was applied in evaluating TGF-â expression.T-test and Wilcoxon rank-sum tests were implemented comparing stellate cell activation with the grade, stage, and degree of steatosis between the two groups.TGF-â expression was compared between the two groups.
Results: The mean stage of fibrosis for the HCV/DM and HCV group were 2.8 and 1.6 respectively (p<.0001).The mean grade of inflammation for the HCV/DM group and HCV group were 1.9 and 1.5 respectively (p=0.03).The mean grade of steatosis for the HCV/DM and HCV group were 1.1 and 0.5 respectively (p=0.01). The average grade of stellate cell activation for all zones for the HCV/DM group and HCV group was 1.3 and 1.2 respectively (p=.39). In both diagnostic groups combined, a significant stellate cell activation was observed in the zone 1 of the acinus and portal tracts for higher stages of fibrosis (>2) vs lower stage disease (p<.0001). A statistically significant increase in stellate cell activation was also observed in zone one for the HCV/DM group as compared to the HCV group (p=.02).The average grade of TGF-â expression in the HCV/DM and HCV group were 0.69 and 0.83 respectively (p=0.32).In advanced stages, prominent staining of septal myofibroblasts by TGF-â was seen.
Conclusion: Activated stellate cells are predominantly present in zone 1 of the acinus, correlating with advanced stages of fibrosis.Zone 1 stellate cell activation is significantly increased in the HCV/DM group as compared to the HCV group.TGF-â expression is increased in lower stage disease with prominent staining of septal myofibroblasts in high stage disease.This may reflect the role of stellate cell activation and TGF-â in early fibrogenesis.

EXPRESSION OF PROTEASE-ACTIVATED RECEPTORS AND TISSUE FACTOR IN HUMAN LIVER

Anne Rullier1,2, Nathalie Senant1, Walter Kisiel3, Paulette Bioulac-Sage1,2, Charles Balabaud1, Brigitte Le Bail1,2 and Jean Rosenbaum1.
1 INSERM, E362, 33076 Bordeaux France ; Université Victor Segalen Bordeaux 2, 33076 Bordeaux France ; IFR 66, 33076 Bordeaux France, 2 CHU de Bordeaux, Hôpital Pellegrin, Department of Pathology, Bordeaux France, and 3 University of New Mexico School of Medicine, Department of Pathology, Albuquerque, New Mexico, USA.

Thrombin, acting via its receptors called Protease-Activated Receptors (PARs) and tissue factor (TF) are major actors of haemostasis and are also known to be involved in inflammation and tissue repair processes and in tumorigenesis. Hepatocellular carcinomas (HCC) usually complicate chronic liver diseases characterized by inflammation and fibrosis. Thus, the aim of this study was to describe the expression of PARs and of TF in normal liver, cirrhosis and HCC.
We performed an immunohistochemical detection of the thrombin receptors PAR-1, PAR-3, PAR-4 and of human TF in formalin-fixed paraffin-embedded human tissue samples from 19 subnormal livers, 33 cirrhosis and 30 HCCs. PAR-1 was found on endothelial cells of sinusoids and larger vessels in all samples. In cirrhosis, spindle-shaped cells within septa and T lymphocytes were also PAR-1-positive. A few PAR-1-positive tumor cells were found in only 10% of HCCs. Whatever the nature of the tissue sample, PAR-4 expression was restricted to macrophages, B lymphocytes and nerves. The expression of PAR-3 was rarely seen. Unexpectedly, TF was found expressed in 95% of normal livers, 94% of cirrhotic livers, but only as in 50% of HCCs (p<0.001). Staining was mostly found in hepatocytes, and sometimes in neovessels and spindle-shaped cells within cirrhotic septa. No association was found between TF labelling and clinicopathological characteristics of HCC.

In conclusion, the pattern of expression of PARs confirms their role in the course of chronic liver disease by promoting inflammation via immune cells and neurogenic stimulation. However, PARs and TF expressions do not support their implication in HCC progression .

EXPRESSION OF CELLULAR RETINOL-BINDING PROTEIN-1 (CRBP-1) AND FIBRILLIN-1 IN HUMAN FŒTAL LIVER: AN IMMUNOHISTOCHEMICAL STUDY OF 28 CASES.

LEPREUX Sébastien (1,2), DESMOULIÈRE Alexis (2), PELLUARD-NEHME Fanny (1), CARLES Dominique (1), CHAPONNIER Christine (3), BALABAUD Charles (2), BIOULAC-SAGE Paulette (1,2)
(1) Service d'Anatomie Pathologique, Hôpital Pellegrin, CHU Bordeaux, France (2) GREF/INSERM E0362, Université Victor Segalen Bordeaux 2, France, (3) Département de Pathologie CMU Genève, Suisse.

In adult human liver, the CRBP-1 (which is involved in vitamin A metabolism) is a relevant marker of the quiescent hepatic stellate cells (HSC). CRBP-1 is also expressed in biliary cells and with a lower intensity in hepatocytes. Fibrillin-1, a component of microfibrils found in elastic fibers, is expressed without elastin as a regular network in the Disse space and is reinforced along the biliary ducts. Little is known on the expression of CRBP-1 and fibrillin-1 in the Disse space and biliary tree during the development of human fœtal liver.
Materials and methods: Twenty-eight fœtal livers at different stages of development (between 7 and 31 weeks of development (WD)) were studied. Immunohistochemistry was performed using antibodies against CRBP-1 on formalin fixed tissue (n=28) and against fibrillin-1 on frozen tissue (n=20).
Results: 1- Disse space. Until the 13th WD (n=13), CRBP-1 was expressed in 0/rare (n=9) or many cells (n=4). After the 13th WD (n=15), all cases showed CRBP-1 expressing cells in the Disse space with a similar density than adult liver in 13/15 cases. CRBP-1 expressing cells were fusiform in the majority of cases before the 16th WD and stellate after the 18th WD. Cellular bodies were stained as well as cytoplasmic processes, but no cytoplasmic lipid droplets were outlined by the staining, in contrast with HSC in adult liver. The expression of fibrillin-1 in the Disse space was discontinuous and irregular, but increased progressively with the age of development.
2- Biliary tree. From the 11th WD, all levels of ductal plate remodeling were observed. Whatever the stage of maturation, biliary cells showed a granular cytoplasmic CRBP-1 staining, lower than in HSC, but higher than in hepatoblasts. No fibrillin-1 staining surrounded the ductal plate. During the remodeling, an irregular deposition of fibrillin-1 surrounded progressively some isolated tubular biliary structures. At the late stage of the ductal plate remodeling, strong and regular deposition of fibrillin-1 around the biliary ducts was observed, as found in adult liver.
Conclusions: These data illustrate i/ the progressive organization of the Disse space with maturation of the HSC and gradual fibrillin-1 deposition, both participating in the sinusoidal architecture and control of the microvasculature tone; ii/ the CRBP-1 expression during the differentiation of biliary cells suggesting that biliary compartment could be early involved in vitamin A metabolism.

FIBROSING CHOLESTATIC HEPATITIS AFTER LIVER TRANSPLANTATION FOR HEPATITIS C VIRUS

GARRIDO Marta, MIQUEL Rosa., GARCIA Montserrat, FORNS Xavier, RIMOLA Antoni and BRUGUERA Miquel .
Pathology Department and Liver Unit.
Hospital Clinic. IDIBAPS. University of Barcelona.

Introduction. Fibrosing cholestatic hepatitis (FCH) is an infrequent severe histologic form of viral hepatitis that leads to a rapid and usually fatal early liver failure. Initially described in hepatitis B infected renal transplant recipients, it has also been reported exceptionally in other organ transplant recipients with hepatitis C or B infection, and in subjects with HIV-HCV/HBV co-infection and in HBV infected patients receiving chemotherapy.
Objective. The aim of this study was to investigate the incidence, clinical and histological data and outcome of the FCH in liver transplant (LT) recipients, in our institution.
Patients and Methods. A cohort of 116 consecutive HCV-infected patients undergoing 117 LT in our center between March 2000 and August 2003 were followed-up, including HVC-RNA quantification and systematic liver biopsies. The median follow-up was of 22 months.
Results. The liver biopsies of 7 of the patients (6 %) showed histologic characteristics of FCH, with marked irregular and expansive periportal fibrosis associated with mild inflammatory activity, presence of periportal ductular proliferation and periportal hepatocyte ballooning and cholestasis. Bile duct disorders were excluded clinically in each of these patients. FHC was diagnosed at a median of 12 months postransplant (5-18 months). The mortality of the group of patients with FHC was statistically significative higher (p=0.029) than the rest of the series. The development of FHC was associated with a young recipient age (p=0.032), and a trend to have higher pretransplantation (p=0.089) and higher HCV viral load at 1 and 3 months after transplantation (p=NS) was observed. The type of donor (cadaveric or living), old donor age, and administration of steroid boluses did not correlate with the presence of FCH.
Conclusions. Fibrosing cholestatic hepatitis is an aggresive form of viral C hepatitis that has been identified in 6% of the patients with HCV recurrence after LT in our series, emphasizing the importance of the histologic recognition of this condition because it represents a major cause of graft loss and dead. Further studies are needed in order to investigate the potential benefit of antiviral treatment in these patients.

LIVER HISTOLOGICAL LESIONS IN MULTIDRUG-RESISTANCE-3P-GLYCOPROTEIN HETEROZYGOUS GENE MUTATIONS CARRIERS : A CASE CONTROL STUDY IN ADULTS

ZIOL Marianne (1), FRASSATI-BIAGGI Annonciade (1), HANDRA-LUCA Adriana (1), BEAUGRAND Michel (2), GANNE-CARRIE Nathalie (2).
1:Pathology Department and 2: Liver Unit, CHU Jean Verdier and Paris 13 University, Bondy, France

Multidrug-resistance-3 P-glycoprotein (MDR3) is a canalicular phospholipid translocator involved in the biliary secretion of phospholipids. MDR3 gene mutations result in a spectrum of cholestatic liver diseases including adult cholelithiasis, intrahepatic cholestasis of pregnancy and progressive familial intrahepatic cholestasis type 3 (PFIC). Apart from PFIC, histological liver lesions have been very rarely described in other MDR3 mutation related phenotypes. We aimed to report clinical and biological characteristics and to describe histological liver lesions in 10 adults with MDR3 gene mutations.
Methods: 19 patients (16-57 years) referred for unexplained anicteric cholestasis and/or increased aminotranferases had both liver biopsy and MDR3 gene sequencing. Previously, the main causes of chronic liver disease and obstructive extrahepatic biliary disease were ruled out. Liver biopsies were retrospectively analyzed by 2 pathologists (MZ and

AFB). Clinical, biological and histological characteristics of patients with and without MDR3 gene mutations were compared.
Results: 10 patients had heterozygous gene point mutations (group A) and 9 had no mutation (group B). No significant differences were found between the groups for age (mean 34,6 vs 37 for group A and B respectively), sex ratio (H/F:8/10 vs 7/9), biliary lithiasis related symptoms (n=3 vs n=2), and alkaline phosphatases (2x upper limit of normal vs 1,8). Liver biopsies from the 10 patients with MDR3 mutation showed in all cases characteristic biliary fibrosis ranging from portal fibrous enlargement without septa (n=5) to septal fibrosis (n=5) with varying degrees of ductular proliferation. Slight alterations of interlobular bile duct epithelium with discrete lymphocytic exocytosis were observed in all cases except 2 showing severe ductopenia. No florid nor sclerosing cholangitis or lobular lesions was observed. In group B, biliary fibrosis and ductular proliferation were observed in 2 of 9 cases (one patient with severe ductopenia, one with advanced sclerosing cholangitis). Two biopsies did not show any significant lesions, 2 were suggestive of nodular regenerative hyperplasia, one of non alcoholic steatohepatitis and one of chronic hepatitis.
Conclusion: The results of this case-control study 1) underscore that anicteric cholestasis without biliary symptoms could be added to MDR3 mutation phenotype and 2) show that heterozygous MDR3 can result in significant liver biliary fibrosis.

O-45
EXPRESSION AND ROLE OF GAS6 AND OF ITS RECEPTOR AXL IN HEPATIC REGENERATION FROM OVAL CELLS.

COUCHIE Dominique*, LAFDIL Fouad*, MARTIN Nadine#, LAPERCHE Yannick*, ZAFRANI Elie Serge *#, MAVIER Philippe *. INSERM U581* and Département de Pathologie#, Hôpital Henri Mondor, Université Paris XII-Val de Marne, 94010 Créteil cedex, France.

Introduction. After submassive necrosis or when hepatocyte replication is severely impaired, hepatocyte regeneration takes place from precursor cells called oval cells. These cells proliferate in periportal areas and differentiate into hepatocytes. Gas6 is a vitamin K-dependent protein that binds to the Axl subfamily of tyrosine kinase receptors. Gas6 has anti-apoptotic and proliferative properties and plays a role in development and tissue remodeling.
Aim of the study. To evaluate the expression and role of Gas 6 and of its receptor Axl in hepatic regeneration from oval cells.
Methods and results. Hepatic regeneration from oval cells was induced by treating rats with acetylaminofluorene followed by partial hepatectomy. Rats were sacrificed the day of surgery and at days 1, 5, 9, 14 and 21 after partial hepatectomy. Oval cell accumulation was moderate at day 5, marked at day 9 and 14 and declined thereafter. Oval cells expressed Gas6, as demonstrated at the mRNA level by in situ hybridization and at the protein level by immunohistochemistry. Oval cells also expressed Axl by immunohistochemistry, and Axl mRNA level, measured by quantitative RT-PCR, paralleled the degree of precursor cell accumulation. Gas6 and Axl expression was also demonstrated in vitro by RT-PCR and immunoblotting in WB-F344 cells, a hepatocytic precursor cell line. We studied the effect of recombinant Gas6 on WB-F344 survival. After a 7 day-incubation in serum-free medium, the percentage of viable cells assessed by MTS test was 76% in the absence of Gas6 and 93% in its presence ($p<0.01$). In addition, inhibition of 15-d-prostaglandin J2-induced WB-F344 cell apoptosis by Gas6 was demonstrated morphologically and by a 45% decrease of caspase 3 activity in cells incubated with Gas6. Gas6 did not stimulate WB-F344 proliferation measured by thymidine incorporation.
Conclusion. Oval cells express in vivo Gas6 and its receptor Axl during hepatic regeneration from precursor cells. In vitro, the Gas6/Axl couple protects from apoptosis a hepatocytic precursor cell line. These results strongly suggest that the Gas6/Axl couple favours oval cell accumulation in regenerating liver by an autocrine/paracrine mechanism.

DETECTION OF HEPATITIS B VIRUS CCCDNA IN LIVER BIOPSY SPECIMENS

KOTOULA Vassiliki, SOULTOYANNIS Ioannis, AKRIVIADIS Evangelos, KOUSTIANI Georgia, NIKOLAKAKI Eleni, PAPADIMITRIOU Constantine, HYTIROGLOU Prodromos.
From the Departments of Pathology and Internal Medicine, Aristotle University Medical School, Thessaloniki, Greece.

Introduction: The major transcriptional template of hepatitis B virus (HBV) is the covalently closed circular DNA (cccDNA). Chronicity of infection and resistance to treatment are believed to be due to inability of the immune system and antiviral agents to clear hepatocytes of cccDNA. Molecular methods for detection of cccDNA have recently been described.
Purpose of study: To assess the presence of cccDNA in liver biopsy specimens of patients with chronic HBV infection, and to correlate the findings with pathologic features.
Methods: A real-time polymerase chain reaction (PCR) methodology for quantitative assessment of cccDNA and HBS gene sequences was developed. Total DNA was extracted from 37 needle liver biopsy specimens, obtained from 33 patients with chronic HBV infection and 4 patients with other diseases. Thirty of the 33 patients were HBeAg-negative in serum. A small fragment of each biopsy specimen was used for DNA extraction, while most of the material was processed for histologic and immunohistochemical examination. Real-time PCR reactions were run in an Opticon DNA Engine. The detection standard limits for cccDNA and HBS DNA were 1.5fg and 7.5fg, respectively.
Results: On histologic evaluation, the biopsies from the 33 patients with HBV infection showed the following grades of necroinflammatory activity: minimal: n=6 ("inactive carriers"); mild: n=11; moderate: n=9; severe: n=7. Fibrosis was staged as: absent: n=3; mild: n=6; moderate: n=11; severe: n=10; cirrhosis: n=3. Positive immunohistochemical staining for HBsAg and HBcAg was observed in 30 and 14 biopsies, respectively. HBS gene sequences were detected by real-time PCR in 30 out of the 33 specimens. The values ranged from 0.3pg to 94.7pg. Detectable cccDNA was found in 12 out of the 33 specimens. cccDNA values were low and ranged from <0.1fg to 0.2pg. In 2 of these 12 cases, necroinflammatory activity was mild, in 4 moderate, and in 6 severe ($p<0.01$). There was a clear-cut association between detectable cccDNA and positive immunostaining for HBcAg ($p<0.001$). No cccDNA or HBS gene sequences were detected in specimens from patients without HBV infection.
Conclusions: 1) Detectable cccDNA in liver biopsy specimens from patients with chronic HBV infection correlates with the grade of necroinflammatory activity, as well as with positive immunohistochemical staining for HBcAg. 2) In this predominantly HBeAg-negative patient population, the level of cccDNA in liver tissue is generally low.

O-47
HEPATIC TUMORS WITH SPINDLE CELL COMPONENT : A RARE AND HETEROGENEOUS GROUP WITH A HIGH RATE OF MALIGNANCY

ANDRIAMAMPIONONA Francine (1), BIOULAC-SAGE Paulette (1), BLANC Jean-Frédéric (2), SARIC Jean (3), LE BAIL Brigitte (1)

(1) Service d'Anatomie Pathologique, Hôpital Pellegrin; (2) Services d'Hépato-Gastroentérologie et (3) de Chirurgie Digestive, Hôpital Saint-André, CHU Bordeaux, France.

Spindle cell tumors, either primitive or secondary seem to be rare in the liver and the diagnosis is difficult.
Our aims were to evaluate the prevalence of hepatic tumors with spindle cell component (HTSC), their histological type, the proportion of primitive and secondary neoplasms and to determine the appropriate panel of antibodies to use for diagnosis.
We perform a retrospective review of HTSC seen in our institution from January 1994 to March 2005, either in liver biopsies or operative specimens.
During this period, only 42 HTSC were found. The prevalence among all hepatic tumors during the 6 last years was 2.9%. In 26 (61.9%)HTSC, spindle cells constituted the only/main component of the tumor and in the remaining ones (16 = 38.1%), spindle cells were in minority and associated with other cell types. The tumors were classified as malignant in 31 cases (73.8%), either primitive (n=18) or metastatic (n=13). The most common diagnosis were vascular tumors in 23.8%, with a high rate of angiosarcoma (80%); metastatic spindle cell melanoma (14.3%); leiomyosarcoma (11.9%); metastatic GIST (9.5%); solitary fibrous tumor, angiomyolipoma, and undifferentiated hepatic sarcoma (7.1% each). The origin of metastasis was mainly melanoma whereas primitive malignant tumors were mostly angio- and leiomyosarcomas. Primitive hepatic carcinomas were unfrequent : spindle cell hepatocellular carcinoma , spindle cell cholangiocarcinoma and hepatoblastoma with spindle cell component, 1 case each. Among benign tumors, solitary fibrous tumors were the most frequent (n = 3), followed by angiomyolipomas and epithelioid hemangioendotheliomas (2 each).The most usefull markers were: endothelial (CD 34 and CD 31) and muscular (AML and caldesmone) ones for sarcoma and solitary fibrous tumor, HMB45 and PS100 for melanoma and angiomyolipoma, CD 117 for metastatic GIST, CK 7 and Pancytokeratin for spindle cell carcinoma, anti-Hepar and anti-AFP for undifferentiated hepatocellular carcinoma; vimentine was totally aspecific.
Conclusion: in our series, HTSC represent 2.9% of hepatic tumors. 74% are malignant, mostly of mesenchymal origin with vascular or muscular differentiation. A restricted panel of markers (less than 12) is usefull, depending on the histology and on the patient's clinical history. The search of a primitive tumor may be necessary, especially for a GIST or a cutaneous or ocular melanoma. Benign tumors are rarer, mostly represented by solitary fibrous tumors.

O-48
CHORION NODOSUM: A PLACENTAL HALLMARK OF THE LIMB BODY WALL COMPLEX/SHORT UMBILICAL CORD SYNDROME

STANEK Jerzy, ADENIRAN Adebowale. Department of Pathology and Laboratory Medicine, University of Cincinnati College of Medicine, Cincinnati, OH, U.S.A.

Recently we reported the statistically significant association between amnion nodosum (AN) and clinical oligohydramnios, macerated stillbirths, malformations, and chronic twin-twin transfusion syndrome. On microscopic examination of some chorionic discs devoid of amnion (extraamniotic pregnancies), we noticed vernix-containing nodules identical to those of AN, but attached directly to the chorionic mesenchyme, which we named chorion nodosum (ChN). This study was undertaken to characterize the clinical setting of ChN.

Our surgical pathology (placentae and previable fetuses) and perinatal autopsy database, and relevant histology slides were reviewed to identify all AN and ChN cases examined from 1994 to 2004.

Among all consecutive 4356 placentae, there were four placentae with ChN (0.1%). Among 450 perinatal autopsies and 521 surgical pathology examinations of previable fetuses, six limb-body wall complex/short umbilical cord syndrome (LBWC) cases were identified (0.6%). The diagnosis of LBWC was based on coexistence of at least two of three features: exencephaly/encephalocoele/facial clefts, thoraco/abdominoschisis, and limb defects. All four ChN cases were associated with LBWC. In those cases, mean gestational age was 22 weeks, fetal weight 499 gm, fetal length 24 cm, and placental weight 165 gm. In two cases of LBWC without placental ChN, the corresponding means were: 18.5 weeks, 255 gm, 25 cm, and 130 gm.

ChN is a relatively infrequent finding (17 times less frequent than AN in our material). Severe oligohydramnios seems to be operational in the pathogenesis of AN and ChN. We believe that absence of the underlying amnion in ChN justifies a formal separate designation, distinct from AN. The term AN in such situation would be a misnomer because the nodules are attached directly to the chorionic mesenchyme and not to the amnion. ChN is a lesion characteristic of the spectrum of the LBWC. The pathomechanism of ChN is most probably related to prolonged direct contact of the fetal body with the chorionic mesenchyme denuded of amnion because we did not observe ChN in any case of the oligohydramnios sequence, early amnion rupture sequence, or extraamniotic pregnancies without LBWC. The absence of ChN in two cases of LBWC may be due to sampling, but it is likely that the duration of direct fetal-placental contact may be important, since the mean gestational age at delivery in these two cases was 3.5 weeks shorter than in the LBWC cases with ChN.

O-49
FOCALLY INCREASED AMOUNT OF INVASIVE INTERMEDIATE TROPHOBLASTS IN MATERNAL FLOOR IN OCCULT PLACENTA ACCRETA

DRUMMOND Zarius, STANEK Jerzy. Department of Pathology and Laboratory Medicine, University of Cincinnati College of Medicine, Cincinnati, Ohio, USA

We reported about the absence of significant differences in intensity of immunostaining for galectin 3 and E-cadherin in implantation site intermediate trophoblasts (isit) in placentae with basal plate myometrial fibers (bpmf). Increased number of isit was found in hysterectomy specimens with placenta creta but we are not aware of quantitative isit studies in spontaneously delivered placentae with bpmf. Consequently, the aim of this study is to verify whether the cell number, thickness and density of isit are different in the basal plates of such placentae in patients without clinical signs and symptoms of abnormal placental separation.

Among consecutive 4040 placentae, there were 25 cases (0.6%) in which routine histopathologic examination revealed the presence of bpmf apposed to chorionic villi or isit, but without intervening decidua ("occult" placenta creta, study group, sg). The control group (cg) comprised 25 placentae matched for gestational age (23-41 weeks) but without bpmf. There were no hysterectomies, cesarean sections, obstetric hemorrhage or manual extraction of placenta in either group. Archival formalin-fixed, paraffin embedded placental sections were immunostained for CD146 (Vector Laboratories), a cell adhesion molecule that highlights the intermediate trophoblasts. Number of isit cells was counted and thickness of the isit layer between chorionic villi and bpmf (sg) or chorionic villi and decidua (cg and sg away from bpmf) was measured by micrometry at two non-contiguous areas at bpmf spots and away from bpmf. From these measurements, density of isit was calculated. The results were compared statistically by ANOVA.

The micrometry thickness and cell number of isit were statistically significantly ($p<0.005$) larger in sg at sites with bpmf than away from bpmf and in cg (0.6 ±0.3, 0.3± 0.1, 0.4±0.1 mm, and 11.4±6.5, 6.7± 3.5, 7.0±3.5 cells, respectively), while the isit density was statistically not different ($p>0.05$) between sg at or away from bpmf, and in cg (20.4±10.4, 19.8± 7.6, 17.2± 22.6 cells/mm respectively).

In conclusion, the occult placenta accreta features an increased amount of proliferating isit in its basal plate only at sites of bpmf, but not in the remaining maternal floor. This may be related to the pathogenesis of placental ingrowth in placentae cretae. Pathogenetically, the occult placenta creta fills the gap between normal placental implantation and the symptomatic placenta creta.

O-50
STUDY OF BIRTH DEFECTS DETECTED IN A SERIES OF 2019 CONSECUTIVE PEDIATRIC AUTOPSIES

Piram, Adriana, MD – Department of Genetics, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, São Paulo, Brazil
Peres, Luiz Cesar, MD – Department of Pathology, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, São Paulo, Brazil
Pina-Neto, Joao Monteiro, MD – Department of Genetics, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, São Paulo, Brazil

Birth defects are an important cause of infant and child morbidity and mortality. A series of 2019 consecutive autopsies performed on patients aged 0 to 14 years of age from a referral university hospital was studied to determine the frequency and the pattern of birth defects or genetic diseases. We reviewed the records of autopsies performed over a 10 years period (1994-2003) at the Department of Pathology of the University Hospital at the School of Medicine of Ribeirão Preto, São Paulo University. The data of all pediatric autopsies were reviewed, summarized and catalogued according to the age, sex, and categories of the main cause of death. Cases presenting birth defects and genetic diseases were selected, and data from medical charts, photographic documentation, radiological studies, and records from the Departments of Pathology and Medical Genetics were reviewed and analyzed. Perinatal disorders were the leading cause of death (51.8%), followed by birth defects (29.3%) and infections (15.6%). Birth defects or genetic disorders related or not to the cause of death were found in 712 (35.3%) cases of which 183 (25.7%) had a confirmed isolated defect and other 70 (9.8%) had a probable isolated defect; 159 (22.3%) had a confirmed sequence and 7 (1.0%) had a probable sequence. Multiple defects were observed in 260 (36.5%) cases, of which 183 (25.7%) presented a defined diagnosis. Other genetic conditions such as metabolic or inherited neurological disorders were confirmed in 30 (4.2%) cases, and 3 (0.4%) were suspected. Birth defects and genetic diseases are an important cause of pediatric mortality pointing to the need for a collaborative study between Pathology and Medical Genetics using the available diagnostic resources in order to define the clinical and etiological diagnosis after which the recurrence risk, the ultimate and fundamental information for genetic counseling to the families, can be known.

O-51
PATHOLOGY OF SELECTED DEVELOPMENTAL VESTIGES

SOTELO-AVILA Cirilo , deMELLO Daphne, SOTELO-RAMPY Andrea K. Department of Pathology, SSM Cardinal Glennon Children's Hospital, St. Louis, MO, USA

Developmental Vestiges (DV), a topic of confusion and misunderstanding among pathologists, are defined as surviving traces, residues, marks or signs of something that existed during normal human embryonic or fetal development. "Something" applies not only to an anatomic structure but also to a condition or quality serving as indication of its former existence, e.g., ventricular septal defect (VSD), patent ductus arteriosus (PDA) and patent foramen ovale (PFO).

DV are important to pathologists because of their

· tendency to manifest clinically through hyperplastic or neoplastic growth causing compression of surrounding anatomic structures; tendency to undergo cystic dilation, infection, inflammation or torsion thus presenting as acute medical emergencies; occasional functional continuity from intrauterine to extrauterine life beyond newborn period with devastating consequences if not corrected, e.g., VSD, PDA, PFO; relative frequency in routine surgical pathology and in postmortem examinations. A complete understanding of normal embryologic and fetal development of these lesions along with the natural history and significance are as essential as their correct diagnosis. DV may

remain dormant for years and eventually undergo spontaneous involution and disappearance; undergo hyperplastic growth or neoplastic induction to form benign or malignant tumors in children and adults, but most commonly, they mature into dysplastic structures.

DV are classified as normal or common when they are present in most individuals, e.g., appendix testis and paraovarian ducts, and; abnormal or uncommon when they are absent in most individuals, e.g., branchial cysts, notochord remnants, etc.

A 23-year review of the surgical pathology files of SSM Cardinal Glennon Children's Hospital (72,735 specimens) disclosed numerous examples of common and some uncommon DV including caudal vestiges, pilonidal sinuses with subcutaneous neuroglia and ependymal rests, glomus coccygeum, tails and tailgut cysts, sequestered meningoceles of the scalp and some rare associations such as a sacrococcygeal dedifferentiated chordoma with malignant fibrous histiocytoma. Common and uncommon examples will be illustrated.

3Centro di Ricerca Osp.S.Pietro Fatebenefratelli, AFaR, Roma, Italy;
4Istituto di Neurobiologia Medicina Molecolare, CNR, Roma, Italy;
5II Facoltà di Medicina e Chirurgia, Osp. S. Andrea, Università La Sapienza di Roma, Italy.

HGF/c-met/STAT3 signaling pathway plays a role in cellular morphogenesis and organogenesis. Placentas of malformed fetuses showed low expression levels of proteins involved in this pathway, when compared with fetuses without any malformation. This observation suggests a possible role of this pathway in the pathogenesis of malformations. However, no data are currently available on the expression levels of any

member of this pathway, directly evaluated in the malformed organ. TP53, exerting a stimulatory effect on transcription of both murine HGF and c-met genes, may regulates cell growth as well as differentiation, even if its role in organogenesis is not well established yet.
Aim of our study is to evaluate the mRNA expressions of HGF, c-met and STAT3 in placentas and organs of fetuses with nervous system malformations (NSM)s and to correlate this results with p53 expression levels. Four fetuses, dead between 16th and 28th week of gestation, showing NSMs but non-malformed lungs and kidneys, have been selected for the study. Total RNA was extracted from malformed nervous system, lung, kidney and placenta of each fetus and analyzed by Reverse Transcriptase-PCR, using specific primers for HGF, c-met STAT3 and p53. Reduced expression or absence of HGF, c-met and STAT3 transcripts has been observed in all malformed nervous systems, as well as in the placentas. The reduced expression of all the members of HGF/c-met/STAT3 pathway, observed in both malformed nervous systems and in placentas, correlates with the absence of p53 in all these samples. On the contrary, detectable expression levels of p53, as well as HGF, c-met and STAT3 have been observed in non-malformed lungs and kidneys from the same fetuses.
In conclusion, the correlation between expression levels of p53 and of HGF/c-met/STAT3 pathway members suggests a role of this transcription factor in the pathogenesis of NSMs. The demonstration of occurrence of the same alterations in both malformed nervous systems and in the placentas, raises the possibility to perform the analysis of expression levels of these genes in placental tissue to diagnose NSMs during gestation.

ETHANOL AND NEURAL TUBE DEFECT IN MICE.

Cristiane Minot Gutierrez and Luiz Cesar Peres
Associate Professor, Department of Pathology, Faculty of Medicine of Ribeirao Preto, University of Sao Paulo

The clinical and experimental teratogenic effects of ethanol are well recognized. Nevertheless it is still the most important exogenous teratogen widely used by women in childbearing age. Ethanol has been implicated in congenital heart disease, limb anomalies and Neural Tube Defect (NTD). The aim of the present study was to determine the effects on the fetuses of low and high doses of ethanol given to pregnant mice. Female Swiss mice were randomized into Control (C), low ethanol (E1) and high ethanol (E10) groups with six animals each, kept in individual plastic cages in a controlled environment with commercial mouse chow and water ad libitum throughout the experiment. On the 8th, 9th, and 10th day of gestation all animals received intraperitoneal injections. Group C received saline, the experimental groups received ethanol diluted in saline 25% (v/v) of a dose of 0.4 g/Kg body weight for Group E1 and 4.0 g/Kg for Group E10. The animals were killed on the 19th gestational day in a CO2 chamber. The number of implants, resorptions, late fetal death, presence of NTD, weight and length of fetuses and placentas were recorded. NTD was found only in Group E10 (2.86%). Statistically significant difference was observed for late fetal death, body weight and length of male, female or both fetuses of Group E10 when compared to Groups C and E1($p<0.05$). No difference was observed for implants, resorptions, and the number of live fetuses in all groups as well as for all parameters between groups C and E1. Body weight and length was statistically different between male and female fetuses in each respective group. The finding of NTD only in group E10 indicates that the teratogenic effects of ethanol are dose dependent. Group E1 received ethanol equivalent to 28 g/Kg of body weight in man, a dose corresponding roughly to 2 cans of beer. Group E10 received a dose high enough for the mice to become comatose. Low ethanol dose in mice do not interfere with fetal survival and development, the opposite of high dose. In conclusion, high ethanol dose induces developmental restriction, late fetal death and NTD in Swiss mice when administered for a short period in early pregnancy. Since Swiss mice suffer less deleterious effects when exposed to ethanol during pregnancy than C57B, which present more resorptions and NTD, caution in the interpretation of results must be taken in respect to the teratogenic effects of ethanol.

O-54
COMPARISON OF MORPHOLOGY, GRADE, AND CYTOGENETIC ABNORMALITIES IN T(14;18) AND NON-T(14;18) FOLLICULAR LYMPHOMAS: DOES ANYTHING CORRELATE?

KELLER Christian, College of Physicians and Surgeons, Columbia University, VAKIANI Efsevia, College of Physicians and Surgeons, Columbia University, MURTY Vundavalli, College of Physicians and Surgeons, Columbia University, FRIZZERA Glauco, Joan and Sanford I. Weill Medical College, Cornell University, ALOBEID Bachir, College of Physicians and Surgeons, Columbia University, BHAGAT Govind, College of Physicians and Surgeons, Columbia University

Background: Two subtypes of follicular lymphoma (FL), with and without t(14;18) have been described. Distinct cytogenetic abnormalities have also been reported in the different subgroups of FL3. We investigated whether we could 1) stratify FL diagnosed at our institute, according to specific cytogenetic abnormalities and 2) discern morphologic and cytogenetic abnormalities between the t(14;18) and non-t(14;18) groups. Methods: We obtained 33 successive cases of FL from our departmental files with an informative karyotype, diagnosed between 1997-2004. Morphologic features and grade were reviewed by 2 pathologists, blinded to the cytogenetic findings. All cases were graded according to the current WHO criteria and divided into 2 groups; FL with t(14;18) or without t(14;18). Cases were further subdivided according to the presence or absence of 3q27 abnormalities. Statistical analysis was performed using Fisher's exact and Student's t-tests. Results: 24 of 33 (73%) cases had t(14;18) group I, while 9 cases lacked t(14;18) group II. In group I, 20 cases lacked group 1a and 4 cases had 3q27 abnormalities group Ib. Group II consisted of 6 cases without group IIa and 3 cases with 3q27 aberrations group IIb; 3q27 abnormalities consisted of translocations (n=4), inversions (n=2) and deletions (n=1). Signet ring cell differentiation (n=2) was only seen in group I while large, expansile follicles (n=3) and plasma cell differentiation (n=1) was seen in group II. No significant differences in grade of FL or number of cytogenetic abnormalities were seen within and between groups I and II (mean 8.1 vs. 6.6). Groups Ib and IIb had a higher number of chromosomal abnormalities (means 10.8 and 10.3) compared to groups Ia and IIa (means 7.6 and 4.7) (p=0.04), but no significant differences were seen on comparing similar grades. FL3a was more common in group 2 (n=3) compared to group 1 (n=1) (p=0.05); FL3b (n=1) was only seen in group 1. Two of three FL3a in group II but none of the FL3a (or 3b) in group I had a 3q27 abnormality. All cases in group Ib were FL2 while group IIb comprised of FL2 (n=1) and FL3a (n=2). Conclusions: Morphologic variants unique to t(14;18) and non-t(14;18) groups were observed. Overlapping and non-significant differences in the number of cytogenetic abnormalities were seen across all 3 grades of FL in both groups. We did not observe any correlation between presence of 3q27 abnormalities and specific grades of FL, contrary to prior reports.

We used DNA-microarrays analyses to identify gene expression signatures (GES) that could predict the outcome of Follicular Lymphoma (FL) patients. Gene expression profiling was performed using DNA-microarrays on 21 FL samples. These FL samples were all collected at the time of initial diagnosis prior to any systemic therapy for all patients. These tumour samples were either grade 1 or grade 2 FL according to the 2001 WHO classification of tumours of lymphoid tissues.
We identified 2 distinct gene GES that allowed a clear segregation between relapsing and non relapsing FL patients ("relapse" GES), and alive and dead FL patients ("survival" GES), respectively. No FL patient was misclassified. Among the 13 genes included in the "relapse" GES, the T-cell marker CD2 was overexpressed in non relapsing FL patients. Further more, the pro-apoptotic factor BID was overexpressed, whereas cytochrome b-5 (CYB5) was underexpressed in relapsing patients. Among the 17 genes included in the "survival" GES, the transcription factor HOXA2 was underexpressed, whereas the interferon-inducible protein viperin (CIG5) was overexpressed in alive FL patients. No prognostic relevance of the T-cell marker CD3 was evidenced by immunohistochemistry (IHC) on tissue-microarrays.
Our results provide insights into FL biology and suggest that, in agreement with previous reports, T-cell immune response may have an effect on FL patients outcome. The lack of prognostic relevance of CD3 IHC expression may imply that the T-cell effect on FL outcome is probably more qualitative than quantitative. The prognostic GES we evidenced herein need further validation on prospective studies before clinical application may be considered.

ASSESSMENT OF PROGNOSTIC FACTORS IN PLASMA CELL MYELOMAS ON TISSUE MICROARRAYS USING IMMUNOHISTOCHEMISTRY AND FISH ANALYSIS

Jenni Bettina1,2, Reineke Tanja1, Korol Dimitri2, Kofler Andreas2, Moch Holger1, Probst-Hensch Nicole-M2,Tinguely Marianne1

Aim
Plasma cell myeloma (PM) exhibits a clinical and molecular heterogeneity. Traditional morphological and immunohistochemical prognostic factors in PM are of limited value. In PM, translocations involving the IgH are observed in up to 80% of patients. Some of those have a prognostic impact on the disease outcome and/or a predictive value for the success of particular treatments. In situations, where no fresh samples are available, inter-phase FISH analysis is a method to specifically search for distinct translocations on formalin fixed, paraffin embedded tissues.
We investigated PMs from bone-containing surgical biopsies on a tissue microarray (TMA) for prognostic factors, including IHC and FISH analysis. We looked for translocations with a favourable (t(11;14)) and unfavourable (t(4;14)) behaviour. The correlation of the IHC with FISH and the molecular data with the survival of the patients were analysed.
Materials and Methods
49 formalin fixed, paraffin embedded specimens (44 osseous, 5 extra-osseous) from 41 patients with PM were arranged on a TMA. From each biopsy, two tissue scores were punched out. The investigations included morphology, IHC (CD20, CD79a, CD38, CD138, CD56, CyclinD1 and MIB1) and inter-phase FISH analysis specific for the t(4;14) and t(11;14).
Results
Biopsies were regarded as eligible, if at least one of the scores contained 30% of tumour cells.
All of the 49 samples fulfilled these criteria for morphology and IHC. Overall, in 26/41 (61%) patients and in 21/36 (58%) of the osseous biopsies, the FISH analysis was interpretable. 4/26 (15%) of PM showed a t(11;14) and 2/26 a t(4;14) (8%). Cyclin D1 was positive in 8/41 PMs and was concordant with FISH and either associated with a t(11;14) or an amplification of the bcl1 gene. A tendency of higher Mib1 expression in CyclinD1 positive PMs, was not significant (p=0.06). The mean survival time from diagnosis was 65 and 34 mo in patients with t(11;14) and t(4;14) respectively.
Conclusions
TMAs are applicable on bone-containing tissues. The percentage of t(11;14) and the mean survival time for both translocations is in agreement with the one reported in the literature, suggesting, that TMAs are suitable for testing new prognostic markers including molecular analysis in PM. The results need to be validated and statistically underlined by extending the series. Prospectively, optimized decalcification procedures should lead to a higher yield of interpretable FISH.

RELATION BETWEEN PHENOTYPE AND CHROMATIN TEXTURE IN ACUTE LEUKEMIAS

Metze K, Silva RC, Adam RL, Pereira FF, Leite NJ, Lorand-Metze I
Department of Pathology Department of Internal Medicine, Faculty of Medicine, Institute of Computing, State University of Campinas, Brazil

Chromatin structure is a fundamental hallmark for morphological diagnosis in routine cytology. Changes of chromatin arrangement as well as the expression of cytoplasmic or membrane proteins reflect the degree of cellular differentiation. The aim of our study was to correlate chromatin texture features with the expression of membrane and cytoplasmatic proteins in blasts of patients with acute leukemia. We examined the diagnostic bone marrow aspirates from 32 patients with acute lymphatic leukaemia (ALL) and 31 patients with acute myeloid leukemia (AML). Diagnosis was based on cytologic features, phenotype (determined by flow cytometry) and cytogenetic analysis. Texture analysis was done on gray-scale transformed digitalized images of 100 cells of routinely stained May-Grünewald-Giemsa smears. We measured granulometric features (using the gray level height of the basins as filter parameter) as well as Shannon´s entropy and the fractal dimension in images after application of thick and thin contour detection. Antigen expression was quantified by mean flourescence intensity (analysis: Paint-a-gate software; 10 000 cells / case).
In ALL, there was a negative correlation between the expression of immunoglobulins (light chains) and the number of granulometric residues at lower gray levels (r = - 0.54; p =

0.005). Furthermore, we found a positive correlation between the CD20 expression and the fractal dimension after morphologic gradient filtering (r = 0.39; p = 0.036).
In AML patients, the number of granulometric residues at lower gray levels had a negative correlation with CD7 (= - 0.50; p = 0.004) and myeloperoxidase expression (r= - 0,42; p=0,036). A positive correlation was found between CD45 and the number of granulometric residues at higher gray levels (r = 0,45; p = 0,038).
We conclude that, in acute leukemias, changes of chromatin structure may express differences in maturation measured by quantitative expression of antigens routinely used in diagnosis.

Introduction. Primary mediastinal large B-cell lymphoma (PMLBCL) is a well-defined lymphoma entity whose molecular pathogenesis is incompletely understood, and also lacking well-established diagnostic markers. Recently, the presence of overlapping features between Classical Hodgkin's Lymphoma (CHL) and PMLBCL was highlighted by gene expression profiling as well as morphological studies. Purpose of the study. We investigated the expression of TP73L (commonly known as p63) isoforms in PMLBCL at both protein and mRNA level by immunohistochemistry and Real-Time PCR. Results. We demonstrated the exclusive presence of transactivating (TA) isoforms in all cases, and that TP73L is expressed in a subset of germinal center B-cells (GCBC), as well as in some Diffuse Large B-cell Lymphomas (DLBCL), but it is never present in CHL. Nodular Lymphocyte Predominance Hodgkin's Lymphoma (NLPHL) also showed TP73L positivity by immunohistochemistry. Isoform analysis by Real-Time PCR showed that TA-TP73L alpha is the most represented in PMLBCL, but TA-TP73L gamma is the most differentially expressed in comparison to both GCBC and DLBCL. Conclusions. TP73L expression proved a useful diagnostic marker of PMLBCL, and gave new insights in the molecular pathways playing a role in this lymphoma.

CORRELATION BETWEEN MOLECULAR AND HISTOPATHOLOGICAL DIAGNOSES OF BONE MARROW SPECIMENS IN B-CELL NEOPLASMS

KAYASUT Kanita, LE TOURNEAU Agnès, AUDOUIN Josée, DIEBOLD Jacques, DEVEZ Francis, DUCRUIT Véronique, BOUCHET Pierre-Etienne, MOLINA Thierry Jo.
Department of Pathology, Hôtel-Dieu, AP-HP, Université Paris 5, Paris, France

Introduction. Histopathological study of bone marrow (BM) biopsy is routinely performed for evaluation of lymphoma involvement during diagnosis, staging and follow-up. Polymerase chain reaction (PCR) for antigen receptor gene and oncogene rearrangement has been shown to detect a clonal population below the morphological threshold.
Purpose of the study. To correlate the morphological and immunohistochemical evaluation of B-cell lymphoid neoplasms in BM biopsies with immunoglobulin heavy chain (IgH) gene and Bcl-2 rearrangement by PCR in concurrently obtained aspirates.
Methods. We retrospectively evaluated 99 BM specimens from 78 patients with B-cell neoplasms (81 small B-cell and 18 large B-cell lymphomas) which were selected according to the presence of a clonal marker of the disease (IgH or Bcl-2). PCR analysis was performed, using Bcl-2 MBR and the consensus IgH primers (FR1, FR2, FR3).
Results. Considering IgH-PCR alone, a monoclonal B-cell population was detected in 87% (55/63) and 30% (11/36) in the histopathologically (H) positive and negative groups, respectively. The concordant rate was 80% (55 H+, PCR+ and 25 H-, PCR-). The discordant group (H+, PCR-) contained 8 cases, including 6 follicular lymphoma (FL) and 2 mantle-cell lymphoma (MCL). Four FL showed at least 20% BM involvement while all two MCL showed minimal (= 10%) and focal involvement. All these 6 FL although IgH PCR-, were Bcl2 MBR+. We identified a clonality in H- group, including 4 diffuse large B-cell lymphomas (DLBCL), 1 FL and 6 other small B-cell lymphomas. When considering Bcl-2 MBR, we additionally detected a clonality of 5 DLBCL (3 associated with FL) and 8 FL.
Conclusion. The sensitivity (87%) for the IgH-PCR assay in BM aspirates in our study is higher than the published studies due to our selection criteria. However, IgH-PCR alone missed few cases of strongly histopathological positive in FL, probably due to ongoing somatic mutation whereas they had a Bcl-2 MBR marker. When lymphoma involvement was focal and minimal, IgH-PCR might be negative probably due to sampling problem. Complementary use of Bcl-2 MBR can increase detection rate of monoclonality in both H+ and H- groups of FL. Therefore, we suggest that especially in FL, IgH-PCR alone is not good enough for BM assessment. On the other hand when Bcl-2 MBR is a marker of disease, this molecular test on BM aspirates may replace BM biopsy for evaluation of disease.

NPM-ALK REGULATED ACTIVATION OF THE AP-1 TRANSCRIPTION FACTOR IN ANAPLASTIC LARGE CELL LYMPHOMAS (ALCL)

VESELY Paul(1), STABER Philipp B.(2), MOSER Gerit(1), SCHAUER Silvia(1), DIRKS Wilhelm(3), KADIN Marshall E.(4), STERNBERG David W.(5), HOEFLER Gerald(1).

5 Division of Hematology/Oncology, Mount Sinai School of Medicine, New York, New York

Introduction: Translocation (2;5)(p23;35) causing a nucleophosmin-anaplastic lymphoma kinase (NPM-ALK) fusion gene leading to high expression of the ALK tyrosine kinase is the defining feature of the majority of anaplastic large cell lymphomas (ALCL).
Purpose of the study: To identify molecular events regulated by NPMALK, we studied consequences of the kinase activation on gene expression and on the proteomic level.
Methods: SSH libraries were created using mRNA from pools of NPM-ALK positive and negative ALCL cell lines as well as human embryonic kidney (293) cells transfected with active and kinase-dead NPM-ALK constructs. mRNA expression patterns were analyzed in individual cell lines using cDNA arrays utilizing cDNA clones resulting from the SSH libraries as well as genes relevant for cancer development. Quantitative RT-PCR of 20 selected genes

validated the mRNA expression data. The activation status of key proteins was determined using EMSA and Western-blot analysis.
Results: In 293 cells, the active NPM-ALK construct confers significant changes in the expression of 38 genes. Expression of 102 genes distinguishes NPM-ALK-negative (FE-PD, MAC-2A) from NPM-ALK-positive ALCL cell lines (SU-DHL-1, JB-6, SUP-M2, SR-786, DEL and Karpas 299). The majority of these genes are involved in regulation of cell cycle and apoptosis. A specific subset of genes regulated by NPM-ALK indicates increased activation of AP-1 transcription factors. We verified NPM-ALK dependent AP-1 DNA binding activity by electrophoretic mobility shift assays using lysates from 293 cells transfected with active or kinase-dead NPM-ALK constructs, Ba/F3 murine hematopoietic cells expressing stably or doxocyclin induceable NPM-ALK, as well as NPM-ALK positive and negative ALCL cell lines. Super Shift experiments revealed JunB to be the major AP-1 transcription factor involved.
Conclusion: In this study we present a set of genes regulated by NPM-ALK and demonstrate that this fusion gene enhances AP-1 activation by selectively up-regulating JunB. Our data might indicate a new mechanism for regulation of AP-1 activity.

Institute, Sýhhiye, Ankara, Turkey
4 Current Address: Mesa Hospital, Ankara, Turkey

Background: PTEN is a tumor suppressor gene located on chromosome 10q23 and is amongst the most commonly mutated genes in human cancers. The lipid phosphatase activity of Pten enables it to dephosphorylate PIP3, hereby antagonizing growth factor stimulated PI3-kinase signaling mediated by AKT/PKB. The growth inhibition effect of PTEN has been shown to be mediated by p27 which is one of the important effector molecules downstream of the AKT pathway. Recently the importance of Pten and PKB/AKT pathway in the regulation of the immune system and development of hematological malignancies have been shown.
Materials and methods: Loss of Pten and p27 expressions were examined immunohistochemically in 45 patients with peripheral T and NK cell lymphoma.
Results: Partial or complete loss of Pten was detected in 66.7% of the cases of anaplastic large cell lymphoma (ALCL) compared to only 12.5% of all other mature T/NK cell lymphomas combined. Loss of p27 was identified in 64.9% of cases, which showed a positive correlation with Pten loss.
Conclusion: In this study, we showed that loss of Pten is more frequent in ALCL as compared to other mature T/NK cell lymphomas, which strongly correlates with the loss of p27 expression. Our findings provide further evidence for the importance of the deregulation of the PI3K-AKT pathway in ALCL.

PRIMARY NASAL NK/T CELL LYMPHOMA: CYTOLOGY AND LEVEL OF THE ANTIAPOPTOTIC PI9 PROTEIN HAVE PROGNOSTIC RELEVANCE.

Céline Bossard 1*, Karim Belhadj 2*, Felix Reyes 2, Nadine Martin-Garcia 1*, Alain Kümmer 3*, Françoise Berger 4*, Josette Brière 5*, Anne-Catherine Baglin 6*, Odile Casiraghi 7*, Eric Lepage 8* and Philippe Gaulard, for the GELA 1*. 1 Département de Pathologie et Inserm U617, Hôpital Henri Mondor, Créteil, France; 2 Service d'Hématologie Clinique, Hôpital Henri Mondor, Créteil, France; 3 Department of Pathology, Free University Hospital, Amsterdam, Netherlands; 4 Service d'Anatomie et de Cytologie Pathologiques, Centre Hospitalier Lyon Sud, Pierre Benite, France; 5 Département de Pathologie, Hôpital Saint Louis, Paris, France; 6 Département de Pathologie, Hôpital Foch, Suresnes, France; 7 Département de Pathologie, Institut Gustave Roussy, Villejuif, France and 8 Département d'Information Médicale, Hôpital Henri Mondor, Créteil, France.

Nasal NK/T cell lymphoma is a rare disease entity characterized by a nasopharyngeal presentation, a common origin from NK cells, an association with EBV and a predilection for Asians and South Americans contrasting with its rarity in Western countries. Several studies (Chim CS, 2004; Li CC, 2004) indicate that the disease has a poor outcome following conventional combined chemoradiotherapy treatments, which might be related to resistance to therapy-induced apoptosis. It has been shown (Hermine O, 1996; Ten Berge R, 2002) that high level of expression of antiapoptotic proteins by lymphoma cells is associated with poor outcome in a variety of lymphomas.
In a retrospective analysis of 37 patients treated with first-line chemotherapy (n=34) or chemoradiotherapy (n=3) according to the LNH87, LNH93 and LNH98 trials of the GELA, we have analyzed by immunohistochemistry the expression of the granzyme B-protease inhibitor 9 (PI9) regarded as an inhibitor of apoptosis, and of the active form of caspase-3 (aC-3), an effector of apoptosis. The diagnosis was based on biopsies of the upper respiratory tract showing a proliferation of neoplastic cells with a CD3+/CD5- (100%), CD56+ (90%), TIA1/GrB+ (100%) phenotype and EBV association (100%). Among the 37 patients, 73% were < 60y, 68% were male. 76% had stage I, 5% Stage II, 19% stage IV and 68% had an IPI score of 0-1. With a median follow-up of 6.3 y, 5y-event-free and overall survivals were 38% and 47%. According to cytology, tumors were subclassified into predominantly small cell (52%) and large cell (48%) categories. PI9 was scored as positive (>10% of tumor cells) in 68% of the cases, whereas 35% were assigned a high number (>10 per field at high magnification) of aC-3 positive tumor cells. Univariate analysis showed that small cell cytology and absence of PI9 expression were associated with poor outcome. By multivariate analysis, cytology and PI9 downregulation were shown to independently affect event-free (P=0.01 and 0.05) and overall survival (P=0.009 and 0.006).
We conclude that nasal NK/T cell lymphomas disclose cytological heterogeneity which has prognostic relevance. We also found that downregulation of PI9 is associated with poor outcome, an unexpected finding in view of the known antiapoptotic function of this protein. Since PI9 is constitutively expressed by normal NK cells, it might be postulated that its impaired expression in tumor cells reflects a yet unknown mechanism associated with progression

Bordeaux 2, France
2: Department of Hematology, Hopital of Haut-Lévêque, 33604 Pessac, France

To further characterize blastoid variant (BV) of mantle cell lymphoma (MCL), 18 MCL cases were analyzed for their clinicopathological features, proliferation MIB-1 index, CDK4 and cyclin D1 expression and CCND1 genetic profile. Thereafter, 14 cases were recognized as common MCL and 4 cases as BV-MCL including one secondary BV-MCL.
Despite common clinical features at presentation. BV-MCL vs common MCL was characterized by a shorter overall duration of response after first line therapy (11 months vs 28 months) and shorter overall survival (20 months vs 42 months). Interphase FISH showed a characteristic t(11;14) fusion pattern in the 14 tested cases. Furthermore, the 4 blastoid cases were characterized by extracopies of CCND1 signals. Using additionnal probes of chromosomes 11, 18, 21, these signals were shown to be the result of hypotetraploidy and not of a specific amplification of the normal or the translocated CCND1 allele. There was no significant difference in the overexpression level of cyclin D1 isoforms transcripts between BV and common MCL cases as determined by real-time RT-PCR. However the BV-MCL cases were characterized by a combined percentage of cyclinD1 and/or CDK4 immuno-positive cells with a proliferation MIB1 (Ki67) index above 50%. Such features allowed the recognition of areas of large cell transformation in the secondary BV-MCL case. Since distinction between BV and common MCL is of clinical relevance, our data underline the need to add phenotypic and cytogenetic criteria for a better recognition of BV-MCL

Primary central nervous system lymphomas (PCNSL) of immunocompetent patients are usually diffuse large B-cell lymphomas (DLBCL), which are characterized by a poorer prognosis as compared to systemic cases. Systemic DLBCL is a heterogeneous entity, with at least two identified subgroups: germinal centre (GCB) and activated B-cell like (ABC). GCB subgroup is characterized by a better prognosis than ABC. In the literature, a GCB origin of PCNSL has been hypothesized based on BCL-6 expression and presence of ongoing mutational activity. The goal of the present study was to determine by immunohistochemistry the proportion of GCB and ABC cases in a large series of 83 PCNSL and to determine its prognostic significance. CD10, BCL-6 and MUM1 were expressed by tumour cells in 2.4%, 56% and 92.6% of the cases, respectively. None of the tested cases expressed CD138. All but three cases were classified in the ABC subgroup. Half of these ABC cases displayed BCL-6+/MUM1+ co-expression, favouring an 'activated GCB' origin whereas the others showed an 'activated non GCB' pattern, as demonstrated by MUM1 expression alone. These findings lead to new insights in interpreting the poor prognostic of PCNSL, which may be due in part to biological aggressiveness related with the activated B-cell like pattern of tumour cells.

THE RELATIVE LEVELS OF CYCLIN D1 [A] [B] ALTERNATE TRANSCRIPTS IN MANTLE CELL LYMPHOMA MAY DEPEND MORE ON THE SAMPLE ORIGIN THAN ON CCND1 GENE POLYMORPHISM.

Nathalie Carrère, Marc-Antoine Belaud-Rotureau, Pierre Dubus, Marie Parrens, Jean-Christophe Garoste, Antoine de Mascarel, Jean-Philippe Merlio
Pathology Laboratory, Hôpital Haut-Lévêque, Pessac, France and Histology and Molecular Pathology Laboratory, Victor Segalen University, Bordeaux, France

Background and Objective: The t(11;14)(q13;q32) leads to cyclin D1 overexpression in mantle cell lymphoma (MCL). Two [a] and [b] transcripts of CCND1/cyclinD1gene may be alternatively expressed. Real-time RT-PCR was used to determine the relative amount of [a] and [b] transcripts in a series of typical MCL. We also investigated whether genetic polymorphism at position 870 may influence the overexpression of each isoform.
Design and methods: 39 MCL samples and 2 CLL samples were analyzed by real-time RT-PCR. The relative amount of each isoform was normalized and expressed as a cyclin D1 to GAPDH ratio. Overexpression of cyclin D1 was also determined by ratio calculation over the basal expression rate in the same tissue category.
Results: Both a and b isoforms were detected in tumoral and control tissues. At least a five-fold overexpression was observed for both isoforms in 28/39 MCL cases and for only one isoform in 10/39 MCL (7 a and 3 b). No correlation was observed between genotype and overexpression of either a or b CCND1 isoforms. Their relative level varied according to the tissular origin and may also depend on the relative amount of tumoral cells.
Interpretation and Conclusions. Cyclin D1 overexpression was found above a five-fold threshold in all MCL samples except in one case with RNA degradation. The interest of monitoring of each cyclin D1 isoforms should be evaluated in homogeneous samples such as peripheral blood because the basal expression of both isoforms is very low at this level in healthy donors.

LOCALIZED NEUROBLASTOMA: PROGNOSTIC SIGNIFICANCE OF CD44 AND TRKA EXPRESSION.

K. Ernestus 1,2, B. Hero 2, R. Spitz 2, F. Berthold 2
1 Department of Pathology, University of Cologne
2 Childrens Hospital, Department of Pediatric Oncology and Hematology, University of Cologne

Introduction: Neuroblastoma is the most common solid pediatric tumor except from brain tumors. Clinical behaviour is variable, ranging from spontaneous regression to progression and death. MYCN amplification, stage, age, and deletion 1p, are known and utilized as prognostic factors.
Purpose: This retrospective study was performed to analyse the prognostic significance of trkA and CD44 expression in a large series of unselected neuroblastoma focussed on localized neuroblastoma.
Methods: Frozen tumor sections from 248 neuroblastic tumors without treatment prior to biopsy were investigated by semiquantitative immunohistochemistry for CD44 and trkA expression. MYCN amplification and deletion 1p were analysed by FISH.
Results: In localized neuroblastoma 92% of the tumors expressed CD44, while trkA was expressed in 82%, respectively. In these cases expression of trkA or CD44 correlated with a significant better outcome (CD44: 3-year event free survival (EFS) positive 87±3% versus negative 36±16%, $p<0.0001$). The subgroup of localized neuroblastoma without MYCN amplification demonstrated inferior EFS for trkA negative tumors, while CD44 expression did not discriminate. In a multivariate analysis, including the variables MYCN amplification, trkA and CD44 expression both MYCN amplification and trkA expression were determined as independent prognostic factors.
Conclusions: In localized neuroblastic tumors absence of trkA expression is a strong independent prognostic factor. In particular, in the subgroup of MYCN non amplified tumors absence of trkA expression defines patients with unfavourable outcome.

The integrity of pulmonary surfactant is of paramount importance for lung function. Previously, ABCA3 mutations were described in newborns with fatal surfactant deficiency. By means of immunohistochemistry, transmission, and immuno electron microscopy (EM), as well as Western blotting, we studied the pulmonary surfactant system in consanguineous and non-consanguineous full-term babies with unexplained respiratory distress syndrome (URDS). In eight patients with a variable combination of histological patterns of non-specific interstitial pneumonia, desquamative interstitial pneumonia, and pulmonary alveolar proteinosis, we found an abnormal staining pattern or lack of ABCA3 by means of immunohistochemistry. At the ultrastructural level, we found membrane bound electron dense bodies instead of lamellar bodies in type II pneumocytes. Sequencing of the ABCA3 gene revealed homozygote splice site, frameshift, and missense mutations in consanguineous as well as compound heterozygote frameshift and missense mutations in non-consanguineous patients. Since all but one patient showed clinical symptoms of severe neonatal surfactant deficiency and died shortly after birth due to respiratory insufficiency, immunohistochemical, immuno-EM, and Western blot analyses of lung tissue and BAL fluids for SP-B were performed. In line with low levels of mature SP-B in the alveolar surfactant, type II pneumocytes showed only a weak dot-like staining pattern. By means of immuno-EM, SP-B was localized over the dense core and the lysosomal aspartic protease cathepsin D over the matrix of electron dense bodies. Since lung function improved in one patient after high dose steroid treatment, successful heart-lung transplantation could be performed at the age of 18 months. Surprisingly, in the explanted lung we found not only electron dense bodies but also a few typical lamellar bodies in type II pneumocytes. In conclusion, our data indicate that ABCA3 mutations are associated not only with an abnormal distribution or lack of ABCA3 but also the formation of aggregates of mature SP-B in lysosomal organelles in type II pneumocytes leading to severe alterations of the pulmonary surfactant system. High dose steroid treatment might be helpful to improve respiratory function in a subset of patients. Our findings highlight the importance of immunohistochemistry and electron microscopy in the examination of lung tissue from babies with URDS.

Leigh syndrome (LS) is one of the most frequent presentations of respiratory chain dysfunction in children. The discovery of SURF1 gene and its mutations leading to autosomal recessive cytochrome oxidase deficient Leigh syndrome was the breakthrough in mitochondrial medicine.
Retrospective pathological studies were performed in 22 children from 21 families with LS clinical phenotype and SURF1 gene mutations. In all patients in whom the biopsy was performed spectrophotometric study confirmed the presence of complex IV deficit. Nineteen skeletal muscle samples and 4 autopsies were reassessed.

Skeletal muscle consistently showed diffuse total or pronounced histochemical cytochrome oxidase deficiency, variable degree of lipid increase, and mild to moderate variability in muscle fibre size. Electron microscopy revealed focal intermyofibrillar or subsarcolemmal accumulations of structurally normal mitochondria with accompanying increase of small lipid droplets. Neither ragged red fibers nor other ultrastructural alterations of mitochondria were seen. Three patients showed mixed or microvesicular liver steatosis of severity ranging from mild to severe. One girl showed lipid accumulation in cells lining proximal convoluted tubules. Central nervous system revealed typical LS lesions, some of them detectable only microscopically. In two children the lesions were obscured by post mortem changes.
Conclusions: In children with SURF1 dependent COX deficient LS - skeletal muscle shows reproducible abnormalities with COX deficit as a salient feature; omitting of COX histochemical assessment may lead to misinterpretation of biopsy; post mortem detection of CNS lesions requires careful microscopical assessment; variable degree of liver steatosis may be present.

EFFECT OF ETHANOL AND ALLOXAN INDUCED DIABETES IN THE OUTCOME OF THE PREGNANCY IN THE MOUSE.

Camila Nunes Ribeiro, postgraduate student, Department of Pathology, Faculty of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil.
Luiz Cesar Peres, MD, Department of Pathology, Faculty of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil.

Congenital anomalies in fetuses born to diabetic mothers are 2 to 3 times more frequent than normal ones. Ethanol is the most widely exogenous teratogen used by women in childbearing age, being implicated in NTD, congenital heart disease and limb abnormalities as diabetes. The aim of this study was to investigate the effects of diabetes, ethanol and the association of both on the outcome of pregnancy. Swiss mice were randomly allocated into 4 groups with 6 animals each: Control (C), Diabetes (D), Ethanol (E), and Diabetes and Ethanol (DE). Animals of groups D and DE received an i.v. dose Alloxan (40mg/Kg) prior to mating. Animals of groups E and DE received an i.p. injection of ethanol 4g/Kg of a saline solution 25% (v/v) on the 7th gestational day, while animals of groups C and D received saline. Killing was in a CO2 chamber on the 18th gestational day and the number of implantations, resorptions, late fetal death, and live fetuses with and without NTD, and placental weight and diameter were recorded. Blood glucose level was normal on the 18th gestational day in groups C and E and elevated in groups D and DE, being highest in D. There was no difference for implantation for all groups and for all parameters between groups C and E. Resorption was highest in group D and late fetal death in group E. Group D fetuses and placentas were smaller and lighter than those of group C. Group DE placentas and female fetuses, but not male, were smaller and lighter than group C and E ones. Fetal length, but not weight, was different between groups D and DE. Tail length was smaller in group D. High single dose of ethanol given to pregnant swiss mice on the 7th gestational day did not induce IUGR and placental growth and as did diabetes, associated or not to ethanol. When given to diabetic mice, ethanol improves male fetal weight and length indicating that female fetuses are more prone to the detrimental effects of diabetes. Ethanol reduces resorptions but increases late fetal death and also enhances the effects of diabetes inducing NTD. Diabetes has a negative effect on the placenta that is not affected by ethanol. These results may indicate that ethanol may have a favorable action in early gestation probably by contributing to energy metabolism but it is known to increase cell damage that will eventually result in NTD, late fetal death and reduction of the placental mass.

The prevalence of chronic liver disease in children is low , but the etiologies are multiple and a severe fibrosis at presentation is frequent. Although very invasive, liver biopsy remains the gold standard to evaluate and to follow up fibrosis in this population. Unfortunately, there is no consensus about the best histological system of staging of fibrosis in this heterogeneous group of patients. Recently, novel non-invasive methods to assess liver fibrosis have been validated in adult patients, such as Fibrotest®, based on biochemical seric markers, and transient elastography (FibroScan®), a rapid (< 5 mn) bedside ultrasound based method measuring liver stiffness. Preliminary results suggest that this last method would be very accurate in children.
The aims of this prospective study was to evaluate two histological scores for liver fibrosis in children with chronic liver disease as compared with 2 non invasive tests : FibroScan® and Fibrotest®.
33 consecutive children (20 boys, mean age 11 years (4 months – 20 years)) with chronic liver disease underwent liver biopsy, fibrotest and Fibroscan and were included. The most frequent pathologies were Wilson's disease, biliary atresia, polycystic fibrosis, and autoimmune hepatitis. Fibrosis was evaluated using METAVIR score, from F0 to F4, basing on portal fibrosis, and a more complex semi-quantitative score adapted from Chevallier and coll. (SQS), which takes into account fibrosis in portal tracts, central veins, sinusoids and also consider the number, thickness and lenght of septa. Correlation of histological values with non invasive datas were analyzed using the Spearman coefficient of correlation.
According to METAVIR, fibrosis was F1 in 4 cases, F2 in 6 cases, F3 in 7 cases, and F4 in 16 cases. SSQ ranged from 1 to 23, with 15 cases > 15. FibroScan® and Fibrotest® values ranged from 2.9 to 75 kPa, and 0.004 to 0.97, respectively. Correlation coefficients and associated probability (p), determined on the 19 first cases were : METAVIR score : 0.676 ($p = 0.001$) with Fibroscan and 0.478 (NS)with Fibrotest; SQS : 0.712 ($p < 0.0001$) with Fibroscan and 0.544 ($p = 0.004$) with fibrotest.
Conclusions: In this pediatric series, severe hepatic fibrosis was very frequent and Chevallier's semi-quantitative score correlated better than METAVIR score with FibroScan® and Fibrotest non invasive tests. FibroScan® could avoid liver biopsy in many cases and its usefulness in the follow-up of children should be evaluate

ACTIVATION OF THE WNT/ß-CATENIN PATHWAY IN HEPATOBLASTOMA

Carolina ARMENGOL (1), Stefano CAIRO (1), Monique FABRE (2), Claire-Angélique RENARD (1), Laurence BRUGIÈRES (3), Véronique LAITHIER (4), and Marie Annick BUENDIA (1)
(1) Unité d'Oncogenèse et Virologie Moléculaire, Inserm U579, Institut Pasteur, Paris; (2) Anatomie et Cytologie Pathologiques, CHU de Bicêtre, Le Kremlin-Bicêtre; (3) Département de Pédiatrie, Institut Gustave Roussy, Villejuif; (4) Service de Pédiatrie, CHU de Besançon, Besançon, France.

Hepatoblastoma (HB) is the predominant type of malignant liver tumors in childhood. The etiology of HB is unknown, but an association with congenital abnormalities is well established. HBs are characterized by the proliferation of immature hepatocytes, showing 4 patterns: fetal, embryonal, macrotrabecular, and small anaplastic (undifferentiated) type. Mixed epithelial-mesenchymal tumors also contain myofibroblastic, chondroid and osteoid tissues, and occasional teratoid features, suggesting that they derived from uncommitted stem cells. Genetic analysis has uncovered a high frequency of mutations in the ß-catenin or Axin genes, leading to constitutive activation of the Wnt pathway in a majority of HB cases.
In this study, we aimed to identify downstream genes of Wnt/ß-catenin signaling implicated in the molecular pathogenesis of HB. To this end, we have collected frozen and fixed HB samples from French hospitals. Most patients were enrolled in the international clinical trials of the SIOPEL group. Extensive pathological and clinical annotations were obtained. The ß-catenin mutational status was determined by RT-PCR over exons 3 and 4, and ß-catenin localization was examined by immunohistochemistry. Finally, gene expression profiles were analyzed in 35 tumors and 4 liver samples by using Affymetrix arrays.
Hierarchical cluster analysis clearly separated tumors from normal liver and identified two tumor groups: (i) cluster A: localized tumors with fetal histology, and (ii) cluster B: invasive tumors with less differentiated patterns and bad prognosis.
Supervised analysis according to ß-catenin status (mutated or wild type) revealed significant differences between deregulated genes within each cluster. Overexpression of known ß-catenin target genes related to fatty acid or amino acid metabolism, such as glutamine synthetase (GS), was predominant in cluster A, but not in less differentiated tumors. Conversely, ß-catenin targets related to proliferation and cell cycle, such as c-myc, were strongly activated in cluster B and downregulated in cluster A. Microarray data are currently validated by immunohistochemistry.
In conclusion, the molecular signature of Wnt/ß-catenin signaling in hepatoblastoma seems to be mainly imposed by liver environment, but differs according to developmental stage. This work was supported by grants from the Ligue Nationale contre le Cancer (programme Carte d'Identité des Tumeurs) and from the GIS Institut des Maladies Rares.

AN IMMUNOHISTOCHEMICAL (IH) AND ELECTRON-MICROSCOPIC (EM) STUDY OF IMMATURE GLOMERULI IN CHILDREN WITH NEPHROTIC SYNDROME (NS) GLOMERULOPATHIES (WITH REFERENCE TO CLINICAL FINDINGS).

Aldona Wozniak1, Wieslawa Salwa-Zurawska1, Jakub Zurawski1, Danuta Ostalska-Nowicka2
Departments of Clinical Pathomorphology1 and Pediatric Nephrology2, Karol Marcinkowski University of Medical Sciences, Poznan, Poland

INTRODUCTION
We were not able to find any reports in the available literature on the presence of immature glomeruli in other childhood glomerulopathies than Alport's syndrome, thin membranes syndrome or Finnish type congenital NS. LM evaluation of immature glomeruli is difficult, because hypercellularity masks pathological changes. The aims were: 1/ to determine the relationship between the presence of immature glomeruli and the clinical findings initially and in response to treatment in children with NS glomerulopathies 2/ to carry out an EM and IH study of immature glomeruli.
MATERIAL AND METHODS
The study group consisted of 53 children with minimal change disease (MCD), mesangioproliferative gn (MES GN) and focal segmental glomerulosclerosis (FSGS) (44, 7 and 2 cases, respectively. Control group (no signs of immaturity) consisted of 92 children (43 with MES GN, 49 with MCD), also hospitalized due to the first episode of NS. The paraffin sections were incubated with monoclonal antibodies to vimentin (VIM), CD34, CD31, SMA, synaptopodin (SYN), VEGF and WT1.
RESULTS
EM study confirmed the diagnosis of MCD in 37 cases. MES GN was diagnosed in 14 cases (mesangial cell proliferation and electron dense deposits were evident). Clinical analysis has demonstrated that significantly lower number of children from study group responded to steroids ($p=0.0105$ for MES GN and $p=0.002$ for MCD). Patient age exceeding 1 year ($p=0.0163$ for MES GN and $p=0.017$ for MCD) and serum albumin concentration above 1 g/dl ($p=0.0163$ for MES GN and $p=0.017$ for MCD) have proven to represent favourable prognostic factors. The mesangial cells exhibited very weakly and focally SMA (as immature glomeruli in the late M stage), whereas podocytes strongly expressed VIM. The CD31 IH staining pattern of capillary endothelial cells was similar to normal adult and immature glomeruli. The loss of CD 34 immunostaining, typical for adult glomerular endothelial cells, was not evident. Podocytes of immature glomeruli expressed SYN in MCD less intensively. VEGF expression was not different in immature glomeruli.
CONCLUSIONS
The results obtained indicate the usefulness of EM verification to reveal lesions undetectable by LM. The analysis exhibits significantly more frequent steroid resistance in children with immature glomeruli. The IH staining pattern of glomerular cells did not differ from the results obtained in normal – i.e. healthy immature glomeruli.

CLAUDINS IN ESOPHAGEAL NEOPLASMS AND BARRETT'S ESOPHAGUS

GYORFFY Hajnalka1, HOLCZBAUER Agnes1, KISS Andras1, NAGY Pal2, KUPCSULIK Peter3, PASKA Csilla1, SZABO Zsuzsa4, SCHAFF Zsuzsa1
12nd Department of Pathology, 3 1st Department of Surgery, Semmelweis University,
2Department of Pathology, National Medical Center, 4 St. Laszlo Hospital, Budapest, Hungary

Introduction
Claudins (CLDN), the main transmembrane proteins of tight junctions (TJ), are key molecules participating in cell adhesion, polarity and paracellular transport. Several studies suggested that changes in CLDN expression pattern might play role in carcinogenesis. The aim of the present study was to investigate the changes in the pattern of CLDN 1,2,3,4 and 7 expression in specialized intestinal metaplasia (SIM) of the Barrett's esophagus (BE) and adenocarcinoma (ACC) in comparison to foveolar glandular epithelium, esophageal

normal squamous epithelium and squamous carcinoma (SCC).
Materials and methods
Formalin fixed, paraffin embedded samples of 25 human BEs, 25 ACCs, 25 glandular epithelia from the lower esophageal tract, 25 esophageal normal squamous epithelia and 25 squamous carcinomas were studied by immunohistochemistry. Mouse monoclonal antibodies for CLDN 2 and 4, rabbit polyclonal antibodies for CLDN 1, 3, and 7 were analyzed and scored for areas of positive cells. Significant alterations were analyzed for mRNA expression by Real-Time RT-PCR, using relative quantification with GAPDH as internal control.
Results
CLDN1 and 7 were highly expressed in all groups without significant differences. CLDN3 and 4 were increased in BE and ACC compared to foveolar epithelium (p=0,0022, p=0,0064, p=0,0107). CLDN2 was higher in ACC than in BE and foveolar epithelium (p=0,0001, p=0,0022, resp).
Conclusion
CLDN 3 and 4 show increased expression in BE and ACC, which differentiates these lesions from foveolar glandular epithelium. In addition elevated CLDN 2 expression is characteristic to the carcinoma stage. CLDN expression pattern can be used for differentiation of benign, premalignant and malignant glandular epithelium. Similarities and differences of CLDN pattern in BE and ACC might indicate a sequence of molecular alterations in carcinogenesis, and support the view that BE is a precancerous stage of ACC.

Introduction:
Barrett's esophagus (BE) is a metaplastic process in which the squamous epithelium of the esophagus is replaced by a specialized columnar epithelium. The presence of goblet cells is regarded as pathognomonic of this condition. However in endoscopic biopsies with small foci of BE, the identification of unequivocal goblet cells can be difficult. Guanylyl cyclase C(GC-C) is a receptor selectively expressed in apical membranes of epithelial cells from the duodenum to the rectum, but not by normal esophageal or gastric mucosae in humans. Recent studies demonstrated that GC-C is a useful immunohistochemical marker to identify intestinal metaplasia (IM), dysplasia and adenocarcinomas in the gastrointestinal tract.
Purpose of the study:
To evaluate the expression of GC-C in BE and its utility as a sensitive and specific marker for detecting cells undergoing IM in esophagus.
Methods:
26 biopsies from the lower esophagus exhibiting IM with unequivocal goblet cells in hematoxylin-eosin stains; 6 samples of normal gastroesophageal junction(GEJ) and 6 samples of cardiac-type mucosa (CTM) without IM were evaluated. Formalin fixed paraffin-embedded biopsies were stained for GC-C employing purified IgG from rabbit serum immunized with a peptide derived from human GC-C. Epithelial cells exhibiting apical membrane staining were considered positive for GC-C expression. All specimens were obtained under an IRB-approved protocol.
Results:
GC-C was expressed in all 26 (100%) cases of BE. All goblet cells, either in the surface of the mucosa or in glands, exhibited distinct membrane staining at their apex. No cytoplasmic or nuclear staining was present. Of significance, GC-C reactivity also was present in columnar cells adjacent to goblet cells. In contrast, 6 normal GEJ and 6 CTM did not stain. Moreover, normal squamous epithelia were negative in all cases.
Conclusions:
GC-C is 100% sensitive for BE, since it was consistently expressed in all areas of IM containing "classic" goblet cells. Similarly, GC-C is 100% specific for BE, demonstrated by the absence of staining of normal GEJ, CTM, and normal squamous epithelia. Of importance, GC-C was expressed by columnar cells adjacent to goblet cells in regions of BE. These data underscore the utility of GC-C as a highly sensitive and specific immunohistochemical marker for BE, particularly in histopathologically equivocal biopsies lacking the presence of pathognomonic goblet cells required for the diagnosis

NUCLEAR BETA-CATENIN EXPRESSION PREDICTS RESPONSE AND SURVIVAL AFTER NEOADJUVANT RADIOCHEMOTHERAPY OF OESOPHAGEAL CARCINOMAS

BALDUS Stephan E., ROTHE Birgit, MÖNIG Stefan P., METZGER Ralf, BOLLSCHWEILER Elfriede, MÜLLER Rolf-Peter, THIELE Jürgen, HÖLSCHER Arnulf H., DIENES Hans P., SCHNEIDER Paul M.
Institute of Pathology, Department of Visceral and Vascular Surgery, Department of Radiation Oncology, University of Cologne, Kerpener Str. 62, D-50931 Cologne

Introduction: Patients with locally advanced oesophageal cancer have a poor prognosis. Therefore, neoadjuvant therapeutic approaches have been developed. However, such therapies are expensive and associated with increased complication rates. Consequently, predictive molecular markers indicating response or non-response to neoadjuvant treatment may be of special clinical interest.
Purpose: In the present study, we investigated the expression of beta-catenin in a larger series of patients with oesophageal carcinomas in order to evaluate possible correlations with the response to neoadjuvant radiochemotherapy as well as survival.
Material and methods: Our study included 62 patients with locally advanced oesophageal carcinomas (cT2-T4, cNx, cM0 according to the TNM classification) comprising adenocarcinomas as well as squamous cell carcinomas. After bioptic confirmation of the diagnosis, standardised neoadjuvant radiochemotherapy was performed. Biopsies from 49 patients and the resected specimens of all patients were available and could be included. The grade of regression was assessed histomorphologically. A presence of less than 10 % vital residual tumour cells (VRTC) after therapy was defined as major response, the presence of more than 10 % VRTC was considered as minor response. Beta-catenin was visualised immunohistochemically and its membranous as well as nuclear expression were evaluated semiquantitatively followed by a thorough statistical analysis of the data.
Results: In general, nuclear beta-catenin expression was significantly up-regulated in resected carcinoma specimens as compared with the biopsies. Whereas only 12 % of the biospies contained more than 20 % of tumour cells exhibiting nuclear beta-catenin, about 35 % of the resected specimens

showed the same pattern. Additionally, up-regulation of nuclear beta-catenin expression was associated with a significantly worse response to neoadjuvant radiochemotherapy. Furthermore, a strong nuclear beta-catenin expression in the resected specimens correlated with a reduced survival probability.
Conclusions: An up-regulated beta-catenin expression in oesophageal carcinomas is predictive for a worse response to neoadjuvant radiochemotherapy as well as an unfavourable prognosis of the patients. Therefore, the immunohistochemical beta-catenin determination in such patients may present clinically valuable information.

IMMUNOHISTOCHEMICAL DETECTION OF MYCOPHENOLIC ACID IN GASTROINTESTINAL BIOPSIES OF MYCOPHENOLATE MOFETIL TREATED RENAL TRANSPLANT PATIENTS WITH CHRONIC DIARRHOEA

DERAEDT Karen°, MAES Bart°°, SHIPKOVA Maria°°°, ECTORS Nadine°, GEBOES Karel°
°Department of Pathology, University Hospital Gasthuisberg, Leuven, Belgium
°°Department of Medicine, Division of Nephrology, University Hospital Gasthuisberg, Leuven, Belgium
°°°Department of Clinical Chemistry, Georg-August-Universität, Göttingen, Germany

Introduction. Mycophenolate mofetil (MMF) is used for prevention of rejection. Chronic diarrhoea is a common adverse effect. Studies have shown that diarrhoea in patients treated with MMF is frequently infectious. In a subset of patients Graft-versus-host-like or Crohn's disease-like changes are observed in biopsies. Since reduction of MMF was the effective therapy for the diarrhoea, metabolites of MMF may be a possible cause.
Aim. After oral intake, the inactive MMF is absorbed and completely conversed into the active metabolite mycophenolic acid (MPA). The aim of the study was to investigate the presence of MPA and its distribution in the gastro-intestinal mucosa.
Materials and methods. Biopsies from renal transplant patients receiving MMF and presenting with chronic diarrhoea were snap frozen at -80°C. Samples were available from 7 patients, 4 males, 3 females (age between 30 and 60 years, mean 49.1 years). In one patient the drug was stopped for one year. Samples consisted of gastric and duodenal biopsies in 6 patients and ileal and colonic biopsies in 3 patients. Cryostat sections were stained with haematoxylin and eosin, and with the monoclonal antibody against MPA (DADE international; immunoperoxidase) and analysed without prior knowledge of clinical data.
Results. Gastric biopsies revealed no alterations (n=2), mild reactive gastropathy (n=1), inactive mildly chronic gastritis (n=2), and mildly active, chronic Hp-positive gastritis (n=1). Duodenal biopsies showed no alterations (n=1), architectural alterations and epithelial damage (n=3) and epithelial damage only (n=2). In ileum and colon, mildly active (ileo)colitis (n=2) or minor architectural alterations (n=1) were observed. In 3/6 gastric biopsies, cytoplasmic staining for MPA was observed in parietal cells. In 4/6 duodenal biopsies, focal positivity for MPA was noticed in cytoplasm and brush border of enterocytes. One negative biopsy was from the patient in which the drug was stopped. All samples of ileum and colon were negative for MPA.
Conclusion. Gastric lesions were not mainly Hp-related. Small intestinal and colonic lesions showed IBD-like features. Immunohistochemistry with the monoclonal antibody against MPA revealed focal positivity in the brush border of duodenal enterocytes in patients treated with MMF and suffering from chronic diarrhoea. MPA can thus be detected in the tissue. This technique may help to identify those patients in which diarrhoea and lesions are drug-induced.

SMALL INTESTINAL FOLLICLE ASSOCIATED EPITHELIUM AND VILLUS EPITHELIUM COMPARED BY GENE EXPRESSION PROFILE

P. Verbrugghe, P. Demetter, J. Vandesompele(1), W. Waelput, C. Cuvelier, Academic Department of Pathology, Ghent University, Belgium; (1)Center for Medical Genetics, University Hospital, Ghent, Belgium

INTRODUCTION: The follicle associated epithelium (FAE) overlying the lymphoid follicles of Peyer's patches mediates transcytosis of antigens to the underlying lymphoid tissue, mainly by the presence of M-cells. By its antigen handling function it plays an important role in the pathogenesis of inflammatory bowel diseases (IBD), especially Crohn's disease. A detailed knowledge of the FAE and in particular the M-cell phenotype is lacking. So far, the molecular and biochemical characterization of the FAE and M-cells is at an early stage and few specialized M-cell or FAE specific characteristics are known.
AIMS: In order to identify possible new molecules important for the role and function of FAE and M-cells in normal and IBD small intestinal mucosa, the gene expression profile of FAE was compared with that of villus epithelium (VE).
METHODS: Epithelium was isolated from adult Balb/c murine Peyer's patches and non-Peyer's patch small intestine. Total RNA was extracted from the FAE and VE with the Qiagen RNeasy mini kit. Agilent Mouse Development Oligo microarrays were used to obtain a broad picture of differences in gene expression between FAE and VE. To confirm FAE specific expression of candidate genes, Q-PCR was performed with the iCycler real-time PCR detection system (Biorad).
RESULTS: After microarray analysis and Q-PCR, significant differences (in a range of 2-fold to 10-fold) between FAE and VE were detected for the expression profile of 20 genes. These included previously undescribed genes encoding adhesion molecules, cytokines, cytoskeleton molecules and cathepsin.
CONCLUSION: The finding of gene expression differences in the FAE compared with the VE contributes to a better characterization of the FAE phenotype. The main differences are related to molecules involved in cellular transport and antigen handling. In a next phase, immunohistochemistry and electron microscopy will be performed to detect more M-cell specific molecules.

MICROSCOPIC COLITIS AND UNEXPLAINED DIARRHEA: IS IT WORTHWHILE TAKING MULTIPLE BIOPSIES IF A COLONOSCOPY IS NORMAL? IS IMMUNOHISTOCHEMICAL STAINING OF TENASCIN HELPFUL IN "MINIMAL" COLLAGENOUS COLITIS DIAGNOSIS?

ORLOWSKA Janina[1]*, JAROSZ Dorota[1]*, CWIKLA Maria*, OSTROWSKA Joanna[2], BUTRUK Eugeniusz*, KUPRYJANCZYK Jolanta**
Histopathology Laboratory[1]*, Department of Gastroenterology*, Medical Centre for Postgraduate Education, Oncology Centre; Department of Molecular Pathology**, Oncology Centre; Department of Pathology, Prof. W. Orlowski Clinical Hospital[2], WARSAW, POLAND

Introduction: Collagenous colitis (CC) and Lymphocytic Colitis (LC) belong to the group of Microscopic Colitis (MC), which is a cause of chronic watery diarrhea. Both entities are

possible to establish only when serial biopsies are taken from macroscopically normal colons. CC relies on the histological presence of subepithelial bands of collagen deposits of =10µm in well-oriented sections. Sometimes they may be presented only focally or are too subtle to allow a definitive diagnosis upon routine stainings. Tenascin can better visualize these deposits. The basic histological criterion for LC is increased number of intraepithelial lymphocytes (IEL) = 20/100 surface epithelial cells.
The purpose of this study was:
1. To investigate the diagnostic yield of biopsies taken from patients referred for unexplained chronic diarrhea with macroscopically normal colonoscopy,
2. To estimate the value of Tenascin for the identification histologically "minimal" form of CC.
Material and Methods: The cases had been collected prospectively between July 1999 and March 2005. Slides were stained with H&E, AZAN and Van Gieson or Trichrome in order to visualize the collagenous bands. The monoclonal anti-human Tenascin antibody (1:400, cat. no MAB19101, Chemicon Int.) was used for immunohistochemistry (IHC) in the specimens taken from 11 pts with CC, 9 pts with CCS and 6 control pts. Its expression was scored semiquantitatively as negative (0-0,1) or positive (1, 2, 3).
Results: There were 28 pts with CC, 13 pts suspected for CC (CCS) and 7 pts with LC during the study period: 4M: 24F with CC of average age 61,2; 7M: 6F with CCS of average age 56,5 and 7F with LC of average age 64,8. We have shown that the IHC detection of increased amounts of Tenascin (1, 2 or 3) in subepithelial zone was a specific marker for CC (9/11patients = 81,8%), but it was mostly negative in CCS (8/9 patients = 88,8%). Only in one woman Tenascin staining helped to change a doubtful diagnosis of CCS to CC. Histologically normal specimens taken from 6 pts with normal colon mucosa were negative for Tenascin.
Conclusions:
1. Serial biopsies taken from endoscopically normal colon from patients with unexplained diarrhea are necessary to establish diagnosis.
2. Though Tenascin IHC is useful to better identify the intensity of CC, its most important value concerns the possibility of excluding the doubtfully positive cases of CCS avoiding an unnecessary treatment of patients.

New molecular techniques such as cDNA, protein or antibody arrays allow for highthroughput identification of thousands of potentially disease-related markers on the genome, transcriptome and proteome level. However, these molecular techniques have been mainly developped from surgical specimens. Some human diseases such as inflammatory bowel diseases or IBD [Crohns'disease (CD) and ulcerative colitis (UC)] are most of the time diagnosed from small biopsies taken during endoscopy. The aim of this work was, 1) to assess if some molecular techniques (cDNA arrays and tissue microarrays) can be developped from biopsies obtained in IBD, 2) to correlate from biopsy specimens taken in patients with IBD, data obtained from DNA microarray and from tissue microarray techniques. The quantity and the quality of extracted RNA from digestive biopsies were assessed from the results obtained by bioanalyze (Agilent 2100) and were largely compatible with DNA array experiments (by using a 2500 genes home made array). The results obtained by DNA arrays were always controled by RT-PCR. Among, the different molecules which were upregulated in CD (for example, DAF/CD55 and ubiquitin D) and in UC (for example lipocalin 2 and C4PBP), a strong correlation was most often seen between the transcriptomic results and the levels of corresponding proteins quantified on tissue microarrays. These preliminary data were obtained from heterogeneous populations, without any selection of cohorts of patients. Current works using these molecular approaches are making on different groups of patients with similar epidemiological, and clinical profiles.

Introduction: Conventional microscopy produces diagnostic errors due to incomplete sampling because only a small fraction of the specimens is visualized, and diagnostic errors due to poor orientation because many institutions randomly embed specimens. Furthermore, attempts to avoid these errors by obtaining additional sections or by re-embedding can prolong turnaround time. Purpose: We describe new technology that may eliminate these problems by enabling pathologists to rapidly examine entire specimens and convert poorly oriented mucosa to well oriented mucosa. Methods: Material from biopsies of a putative cecal polyp, for which initial sections appeared normal, was exhaustively sectioned. These sections were digitized using the HI-Scope system then analyzed using the 3D-Scope program. The HI-Scope system is a fully automated digitizer capable of rapidly digitizing hundreds of slides at a time at high resolution. The 3D-Scope program evaluates the 2D digitized images of serial sections with virtual 2D and 3D microscopy. The complete array of 2D digitized images of serial sections may be displayed simultaneously as a gallery of essentially the entire specimen. The 2D images may be automatically stacked and aligned to form a 3D image. This image may be rotated about any axis or sectioned along any plane. Results: From the gallery of 2D images, a tubular adenoma in well oriented mucosa, and a poorly oriented focus were immediately evident in the image of each additional serial section. We selectively cropped the poorly oriented focus from the image of 1 serial section, and the corresponding focus from the images of all other serial sections was then automatically cropped, stacked and aligned to reconstruct a 3D image of the poorly oriented focus. We interacted with the program to rotate the 3D image about various axes and to section the 3D image along various planes until several crypts were sectioned longitudinally, effectively converting the poorly oriented mucosa to neo-well oriented mucosa. This required only a few seconds. Scanning, 3D reconstruction, and diagnosis by virtual microscopy together required only 2.5 hours. Conclusions: We describe new technology, which incorporates exhaustive sectioning, three-dimensional reconstruction and virtual microscopy, that may eliminate problems innate to conventional microscopy by enabling pathologists to rapidly examine entire specimens and convert poorly oriented mucosa to well oriented mucosa.

4 Harvard Medical School
5 Hôpital Saint-Joseph, Paris, France
6 CHU Lille, Lille, France

Introduction: The Prostate Cancer Prevention Trial (PCPT) reported a decreased incidence of prostate cancer for patients treated by finasteride. However, when cancer was present, the finasteride treated men had significantly higher Gleason grade cancer. One possible explanation was an overgrading due to changes in the tumor architecture following long term finasteride treatment similar to that seen with LHRH agonists. Aim of this work: to study the morphologic impact of finasteride on prostate cancer. Methods: Between 1996 and 2004, 53 prostate cancer patients who received finasteride for at least 6 weeks (6-624) were reviewed. A control group of 42 matched patients (age, PSA, digital rectal exam and Gleason score) and a group of 21 patients who had 3-month LHRH agonist before radical prostatectomy were included. Two genitourinary pathologists reviewed the cases in a blinded manner using standard criteria for evaluating hormonal treatment effect such as apoptosis, vacuolated cytoplasm, pyknotic nuclei and small irregular glands. Hormonal effect was scored as either not present (score=0), suspicious for (score=1) or highly suggestive of hormonal treatment (score=2). Results: The mean reviewed Gleason scores were 7.0, 7.4 and 7.3 for the control, finasteride and LHRH groups, respectively. Initial Gleason scores were 6.8, 6.7 and 6.9 respectively. Only the difference between initial Gleason score of finasteride group and reviewed Gleason score was statistically significant. Overall mean treatment scores were 0.33, 0.41 and 1.38 for control, finasteride and LHRH groups, respectively. Surprisingly, there was no significant morphologic treatment effect seen in 73% of the finasteride treated cases. The 27% with treatment effect did not differ from the 25% of control patients who were scored with either suspicious for or highly suggestive of treatment effect. Ki-67 index was assessed in half of control and finasteride patients. It revealed no difference between control and finasteride group. Patients treated with more than 2 years of finasteride (versus less than 2) had higher Gleason (8.4 vs 6.9, $p<0.001$) and treatment scores (1.18 vs 0.22, $p<0.001$). Conclusion: We did not observe any consistent hormonal therapy effects with finasteride as compared to LHRH agonists. Therefore while other aspects of the PCPT design might account for the higher Gleason grades in the study arm, morphologic changes due to long term finasteride treatment are not a likely cause.

RISK OF NON SIGNIFICANT PROSTATE CANCER AFTER AN EXTENSIVE SATURATION 21-NEEDLE BIOPSY PROTOCOL : A STUDY OF 1050 PROCEDURES.

Yves Allory (1,2), Alexandre de la Taille (1,2), Laurent Salomon (1,2), Zahira Mérabet (1), Eric Bonte (1), Dimitri Vordos (1,2), Andras Hoznek (1,2), René Yiou (1,2), Dominique Chopin (1,2), Claude Abbou (1,2).
1 CHU Henri Mondor, Assistance Publique-Hôpitaux de Paris, Créteil, France
2 EMI 0337, INSERM, Créteil, France

Introduction: extensive saturation biopsy is performed to increase prostate cancer detection rate but the potent risk of detecting non significant cancer could limit the clinical interest of this protocol. Aim of this work: to evaluate prospectively the risk of detecting non significant prostate cancer using an extended 21-needle biopsy protocol. Methods: 860 patients underwent prospectively a 21-needle biopsy protocol (peripheral zone, 6; far lateral, 6; transition zone, 6; middle peripheral zone, 3) resulting in 1050 procedures (including 651 "1st biopsy sets", 252 "2nd biopsy sets" and 147 "3rd or more biopsy sets"). Median serum PSA was 12 ng/mL (2-590) and digital rectal examination was T1c (n=654) or T2/T3 (n=206). The results obtained with 21 biopsy protocol (BP) were compared to those obtained in the same patients if a restricted 6 BP (sextant), 12 BP (sextant + far lateral) or 18 BP (sextant + far lateral + transition zone) had been performed respectively. Results: prostate cancer incidence was 25.6 % (6 BP), 31.6 % (12 BP), 34.5% (18 BP) and 35.1 % (21 BP) respectively, with a significant detection rate increase between 6 BP, 12 BP and 18 BP ($p<0.01$). In patients with a preoperative risk of non significant cancer (T1c, PSA <10 ng/mL, only 1 positive biopsy with a total tumor length <3 mm and a Gleason score <7), radical prostatectomy examination showed a significant cancer (stage pT3 or 4, and/or tumor volume >0.5cc and/or Gleason score >=7) in 12/23 (52%) (6 BP), 14/24 (58%) (12 BP), 16/24 (66%) (18 BP) and 7/16 (44%) (21 BP). Of note, among these patients with a preoperative risk of non significant cancer, 29 and 9 patients would not have been diagnosed by 6 BP and 12 BP, 18 (62%) and 5 (55%) of them with a significant cancer in radical prostatectomy, respectively. Conclusion : 1) the prostate 21-needle biopsy protocol is useful in increasing the cancer detection rate without increasing immoderately the rate of non significant cancer detection, 2) the preoperative criteria are not sufficient to predict the risk of non significant cancer and should be improved.

O-83
DOES SAMPLES SURFACE VARIABILITY HAVE ANY IMPACT ON CENTRALLY-REVIEWED PROSTATE CANCER DIAGNOSIS OF PSA-BASED SCREENING BIOPSIES ?

MAZEROLLES Catherine, ZAIRI Anas, SERRES Isabelle, GROSCLAUDE Pascale, RISCHMANN Pascal, DELISLE Marie-Bernadette, VILLERS Arnaud, MALAVAUD Bernard.

Within the ERSPC program, 50-70 years old male participants are offered PSA testing and addressed for 6 TRUS-guided biopsies when PSA >3ng/ml. The initial 94 sets of biopsies (n=878 biopsies) have been centrally reviewed for consistency in diagnosis in relation to the surface of the biopsies.
Materials and Methods: All biopsies were blinded and reviewed by 2 reference pathologists for prostate cancer diagnosis and also assessed in terms of PIN, extensive chronic inflammation, lesion suspect but not diagnostic for malignancy. The surface of all analyzed materials, was measured by image analysis (Image J°). Results are expressed as mean+/-SD.
Results: The mean number of biopsies was 11.3+/-2.5 with a mean surface of 240 +/- 88 mm2 analyzed per patient. The surface ranged from 70 to 510 mm2. Prostate cancer was evidenced in 25 cases by the local pathologists, 3 additional cases being found on central review. The inter-judge kappa coefficient was 0.92 ($p<0.0001$), showing excellent concordance. The three discrepancies befitted the definition of focal cancer (<3mm, one positive biopsy) and were observed in significantly smaller samples than the concordant diagnosis (142+/-32 vs. 243+/-88 mm2, $p=0.05$).

There were no relationships between the surface analyzed and the diagnosis of cancer (220+/-86 vs. 245+/-90 mm2, p=0.250), of isolated PIN (253+/-98 vs. 246+/-88, p=0.82), of acute inflammation or extensive atrophy, while extensive chronic inflammation was associated with significantly larger samples (280+/-87 vs. 230+/-87, p=0.049).
Conclusion: Despite the ERSPC recommendations, we observed some variability in the urologists' practices, with a mean number of biopsies exceeding largely the number recommended in the protocol (11.3 vs.6 per patient). Such variability was even more evident when considering the surface of biopsies available for analysis, albeit it had no overall impact on the diagnosis of prostate cancer and isolated PIN. While inter-judge concordance was good (kappa 0.92), three additional cases of cancer were found at central review, all in significantly smaller samples than in the cases of concordant diagnosis.

(2) Service de Radiologie
(3) Service d'Urologie
CHU La Pitié-Salpêtrière
75013, Paris

Introduction: Histopathology is the gold standard to evaluate prostate cancer on radical prostatectomy. Accurate localization of prostate cancer within the gland is of increasing clinical importance for the treatment of these patients. It is of tremendous therapeutical importance to examine, whether these patients display uni-, bilateral or extracapsular extension of their prostate cancer. To precise evaluation of these parameters, preoperative MRI imaging is employed routinely. Our retrospective study compared preoperative MRI and postoperative histological findings.
Materials and Methods: Fourty-seven patients with biopsy proved prostate cancer underwent endorectal MRimaging before radical prostatectomy. Images were interpreted by two independent radiologists. After prostatectomy, prostates were treated according to the recommendations of the Stanford protocol. Prostate specimens were examined by two independent and experimented pathologists. Invasion of the capsule, extracapsular extension and invasion of the periprostatic tissue were assessed, and results compared to MRI findings.
Results: In 43 (91%) of 47 cases, invasion or integrity of the capsule was predicted by IRM and confirmed by histopathology. 39 cases (82%) with irregular capsule in IRM displayed capsular invasion in histology. Four cases (9%) did not have any sign of capsular invasion in MRI, results were confirmed by histology. Discordance was found in 4 cases (9%).
Concerning extracapsular spread concordance was found in 23 cases (49 %).
In 9 cases (19%) MRI predicted extracapsular spread, histology found extracapsular adenocarcinoma in 12 cases (26%). In 21 cases (44%) MRI suspected extracapsular tumor spread, histology could not confirm these findings. In 14 (30%) cases neither MRI nor histology found extracapsular tumor growth.
Conclusion: Preoperative MRI imaging seems to be a good tool to predict prostate capsule invasion. Concerning extracapsular growth MRI displays weaker specificity, either because tumor spread is confined to one gland, which might be difficult to detect even in light microscopy. On the other side prostate gland does not display a real capsule, fibrosis and inflammation especially surrounding adenocarcinoma may mimic extracapsular growth in radiology. Histology still remains the gold standard although MRI has become a very sensitive tool.

DETECTION OF PTEN DELETION IN PROSTATE CANCER BUT NOT PROSTATIC INTRA-EPITHELIAL NEOPLASIA BY FLUORESECENCE IN SITU HYBRIDIZATION ON TISSUE MICROARRAYS

CUTZ J-C (1,2), YOSHIMOTO M (1), NUIN PAS (4), BAYANI J (1), ZIELENSKA M (5,6), EVANS AJ (1,3,5), SQUIRE JA (1,5)
1 Molecular and Cellular Biology, Ontario Cancer Institute - Princess Margaret Hospital, Toronto, Ontario, Canada; 2 CIHR Molecular Oncologic Pathology Program, Toronto, Ontario, Canada; 3 Dept. of Pathology, Princess Margaret Hospital, Toronto, Ontario, Canada; 4 Dept of Biology, McMaster University, Hamilton, Ontario, Canada; 5 Laboratory Medicine and Pathobiology, University of Toronto; and 6 Dept. of Pathology and Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada

Introduction: Although somatic PTEN alterations have been reported in prostate cancer, including loss of heterozygosity or homozygous deletions, point mutations, and promoter hypermethylation, the relationship between genomic alterations of PTEN and prostatic neoplasia (PIN)remains unclear.
Purpose: The purpose of this study was to determine whether PTEN deletion, as assessed by FISH, is associated with the progression of PIN to invasive cancer.
Methods: Archival formalin-fixed, paraffin embedded tissues from 25 radical prostatectomy specimens were used for tissue microarray (TMA) assembly. Arrayed tissues were examined by haematoxilyn and eosin staining and scored according to Gleason grading criteria. Standard dual-color FISH was performed using commercially-available DNA probes for band 10q23 (PTEN locus) and band region 10p11.1-q11.1 (centromere of chromosome 10). At least 100 nonoverlapped intact interphase nuclei were scored in areas of cancer, PIN, benign glandular epithelium and stroma. The signal counts for areas of neoplasia were compared against those obtained from benign and stromal cell nuclei. Standard immunohistochemistry (IHC)was performed on a contiguous TMA section to evaluate immunoreactivity for total PTEN protein. IHC scoring was performed in areas of PIN, benign and malignant epithelium and stroma taking into account intensity and extent of diaminobenzidine (DAB) staining. Comparisons between PIN and cancer cell PTEN immunoreactivity were made once normalized against stromal cell immunoreactivity in the same tissue core.
Results: Six of 6 (100%) cases of benign hyperplasia and 16/16 cases (100%) of PIN were found to be PTEN deletion-negative while 17/25 (68%) of cancer samples were PTEN deletion-positive ($P < 0.01$). Homozygous PTEN losses appeared to be uncommon in the PTEN deletion-positive group (8%). A negative correlation was observed between PTEN deletion status and intensity of IHC staining for PTEN protein. In silico analysis of the PTEN locus revealed a high frequency of duplicons flanking the PTEN gene.
Conclusions: The results of this study suggest that PTEN deletion plays a role in the progression of PIN to cancer and that local microhomology at 10q23 may provide a mechanism of gene deletion. Further, PTEN deletion appears to be reflected as a relative decrease in immunoreactivity in the affected cells.

PROTOCADHERIN-PC: A POTENTIAL BIOMARKER FOR HORMONE REFRACTORY PROSTATE CANCER AND ITS ASSOCIATION WITH TUMOR PROGRESSION

TERRY Stephane 1, GIL-DIEZ-de-MEDINA Sixtina 1, QUEIRES Luis 1, FAUCON Hugo 1, De la TAILLE Alexandre 1,2, ALLORY Yves 1,2, CHEN Min-Wei 3, ABBOU Clément-Claude 1,2, BUTTYAN Ralph 3, CHOPIN Dominique 1,2 and VACHEROT Francis 1
1 INSERM E 03-37, Université Paris XII,2 Department of Urology of CHU Henri Mondor, Assistance Publique des Hôpitaux de Paris, Créteil, France
3 The Departments of Urology and Pathology of The College of Physicians and Surgeons of Columbia University, New York, NY

Introduction : Previously, we reported the characterization of a novel gene product, protocadherin-PC (PCDH-PC), specifically expressed by apoptosis-resistant variants of the human prostate cancer cell line, LNCaP. In this study, we tested by using LNCaP xenografts models if PCDH-PC could induce a state of hormone-resistance and we examined PCDH-PC mRNA expression level and its localization in human normal prostate and prostate cancer tissues.
Methods : parental and PCDH-PC transfected LNCaP cells were tested for their ability to form tumor xenografts (in intact or castrated male immunodeficient mice). PCDH-PC mRNA expression and its localization were studied by semi-quantitative RT-PCR and by in situ hybridization (ISH) performed on tumor xenografts and human prostate tissues.
Results : By an in situ hybridization procedure, we showed evidence that PCDH-PC mRNA was dramatically upregulated in LNCaP xenografts during the acquisition of hormone resistance following castration of the host. In order to investigate whether protocadherin-PC expression might directly convert parental LNCaP cells to a hormone-resistant state, we implanted into castrated nude male mice either control LNCaP cells or PCDH-PC–transformed LNCaP cells. In contrast to control-transfected cells, PCDH-PC transfected LNCaP cells were able to form tumors in castrated male nude mice. Semi-quantitative RT-PCR procedure demonstrated that normal human prostate cells and tissues expressed little or no PCDH-PC-related mRNA and that this low level of expression was maintained in untreated CaP cells. ISH showed that expression of PCDH-PC-homologous transcripts was restricted to some epithelial cells in normal tissue and to CaP cells in tumors. In contrast, hormone-resistant CaP cells were found to express significantly higher levels of PCDH-PC-related mRNA, by both RT-PCR and ISH analysis. Comparison of PCDH-PC mRNA and androgen receptor mRNA levels in hormone refractory CaP did not show correlation between the overexpression of these two molecules.
Conclusions : Our findings suggest that PCDH-PC may be involved in the generation of hormone-resistance of human prostate cancer.

PATHOLOGY OF HONEYCOMB LUNG –A REAPPRAISAL: SOME HETEROGENEITY AMONG USUAL INTERSTITIAL PNEUMONIA (UIP) OF DIFFERENT ETIOLOGIES

HONMA Koichi, ARAKAWA Hiroaki
Departments of Pathology and #Radiology, Dokkyo University School of Medicine Mibu, Tochigi 3210293, JAPAN

Introduction and Purpose of Study

Honeycomb lung (HL) constitutes a cardinal feature of usual interstitial pneumonia (UIP) regardless of its etiology. There is some morphologic spectrum involving HL. The heterogeneity includes type of honeycomb cysts, some of which still retain at least part of the mural structure of a conducting airway. To find out any relation between morphology of HL and UIP of different etiology, the composition of honeycomb cysts is compared between idiopathic pulmonary fibrosis (IPF)-UIP and exposure-associated (EA)-UIP.
Materials and Methods
Cases showing high-resolution CT features consistent with UIP and confirmed at autopsy as having UIP were used for the study. They consisted of 8 cases with IPF (69.9+/-9.8 yrs) and 17 cases associated with occupational exposure to dust (74.5+/-5.4 yrs). The total number of honeycomb cysts (Nc) which appeared on the representative histologic slides was counted, if they measured greater than 3 mm in diameter and among them, the proportion of airway-type cysts (Nb) was identified. Remodelling index (RI) which presumably indicates stage of evolution in UIP, was defined as: RI = (Nc – Nb)/Nc x 100 (%). The number of fibroblast foci (FF) also was counted in each case on the same microscopic slides used for counting cysts.
Results
A total of 321 cysts were evaluated in IPF-UIP lungs, in which 110 Nb-type cysts were found (RI = 65.8%). EA-UIP had 620 Nb cysts among 1180 cysts (RI = 47.5%). An average of 2.3 FF was found in IPF-UIP per microscopic slide (ca. 4 cm2) in contrast to 0.93 FF per slide in EA cases. These differences were not statistically significant.
Discussions and Conclusions
EA-UIP has more airway-type cysts involving HL than does IPF-UIP. IPF-UIP may represent a more advanced stage of disease and its remodeling process appears to remain ongoing as suggested by a higher FF count.

O-88
MORPHOGENESIS AND MECHANISMS OF PROGRESSION OF DIFFERENT VARIANTS OF IDIOPATHIC DIFFUSE INTERSTITIAL PULMONARY DISEASES

Kogan E.A.

Idiopathic diffuse interstitial pulmonary diseases (IPD) are classified as idiopathic pulmonary fibrosis (IPF) and variants of idiopathic interstitial pneumonias.Particular morphological features, clinical symptoms, prognosis and answer to steroid therapy characterize different variant of IPD. Morphogenesis and mechanisms of progression of different variants of IPD are contradictory in many aspects.The aim of our study was to analyze morphogenesis and mechanisms of progression of different variants IPD in accordance with immunohistochemical, clinical, functional, high resolution CT dates at early and late stages of the disease.102 IPF patients were studied. Open lung biopsy by formal thoracotomy (77 cases), video-assisted thoracoscopy (6 cases) and transbronchial biopsy (19) were performed. Histological classification based on criteria for IPD (European Respiratory Society and American Thoracic society, 2004) was used. CD34 (Novocastra), bTGF (Biosourse International), FRF (DAKO), TNFa (DAKO), p53 (DAKO), Ki-67 (DAKO), PCNA (DAKO), bcl-2 (DAKO), c-myc (Novocastra), CD68 (DAKO), EMA (DAKO) were detected in paraffin sections.Results. Usual interstitial pneumonia (UIP) was found in all cases of IPF. It is characterized by active production of cytokines by interstitial macrophages at early stages that induced proliferation of myofibroblasts, endothelial and epithelial cells. Late stage of UIP results in honeycomb lung and adenomatous hyperplasia without/with cell atypia. Wide spectrum of epithelial changes was found, including new entities, such as atrophy of bronchial and

alveolar epithelium and neuroendocrine hyperplasia in oval structures with background sclerosis. Desquamative interstitial pneumonia differs from UIP by more active alveolar macrophages that induce second type pneumocyte proliferation with “septal” sclerosis and squamous metaplasia. Nonspecific interstitial pneumonia, respiratory bronchiolitis and cryptogenic organizing pneumonia contained cells with cytokine’s production in alveolar lumen and tissue infiltrates, that results in light and moderate rate of pneumosclerosis and epithelial proliferation.Conclusion. The dramatic progression of UIP comparing with other IPD is based on progressive interstitial fibrosis and prominent reconstruction of pulmonary tissue that are induced by cytokine deregulation.

O-89
CHILDHOOD PULMONARY INTERSTITIAL GLYCOGENOSIS ASSOCIATED WITH SELECTIVE POLYSACCHARIDE ANTIBODY DEFICIENCY

deMELLO Daphne, BECKER Brad, SOTELO Cirilo, NOYES Blake. Departments of Pathology and Pediatrics, Saint Louis University School of Medicine and Cardinal Glennon Children's Hospital, St. Louis, MO , U.S.A.

Pulmonary interstitial glycogenosis (PIG), is a new description for the entity of infantile cellular interstitial pneumonitis which causes lung dysfunction. Immaturity of lung interstitial cells is the presumed basis for the glycogenosis. We report two children with PIG who also have selective antibody deficiency with normal immunoglobulins (SAD), suggesting an associated immune disorder.
A girl born at term, had unexplained respiratory distress and hypoxia, and at 12 days of age, a lung biopsy showed PIG. PIG is characterized by the presence of plump interstitial cells with clear cytoplasm, causing widening of interalveolar septa. The cells contain cytoplasmic glycogen, demonstrable by the periodic acid-Schiff (PAS) reaction, and by electron microscopy as monoparticulate pools of cytoplasmic glycogen. At 16 months, because of recurrent respiratory symptoms, fever, and pneumonia, immunologic studies showed normal immunoglobulins, but poor antibody responses to conjugate pneumococcal and tetanus vaccines. Lymphocyte studies were normal except for poor proliferation to antigens, which improved with IL-2. She was weaned off oxygen and placed on intravenous immunoglobulin (IVIG, approximately 500mg/Kg/dose); at 40 months of age she still has occasional wheezing spells.
Patient 2 is a term boy whose lung biopsy was done at 5 weeks of age for respiratory distress. It showed PIG and subsequently he had recurrent respiratory symptoms, fever, and pneumonia that prompted immune studies at 42 months of age. He had normal immunoglobulins, but no antibody response to the polysaccharide pneumococcal vaccine, normal antibody responses to protein antigens and normal lymphocyte studies.
These cases suggest an association of pulmonary interstitial glycogenosis and selective antibody deficiency to polysaccharide antigens. There may be a therapeutic role in these patients for IVIG. The cases also illustrate the importance of considering PIG in infants with cellular interstitial pneumonitis and of the diagnostic role of histochemistry and electron microscopy in the pathologic evaluation of infantile interstitial pneumonia.

ROLE OF BRONCHOALVEOLAR LAVAGE IN CHILDREN WITH CHRONIC PULMONARY ASPIRATION

RIZZO Stefania, GIACOMETTI Cinzia, BARBATO Angelo, PANIZZOLO Cristina, SAETTA Marina, VALENTE Marialuisa, CALABRESE Fiorella
University of Padova Medical School, Padova, Italy

INTRODUCTION: Chronic pulmonary aspiration (CPA) is a common cause of persistent respiratory diseases, particularly in children with gastroesophageal reflux (GER). PURPOSE OF THE STUDY The aims of the study were to establish: a) the accuracy of Lipid-laden Macrophage Index (LLMI) as test for GER-related CPA; b) the role of GER in CPA. Clinico-pathological correlations between ¡°aspirators¡± and ¡°non-aspirators¡± patients (pts) were also performed. METHODS: We prospectively evaluated 37 pts (12 F, 25 M, mean age 4,8 yrs) with chronic respiratory symptoms. All pts underwent esophageal ph-metry and bronchoscopy with bronchoalveolar lavage (BAL) for LLMI analysis. Functional and clinical data, including asthma and atopy were recorded in all pts. GER-related CPA was diagnosed in presence of suggestive clinical history, pathological pH-metry and LLMI¡Ý75% (aspirators). Aspirators (8 pts) were compared with non-aspirators (8 pts) in terms of clinical parameters and molecular viral infections detected on BAL. RESULTS: LLMI sensitivity and specificity were 60% and 67% respectively; the positive and negative predictive value 40% and 82% respectively. GER frequency was detected in 22% of pts. Aspirators were older (mean age 6.4 vs 3.5), less atopic (25% vs 87%) and with lower frequency of laryngitis (12 vs 50%) than non-aspirators (p¡Ü0,05). CONCLUSIONS: LLMI may role out the presence of GER due to its high negative predictive value. GER plays an important role in the development of CPA. Atopy can not be considered a predisposing factor for GER-related CPA.

REDUCED BRONCHIAL EPITHELIAL SMAD7 PROTEIN EXPRESSION IN COPD

ZANDVOORT, Andre 1,2, POSTMA, Dirkje S 2, JONKER, Marnix R 1, NOORDHOEK, Jacobien A 2, VOS Johannes TWM 1 and TIMENS, Wim 1. 1
Dept. Pathology, and 2 Pulmonology, University Medical Center Groningen, Groningen, THE NETHERLANDS.

Introduction: Degradation and repair of the extracellular matrix (ECM) are essential processes in the pathogenesis of COPD. Previously, we have demonstrated an altered decorin expression in the peribronchial area of COPD patients reflecting an alteration in ECM modulation. Decorin transcription is known to be regulated by Smad7, an inhibitory component of the TGF-beta -Smad pathway. This pathway is the key intracellular signal route for ECM gene transcription.
Objective: To determine whether Smad proteins are differentially expressed in lung tissue of COPD patients compared to controls.
Method: Using immunohistochemistry, Smad protein expression was compared in lung tissue of GOLD stage II (n=11) and stage IV (n=8) COPD patients and controls (n=8). Expression was semi-quantitatively analysed.
Results:
In GOLD stage II as well as GOLD stage IV patients, we found a significantly lower epithelial expression of the inhibitory Smad, 7. In addition, we found a significantly lower epithelial expression of TGF-beta in stage II patients.
Discussion: The TGF -Smad pathway appears to be aberrantly regulated in COPD patients, most likely resulting in an atypical ECM modulation. Reduced expression of Smad7 in bronchial epithelial cells could play a role the reduced presence of decorin in the peribronchial area of COPD patients.

MALIGNANCY ARISING IN KAOLIN PNEUMOCONIOSIS OF GEORGIA

Beverly Y. Wang, Cameron C. Avant, Elizabeth D. Loomis, Richard Hessler, Lawrence J. Freant.
Department of Pathology, Medical College of Georgia, Augusta, GA, USA

Background: Kaolinite (Al2O3*SiO2*2H2O) is widely used in rubber, paint, adhesives, fillers in plastics, paper, and as an absorbant. Kaolin clay in Georgia constitutes one of the major open mining operations in the United States. The product is relatively free of silica. Exposure to kaolin has been linked to the development of pneumoconiosis. Rare cases of lung cancers arising in kaolin-related pneumoconioses have been reported. We have examined 4 cases of carcinoma associated with kaolin exposure.
Designs: Four archival specimens from the file of the Medical College of Georgia including wedge excisions and lobectomies obtained between years 2002-2004. The specimens were routinely processed, formalin-fixed and paraffin embedded. Sections were stained with Hematoxylin and Eosin. Review of patient charts and clinical follow-up were performed (Table).
Results: All 4 cases had a histologic background of interstitial lung disease (Fig 1). 3 patients were smokers with emphysema (#1,2,3). One lived in the mining area and was exposed to airborne dust for many years. 2 cases developed adenocarcinoma (#1,4, Fig 2, 3), one had large cell carcinoma (#2, Fig 4), and one squamous cell carcinoma (#3, Fig 5). 3 patients are alive after surgery, 1 is lost to follow up.
Conclusions: 4 kaolin-exposed patients from Georgia USA had kaolin-related interstitial lung disease, and developed a superimposed lung carcinoma. Kaolinosis may be a risk factor for carcinomas of the lung with or without smoking.

O-93
EVALUATION OF MEDIASTINAL NODES AND MASSES BY ENDOSCOPIC ULTRASOUND (EUS)-GUIDED FINE-NEEDLE ASPIRATION BIOPSY (FNAB): A SERIES OF 156 CASES.

DRAK ALSIBAI Kinan (1), FABRE Monique (1), HOMSI Toufik (2), LAZURE Thierry (1), DE PINIEUX Isabelle (2), BALATON André (2), MOLINIE Vincent (2). Anatomie et Cytologie Pathologiques, AP-HP Hôpital de Bicêtre (1), Le Kremlin-Bicêtre; Hôpital saint-Joseph (2), Paris, France

Introduction: FNAB has become an important tool in the evaluation of pancreatic masses, mostly done using EUS allowing both the initial staging and the diagnosis of cancer. Currently, the role of EUS-FNA in identifying mediastinal lesions is under evaluation and early results have been quite promising in the diagnosis and staging of lung cancers.
Aim of the study: To determinate the EUS-FNAB diagnostic performance in mediastinal nodes and masses by retrospective study from two institutions.
Patients and methods: 156 consecutive patients (110 male), median 58 yrs (23-85) who underwent EUS-FNAB for suspicious mediastinal lesions, were studied from January 2003 to January 2005. Mediastinal nodes (n=129) and/or mediastinal masses (n=43) were sampled, using a linear array echoendoscope equipped with Wilson-Cook or Olympus 19 or 22-G needles. An average of 1.8 (1-3) needle passes were performed. The aspirated specimens were analyzed further by using conventional and liquid-based smears (Cytyc Corp.) (n=142) and/or microbiopsy using cytoblock® preparations (n=156).
Results: No serious complications were noted (abdominal pain). In 3/156 specimens (1.9%) no sufficient cell/tissue material could be aspirated. In the remaining 153 specimens, a benign lesion was found in 63/153 cases (41.1%): reactive lymphadenopathy (n=34), tuberculosis (n=14), sarcoidosis (n=11), silicosis (n=2), bronchogenic cyst (n=2). A malignant lesion was found in 90/153 (58.8%). The primary site of metastases was the lung in 65 cases (72.2%) including SCLC (n=27), adenocarcinoma (n=22), SCC (n= 16) and others various organs in 17 cases: kidney (n=6), cardia (n=3), prostate (n=2), breast (n=2) and one case in thyroid, larynx, bladder and testis. Five lymphoma and three sarcoma were also diagnosed. Immunostaining was performed in 66 cases with a mean of 10 antibodies (1-16).The global accuracy of EUS-FNA was 96.8%
Conclusion: This study demonstrates that EUS-FNAB 1) is a safe and minimally invasive diagnostic technique, 2) plays an important role in the diagnostic of benign mediastinal lesions such as granulomatous adenitis when previous pleural, lung and bronchial biopsies are negative, 3) allows an accurate cyto/histologic diagnosis of mediastinal nodal status in patients with lung cancers avoiding invasive mediastinoscopy or thoracotomy. EUS-FNAB is a key step to identify a subgroup of downstaged patients who are not candidates for surgery but are firstly for radio/chemotherapy.

O-94
GRANULOMETRIC ASSESSMENT OF NUCLEAR TEXTURE IN BRONCHIAL BRUSH CYTOLOGY

Adam RL(1,2), Silva PVVT(1), De Carvalho RB(1), Leite NJ(2), Metze K(1)
(1) Department of Pathology, Faculty of Medicine, UNICAMP, Campinas, Brazil
(2) Institut of Computing, UNICAMP, Campinas, Brazil

The assessment of the chromatin texture plays an important role for the diagnosis of cellular differentiation. Wheras classic morphometry does not describe precisely nuclear heterochromatin, granulometry characterizes quantitatively the coarseness of an image in a hierarchical way. It obtains an ordered and complete description of an image from morphologic residues, which are defined as the difference between two consecutive granulometric levels. The aim of this study was to study the chromatin texture in rotine bronchial brush cytology by granulometry in order to characterize cell differentiation. We compared nuclear images of HE-stained bronchial brush cytology of 54 patients (17 without neoplasia, 22 squamous cell carcinomas, 6 small cell carcinomas and 9 adenocarcinomas). In every case final diagnosis was confirmed by subsequent histologic examination. Texture analysis was based on grayscale transformed images. From each granulometric level of gray scale images the residues were extracted by progressive filtering (openings and geodesic reconstruction)with the following filter parameters : 1.height of the basins (in gray levels), 2.area, and 3.volume. Number of seeds and residues were extracted. Comparison was done by analysis of variance. Least density of residues of lower level basins was found in non-neoplastic cells, followed by small cell carcinoma, squamous cell carcinoma, and highest density was seen in adenocarcinomas. At medium and higher basin levels lowest density of residues was calculated for adenocarcinomas, followed by squamous cell carcinoma and small carcinomas, whereas highest values appeared in non-neoplastic epithelium. The area of basins was largest in adenocarcinomas, followed by squamous cell carcinoma, small cell carcinoma, and finally non-neoplastic epithelial cells. The density of seeds was minimum in non-neoplastic epithelium, followed by small cell carcinomas, epidermoid carcinomas and highest in adenocarcinomas. In other words, the three neoplasias and the non-neoplastic cells reveal different ramification pattern of basins, which characterizes the chromatin organization. Neoplastic cells reveal larger heterochromatin clumps, with the maximum values in adenocarcinomas, follwed by squamous cell carcinomas and

small carcinomas. Thus we conclude , that quantification of granulometric residues in digitalized images of bronchial brush cytology may be useful for differential diagnosis.

DO VASCULAR CHANGES IN DONOR KIDNEYS HAVE AN IMPACT ON LATE GRAFT-DYSFUNCTION?

KEMÉNY Éva, NAGY-FRICSKA Adrienn, KISS Andrea, SZEDERKÉNYI Edit, ELLER József, MORVAY Zita, IVÁNYI Béla, SZENOHRADSZKY Pál
Departments of Pathology, Surgery, Radiology and Informatics, University of Szeged, Hungary

Introduction: Morphological studies of "zero-hour" kidney donor biopsies have produced controversial findings over what type of vascular changes -if any- are associated with late graft-dysfunction. Hence we carried an original clinicopathological study involving morphometry to assess this question.
Materials & Methods: 94 consecutive pretransplant "zero-hour" biopsies from cadaver kidney grafts were studied. We examined the frequency and severity of arteriolar hyalinisation (AH), intimal fibroelastosis (IFE), tubular atrophy (TA), interstitial fibrosis (ISF) and glomerulosclerosis (GS) semi-quantitatively. The wall thickness/lumen (W/L) ratio of each vessel present in the biopsy was determined by morphometry. Groups were then differentiated according to their blood vessel size: G1: d<79µm, G2: d=80-149µm, G3: d=150-300µm. Statistical analyses were done to examine the clinicopathological correlations. Follow up examinations were made 48 months after each transplantation.
Results: There was a significant correlation between the mean elevated serum creatinine (SCR) level at 48 months after transplantation and (a) the age of the donors ($p<0.05$), along with (b) the frequency of intracranial hemorrhage as the cause of donor-death ($p<0.05$). In the "zero-hour" biopsies non-specific morphological changes were frequently observed: AH: 84.0%, IFE: 76.6% (moderate: 26.6%), ISF: 25.5%, TA: 71.3% and the mean proportion of sclerotic glomeruli was 5.01%. Among the vascular changes studied only the moderate IFE ($p<0.01$) revealed a significant correlation with SCR at 48 months. In IFE there was also a significant correlation (a) with the non-specific morphological lesions studied ($p<0.001$), and (b) with the frequency of intracranial hemorrhage as the cause of donor death ($p<0.01$). By morphometry a significant association was found between the mean W/L ratios of arteries in the G3 group and the degree of IFE ($p<0.01$).
Conclusion: Our results suggest that donor kidneys with a moderate degree of intimal fibroelastosis -occuring significantly more frequently in kidneys from older donors, and whose cause of death is intracranial haemorrhage- do indeed have a higher risk of late graft-dysfunction. This should be taken into consideration in optimal donor selection.

O-96
POLYOMAVIRUS-ASSOCIATED NEPHROPATHY (PVAN): ROLE OF JC VIRUS

HIRSCH Hans 1, DRACHENBERG Cinthia 2, MUNIVENKATAPPA Raghava 2, MCKINNEY Jamie 3, WALI Ravinder 3, NOGUEIRA Joseph 3, CANGRO Charles 3, RAMOS Emilio 3, PAPADIMITRIOU John C 2
1 Transplantation Virology, and Infectious Diseases, University Hospital Basel, Basel, Switzerland, 2 Departments of Pathology and 3 Medicine, University of Maryland School of Medicine, Baltimore, MD, USA

Background:
PVAN in renal transplants is mainly caused by BK virus, but rare cases have implicated JC virus.
Design and Results:
Over a period of 19 months, 1280 ambulatory renal transplant patients (pt) were screened for decoy cells in urine cytology (n=2845). We identified 139 (10%) with 1 to 11 urine samples positive for decoy cells. In 122 patients with decoy cell-positive urines and at least 12 months of follow up, BK and JC viral load was quantified in urines and in plasma. Patients were classified according to the type of virus present in urine as: BK only (42%), BK+JC (28.6%) and JC only (29.4%). The type of viruria was correlated with the biopsy findings and creatinine (Cr). Patients biopsied were BK:39, BK+JC:27, only JC 26. Serum Cr at biopsy was 2.58 (1.2-7.5), 1.74 (1-3.3) and 1.58 (.9-2.6) respectively. Last Serum Cr was 3.49 (1-10.1), 1.81 (1-4.3) and 1.66 (.9-3.8) respectively. PV nephritis was found in 33/39, 13/27 and 5/26 patients respectively.
Graft loss occurred in 6 patients with BK viruria, 1 patient with BK and JC viruria and in no patient with JC only viruria. A larger proportion of patients with BK viruria had clinical dysfunction, PVAN and graft loss. JC viruria persisted in some patients independently of BK viruria, BK viremia, PVAN or response to intervention including clinical improvement and disappearance of BK viremia.
Conclusions:
Urine cytology identifies high-level replication of both, BK and JC virus. The pathogenic implications and clinical consequences appear to be significantly different in patients shedding one virus or the other. JCV shedding may be associated with histological PVAN in 20%, but graft dysfunction is absent in most patients.

O-97
GLOMERULAR AND TUBULAR CHIMERISM IN RENAL ALLOGRAFTS

FERLICOT Sophie (1), PLES Raluca (1), CREPUT Caroline (2), GUETTIER Catherine (1), DURRBACH Antoine (2)
Services (1) d'Anatomie Pathologique, (2) de Néphrologie, CHU de Bicêtre, le Kremlin-Bicêtre.

Background. After transplantation, many pathologic conditions can damage the kidney and lead to acute renal failure. Regeneration of necrotic cells was initially thought to be based on self-renewal tissues. Recent studies have underlined that cells of donor origin can be found in recipient tissues after transplantation of any solid organ. We investigated whether cells of recipient origin were present in kidney allograft secondary to episodes of kidney injuries.
Methods. To test the hypothesis in humans that extrarenal cells can participate in tissue remodeling, we examined the origin of glomerular and tubular cells in 10 male patients who received a kidney transplant from a female donor. Among these patients, three had no histopathological signs of rejection, one had acute rejection and six had signs of chronic allograft nephropathy. Four patients had developed acute tubular necrosis following transplantation. Fluorescent in situ hybridization was used to detect Y chromosome on frozen biopsies.
Results. All patients showed an intragraft chimerism in interstitial, tubular and glomerular cells. A mean of 8% of tubules and 23% of glomeruli contained Y chromosome cells. No correlation to morphology was found.
Conclusion. Regeneration after injury is not exclusively based on self-renewal of allograft-tissues. This is consistent with the concept that circulating pluripotent progenitor cells exist, capable of differentiating into tubular and glomerular cells. The presence of chimeric cells in a higher level in glomerular cells than in tubules remains unclear.

O-98

LIVER INDUCES IMMUNE TOLERANCE IN PEDIATRIC INTESTINAL TRANSPLANTATION

Damotte Diane, Jugie Myriam , Canioni Danielle , Le Bihan Christine, Sarnacki Sabine, Révillon Yann, Jan Dominique, Lacaille Florence , Cerf-Bensussan Nadine,Goulet Olivier, Brousse Nicole.
Intestinal Transplantation Unit, Necker-Enfants Malades and HEGP Hospital, Paris, INSERM EMI 0212, U255, U580, Faculté Necker, Université René Descartes, Paris V, France

Background and Aims: Small bowel transplantation remains a challenge due to the intestine septic and immune conditions, therefore graft and patient outcome are difficult to predict. In order to assess the putative tolerogenic role of the liver in combined transplantation, and to find new predictive markers of the transplantation outcome, we compared two groups of pediatric intestinal transplantation, seven small bowel graft (SbTx) and eight combined liver-small bowel graft (LSbTx) receiving the same immunosuppressive therapy.
Methods: Fifteen single-center children who underwent small bowel transplantation between 1994 and 1998, were retrospectively reviewed and compared to fifteen controls (normal and inflammatory small bowel mucosa). Transplant and patient overall survival, acute rejection episodes of each group were analysed and compared to epithelial apoptotic body count and to the immunostaining of NF-kB (p65) transcription factor, caspase-3 (CPP-32) and Bax pro-apoptotic factors from day 0 to 20 after transplantation.
Results: LSbTx had a higher graft and patient survival at five years (75% and 75%) as compared to the SbTx (43% and 57% respectively). Small bowel histological analysis recorded a constant higher apoptotic body count in LSbTx ($p=0.05$ at day 5 and $p<0.01$ thereafter). Endothelial, epithelial and lymphoid cells from both groups displayed differential NF-kB and Bax immunostaining at day 0 ($p<0.05$).
Conclusions: Concomitant liver transplantation improved intestinal graft and patient survivals and was associated with different apoptotic body count and NF-kB, Bax staining within the small bowel. Although not clearly demonstrative, these results in pediatric transplantation strenghten the hypothesis of immune tolerance induced by liver.

O-99

PANCREATIC ISLETS PROGENITOR/STEM CELLS IN MICE. THEIR ROLE IN PANCREATIC ISLETS TRANSPLANTATION

Koryna Socha* 1, Marcin Socha 2, Igor Jakoniuk 1, Piotr Fiedor 2. 1 Military Medical Institute, Warsaw; 2 Warsaw School of Medicine, Warsaw. Poland

According to the data which indicates the presence of pancreatic islet progenitor cells in pancreatic ducts, in case of transplantation of nonpure islets suspension, these particular duct cells could also differentiate into hormone producing cells and participate in the process of remodelling and growth of islet grafts.
In this study the syngeneic transplantation of C57BL/6 mice pancreatic islets into the kidney subcapsular space of diabetic recipient (streptozotocine 100mg/kg bw i.p.) was performed. To distinguish cells' origin the graft we used transgenic B.6. mice expressing EGFP under the b actin promoter or sex mismatched model. After the graftectomy (day 14, 30, 100) an immunohistochemical analysis and FISH were performed.
We found that 0.6% of b cells were in the cell cycle (Ki67 expression), the number of Ki 67 positive endocrine cells within pancreas was not significantly lower. In the syngeneic grafts the presence of 1 per 30HPF proliferating bcell of recipient phenotype was showed. We confirmed the coexpression of early pancreatic islets markers and CD 45 in cells of recipient phenotype. Recipient origin cells were found within graft vessels and nerves. An increase of ßcells cross section area, revealed between the 14 day and 100 day grafts, indicated the ßcells growth and this process was significantly increased in case of nonpure islets transplantation.
The results of this study underline the complexity of pancreatic graft cells indicating the presence of cells which can differentiate/transdifferentiate into hormone producing cells and other graft elements. Data points that pancreatic hormone producing cells can enter the cell cycle but also underlines the possible role of the exocrine tissue remnatns in this process. Maiority of insulin producing cells were of the donor origin but the presence of single recipient derived b cells indicates that certain adult cells population can differentiate into islet cells. The important finding is the possible beneficial role of duct cells present within the graft which, if contain progenitor cells, can influence pancreatic islets engraftment. This study remains an indication that adult stem/progenitor cells can be considered as an alternative cell source supplying cell transplantation and also the results underline the regenerative capacity of pancretic islets.

MINOR SALIVARY GLAND DAMAGE AFTER BONE MARROW TRANSPLANTATION IN PATIENTS WITH AND WITHOUT C-GVHD

Cintra ML 1, Alborghetti MR 1, Corrêa MEP 2, Adam RL 1, Coracin FL 2, de Souza CA 2, Metze K 1.
Department of Pathology, Faculty of Medicine 1, Bone Marrow Transplantation Center Hematology /Hemotherapy Center 2 - State University of Campinas, Brazil.

Histological alterations of minor salivary glands (MSG) in patients after bone marrow transplantation (BMT) may be due both to chronic graft-versus-host disease (cGVHD) as well as to pre-transplant treatment. The aim of our study was to evaluate the influence of these factors on the histological changes in MSG. Sequential biopsies performed during cGVHD therapy were evaluated in 14 patients after BMT. As control group, biopsies of 9 BMT patients without cGVHD were used. Histological grading of cGVHD was done by two blinded observers according to Horn's classification. An objective assessment of the volume of secretory units was obtained with the help of digitalized images of standardized PAS-stained sections using a software for texture analysis. The density of inflammatory infiltrate per area was obtained in leukocyte common antigen stained sections. In each patient a detailed clinical history was available. The histological variables as well as Horn's grades in the MSG were closely associated with the diagnosis of cGVHD. Both, the use of antihypertensive drugs and chronic basic disease reduced significantly the volume of PAS+ (acinar) material in a linear multiple regression. The degree of the inflammatory infiltration was related to later biopsy after transplantation and longer duration of pre-transplant disease. In a multivariate regression only cGVHD was predicitive of fibrosis in MSG. Even after treatment glands of cGVHD patients showed still significantly less acinar PAS+ volume when compared to the glands of BMT patients without cGVHD at day 100+. We could not find significant differences of PAS+ acinar volume, leukocyte index, fibrosis and Horn's grades when comparing the glands of all patients before and after treatment of cGVHD. Changes in the Horn score between the two biopsies were only dependent of the patient´s age. Only patients with less than 40 years showed a decrease in the severity of cGVHD. We conclude that MSG functional and structural damage is the result of both: prexisting systemic disease treatment and cGVHD. Even after cGVHD treatment there is no significant recovery of the MSG secretory unit, which explains the persistence of clinical symptoms, such as xerostomia.

EXPRESSION PROFILING OF ENDOMETRIAL STROMAL CELLS TREATED WITH ESTRADIOL AND PHYTOESTROGENS

O'TOOLE Sharon, LAIOS Alex, SHEPPARD Brian, SMYTH Paul, O'REGAN Esther, SHEILS Orla, O'LEARY John.
Departments of Obstetrics and Gynaecology and Pathology, Trinity College Dublin.

Introduction:Phytoestrogens are chemicals that originate from plants and have estrogenic activity. Considerable interest has been shown in these compounds as an alternative for hormone therapy.
Aim: Little is known about the molecular pathways initiated or mediated by these compounds so the aim of this study was to examine the transcriptome profile of normal endometrial stromal cells treated with estradiol and the phytoestrogens tectorigenin, irigenin and apigenin.
Methods:A normal endometrial stromal cell line was cultured and treated with 0.1µM of estradiol and 0.1µM of the phytoestrogen extracts. RNA was extracted from the treated and untreated control cells and processed into Digoxigenin labelled cRNA by reverse transcription-in vitro transcription (RT-IVT). Gene expression analysis was performed using the chemiluminesence based Applied Biosystems array 1700 system which has 31,077 probes and targets a complete annotated and fully curated set of 27,868 human genes from the public and Celera databases. Technical replicates were performed for each sample.Data was normalised using 5% trimmed mean. Genes were filtered based on a signal/noise ratio of greater than 3 in more that 75% of the arrays. Students t-test and bon ferroni analysis were carried out and additional multitest analysis using the R package.
Results: Good reproducibility was seen in technical replicates. Various signaling pathways and transcription factors were initiated by estradiol and the phytoestrogens. Expression was compared to untreated controls and also each extract was compared to estradiol. Of interest was the upregulation of hypoxia inducible factor-1 (HIF-1) by estradiol and tectorigenin. Among the 70 target genes of HIF-1 known so far several are involved in angiogenesis, cell proliferation and cell viability and some of these target genes such as cyclin G2 and PIK3CA were upregulated in this study by estradiol and tectorigenin.
Conclusion: Gene targets are currently been validated using Taqman PCR. The HIF-1 pathway will be further investigated as a possible mechanism for endometrial hyperplasia. The molecular pathways initiated by phytoestrogens need to be fully elucidated before these extracts can be used as an alternative for hormone therapy.

FOCAL ADHESION KINASE EXPRESSION IN ENDOMETRIAL CANCER: CORRELATION WITH CLINICOPATHOLOGICAL VARIABLES

THEOCHARIS Stamatios1, VOULGARIS Zannis2, PAPASPIROU Irini1, SOUMAKIS Konstantinos1, RODOLAKIS Alexandros1, VLACHOS Georgios1, DIAKOMANOLIS Emmanuel1, KYROUDI Aspasia3
Departments of Forensic Medicine-Toxicology1, 1st Obstetrics and Gynecology2 and Histology-Embryology3, Medical School, University of Athens, Athens, Greece

Background-Aims: Focal adhesion kinase (FAK) is an enzyme of the tyrosine kinase group linked to signalling pathways between cells and their extracellular matrix. In tumor cells in vitro, FAK expression was correlated with their ability for invasion and metastasis. The aim of this study was to assess FAK protein expression in tumor samples from 40 patients with endometrial adenocarcinoma and to correlate it with clinicopathological variables.
Patients and Methods: FAK protein expression was examined immunohistochemically on paraffin embedded tissue sections of 40 endometrial adenocarcinoma cases. FAK positivity, overexpression (positivity in more than 75% of tumoral cells), and intensity of staining (mild, moderate, intense) were correlated with clinicopathological variables as patients' age, TNM status, tumor histological type, grade, and proliferative capacity (Ki-67 labeling index).
Results: Thirty-five out of 40 endometrial adenocarcinoma cases (40%) were FAK positive, and 4 out of 40 (10%) presented FAK protein overexpression. In endometrial adenocarcinoma cases examined, FAK positivity was correlated with TNM stage (p=0,031), but not with the other clinicopathological variables. FAK protein overexpression was correlated with tumor proliferative capacity, as tumors that present FAK protein overexpression also present increased Ki-67 labeling index (p=0.045). FAK protein overexpression was not correlated with the other clinicopathological variables. Additionally, FAK intensity of staining did not correlate with any of the examined clinicopathological variables.
Conclusions: In endometrial adenocarcinoma, FAK protein expression was correlated with important clinicopathological variables for patients management, being correlated with TNM stage and tumor cells' proliferative capacity. Further molecular and clinical studies are required in order to delineate the significance of FAK protein expression in endometrial neoplasia.

O-103
ANGIOGENESIS IN UTERINE MALIGNANT MULLERIAN TUMORS OF THE UTERUS.

NÄYHÄ Veera, STENBÄCK Frej. DEPARTMENT OF PATHOLOGY, UNIVERSITY OF OULU, OULU, FINLAND

Malignant mixed mullerian tumors are a heterogeneous group of aggressive malignant neoplasms that contain both carcinomatous and sarcomatous elements. They have a dismal prognosis, current treatment strategies have therapeutic limitations and prognostic indicators are lacking. Angiogenesis is associated with prognosis in epithelial cancers of many organs; studies on angiogenesis of carcinosarcomas are few and inconclusive.
The present study comprises 25 patients with uterine conditions diagnosed as carcinosarcomas of the ovary or uterus. Clinical data, history and follow up were obtained from each patient. To assess vessel involvement, the number, size, shape, structure and locations of vessels in the stroma were determined using quantitative densitometry and morphometry of histological specimens stained with an antibody to vascular endothelium, CD34. All neoplasms diagnosed as carcinosarcomas were classified based on vessel arrangement in immunohistochemistry and automated image analysis.
Angiogenesis was distinct in all neoplasms, related to the number of different sized vessels, resulting in a significant increase in total vessel area and associated with decreased survival. Those with the shortest survival had the largest, most irregular vessels and the highest antibody staining intensity. In solid tumour areas vessel number increased compared to non-neoplastic tissue. Vascular arrangements surrounded these cellular areas in a garland type pattern, vessel arrangement in bursts was uncommon, directional angiogenesis was rare. Fibrillary type neoplasms commonly contained few, regular and diffusely arranged vessels. Vessel dilatation was prominent in all specimens, vessel sprouting, and extensions of vessels, occurred as increased vessel shape factor/vessel area.
This study showed angiogenesis to be a fundamental part of the biological behaviour of neoplasms of this type. A distinct separation of different components is needed to establish

angiogenesis as an independent predictor of clinical behaviour.

HISTONE DEACETYLASE 2 EXPRESSION IS HIGHLY INCREASED IN ENDOMETRIAL STROMAL SARCOMAS: HDACS INHIBITORS AS CANDIDATES FOR TREATMENT OF ENDOMETRIAL STROMAL TUMORS

HRZENJAK Andelko, MOINFAR Farid, KREMSER Marie-Luise, STROHMEIER Bettina, ZATLOUKAL Kurt, DENK Helmut
Institute of Patohology, Medical University Graz, Auenbruggerplatz 25, A-8036 Graz, Austria

Covalent modifications of histones, in particular de/acetylation of lysine residues, play an important role in the regulation of gene transcription. These processes, which regulate the accessibility of transcriptional regulatory proteins to chromatin templates, are controlled by histone acetyltransferases (HATs) and histone deacetylases (HDACs). A controlled equilibrium between HATs and HDACs is essential for normal cell growth. Nowadays it is obvious that de/acetylation of histones plays an important role in different types of tumors. However, there have been no investigations about these processes in mesenchymal tumors. Endometrial stromal sarcomas are rare uterine malignancies and molecular mechanisms involved in their pathogenesis are poorly understood. Beside surgical excision, quite often followed by recurrences, other therapeutic methods, like chemotherapy, seem to be somewhat neglected.
The present study shows differences in the HDAC2 expression in endometrial stromal tumors and cognate ESS-1 cell line in comparison to healthy endometria. We also examined wheter sodium-valproate, an HDAC inhibitor that preferentially inhibits class I enzymes, is able to mediate cell differentiation, cell cycle arrest and expression of other genes related to malignant phenotype of endometrial stromal tumors. Here we show for the first time that HDAC2 expression is highly increased in endometrial stromal tumors in comparison to healthy endometrial stroma. Furthermore, HDAC2 expression appears to positively correlate with the tumor stage, being further increased in high-grade undifferentiated endometrial sarcomas. In vitro experiments with the endometrial stromal sarcoma cell line (ESS-1) showed that specific HDAC2 inhibitor, Na-valproate, led not only to expected HDAC2 decrement but also to cell differentiation. HDAC2 inhibition in ESS-1 cell caused also significant changes in the cell cycle by inhibiting the G1/S transition. Using QRT-PCR we showed that mRNA amount of secreted frizzled-related protein 4, an important reppressor of the wnt-signalling pathway, was 9-fold increased after HDAC2 inhibition. Regarding immunohistochemical data the HDAC2 expression in endometrial stromal sarcoma seems to correlate with the expression of ß-catenin, another important member of the wnt-signalling pathway.
Taken together this study suggests that HDACs in general and HDAC2 in special might be considered as potential drug-targets in the therapy of endometrial stromal tumors.

PDGFR ALPHA AND BETA, BUT NOT C-KIT ARE EXPRESSED IN ENDOMETRIAL STROMAL SARCOMAS - A THERAPEUTIC OPTION FOR TYROSINE KINASE INHIBITORS

Bernadette LIEGL, Olaf REICH* and Sigrid REGAUER
Institute of Pathology and * Department of Gynecology and Obstetrics, Medical University of Graz, Austria

Aims: Endometrial stromal sarcomas (ESS) are among the rarest primary uterine malignant tumors. The etiology and the genetic mechanisms in the oncogenesis of ESS are still unknown. ESS are hormone sensitive tumors which respond to anti-hormone treatments. Treatment modalities based on oncogene expression, however, are not available for ESS. Stromal tumors in other organs such the gastro-intestinal tract (GIST) expressing the proto-oncogene c-KIT have somatic mutations of the transmembrane tyrosine kinase receptor, which makes them suitable for treatment with tyrosine kinase inhibitors, such as Gleevec. Gleevec has convincing treatment success in GIST through an inhibitory effect on multiple class-3-receptor tyrosine kinase members such as platelet-derived growth factor receptor alpha and beta (PDGFRa, PDGFRß) and c-KIT. C-KIT expression and genetic mutations in mesenchymal unterine tumors are rare and it has been suggested that patients with ESS are unlikely to benefit from treatment with the presently available tyrosine kinase inhibitors. Recent studies on a small group of GIST lacking KIT mutations, however, suggest that patients with c-kit negative GIST can also benefit from Gleevec therapy, based on the identification of PDGFRa mutations as an alternative oncogenic mechanism in GIST. The aim of this study was to investigate the immunohistochemical expression of c-KIT, PDGFRa and PDGFRß in ESS.
Methods: Formalin-fixed,paraffin-embedded tissues of 14 archival ESS were analysed using antibodies against PDGFR-a, PDGFR-ß (Santa Cruz Biotech, CA) and c-KIT (Dako Cytomation Denmark) according to standard procedures. Cases were scored positive when >10% tumor cells showed a positive reaction.
Results: All ESS were negative for c-KIT, only 2/14 cases showed individual single cell staining (<10% of tumor cells). 7/14 ESS showed a strong staining in 80% of tumor cells for PDGFRß, while 2/14 cases were focally and weakly positive in <50% of tumor cells. 5/14 ESS showed no staining for PDGFRß. For PDGFRa, 3/14 ESS showed a strong positivity in >50% of tumor cells. 4/14 cases were focally and weakly positive and 7/14 cases were negative for PDGFRa.
Conclusion: c-KIT negative ESS express PDGFRß in >50% and PDGFRa in 25%. Our observations suggest that some patients with ESS may benefit from treatment with tyrosine kinase inhibitors. Further studies are necessary to prove that immunohistochemical PDGFRa/ß staining correlates with genetic mutations of PDGFRa/ß.

The growth of a tumoral mass requires remodeling of the extracellular matrix. The matrix metalloproteinase (MMP) are a family of endopeptidases that can degrade almost all the extracellular matrix components. Recent immunohistochemical studies have suggested that expression of MMP-2 and MMP-9 in endometrial carcinoma might play a critical role in neoplastic tissue invasion or metastasis, while cyclooxigenase-2 (COX-2) expression was related to immunomodulation and neoangiogenesis. Aim of this study was to investigate the role of MMP in endometrial carcinoma and the possible correlation with COX-2 expression.
mRNA expression of MMP-2 ,MMP-9 and COX-2 genes in 30 paraffin-embedded endometrial carcinomas and in 20 non neoplastic endometrial samples obtained from matched controls were investigated. Amplification of mRNA was

detected by reverse transcription-polymerase chain reaction (RT-PCR) assay and was measured quantitatively.
Amplification of MMP-2, MMP-9 and COX-2 was detected respectively in 62.5%, 25% and 25% of the endometrial carcinoma cases, while it was not detected in any non neoplastic endometrial samples. We observed a relation between the quantitative expression of MMP-2 in 1B and 1C FIGO stages compared to 2 and 3 stages. There was no significant relationship between the expression of MMP-9 and COX-2 and FIGO stages nor grade of differentiation nor clinical outcome possibly because of the low amplification. Interestingly, we observed a relationship between the expression of MMP-9 and of COX-2 possibly indicating a common role on tumor related angiogenesis. To our knowledge this is the first report describing MMPs and COX-2 quantitative expressions in endometrial cancers by molecular biology techniques.

O-107
THE ROLE OF LEIOMYOCITE'S PROLIFERATION, HYPERTROPHY AND APOPTOSIS IN UTERUS LEIOMYOMAS.

PhD VE Ignatova
Prof. EA Kogan

Introduction. The mechanisms of growth of benign and malignant tumors are different. Uterus leiomyomas are benign tumor but sometimes they may grow very rapidly . So the purpose was to investigate the role of leiomyocite's proliferation, hypertrophy and apoptosis in uterus leiomyoma's histological variants.
Methods. The research was conducted basing on operating materials, which were taken from 75 patients of age from 18 up to 76 years old with diagnosis of Lm of uterus. Histological researches were conducted with paraffin slides with hematoxylin and eosin staining. Immunohistochemical staining was carried out on serial paraffin slides according to the standard methods with antigen retrieval in microoven and with the usage of primary antibody to EGF (Santa Cruz Biotechnology, 1:100), EGF-R (Santa Cruz Biotechnology, 1:100), PDGF (Calbiochem, 1:100), IGF-1 (Pepro Tech EC LTD, 1:100), Ki-67 (DAKO, 1:50), PCNA (DAKO, 1:100), Fas receptor (DIANOVA, 1:50). LSAB KIT (DAKO) was used for secondary antibodies and visualizing system.
Results. The leiomyoma (Lm) and her variants cellular and mitotically activite Lm distinguish themselves in morphological structure and the mechanisms of growth. The main pathological processes in the growth of Lm are: proliferation, hypertrophy and apoptosis of leiomyocites, stroma formation and secondary changes in the growth. In the different types of Lm, the correlation of these processes may vary. The maximum level of proliferation markers is observed in mitotically activite Lm and defines the development of the tumor. The highest level of apoptosis of leiomyocites is detected in Lm. The lowest level of apoptosis – in the cellular and mitotically activite Lm, what may contribute to the prolongation of the life cycle of leiomyocites in combination with relatively high proliferation of cells accumulation and the development of the tumor growth. The correlation of proliferation processes and apoptosis in the Lm and her variants cellular and mitotically activite Lm varies, and according to this fact, we draw the conclusion about the different mechanisms of their growth. The increase of size of Lm is the result not only of proliferation of tumor cells, but also of hypertrophy under the influence of EGF, EGF-R, IGF-1, PDGF and also the proliferation of stroma elements and its secondary modifications.

O-108
OVARIAN CARCINOMA CELLS AND IL-1BETA ACTIVATED HUMAN PERITONEAL MESOTHELIAL CELLS ARE POSSIBLE SOURCES OF VASCULAR ENDOTHELIAL GROWTH FACTOR IN INFLAMMATORY AND MALIGNANT PERITONEAL EFFUSIONS

STADLMANN Sylvia,1 AMBERGER Albert,2 POLLHEIMER Juergen,3 GASTL Guenther,4 OFFNER Felix Albert ,5 MARGREITER Raimund,2,6 ZEIMET Alain Gustave 7

Objective: Inflammatory or malignant peritoneal diseases are associated with high levels of ascitic vascular endothelial growth factor (VEGF). We compared the VEGF secretion by human peritoneal mesothelial cells (HPMC) and ovarian carcinoma (OVCA) cells and its regulation by pro-inflammatory cytokines.
Material and methods: VEGF secretion in cultured HPMC, established human OVCA cell lines, and inflammatory or OVCA-associated ascites was determined by enzyme linked immunosorbent assay.
Results: HPMC constitutively produced VEGF at median levels of 43 ± 7 pg/105 cells. Treatment of HPMC with 1 ng/ml IL-1? (567 ± 213 pg/105 cells;) or TNF-? (89 ± 1 pg/105 cells) resulted in a 13-fold ($p < 0.01$) or 2-fold ($p < 0.05$) elevation of the VEGF secretion. In OVCA, the constitutive VEGF expression was 8-fold higher than VEGF levels in HPMC (364 ± 185 pg/105 cells; $p < 0.001$). VEGF secretion in OVCA cells was also increased by IL-1? (514 ± 105 pg/105 cells; $p < 0.01$) or TNF-? (458 ± 168 pg/105 cells; $p < 0.01$) reaching similar levels as in IL-1? activated HPMC. Median VEGF levels in malignant ascites (2,761 ± 1549 pg/ml) were 11-fold higher compared with levels in inflammatory fluids (244 ± 170 pg/ml; $p < 0.01$). VEGF levels in both, inflammatory- and OVCA-associated fluids, correlated with ascitic IL-1? levels ($p < 0.05$).
Conclusion: We identified ovarian cancer cells and/or IL-1? activated peritoneal mesothelial cells as important sources of ascitic VEGF. The present data indicate that IL-1? triggered VEGF production by neoplastic and normal cells is a common pathomechanism for ascites formation in both inflammatory and malignant conditions.

USE OF MESOTHELIN IN DIAGNOSING PANCREATIC CARCINOMA ON FNA SPECIMENS.

Molinié Vincent (1), Marty Olivier (2), De Pinieux Isabelle (1), Homsi Toufik (1), Balaton André (1). Pathology (1) and gastro enterology (2) department Hôpital saint Joseph Paris France.

Background: diagnosis of fine needle aspiration (FNA) of pancreatic carcinoma can be difficult due to morphologic overlap with reactive processes. Mesothelin is a 40kDa glycoprotein attached to the cell surface by phosphatidylinositol. Overexpression of mesothelin has been reported in the majority of the pancreatic ductal carcinoma but not non-neoplastic ductal epithelium. This objective of the study is to evaluate the use of mesothelin as a marker for pancreatic ductal adenocarcinoma on FNA specimens.
Design: 30 cell blocks of pancreatic EUS-FNA from 30 patients (18 females and 12 males with a median age of 62 years) were retrieved. All cases were AFA fixed an paraffin embedded. Sections were cut at 4 microns and immunostained with anti-mesothelin antibody (clone: 5B2; dilution 1:60; Novocastra Lab Ltd., New Castle upon Tyne, UK). Immunostaining was performed on an automated stainer (Dako stainer). Seven FNAs were from patients with reactive/inflammatory conditions. The remaining 23 FNAs included 16 pancreatic ductal carcinoma, 1 intracystic papillary mucinous carcinoma (IPMT), 5 neuroendocrine cell neoplasm, 1 lymphoma. The presence of immunoreactivity in

more than 10% of the tumor cells, irrespective of level of intensity, was considered positive for mesothelin expression.
Results: 80% of the pancreatic ductal carcinomas and the IPMT demonstrated positive staining with mesothelin, ranging to focal to diffuse. Positive staining epithelial cells showed intense cytoplasmic staining especially at the apical (luminal) aspects with variable membranous staining. None of the benign aspirates was positive for mesothelin. None of the non-ductal neoplasms demonstrated mesothelin expression. The difference in mesothelin expression between pancreatic ductal carcinoma and other lesions was statistically significant ($p<0.0001$, Fisher exact test). The sensitivity and specificity of mesothelin as a marker for pancreatic ductal carcinoma were 97% and 90%, respectively.
Conclusions: Mesothelin is overexpressed in pancreatic ductal carcinoma with an intense apical cytoplasmic and variable membranous staining pattern. Our results suggest that the phenotypic expression of mesothelin can be used as a diagnostic marker of pancreatic ductal adenocarcinoma in EUS-FNA specimens.

DIFFERENT PATTERN OF P16 AND P53 PROTEIN EXPRESSION IN INTRADUCTAL PAPILLARY-MUCINOUS NEOPLASMS AND PANCREATIC INTRAEPITHELIAL NEOPLASIA

KUME Keiko, SUDA Koich, YAMASAKI Sigetaka, SONOUE Hiroshi, MITANI Keiko, NOBUKAWA Bunsei
Department of Pathology I, Juntendo University School of Medicine, Tokyo Japan

Introduction Intraductal papillary-mucinous neoplasms (IPMNs) are precursors of invasive ductal adenocarcinoma of the pancreas as the same way pancreatic intraepithelial neoplasias (PanINs) are. Their morphological similarity causes some confusions of their nomenclature and criteria. An illustrated consensus classification of the intraepithelial lesions in the pancreatic ducts, PanINs and IPMNs, are achieved in 2004. Though IPMN is recognized as a distinct group of lesions apart from PanINs, their genetic progression models for pancreatic cancer are thought to be considerably common.
Purpose The purpose of this study is to examine aberrations and differences of cell cycle regulatory proteins between IPMNs and PanINs.
Materials and Methods The protein expression of p16, p53 and 14-3-3ƒÐ were examined by immunohistochemistry both in 47 IPMN lesions (22 hyperplastic lesions, 12 adenomas and 13 adenocarcinomas) from 26 patients with IPMN and in 40 PanIN lesions (12 PanIN1, 20 PanIN2 and 8 PanIN3) from 11 patients with invasive pancreatic ductal cancer. We compare the percentage of immunohistochemical positivity between groups as follows: PanIN1 and hyperplastic lesion of IPMNs, PanIN2 and adenoma of IPMNs, PanIN3 and carcinoma in situ of IPMNs. Ki-67 labeling index (LI) was also counted in each lesion. Statistical analysis was conducted with Fisher• fs exact test and Kruskal-Wallis test, respectively.
Results Loss of p16 protein expression was much more frequently observed in PanIN3 than in intraductal papillary-mucinous carcinoma (IPMC) ($p=0.046$). Overexpression of p53 protein was much more prominent in PanIN1 and PanIN2 than in hyperplastic lesions and adenoma of IPMNs ($p=0.011$ and 0.004, respectively). Ki-67 LI was correlated with histological grades of both PanINs and IPMNs ($p=0.0001$, $p=0.0001$). The percentage of 14-3-3ƒÐ protein expression was not significantly different between IPMNs and PanINs.
Conclusion Loss of p16 protein expression might be a supportive factor for distinction between PanIN3 and IPMC. It may be possible to distinguish PanIN1 and PanIN2 from IPMNs showing the same as degree of dysplasia by using p53 immunohistochemical stain.

O-111
FROZEN-SECTIONS OF THE PANCREATIC CUT SURFACE DURING PANCREATECTOMY FOR INTRADUCTAL PAPILLARY AND MUCINOUS TUMOURS (IPMT) ARE USEFUL AND RELIABLE: A PROSPECTIVE EVALUATION.

COUVELARD Anne (1), KIANMANESH Reza (2), HAMMEL Pascal (3), COLNOT Nathalie (1), LEVY Philippe(3), RUSZNIEWSKI Philippe (3), BEDOSSA Pierre (1), BELGHITI Jacques (2), SAUVANET Alain (2). Departments of Pathology (1), Digestive Surgery (2) and Gastroenterology (3), Beaujon hospital, AP-HP, University Paris VII, Clichy, France.

Introduction: IPMT are associated with a significant risk of malignant transformation which is higher for main-duct (MD) types than branch-ducts (BD). Preoperative imaging is not reliable for precise evaluation of tumour topography. Frozen-sections (FS) of the pancreatic cut surface have been proposed into guide pancreatic resection.
Aims: Evaluate the accuracy of FS of the pancreatic cut surface during pancreatectomy for IMPT and its influence on the surgical procedure.
Patients and Methods: From 1996 to 2004, 154 pancreatectomies were performed for IPMT at our institution. IPMT type included: 56 BD and 98 MD or mixed variants, with no dysplasia (IMPT-adenoma [A]; n=55), moderate dysplasia (IPMT-borderline [B]; n=27), carcinoma in situ (CIS; n=35) or infiltrating carcinoma (n=37). FS was performed in 127 procedures, including 90 pancreaticoduodenectomies (with 1-4 successive FS, giving a total number of 132 FS), 23 distal pancreatectomies (1-2 FS; total=26) and 14 medial pancreatectomies (2-4 FS; total=30). Pancreatectomy was extended if FS revealed at least IPMT-adenoma on the main duct or IPMT-borderline on branch ducts (so-called “significant” lesions).
Results: (a) Results of FS (n=188): MD epithelium was normal (n=120), eroded (n=15) or revealed A (n=33), B (n=11) or CIS (n=5) lesions. BD epithelium was normal (n=106) or revealed A (n=65), B (n=8) or CIS (n=5) lesions. FS revealed infiltrating carcinoma in 4 cases. Overall, 54/188 (29%) of FS revealed « significant » lesions. (b) Comparison FS-definitive pathology: definitive pathology and FS were identical in 176/188 cases (94%). 12 conflicting results included 9 cases of «underestimation» and 3 cases of «overestimation» by FS. (c) Influence of FS on surgery: 54 FS with significant lesions lead to 46 additional resections (n=38 patients, 30%). Additional resection was not performed in 8 cases due to either high operative risk or simultaneous diagnosis of infiltrating carcinoma of poor prognosis. The 134 FS without «significant» lesions were associated with additional resection in 7 patients, due to either macroscopic suspicion of tumour in another localization or erosion of epithelium. Inadequate results of FS resulted in inadequate resection in 4 patients (3%).
Conclusions: During pancreatectomy for IPMT, frozen sections of the pancreatic cut surface is useful since it changes the extent of resection in 30% of patients. It is reliable, resulting in adequate resection in 97% of patients.

Introduction: The identification of precursor lesions has a great impact on the understanding of tumorigenesis. Precursor lesions of endocrine tumors are known to occur in the setting of the MEN1 syndrome. Purpose of the study: The aim of this study was to test the hypothesis of the development of MEN1-associated duodenal gastrinomas from preneoplastic gastrin cell proliferations. This hypothesis is based on the fact that MEN1-associated duodenal gastrinomas are usually multiple, in contrast to sporadic gastrinomas. Methods: The distribution of endocrine cells in the nontumorous duodenal tissue was analyzed qualitatively and quantitatively in 25 patients, who underwent surgery for duodenal gastrinoma. The MEN1 status was assessed clinically and by PCR based mutational analysis. Results: Fourteen of 25 gastrinoma patients had proliferative, hyperplastic lesions consisting of gastrin cells in the nontumorous duodenal mucosa similar to the gastric ECL cell lesions observed in chronic atrophic gastritis. All ZES patients with proven MEN1 had such proliferative gastrin cell lesions, and all ZES patients without precursor lesions were MEN1 negative. Conclusions: Duodenal gastrinomas in MEN1, but not sporadic duodenal gastrinomas, are associated with gastrin cell proliferation within the nontumorous mucosa. It is likely that these lesions precede the development of MEN1-associated duodenal gastrinomas.

MARKEDLY ALTERED EXPRESSION OF TIGHT JUNCTION PROTEINS DIFFERENTIATE PRIMARY HUMAN HEPATOCELLULAR CARCINOMAS AND METASTATIC LIVER TUMORS.

KISS Andras1, PASKA Csilla1, ORBAN Erika1, SZIJARTO Attila2, KUPCSULIK Peter2 and SCHAFF Zsuzsa1
1 2nd Inst. of Pathology, Semmelweis Medical University, Budapest, Hungary
2 1st Dept. of Surgery, Semmelweis Medical University, Budapest, Hungary

Background: Tight junction proteins as claudins, occludin and JAM or peripheral zonula occludens (ZO) proteins are widely implicated in carcinogenesis. Claudins (1-24) have been recently identified as integral proteins of the tight junction strands. Claudin-4 has not been found in normal hepatocytes or bile duct epithelium. Claudin 3 and 4 can function as the receptor of the Clostridium perfringens enterotoxin. Further, downregulated claudin 1 is associated with poor prognosis of colon carcinoma and claudin 10 expression is associated with the recurrence of hepatocellular carcinoma (HCC). Aim: The objective was to characterize the expression of claudin 1-4, 7, occludin, JAM 1-2 and ZO 1-3 in human HCCs and liver metastases. Material and methods: 19 human HCC, 15 colon metastasis samples, surrounding nontumorous livers and 7 normal livers were examined by real-time RT-PCR, immunohistochemistry and Western blotting. Results: Claudin 4 in HCCs was found downregulated 3.4 folds and 43 folds compared to normal livers and metastases, respectively. Western blot data confirmed minimal expression of claudin 4 in HCC, however, immnohistochemistry detected the presence of claudin-4 on bile ducts. Claudin 3 mRNA epression was 12 fold higher in metastases compared to HCC. Metastatic tumors showed strong claudin-3 and 4 immunolabeling while HCC cells gave only partial and weak positivity. Claudin 1, nevertheless, showed 3 fold higher expression in HCCs. Claudin 2 in HCCs revealed 3 fold downregulation in comparison to normal liver, however, there was no significant difference between HCCs and metastases. Claudin 7 mRNA expressions were eleveted in metastases and HCCs in comparison to normal liver but there was no significant difference between primary and metastatic liver tumors. Western blot analysis supported the results found by immunohistochemistry. ZO-2 and JAM-2 mRNA expression was found significantly decreased in HCCs compared to the surrounding tissue: 4 and 3 fold, respectively. Conclusion: Taken together, pronounced downregulation of claudin 3 and 4 and higher expression of claudin 1 might differenciate primary hepatocellular carcinomas from metastatic colorectal tumors. The high level of claudin 3 and 4 in liver metastases might serve as target of adjuvant therapy. Biological role and significance of altered claudin expression should be elucidated. The project was supported by grants: NKFP-1/0023/2002, NKFP-1A//002/2004, OTKA T-049559

Background: Hepatocellular adenomas are benign tumors that can be difficult to diagnose. To refine their classification, we performed a comprehensive analysis of their genetic, pathological and clinical features.
Methods: A retrospective multicentric series of 96 liver tumors with a firm or possible diagnosis of hepatocellular adenoma was reviewed by a panel of liver pathologists. In all cases, the genes coding for hepatocyte nuclear factor 1alpha (HNF1alpha) and ß-catenin were sequenced.
Results: No tumors was mutated in both HNF1alpha and ß-catenin enabling tumors to be classified into 3 groups, according to genotype. Tumors with HNF1alpha mutations formed the most important group of adenomas (44 cases). They were phenotypically characterized by marked steatosis ($p<10^{-4}$), lack of cytological abnormalities ($p<10^{-6}$) and inflammatory infiltrates ($p<10^{-4}$). In contrast, the group of tumors defined by ß-catenin activation included 13 lesions with frequent cytological abnormalities and acini foci ($p<10^{-5}$). In the third group of tumors, without HNF1alpha or ß-catenin mutation, we identified a subgroup of 17 inflammatory lesions, resembling telangiectatic focal nodular hyperplasias, with frequent cytological abnormalities ($p=10^{-3}$), ductular reaction ($p<10^{-2}$) and dystrophic vessels ($p=0.02$). In this classification, hepatocellular carcinoma associated with adenoma or borderline lesions between carcinoma and adenoma is found in 46% of the ß-catenin

mutated tumors whereas they are never observed in inflammatory lesions and are rarely found in HNF1alpha; mutated tumors (p=0.004).
Conclusions: The molecular and pathological classification of hepatocellular adenomas permits the identification of strong genotype-phenotype correlations and suggests that non-inflammatory adenomas and particularly those with ß-catenin activation have a higher risk of malignant transformation.

COMBINED HEPATOCELLULAR-CHOLANGIOCARCINOMA IN A SINGLE EUROPEAN CENTER: CLINICO-PATHOLOGIC FEATURES AND OUTCOME.

D Cazals-Hatem, F Dondero, V Paradis, O Farges, F Durand, C Francoz, J Belghiti, P Bedossa.
Departments of Pathology, Hepatology and Surgery, Hôpital Beaujon, 92118 Clichy, France

Backgrounds: Combined hepatocellular-cholangiocarcinomas (HCC-CC) are rare and described in Asia as an aggressive hepatocellular carcinoma (HCC) variant. In United States, none of the HCC-CC recently reported arose in cirrhosis. Clinical, pathological and prognostic features of HCC-CC observed in Europe are not established.
Patients & Methods: between 1988 and 2004, 712 patients underwent liver resection or transplantation for primary liver cancer in a single center; HCC-CC was diagnosed in 29 patients on histological analysis. Clinical, pathological, immunohistochemical and follow-up data were retrospectively analyzed (using antibodies of cytokeratin (CK)7, CK19, CK20, of Hep Par 1 and p53).
Results: All patients (mean age at diagnosis: 58 yo) were Caucasian and 90% were men (26 out of 29 patients). The prevalence of positive hepatitis B or C serology and of genetic hemochomatosis cirrhosis were 38% and 10% respectively. Twelve patients (41%) displayed cirrhosis and 12 (41%) a normal background liver. Mean tumor size was 6.2 cm; 19 patients (66%) needed a major hepatectomy and 7 patients (24%) were transplanted. Most HCC-CC presented with a single mass with admixed hepatoid and cholangiolar components both positive for CK7 and/or CK19; p53, Hep Par1 and CK20 expression were present in 50%, 41% and 23% of them respectively. Vascular invasion, satellite nodules and metastasis were observed in respectively 90%, 62% and 21% of all HCC-CC. The median overall survival after resection was 34 months. One, 3, 5 years survivals were respectively 69%, 45% and 36%. Five of the 7 transplanted patients were alive at 3 years without recurrence (48±28 months).
Conclusion: HCC-CC in Europe presented with intermediate clinico-pathologic features between Eastern and Western series and similar adverse outcome. LT should offer curative treatment for HCC-CC if Milano criteria are respected, similarly to HCC.

EXPRESSION OF CLASS I MHC MOLECULES AND TAPASIN IN PRIMARY HUMAN HEPATOCELLULAR CARCINOMA

FRANCESCHINI Barbara (1, 3), GRIZZI Fabio (1, 3), BOSSI Paola (2), CEVA-GRIMALDI Giorgia (1, 3), DIOGUARDI Nicola (1, 3), CHIRIVA-INTERNATI Maurizio (4)
1) Scientific Direction and 2) Pathology Department, Istituto Clinico Humanitas, Rozzano, Milan, Italy; 3) “M. Rodriguez” Foundation, Milan, Italy; 4) Department of Microbiology and Immunology, Texas Tech university, Lubbock, TX, USA.

Introduction. Major histocompatibility complex (MHC) class I molecules present short peptides, produced in cytosol through proteolytic breakdown of antigens, to cytotoxic T lymphocytes. The stable assembly of MHC class I molecules with peptides in the endoplasmic reticulum involves several resident chaperones. One of these accessory proteins is called Tapasin. It is a trasmembrane protein that mediates the binding of MHC class I molecules to the peptide transporter associated with antigen processing. Tapasin also plays a quantitative role in antigen presentation, and deficient tapasin expression appears to be a frequent event in human neoplastic cells of unrelated histological origin. Purpose. To investigate the expression of MHC class I molecules and tapasin in primary hepatocellular carcinomas (HCC). Methods. MHC class I molecules [heavy chain (HC-10) and ß2-microglobulin] and tapasin expression were recognized by immunohistochemistry in paraffin-embedded and formalin-fixed specimens taken from patients free of neoplastic liver disease (n=5), and affected by primary HCC (n=20). Results. All the investigated proteins were found in scattered normal hepatocytes and infiltrated T lymphocytes. Biliary cells were also found immunopositive, while sinusoids express only MHC class I molecules, but not tapasin. Although trabecular HCCs were immunonegative, the pseudoglandular histotype was found lowly immunopositive for all the investigated antigens. Conclusions. The obtained results demonstrate that liver parenchymal cells moderately express MHC class I molecules and tapasin. This seems linked to the liver complex organismal functions. Interestingly, pseudoglandular tumour express MHC class I molecules and tapasin. However the un-expression of these molecules in some HCCs (i.e. trabecular histotype) stimulate us to further investigate their association with the prognosis of the neoplastic disease, and to explore this peculiar behavior as tumor escape mechanism.

(2) Research Fellow FNRS(National Fund of Scientific Research), BELGIUM
(3) Department of Intensive Care and Thoracic Oncology, Institut Jules Bordet, Brussels, BELGIUM
(4) Department of Pneumology, Saint-Pierre University Hospital, Brussels, BELGIUM

Background:P53 is one of the most important genes in oncogenesis and in the development of lung cancer. MDM2 is one of the proteins playing an essential role in p53 regulation.
The objective of the present study is to assess MDM2 expression in different grades of bronchial squamous precursor lesions and in invasive squamous cell carcinoma (SQCC). We also tried to correlate MDM2 and p53 expression in the same biopsies.
Patients and methods: An immunohistochemical assessment of MDM2 and p53 expression was performed in 91 biopsies obtained by fluorescence bronchoscopy in patients at high risk for lung cancer.
Results: 38 biopsies (46%) overexpressed MDM2. Overexpression of MDM2 was found in 23 % of normal tissues, 25% of hyperplasias, 40% of epidermoid metaplasias, 86% of mild dysplasias, 83 % of moderate dysplasias, 83 % of severe dysplasias, 100% of carcinomas in situ and in 75 % of invasive carcinomas. MDM2 expression was found to be significantly different in low versus high grade lesions. When MDM2 expression was increased, the positive predictive

value (PPV) to be a high grade bronchial premalignant lesion was 26%. With reference to high grade dysplasia, lack of MDM2 overexpression had a negative predictive value (NPV) of 95.5%.
Seventy-two percent of the biopsies were positive for p53. We found a high statistically significant association between positivity for MDM2 and p53 (p=0.0015). When the biopsy was overexpressing neither MDM2 nor p53, the NPV for a high grade lesion was 92.7%.
Conclusion: MDM2 which is an important negative regulator of p53, is overexpressed early in bronchial preneoplastic lesions from the stage of mild dysplasia, playing thus an early role in lung SQCC carcinogenesis. Lack of MDM2 expression predicted the absence of high grade lesion better than the negativity of the p53 protein.

KLF-4 AND C-FOS ARE DOWNREGULATED IN NON-SMALL CELL LUNG CARCINOMAS. A GENE EXPRESSION AND TISSUE MICROARRAY ANALYSIS

GOMEZ-ROMAN Jose Javier, RODRIGUEZ Ana1, LOPEZ-BREA Marta2, MONS Roberto3, CUEVAS GONZALEZ Jorge, VAL-BERNAL J. Fernando
Dpto Anatomía Patológica, 1Genómica SAU. Madrid, 2S. Oncología Médica, 3S. Cirugía Torácica. Hospital Universitario Marqués de Valdecilla. Santander (Spain)

Background: Lung cancer can be classified in two groups Small and Non small cell carcinomas, because the different clinical setting, biological behaviour, molecular properties, and treatment. On the other hand, genetic changes contributing to tumor development determine tumor phenotype. Thus, markers based on those genetic changes should provide predictive power and robust diagnostic tools. In this sense, DNA array technology is a powerful tool to monitor the expression of thousands of genes. The term gene expression profiling means the process of establishing the pattern of expression of thousands of individual genes simultaneously in a given cell or tissue sample by extracting its RNA, converting it to cDNA and hybridizing the labeled cDNA or cRNA to a DNA microarray. We show here the results of a collaborative project between the Pathology Department of the Hospital Universitario Marqués de Valdecilla in Santander (Spain) and Genomica SAU (Madrid). Our aims were to describe the gene expression pattern in pulmonary non-small cell carcinomas.
Methods: 29 non-small cell lung carcinomas and 18 pulmonary non-neoplastic tissue samples from the frozen sample tissue bank of the Pathology department (Spanish tumor network), were evaluated by cDNA microarrays. A 9128-cDNA clonal elements microarray from a commercial library (Human UniGene 1, Incyte Genomics) was constructed (MICROGRID II, Biorobotics). In each microarray the expression profiling of tumoral and non-neoplastic samples was compared to the results of a control cell line. In all cases, we perform a sample morphological control (frozen section H&E stained). Moreover, as an internal control, a set of Housekeeping Genes was included in each assay. KLF-4 and c-Fos were validated by quantitative RT-PCR. Tissue microarray immunohistochemistry was performed in 146 carcinomas.
Results: We have found several groups of genes differentially expressed in adenocarcinomas, squamous cell carcinomas and large cell carcinomas, as well as differences between clinicopathological stages. In supervised bioinformatic analysis, 78 genes were capable to discriminate between neoplastic and non neoplastic samples with a positive predictive value higher than 83%. KLF-4 and c-Fos were both downregulated in mRNA and protein validation studies.
Conclusions: It is possible to establish a molecular signature in non-small cell lung carcinomas. KLF-4 and c-Fos could act as tumor suppressor genes in these kind of neoplasms.

O-119
TUMOUR EXPRESSION AND ACTIVITY OF MMP-2 AND MMP-9 METALLOPROTEINASES IN NON SMALL CELL LUNG CANCER ACCORDING TO TFPI-2 GENE EXPRESSION.

BLECHET Claire, ROLLIN Jerome, IOCHMANN Sophie, LEMARIE Etienne, REVERDIAU Pascale, GUYETANT Serge, GRUEL Yves.
INSERM U618 "Protéases et vectorisation pulmonaire" and IFR 135 Faculté de médecine 10 Bd Tonnelé 37032 TOURS Cedex

Background
MMP-2 and MMP-9 are two metalloproteinases that degrade components of extracellular matrices (ECM) and thus are playing a key role in tumour invasion. Their activation in ECM could be regulated by Tissue factor pathway inhibitor 2 (TFPI-2), a serine protease inhibitor that reduces tumour invasion. We recently demonstrated that TFPI-2 gene expression was decreased in part of non small cell lung cancer (NSCLC). The aim of this study was therefore to determine MMP-2 and MMP-9 expression and activity in NSCLC and to investigate if a relationship could be found in NSCLC between tumour TFPI-2 expression and levels of activated MMP-2 and -9.
Methods
MMP-2 and MMP-9 mRNA expression was first evaluated by specific real-time PCR in tumours and non-affected lung tissues of 57 patients who had underwent surgical excision for NSCLC. We then established, by immunohistochemistry, immunostaining scores of stromal cells and tumour cells for both proteins, and we studied the MMP-2 and MMP-9 activity by gelatine zymography in 27 patients selected according to TFPI-2 tumoral expression that was previously quantified by real-time PCR. In 14 NSCLC tumours (“TFPI-2 low”), less than 300 TFPI-2 mRNA copies were measured while in the 13 other cases (“TFPI-2 high”) TFPI-2 gene expression was higher (> 2000 copies).
Results
The expression of MMP-9 was significantly higher in lung tumours than in corresponding normal tissues (95 vs 30 mRNA copies, p=0,0005) whereas MMP-2 mRNA levels were not significantly different (4382 vs 4241 mRNA copies, p=0,51). The levels of MMP-2 and MMP-9 mRNA in tumours were negatively related to lymph nodes status (p=0.05 and p=0.025 respectively).
All tumours expressed MMP-2 and MMP-9 proteins. However, MMP-2 immunostaining scores were higher in stromal cells that in cancerous cells (80 vs. 20 respectively, p=0.004) whereas MMP-9 scores were higher in cancerous cells than in stromal cells (110 vs. 40 respectively, p=0.0016). The relative amounts of activated forms of MMP-2 and MMP-9 were significantly higher in tumours compared with non-affected tissues, but without significant difference between “TFPI-2 high” and “TFPI-2 low” groups.
Conclusions
MMP-2 and MMP-9 are mainly expressed by different cells in NSCLC, i.e. cancerous cells for MMP-9 and stromal cells for MMP-2. A low TFPI-2 gene expression does not appear to be associated with increased amounts of activated MMP in NSCLC tumours as evaluated by zymography.

Lung cancer is a leading cause of mortality worldwide and despite progress in management the 5 years survival rate remains under 15%. In this group of cancers, it is known that non small cell lung cancer (NSCLC) is genetically and morphologically heterogeneous. Classifying cancer upon genetic abnormalities has become a challenge since the evidence that the success of targeted therapy is closely related to the existence of specific molecular alterations One evidence in NSCLC is the recent identification of a subgroup of patients with obvious response to gefitinib (Iressa), an inhibitor of EGFR. It was shown that sensibility to gefitinib was linked to the presence of EGFR mutations in tumors. EGFR activates intracellular proliferative and anti-apoptotic signaling pathways. The inhibition of mutated EGFR by getifinib leads to dramatic tumor response.
The goal of this work was to individualize tumors based upon EGFR pathway abnormalities. Ninety-four patients (48 men and 46 women) with surgery as first line treatment for NSCLC were enrolled in this study. Clinicopathological parameters were collected (age at surgery, smoking status, histology and tumor stage). For each subjects a frozen tumor sample was speared for DNA extraction and pathological control. Moreover Immunochemistry (IHC) with anti EGFR antibody was performed on paraffin sections. Tumors were screened for mutations in EGFR, HER2, HER3, K-ras and TP53 and in major down stream effectors by direct sequencing.
Fourteen patients harbored EGFR mutated tumors (14/96) and showed a particular phenotype. EGFR alterations were statistically linked to female gender, absence of smoking, adenocarcinoma with a BAC compound and absence of K-ras mutation. No correlation was found with TP53 mutations or anti EGFR IHC analysis.
The finding that EGFR mutations segregated essentially in BAC or in adenocarcinoma with BAC compound, raised the question of which adenocarcinoma subtypes harbor the mutated allele. To answer this question, EGFR mutation screening in microdissected tumors harboring adenocarcinoma with BAC compound will be undertaken separately on each subtype. The restriction of the mutation to a cluster of tumor cells could have important consequences on gefitinib response rates and the quantification of the BAC compound in adenocarcinoma could have major clinical impacts.

SARCOMATOID CARCINOMAS OF THE LUNG – ARE THESE HISTOGENETICALLY HETEROGENEOUS TUMOURS?

Markus Blaukovitsch, Iris Halbwedl, Hannelore Kothmaier, Helmut H. Popper
Laboratories for Molecular Cytogenetics, Environmental and Respiratory Tract Pathology, Institute of Pathology, Medical University of Graz, Austria

Introduction: Sarcomatoid carcinomas (SC) of the lung are a heterogeneous group of poorly differentiated, rare non-small cell lung carcinomas (NSCLC) containing a sarcoma or sarcoma-like component. SC may represent malignant epithelial neoplasm undergoing divergent tissue differentiation originating from a single clone. Furthermore, epithelial mesenchymal transition (EMT) best describes the origin of the sarcoma-like appearing components of the SC.
Purpose: The aim of this study was to find any concordant chromosomal aberrations within the subgroups of SC and how they correlate with the EMT hypothesis.
Methods: 23 cases of SC were investigated by means of chromosomal comparative genomic hybridisation (c-CGH). Immunohistochemical staining was performed with antibodies reactive with E-Cadherin (epithelial marker) and Snail, TGFß1, c-Fos (EMT related proteins).
Results: In contrast to the predominant NSCLC-types, where gains and losses are equally distributed, in our study gains occurred more frequently than losses (70, 5 % versus 29, 5 %). The shortest regions of overlap were gains on 8q and 7 followed by 1q, 3q and 19. We were also able to detect gains on chromosomes 11, 12p, 17q, 20q and 22q; losses were found on chromosomes 4q, 5q, 6q, 10q, 11q, 13, 15 and 16q.
The IHC revealed in 13 of 23 (56, 5 %) cases a negative and in 5 of 23 (22 %) cases a weak reaction for E-Cadherin. 20 of 23 (87 %) and 21 of 23 (91 %) cases were positively stained for TGFß1 and Snail, respectively. In addition 18 (78 %) of 23 cases had a positive reaction for c-Fos.
Conclusion: To our knowledge this is the first c-CGH study in SC. Our data show a homogenous pattern of chromosomal aberrations, which would support the single clone hypothesis. The corresponding IHC results suggest that the sarcomatoid appearing components of SC have undergone EMT and are of epithelial origin. To further elucidate EMT other members of this pathway will be investigated by IHC.

MALIGNANT LYMPHOMA INITIALLY DIAGNOSED IN THE LUNG – WHAT IS NECESSARY?

Ulrike Gruber-Mösenbacher1, Christine Beham-Schmid[2], Felix Offner1, Johannes Rothmund[2], Helmut H.Popper[3], Institutes of Pathology1, Department of Pulmology2, Academic Teaching Hospital Feldkirch1, and Medical University Graz3, Austria

Introduction: Malignant lymphomas affecting the lung are rare, especially primary non-Hodgkin-lymphomas (NHL). Secondary involvement of the lung in extrapulmonary NHL is reported in 25-40% of cases, but initial manifestation in the lung has rarely been reported. Especially clinically "indolent" courses of lymphomas tend to be overlooked and not included into the clinical differentials.
Material and Methods: 19 cases of NHL, initially diagnosed in the lung, were reviewed and classified according to the WHO. Demographic data, clinical and radiological diagnoses, extension of the infiltrates and types of diagnostic procedures were compared. All cases were immunotyped using a panel of CD-antibodies.
Results and Discussion: The histological diagnoses were: 6 diffuse large B-cell lymphomas (DLBCL), 6 marginal zone B-cell lymphomas of the mucosa-associated lymphoid tissue (MALT) type, 3 lymphomatoid granulomatoses (LYG), 2 peripheral T-cell-lymphomas, 1 post-transplant lymphoproliferative disease (PTLD). All DLBCL formed masses, and were easily diagnosed in the first biopsy (endobronchial or transbronchial) by routine stains and immunohistochemistry. The 6 marginal zone B-cell lymphomas were clinically uncharacteristic, presented radiologically as longstanding and often therapy-resistant "pneumonias" or atelectases. Three of them could be diagnosed in endo-or transbronchial biopsies, one of them in the third repeated biopsy. Three cases were only diagnosed in biopsies obtained by video-assisted thoracoscopic surgery (VATS). In the 2 peripheral T-cell-lymphomas the diagnosis could be established in small endoscopic biopsies, however, in these cases diagnosis was challenging. One of the lymphomatoid granulomatoses cases was diagnosed in CT-

guided needle biopsies, the two other cases of LYG were seen in wegde-resections.
Establishing the diagnosis in marginal zone B-cell lymphomas, lymphomatoid granulomatosis, and also in peripheral T-cell-lymphomas requires experience and may in some cases be exceedingly difficult. Especially when dealing with small endobronchial or transbronchial biopsies, the diagnostic features may be easily missed. Frequently there are also reactive changes, such as interstitial pneumonia, which may obscure the tumor cell infiltration. Molecular analyses of B-cell clonality or T-cell rearrangement may be necessary to firmly establish the diagnosis in some cases. Good clinical information is important for a timely diagnosis.

O-123
E-CADHERIN, N-CADHERIN, TTF-1 AND CD56 - ANTIBODIES THAT MAY HELP DISTINGUISH MESOTHELIOMATOUS FROM CARCINOMATOUS SPINDLE CELLS IN THE LUNG AND PLEURA.

FABRE Aurelie, PELLING Nathalie, RYAN Deirdre, NICHOLSON Andrew
Department of Histopathology, Royal Brompton and Harefield NHS Trust, London

Whilst well established for epithelioid neoplasms, the role of immunohistochemistry in differentiating malignant spindle cell lesions within lung and pleura is less certain.
Purpose of the study: We have therefore compared the immunophenotype of malignant spindle cells in 28 mesotheliomas to those in 23 primary pulmonary carcinomas.
Methods: Single tumour blocks (archival formalin-fixed paraffin-embedded tissue) from 28 mesotheliomas (sarcomatoid (n=21), biphasic (n=7)) and 23 primary pulmonary carcinomas (pleomorphic (n=21), spindle cell (n=1) carcinosarcoma (n=1)) were stained using the antibodies: anti-pan cytokeratins (CK) (MNF116), anti-TTF-1, a “mesothelioma” panel (anti-CK5/6, anti-calretinin anti-thrombomodulin) anti-CD56, anti-E-cadherin and anti-N-cadherin, Staining was assessed semi-quantitatively for intensity (strong = +++, moderate = ++, weak = +) and distribution (3 = > 50%, 2 = 10-50%, 1= <10% of cells).
Results: In terms of at least moderate intensity and distribution, 100% of mesotheliomatous and 96% carcinomatous spindle cells were positive for MNF116 (negative in carcinosarcoma only). All cases showed nuclear positivity for E-cadherin, but only carcinomatous spindle cells showed membrane staining with E-cadherin (0% vs 35%). This was mainly seen when spindle cells were part of cohesive sheets of tumour. N-cadherin (61% vs 4%) and CD56 (36% vs 0%) showed good specificity for mesotheliomatous spindle cells although weaker staining (1+) was more frequently seen (82% vs 26% and 60% vs 8% respectively). TTF-1 only stained carcinomatous spindle cells (30% vs 0%). Calretinin (65% vs 39%) and thrombomodulin (35% vs 17%) showed greater sensitivity for mesotheliomas but specificity was low. CK5/6 stained more carcinomas (8% vs 9%).
Conclusion: TTF-1, anti-E-cadherin (membranous staining), anti-N-cadherin, and CD56 antibodies may help in differentiating malignant spindle cell lesions of pleural mesotheliomas and pulmonary carcinomas, although interpretation must be in the context of histological appearance and clinical presentation.

O-124
AMPLIFICATION OF TOPOISOMERASE 2A GENE (TOP2A) IN MALIGNANT MESOTHELIOMA CELL LINES INVESTIGATED BY FLUORESCENCE IN SITU HYBRIDIZATION.

ORECCHIA Sara, SCHILLACI Francesca, SALVIO Michela, LIBENER Roberta, BETTA Pier-Giacomo. Pathology Unit. Dept of Oncology. Azienda Sanitaria Ospedaliera. Alessandria. Italy.

Introduction. Malignant mesothelioma (MM) is a tumour type that is particularly refractory to a number of different chemotherapy agents, yet the mechanisms by which resistance occurs are poorly understood. The pattern of resistance is consistent with disruption of topoisomerase (topo) function or expression. Topo enzymes help to relieve helical winding and DNA tangling problems produced by transcription or replication complexes tracking along DNA. The human genome contains five family members: topo I, IIA, IIB, IIIA and IIIB. Topo IIA is encoded by TOP2A gene adjacent to the HER2 oncogene at the chromosome location 17q12-q21. TOP2A amplification is often accompanied by HER2 gene amplification, e.g. in breast and bladder cancers. Amplification or deletion of TOP2A may account for sensitivity or resistance to topo II targeting drugs.
Purpose of the study. As part of an effort to evaluate the contribution of topo II alterations to drug sensitivity and resistance in MM, we have sought to identify the frequency of amplification of the TOP2A gene in a panel of human MM cell lines in which immunohistochemistry and fluorescence in situ hybridization (FISH) had previously demonstrated neither HER2 gene amplification nor overexpression.
Methods. 15 human MM cell lines established from pleural effusion samples from histologically confirmed MM patients, were analyzed by FISH using TOP2A FISH pharmDx™ Kit (DakoCytomation), designed to determine the copy number of the TOP2A gene related to the centromere of chromosome 17 (the TOP2A/CEN-17 ratio; ratio >2: TOP2A gene amplified).
Results. We found that 7/15 MM cell lines had disomy of TOP2A gene copy; in a MM cell line TOP2A gene and centromere 17 signals were located in two different chromosomes. Polysomy was present in 6/15 MM cell lines and the increase of TOP2A gene copies was related to chromosome 17 aneuploidy (4-5 copies/cell). TOP2A gene amplification was detected in 2/15 MM cell lines: two 17 isochromosomes were found in a MM cell line and in the other MM cell line the TOP2A/CEN-17 ratio was > 2.
Conclusions. While further study is required, we present preliminary evidence that the TOP2A gene amplification may occur without HER-2 coamplification, at least in one MM subset. This finding also highlights the importance of screening for TOP2A gene copy number aberrations when topo II inhibitors are considered either alone or combined with other chemotherapeutic drugs for the targeted treatment of MM patients.

TTF-1 EXPRESSION IN PLEOMORPHIC CARCINOMAS FROM THE LUNG AND PLEOMORPHIC MESOTHELIOMAS; THE EXPERIENCE OF THE MESOPATH GROUP

PACIENCIA Maria(1), ROULEAU Vincent(1), FLEURY Céline(1), DE QUILLACQ Anne(1,2,3), LAUNOY Guy(2), GALATEAU-SALLE Françoise(1,2,3) on the Behalf of the Mesopath Group(1) and under the auspices of the PNSM(3).
(1)Departement of Pathology-CHU de Caen, France
(2)INSERM ERI3-CHU Caen, France
(3)InVs, Hopital St Maurice, France

Background: Mesothelioma is a great mimicker of adenocarcinomas, other carcinomas and sarcomas and may be source of diagnostic difficulties.
The new 2004 WHO classification of lung tumors had proposed a new concept and unified a heterogenous group of non small cell carcinoma that contain sarcoma and sarcoma-like component under the designation: carcinoma with pleomorphic,sarcomatoid or sarcomatous elements (PC).

Mesothelioma was classified in four categories: epithelioid, sarcomatoid, desmoplastic and biphasic. Both sarcomatoid and epithelioid poorly differentiated mesothelioma may present pleomorphic features (PM) that are very misleading with PC.
The aim of this study is to analyse the relevancy of immunohistochemistry in the diagnosis of neoplasms with pleomorphic features and to evaluate the value of TTF1 alone or in combination with other markers to differentiate PM and PC.
Methods: 1779 mesotheliomas were selected from the Mesopath group diagnosed between April 1996-2003 and were validated according to the procedure of certification instituted by the Mesopath group. 2080 primary lung carcinomas were retrieved during the same period of time from the files of the departement of pathology CHU Caen.
Immunohistocheminal staining was performed using Ventana automated stainer with avidin-biotin-peroxydase methods. Negative control were included in each test by omission of the primary antibody and alveolar type 2 positive were used as a positive control for TTF1 and pan CK's, squamous cell carcinoma for CK5/6 and brain for calretinin. A tumor was considered postive if>10% of the neoplasic cells reacted with a clear cut signal on the relevant localization.
Results: 30 PM out of 1779 mesotheliomas were retrieved (<1,6%) and 31 PC out of 2080 primary lung carcinoma according to the WHO classification 2004 (<1,4%). AE1/AE3, KL1 and CK5/6 expression was observed respectively in 81%, 58% and 10% of PC and in 77%, 43% and 37% of PM. Calretinin expression was observed in 73% PM and in none PC while TTF1 expression was observed in 32% PC and in none PM.
Conclusion: We found that the combination of both calretinin and TTF1 was extremely useful in differentiating PM from PC. Additionally, we found that KL1 expression (80%) was more sensitive than AE1/AE3 expression (40%) for the diagnosis for PM while CK5/6 was poorly sensitive in both tumors (PC 10% and PM 32%).

WHAT ABOUT A SCALED SCORE FOR PAPILLARY CARCINOMA OF THE THYROID?

VERHULST Priscilla(1), DEVOS Patrick(2), AUBERT Sebastien(1), BUOB David(1), CRANSHAW Isaac(3), CARNAILLE Bruno(3), WEMEAU Jean-Louis(4), LETEURTRE Emmanuelle(1).
from departements of Pathology(1), Biostatistics(2), General and Endocrine Surgery(3) and Endocrinology(4), Lille, France.

The gold standard for the diagnosis of papillary thyroid carcinoma (PTC) remains morphologic criteria. This diagnosis, especially for the follicular variant of PTC, is subjective and variable even among experienced thyroid pathologists. The purpose of the study was to analyse the frequency of PTC morphologic features classically described in a series of 132 thyroid tumours. Then, we created a scaled score based on these morphologic features. We hoped this would illustrate the variety of morphologic presentations of follicular adenoma (FA) and PTC. Methods: 66 PTC and 66 FA were selected and matched for age, sex and presence of thyroiditis. Two independent observers delineated the following PTC morphologic features: papillary architecture; psammoma bodies; nuclear pseudoinclusion and grooves; enlarged, ground glass, ovoid, irregularly shaped and overlapping nuclei; lack of polarization in the cells; dark staining colloid; irregular contours of follicles; multinucleated macrophages. Statistical analyses were performed. Results: Under univariate analysis, all the PTC morphologic features were significantly more frequent in PTC than in FA (p<0,05). Under multivariate analysis, the most important criteria were: dark staining colloid (>25% of the tumour), nuclear grooves, enlarged nuclei, ovoid nuclei (>5% of tumour cells) and lack of polarization in the cells. Using factorial discriminant analysis, these 5 criteria allowed us to define a scaled score (range 0-79). If the threshold score for malignancy was set at >30, the score had a sensitivity of 98,5% and a specificity of 100% for the original diagnosis of PTC. On a validation population (29 PTC/29 FA), a score >30 was in agreement with the original diagnosis of PTC with a sensitivity of 72% and a specificity of 100%. 21/29 PTC scored >30 and 8/29 PTC scored <30 but >7. The majority of FA (21/29) scored < or =7, but a minority (8/29) had a score between 7 and 30. Therefore, there was a "grey zone" for cases which scored between 7 and 30. The original diagnosis for these cases included both FA and PTC. Conclusion: This score illustrates the variety of morphologic presentation of FA and PTC. However, we were unable to demonstrate a clear cut-off between the diagnoses of FA and PTC. The "grey zone" we have defined could argue for a category of "well differentiated tumour of uncertain malignant potential". The score could help in evaluation of new molecular markers for the diagnosis of PTC.

O-127
POST MENOPAUSE IS A PREDICTOR OF RECURRENCE IN PAPILLARY THYROID CARCINOMA AND IS ASSOCIATED WITH EPIDERMAL GROWTH FACTOR RECEPTOR – EGFR- EXPRESSION AND HIGHER FOLLICULAR CELL PROLIFERATION

GAMBOA-DOMINGUEZ Armando, SAQUI-SALCES Milena, ROCHA Brenda, CANDANEDO-GONZALEZ Fernando.
Patología. Instituto Nacional de Ciencias Médicas y Nutrición Salvador Zubirán. Mexico

Background: Papillary thyroid carcinoma (PTC) has worse prognosis after 45 years age. Aim: Identify if hormonal changes in women with PTC correlate with TNM, recurrence, EGFR and Ki-67 expression.
Design: Case control study nested in a retrospective cohort. Clinical data, hormonal status, follow-up, size, multicentricity and extra thyroid invasion were obtained from charts. Staging and classification were performed using AJCC/WHO systems. Post menopause was defined as absence of uterine bleeds >1 year and all were submitted to similar surgical procedures. Tissue arrays including one of remnant thyroid were constructed. EGFR (EGFRpharmDx) and Ki-67 (Dako) immunohistochemistry detection were performed; EGF-R was graded as 0, 1, 2, 3, and Ki-67 as an index of +ve cells. Post menopause, age and stage correlate with each other, and were analyzed separately. Uni and multivariate analysis were performed.
Results: 215 women were included, 154 pre and 61 postmenopausal with a mean follow-up of 71 months. At the time of diagnosis no differences were observed in pT, pM and higher pN was identified in pre menopause. Recurrences were observed in 30 patients (14%); mainly post menopause (p=0.008). Cox regression model controlled by size, node or distant metastases and, extra thyroidal invasion showed that post menopause had adverse effect on recurrence-free survival (p=0.041). EGFR was mainly expressed in postmenopausal (p<0.02) with higher Ki-67 indexes.
Conclusions: Postmenopausal status is an adverse factor in women with differentiated PTC and is associated with EGFR/Ki-67 +ve tumors. This is a biological explanation for currently used UICC/AJCC 45 y-o prognostic cutoff.

O-128
LYMPHATIC VESSEL DISTRIBUTION AND VEGF-C/VEGF-D PRODUCTION IN PAPILLARY CARCINOMA OF THE THYROID

Arianna Di Napoli*, Flavia Melotti*, Stefania Scarpino* and Luigi Ruco*
*Dipartimento di Diagnostica di Laboratorio, Ospedale Sant¡¦Andrea, Università ¡§La Sapienza¡¨, Roma, Italia

Introduction Lymphatic metastatization is the initial step of generalized spreading of papillary carcinoma of the thyroid. Because of the absence of specific markers for lymphatic endothelium, very few information is available about the lymphatic vascularization of papillary carcinoma, In the present study we have investigated the lymphatic vessel distribution in 22 cases of papillary carcinoma, and we have attempted a correlation with the levels of VEGF-C and VEGF-D present in tumour tissue and in primary cultures of papillary carcinoma.
MethodsThe lymphatic vessel distribution and the presence of VEGF-D were demonstrated in paraffin sections of 22 cases of papillary carcinoma using a mouse monoclonal antibody(IgG1) raised against podoplanin,1:50 dilution and a mouse monoclonal antibody(IgG1) anti human VEGF-D1:200dilution.
Total RNA was extracted from the tumour and from the peri-tumoral normal thyroid tissue microdissected from 6-8 ƒÝm frozen sections in 14 cases of PTC.RNAtranscripts for VEGF-C and VEGF-D, were evaluated by real time quantitative RT-PCR using the ICycler System.VEGF-C and VEGF-D expression was also investigated in RNA extracts obtained from 6 cases of primary cultures of PTC.
Results In all the investigated cases, podoplanin-positive lymph vessels could not be demonstrated inside the tumour. Large lymphatic lacunae, lined by podoplanin-positive flat endothelial cells, were frequently observed in the peritumoral normal thyroid; these latter showed occasional images of invasion by tumour cells. Quantitative analysis of RNA transcripts for VEGF-C and VEGF-D has indicated that these growth factors were more abundantly produced in the normal thyroid tissue as compared with the corresponding tumour tissue. VEGF-D mRNA transcripts were completely absent or poorly present in 6/6 cases of primary cultures of papillary carcinoma cells. Immunostaining for VEGF-D could be demonstrated in some normal thyroid follicles lined by tall cells.
Conclusion Our findings clearly indicate that most cases of papillary carcinoma do not contain intratumoral lymph vessels. This implies that metastatization to the lymph nodes requires tumour cell invasion of lymphatic vessels of the surrounding normal thyroid. Our study indicate that a defective production by tumour cells of growth factors involved in lymphangiogenesis such as VEGF-D and VEGF-C may be one of the molecular mechanism leading to a poorly developed intratumoral lymphatic vascularization.

USEFULNESS OF CYTOKERATIN 19 AND GALECTIN-3 IN THE DIAGNOSIS OF FOLLICULAR VARIANT OF PAPILLARY THYROID CARCINOMA.

BELLA Maria Rosa, ORELLANA Ruth, COMBALIA Neus, GIMENEZ-PEREZ Gabriel*, CASALOTS Alex, MARQUÈS Gabriel**, FERNANDEZ Sara, DINARÉS Maria Carme, PARRA Tamara, ESCODA Maria Rosa, REY Mercè. Pathology Dept., Endocrinology Unit*, Surgery Dept**. Corporació Sanitària Parc Taulí – UDIAT-CD. Sabadell (Barcelona). Spain.

INTRODUCTION: Follicular variant of papillary thyroid carcinoma (FVPC) is not an unusual neoplasm that can raise diagnostic problems in fine needle aspiration biopsy (FNAB) and in surgical specimens. On the other hand, immunohistochemical markers as Cytokeratin 19 (CK19) and Galectin-3 (Gal3) are usually positive in papillary carcinoma (PC).
PURPOSE OF THE STUDY: To determine the expression of CK19 and Gal3 in FVPC compared to other entities included in its differential diagnosis.
METHODS USED: 26 FVPC, 5 nodular hyperplasia, 5 follicular adenomas (FA) and 5 follicular carcinomas (FC) were examined by immunohistochemistry (IHC) for CK19 and Gal3. Semiquantitative evaluation of each marker alone (0 to 3+) and combined (0 to 6+), and analysis of the results were performed.
RESULTS: Considering positive 2+ and 3+, Gal3 and CK19 have a sensitivity of 100 and 92 %, and a specificity of 92 and 75% respectively for FVPC in histologic specimens. Adding the two immunostaining results, values of 5+ or more give a sensitivity of 88%, but specificity reaches 100%. Cases of FVPC that don't reach 5+ correspond to macrofollicular variant or had focal oncocytic change.
In 7 cases of FVPC, a conclusive diagnosis of PC was not established in the previous FNAB (neoplasm, suspicious of PC, undetermined, benign). IHC on the cell blocks would favour PC diagnosis in 3/7, in which Gal3 was positive and combined values of 5+ or more were reached. The four remaining cases correspond to macrofollicular variants or cases with focal oncocytic change.
Gal3 is more specific, supported by the evidence that only two cases of other entities (1 FA and 1 FC) reached values of 2+ on histologic material, and never exceeded 1+ on FNAB cell block.
CONCLUSION: Cytokeratin 19 and Galectin-3, preferably together, can be useful in the diagnosis of FVPC, both in surgical specimens and in FNAB, with some limitations in macrofollicular and oncocytic variants.

VIRTUAL MICROSCOPY AND THYROID PATHOLOGY QUALITY ASSURANCE ON A NATIONWIDE SCALE IN FRANCE

FRANC Brigitte 1, BERGER Nicole 2*, CAILLOU Bernard 3*, CAVERIVIÈRE Paul 4*, COURTIN Philippe 5*, DE MICCO Catherine 6*, ETTORE Francette 7*, FOULET Armelle 8*, FROMENT Nicolas 9*, GUYÉTANT Serge 10*, KETTANI Sami 11*, KADI-HANIFI Anne-Marie 12*, BELLOCQ Jean Pierre 13**, PATEY Martine 14*
*Members of Committee n°6 "thyroid", working on behalf of **AFAQAP (French Association for Quality Assurance in Pathology).1 Department of Pathology, A. Paré Hospital (APHP), 92100, Boulogne-Billancourt, France, 2, 3, 4 , 5, 6 , 7 , 8, 9 , 10, 11, 12 , 13. (Lyon, Villejuif, Toulouse, Lille, Marseille, Nice, Le Mans, Metz, Tours, Angers, La Roche Sur Yon, Strasbourg, Reims

Several studies testing observer variation in borderline thyroid lesions had underlined their low diagnostic reproducibility. Little is known about typical thyroid lesion general practice assessment in France.
Virtual slides (VS) offered the opportunity to regularly test diagnostic performances on a wide scale. After the test, participants had access to the comments associated with the slides.
The test, performed with the NAVIQAP® (VS) system (Samba Technologies), was composed of a set of 10 thyroid lesions (3 benign: oncocytic adenoma [OA], Graves' disease [GD], hyalinizing trabecular adenoma [HTA], and 7 malignant: insular carcinoma [ITC], medullary thyroid carcinoma [MTC], widely invasive follicular thyroid carcinoma oncocytic variant [WIFTCOV), diffuse papillary sclerosing variant [DPSV], papillary carcinoma follicular variant [PTCFV], minimally invasive follicular carcinoma [MIFTC], and widely invasive follicular carcinoma with anaplastic carcinoma [WIFTC-ATC]). A total of 133 general pathologists, either private or public practitioners, (43% and

57% respectively) belonging to 118 different French laboratories filed the associated questionnaire.
The median global score was 15/20: 7% of the pathologists were quoted between 4 and 10, 40% between 11 and 15; 4% of the pathologists perfectly diagnosed all ten diagnoses.
Malignancy was recognised by 94% to 100% of the participants except the MTC and the WIFTCOV identified as malignant by 82% and 87% of the participants. Benignity was identified by 83% to 87% of the participants according to cases. When considering the malignant diagnosis, an almost perfect diagnosis was reached by 41%, 80%, 12%, 51%, 89%, 63% and 34% of the participants, for ITC, MTC, WIFTCOV, PDSV, PTCFV, MIFTC, WIFTC-ATC respectively. Difficulties with a malignancy diagnosis concerned ITC, MTC, and WIFTCOV, which were not diagnosed as malignant by 6%, 18% and 13% of the participants respectively. In addition, ITC and WIFTC-ATC were misdiagnosed as MTC by 3% and 8% of the participants respectively. The WIFTCOV was considered as MTC by 4,5% of the participants or as partly or completely anaplastic by 4,5% of them.
Those results permitted to focus teaching efforts on obvious mistakes such as under-diagnosis of WIFTCOV and under- or over-diagnosis of MTC.
Virtual microscopy appeared to be a splendid tool in identifying diagnostic difficulties on a nationwide scale and to provide the participants with a learning aid.

With the current explosion of new technologies fitting to human tissue (such as DNA microarray, protein array, high-density tissue array, and laser capture microdissection methods), it is actually crucial to control the different steps between the resection of the human tissue specimens and these different analysis. One of the goal of a biobank tissue should be to ensure these controls before using tissue for research studies. In this regard, we began to set up a thyroid tissue bank following several procedures allowing us to get tissue and tissue products (RNA and DNA) with a high label of quality. All specimens stored in the bank are accompagnied by a signed agreement of the patient; selection of representative specimens is made by a well trained pathologist; time between the surgical excision and the frozen procedure is less than 15 min; several specimens are taken both in lesions and in adjaccent normal areas; all specimens are weight before freezing; visual control of a section from a “mirror sample” is obtain in regard of the frozen tissue; RNA quality is assess by the Agilent bioanalyser; complete histological, epidemiological and clinical data are recording; moreover, paraffin tissue blocks of the corresponding tissue are available to set up tissue microarrays (TMAs). Thus, from September 2004 to March 2005, we have collected, according to this procedure, more than 120 thyroid specimens (from both lobectomies and thyroidectomies). Among these specimens, there are 38 carcinomas (13 papillary carcinomas and 6 microcarcinomas, 10 medullary carcinomas, 5 follicular carcinomas, 4 anaplastic carcinomas); 62 adenomas or nodular hyperplasias; 17 lymphocytic thyroiditis and 13 Graves’ disease. A mean of 18 frozen tissue specimens (both from lesional and normal areas; 15 mg to 80 mg) was obtained by each thyroid. Mean RNA 28s/18s ratio was 1.39; mean DNA 260 nm/280 nm ratio was 1.79. In parallel, TMAs were set up for each subgroup of lesion (with both adjacent non lesional and lesional tissues)

INTERNET EXPERT SYSTEMS FOR SKIN DISEASES (WWW.MUNI.CZ/ATLASES)

FEIT Josef
Institute of Pathology, University Hospital Brno, Czech Republic
JEDLICKOVA Hana,Department of Dermatology, St. Anna University Hospital, Brno, Czech Republic
MATYSKA Ludek, FRIML Tomas, Faculty of Informatics, Masaryk University, Brno, Czech Republic
KEMPF Werner, BURG Gunter,Department of Dermatology, University Hospital, Zurich, Switzerland

Introduction
The Internet atlas of skin pathology with clinical and histological images will be described. The atlas is equipped with expert systems to help the diagnostic process. Purpose of the study. To prepare the digital atlas of pathology with high resolution histological images and tools to make the diagnostic process easier.
Methods
The atlas is available through the Internet. The HTML document
is created from XML data sources. Users need an internet browser to access all features of the atlas. Special interfaces for the access to the high resolution images and to the expert systems are available.
Summary
The atlas of skin pathology has been available on the Internet since 1998. At present the atlas consists of about 3600 images, clinical and histological. Histological images are available in very high resolution (up to 7000×7000 px).The images are annotated and arrows pointing to important signs can be activated. In addition to the table of contents and extensive index a Diagnostic Key to the Epithelial Tumors and Cysts is available. This diagnostic tool is organized in a similar way to botanic keys: a sequence of questions leads to a diagnosis. About 200 diagnostic targets are available. The key is linked to the atlas, so that the target diagnosis can be easily verified. Thanks to the hypertext structure it is easy to backtrack when the diagnostic process reaches the dead end.. Another diagnostic tool will be demonstrated: the Expert System for Non-tumorous Skin
Diseases. The universal structure describing the main pathological changes of skin lesions was created and a database of descriptions of diagnostic units was prepared. The user during the consultation receives a three level menu, through which the lesion in question can be described. The data are sent to the server, where the description is compared with the database using fuzzy scoring function. According to the achieved score the diagnostic units are sorted and (together with the previous description) are sent back, so that the user can refine the descriptions and repeat the process if necessary. The system is designed to run on the Internet and does not require permanent relation to the server. The expert system and the atlas are continuously maintained. The number of diagnostic units is over 150 and new units are being added.
Conclusion
The atlas is available at www.muni.cz/atlases and serves as a source of image material and information.

MORPHOLOGICAL AND IMMUNOHISTOCHEMICAL STUDY OF 83 CASES OF DERMATOFIBROSARCOMA PROTUBERANS (DFSP): ELABORATION OF A GRADING.

MAMERI Saâdia (1) ZIANI Farid (2), OUAHIOUNE Wahiba (1), BOUZID-BENDISARI Kheira (3)
(1)Laboratory of Pathology,Hospital of Douera,Douera, Algiers Algeria
(2)Orthopaedics surgery unit, Hospital of Douera,Douera, Algiers Algeria
(3) Laboratory of Pathology,Hospital of Beni-messous,Algiers Algeria

Introduction: The DFSP is a malignant mesenchymal tumor of the skin, characterized by frequent recurrences, rarely metastasizant , which presents under several morphological aspects named variants: sclerosant, schwanian, myxoïd, withgiantcells, pigmented, atrophic, myofibroblastic ,fibrosarcomatous. Until now, there is no grading of DFSP.
Purpose of the study: This study aims, through the analysis of 83 cases of DFSP observed during 7 years, to repertory the histological criteria which can predict the behavior of the tumor.
Methods used: 83 cases of DFSP and their 128 recurrences are viewed prospectively and retrospectively. Sections on paraffin blocks are realized for all the cases, with hematoxylin-éosin-safran(H.E.S) stainings.Special histochemical stainings are achieved: P.A.S (Periodic acid of Schiff)-Blue Alcian-Fontana-Trichrome of Masson. An immunohistochemical study using a broad panel of antibodies is performed: .CD34 - CD117 or C.Kit-Protein S100- FactorXIIIA -FactorVIII - CD68-
Summary of the results: The global analysis reveals that the type of the variant, the cellular atypia, the mitotic index and necrosis are microscopic predictive factors for the evolution of the DFSP. They serve to set up a grading. This grading is obtained on the basis of a score which results from the quantification of all these criteria.
Conclusion: An histopronostical grading of DFSP is obtained from these microscopic factors, giving three grades; the first one of good prognosis , the second one of intermediate or median prognosis , and the last, of bad prognosis.

O-134
RECURRENT GENOMIC IMBALANCES OF TRANSFORMED MYCOSIS FUNGOIDES

Prochazkova Martina, Chevret Edith, Beylot-Barry Marie, Mainhaguiet Guillaume, Vergier Béatrice, Belaud-Rotureau Marc-Antoine and Merlio Jean-Philippe
Histology and Molecular Pathology Laboratory EA 2406, Victor Segalen University, Bordeaux, France

Mycosis fungoides (MF) is the most common form of cutaneous T-cell lymphoma, representing roughly half of all cutaneous lymphomas originating in the skin. MF is characterised by an epidermotropic infiltrate of malignant CD4+ helper T-cells that present in most cases a clonal T-cell receptor gene rearrangement. The clinical course is usually indolent, except when MF transforms to large T-cell lymphoma (T-MF), which occurs in 8% to 23% of patients. This transformation is associated with clinical progression and a short survival. Whereas histopathological features of T-MF are now well defined, little is known about the genetic mechanisms underlying the transformation. To address this issue, we analysed 19 tumours with T-MF obtained from 12 patients. We used comparative genomic hybridization (CGH) and in some cases chromosome banding, fluorescence in situ hybridisation (FISH) and DNA content analysis.
In 13 T-MF, DNA measurements of tumour skin nuclei isolated from formalin embedding tissues revealed a DNA content elevated above the diploid value (DNA indices range from 2.4n to 3.2n, mean 2.72n +/- 0.34, P = 0.001). Karyotypes and FISH analysis of 5 T-MF tumours revealed recurrent near-tetraploidy karyotypes whereas such abnormality was not detected by the analysis of peripheral blood lymphocytes. Hence, we suggest that polyploidisation observed at the skin level is a recurrent T-MF abnormality comparably to blood findings for large cells transformation of Sézary syndrome, a leukemic variant of MF.
In 19 T-MF tumours, CGH analysis identified imbalances in 89% of the cases (17/19). Imbalances were recurrently observed for chromosomes 1 (82%), 7 (47%), 9 (76%), 10 (35%), 17 (59%) and 19 (47%). The minimally involved regions were gain of 1p36, 7, 9q34, 17q24-qter, 19 and loss of 9p21, 10p11-p13, 10q22, 17p. Previous cytogenetics studies in MF have already identified the presence of an isochromosome 17q, loss of chromosome 10 and a 9p21 deletion at both early and advanced stages of MF. However such studies have not discriminate tumour stage of MF without large cells from T-MT. Thus, these abnormalities cannot be considered as hallmark for T-MF although they may have biological impact on transformation. Therefore, we are screening whether the imbalances revealed by our CGH study may involve genetic pathways leading to polyploidisation.

GENETIC ALTERATIONS OF PRIMARY CUTANEOUS LYMPHOMAS ARE RELATED TO CLINICOPATHOLOGICAL SUBTYPES

Marc-Antoine Belaud-Rotureau (1, 2), Virginie Marietta (1), Beatrice Vergier (1, 2), Guillaume Mainhaguiet (1), Michelle Turmo (1), Marie Beylot-Barry (1, 3), Jean-Philippe Merlio (1, 2)
1: EA 2406 Histology and Molecular Pathology of tumours, University Victor Segalen, Bordeaux
2: Pathology Laboratory, Haut-Lévêque Hospital, CHU Bordeaux
3: Dermatology Department, Haut-Léveque Hospital, CHU Bordeaux

Few studies have investigated genetic alterations in primary cutaneous B-cell lymphomas (PCBCL). Therefore, we performed comparative genomic hybridization (CGH-array) and fluorescent in situ hybridization (FISH) assays on a series of 21 PCBCL.
Frozen cutaneous biopsies of 21 patients were selected : large cells lymphomas of the leg (LCLL, N=5), large cells lymphomas with another localisation than the leg (LCLA, N=5), small cells centrofollicular lymphomas with unique lesion of the head or trunk (CFU, N=4), small cells centrofollicular lymphomas with multiple lesions (CFM, N=3) and small cells mucosa associated lymphoid tissues lymphomas (MALT, N=4). All samples were assayed by CGH-array with the Array-300 (Abbott-Vysis). FISH analyses were also performed 1) to assess translocations or genes rearrangements (IGH, MALT1, IGH-CCND1, IGH-MYC, IGH-BCL-2) and 2) to confirm the data of the CGH-array assays (p16, AML1, TOP2A, 7ptel, 19qtel).
The FISH analysis demonstrated a t(8;14)(q24;q32) (IGH-MYC) in 2/5 LCLL. By contrast with lymphomas of the lymph nodes, no other abnormality was found. The CGH-array assays showed a more important number of total and/or recurrent genetic alterations in LLCL (mean 59, $p<0.05$) than in LCLA (mean 29, $p<0.05$). Inversely, MALT and CFM exhibited rare alterations (mean 6 and 10, $p<0.01$). Compilation of these data and FISH analyses led to the determination of genetic profiles associated with the LCLL

and LCLA. Particularly, recurrent deletions in 9p21 (p16) were a constant finding in LCLL (5/5). Inversely, LCLA demonstrated recurrent 1p36 deletions (4/5) without deletion in 9p21. Finally, these results suggest that the different prognosis of LCLL and LCLA is supported by specific genetic aberrations.

O-136
CD158K/KIR3DL2 FOR THE DIAGNOSIS OF ERYTHRODERMA IN SKIN SPECIMENS

ORTONNE Nicolas (1,2), WECHSLER Janine (1), BAGOT Martine (3), MARTIN-GARCIA Nadine (1), BENSUSSAN Armand (2).
1 : Département de Pathologie, hôpital Henri Mondor, Créteil
2 : Unité INSERM U659, faculté de Médecine de Créteil
3 : Service de Dermatologie, hôpital Henri Mondor

INTRODUCTION. Erythroderma may result from different causes, including cutaneous T-cell lymphoma (CTCL) and inflammatory diseases, and diagnosis on skin specimens is often problematic. It has been shown recently that CD158k/KIR3DL2 is a marker of Sezary cells, expressed in the blood and skin of Sezary syndrome (SS) patients. The aim of this study was to determine whether CD158k may help for the diagnosis of erythroderma in tissue samples.
METHODS. 35 skin specimens from erythrodermic patients were analyzed. 12 had CTCL (10 SS and 2 erythrodermic mycosis fongoides (EMF)) and 23 had erythrodermic inflammatory diseases (EID) (drug reactions, psoriasis, eczema). In 3 SS patients, the malignant T cell clone, identified in the blood, was shown to be present in the skin by the immunoscope technique. Immunohistochemistry for CD158k, CD3, CD4, CD8 was performed on frozen sections. The CD8/CD3 and CD158k/CD3 ratios were evaluated in the epidermis and in the dermis. In addition, RT-PCR for CD158k was performed in 12 cases.
RESULTS. All cases displayed subepidermal band-like lymphocytic infiltrates with epidermotropism. As expected, CD158k was positive in all CTCL, including EMF. However, CD158k+ cells were also observed in 17 EID. Erythrodermic CTCL displayed lower CD8/CD3 ratios in both the epidermis (mean CD8/CD3 ratio : 12% in CTCL versus 38 % in EID) and dermis (83% of CTCL vs 38% of EID had CD8/CD3<25%). Mean CD158k/CD3 ratios were similar in both groups in the epidermis. However, EID had a lower CD158k expression in the dermis (33% CTCL vs 74% EID with CD8/CD3<25%). RT-PCR, performed in 12 cases displaying similar CD158k+ infiltrates, showed a stronger expression of CD158k mRNA in CTCL.
DISCUSSION. A significant proportion of CD158k+ lymphocytes are present in the skin of erythrodermic patients. Whether these lymphocytes are recruited from the blood and expand in the skin, or correrspond to skin resident lymphocytes is an interesting issue. Although CD158k+ lymphocytes are present both in CTCL and EID, there is a stronger expression of CD158k mRNA in CTCL, what may suggest functional recruitment of CD158k by its ligands in this context.
CONCLUSION. CD158k may be expressed in EID but CTCL have a higher proportion of positive cells in the dermis. Whether the use of CD158k RT-PCR and immunohistochemistry in combination might be more accurate for the diagnosis of erythroderma in cutaneous specimens remains to be confirmed.

GRANULOMA FACIALE : A CLINICOPATHOLOGICAL STUDY OF 66 PATIENTS

ORTONNE Nicolas (1), WECHSLER Janine (1), BAGOT Martine (2), GROSSHANS Edouard (3), CRIBIER Bernard (3)
1:Département de Pathologie, Hôpital Henri Mondor, Créteil, France
2:Service de Dermatologie, Hôpital Henri Mondor, Créteil, France
3:Clinique Dermatologique de Strasbourg, Hôpital civil de Strasbourg, France

INTRODUCTION : Granuloma faciale (GF) is a rare cutaneous disease usually occuring on the face, that follows a chronic course and has a tendency for recurrence. Only case reports or small series of patients have focused on GF so that the frequency of morphologic changes has never been established. The aim of the study was to describe the clinicopathological characteristics of GF in a large series of 66 patients.
METHODS: 66 patients diagnosed with GF were rincluded in the study and 73 skin specimens were retrospectively analyzed. Among histopathological parameters, GF were categorized as having acute, chronic or mixed inflammatory infiltrates. Statistical analysis evaluated the correlation between histopathological criteria and duration of the lesions.
RESULTS: Mostly, GF presented a one or several, reddish or violaceous, plaques or nodules on the face of middle-aged adults, with a slight male predominance. Five patients had extrafacial lesions and multiple localisations were present in one third of cases. Diagnosis of GF was clinically proposed in only 10 cases whereas sarcoidosis, lymphoma, lupus, and basal cell carcinoma were the most frequent differential diagnoses. Most frequent histopathological features were presence of a grenz zone, neutrophils and telangiectases. Vasculitis was considered to be present in a half of cases, but vessels wall necrosis was very rare. Acute and chronic inflammatory changes were often associated and lesions of longer duration were more likely to have a larger size, what suggest a progressive course with reccurrent acute phases.
CONCLUSION: GF is often clinically misdiagnosed. Criteria usually considered to be of diagnostic value, such as eosinophil infiltration, may lack. Extrafacial localisations, evidences of vascular injuries, lack of eosinophils and presence of a patterned fibrosis in a significant number of cases suggest that GF, erythema elevatum diutinum and localized chronic fibrosing vasculitis may be related.

FRANCE

INTRODUCTION: DRESS syndrome (DS) is a life-threatening drug hypersensitivity reaction, characterized by a febrile eruption, hypereosinophilia, and visceral involvement. Although skin biopsy belongs to diagnosis criteria, the morphologic changes in DS have never been investigated on large series. The aim of the study was to characterize whether DS has a distinctive histopathological aspect. METHODS: We retrospectively reviewed 43 cutaneous specimens from patients with a diagnosis of drug reaction with eosinophilia and systemic symptoms. Patients were clinically categorized in 4 drug reactions groups: DS definite (n=9); DS probable (n=14); DS not excluded (n=15) and DS excluded (n= 5). RESULTS: Mean age in definite and DS probable was significantly higher than in DS excluded (35 vs 60 years). In definite and probable DS, density of inflammatory infiltrate,

intensity of interface dermatitis and lymphocytic exocytosis were significantly more important than in DS excluded. Although eosinophils and atypical lymphocytes in the blood are diagnosis criteria for DS, eosinophils were absent in most of specimens and atypical lymphocytes were never seen. CONCLUSION: Although not specific, skin biopsy analysis provides help in differenciating DS from other cutaneous drug reactions. Absence of eosinophils and atypical lymphocytes on skin biopsy does not rule out the diagnosis of DS.

QUANTITATIVE ANALYSIS OF CXCL12 AND CXCR4 EXPRESSION IN HUMAN PRIMARY AND METASTATIC CUTANEOUS MALIGNANT MELANOMA.

MONTEAGUDO Carlos*, LOPEZ-GUERRERO José Antonio**, RAMOS David*, ALONSO Vicent***, JORDÁ Esperanza***, PELLIN Antonio*, LLOMBART-BOSCH Antonio*.
*Department of Pathology, University of Valencia, **Fundación Instituto Valenciano de Oncología, and ***Department of Dermatology, Hospital Clínico Universitario, Valencia, Spain.

Introduction: A role for the CXCR4 chemokine receptor in tumor cell migration during melanoma progression has been proposed. The fact that expression of CXCL12, the only CXCR4 ligand, is higher in lymph nodes, liver, bone marrow, and lung, than in normal skin supports the hypothesis that a gradient concentration of this chemokine might facilitate metastatic colonization. In this regard, CXCR4 antagonists are currently being tested in experimental models in order to prevent metastatic dissemination. Purpose: Our goal was to quantify CXCL12 and CXCR4 mRNA expression in primary and metastatic human cutaneous malignant melanomas in order to determine if there is a gradient expression of both molecules between primary and metastatic lesions which could support the value of a therapeutic blockade in order to inhibit the metastatic dissemination of human melanoma. Methods: CXCL12 and CXCR4 mRNA expression was evaluated by real-time quantitative PCR in 45 frozen tissue samples from primary and metastatic melanoma (<=1 mm, >1mm, in transit, lymph node, and distant metastasis). An immunohistochemical study was also performed in adjacent frozen sections with monoclonal antibodies to CXCL12 and CXCR4 (MAB350 and MAB172, R&D Systems) in order to evaluate the cell types responsible for chemokine ligand and receptor expression. Results: CXCL12 mRNA levels were much higher in thin primary melanomas than in thick primary tumors, lymph node metastases and distant visceral metastases (9, 10 and 83 fold respectively). CXCR4 mRNA levels were higher in lymph node metastases than in thin and thick primary tumors or distant metastases (1.2, 5.5 and 7.3 fold respectively). CXCL12 immunostaining was present in most tumor cells in primary and metastatic tumors as well as endothelial, and other stromal and dendritic cells. CXCR4 immunostaining was found in a subpopulation of tumor cells in primary and metastatic tumors as well as endothelial cells and lymphocytes. Conclusions: The fact that the highest CXCL12 mRNA levels are present in thin melanomas suggests that CXCL12 might retain CXCR4+ tumor cells in the primary site in these patients. In contrast, the lower levels of both CXCL12 and CXCR4 in thick melanomas support the potential dissemination of CXCR4+ tumor cells to lymph nodes or distant sites where mean receptor and ligand levels are similar or higher.

CLINICALLY DETECTED BENIGN NOTOCHORDAL CELL TUMORS: LESIONS THAT ARE IMPORTANT TO DISTINGUISH FROM INTRAOSSEOUS CHORDOMA

YAMAGUCHI Takehiko 1), IWATA Jun 2), SUGIHARA Shinsuke 3), McCARTHY Edward 4), KARITA Michiaki 5), MURAKAMI Hideki 5), KAWAHARA Norio 5), TSUCHIYA Hiroyuki 5), TOMITA Katsuro 5)
1) Department of Clinical Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan
2) Department of Laboratory Medicine, Kochi Health Science Center, Kochi, Japan
3) Department of Orthopaedic Surgery, Kochi Health Science Center, Kochi, Japan
4) Department of Pathology, John Hopkins Hospital, Baltimore, USA
5) Department of Orthopaedic Surgery, Kanazawa University, Kanazawa, Japan

Introduction: Benign notochordal cell tumor is a recently discovered intraosseous benign lesion of notochordal cell origin that can be precursors of chordoma. The anatomical distribution is identical to that of chordoma. They are usually small and found at autopsy. The concepts or clinicopathological features have not been widely accepted although clinically found cases have been sporadically documented.
Purpose: To know clinicopathological features of clinically detected benign notochordal cell tumors.
Materials and Methods: We collected seven cases of clinically detected benign notochordal cell tumor and examined their histology and clinical records including follow-up information, conventional radiograph, computed tomography scan, and magnetic resonance imaging.
Results: The patient group consisted of 3 men and 4 women with an average age of 44 years old. Two patients had two lesions at different sites. The lesions involved the cervical spine in 4, lumbar spine in 2, sacrum in 2, and coccyx in 1. The most common symptom was mild pain. Two patients were found to have lesions incidentally on imaging study for unrelated conditions. Five patients underwent surgical procedure. All patients but one who died of surgical complications were well without recurrent or progressive disease for 13 to 84 months. X-rays did not reveal significant abnormality in 5 lesions. In one patient who was found to have two lesions, the tumors exhibited diffuse sclerotic changes. Computed tomography scan demonstrated increased density within the vertebral bodies. The lesions showed homogeneous low signal intensity on T1-weighted magnetic resonance imaging and high on T2-weighted imaging. Microscopically, the lesions consisted of sheets of adipocyte-like vacuolated cells without myxoid matrix. The nuclei were usually bland but occasionally polymorphic. The affected bone trabeculae were sclerotic. The tumor cells stained immunohistochemically positive for vimentin, S-100 protein, and epithelial markers.
Conclusions: Benign notochordal cell tumor is a benign bone lesion and may be clinically found in the cervical or lumbar vertebral body. The differential diagnosis includes fatty marrow, chordoma, and metastatic clear cell carcinoma. They do not require any surgical management until they undergo malignant transformation. Benign notochordal cell tumors should be recognized in pathologists, radiologists, and orthopedic surgeons to prevent unnecessary surgical management.

O-141

BENIGN NOTOCHORDAL CELL TUMORS: A COMPARATIVE HISTOLOGICAL STUDY OF BENIGN NOTOCHORDAL CELL TUMORS, CLASSIC CHORDOMAS AND NOTOCHORDAL VESTIGES OF FETAL INTERVERTEBRAL DISKS

YAMAGUCHI Takehiko, HASEGAWA Tadashi

Department of Clinical Pathology, Sapporo Medical University School of Medicine, Sapporo, Japan

Introduction: Chordoma has been believed to arise in residual notochordal tissue; however, we established a new concept intraosseous "benign notochordal cell tumor" that may undergo malignant transformation to classic chordoma.
Purpose: To know morphological and immunohistochemical features of benign notochordal cell tumors.
Materials and methods: The material consisted of 34 benign notochordal cell tumors found in 25 autopsy cases. The patient group consisted of 19 males and 6 females with a mean age of 63 years. This study attempted to define the morphological and immunohistochemical features of benign notochordal cell tumors by contrasting them with classic chordomas (n=3) and notochordal vestiges in fetal intervertebral disks (n=27).
Results: The average tumor size was 4 x 2 mm. The location of 34 tumors was as follows: 8 tumors were in the clivus, 6 in the coccyx, 5 in the second cervical vertebra (C2), 4 in the fourth segment of the sacrum (S4), 3 in S3, 2 each in the third lumbar vertebra (L3) and L4, and one each in C5, S1, S2, and S5. No lesions were found in the intervertebral disks. Benign notochordal cell tumors were morphologically characterized by well demarcated but unencapsulated sheets of adipocyte-like vacuolated and less vacuolated eosinophilic cells within axial bones. The round nuclei were mildly polymorphic but bland. The tumor cells often contained cytoplasmic eosinophilic hyaline globules and lacked any intercellular myxoid matrix or necrosis. The host bone trabeculae were often sclerotic without bone destruction. Vimentin, S-100 protein, epithelial membrane antigen, AE1/AE3, and CAM5.2 were positive in benign notochordal cell tumors, classic chordomas, and notochordal vestiges; however, only notochordal vestiges failed to demonstrate any positive reaction for cytokeratin 18.
Conclusions: The histological features were different from those of both notochordal vestiges in fetal intervertebral disks and classic chordomas. There was overlap in immunohistochemical reactivity of benign notochordal cell tumors and chordomas but notochordal vestiges failed to demonstrate cytokeratin 18 positivity. A more appropriate term for the lesions is "benign notochordal cell tumor" rather than "notochordal rest" or "notochordal hamartoma" as they are not rests and do not fulfill the definition of hamartoma. Benign notochordal cell tumors do not need any surgical procedure and must be adequately recognized in order to prevent unnecessary operations.

O-142
THE JNK AND ERK MAPK SIGNALING PATHWAYS ARE IMPLICATED IN PATHOGENESIS AND PROGRESSION OF HUMAN CHONDROSARCOMAS VIA COOPERATIVE UP-REGULATION OF THE ANGIOGENIC FACTOR VEGF

Dionysios J. Papachristou (1,2), Georgios I. Papachristou (2), Odysseas A. Papaefthimiou (1), Niki J. Agnantis (1), Effie K. Basdra (3), Athanasios G. Papavassiliou (2)

Introduction: Chondrosarcoma is the second most common primary skeletal malignancy. Nonetheless, its pathogenesis has not been adequately explored. In vitro data have documented that the JNK and ERK MAP kinases, and their downstream effectors c-Jun and c-Fos (AP-1 transcription complex), are involved in chondroblastic differentiation/proliferation. These oncoproteins functionally interact with the transcription factor Runx2, which is also engaged in cartilage biology. Previous studies have shown that VEGF, a major angiogenic factor, is up-regulated in human chondrosarcomas through yet unidentified mechanisms.
Purpose: 1) To investigate the role of JNK–AP-1 and ERK signaling cascades, Runx2 and VEGF in cartilaginous tumors pathogenesis; 2) To assess these proteins as possible molecular markers for the prediction of chondrosarcomas' clinical behavior.
Materials and Method: We employed immunohistochemistry to examine normal cartilage and neoplastic cells in paraffin-embedded chondrosarcomas (n=45) and enchondromas (n=21). We evaluated the cellular levels of JNK2, p-JNK (phosphorylated/active form of JNK2), c-Jun (JNK's major substrate), pc-Jun (phosphorylated/active form of c-Jun), c-Fos, p-ERK (ERK's phosphorylated/active species), Runx2 and VEGF.
Results: Positive immunostaining for all proteins was observed in the majority of the chondrosarcomas but in a small percentage of enchondromas. Normal chondrocytes were devoid of these immunoreactivities. The cellular levels of all proteins were positively and significantly correlated to each other (Kendal's Tau = 0.44-0.809, $p<0.01$). Their expression levels were substantially augmented in high grade (G2, 3) compared to low grade (G1) chondrosarcomas, and in low grade tumors compared to benign enchondromas (Mann-Whitney test, $p<0.005$ for all). VEGF predicted accurately the grade in 88% of the chondrosarcomas (OR 43.7, $p<0.005$).
Conclusions: 1) The (JNK / ERK)–AP-1 / –Runx2 signal transduction pathways are up-regulated in chondrogenic tumors in a well-orchestrated fashion; 2) the JNK and ERK cascades are associated with chondroblastic malignant transformation and chondrosarcoma development, either independently or through up-regulation of VEGF; 3) VEGF can qualify as molecular marker to predict high grade chondrosarcomas; 4) the use of highly selective agents targeting the JNK/ERK pathways and VEGF might constitute a novel complementary therapy for chondrosarcoma patients.

EXTRACELLULAR AND INTRACELLULAR EXPRESSION OF CD52 IN SKELETAL TUMORS

GUENTHER Raphaela1, MORAWIETZ Lars1, GRUETZKAU Andreas3, MELCHER Ingo2, SCHASER Klaus-Dieter2, SERS Christine1, KRENN Veit1
1 Institute for Pathology, Charité University Hospital, Berlin, Germany
2 Center for Musculoskeletal Surgery, Charité University Hospital, Berlin, Germany
3 German Arthritis Research, Charité University Hospital, Berlin, Germany

CD52 is a GPI-anchored glycoprotein which is expressed abundantly on all lymphocytes, monocytes, macrophages and eosinophils as well as in the male genital tract. The sperm CD52 antigen differs from CD52 on lymphocytes by its carbohydrate structure, but the protein core is identical. To date, the physiological role of CD52 on lymphocytes is not clear. However, an antibody directed to CD52 called CAMPATH-1H is capable of complement activation as well as antibody-mediated cellular cytotoxicity leading to a depletion of lymphocytes. Presently, CD52-specific antibodies are used to treat lymphoproliferative disorders. Recently, we detected CD52 on giant cell tumours of the bone (GCT) by microarray analysis, suggesting a role of the CD52-antigen in bone tumorigenesis, especially in GCTs, osteosarcomas (OS) and chondrosarcomas (CS).
In this study we analyzed GCT, OS and CS tissues as well as cell lines by immunohistochemical staining and RT-PCR analysis to investigate the expression of CD52 mRNA and protein. We used flow cytometry to analyze the intensity of intracellular and extracellular expression of CD52.

Furthermore, western blot was used to determine differences in the size of CD52 on GCTs, OSs and CSs cells as compared to the lymphocyte-form of CD52.
With RT-PCR we could confirm the expression of the CD52 mRNA in GCTs, OSs and CSs both in vivo (tissue) and in vitro (cell lines). Immunohistochemical staining as well as the FACS scan revealed, that CD52 was not only expressed on the surface of the tumour cells, but also cytoplasmic with a golgi-association. By western blot analysis we confirmed the GPI-anchoring of the CD52 peptide. Multiple bands representing the glycosylation of the antigen were different from bands detected in lymphocytes. This suggested a cell type specific modification of CD52.
The current study demonstrated CD52-expression in GCT, OS and CS tissues as well as cell lines and suggested a role for CD52 in the development of bone tumours. Interestingly, the immunohistochemical as well as the FACS analysis revealed not only the extracellular GPI-anchored CD52, but also a cytoplasmic expression of CD52. In the future, we want to evaluate the expression of CD52 in normal bone and cartilage and the potential of the CAMPATH-1H antibody to recognize CD52 on GCTs and to activate the complement cascade for specific lysis.

(3) Oligene GmbH, Berlin
(4) Department for Rheumatology, University Hospital Charite, Berlin

Aims: To establish a standardized and feasible graduation system ("synovialitis-score") for the degree of inflammation in synovectomy specimens, applicable to all forms of synovialitis irrespective of etiology.
Materials and Methods: Three features of chronic synovialitis are separately graded in a semiyuantitative manner (from 0=absent to 3=strong): enlargement of lining cell layer, activation of stroma (i.e. resident) cells, leukocytic infiltrate. The sum of the three criteria resembles the synovialitis-score, which is interpreted as follows: 0-1: no synovialitis, 2-3: slight synovialitis, 4-6: moderate synovialitis, 7-9: strong synovialitis. 559 synovectomy specimens were graded by two independent observers. Clinical diagnoses were osteoarthrosis (OA; n=212), posttraumatic arthritis (PtA; n=21), rheumatoid arthritis (RA; n=246), psoriatic arthritis (PsA; n=22), reactive arthritis (ReA; n=9), and controls (Co, n=49) from necropsies of patients without joint damage.
Results: Median synovialitis scores when correlated to clinical diagnoses were: Co 1.0, OA 2.0, PtA 2.0, PsA 3.5 ReA 5.0, RA 5.0. The differences in scores between Co and all other groups were highly significant ($p<0.001$). A synovialitis-score of 4 points and more was strongly associated with rheumatic joint diseases (sensitivity 84.1%, specificity 77.6%). The correlation between the two observers was high ($p<0.001$).
Conclusion: The proposed synovialitis-score is based on well definable histopathological criteria. It enables a standardized evaluation of synovectomy specimens in routine histopathology and may contribute to the diagnosis of rheumatic and non-rheumatic joint diseases. Furthermore, it represents a rational basis for usage of synovectomy specimens in experimental rheumatology. Tissue microarrays (TMAs) for experimental studies have been made (Oligene GmbH, Berlin, Germany) using synovectomy samples graded according to this graduation system.

4 DEP of PATHOLOGY, UNIVERSITE LA SAPIENZA, ROME, Italie.

Purpose: It is well know that tumor cells resemble embryonic cells. As a result of the progress made lately in molecular biology it is possible to elucidate the molecular mechanisms that determine (induce) and control tumor phenotypes.
Signal transducers and activators of transcription (STATs) mediate biological actions such as differentiation, cell proliferation and survival in response to cytokines and growth factors. STATs are also important in epithelial–mesenchymal transition during gastrulation, organogenesis and cancer progression. Recently, a relationship between STAT3 and E-caderin bas been reported in digestive tumor: STAT3 seems to decrease E-cadherin expression in tumor cell which could lead to cell mobility. In this study we investigate the role of STAT3 and molecular adhesion proteins (E-cadherin, a and b cathenin) in gastric cancer in order to distinguish the eventual difference of expression in intestinal and diffuse type.
Patients and methods: 120 patients with intestinal type adenocarcinoma and 75 patients with diffuse type adenocarcinoma were analyzed by Immunohistochemistry – Tissue array technique for STAT3, E-cadherin, a and b catenin. Mean expression levels were compared by "t" test.
Results: The expression of a, b catenin and E-cadherin were significantly higher in intestinal than in diffuse type: a-catenine (98% versus 38%, $p < 0.0001$), b-catenin (96% versus 48%, $p < 0.0001$) and E-cadherin (99% versus 62%, $p < 0.0001$). For Stat3 the expression is higher in diffuse type than in intestinal type (31% versus 14%, $p = 0.0029$).
Conclusion: The molecular mechanisms of adhesion molecules are different in intestinal and diffuse type adenocarcinomas. Stat3 molecule, which is involved in epithelial–mesenchymal transition during embryogenesis, seems to play an important role in determining tumor phenotype of diffuse type adenocarcinoma. Theoretically its aggressive nature might be decreased by partial or total inhibition of Stat3. Further investigation is needed to clarify these findings.

Aims: Microsatellite instability (MSI) is a frequent event in gastric carcinogenesis and shows a trend towards distinct clinical and pathological characteristics of gastric cancer (GC). We investigated the role of MSI in GC in order to

elucidate the possible clinical implications of MSI in GC prognosis.
Methods: A series of 159 GC cases were originally identified in the GC high-risk area surrounding Florence (Central Italy) and were actively followed up until recently. Formalin-fixed and paraffin-embedded histological specimens and information on clinico-pathological characteristics, vital status at 5 years, age and family history were available for all patients. A panel of six dinucleotide (D1S104, D2S123, D3S1611, D5S107, D17S261, D18S34) and two mononucleotide (BAT25, BAT26) markers were used to determine the MSI status. Tumours were classified as MSI-high when showing contraction(s) in BAT26 and/or BAT25, as MSI-low when instability was limited to dinucleotide loci, and as MSI negative when no instability was observed at the loci tested. GC cases with low-frequency MSI were included in the MSI negative group for statistical analysis.
Results: Overall, 132 (83.0%) tumours were classified as MSI negative and 27 (17.0%) as MSI-high. The MSI high-phenotype was positively associated with the female sex, but not with other individual characteristics (including age at diagnosis, GC family history, pT or pN status). A strong association was found with vital status at 5 years: 15/27 MSI high-positive cases (55.6%) were still alive at 5 years vs 44/132 MSI negative (33.3%) (p=0.04). A multivariate regression model, including terms for sex, age at diagnosis, pT and pN status, confirmed the positive association between MSI high-phenotype status and survival at 5 years (p=0.03).
Conclusions: MSI high-phenotype may have strong implications in the prognosis of GC, with MSI high-positive patients showing increased survival at 5 years.

Introduction: Vascular endothelial growth factor family is composed of four members: VEGF-A, VEGF-B, VEGF-C, VEGF-D. VEGF-A is a key regulator of blood vessel growth, whereas VEGF-C and VEGF-D regulate lymphatic angiogenesis. The effects of VEGF-A are mediated by binding to VEGF-R1 and VEGF-R2, receptor tyrosine kinases expressed on the surface of vascular endothelial cells, while VEGF-R3 is a receptor for VEGF-C and VEGF-D.
Purpose: The aim of the study was to examine the expression of VEGF-A, VEGF-C, VEGF-D and their receptors VEGF-R1, VEGF-R2, and VEGF-R3 in advanced gastric cancer.
Materials and methods: The study was performed on 106 surgical specimens. All cases were classified according Lauren classification; pTNM staging was performed using the last AJCC criteria from 2002. The expression of the three growth factors and corresponding receptors was evaluated immunohistochemically on both primary tumor and metastatic lesions. In addition microvessel density was assessed by using the pan-endothelial marker CD31 (DAKO) and D2-40 (DAKO), specific for lymphatic endothelium.
Results and discussion: We could not demonstrate expression of VEGF-A. All specimens (both primary and metastatic lesions) were completely negative. VEGF-A was detected only in small proliferating vessels. At the same time the assessment of angiogenesis by CD31 showed quite high microvessel density in the main tumor mass, as well as in many of metastatic lymph nodes and in haematogenous metastases. VEGF-C was expressed in 78 % of all primary tumors and 71 % of all positive carcinomas showed high, strong staining intensity in more than 50 % of the tumor cells. Diffuse type tumors or mixed carcinomas with diffuse component demonstrated stronger VEGF-C expression than intestinal carcinomas. That high expression of one of the regulators of lymphatic angiogenesis was in contradiction with relatively low lymphatic microvessel density. The new monoclonal antibody D2-40 (IgG1) detects an oncofetal antigen associated with germ cell neoplasia and is also a selective marker of lymphatic endothelium. We found a peculiar expression of that antigen by stromal fibroblasts and a condensation of stromal positive “hot spots” in the infiltrative board of the primary tumor.
It seems that in primary gastric cancer VEGF-A plays lesser role in the regulation of angiogenesis than VEGF-C. On the other hand M2A antigen, detected by D2-40 probably plays important role in tumor-stroma interactions.

Introduction: There are sufficient data to suggest that Helicobacter pylori, through direct pathogenic mechanisms, contributes significantly to the gastric mucosal injury associated with this infection, and may enhance the suceptibility of gastric epithelial cells to carcinogenic conversion. Clinical outcome of H. pylori infection may be associated with specific virulence-associated bacterial genotypes. Moreover, polymorphism genotype in host gastric mucosa may be linked with different outcome of the disease. Thus, host genetic factors have been shown to be important in determining the immune response to H. pylori infection and the propensity to develop gastric atrophy, hypochlorhydria and gastric cancer. Aim : The aim of this study was to evaluate differential expression of genes in human gastric epithelial cells infected or not by H. pylori. Methods : We used microarray analysis to identify gene expression profiles among 29 patients infected by different strains of H. pylori and among 25 patients non infected by H. pylori. The obtained profiles were correlated with the H. pylori BabA2, vacAs1/s2, vacAm1/m2, and cagA status determinated by polymerase chain reaction. Antrus and corpus histopathology was examined according to the updated Sydney classification. Results: Of the 29 infected patients, 17 (58.6 %) harboured cagA+ strains, 13 (44.8%) BabA2 strains, 9 (31%) vacAs1m1 strains, 14 (48.2%) s1m2 strains and 5 (17.2%) s2m2 strains. CagA+ H. pylori strains were found to change the expression of gene encoding apoptosis proteins, metalloprotease-disintegrin proteins, tissue inhibitors of metalloproteinases, growth factors and cytokine/chemokines. Marked differences in gene expression profiles were observed following cagA+ and cagA- infection with 96 known genes being differentially expressed. This study demonstrated the usefulness of cDNA array analysis of human biopsies for investigating H. pylori-induced changes in host gene expression.

Gastrointestinal stromal tumors (GIST) are the most frequent mesenchymal tumors of the digestive tract and are poorly responsive to chemotherapy. Recently, a treatment with a tyrosine kinase inhibitor, Imatinib Mesylate, was shown to have anti-tumor effects in metastatic patients. However, this drug is a substrate for multidrug resistance (MDR) proteins. We thus investigated the expression of Pgp and MRP1 by Western blot in 21 GIST and 3 leiomyosarcomas, and correlated these results with clinico-pathological characteristics. All the GISTs were positive for either Pgp or MRP1 expression, in 86% and 62% of the case respectively. Pgp was expressed in all gastric GIST, while in only 67% in other localization. By contrast, MRP1 was more expressed in non-gastric tumors (78% versus 42%). Furthermore, the levels of these MDR proteins in gastric GISTs were higher for Pgp (P=0.007) and lower for MRP1 (P=0.004), when compared to other localizations. No correlation was found between MDR expression and the risk assessment. None of the 6 patients treated with Imatinib was resistant, although all were positive for at least one MDR protein. These results confirm that gastric and non-gastric GISTs have different biological characteristics, and suggest that MDR proteins do not impair initial response to Imatinib.

O-150
GASTROINTESTINAL STROMAL TUMORS: A MULTICENTER STUDY OF 645 TURKISH CASES

GIST Working Group, Turkish Society of Pathology, Turkey

INTRODUCTION : Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors arising from the gastrointestinal tract, omentum, and retroperitoneum. The aim of this multicenter study was to determine the histopathological features and immunohistochemical profiles of GISTs diagnosed in Turkish patients.
METHODS: Twenty participating centers registered GIST cases on a nationwide database. The diagnosis of GIST relied upon H&E features and the results of immune antibody panel including CD117, CD34, Desmin, SM Actin, S-100 protein, and Ki67. The database consisted of parameters including patient age and gender, tumour location, size, number of mitoses/50 HPF and other histopathological and immuno-histochemical findings. Statistical analysis was performed using Kruskal Wallis and Multiple Comparison Tests.
RESULTS: From a total of 701 GISTs registered into the database, 645 cases with a male to female ratio of 1.34 and a mean age of 56.19 years were included in the study after eliminating the cases with incomplete data. Most common location was stomach (40.8%) followed by small intestine, omentum and peritoneum, large intestine, and esophagus (32.9%, 13.5%, 10.4%, 0.5%, respectively). The risk groups consisted of 5.7% very low, 20.3% low, 20.0% intermediate and 54.0% high risk cases. There were significant differences ($p<0.001$) between the risk groups and mean size and number of mitoses in relation to tumour location. Spindle pattern was inversely, however, mixed pattern was positively correlated with increasing risk ($p<0.001$). CD117 was positive in 94.3% of GISTs whereas 73.5% were CD34, 51.9% SMA, 10.7% Desmin, 21.2% S-100 positive. Though no significant relation was found between CD117 expression and tumour location, CD34, SMA, S-100 and Ki67 expressions significantly varied in different locations ($p<0.001$). A similar difference was observed in CD117, CD34, Desmin, Ki67 expressions in relation to risk groups: CD117and Ki67 expressions increased in parallel with the risk while CD34 and Desmin decreased.
CONCLUSIONS: The results of this multicenter study demonstrated that features other than tumour size and mitosis, and other immune markers besides CD117 and Ki67 included in the antibody panel also seem to be useful predicting risk factors. Studies with long follow-up and response to therapy of GIST cases will form the basis of our future projects in order to determine the biological behavior of these tumors in our country.

*** Department of Biometrics of the Otto-von-Guericke University Magdeburg,Germany

INTRODUCTION: Gastrointestinal stromal tumors (GISTs) represent the most common mesenchymal neoplasm of the GI tract. In the last few decades this entity has became of incredible interest given the new insights derived from the discovery of its derivation from the interstitial cells of Cajal, of the invariable C-kit immunoreaction and of its sensitivity to a RTKs inhibitor drug.
OBJECTIVE: To ascertain the clinicopathologic features and biologic behaviour of these tumors, we reviewed a large series of GISTs with an immunohistochemical and molecular analysis, along with a correlation with clinical outcome.
METHODS: 94 primary GIST were retrieved from the files of the Departments of Anatomic Pathology of Naples-Italy and Basel-Switzerland that we reviewed, both at morphological and molecular level. 9 known oncogenes (CMYC, MDM2, GLI1, CDK4, HER2, EGFR1, CCND1, FGF3, EMS) were analyzed by fluorescent in situ hybridization (FISH) on a tissue microarray (TMA). Moreover the above 94 tumors were included in a larger group of 284 GISTs , retrieved from the Department of Pathology of the University of Magdeburg, Germany. P16 protein expression was analyzed by immunohistochemical staining on TMA, as well as on large sections.
RESULTS: A significant correlation between necrosis, cellularity, mitoses and risk categories of tumors, and the overall survival was found. Amplification was found for CMYC in 3 of 90 (3.3%), for MDM2 in 5 of 94 (5.3%), for EGFR1 in 5 of 94 (5.3%), and for CCND1 in 7 of 79 (8.9%) evaluable cases. No amplifications were seen for HER2, GLI1, CDK4, FGF3, EMS. Amplifications of MDM2 and

CCND1 were associated with clinical and histological malignancy. P16 loss was found in 50% of GISTs. Patients having p16-negative tumors had a worse prognosis than those with p16-positive tumors (p=0.012) with a 2.3-fold relative increased risk of dying of disease.
CONCLUSIONS: Interestingly, we found in a quite large number of cases of GIST, an association of morphologic parameters to aggressiveness of tumors. Moreover, MDM2/CCND1 amplification, and p16 loss may represent respectively molecular and immunohistochemical features to determine subsets of GISTs with poor prognosis. In conclusion our data show clinicopathologic implications in the prognosis of patients with GIST.

O-152
EXPRESSION OF HEDGEHOG SIGNALING COMPONENTS IN STOMACH AND GASTRIC LESIONS

ALINGER Beate, DATZ Christian, KOLLMANN Karoline, BLAAS Leander, ESTERBAUER Harald, ABERGER Fritz, DIETZE Otto, HAUSER-KRONBERGER Cornelia
Department of Pathology, General Hospital Salzburg; Department of Internal Medicine, Oberndorf Hospital; Department of Molecular Biology, University of Salzburg.

The Hedgehog signaling cascade has been shown to play an essential role in embryogenesis, especially in patterning and specification of several tissues. The pathway is involved in the development of the gut and the differentiation of gastric glandular cells. Hedgehog signaling components like the ligand Sonic Hedgehog (Shh) and its receptor Patched (Ptch) have been demonstrated to be expressed within the embryonic stomach. Main components of the Hedgehog pathway are expressed within the adult stomach, proposing an active role of the signaling also in mature stomach. Mutation of just one of the Hedgehog signaling components can lead to disregulation of the pathway resulting in gastric dysfunction and gastric malformations like intestinal metaplasia, gastric atrophy or even cancer.
In the present study normal gastric tissues from human, mouse and rat were analyzed using immunohistochemical methods. The antibodies used are directed against the main components involved in the Hedgehog signaling cascade, including the ligands Sonic, Indian and Desert Hedgehog, the transcription factors Gli1, Gli2 and Gli3 as well as the receptor Patched. Additionally 34 cases of benign and malignant human gastric lesions had been examined. Benign lesions comprise antrum gastritis, hyperplastic polyps, tubular adenomas and intestinal metaplasia, and malignant lesions intestinal adenocarcinoma, diffuse adenocarcinoma, neuroendocrine carcinoma and epithelial dysplasia with early adenocarcinoma. Several components of the Hedgehog signaling cascade are localized in human, and also in mouse and rat normal stomach, indicating an active Hedgehog pathway in the mature stomach. The expression is mainly restricted to the chief and the parietal cells. This may indicate a communication between these main cell types of the gastric glands resulting in a well coordinated and balanced regulation of the number of cells and of digestive processes. Additionally the ligands, the receptor and the transcription factors have been demonstrated in neuroendocrine cells and the myenteric plexus. Case dependent expression pattern of components of the Hedgehog signaling cascade in benign and malignant lesions may correlate with an individual up- or down-regulation of the pathway.
Our findings leads to the presumption that defective proceeding of one or even more of the hedgehog signaling steps may induce gastritis, dysplasia or even gastric cancer.

CHRONIC URTICARIA INVOLVES THE GASTRODUODENAL MUCOSA AS WELL AS THE SKIN

F Minnei1, C Wetzels2, G De Hertogh2, P Van Eyken2, R Ambu1, G Faa1, A-M Kochuyt3, K Geboes2
Dpt of Cytomorphology, Division of Pathology, University of Cagliari, Italy (1)
Dpts of Morphology & Molecular Pathology (2) and Allergy – Immunology (3), University Hospitals KUL, Leuven, Belgium

BACKGROUND & AIM
Chronic urticaria (CU) is characterized by recurrent episodes of itching, raised smooth and pink skin eruptions twice a week for more than six weeks. It can be initiated by food intake and may be associated with digestive symptoms. Quantitative cell counts have revealed an increased number of mast cells in biopsies from skin lesions of CU. The aim of the present study is to detect a possible relationship between a clinical history of CU and the number of mast cells in the gastroduodenal mucosa.
MATERIALS & METHODS
Two groups were defined as follows: (1) CU patients: 52 Belgians (20 males; mean age 44 y); (2) controls: 16 Belgians (8 males, mean age 43y) and 34 Italians (9 males, mean age 39 y) with upper abdominal complaints and normal endoscopy and histology. Formalin-fixed, paraffin-embedded biopsy specimens were stained with haematoxylin and eosin for routine analysis. We then detected mast cells in the gastroduodenal mucosa using immunohistochemistry for tryptase and c-kit (CD117). The number of mast cells was counted in 5 high power fields (HPF).
RESULTS
All the biopsies from the controls showed a normal histology of the gastroduodenal mucosa. The mean number of c-kit + cells was 21.0/HPF in the stomach and 34.8/HPF in the duodenum. The mean number of tryptase + cells in the stomach was 19.9/HPF for the Belgian controls and 18.4/HPF for the Italian controls. The values for the antrum and the corpus were 19.9 and 20.7/HPF. In the duodenum the mean numbers of tryptase + cells were 32.0/HPF for the Belgian controls and 32.6/HPF for the Italian controls.
In the CU patients the number of tryptase + cells was 31.7 ± 10.9/HPF (mean ± standard deviation, SD) in the stomach and 44.4 ± 16.3/HPF in the duodenum.
CONCLUSIONS
The number of c-kit + cells in the gastroduodenal mucosa of controls was slightly higher than the number of the tryptase+ cells (c-kit also stains degranulated cells). The number of tryptase+ cells was the same in the normal gastroduodenal mucosa from Belgian and Italian controls. Therefore we presume that dietary habits have no influence upon the number of mast cells in the gastroduodenal mucosa. The number of tryptase + mast cells was significantly increased in the gastroduodenal mucosa from patients with CU when compared with controls ($P < 0.0001$). It thus appears that CU is a syndrome which may involve the gastroduodenal mucosa, with presence of associated digestive symptoms.

PLEOMORPHIC HYALINIZING ANGIECTATIC TUMOR OF SOFT PARTS: A RECENTLY DESCRIBED ENTITY. ULTRASTRUCTURAL ANALYSIS OF ONE CASE.

CAPOVILLA M (1, 2), BIREMBAUT P (1), DE SAINT-MAUR PP (2), CUCHEROUSSET J (1), FLEJOU JF (2), PLOTON D (1).
(1) Laboratoire Pol-Bouin, Hôpital Maison-Blanche, Reims, France.

(2) Service d'Anatomie Pathologique, Hôpital Saint-Antoine, Paris, France.

The Pleomorphic Hyalinizing Angiectatic Tumor (PHAT) is a rare lesion of uncertain lineage that occurs in the superficial soft tissues of the distal extremities and trunk. It was first described by Smith et al. in 1996 with a series of 14 cases and, to date, fewer than 100 cases have been reported. Morphologically, it shares common features with ancient schwannomas and malignant fibrous histiocytomas. In fact, it is characterized by the presence of prominent ectatic vessels with hyalinized walls, pleomorphic spindle stromal cells with intranuclear inclusions and a variable inflammatory component. Despite the presence of numerous atypical cells, mitotic rates are extremely low and this lesion seems to behave as a low-grade neoplasm with possible local recurrences but, not to date, metastases. Only 3 cases of PHAT have been previously studied by electron microscopy. They appeared constituted of primitive mesenchymal cells with bizarre nuclei and numerous intermediate-sized cytoplasmic filaments. The histogenesis and lineage of PHAT are currently unknown; some features are consistent with a reactive process secondary to vascular damages but a unique cytogenetic analysis is more in favour of a neoplastic lesion because of presence of additional ring chromosomes in the neoplastic nuclei. Some authors have recently reported a putative precursor lesion, so-called "early-PHAT". Thus, PHAT should be considered as a low-grade mesenchymal neoplasm and complete surgical excision may be the treatment of choice.

We report a case of PHAT arising from the right buttock of a 66 year-old man. Histologically, it presented areas of typical PHAT and two original features with the presence of a large central area of ischemic necrosis and ganglion-like cells. The tumor cells expressed vimentin and VEGF but not CD34. Ultrastructural analysis revealed primitive mesenchymal cells with pleomorphic nuclei, abundant granular endoplasmic reticulum and numerous intracytoplasmic intermediate filaments. A collagen-rich extracellular matrix with incomplete basal membranes surrounded each cell. The vascular walls were very thickened by abundant hyaline material.

This observation supports the hypothesis of a proliferation of primitive mesenchymal cells. However, further pathologic, cytogenetic and molecular analysis are needed to establish that PHAT is really a neoplastic lesion and to study its natural history.

NON-INVOLUTING CONGENITAL HEMANGIOMA PRESENTING AS ATYPICAL LARGE LESIONS IN THE NECK

WASSEF Michel (1), SALHI Aïcha (2), KOZAKEWICH Harry (3), BREVIERE George-Marie (4), MULLIKEN John (3), ENJOLRAS Odile (1)

(1) Department of pathology and Consultation des angiomes, hôpital Lariboisière, Paris, France. (2) Consultation des angiomes University Hospital Algiers, Algeria. (3) Center for vascular anomalies, Childrens hospital, Boston, USA. (4) Department of cardiology, hôpital Nord, Lille, France.

Aim: Non-involuting congenital hemangioma (NICH) is a recently described vascular tumor that generally manifests as a round or oval plaque-like or bossed lesion of limited extension, with an average size of 6 cm diameter, mainly affecting the face and the limbs. These lesions are clinically and histologically distinct from common hemangioma of infancy.

We describe a series of a peculiar vascular tumour, presenting as a large plaque-like lesion in the neck and shoulder, and histologically resembling NICH.

Patients: There were 11 patients in this series (8 females and 3 males).

Results: All lesions were congenital; none evidenced postnatal disproportionate growth; and subsequently either were stable or altered slightly. They involved the entire posterior and lateral aspect of the neck, from hairline to upper trunk, unilaterally in 7 patients, bilaterally in 4. Three also extended to the mandibular area. All resembled proliferating phase or involuting phase infantile hemangioma, rather than NICH. In addition, all had a distinctive peripheral bluish or white halo and scar-like atrophic areas. US/Doppler or arteriogram indicated fast-flow, without arteriovenous fistulas, causing diagnostic confusion with arterio-venous malformation.

Histological specimens were available for 8 patients and showed an admixture of veins and arteries, many of which appeared abnormal and lobular aggregates of small vessels. These vessels were lined by endothelial cells with barely visible cytoplasm and contained small, dark, hyperchromatic nuclei protruding in the lumen, creating a hobnailed appearance. Some anisokaryosis was present but mitoses were rare. In some specimens, small clusters of endothelial cells contained round, eosinophilic globules in their cytoplasm. These features were reminiscent of NICH.

Conclusion: Besides the limited plaque-like or bossed lesion initially described, non-involuting congenital hemangioma may present as large extensive lesion in the neck and shoulder area.

O-156
MDM2 AND CDK4 IMMUNOSTAININGS ARE USEFUL ADJUNCTS IN DIAGNOSING WELL-DIFFERENTIATED AND DEDIFFERENTIATED LIPOSARCOMA SUBTYPES. A COMPARATIVE ANALYSIS OF 561 SOFT TISSUE NEOPLASMS WITH GENETIC DATA.

BUI NGUYEN BINH Matthieu, SASTRE-GARAU Xavier, GUILLOU Louis, DE PINIEUX Gonzague, TERRIER Philippe, LAGACE Réal, AURIAS Alain, HOSTEIN Isabelle, COINDRE Jean Michel.

From the departments of pathology at the Curie Institute Paris (MBNB, XSG), the University Institute of Pathology, Lausanne, Switzerland (LG), Cochin University Hospital, Paris (GP), the department of pathology at the Gustave Roussy Institute (PT), Hotel-Dieu University Hospital, Montreal, Canada (RL), Bergonié Institute , Bordeaux (IS, JMC), University Victor Ségalen, Bordeaux (JMC) and INSERM Unit 509, the Curie Institute, Paris (AA).

Introduction: atypical lipomatous tumor - well differentiated liposarcoma (ALT-WDLPS) and dedifferentiated liposarcoma (DDLPS) may be difficult to distinguish from benign adipose tumors and from poorly differentiated sarcomas, respectively. Genetically, they are characterized by amplification of MDM2 and CDK4 genes on chromosome 12q13-15.

Purpose of the study: we studied MDM2 and CDK4 immunoexpression in a large series of soft tissue sarcomas to evaluate the correlation between staining, pathological diagnosis and genetic data.

Materials and methods: we examined a series of 559 soft tissue tumors (44 ALT-WDLPS, 61 DDLPS, 49 benign adipose tumors, and 405 non-ALT-WDLPS/DDLPS sarcomas) for MDM2 and CDK4 expression using immunohistochemistry either on whole tissue sections and/or tissue microarrays. MDM2 and CDK4 immunoexpressions were compared to gene amplification status (as assessed by quantitative PCR and/or comparative genomic hybridization) in 239 neoplasms.

Results: most ALT-WDLPS/DDLPS expressed MDM2 (97%) and CDK4 (92%) as opposed to few benign adipose tumors (MDM2: 5%; CDK4: 2%) and a limited number of

non-ALT-WDLSP/DDLPS sarcomas (MDM2: 18%; CDK4: 6%). The sensitivity and specificity of MDM2 and CDK4 immunostainings in identifying ALT-WDLPS/DDLPS among other soft tissue tumors were 97% and 92%, and 83% and 95%, respectively. MDM2 and CDK4 immunostainings were particularly useful to separate ALT-WDLPS from the large group of differentiated adipose tumors, and to distinguish DDLPS from poorly differentiated sarcomas. A strong correlation was observed between MDM2 and CDK4 stainings and gene amplification status. MDM2 and CDK4 stainings were comparable whether they were performed on tissue microarrays or on whole tissue sections.
Conclusion: MDM2 and CDK4 immunostainings, which correlate with gene amplification, are helpful adjuncts to differentiate ALT-WDLPS from benign adipose tumors and to separate DDLPS from poorly differentiated sarcomas.

EVALUATION OF MDM2 GENE AMPLIFICATION AND EXPRESSION AS POTENTIAL TOOLS FOR THE DIAGNOSIS OF ATYPICAL LIPOMATOUS TUMORS/WELL-DIFFERENTIATED LIPOSARCOMAS IN PARAFFIN-EMBEDDED MATERIAL

Speel EJM, Meulemans EV, Rüland AM, Pauwels P
Department of Pathology, University Hospital Maastricht, The Netherlands

The distinction between lipomas and atypical lipomatous tumours/well differentiated lipo-sarcomas (WDLs) may be difficult to make on basis of histology and is one of the most frequent problems encountered when consultative second opinions are sought. Lipomas are cytogenetically characterized by a variety of balanced rearrangements often including the chromosome 12q13-15 region, whereas in WDLs supernumerary ring and giant marker chromosomes have been reported containing amplified 12q sequences. The MDM2 gene, located within the 12q13-15 region, is an important candidate for amplification, which may result in protein overexpression. This may permit override of the block operated by the G1-S cell cycle checkpoint on cell proliferation. The goal of this study was to determine if overexpression of MDM2 and/or MDM2 gene amplification can be used as (a) diagnostic marker(s) for the differential diagnosis of lipoma and WDL. For this purpose, we analyzed paraffin-embedded material of a series of 18 lipomas (including 4 arguable cases) and 9 liposarcomas (7 WDL, 2 dedifferentiated tumors) for MDM2 protein accumulation by routine immunohistochemistry and for MDM2 gene amplification by multicolor fluorescence in situ hybridisation (FISH) using MDM2 and centromere 12-specific probes. Three of the 18 lipomas showed MDM2 overexpression, particularly in areas with inflammation, whereas no gene amplification was detected in these tumors. In the liposarcomas, 8 tumors showed MDM2 protein accumulation except for 1 WDL. FISH analysis, however, revealed MDM2 gene amplification in this WDL as well as in 6 additional tumors, but showed two copy numbers per nucleus for both probes in 1 WDL and 1 dedifferentiated liposarcoma positive for MDM2 protein expression. Thus, although MDM2 immunostaining and MDM2 gene amplification detection by FISH show a high amount of concordance, the latter approach might be preferred in the differential diagnosis of lipoma and liposarcoma, because MDM2 immunostaining is unreliable in case of inflammatory infiltrates present in the tumor.

LOCAL RECURRENCE OF MYXOFIBROSARCOMA IS ASSOCIATED WITH INCREASE IN TUMOUR GRADE AND CYTOGENETIC ABERRATIONS, SUGGESTING A MULTISTEP TUMOUR PROGRESSION MODEL.

WILLEMS Stefan M (1), DEBIEC-RYCHTER Maria (3), SZUHAI Karoly (2), SCIOT Raf (4) and HOGENDOORN Pancras CW (1)
Departments of (1) Pathology and (2) Molecular Cell Biology, Leiden University Medical Center,Leiden, The Netherlands;
Departments of (3) Human Genetics and (4) Pathology, Catholic University of Leuven, Leuven, Belgium

Myxofibrosarcoma is one of the most frequent soft tissue tumours in elderly patients, mostly arising in the extremities. Low-grade lesions are only locally aggressive whereas intermediate and high-grade lesions have metastatic potential. The differential diagnosis contains several other benign myxoid soft tissue tumours. A number of sarcomas are characterized by specific cytogenetic aberrations, giving not only insight in their biological pathways; they also serve as helpful molecular markers in difficult diagnosis. However, cytogenetic data on myxofibrosarcomas are scarce with only a few isolated cases described in the literature. No specific chromosomal aberrations have been detected so far. Moreover, molecular pathways in tumorigenesis and progression of myxofibrosarcomas are barely understood.
Here we describe the clinicopathologic data and karyotypes of 32 myxofibrosarcomas. These include 8 low-grade, 8 intermediate-grade and 16 high-grade lesions. Twenty-two were primary tumours, nine were local recurrences and 1 a lymph node metastasis. Complex cytogenetic anomalies were found in all grades, including the presence of ring chromosomes. However, no tumour-specific chromosomal abnormalities could be withdrawn. Local recurrences showed increase in grade compared to their primary lesions. Interestingly, these local recurrences showed more complex cytogenetic aberrations. Thus increase in grade parallels increase in cytogenetic aberrations and malignant potential. Since the chromosomal aberrations found were not tumour type specific, we think that they are rather the result of secondary events in tumour progression. Based on these findings, we suggest that tumorigenesis of MFS is mainly a multistep genetic process.

O-159
DETECTION OF LOW-GRADE FIBROMYXOID SARCOMA (LGFMS) T(7;16) (FUS-CREB3L1/2) TRANSLOCATION IN PARAFFIN-EMBEDDED TISSUES, USING RT-PCR. A USEFUL DIAGNOSTIC ADJUNCT.

Louis Guillou (1), Carole Gengler (1), Jean-Michel Coindre (2), Gabrielle Gallagher (1), Dominique Ranchère-V. (3), Jean Benhattar (1), and the Members of the French Sarcoma Group. University Institute of Pathology, Lausanne, Switzerland (1), Bergonié Institute, Bordeaux (2), and Léon-Bérard Cancer Center, Lyon (3), France.

Introduction. Separating LGFMS from benign mimics (e.g. desmoid tumors, perineuriomas,..) is often problematic for pathologists. Over 90% of LGFMS bear the t(7,16) (q32-34;p11) translocation, involving either FUS and CREB3L2 (BBF2H7) genes (95% of cases) or FUS and CREB3L1 genes (5%). FUS-CREB3L1/2 fusion transcripts are detectable in frozen tissues, using RT-PCR. Experience regarding their detection in paraffin-embedded tissues is limited.
Purpose of the study. To develop a sensitive and reliable method to detect FUS-CREB3L1/2 fusion transcripts in paraffin-embedded tissues.
Materials and methods. 35 fixed, paraffin-embedded soft tissue neoplasms (30 primaries, 3 local recurrences, 2 lung metastases) with morphologic features suggestive of LGFMS,

and 31 non-LGFMS tumors were examined for the presence of FUS-CREB3L1/2 transcripts.
Results. PCR products were detected in 59 of 66 (89.4%) neoplams, including 34 (97%) potential LGFMS and 25 (80%) non-LGFMS. 26 of 34 (sensitivity: 76.5%) neoplams showing morphologic features most consistent with LGFMS contained detectable FUS-CREB3L2 (25/26; 96%) and FUS-CREB3L1 (1/26) fusion transcripts. In addition, 2 non-LGFMS, initially diagnosed as sclerosing epithelioid fibrosarcomas contained FUS-CREB3L2 transcripts; all other (n=23) non-LGMFS neoplasms were negative for FUS-CREB3L1/2 transcripts (specificity: 92%), including 9 desmoid tumors, 4 cellular myxomas, 3 sclerosing epithelioid fibrosarcomas, 3 ossifying fibromas, 1 desmoplastic fibroblastoma, 1 low-grade myxofibrosarcoma, and 2 unclassified non-LGFMS fibromyxoid sarcomas. Patients with t(7;16)-positive tumors (n=28) included 15 females and 13 males, aged from 13 to 75 years (median: 39.5 years). Tumor size on 19 cases varied between 3 and 19 cm (median: 8 cm). Tumor sites included lower extremity (11/28, 9 in the thigh), trunk wall (9), buttock (1), internal trunk (4), head and neck (2), and upper extremity (1). All but one neoplasms were deep-seated. Immunohistochemically, t(7;16)-positive LGFMS expressed epithelial membrane antigen (15/20), at least focally, but were consistently negative for S100 protein (0/23), CD34 (0/22), smooth muscle actin (0/22), desmin (0/19), and keratins (0/16).
Conclusion. The t(7;16) FUS-CREB3L1/2 translocation seems to be specific for LGFMS but fusion transcripts are detected in only 76.5% of those neoplasms initially diagnosed as potential LGFMS. 75% of t(7;16)-positive LGFMS express EMA.

CHROMOSOMAL INSTABILITY PREDICTS THE MALIGNANT PHENOTYPE IN SPORADIC INSULINOMAS

Ernst-Jan M. Speel1, Yvonne M.H. Jonkers1, Sandra M.H. Claessen1, Aurel Perren2, Sonja Schmid2, Paul Komminoth3, Albert A. Verhofstad4, Leo J. Hofland5, Ronald R. de Krijger6, Piet J. Slootweg7, Frans C.S. Ramaekers1

Insulinomas are the most frequently encountered functioning endocrine pancreatic tumors to occur in humans. The metastatic potential of insulinomas can frequently not be predicted using histopathological criteria, and also molecular markers indicating malignant progression are unreliable because of the small number of cases per subtype studied so far. For the identification of reliable indicators of metastatic disease, we studied 62 sporadic insulinomas (44 benign and 18 tumors with metastases) by means of comparative genomic hybridization (CGH). In addition, the role of MEN1 gene mutations was determined to assess specific chromosomal alterations associated with dysfunction of this endocrine tumor-related tumor suppressor gene. Only one case with a somatic MEN1 mutation was identified (1527del7bp), indicating that the MEN1 gene plays a minor pathogenic role in sporadic insulinomas. CGH analysis revealed that 1) the total number of aberrations per tumor differs strongly between the benign and the malignant group (4.2 vs 14.1; $p<0.0001$), and 2) chromosome 9q gain is the most frequent aberration in both benign and malignant insulinomas, whereas chromosome 6q losses and 12q, 14q and 17pq gains are strongly associated with metastatic disease. Our study shows that chromosomal instability, as defined by 5 or more gains together with 5 or more losses, or a total number of gains and losses of 8 or more, rather than parameters such as tumor size, is the most powerful indicator for the development of metastatic disease in patients with sporadic insulinoma. Furthermore, the identified genetic changes may indicate novel genes important in the tumorigenesis of insulinomas.
This study was supported by grants from the Association for International Cancer Research and the Netherlands Foundations Vanderes and Sacha Swarttouw-Hijmans.

THE PROGNOSTIC SIGNIFICANCE OF CYTOKERATIN 19 EXPRESSION IN PANCREATIC ENDOCRINE TUMORS (PETS)

LA ROSA Stefano, BIANCHI Veronica, RIGOLI Elena, UCCELLA Silvia, CAPELLA Carlo
Dept. of Pathology, Ospedale di Circolo and University of Insubria, Varese, Italy

Introduction: pancreatic endocrine tumors are a heterogeneous group of neoplams showing different clinical, morphological and molecular features. They are currently classified according to the criteria of the recent WHO classification into well and poorly differentiated tumors. The latter represent a very aggressive category with poor outcome and well defined histology. Well differentiated tumors include benign, malignant or borderline subtypes and their prognosis is difficult to establish on a pure morphological background. In recent years, several attempts have been made to identify prognostic markers and, among them, the expression of cytokeratin 19 (CK19) has been recently proposed as an indicator of unfavorable outcome. However, this finding remains to be verified and to be compared with more used prognosticators such as Ki67 and mitotic index, vascular and/or perineural invasion.
Aim: was to evaluate the expression and the role of cytokeratin 19 as prognostic marker in PETs.
Methods: 145 well characterized PETs have been immunohistochemically studied using two different anti-CK19 monoclonal antibodies (BA17 and RCK108). Results were statistically compared with clinicopathological features, Ki67 and mitotic index and vascular and perineural invasion.
Results: By univariate analysis, only the CK19-immunoreactivity obtained with the RCK108 antibody correlated with prognosis. In particular, RCK108 staining correlated with prognosis when the whole group of PETs was considered and in the group of insulinomas. On the contrary, it did not show a prognostic meaning among nonfunctioning neoplasms. Ki67 index, mitotic count, vascular and perineural invasion were all statistically correlated with prognosis at the univariate analysis. However, at the multivariate Cox test analysis, only the Ki67 index (>2%) proved to be an independent prognostic marker.
Conclusion: CK19 expression when tested with the RCK108 antibody correlates with the prognosis of patients with PETs, and especially for those harboring insulinomas. However, Ki67 index appears to be a more significant prognostic predictor.

DOES EXPRESSION OF CYTOKERATIN 19 IN PANCREATIC ENDOCRINE TUMORS CORRELATE WITH THE WHO CLASSIFICATION?

KAPRAN Yersu*, OZTURK A. Sanem*, GULLUOGLU Mine G.*, ERBIL Yesim**, GILES Yasemin**, BILGE Orhan**, DIZDAROGLU Ferhunde*
*Istanbul University Istanbul Faculty of Medicine, Department of Pathology

**Istanbul University Istanbul Faculty of Medicine, Department of General Surgery

Expression of cytokeratin 19 in islets is restricted to fetal pancreas, whereas strong expression remained in the ductal cells of the adult pancreas. In compatible with this feature ductal carcinomas positively stain with CK19, while CK19 expression has not been systematically investigated in pancreatic endocrine tumors (PETs). A recent study suggests that CK19 positivity is a highly specific marker of adverse outcome in PETs. Our aim was to evaluate the expression of CK19 in PETs classified according to the WHO classification. Our study included 22 tumors of which 8 were well-differentiated benign PETs, 10 well-differentiated PETs with uncertain behavior and 4 well-differentiated malignant PETs. In the benign group only one tumor showed focal weak CK19 positivity (1/8), while all tumors in the uncertain behavior (10/10) and malignant group (4/4) had diffuse and moderate to strong positivity ($p<0.001$). Our results indicate a close association between CK 19 immunoexpression and WHO classification. CK19 can be used to discriminate the benign tumors from other groups, though it does not show any difference between tumors with uncertain behavior and malignant ones.

Introduction: Adrenocortical carcinoma is a rare cancer with a very poor prognosis. The genetic alterations identified to date in adrenocortical tumors (ACT) are limited. Activating mutations of the Wnt signaling pathway have been observed in more frequent cancers, particularly digestive tract tumors. We investigated whether Wnt pathway activation is involved in ACT tumorigenesis.
Material and methods: Sporadic adrenocortical tumor (other than Conn's adenoma) was diagnosed in 39 adult patients. Immunohistochemical study with an anti ß-catenin antibody was performed from formalin-fixed tissue embedded in paraffin. For mutation analysis exon 3 and the flanking intronic sequences of the beta-catenin gene were amplified by PCR from tumoral as well as leucocyte DNA.
Results: Immunohistochemistry (IHC) revealed abnormal cytoplasmic and/or nuclear accumulation of ß-catenin in 10 of 26 adrenal adenomas (AA) and 11 of 13 adrenal carcinomas (AC). An activating somatic mutation of the ß-catenin gene was demonstrated in 7 AA (7/10 with abnormal IHC) and 4 AC (4/11); most of these mutations were point mutations altering the serine 45 of exon 3 (in the consensus GSK3ß/CK1 phosphorylation site), although deletions were also observed in two ACT. This is the first molecular defect to be reported with the same prevalence in both benign (7/26) and malignant (4/13) ACT. ß-catenin mutations are also the most frequent genetic defect currently known in AA. In AA, ß-catenin alterations seem to be more frequent in non functional tumors, suggesting that ß-catenin pathway activation might be involved in the development of non secreting AA and AC. The very frequent and substantial accumulation of ß-catenin in AC suggests that other alterations might also be involved as APC or axin mutations.
Conclusion: The finding of activating mutations of the Wnt signaling pathway in adrenocortical tumors may contribute to new therapeutical approaches targeting the Wnt pathway in malignant ACT, for which only very limited medical therapy is available.

1Department of Molecular Cell Biology, University of Maastricht, Departments of Pathology, 2Josephine Nefkens Institute, Erasmus University Medical Center Rotterdam and 4University Medical Center Nijmegen, The Netherlands and 3Department of Cancer Genetics and Developmental Biology, British Columbia Cancer Research Center, Vancouver, Canada

Pheochromocytomas (PCCs) are relatively rare neuroendocrine tumors, mainly of the adrenal medulla. They occur sporadically or as part of inherited cancer syndromes, such as MEN2, NF1 or VHL. Because to date no reliable histological or molecular markers are available to distinguish benign from malignant PCCs, and VHL-related PCCs exhibit genetic alterations different from sporadic PCCs, we used conventional CGH analysis to identify chromosomal alterations involved in tumor development and metastatic progression in 55 sporadic, 10 MEN2- and 3 NF1-related PCCs. In addition, 24 of these tumors were analyzed by CGH on a microarray of 642 overlapping BAC clones mapped to 1p11.2-1p36.33 to identify the critical regions on this most frequently lost chromosome arm in PCCs. ArrayCGH showed that the consensus regions of deletion involved 1cen-1p32.3 and 1p34.3-1p36.33. Conventional CGH analysis revealed that 1) 1p and 3q losses are frequent, 2) amplifications in each of 3 sporadic tumors are detected at 7p13-q22, 10q11.2 and 19p13.2-13.3, 3) the average number of alterations, gains and losses per tumor differed significantly between benign sporadic and MEN2-related PCCs, i.e. 5.4 versus 9.6 ($P<0.0001$), 1.2 versus 3.5 ($P=0.003$) and 4.1 versus 6.1 ($p=0.007$), respectively, 4) losses of 3q, 8q, 9p and 13q and gains of 1q, 17q and 20q were more often observed in MEN2-related PCCs, whereas losses of 6q and 11p were exclusively found in the sporadic PCCs, 5) benign tumors are significantly smaller than malignant ones (d= 6.2 versus 10.5 cm; $P=0.001$), 6) the total number of aberrations per tumor differs strongly between benign and malignant PCCs (5.4 versus 9.4; $P=0.004$), as does the number of gains (1.2 versus 2.9; $P=0.04$) and losses (4.1 versus 6.6; $P=0.008$), and 7) losses of 8p and 18p and gains of 5p, 7p and 12q are detected significantly more frequent in malignant PCCs (P¡Ü0.047). Our study indicates that losses of 1p and 3q are early genetic events in the pathogenesis of sporadic and syndrome-related PCCs, but that sporadic and MEN2-associated tumors further evolve along different genetic pathways. Malignant PCCs appear to be associated with chromosome 8p and 18p losses and 5p, 7p and 12q gains. The identified chromosomal

regions may lead to the discovery of novel genes that play a role in PCC tumorigenesis and may help to predict their biological behavior.
This study was supported by the Netherlands Van Walree Fund and the Dutch Cancer Society.

O-165
CORRELATION OF ACCUMULATION OF MICROSATELLITE ABNORMALITIES AND SOMATIC DOWN-REGULATION OF MISMATCH REPAIR PROTEINS IN MALIGNANT PHEOCHROMOCYTOMAS

Salvador J. Diaz-Cano(1,2) and Alfredo Blanes(2)
(1) King's College Hospital-GKT School of Medicine, London, UK
(2) University of Malaga School of Medicine

Background: Adrenal pheochromocytomas (PCC) have been extensively studied at the molecular level, but no information is available on the microsatellite profile by topographic compartments of malignant and locally-invasive PCC. The contribution of DNA mismatch repair abnormalities to this profile remains unknown.
Design: Microdissected samples from the peripheral and internal zones of 143 PCC (95 sporadic, 48 associated to MEN 2A) were selected for loss of heterozygosity (LOH) and single nucleotide polymorphism (SNP) analyses. Five polymorphic DNA regions from TP53, RB1, WT1, and NF1 were systematically studied by polymerase chain reaction-denaturing gradient gel electrophoresis. PCC were classified malignant (16 sporadic tumors with distant metastases), locally invasive (30 sporadic tumors showing showing retroperitoneal infiltration only), and benign (all remaining tumors). Statistical differences were evaluated using Fisher's exact test. Mismatch repair was assessed by mlh1 and msh2 sequencing and immunostaining in PCC with >2 abnormal microsatellite loci.
Results: LOH/SNP involved TP53 in 40/134 informative cases (29.9%), RB1 in 22/106 informative cases (20.8%), WT1 in 32/120 informative cases (26.7%), and NF1 in 32/80 informative cases (40.0%). More genetic abnormalities involving the peripheral compartment were revealed in 34 PCC (23.8%): 12/16 malignant, 10/30 locally invasive, and 12/97 benign. Multiple and coexistent genetic abnormalities characterized malignant PCC ($p<0.001$), whereas locally invasive PCC showed significantly higher incidence of NF1 alterations ($p<0.001$).
A significant decrease of MLH1/MSH2 protein expression was observed in the peripheral compartment, but with no gene mutations identified in PCC with high microsatellite instability.
Conclusions: 1. Somatic topographic down-regulation of mismatch repair proteins contributes to both the accumulation of microsatellite lesions in the peripheral compartment and intratumor heterogeneity, the trwo key features characterizing malignant PCC and supporting multistep tumorigenesis for these neoplasms. 2. In contrast, locally invasive PCC frequently reveals single locus alterations, especially involving NF1.

Introduction. Cortistatin (CST) is a novel hormone firstly described in the rat, mouse and human cerebral cortex, with structural and functional similarities to somatostatin (SRIF). CST binds to all five somatostatin receptors, and, differently from SRIF, also to other receptors, such as the growth hormone secretagogue receptor (GHS-R) type 1a and MrgX2, recently identified as its specific receptor. Little is known on CST and MrgX2 distribution in peripheral non-tumoral and neoplastic tissues, although the presence of CST has been reported in the human endocrine pancreas and immune system.
Purpose of the study. Our aim was to determine CST and MrgX2 distribution, at both protein and mRNA level, in human non-tumoral and neoplastic tissues, with special reference to neuroendocrine ones.
Methods. CST and MrgX2 immunohistochemistry and mRNA analysis (RT-PCR) were performed in 56 non-tumoral and 108 tumoral human tissues. Co-localization experiments with double-label immunofluorescence and immunohistochemistry were also performed.
Results. Despite the high amount of CST mRNA expression in non-tumoral and tumoral (both neuroendocrine and non-neuroendocrine) tissues, the presence of immunoreactive CST was confirmed in a subset of gastroenteropancreatic (GEP), parathyroid, and pituitary non-tumoral cells only, and, focally, in 24/43 neuroendocrine tumors. No immunoreactivity was observed in non-neuroendocrine tumors. Colocalization experiments in the GEP system demonstrated that the normal CST producing cells are ä cells, while in the adenohypophysis no preferential co-localization of CST with any of the pituitary hormones was observed. MrgX2 mRNA was variably detected in the hypothalamus, pituitary, thyroid, lung, GEP tract, testis and ovary, and was negative in the cerebral cortex, parathyroid and adrenal, as well as in a variety of tumor types. Conversely, immunolocalization of MrgX2 protein was restricted to neurohypophysis and testis, being all tumors analyzed negative. Moreover, MrgX2 protein was widely detected in blood vessels, scattered lymphocytes and gastrointestinal ganglia, of both normal and neoplastic samples.
Conclusion. Our findings demonstrate a selective distribution of CST in normal and neoplastic neuroendocrine tissues suggesting that CST might have a broader functional role than previously assumed. In tumors, autocrine/paracrine CST actions are probably mediated by receptors (ie somatostatin receptors) other than MrgX2.

GALECTIN-3 IMMUNOHISTOCHEMICAL DETECTION IN THE DIFFERENTIAL DIAGNOSIS OF PARATHYROID LESIONS.

VOLANTE Marco*, BERGERO Nicoletta, RAPA Ida, ROSAS Rosj, SACERDOTE Carlotta*, GASPARRI Guido, BUSSOLATI Gianni*, PAPOTTI Mauro

Introduction. The differential diagnosis and classification of parathyroid lesions needs complementary evaluation of clinical data and morphologic features. No strict microscopic criteria have been unequivocally defined, especially in the identification of malignant lesions without clear-cut invasive growth or metastases. Proliferation markers (Ki-67 and others) have been proposed to distinguish adenomas from carcinomas, but a some overlap exists between benign and malignant lesions, thus limiting their diagnostic applicability.

Purpose of the study. We aimed to analyze the expression of galectin-3 (gal-3), a well-established marker of malignancy in thyroid follicular nodules, as a possible diagnostic adjunct in the classification of parathyroid hyperplastic/neoplastic lesions.
Methods. A retrospective series of 112 parathyroid lesions, including 26 carcinomas (PC) (diagnosed on the basis of capsular/vascular invasion in 26 cases, extra-parathyroid infiltration in 16 cases, local recurrence in 9 cases and distant metastases in 6 cases), 35 adenomas (PA), 4 primary hyperplasias (PHP), 50 secondary hyperplasias (SPH) and 7 tertiary adenomas (TPA), was collected and screened by immunohistochemistry for Ki-67 and gal-3. Results were statistically validated in terms of sensitivity, specificity and p values determined by Fisher and Mann-Whitney tests.
Results. As expected, Ki-67 proliferative index was higher in PC (mean 6.7%) than PA (2.2%), PHP (0.3%), SHP (1,8%), and TPA (0.1%) ($p<0.001$). Gal-3 was expressed by 92.3% of PC (24/26) and 3.3% of PA (1/35) ($p<0.001$). All metastatic PC cases were gal-3 positive. The association of gal-3 with Ki-67 (using a cut-off of 6%) increased sensitivity to 96.2% and specificity to 90%. PHP and TPA were gal-3 negative in all but one case each, while SPH showed gal-3 immunoreactivity in 62% of cases, with a slightly higher expression (percentage of case and also intensity) in recurrent cases.
Conclusion. In highly proliferating (Ki-67 >6%) primary parathyroid lesions, gal-3 expression is a valuable additional tool to support a diagnosis of PC. By contrast, gal-3 over-expression in most SHP is unrelated to malignancy, and, although limiting its diagnostic utility in secondary hyperparathyroidism, may suggest a possible role of specific gal-3 modulators linked to renal failure and active in its up-regulation.

Institut Curie, 26, rue d'Ulm, 75248 Paris.

Background: HPV DNA sequences are associated with the large majority of genital cancer but the oncogenic role of these viruses in head and neck tumors is less documented. We have analyzed a series of cases to determine whether tumors of the oral cavity were more likely to be linked to HPV.
Material and Methods. A series of 80 cases of oral invasive squamous cell carcinoma has been analyzed. These cases corresponded to tumors developed in the tonsil (51 cases) or in other localizations of the oro-pharyngeal region (tongue, gingiva …) (29 cases). For each case, a DNA extraction and HPV typing have been performed by PCR using primers specific for HPV16, HPV18, HPV6/11, HPV33, HPV45 or using consensus primers.
Results: HPV DNA sequences were found in 38 of the 80 cases analyzed (48%). A striking difference was observed between the HPV positive rate in tonsil carcinoma (61%) and that in other localizations (24%). Most of the HPV positive carcinoma of the tonsil were found associated with HPV16 (25/31;81%). In contrast, only 3 of the 7 tumors at other localizations were associated with this type of virus.
Conclusion: A high incidence of HPV 16 is observed in tonsil carcinoma, in contrast with that found in other tumors of the oral cavity. Further studies are in progress to determine whether clinical, pathological and epidemiological features distinguish HPV positive from negative carcinoma of the tonsil. These data may be important for a better knowledge of the pathogenesis of head and neck tumors and for the development of specific therapy.

HPV 16 IN RELATION TO SMOKING AS PROGNOSTIC INDICATORS FOR PATIENTS WITH TONSILLAR CARCINOMAS

Speel EJM1,3, Hafkamp HC2, Schepers M2, Bot FJ3, Haesevoets A1, Claessen SMH1, Voogd AC4, Hopman AHN1, Ramaekers FCS1, Manni JJ2.
1Departments of Molecular Cell Biology and 4Epidemiology, University of Maastricht, and Departments of 2Otorhinolaryngology, Head and Neck Surgery and 3Pathology, University Hospital Maastricht, The Netherlands

Apart from alcohol and tobacco, oncogenic human papillomavirus (HPV) is a causative agent for a subgroup of head and neck squamous-cell carcinomas (HNSCC), particularly tonsillar carcinomas. The literature, however, is controversial with respect to the physical status of HPV DNA (episomal and/or integrated) in the tumor cells, the use of p16INK4A overexpression as a surrogate marker for HPV detection, and the clinical course and prognosis of HPV-related HNSCC. Formalin-fixed, paraffin-embedded tissue sections of 81 tonsillar carcinomas were subjected to HPV 16-specific fluorescence in situ hybridization (FISH) and p16INK4A-specific immunohistochemistry to assess the frequency of tumors exhibiting HPV integration and p16INK4A overexpression. Medical records were screened for (clinical) patient data, and results were statistically evaluated. FISH detected HPV 16 integration in 33/81 (41%) carcinomas, 32 of which also showed p16INK4A accumulation. Only 5/48 HPV-negative carcinomas did stain for p16INK4A. The presence of HPV in the tumor thus correlates very strongly with p16INK4A overexpression ($P<0.0001$), as well as with low amounts of tobacco and alcohol intake, poor differentiation grade, small tumor size, presence of local metastases and a decreased recurrence rate (P,,T0.039). Kaplan Meier analysis revealed that particularly non-smoking patients with HPV-containing tumors show a remarkable improved disease-specific survival as compared to smoking patients with or without detectable HPV. In conclusion, our data show that approximately half of the tonsillar carcinomas harbor integrated HPV 16 DNA. Virus integration is strongly correlated with p16INK4A accumulation, suggesting that p16INK4A may be considered as an alternative biomarker for HPV detection in tonsillar carcinomas. HPV 16-associated tonsillar tumors predict an improved prognosis in non-smokers.
Supported by the Medical Research Foundation of the University Hospital Maastricht.

A FRENCH STUDY OF 58 TONSILLAR CARCINOMAS: HPV TESTING AND EXPRESSION OF P16 PROTEIN

GUILLOU Pierre-José, COISSARD Cyrille, VITRY Fabien, LORENZATO Marianne, CHAYS André, PLUOT Michel, BIREMBAUT Philippe, DIEBOLD Marie Danièle, CLAVEL Christine, MEROL Jean-Claude
Laboratoire Central d'Anatomie et de Cytologie Pathologiques, Laboratoire Pol Bouin, Unité d'Aide Méthodologique et Service d'Oto-Rhino-Laryngologie
CHU de Reims, 45 rue Cognacq-Jay, 51092 REIMS CEDEX, France

Oncogenic Human Papillomavirus (HR-HPV -High Risk HPV-), the causal agent of cervical cancer, appears to be involved in the etiology of the cancers of oropharynx, especially in tonsillar carcinomas (TC). Interactions between HR-HPV oncoproteins (E6/E7) and cell cycle proteins as p16 encoded by the CDKN2A tumor suppressor gene are involved in carcinogenesis and p16 overexpression is postulated to be a

specific biomarker of cervical neoplasia. The prevalence of HPV detection may vary depending on the population and the detection procedure. Our aim was to evaluate the frequency and type of HPV DNA in a retrospective series of TC and its association with 3 immunohistochemical markers: p16, p53 and MIB1. 58 case patients with TC were recruited in this retrospective study in the C. H. U. of Reims from 1987 to 2004: 54 men (mean age: 55.7) and 4 women (mean age: 54.1). Patients were mainly heavy smokers and drinkers. All the tumors were squamous carcinomas: 53 well or moderately differentiated and 5 poorly differentiated. Total DNA was extracted from paraffin-embedded tissues. HPV detection and genotyping were performed using the Line Blot Assay (Roche). This assay allowed the genotyping of 21 HR-HPV and 16 LR-HPV (low risk HPV). Immunohistochemistry was processed using p53, p16 and MIB1 antibodies. P16 immunostaining was scored according to Klaes. The threshold of p53 positivity was 10%. We detected HPV DNA in 20.7% of cases, represented by HPV-16 in 66%. 21 % of all tumors were positive for p16 protein. P53 was detected in 47% of cases. For MIB1, the mean value of positivity was 44% +/- 25. 58% of HPV positive tumors were p16 positive versus 11% of HPV negative tumors (p=0.001). There was no significant difference between the two groups with p53 and MIB1. HPV status was correlated neither with histological differentiation nor TNM staging. Analysis showed less smokers (10/12 vs 45/46) and drinkers (9/12 vs 44/46) among patients with a HPV + tumor. Age and gender were not different between the two groups. The rate of HPV positivity in our study is inferior to previously published results for tumors at the same site and similar to HPV prevalence reported in the head and neck carcinomas in general. In spite of a tendency of less smokers and drinkers in HPV + patients, the 2 groups were characterized by heavy tobacco and alcohol exposure which may explain these results. P16 expression was correlated with HPV status with less specificity than previously reported.

EVALUATION OF FROZEN SECTION VERSUS DEFINITIVE PATHOLOGIC DIAGNOSIS IN 721 PAROTID GLAND LESIONS

BADOUAL Cécile (1), ROUSSEAU Audrey (1), HEUDES Didier (1), CARNOT Françoise (1), BRUNEVAL Patrick (1), BRASNU Daniel (2), LACCOURREYE Ollivier (2).
(1) Department of Pathology,
(2) Department of Otorhinolaryngology - Head & Neck Surgery,
Hôpital Européen Georges Pompidou, Assistance Publique des Hôpitaux de Paris, Université Paris V, Paris, France.

We report a large series of 721 patients operated on for a parotid mass. In each case, a frozen section was performed during surgery. Results of frozen section examination were evaluated in comparison with the corresponding definitive pathologic diagnosis.
On frozen section, 97 (13.5%) and 624 (86.5%) specimens were considered as malignant and non malignant, respectively. On definitive examination, 124 patients (17.2%) presented a malignant tumor and 597 patients (82.8%) had a benign lesion. For malignant versus benign lesion assessement, frozen section examination had a sensitivity of 74% and a specificity of 99%, with 6 false positive (0.83%) and 24 (3.5%) false negative cases. Carcinoma was correctly diagnosed in 74.1% malignant cases, as was adenoma in 95.9% benign lesions. But the exact tumor type could be established in only half cases, with the exception of Warthin tumor and pleomorphic adenoma which were accurately diagnosed in more than 90% cases. Cysts were interpreted as benign lesions in all instances. Lymphoma was correctly identified in 65% cases and was mostly misdiagnosed as adenopathy in the remaining cases. Metastases and non epithelial tumors were accurately interpreted in more than 90% cases. Frozen section examination during surgery is a useful diagnostic tool in correlation with clinico-radiological and preoperative cytological data if both the surgeon and the pathologist are aware of its performance and difficulties.

ANGIOGENIC AND LYMPHANGIOGENIC MICROVESSEL DENSITY IN CARCINOMA EX PLEOMORPHIC ADENOMA AT AN EARLY PHASE OF THE CARCINOMATOUS TRANSFORMATION

SOARES Andresa*,JULIANO Priscila*, METZE Konradin*, ARAUJO Vera **, ALTEMANI Albina*
* Department of Pathology, Medical Science Faculty, University of Campinas - UNICAMP, Brazil
** CPO São Lepoldo-Mandic, Campinas, Brazil

Carcinoma ex pleomorphic adenoma (CXPA) is an epithelial malignancy that arises in or from a pleomorphic adenoma (PA). Based on the extent of invasion beyond the PA capsule, the carcinoma may be classified as intracapsular, minimally invasive, and frankly invasive. Intracapsular and minimally invasive carcinomas have been considered low-grade tumors that behave benignly. However, metastases have recently been reported in intracapsular CXPA and minimally invasive CXPA. As angiogenesis and lymphangiogenesis are critical processes for tumor growth and invasion, the aims of this study were to evaluate the microvessel density and the presence, if any, of lymphatic vessels in intracapsular and in minimally invasive CXPA comparing the benign and malignant areas of the tumor. We measured blood and lymphatic vascular microvessel density in 7 CXPAs (3 intracapsular and 4 minimally invasive) using immunohistochemical vascular marker CD34 and lymphatic marker D2-40 (both from Dakocytomation). No patient presented metastasis. Vessels were counted in representative high magnification fields in benign and malignant areas and then the mean microvessel density for CD34 and D2-40 was calculated for each one. In six cases (85.7%), the carcinoma was high-grade with nuclear pleomorphism ranging from moderate to severe. Lymph vessels were found neither in the benign nor in the malignant areas of the tumor. The peritumoral lymphatics were morphologically similar to normal tissue vessels. Microvessel density within individual tumors was heterogeneous and correlated directly with the cellular density. The carcinomatous areas, which were highly cellular in all cases, presented microvessel density (mean 4.29, std ±0.81) similar to the benign portions of the cellular type (mean 4.94, std ±1.02), in which the epithelial element predominates. Benign areas composed largely of myxochondromatous element showed significantly lower microvessel density (mean 3.38,std ±0.72) than cellular portions of the lesion, regardless if the latter were benign or malignant. The peritumoral tissue around the microinvasive areas of the carcinoma beyond the PA capsule showed slight increase of the microvessel density. In conclusion, the malignant transformation in PA does not promote significant increase of the vascular proliferation. Similar to other solid glandular tumors there is absence of intratumoral lymph vessels in CXPA.

ACINAR CELL CARCINOMA VERSUS ADENOID CYSTIC CARCINOMA: THE PIVOTAL ROLE OF ELECTRON MICROSCOPY IN ASSESSING THE CORRECT DIAGNOSIS

RESTA Leonrado, FIORE Maria Grazia, SANGUEDOLCE Francesca, PISCITELLI Domenico
DAP-Department of Anatomic Pathology, University of Bari, ITALY

The importance of electron microscopy as an ancillary technique in pathology has decreased with the development of immunohistochemistry and molecular biology; nowadays, it still plays an important role in research, but seems to have little practical diagnostic use. We report here the case of a 62-year-old man who presented with a 1-year history of a mass located at left parotid region. CT scan revealed a well-defined solid tumor involving the middle third of the left parotid gland. Macroscopic examination of the surgical specimen showed an oval soft greyish tumor of 2,8 cm in its largest dimension. The light microscopy diagnosis, made on the basis of its architectural and cytological features, was of acinar cell carcinoma with microfollicular pattern. The case was submitted to ultrastructural examination within a review of parotid neoplasms, showing the presence of true glandular lumina and pseudocysts, and a reduplication of basal membrane surrounding myoepithelial cells; such findings allowed us to finally make the correct diagnosis of tubular type adenoid cystic carcinoma. A further confirmation came from immunohistochemistry, that revealed vimentin and CD117/c-kit positivity of neoplastic cells.
In our case, electron microscopy played a major role in assessing the diagnosis, thus confirming its importance in pathological practice especially in a field as tricky as salivary gland tumors.

INVOLVEMENT OF UBIQUITINATION AND SUMOYLATION IN URINARY BLADDER CARCINOGENESIS INDUCED BY PERSISTENT LONG-TERM LOW DOSE IONIZING RADIATION IN HUMANS

Prof. Alina Romanenko, Prof. Alexander Vozianov, Prof. Shoji Fukushima
Dept. of Pathology and Urology, Institute of Urology, Kiev(Ukraine), Dept. of Pathology, Osaka University Medical School (Japan)

Introduction.
The incidence of urinary bladder cancer in the Ukraine increased from 26.2 to 50.3 per 100, 000 population between 1986 and 2003 after the Chernobyl accident. Cesium 137 accounts for 90% of the internal radioactivity in the Ukrainian population and it is known to be eliminated via the urine. The present study was conducted to determine whether ubiquitination and sumoylation processes in cell proteolysis are altered in urinary bladder urothelium by chronic long-term persistent low doses of ionizing radiation (IR) in male patients with benign prostate hyperplasia and females with chronic cystitis living more than 19 years in Cesium 137 contaminated areas after the Chernobyl accident in Ukraine.
Material & Methods.
Bladder urothelial biopsies from 45 patients were subjected to histopathological and immunohistochemical studies of ubiquitin (Ub), the small Ub-related modifier 1 (SUMO1), SUMO E2 conjugating enzyme Ubc9, and the cell cycle inhibitors p53 and p27Kip1.
Results.
Chronic proliferative atypical cystitis ("Chernobyl cystitis"), featuring multiple foci of dysplasia, and carcinoma in situ (CIS) were observed in 23 (92%) and 19 (76%), respectively, of 25 group 1 patients from radio-contaminated areas, in addition to one small pTa grade 1 urothelial carcinoma. Chronic cystitis with areas of mild dysplasia and urothelial hyperplasia were detected in 2 (10%) and 3 (15%) of 20 patients in the control group 2 from so-called clean (without radio-contamination) areas of Ukraine. Strongly elevated levels of Ub, SUMO1, Ubc9 and p53 as well as decreased levels of p27Kip1, were evident for patients in group 1, as compared to group 2 (all $p < 0.001$).
Conclusion.
Activation of ubiquitination and sumoylation processes in Chernobyl cystitis might be a compensatory reaction in response to the insufficient proteolysis of aberrant p53 and, on the other hand, lead to unscheduled degradation of p27Kip1 cell cycle negative regulator occurred due to the long-term low dose rate IR exposure that may contribute to urothelial carcinogenesis caused by IR.

O-175
MOLECULAR ANALYSIS OF INVERTED TUMORS OF THE URINARY BLADDER: FGFR3 MUTATION STATUS AND KI-67 INDEX CAN RESOLVE DIFFICULT CASES.

Arndt Hartmann, Matthias Eiber, Joke Van Oers, Ellen Zwarthoff, Peter Wild, Robert Stoehr, Stephan Störkel, Theo Van der Kwast, Guido Sauter, John C. Cheville, Mahul Amin, Ferdinand Hofstaedter, Regine Schneider-Stock, Hagen J. Blaszyk. Institute of Pathology, University Regensburg, Germany, Institute of Pathology, Erasmus MC Rotterdam, The Netherlands, Clinic of Urology, University Regensburg, Germany, Institute of Pathology, Helios Clinic Wuppertal, Institute of Pathology, University Basel, Switzerland, Mayo Clinic, Rochester, MN, Institute of Pathology, Emory University Atlanta, GA, Institute of Pathology, University Magdeburg, Germany, Institute of Pathology, University of Vermont, VT

Purpose: Inverted papilloma of the urinary tract (IP) is thought to be benign, but some urothelial carcinomas show a prominent inverted growth pattern (invUC) which may pose a diagnostic dilemma. Ancillary markers may help to resolve diagnostically challenging cases. Design: 89 inverted urothelial lesions of the urinary tract were reviewed by five uropathologists. Four European pathologists diagnosed these lesions as inverted papilloma, low grade UC and high grade UC, whereas one American pathologist used the new WHO classification criteria (IP, PUNLMP, low grade UC, high grade UC).
Genetic alterations frequently found in non-invasive papillary UCC were investigated after microdissection. Deletion of chromosome 9p/q, 17p (LOH) and microsatellite instability (MSI) were determined by microsatellite analysis. Mutations in FGFR3 were analyzed by SNaPshot. Promotor methylation of p16, DAPK, E-cad, RASSF1 and hMLH1 was investigated by methylation sensitive PCR (MSP). Expression of p53, Ki67, CK20, hMLH1, hMSH2 and hMSH6 was studied immunhistochemically. Ploidy and deletion status of 9p21 (p16) was investigated by FISH (Urovysion®).
Results: MSI and loss of mismatch-repair-protein within the European consensus was very infrequent in contrast to inverted tumors of the upper urinary tract. LOH of chromosome 9q was detected in 7/53 IP with a higher percentage in invUC (8/22). Methylation was found in 18 of 53 IP (mostly in DAPK, hMLH1 and p16). Clinical data revealed a significant difference ($p=0.002$) concerning recurrence in IP (3/51) vs. invUC (6/14). No patient with IP showed a history of UCC, whereas 3/12 invUC did ($p=0.001$). Ki67 proliferation index and FGFR3-mutation correlated strongly with the histological diagnosis ($p<0.0001$). In contrast, with regard to the American diagnosis there was a lower significant difference between IP and invUC with Ki67 labeling index and FGFR3 status ($p=0.012$ and $p=0.041$, respectively) and no association to clinical data.
Conclusions: MSI, deletions in chromosome 9 and 17 and FGFR3 mutations are rarely seen in IPs. IPs does not show molecular changes associated with a malignant urothelial genotype. Our data strongly suggest that IP are benign urothelial lesions. In our view inverted tumors without clear features of malignancy should not be classified as a malignant lesion or PUNLMP. The presence of FGFR3 wildtype and a Ki67 proliferation index <5% favors a diagnosis of IP over invUC. This could help resolve ambiguous cases.

O-176
ALPHA-METHYLACYL-COA RACEMASE EXPRESSION IN TRANSITIONAL CELL CARCINOMA OF THE UPPER URINARY IS ASSOCIATED WITH DISEASE PROGRESSION

Cord Langner1, Gerhild Rupar1, Peter Rehak2, Gerald Hofler1, Richard Zigeuner3
1Institute of Pathology, 2Department of Surgery, Division of Biomedical Engineering & Computing and 3Department of Urology, Medical University of Graz, Austria

Introduction
Alpha-Methylacyl-CoA Racemase (AMACR) is a cytosolic enzyme that plays an important role in peroxisomal beta-oxidation of branched fatty acids. Recently, this protein has been identified as a marker of prostate cancer, whereas most benign prostates lack AMACR expression. AMACR is known to be present in a subset of transitional cell carcinomas (TCCs). However, data correlating AMACR expression with tumour stage, grade and morphologic features of aggressive tumour growth, such as angioinvasion, as well as patient outcome are currently lacking.
Methods
51 upper urinary tract TCCs were immunostained for AMACR using a tissue microarray technique. Immunoreactivity was analyzed semiquantitatively with respect to associations with pT-stage, tumour grade as well as lymphatic and/or venous invasion applying the Fisher¡¯s exact test. Specimens of normal pelvic urothelium, low and high grade intraurothelial neoplasia and urothelial carcinoma in situ were analyzed for comparison. The prognostic impact (regarding metastasis-free survival) was analyzed using the Kaplan-Meier method and the log-rank test. For multivariate analysis a Cox¡¯s proportional hazard regression model was used.
Results
Distinct finely granular cytoplasmic AMACR immunostaining was noted in 30/51 (59%) tumours. High AMACR expression (¡Ý50% of tumour cells) was correlated with high tumour stage (3/31 (21%) pT1/pT2 vs. 10/20 (50%) pT3; p=0.002) and high tumour grade (2/28 (7%) low grade vs. 11/23 (48%) high grade; p=0.001). However, AMACR expression was found to be independent from angioinvasion, since 5/12 (42%) tumours showing lymphatic and/or venous invasion showed AMACR immunoreactivity compared to 8/39 (21%) tumours lacking angioinvasion (p=0.3). Non-neoplastic urothelium lacked AMACR immunostaining, whereas intrauothelial neoplasia (high grade > low grade) and urothelial carcinoma in situ showed specific labelling. With respect to patient outcome, AMACR immunoreactivity proved to be a new independent prognostic marker in multivariate analysis with a risk ratio of 9.0 (95% confidence interval 1.8-45.6; p=0.008).
Conclusion
Our preliminary study suggests that AMACR is associated with tumour progression in upper urinary tract TCCs. Moreover, AMACR proved to be a independent prognostic marker with respect to metastasis-free survival. However, further studies including more patients are needed to substantiate our results.

O-177
ASSESSMENT OF ERBB2 MRNA EXPRESSION LEVELS IN A LARGE SERIES OF BLADDER TUMORS BY QUANTITATIVE REAL-TIME REVERSE TRANSCRIPTION POLYMERASE CHAIN REACTION (RT-PCR), CORRELATION WITH IMMUNOHISTOCHEMESTRY (IHC).

Delphine Amsellem-Ouazana*, Department of Urology, Paris, France; Vincent Molinié, Department of Pathology, Suresnes, France; Ivan Bièche, Sengül Tozlu, Genetic Oncology, Saint-Cloud, France; Annick Vieillefond, Department of Pathology, Paris, France; Henry Botto, Department of Urology, Suresnes, France; Bernard Debré, Department of Urology, Paris, France; Rosette Lidereau, Genetic Oncology, Saint-Cloud, France.

Introduction.ERBB2 (also known as HER2) is known to be implicated in bladder cancer. The ErbB2 protein encoded is the aim of new targeted therapies. The aim of this study was to assess ERBB2 expression levels in a large series of bladder tumors using both quantitative real-time RT-PCR (at the mRNA level) and IHC (at the protein level) and to compare the results of these two methods.
Methods: 73 tumors and 5 normal bladder samples were obtained by trans urethral bladder resection or cystectomy. Samples were staged and graded as follows: 22 pTaG1, 10 pTaG3, 21 pT1G3, and 20 T2-T4. Real time quantitative RT-PCR allowed to obtain quantitative values of ERBB2 mRNAs. IHC was performed with a polyclonal antibody. Beside the percentage of tumoral stained cells, the intensity of the staining was graded: 0/+/++/+++. Relationships between median ERBB2 mRNA levels and clinical, histological parameters were based on the Chi2 or Mann Whitney test.
Results: RT-PCR. ERBB2 mRNA levels ranged from 0.21 to 54.39 with a median value of 2.26 (median value for normal bladder samples was 1). Over-expression was noted in 23 tumors (31.5%); 7 pTaG1 (31.8%), 4 pTaG3 (40%), 6 pT1G3 (28.6%) and 6 T2-T4 (30%). ERBB2 expression levels were significantly higher in tumors versus normal bladder (p=0.0093), in pTaG1 versus normal samples (p=0.0033) and in T2-T4 tumors versus pTa+pT1 tumors (p=0.037).
IMMUNO-HISTOCHEMESTRY. Positivity of ErbB2 immunostaining was not different in tumors (78.7%) versus normal bladder (60%) (p=0.34). Moreover, positivity was not related to tumor stage (p=0.09). Intensity of immunostaining showed no difference as well.
COMPARAISON RT-PCR / IHC. ERBB2 mRNA quantification by RT-PCR was correlated to positivity (p=0.01) and intensity (p=0.00549) of immunostaining. The level of mRNA over-expression was correlated to the percentage of tumoral immunostaining (p=0.019).
Conclusions: Over-expression of ERBB2 mRNA occurs in one third of bladder tumors. Before an eventual anti ErbB2 protein targeted therapy, ErbB2 status could be assessed both by real-time RT-PCR assay and IHC.

Urothelial carcinoma (UC) has an incidence of 3000 annual new cases in France, mainly with transitional differentiation. UC are defined into 3 groups: superficial non invasive neoplasms (pTa), chorion invasive neoplasms (pT1) and muscle invasive cancers (pT2 to pT4). Their clinical outcome depends on the tumor stage, approximately 25 % of non invasive tumors may progress to invasive tumors with poor clinical outcome. The aim of our study was to detect changes of gene expression associated with bladder carcinogenesis

using a molecular approach able to identify some key-genes involved in the progression of the disease.
49 bladder tumors, including 18 pTa/pT1(12 pTa, 6 pT1) and 31 pT2-pT4 tumors(3 pT2, 20 pT3 and 8 pT4N+), from trans ureteral resections or cystectomy specimens, were studied. 12 control samples of histologically normal bladder were taken from the same specimens at tumor distance. mRNA levels of a set of 11 genes were quantified by real-time RT-PCR from dissected epithelial component for each case. Expression level of deregulated molecules was evaluated by immunohistochemistry in the same samples.
mRNA expression in normal bladder versus invasive tumors showed 5 genes significantly downregulated and 1 gene (STK-6, Aurora-A) upregulated in cancer samples. GJA1(connexine 43), was among the most discriminating between both groups ($p < 0.001$). Comparing pT2/pT3 group versus normal tissue, similar differential gene expression was seen, with significant increase of STK6 ($p<0.0001$) and GJB2 (Connexin 26) ($p=0.005$) and significant decrease of LYVE-1 ($p=0.02$), VEGF-D (vascular endothelial growth factor D)($p=0.004$) and PROK-1 (Prokinase-1)($p=0.005$) in tumoral samples. By comparing normal versus pTa/pT1 tumors we found significant deregulation for 6 genes, STK-6 was upregulated in tumoral tissues versus normal bladder ($p=0.0004$) and 5 downregulated (GJA2, VEGF-D, PROK-1, LYVE-1 (Lymphatic vessel hyaluronan receptor 1), TATP63 (transmembrane proteine 63)). Immunohistochemistry (IHC) for STK-6, connexin 26, p63 and VEGF confirmed gene expression data.
This study identified key-genes associated with different stages of bladder carcinogenesis. 6 of 11 selected genes studied were deregulated as soon as the earliest stage of bladder carcinoma such as pTa tumors. Our results suggest that these genes play a crucial role in cancer development, and a potential role in tumor progression. IHC may be a valuable tool to discriminate UC having poor evolution.

Backgrounds and aims: The prognostic markers of human urothelial tumours of the bladder are the histological determination of stage of invasion and tumour grades and recently the classification was revisited (WHO/OMS histological classification published in 2004). The aim of our study was to explore new diagnostic and pronostic perspectives offered by the detection of telomerase components including an RNA subunit (hTR) and a reverse transcriptase subunit (hTERT).
Materials and Methods: We investigated the expression of hTR and hTERT respectively by in situ hybridization and immunohistochemistry in bladder non-invasive tumours and infiltrating carcinomas at various grades and stage of invasion and non-tumoral urothelium (70 cases).
Results: The cells exhibited a hTR labeling in non-tumoral urothelium and in urothelial carcinoma, but the level of expression of hTR was significantly higher in urothelial tumours than in non-neoplastic urothelium ($p<0.05$). In non-invasive tumours, the number of cells which expressed hTERT protein at cytoplasmic level or/and at nuclear level was significantly higher than in non-neoplastic urothelium ($p<0.05$). In infiltrating carcinomas, the number of cells which expressed hTERT protein at cytoplasmic level was significantly higher than in non-neoplastic urothelium ($p<0.05$). There was no significant difference of expression of telomerase between the superficial part and the deep part of the infiltrating urothelial carcinomas (>pT1). There was no relation between the telomerase expression levels and the progression of tumour grades and/or stage.
Conclusions: This study demonstrates at the morphological level that the overexpression of telomerase is associated with bladder urothelial tumours and that the expression of telomerase in the superficial part of the deep infiltrating carcinomas that potentially produces exfoliating cells faithfully reflects expression of all tumoral cells.

PATHOLOGICAL FEATURES OF SURGICALLY TREATED PROSTATE CANCER IN THE "PSA ERA"

BOLLITO Enrico, BERGERO Nicoletta, TERRONE Carlo*, GRANDE Susanna*, GUERCIO Stefano#, BELLINA Maurizio#, SCARPA Roberto Mario*
Divisions of Pathology and of *Urology, University of Turin and San Luigi Hospital, Orbassano, and #Division of Urology, Rivoli Hospital, Turin, Italy

INTRODUCTION: In the last decade, the clinical routine use of serum prostate-specific antigen (PSA) dosage has highly modified the epidemiology of prostate carcinoma (PC). Furthermore, a remarkable tumour volume and pathological stage reductions have been reported in countries where PC screening became a common health policy. The aim of this study was to analyze the histomorphological features of PC treated with radical prostatectomy in two Italian institutions.
MATERIALS AND METHODS: In the period 1991-2005, 493 cases of PC were treated by radical prostatectomy in our Hospitals. PSA evaluation was done in all patients before the diagnosis of PC. Ninety-two patients who underwent neo-adjuvant therapy were excluded and in the remaining 401 (median age 65, range 46-76), the volume of the tumour and that of the whole prostate gland were calculated as proposed by the Italian Group of Uropathology in 2001. In addition, Gleason score and pathological TNM stage (6th ed., 2002) were evaluated. Statistical analysis was performed by Mann-Whitney U and Kruskal-Wallis tests.
RESULTS: The median serum PSA level was 8.5 ng/ml (0.8-60). A significant difference in median PSA values has been observed between the periods 1991-1999 and 2000-2005 (11.0 vs 8.0 ng/ml; $p< 0.001$). The PCs were staged pT2 in 222 patients, pT3a in 123, pT3b in 44, and pT4a in 12. In cases operated in years 2000-2005, a significant increase ($p<0.0001$) of the number of pT2 cases has been detected, compared to the cases operated in 1991-1999. No significant differences between the time periods considered above were observed in the median Gleason score (6, range 5-9), or in the median tumour volumes (3.5 ml, range 0.3-21). In these cases, the median prostate volume was 36.0 ml (15.9-152.5), and the median tumour/prostate volume ratio was 9.9% (0.6-45.4). A tumour volume <0.5 ml was encountered in only the 2.4% of the cases operated in both time periods.
CONCLUSION: These data, derived from a suburban area of Turin in which the routine use of PSA regular evaluations is established since 1991, indicate that the significant reduction of both median tumour volumes and high Gleason score tumours observed in areas covered by a PSA-based PC screening program was not observed. However, a significant reduction of median PSA values and of high (pT3-pT4) stage carcinomas was recorded in the last five years (compared to years 1991-1999), in association with regular PSA evaluation

by the adult male population.

(3) Department of urology, Hopital tenon, 14 rue de la Chine, 75020 Paris, France.

Prostatic cancer is considered as a latent cancer with a falling mortality rate due to large screening of prostate confined cancer on biopsies. This screening is a new challenge for uropathologists because it implies to diagnose prostate cancer on more and more small focuses. There is actually no consensus on criteria and treatment of small foci of cancer.
The aim of this analyse was to determine predictive factors of extraprostatic extension and tumoral volume. We correlated prostate needle biopsies findings with prostatectomy outcomes of 80 patients treated during 1998 and 2003. We were more particularly interested in focus carcinoma (one positive biopsy and three mm length).
Method : Preoperative factors and radical prostatectomy outcomes were analysed in this retrospective report of 80 consecutive prostate carcinoma cases collected in a single institution, from 1999 to 2003. Preoperative factors (PSA concentration, number of positive biopsies, length of cancer in mm, proportion of cancer on biopsies, Gleason score) were correlated with histopathological data on prostatectomy (tumoral volume in cm3, extraprostatic extension).
Results : In multivariate analysis, two histoprognostic factors of tumoral extension were pointed out (p=0,004) : number of positive biopsies (> 1 ; = 1) and length of cancer (>three mm ; ¡Ü three mm).
The 23 patients with one positive biopsy and length of cancer ¡Ü three mm had an intraprostatic cancer (pT2). On these 23 patients, 16 patients had a bilateral cancer (pT2c), 2 had more than half of a lobe involved (pT2b), 5 had half of a lobe or less involved (pT2a).
Among the 43 patients with more than one positive biopsy and length of cancer > three mm, 17 had an extraprostatic extension (pT3). Risk of extraprostatic cancer was 10-fold higher in this group (p=0,003). Among the 14 patients with either one positive biopsy or length of cancer ¡Ü three mm, 12 had an intraprostatic cancer and 2 patients had an extraprostatic extension. On the 31 patients with one positive biopsy, the length of cancer was not predictive of tumoral volume : 8 patients with focus carcinoma had non significant tumoral volume (<0,2 cm3), 2 patients with focus carcinoma had a tumoral volume between 0,2 and 0,5 cm3 and 21 patients had tumoral volume > 0,5 cm3 of which 13 had focus carcinoma.
Conclusion : One positive biopsy and length of cancer three mm on biopsies were predictive of intraprostatic cancer but were not predictive of tumoral volume.

CD 34 IN PROSTATIC BIOPSIES WITH ADENOCARCINOMA. A DOUBTFULL MARKER FOR MICROVESSEL DENSITY (MVD) ASSESSMENT.

ASIMAKI Niki, TANOGLIDI Anna, SAMARAS Vasilis, KALANTZAKIS Spyros, BARBATIS Calypso.
Department of Pathology, Hellenic Red Cross Hospital
Athens, Greece.

INTRODUCTION: Angiogenesis is essential for tumor growth. Studies on the importance of MVD in prostatic adenocarcinoma (pCa) as an independent predictor of biological behaviour after radical prostatectomy are controversial because of the problematic methodology of MVD measurements. CD34 a myeloid progenitor cell antigen expressed by endothelial and other mesenchymal cells has been reported as a better marker for intratumoral vessel counting, compared to other endothelial cell specific molecules.
AIM OF THE STUDY: To evaluate the expression of CD34 in normal and neoplastic prostatic tissue and its use for the assessment of MVD in pCa.
MATERIALS AND METHODS: 58 cases of prostatic biopsies with adenocarcinoma were included in the study: Gleason's score: 5(7), 6(9), 7(18), 8(13) and 9(4). The immunohistochemical method of Envision-HRP was used using an anti CD34 mAb. The specific endothelial cell marker CD31 was also studied in parallel sections.
RESULTS: CD34 was widely expressed in prostatic tissue.The endothelium of all blood vessels (capillaries, arterioles, veins, arteries) was CD34+. There was strong albeit focal CD34 positivity of stromal cells in benign areas with a characteristic linear distribution around normal prostatic glands and CD34 expression in nerve sheaths. A distinct concentric perivascular CD34+ spindle cell arrangement was also observed. In our study it was impossible to use CD34 as a marker for MVD assessment as there was marked stromal and periglandular CD34 expression concealing the capillaries in 45/58 tumors with the exception of solid, cellular areas of type 5 growth pattern, where intratumoral CD34+ capillaries with negative stroma could be identified. A distinct linear CD34 positivity around malignant glands was observed reminiscent of the normal tissue pattern.
There was an obvious marked increase in stromal CD34 expression in pCa, either diffuse or focal compared to the normal prostatic tissue.
CD31 stained the endothelium of large blood vessels and occasional capillaries but despite its specificity it lacks sensitivity for pCa angiogenesis.
SUMMARY: CD34 is widely expressed in normal epithelial prostatic cells with distinct distribution. The marked CD34 increase in the stroma of most pCas does not allow accurate MVD measurements, except in cases of high grade with solid hypercellular growth pattern and minimal stromal production.

O-183
CYTOKERATIN 5/6 AND ALPHA-METHYLACYL-COA RACEMASE (AMACR) ARE USEFUL IN EVALUATING PROSTATE SPECIMENS AFTER THERAPY

Kiril Trpkov and Asli Yilmaz. Anatomical Pathology, Calgary Laboratory Services and University of Calgary, Calgary, Alberta, Canada.

Introduction and purpose: Reliable evaluation of prostate specimens after radiotherapy (RT), cryotherapy (CT) and hormonal therapy (HT) remains a diagnostic challenge. Diagnostic utility of immunopanel that includes high molecular weight cytokeratin 5/6 (CK 5/6) and AMACR has not been examined in post-treatment prostate specimens.
Method: We evaluated prospectively 58 prostate biopsies (37 post-RT, 21 post-CT) and 4 prostate specimens post-HT (3 radical prostatectomies and 1 transurethral resection) using CK 5/6 and AMACR. Immunostains were performed to aid in establishing the final diagnosis and were correlated with the morphology. The results for both stains were scored as: negative (0), weak (1+), moderate (2+), or strong (3+).
Results: Final diagnosis of prostate cancer (pCa) was established in 37 cases (16 post-RT, 17 post-CT, 4 post-HT) and benign diagnosis (post-RT atypia and post-CT atypia) was rendered in 25 cases (21 post-RT and 4 post-CT). CK 5/6

did not stain any case of pCa after treatment (100% specificity). Moderate (2+) to strong (3+) basal cell staining for CK 5/6 was seen in all benign glands showing post-treatment atypia (both in cases with and without pCa). AMACR demonstrated combined sensitivity for post treatment pCa of 86.5% (87.5 % post-RT, 94% post-CT and 50% post-HT). Staining intensity for AMACR was moderate (2+) to strong (3+) in 88.9% of cases. All five pCa negative for AMACR (2 post-RT, 1 post-PC, 2 post-HT) were also uniformly negative for CK 5/6, which allowed to establish the final diagnosis of pCa. Of 6 AMACR positive cases with non-pCa diagnosis (3 each with 1+ and 2+), all 6 cases showed focal positivity for CK 5/6 (one with PIN, 4 with post-treatment atypia, and one with atypia of uncertain significance).
Conclusions: 1.) Majority of problematic foci in treated prostate specimens can be reliably diagnosed as pCa or benign post-treatment atypia using a panel of CK 5/6 and AMACR in correlation with the morphology. 2. The immunopanel allowed for confirmation of suspected pCa foci, establishing the extent of pCa on biopsy, as well as appreciating better the areas of post-treatment atypia 3.) In suspicious cases negative for AMACR, uniform lack of CK 5/6 staining supported a definitive diagnosis of pCa. 4.) Although we evaluated only few pCa specimens after hormonal therapy, AMACR expression appears to be variable in this setting.

O-184
INCREASED APOPTOSIS IN CERVICAL INTRAEPITHELIAL NEOPLASIA FROM HUMAN IMMUNODEFICIENCY VIRUS (HIV)-INFECTED WOMEN: ASSOCIATION WITH ONCOGENIC HUMAN PAPILLOMAVIRUS, CASPASES AND LANGERHANS' CELLS.

WALKER Francine (*§), ADLE-BIASSETTE Homa (*), MADELENAT Patrick (#), HENIN Dominique (*), LEHY Thérèse (§).* Department of Pathology, § INSERM U683, # Department of Gynaecology, Hôpital Bichat-Claude Bernard, Paris, France.,

Purpose : Increasing risk of squamous cervical intraepithelial neoplasia (CIN) exits in human immunodeficiency virus (HIV)-infected women. However, the relatively low incidence of invasive carcinoma in the untreated HIV-infected population suggests an imbalance between cell proliferation and apoptosis. We investigated apoptosis and caspases in cervical samples from this population comparatively to non HIV-infected and control subjects.
Experimental design : Apoptotic TUNEL method, immunohistochemistry for caspases -2, -3, -8, -9 and other apoptosis markers were performed on 12 normal cervical samples and 103 low- and high-grade cervical lesions, containing human papillomavirus(es), from 35 HIV-negative and 33 HIV-positive women before tritherapy advent.
Results : 1) The apoptotic index (AI) in epithelial cells did not vary between normal mucosa and condyloma acuminata infected or not with HIV; 2) AI augmented with the CIN severity in HIV-positive and HIV-negative women; 3) AI dramatically increased in oncogenic HPV-infected CIN of HIV-positive population compared to the CIN of similar grade in HIV-negative one. This was associated with a greater expression of caspase-8, active caspase-9 and active caspase-3 in those samples. Moreover, densities of Langerhans' cells - involved in apoptotic bodies engulfment- were greatly reduced in CIN of HIV-positive women. In samples, these densities were highly inversely correlated with AI ($r = - 0.88$, $P< 0.002$).
Conclusions : This study provides the first evidence for the strongly enhanced apoptosis levels and caspase expression in CIN of untreated HIV-infected women. We suggest that the reduction in Langerhans' cell number could contribute at least partly to apoptotic cell accumulation.

O-185
HUMAN PAPILLOMAVIRUS FINDINGS IN CERVICAL INTRAEPITHELIAL NEOPLASIA: A STUDY ON 416 SPANISH WOMEN, USING PCR FOR DETECTION AND TYPING OF HPV.

MEIZOSO Telma, GARRIDO María, ENGUITA Ana Belén, RODRIGO Maximiliano, NAVAS Rafael, SEGOVIA Beatriz, RODRIGUEZ José Luis.
SERVICIO DE ANATOMIA PATOLÓGICA. 12 DE OCTUBRE UNIVERSITY HOSPITAL, MADRID, SPAIN

INTRODUCTION:
Cervical cancer represents the second most common cancer in women worldwide.
This cancer is a consequence of an infection by some types of Human Papillomavirus (HPV) sexually transmitted.Twenty nine different types of HPV have been characterized, and classified into three diferent oncogenic risk categories: low, medium and high potential
There are esentially three different types of nucleic acid hybridization method formats for detecting HPV, including Southern blot, hybrid capture and polymerase chain reaction.
The aim of this study is to evaluate the HPV distribution in cervical diseases, specially in CIN lesions.
MATERIAL AND METHODS:
416 cervical lesions were collected from the pathology department files of "12 de Octubre" University Hospital, Madrid, Spain between 1998 and 2003 years.
The tissue was fixed in formalin, embedded in paraffin, stain with hematoxylin and eosin and diagnosed under light microscopy. On the other hand, DNA extraction and HPV detection were performed by PCR method.
RESULTS:
HPV DNA was detected in 174 specimens (41.9%) of all biopsies.
HPV 16 was present in 27.5% of this positive samples, HPV 18 in 4.6%, HPV 6/11 in 5.8%, HPV 31/33 in 2.9% and 54% of the cases HPV type were no classified.
HPV was detected in 73 of 94 (77,6%) high grade cervical lesions: in 38.3% of them were HPV 16, 6.5% HPV 18, 2.2% HPV 6/11 and 1.1% HPV 31-33. HPV was detected in 68 of 129 low grade cervical lesions: in 6.2% of them were HPV 16, 6.2% HPV 18, 2.3% HPV 31/33, and 3.1% HPV 6/11.
DISCUSSION:
HPV prevalence rate in high grade cervical intraepithelial neoplasia has been reported between 77 and 84.2%. In our study was 80.2%.
The distribution of HPV types varies with the histological diagnosis and its oncogenic risks. Therefore high risk viruses including HPV 16 or 18 were associated in our cases with CIN II-III (45.7%) and low risk types such as 6 were associated with condylomas (75%). These results agree with others Spanish and European studies but differs with assian´s ones.
In populations where cytology based programmes are established it would be beneficial to add HPV testing to the screening protocol. Prevention of exposure to high risk HPV types by vaccination would be the most efficent preventive intervention for cervical cancer. Nowadays this is not possible and the prevention and treatment of HPV infections are necessary.

O-186
MORPHOLOGICAL CHANGES IN UTERUS CERVIX AFTER RADIOCONIZATION UNDER THE CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN)

DERIZHANOVA Irina, NECHITAILO Tatyana

The aim of the research is to study morphological changes in tissues and peculiarities in postoperative uterus cervix wound repair after radioconization under CIN. The Surgitron portable instrument was used. 224 uterus cervix pieces ablated from 56 patients, 30 cervical channel biopsies and 120 smears-prints of cervical surface (neutral zone, cervix channel, front and back lip) were studied at 1, 7 and 21 day. Histological and cytological pieces were colored in standard way. CIN II was found in 51 patients, CIN III in 3 cases, Ca in situ in 2 ones. Using PCR for all patients various HPV cultures were found, in 60% - types 16 and 18. Morphological changes in ecto- and endocervix after radioconization depend on radio-wave power and exposition. The fixed current with 45-50 W power seems to be optimal, the coagulant necrosis zone under it does not exceed 0.05-0.4 mm, epithelial dystrophic a! nd necrobiotic changes are not clearly shown and do not prevent histological CIN diagnostics in operation matter. Under radio wave exposure the vascular smooth muscles spasm accompanied by abrupt luminas narrowing down to obturation took place; there were endothelium desquamation, agglutination with nuclei pyknosis. During the first 7 days the necrotic tissues rejection from the wound surface occurred as very tiny fragments among fibrin and few neutrophilicus leukocytes. Bacillus and coccus flora, neutrophilicus leukocytes in phagocytosis and lysis stages predominated. In periphery zone the integument epithelium regeneration prevailed in form of layer clusters of parabasal cells.

At 21-day reconstruction of the cervix channel mucous membrane and epithelization of significant wound part occurred. Leukocytes infiltration is manifested poorly. Relative pathogenic flora was substituted by lactobacilli. Uterus cervix complete epithelization came in 30-45 days. In 6 month in biopsies the cervix and cervix channel complete reconstruction was observed. CIN signs were lacking. Only one patient got HPV infection relapse with condyloma forming.

Conclusion: radio-wave CIN treatment method in form of Uterus cervix conization leads to minimal tissue lesions and causes vessel changes, preventing bleeding; by changing microcenosis it accelerates wound healing.

O-187
P-53 IMMUNOSTAINING IN LICHEN SCLEROSUS IS RELATED TO ISCHEMIC STRESS AND NOT A MARKER OF DYSPLASIA AND D-VIN

Bernadette Liegl and Sigrid Regauer
Institut für Pathologie, Medizinische Universität Graz Austria

Introduction:"Differentiated VIN" (d-VIN), a postulated rapidly progressing precursor lesion for LS-associated vulvar squamous cell carcinoma (SCC), shows an atypical basal keratinocyte proliferation with p53-positive basal/suprabasal keratinocyte nuclei. p53-staining is considered a marker for progression to invasion.

Purpose of the study was (1) to investigate the frequency of d-VIN in LS and LS-associated SCC in our collective of over 200 patients with LS and (2) to identify the p-53 staining profile of different subtypes of LS and precursor lesions of vulvar SCC.

Material and Methodes: We analyzed archival formalin-fixed and paraffin-embedded tissue of 207 biopsies, excisions, vulvectomies and circumcisions for LS 148 patients,33 patients with vulvar SCC arising in LS, 26 pediatric patients with penile (23) and vulvar (3) LS. The control group included vulvar biopsies (15)and (15)circumcisions LS. H&E stained sections were evaluated for morphological citeria of HPV-infection, types of inflammatory infiltrates, vascular changes and Candida infections with a PAS reaction. Depending on the histological features, LS was divided into early (40), classical (78) and hypertrophic stages. Immunohistochemistry was performed with monoclonal antibody to p53 (DAKO Corp. Carpinteria, CA).p-53 staining was scored as negative, when LI was less than 10% of basal keratinocyte nuclei. p-53 staining was divided into discontinuous linear, continuous linear and basal and suprabasal staining of keratinocyte nuclei according to LI under 50% and at least 70% (continuous and basal and suprabasal) respectively.

Results and Summary: Nuclear p53 staining was observed in 175/ 207 LS of biopsies. 80% of early and 69% of pediatric LS showed p53-staining in basal keratinocytes. Classic LS showed no p-53 staining in 17%, discontinuous basal keratinocyte staining in 20%, continuous basal keratinocyte staining in 58%, basal/suprabasal staining in 5%. Hypertrophic LS revealed basal keratinocyte staining in 32% and basal/suprabasal staining in 61%. p53-staining showed a strong association with sclerosis of blood vessels and dermis, lymphoid infiltrates, vasculitis and hypertrophic LS. d-VIN was seen in 2% of lone LS and 24% of SCC-associated LS. p53-staining in LS was frequent and best explained as ischemic stress response due to poor oxygenation, vasculitis and inflammation. Evaluation of p-53 expression is a poor screening tool for identifying precancerous lesions in LS.

O-188
VULVAR SQUAMOUS CELL CARCINOMAS HARBOUR LOW AND HIGH RISK HPV GENOTYPES

REGAUER S, AIGELSREITER A, REICH O* and BEHAM-SCHMID Ch.
Institute of Pathology and *Gynecology and Obstestrics, Medical University of Graz, Austria

Aims: Vulvar squamous cell carcinomas (SCC) are divided traditionally into keratinizing lichen sclerosus (LS) associated SCC and basaloid Human Papilloma Virus (HPV)-induced SCC, mostly due to high risk HPV16 genotype. Classification of HPV is almost entirely based on molecular characteristics. PCR is the most widely used target amplification method. The aim of this study was to analyse the distribution of 25 different individual HPV genotypes in vulvar SCC with and without LS.

Methods: Formalin-fixed, paraffin-embedded material of 47 vulvar SCC (17 LS-associated SCC and 30 non-LS associated SCC) were analyzed with the INNO-LIPA HPV-Genotyping for individual HPV genotypes 6,11,16,18,31,33,34,35,39,40,42,43,44,45,51,52,53,54,56,58, 59,66,68,70,73,74. INNO-LIPA HPV-Genotyping is based on broad spectrum amplification of HPV genotypes using SPF10 primers, which amplify only 65 base pairs at the L1 region (Innogenetics, NL) . Selected SCC were also analysed with primers against E6 and E7 of HPV16 genotype with conventional PCR analysis. Five SCC had to be excluded due to poor DNA quality.

Results: No HPV-DNA was detected in 7/14 LS-associated SCC and 6/28 non-LS-associated SCC. One LS-associated SCC each revealed HPV-DNA genotypes 6, 18, 31, 33 and 6&16. Two SCC contained HPV 6&33. In the non-LS associated SCC group, HPV-DNA 6, 33 and 6&52 were detected in one SCC each, HPV-DNA 6&16,6&18 and 6&51 in two SCC each and HPV 6&31 in 3 SCC. HPV16 genotype alone was identified in 10/28 SCC. Detection of HPV16 genotypes using the INNO-LIPA HPV-Genotyping corresponded to results obtained by PCR analysis using primers against E6 and E7 of the HPV16 genotype.

Conclusion: 30% of LS-associated SCC were negative for the major HPV genotypes. 30% each were characterized by detection of only one HPV genotype and by co-infection of a low risk and a high risk HPV genotype. HPV16 genotype was identified in only 1/14 LS-associated SCC. In the basaloid SCC group, only 20% of SCC contained no HPV genotypes. A single HPV genotype, mainly HPV16, was identified in

45% of basaloid SCC and two HPV genotypes, a low and a high risk genotype, were identified in 35%. Multiple HPV genotypes (>2) were not detected in our analysis. Demonstration of HPV genotypes in LS-associated SCC is more common than previously assumed. Although HPV16 genotype is the most common individual infectious agent in non-LS-associated basaloid vulvar SCC, co-infections with two HPV genotypes are common.

O-189
PATTERN OF MIB-1 IMMUNOSTAINING ASSISTS IN THE DIAGNOSIS OF SQAMOUS INTRAEPITHELIAL LESIONS OF THE UTERINE CERVIX

DJORDJEVIC Biljana, MIHAILOVIC Dragan, VELICKOVIC Ljubinka, ZIVKOVIC Vesna, MILENTIJEVIC Maja, STANOJEVIC Zorica*
Institute of Pathology, Medical Faculty University of Nis, Serbia and Montenegro
* Clinic of Oncology, Medical Faculty University of Nis, Serbia and Montenegro

The aim of this study was to compare pattern of MIB-1 immunostaining in normal squamous epithelium (NSE), metaplastic squamous epithelium (MSE), low grade squamous intraepithelial lesions (LSIL), and high grade squamous intraepithelial lesions (HSIL) of the uterine cervix.
Material and methods. Formalin fixed and paraffin embedded tissue from 20 NSE, 20 MSE, 20 LSIL, and 40 HSIL was immunostained for MIB-1 (DAKO). For the analysis of the staining a four-tired scale was used both for the intensity of nuclear staining (negative, weak, moderate, strong) and the percentage of positive nuclei (<10%, 10-50%, 50-80%, >80%). A total score was obtained by multiplying both parameters. Score 1-3 was classified as weakly, 4-8 as moderately, and 9-12 as strongly positive.
Results. MIB-1 expression was exclusively confined to the basal and parabasal layers of NSE and MSE. There were no significant differences of MIB-1 immunostaining between NSE and MSE. In SIL specimens, the staining was markedly increased in the basal and parabasal layers and MIB-1 positive cells were also distributed in the intermediate (LSIL) or all layers (HSIL) of squamous epithelium. Significant differences for MIB-1 staining were found in comparations between NSE or MSE and SILs and between LSILs and HSILs.
Conclusions. These results indicate that MIB-1 immunostaining is useful in evaluating of squamous intraepithelial lesions of the uterine cervix.
Key words. Uterine cervix, Squamous intraepithelial lesions, MIB-1

CERVICAL NEOPLASIA OR A BENIGN MIMIC?

Ring M, Heffron CCBB, Murphy N, Astbury K, Martin C, Hughes C, O'Leary JJ.
Department of Pathology, Coombe Women's Hospital, Dublin 8 and Trinity College Dublin, Ireland.

Background: Differential diagnosis of cervical neoplastic lesions from their 'mimics' is fraught with difficulty. An ongoing search for a specific and sensitive marker for cervical dysplasia is occurring. The tumour suppressor protein, p16 INK4A, has been widely reported to be of significant diagnostic utility in identification of cervical squamous and glandular dysplasia. However, it is occasionally expressed in benign glandular lesions giving rise to a false impression of malignancy. Our group has evaluated a panel of biomarkers for use in these diagnostic dilemmas. A number of proteins play an important role in the control of DNA replication, these include the mini chromosome maintenance proteins (MCM) of which, MCM 2, MCM3 and MCM5 were assessed along with cell division cycle protein 6 (CDC6)) and topoisomerase II alpha. In addition, a marker of cell proliferation MIB 1(Ki-67), and bcl2 were assessed.
Design: 100 cases in total were assessed. Benign lesions included normal and reactive squamous lesions, benign glandular lesions (microglandular hyperplasia, reactive atypia, tuboendometrioid metaplasia). Cervical lesions included cervical intraepithelial neoplasia (CIN) grades 1,2,3, cervical glandular intraepithelial neoplasia (cGIN), invasive squamous carcinoma, and invasive adenocarcinoma (including villoglandular adenocarcinoma). All cases were retrieved from the pathology files of the Coombe Women's Hospital. Immunohistochemical staining with antibodies for p16 INK4A, MIB1, bcl2, MCM2, MCM3, MCM5, CDC6 and topoisomerase II alpha was performed on all cases. A score of 0 – 3 was given for each antibody in each case.
Results: Immunopositivity was noted in the majority of pre-malignant and malignant cervical lesions for p16 INK4A, MIB1, MCM 2,3,5, CDC6 and topoisomerase II alpha while bcl2 was negative or focally positive.
In the benign cervical lesions analysed, bcl2 was strongly positive with focal positivity for p16 INK4A, MIB1 was negative in normal cervical glands although positive in the basal cells of the squamous epithelium, and MCM 2/3/5 and CDC6 showed variable staining.
Conclusion: The accurate diagnosis of cervical dysplasia from its 'mimics' can be time consuming and difficult. We propose that a panel of biomarkers should be available for the diagnosis of such cases. Biomarkers that may prove most useful when used in addition to p16 INK4A include MIB1, bcl2, and MCM3.

O-191
INCIDENCE OF HIGH-GRADE DYSPLASIAS IN PATIENTS WITH ASCUS-H PAP SMEARS

S. Latif 1, J. Matthews-Greer1,2, R. Reyes1, D. Rivette 1, E. A. Turbat-Herrera 1, Department of Pathology1 and Pediatrics2, Louisiana State University HSC, Shreveport, LA

Introduction: The diagnostic category for atypical squamous cells, cannot exclude high-grade dysplasia (ASCUS-H) is a recent addition and was first introduced in Bethesda 2001 to differentiate between immature squamous metaplasia and high-grade squamous intra-epithelial lesions (HSIL). At present, in the USA many institutions are performing HPV reflex testing for ASCUS; the most common test done is for HR HPV. It is known that young women, particularly adolescents, are more likely to get dysplasia and rapid progression of their dysplasia as a result of HPV infection. In our adolescent patient population the prevalence of cervical abnormalities, namely (ASC-US and above) is high 24%. HPV testing is performed in our institution using the Hybrid Capture II (HCII) assay.
Purpose of the study: This study was undertaken to establish the prevalence of HSIL in our ASCUS-H patients and determine their high risk HPV status.

Methods: Twenty patients with ages ranging 19-79 years underwent cervical biopsy for ACUS-H at our institution. Liquid-based pap smears were prepared in the standard fashion. The remaining sample was submitted for HCII assay for detection of HR-HPV using a cut-off of 1.2 to prevent true positives from being missed.
Results: Out of twenty cervical biopsy specimens, 7 were positive for HSIL, 9 for LSIL and four biopsies were normal. All HSIL were positive for HR-HPV. In the low-grade (LSIL) group, all five cases tested were negative for HR- HPV.
Conclusion: Thirty-five percent of ASCUS-H pap smears were diagnosed as high-grade dysplasia on cervical biopsy and forty-five percent as low-grade. We believe as more cases of ASCUS-H are studied we will understand the implications of this entity better.

MITOGEN-ACTIVATED PROTEIN KINASE (MAPK) ACTIVATION HAS DIFFERENT CLINICAL SIGNIFICANCE IN CANCER CELLS OF OVARIAN, BREAST AND MESOTHELIAL ORIGIN IN EFFUSIONS

VINTMAN Lina, M.Sc.1, KONSTANTINOVSKY Sophya, M.Sc.1, RISBERG Björn, MD PhD2, BERNER Aasmund, MD PhD2, NESLAND Jahn M., MD PhD2, REICH Reuven, PhD1, DAVIDSON Ben, MD PhD2
1 Department of Pharmacology and Experimental Therapeutics, School of Pharmacy, Faculty of Medicine, The Hebrew University of Jerusalem, Jerusalem 91120, Israel
2 Department of Pathology, The Norwegian Radium Hospital, Montebello N-0310 Oslo, University of Oslo, Norway

Introduction: The mitogen-activated protein kinase (MAPK) pathway mediates major intracellular signaling events, including proliferation and apoptosis. Molecular events related to intracellular signaling in cancer cells in effusions are poorly defined.
Purpose: To compare the expression (level) and phosphorylation status (activity) of the three MAPK, extracellular-regulated kinase (ERK), c-Jun amino-terminal kinase (JNK) and high osmolarity glycerol response kinase (p38), in ovarian and breast carcinoma, malignant mesothelioma (MM) and reactive mesothelium (RM) in effusions.
Methods: 135 pleural and peritoneal effusions from patients diagnosed with ovarian carcinoma (=64), breast carcinoma (=25), MM (=32) and RM (=14) were studied using immunoblotting with antibodies detecting the total (pan-) and activated fraction (phospho-,
p-) of ERK, JNK and p38. Values for pan-MAPK and p-MAPK expression and the
p-MAPK/pan-MAPK ratio were compared. Results were corroborated using immunocytochemistry in selected cases. The predictive value of MAPK expression and activation was analyzed in breast carcinoma and compared to previous data for ovarian carcinoma.
Results: Pan-ERK, -JNK and -p38 expression and activation was found in the majority of specimens. Ovarian and breast carcinomas showed significantly higher activation of ERK and p38 compared to MM ($p=0.001$ for both). MM and RM showed similar MAPK expression, activation and activation ratio (Mann-Whitney test, $p>0.05$). Higher p38 activation ratio predicted worse disease-free (DFS, $p=0.018$) and overall (OS, $p=0.004$) survival in breast carcinoma. Conversely, pan-ERK ($p=0.008$), pan-JNK ($p=0.038$) and p-ERK ($p=0.034$) predicted better OS in ovarian carcinoma.
Conclusions: This study presents the first evidence of in vivo activation of MAPK in malignant effusions. The similar MAPK profile in benign and malignant mesothelium, and their correlation with better survival in ovarian carcinoma question the validity of MAPK as molecular therapeutic targets in these cancers. MAPK activation may be a molecular marker of disease aggressiveness in breast cancer.

MULTICENTRIC DETERMINATION OF THE BEST INTEROBSERVER CONCORDANCE USING THE FUHRMAN GRADING SYSTEM IN RENAL CELL CARCINOMA.

LINDNER Véronique(1), De FROMONT Marc (2), MOLINIE Vincent (3), LETOURNEUX Hervé (4), MEYER Nicolas (5), LANG Hervé (4), JACQMIN Didier (4).
(1) University Hospital, Pathology, Strasbourg, France (2) University Hospital, Pathology, Marseille, France (3) St Joseph Hospital, Pathology, Paris, France (4) University Hospital, Urology, Strasbourg, France (5)University Hospital, Statistics, Strasbourg, France.

Introduction :
The Fuhrman grading system is the nuclear grade most often used in the world for renal cell carcinoma (RCC). This grading is recognized as an significant prognostic factor. However according to the few previous studies, its reproductibility appears to be low.
Material and method :
Between 1980 and 1990, 255 RCC (pT1, pT2, pT3a and b, N0 M0)were treated by radical nephrectomy. In a retrospective multicentric study, three pathologists independently classified 241 cases according to the Fuhrman grading system. We analysed the concordance between the three pathologists. We then searched the best interobservers concordance by collapsing into a three, then a two level grading system. At the same time, the overall survival curves were evaluated for each pathologist according to the classical 4-scheme and for the scheme giving the best concordance. The statistical analysis used the kappa index to measure concordance between each pair of observers and the Cox model for multivariate survival analysis.
Results :
The mean interobserver kappa value was 0.22 (0.09 to 0.36). The best concordance was obtained by collapsing to a low grade (grades 1 and 2) versus a high grade (grades 3 and 4): kappa = 0.44 (0.22 to 0.55). The Fuhrman grading system was an independent prognostic factor for each pathologist ($p=0.01$, $p<0.0001$, and $p=0.004$). With the 2-grade scheme, the nuclear grade remained an independent factor for each pathologist ($p=0.004$, $p=0.0003$ and $p=0.005$).
Conclusions :
Reducing the Fuhrman system to a 2-grade scheme improves the interobserver agreeement and remains an independant prognostic factor.

PLATELET-ACTIVATING FACTOR RECEPTOR EXPRESSION IN HUMAN RENAL CELL CARCINOMA

MITROPOULOS Dionissios1,2, SERAFETINIDES Efraim1, KYROUDI Aspasia2, KITTAS Christos2, THEOCHARIS Stamatios3
Departments of Urology1, Histology-Embryology2 and Forensic Medicine- Toxicology3, Medical School, University of Athens, Athens, Greece

Background-Aims: Platelet-Activating factor (PAF) is a potent lipid mediator, participating via its specific receptor (PAF-R) in inflammatory and physiological responses. It has been reported that PAF and other PAF-like lipids could inhibit cell proliferation and invasive capacity of tumoral cells. The aim of this study was to examine the expression of PAF-R in human renal cell carcinoma (RCC) cases and to correlate it with clinicopathological variables and patients' survival.
Materials and Methods: PAF-R expression was examined immunohistochemically
on paraffin embedded tissue sections of 37 RCC cases. PAF-R positivity, overexpression (positivity in more than 40% of tumoral cells), distribution (cytoplasmic, nuclear, cytoplasmic and nuclear pattern) and intensity of immunostaining were correlated with patients' sex, age, clinical stage, tumor histological type and grade and patients' survival.
Results: Thirty six out of 37 (97%) RCC cases were PAF-R positive, while PAF-R overexpression was noted in 30 out of 37 (81%). PAF-R cellular distribution was mainly cytoplasmic and nuclear. In the majority of cases, moderate or intense immunostaining was noted. PAF-R positivity, distribution and intensity of staining were not correlated with

any of clinicopathological variables examined and patients' survival. PAF-R overexpression was statistically significantly correlated with patients' survival (p=0.034) but not with the other clinicopathological variables examined.
Conclusions: Our data suggest a possible involvement of the lipid mediating PAF-R in RCC. Further experimental data at clinical and molecular levels are needed to delineate the implication of PAF/PAF-R system in renal neoplasia.

Objective: To evaluate the prognostic value of angiogenesis measured by VEGF immunostaining in a series of pT3 renal tumors.
Material and methods: 112 patients were included in this retrospective study. Tumors were classified according to the 2002 revised TNM and Fuhrman grade systems. All slides were reviewed by a single pathologist. VEGF was determined by immuno-histochemistry. The following variables were evaluated, using univariate and multivariate analysis, for their impact on the risk for death from renal cancer: age, gender, tumor size, fat, adrenal or vein invasion, inferior vena cava involvement, Fuhrman grade, ECOG performance status and VEGF expression.
Results. There were 71 men and 41 women and mean age at surgery was 65 years. A total of 62 patients were dead at last follow-up, including 49 (43,8%) from RCC. A 30% VEGF cut-off was determined according to Roc curves. Tumor size, nodal invasion, distant metastasis, fat invasion, VEGF expression ($p<0.01$), and Fuhrman grade (p:0.02) were significantly associated to survival in univariate analysis. Only the following variables remained significant in multivariate analysis: Fuhrman grade, fat invasion, renal vein invasion, distant metastasis ($p<0.01$) and VEGF expression (p:0.01) (Odd ratio: 3,187 [1,248 – 8,140]).
Conclusion: In this study, VEGF expression was confirmed as being an independent prognostic factor for predicting survival in pT3 renal tumors. Utilizing it, in addition to the known TNM and Fuhrman variables, may provide a rationale for including high-risk pT3 renal cancer patients in trials with adjuvant angiogenesis inhibitors.

THE USE OF E-CADHERIN, P53, CK19 AND 34BE12 IN SUBTYPING RENAL CELL CARCINOMA (RCC). AN IMMUNOHISTOCHEMICAL STUDY.

SAMARAS Vasilis*, TANOGLIDI Anna*, NOMIKOS Alexandros*, TSAMOURI Magdalini*, KEFALA Maria*, POULIAS Hercules**, BARBATIS Calypso*.
Hellenic Red Cross Hospital, Departments of Pathology* and Urology**. Athens. Greece.

INTRODUCTION: RCC represents almost 2% of all human carcinomas with definite prognostic factors the histological grade, type and stage. Correct classification of RCCs and the assessment of probable prognostic factors are constantly investigated with emphasis on molecules related to tissue organization, survival and cell differentiation.

AIM: An immunohistochemical study of E-cadherin, p53, CK19 and 34BE12 in subtyping RCCs and their relationship with pT stage and histological grade.
MATERIALS-METHODS: 40 RCCs were studied; 31 Conventional (cRCCs), 4 Papillary (pRCCs), 4 Chromophobe (chrRCCs) and one collecting duct (cd). Histological grade: G1 (9), G2 (20), G3 (7), G4 (4), pT-stage: T1 (20), T2 (11), T3a (1), T3b (2) according to Fuhrman's and UICC/AJCC/TNM classification systems, respectively. With the immunohistochemical method of Envision-HRP and the use of monoclonal antibodies, the topography of the cell adhesion molecule E-cadherin, the nuclear phosphoprotein p53 and two types of cytokeratins that are expressed along the distal nephron were studied.
RESULTS: E-cadherin: we confirmed the E-cadherin expression in Bowman's capsule, distal tubules collecting ducts as it has been reported in a few studies but focal, minimal expression was seen only in 3/31 cRCCs, in contrast to all 4 chrRCCs where a diffuse cytoplasmic membrane positivity was observed. pRCCs and collecting duct cases were negative.
P53: p53 nuclear expression >5% was observed in 2/4 pRCCs, 1/31 cRCC and one cd. Only grade 3 and 4 tumors were expressing p53.
CK19: strong cytoplasmic, diffuse positivity was observed in 3/4 pRCCs and the collecting duct. All conventional types were negative but scatter CK19 (+) cells were observed in one chrRCC.
34BE12: Strong diffuse positivity characterised the collecting duct and 1/4 pRCCs. All other cases were negative.
CONCLUSIONS: E-cadherin expression was undetectable in all, exept the chromophobe subtype of RCCs. P53 was uncommon in all types of RCCs hence it couldn't be used as a prognostic factor. CK 19 is commonly expressed in pRCC and 34BE12 is also a marker of distal nephron differentiation.

INTRODUCTION
Biallelic Von Hippel-Lindau (VHL) gene defects, a rate-limiting event in the carcinogenesis, occur in approximately 75% of sporadic clear-cell Renal Cell Carcinoma (RCC). In 19% of sporadic clear-cell RCC, methylation of the VHL gene promoter appeared to be involved, and in 10%-20% no alteration in the VHL alleles was detected, indicating that other genes are involved.
Several risk factors for developing RCC have been identified e.g. tobacco smoking, hypertension and/or its medication, and occupational exposures. Multiple and specific types of VHL mutations in RCC have been associated with exposure to trichloroethylene. Consumption of vegetables and citrus fruit decreased the frequency of VHL mutations among smokers.

Therefore, mutational patterns in the VHL gene may serve as an etiological imprint to factors causing renal cancer.
PURPOSE
We studied the VHL mutation status of RCC cases identified within a population-based cohort of 120,852 men and women which was recruited in the Netherlands to study associations between dietary habits, lifestyle and cancer occurrence.
METHODS.
Within this Netherlands cohort study, after 11.3 years of follow-up, 337 incident cases with histologically confirmed epithelial cancers were identified. DNA was isolated from paraffin material collected from 51 pathology laboratories and revised by one pathologist, leaving material from 235 cases with RCC. VHL mutational status was assessed by SSCP followed by direct sequencing, after testing SSCP as a screening tool in a subsample.
RESULTS
The number of mutations was significantly higher for clear-cell RCC compared to other histological types. We observed 131 mutations in 114 out of 187 patients (61%) with clear-cell RCC. The majority of mutations were truncating mutations (47%). The mean tumor size was 72.7 mm for mutated tumors compared to 65.3 mm for wildtype tumors (p=0.06). No statistically significant differences were observed for nuclear grade and TNM stage. In other histological types, we observed 8 mutations in 7 out of 48 patients (15%), 1 mutation in 1 of 6 oncocytoma, 3 mutations in 2 of 7 chromophobe RCC, 2 mutations in 2 of 30 papillary RCC, no mutations in 1 collecting duct carcinoma and 2 mutations in 2 of 4 unclassified RCC.
CONCLUSIONS
VHL mutations were detected in 61% of sporadic clear-cell RCC and in 15% of non-clearcell RCC. VHL mutated and wildtype clear-cell RCC did not differ with respect to most investigated parameters.

1.Service d'Anatomie Pathologique - Hôpital Necker, Paris, 2.Service d'Anatomie Pathologique, - Hôpital Val de Grace, Paris, 3.Service de Génétique Oncologique - Institut Curie, Paris, 4.Service d'Anatomie Pathologique - Hôpital Tenon, Paris, 5.Service d'Anatomie Pathologique – CHU de Bicêtre, 6.Service d'Anatomie Pathologique – CHU de Poitiers, 7.Service d'Anatomie Pathologique – CHRU de Lille, 8.Service d'Anatomie Pathologique - Hôpital Armand-Trousseau, Paris, 9.Service d'Anatomie Pathologique - Institut Curie, Paris, 10.Service d'Anatomie Pathologique - Hôpital Cochin, Paris.

Background: Recently, a new entity was individualized in the 2004 WHO classification of tumors of the kidney: renal cell carcinomas (RCCs) associated with Xp11.2 translocations/ TFE3 gene fusions. These neoplasms, that mainly affect children and young adults, were formerly recognized as « juvenile renal carcinoma » (JRC). The diagnosis is supported by cytogenetic and /or molecular analysis demonstrating several different translocations, always involving Xp11.2, all resulting in gene fusions involving the TFE3 transcription factor gene. Interestingly, the TFE3 antibody, directed against the C-terminal part of the TFE3 protein, is a sensitive and specific marker of RCCs associated with Xp11.2 translocations as experimented by Argani et al., 2003 (1).
Design: We sought to evaluate TFE3 immunohistochemical expression on paraffin-embedded tissue sections. We studied a panel of 28 RCCs with JRC features and 50 adult-type RCCs, including 23 clear cell, 10 papillary and 17 unclassified RCCs. The 28 tumors with JRC features presented intermigled papillary and clear cell pattern and/or occured in children or young adults. A cytogenetic study was performed for 8 tumors with JRC features : 7 tumors presented a t(X;1)(p11.2;q21) and 1 tumor a t(X;17)(p11.2;q25).
Results: A strong nuclear expression of TFE3 was observed in 20 (including the 8 cytogenetically studied tumors) of the 28 tumors displaying JRC features. The 20 patients (6 males and 14 females) were young adults (age ranging from 8 to 42 years old with a mean of 21 years). In contrast, only one of the adult-type RCCs expressed TFE3 (unclassified tumor occurring in a 78 years old man).
Conclusion: We recommend to evaluate the TFE3 immunohistochemical expression in RCCs with mixed papillary and clear cell pattern, especially in young patients but also in older patients with unclassified RCCs. Diagnosis of RCCs associated with Xp11.2 translocations is therefore possible, even retrospectively, on paraffin-embedded tissue sections when fresh or frozen materiel was not available for cytogenetic and/or molecular biology analysis. This new tool will allow a better evaluation of the frequency and prognosis of these neoplasms.

INTERPHASE CYTOGENETIC IN METASTATIC CHROMOPHOBE RENAL CELL CARCINOMA (RCC).

BRUNELLI Matteo (1,3), COSSU ROCCA Paolo (2), PEA Maurizio (1), MENESTRINA Fabio (1), BONETTI Franco (1), SCARPA Aldo (1), CHILOSI Marco (1), COLOMBARI Romano (3), MINA Maria Mihaela (1), GOBBO Stefano (1), BADOUAL Cecile (4), MARTIGNONI Guido (1,2).
Department of Pathology, Università di Verona (1) and Sassari (2), Arzignano Hospital, Vicenza (3), Italy, Hopital Europeen George Pompidou, Paris (4), France.

Introduction. Chromophobe RCC is a low grade malignancy which can metastatize many years after the nephrectomy. Primary chromophobe RCC shows frequent genetic anomalies as the losses of multiple chromosomes from among chromosomes 1, 2, 6, 10, and 17 but little is known about the genetics of their rare metastases.
Purpose. To characterize the genetic anomalies associated with metastatic disease, we assessed the status of three chromophobe RCCs in matched primary and metastatic samples.
Material and Methods. Three classic variant primary chromophobe RCCs and their metastatic lesions that occurred in the lung, pancreas and retroperitoneal lymph-nodes respectively 10, 12 and 5 yrs after the nephrectomy were studied. The samples were investigated by interphase fluorescence in situ hybridization on 5 micron paraffin-embedded tissue sections with centromeric probes for chromosomes 1, 2, 6, 10, and 17 (Vysis, Abbott). Signals were counted in 100-200 neoplastic nuclei from each tumor.
Results. In two cases (67%) both the primary and the metastatic tumors showed loss of chromosomes 1, 2, 6, 10 and 17 (single signal ranged from 79-88% of neoplastic nuclei) whereas no chromosomal losses were detected in the third primary chromophobe RCC and its lymph-nodal metastases.
Conclusions. We conclude that 1) primary and metastatic chromophobe RCCs show the same genetic patterns; 2) metastases of chromophobe RCC show presence (67%) or absence (33%) of losses of chromosomes 1, 2, 6, 10, and 17;

3) the presence or absence of losses of chromosomes 1, 2, 6, 10, and 17 could be related to the haematogenous (67%) and the lymphatic (33%) neoplastic spreading respectively.

O-200
EXPRESSION OF ALPHA-METHYLACYL-COA RACEMASE (AMACR/P504S) IN RENAL NEOPLASMS.

Molinié Vincent (1), De Pinieux Isabelle (1), Guillou Louis (2), Homsi Toufik (1),Balaton André (1). Pathology department, Hôpital Saint Joseph (1), Paris France, CHU Lausanne (3) Suisse.

Background: Alpha-methylacyl-CoA racemase (AMACR), also known as P504S, has recently been utilized as a biomarker for prostate carcinoma. Expression of AMACR is also recognized in normal renal tubules. The aim of the present study was to evaluate the expression of AMACR/P504S in different subtypes of renal tumors.
Design: 110 cases of renal neoplasms were selected from the surgical pathology files of 2 department of pathology, including conventional clear cell type (n=25), papillary renal cell carcinoma (n=55) (type 1 n = 33, type 2 n = 22), mucinous tubular and spindle cell carcinoma (n=5), chromophobe carcinoma (n=6), oncocytoma (n=9), urothelial carcinoma (n=2), angiomyolipoma (7), and bellini carcinoma (n=1). One paraffin block of representative renal tumor and normal kidney in each case were studied. Sections were cut at 4 microns and stained with AMACR/P504S monoclonal antibody (Prédiluted, Menarini Diagnostics) on an automated immunostainer (Dakostainer). AMACR/P504S staining was evaluated as negative, focally positive, or diffusely positive. The percentage of positive cells were evaluated in each case.
Results: No expression of AMACR/P504S was observed in Bellini and urothelial carcinoma. A weak and focally expression of AMACR/P504S was observed in conventional clear cell carcinoma (16%), chromophobe carcinoma (16%), and oncocytoma (7%). In papillary renal cell carcinoma 3.6% (2/55), and 96.4 % (53/55) of papillary carcinoma showed focally and diffusely positive for AMACR, respectively, without no difference expression in different subtype (Type 1 or 2). All 5 mucinous tubular and spindle cell carcinoma were strongly positive for AMACR/P504S.
Conclusions: High expression of AMACR/P504S is found in papillary renal cell carcinoma (even type 1 or 2), and in mucinous tubular and spindle cell carcinoma. This should be exercised in using P504S immunohistochemical staining for the diagnosis of papillary renal cell carcinoma, and particularly in case of biopsy to differentiate different eosinophilic renal tumor. A weak and focal AMACR staining could be present in case of clear cell and chromophobe carcinomas, and even in oncocytoma.

PAX2: A RELIABLE IMMUNOHISTOCHEMICAL MAKER FOR NEPHROGENIC ADENOMAS

TONG Guo-Xia1, MELAMED Jonathan2, MANSUKHANI Mahesh1, MEMEO Lorenzo1, WAISMAN Jerry2
1Department of Pathology, Columbia University Medical Center, 2 Department of Pathology, New York University Medical Center, New York NY.

INTRODUCTION: The diagnosis of nephrogenic adenoma (NA), characterized by a proliferation of small tubules and cystic structures in the lamina propria, sometimes with polypoid papillary projections on the surface of the urinary tract is usually straightforward. However, misdiagnosis may occasionally occur. Immunohistochemical markers to differentiate NA from adenocarcinomas have had only partial success. The demonstration of the origin of NA from renal tubular epithelium in renal transplant patients, suggests that its histogenesis may help differentiate it from tumors of the urinary tract.
PURPOSE: We investigated the value of the expression of PAX2 - a renal transcription factor - CD10, and uroplakins, to differentiate NA from adenocarcinoma of prostate gland (AOP), and urothelial carcinoma (UC) of the urinary tract.
METHODS: 39 cases of non-renal transplant related NA - 25 vesical, 1 ureteral, 11 prostatic urethral and 2 distal urethral - retrieved from Tisch Hospital of NYU Medical Center and Columbia University Medical Center, and tissue microarrays (TMA) of 100 AOP, 47 invasive UCs of the urinary bladder, and 100 samples of normal prostate tissue were used in the study. Normal urothelium and normal prostate acini in the NA specimens were used as internal controls. Immunohistochemical staining for Pax2 (Zymed), CD10 (Dako) and uroplakins (kindly provided by Dr. T.T. Sun in NYU) were performed with biotin-avidin method following antigen retrieval.
RESULTS: Strong nuclear staining of PAX2 was found in all 39 cases of NA (100%) regardless of histologic pattern. PAX2 was not detected in AOP, invasive UC, normal prostate, and normal urothelium. Focal CD10 was detected in 6 of 13 NA, mainly in the superficial papillary component. In addition, CD10 was detected in normal prostate tissue, normal urothelium, AOP, and UC. No uroplakins were detected in any NA.
CONCLUSION: In this study, we found that NA in non-renal transplant patients consistently expressed PAX2, consistent with a renal tubular origin. Distinct nuclear staining in all NA, but not AOP or UC indicates that PAX2 is useful in distinguishing NA from common lower urinary tract malignancies.

O-202
MCM3 AND KI67 AS PROGNOSTIC MARKERS FOLLOWING SURGERY FOR RENAL CELL CARCINOMA.

MEMEO Lorenzo 1, MITCHELL Robert 2, PARSONS Ramon 1, HIBSHOOSH Hanina 1, ASSAAD Adel 1, MCKIERNAN James 2, MANSUKHANI Mahesh 1.
1 Department of Pathology and 2 Department of Urology, Columbia University Medical Center, New York NY.

INTRODUCTION: Minichromosome maintenance proteins (MCM2-7) accumulate in cycling cells, enabling DNA replication in a process called “licensing”. Ki-67, another marker of cycling cells, starts to accumulate later in G1.
PURPOSE: We undertook this study to evaluate the role of Ki-67 and MCM3 expression in predicting lymph node or distant metastases and survival following radical or partial nephrectomy for renal cell carcinoma (RCC).
METHODS: Immunohistochemical analysis for Ki-67 and MCM3 was performed on tissue microarrays containing tumor tissue from 99 patients who underwent nephrectomy for renal cortical carcinomas at our institution between 1999 and 2004. Pathologic variables (tumor diameter, grade, histology, lymph node status) and follow-up data pertaining to these patients were obtained from the Columbia University Comprehensive Urologic Oncology Database. The proportion of tumor cell nuclei expressing these proteins was estimated and scored as “0” through “4”. Expression of Ki-67 was correlated with that of MCM3. Using logistic regression and Cox proportional hazards models, the impact of the expression of these proteins in estimating hazard of lymph node and distant metastases, and overall survival, disease free survival, and disease specific survival was evaluated.
RESULTS: The expression of Ki-67 linearly correlated with that of MCM3 (Pearson correlation coefficient, 0.571, $p<0.001$). Tumors expressing high levels of Ki-67 (“3” and “4”) were 9.25 times more likely to be associated with lymph

node or distant metastases at the time of surgery (p=0.001). On univariate analysis of recurrence free survival, Ki-67 and MCM expression showed a statistically significant negative impact on disease free survival (p<0.001 and p= 0.032). Using a multivariate model (including diameter, grade, histology, and Ki-67), Ki-67, grade, and diameter were statistically significantly associated with an increased hazard of disease recurrence (p=0.030, 0.013, and 0.026, respectively).
CONCLUSIONS: This study demonstrates a correlation between MCM3 and Ki-67 expression, and confirms the prognostic importance of Ki-67 as an independent marker for disease progression

O-203

EXPRESSION OF PDGFR-ALFA IN 140 RENAL CELL CARCINOMAS USING TISSUE MICROARRAYS

GASPA Albert*, PETIT Anna*, TRUAN David^, MELLADO Begonya', PALACIN Antonio*, FERNANDEZ Pedro, MALLOFRE Carme*.
Department of Pathology*, Oncology' and Urology^. Hospital Clinic de Barcelona. IDIBAPS. University of Barcelona.

SHORT INTRODUCTION:Platelet derived growth factor receptor alfa (PDGFRa) is a transmembrane tyrosin kinase receptor that is considered a therapeutic target because it can be specifically inactivated by small-molecule tyrosine kinase inhibitors such as Imatinib (STI-571). The expression of PDGFRa in Renal Cell Carcinoma (RCC) has not been extensively studied in vivo and has interest because there is currently no effective treatment for patients with metastatic or recidivant RCC.
PURPOSE OF THE STUDY:The aim of the study is to evaluate the immunohistochemical expression of PDGFRa in different subtypes of RCC using tissue microarrays in order to assess whether Imatinib could be a potentially useful therapeutic target in these neoplasms.
METHODS USED:We constructed five tissue microarrays with representative areas from 140 RCC: 60 Clear Cell RCC (CCRCC), 36 Chromophobe RCC (ChRCC), 29 Papillary RCC (PRCC) and 15 RCC with Sarcomatoid differentiation (SRCC). Immunohistochemical study was performed using polyclonal antibody PDGFRa (c-20, Santa Cruz, dilution 1:100). The percentage of positive staining cells was categorized as focal (1-25% of tumor cells), moderate (25-50%) and diffuse (>50%).The intensity of expression was evaluated on a three-grade scale and the staining pattern (cytoplasmic, membranous, or nuclear) was also considered. In the cases of SRCC only the sarcomatoid part of the tumour was analysed.
RESULTS: 98% of CCRCC, 88% of ChRCC, 86% of PRCC and 100% of SRCC expressed PDGFRa. Of the positive CCRCC, 64% showed membranous, 50% cytoplasmic and 40% nuclear staining. In all these cases the expression was weak (intensity 1/3) and 55% presented focal positivity. ChRCC and PRCC exhibited a weak cytoplasmic staining pattern in >80% of cases. All SRCC showed cytoplasmic positivity for PDGFRa that was diffuse in 77% of cases and with moderate intensity (2/3) in 66% of cases.
CONCLUSIONS:Most of RCC show expression of PDGFRa being the cytoplasmic staining pattern and the weak intensity (1/3) the most frequent ones. However 65% of CCRCC also showed a membranous staining pattern and only SRCC reveal a more intense and diffuse cytoplasmic positivity for PDGFRa compared with the rest of the subtypes. The meaning of the expression of this protein and its role in the pathogenesis of RCC is not clear and deserve further studies in order to consider its possible use as a therapeutic target.

IMMUNOHISTOCHEMICAL STUDY OF 310 ADULT RENAL CELL TUMOURS USING TISSUE MICROARRAYS TECHNOLOGY

Céline Bazille (1), Philippe Camparo (2), Yves Allory(3), Vincent Molinié (4), Marine Lefèvre (5), Patrice Callard (5), Annick Vieillefond (6), Mathilde Sibony (5).
(1) Hôpital Lariboisière, Paris. (2) Hôpital du Val de Grâce, Paris. (3) Hôpital Henri Mondor, Créteil. (4) Hôpital St Joseph, Paris. (5) Hôpital Tenon, Paris. (6)Hôpital Cochin, Paris.

Background: While most adult renal epithelial tumours can be classified according histologic criteria and cytogenetic data, some morphologic aspects may be confusing. As renal tumours have different prognoses, it would therefore be of interest to establish distinctive immunophenotype patterns.
Materials and methods: Using Tissue Micro-Array technique, we analysed the immunoprofile of the four main renal epithelial tumours occurring in adults, with emphasis on uncommon lesions such as chromophobe renal cell carcinomas and oncocytomas. 310 tumours were analysed : 75 clear cell renal cell carcinomas (ClCRCC), 89 papillary renal cell carcinomas (PRCC), 50 chromophobe renal cell carcinomas (CRCC) and 96 oncocytomas (ONC). Immunostaining was performed in all cases using a large panel of antibodies.
Results: Main antibodies and percentage of positivity in each subtype tumour (ClCRCC, PRCC, CRCC and ONC) are for CK7 (0;79;81 and 9%), Vim (54;85;0 and 2%), CD10 (86;65;39 and 14%), RCC (38;55;0 and 2%), CD117 (0;0;57, and 57%), E-Cadherin (12;16;100 and 48%) Racemase (3;87;0 and 0%) and Aqp1 (8;53;0 and 2%).
AE1-AE3, EMA, CK19, cyclin D1 and Muc-1 were variably expressed in all kinds of tumours. 34betaE12 and C-erbB2 were positive in rare cases. CK5/6, CK10/13, CD15, Aquaporine 2, Aquaporine 3 and CD99 were negative in all tumours. These antibodies were not useful for diagnosis.
When combining antibodies, we obtained some immunohistochemical profiles. Antibodies patterns suitable as routine tools with sensibility (Se) and specificity (Sp) are :
ClCRCC CK7- Racemase- Vim+/- CD10+ (Se 74,5%, Sp 92%)
PRCC CK7+ Racemase+ Vim+/- CD10+/- (Se 68,5%,Sp 100%)
CRCC CK7+ Racemase- Vim- CD10+/- (Se 80%, Sp 97%)
ONC CK7- Racemase- Vim- CD10- (Se 68%, Sp 97,5%)
Conclusion : In case of unclear morphological features, antibody panel (CK7, Racemase, Vim and CD10) permits to determine with more precision histological subtypes of epithelial renal cell tumors. CD117, and E-Cadherin may be helpful as second line panel.

PRIMARY EWING'S SARCOMA/PNET OF KIDNEY. CLINICOPATHOLOGIC AND MOLECULAR ANALYSIS OF 7 CASES.

Carole Gengler (1), Annick Vieillefond (2), Dominique Ranchère (3), Philippe Beuzeboc (4), Gabrielle Gallagher (1), Jean Benhattar (1), Louis Guillou (1). University Institute of Pathology, Lausanne, Switzerland (1), Departments of Pathology (2) and Medical Oncology (4) , Cochin Hospital, Paris, and Léon-Bérard Cancer Center, Lyon (3), France.

Introduction. Ewing's sarcoma (ES) is mostly observed in bone and soft tissue. Its occurrence in viscera, including kidney, is a rare event.
Purpose of the study. To report the clinicopathologic features of seven translocation-positive ES primary of kidney.
Materials and methods. 7 ES primary of the kidney were retrieved from the consultation files of the authors. Histology and immunohistochemical features were reviewed. Molecular

analysis was performed on formalin-fixed, paraffin-embedded tissue, using RT-PCR.
Results. There were 5 males and 2 females, aged from 17 to 52 years (median, 35 yrs). 4/6 tumors were located in the right kidney (missing data, 1). Tumor size varied from 6 to 26 cm (median, 11 cm). Tentative pathologic diagnoses included, in addition to ES, nephroblastoma (2), poorly-differentiated synovial sarcoma (1), and small cell carcinoma (1). All tumors, which were fixed in formalin, presented histologically as primitive small round cell proliferations. Immunohistochemical findings were as follows: CD99+ 6/6, Fli-1+ 3/4, keratins+ 1/6, EMA+ 1/6, S100 protein+ 0/5, chromogranin-A+ 0/5, synaptophysin+ 1/5, desmin+ 0/5. EWS-FLI1 fusion transcripts were detected in all paraffin-embedded tumors, using RT-PCR. Breakpoints included EWS exon 7-FLI1 exon 6 (EWS-FLI1 - type 1) (2/7), EWS ex 7-FLI1 ex 5 (EWS-FLI1 - type 2) (3/7), EWS ex 10-FLI1 ex 6 (1/7), data not available (1/7). For 2 cases, breakpoints which have previously been identified in another laboratory (Curie Institute, Paris, F; Drs E. Guilbert & O. Delattre) using frozen tissue samples and multiplex RT-PCR, were identical in both frozen and corresponding paraffin-embedded tissue samples. Unusual transcripts were confirmed by sequencing. Clinical data were available for 6 cases. Five patients had localized disease at diagnosis. Two patients recurred locally 10 and 27 months after diagnosis, and two additional patients developed distant metastases to lung and femur 7 and 17 months after diagnosis. Two patients were alive without disease at 6 and 56 months, 2 were alive with disease at 22 and 29 months, and 2 died of disease 12 and 18 months after diagnosis. Median overall survival was 20 months (range: 6-56 months).
Conclusion. Similarly to ES of bone and soft tissue, ES primary of kidney are rare, highly aggressive neoplasms, of which most seem to bear the t(11;22) EWS-FLI1 translocation.

O-206
PRIMARY EWING'S SARCOMA (ES) / PNET OF URINARY BLADDER AND PROSTATE. CLINICOPATHOLOGIC AND MOLECULAR ANALYSIS OF 6 CASES.

Carole Gengler (1), Gérard Bertrand (2), Gabrielle Gallagher (1), Jean Benhattar (1), Louis Guillou (1). University Institute of Pathology, Lausanne, Switzerland (1), and Anatomic Pathology Center, Angers, France (2).

Introduction. ES most commonly develops in bone and soft tissues of adolescents and young adults. Its occurence in prostate and urinary bladder is exceptional. 85-90% of ES bear the t(11,22) (q24;q12) translocation involving EWS and FLI1 genes. EWS-FLI1 fusion gene transcripts which are specific for ES can be detected in frozen and paraffin-embedded tissues, using RT-PCR.
Purpose of the study. To report the clinicopathologic and molecular features of 6 ES primary of the urinary bladder and prostate.
Materials and methods. 6 ES primary of the urinary bladder (n=4), of prostate (n=1), and of both organs (n=1) were retrieved from the consultation files of the authors. Histology and immunohistochemical features were reviewed. Molecular analysis was performed on formalin-fixed, paraffin-embedded tissue (6/6), using RT-PCR.
Results. There were 4 males and 2 females, aged from 20 to 53 years (median, 28 yrs). Four patients (2 females and 2 males, median age, 25 yrs) presented with large locally infiltrative masses of the urinary bladder (median size, 6 cm), one patient had a 6 cm tumour confined to the left prostatic lobe, and one patient had a 9 cm pelvic mass centered on the prostate and urinary bladder. All but one patients had localized disease at diagnosis. Histologically, all neoplasms presented as primitive small round cell proliferations that expressed CD99 (6/6) and EMA (1/6, focal reactivity) but were negative for keratins, desmin, S100 protein, chromogranin-A, synaptophysin, and CD45 (0/6, each). EWS-FLI1 fusion transcripts were detected in all cases. Breakpoints included EWS exon 7-FLI1 exon 6 (type 1) (4/6) and EWS ex 7-FLI1 ex 5 (type 2) (2/6). Treatments consisted of varying combinations of surgery, chemotherapy and radiation therapy. Three patients were alive and well 6, 8, and 13 months after treatment completion. The patient who presented with a large pelvic mass died of disease at 27 months. One patient who was metastatic at presentation died at 7 months, and one patient died of treatment complications (radiation colitis) at 12 months.
Conclusion. This study shows that ES/PNET can (rarely) develop in the urinary bladder and prostate as a primary neoplasm. Clue to diagnosis include CD99 positivity, negativity for epithelial, muscular, and lymphoid markers, and the detection of ES translocations and/or fusion transcripts.

O-207
THE TESTICULAR BIOPSY IN THE ASSESSMENT FOR FERTILITY TREATMENT

YOUNG Rebecca, HAMILTON Judith, CHANDRA Ashish

Introduction: The current standard method for assessment of infertility on testicular biopsy is the Johnsen Maturity Index (JMI), in which 10 randomly chosen seminiferous tubules are each assigned a score of 1-10 according to the stage of spermatogenesis, their mean score providing the JMI. Fertility treatment is offered to patients on the assumption that mature spermatozoa are unlikely to be harvested with JMI <4.5. However, spermatozoa may be demonstrated on biopsies with JMI <4.5 and the converse is also true.
Method: This study was designed to investigate the reproducibility of JMI and offer an improvement on the current reporting of testicular biopsies. The details of 50 patients with testicular biopsies for infertility during the period 2000-03 were obtained from the archives. The original histological sections were reviewed for the following information - 1. Total number of seminiferous tubules in the biopsy, 2. JMI and 3. Percentage of tubules containing spermatozoa. The original histology report was then reviewed for comparison.
Results: Of the 40 patients studied, 6 had biopsies with originally reported JMI <4.5; review revealed small numbers of mature spermatozoa in these cases. In retrospect, we believe that these additional 6 (15%) cases could have been offered IVF. In 3 cases, mature spermatozoa in small numbers were seen in >10% tubules on the biopsy.
Two cases with JMI >4.5 showed no spermatozoa on the biopsy.
On review, JMI varied from the original by >1.0 in 7 patients including 3 cases where it was revised to >4.5.
Conclusions: These findings highlight drawbacks of using JMI alone, the most important being that it does not identify all men to whom sperm harvesting for IVF could be offered. Also, significant variation between observers is more likely with as many as 10 numeric scores for each tubule.
We propose a system of reporting testicular biopsies that combines a score of highest maturity with the extent of spermiogenesis for selection of men for sperm harvesting.

O-208
DEVELOPING EXTERNAL QUALITY ASSURANCE IN BREAST SCREENING PATHOLOGY IN THE GERMAN POPULATION BASED PROGRAMME: FIRST RESULTS

DECKER Thomas, HUNGERMANN, Daniela, BÜRGER Horst, KERSTING Christian, BÖCKER Werner
Gerhard-Domagk-Institute of Pathology
University of Muenster

Introduction: In 2005, a population based mammography screening program for Germany based on the European guidelines will start. Without improving the pathology service, the benefit of screening may be reduced or even lost. Especially specimens from minimal invasive diagnosis (MIB) of screened women provide pathologists with problems. To prepare pathologists who intend to participate in the program the authors provide courses on breast screening pathology for continuous education as the most important tool within an external quality assurance scheme.
Purpose of the study: 1. to evaluate the effect of the training courses on diagnostic performance, 2. to assess the performance of German pathologists interested in breast cancer screening, and 3. to identify the diagnostic problems.
Methods: Till November 2005 about 280 pathologists will participate in 16 diagnostic courses, each for 20 participants. Each course includes 4 microscopic tutorials and 8 presentations. It starts and ends with a diagnostic test using the same set of 11 slides of MIB specimens selected within broad diagnostic categories (only cases with complete agreement among the coordinators). Participants reading the slides use a form planned as standard reporting form for the German Screening Project including the B category according to the EU Guidelines. Kappa statistics are calculated separately for the entry and the closing test. The advantage of these statistics is that kappa values are independent of the diagnosis; they simply reflect the consistency of ratings by the participants. The following limits were used for interpretation: <0.0: poor, 0.0-0.2: slight, 0.21-0.4: fair, 0.41-0.6: moderate, 0.61-0.8: substantial, and 0.81-1.0: very good. (180 participants by September 2005).
Results: (preliminary 100 participants) 1. After the course the rate of cases with substantial and very good consistency rises from 7 to 9/11 cases. 2. The overall consistency of the participants' B-categories is 0.68. 3. There are 4 cases with poor to fair agreement: columnar cell change, columnar cell hyperplasia, DCIS low grade, and phyllodes tumor.
Conclusions: 1. The training course improves the consistency of the diagnosis in MIB. 2. The consistence of attending German pathologists in MIB diagnosis is in general at least substantial (kappa >0.6) 3. To improve the performance further education should include columnar cell lesions and non-high nuclear grade DCIS / ductal hyperplasia, respectively.

O-209
ATYPICAL DUCTAL HYPERPLASIA, FLAT EPITHELIAL ATYPIA AND BREAST CANCER RISK

DAUPLAT Marie-Mélanie, MISHELLANY Florence, FOUILHOUX Genevieve, DELATOUR Monique, FEILLEL Viviane, LEBOUEDEC Guillaume, LEMERY Sylvie, PENAULT-LLORCA Frédérique;

Background: With the development of breast screening mammography atypical ductal hyperplasia (ADH) and the recently described flat epithelial atypia (FEA) or columnar cell atypia are frequently reported. Those lesions are considered as potential markers of risk of breast cancer. Their finding on core biopsies for micro calcifications implies a surgical procedure. But their involvement in breast carcinogenesis remains still badly defined. Material and methods: We conducted a retrospective study on 394 patients operated on for benign lesions between 1986 and 1998, in order to revalue the presence of atypical breast lesions and to study their relationship to the risk of cancer. The slides were reviewed, blindly by two pathologists. Follow up was 13.1 years. Results: Middle age was 55.6 yearss. 116 patients (29.5%) had family history including 23% at first degree. 196 patients took a hormonal treatment (oral contraception (6.3%), progestative treatment (10.4%) and hormonal replacement therapy (HRT)(33%)). Atypical breast lesions: ADH (14%), FEA (20%) and both (5%). Among these 394 patients, 9.5% developed a breast cancer (in situ or invasive) during their follow up. The middle age at the occurence of the cancer was 56.5 years. 28% of the patients had family history at first degree and 36% received a hormonal treatment. 55.5% had atypical lesions (28% ADH, 19.5% FEA and 8% both lesions). A significant increase in the relative risk (RR) was observed in case of ADH (RR=2), FEA in a context of family history (RR=2.5%) and, ADH associated either family history (RR=3.5) or HRT (RR=4.5%) or progestative treatment (RR=8.4).
Conclusion: Our data support the breast cancer risk associated with atypical breast mesions, especially in case of an association with a hormonal treatment. Only prospective studies with molecular tests will make possible the understanding of their behaviour.

O-210
DOES DIAGNOSTIC MANIPULATION OF THE PRIMARY BREAST CANCER INCREASE INCIDENCE OF SENTINEL LYMPH NODE METASTASIS?

M Amini L Costarelli, FR Piro, L Fortunato (*), M Farina (*), CE Vitelli (*), A dell'Osso (°)
"San Giovanni Addolorata" Hospital, Department of Pathology and Surgical (°) – Roma, Italy "MG Vannini" Hospital, Department of Surgery (*) – Roma, Italy

Introduction: Sentinel lymph node biopsy has been stated by numerous studies. It can be helpful to identify positive cases, as it may avoid patients' morbidity of surgical excision of axillary lymph nodes. Recent publications reported that a previous fine needle aspiration (FNAC) or core biopsy (CB) or incisional biopsy (IB) of the primary tumor are associated with passive dislodgement of tumor cells in the sentinel lymph node.
Purpose: We present 503 cases of primary breast cancer that were retrospectively evaluated to assess if a previous manipulation of primary tumors increases incidence of metastases in sentinel lymph node, actually.
Methods: 503 consecutive patients (meadian age 61 yrs) with primary breast cancer (median diameter 1,5 cm) were retrospectively evaluated. They came from two different institutions (SGA and MGV). A group of patients, coming from SGA, were studied preoperatively with FNAC, core biopsy or incisional biopsy of the primary breast tumor; the other group, coming from MGV, were studied intraoperatively and breast tumor and SLN were excised simultaneously. All sentinel lymph nodes were evaluated by conventional staining and immunoistochemistry according to our step analysis protocol. First section obtained from each SLN was called Level 0 and routinely processed; if negative, at least six additional couples of section were obtained at 100 micron of distance and were analysed with conventional staining and immunoistochemistry. SLN metastases were called micrometastases (MICRO) when less than 2mm in diameter and isolated tumor cells (ITC) when less than 0,2 mm in diameter.
Results: FNAC (n=88), CB (n=16), or IB (n=100) was performed in 204 cases from 4 to 60 days (median time 11 days) before SLN biopsy procedure. FNAC and CB cases represented GROUP 1, IB cases represented GROUP 2. After intraoperative examination, a simultaneous excision of primary breast tumor and SLN was performed in 299 patients (GROUP 3).We observed SLN+ in 37,5% GROUP 1, 33% GROUP 2 and in 42,1% GROUP 3 (p=0,2). Macrometastases were 18 in GROUP 1, 18 in GROUP 2 and 77 in GROUP 3 (p=0,1). Micrometastases were 11 in GROUP 1, 5 in GROUP 2 and 31 in GROUP 3 (p=0,2). ITC were 10 in GROUP 1, 10 in GROUP 2 and 18 in GROUP 3 (p=0,2).
Conclusions: We could not identify any increased incidence of sentinel lymph node MICRO or ITC after diagnostic

manipulation of the primary tumor. These results are not in accord with other studies.

O-211
INTRAOPERATIVE EXAMINATION OF SENTINEL LYMPH NODES FREQUENTLY CHANGES SURGICAL MANAGEMENT IN WOMEN WITH BREAST CANCER

M Amini, L Costarelli, FR Piro, L Fortunato (*), Massimo Farina (*), A Dell'Osso (°), CE Vitelli (*)
"S.Giovanni Addolorata" Hospital, Department of Pathology and
Surgical (°) – Roma, Italy
"MG Vannini" Hospital, Department of Surgical – Roma, Italy

Introduction: Sentinel lymph node (SLN) biopsy has rapidly changed the surgical management of patients with breast cancer. Intraoperative identification of positive cases can be helpful, as it may avoid patients' return to the operating room.
Methods: We studied 418 consecutive patients (median age 64 years) with primary breast cancer (median diameter 1.5 cm) who underwent SLN biopsy from January 1999 to August 2003. At the discretion of the operating surgeon, an intraoperative examiation (IE) of the SLN was obtained, and the material stained with toluidine blue. After surgery, SLN's were step sectioned, and at least six additional couples of sections obtained from each SLN at 75 micron distance were analysed with conventional staining and immunohistochemistry (IHC – MNF 116).
Results: IE was obtained in 236 patients (56%) with either frozen section (FS; n=68) or with touch prep cytology (TP; n=168), according to different periods of the study. Intraoperative examination resulted in an accuracy of 89% (209/236), but identified only 52/77 positive cases (sensitivity 68%). There were 25 false negative cases (9%), of which 7 cases were represented by macrometastases and 18 cases by micrometastases ($p < 0.001$). Six of the macrometastases were missed by TP, and one by FS ($p= 0.9$). A change in surgical management with IE, resulting in synchronous axillary dissection, occurred in 10% of patients with tumors less than 1 cm in diameter (6/63), in 20% of those between 1-2 cm (24/119), and in 34% of those more than 2 cm in diameter (18/53) ($p=0.05$). In additional 14 cases isolated tumor cells (ITC) were diagnosed at final SLN analysis with IHC, and IE failed to identify them in 12 cases. Lobular histology, but not tumor diameter or age, was the only factor associated with the presence of ITC ($p=0.008$).
Conclusions: IE is highly accurate, but has mediocre sensitivity, particularly for micrometastases. FS and TP are roughly equivalent. The advantage of the latter is mainly represented by the preservation of tissue for subsequent step analysis and IHC. IE is particularly helpful in larger tumors. An accurate and feasible method of intraoperative examination needs to be standardized.

O-212
PRONOSTIC VALUE OF PROLIFERATION MARKERS IN SMALL SIZE NODE NEGATIVE BREAST CANCER. A RETROSPECTIVE STUDY OF 104 CASES

S. Bellefqih1, A. Al Ghuzlan1, M. Caly1, L. Gambotti2, A. Vincent-Salomon1,
L Chneker1, M. Lae1, V. Dieras3, B Sigal-Zafrani1, X Sastre-Garau1
Department of Pathology1, Biostatistics2, and Oncology3,
Institut Curie, 26 rue d'Ulm 75248 Paris, France

Background :
Biological prognostic parameters in node negative breast cancer are needed to select patients (pts) likely to take benefit from adjuvant chemotherapy. We have retrospectively analysed the prognostic value of Ki67 (MIB1) and mitotic index (MI) in T1/T2 breast cancer with long follow-up.
Material and methods :
A series of 104 cases of node negative breast cancer (mean pathological size 15.6 mm) treated by surgery without adjuvant chemotherapy between 1995 and 1996 has been retrospectively analysed. Ki67 and MI were assessed for all pts. Overall survival (OS), metastasis free survival (MFS) and disease-free survival (DFS) were calculated using the Kaplan-Meier estimates and comparisons for survival curves are based on the log-rank test.
Results :
The mean age of pts was 55.6. Median follow up was 92 months (9-109 m). The MI was <10 mitosis in 60 cases, 10 - 19 mitosis in 24 cases and >20 mitosis in 20 cases (mean 10,88; median 7). The MIB1 score was <33% in 70 cases, 34-66% in 18 cases and 67-100 in 16 cases (median = 15%). MIB1 score was a parameter significantly associated with MFS ($p=0.04$) and OS ($p=0.03$) but not with DFS ($p=0.5$). Also, MI was more significantly associated with MFS ($p=0.002$) and OS (0.01), underlying a trend for DFS ($p=0.05$).
Conclusion :
In this study, both MI and KI67 scores were significant predictors of the outcome of small size node negative breast carcinoma but the discriminative value of MI was higher than that of MIB1. A larger series of cases will be analysed to confirm this result. Proliferation index should be considered as a biological marker of value to take into account for the indication of adjuvant chemotherapy

O-213
ASSESSMENT OF EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR) BY IMMUNOHISTOCHEMISTRY AND CHROMOGENIC IN SITU HYBRIDIZATION (CISH) IN METAPLASTIC CARCINOMAS OF THE BREAST

Milanezi F 1,2, Reis-Filho JS 3, Carvalho S 1, Simpson PT 4, Lakhani SR 4, Schmitt FC 1,5.
1 IPATIMUP- Institute of Molecular Pathology and Immunology of Porto University, Porto – Portugal; 2 School of Health Sciences, University of Minho, Braga – Portugal; 3 The Breakthrough Toby Robins Breast Cancer Research Centre, Institute of Cancer Research, London – UK; 4 Molecular & Cellular Pathology, Mayne Medical School, University of Queensland, Queensland Institute of Medical Research and Royal Brisbane and Women's Hospital, Brisbane, Australia; 5 Medical Faculty of Porto University, Porto – Portugal

INTRODUCTION: Metaplastic breast carcinomas (MBCs) account for less than 1% of all invasive mammary carcinomas. They are a heterogeneous group of neoplasms generally characterized by an intimate admixture of adenocarcinoma with dominant areas of spindle cell, squamous, and/or mesenchymal differentiation. These tumours are reported to show an aggressive biological behaviour. In previous studies, we have demonstrated that up to 80% of MBCs overexpress the epidermal growth factor receptor (EGFR). HER2 and EGFR have received great attention in the medical literature over the last few years owing to the fact that humanised monoclonal antibodies against HER2 and therapies against the extracellular ligand binding domain or the intracellular tyrosine kinase domain of EGFR have proven to be successful for the treatment of certain types of human cancer.

AIM: To investigate the presence of overexpression and amplification of EGFR and HER2 in MBCs.
METHODS: EGFR and HER2 protein levels were assessed by IHC in 24 formalin-fixed, paraffin-embedded MBCs using a monoclonal antibody (31G7) for EGFR and a polyclonal antibody for HER2 and scored according to the Herceptest scoring system. Gene amplification was evaluated by chromogenic in situ hybridisation (CISH) using digoxigenin-labeled EGFR probe. The results were evaluated by bright-field microscopy under a 63x objective lens.
RESULTS: Nineteen tumours had strong expression of EGFR protein (79.2%), two had weak staining (8.3%) and three were negative (12.5%). Five cases (20.8%), 2 carcinomas with squamous differentiation and 3 spindle cell carcinomas, showed EGFR amplification as defined either by large gene clusters or >10 signals/nucleus. The 19 remaining cases (79.2%) showed a normal gene status (up to 2 dots/nucleus). All the tumours with EGFR amplification had overexpression at the protein level. All tumours lacked HER2 overexpression (3+).
CONCLUSION: MBCs frequently show EGFR overexpression which is associated with EGFR gene amplification in approximately 20% of the cases. On the other hand, MBCs proven not to harbour HER2 overexpression. Take together; our findings suggest that some patients with MBCs might benefit from the new developed therapies that target the EGFR. As some MBCs show EGFR overexpression without gene amplification, further studies evaluating EGFR activating mutations are warranted.

O-214
HER-2/NEU AMPLIFICATION AND EXPRESSION ASSESSMENT : COMPARISON OF IMMUNOHISTOCHEMISTRY, QUANTITATIVE PCR AND RT-PCR.

LABERGE-LE COUTEULX Sophie1, CORNIC Marie1, BLOT Emmanuel2, GUILLEMET Cécile2 et PICQUENOT Jean-Michel1. Service d'Anatomie et Cytologie Pathologique, Service d'Oncologie Médicale, CLCC Henri-Becquerel, Rouen, FRANCE.

INTRODUCTION: HER-2/neu overexpression/amplification is described in 30% of breast carcinomas and has prognostic and therapeutic implications. Conventional methods to detect it includes immunohistochemistry (IHC) and fluorescent in situ hybridization(FISH). Molecular biology offers new methods which can be automated and less expensive, though reliabililty of such methods is not well established.
MATERIAL AND METHODS: We studied 200 consecutives samples of breast carcinomas from january 2001 to december 2002 using quantitative PCR (Q-PCR) of exons 3 and 23 regions on paraffin embedded tissue and snap frozen tissue, quantitative RT-PCR(Q-RT-PCR) of exons 3 and 23 regions on snap-frozen tissue and IHC on paraffin embedded tissue. Discordant results between methods and positive IHC samples were assessed by FISH.
RESULTS: DNA extraction from paraffin embedded tissue was suitable in 166 samples (79%), from 199 (99,5%) snap frozen tissue and RNA extraction from 147 (73%)samples. A total of 119 samples from 113 patients was analyzed with all methods. Average tumor size was 26mm, with 48 (42%) patients with metastatic lymph nodes. Mean age was 61 years with 64% of post-menopause patients. Eighty-five percent of cases were invasive ductular carcinoma non special type, 9% of lobular carcinomas and 6% of others, 80% of cases expressing hormonal receptors. IHC revealed 11(10%) cases 3+, 2 cases 2+ and the remaining cases negative. Results for molecular biology showed 14(13%) cases positive in paraffin embedded tissue by Q-PCR, 24 (22%) positive samples in snap frozen tissue and 12(10%) samples were positive by Q-RT-PCR. All IHC positive samples (except one 2+ case) were positive in molecular biology. Q-PCR on frozen tissue was found to be the more sensitive and more specific method, though false positive cases were often aneuploid for chromosome 17. Interestingly, some cases showed augmented HER-2/neu RNA with negative IHC and without amplification. In rare cases, there was an imbalance between copy of exon 23 and exon 3. With a follow-up of 3,5 years there was no correlation between either IHC, Q-PCR or Q-RT-PCR and disease free survival (15 patients are metastatic).
CONCLUSION: Q-PCR on snap frozen tissue is a reliable and relatively cheap method to assess HER-2 amplification on large series of patients and can easily be done in routine. Confirmation by either IHC or FISH allows a great specificity. Cost effectiveness evaluation needs larger series to be don.

NEOADJUVANT CHEMOTHERAPY FOR INVASIVE LOBULAR CARCINOMAS OF THE BREAST: A POOR PATHOLOGICAL RESPONSE BUT SAME PROGNOSIS THAN INVASIVE DUCTAL CARCINOMA

Anne Vincent-Salomon, Chantal Gautier, Brigitte Sigal-Zafrani, Paul Fréneaux, Marick Laé, Christophe Rosty, Bernard Asselain, Rémy Salmon, Jean-Yves Pierga, Xavier Sastre-Garau.
Institut Curie, 26 rue d'Ulm 75005 PARIS, France

Background: Invasive Lobular Carcinomas (ILC) at initial presentation are larger tumors, with a low proliferative rate and higher hormonal receptors positivity compared to invasive ductal carcinomas (IDC), characteristics known to be negative predictive factors for response to neoadjuvant chemotherapy. Our aim was to retrospectively analyse the overall response rate of the ILC to neoadjuvant chemotherapy and compared it to those of ductal carcinomas (IDC).
Material and methods: We selected from our database, patients presenting a T2T3 (< 7cm) N0-N1a N1b ductal or lobular unilateral breast carcinoma, treated with neoadjuvant chemotherapy (4 cycles of anthracyclines-based chemotherapy) from 1990 to 1999. All slides of lobular carcinomas were retrospectively reviewed. The E-cadherin expression was assessed by immunohistochemistry. We retrospectively analysed, the clinical and pathological response rates to chemotherapy of the lobular compared to the ductal carcinomas. We also determined the conservative treatment and the survival rates (overall OS, disease-free DFS and metastasis-free survival MFS) for patients in each group.
Results: 802 patients were studied (median follow-up: 109 months), 86 with an ILC and 716 with an IDC. All ILCs except 3 were E-cadherin negative. The pathological characteristics showed that ILC, when compared to IDC, were more frequently grade I (39% for ILC, 12% for IDC, $p< 0.0001$) and ER positive (77% for ILC and 64% for IDC, $p= 0.02$) and PR positive (75% for ILC and 61% for IDC, $p=0.02$). A conservative surgery was possible for 53% of the ILC and for 64% of the IDC ($p=0.04$). Pathological response was available for 584 patients (532 IDC, 52 ILC) and showed that only one patient with ILC presented a complete pathological response contrasting with to 32 complete pathological response in the IDC group. The DFS, MFS and OS were identical within the two groups of patients.
Conclusion: We showed that after neoadjuvant chemotherapy, a conservative treatment was less frequently possible for ILC than for IDC and that no complete pathological response to neoadjuvant chemotherapy was observed in ILC. But patients with ILC presented the same outcome than patients with IDC. This poor response to neoadjuvant chemotherapy can be related to the biological characteristics of ILC. As one of the major goal of neoadjuvant chemotherapy is to increase breast conservative surgery, the ILC patients are not good candidates for this treatment.

Introduction: Immunohistochemical analysis of E-cadherin has changed the way lobular neoplasia is perceived. It has helped to classify difficult cases of carcinoma in situ with indeterminate features and led to the identification of new variants of lobular carcinoma. Pleomorphic lobular carcinoma (PLC) and pleomorphic lobular carcinoma in situ (PLCIS), recently described variants of invasive and in situ classic lobular carcinoma, are reported to be associated with more aggressive clinical behaviour. Although PLC/PLCIS show morphological features of classic lobular neoplasia and lack E-cadherin expression, it is still unclear whether these lesions evolve through the same genetic pathway as lobular carcinomas or are high grade ductal neoplasms that have lost E-cadherin.
Material and Methods: A 44-year-old female patient presented with a breast lump in the left upper outer quadrant. Histological and immunohistochemical analysis revealed extensive PLCIS and invasive PLC associated with foci of E-cadherin negative carcinoma in situ with indeterminate features. Multiple foci of preinvasive and invasive carcinoma were analysed with i) immunohistochemistry with antibodies for E-cadherin, beta-catenin, estrogen receptor (ER), progesterone receptor (PgR), androgen receptor (AR), HER2, epidermal growth factor receptor, p53 and p63; ii) chromogenic in situ hybridisation with probes for HER2, EGFR and c-myc and centromeric probes for chromosomes 7 and 8; iii) high resolution comparative genomic hybridisation (CGH) and iv) array-based CGH with the 4.6K Breakthrough Breast Cancer Research Centre Array CGH platform, which has a resolution of <1Mb.
Results: All lesions lacked E-cadherin and *f*Ò-catenin, were positive for hormone receptors and showed gain of 1q, 7p, 8p, 9p and 20p and loss of 1p and 16q. In addition, HER2 overexpression (3+) and amplification of c-myc and HER2 were detected in the PLCIS and invasive PLC.
Conclusion: The combination of gain of 1q and loss of 16q associated with lack of E-cadherin and beta-catenin expression are typically observed in lobular carcinomas and not seen in high grade ductal lesions. Amplification of c-myc and HER2 may account for the high grade features in this case and the reported aggressive clinical behaviour of PLC. Taken together, these data suggest that at least some PLCs may evolve from the same precursor or through the same genetic pathway as classic lobular carcinomas.

TUBERCULOSIS IN RHEUMATOID ARTHRITIS

Miklós Bély MD, PhD, DSc1 and Ágnes Apáthy MD2
1Department of Pathology,
Policlinic of the Hospitaller Brothers of St.John of God, Budapest, Hungary
2Department of Rheumatology,
National Institute of Rheumatology and Physiotherapy, Budapest, Hungary

Objective
Tuberculosis is one of the most important diseases accompanying rheumatoid arthritis (RA). The risk of miliary dissemination of post-primary tuberculosis is high, because of the poor immune status of elderly patients with an autoimmune disease which is treated with steroids, and/or immunosuppressive drugs.
The aim of this study was to determine
1. the prevalence of post-primary fibrous, or fibrocaseous tuberculosis (Tb) in RA
2. the incidence of miliary disseminated tuberculosis (mTb) in RA
3. the incidence of organ involvement by Tb and mTb
4. the relationship between Tb and mTb in RA.
Patients and Methods
A randomized (non-selected) autopsy population of 234 in-patients with RA was studied. RA was confirmed clinically according to the criteria of the ACR.
Post-primary fibrous, or fibrocaseous tuberculosis, and miliary dissemination of tuberculosis was confirmed histologically. The link between tuberculosis and disseminated miliary tuberculosis was determined by c;²-tests.
Results
1. Post-primary fibrous, or fibrocaseous tuberculosis accompanied RA in 27 (11.54 %) of 234 cases. Post-primary tuberculosis was localized to the lung. Twelve of 27 post-primary Tb cases were histologically fibrocaseous, and 15 of 27 revealed only fibrous scars due to documented tuberculosis.
2. Eight (3.4%, 29.6 rel%) of 27 post-primary fibrous, or fibrocaseous tuberculosis cases were complicated by disseminated miliary tuberculosis.
3. Proliferative, or exudative epithelioid granulomatous tuberculosis involved different organs, such as lungs, liver, spleen, adrenal glands, synovial membrane, vertebrae, pituitary gland, and/or lymph nodes.
4. There was a statistically significant association between Tb and mTb ($Chi^2 = 54.84$, $p<0.0001$, $q=1$), or fibrocaseous character of Tb and mTb ($Chi^2 = 68.9$, $p < 0.0001$).
Conclusion
A focus of post-primary fibrocaseous tuberculosis (mostly in the lung) represents a high risk of miliary dissemination in RA.
In our autopsy material the miliary dissemination of tuberculosis was the result of exacerbation of endogenous Tb, based on the high value of Youle's association coefficient.
The miliary dissemination of tuberculosis may be considered as a terminal phenomenon, because the limited number of granulomas involved only a few organs.
The exudative character - beside proliferative epithelioid granulomas - must be regarded as histological evidence of impaired immunologic reactivity.

CHARACTERIZATION OF RABBIT MODEL FOR EPSTEIN-BARR VIRUS-ASSOCIATED LYMPHOPROLIFERATIVE DISEASE WITH HEMOPHAGOCYTIC SYNDROME AND ITS THERAPEUTIC TRIALS.

K. Hayashi, K. Takashima, Y. Kitamura, W. Oda, I. Ogahara, M. Ohashi,* T. Sairenji.*
Divisions of Molecular Pathology and Biomedical Science,* Tottori University Faculty of Medicine, Yonago-city, Japan

Introduction: Epstein-Barr virus associated hemophagocytic syndrome (EBV-AHS) is often associated with T-cell lymphoproliferative diseases (LPD). The therapy of this disease is one of the most challenging goals in medicine. Purpose: To elucidate the exact nature of fatal LPD observed in Herpesvirus papio (HVP)-induced rabbit LPD with hemophagocytic syndrome (HPS), we analyzed sequential development of HVP-induced rabbit LPD and their cell lines. To develop some therapeutic interventions for EBV-AHS, we examined the effectiveness of antiviral agent or chemotherapy, using this rabbit model. Methods & Results: All of the seven Japanese White rabbits inoculated intravenously with HVP died of fatal LPD or HPS 18 to 27 days after inoculation. Sequential autopsy revealed splenomegaly and swollen lymph nodes, often accompanied by bleeding. Atypical lymphoid cells with HVP-RNA-1 expression infiltrated many organs with a 'starry sky' pattern, frequently involving the spleen, lymph nodes and liver. HVP-ISH of immunomagnetic purified lymphoid cells from spleen or lymph nodes revealed HVP-EBER1+ cells in each CD4+, CD8+ or CD79a+ fraction. Hemophagocytic histiocytosis was observed in the lymph nodes, spleen and bone marrow. HVP-DNA was detected in the infected rabbits by PCR or Southern blot analysis. Six IL-2 dependent rabbit T-cell lines were established from transplanted scid mice tumors of LPD. Three of them showed tumorigenicity in nude mice. Furthermore, three HVP-infected rabbits treated with vidarabine died of HPS between days 23 and 28, which were not different from the untreated rabbits. Three of the infected rabbits that were treated with CHOP treatment died of HVP-induced LPD and HPS with a bleeding tendency and/or with opportunistic infections. They died on the 26th, 62nd and 105th day, respectively. The most interesting finding of this experiment was observed in the rabbit with the longest survival time: HVP-negative lymphomas surrounded by HVP-induced LPD developed in the larynx and ileum of this rabbit. Conclusion: HVP-induced fatal LPD with HPS in rabbits are almost reactive oligoclonally in nature, but contain some pre-neoplastic T-cell clones. Our data from therapeutic trials using EBV-AHS rabbit model indicate that vidarabine is not effective to treat HVP-infected rabbits, and even the cytotoxic chemotherapy of CHOP is not sufficient to cure the HVP-infected rabbits. Further studies will be required to develop better therapies to treat EBV-AHS.

O-219
SIALIC ACID EXPRESSION IN PAEDITRIC AND ADULT RESPIRATORY TRACTS

NICHOLLS John, BOURNE Anthony, PEIRIS Malik

INTRODUCTION:
Influenza virus infection of humans involves binding of the virus to cells of the respiratory tract and sialyoligosaccharides are responsible for the viral-cell interactions. Human strains preferentially agglutinate red blood cells with N-acetylneuraminic acid (sialic,SA) alpha 2-6 Gal linkages and avian strains preferentially bind alpha 2-3 sequences. Previous research indicated that ciliated cells primarily display SA alpha 2-6Gal sequences whilst goblet cells contain the SA alpha 2-3Gal sequence. Recent studies on cultured human tracheo-bronchial epithelium however appeared to show a contrary view. These differing findings are of importance for the understanding of the development of avian influenza infection in humans, which appeared first in Hong Kong in 1997 and has recently resulted in outbreaks in Thailand, Vietnam and Cambodia.

PURPOSE OF STUDY
It was felt that it was necessary to readdress the distribution of the SA alpha 2-6Gal and SA alpha 2-3Gal in human tissues to determine whether the culture model could be applied to human cases and to determine if there was real variation in the distribution of these two receptors.
METHODS USED:
Archival fetal and neonatal autopsies, biopsy specimens of children with congenital cystic adenomatoid malformation (CCAM) and biopsy specimens of bronchial mucosa.
RESULTS:
There is greater expression of SA alpha 2-3Gal in perinatal and paediatric respiratory epithelium than in adults with ciliated epithelium as well as goblet cells showing membranous and cytoplasmic staining. In adult tissues metaplastic mucosa shows increased staining of SA alpha 2-3Gal.
CONCLUSION:
The increased expression of SA alpha 2-3Gal is one explanation for the high incidence of avian influenza in a paediatric population and may also serve to highlight susceptible populations for this type of influenza

"Institute of pathology, Hospital München-Bogenhausen, FRG

The present study is based on an initiative for quality assurance of the German Society of Pathology and the Professional Association of German Pathologists. Four panel laboratories with experience and expertise in PCR detection of M. tuberculosis were selected to establish the prerequisites for continuous external laboratory trials, in particular by providing pre-tested specimens and evaluation criteria for participating institutes.
In a first step, the four panel laboratories performed an internal trial to test their own reliability and reproducibility.
Paraffin sections and DNA preparation from 32 clinical specimens and 2 experimentally generated tissues totalling to 66 samples were evaluated by each panel institute according to their own protocols using different methodologies. Despite these differences, a high degree of inter-laboratory reliability was achieved. The correlation with the histological findings revealed that the extent of necrosis was the only significant parameter being associated with PCR positivity. The detailed results will be published (Virchows Archiv, 2005, in press) providing recommendations for applying PCR-based methodology for the detection of mycobacterial DNA in surgical specimens of pathology.
Pre-tested specimens are now available for the external trail and can be ordered from the steering institute via Oligene (www.oligene.com). All molecular pathology laboratories are invited to participate in this quality assurance initiative.

CONCENTRATION OF SERUM IS ONE OF THE DETERMINING FACTORS AFFECTING THE PURITY AND THE QUANTITY OF OBTAINED SCHWANN CELLS

Vahid Bayati, Farideh Etesam, Abbas Abdolvahhabi, Mohammad Ali Shokrgozar, Aligholi Sobhani*, Mohammad Barbarestani

Abstract:

Aims of Investigation: Finding a way to gain Schwann cells (SCs) with maximal purity and numbers in order to use them for autologous cellular transplant was the aim which made us to study the role of various concentrations of Fetal Bovine Serum (FBS) on SCs culture in RPMI-1640 medium.

Methods and Materials: We used adult rat sciatic nerve model (one to three nerve per primary culture) after a 10 days period of in vivo predegeneration of nerve induced by surgery, followed by isolating SCs and subcultivating two times during a week. Then the obtained cells were cultured in 8 groups with various concentrations of FBS (5%, 2.5%, 1.25%, 0.625%) and different times of application (4 dishes containing these concentrations to day 4 and from day 5 to 10, without any serum supplementation and the other 4 dishes containing the same concentrations to day 10) to the RPMI-1640 medium for 10 days. Finally the SCs were immunocytochemically (using rabbit anti- S100 antibody) and morphologically characterized and counted using fluorescence Microscope equipped with phase-contrast, fluorescein optics.

Results: This investigation demonstrated that the RPMI-1640 supplemented with 0.625% FBS results in 360×10^3 cells with the approximate purity of 99% in a 35mm dish.

Conclusion: According to results we conclude that the manipulation of serum concentrations may be a new approach for purifying SCs culture during isolation.

Key Words: Adult Schwann cell, Purity, Fetal bovine serum, Subcultivation

DIAGNOSIS OF METASTATIC CARCINOMA IN CHOROID BY FNA: REPORT OF THREE CASES.

DREHER IRION Luciane Cristina 1, CORRÊA Zelia Maria 2, MARCON Italo 2, GAIGER Ana Maria 3.

1.Consultant Histopathologist The Royal Oldham Hospital, UK and Laboratório Patologistas Reunidos, Porto Alegre, Brasil.

2.Ophthalmologist Complexo Hospitalar Santa Casa/FFFCMPA, Porto Alegre, Brasil.

3.Head Pathologist Laboratório Patologistas Reunidos, Porto Alegre, Brasil.

Introduction: Although uncommon, metastatic lesions in the eye ball should be kept in mind, and the differential diagnosis with a primary tumour, especially melanoma, is fundamental. Clinical data: Two male patients (case 1: 35 years old and case 2: 56 years old) and one female patient (case 3: 39 years of age) had subito loss of sight, ocular pain and conjunctival hyperaemia. Ultra-sonound scans showed partial retinal detachment and a choroidal mass. Patient 1 was undergoing an investigation of a pulmonary lesion. Patient 2: history of surgery for renal carcinoma 6 years before and case 3: the ocular lesion was the 1st clinical sign. Diagnostic methods: After US scans with suspicious choroidal lesions, a FNA has been performed in each case in order to differentiate between primary and metastatic lesion. The transvitreal FNA has been done with indirect binocular ophthalmoscopy under peribulbar anaesthetics and sedation. Microscopic findings: The aspirate from all cases was satisfactory and a Papanicolaou stain was used. Case 2 has shown malignant looking large epithelial cells and haemorrhage, in keeping with metastatic lesion from renal tumour due to past history. Cases 1 and 3: malignant epithelial cells demonstrated and immunocytochemistry has been performed for differential diagnosis. In both cases AE1/AE3, CK7 and TTF1 were positive and CK20, S100 and HMB45 were negative, suggesting metastatic carcinoma from lung as primary source. Comment: The possibility of intraocular metastases should be kept in mind. In experienced hands, a FNA along with immunocytochemistry can be helpful for a definite diagnosis.

O-223
CORONARY THROMBOSIS IS FREQUENTLY INITIATED DAYS OR WEEKS BEFORE THE CLINICAL ONSET OF MYOCARDIAL INFARCTION

VAN DER WAL Allard, RITTERSMA Saskia, KOCH Karel, PIEK Jan, DE WINTER Rob Academic Medical Center, Amsterdam, The Netherlands

Introduction.

Acute Myocardial Infarction (AMI) is caused by fibrous cap disruption of a coronary atherosclerotic plaque, leading to occlusive thrombosis. Both the onset of plaque complications (rupture) and the onset of symptoms (chest pain) can be seen as acute events, but at present there is limited insight in the time lag between both processes. In order to relate the onset of thrombus formation with the clinical onset of AMI ,we systematically studied the age of intracoronary thrombi of AMI patients using histopathological and immunohistochemical parameters.

Methods.

Percutaneous intracoronary thrombectomy (thrombosuction) was performed in 211 AMI patients prior to angioplasty (balloon dilation with or without stent implantation). The aspirated material was collected in a bottle, fixed in formalin, filtered and embedded in paraffin. Sections were cut at 6 levels and stained with Haematoxlin and Eosin and Elastic van Gieson stains. Additional immunohistochemistry was performed with monoclonal antibodies anti-CD68, anti-CD31, anti-CD61 and anti-smooth muscle actin. Thrombus age was classified as 1:fresh thrombus (layers of intact platelets, fibrin, erythrocytes and granulocytes) 2:lytic thrombus(colliquation and karyorrhexis, 1 to 5 days old) and 3:organized thrombus, (more than 5 days up to weeks old).

Results.

In 199 of 211 patients (95%) materials were retrieved;in 114 of 199 patients (54%) only thrombus was found, in 12 patients (5%) only plaque components were identified and in 85 patients (41%), both thrombus and plaque fragments were aspirated. Plaque materials consisted in all instances of soft plaque constituents: CD68+ foamcell macrophages and extracellular lipid debris with cholesterol clefts. In 101 of 199 patients who showed thrombus (51%) the age of thrombus was classified as at least partially lytic (35%, 1 to 5 days old) or at least partially organized (16%, older than 5 days). In organized thrombus the ingrowth of actin + immunostained smooth muscle cells could be demonstrated, with or without deposition of young collagen and in some instances in combination with ingrowth of CD31+ microvessels.

Conclusion.

Intracoronary materials retrieved from AMI patients is frequently heterogenous of composition in terms of thrombus age. In 51% of cases older thrombus is present, indicating an important discrepancy (in terms of days up to weeks)between the time of onset of thrombosis and the occurence of acute clinical symptoms.

O-224
INCREASED MMP-2/-9 ACTIVITIES IN THE MYOCARDIUM CORRELATE WITH IMPAIRED CARDIAC FUNCTION AND APOPTOSIS DURING EARLY MULTIPLE ORGAN FAILURE IN SHEEP

Jeremias Wohlschlaeger1, Henning D. Stubbe2, Klaus J. Schmitz1, Naomasa Kawaguchi1, Atsushi Takeda3, Nobuakira Takeda3, Frank Hinder2 , Hideo A. Baba1

1Institut für Pathologie, Universität Essen, Germany, 2Klinik und Poliklinik für Anästhesiologie und operative Intensivmedizin, Universität Münster, Germany and 3Department of Internal Medicine, Jikei University, Tokyo, Japan

Objective: Matrixmetalloproteinases (MMP) degrade extracellular matrix (ECM) and are involved in systemic inflammation and heart failure. We investigated the roles of MMP-2, MMP-9, MT1-MMP, focal adhesion kinase (FAK) and Paxillin in ovine hearts during early multiple organ failure induced by norfenefrine-masked hypovolemia and endotoxinemia.
Design: Fifteen adult instrumented sheep were randomly assigned to one of three groups: 1. norfenefrine-masked hypovolemia plus endotoxemia (NMH+ENDO), 2. norfenefrine-masked hypovolemia without endotoxemia (NMH), 3. recurrent endotoxemia during normovolemia (ENDO). Three healthy sheep served as untreated controls (CONTROLS).
Measurements and results: Cardiac tissue was analysed by gel zymography and Western blots. Apoptosis was determined by TUNEL-staining. Gel zymography revealed significantly increased MMP-2 activity in NMH+ENDO compared to ENDO and controls. MMP-9 activity was significantly elevated in all experimental groups.
MMP-2 was significantly increased on the protein level, while MMP-9 was unaltered. MT1-MMP was not significantly altered in any group.
MMP-2 and -9 activities correlated positively with heart rate and negatively with parameters of cardiac function. MMP-2/-9 activity and p-Paxillin expression correlated positively with cardiomyocyte apoptosis.
Conclusions: MMP-2 and -9 activities are significantly increased in combined vasoconstrictor-masked hypovolemic and endotoxinemia shock in sheep. Increased MMP-2 activity appears to be mainly due to enhanced synthesis, whereas increased MMP-9 activity obviously follows posttranslational activation of pro-MMP-9. Increased cardiac apoptosis during MOF is probably partly due to MMP-associated ECM degradation. This study provides evidence to the pivotal roles of MMPs in acute cardiac dysfunction during early multiple organ failure.

O-225
INCREASED EXPRESSION AND ACTIVITY OF MATRIX METALLOPROTEINASES CHARACTERIZE EMBOLIC CARDIAC MYXOMAS

Augusto Orlandi1, Alessandro Ciucci1, Amedeo Ferlosio1, Antonio Pellegrino2, Luigi Chiariello2, Luigi Giusto Spagnoli1
1Anatomic Pathology, Tor Vergata University, Rome, Italy
2Cardiovascular Surgery, Tor Vergata University, Rome, Italy

Myxomas are the most frequent primary cardiac neoplasms, accounting for 50% of all tumors. Myxomas are considered tumors with an endocardial origin whose name derives from their prevalent myxoid extracellular matrix, rich in mucopolysaccharides. Cardiac myxomas are benign tumors which are unable to infiltrate the myocardium or give rise to metastases. Nevertheless, they are considered “clinically malignant” tumors because of their susceptibility to embolize to distant organs, that occurs in 30 to 50% of all cases, cardiac myxoma, but the causes are still uncertain. Matrix metalloproteinases (MMPs) are a large family of zinc-dependent proteolytic enzymes that degrade the extracellular matrix in both normal and pathological processes. Many MMPs are released into the extracellular milieu in a pro-enzyme state with affinity to specific extracellular matrix proteins. Purpose of the study was to evaluate MMP activity in cardiac myxomas with the hypothesis of its possible role in the pathogenesis of tumor embolism. Methods used: we examined 27 left atrium-sided myxomas; 10 of them showed clinical signs of peripheral embolism. Immunohistochemistry in all cases and Western blotting, in situ and in-gel zymography in 4 embolic and 6 non-embolic consecutive tumors. MMP expression was also evaluated in myxoma cells in vitro. Summary of the results: we observed in embolic myxomas a higher expression and activity of MT1-MMP, pro-MMP-2 and pro-MMP-9, whereas pro-MMP-1, MMP-3 and TIMP-1 levels were similar to those of non-embolic tumors. RT-PCR demonstrated that increased MMP activity was due, at least in part, to increased transcription and also documented increased TIMP-2 transcripts in embolic myxomas. In vitro, embolic tumor cells retained higher MT1-MMP and pro-MMP-2 levels in basal condition and after stimulation with IL-1b and IL-6. Conclusions: our results show in embolic cardiac myxomas an increased MMP expression and activity. The latter may induce an excessive degradation of tumor extracellular matrix, with consequent increase of the tumor friability, and/or an increased risk of detachment of superficial thrombi.

HISTOMORPHOMETRIC SEMIQUANTITATIVE ASSESSMENT OF EFFECTS OF PARTIAL LEFT VENTRICULECTOMY: ONE-YEAR FOLLOW-UP:

VASILJEVIC D. Jovan, OTAŠEVIC Petar, POPOVIC V. Zoran , GRADINAC Siniša, GLUMAC Sofija , NEŠKOVIC Aleksandar
Institute of Pathology, Belgrade University School of Medicine, Serbia and Montenegro; Dedinje Cardiovascular Institute, Belgrade, Serbia and Montenegro

INTRODUCTION: left ventricular contractility may be improved by partial left ventriculectomy (PLV) in patients with severe heart failure.
PURPOSE: histological assessment by using semiquantitative morphometric parameters of the left ventricle after surgery, and endomyocardial biopsies (EMB) one-year postoperatively.
MATERIAL AND METHOD: The study group consisted of 15 consecutive PLV survivors, predominantly male (13/15), aged 45+12 years. Surgical specimens were taken from the inferior- and/or lateral wall of the LV, processed routinely, and stained with Masson-trichrome. Postoperative EMB, 3 to 5 per patient, were taken 12 months later and processed in the same manner. The following morphometric parameters were assessed: (1) degree of hypertrophy and attenuation (fibre diameter); (2) nuclear evidence of hypertrophy (diameter); (3) myofibrilar volume fraction; (4) degree of degenerative, vacuolar changes, and (5) fibrosis volume fraction. These parameters were graded in the usual fashion (0-none, 1-mild, 2-moderate, 3-severe).
RESULTS: Both NYHA functional class and EF improved 12 months following operation as compared to preoperative values (2.40+0.69 vs. 3.33+0.49, $p<0.001$, and 33.21+12.05% vs. 20.21+9.07%, $p<0.001$, respectively). Semiquantitative morphometric analysis demonstrated postoperative decrease in the degree of attenuation as compared to preoperative values (1.40+0.51 vs. 2.47+0.64, $p<0.01$), as well as decrease in fibrosis volume fraction (2.07+0.80 vs. 2.67+0.49, $p<0.001$) and nuclear hypertrophy (1.27+0.46 vs. 1.67+0.62, $p<0.05$). There was postoperative increase in myofibrilar volume fraction (1.87+0.61 vs. 1.40+0.61, $p<0.01$). There was no difference in post- and preoperative degree of myofibrilar hypertrophy and degenerative changes.
CONCLUSION: One-year postoperatively, PLV had favourable effects on myocardial morphology that parallels

improvement in patient's functional status and LV systolic function.

LYMPHATIC VASCULATURE IN HUMAN HEARTS IN CHILDREN AND ADULTS

1KHOLOVÁ Ivana, 2HÁJKOVÁ Petra, 1HAZES Thierry, 1KASKENPÄÄ Nina, 2ŠTEINER Ivo, 1YLÄ-HERTTUALA Seppo
1Department of Molecular Medicine and Biotechnology, A.I.Virtanen Institute for Molecular Sciences, University of Kuopio, Kuopio, Finland
2Fingerland Department of Pathology, Charles University Hospital, Hradec Králové, Czech Republic

Introduction: Gene therapy of myocardial ischaemia using vascular growth factors has raised the question of the arrangement of lymphatics in normal/diseased human heart. Recent establishment of lymphatic specific antibodies enables to study the presence and relationship of lymphatic vasculature in the human heart.
Purpose of the study: To analyze the presence and arrangement of cardiac lymphatics in different compartments of the heart under normal and pathological conditions both in children and adults.
Materials and methods: Using commercially available LYVE-1 antibody we studied lymphatics in autopsied hearts in children (n = 25, age range 1 months - 18 years) and adults (n = 10).
Results: In ventricles, lymphatic capillaries form an arcade net in epicardium and a ramified net is also present in endocardium. In myocardium lymphatics are only scarcely present. In atria, the lymphatic net is less developed. Under normal conditions, lymphatics are collapsed, but dilatation accompanies cardiac fibrosis.
Conclusions: Lymphatic specific antibodies were found as a useful tool to study cardiac lymphatic system. Other lymphatic markers will also be discussed. The profound knowledge of cardiac lymphatic system has an impact on further studies on therapeutic vascular growth and improvement of new therapeutic approaches.

O-228
LEFT ATRIAL MYOCARDIAL EXTENSION INTO PULMONARY VEINS AND ITS POTENTIAL ROLE IN ATRIAL FIBRILLATION: AN AUTOPSY STUDY OF 100 HEARTS

STEINER Ivo
Department of Pathology
Charles University Faculty of Medicine and University Hospital, Hradec Kralove
Czech Republic

Atrial fibrillation (AF) is the commonest cardiac arrhythmia and particularly prevalent in the older population. Electrophysiological studies have established the critical role of pulmonary veins (PVs) in the initiation of AF, but there is a paucity of data about PV morphology as an arrhythmogenic substrate.
The venous wall comprises a thin endothelium, an irregular media of smooth muscle and fibrous tissue, and a thick fibrous adventitia. Extensions of left atrial myocardium into PVs, known as 'myocardial sleeves', are positioned externally on the adventitial side. These myocardial sleeves are considered responsible for the generation of ectopic beats.
In-depth morphological analysis was undertaken of atrial myocardium in the PVs of 100 human hearts obtained at autopsy from 50 patients with and 50 without AF. This is the largest series on this aspect of cardiac pathology so far studied and the first to examine the presence of senile isolated atrial amyloid (IAA) in the myocardial sleeves.
Cross sections of the complete PV circumference were obtained in 3-4 mm increments from the pulmonary hilum to the veno-atrial junction. A total of 1151 sections was stained with H and E and by the elastica-Van Gieson method and IAA was sought with the Sirius red stain and by immunohistochemical localization of atrial natriuretic peptide.
Of the total 393 PVs examined, myocardial extensions (sleeves) were revealed in 349 veins (88.8 %). In all hearts, at least one PV had a sleeve. The sleeves were longer in the upper veins than in the lower ones, and in the left than in the right. Histologically, in the myocardium of the sleeves, there was focal fibrosis (scarring) in 89 hearts and deposition of IAA in 58. The extent of both of these changes was graded semiquantitatively by visual assessment of the microscopic images. The lesions were more pronounced in patients with AF as compared with patients without this arrhythmia.

HETEROGENOUS IMMUNOHISTOCHEMICAL EXPRESSION OF HER2/NEU IN AXILLARY LYMPH NODE NEGATIVE BREAST CARCINOMAS

ERGUN Dilhan*, PERCÝNEL Sibel*, DÝZBAY SAK Serpil*, KUZU Isinsu*, ELHAN Atilla Halil**, ERDEN Esra*
Departments of Pathology* and Biostatistics**, Ankara University School of Medicine, Ankara, Turkey

Introduction: HER2/neu (c-erbB2) is an important prognostic parameter in node positive breast carcinoma patients and it is also helpful in the selection of therapeutic regimen. Although flourescence in situ hybridization (FISH) has disadvantages, it is safer and more objective in the evaluation of HER2/neu status especially in small biopsy specimens when compared with immunohistochemistry (IHC).
Aims: 1. To determine HER2/neu status by IHC and FISH in axillary lymph node negative breast carcinoma patients, using low density manual tissue microarray and to correlate the results with prognosis.
2. To determine heterogeneity by IHC and FISH within a single tumor using multiple tissue cylinders.
Materials and Methods: Tissue cylinders of 4 mm diameter from paraffin blocks of 85 invasive breast carcinomas were arrayed in 25 recipient paraffin blocks. We analyzed HER2/neu status of 85 carcinoma cases (2-5 cylinders/case) by IHC (DAKO), using streptavidin biotin immunodetection system and 75 carcinoma cases (2 cylinders/case) by FISH (Q-biogene).
Results: Immunohistochemically, 35.2%, 25.9%, 20% and 18.9% cases were scored as 0, +1, +2 and +3 respectively. Seventy-five cases were evaluated by at least two tissue cylinders and immunohistochemical scores of different cylinders (2-5 cylinders/case) of the same tumor were compared. In 52% of the cases, same immunohistochemical score was observed in all tissue cylinders from the same case. In 4 cases, there was important discordance between the scores of cylinders that could affect the treatment regimen of the patients.
Two tissue cylinders/case were used in 44 cases by FISH. Amplification was obtained in 16% of the cases. There was no evidence of HER2/neu gene amplification in the cases scored as 0 and +1 by ICH. Only 1/15 of immunohistochemically +2 tumors was FISH positive. 83.3% of +3 cases was positive by FISH. However, 2 cases that were scored as +3 by IHC, were found to be negative by FISH. There was no discordance between the two cylinders with respect to amplification.
No correlation was detected between the clinicopathological and prognostic parameters and immunohistochemical and amplification findings.

Conclusion: 1. Evaluation of HER2/neu by IHC may be risky that could affect the treatment regimen of the patients in small biopsy specimens because of tumor heterogeneity
2. FISH is safer and more objective in the evaluation of HER2/neu in small biopsies when compared to IHC.

O-230
NATIONAL PROGRAM OF HER2 BREAST CARCINOMA TESTING: EXPERIENCES FROM SLOVAKIA FROM THE PERIOD 2003-2004

PLANK Lukáš, KAJO Karol, JANÁKOVA ¼uba, KVIATKOVSKÁ Zuzana
Department of Pathology, Comenius University, Jessenius Medical Faculty and Faculty Hospital, Martin, Slovak Republic

Introduction: For the selection of an appropriate therapy of the patients with invasive breast carcinoma, the HER2 protein and gene testing of biopsy material seem to be a condition sine qua non. Purpose of the study: To develop a national system of a standardized HER2 testing of all diagnosed breast carcinomas and its quality control. Methods used: Due to a cooperation of the Slovak pathologists and on the basis of accepted regional centralization, a national network system of a breast carcinoma biopsy diagnosis was introduced in Jan. 2003. The network consists of 8 regional and university departments using a standardized diagnostic approach, incl. immunohistochemical HER2 protein testing (HercepTest, DAKOCytomation). In the cases showing 2+ or 3+ protein positivity, the HER2 gene amplification may be confirmed by FISH and/or CISH techniques in the centrum of the project. All the results are reported in standardized biopsy protocols. The quality of HER2 protein testing was controlled by 'a panel of experts' using blind testing cases being examined in the involved centres. The control was followed by an educational joint conference of the departments. Summary of the results: Biopsy examinations of 2260 cases diagnosed in 2003-2004 in 8 centres proved HER2 protein positivity in 523 cases (23.1%): 3+ positivity in 283 (12.5%)and 2+ in 240 (10.6%). After first 9 months, some technical problems and problems of HER2 protein positivity grade interpretation were identified by the quality control and discussed by the educational conference. Finally, all immmunohistochemically 2+ and 3+ positive cases tested by CISH, FISH or by both the techniques showed HER2 gene amplification, in few cases minor differences in the amplification degree were recognized. In addition, the correlations of HER2 status and other parameters (incl. histological grade, ER, PR and lymph node status) seem to be statistically significant. Conclusions reached: The described program brought standardized results representing a good basis for the therapeutical considerations and for further optimization of HER2 testing and studies of all the parameters of the disease. The program continues also in 2005.

O-231
INTRAOPERATORY CYTOLOGICAL IMPRINT AND METASTASIS DETECTION OF MAMMARY CARCINOMA IN SENTINEL LYMPH NODES

VILELA Rafael Sarlo, MOURÃO Mario, OSÓRIO Cynthia A B Toledo. Research and Medical Center Hospital do Cancer, São Paulo, Brazil.

INTRODUCTION: The study of sentinel lymph node (SLN), in the attempt to increase detection of metastasis, was intensified since 2002, when it was included in the TNM staging of breast cancer.
AIM: Relate the effectiveness of detection of mammary carcinoma metastasis (MCM) by cytological imprint (CI).
MATERIALS AND METHODS: We studied 148 SLN from 83 patients. The SLN were identified by vital blue coloring or colloidal albumen injection with radioactive markers. The CI was obtained of the transversal cutting faces of SLN during surgery. Subsequent histological interpretation of slides from paraffin embedded tissue were performed. Negative cases for MCM in paraffined tissues had been submitted to immunohistochemical reaction with cytokeratin AE1/AE3 for diagnostic confirmation or detection of micrometastasis. This reaction was not carried in negative specimens of patients with 1 or more metastatic SLN, previously detected by CI or paraffined tissues.
RESULTS: Malignant epithelial cell plugs measuring 2 mm or less were considered micrometastasis. Of 148 SLN analised in this study, 11 showed positivity in the CI (one micrometastatic lesion measuring 0,76 mm and 10 macrometastasis measuring 3 to 20 mm). Of the 83 patients involved in this work, 18 presented positive SLN. 9 patients presented positive SLN in the CI and had been submitted to axillary lymphadenectomy in the same surgical act. The 9 remaining patients showed positivity in paraffined tissues. 3 of them were submitted to axillary lymphadenectomy in the first surgical act, defined by clinical criteria, 4 of them in a second surgical intervention and the last 2 ones were not submitted to new surgeries until the moment. Of the 137 negative SLN in the CI, 11 became positive in paraffined material (6 micrometastasis measuring 0,32 to 1,75 mm and 5 macrometastasis measuring 2,95 to 8 mm). The immunohistochemical reaction of the negative SLN in CI and paraffined tissue previous analyses showed no positivity in all specimens.
DISCUSSION: CI showed high effectiveness detecting metastasis. This fact helps to prevent second surgeries in patients with metastatic axillary lymph nodes. Moreover, surgical specimens are preserved for accomplishment of immunohistochemical reactions, if necessary.
CONCLUSION: Our results showed the importance of CI in the study of the SLN. Surgical interventions can be avoided, propitiating reduction of costs and morbidity.

O-232
IGF II EXPRESSION IN BREAST CANCER (BC) TISSUES. RELATIONSHIP WITH THE MOST IMPORTANT PREDICTIVE PARAMETERS IN BREAST MALIGNANCY.

E.Giustarini, A.Pinchera, D.Campani*, P.Fierabracci, M. E. Lippman°, C.Giani
Dipartimento di Endocrinologia e Metabolismo, University of Pisa. *Dipartimento di Oncologia, University of Pisa (Pisa, Italy). °V.T. Lombardi Cancer Research Center Georgetown University (Washington DC, USA).

Recent in situ hybridization data showed high content of IGF-II mRNA in the stroma of breast cancer. The aim of this study was to examine the relationship between IGF-II protein expression and several prognostic parameters in 75 ductal infiltratimg carcinoma (DIC) of the breast.
The tissue sections were evaluated for proliferating activity, IGF II protein, ER, PR, p53, P21 expression using immunohistochemical procedures. The amoumt of the stromal proliferation was assessed. The menopausal status. the axillary nodes and the nuclear degree were known . Thirty-five patients (44.3%) were pre-menopausal and 47 (62.6%) had node metastases. Marked stromal proliferation was found in 34 (45.3%) specimens and high nuclear grade in 20 (26.5%). Eighteen tumors (24%) showed no IGF-II immunostaining. In the positive cases, IGF-II was detected in the stroma as well as in the cytoplasm of epithelial cancer cells: marked IGF-II content was found in 12 specimens (16.0%) , slight in 14 (18.7%) and moderate in 31(41.3%). Twenty-four tumors (32.0%) showed high proliferating activity. Both ER and PR were expressed in the nucleus of cancer cells: 49 tumors (65.3%) were ER positive (ER+) and 34 (45.3%) PR positive (PR+). p21 protein was detected in 37

tumors (49.6%) and p53 in 12 (16%). IGF-II protein was not related with menopausal status. lymph-node metastases, nuclear grade, proliferating activity, ER and p53 oncogene. In contrast, IGF-II was strongly correlated with stromal proliferatiom ($p<0.001$), with PR ($p:0.04$) and with p21 oncogene ($p:0.01$). The results of this study demonstrate that in DCI of the breast IGF-II protein is expressed in the epithelium as well as in stroma of the majority of tumors and that it is correlated with stromal amount, with PR and p21 oncogene expression. These findings indicate that in breast cancer, IGF-II expression is connected with the stromal proliferation and with two important regulators of breast cancer growth and differentiation.

Introduction
Ovarian serous borderline tumors (SBTs) are characterized by arborizing edematous papillae lined by stratified epithelial cells resembling those of the fallopian tube, varying degree of nuclear atypia and absence of frank stromal invasion. Originally, these tumors have been classified as 'borderline' because they behaved in a remarkably indolent manner despite pathological features suggesting malignancy. Even with widespread tumor deposits called implants at laparotomy and the presence of lymph node involvement the prognosis of such lesions generally remains excellent.
Tumor biology studies of SBTs are in progress. High-prevalence of B-RAF/K-RAS mutations in SBTs in contrast to serous carcinomas (SCAs) indicates that the mitogenic RAS-RAF-MEK-ERK-MAP-kinase pathway is crucial for the pathogenesis of SBTs.
The purpose of this study was to further unravel the genetic pathways through which SBTs develop with a special focus on explaining the in general benign SBT behavior despite its frequent widespread disease and activated mitogenic pathway.
Materials and Methods
We generated RNA expression profiles of 38 ovarian serous neoplasms including 11 SBTs, 10 low-grade SCAs, and 15 high-grade SCAs. Global Test pathway analysis and Significance Analysis of Micro arrays (SAM) of the expression profiles was performed.
Results
Global Test analysis of the expression profiles showed that in SBTs the mitogenic RAS-RAF-MEK-ERK-MAP kinase pathway and genes involved in downstream protease activation are uncoupled. This was substantiated by the finding that in SBTs the matrix metalloproteinase 9 (MMP-9) mRNA expression value was 2.1-fold decreased compared to SCAs, which was confirmed on a biological level by MMP-9 zymography. SAM analysis enabled us to identify two candidate key-regulator genes involved in uncoupling the mitogenic pathway and downstream genes involved in ECM: (ERK-inhibitor) Dusp 4 and (uPA-inhibitor) Serpina 5. Both genes were consistently down regulated in the SCAs when compared to the SBTs. The mean mRNA Dusp 4 expression for SCAs was 3.1 fold decreased compared to SBTs. The mean Serpina 5 mRNA expression for SCAs was 5.3 fold decreased compared to SBTs. The microarray data on Dusp 4 and Serpina 5 were substantiated for all 38 cases by q-RT-PCR assays.
In conclusion, we propose that the putative tumor suppressor genes Dusp 4 and Serpina 5 provide a major clue to the indolent behavior of the large majority of SBTs.

Introduction: The biological effect of nerve growth factor (NGF) is mediated through the effects of two receptors, p75 (low affinity) and the tyrosine kinase receptor TrkA (high affinity). We previously showed that the activated p-TrkA is a predictor of poor survival in advanced-stage ovarian carcinoma.
Purpose: To analyze p-TrkA and p75 expression in ovarian borderline tumors and FIGO stage I carcinomas and compare it to the expression in advanced-stage (FIGO stage III-IV) tumors.
Methods: Sections from 50 borderline tumors, 50 FIGO stage I invasive ovarian carcinomas and 56 advanced-stage carcinomas were evaluated for expression of the TrkA and p75 using immunohistochemistry.
Results: p-TrkA membrane expression was significantly higher in advanced-stage carcinomas compared to both borderline and stage I tumors ($p<0.001$, Chi-square test), with opposite results for cytoplasmic expression. p75 membrane expression was comparable in the three groups ($p>0.05$).
Conclusions: Expression of biologically active p-TrkA receptor at the cell membrane is upregulated along tumor progression in ovarian carcinoma, while p75 expression remains unaltered. These data provide further proof to the clinical role of p-TrkA in ovarian carcinoma.

O-235
HISTOPATHOLOGICAL AND CLINICAL STUDY OF 70 SEROUS BORDERLINE TUMORS OF OVARY

NOHRA Olivier, KAMBLE Meenal, MISHELLANY Florence, CANIS Michel, DAUPLAT Jacques, PENAULT-LLORCA Frederique
Centre JEAN PERRIN-CLERMONT-FERRAND-FRANCE

Introduction: International community of pathologists is still divided about serous borderline tumor of the ovary (SBOT). In one hand, a minority of pathologists wishes to split SBOT in 2 separates entities. In the other hand, other pathologists wish to retain this category.
Purpose of the study: try to draw prognostic factors of recurrence of SBOT. Assess the effect of histopathological subtype (including micropapillary (MP) and slight MP category), implants, benign associated lesions and treatment on SBOT behavior.

Method used: a retrospective and descriptive clinicopathological study of SBOT was performed on 70 patients (PTS) between 1986 and 2004. Both in academy hospital and in anti cancer center of Clermont-Ferrand, France, PTS were retrieved by using ADICAP computing database. All PTS clinical files were reviewed and added to the database. All histopathological slides were reviewed by two pathologists following 2003 WHO classification of SBOT.
Summary of the results: there were only six consultation cases. The mean follow-up was seven years. FIGO stage : 63 stage I, 4 stage II and 3 stage III. Recurrence rate was 17% and was only relevant to stage I. For 1 PT, the recurrence was an invasive adenocarcinoma. All recurrences occurred after conservative surgery. Seven patients were treated by adjuvant chemotherapy. Mean time from diagnosis to recurrence was 7.1 years. Mean time from recurrence to last news was 3.8 years. No patient died of the disease. The predictive factor suggestive of recurrence was conservative surgery (p=0.025). A trend to recurrence was present when endosalpingiosis was diagnosed (p=0.068), and when SBOT was exophytic (p=0.24). A correlation was found between exophytic tumors and peritoneal implants (p=0.013). There was no correlation between aneuploid tumors and recurrences (p=0.90). We could not draw any conclusion about the MP subtype of SBOT because our series contained only 2 cases. Furthermore, no correlation was found between 21 SBOT with slight MP structure and recurrences.
Conclusion reached: a minimal five years or 10 years follow-up is recommended for patients treated by conservative surgery. Besides, among FIGO stage I, laparoscopic follow up is needed to avoid recurrences.

O-236
PARP, CAF-1 AND DNA PLOIDY AS FACTORS INFLUENCING PROGNOSIS IN OVARIAN GRANULOSA CELL TUMORS.

STAIBANO Stefania°, MIGNOGNA Chiara°, MASCOLO Massimo°, MEZZA Ernesto°, SALVATORE Gaetano^, DI BENEDETTO Maria^, NUGNES Loredana°, NAPPI Carmine*, DE ROSA Gaetano°.
°Department of Biomorphological and Functional Sciences, Pathology Section, ^Department of Medicine and *Department of Obstetrical-Gynaecological and Urological Sciences and Reproductive Science, “Federico II” University, Naples, Italy.

Ovarian granulosa cell tumors (OGCT) are sex-cord stromal tumors that represent 1.5-3% of primary ovarian tumors. OGCT have a low/moderate potential of malignancy. However, metastases have been reported from 7% to 53% of cases in a ten-years interval. Classical clinical-pathological parameters are unable to predict the biological behaviour of these tumors.
Chromatin assembly factor I (CAF-1) is a heterotrimeric protein complex formed of three subunits, p150, p60, and p48, involved in cell replication and DNA repair. P150 interacts directly with proliferating cell nuclear antigen (PCNA) and seems responsible of the DNA-repair process; the p60 subunit has been directly correlated with cell proliferation, and has been proposed as a novel sensible proliferation marker in tumors. Overall, it has been hypothesized for CAF-1 a role as a new prognostic indicator in human cancer.
Poly(ADP-ribose) polymerase 1 (PARP-1) is a zinc finger DNA-binding protein involved in the control of genomic stability, DNA repair and regulation of apoptosis. Its potential role in carcinogenesis has not been evaluated. During apoptosis, PARP is cleaved by caspases. Recent studies reported the over-expression of full-length PARP-1 in a variety of tumors with aggressive phenotype and poor clinical outcome. The aim of this study was to establish if a correlation exists between the immunohistochemical expression of PARP-1 and CAF-1 p60 and p150, DNA-ploidy pattern and clinical behavior of OGCT.
We found that a high expression of the uncleaved form of PARP-1 and CAF-1 p60, aneuploidy and low expression of CAF-1 p150 were statistically correlated with a worse prognosis. On the contrary, a prevalent expression of cleaved PARP-1, low levels of CAF-1 p60, euploidy or aneuploidy associated with an euploid cell population and appreciable levels of CAF-1 p150 were found in tumors with a clinical “indolent” behaviour.
These preliminar results suggest that CAF-1 p60 may have a role as new proliferation marker in OGCT. Moreover, variation of its expression are correlated with altered expression of PARP-1, CAF-1 p150 and DNA ploidy pattern in a subset of tumors, suggesting the potential role of these factors as prognostic markers in OGCT.

O-237
ANALYSIS OF BRAF/ERK AND P16 IN OVARIAN ENDOMETRIOID LESIONS

SCHLOSSHAUER Peter, IDREES Muhammad, NEZHAT Farr, DELIGDISCH Liane, DONG Jianli

Introduction: Either activation of the BRAF/ERK pathway or inactivation of the tumor suppressor p16 have been reported in a variety of neoplasms including ovarian carcinomas.
Purpose of study: To explore the correlation between BRAF/ERK activation and loss of p16 in ovarian endometrioid lesions.
Methods: 22 cases of pelvic (including 19 ovarian) endometriosis, 13 ovarian endometrioid adenofibromas (AF), and six cases of ovarian endometrioid adenocarcinoma (OEC) arising in an AF were analyzed. Formalin fixed, paraffin embedded tissue sections were immunostained for p16, total (t-) and phosphorylated (p-) ERK and evaluated by three pathologists. PCR-RFLP and direct sequencing were used for mutational analysis of BRAF codon 600 on genomic DNA extracted from laser capture microdissected epithelial cells.
Results: Nuclear p16 expression was seen in 11/21 (52%) of endometriosis cases and 8/13 (62%) of adenofibromas, ranging from sporadic to 20% of epithelial cells. Cytoplasmic staining for p16 was present in 17/21 (81%) endometriosis cases and 11/13 (85%) adenofibromas, including all cases with nuclear positivity. One of six (17%) carcinomas showed strong nuclear but no cytoplasmic expression in 10% of the cells from both the AF and OEC components. 4 of 6 (66%) carcinomas had weak cytoplasmic p16 expression in 10-50% of cells of both AF and OEC elements. ERK expression was generally strong in endometriosis, intermediate in AF and variable in OEC. P-ERK tended to be less diffusely present and more concentrated within nuclei than t-ERK. No oncogenic BRAF mutations were identified.
Conclusions: While cytoplasmic p16 expression is present in the majority of all types of ovarian endometrioid lesions, nuclear p16 expression appears to decrease during tumor progression from adenofibromas to carcinomas. One carcinoma case showed nuclear staining only, which may be associated with inactivating p16 mutations. Our results suggest that (1) The co-expression of p-ERK and p16 in benign lesions inhibits ERK-driven cell proliferation; (2) In carcinomas, even weak p-ERK activity may have a proliferative effect in the absence of functioning p16; (3) Oncogenic BRAF mutations appear not to be a pathogenetic factor in ovarian endometrioid tumorigenesis; (4) The BRAF/ERK/p16 profile in ovarian endometrioid neoplasms differs from that in serous tumors, confirming that morphologically distinct ovarian lesions are associated with different molecular pathogenetic mechanisms.

O-238
EXPRESSION ANALYSIS OF BMI1 IN MEDULLOBLASTOMAS AND CORRELATION

TO HISTOLOGICAL AND MOLECULAR CHARACTERISTICS.

RODUNER Sarah, LEUNG Carly, SUTTER Catherine, STORZ Martina, MOCH Holger and MARINO Silvia
Institute of Clinical Pathology, University Hospital, Zürich, Switzerland

Medulloblastomas, highly aggressive embryonic tumors of childhood, originate from deregulated proliferation of cerebellar granule cell progenitors. The Sonic Hedgehog (Shh), Notch and Wnt pathways are well known regulators of the proliferation and differentiation of these progenitor cells during embryonic and postnatal cerebellar development and have been implicated in medulloblastoma pathogenesis. We recently identified BMI1, a member of the Polycomb group of transcription repressors, as a crucial player in controlling proliferation and possibly differentiation of granule progenitor cells in the mouse.
The aim of this study was to determine BMI1 expression in human medulloblastomas and to correlate it to the expression of other key players of the Sonic Hedgehog, Notch and Wnt pathways.
A tissue microarray with 63 human and 24 experimental murine medulloblastomas was constructed to allow high throughput analysis of gene expression by means of immunhistochemistry and mRNA insituhybridization. BMI1 expression was correlated with histologic characteristics of medulloblastomas and with expression of PTCH1, Gli1, Gli2, Hes1, Hes5, bcatenin and CyclinD1.
Overexpression of BMI1 did not correlate with the histological subtype of the tumors or with the degree of neuronal and glial differentiation. The data showed that activation of the Wnt pathway is rare in medulloblastoma and is not associated with BMI1 overexpression. However, overexpression of PTCH1 in all tumors overexpressing BMI1 suggested that activation of the Sonic Hedgehog pathway is involved in the development of the majority of human medulloblastoma.

PROGNOSTIC SIGNIFICANCE OF SURVIVIN EXPRESSION AND APOPTOTIC RATE IN MEDULLOBLASTOMA

Joze Pizem1, Andrej Coer2, Lorna Zadravec-Zaletel3, Mara Popovic1
1 Institute of Pathology, Medical Faculty, Ljubljana, Slovenia
2 Institute for Histology and Embryology, Medical Faculty, Ljubljana, Slovenia
3 Institute of Oncology, Ljubljana, Slovenia

Introduction. To improve the treatment of medulloblastoma, new prognostic markers are needed. Survivin is a member of the inhibitor of apoptosis protein family, which is over-expressed in many human cancers. Apoptosis is a major contributor to cell loss in medulloblastoma, either spontaneous or induced by therapy.
Purpose. Our aim was to analyse survivin expression in medulloblastoma, its association with aberrant activation of the WNT (wingless) pathway and apoptotic rate. We tested prognostic significance of survivin expression and apoptotic rate.
Methods. We immunohistochemically analysed survivin expression and localisation of â-catenin, a downstream mediator of the WNT pathway, in 56 cases of medulloblastoma. We also determined the apoptotic rate using an antibody against cleaved caspase 3, a specific marker of apoptotic cell death.
Results. Survivin was detected in the nuclei of tumour cells in all cases, but the proportion of positive nuclei varied from 0.5 to 31.3%. Survivin expression tended to be higher in medulloblastomas with an aberrant activation of the WNT pathway (nuclear localisation of â-catenin), but did not correlate with histological type, age group or dissemination via cerebrospinal fluid pathways. The apoptotic rate varied considerably among medulloblastomas (0.1-25.9%, median 1.1%). Apoptotic cells were relatively evenly distributed in 38 cases, while in 18 cases, an uneven distribution with foci of an increased number of apoptotic cells and their clustering was observed. Clusters of apoptotic cells were found around necrotic areas, in contrast, necrotic cells were caspase 3 negative. The apoptotic rate was higher in medulloblastomas with CSF dissemination, tended to be higher in desmoplastic medulloblastomas, but there was no association with age group, sex or survivin expression. In the analysis of disease-specific overall survival, the apoptotic rate had no prognostic value, while survivin expression and dissemination status were two independent negative prognostic variables.
Conclusions. Survivin is up-regulated in medulloblastomas. It is a negative prognostic marker and a potential therapeutic target. The variation in apoptotic rate among medulloblastomas is very likely predominantly associated with variations in tumour microenvironment, as supported by apoptotic cell clustering and rimming around necrotic areas. The apoptotic rate in medulloblastoma resection specimens does not seem to be of prognostic value.

O-240

FISHING FOR CYCLIN-D1 IN GLIOMAS. IS THERE ANY CORRELATION BETWEEN HISTOLOGY AND GENETICS?

Kathryn McFadden#, Diana Ionescu#, Kathy Cieply#, Dafna Fernandez Burguera, Alicia Gude+, Ester Anton Valenti*, Clayton Wiley#, Marta E. Couce Matovelle*. # University of Pittsburg Medical Center, Pittsburg, USA.,+ Facultad de Matemáticas, Universidad de Santiago de Compostela, Spain. *Hospital Universitario Son Dureta and Hospital Son Llatzer, Palma de Mallorca, Spain.

Introduction and Purpose of the study: Gliomas frequently show aberrations in genes coding for cell cycle regulatory proteins involved in the control of G1/S phase transition. The D-type cyclins promote cell cycle progression from G1 to S phase by binding to and activating cyclin dependent kinases. Overexpression of cyclin D1 has been shown in many tumors, but there are still some controversies regarding the significance of overexpression of cyclin D1 in gliomas. The purpose of this study was to identify cyclin D1 amplification in gliomas, and to analyze the potential correlation of this amplification with histologic diagnosis, other genetic aberrations, and prognosis.
Methods: The study was approved by the Institutional Review Board of the University of Pittsburgh Medical Center. Thirty five patients with glial tumors were identified in the archives of the University of Pittsburgh Medical Center. Cytogenetic aberrations of the gene locus at chromosome 11q13 (Cyclin D1) were evaluated using fluorescence in situ hybridization (FISH). Mutational genotyping was performed using polymorphic microsatellites situated within or adjacent to known tumor suppressor genes or genomic sites potentially involved in human brain carcinogenesis, at 1p, 9p, 10q, 17p and 19q. PCR amplification products were analyzed for loss of heterozygosity (LOH) by capillary gel electrophoresis using a multi-color fluorescence-based DNA analysis system (ABI Prism 3100 Genetic Analyzer, Applied Biosystems, Foster City, CA).
Results and Conclusions: The analysis showed a statistically significant association between the histologic diagnosis of oligodendrogliomas or oligoastrocitomas and the presence of cyclin-D1 amplification (Fisher exact test, alpha >= 0,001). We also demonstrated that amplification of Cyclin-D1 was more common in low grade gliomas. Although there was no significant correlation between cyclin-D1 amplification and survival in these patients; its presence was more common in those cases with better outcome. The occurrence of other

variables, such as young age at presentation and low grade tumors were strongly linked to survival. Additionally, there is no statistically significant association between Cyclin-D1 amplification and the presence of LOH for any of the genes examined.
In summary, the detection of Cyclin-D1 amplification by FISH in gliomas could represent an important adjuvant technique for diagnosis.

O-241
AUTOMATIC ASSESSMENT OF 1P36-19Q13 STATUS IN GLIOMAS BY INTERPHASE FISH ASSAY

Marc-Antoine Belaud-Rotureau (1, 2), Nelly Meunier (1), Sandrine Eimer (3), Michelle Turmo (1), Pierre Dubus (1, 2), Anne Vital (3), Hugues Loiseau (4), Jean-Philippe Merlio (1, 2)
1: EA 2406 Histology and Molecular Pathology of tumours, University Victor Segalen, Bordeaux
2: Pathology Laboratory, Haut-Lévêque Hospital, CHU Bordeaux
3: Pathology Laboratory, Pellegrin Hospital, CHU Bordeaux
4: Neurosurgery Department, Pellegrin hospital, CHU Bordeaux

The histological classification of glial tumours is not sufficient for the prediction of patient prognosis and therapeutic response to chemotherapy. Genetic analyses have shown that combined 1p36 and 19q13 losses are associated with chemosensitivity and a longer survival in oligodendrogliomas (O). The prognostic significance of such deletions in astrocytomas (A) and mixed oligoastrocytomas (OA) is still a matter of debate. The 1p/19q status can be determined either by fluorescent in situ hybridization (FISH) assay or by molecular testing for loss of heterozygosis (LOH). Frozen samples of 25 patients with a grade II or III glioma (5 O, 14 A, 6 OA) were selected and checked on cryostat sections. Thereafter, touch imprints of this representative frozen material were collected and stored at room temperature until use. The interphase FISH assay was performed using the LSI 1p36/LSI 1q25 - LSI 19q13/19p13 Dual-Colour Probe Sets (Abbott-Vysis) in comparison with previously assayed probes. The automatic assessment of hybridization patterns was performed using the Metafer 4 software (Metasystems) in comparison with visual analysis by two independent observers. Results were interpreted according to the guidelines of the International Society of Pediatric Oncology for studies of peripheral neuroblastic tumours.
The use of both LSI-probes and frozen imprints of control tissues allowed to establish a cut-off threshold at 6% (mean + 3 SD). Frozen tumour imprints provided few truncated nuclei and strong and compact fluorescent signals were observed. The automatic assessment of the hybridization patterns provided similar results to the visual count and was 3 times more rapid. It allowed an objective capture of all the nuclei and a better standardization of the assay.
FISH analysis demonstrated a combined 1p-19q losses for 5 patients (1A, 2O, 2OA). No isolated 1p36 or 19q13 deletion was detected. A complex profile with 1p-19q imbalance was observed in one patient. Despite the low size of our cohort, the clinical follow-up of our patients suggested that 1p-19q losses may be associated with a significant higher time to progression and overall survival in gliomas with an astrocytic component (A and OA). Finally, automated FISH analysis of fresh or frozen tumour imprints allow a powerful assessment of the 1p/19q status in gliomas. The prognostic relevance of such deletions in gliomas with an astrocytic component needs to be confirmed on larger series

Background-Aims: Neuroblastoma is an heterogenous tumor of neural crest origin cells that form the adrenal medulla and sympathetic ganglia. Metallothionein (MT) is a multifunctional protein implicated in cell cycle-apoptosis, drug and radiotherapy resistance and several aspects of carcinogenic evolution. The aim of this study was to examine immunocytochemically the expression of MT in neuroblastoma cells obtained at initial diagnosis by Fine-Needle Aspiration (FNA) from neuroblastoma patients in order to estimate any possible clinical significance.
Materials and Methods: Ultrasound-guided FNA aspirates from 30 patients were obtained and maintained as ThinPrep preparations. Tumor cells were immunostained using the streptavidin-biotin immunoperoxidase technique in order to evaluate MT expression. MT positivity and overexpression (positivity in more than 50% of tumor cells), pattern (cytoplasmic, nuclear, cytoplasmic and nuclear) and intensity of immunostaining (mild, moderate, intense) were correlated with clinicopathological variables as patients' clinical stage, tumor cells' DNA ploidy and proliferative capacity (estimated as S-phase fraction) and MYCN oncogene amplification that is associated with a more aggressive clinical outcome.
Results: All of our cases proved MT positive, while in 24 out of 30 (80%) MT overexpression was also noted. Neither MT positivity nor MT overexpression were correlated with patients' clinical stage, tumor cells' DNA ploidy and proliferative capacity or MYCN oncogene amplification. MT distribution and intensity of staining in neuroblastoma tumor cells were not correlated with any of the clinicopathological variables examined.
Conclusions: MT expression and overexpression are prominent in human neuroblastoma cases examined, nevertheless no correlation was found with clinicopathological parameters important for their outcome. Our data suggest that involvement of MT in diagnosis or management of neuroblastoma patients is uncertain.

THE SIGNIFICANCE OF IMMUNOHISTOCHEMICAL EXPRESSION OF KI-67, P53, P21, AND P16 IN MENINGIOMA TISSUE ARRAYS

TERZI Aysen, BARAK Anil, SOYLEMEZOGLU Figen
Hacettepe University, Faculty of Medicine, Department of Pathology and Biostatistics, Ankara, Turkey

Although histologic grading of meningiomas has prognostic and clinical implications, in some cases it is difficult to predict the outcome of patients. There has been several efforts to evaluate the use of different immunohistochemical markers for predicting meningioma prognosis.

In this study we aimed to determine the prognostic utility of Ki-67, p53, p21, and p16 proteins in meningiomas. We analyzed the immunohistochemical expression of Ki-67, p53, p21, and p16 proteins in 130 meningiomas (64 benign, 39 atypical, and 27 malignant, including 5 papillary and 15 rhabdoid variants). The tumours were graded according to WHO 2000 classification. The study was carried out on tissue arrays.

There was a statistically significant corelation between the expression of Ki-67, p53, p21, p16 and the grade of

meningiomas (p<= 0,001). By ordinal logistic regression; p53 and Ki-67 were significantly associated with grade, and an increase of 1% in labeling index, resulted in an increase in the risk of raising the grade by 2,17 and 1,49, respectively.

Histologic grade, p53 and Ki-67 labeling indeces were strongly associated with decreased recurrence free survival in univariate analysis. In contrast multivariate analysis revealed that only tumour grade is an independent factor for predicting meningioma recurrence.

We conclude that the Ki-67 and p53 labeling indeces are useful additional tools in discriminating atypical from benign or anaplastic meningiomas, especially in histologically borderline cases.

FAMILIAL AORTIC ANEURYSM AND DISSECTION WITH CYSTIC MEDIAL NECROSIS CAUSED BY SMOOTH MUSCLE MYOSIN HEAVY CHAIN (SM-MHC) GENE MUTATION: THE NEW CONCEPT OF CONTRACTILE PROTEIN SMOOTH MUSCLE CELL DISEASE OR VASCULOMYOPATHY

BRUNEVAL Patrick(1), ZHU Limin(1), KHAU VAN KIEN Philippe(2), JEUNEMAITRE Xavier(1). (1) Hopital Europeen Georges Pompidou, Paris and (2) CHU de Dijon. France.

Cystic medial necrosis and vascular smooth muscle cell (VSMC) loss are frequently, but inconstantly, observed in the media from cases of aortic aneurysms and/or dissections. These histologic changes are not specific: although they are sometimes related to a clearly characterized Marfan's syndrome, most frequently they are not associated with any clear-cut disease. For that latter condition, an extracellular matrix (ECM) involvement, not yet characterized, is usually considered as a potential culprit.

Thoracic aorta aneurysm tissues from two male patients of 37 and 56 year-old respectively were obtained during surgical repair and were studied to assess aorta wall structure (H&E and elastic stains) and VSMC phenotype (immunohistochemistry for alpha-smooth muscle actin, h-caldesmon, vimentin, and SM-MHC). These patients belong to a large kindred characterized by an unusual incidence of sudden death, aortic aneurysms or dissections, and patent ductus arteriosus. Genetic analysis performed in this kindred showed a mutation in the MYH11 gene encoding for SM-MHC.

Both thoracic aortas showed similar figures of media thinning, cystic medial necrosis with severe involvement of elastic fibers, and dramatic loss of VSMC. VSMC normally expressed alpha-smooth muscle actin, h-caldesmon, and vimentin. For the expression of SM-MHC, four different commercially available antibodies raised against different epitopes of SM-MHC were tested. VSMC in the patient aortas were negative with an antibody, the one directed against the mutated epitope of SM-MHC, and positive with the three others, whereas VSMC from normal and Marfan's syndrome control aortas were constantly positive for all antibodies.

It can be concluded that: 1) Alterations of a major VSMC contractile protein can lead to an arterial phenotype characterized by aneurysms or dissections with cystic medial necrosis, elastic fiber and VSMV loss, as do Marfan's syndrome, the best characterized ECM genetic disease. Thus, besides ECM protein diseases, VSMC diseases or vasculomyopathies, i.e. contractile protein diseases, should be now considered as a possible mechanism leading to cystic medial necrosis; 2) The variability of reaction of different antibodies against mutated proteins precludes the use of immunohistochemistry for the reliable detection of some genetic defects as those affecting SM-MHC.

DISTINCT PHENOTYPE OF HUMAN ARTERIAL SMOOTH MUSCLE CELLS EXPRESSED PLATELET-ACTIVATING FACTOR RECEPTOR. FUNCTIONAL IMPLICATIONS.

BROCHERIOU Isabelle*°, STENGEL Dominique*, KARABINA Sonia-Athina*, DURAND Hervé*, PICKERING Geoffrey#, CAPRON Frederique*° and NINIO Ewa*.

*INSERM U525, Paris, France; Institut Fédératif 14, Paris, France; Université Pierre et Marie Curie and Faculté de Médecine Pitié-Salpêtrière, Paris, France; °Service d'Anatomie-pathologie, Hôpital Pitié-Salpêtrière, Paris, France; # Robarts Research Institute (Vascular Biology Group), London Health Sciences Centre, Departments of Medicine, Biochemistry, Medical Biophysics, University of Western Ontario, London, Canada.

Objective- Platelet-activating factor (PAF) and its structural analogues formed upon low density protein oxidation are involved in all stages of atherosclerotic plaque formation and may signal through a specific G-protein coupled receptor, PAF-receptor (PAF-R) found in human macrophages and in certain smooth muscle cells (SMCs) in the media, but rarely in the intima of human plaques. The diversity of SMC phenotypes in normal arteries has been described and led to the suggestion that distinct subsets of SMC might participate in the lesion development.

Methods and results- Circulating SMC progenitors and two phenotypically distinct clones of proliferative, epithelioid phenotype vs contractile, spindle-shaped SMCs from the media of a single fragment of adult internal thoracic artery were studied for the presence of PAF-receptor (PAF-R). Only the subset of SMCs of spindle-shaped of synthetic phenotype expressed both mRNA and PAF-R protein and in the functional test only these cells migrated in the presence of PAF. Two unrelated, specific PAF-R antagonists inhibited PAF-induced migration, but did not modify the migration initiated by PDGF.

Conclusions- The observation that the arterial spindle-shaped SMCs of synthetic phenotype express PAF-R opens new avenues concerning the migration of these cells from the media into the intima and atherosclerotic plaques formation.

O-246
ANALYSIS OF INTERCALATED DISC REMODELING IN EXPLANTED HEARTS FROM CHILDREN WITH CONGENITAL HEART DISEASES OR DILATED CARDIOMYOPATHY

P. Francalanci, A. Tessa°, F.M. Santorelli°, F. Diomedi Camassei, F. Parisi^, R. Devito, R. Boldrini, F. Callea. Dep. of Pathology, ° Molecular Medicine and ^Dep. of Cardiology and Cardiac Surgery, Bambino Gesù Children's Hospital, Rome, Italy

The cadherin family of trans-membrane proteins mediates mechanical junctions at the level of intercalated discs (ID) where the ends of thin and intermediate filaments are anchored to polar sarcolemma via adherents junctions (AJ) and desmosomes, respectively. In the AJ, the barb ends of actin of terminal sarcomeres are believed to link N-cadherin through binding to alfa-actinin or vinculin, which joins a-catenin, which links beta- or gamma-catenin.

Previous study in hamster and human hypertrophic cardiomyopathy demonstrated a remarkable accumulation of N-cadherin and beta-catenin in disarrayed ID and that the alteration of this pathway could play a key role in modulation of genes directly related to the onset of the hypertrophic phenotype.

Purpose: Aim of this study is to evaluate whether in end-stage cardiac hypertrophy due to dilated cardiomyopathy (DCM) or congenital heart disease (CHD) the ID remodeling is associated with abnormal expression of cadherin/catenin complex in AJ as well as of connexin 43 (Cx43) in gap junction (GJ).
Methods: Ventricular samples of explanted hearts obtained from 11 children (aged 1-15 years) with DCM and from 7 children (aged 9-24 years) with CHD were studied by light microscopy, immunohistochemistry and Western blot analysis.
Results: Both DCM and CHD displayed hypertrophic and disarrayed myocells with disorganized morphology of the IDs. N-cadherin expression was nearly normal in both DCM and CHD. In disarrayed ID, beta-catenin immunostaining was increased and fragmented in all samples, while gamma-catenin stain was almost regular in DCM and faint in CHD. Cx43 expression was abnormal in all, showing a distribution over the entire surface of the myocytes, consistent with neonatal distribution. By Western blotting analysis, beta-catenin was significantly increased in 12 samples, 7 DCM (+53%) and 5 CHD (+31%). Contrariwise, gamma-catenin expression was unaffected in DCM, whereas it was reduced (-25%) in 4/7 patient with CHD. N-cadherin and Cx43 were normal.
Conclusions: This study suggests that beta-catenin deposits occur at the AJ in end-stage hypertrophic ventricular myocytes, regardless of the primitive heart pathology, either DCM or CHD. This seems not associated with simultaneous down-regulation of gamma-catenin, at least in DMC, or with modification of N-cadherin. Remodeling of adhesions junctions does not lead to a quantitative changes of Cx43, although the expression of this protein can be abnormal.

O-247
EXPRESSION OF PROINFLAMMATORY CYTOKINE AND CHEMOKINE IN LYSOPHOSPHATIDIC ACID-TREATED VASCULAR SMOOTH MUSCLE CELLS: A ROLE OF MITOGEN-STIMULATED SMOOTH MUSCLE CELLS IN THE VASCULAR INFLAMMATORY SYSTEM.

KANEYUKI Utako1,2, KATO Seiya2, UEDA Seiji1, YAMAGISHI sho-ichi3, INAGAKI Yosuke3, YOSHIMURA Junko1,2, IMAIZUMI Tsutomu3, OKUDA Seiya1. Departments of 1Nephrology, 2Pathology, and 3Internal Medicine III and the Cardiovascular Institute, Kurume University School of Medicine, Kurume, Japan.

Atherosclerosis is recognized as a chronic inflammatory disease, however functional involvement of each vascular constituent has not been clearly understood. Vascular smooth muscle cells (SMC) are major constituent of the vascular structure. At the site of vascular insult, mitogens promote proliferative (myofibroblastic) phenotype of SMC, resulting in the neointimal hyperplasia. Here we tested the hypothesis that mitogen-stimulated SMC may contribute to the vascular inflammatory system other than proliferative response. Lysophosphatidic acid (LPA), a platelet-activating component of mildly oxidized low-density lipoprotein, has been known to act as a SMC mitogen via the activation of intracellular protein kinases. Cultured human aortic SMC are stimulated with 10-100uM of LPA in the serum-free condition. NADPH-driven reactive oxygen species (ROS) generation and proinflammatory gene expressions were examined. HMG-CoA reductase inhibitor, Pitavastain, was also tested for the inhibition of LPA-induced inflammatory response. LPA-treated SMC showed up-regulation of mRNA levels of p22phox and gp91phox, membrane components of NADPH oxidase, and intracellular ROS generation, which were completely inhibited by diphenylene iodonium (DPI), an inhibitor of NADPH oxidase, as well as by Pitavastatin. LPA also stimulated the expression of interleukin-18 and monocyte chemoattractant protein-1 genes in SMC, which were significantly prevented by DPI, N-acethylcystein, an antioxidant, and Pitavastatin. Our data suggested that mitogen-stimulated SMC potentially produce proinflammatory cytokine and chemokine via the up-regulation of intracellular ROS. Proliferating SMC may involve in the vascular inflammatory system at least two ways: One is as myofibroblastic proliferating cells for the vascular remodeling, and the other is as inflammatory cells directly producing inflammatory mediators. The lipid-lowering agent, Pitavastatin, would exert the atheroprotective property in mitogen-stimulated SMC with the anti-oxidative and anti-inflammatory effects.

O-248
STRUCTURAL-FUNCTIONAL STATUS, NUCLEAR PLOIDY IN INTERVENTRICULAR SEPTUM CARDIOMYOCYTES FROM CHILDREN AND ADULTS WITH OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY.

2- Faculty Therapy department, State Pavlov Medical University, St.Petersburg, Russia
3)Bakulev Reseach Center of Cardiovascular Surgery, Moscow, Russia
4)Cytology Research Institute, St.Petersburg, Russia

Aim: to study structural-functional status and nuclei ploidy of adult and children cardiomyocytes from patients with obstructive hypertrophic cardiomyopathy (OHCMP).
Material and methods: material from 61 patients with OHCMP was included into the study. Among those, 19 were below 21 y.o. and named as "children". The rest 41 patients were over 21 y.o. and named as "adults". The material was obtained upon the surgical interventions as well as upon express autopsies from the right side of the interventricular septum. The samples were stained with hematoxylin-eosin technique and by the method of nucleolar organizer regions silver staining. Histological index was estimated according to Noorden (1971). Nuclear area was calculated by morphometry. DNA content was estimated by Felgen method on dissociated cardiomyocyte nuclei and assessed by cytophotometry. One hundred tissue lymphocytes were used as a control for diploidal DNA content.
Clinical and echocardiographic data were obtained from case histories.
Results: There was no statistical difference between children and adults in LVMI and IVS thickness in the outflow tract. Histological index in children varied from 80 to 100 % with a mean 94,2¦ 2,3 and was significantly higher, then in adults (71,1%¦ 1,4 p<0,05). There was no significant difference in nuclear area between children and adult group (94,8¦ 2,6 and 93¦ 2, p>0,05), however, severe nuclear polymorphism was noticed in children group. In this group the percentage of "huge" cardiomyocyte nuclei with area >200,0 was significantly higher, then in adult group (21,2% 1,5 and 11,5%¦ 1,6, p<0.000). The percentage of micronuclei (area <30%od mean cardiomyocyte area) was significantly higher in children group as well (10,2%¦ 1,7 and 5,4%¦ 1 p<0,017). There was significant increase in pared nuclei content (11,6%¦ 0,1 and 7,5%¦ 0,6 p<0,017) and a tendency to the multiple nuclei cardiomyocytes (8,4%¦ 1,6 and 4%¦ 0,4) in children group. The average DNA content ! was higher in

children group a (15,2¦ 2,2 and 9,9 ¦ 0,7 correspondingly, p<0,017).
Conclusion: the children group with OHCMP is characterized by highest degree of myocardial hypertrophy, accompanied by increase nuclear polymorphism and nuclear area. The significant increase of pared nuclei, cardiomyocytes with multiple nuclei (caryokinesis without cytokinesis), the percentage of hyperploidy and average DNA content in cardiomyocytes characterizes the grow potential of hypertrophic and hyperplasia processes in children.

THE ROLE OF ELECTRON MICROSCOPY IN THE DIAGNOSIS OF SYSTEMIC VASCULITIS IN RHEUMATOID ARTHRITIS

Miklós Bély1, Pál Kapp1, Tamás Szentjóbi Szabó1, and Ágnes Apáthy2
1Department of Pathology,
Policlinic of the Hospitaller Brothers of St.John of God, Budapest, Hungary
2Department of Rheumatology,
National Institute of Rheumatology and Physiotherapy, Budapest, Hungary

Introduction
Systemic vasculitis is the most likely lethal complication; moreover it is missed clinically with a high probability in rheumatoid arthritis.
The high prevalence of vasculitis in the peripheral nerves and skeletal muscles makes biopsy of the sural nerve (with surrounding muscles) a good target for the confirmation of suspected systemic vasculitis (with, or without visible involvement of the skin).
The aim of this study was to demonstrate the ultrastructural changes in sural nerves, and to demonstrate the value of electron microscopic examination in the diagnosis of systemic vasculitis.
Patients and Methods
Biopsy samples of 25 sural nerves, and 31 samples of skeletal muscle (surrounding the nerve) were studied from 36 autopsy patients who had rheumatoid arthritis with histologically confirmed systemic vasculitis.
The tissue samples were examined by light and electron microscopic methods.
Results
Vasculitis of nutrient vessels was confirmed by light microscopy in 13 (18.7%, 52 rel %) of 25 sural nerves, and in 17 (19.7%, 54.8 rel %) of 31 samples of skeletal muscle.
Ultrastructural changes of neurons were present in all 25 tissue samples, with or without visible vasculitis by light microscopy.
The changes included loss of myelinated fibers, thinning of myelin sheeths, demyelization, degeneration of Schwann cells and intracytoplasmic onion bulbs (indicating active demyelization), furthermore axonal degeneration. The myelinated nerve fibre density decreased, and axonal clusters developed.
The ultrastructural changes were accompanied by endo- and perineural increase of collagen fibrils.
The ultrastructural alterations were present with different degrees of severity and in different stages of its development.
Discussion
Vasculitis involves a segment, or a sector of the vessel walls. Sporadic vasculitis (because of the lower density of inflammatory segments in the vessel walls) may be missed by traditional light microscopic examination of sural nerve biopsies.
Vasculitis of the nutrient vessels around the neurons is accompanied by secondary (longitudinal) changes [degeneration, demyelization, or endo- and perineural fibrosis].
Early stages or mild forms of neural degenerative processes (ultra- structural changes) may be detected only by electron microscopy.
The ultrastructural changes of neurons may indirectly indicate the presence of vasculitis in case the inflamed segments are not in the plane of sectioning

(2) IGF, CNRS UMR5203, INSERM U661
(3) Epileptology Unit, CHU Gui de Chauliac
Montpellier FRANCE

We recently described an increased number of microvessels in chronic epileptic foci, particularly in case of severe lesions and neuro-glial reorganization.
Here we attempted to evidence an angiogenesis in chronic foci of adult patients with intractable temporal lobe epilepsy (TLE). To approach the mechanisms of this neo-vascularization, we looked for the kinetic of angiogenic processes in murine models of TLE.
Human subjects: hippocampi were obtained in 30 patients who underwent surgery for intractable TLE (with various etiologies and different degrees of neuronal loss) and in 4 non epileptic, autopsied patients (NE).
Animal model: 20 rats underwent status epilepticus after lithium-pilocarpine injection and developed a chronic limbic epilepsy.
Hippocampi were used for immunohistochemistry and western blotting to check the expression of angiogenic factors or their receptors and markers of immature endothelial cells.
:
In human, microvessels were more numerous in the hippocampus of TLE patients than in NE hippocampi. Particularly in case of hippocampal sclerosis, neo-microvessels were positive for various markers of immature endothelial cells in injured areas and in the dispersed dentate granular layer. In most patients, VEGF was strongly expressed by pyramidal and granular neurons and also by astrocytes. In animals, angiogenic factors were rapidly detected in hippocampal neurons and astrocytes after experimental seizures.
Angiogenic processes appear to be concomitant to the neuro-glial reorganization which occurs in lesional epilepsy of adult patients. Even if VEGF expression reflects a protective mechanism triggered by the seizure itself, the neo-vascularization could participate in the pathological remodeling of the chronic focus (gliosis, inflammation, blood brain barrier leakage and drug resistance).

Biomedical Research and Wayne State University, Detroit, MI, USA

Introduction: A relatively new method of data acquisition and image processing called susceptibility weighted imaging (SWI), that exploits susceptibility differences between signals from various tissue types, can provide more accurate information in the early diagnosis of vascular lesions, brain trauma, stroke, and tumors. Unlike conventional neuroimaging, it also has the unique capability of detecting microscopic hemorrhages, mineralization, and alterations in iron metabolism in vivo, and is a potentially useful research tool in cerebrovascular and neurodegenerative disease. Purpose of study: Till recently, very little validation of SWI has occurred from a neuropathologic perspective. An earlier retrospective study from the group had indicated that SWI is highly sensitive in detecting microscopic hemorrhages in human acute cerebral infarcts, and our group is actively involved in evaluating this technique in animal models. Methods:In a pilot experiment (approved by the Institutional Animal Care and Use Committee), four spontaneous hypertensive adult rats underwent monofilament middle cerebral artery (MCA) occlusion for 90 minutes using standard methods for inducing focal cerebral ischemia in rodents.. The monofilament was withdrawn and human recombinant tPA was administered intravenously for 30 minutes. The rats underwent neuroimaging in a Micro CT scanner, and MR imaging including spin-echo T1, T2, diffusion-weighted imaging, and SWI scans at 24, 48 and 72 hours. At 72 hours, the rats were sacrificed, and brain was examined with H&E and Prussian Blue stained sections. Results and Discussion: All rats showed infarcts in the MCA territory, of which two showed associated hemorrhage. The extent of hemorrhage seen on SWI was larger and more accurate than conventional imaging, and was confirmed by histopathology. More animals are under study to further explore the sensitivity of this technique, and additional findings will be presented. Other ongoing projects, including a rodent model for validation of SWI as a means of studying brain iron metabolism will also be discussed.

SPORADIC CREUTZFELDT-JAKOB DISEASE. CLINICAL, PATHOLOGICAL AND MOLECULAR STUDY OF 8 CASES FROM THE GALICIAN COMMUNITY.

RIVAS Eloy*, TEIJEIRA Susana*, BARROS Francisco**, SAN MILLAN Beatriz*, NAVARRO Carmen*
* Department of Pathology and Neuropathology, Hospital Meixoeiro, Vigo (Spain)
** Molecular Medicine Unit, Hospital Clinico Universitario, Santiago de Compostela (Spain)

INTRODUCTION: Sporadic Creutzfeldt-Jakob disease (sCJD) is the more common form of human transmissible spongiform encephalopathies (TSE) that may present as sporadic, genetic or infectious diseases. TSE are fatal neurodegenerative disorders caused by prions, pathological isoforms (PrPsc) of the normal cellular prion protein (PrPc). Accumulation of these protease-resistent isoforms of PrP in neural cells leads to vacuolization and cellular death. Sporadic CJD typically presents as a rapidly progressive dementia often associated with cerebellar ataxia, myoclonus, periodic sharp-wave encephalographic (EEG) activity and death within the first 6 months. Different clinical profiles can be correlated with the type of PrPsc glycoform, based on Western blot migration patterns, and the genotype at codon 129 of the prion protein gene(PRNP). We present clinical, pathological and molecular data from 8 cases of sCJD.
MATERIAL AND METHODS: From 2002 to 2004, brains from 8 patients fulfilling clinical criteria of probable CJD were studied in our Centre. Neuropathological evaluation was carried out using standard histological stains and immunohistochemistry with GFAP, b-amyloid and PrP antibodies. Western blot analysis was performed, allowing PrP differentiation of type 1 (21 kDa) and type 2 (19 kDa) based on electrophoretic mobility. Genomic DNA was extracted from brain tissue and used to determine the genotype at codon 129.
RESULTS: All cases were sporadic. Ataxia was the most frequent clinical presentation (5/8). Myoclonus was present in all cases, characteristic EEG in 5/8, positive 14-3-3 protein in CSF in 7/7, and typical MRI findings in 3/8. All but one died before 6 months after the onset. Cortical spongiosis was severe in 5/8 cases. All cases had moderate-severe lesions in basal ganglia and cerebellum. In 5 out of 7 cases, type 1 PrP isoform was detected and the other two corresponded to type 2.
CONCLUSIONS:This study confirms the phenotypic variability in sCJD and predominance of the PrP type 1 isoform. Moreover, some correlations could be established: the two cases with PrP type 2 showed atypical EEG, predominant subcortical and cerebellar involvement, plaque-like pattern of PrP deposit and a longer disease-duration in one of the two cases. The use of Western blot analysis in Neuropathology laboratory is a useful diagnostic tool in cases of TSE, allowing a rapid confirmation of the diagnosis, the differentiation of PrP isoforms and the type of prion disease.

USA;
2Department of Carcinogenesis, The University of Texas M.D. Anderson Cancer Center Science Park-Research Division, Smithville, Texas, USA

Neuronal degeneration in mice infected with the retrovirus MoMuLV-ts1 is a model for human immunodeficiency virus (HIV)-induced neurodegeneration in humans. The precursor of the neurotrophin nerve growth factor (NGF), proNGF, has been suggested to be a death-inducing ligand for the neurotrophin receptor p75 (p75NGFR) which is also induced by various injuries to the nervous system. We investigated whether expression of p75NGFR and proNGF are increased in the brainstem tissues of ts1-infected mice. Levels of proNGF and p75NGFR mRNAs and proteins were increased in the brainstem tissues of ts1-infected mice compared with controls. We demonstrate that proNGF is the predominant form of NGF in the brainstem tissues of ts1-infected mice, whereas little or no mature NGF is detected. In brainstem sections, we found that astrocytes surrounding spongiform lesions contain increased amounts of immunoreactive NGF, but little in microglial cells, and that immunoreactive p75NGFR was located in the neurons undergoing degenerative changes. Together, these data suggest that ts1 infection-mediated neuronal degeneration in mice may result from the proNGF/p75NGFR signaling pathway.

Background: Cerebral amyloid angiopathy CAA is defined by beta-amyloid peptide (Ab) depositions in cerebral vessels and is associated with Alzheimer disease (AD). In addition CAA has been shown recently to be an independent risk factor for cognitive decline. The relationship between sporadic CAA and AD is poorly understood and the origin of Ab in CAA remains unclear. The aim of our study was to further investigate the relationship between CAA and AD.
Material and methods: 113 autopsy brains (61.1% female, 55.8% clinically demented, age range 54-102, mean 83.5 ±9.9 years) underwent standardized neuropathological assessment of AD using CERAD, Braak stages, and NIA-RI Criteria. CAA was evaluated in frontal, frontobasal, hippocampal and occipital regions. For detection of Ab in cerebral vessels sections were immunostained with commercially available Ab antibody (4G8, Signet). The severity of Ab depositions in vessels was assessed semiquantitatively for each region separately. In 53 cases APOE genotype was evaluated using real time PCR.
Results: CAA was present in 77 cases (68.1%), with the occipital region being affected significantly more often and more severe than other regions (P<0.01). The overall prevalence of CAA was significantly higher in cases with high grade AD pathology compared to cases with no to medium grade AD pathology (P<0.01). 23.5% of brains without any AD pathology revealed CAA, while 24% with AD pathology did show no CAA. The severity of CAA significantly increased with increasing AD pathology, in the occipital region significantly stronger than in all other regions, respectively (P<0.01). Univariate ANOVA to test the combined influence of CAA, CERAD, Braak stages, NIA-RI-Crit., age, and APOE e4 on clinical dementia, revealed that only each CAA (P<0.05), CERAD, Braak stages, and NIA-RI-Crit. (P<0.01) remained significant. When controlling the positive correlation between CAA and clinical dementia seperately for each CERAD, Braak stages, and NIA-RI-Criteria, however no significance was observed.
Discussion: Our results do not unequivocally support the concept of CAA being an independent risk factor for cognitive decline but suggest a strong association of AD with CAA. There are, however, cases with severe CAA lacking AD pathology and vice versa. We conclude that CAA might be an entity of its own, which is aggravated by AD pathology and that evaluation of the occipital region is mandatory in the diagnosis of CAA.

DEVELOPMENTAL EXPRESSION OF CELLULAR PRION PROTEIN (PRPC) IN HUMAN CEREBRAL CORTEX

ADLE-BIASSETTE Homa (1,2), VERNEY Catherine (2), PEOCH Katell (3), DAUGE Marie-Christine (1), RAZAVI Féreshté (4), CHOUDAT Laurence (5), GRESSENS Pierre (2), BUDKA Herbert (6), HENIN Dominique (1,2)
1- Service d'Anatomie Pathologie, Hôpital Bichat-Claude Bernard, 75877 Paris France, 2- INSERM E9935, Hôpital Robert-Debré, 75019 Paris, France, 3- Service de Biochimie, Hôpital Lariboisière, Paris 75018, France, 4- Service d'Histologie Embryologie, Hôpital Necker-Enfants Malades, 75015 Paris, France, 5- Service d'Anatomie Pathologie, Hôpital Robert Ballanger, 93602 Aulnay sous bois Cedex, France, 6- Institute of Neurology, Medical University Vienna, AKH 4J, POB 48, A-1097, Austria

The cellular prion protein (PrPc) is an ubiquitous copper-binding membrane sialoglycoprotein. Its posttranslational modifications in prion diseases leads to the accumulation of the protease resistant conformer (PrPsc). The functions of PrPc are unknown. In adult central nervous system, PrPc is mainly a synaptic protein. We investigated the developmental expression of PrPc in the cerebral cortex of fetuses in whom was searched the polymorphism of codon 129 of PrPc gene. Five anti PrPc monoclonal antibodies (12F10, KG9, 6H4, 3F4 and BG4) were used for immunohistochemistry. Double immunofluorescence and confocal microscopy were performed using GFAP, Iba-1, MAP2, doublecortin, calretinin, synaptophysin, synapsin and GAP-43. PrPc-immunoreactivity (IR) followed the rostrocaudal gradient of development. At 11-15 gestational week (GW) PrPc IR was observed in elongating fiber tracts and in the molecular layer. Between 17 and 22 GW, in addition to growing fibers tracts, some positive neurons were detected in the subplate and in the cortical anlage. Microglial cells were also immunoreactive. From 24 WG until the perinatal period PrPc immunoreactivity was still strongly expressed in fiber tracts in the subplate. In parallel, PrPc labelling of synaptic profile increased until the perinatal period. In contrast in adults, PrPc IR was very weakly detected in the white matter and extensively present in the neuropil of the gray matter. At all ages, choroid plexus was strongly immunoreactive but ependymal staining was absent in adults. In some pathological cases, over expression of PrPc was observed in vessels, perivascular (micro)glial cells, in some neurons and axonal bundles. Our results show that during development PrPc is predominantly expressed in axonal growth cones and in synapses along synaptogenesis. It is also expressed in various nonneuronal cells. Several presumed functions of PrPc are plausible.

THE PATHOLOGICAL RESPONSE TO NEOADJUVANT TAMOXIFEN THERAPY IS ASSOCIATED WITH ERB EXPRESSION IN INVASIVE BREAST CARCINOMA

Christophe Rosty, Jerome Verine, Fabien Reyal, Patricia de Cremoux, Brigitte Sigal-Zafrani, Marick Lae, Paul Freneaux, Veronique Girre, Remy Salmon, Xavier Sastre-Garau, Anne Vincent-Salomon
Institut Curie, 26 rue d¡¯Ulm, 75005 Paris

Introduction and purpose of the study: Neoadjuvant endocrine therapy is a therapeutic option for post-menopausal women with advanced stage hormone receptor-positive invasive breast carcinoma. Estrogen receptor b (ERb) is an isoform of ER which was shown to be associated with the response to adjuvant tamoxifen therapy. To determine if ERb expression may predict response to neoadjuvant endocrine therapy, we conducted a retrospective study on 55 women treated with tamoxifen before breast surgery.
Methods: Selected patients were diagnosed with invasive breast carcinoma on needle core biopsy with significant expression of ERa, and treatment by tamoxifen during at least 3 months, followed by surgical excision of the residual tumor. Pathological response was evaluated in the surgical tumor specimen by decrease in the mitotic index (MI), using the deltaMI ratio defined as (MI before therapy ¨C MI after therapy) divided by MI before therapy. A tumor with a deltaMI value of 50% or greater was considered as responsive to therapy. Immunohistochemistry for ERb was performed using the PPG5/10 antibody (Serotec). Cases with ¡Ý10% nuclear immunostaining were considered positive.
Results: All 55 selected patients were post-menopausal women with a mean age of 70.6 ¡À 6.5 years (range: 52-83). Initial diagnosis was invasive ductal carcinoma in all cases (grade I: 36%; grade II: 53%; grade III: 11%). A clinical partial response was present in 37 patients (67%) while the remaining 25 patients had no response (4 patients, 7%) or stable disease (14 patients, 26%). deltaMI was ¡Ý50% for 21 tumors (41%), which were considered as pathological

responsive to tamoxifen. We did not observe any correlation between PR expression and the pathological response. ERb was expressed in all invasive breast carcinomas with 1% to 80% stained nuclei. The percentage of stained tumor cells was positively associated with the deltaMI ratio (r= 0.36, P = 0.01). With a 50% cut-off to define tamoxifen-responsive tumors, we found that 17/32 (53%) of ERb-positive breast carcinomas had a pathological response to therapy whereas only 4/19 (21%) ERb-negative breast carcinomas responded (P = 0.04).
Conclusion: High expression of ERb in invasive breast carcinoma is associated with a better pathological response to neoadjuvant tamoxifen therapy in post-menopausal women. This result suggests that the determination of ERb expression may be used to select patients who may benefit from neoadjuvant tamoxifen therapy.

ALLELIC IMBALANCES IN LOCALLY ADVANCED BREAST CANCERS BEFORE AND AFTER HIGH DOSE ANTHRACYCLIN / CYCLOPHOSPHAMIDE CHEMOTHERAPY

VARNA Mariana (1), SOLIMAN Hany (2), FEUGEAS Jean-Paul (2), TURPIN Elisabeth (2), ESPIE Marc (3), CHAPELIN Dominique (2), MISSET Jean-Louis (3), JANIN Anne (1), de THE Hugues (2), BERTHEAU Philippe (1)
(1) INSERM U728 and Department of Pathology, (2) Department of Biochemistry, (3) Department of Oncology, Hosp St-Louis, Paris, France

Locally advanced breast cancers (LABC) are best treated by first line chemotherapy. We previously showed in non inflammatory LABC that complete pathologic responses to high dose epirubicin / cyclophosphamide chemotherapy were observed in 60% tumours with TP53 mutations, while no complete response was observed among tumours without TP53 mutations. We hypothesized that the absence of response in tumours without TP53 mutations could be linked to epirubicin induced p53 dependant cell cycle arrest and subsequent resistance to cyclophosphamide while tumours with TP53 mutations would accumulate genetic alterations leading either to tumour progression or to complete tumour response through mitotic catastrophes.
In order to explore genetic alterations in these tumours, we analyzed allelic profiles in 32 LABC with or without TP53 mutations (10 and 22 cases, respectively), biopsied before and mastectomized after 6 courses of high dose epirubicin / cyclophosphamide, and having not responded to that treatment. After laser tissue microdissection, PCR were performed for 10 microsatellites located on chromosomes 3, 5, 7, 8, 11, 13, 16 and 17. Allelic profiles before and after chemotherapy were compared, looking for improvement or worsening of imbalances as well as new alleles. For each tumour, we analyzed the global changes of the ten allelic profiles after chemotherapy defining four categories : better, worse (including new alleles), unchanged and combined better/worse.
Our results showed 7 tumours with a “better” profile and 10 with a “worse” profile, distributed in similar proportions in both TP53 mutated and not mutated tumours. 15 tumours had “unchanged” or “combined better/worse” profiles. Clinical data and follow-up did not show significant differences between groups.
In conclusion, important changes in allelic profiles can be observed after high dose chemotherapy in LABC, with both improved and worsened profiles. Tumours showing complete disappearance of allelic imbalances after chemotherapy raise questions about the mechanisms involved in tumour cells targeting by treatments. Unexpectedly, p53 did not prove to be an important regulator of genetic changes in these settings.

O-258
PROGNOSTIC SIGNIFICANCE OF OCCULT AXILLARY LYMPH NODE METASTASIS IN EARLY BREAST CARCINOMA

FRKOVIC GRAZIO Snjezana, SUSNIK Barbara*, BRACKO Matej
Institute of Oncology Ljubljana, Slovenia
*Medical College of Wisconsin, Milwaukee, USA

Background and aims: The most relevant factor for the assessment of risk in operable breast cancer in general remains the axillary nodal status and the number of lymph nodes involved. Our study was undertaken to assess the prognostic value of occult metastases in axillary lymph nodes in patients in whom metastases were not seen on initial assessment of H&E sections and to evaluate their relative importance with regard to traditional prognostic factors and some immunohistochemical markers.
Methods: Lymph nodes from 222 patients with breast carcinoma that were originally categorized as T1N0M0 were reassessed with 3 additional H&E levels and IHC for cytokeratin. Histologic features of the primary tumour (size, type and grade, lymphovascular invasion and mitotic index) and staining for ER, PR, CEA, HER-2, p53, bcl-2 and MIB-1 were also evaluated. The results were correlated with cancer specific (CSS) and metastasis-free (MFS) survival in univariate and multivariate analysis.
Results: During the follow up (median, 15.7 years), there were 68 occurrences of distant metastasis and 53 cancer related deaths. Lymph node tumour deposits were found in 40 (18%) out of 222 cases and were classified as macrometastasis (>2 mm) in 5 cases, as micrometastasis (>0.2 mm and up to 2 mm) in 17 cases, and as individual cells or clusters (ITC, up to 0.2 mm) in 18 cases; 22 cases (10%) were thus upstaged to T1N1M0 category. Whereas the presence of ITC was of no prognostic significance, CSS and MFS were significantly worse in the group of patients with upstaged disease (P=0.02 for CSS and P=0.002 for MFS).
Apart from upstaged nodal status, mitotic index, vascular invasion, HER-2 and CEA expression were also significant predictors of MFS and CSS in univariate analysis. In multivariate analysis of the whole group, upstaged nodal status, HER-2, lymphovascular invasion and mitotic index were significant independent prognostic factors for both MFS and CSS, whereas histologic type influenced only CSS and expression of CEA only MFS. The presence of ITC was of no prognostic significance in the 'new' T1N0M0 group of patients.
Conclusions: In our study the presence of occult macro- and micrometastases but not ITC in axillary lymph nodes proved to be a significant independent prognostic factor for CSS and MFS in the group of patients with breast carcinomas that were initially regarded as T1N0M0.

O-259
C-MYC EXPRESSION IN BREAST LESIONS ASSOCIATED TO MICROCALCIFICATIONS DETECTED BY ROUTINE MAMMOGRAPHY.

LOGULLO ângela, MAZZINI renato, TAKANO daniela, OSHIMA celina, KEMP Claudio. Departamentos de Patologia e Mastologia da UNIFESP

Introduction: c-myc is a proto-oncogene associated to cell cicle control. Amplification and super-expression of c-myc is involved in early stage of many human neoplasias. Recently a possible role of c-myc in breast carcinogenesis has been hypothesized in literature.
Objective: To evaluate c-myc expression in biopsies from early detected breast lesions by mamography. To compare c-myc expression to histopatological and clinical variables.
Methods: in a retrospective analysis 51 female patients

diagnosed and treated at Universidade Federal de São Paulo from 1998 to 2003 were elected. All cases were submitted to percutaneous biopsy of breast lesions containing microcalcifications classified as BI-RADS 4 and 5 in routine mamomagraphy. Morphology and immunohistochemistry were analysed by two independent observers. Final diagnosis sub-divided the cases in two groups, non-malignant lesions and malignant lesions. C-myc expression was evaluated with standard ABC immunohistochemical essay considering nuclear staining as positive.
Results: median age was 53,7 years. From 51 cases, 20 were malignant (39,2%), including infiltrative and in situ ductal or lobular carcinoma, and 31 cases (60,8%) non-malignant (fibrocistic changes and ductal hiperplasias). C-myc was positive in 19 (37,3%) cases and negative in 32 (62,7%). Among the malignant cases, 9 (45%) were c-myc negative and 11 (55%) positive, whereas between the 31 non-malignant lesions, 8 (25,8%) exhibited c-myc expression and 23 (74,2%) were negative; with a significant association (p=0,035). However, clinical variables (age, Gynecological history, hormone therapy, evolution) did not correlate to c-myc expression in both groups.
Conclusion: c-myc protein identification was more frequent in malignant than non-malignant early detected breast lesions suggesting that alterations in c-myc expression is not a early event in breast carcinogenesis. The role of c-myc expression on detecting potential malignant lesions must be further addressed.

PROGNOSTIC SIGNIFICANCE OF A COMBINED CLINICOPATHOLOGIC SCORE FOR RESPONSE TO PRIMARY SYSTEMIC THERAPY IN LOCALLY ADVANCED BREAST CANCER

BERTHEAU Philippe, LEREBOURS Florence, MOUNIER Nicolas, DE ROQUANCOURT Anne, ESPIE Marc, CLOT Philippe, SERVANT Jean-Marie, MISSET Jean-Louis, MARTY Michel, JANIN Anne

The response to chemotherapy is one of the best indicators of prognosis in locally advanced breast cancer (LABC). The pathologic response (pR) of 108 LABC patients was analysed and compared with their clinical response (cR). Our aim was to define a new combined clinicopathologic response score (cpR) and to explore its correlation with survival data.
The 108 stage IIB to IIIB breast carcinomas were first treated with high-dose anthracycline-based chemotherapy. Standard criteria were used to assess cR. Pathologic analysis of surgical specimens allowed the definition of 5 types of pR. Three groups of combined clinicopathologic response were defined.
Twenty-two patients (20%) had complete or almost complete pR. Most patients (88, 81%) had partial cR. This large group of partial cR was very heterogeneous, ranging from pR1 to pR5 and from cpR1 to cpR3. In univariate analysis, pR and cpR both strongly correlated with EFS. cR, pR and cpR all correlated with OS. Subgroups of incomplete pathologic responses were not prognostically different. In multivariate analysis, only cpR correlated strongly with both EFS and OS ($p<0.002$), identifying good (20%), intermediate (61%) and poor (19%) prognosis patients.
In conclusion, in 108 stage IIB to IIIB breast cancer patients initially treated by high-dose chemotherapy, combined grading of clinical and pathologic responses in a single score allowed accurate prediction of outcome.

INTRODUCTION Neoplastic embolization and metastatic dissemination are widely recognised as main factors affecting breast tumors behaviour. Immunohistochemical expression of Flt-4/VEGFR-3, a protein involved in tumoral lymphatic angiogenesis that could have a significant role in these processes, is still scarcely indagated in these tumors. AIM OF THE STUDY To evaluate the expression of the protein Flt-4 in a group of patients with limited breast tumors and to investigate its predictive value in tumor embolization and tumor metastatic aptitude towards axillary district. METHODS 47 cases of pT1 staged (< 2 cm size) tumors treated with conservative surgery and SN resection were selected from July 2004 to january 2005 Sections from breast lesions were stained with PoAb Ftl-4 (Santa Cruz Biotech.). RESULTS Normal duct epithelium had intense membrane staining (pos+++) for Flt-4, and sporadic vessels were faintly stained in normal parenchyma. 20 tumors (46%) had good (pos++) cytoplasm positivity, associated with an intense membrane staining in 8 cases. Most intensely stained areas were mainly in peripheral portion of the tumors. In 17 cases tumor cells cytoplasm were faintly stained (pos+) with the PoAb and 3 of them presented membrane staining. 10 cases were negative. In 20 carcinomas out of 46 cases evaluated (42%) we could detect a good positivity of several small vessels (>10xHPF) in peritumoral stroma; 3 ITC and 2 metastases were detected in SN in this subgroup, and 4 of this cases had evidence of embolization in peritumoral vascular structures. In 8 cases only a small number of vessel were present (2 metastasis in SN, 3 cases with embolization), and 18 case no vascular structure were stained (1 ITC and 1 metastasis in SN, 6 cases with embolization). Only 2 of the 10 negative tumors belonged to the first group, while 8 out of the 20 tumors with intense staining fit in the same group. CONCLUSION In our study Flt-4 stained peritumoral vascular structures in 42% of the selected carcinomas: we could not find statistical relations between the occurrence of peritumoral Flt-4 positive vessels and the presence of tumoral cells (ITC and metastasis) in SN, tumoral neoangiogenesis, and evidence of peritumoral vascular embolization. Moreover, immunohistochemical expression of the protein Ftl-4 was detected in cancer cells in 46 % of cases This feature was statistically related with the occurrence of Ftl-4 positive vessels in peritumoral stroma (p= .03).

O-262
ABNORMAL EZRIN EXPRESSION IN INVASIVE BREAST CARCINOMAS

Socorro María Rodríguez-Pinilla, 1 David Sarrió,1 Ana Dotor, 2 David Hardisson, 3 and José Palacios.1
1 Breast and Gynaecological Cancer Group, Molecular Pathology Programme, Centro Nacional de Investigaciones Oncológicas (CNIO), Madrid, Spain;
2 Spanish National Tumour Bank Network, Molecular Pathology Programme, Centro Nacional de Investigaciones Oncológicas (CNIO), Madrid, Spain;
3 Department of Pathology, La Paz Hospital, Madrid, Spain;

Introduction: The membrane-cytoskeleton crosslinker ezrin is associated with malignant progression and metastasis in human neoplasias.
Material and Methods: We assessed ezrin expression in 577 breast carcinomas using tissue microarrays. Immunohistochemical staining for ezrin, p53, ki-67, phospho-

Akt, HER2, and estrogen (ER) and progesterone (PR) receptors was performed. Ezrin expression was also studied in breast cancer cell lines by confocal microscopy and western blot.
Results: Ezrin staining in normal breast epithelium localized at the apical cell surface, whereas, in most breast tumor cases (298, 64%), it localized in the cytoplasm. Complete membranous staining occurred in 114 (24%) samples, and apical staining was seen in 57 (12%) cases. Only 48 (9.3%) breast tumors did not express ezrin. There were significant positive associations between cytoplasmic ezrin localization and adverse tumor characteristics, such as higher grade, high Ki-67, p53 positivity, ER and PR negativity, and lymph-node metastases. Apical ezrin staining was associated with favorable clinicopathological features, and membranous ezrin staining with stronger p-Akt expression. Weak ezrin staining or its complete absence was associated with the presence of lymph-node metastasis, ER negativity and reduced p-Akt expression. Western blot revealed no clear differences in total ezrin levels among the breast cancer cell lines studied. However, immunofluorescence staining revealed that ER-positive, noninvasive and nontumorigenic cell lines concentrated ezrin at the apical surface, whereas invasive cell lines had more diffuse, cytoplasmic staining.
Conclusion: The abnormal ezrin expression, either negative or diffusely positive in the cytoplasm, is correlated with adverse features in invasive breast tumors and cancer cell lines.

KIT IS HIGHLY EXPRESSED IN ADENOID CYSTIC CARCINOMA OF THE BREAST, A "BASAL-LIKE" CARCINOMA ASSOCIATED WITH A FAVORABLE OUTCOME.

AZOULAY Sandy 1, LAE Marick 1, FRENEAUX Paul 1, MERLE Solange 1, ROSTY Christophe 1, AL GHUZLAN Abir 1, SIGAL-ZAFRANI Brigitte 1*, SALMON Rémy 2, FOURQUET Alain 3, SASTRE-GARAU Xavier 1, VINCENT-SALOMON Anne 1.
Departments of 1Pathology, 2 Surgery, 3 Radiotherapy, * on behalf of the Breast Cancer Study Group. Institut Curie, 26 rue d'Ulm, 75248 Paris Cedex05, France.

The objective of this study was to assess the clinical, morphological and immunophenotypic characteristics of adenoid cystic carcinoma (ACC) of the breast. Eighteen cases were identified from our files. Clinical information was available for 16 patients with a follow-up ranging from 1 to 15 years. Fifteen patients were treated by surgery followed by radiotherapy for 9 of them and one by exclusive radiotherapy. Fourteen patients were alive. Two of them presented a local recurrence. Two patients died, one of the disease (the patient was treated by radiotherapy exclusive) and one of another cause. Morphologically, all tumors were graded according to the system used for ACC of the salivary glands. Seven out of the 18 cases studied were grade I (39%), 7 grade II (39%) and 4 grade III (22%). Immunophenotype was assessed with anti ER, PR, HER-2, KIT, ''basal'' and luminal cytokeratins (CK5/6, CK8/18), Smooth Muscle Actin (SMA) and p63 antibodies. All cases were ER, PR and HER-2 negative and in contrast, all cases (100%) were KIT positive. The 18 cases were labeled with basal CK5/6, luminal CK8/18, myoepithelial p63 and SMA markers. Epithelial cells were strongly positive around glandular lumens. P63 and SMA labeled cells in solid areas and cells surrounding pseudocystic spaces. In addition, different populations of cells were identified: stem cells (CK5/6+), glandular precursor cells (CK5/6+/CK8/18+), glandular cells (CK8/18+) and myoepithelial cells (p63+/ SMA+.
Our study has showed that ACC of the breast is a special type of "basal like" breast carcinoma, harboring an excellent prognostic with a specific immunophenotype ER, PR, HER-2 negative and KIT highly positive.

O-264
IMMUNOREACTIVITY OF A SIALYLATED MUC1 EPITOPE AS DETECTED BY MONOCLONAL ANTIBODY MY1.E12 PREDICTS A BETTER PROGNOSIS OF MAMMARY CARCINOMA PATIENTS

BALDUS Stephan E., WIENAND Jens R, WERNER Jan P., LANDSBERG Stephanie, HANISCH Franz-Georg, DIENES Hans P.
Institute of Pathology and Center of Biochemistry, University of Cologne, Kerpener Str. 62, 50931 Cologne, Germany

Introduction: MUC1 represents a promising marker in breast cancer. However, due to the structural complexity of the MUC1 glycoprotein, multiple epitopes can be detected by monoclonal antibodies. This fact may be responsible for the contradictory results of previous investigations regarding the clinical and prognostic relevance of MUC1 expression in breast cancer.
Purpose: Therefore, we tried to evaluate the role of different glycosylated and non-glycoslyated MUC1 epitopes as well as other mucin-associated peptides (MUC2) and carbohydrates (Thomsen-Friedenreich antigen, sialyl-Lewis a, sialyl-Lewis x) as predictors of the clinical course and prognosis in mammary carcinomas.
Material and methods: An immunohistochemical study applying numerous monoclonal antibodies (mabs) was performed to characterize the expression of a selected panel of MUC1 epitopes, and of MUC2, Thomsen-Friedenreich antigen, sialyl-Lewis a, and sialyl-Lewis x in a series of 140 patients with breast cancer. The results were correlated with clinicopathological variables as well as overall survival.
Results: Generally, more than 90 % of the mammary cancers, were strongly stained with the MUC1-specific mabs. Especially ductal and lobular carcinomas were strongly MUC1 and sialyl Lewisa positive, whereas MUC2 binding was significantly elevated in mucinous neoplasms. Associations between the immunoreactivity of any mab under study and tumor progression as reflected by pTNM staging could not be observed. However, expression of the sialylated MUC1 epitope detected by mab MY1.E12 revealed as a favourable independent prognostic factor.
Conclusions: These results confirm that MUC1 is generally strongly expressed in mammary carcinomas. As an exception, mucinous carcinomas are significantly less MUC1 reactive, but express strongly MUC2. Our data suggest that only the presence of a sialylated short-chain MUC1 glycoform is associated with a better prognosis, whereas the other molecules under study are not correlated with the course of disease and survival probability.

CLINICAL, HISTOPATHOLOGIC AND IMMUNOHISTOCHEMICAL CHARACTERISTICS OF BREAST CANCERS PRESENTING DURING PREGNANCY OR LACTATION

Mazyar Shadman , MD.
Mohammad Sadegh Fazeli , MD.
Isa Jahanzad , MD
Shahram Nikbakhtian
Imam Khomeini General Hospital, Cancer Institute

Introduction:
As a rare condition, pregnancy associated breast cancers are of the most challenging medical issues. The poor prognosis and disappointing nature of these kinds of cancers have made them an area of research interest in the past years. There been controversy regarding the independent role of pregnancy alone in making such poor outcomes. We conducted this descriptive cases series study to determine the different aspects of this kind of breast cancer.
Method and Materials:
All the charts and medical records of breast cancer patients presenting in Cancer Institute of Imam Khomeini General Hospital were reviewed to find the patient who were pregnant or had a childbirth 6 months before the diagnosis of breast cancer. The patients were evaluated regarding the presenting complaint, diagnosis method, tumor histopathologic pattern and immunohistochemical studies like Estrogen and Progesterone receptors positivity and determining HER-2/neu (c-erb-B2) and P53. Immunohistochemical studies performed using pathologic blocks if IHC data was insufficient for the study purposes.
Results:
We found 10 patients, 7 of which were pregnant, 2 were lactating and one was in the postpartum period but not lactating. Mean age was 32 (27-38) and the mean weight was 70.9(63-81). The mean gestational age was 17.4 weeks (6-35) and the mean number of previous pregnancies was 1.8 (1-3). Seventy percent of patients had a positive history of breast-feeding with a mean of 20 months. Eight patients (80%) presented with a breast mass and two with nipple bloody discharge. One patient was in the Stage 1 (10%), 6 patients in Stage 2 and 3 in the stage 3. The most common histopathologic pattern has been Invasive ductal Carcinoma (7 Patients, 70%) followed by Invasive lobular (1 Patients, 10%) and Mocinous (1 Patients, 10%) and pure DIC (1 Patients ,10%).
50% of patients were ER positive , 62.5 % PR positive and 57.1 % were positive for both. P53 and HER-2/neu has been positive in 50% and 33% of patients, respectively.
Conclusion:
Most of the obtained results were comparable with previous studies. Because of the controversial nature of the disease, further studies for comparison between such patients and non-pregnancy associated breast cancer patients are needed considering the different confounding factors. Because of determination of most important confounding factors, Data of current study can be used as a base for further cohort studies.

P 2

TNM STAGING AND CLASSIFICATION OF BREAST CANCER (FAMILIAL AND NON-FAMILIAL) IN JORDANIAN FEMALES

Dr. Manr Atoum and Dr. Salem Akel

Introduction: Cancer becomes one of the most common diseases in our lives today, and breast cancer is the women's worst enemy.
Purpose: Staging or morphology of breast tumor has important implications for treatment and prognosis and it would be of interest to determine the relation between various morphological types and age of patient as well as the frequency of each stage among familial and non-familial breast cancer.
Results: Out of ninety-nine breast cancer females enrolled in this study, forty three were familial females and fifty six were non-familial females. Breast cancer cases were staged depending on the combination of TNM category into in situ, early invasive, advanced invasive and metastatic.
One female breast cancer Jordanian females was diagnosed with in situ cancer, fifty cases were in early stages of invasive cancer. The remaining was diagnosed with advanced invasive (29 cases) and metastatic (19 cases) breast cancer.
Stage 2b was the most common stage of early invasive cases and represented 48% of the staged cases. On the other hand, among cases diagnosed with advanced invasive breast cancer, stage 3a was the most common stage and represented 89.6% of cases. Interestingly, all cases of stage 3a belonged to TNM stages of T2N2M0 and T3N1M0. The tumor size in all cases of Jordanian females diagnosed with advanced invasive breast cancer exceeded the 2 cm size.
The incidence of non familial breast cancer was slightly higher (56.4%) than that of familial type (43.4%) among studied Jordanian females. Sixty two percent of cases diagnosed as early invasive belonged to familial breast cancer type. In contrast, most (72% and 84%) of advanced invasive and metastatic breast cancer cases, respectively were of non familial type.
Young females below 40 years were diagnosed with in situ (5.2%), early invasive (26.3%), advanced invasive (31.6%) and metastatic (36.8%) breast cancer. Among females older than 40 years, frequency of early invasive stage was higher (56.3%) than that of advanced invasive (28.7%) and metastatic (15.0%). Among age of 51-60 years, cases of early invasive represented 63.9% of cases.
Conclusion: Non-familial breast cancer is more common than familial breast cancer, most breast cancer females were diagnosed at early invasive stage. Non familial breast cancer were more frequent at lower stage, while familial breast cancer were more frequent at higher stage.

P 3

PAGET DISEASE (PD) OF THE NIPPLE MAY BE DERIVED FROM LOBULAR CARCINOMA IN SITU (LCIS).

Sabine Fransis, MD; Isabelle Vandenbempt; Maria Drijkoningen, MD, PhD.
Pathology Department, University Hospital Leuven, Leuven, Belgium.

PD occurs in about 1-4% of patients with breast cancer and is characterized by the presence of neoplastic "glandular" cells within the epidermis of the nipple-areola complex. PD is usually associated with poorly differentiated ductal carcinoma in situ (DCIS) located in the lactiferous ducts, with or without invasive ductal adenocarcinoma (IDC). DCIS and PD show similar morphological features and an identical immunocytochemical (ICC) profile: both are positive for low molecular weight cytokeratins (CK), HER-2/neu and carcino-embryonic antigen (CEA).Therefore, PD is regarded as a high grade DCIS that is present in the epidermis. The intra-epidermal location of PD cells may be explained by epidermotropic migration of cells of the underlying DCIS, facilitated by the HER-2/neu receptor.
In our lab, 11 of the 570 mastectomies received between 1/8/2001 and 31/12/2004, showed PD. 8/11 cases were associated with poorly differentiated DCIS and IDC. However, in 3/11 cases LCIS and invasive lobular carcinoma (ILC) were present. In all 3 cases, LCIS extended into the

lactiferous ducts and PD consisted of single cells only. Cells of ILC, LCIS as well as PD expressed CK 8/18, epithelial membrane antigen (EMA) and CEA, but were consistently negative for epithelial cadherin (E-cadherin) and HER-2/neu. Expression of CK8/18, EMA and CEA is suggests glandular differentiation, while absence of E-cadherin typically points towards a lobular phenotype. However, in PD cells the absence of staining for E-cadherin was difficult to corroborate, since they are sprinkled as single cells in between E-cadherin positive keratinocytes. The strongest evidence against an origin from DCIS in these 3 cases lies in the absence of HER-2/neu overexpression by PD cells.
In conclusion, morphologic as well as ICC findings indicate that in these 3 cases PD is not derived from DCIS, but from LCIS. To our knowledge, only one such case has been previously reported by Rosen et al, 2002. As a consequence, the mechanism by which PD cells end up in the epidermis has to be re-evaluated , since it is obvious that in PD derived from LCIS, there is no role for HER-2/neu as an facilitator of intra-epidermal migration of adenocarcinoma in situ cells.

Introduction: The axillary lymph node status of patients with newly diagnosed breast cancer remains the most important prognostic information available at the moment. The incidence of metastases in axillary lymph node (MAL) is related with the neoplasia's diameter. In breast cancer < cm1 in diameter, it has been observed a low incidence of MAL, because only a minority of patients presents with such node metastases at diagnosis. It may be possible to forecast the MAL by prognostic factors variation other than axillary lymph node dissection.
Purpose: We reviewed our database to find which factors are associated with MAL.
Methods: We studied 500 consecutive cases of breast cancer < or equal 2 cm in diameter (pT1) from 1999 to 2004 and we evaluated immunoistochemistry expression of the estrogenic and progestinic receptors and prognostic factors pS2, Ki67, bcl2, p53 e c-erbB2 (neu). We considered positive the nuclear (ER, PgR, p53), cytoplasmatic (pS2 e bcl2) and complete of membrane (neu) expression in over than 10% cells. Proliferative Index was calculated with immunoistochemitry expression of Ki67. These dates are related with MAL, grade and istotype of the tumor, diameter of the neoplasia, patient's age, multifocale tumoral nodes. The statistical analysis was performed with c2 test and a multiple regression logistic model.
Results: Significative statistical resultes were observed as like as MAL and age (p<0,01), MAL and tumoral grade (p<0,001), MAL and tumoral size (p<0,001), MAL and P.I. (p<0,001) and MAL and p53 expression (p<0,01). We did not observed statistical correlance between MAL and tumoral type, multifocal tumor, ormonal receptrors expression , PS2, bcl-2 and c-erbB2. Cut off was 6.5 with sensivity of 77,2% and specifity of 50%. ROC-curve result was 0,69.
Conclusion: We found that age inferior to 50 years, high grade, diameter superior to cm 1, elevated ki-67 and expression of oncogene p-53 are all factors associated with lymph node metastases

P 5
SENTINEL LYMPH NODE IN BREAST CANCER: IS IT POSSIBLE A STANDARD EXAMINATION?
M Amini, L Costarelli, FR Piro, L Fortunato (*), M Farina (*), A Dell'Osso(**), CE Vitelli (*)
"San Giovanni Addolorata Hospital", Department of Pathology and
Surgical (**) Rome - Italy
"MG Vannini Hospital", Department of Surgical (*) Rome - Italy

Introduction: Sentinel lymph node (SLN) biopsy allows enhanced pathology through serial sections and immunoistochemical analysis of the retrieved node, with detection of micrometastases (MICRO) and isolated tumor cells (ITC) not otherwise recognized and this tecnique is usually applied in most of surgical oncology centers.
Purpose: We present our experience with an effective protocol for analysis of SLN in breast cancer.
Methods: We studied 416 consecutive patients (median age 63 years) with primary breast cancer (median diameter 1.5 cm) who underwent SLN biopsy from March 2001 to December 2004 in two different hospital. After surgery, SLN's were step sectioned. First section obtained was called "Level 0" and routinely processed. If first section was negative, at least six additional couples of sections were obtained from each SLN at 100 micron distance (Level I, II and III) and were analysed with conventional staining and immunohistochemistry (IHC–MNF 116). SLN metastases were classified according to TNM 2002 and called MICRO when less than 2mm in diameter and ITC when less than 0,2 mm in diameter.
Results: With conventional analysis, SLN was positive al Level 0 in 25% of cases (106/416). Further metastases or ITC was discovered in 14,5 cases (61/416): 8,9% at Level I, 4% at Level II and 1,6% at level III, of which ITC were 62% (38/61), MICRO were 36% (22/61) and 2% were macrometastases (1/61). Our protocol discovered MICRO or ITC in 13% of patients with tumors less than 2 cm in diameter (T1) and in 15% of those more than 2 cm in diameter (T2) (p=0.7). Evidence of MICRO and ITC at level III was 1,3% in T1 patients and 3,8% in T2.
Conclusions: SLN step analysis is most useful to discover MICRO and ITC in a good percentage of cases. This tecnique allows to study more accurately women with breast cancer. Our protocol seems best possible because in our experience the incidence of MICRO and ITC at Level III is very low, expecially in T2 tumors. Currently, it doesn't known which is prognostic relevance of MICRO and ITC

P 6
FINE NEEDLE ASPIRATION CYTOLOGY OF MAMMARY CARCINOMA WITH OSTEOCLAST-LIKE GIANT CELLS. A REPORT OF NINE CASES
GONZALEZ-PERAMATO Pilar, JIMENEZ-HEFFERNAN Jose A, VICANDI Blanca, LOPEZ-FERRER Pilar, PEREZ-CAMPOS Ana, HARDISSON David, VIGUER Jose M.
Departments of Pathology, University Hospitals Guadalajara and La Paz, Madrid, Spain

Inroduction: Carcinoma with osteoclast-like giant cells (OCGC)is an uncommon neoplasm characterized by giant cells, prominent vascularization, haemorrhage and areas of cribriform epithelial growth with moderate atypia. Multinucleated giant cells have been described in several other breast lesions raising an interesting differential diagnosis, mainly with benign disorders. Due to its rarity few cases have been described cytologically.
Purpose of the study: To determine if mammary carcinoma with OCGC shows cytologic features characteristic enough to

permit a specific preoperative diagnosis using fine needle aspiration.
Methods: We retrospectively reviewed 13 fine needle aspiration samples from 9 patients with this variant of carcinoma. Nine corresponded to breast tumours and four to axillary, liver, subcutaneous and mediastinal metastatic lesions. The expression of CD68 by giant cells was evaluated immunocytochemically in six cases. All patients had a complete pathologic study of the breast neoplasm.
Results: Smears showed a double component of epithelial and giant cells. Epithelial clusters were predominantly of intermediate size with irregular contours. Most were cohesive but others showed cellular dissociation with scarce to moderate cellular pleomorphism. Giant cells had a well defined, deeply stained cytoplasm and round to elongated morphology. Two metastatic cases were devoid of them. Hemosiderin-laden macrophages were common in smears from breast tumors. In the six cases tested CD68 was expressed in multinucleated giant cells. Except for one case that was diagnosed as suspicious of malignancy all the cytologic diagnoses were of carcinoma. There were no false negative diagnosis.
Cconclusion: Cytologic features of mammary carcinoma with osteoclast-like giant cells correlate closely with the histologic ones. Most cases are clearly recognizable as malignant but in others cytologic atypia may be minimal mimicking a benign lesion. In difficult cases the presence of hemosiderin-laden macrophages and the histiocytic nature of the MGC are helpful diagnostic features.

P 7

PATHOLOGY EVENTS (MALIGNANT OR NOT) IN PATIENTS WITH BREAST CANCER TREATED WITH TAMOXIFEN WITH OR WITHOUT CHEMOTHERAPY

Arapantoni-Dadioti P., Britsou M., Terzi M., Trihia H., Tzaida O., Lekka J.
Pathology Dpt. METAXA Cancer Hospital , PIRAEUS - GREECE

The benefit from prolonged use of tamoxifen in reducing the incidence of breast carcinoma is considered sufficiently great to justify its use as a chemopreventive agent despite the risk of undesirable side effects.
AIMS: To determine the spectrum of pathological findings in breast cancer patients treated with tamoxifen.
METHODS: The study population comprised 109 breast cancer patients, out of 1009 diagnosed with the disease in our laboratory over a period of five years (1997-2001). The above patients were treated with tamoxifen and presented with secondary pathological findings, other than metastatic disease. The data were collected retrospectively and included 73 patients with D&C and hysterectomy/oophorectomy specimens for tamoxifen-associated gynaecological symptoms and 36 patients with other than gynaecological pathology.
RESULTS: Of the 73 patients who underwent D&C or surgery for gynaecological symptoms, 28 had normal endometrium (16 atrophic), 15 simple hyperplasias, 30 hyperplastic endometrial polyps, 5 endometrial carcinomas, 5 endometrial sarcomas, 18 leiomyomas, 8 adenomyomatosis, 6 ovarian cysts, 2 ovarian endometriosis, 1 ovarian adenocarcinoma, 6 ovarian stromal tumors, 1 ovarian teratoma, 2 Brenner tumors, 3 CINIII and 1 squamous carcinoma of the cervix.
In 12 patients, a second malignancy, other than gynaecological, was diagnosed: 3 in the contralateral breast, 2 renal cell carcinomas, 3 thyroid carcinomas, 1 urothelial carcinoma, 1 adenocarcinoma of the colon, 1 Hodgkin's disease and 1 multiple myeloma.
In 9 patients there were diagnosed 3 adenomas of the colon, 2 neurofibromas and 1 GIST.
In the remaining 15 patients, the specimens concerned gallbladders with lithiasis or chronic cholecystitis.
CONCLUSIONS: In our study 67% of the women treated with tamoxifen presented with gynaecological-related pathology concerning the endometrium and the ovaries, 16,4% of which were malignant in nature. In 11% malignant disease in other organs was diagnosed. Interestingly 13,7% of the patients showed biliary tract- related problems, propably due to tamoxifen-producing cholestasis.

P 8

PLEOMORPHIC LOBULAR NEOPLASIA (PLN) OF THE BREAST NEEDS TO BE EXCISED AND BEHAVES LIKE A PRE-INVASIVE ENTITY: AN HISTOLOGIC AND PHENOTYPIC STUDY FROM A SERIE OF 15 NEEDLE CORE BIOPSIES (NCB) AND THEIR SUBSEQUENT SURGICAL SPECIMENS

BIBEAU frédéric 1, CHATEAU marie-christine 1, MICHENET patrick 2, BORRELLY cécile 1, ESSLIMANI-SAHLA majida 1, DELFOUR christophe 1 , LAVAILL rosy 1, BOISSIERE florence 1, MASSON Bruno 1. 1 Pathology and Radiology Departments, Val d'Aurelle Cancer Center, Montpellier, France, 2 Pathology Department, Hôpital La Source, Orléans, France.

Introduction: Lobular neoplasia is considered to be a marker of cancer risk, but its appropriate management is still controversial. The increasing use of percutaneous NCB for non palpable breast lesions, has highlighted evolving entities such as PLN.
Purpose: Our goal is to emphasize this pleomorphic variant, whose presentation differs from the classical form of lobular neoplasia and whose recognition has clinical relevance.
Methods: Fifteen PLN were primarly diagnosed from fourteen 8 or 11 Gauge (G) Mammotome® procedures, using stereotactic mammography and one 14 G biopsy, using ultrasound guidance. All PLN, but one, were mammographically detectable, because of microcalcifications. Subsequent surgical specimens were obtained in 13 cases, during which 7 sentinel lymph node procedures or 3 axillary dissection were performed. An immunohistochemical study for estrogen and progesteron receptors (ER, PR), c-erbB2, E-Cadherin and high molecular weight cytokeratin 34 beta E-12 (HMW-CK), was realized on NCB and excision specimens.
Results: Among the 15 PLN cases, 5 were associated with an invasive lobular carcinoma (ILC) and 3 with a microinvasive lobular carcinoma. Seven invasive or microinvasive cases were already identified on NCB. One ILC was identified on the surgical resection alone. ILC and microinvasive carcinoma were always closely located to the PLN areas, both on biopsies and surgical specimens. Morphologically, PLN cases were composed of pleomorphic, dyshesive cells with comedo-like, apocrine and signet ring features. Comedo-like patterns with central necrosis were associated with microcalcifications. PLN presented the following phenotype: ER 13+/15, RP 5+/15, CerbB2 3+/15, E-cadherin 0+/15, HMW-CK 15+/15. PLN and their invasive/microinvasive counterparts shared a similar phenotype. Two metastatic axillary involvement were noted.
Conclusions: These clinical, histological and phenotypic data support the evidence that PLN looks more like a preinvasive lesion than a marker of increased risk. Thus, percutaneous biopsies with PLN should be evaluated diligently for the presence of an invasive or microinvasive lobular component and require a subsequent surgical excision. Pathologists, as well as physicians involved in the management of breast disease, should be aware of this mammographically detectable entity, which has distinct histologic patterns and behaviour.

P 9

PROGNOSTIC FACTORS IN PRIMARY MUCINOUS BREAST CARCINOMAS

Ulrika Klopèiè, Snježana Frkoviæ-Grazio*, Marija Us-Krašovec
Department of Cytopathology and Department of Pathology*, Institute of Oncology, Zaloška cesta 2, 1000 Ljubljana, Slovenia

Background
Pure and mixed mucinous breast carcinomas (MCs) are separate morphological entities, with different biological potential and prognosis. The recent WHO classification of breast carcinomas suggests that 100%, and not the generally used 90% cut-off value, of mucinous component must be present for a diagnosis of pure MC.
Aims of the study
To analyse clinical, cytological and histological features of MCs of the breast and to determine their prognostic significance.
Material and methods
Altogether 98 patients with primary breast MCs were included in the study. A mucinous component of 90% has been routinely required for pure MCs at our institution. Clinical (age of patient, tumour size, regional lymph nodes status, distant metastases, treatment), cytological (amount of mucin, sample cellularity, nuclear pleomorphism, cytoplasmic features, presence of capillaries), histological (grade, amount of mucin) parameters, and DNA ploidy were assessed and their influence on survival was analysed.
Results
Among 98 breast MCs, 64 were classified as pure and 34 as mixed. Regional lymph node metastases were found in 5 of 60 pure MCs and in 21 of 30 mixed MCs. Distant metastases were present in 5 of 64 pure MCs and in 17 of 34 mixed MCs. Overall 5 and 10 year survival for pure MCs was 89.0% and 83.0%, and 78.9% and 46.5% for mixed MC. The difference in survival was statistically significant ($p=0.004$).
Univariate analysis revealed that histological type, axillary lymph node status, tumour size and cytologically assessed nuclear pleomorphism had a statistically significant impact on survival ($p<0.05$). The histological type and size of tumour influenced survival of patients without axillary lymph node metastases. Axillary lymph node status and tumour size were found by multivariate analysis to be independent prognostic factors.
The 5 and 10 year survival was 93.7% for MCs with 100% of mucinous component, but dropped to 85.3% and 65.1% for MCs containing about 90% of mucinous component ($p>0.05$).
Conclusions
Regional lymph node status is the most important independent prognostic factor for breast MCs, followed by tumour size.
The present study supports the recent recommendations by WHO classification of breast carcinomas that 100% and not 90% of mucinous component is required for pure MCs. Since the component other than mucinous has a great influence on the survival of patients with MCs of the breast, a meticulous sampling of the tumour is necessary.

P 10

METASTATIC INVOLVEMENT IN INTERPECTORAL (ROTTER'S) LYMPH NODES RELATED TO LOCATION, SIZE AND GRADE OF BREAST CANCER

VELIMIR VRDOLJAK Danko, KNEŽEVIÆ Fabijan
University Hospital for Tumors, Zagreb, Croatia

Aims and background: The study was aimed at analyzing metastatic involvement in interpectoral (Rotter's) lymph nodes related to site, size and grade in primary breast cancer.
Methods: The study includes 210 female patients undergoing surgery for breast cancer at the University Hospital for Tumors, Zagreb, Croatia from November 2001 to March 2004. In addition to the standard surgical procedure, interpectoral (Rotter's) lymph nodes were removed in all of the patients. Metastatic involvement of interpectoral lymph nodes was confirmed by histological and immunohistocemical examinations.
Results: Rotter's lymph nodes were identified in 66,2% of the patients, with metastatic involvement revealed in 18,5% of the Rotter's nodes. Metastatic involvement of Rotter's nodes in patients with negative and positive axillary lymph nodes was 2,8% and 34,6%, respectively. Considering location of the tumor in patients with metastatic involvement of Rotter's nodes, it was shown that tumors located in the upper breast quadrants were more prone to metastasis to Rotter's nodes, demonstrating a significant positive correlation between tumor location within the breast and positive Rotter's lymph nodes ($r=0.93$, $p=0.02$). As regards tumor size, Rotter's nodes were identified in 15%, 20% and 60% of stage T1 (<2 cm), T2 (2-5 cm) and T3 tumors (>5 cm), respectively with a significant positive correlation ($r=0.759$, $p=0.09$). Also considering tumor grade it was shown that metastatic involvement of Rotter's lymph nodes was 3,8%, 17,6% and 31,6% of histological grade I,II and III, respectivly with a significant positive correlation ($r=0.993$, $p=0.08$).
Conclusions: The results show that almost one-fifth of breast cancer patients, or even one-third of them with positive axillary lymph nodes, are discharged with positive interpectoral lymph nodes that remain undiagnozed and non-extirpated. As the interpectoral nodes can be surgically removed without additional mutilation, the exploration of Rotter's lymph nodes should be introduced into routine clinical practice. In upper breast quadrants tumors were more prone to metastase in to Rotter's nodes, as well as higher tumor size and grade.
Key words: breast cancer, interpectoral (Rotter's) lymph nodes

P 11

OUTCOME OF PURE AND ATYPICAL MEDULLARY CARCINOMAS OF THE BREAST

KARAYIGIT Ebru (*), YAVUZ Ekrem (*), TUZLALI Sýtký (*), ILHAN Rýdvan (*), DERIN Duygu (†), GUNEY Neþe (†), ASOGLU Oktar (**), AKHAN Süleyman (***), IPLIKCI Altan (*)
Istanbul University, Istanbul Faculty of Medicine, Departments of Pathology (*), General Surgery (**) and Gynecology & Obstetrics (***)
Istanbul University, Institute of Oncology, Department of Medical Oncology (†), Turkey

Pure medullary carcinoma (PMC) of the breast is a rare neoplasm. Using strict morphologic diagnostic criteria, it usually displays a favourable outcome. Atypical medullary carcinoma (AMC) of the breast has some medullary features and its prognostic significance is controversial. In this study, we aimed to compare our PMC and AMC cases, using clinicopathological findings and to reach a conclusion, concerning the diagnostic criteria of breast carcinomas with medullary features. For this reason, we retrieved 19 cases of PMC and 106 cases of AMC from almost 4000 breast carcinomas that were diagnosed at our department between years of 1988 and 2004. Of these, 7 PMC and 48 AMC cases with available follow-up were compared. The following data, including patient age, menopausal status, tumor size, grade, stage, lymph node status, estrogen and progesterone receptor status, existence of distant metastasis, disease free survival (DFS) and overall survival (OS) were recorded as well. The median follow-up time was 55 (range 8-156) months for all the cases (n=55), 96 (range 13-145) months for PMC cases (n=7) and 48 (range 8-156) months for AMC cases (n=48). All of the PMC cases were lymph node-negative, while 20 AMC cases showed lymph node metastasis. None of the PMC patients has died, while 8 patients with AMC had died during the follow-up. No recurrence was noted, except for a patient

who developed a new primary PMC at the contralateral breast 7 years after the diagnosis, among the PMC cases. Cumulative survival rates of the AMC cases was 69.7 % at sixty-five months with Kaplan Meier analysis (SE: 0.091). There was no significant difference between the survival curves of two groups by log-rank test with Kaplan Meier analysis (log-rank:1.86, df:1, p:0.172). We concluded that a favourable outcome can be expected for PMCs and some AMCs. Also, a redefinition of morphologic diagnostic criteria should be made for breast carcinomas with medullary features.

P 12
PANNICULITIS-LIKE INVASIVE CARCINOMA OF THE BREAST

ICHIHARA Shu, MORITANI Suzuko
Department of Pathology, Nagoya Medical Center

Introduction: In the boundary between the invasive mammary carcinoma and the adipose tissue, isolated or groups of infiltrating tumor cells are often blended with fat cells. This pattern is responsible for an echogenic rim surrounding the hypoechoic mass of invasive breast carcinoma observed by ultrasound. We termed this pattern panniculitis-like infiltration (PLI) because this pattern resembles inflammation of the adipose tissue. Invasive lobular carcinomas are occasionally composed predominantly of PLI without a significant desmoplastic reaction, resulting in a spider• fs web-like structure. However, the clinicopathological significance of such pattern in non-lobular invasive carcinomas are not known. Methods: We reviewed all the histological slides of 155 consecutive invasive carcinomas of the breast and classified the degree of PLI into three degrees; PLI-1 (<10%), PLI-2 (10-50%) and PLI-3 (>50%) according to the extent of this pattern in invasive area. The relationships between PLI and histological types, grade, steroid receptors, lymph node status were examined. Results: We found that the number of cases in invasive mammary carcinoma with PLI-1, PLI-2 and PLI-3 were 113 (73%), 30 (19%) and 12 (8%), respectively. Invasive mammary carcinoma with PLI-3 was composed of 9 panniculitis-like invasive ductal carcinomas (PLIDC) and 3 panniculitis-like invasive lobular carcinomas (PLILC). Remarkably, two PLIDC were composed purely (>90%) of this pattern and presented echogenic masses without hypoechoic cores in fatty breast of the elderly women. Pure PLIDC and PLILC may be overlooked unless the examiners keep this unusual ultrasound pattern of invasive carcinoma in mind. Mammographically, most PLIDC presented distortion or spiculated masses less dense than common invasive ductal carcinoma. Most (11/12) PLIDC and PLILC showed estrogen-receptor positive and HER2 negative immuno-phenotypes (P<0.05). In spite of relatively small size by palpation, the half cases had positive axillary lymph nodes. Definite diagnosis by aspiration cytology was unsuccessful in five cases. This is due to hypocellularity and frequent co-existence of benign ductal elements in the cytological specimens. Core needle biopsy may be a more reliable tool for pre-operative diagnosis of PLIDC and PLILC.
Conclusions: Panniculitis-like invasive carcinoma is a new clinicopathological entity with unique histopathological and ultrasound features.

P 13
ACCURACY OF TYPING AND GRADING MAMMARY LESIONS ON CORE BIOPSIES AND COMPARISON WITH THE EXCISIONAL SPECIMENS.

CATTANI Maria Grazia
U.O. Anatomia Patologica, Ospedale Maggiore, Azienda USL Bologna, Bologna (Italy)

INTRODUCTION. Needle core biopsy of palpable lesion (NCB;14 gauge) and stereotactic vacuum assisted biopsy (SVAB;11 gauge) of non-palpable mass are the majors preoperative methods of breast diagnosis. The UKNHS Breast Screening Project recommends the use of a core biopsy reporting form that recognize five diagnostic categories (B1-B5). Purpose of this study was to evaluate the incidence and the predictive value of the two categories: B4 (suspicious of malignancy) and B3 (lesion of uncertain malignant potential) in lesions diagnosed by NCB and SVAB and to assess the accuracy of the two methods in typing and grading infiltrating and in situ breast carcinomas.
MATERIALS AND METHODS. 2170 core biopsies (893 NCB and 1277 SVAB) were performed between January 2000 and February 2005. In 879 cases, the correlation between biopsy results and subsequent surgical excision was available.
RESULTS. The frequency of B3 diagnosis was 8 % (72 cases) in NCB and 9 % (115 cases) in SVAB. The B4 category was reported in 7 % (62 cases) of NCB and in 3 % (38 cases) of SVAB. At definitive histology, 24 % of B3 (NCB:32 cases, SVAB:12 cases) and 87 % of B4 (NCB: 54 cases, SVAB: 33 cases) showed invasive carcinomas or ductal carcinoma in situ. Type and grade of the invasive and in situ carcinoma, were determined in both biopsy and definitive excision and the results compared. For histological type, 12 % of NCB and 3 % of SVAB were changed to a different category. The agreement with overall grade was of 85 % with SVAB and of 62 % with NCB. On 94 cases that differed, 98 % differed by one grade and 63 % were upgraded.
CONCLUSIONS. SVAB has been shown to have a greater accuracy in diagnosis, mainly because of the increased quality and quantity of tissue obtained. However, the incidence of B3 category is comparable with SVAB and NCB methods. This behaviour could be explained considering that the B3 category often refers to atypical intraductal epithelial proliferation, most frequently associated to clustered microcalcifications sampled by SVAB. Grading based on NCB is not as accurate as SVAB, and its evaluation should be delayed until the surgical specimen examination.

P 14
AUTOMATIC CLASSIFICATION OF CLUSTERED MICROCALCIFICATIONS IN BREAST CANCER

Marek Ustymowicz1 and Katarzyna Guziñska-Ustymowicz2
1 Technical University of Bialystok, Mechanical Department, Bialystok, Poland,
2 Medical University of Bialystok,

Introduction: Breast cancer is a significant public health problem worldwide. Plenty of mammographic screening programs resulted in the detection of breast carcinomas at early stage. The presence of microcalcifications in mammogram not only correlates with breast cancer in many cases, but also sometimes is the only early sign of this disease. Nowadays, Computer Aided Diagnosis (CAD) systems may help radiologists detecting and classifying clustered microcalcifications, which is vital for proper treatment.
Objectives: The objective of this work was to evaluate the performance of the computerized classification method for automatically detected clusters of microcalcifications.
Materials and Methods: In our research we used 106 images from Digital Database for Screening Mammography (DDSM), among which 67 presented malignant and 39 benign cases. Our experiments were carried out in two steps: automatic detection and automatic classification. For the detection, previously developed morphological method has been used. Before the classification task was conducted, the whole set of mammograms was divided into two groups: training and testing sets, including the same number of images. Only images from training set were used to train the

Support Vector Machine (SVM) classifier. The performance of the classifier has been tested on images from testing set.
Results: Automatic classification of clustered microcalcifications in mammograms is a final stage of CAD system which helps the radiologist in diagnosis. According to ROC analysis the presented algorithms yielded Az=95,23%.
Conclusions: The SVM classifier used in experiments gave very good results and will be used in further research on complex CAD system.

P 15
BILATERAL BREAST CARCINOMA – THE HISTOLOGICAL PATTERN
P. Wisniewski MD, K. Socha MD PhD*, J. Patera MD, W. Kozlowski MD PhD
Department of Clinical Pathology, Military Medical Institute, Warsaw, Poland

Histological grade and tumor biology remain important predictors of clinical behaviour of breast carcinomas. The aim of this study was to compare the histopathological and genetical / BRCA-1 mutation/ patterns of breast carcinomas in women who underwent a surgery due to invasive carcinomas and in which the bilateral invasive carcinoma presence was ascertained.
From 1995 to 2004 year 542 women underwent mastectomy in our Military Medical Institute. In 13 patients /2.4%/ a bilateral invasive carcinoma was diagnosed. There were 9 synchronous and 3 metachronous breast carcinoma patients. In order to estimate the estrogen /ER/ and progesteron /PR/ receptors status and an overexpression of HER2 in primary tumors immunohistochemical examinations were performed. Furthermore, these receptors rates/expression was evaluated in metastases to regional lymph nodes and in remote metastases. In 10 patients the presence of the invasive ductal carcinoma was ascertained in one breast at least; in 6 cases the ductal carcinoma was bilateral. The tubular carcinoma was diagnosed in 4 patients / in 1 woman it was bilateral/. The lobular carcinoma was diagnosed in 3 cases /in 2 cases it was bilaterally/.
There was no difference found in the status of ER, PR in patients with bilateral tumors of the identical histopathological pattern. No correlation of receptor's status was stated in all other cases. In metastases the ER and PR status corresponded with the receptor's status of one of primary tumors. BRCA-1 mutation analysis confirmed its presence in 1.4% of 427 examined breast carcinoma cases but none woman with bilateral cancer carried such mutation. Compare to unilateral cancers the bilateral one was mostly present in women under the 40 year of age. Thus, also the other genetical risk factors should be searched in order to predict the development of bilateral breast cancer. Our findings indicate that synchronous bilateral breast carcinoma showed a higher frequency of invasive ductal carcinoma. Also they indicate problems in estimating the TNM status of bilateral cancers, especially concerning metastases into regional lymphnodes. The examination of receptors rates and HER2 overexpression of both tumors in bilateral breast carcinomas and their metastases is required and their analysis remains an important predictor of the clinical behaviour of breast carcinomas.

PANNICULITIS-LIKE BREAST CANCER
ICHIHARA Shu, MORITANI Suzuko
Departmant of Pathology, Nagoya Medical Center

Background: In the boundary between the invasive mammary carcinoma and the adipose tissue, isolated or groups of infiltrating tumor cells are often blended with fat cells. This pattern is responsible for an echogenic rim surrounding the hypoechoic mass of invasive breast carcinoma observed by ultrasound. We termed this pattern panniculitis-like infiltration (PLI) because this pattern resembles inflammation of the adipose tissue. Invasive lobular carcinomas (ILC) are occasionally composed predominantly of PLI without a significant desmoplastic reaction, resulting in a peculiar spider'
s web-like structure. However, the frequency and clinicopathological significance of such lace-like pattern in invasive ductal carcinomas (IDC) is unknown. Material and Methods: We reviewed all the histological slides of
155 consecutive invasive carcinomas of the breast and classified the degree of ! PLI into three degrees; PLI-1 (<10%), PLI-2 (10-50%) and PLI-3 (>50%) according to the extent of this pattern in invasive area. The relation of PLI to histological types, grade, hormone receptor and lymph node status were examined. Results: We found that the number of cases in invasive mammary carcinoma with PLI-1, PLI-2 and PLI-3 were 113 (73%), 30 (19%) and
12 (8%), respectively. Invasive mammary carcinoma with PLI-3 was composed of
9 IDC and 3 ILC. Remarkably, two IDC with PLI-3 were composed solely (>90%) of this pattern and presented pure echogenic masses without hypoechoic cores in fatty breast of the elderly women. Pure panniculitis-like IDC and ILC may be overlooked unless the examiners keep this unusual ultrasound pattern of invasive carcinoma in mind. Mammographically, most panniculitis-like IDC presented distortion or spiculated masses less dense than common IDC. Most
(11/12) invasive carcinomas with PLI-3 showed estrogen-receptor positive and! HER2 negative immuno-phenotypes ($P<0.05$). In spite of relatively s mall size by palpation, the half cases showed positive axillary lymph nodes metastasis. Definite diagnosis by aspiration cytology was unsuccessful in five cases. This was due to hypocellularity and frequent co-existence of benign ductal elements in the cytological specimens. Core needle biopsy may be a more reliable tool for pre-operative diagnosis of invasive carcinomas of PLI-3.
Conclusions: Predominant panniculitis-like infiltration is associated with unique histopathological and ultrasound features and occurs in a subset of IDC as well as ILC.

P 17
PROGNOSTIC VALUE OF PLASMOCYTOID DENDRITIC CELLS INFILTRATE IN POOR PROGNOSTIC BREAST CARCINOMAS.
M C. Mathieu , F. André, A. Dunant, L. Zelek, M. Spielmann, P.Chomarat, and L. Zitvogel. Departments of Pathology, of Statistics, of Medical Oncology Institut Gustave Roussy, Villejuif, France

Lymph node status is the most important prognostic factor to select high-risk patients for chemotherapy. However, the classical progostic factors did not explain the 30% 10-year survival of patients with a large axillary involvement (> 8N+) without chemotherapy. Our purpose was to determine the prognostic impact of dendritic cells (DC) for this group of patients.
In a retrospective series of 248 patients with > 8 N+ treated at the IGR between 1972 to 1983 without chemotherapy, a group of 37 patients without relapse within 15 years was matched to 37 patients who relapsed and dead within 15 years. The matching was done on number of N+, grade, estrogen receptor status, year of diagnosis, age
Immunohistochemistry staining was used to determine the infiltration of immature DC (CD1a, Immunotech), mature DC (DC-lamp and p55, Schering Plough), plasmocytoid DC (CD 123, Schering Plough). The staining was assessed using a semi-quantitative grading system and consider negative for absent or low infiltrate and positive for intermediate and high infiltrate.
In long terms survivors, 16%, 21%, 37% of tumors contained CD1a, p55, DC-lamp cells. These infiltrates did not

significantly differ from those of matched control tumors. A significant higher infiltrate of plasmocytoid DC (pDC) (CD 123+) was observed in long survivors patients (38%) compared to control group (13%) (p = 0.006). Plasmocytoid DC were localized in the stroma of the tumor. The presence of pDC was not correlated to number of N+, grade and estrogen receptor status.
These results allow us to hypothesize a protective role of plasmocytoid DC infiltrate in this group of high-risk tumors. pDC may produce interferon type I who promote their differentiation into antigen presenting tumor cells and may also hamper tumor cell growth.
Further studies are thus needed to determine the role of pDC and their potentiel therapeutic use.

SENTINEL LYMPH NODE IN BREAST CARCINOMA: THE EXPERIENCE OF DEPARTMENT OF PATHOLOGICAL ANATOMY - BARI

GIARDINA Carmela, TRAVERSI Carmela, D'EREDITA' Giovanni***, PASCAZIO Francesco**, NAPOLI Anna, CIAMPI Luigia, INGRAVALLO Giuseppe, SERIO Gabriella, FIORE Grazia, RUBINI Giuseppe* and MAIORANO Eugenio.
Dipartimento di Anatomia Patologica; *Dipartimento di Radiologia; **Dipartimento di Scienze Chirurgiche e Specialistiche; **U.O. di Chirurgia Generale II - BARI (Italy)

Introduction:Assessment of axillary lymph node status in breast cancer is a collaborative and multidisciplinary work between surgeons and pathologists. Sentinel lymph node (SLN) biopsy can truthfully predict the axillary nodal status in clinically node-negative breast cancer patients. The pathological examinations of SLN typically involves the evaluation of multiple tissue levels and/or keratin in immunohistology.
Purpose: of our study was to estimate the usefulness of SLN examination by evaluation of multiple-level sectioning in SLN and to assess the value of SLN as the only method in nodal staging in breast cancer patients.
Matherial and Methods: From January 1999 to December 2004, 253 patients underwent SLN procedure for breast cancer. The mean age was 56 (range 30-82). The tumors were: 27 Tis (10%), 64 T1b (25%), 105 T1c (41%) and 57 T2 no larger than 3 cm.
A mean number of 1.4 nodes were examined per case for a total of 354 lymph nodes.
SLN was completely and serially examined after wax embedding and E-E staining. Cytokeratin were performed only in case of dubious metastasis. The mean number of histologic section for each SLN was 19,2.
One hundred seventy six of patients also underwent axillary dissection.
Results: SLN revealed in 55 (21.7%) cases metastatic deposits: 38 (69%) macrometastases (> 2 mm) and 17 (31%) micrometastases (<= 2 mm). In 27 (49%) cases SLN was the only metastatic node
In 198 cases SLN was metastasis free; of these patients 121 underwent also axillary dissection; metastases in non sentinel node (NSLN) were detected in 9 of them. The false-negative rate (FNR) was 8%. In five of these cases only one other node was involved, in one case 2 nodes and in three cases 3 nodes. In two cases there were micrometastases.
The comparison between these cases and the other ones, did not show any relevant differences.
Micrometastases in SLN were associated with axillary involvement in 4 (23.5%) cases: in 3 cases one only other node was involved, in one case four nodes.
Macrometastases were associated with axillary involvement in 23 cases (60.5%).
No cases of in situ carcinoma showed metastatic involvement of SLN.
Conclusions Our results confirm the importance of this method to avoid unnecessary axillary dissection in node negative patients and of the extension of metastases in the SLN in relation to the different rate of axillary involvement.

CORRELATIONS BETWEEN NUCLEAR PLEOMORPHISM AND INTRATUMORAL STROMAL COMPONENTS IN INVASIVE DUCTAL CARCINOMA OF THE BREAST

ENACHE Stelian Danut***, PLESEA Iancu Emil*, ZAHARIA Bogdan*, POPESCU Carmen***, GILUSI Mirela***, MUNTEANU Marian****, GHEONEA Dan Ion*, ALEXANDRU Dragos**
*Department of Pathology, **Department of Informatics, University of Medicine and Pharmacy Craiova, Romania
***Department of Pathology, ****Department of Surgery, Universitary Hospital, Craiova, Romania

Introduction, Aims: The authors made a preliminary assessement of possible correlations between the degree of nuclear pleomorphism and the amount of fibrillary components and capillaries of intratumoral stroma in 20 cases with invasive ductal carcinoma of the breast.
Methods: The samples were fixed in buffered formalin and included in paraffin wax. Stromal components were marked silver staining (Gömöri) and antibodies for CD34 Classs I. Five fields with no necrosis were selected randomly using x10 objective, for each case, from the most representative slide for the tumoral pattern. The selected tumoral areas were aquired using a Nikon DN100 digital camera and a LuciaNet 1.16.2 soft. The quantitative determinations were performed, after image calibration, with analySIS Pro 3.2 soft. The 100 selected fields were subdivided in three groups following the degree of nuclear pleomorphism: group I (mild atypia), group II (moderate atypia), group III (severe atypia). The studied parameters for each group were: area occupied by stromal fibrillary elements, area occupied by malignant cells and capillary densities related to tumoral area, to malignant cells area and to stromal fibrillary components.
Results. The group with moderate nuclear atypia on the field area was the most numerous. Stromal fibrillary component ranged between 25,85% in group II, with a good Confidence Level (95%) of 2,93, and 34,9% in group III but with a Confidence Level (95%) of 9,07 (group III). Vascular density related to whole tumoral area was higher in groups with intermediate and severe pleomorphism but with a better Confidence Level (95%) of 5 for group II only. Vascular density related to epithelial malignant cells had an increasing trend from group I to group III, but the latter had a small number of analysed fields and a large range of values, reflected in a Confidence Level (95%) value of 13,23. Vascular density related to stromal fibrillary components had high mean values in the second group (193/mm2) but with large intervals of range in all three groups and especially in the third.
Conclusions. Our preliminary data showed that severe nuclear atypia seems to be present in tumoral areas with an increased amount of stromal fibrillary components No significant correlation was found between the vascular density and the degree of nuclear atypia, despite the relative increasing trend of vascular density related to tumoral parenchyma from areas with mild to those with severe atypia.

P 20
CORRELATIONS BETWEEN TUBULE FORMATION AND INTRATUMORAL STROMAL COMPONENTS IN DUCTAL INVASIVE CARCINOMA OF THE BREAST

***Department of Pathology, ****Department of Surgery, Universitary Hospital, Craiova, Romania

Introduction, Aims. The authors made a preliminary assessement of possible correlations between the amount of fibrillary components and capillary network of intratumoral stroma and the degree of glandular formation in 20 cases of invasive ductal carcinoma of the breast.
Material and Methods. The samples were fixed in buffered formalin and included in paraffin wax. Stromal components were marked silver staining (Gömöri) and antibodies for CD34 Classs I. Five fields with no necrosis were selected randomly using x10 objective, for each case, from the most representative slide for the tumoral pattern. The selected tumoral areas were aquired using a Nikon DN100 digital camera and a LuciaNet 1.16.2 soft. The quantitative determinations were performed, after image calibration, with analySIS Pro 3.2 soft. The 100 selected fields were subdivided in three groups following tubule formation: group I (score 1), group II (score 2), group III (score 3).
The studied parameters for each group were: area occupied by stromal fibrillary elements, area occupied by malignant cells and capillary densities related to tumoral area, to malignant cells area and to stromal fibrillary components.
Results. The group with less than 10% tubule formation (score 3)on the field area was the most numerous, followed by the group with score 2. Fibrilary component represented between 27,6% (group II) and 30% (group III), with a Confidence Level (95%) between 4,52 (group I) and 3,66 (group III). Vascular density related to whole tumoral area ranged between 39/mm2 (group I) and 43/mm2 (group II) with a Confidence Level (95%) between 8,72 (group I) and 4,68 (group III). Vascular density related to epithelial malignant cells was higher (around 66/mm2) in groups II and III, with a Confidence Level (95%) between 8,18 (group II) and 7,1 (group III). Vascular density related to stromal fibrillary components had its highest value in third group (191/mm2) but with large intervals of range in all three groups.
Conclusions. These preliminary data showed no significant variations of the intratumoral stroma and capillaries amounts in different areas of ductal invasive breast carcinomas and also no significant correlation between stromal components variations and the degree of tubule formation.

P 21
FINE NEEDLE ASPIRATION CYTOLOGY AND CORE NEEDLE BIOPSY BY MAMMOTOME IN THE EVALUATION OF NON PALPABLE BREAST LESIONS.

GIARDINA Carmela, INGRAVALLO Giuseppe, GUERRIERI Angela*, CASSANDRO Giovanna*, ZACCARIA Monica, CIMMINO Antonella, NAPOLI Anna and RICCO Rosalia.
Dipartimento di Anatomia Patologica - Università di Bari;*Servizio Autonomo di Radiologia a Indirizzo Senologico - Policlinico di Bari (Italy)

Introduction: Radiologically dubious breast lesions, often requires a second diagnostic step, generally consisting in a FNAC (Fine Needle Aspiration Citology) or in a core biopsy.
Purpose: -to evaluate the distribution of lesions in C1-C5 and B1-B5 categories and the meaning of them in respect to the final diagnosis -to compare the quality assurance of the two methods.
Matherial and Methods: During the last 5 years 1519 patients underwent FNAC under stereotactic or ultrasound guidance (needle 23-24 gauge) and 504 patients had a core needle biopsy by Mammotome (11 gauge). All patients had non palpable breast lesions.
Cytological smears were classified as: C1: 433(28.5%), C2: 590(38.8%), C3: 100 (6.5%), C4: 131(8.6%), C5: 265(17.4%); Mammotome biopsies as: B1: 3(0.6%), B2: 279(55.2%), B3: 36(7.3%), B4: 6(1.2%), B5: 180(36%).
Results: histology was available in 365 cases of cytologies: 46 C1 (10.6%), 36 C2 (6%), 25 C3 (25%), 61 C4 (46%), 147 C5 (55%).
C1 were malignant in 29 (60%), benign in 16 (33%); one case (2%) was diagnosed as atypia.
C2 resulted malignant (false negative) in 19 (52.7%) and benign in 17 (47.2%).
Of C3 lesions 12 (48%) resulted benign and 13 (52%) malignant.
C4 were malignant in 43 cases (70%), benign in 17 (28%); one case was atypia.
C5 were malignant in 144 cases (98%), atypical in 2 cases (1.37%) and benign (false positive) in one case (0.6%).
183 cases of core biopsy had definitive histology: B1: No case had surgery. Of B2: two were benign one was a cancer (liponecrosis on the Mammotome). Of B3: 15 were benign and 2 malignant.
Among B4 cases (4) having surgery: three were atypical, one was a DCIS. A definitive histology was available in 159 of B5 cases. Diagnosis was confirmed in 151 cases (95 in situ and 56 invasive), 7 cases did not show tumor any more and one case (0.6%) was atipical duct hyperplasia.
Sensibility was 71% for FNAC and 97.8% for core biopsy. Specificity was 96.7% for FNAC and 99.6% for core biopsy. PPV of cytology was 99.2 (C5), NPV was 96.8%. PPV of microbiopsy was 99.4% (B5), NPV was 99.6%.
Conclusions: “C” and “B” categories showed a different distribution of lesions with a different meaning in relation to the final diagnosis.
Core biopsy presented a higher specificity, sensibility, PPV and NPV than FNAC; it, in spite of its high rate of inadeguate samples, probably due to the small dimension of the lesions, can be still considered a valid approach for breast lesions.

P 22
STEROID AND HER2 RECEPTORS’ STATUS IN BREAST CARCINOMA – 4493 CASES FROM POPULATION-BASED STUDY IN POLAND

OLSZEWSKI Wlodzimierz, OLSZEWSKI Wojciech, MROZKOWIAK Anna. Department of Pathology, Institute of Oncology, Warsaw, on behalf of HER2 Polish Working Group

The study is a part of national HER2 screening project in Poland, which started in 2002 and continues. Until April 2004, 11 557 cases of invasive breast carcinoma cases were included.
Breast cancer diagnostics, aside from well-established prognostic and predictive factors (e.g. histological type, histological grade, pTNM, lymph node status) employs the assessment of other parameters in order to make pathological report sufficient for oncological management. These parameters are estrogen (ER), progesterone (PGR) and HER2 status.
The aim of the study was the description of dependency between HER2 and estrogen/progesterone status.
Materials and methods: The study was performed on 4493 non-selected cases of breast cancer. The data originated from 14 oncological centers in Poland and were collected between April 2003 and March 2004. The estrogen, progesterone and HER2 receptor status were evaluated immunohistochemically (IHC).
HER2 IHC results were classed into 4 groups (DAKO criteria system: 0,1+, 2+, 3+). The cases classed as 0, 1+ and 2+ were considered to have negative HER2 status. The remaining cases (3+) were clinically HER2-positive.

Steroid receptors positive cases were grouped by presence of 10% or more positively stained cancer nuclei, regardless of strength of the stain. ER/PGR status was stated positive, when the presence of ER/PGR receptors was detected. A mixed group consisted of cases, in which one steroid hormone was present.
Results: The group of cases described by IHC as "0", "1+" and "2+" showed the presence of at least on steroid receptor expression in more than two thirds of all cases (71%, 80,1% and 79,1%, respectively). Among the tumors exhibiting very strong HER2 receptor expression (3+), 48,2% were steroid receptors negative.

Discussion: The results indicate the difference between the expression of estrogen and progesterone receptors and HER2 status. Results suggest necessity of independent evaluation of both steroid receptors and HER2 status. The probability of existence of positive steroid receptor status in clinically HER2-positive group is much lower, than in clinically HER2-negative groups (0, 1+, 2+).

P 23
THE USE OF FISH METHOD IN HER2 EVALUATION ALGORITHM IN BREAST CANCER
MROZKOWIAK Anna, OLSZEWSKI Wojciech, PIASCIK Agata, SZEWSKI Wlodzimierz, Department of Pathology, Institute of Oncology, Warsaw

There are two main techniques of evaluation of HER2 status: immunohistochemistry (IHC) for the protein expression and fluorescence in situ hybridisation (FISH) for amplification of HER2 gene.
During the year 2004, in our Department of Pathology, 1409 consecutive cases of invasive breast carcinoma were diagnosed and included in the study. Among them 365 were described by IHC as 2+. According to the algorithm of the diagnostic procedure, those cases were additionally examined with FISH method.
The aim of the study was to compare the results obtained by IHC and FISH methods in determination of HER2 status in breast cancer.
Materials and Methods: The material originated from 414 patients operated in Institute of Oncology in Warsaw. FISH method was preformed in every 2+ (365) case and, in randomly selected cancers exhibiting 0/1+ (14 cases) and 3+ (35 cases) IHC stain. IHC was performed with DAKO HercepTest. The results were classed into 4 groups, accordingly to the four-tier DAKO criteria system (0,1+, 2+, 3+). FISH evaluation was performed with PathVysion (Abbott) reagents. The results were divided into three groups: NA - no amplification, LA - low amplification and HA - high amplification. The number of copies of chromosome 17 was also assessed.
Over 90% of cases described by IHC as 3+ exhibited amplification of HER2/neu gene. The majority of cases classed by IHC as 2+ were negative by FISH (74,5%) or showed no amplification of HER2/neu gene combined with aneuploidy of chromosome 17 (6,6%). Almost one fifth of IHC 2+ tumours presented gene amplification (18,9%). All cases described by IHC as 0/1+ were HER2-negative by FISH.
IHC is well-established method of assessing HER2 status in breast cancer. Nonetheless, group of cases described as 2+ should be additionally examined using FISH. The results obtained by the latter method are more reliable. With FISH method twenty percent of clinically negative 2+ group are potential beneficiates from Herceptin therapy.

P 24
EVALUATION OF C-ERB-B2/HER-2/NEU EXPRESSION IN INFILTRATING BREAST CARCINOMA IN A GREEK POPULATION COHORT OF 1100 CASES BY IMMUNOHISTOCHEMISTRY AND CHROMOGENIC IN SITU HYBRIDIZATION. EARLY DATA OF THE GREEK MULTICENTER STUDY.

Dept. of Pathology, Alexandra General Hospital, Athens,Greece, 6. Dept. of Pathology, Theageneio Cancer Hospital,Thessaloniki,Greece, 7. Dept. of Pathology, A.Fleming General Hospital, Athens,Greece

OBJECTIVE: To evaluate the expression of c-erb-B2/HER2/neu in infiltrating breast carcinomas in Greek patients by immunohistochemistry, to compare the reactivity against HER2 of three different antibodies and to correlate HER2 expression levels to its gene amplification by CISH.
MATERIALS AND METHODS: In this study, 1100 specimens of infiltrating breast carcinoma (ductal and lobular) were analysed immunohistochemically, using three different antibodies against HER2 , AO485 (DAKO), TAB-250 (Zymed) and CB11 (Biogenex). Immunostaining was evaluated as membranous, and the intensity was graded 0 (negative), 1+ (weak), 2+ (moderate) and 3+ (strong). Cases been evaluated as 1+ and 2+ in IHC were analysed by CISH (Zymed kit) to determine the presence or not of HER2 gene amplification. Gene amplification was graded as negative (2-5 gene copies/nucleus), low amplification (6-10 gene copies/nucleus) and high amplification (>10 gene copies/nucleus).
RESULTS AND CONCLUSIONS:
1. By using the commonly used AO485 antibody, 22.81% of the tumors were 3+, 16.50% showed 2+ and 27.66% exhibited 1+ HER2 reactivity.
2. There was discordance in evaluating HER2 expression among the three different antibodies, especially in the cases that have been graded as 1+ and 2+.
3. Concerning CISH, among 1+ IHC cases, 92.59% had no gene amplification,4.93% displayed low gene amplification and 2.47% high gene amplification. On the other hand, 2+ cases showed low gene amplification in 11.69%, high gene amplification in 11.69% and no amplification in 76.62% of the cases. We conclude that CISH is a highly accurate method in evaluating HER2 gene status, more sensitive than IHC and should be used not only in 2+ IHC cases but also in 1+ IHC ones.

Introduction

The aim of this study was to analyse the presence of gene amplification and/or overexpression of the HER-2/neu (c-erbB-2) proto-oncogene in invasive breast carcinomas. Furthermore, to ascertain the ability of our laboratory to create specific for HER-2/neu probe and test it versus the commercially available assay (Abbott ¨C Vysis, Downers Grove, IL).
Materials and Methods
Forty cases of invasive breast carcinomas were evaluated by immunohistochemistry (IHC). Interpreted 2+ borderline reactions were considered inconclusive and referred to FISH analysis (Guidelines of HER-2/neu, 2003). The amplification of the HER-2/neu gene was determined by dual-colour FISH using the c-erbB-2 specific probe (SpectrumOrange) and the chromosome 17 centromere specific probe (SpectrumGreen) from the commercially available kit (Abbott ¨C Vysis). FISH probe, generated by our team, from BAC clone, specific for HER-2/neu gene, was also tested and both, the Vysis assay versus ours were compared in order to evaluate their efficacy.
Results
According to the scoring criteria, HER-2/neu to chromosome 17 ratio < 2 signifies non amplification of the HER-2/neu gene, whereas HER-2/CEP17 ¡Ý 2 is considered amplified.
From the studied cases 31 of 40 (77.5%), showed no amplification of the c-erbB-2 gene and 4 (10%) demonstrated amplified signals after FISH examination. The test failed in the remaining five cases (12.5%) because the intensity of the hybridization signals was too faint to be counted. Both the generated probe of HER-2/neu gene and the commercially available probe (Abbott ¨C Vysis) showed the same results with the same intensity and hybridization efficacy in FISH analysis.
Discussion
Despite the tendency of IHC interpreted 2+ cases to present HER-2/neu amplification, a high percentage of non-amplified cases (77.5%) was observed. Although, a possible failure in IHC cannot be excluded due to non-specific staining and the subjective nature of interpretation that led to misclassification, further number of new cases will allow statistical analysis to be performed for final conclusions.

v Medical Research Institute, Alexandria University; Alexandria – Egypt

Introduction: HER2/neu protein has garnered a great deal of interest in the popular media. However, it has long been known amongst pathologists and oncologists for its potential role as a tumor and prognostic marker. This protein exists on the surface of epithelial cells and functions in the normal cell as a receptor for a cellular growth factor. Aim of the study: is to determine the association of HER-2/neu and p53 as well as hormonal receptor status with conventional common pathologic parameters in a series of Egyptian women with invasive ductal carcinoma of breast. Methods: expression of HER-2/neu and p53 was examined by immunohistochemistry in samples of breast tissue from 50 patients with invasive ductal carcinoma and their significance for prognosis was analyzed. Results: Of the 50 carcinoma tissue samples, 26% were positive for HER2 over-expression. In the present study there was a high significant association between HER-2 over expression and the accumulation of nuclear p53 (p=0.0017) also there was an inverse significant association with ER (p=0.0001) and PR status (p=0.0003). There was a significant association between HER-2 over expression and the increased size of tumor (p=0.0115) as well as the high grade tumors (p=0.0001). Meanwhile no significant association was there as regard number of the invaded lymph nodes, grade of tumor necrosis and menopausal status. Conclusion: The study had indicated that Her-2/neu may be a powerful predictor of poor prognosis as it's over expression was strongly directly correlated with p53 nuclear accumulation, tumor size, tumor grade and inversely correlated with hormonal receptors status, of breast carcinoma. Meanwhile; no significant associated for number of invaded lymph nodes and the menopausal status.
Key words: Immunohistochemistry, Her-2/neu, p53, hormone receptors, clinicopathological prognostic parameters & breast cancer

P 27
COMMON EXPRESSION OF EGFR (HER-1) IN METAPLASTIC BREAST CARCINOMAS: POTENTIAL RELEVANCE TO ADJUVANT THERAPY WITH EGFR-INHIBITORS?
LEIBL Sebastian, MD, MOINFAR Farid, MD
Department of Pathology, Medical University of Graz, Austria

Metaplastic carcinomas (MCs) of the breast rarely express steroid receptors and Her-2, which minimizes the options for adjuvant therapy in patients with advanced disease.
We immunohistochemically assessed the expression of steroid receptors and 4 members of the EGFR/Her-family (EGFR/Her-1, Her-2, Her-3 and Her-4) in a collective of 20 MCs (8 MCs with heterologous elements, 7 spindle cell MCs, 4 carcinosarcomas and 1 matrix producing carcinoma). 14 out of 20 MCs (70%) showed positive reactions for EGFR (Her-1). Among these cases, 1+, 2+ and 3+ reactivity was observed in 2, 4 and 8 cases, respectively. Her-2 was only present in one MC with 1+ reactivity. Her-3 (1+ reactivity), Her-4 (2+ reactivity) and Androgen receptors (2+ reactivity) were also expressed by one tumor. Estrogen and Progesterone receptors (3+ reactivity each) were only detected in the epithelial component of 2 carcinosarcoma-type MCs.
Compared to collectives of not otherwise specified (NOS) breast carcinomas investigated in previous studies, the MCs in our study expressed EGFR considerably more frequently. Therefore, we conclude that they represent a promising subject for future studies (especially molecular analyses to detect specific mutations in EGFR-exons) on EGFR expression in breast carcinomas. Androgen receptor targeted therapy or anti-Her 2 therapy do not seem to be an option for adjuvant treatment of MCs according to our results, but patients suffering from this aggressive variant of breast carcinoma might benefit from treatment with protein kinase inhibitors such as gefitinib or cetuximab.

Introduction: The study of lymphatic vessels and lymphatic-derived tumours is frequently complex, due to common characteristics of morphological features between blood and lymphatic endothelial cells, as well as to the lack of specific lymphatic endothelial markers. Prox-1, a homebox gene cloned by homology with the Drosophila gene prospero, that codifies a nuclear transcription factor that plays a major role during embryonic lymphangiogenesis and is supposed to be a useful marker to differentiate lymphatic from blood endothelial cells. Purpose: We studied a series of breast carcinomas in order to observe the specificity of this marker in lymphatic vessels. Methods: Tissue–array from formalin-fixed and paraffin-embedded samples of 116 invasive ductal carcinomas recovered from the Pathology files of IPATIMUP, Porto, Portugal were immunostained with a primary antibody raised against Prox-1 (diluted 1:133; Research Diagnostics, Inc., Flanders, NJ, USA). Results: Prox-1 immunostaining highlighted the lymphatic vessels, and was also detected in the cytoplasm and nuclei of neoplastic cells in 94.8% (110/116) of the cases. Conclusion: Our results suggest that invasive breast carcinoma cells can express Prox-1. Further studies are needed to understand the real meaning of this finding.

P 29

UNUSUAL CYTOPLASMIC IMMUNOPOSITIVITY FOR MIB1 IN BREAST CARCINOMA

CHARFI Lamia (1), PALLUD Claude (1), CHAMPY Odile (1), BELICHARD Catherine (2), GUINEBRETIERE Jean Marc (1)
(1) Department of pathology (2) Department of surgery. Rene Huguenin centre. 35 Dailly street. 92210 Saint Cloud. France

INTRODUCTION:
Tumour cell proliferation can be assessed by a large number of antibodies: Ki-67, PCNA, KiS1… MIB1, the most commonly used, is a monoclonal antibody raised against the recombinant part of the Ki67 antigen. It reacts with cells in the late G1, S, G2 and M phases of the cell cycle and only stains nuclei with various intensity.
We report herein 2 cases of breast carcinoma with cytoplasmic immunoreactivity for MIB1.
POPULATION:
One occurred in a 62 year-old women, a 12 cm invasive ductal carcinoma, histoprognostic SBR grade 3. The second occurred in a 54 year-old women, a 23mm invasive ductal carcinoma, histoprognostic SBR grade 1. None of these patients received preoperative treatment.
Immunohistochemistry was done with MIB1 (Dako) after antigen retrieval (water bath) with LSAB kit and DAB revelation. The test was repeated at different times and with different blocks of the fixed tumour (Formaline, AFA) with the same results. The others immunohistochemistry (RE, RP, HER) didn't shown abnormal staining (nuclear staining for RE and RP, cytoplasmic staining for HER).
DISCUSSION:
In 1995, Hirokawa and al, first reported the cytoplasmic immunoreactivity for MIB1 in hyalinizing trabecular adenoma of the thyroid. Recently, two reports showed this unusual staining in atypical pleomorphic adenoma of the salivary gland and sclerosing haemangioma of the lung. To the best of our knowledge, this immunoreactivity hasn't been reported in breast tumours. Significance of this unusual staining is still unknown. There was no correlation between the properties of the cells stained and the mitotic count which suggests a cross-reaction of this immunostaining.
CONCLUSION:
Pathologists should be aware of this unusual MIB1 cytoplasmic staining. This pattern of reactivity of MIB1 in breast carcinoma may be a result of cross-reaction of the antibody.

P 30

IGF-II MRNA EXPRESSION IN BREAST CANCER (BC) TISSUES AND CLINICAL OUTCOME.

C.Giani, P.Fierabracci, E.Giustarini, D.Campani*, K.Cullen. Dipartimento di Endocrinologia e Metabolismo, Università di Pisa. *Dipartimento di Oncologia, Università di Pisa. V.T. Lombardi Cancer Research Center Georgetown University, Washington Dc, USA.

Insuline like growth factor II (IGF II) is an important regulator of neoplastic growth and it is generally expressed in stroma of BC tissues. Estrogen and Progesterone receptor (ER, PR) are considered a good prognostic predictors in BC. The aim of the study was to evaluate the impact of IGF II mRNA expression in clinical outcome in a large series of BC. The study group included 75 women (mean age +/- SD= 53.3+/-15.6 yr) submitted to radical mastectomy for ductal infiltrating breast carcinoma. The BC specimens was assessed for IGF II mRNA using in situ hybridization method and ER and PR by immunohistochemistry. Five years clinical follow-up was available in 65/79 BC (82.3%) and 46/65 (70.8%) were still alive and relapse free. ER+ was found in 39/65 (60%), PR + in 30/65 (46.2%) and stromal IGF II mRNA expression (IGF II +) in 33/65 (50.8%). 22/65 (33.8%) BC were IGF II+ ER+ and 19/65 (29.2%) IGF II+ PR+. No relationship was found between ER, PR, IGF II separately examined and clinical outcome. The better 5 yr survival was found in ER+ IGF II+ (16/22: 72.7%) and IGF II+ PR+ BC (14/19: 73.7%) and in contrast, the worse survival was found in IGF II+ ER- (6/11: 54.5%) and IGF II+ PR- (57.1%) groups. (p=0.006, p=0.02, respectively). These data indicate that stromal IGF II may be considered a new important predictive factor in BC and suggest that this growth factor may have a role in both differentiation or proliferation of BC cells

P 31

CORRELATION BETWEEN CYCLOOXYGENASE-2 EXPRESSION AND CELL PROLIFERATION IN INVASIVE DUCTAL BREAST CANCER

ŠARÈEVIÆ Božena,MILAS Ivan,KUJUNDŽIÆ-TILJAK Mirjana,MARUNICA Jelena
University Hospital for Tumours, Depart.of Pathology Medical School

INTRODUCTION:Cyclooxigenase-2(COX-2)is overexpressed in breast cancer and may have a role in tumor development and progression.There has been inconsistency in the literature regarding the precise significance of this.Some studies have found no clinicopathological relevance at all, while others have concluded Cox-2 expression is an important biomarker in invasive disease, correlating with poor prognosis features.The aim of this study was to determine the relationships between Cox-2 expression and cell proliferation in breast cancer, and to correlate the expression of this enzyme with classic clinicopathological parameters.
MATERIAL AND METHODS:We retrospectively analyzed 150 breast tumors in paraffin embeded tissue and from medical records, obtained clinicopathological data.Regarding to tumor grade we had three groups of patients and each group consisted of 50 patients.Cox-2 expression was investigated by immunohistochemistry using monoclonal antibody. Immunohistochemistry was done following protocol on DAKO TechMate Horizon automated immunostainer.S-phase fraction (SPF)determined by flow cytometry used as a marker of cell proliferation.
RESULTS:Cox-2 expression was detected in 86%of all tumors studied.The preliminary results have shown that Cox-2 protein expression significantly correlates only with tumor

grade but not with SPF.We have found statistically significant difference in expression of Cox-2 in different grade of tumors (p=0.02).Comparing different grade with SPF we found statistically significant higher SPF in poorly differentiated tumors (p<0.001).
CONCLUSIONS:We have confirmed that Cox-2 expression does occur in invasive breast ductal cancer and is associated with tumor grade.It remains to be investigated whether treatment with selective inhibitors of Cox-2 may be an additional therapeutic option for patients with breast cancer.

P 32
IMMUNOHISTOCHEMICAL ANALYSIS OF RET AND ITS LIGAND GDNF IN 139 CASES OF BREAST CANCER

Gordillo, J.; Moreno, J.; San José, C.; Limón, M. and Pichel, J.G.*
Department of Pathology and Laboratory of Investigation, Hospital de Mérida, Mérida, Spain. *IBMCC/CSIC. Centro de Investigación del Cáncer, Salamanca. Spain.

Introduction: The RET proto-oncogene tyrosine kinase receptor is activated by a ligand complex comprising glial cell line-derived neurotrophic factor (GDNF) and GDNF family receptor alpha1 (GFRalpha1). They are expressed in multiple organs during development and in some types of human tumors in adults. In this study we evaluated the expression of RET, and GDNF in different types of breast cancer.
Material and Methods: RET, expression was analyzed in samples of formalin-fixed tissues from tumoral zone, from 139 patients with different types of breast cancer: 109 IDC; 5 IC; 7 ILC; 6 mucinous carcimomas; 4 medullary carcinomas; 3 papillary carcinomas 2 tubular carcinomas and others (3) using immunohistochemical methods.
Results: A total of 98/137 (71,6%) of breast tumors showed citoplasmic immunoreactivity for RET, and 130/138 (71,6%) for GDNF. By statistical analysis based on 111 months follow up showed that RET expression was associated with less tendency to the regional lymph nodes metastases (p<0,0001); less tendency to relapse (p<0,004); increase of overall survival (p<0,0004); There was no statistically significant correlation of RET or GDNF expression with the histological grade, microscopic type, size or stage. Those findings were not supported by multivariant analysis.
Conclusions: We found that RET and its GDNF/GFRalpha1 ligand complex were expressed in normal breast tissues and in a high percentage of different types of breast tumors using immunohistochemical methods. The presence of RET did not show clear association with any particular light microscopic growth pattern or special tumor subtype, but interestingly, this expression was associated with less tendency to the lymph nodes metastases and increase of overall survival. In summary RET determination by immunohistochemical analysis could be used as a prognostic factor in breast cancer.

P 33
PROGNOSTIC VALUE OF MIB1 PROLIFERATION INDEX AND C-ERBB2 IN PATIENTS WITH STAGE II BREAST CANCER AND LYMPH NODE INVOLVEMENT

Soriano P1, Vicente F2, Guerrero D3, Miranda C2, Mart¨ªnez-Peñuela JM4, C¨®rdoba A4, B¨¦rtolo C3, Caballero MC4, Amat I4, Lera JM2
1Servicio Cirug¨ªa General. Fundaci¨®n Hospital de Calahorra. 2Servicio de Cirug¨ªa General y Digestiva, Hospital de Navarra. Servicio Navarro de Salud. 3Centro de Investigaci¨®n Biom¨¦dica, Servicio Navarro de Salud 4Servicio de Anatom¨ªa Patol¨®gica, Hospital de Navarra. Servicio Navarro de Salud.

INTRODUCTION: Breast cancer is the first leading cause of cancer in women from Spain, and its incidente rates have increased in the recent last years. Study of prognostic value of different factors in breast cancer patients with lymph node involvement can identify subgroups of patients with high risk for more effective clinical management. C-erbB2 that encodes HER2/ Neu protein (p185HER2), and MIB1 proliferation index are useful parameters to assess this issue.
PURPOSE: The goal of this study was to evaluate if the prognostic role of c-erbB2 and MIB-1 proliferation index, p53, S-phase, were dependent or independently useful to characterise more aggressive breast tumors.
PATIENTS AND METHODS: 87 positive-node infiltrating breast cancer patients classified as stage II (T2N1). C-erbB2, p53, MIB-1 proliferation index, estrogen (ER) and progesteron receptors (PR) were determined immunohistochemically by assigning a score with an analysis image software. C-erbB2 membrane expression was graded negative, indeterminate, 1+, 2+, 3+ when ¡Ý5%, 20%-30%, 30%-50%, and more than 50% of cells were stained, respectively. Comparisons in distributions were analyzed by ANOVA and Pearson tests, using SPSS. Differences in disease-free and overall survival were evaluated by using the log-rank test.
RESULTS: 48.3% of the patients resulted to be negative for c-erbB2, whereas 12.6%, 18.4%, 15% and 5.7% of the patients were indeterminate, 1+, 2+ and 3+, respectively. C-erbB2 immunostaining was correlated to node involvement and number of positive nodes (P= 0.022, P=0.023, respectively), tumor size (P= 0.037) and PR (P=0.03). There are no correlations between c-erbB2 immunostaining, age, ploidy, MIB-1 and ER. The median follow-up time was 90 months. Disease-free survival is inversely correlated to c-erbB2 immunostaining (P= 0.027), number of positive nodes (P=0.037) and tumor size (P=0.042), being nearly significant for MIB1 (p=0.09). Predictive value for c-erbB2 was confirmed with a relative risk of 2.5 times in multivariate analysis.
CONCLUSIONS: 1. Higher proliferation index is a bad prognosis factor in patients with infiltrating breast cancer patients, stage II tumors and lymph node involvement. 2. C-erbB2 oncogene is an indicator of bad prognosis in these patients. 3. Patients that were negative for proliferation index and C-erb-B2 presented longer overall survival.

P 34
PLATELET-DERIVED GROWTH FACTOR RECEPTOR-ALPHA (PDGFR-ALPHA) EXPRESSION IN INVASIVE BREAST CARCINOMAS

Ines Carvalho, BSc1,2; Fernanda Milanezi, MD1,2; Albino Martins, BSc2; Rui Reis, MD PhD2; Fernando Schmitt, MD PhD1,3
1IPATIMUP, Institute of Molecular Pathology and Immunology of Porto University, Porto, Portugal
2 School of Health Sciences, University of Minho, Braga, Portugal
3 Medical Faculty of Porto University, Porto, Portugal

Introduction: Receptor tyrosine kinases have been extensively studied due to their frequently abnormal activation in the development and progression of many human cancers. Platelet-derived growth factor receptors (PDGFRs) are receptors with intrinsic tyrosine kinase activity that regulate several functions in normal cells and are widely expressed in a variety of malignancies. After the demonstration that GISTs without c-kit mutations harbour PDGFR-alpha activating mutations, and that it is also a therapeutic target for imatinib mesylate, the interest for this receptor increased considerably. Since breast cancer is one of the most frequent neoplasia in women worldwide, and there are only one study reporting PDGFR-alpha expression in breast carcinomas, the aim of this work was to investigate the potential meaning of PDGFR-alpha expression in invasive mammary carcinomas.

Methods: We used immunohistochemistry to detect PDGFR-alpha overexpression on a series of 181 formalin-fixed paraffin-embedded invasive ductal breast carcinomas and associated its expression with known prognostic factors. We also performed PCR-SSCP and direct sequencing in order to screen for PDGFR-alpha gene mutations.
Results: PDGFR-alpha expression was demonstrated in 39.2% of the breast carcinomas and showed an association with lymph node metastasis (p=0.0079), HER-2 expression (p=0.0265) and Bcl2 expression (p=0.0121). It was also found a correlation with PDGF-A ligand expression (p=0.0194). Screening for mutations revealed the presence of the 2500 A>G and 2529 T>A alterations in exon 18, the 2472 C>T (exon 18) and 1701 G>A (exon 12) missense mutations, and also the presence of the intronic insertion IVS17-50insA at exon 18 in all sequenced cases. These mutations did not correlate with PDGFR-alpha expression.
Conclusions: PDGFR-alpha is expressed in invasive breast carcinomas and is associated with biological aggressiveness factors. The mutations found did not show any correlation with PDGFR-alpha expression.

P 35
CA-125 IS A USEFUL TUMOURMARKER IN BRCA2 ASSOCIATED BREASTCANCER AND IN POORLY DIFFERENTIATED SPORADIC TUMOURS.
L. Luts 3, H. Olsson 1,2, A. Borg 1, N. Loman 1.
From Departments of 1) Oncology, 2) Cancer Epidemiology, and 3) Pathology, University Hospital, Lund, Sweden.

CA-125 is a useful tumour marker for ovarian cancer. As such the marker is not specific for ovarian cancer. A number of other tumours diseases and conditions have been found to be related to elevated plasma levels of CA-125. In breast cancer overall 5-80% (median 30%) have been found to be positive for CA-125.
In twenty one consecutive patients with BRCA2 germ line mutations the breast tumours were stained for Ca-125 immunoreactivity. 8/21 BRCA2 tumours showed moderate to strong immunostaining and in the sporadic tumours 8/17 showed similar immunostaining. 5/8 BRCA2 tumours where classified as histological grade 3 tumours while all of the the tumours that showed positive immunoreactivity for CA-125 where classified as histological grade 3 tumours. Two of the BRCA2 patients had a recurrence and the tumour recurrence correlated with an elevation of plasma Ca-125. The elevation occurred before metastatic symtoms. Further one of the patients progressed twice while first responding favourably to endocrine therapy and later to chemotherapy with the tumour status strongly correlated with Ca-125 levels.
Immunohistochemistry and serum assay were used to detect CA-125.
Tumour cells diplaying Ca-125 were demonstrated in eight of twenty one BRCA2 tumours. Six of these tumors were ductal carcinomas and two were lobular carcinomas. Five of these eight tumors expressed both estrogen –and progesterone receptor immunoreactivity. Three men with breast cancer were included and none of them expressed CA-125 immunoreactivity in their breast tumours.
In the sporadic tumours Ca-125 immunoreactivity were demonstrated in eight of seventeen tumours. All of these tumors were ductal carcinomas and the tumours were poorly differentiated and classified as histological grade 3 tumours. Six of these eight tumors were negative for both estrogen – and progesterone receptor immunoreactivity.
The data demonstrate that Ca-125 is a useful early tumour marker in a subset of breast cancer patients associated with BRCA2 mutations and possibly also in other high grade tumours in the breast.
This knowledge is of importance as Ca-125 is used to screen for ovarian tumours in BRCA1/2 patients. The finding that Ca-125 is an early marker of breast tumours in a subset of BRCA2 cases lends hope that this marker also could be used in therapeutic settings.

P 36
ESTROGEN RECEPTOR (ER) NEGATIVE INVASIVE BREAST CARCINOMAS FREQUENTLY EXPRESS MYOEPITHELIAL MARKERS
Emanuele Dainese, Selenia Casnedi, Donata Micello, Cristina Riva, Carlo Capella, Fausto Sessa
Department of Pathology, University of Insubria, Varese, Italy

Introduction: Luminal, basal and myoepithelial cell differentiation have been reported in ductal breast cancer (BC), using several markers, including cytokeratins (CKs) 5, 14, 8, 18, actin, S100, and vimentin. Luminal type BCs are associated with ER and PgR positivity and a good prognosis. Few studies documented basal and myoepithelial markers expression in relationship to p53 positivity and tumor grade. The aim of our study was to investigate the expression of basal (CK5 and CK14) and luminal (CK8 and CK18) cytokeratins in high-grade p53+, ER- and PR- BCs, and to correlate them with the expression of myoepithelial markers (a-smooth muscle actin, vimentin and S100).
Design: Formalin-fixed, paraffin-embedded sections from 60 selected p53+, ER-, PgR-, c-erb-B2-negative BCs, including 56 NOS invasive ductal and 4 medullary carcinomas, were immunostained for CK14 (Novocastra), CK5 (Novocastra), CK8 (Dako), CK18 (Novocastra), a-smooth muscle actin (Sigma), S100 (Dako) and vimentin (Dako).
Results: All cases were G3, ER-, PR-, c-erb-B2-negative, p53-positive BCs. The mean age was 59 years ranging from 29 to 87. Twenty of sixty cases (33%) had lymph node metastases (15 N1 and 5 N2). The most common morphological features were the presence of large sheets of cells sometimes with spindle appearance, festoon-like pattern, pushing margins and occasional large central acellular zones, represented by foci of tissue infarction and deposits of collagenous or hyaline-like material. The proliferative index (Ki-67) and p53 expression were high in all cases (mean percentage of 63% and 81% respectively). Forty-four of 60 (73%) BCs were positive for S100, 31/60 (52%) for vimentin, 5/60 (8%) for a-smooth muscle actin, 43/60 (72%) for CK5, 20/60 (33%) for CK14, 55/60 (92%) for CK8 and 31/60 (52%) for CK18. Coexpression of basal and luminal CKs was seen in 43 cases (72%); 39 of these cases were positive for at least a myoepithelial marker.
Conclusions: Our study suggests that a subset of high grade ER/PR/c-erb-B2- and p53+ BCs frequently displays an intermediate luminal/basal phenotype (immunoreactive both for basal and luminal CKs), often coexpressing myoepithelial markers. This particular phenotype could be the result of a peculiar pathway of breast carcinogenesis of great clinical relevance because of the high rate of lymph node metastasis. The results suggest that p53+, ER-, BCs should be investigated for the expression of basal and myoepithelial markers.

P 37
PROGNOSTIC SIGNIFICANCE OF TOPOISOMERASE II ALPHA IN BREAST CANCER PATIENTS
OZTURK Figen, OZKAN Metin, SOYUER Isin, SOYUER Serdar
Department of Pathology, Medical Oncology and Radiation Oncology,
Medical Faculty of Erciyes University

Introduction: There are many studies that show tumors overexpressing TOPO II have better response to anthracyclines. In our study we aimed to show the expression

of this enzyme at high and low risk breast cancer patients and the effect of this activity on prognosis of this disease.
Material and Methods: Thirty-seven operable breast cancer patients including 21 high risk and 16 low risk who were followed at Erciyes University Medical Oncology clinic between March 1999 and June 2003 were enrolled into this study. High risk patients received adjuvant chemotherapy consisting taxane and anthracycline and radiotherapy, 3 of the low risk patients received no adjuvant therapy, 4 adjuvant hormonal therapy, 9 adjuvant CT. Only one patient received RT in this group. TOPO II alpha expression was categorized in 4 groups according to cell numbers showing nuclear staining, 35% and higher expression (3+ and 4+ nuclear staining) was accepted as positive and others negative.
Results: Median age of all patients was 42 years (range 23-78). Histopathologically 32 patients(86.5%) were diagnosed as IDC. Two patients were stage I, 15 stage II, 20 stage III. Median follow-up time was 32.5 months (range 18-64). TOPO II alpha expression was positive in 45.9% of the patients. Ten patients (58.8%) among 17 patients showing TOPO II expression had also HER-2 expression. There was statistically significant relationship between TOPO II alpha expression and tumor grade (p=0.015), diameter (p=0.019), lymph node positivity (p=0.001), increased number of lymph nodes (p=0.033) and age (p=0.039). There was statistically significant relationship between disease free survival (DFS) and lymph node positivity and increased number of lymph nodes (p=0.04 and 0.03, respectively), however no significant relation was detected between TOPO II alpha expression and DFS (P=0.14). Discussion: TOPO II alpha expression seemed to be related to the aggressive behavior of the tumor in this study, however there is a need to confirm these findings in larger studies. High expression of TOPO II alpha and HER-2 in this group may be due to many factors, and this may also show that tumor behavior and anthracycline response may be different in our patients compared to other group of patients.

P 38
EXPRESSION OF CD10 IN STROMAL FIBROBLASTS IN INVASIVE BREAST CANCER
1 - Nurija Bilalovic, MD PhD;
2 - Semir Vranic MD;
1 - Department of Pathology, Sarajevo University School of Medicine, Sarajevo, Bosnia and Herzegovina
2 - Sarajevo University School of Medicine, Sarajevo, Bosnia and Herzegovina

Aim: To explore presence and prognostic value of CD10 in stromal fibroblasts in invasive breast cancer and its correlation with other basic histopathological parameters, hormonal status (Estrogen receptor, ER and Progesterone receptor, PR), bcl-2 and cyclin D1.
Material and methods: Medical records of 46 patients, diagnosed in 1998, from Central Database of Institute of Oncology, Clinical Center University of Sarajevo were analysed. The median follow-up was 67 months (range: 4-103 months). Routine histopathological evaluation was performed for 46 formalin fixed and paraffin embedded tissue samples. For immunohistochemical staining we used monoclonal antibodies for ER, PR, bcl-2, cyclin D1 and CD10.
Results: Twenty three (50%) out of 46 samples were negative for CD10; 9 (19.6%) showed expression 1, 8 (17.4%) expression 2 and 6 (13%) expression 3. Expression of CD10 inversely correlated only with ER (p=0.05)) and no significant correlation was found with other parameters analysed in our study. Patients with higher CD10 expression had shorter overall survival but not relapse-free survival (p=0.006). Cox regression analysis for overall survival (OS) showed that lymph node status, tumor size, age, bcl-2 and CD10 expressions were independent prognostic factors (p=0.009, 0.029, 0.019, 0.034 and 0.049, respectively).
Conclusion. Expression of CD10 is associated with worse disease outcome in invasive breast cancer.
Key words: Breast cancer, CD10, stromal fibroblasts, prognostic factors.

P 39
HIF-1 ALPHA AND CA IX : TWO PROGNOSTIC FACTORS IN INVASIVE BREAST CARCINOMA
Cynthia Trastour1, Francette Ettore2, Emmanuel Benizri1, Alain Ramaioli3, André Bongain4, Jacques Pouysségur1, and Edurne Berra1
1Institute of Signaling, Developmental Biology and Cancer Research, CNRS UMR-6543, Centre Antoine Lacassagne, 33 Avenue Valombrose, 06189, Nice, France.
2Department of Pathology, Centre Antoine Lacassagne.
3Department of Biostatistics, Centre Antoine Lacassagne.
4Department of Gynecology-Obstetrics, University Archet II Hospital, 151 route St-Antoine de Ginestière, BP 3079 06202 cedex 3 Nice, France.

Introduction : Hypoxia inducible factor 1 (HIF-1) is a key regulator of oxygen homeostasis and controls the expression of several genes involved in various aspects of cancer progression (metabolic adaptation, angiogenesis and cell survival). Among those genes, ca9 (carbonic anhydrase 9) plays a role in extra-cellular pH regulation. HIF-1a, one of the 2 subunits of HIF-1 is stabilized by hypoxia.
We retrospectively studied the impact of HIF-1a and CA IX expressions on the outcome of patients with breast cancer.
Methods : Immunohistochemical stainings of HIF-1a and CA IX were evaluated in an unselected cohort of 132 patients with invasive breast carcinoma. The follow-up was more than 10 years. We examined overall survival, distant metastasis-free and disease-free survivals by univariate and multivariate analyses. Correlations to clinicopathological parameters (tumour size, nodal status, histological grade, hormonal receptors and carcinoma in situ associated with the invasive tumour) were performed using Chi-square test. The level of significance was 5% (P<0.05).
Results: No significant correlation exists between tumour size or nodal status and the expression of HIF-1a or CA IX. HIF-1a or CA IX staining is however statistically associated with the histological grade (P<0.0001 et P=0.0004, respectively). Both markers are in general negative in low grade tumours and HIF-1? is positive in high grade tumours. HIF-1a and CA IX are significantly positive when hormonal receptors are lost, mainly estrogen receptors (P<0.0001). HIF-1a is also expressed in tumours associated with carcinoma in situ (P=0.0022).
Expression of HIF-1a or CA IX is correlated to worse overall survival (P=0.0005 and 0.048, respectively), distant metastasis-free survival (P=0.0001 and 0.0066) and disease-free survival (P<0.0001 and P=0.0129). Stromal CA IX expression is correlated with worse overall survival (P=0.0014). Multivariate analysis, regarding overall survival and including all parameters correlated with HIF-1a, shows that the grade is the most significant factor. HIF-1a positive immunoreactivity is more significant than CA IX's.
Conclusion : This preliminary study confirms that HIF-1a and CA IX are poor prognostic factors in breast cancer, but mainly related with the grade in our hands. One larger study is ongoing to confirm these results and evaluate the impact of these markers in therapeutic response to establish a putative predictive role.

P 40
MICROSATELLITE INSTABILITY AND LOSS OF HETEROZYGOSITY IN BREAST CARCINOMA
*SEO Seung-Won, *JAEGAL Young-Jong, KIM Hyun-Joong, NAM Jong-Hee, PARK Chang-Soo
Department of *Surgery and Pathology, Chonnam National University Medical School, Gwangju, Korea

Previous studies have shown that younger women exhibit more aggressive pathologic features of breast cancer in comparison with older women. Young age could be an independent predictor of adverse prognosis. In order to evaluate any existing differences in the molecular progression of breast cancer between younger and older women, Microsatellite instability (MSI) and loss of heterozygosity (LOH) was investigated in paired tumour and normal tissue DNA from 32 younger (less than 40 years old) and 32 older (more than 50 years old) breast cancer patients for 12 simple repeated primer sets.

MSI was observed at a single locus in 5 (15.6%) of younger patients and 8 (25.0%) of older patients. LOH was noted at a single locus in 7 (21.8%) and at multiple loci in 22 (68.7%) of 32 younger patients. In older patients, LOH was revealed at a single locus in 9 (28.1%) and at multiple loci in 15 (46.9%). Greatest frequency of LOH was at loci UT5320 (37.5%), D8S321 (34.4%), D9S242 (31.3%), and D19S394 (31.3%) in younger patients and L17686 (34.4%) and D19S394 (28.1%) in older patients. LOHs at D19S394 and L17686 were highly identified in both age groups. LOHs at D9S242 and D8S321 were significantly higher in the carcinoma of younger women. LOH status was unrelated to clinical stage, nodal status, tumour size, histologic grade or estrogen receptor (ER) status. LOH at D8S321 was associated with tumor size and LOH at UT5320 was associated with histologic grade and ER status. Amplification of CyclinD1 was relatively higher and was associated with histologic grade, nodal status and clinical stage in the younger women, indicating its prognostic significance.

These results indicate that the pattern of chromosomal alterations are not exactly same, especially at D9S242 and D8S321, in the carcinomas in the two age groups and suggest that the molecular pathogenesis of the carcinomas is not similar.

P 41

EVALUATION OF CYCLIND1 EXPRESSION IN DUCTAL CARCINOMA OF BREAST AND ITS CORRELATION WITH CLINICOPATHOLOGIC ASPECTS

Introduction:

Breast carcinoma is the most common malignant tumor and the leading cause of carcinoma death in women.CyclinD1 is a key cell cycle regulatory protein with demonstrated oncogenic activity in a variety of malignancy including breast cancer. We analyzed expression of cyclinD1 in ductal carcinoma of breast and its correlation with clinicopathologic parameters such as age, lymph node status, tumor size and grade.

Materials& Method

Formalin fixed tissue samples from 54 patients diagnosed as ductal carcinoma of breast were analyzed by Immunohistochemistry .We designed a Scoring system based on intensity and percentage of staining cells. Then we performed a statistical analysis to investigate the relationship between clinicopathologic parameters and cyclinD1 expression.

Result:

CyclinD1 expression was observed in all of cases with cytoplasmic pattern. We found positive significant correlation between intensity of staining and number of involved lymph nodes (P=0.013) .Also we observed positive significant correlation between percentage of positive cells and tumor size (P=0.016). No relationship was seen between tumor grade and cyclinD1 expression (P>0.05). Also no relationship was seen between patient's age and cyclinD1 expression (P>0.05). In additional studies we found positive correlation between tumor grade and number of involved lymph nodes (P=0.01).

Conclusion:

According to our finding we conclude evaluation of cyclinD1 expression could be useful for evaluation of lymph node status, tumor size and thus prognosis.

EXPRESSION OF THE INSULIN RECEPTOR SUBSTRATE 1 IN PRIMARY TUMORS AND LYMPH NODE METASTASES IN BREAST CANCER: CORRELATIONS WITH ERÁ, KI-67, BCL-XL AND BAX PROTEINS.

KODA Mariusz, SULKOWSKA Mariola, KANCZUGA-KODA Luiza, GOLASZEWSKA Jolanta, BALTAZIAK Marek, KISIELEWSKI Wojciech, RESZEC Joanna, WINCEWICZ Andrzej, SULKOWSKI Stanislaw
Department of Pathology, Medical University of Bialystok, Waszyngtona 13, 15-269 Bialystok, Poland

Insulin receptor substrate 1 (IRS-1) transmits signals from insulin-like growth factor I receptor (IGF-IR) and insulin receptor (IR) and it has been associated with pathogenesis of cancer disease. IRS-1 down-regulation was suggested with breast cancer progression, but simultaneous assessment of IRS-1 expression in primary and metastatic breast cancer have never been reported before. Consequently, we examined by immunohistochemistry IRS-1 expression in 109 samples of primary breast cancer and in 42 matched pairs of primary and metastatic tumors. Additionally, we correlated IRS-1 expression with selected clinicopathological features, including the ERá status and proliferation marker Ki-67 as well as with antiapoptotic Bcl-xL and proapoptotic Bax proteins. We found positive, cytoplasmic IRS-1 immunostaining in 69.7% and 76.2% of studied primary and metastatic tumors, respectively. Both IRS-1-positive and IRS-1-negative primary tumors were found to produce IRS-1-positive as well as IRS-1-negative metastases. IRS-1 expression in primary tumors correlated with poorly differentiated (G3) breast cancer ($p<0.005$) and with lymph node involvement ($p<0.05$). In primary tumors as well as in lymph node metastases, IRS-1 expression did not significantly correlate with ERá and Ki-67 expression. However, in the subgroup of ERá-positive primary tumors IRS-1 expression positively correlated with Ki-67 ($p<0.02$, $r=0.351$). In primary tumors, we found a significant positive correlation between IRS-1 and Bcl-xL ($p=0.001$, $r=0.315$) as well as between IRS-1 and Bax expression ($p<0.0001$, $r=0.346$). Additionally, in lymph node metastases we also observed positive correlation between IRS-1 and Bcl-xL ($p=0.004$, $r=0.447$) as well as between IRS-1 and Bax expression ($p=0.037$, $r=0.356$). Thus, our results could suggest that IRS-1 might affect turnover of cancer cells and breast cancer progression through activation of mitogenesis and participation in the regulation of the balance between anti- and proapoptotic pathways. Moreover, we suppose that knowledge about heterogeneity between primary and metastatic tumor might help to understand mechanisms of breast cancer progression as well as lead to the development of more effective anti-cancer drugs.

P 43

PROLACTIN RECEPTOR EXPRESSION IN BENIGN AND MALIGNANT BREAST LESIONS OF MALE AND FEMALE PATIENTS

FERREIRA Marco, MESQUITA Marta, QUARESMA Manuela, ANDRÉ Saudade
Serviço de Anatomia Patológica, Instituto Português de Oncologia Francisco Gentil CROL SA, Lisboa, Portugal

Background: Despite the well established function of prolactin (PRL) in normal breast development, the role of this

pituitary hormone in breast cancer pathogenesis is still controversial. PRL activity is dependent on the activation of a transmembrane protein, the PRL receptor (PRLR). The expression of PRLR is common in female breast carcinoma (FBC), but, to our knowledge, no studies were reported in male breast carcinoma (MBC).
Objective: Evaluate and compare PRLR expression in male and female breast carcinoma, as well as in gynaecomastia and benign female breast lesions.
Methods: PRLR expression was detected immunohistochemically, using a monoclonal antibody (clone B6.2), in formalin-fixed paraffin-embedded tissue of 30 cases of gynaecomastia, 30 cases of benign female breast lesions (including ductal hyperplasia, fibroadenoma, sclerosing adenosis, papilloma and radial scar), 30 cases of MBC and 30 cases of FBC (all invasive ductal carcinomas NOS). The whole series was also assessed for estrogen receptors (ER), progesterone receptors (PR) and androgen receptors (AR). A cut-off of 10% was used as positivity criteria. Histological type was evaluated according to the WHO classification. Tumour differentiation and pathological stage were assessed using the Elston & Ellis grading system and TNM-UICC system, respectively. Statistical analysis was performed with Fisher's Exact Test.
Results: PRLR positivity was seen in 20% of gynaecomastia cases, in 20% of benign female breast lesions, in 60% of MBC and in 50% of FBC. PRLR expression was significantly higher in MBC than in gynaecomastia (p=0,003). Likewise, it was significantly higher in FBC than in benign female breast pathology (p=0,029). No statistically significant differences between gynaecomastia and benign breast lesions or between MBC and FBC were found (p=1,000 and p=0,604, respectively). There was no statistically significant correlation between PRLR expression and ER, PR, AR, pTNM, histological grade or patients' age.
Conclusions: The results indicate that: 1) there is no difference in PRLR expression between male and female benign breast lesions; 2) there is no difference in PRLR expression between MBC and FBC; 3) PRLR is significantly more expressed in invasive carcinoma than in benign male and female breast lesions, suggesting a role of PRL in breast carcinogenesis.

P 44
THE BRMS1 (BREAST METASTASIS SUPPRESSOR GENE 1) GENE IS RELATED TO TUMOR PROGRESSION IN HUMAN BREAST CANCER
LOMBARDI Grazia, DI CRISTOFANO Claudio, CAPODANNO Alessandra, ARETINI Paolo, ISOLA Patrizia*, TANCREDI Mariella, COLLECCHI Paola, NACCARATO Giuseppe, BEVILACQUA Generoso, CALIGO Maria Adelaide.
Division of Surgical, Molecular and Ultrastructural Pathology, Department of Oncology, University of Pisa and Pisa University Hospital, Pisa, Italy;
*Department of Pathology B.M.I.E, University of Pisa, Pisa, Italy.

The BRMS1 (Breast Cancer Metastasis Suppressor Gene 1) gene has been identified by differential display, using mRNA extracted from the metastatic cell line of human mammary carcinoma (MDA-MB-435) and from the parental cell line stably transfected with chromosome 11. Experimental evidences show that BRMS1 reduces the metastatic ability, without affecting tumorigenicity, of both human and murine breast cancer cells in vivo metastasis assays. Preliminary studies into the mechanism of the observed metastasis suppression suggest that BRMS1 is a protein involved in a complex that represses gene expression, and that it is associated with regulation of cell-cell communication.
So far, BRMS1 gene involvement in human cancer has not been demonstrated. Aim of this study is to determine if BRMS1 might play a role in tumor progression by using an in vivo system (paired samples from human primary breast tumors and local metastasis) and to verify the correlation between BRMS1 expression and cell proliferation in vitro (human breast carcinoma cell line Hs578T).
BRMS1 mRNA expression was quantified by TaqMan assay in peritumoral, carcinoma tissues and in lymph-nodal metastasis of breast cancer patients with at least 10 years follow-up and in Hs578T cell line. Total cellular RNA has been extracted from laser-microdissected cells isolated from fresh frozen tissues.
The BRMS1 mRNA is expressed in all tissues analyzed. BRMS1 expression in carcinoma cells is generally higher than in matching normal cell populations (10/14 cases; p=0,0005), it decreases then in lymph-nodal carcinoma cells (9/15 cases; p=0,001). The BRMS1 mRNA was then quantified in 47 breast cancers from selected patients with a good (free from disease and/or alive) or a poor (recurrence and/or breast cancer mortality) outcome. Univariate (Log-Rank test: p=0,007) and multivariate analysis (Cox regression: HR=4,0; p=0,054) have shown that BRMS1 higher expression is associated with a shorter disease free survival and overall survival of breast cancer patients. BRMS1 higher expression was not related to cell proliferation rate of tumor cells as shown by an in vivo (breast carcinoma tissues) and in vitro system (Hs578T).
This study is the first and a preliminary evidence of BRMS1 involvement in human breast carcinoma. The BRMS1 expression decreases during tumor progression. However our data suggest that BRMS1 higher expression in primary breast carcinoma is correlated to a poor prognosis.

EXPRESSION OF MISMATCH REPAIR PROTEINS IN SPORADIC AND FAMILIAL INVASIVE AND IN SITU BREAST CARCINOMA
1Arkoumani E, 1Stefanou D, 1Batistatou A, 1Balasi E, 2Briasoulis E, 3Kontostolis E and 1Agnantis NJ.
1Department of Pathology, 2Department of Medical Oncology, 3Department of Obstetrics and Gynaecology, University of Ioannina, Medical School, Ioannina, 45110, Greece

Introduction:Microsatellite instability appears to be one of the various genetic alterations found in breast tumors, however the results differ considerably in various studies concerning sporadic as well as familial breast cancer. It is not clear yet whether defects in the mismatch repair system accompany this instability.
Aim:The purpose of this study is to explore the expression of two of the proteins encoded by the DNA mismatch repair genes, namely MLH1 and MSH2, in sporadic and familial in situ and invasive breast carcinoma.
Materials and Methods:MLH1 and MSH2 expression was monitored immunohistochemically using the monoclonal antibodies MLH1 and MSH2 (BIOCARE MED-Menarini Diagnostics) in 60 sporadic breast carcinomas (20 in situ and 40 invasive of various types and grades) and in 30 familial breast carcinomas (ductal and lobular type) defined based on published criteria. In the familial cases we examined concomitantly the invasive and the in situ component.
Results:Nuclear staining for MLH1 and MSH2 was observed in all cases of sporadic in situ carcinoma examined.In only one case of DCIS, papillary type the staining for MLH1 was stronger than that of the adjacent normal breast tissue while the staining for MSH2 was similar.Immunostaining for MLH1and MSH2 revealed preservation of expression in all cases of sporadic invasive carcinoma.Regarding MLH1 only one papillary carcinoma exhibited decrease in percentage and intensity of staining.Interestingly, 6 out of 8 papillary carcinomas displayed increase in MSH2 staining intensity compared to normal tissue.In contrast, in familial breast

carcinomas we found loss of expression of MLH1 in 8/30 (26%) and of MSH2 in 4/30 (13%) of the cases examined. Three carcinomas (10%) were negative for both MLH1 and MSH2. Staining for both antibodies was observed in all cases in the adjacent in situ carcinoma, however a clear degradation in the expression was noted in the in situ foci of MLH1 and MSH2 negative cases.Although not statistically significant, there was an association between loss of expression of MLH1 and MSH2, negative estrogen receptor status and higher grade of the tumor.
Conclusions:Our data suggest that the DNA MMR pathway may be involved in the development of familial breast cancer. Regarding sporadic neoplasms, the increased expression of MSH2 in papillary carcinomas can be another clue of their unique differentiation profile. Further molecular studies are necessary for definite conclusions.

HORMONE RECEPTORS AND ONCOGENE EXPRESSION IN APOCRINE CARCINOMAS
Kaya H1, Erbarut I1, Bozkurt SU1, Gulluoglu B2, Elder J3
Marmara University Hospital, Department of Pathology, Istanbul, Turkey
Marmara University Hospital, Department of Surgery, Istanbul, Turkey
Countess of Chester Hospital, Department of Histopathology, Chester, UK

Introduction:Apocrine carcinomas are 1%-2% of breast carcinomas. 98% of apocrine lesions have been reported as ostrogen and progestron receptors negative. Androgen receptor expression was found to be high rates in this rare type of tumors comparing to more common types of the breast as ductal carcinoma or lobular carcinoma.
Purpose of the study: The main aim of the study was to search the GCDFP-15, ostrogen receptor (ER), progesteron receptor (PR), androgen receptor (AR), p53 and c-erbB-2 immunoexpressions in apocrine carcinomas of the breast.
Methods: In Marmara University Hospital, Department of Pathology we have diagnosed 13 (2.47%) cases from 526 breast biopsies as apocrine carcinoma of the breast. In thirteen cases, we determined ER, PR, AR, GCDFP-15, c-erbB-2 and p53 immunoexpression with Sr.ABC/HRP.
Result: All of the cases were GCDFP-15 positive. ER was positive in five cases (38.5%), PR was positive in four cases (30.8%), AR was positive in eight cases (61.5 %), c-erbB-2 was positive in eleven cases (84.6%), and p53 was positive in five cases (38.5%).
Conclusion: High rates of AR and c-erbB-2 expression brings the discussion of spesific treatment protocols in apocrine carcinomas rather than the classical treatment protocol of the breast carcinomas.

Introduction: Lymph node metastasis is a frequent complication in breast cancer. However, the extent to which this depends on lymphangiogenesis or on invasion of pre-existing lymphatic vessels remains controversial.
Purpose: To address this issue, we investigated lymphatic vasculature in 60 primary breast cancer patients.
Experimental Design: We used immunostaining for the specific lymphatic endothelium marker podoplanin. We examined whether intratumoral lymphatics were present in our tissue samples, and quantified peritumoral lymphatic density. Furthermore, we recorded the presence of peritumoral lymphatic invasion, and addressed the association of all the above parameters with various clinicopathological features.
Results: We did not observe any intratumoral lymphatic vessels. Podoplanin positive lymphatic vessels were confined to tumor periphery, and their density was generally low. Higher peritumoral lymphatic density was associated with lower differentiation (x2 p=0.019) and higher incidence of peritumoral lymphatic invasion (x2 p=0.002). We observed a trend towards a correlation of higher peritumoral lymphatic density with the presence of lymph node metastasis at diagnosis, but the observed association was not formally significant (Mann Whitney p=0.07).
Conclusion: The above results are in accordance with previous studies, and suggest that breast carcinomas preferentially invade and metastasize via pre-existing peritumoral lymphatics rather than promoting lymphangiogenesis.

P 48
PURE MUCINOUS CARCINOMAS OF THE BREAST: PROGNOSTIC INTEREST OF DNA-FLOW CYTOMETRY.
Morand C.1, Verrièle V.2, Valo I.2, Paillocher N.3, Chassevent A.4.
1 Département de radiothérapie, Centre Paul Papin, 2 rue Moll 49933-Angers Cedex 9, France ; 2 Service d'anatomo-pathologie, Centre Paul Papin ; 3 Service de gynécologie-obstétrique, CHU Angers ; 4 Laboratoire de cytométrie, Centre Paul Papin.

Pure mucinous carcinomas (PMCs) of the breast are considered as a quite specific entity which represents less than 2% of all breast cancers and are said to have a favorable prognosis. There is a lack of investigation concerning DNA-ploidy and S-Phase fraction (SPF) as prognostic factors for this histologic subtype. This study included 69 patients with pure mucinous carcinomas where DNA flow cytometry was performed on fresh or frozen samples in this purpose.

A tumor size higher than 2 cm was observed in 56.5% of cases. A lymph node involvement concerned only 12% of all patients and just 3% when tumor size was lower than 2 cm. Hormone receptors were negative in only 16% of cases. Aneuploidy concerned 26% of tumors which is a lower rate comparing with invasive ductal carcinomas. A high SPF was observed in only 7.5% of cases.

A higher tumor size (> 2cm) was predictive (p=0.03) of shorter disease-free survival (DFS) and overall survival (OS). No correlation was found between nodal involvement, hormone receptor status, S phase fraction and DFS or OS. DFS was shorter for patients with aneuploid tumors compared to diploid ones (p=0.048). A prognostic classification based on tumor size and DNA-ploidy was obtained (p<10-3 for OS and DFS): a bad prognosis concerned six patients with large (>2cm) aneuploid tumours whose 5-year DFS rate was 16.7%.

Conclusion: the good prognosis of PMCs has to be questioned and this study discriminates a bad prognosis group of patients taking into account tumour size and DNA-ploidy.

ALTERNATIVE SPLICING OF CYCLIN D1 TRANSCRIPTS HAVE DIFFERENT EFFECTS ON CELL CYCLE REGULATION IN BREAST CANCERS
Cheng-Ping YU, Department of Pathology, Tri-Service General Hospital, Taipei, Taiwan, R.O.C.

Jyh-Cherng YU, Division of General Surgery, Tri-Service General Hospital, Taipei, Taiwan, R.O.C.
Yia-Tang YIANG, Department of Pathology, Armed Forces Taichung General Hospital, Taiping,
Taichung, Taiwan, R.O.C.
Sheng-Chuan HSI, Division of General Surgery, Armed Forces Tao-Yuan General Hospital, Tao-Yuan, Taiwan, R.O.C.

Introduction
The cyclin D1 (CCND1) plays a key role in early G1 phase progression of cell cycle. The amplification and/or overexpression of CCND1 gene have been detected in different types of cancer, such as esophagus, stomach, liver, lung, urinary bladder, head and neck, and breast. It has been reported that a A/G single nucleotide polymorphism (SNP) at the intron 1-exon 1 junction (G870A)of CCND1 gene, and the A-allele has higher risk for cancer generally. This SNP can produce two transcripts (a and b) by alternative splicing, and they may have different functions in cell cycle regulation.
Purpose of Study
In this study, we analyze this G870A SNP of CCND1 gene, the expression levels of CCND1 transcripts a and b, and correlate with cell proliferative index in breast cancers, to evaluate their functions in cell cycle proliferation.
Materials and Methods
The study population consisted of 97 sporadic infiltrating ductal carcinoma of breast who were treated at Tri-Service General Hospital between September 1997 and March 2002. All patients were diagnosed histologically with specimens both fresh and paraffin-embedded. Clinical and histologic information were obtained from patient charts and pathologic reports. Tumor stage was assigned according to the tumor-node-metastasis (TNM) staging system. Pathologic grade of tumors was determined according to the Modified Bloom-Richardson histologic grading criteria. The SNP of G870A was analyzed by PCR-RFLP methog from fresh tissue extracted genomic DNA. The expression levels of transcripts a and b were determined by RT-PCR method. The proliferative index of cancer cells was evaluated by immunohistochemistry of Ki-67 (A0047, Dako, Denmark). One-Way ANOVA and Independent-Samples T tests were applied for statistic analysis.
Summary of Results
The A-allele of CCND1 G870A is more prevalent in breast cancer than the G-allele. Compared with GG or AG+GG, the AA genotype has higher proliferative index. Compared with GG, the AA genotype has higher levels of transcript b. The levels of proliferative index have no significant correlation with the expression levels of transcripts a and b. Higher levels of transcript a have higher tumor grade.
Conclusions
The A-allele of CCND1 G870A is a risk factor for breast cancers. The genotypes of G870A have effects on differential expression of CCND1 transcripts in breast cancer, and this differential expression is grade-related but not proliferation-related.

P 50
EXPRESSION OF TOPOISOMERASE IIÁ IN BREAST CANCER. CORRELATION WITH CERBB2 AND OTHER PREDICTIVE FACTORS

ANDREI Florin 1, CEAUSU Mihai 1, NEAGU Maria 1, BUTUR Georgeta 1, ARDELEANU Carmen 1
1. Victor Babes National Institute of Pathology, Bucharest, Romania

Top2a is a fairly new molecular marker, involved in prediction of response to anthracycline therapy in breast cancer. Prior studies described a possible correlation between Top2a and Her2 neu. Aim of this study was to assess the expression of Top2a related to commonly used markers in breast cancer.
Indirect tristadial ABC method was performed on formalin fixed paraffin embedded tissue from serial file biopsies of 142 patients using the following antibodies: TOP2A, CerbB2, ER, PGR, and PCNA. The cases with strong expression for CerbB2 were confirmed by FISH.
From 110 cases that presented low or negative expression of CerbB2, 20 were positive for Top2A (18.2%); from 20 cases with moderate expression of CerbB2, 9 were positive for Top2A (45%); from 11 cases with strong expression of CerbB2, 2 were positive for Top2A (18.2 %). After removal of 92 cases with no expression of both markers, using multiple regressive analysis, a negative correlation between Top2A and CerbB2 was found (r=-0.43) with a high statistical significance (p=0.001). A very low correlation with no statistical significance was found between Top2a and PCNA (r=0.2, p=0.09) and a direct positive correlation between PGR and CerbB2 was found (r=0.97) with statistical significance (p=0.02). A low negative correlation with statistical significance was found between ER, PGR and TOP2A (r=-0.2 and -0.3, p=0.006).
In conclusion overexpression of CerbB2 associates high levels of Top2A but they show a significant reverse proportional correlation, and TOP2A expression proved to be independent to hormonal receptors and proliferating index.

P 51
FASCIN AND CAVEOLIN EXPRESSION ARE ASSOCIATED WITH THE BASAL –LIKE SUBTYPE OF INVASIVE BREAST CARCINOMA.

3. Department of Pathology. 12 de Octubre Hospital. Madrid. Spain.
4. Department of Pathology. La Paz Hospital. Madrid. Spain.

INTRODUCTION: Using cDNA expression profiling, previous studies classified breast carcinomas into different groups: the “luminal” (estrogen receptor positive), the “normal breast-like”, the “HER2 positive”, and the “basal-like” subtypes. The latter two groups have also been associated with poor outcomes. Basal-like tumours are typically negative for estrogen receptor (ER), progesterone receptors (PR) and HER2, but positive for basal cell (myoepithelial) markers, such as cytokeratins 5/6 (CK5/6) and Epidermal Growth Factor Receptor (EGFR). However, basal-like tumours remain poorly characterized. Caveolin and fascin proteins are expressed by breast myoepithelial cells. Furthermore, caveolin was identified as a tumor suppressor gene, whereas fascin has been involved in cell-to-matrix interactions, and tumour invasion.
AIMS: To study caveolin and fascin expression in breast tumors, and to assess whether these makers are associated with the basal-like phenotype.
MATERIALS AND METHODS: We studied caveolin and fascin expression in a tissue microarray (TMA) including 226 node-negative invasive breast carcinomas. In addition, we evaluated ER, PR, HER2, CK5/6, EGFR, p53, and ki-67 expression.
RESULTS: Overall, 21 (9.3%) and 56 (24,8%) breast carcinomas expressed caveolin and fascin, respectively. The basal-like phenotype (RE-/HER2-/CK5+ and/or EGFR+) was found in 28 (12,4%) carcinomas. Interestingly, 25% (7/28) of tumours with the basal-like phenotype, but only 7.1% (14/197) of non-basal tumours expressed caveolin. Likewise,

fascin was more frequently expressed in basal-like tumours (14/27, 52%) than in non-basal carcinomas (42/196, 21,4%). Therefore, a direct statistically significant correlation was found between caveolin and fascin expression and the basal-phenotype (p=0,007 and p=0,001 for caveolin and fascin, respectively).
CONCLUSION: These data indicate that caveolin and fascin expression is associated to breast cancers with basal phenotype and thus, they could serve to identify more accurately this subgroup of tumours.

P 52
THE EFFECT OF PHYSICAL CONDITIONS AND SLIDE AGING ON STINING QUALITY OF BREAST CARCINOMAS FOR C-ERB-B2, ESTROGEN (ER) AND PROGESTERON (PR) RECEPTORS
OLTULU Turkuler, SAK Serpil D, PERCINEL Sibel , KUZU Isinsu.
Department of Pathology , School of Medicine, Ankara University, Turkey

Fixation and tissue processing conditions effect the staining quality and may create difficulties on interpretation of immunostaining for receptors (ER, PR) and c-erb-B2 in breast carcinomas. There are also evidences about the negative effects of tissue section's age (slide age) and storage temperature on the staining intensity of these prognostic markers. Today slide aging is becoming more important, because of the need for storage of hundreds of tissue microarray sections for future planned studies concerning immunohistochemistry (IHC) or in-situ hybridisation methods. Our aim in this study was to examine the effects of age and the storage conditions on immunostaining quality of ER, PR, and c-erb-B2 on breast carcinoma cases.
MATERIALS AND METHODS:
Tissue cores optained form 14 donor paraffin blocks of different breast carcinomas previously scored for receptors and c-erb-B2, were re-bloked in an order to prepare the tissue array block. Four micron sections of the tissue array block were stored for 36, 24, 12 weeks in 4 different conditions: 1- Room temperature dry, 2- Room temperature humid, 3- Room temperature sealed by paraffin, 4- at 4oC. The slides were stained with primary antibodies against ER (NCL-ER-6F11, 1/50), PR (NCL-PGR, 1/600) and cer-b-B2 (Neomarkers e2-4001+3B5,1/700) by using Ventana Benchmark autostainer on the same session. The results of the staining intensity of all groups were compared with newly cut paraffin section. Freidman test was used for statistical analysis.
CONCLUSIONS
We examined that the staining intensity of immunostaining for breast cancer prognostic markers were decreased when the paraffin slides are stored in humid conditions.
Sealing the slides by paraffin does not have any conservative effect on staining quality.
The staininig quality of the slides decrease by the length of the storage period.
Keeping the slides at 4oC can decrease the negative effect of slide aging on immunostaining.

P53, C-ERBB-2, OSTROGEN AND PROGESTERON RECEPTOR EXPRESSION: CORRELATION WITH THE HISTOPATHOLOGICAL PROGNOSTIC PARAMETERS IN DUCTAL CARCINOMAS OF THE BREAST
Kaya H1, Erbarut I1, Bozkurt SUB1, Gulluoglu B2, Aribal E3
1Marmara University Hospital, Department of Pathology, Istanbul, Turkey
2Marmara University Hospital, Department of Surgery, Istanbul, Turkey
3Marmara University Hospital, Department of Radiology, Istanbul, Turkey

Until today many prognostic factors have been studied on ductal carcinomas of the breast in order to find out the clinical and therapeutic implications.
The aim of this study was to search the p53, c-erbB-2, ostrogen receptor (ER) and progesteron receptor (PR) expression in ductal carcinomas of the breast and correlation with the well known histopathological prognostic parameters.
Material-Method:
55 cases of invasive ductal carcinomas were retrieved from the archives of Marmara University Hospital, Department of Pathology. Immunohistochemical detection was performed by the StreptAvidin-Biotin complex method on 5 ? m sections from archival representative paraffin embedded blocks.
Results: The cut of values for p53, ER and PR were 10%. The cut of value for c-erbB-2 was considered as positive when we have revealed ++ and/ or +++ spessific membranous staining.
31% of the cases had immunoexpression with c-erbB-2. 41% of them were positive with p53. 53% of the cases were also positive with ER/PR, 65% of the same cases were advanced stages as T2, T3 or T4, 88% were either grade 2 or 3 and 47% of them had lymph node metastasis .
35% of the invasive ductal carcinoma cases were positive with p53. p53 positive cases demonstrated 68% ER/PR positivity, 79% were advanced stages, 89% were either grade 2 or 3, and 42% had lymph node metastasis.
Discussion:
In the literature, c-erbB-2 protein overexpression is shown to be independently associated with poor prognosis in women with node-positive breast cancer. In this recent study immunoexpression results of c-erbB-2 have concordance with the literature as
c-erbB-2 has a statistically significant correlation with the tumor grade, stage and lymph node metastasis. Although

ER/PR positivity are known to be as good prognostic parameters we have revealed ER/PR positivity of 53% of the c-erbB-2 positive cases. ER/PR positivity have also been observed in p53 positive cases. p53 positivity have also been revealed in advance stages and high grades.
Conclusion: Results of our study is concordance with the literature except the high immunoexpression ratios of the ER/PR. This result could be attributable to the geographic, social differences with Western Europe.

P 55
CELL CYCLE CONTROL RELATED PROTEINS (P53, P21, AND RB) AND TRANSFORMING GROWTH FACTOR-BETA (TGF-BETA) IN 'IN SITU' AND INFILTRATING HUMAN BREAST CANCER: AN IMMUNOHISTOCHEMICAL STUDY.
GARCÍA-TUÑON Ignacio, RICOTE Mónica, FRAILE Benito, PANIAGUA Ricardo and ROYUELA Mar
Department of Cell Biology and Genetics, University of Alcalá. 28871 Alcalá de Henares. Madrid. Spain. E-mail: ignacio.tunon@uah.es

INTRODUCTION: It has been reported that several regulators of the cell cycle –including mtp53, p21, pRB, and TGF-beta are altered in many malignant tumors.
PURPOSE: The aim of this study was to investigate the expression patterns of p53 (mutated form), p21, Rb, pRb and TGF-beta in order to elucidate the possible roles of this cell cycle regulatory system in breast cancer.
METHODS AND METHODS: A comparative study of the products of the cell cycle control genes p53 (mutated form), p21, Rb (non-phosphorylated and phosphorylated form) and TGF-beta was performed by immunohistochemistry and Western blot, in 17 benign breast disorders and 62 breast cancer (17 'in situ' and 45 infiltrating tumors) samples.
RESULTS: For these proteins studied, the relative numbers of positively stained cells were higher in 'in situ' carcinoma than in benign breast diseases. In infiltrating breast tumors the relative numbers of positively stained cells were even higher than in 'in situ' tumor, except for the percentage of pRb immunostained cells, which decreased slightly in infiltrative tumors. For the other proteins, the percentages of positively stained cases were similar to those found in 'in situ' tumors. In the three groups of patients, TGF-beta immunoreaction appeared in the cytoplasm while immunoreactions to p53, p21, Rb and pRb were always found in the nucleus, except for p21 in 'in situ' tumors, which showed cytoplasmic immunoreaction to this protein.
CONCLUSIONS: Present results suggest that accumulation of mutated p53, cytoplasmic p21, and pRb in breast gland epithelium might be a crucial point in the development of 'in situ' adenocarcinoma. In the infiltrating tumors, the expression of p21 in the nuclei and the decrease in pRb expression suggest an insufficient attempt to hinder cell proliferation.

INTERFERON-GAMMA AND ITS FUNCTIONAL RECEPTORS IN IN SITU AND INFILTRATING HUMAN BREAST CANCER: AN IMMUNOHISTOCHEMICAL STUDY.
GARCÍA-TUÑON Ignacio, RICOTE Mónica, FRAILE Benito, PANIAGUA Ricardo and ROYUELA Mar
Department of Cell Biology and Genetics, University of Alcalá. 28871 Alcalá de Henares. Madrid. Spain. E-mail: ignacio.tunon@uah.es

INTRODUCTION: Interferons are a group of proteins that trigger multiple responses including prevention of viral replication, inhibition of cell growth, and modulation of cell differentiation. In different mammary carcinoma cell lines IFNgamma induces growth arrest at mid-G1. At the present there are no in vivo studies in human breast.
PURPOSE: The aim of this study was to investigate the expression patterns of IFNgamma and its two receptors (IFNgamma-Ralpha and IFNgamma-Rbeta) in order to elucidate its role in the different types of human breast cancer (in situ and infiltrative).
METHODS AND METHODS: A comparative study of IFNgamma and its two receptors (IFNgamma-Ralpha and IFNgamma-Rbeta) was performed by immunohistochemistry and Western blot, in 17 benign breast disorders and 62 breast cancer (17 in situ and 45 infiltrating tumors) samples.
RESULTS: For IFNgamma, IFNgamma-Ralpha and IFNgamma-Rbeta, the relative numbers of positively stained cells were higher in benign breast than in carcinoma. In in situ tumors the relative numbers of positively stained cells were even higher than in infiltrating breast. In the three groups of patients, IFNgamma and IFNgamma-Ralpha immunoreactions appeared in the cytoplasm while IFNgamma-Rbeta also was found in the nucleus.
CONCLUSIONS: The decreased expression of IFNgamma and its receptors in cancer could be regarded as an attempt, although insufficient, to inhibit the uncrontrolled cell proliferation. The mechanism causing the antiproliferative effect could be related to the other factors variation as wild p53 or Rb.
ACKNOWLEDGEMENTS: This work was supported by grants from Fondo de Investigaciones Sanitarias (PI020383) and the University of Alcalá.

THE STATUS OF EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR), GRADE AND AXILLARY LYMPH NODES INVOLVEMENT IN PRIMARY BREAST CANCER
Jalali Nadoushan Mohammad Reza,Neisani Elham,Valaei Naser
Shahed University

Introduction: The breast cancer is the most common worldwide malignancy of women. The number of prognostic factors in breast cancer has grown recently. A conceptual framework is now emerging that outlines how certain principles of EGFR may be employed in the future management of patients with Breast cancer.
In this study, we want to show the status of EGFR and its correlation with grade and axillary lymph nodes involvement in primary breast cancer.
Material and Methods: In a cross-sectional double-blind study, 57 paraffin blocks from patients with breast cancer from pathology department of shaheed Mostafa Khomeini hospital, since 2000-2003 were obtained and from each one, 3 micron sections were provided. One of the tumoral section and one of the lymph node section were stained by H & E. We determined size and type of tumor, number of lymph nodes and grade according to Natingham modification of Bloom-Richardson criteria. We studied EGFR on the other section by IHC. We had 10-parraffin blocks without breast cancer.
Result: Our study showed that 89.5% were positive and 10.5% were negative for EGFR. The most patients were Grade III (43.9%) and the lowest patients were Grade I (22.8%). 66.7% had axillary lymph nodes involvement. In this study, we didn’t find significant correlation between EGFR and axillary lymph nodes involvement.
Conclusion: The high expression of EGFR in patients with breast cancer is important to note as a prognostic factor in the world and Iran, but further investigions with more specimens and follow-up are required to clarify the exact role of EGFR in prognosis of breast cancer.

ANDROGEN RECEPTORS ARE FREQUENTLY EXPRESSED IN MAMMARY AND EXTRAMAMMARY PAGET`S DISEASE.

LIEGL B. (1), L.C. HORN (2), F. MOINFAR (1)
(1)Institut für Pathologie, Medizinische Universität Graz Austria
(2)Institut für Pathologie, Universität Leipzig Deutschland

Aims: Mammary paget`s disease (MPD) and Extramammary paget`s disease (EMPD) are rare intraepithelial neoplasms. MPD is almost exclusively associated with underlying invasive breast carcinoma (IDC) or high grade Carcinoma in situ, DCIS (ductal intraepithelial neoplasia, DIN). EMPD arises in areas rich in apocrine glands and is thought to have apocrine gland origin. The aim of the study was to investigate the presence of estrogen receptor (ER), progesterone receptor (PR), androgen receptor (AR) and Her2/neu in a large number of cases.
Methods: We investigated 81 cases of MPD (58 cases) and EMPD (23 cases). Formalin fixed and paraffin-embedded tissues were analyzed using antibodies against AR, PR, ER and Her2/neu according to standardized guidelines.
Result: In MPD, positive immunoreactions for Her2/neu, AR, and ER were observed in 56 of 58 (97%), 51 of 58 (88%), and 6 of 58 (10%) cases, respectively. All cases of MPD were negative for PR. MPD showed a co-expression of Her2/neu and AR in 51 out of 58 cases (88%). In EMPD, positive immunoreactions for AR, Her2/neu, and ER were observed in 18 of 23 (78%), 12 of 23 (52%),and 1 of 23 (4%)cases, respectively. All cases of EMPD were negative for PR. EMPD showed a co-expression of AR and Her2/neu in 12 out of 23 cases (52%).
Conclusion: In contrast to ER and PR, AR and Her2/neu are commonly expressed in MPD and EMPD. The immunohistochemical determination of AR in paget`s disease could lead to the development of a new adjuvant therapy, particularly in patients with recurrent disease.

CLINICOPATHOLOGIC AND IMMUNOHISTOCHEMISTRY FEATURES ASSOCIATED TO THE BASAL PHENOTYPE OF INVASIVE BREAST CARCINOMAS

Alfredo Ribeiro-Silva, MD, PhD
Leandra Náira Zambelli Ramalho, MD, PhD
Sérgio Zucoloto, MD, PhD
Department of Pathology, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Brazil

In the normal breast, the majority of luminal cells express the cytokeratins 7, 8, 18 and 19, while the basal myoepithelial cells express the cytokeratins 5, 14, 15 and 17. However, there is a subset of normal mammary luminal cells that are positive for CK5/6 and negative for CKs 8/18/19. These cells have the capacity to differentiate toward a glandular phenotype (CKs 8/18/19 positive) with intermediate populations that are positive both for CK5 and CKs 8/18/19. Considering that all of these cells can undergo malignant change, the breast carcinomas can be classified as expressing a basal (CK5+ CKS 8/18/19- or CK5+ CKs 8/18/19+) or a luminal phenotype (CK5- CKS 8/18/19+). This work aims to study the immunoprofile of CK-5 positive breast carcinomas and its relationship with pathologic features of clinical significance. Immunohistochemistry with the antibodies CK5, CK8/18, p63, BRCA1, estrogen receptor, progesterone receptor, p53, c-erbB-2, and Ki67 were performed in 102 formalin-fixed paraffin-embedded samples of invasive ductal carcinomas. The clinical data were collected from the medical files. Conventional clinical features were evaluated, including age, menstrual status, pathological grading, tumor size and lymph node metastasis. Focal expression of CK5 was seen in 18.6% of carcinomas. CK5 expression was significantly correlated with younger age, high tumor grade, positive nodal status, negativity for hormonal receptors, and high proliferative rate. There was a strong relationship between CK5 and p63 expression in breast carcinomas indicating that p63, like CK5, may be considered a marker for the basal phenotype of breast cancer. There was also a strong relationship between reduced expression of BRCA1 with both p63 and CK5 expression as well as there was an inverse correlation between p63 and CK8/18 expression suggesting that lost of p63 expression is required for the transition between the basal to luminal phenotype of breast carcinomas. Since p63 is thought to be a marker of stem cells and may act as an oncogene our data reinforce that BRCA1 acts as stem cell regulator.

P 60

PROGNOSTIC SIGNIFICANCE OF P63-POSITIVE NEOPLASTIC CELLS IN INVASIVE BREAST CARCINOMAS

Alfredo Ribeiro-Silva, MD, PhD
Heveline Becker de Moura, MD
Sérgio Zucoloto, MD, PhD
Department of Pathology, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Brazil

P63 is a p53 homologue gene located on chromosome 3q27-29. P63 protein is highly expressed in embryonic ectoderm and in the nuclei of basal cells of many epithelial tissues in the adult including skin, oral epithelium, prostate and urothelium In the normal mammary gland p63 is considered to be a myoepithelial cell marker but p63-positive neoplastic cells may be found in up to 11% of invasive breast carcinomas. The prognostic significance of this finding, however, is still unknown. This work aims to study the overall survival and the disease-free survival associated with p63-positive breast carcinomas. Immunohistochemistry with the antibody p63 (clone 4A4) was performed in 100 formalin-fixed paraffin-embedded samples of invasive ductal carcinomas diagnosed between 1992 and 1995. Clinical data concerning the outcome of the patients were retrieved from the medical files. Sixteen of 100 carcinomas showed rare and scattered neoplastic cells stained for p63 and were interpreted to be p63-positive. The median age of patients (n=100) included in this study was 54.2 years (range 25-85 years). Median follow-up was 6.5 years (range 1-10 years). The average overall survival of patients whose tumors were positive and negative for p63 was 6.5 and 6.9 years, respectively (p=.8134). The average disease-free survival of patients whose tumors were positive and negative for p63 was 4 and 5.8 years, respectively, with the difference being statistically significant (p=.0474). These data indicate that p63 might be used in routine practice to identify patients at high risk of precocious recurrence or metastasis.

P 61

IMMUNOPROFILE OF P63-POSITIVE INVASIVE BREAST CARCINOMAS

Alfredo Ribeiro-Silva, MD, PhD
Heveline Becker de Moura, MD
Sérgio Zucoloto, MD, PhD
Department of Pathology, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Brazil

P63 is a p53 homologue gene that is essential for the maintenance of a stem cell population in several epithelial tissues. P63 expression is associated with several malignancies including squamous cell carcinomas of the head and neck, primary cutaneous adnexal neoplasms, lung carcinomas, endometrial carcinomas, esophageal squamous cell carcinomas, transitional cell carcinomas of the urinary tract, and papillary thyroid carcinomas. These data indicate

that p63 may act as an oncogene in the genesis of these tumors. In breast carcinomas, p63 expression correlates with several indicators of aggressiveness, including advanced pathologic stage, tumor size, lymph node metastasis, high histological grade, and negativity for estrogen receptors. Very little is known about the molecular profile of p63-positive carcinomas. Thus, this study was carried out to study the expression of several key regulators of the cell cycle including oncogenes and apoptosis-related proteins in p63-positive carcinomas. Immunohistochemistry with the antibodies BAG-1, Bcl-2, c-erbB-2, c-erbB-3, Checkpoint Kinase 2 (CHK2), Cyclin D1, Epidermal Growth Factor Receptor (EGFR), Telomerase (hTERT), Osteopontin (OPN), p16, p21, and p27 was performed in 100 formalin-fixed paraffin-embedded samples of invasive ductal carcinomas. Association between p63 expression and other markers was determined by the Fisher exact test. Sixteen of 100 carcinomas expressed p63-positive neoplastic cells. P63 correlated only with the expression of hTERT. The transcriptional activation of telomerase is considered to be a crucial step in the development of malignancy and is responsible for the continued growth and immortalization of cancer cells. In breast carcinomas hTERT is associated with aggressiveness and a poor clinical outcome. It is frequently activated in early breast carcinogenesis and this activity is associated with nodal metastases and cellular proliferation. These data suggest that differential regulation of h-TERT in p63-positive breast carcinomas may contribute to the clinically more aggressive behavior of these neoplasms.

P 62
BRCA1 EXPRESSION IN SPORADIC BREAST CARCINOMAS: A CLINICOPATHOLOGIC AND IMMUNOHISTOCHEMICAL STUDY

Alfredo Ribeiro-Silva, MD, PhD
Sergio Zucoloto, MD, PhD
Department of Pathology, Faculty of Medicine of Ribeiro Preto, University of São Paulo, Brazil

Although mutations in BRCA1 are rare in non familiar breast carcinomas, it is common the lost of expression of the protein codified by this gene probably due to epigenetic changes. The prognostic importance of this finding is not well established. This work aims to analyze the immunohistochemistry expression of BRCA1 in sporadic breast carcinomas and to compare the results with clinical and histopathologic data of prognostic significance.
Immunohistochemistry with the antibodies BRCA1, estrogen receptor, progesterone receptor, p53, c-erbB-2, and Ki67 was performed in 102 formalin-fixed paraffin-embedded samples of not otherwise specified invasive ductal carcinomas. BRCA1 expression was graded as follow: 0/+ (negative or positivity in less than 25% of neoplastic cells), ++ (positivity between 25 to 50% of neoplastic cells), and +++ (positivity in more than 50% of neoplastic cells). Conventional clinical features were evaluated, including age, menstrual status, pathological grading, tumor size and lymph node metastasis. The clinical data were retrieved from medical files. Association between BRCA1 expression and other pathologic variables was determined by the Fisher exact test (2 groups) or ÷2 test (3 or more groups). In normal epithelium, BRCA1 showed only nuclear staining, while the carcinomas showed either nuclear or cytoplasmatic staining. The histological analysis of BRCA1 showed that 25.5% of carcinomas were graded as 0/+, 25.5% were graded as ++, and 49% were graded as +++. Carcinomas with reduced expression of BRCA1 (0/+) were poorly differentiated, with high proliferative rate, negative for hormonal receptors, and positive for c-erbB-2. There was not correlation between BRCA1 expression with age, menstrual status, tumoral size, lymph nodes status, pathologic stage, and p53 expression. The mean survival and disease-free survival of patients which tumors expressed less and more of 25% of neoplastic cells stained for BRCA1 were 4.2 and 3.9 ($p<0,001$); and 7.8 and 6.3 ($p=0,0095$) years respectively. In conclusion, BRCA1 may be considered a useful marker in identification of sporadic carcinomas of poor prognosis that is in high risk for precocious recurrence.

P 63
THE RELATIONSHIP BETWEEN CYTOKERATIN 5, CYTOKERATINS 8/18, P63 AND MATRIX METALLOPROTEINASE-19 IN MAMMARY CARCINOMAS INDUCED BY 7,12 DIMETHYLBENZ[A]ANTHRACECENE IN MICE FED WITH FAT DIET

Alfredo Ribeiro-Silva, MD, PhD1
Leandra Náira Zambelli Ramalho, MD, PhD1
Fernando Silva Ramalho, MD, PhD2
Sérgio Zucoloto, MD, PhD1
Departments of Pathology1 and Surgery & Anatomy2, Faculty of Medicine of Ribeirão Preto, University of São Paulo, Brazil

Human Breast carcinomas usually express cytokeratins 8/18 (CK8/18) but a reduced expression of CK8/18 may be found in up to 40% of poorly differentiated tumors. CK5 is a 58 kD protein found in many non-keratinizing stratified squamous epithelia. There is a subset of human breast carcinomas that express CK5. P63, unlike its homologue p53, is not a classical tumor suppressor gene, being essential for the maintenance of a stem cell population in several epithelial tissues. The expression of CK5 and p63 in experimentally induced mammary tumors is still unknown. Unlike most matrix metalloproteinases, MMP-19 is downregulated during malignant transformation and histologic dedifferentiation. This study was carried out to verify the expression of p63 and cytokeratin 5 (CK5), as well as their relationship with cytokeratins 8/18 (CK8/18) and metalloproteinase 19 (MMP19), in DMBA-induced mammary tumors in mice fed a diet enriched with linoleic acid. Sixty 8-week-old virgin female balb-c mice were given by gavage 1 mg of 7,12 dimethylbenz[a]anthracecene (DMBA) dissolved in 1 ml of corn oil once a week for 6 weeks. Linoleic acid was supplied as 15 g of corn oil for each 100 g of standard diet. When tumors reached 1 cm in size, euthanasia was performed and mammary tissue was pooled for analysis. Formalin-fixed paraffin-embedded tumors were submitted to immunohistochemical study with CK5, p63, CK8/18 and MMMP19. Sixteen animals developed poorly differentiated adenosquamous carcinomas which were diffusely positive for CK5 and p63 and focally positive for CK8/18 and MMP19. Like p63, CK5 stained the poorly differentiated areas as well as the foci of squamous differentiation, suggesting that they may be used together in immunohistochemical panels to characterize squamous differentiation in poorly differentiated carcinomas. The focal positivity for CK8/18 may be attributed to suppressed gene expression or accelerated protein degradation. MMP19 expression indicates that progression towards an invasive phenotype and neoplastic dedifferentiation led to the disappearance of MMP-19 from tumor cells. In conclusion, the addition of linoleic acid to the diet of mice given DMBA induces mammary carcinomas with immunoprofile similar to the poorly differentiated human carcinomas suggesting that a fat diet may be involved in the pathogenesis of these neoplasms.

BREAST TUMOR RESEMBLING THE TALL CELL VARIANT OF PAPILLARY THYROID CARCINOMA

CAMESELLE-TEIJEIRO José1, ABDULKADER Ihab1, RUIZ-PONTE Clara2, REYES-SANTÍAS Rosa1, BARREIRO Francisco3, SOBRINHO-SIMÕES Manuel4

1Department of Pathology, 2Molecular Unit, and 3Department of Surgery, Hospital Clínico Universitario, University of Santiago de Compostela, Santiago de Compostela, Spain; 4Institute of Molecular Pathology and Immunology, University of Porto, Porto Portugal

The breast tumor resembling the tall cell variant of papillary thyroid carcinoma (BTRPTC) is a very unusual mammary carcinoma whose histologic and predominant nuclear features mimic a papillary thyroid carcinoma. We report a case of BTRPTC with cytologic, pathologic and molecular analysis. A 64-year-old woman presented with a palpable nodule in the right breast. Fine needle aspiration of breast mass disclosed abundant cellularity with isolated cells, sheets and papillary formations of epithelial cells with nuclear grooves. The tumor measured 5.2 cm. Histologically, the neoplastic cells were arranged in a solid to papillary architecture, with areas showing a follicular or cribriform pattern of growth. The neoplastic nests and papillae were made up of columnar to cuboidal cells with eosinophilic cytoplasm. In addition, the neoplastic cells showed numerous nuclear grooves and occasional eosinophilic pseudo-inclusions. Tumor cells were positive for cytokeratins (CAM5.2 and AE1/AE3), estrogen receptor-alpha and –beta, progesterone receptor, androgen receptor, CEA, and bcl-2. Thyroglobulin, thyroperoxidase, calcitonin, TTF-1, chromogranin, synaptophysin, vimentin, and galectin-3 were consistently negative. Because of the peculiar nuclear appearance of the cells of the BTRPTC, a previous study for RET/PTC rearrangements had been reported in the literature with negative results. Due to the fact that RET/PTC rearrangements and BRAF mutations are mutually exclusive etiopathogenetic events in papillary thyroid carcinomas we also searched for BRAF mutations, but no mutations were found. The awareness of the existence of mammary tumors that histologically mimic the tall cell variant of papillary thyroid carcinoma will avoid unnecessary clinical investigations. This work was supported by research grant (PGIDE 99PXI 90201B) sponsored by Xunta de Galicia, Spain.

PRIMARY ANGIOSARCOMA OF THE BREAST: CLINICOPATHOLOGICAL AND IMMUNOHISTOCHEMICAL ANALYSIS ON 4 CASES

OZLUK Yasemin(*), TUZLALI Sitki(*), YAVUZ Ekrem(*), DERIN Duygu(**), ASOGLU Oktar(***), ILHAN Ridvan(*), Iplikçi A(*)
(*)Istanbul University, Istanbul Faculty of Medicine, Department of Pathology
(**)Istanbul University, Institute of Oncology, Department of Medical Oncology
(***)Istanbul University, Istanbul Faculty of Medicine, Department of Surgery

Primary angiosarcoma of the breast (PAB) is an unusual neoplasm with an adverse outcome. The incidence of its association with pregnancy is reported as 6% of PAB.

The aim of this study is to detect the incidence, the hormonal status and the prognostic indicators of PAB.

The archieve material of our department was reviewed to identify clinicopathological features of PAB. Immunohistochemical analyzes were performed for antibodies CD31, CD34, ER, PR and Ki-67. During a 17-year period 4 cases of PAB were established out of almost 5000 breast biopsies. All patients clinically presented with a palpable mass. Two patients were at the end of their first trimester in pregnancy. The mean patient age at diagnosis was 40.8 years (29-56). All patients underwent simple mastectomy after an initial diagnosis on either excisional or incisional biopsy. None of the patients had received prior radiotherapy. Grossly, all tumors had hemorrhagic cystic spaces with solid, white coloured areas and ill-defined borders. The mean tumor size was 8.37 cm (2.5-12). One case revealed two masses of PAB, 9 cm and 1.3 cm in diameter. Two of the tumors were Grade I, one of the tumors was Grade II and one was Grade III, histologically. Immunohistochemistry revealed positivity for CD31 in all tumors and CD34 in 3. The mean score of Ki-67 index was 28.6% (2-54.6%). The tumor without CD34 immunoreactivity was Grade III and exhibited the highest Ki-67 index (54.6%). Two patients with Grade I tumor and with the lowest Ki-67 index were alive with no evidence of disease 7-8 years after surgery. One of the pregnant patients, having two foci of Grade II tumor, is still alive after 1 year follow-up with distant metastasis 5 months after surgery and has been receiving radiotherapy and chemotherapy. The patient with Grade III tumor died with disseminated disease one year after initial diagnosis.

Since, it was previously stated that grading is the most important prognostic indicator, we suggest that Ki-67 proliferation index may also be used for the same purpose. We also propose that at least two endothelial markers must be used in differential diagnosis, especially in poorly differentiated tumors in which expression of endothelial markers may be lost. No evidence of an association with hormonal status could be drawn, therefore, the occurrence with pregnancy should be related to the age of incidence. These statements need further investigations on large series of PAB.

P 66

LYMPHOEPITELIOMA-LIKE CARCINOMA OF THE BREAST: IS IT A DISTINCT ENTITY?

Reguero ME, Camarasa N, Gª Martos M, Santon A, Gª-Cosio M, Capote LF, Gonzalez-Palacios JF.

INTRODUCTION:
Lymphoepitelioma (LE), a tumor originally described within the nasopharynx, is an undifferentiated carcinoma with prominent lymphoid infiltration and with variable expression of the Epstein-Barr virus (EBV) genome within the tumor cells. There are only 13 cases of lymphoepitelioma involving the breast described in the literature, none of them associated with EBV. It is considered to be a less aggressive type of breast carcinoma.
MATERIALS AND METHODS:
A set of 30 breast cancer with prominent lymphoid intersticial infiltration were examined and selected from a total of 1226 reviewed biopsies. There were excluded from the study cases following the criteria for medullary carcinoma, cases with syncitial growing patterns higher than 75%, papillary areas, glands or carcinoma in situ, and cases with morphological features not consistent with LE.
The presence of EBV was subsequently analysed in 14 histologically confirmed cases of LE by immunohistochemistry (LMP-1), in situ hybridisation (EBERs) and PCR (LMP-1 terminal region and EBNAs). Morphological and complementary data (hormonal receptors, proliferation index, p53, and Her-2) were also evaluated.
RESULTS:
None of the cases were associated with EBV, 11 of them were N+, and all of them showed histological findings suggestive of high grade tumors (GIII), high proliferative activity (>25%), negative hormonal receptors (13) and high p53 expression (10). Two cases were HER 2 (+++).
CONCLUSIONS:
There is no evidence to considerer LE as a distinct entity of infiltrating breast carcinoma.

P 67

NON-HODGKIN'S LYMPHOMAS OF THE BREAST

P. Xirou1, V. Christoforidou1, D. Anestakis1, A. Bousoulegas2, F. Patakiouta1
Departments of Pathology1 and Breast Surgery2, "Theagenion" Anticancer Hospital, Thessaloniki, Greece

Introduction: Primary non-Hodgkin's lymphoma of the breast is a rare disease, constituting less than 1% of malignant mammary neoplasms. Lymphomas secondarily involving the breast are also uncommon. A lymphoma is considered primary if the breast is the first or major site of presentation, without concurrent nodal disease except for the involvement of ipsilaterar axillary nodes and with no previous history of extramammary lymphoma.
Materials and Methods: We report 5 cases of breast lymphoma, 3 primary and 2 secondary. All patients were female, ranging in age from 42 to 85 years. Of the 3 primary cases, one was classified as extranodal marginal zone B-cell lymphoma of MALT type, one as diffuse large B-cell lymphoma arising in a pre-existing maltoma and one as Burkitt lymphoma. In the other 2 cases, breast was secondarily involved by a MALT lymphoma of salivary gland and a nodal diffuse large B-cell lymphoma.
Discussion: Primary non-Hodgkin's lymphomas of the breast are uncommon. Two distinct clinicopathologic types have been described. One type occurs in pregnant or lactating young women as massive bilateral breast swelling and corresponds to a Burkitt lymphoma. The second and larger type usually affects postmenopausal women and presents with clinical features identical to those of carcinoma of the breast. This latter type, histologically, is usually a diffuse large B-cell lymphoma.
Differentiation must be made from benign lymphocytic infiltrations and non lymphoid neoplasms of the breast.
Primary lymphomas of the breast behave in a way similar to lymphomas of corresponding type and stage in other sites. Therapeutic management is controversial and consists of various combinations of surgery, radiation therapy and chemotherapy.

DIABETIC MASTOPATHY: REPORT OF FIVES CASES
S Hannachi Sassi, I Kadri, K Mrad, R Dhouib, I Abbes, M Driss, K Ben Romdhane.
Department of Pathology, Salah Azaiez Institute, Tunis, Tunisia.

Introduction: The diabetic mastopathy (D.M) is a benign disease of the breast parenchyma but may clinically simulate a breast carcinoma. This mastopathy usually occurs in women who suffered from insulin-dependent diabetes mellitus for some years.
Aims: To describe the clinical, radiological, histological features of this benign disease. M.D is little known by clinician, radiologist and pathologist.
Materials and methods: Five cases of M.D were examined during 7-year period from 1997-2003. We analysed the clinocopathological and immunohistochemical findings of the lobular lymphocytic infiltrate. Immunohistochemical profile (CD20 and UCHL-1) was analysed using avidin-biotin-immunoperoxidase technique.
Results: All cases were female. Three cases had type 1 insulin-dependant diabetes and one case had type 2 insulin-independant diabetes. In one case the type of diabetes was unknown. The mean age at presentation was 40.8 years (33-57). The mean duration of diabetes was 18.25 years (12-24). In one case the patient was treated 6 years ago for a medullary carcinoma of the homolateral breast (T1N0M0). All the palpable lesions were dense at mammography. Macroscopically, the mean size was 5.7 cm (2.5-8). The parenchyma was found to be a white and fibrotic plaque indistinctly separate from surrounding normal breast tissue. Histologically, the lesion was characterized by the association of three elements: a lobular lymphocytic infiltrate, perivascular lymphocytic infiltrate of variable intensity, often organized in lymphoid nodules and stroma fibrosis with myofibroblast hyperplasia. The lymphocytic infiltrate was predominantly of B phenotype in 2 cases, predominantly of T phenotype in 2 cases and equally B and T phenotype in 1 case.
Conclusion: Our epidemiological, clinical and radiological findings are in agreement with published data. The diagnosis of M.D is based on the confrontation of the clinical context, radiological and characteristic histological features.

P 69
GYNAECOMASTIA IN HIV-INFECTED MEN ON HIGHLY ACTIVE ANTIRETROVIRAL THERAPY: A CASE REPORT AND REVIEW OF THE LITERATURE
CARVALHO Leda, BOMBONATTI Fernanda, DALTRO Barbara, BRANDÃO Luis Felipe, ALVES Gustavo, TARRICONE Vicente
Faculty of Medicine – Fundação Lusíada/ Hospital Guilherme Álvaro-Santos, SP, Brazil.

An estimated 610.000 individuals were infected with HIV/AIDS in Brazil in 2001. The rate of reported AIDS cases increased from 10.6 per 100.000 in 1992 to a high of 18.7 per 100.000 in 1998. Brazil has experienced a stabilizing trend with rates of 16.5, 16.4, and 14.8 per 100.000 in 1999, 2000, and 2001, respectively. Since 1998, the death rate from AIDS has stabilized at 6.3 per 100.000. This tendency is attributed to Brazil´s guarantee of access to free antiretroviral drugs since 1996. HIV-infected patients who are treated with highly active antiretroviral therapy (HAART) can developed breast enlargement due to benign and malignant diseases. Benign disorders comprise gynaecomastia (GM), pseudoangiomatous stromal hyperplasia and lipomastia. We describe a case of HAART-induced left-sided gynaecomastia in a 42-year-old HIV-infected man treated with lamivudine and efavirenz for 2 years and discuss the pathogenesis of these lesions according to the literature. Physical examination showed a nontender, freely mobile nodular mass in the periareolar area of left breast measuring 6.5x5.0 cm. The patient underwent a complete excision of the lesion. The pathological examination revealed gynaecomastia with extensive pseudoangiomatous stromal hyperplasia. The patient developed GM of the contralateral breast after 7-month follow-up period. Gynaecomatia is not uncommun in HIV-infected men under HAART, especially in those taking efavirenz and didanosine.The role of antiretroviral therapy on GM development is still discussed.

SOLITARY FIBROUS TUMOR OF THE MALE BREAST: A CASE REPORT
CARVALHO Leda* , PERUSSO Vanessa* , TROCOLI Felipe* , SANTOS Erika* , GAVINO Joyce*, TARRICONE Vicente*, PEREIRA Emilio**
*Faculty of Medicine- Fundacao Lusiada/ Hospital Guilherme Alvaro- Santos, SP, Brazil
**Salomao e Zoppi Laboratories- Sao Paulo, SP, Brazil

Solitary fibrous tumor is currently recognized as a benign soft tissue neoplasm that may occur in almost every site in the body. The breast is rarely involved. We describe a case of this rare lesion with the clinicopathological and immunohistochemical findings. A 64-year-old- white man presented a left breast mass that grew in a 18-month period. He denied any steroid abuse and did not disclose any sign or symptom of endocrinopathy. Physical examination showed a large, firm, round, well circumscribed tumor measuring 14x12 cm, replacing the entire left breast. Contralateral breast was normal. The patient underwent a simple mastectomy. The gross appearance was that of a well circumscribed but unencapsulated solid nodule. On cut section, the tumor was pale white to grayish. Histological examination showed a spindle cell tumor with pushing borders, which was

composed of bland spindle cells, haphazardly arranged and admixed with collagen fibers. There were hypercellular areas alternated with hypocellular fibrotic areas. Mitosis, necrosis and haemorrhages were not seen. Immunohistochemistry revealed that the tumor cells were diffusely positive for vimentine, CD34 while myogenic markers (Desmine [D33], á-smooth muscle actin [1A4]), cytokeratin AE1/AE3 and S-100 protein were negative. The pathological diagnosis was Solitary Fibrous Tumor of the breast on the basis of the gross, histological and immunohistochemical findings. No recurrence or any other clinical problems have been noted in the 6-month follow-up period. The structural and immunohistochemical characteristics of these tumors are similar to those of a myofibroblastoma. Some investigators attempted to distinguish between the two entities and the diagnosis of solitary fibrous tumor is reserved for lesions actin-negative and CD34-positive.

University of Medicine and Pharmacy Iasi, Romania

Phyllodes tumor represents a type of fibroepithelial breast tumor, previously named cystosarcoma phyllodes or periductal stromal tumor. The purpose of our study was the evaluation of the variability of clinicopathological features and its correlation with prognosis in this type of breast tumor. We present 6 cases of phyllodes tumors, diagnosed in patients of 34-59 years old. Fine needle aspiration cytology (FNAC) or needle core biopsies were applied in 3 cases, followed by intraoperatory examinations, in 2 cases. Fragments from the excisional biopsies were stained with usual stainings. Immunohistochemistry for vimentin, actin and desmin was applied. The clinical aspect was that of a firm, palpable, solitary, unilateral breast tumor, larger than 4 cm diameter (maximum 8.5 cm) and in only one case the tumors were multifocal, with diameter of 1 and 2 cm respectivelly, and history of rapid growth. Mammography revealed a rounded, lobulated, opaque mass, sharply defined in 4 cases and with indistinct borders in 2 cases. Cytology aspect was that typical of a fibroepithelial tumor, with excess bipolar stromal cells and fragments in the background. Gross pathology revealed nonencapsulated, well circumscribed external surface of nodules in 4 cases and a less circumscribed surface in 2 cases. Sections presented firm, bulging gray tissues, with papillary aspects. In 2 cases, small foci of necrosis and hemorrhage were observed. The main histologic hallmark was represented by an exaggerated structure of intracanalicular fibroadenoma (rising also issues of differential diagnosis) with increased cellularity, with epithelial-lined clefts and variable degree of epithelial hyperplasia. Three cases were diagnosed as benign, exhibiting well defined border, only few mitoses, modest cellular overgrowth and slight cytologic pleomorphism, with a correlation between the degree of epithelial proliferation and appearance of the stroma. 1 case presented invasive aspect, in the form of secondary fibroepithelial stromal overgrowth. One case presented the aspect of low-grade malignant phyllodes tumor, exhibiting microscopically invasive border, less than 5 mitoses/ 10 hpf, and moderate stromal cellularity. Immunohistochemistry expressed vimentin postivity, actin and desmin variable positivity. In one case a local recurrence was registered, corresponding to the high grade of the initial tumor.

P 72
EFFECTS OF ESTROGEN THERAPY IN POST-MENOPAUSAL WOMEN BREAST TISSUE MORPHOLOGICAL AND IMMUNOHISTOCHEMICAL EVALUATION.
LOGULLO angela, ELIAS Simone, HEINKE thais, KEMP Claudio BARACAT Edmund.

Introduction: Estrogen replacement therapy, isolated or combined with progestin has been prescribed widely in the past decade. However, many studies associate hormone replacement therapy (HRT) over 5 years with increased risk of breast cancer. Despite this important evidence, not much is known about the mechanisms by which hormones act on normal breast epithelium.

Objective: To analyze breast tissue of postmenopausal women before and after 6 months of continuous HRT with combined estrogen-progestin (0.625 mg of conjugated equine estrogens associated with 2.5 mg of medroxyprogesterone acetate).

Methods: All patients were evaluated before and considered clinically eligible to the HRT. Samples were obtained from the upper outer left quadrant, through a percutaneous large-core breast biopsy. All microscopic variables were evaluated by two independent observers. Morphology assessment included epithelial density and nuclear volume on hematoxylin-eosin stained slides. Morphometry was graphically analyzed with the use of IMAGELAB 2000 software, after image capture by the VIDCAP 32 system. Immunohistochemical reactions used a standard ABC method and included epithelial proliferative activity (Ki-67 index), expression of the estrogen and progestin receptors, and angiogenesis (CD-34).

Results: After 6 months of estrogen-progestin HRT, there was a significant increase in nuclear volume in late postmenopausal women. There was no difference in epithelial density, neither in Ki-67 labeling index and angiogenesis. Estrogen and progestin receptors expression did not change with the HRT.

Conclusions: Estrogen-progestin HRT during 6 months induced an enhanced nuclear volume of breast epithelial cells, suggesting an increase in their metabolic activity. However, it is this finding was observed only in late postmenopausal women. Other factors such as the exposure length, the type of hormone utilized, the timing of therapy initiation, the treatment regimen used and individual characteristics must be further evaluated.

P 73
MYOEPITHELIAL CARCINOMA ARISING IN AN ADENOMYOEPITHELIOMA OF THE BREAST: A CASE REPORT WITH IMMUNOHISTOCHEMICAL AND MUTATIONAL ANALYSIS
Ichiro Mori, Bo Han, Misa Nakamura, Yasushi Nakamura, Kennichi Kakudo
Department of Pathology, Wakayama Medical University

Adenomyoepithelioma of the breast is an uncommon tumor characterized by biphasic proliferation of both epithelial and myoepithelial cells. It was first recognized by Hamperl in 1970, and approximately 140 cases of adenomyoepithelioma in breast have been reported in English literature. Although most of adenomyoepithelioma has been considered to be benign, they can progress a malignant change and give rise to metastases in rare instances. Malignant transformation may involve epithelial, myoepithelial or both cellular elements of an adenomyoepithelioma. We report a 69-year-old female with a 2.5 cm mass in her right breast. Histological examination revealed a highly cellular neoplasm, consisting of a predominantly spindle cell proliferation admixed with scattered glandular epithelial lined spaces. The spindle cell component, which was surrounding the latter, proliferated in broad sheets, strands or multinodular fashion, and was separated by hyalinized collagenous stroma of varying thickness. Immunohistochemically, the spindle cells of the

tumor were diffusely positive for S-100, ƒ¿-SMA, GFAP (Glial fibrillary acidic protein), p63, and cytokeratin (CK) 14, whereas the glandular epithelial cells were strongly positive for EMA, CK19. Both glandular and myoepithelial cells were consistently negative for estrogen receptor (ER), progesterone receptor (PgR) and HER2/neu. These results confirmed biphasic epithelial and myoepithelial character of the tumor. On the basis of overall architecture, the tumor was classified as the spindle cell type of adenomyoepithelioma, and diagnosed as • gmyoepithelial carcinoma arising in an adenomyoepithelioma• h because of cytological atypia, high mitotic rate, and local invasion of the myoepithelial component. MIB1 index was high (>70%) in myoepithelial cells. Immunohistochemical study also revealed strong expression of P53 and phosphorylated extracellular signal-regulated kinase (ERK) 1/2 in myoepithelial carcinoma cells, but not glandular epithelial component. We hypothesized that myoepithelial cells in this tumor might possess p53 gene mutation. Laser capture microdissection (LCM) technique and mutational analysis revealed point mutation of p53 gene (T->C transversion at codon 176) in myoepithelial cells but not in glandular epithelial component and adjacent normal ductal epithelium. To our knowledge, this is the first report using mutational analysis on a malignant adenomyoepithelioma of the breast.

MYOEPITHELIAL LESIONS OF THE BREAST- THE DIAGNOSTIC PROBLEMS

CHMIELIK Ewa, SMOK-RAGANKIEWICZ Anna, WOLOSZYNSKA-PREIDL Krystyna, PONIKIEWSKA Dorota, STOBIECKA Ewa, JAWORSKA Magdalena, , SZCZENIAK-KLUSEK Bogna, GORAJ-ZAJAC Aleksandra , LANGE Dariusz
Department of Tumor Pathology, Centre of Oncology, M. Sk³odowska-Curie Institute, Gliwice, Poland

Introduction The myoepithelial cells are an integral part of the normal histology of the mammary glands. Lesions with striking overgrowth of myoepithelial cells are rare. Histologically and cytologically they may disclose different patterns, and some additional features may result in diagnostic errors.
Aim We report two cases of adenomyoepithelioma (tubular variant and spindle cell variant) and one case of adenomyoepithelial adenosis.
Material and methods We analysed their histologic, cytologic, immunohistochemical features and their differential diagnosis. The tumors were characterized by a bicellular pattern of gland-forming epithelial cells and proliferative myoepithelial cells. They showed foci of monotonous growth of myoepithelial cells devoid of glands with low mitotic rate (1-2 figures/10HPF) or middle mitotic rate (3-6 figures/10 HPF). Immunohistochemically myoepithelial cells were reactive with SMA, Actin, Calponin, but negative for Desmin. The cytologic features of adenomyoepitheliomas characterized by hypercellularity and clusters of regular polygonal cells with abundant pale cytoplasm (tubular variant) or sheets of spindle cells (spindle cell variant). The nuclei were round to oval with dispersed chromatin and small nucleoli.
Conclusion Failure to recognize adenomyoepithelioma or adenomyoepithelial adenosis may lead to an inappropriate diagnosis such as fibroadenoma, sclerosing adenosis, tubular adenoma, and even invasive carcinoma. Immunohistochemical examination is needed to distinguish epithelial cell proliferation from myoepithelial cell proliferation.

Departments of Pathology and Breast Surgery*, Theagenion Anticancer Hospital, Thessaloniki, GREECE

Introduction: Adenomyoepithelioma (AME) of the breast is a very rare low-grade malignant biphasic tumor, morphologically and immunohistochemically identical to epithelial-myoepithelial cell carcinoma of salivary gland.
Materials and methods: We report 10 cases of adenomyoepithelioma of the breast. All patients were female, ranging in age from 27 to 87 years (average 58 years). One patient had a history of chronic lymphocytic leukemia, two patients had coexistent ductal carcinoma and another one had fibroadenomas in both breasts.
All tumors presented as palpable nodules, ranging from 1-7 cm in maximum diameter and were located in the peripheral portion of the breast (8 cases) or near the areola (2 cases). Patients were treated by local excision.The excised tumors had the typical macroscopical, histological and immunohistochemical features of adenomyoepithelioma.
Discussion: Breast and salivary gland tumors can share morphological features, but often differ in incidence and clinical behavior. Breast tumors showing pure myoepithelial or epimyoepithelial differentiation are rare.
AME of the breast is a biphasic tumor, with a distinctive architectural growth pattern (tubular, papillary or solid), that is composed of two cell types, epithelial and myoepithelial. It usually affects adult female patients and presents as a palpable nodule. Tumors are treated by local excision.
AMEs of the breast are currently classified as low grade malignant tumors that may recur and rarely metastasize, but their histoprognostic factors are not yet defined.
The prognosis of adenomyoepithelioma is usually good. Local recurrences can occur when the primary tumor has a tubular growth pattern and has been incompletely excised. Tumors consisting mainly of myoepithelial cells and/or with increased mitotic activity (> 2/10 H.P.F) can behave in a malignant fashion. Lung is the most frequent site of distant metastases.
As regards our patients, all are well, without recurrences and distant metastases.

P 76
EVALUATION OF FREQUENCY OF EPSTEIN-BAR VIRUS (EBV) IN VARIOUS HISTOLOGICAL SUBTYPES OF HODGKIN'S DISEASE

SHARIFI Noorieh MD , KATEBI Mehrdad MD

Introduction: The incidence of Hodgkin's disease (HD) shows marked heterogeneity according to age, gender, race, geographical state, socioeconomic position and histological subtypes. Recently, multiple studies in different countries applied by newer technologies such as Immunohistochemistry (IHC) and polymerase chain reaction (PCR), to being more familiar with the pathogenesis of this neoplasm. The Epstein-Barr virus (EBV) is detected with high incidence in HD cases, approximately 40-50% in developed countries and much more (up to 95% of cases) in developing countries. There is evidences that mixed cellularity (MC) Hodgkin's disease is more likely to be EBV-associated which is against association of nodular sclerosis (NS) subtype.
Purpose of the study: With regard to the geographical location of Iran and absence of similar documented research in our knowledge, it is need to perform studies like this.
Methods & Materials: This study was done by IHC method with antibody against latent membrane protein-1 (LMP1) antigen of EBV for assessment of relationship between EBV infection and parameters such as age, gender and histological subtype. We collected 30 paraffin section samples of HD and positive cytoplasmic reactivity of Reed-Steinberg (RS) cells was evaluated.

Results: From 30 cases that surveyed in this study only 2 cases were not immunoreactive for EBV marker which both was NS subtype in two adult male .We confirm frequency of 93% EBV associated HD in our cases and also confirm the above histological subtype distribution and that childhood cases are more likely to be EBV-associated than adult cases. There is possible female predominant of EBV associated HD. This survey as a pilot study needs further studies with more cases for distinct confirmation.
Conclusion:
It seems EBV is a strong etiologic factor especially in developing countries like Iran and in childhood cases.

2 Institute of Pathology, Medical University of Innsbruck, Austria
3 Chair of Pathologic Anatomy & Lymphoma Unit, Institute of Hematology and Clinical Oncology "L. & A. Seràgnoli", University of Bologna, Italy

Abstract (265 words)
Introduction and purpose of the study: In most instances, Hodgkin and Reed-Sternberg cells (HRSC) of classical Hodgkin lymphoma (cHL) are of B-cell origin. Nevertheless, expression of T-cell related antigens on HRSC has been observed in some cases, pointing to a possible T-cell origin. We comprehensively analyzed the expression of a panel of T-cell antigens in a large serie of classical Hodgkin lymphoma (cHL) cases under standardized conditions using the tissue microarray (TMA) technique.
Methods: A TMA containing 330 cHL cases was used. Expression of the T-cell antigens CD2, CD3, CD4, CD5, CD7 and CD8 was analyzed immunohistochemically. A case was considered positive if >20% of HRSC demonstrated specific staining. The HRSC of T-cell marker positive cases were microdissected (75 to 120 HRSC per case) and analyzed by a multiplex PCR for clonal immunoglobulin heavy chain- and T-cell receptor gamma (TCRg) gene rearrangements.
Results : Twelve cases (5%) expressed at least one T-cell marker in the following order: CD2 in 10 cases, CD4 in 5 cases, CD3 in 2 cases and C5 and CD8 in 1 case each. There was no CD7-positive case. The expression of more than one T-cell antigen was seen in 5 cases (2%). In the positive cases, a mean fraction of 40% of the HRSC (range 20-100%) expressed the T-cell markers analyzed. In two cases (<1%) a clonal TCRg gene rearrangement was demonstrated.
Conclusions: The expression of T-cell antigens in HRSC of cHL is rare (5%) and in most cases due to aberrant expression of these markers on HRSC of B-cell origin. Only isolated cHL cases may be true clonal T-cell proliferations.

SENSORY NEUROPATHY REVEALING A HODGKIN'S LYMPHOMA.
O.LAOUAR*, C.KAIDI*, N.OUKID*, N.LANKAR**, M.TAZIR**, A.LANKAR*
* Laboratoire d'Anatomie et de Cytologie Pathologiques CHU Annaba-Algérie.
** Service de Neurologie CHU Mustapha Alger-Algérie

Association of a sensory neuropathy with a Hodgkin's lymphoma is rare.
Causes of a such neuropathy might vary. They are either due to the Hodgkin's lymphoma itself, infiltrating the peripheral nervous tissue, to opportunistic infections, viral in particular such as the HIV, to neurotoxic effects of chemotherapy or to a systemic reason leading to a paraneoplastic syndrome.
Hereby, we report a case in which a young woman aged 30 years presented progressive worsening gait troubles for 8 months with pain and lower limbs heaviness, a fall of 15 kg weight and a pruritus on trunk and hands.
Bilateral upper and lower limbs reflexes were abolished, with tactile and vibratory hypoaesthesia. EMG confirmed the sensory neurogenic fit.
Chest and abdominal scanner showed large mediastinal and intra and retroperitoneal adenopathies. It also revealed the presence of numerous micro-nodules in lung, liver and spleen.
Biopsy of a right upon-clavicle node which appeared during hospitalization concluded to a scleronodular form of Hodgkin's lymphoma.
Medullary and sural nerve biopsy did not show any tumoral cells infiltration.
As far as etiopathogeny is concerned, the retained hypothesis is the one of a systemic origin

Although bone involvement in the later stages of Hodgkin's disease is an expected phenomenon, bone involvement in early stages of the disease are very rare. About forty-nine cases of Hodgkin's disease presented with bone involvement were reported in the literature. We reported a 14 years old boy initially evaluated with the pain at the left ilium localization. Although all the radiological examinations were targeting an osseous anomaly, pathologic evaluations of the pelvic lymphadenopathies determined the disease. We discussed the possible differential diseases and reviewed the literature for the osseous presentation of Hodgkin's disease.

P 80
EPSTEIN-BARR VIRUS INDUCED B-CELL PROLIFERATION OF HODGKIN AND REED-STERNBERG CELL GENO- AND PHENOTYPE MAY DEVELOP IN PERIPHERAL T-CELL LYMPHOMAS
PAJOR László, KAJTÁR Béla, JÁKSÓ Pál, LACZA Ágnes, LÁSZLÓ Renáta
Department of Pathology, Faculty of Medicine, University of Pécs, Pécs, Hungary

Introduction. Peripheral T-cell lymphoma (PTCL) can display not only a morphological, but also an immunophenotypical overlap with classical Hodgkin lymphoma (cHL) as PTCL may contain CD30 and CD15 as well as T-marker positive Hodgkin-Reed-Sternberg (HRS) cells of cHL type in a mixed inflammatory background of eosinophils, lymphocytes, histiocytes and plasma cells . The distinction between PTCL and cHL is further complicated by the rare variant of PTCL resembling cHL because of the presence of HRS type of cells which are constantly Epstein-Barr virus (EBV) and CD30 positive. Single cell molecular analysis of these cells indicated B-cell genotype, but lack of monoclonality.

Purpose of the study. To clarify the nature of the scattered HRS-like cells, without the aspecific inflammatory background of cHL, in PTCLs.
Methods. Three cases of PTCLs with scattered giant cells of HRS type, resembling classical cHL because of the inconspicuous to moderate atypia of the PTCL cells, are described. Immunohistochemistry, in situ hybridization for EBV encoded RNA (EBER) and immunoglobulin (Ig) light chains, antigen receptor gene rearrangement studies on whole tissue as well as sequencing and mutational analysis of the FRI-J region on DNA obtained from EBER+, flow sorted nuclei were performed.
Results. Monoclonal rearrangement of the T-cell receptor gamma gene in whole tissue DNA extract as well as constant EBV association (EBER+, LMP-1+) of the HRS cells could be proved in all three cases. In one tumor, the HRS cells exhibited the CD15-, CD20+, CD30+, CD45+ phenotype and polyclonal Ig heavy chain (IgH) gene rearrangement in flow sorted, EBER+ nuclear preparation. In the other two lesions, however, the HRS type cells exhibited the CD15---/+, CD20--/+, CD30+, CD45- phenotype, lacked any light chain mRNA expression and showed clonal IgH gene rearrangement. In one of these two cases the IgH-V gene mutation and Ig gene associated transcription factor (Oct2, BOB.1/OBF.1) expression patterns corresponded to those of HRS cells in cHL.
Conclusion. EBV induced B-cell proliferation in a PTCL related immunosuppression may range from a polyclonal activation state even to HRS cells being indistinguishable in pheno- and genotype from those in cHL of B-cell origin and these latter cells might be the neoplastic precursor cells for a pathomorphologically overt cHL.

P 81

TITLE: IMMUNOHISTOCHEMICAL MARKERS CAN BE OF PREDICTIVE VALUE IN HODGKIN'S LYMPHOMA RESPONSE TO TREATMENT. A PRELIMINARY STUDY OF 23 CASES.

CANIONI Danielle, DEAU Bénédicte, TAUPIN Pierre, DELARUE Richard, VASILIU Viorel, BROUSSE Nicole, HERMINE Olivier.
Pathology, Hematology and Biostatistics Departments, Hôpital Necker, Paris, France and Université René Descartes, Paris V, France.

Hodgkin's lymphoma (HL) belong to the most curable tumor diseases in adults and about 80% of patients can be cured with modern treatment strategies. However, some HL are primary refractory to usual treatments and only clinical factors are considered as relevant for prognosis. In the current study we evaluate immunohistochemical markers of apoptosis, proliferation and of the environmental non neoplastic cells in HL in order to predict their prognostic value in treatment response. A retrospective study was performed on pre-treatment biopsy specimen of 23 patients presenting with HL, 8 with primary refractory HL and 15 responding well to chemotherapy and free of disease for 2 or 3 years. These patients ranged in age from 23 to 52 years old (median= 36.5 years) for refractory HL and from 21 to 75 years old (median = 37.9 years) for responding patients. All refractory HL, except one for whom histological type could not be precised(too small biopsy), had a nodular sclerosis (NS) histological type. The histological type was NS in 13 responding patients and mixed cellularity for the 2 others. The semi-quantitative immunohistochemical study used CD30, bcl2, p53, Ki67, TiA1 and c-kit antibodies. The results were statistically evaluated using a Wilcoxon sum rank test. CD30 and Ki67 were strongly expressed on Hodgkin (Hg) and Reed-Sternberg (RS) cells whatever patients were refractory or responded well to chemotherapy. By contrast, p53 and bcl2 had a significantly higher expression on Hg or RS cells in refractory patients (median = 90% & 60%) compared to responding HL (median = 42.5% & 8%) (p=0.0001 & p=0.026 respectively). The cytotoxic marker TiA1 stained a significantly higher number of small lymphocytes in refractory HL (median=53 per high power field (hpf)) compared to responding patients (median=24 per hpf) (p= 0.0003). C-kit antibody was negative in Hg or RS cells but stained significantly more mastocytes in refractory HL (median=13 per hpf) comparing to responding HL (median=3.8 per hpf) (p= 0.001). These results indicate that some immunohistochemical markers may be useful for predicting the response to therapy of HL. A high expression of bcl2 and p53 in refractory HL supports the notion that an intact apoptosis cascade is essential for cell killing effect of chemotherapy. The increasing of TiA1 and c-kit positive cells raises the importance of the environmental non-neoplastic cells in HL. A larger study is mandatory to confirm these preliminary results.

P 82

EPSTEIN-BARR VIRUS (EBV) AND HODGKIN'S DISEASE IN A MOROCCAN CENTRE

L. Jabri*, F. Marnissi*, M. Karkouri*, A. Madani**, A. Iraqi*
* Pathology Department, ** Hematology and pediatric oncology; University Hospital Ibn Rochd, Casablanca, Maroc

The Epstein-Barr virus (EBV) has been implicated as a contributing factor in the development of Hodgkin's disease (HD). Western cases of Hodgkin's disease have shown the presence of EBV in tumoral cells in approximately 50%. The presence of EBV varied according to the histological subtype. Mixed cellularity HD is more like to be EBV-positive compared with nodular sclerosis. The purpose of our study is to analyse the prevalence of EBV in this disease in a Moroccan population using immunohistochemical detection of latent membrane protein LMP-1.
We studied a total of 62 cases of classical Hodgkin's disease, diagnosed between January 2004 and December 2004. Of 10 patients (16 %) less than 15 years of age (childhood), 5 had a nodular sclerosis subtype, 4 mixed cellularity, and one unclassified. Of the 52 from patients aged 15 years and above, 30 (58%)
had nodular sclerosis, 20 (38,50 %) mixed cellularity, and 2 unclassifiable. 11 patients were 50 years and above (5 sclerosis nodular, 5 mixed cellularity and 1 unclassified). All the cases were tested for CD30 and CD15. 95% were CD30 positive and 83% were CD15 positive.
Positive immunostaining for LMP1 was demonstrated in 39 / 62 cases (63 %) respectively 50% in sclerosis nodular and 47 % in mixed cellularity . In the younger age group, 7 of the 10 cases (4 mixed cellularity, 2 nodular sclerosis) showed the presence of EBV (70 %). In the older age group, EBV was detected (61,50%) in the following proportion: 33% nodular sclerosis, 29 % mixed cellularity.
The results of the current study showed that nodular sclerosis HD is more frequent (53 %) than mixed cellularity (42%), without bimodal distribution. The peak of incidence was between 15 and 50 years. The findings suggest also, a strong association of EBV with Hodgkin's disease in Moroccans (39/62, 63%), especially in children when it reach 70%. In this study there was no evidence of predominance association of EBV in mixed cellularity HD. Our results must be confirmed by in situ hibridization.

B-CELL DIFFERENTIATION IMMUNOPHENOTYPES IN CLASSICAL HODGKIN LYMPHOMAS

V. Panoulas (1), A. Papoudou-Bai (2), S. Kamina (1), N. Horianopoulos (1), P. Kitsoulis (2), K. Stefanaki (3), D. Rontogianni (4), N.J. Agnantis (1), P. Kanavaros (2), M Bai (1)

Department of Pathology (1) and Department of Anatomy-Histology-Embryology (2), Medical Faculty, University of Ioannina, Department of Pathology, Agia Sophia Hospital, Athens (3), Department of Pathology, Evangelismos Hospital, Athens (4), Greece

The bcl6/CD10/MUM1/CD138 B-cell differentiation immunophenotypes were analyzed in 101 cases of classical Hodgkin lymphomas (cHL) in order to gain further insight in their histogenesis.
Three major bcl6/CD10/MUM1/CD138 immunophenotypes were distinguished on the basis of the immunohistochemical positivity of Hodgkin and Reed-Sternberg (H/RS) cells: a) the late germinal center (GC)/early post GC B-cell-like immunophenotype (bcl6-/CD10-/MUM1+/CD138-); 59/101 cases (59 %), b) the post GC B-cell-like immunophenotype (bcl6-/CD10-/MUM1+/CD138+); 24/101 cases (24 %) and c) the indeterminate immunophenotype 18/101 cases (18 %) (bcl6+/CD10-/MUM1+/CD138-: 14 cases and bcl6+/CD10-/MUM1+/CD138+: 4 cases).
The above findings indicate that H/RS cells in most cHL display bcl6/CD10/MUM1/CD138 immunophenotypes consistent with late GC/early post GC or post GC B-cell differentiation. In addition, H/RS cells in a small fraction of cHL display indeterminate bcl6/CD10/MUM1/CD138 immunophenotypes which are characterized by simultaneous expression of GC, late GC/early post GC and post GC B-cell differentiation proteins. These immunophenotypes do not correspond to the differentiation immunophenotypes of normal B-cells and their identification in a part of cHL suggests that the differentiation process of H/RS cells is not complete in a fraction of these cells and/or is still ongoing at the time of observation.

P 84
PROLIFERATION PROFILE OF CLASSICAL HODGKIN'S LYMPHOMAS. INCREASED EXPRESSION OF THE PROTEIN CYCLIN D2 IN HODGKIN AND REED-STERNBERG CELLS.

E. Tsanou (1), A. Goussia (1), S. Kamina, (1), C. Grepi , (1), K. Stefanaki (2), D. Rontogianni (3), V. Galani (4), N. J. Agnantis (1), P. Kanavaros (4), M. Bai (1)
Department of Pathology, Medical Faculty, University of Ioannina (1), Department of Pathology, Agia Sophia Hospital, Athens (2), Department of Pathology, Evangelismos Hospital, Athens (3), Department of Anatomy-Histology-Embryology, Medical Faculty, University of Ioannina (4), Greece

There is accumulating evidence that Hodgkin and Reed-Sternberg cells of classical Hodgkin's lymphomas display multiple and concurrent alterations in different pathways and checkpoints of the cell cycle. However, the expression of cyclin D2 and its relation to other major cell cycle proteins has not been analyzed in classical Hodgkin's lymphomas.
The aim of the present study was to assess expression of cyclin D2, Ki67, cyclin A, cyclin B1, cyclin D1, cyclin D3, cyclin E, p53, Rb, p16 and p27 proteins in order to gain further insight in the proliferation profile of classical Hodgkin's lymphomas.
Overexpression of cyclin D2 in Hodgkin and Reed-Sternberg cells was detected in 64/89 (72%) cases of classical Hodgkin's lymphomas. This finding, in view of recent in vitro data showing that constitutive activation of nuclear factor (NF)-kB could upregulate cyclin D2 expression in part via signal transducer and activator of transcription (STAT)-5a, suggests that induction of cyclin D2 expression may support the proliferation of Hodgkin and Reed-Sternberg cells. In addition, the present study showed that 1) increased p27 expression status was significantly correlated with higher levels of cyclin A expression ($p=0.048$) and 2) increased p53 expression status was significantly correlated with higher levels of cyclin A ($p<0.001$) and cyclin B1 ($p=0.040$) expression. The association between increased p27 and p53 expression status and higher expression levels of G2/M cyclins suggests that the impairment of the growth inhibitory activity of the p27 and p53 tumor suppressor pathways may promote the proliferation of Hodgkin and Reed-Sternberg cells.

P 85
RECTAL EPSTEIN BARR VIRUS POSITIVE HODGKIN LYMPHOMA IN A PATIENT WITH CROHN'S DISEASE

S. Kamina (1), M. Economou (2), K. Katsanos (2), Ch. Bali (3), E. Arkoumani (1), E, Balasi (1), E. Sintou-Mantela (1), A. Kappas (3), E. Tsianos (2), M. Bai (1)
Department of Pathology (1), Departnent of Hepato-Gastroenterology (2) and Department of Surgery (3), Medical Faculty, University of Ioannina, Greece

Primary gastrointestinal Hodgkin lymphomas arising in the setting of Crohn's disease (CD) are rare. Only ten cases have so far been reported. A strong association with Epstein Barr virus (EBV) infection, similar to that found in post-transplantation immunosuppression-related lymphoproliferative disorders, has been suggested.
We present a 35-year-old man with ileocolonic Crohn's disease diagnosed at the age of 27, several months after an operation for a colorectal adenocarcinoma. Patient was on maintenance treatment with immunosuppressants and additionally he received two doses of infliximab. Seven years after adenocarcinoma diagnosis, the patient presented with anal pain and diarrhea. At that time digital examination revealed a small rectal area, which was thick in digital contact leaving blood traces at palpation. Rectosigmoidoscopy and subsequent biopsies from this area located 5 cm above the anal ring were compatible with rectal Hodgkin lymphoma. Histopathological examination revealed extensive ulcerations of the mucosa and diffuse infiltration composed by a mixed inflammatory cell population and numerous Hodgkin and Reed-Sternberg cells. The tumor cells showed the immunophenotype of classical Hodgkin lymphoma (CD15+, CD30+, CD45-, CD20-, CD3-, EMA-). In situ hybridization study with EBV RNA 1/2 (EBER 1/2) probes and immunohistochemistry for the latent membrane protein-1 (LMP-1) showed that almost all tumor cells carried EBV infection. No peripheral lymph nodes were noticed and CT examination showed no evidence of visceral lymph node enlargement or hepatosplenic lesions. Anal ultrasonography showed a hypo-echogenous lesion (1.5X2 cm2) extending to the one third of the whole rectal wall perimeter. Perirectal fat was invaded. Bone marrow biopsy was normal. Infliximab administration was discontinued and patient underwent chemotherapy. After a eighteen-month follow up, the patient does well with no evidence of secondary lesions or further local progression.
We present herein a primary rectal EBV positive Hodgkin lymphoma metachronous to a colorectal adenocarcinoma in a Crohn's disease patient who was on maintenance treatment with immunosuppressants. It is suggested that immunosuppressive drugs may facilitate the emergence of a EBV-positive neoplastic clone, but this scenario still remain only theoretical.

Introduction: Bone marrow (BM) infiltration is present in 5-15% of patients with Hodgkin's lymphoma. It is usually associated with prominent fibrosis and proliferation of blood vessels. Limited information exists about the significance of neoangiogenesis and expression of "homing receptor" CD44 in Hodgkin's lymphoma.
Aims: In this study we analyzed immunohistochemical expression of CD34, VEGF and CD44 in lymph node (LN) and BM infiltrate by Hodgkin's lymphoma.
Methods: We identified 40 patients (29 male and 11 female, median age 45 years) with BM infiltration by Hodgkin's lymphoma. The most frequent histological type was nodular sclerosis (28/40). Slides from paraffin embedded LN and BM biopsy of the same patient were stained with haematoxylin&eosin and reticulin fibers (Gordon-Sweet). Microvessels were visualized by immunohistochemical staining for CD34. We counted the number of vessels per 400x high power field (hpf) in the area of most dense vascularization. All samples were further analyzed for the expression of VEGF and CD44 in neoplastic Hodgkin-Reed-Sternberg (HRS) cells. The intensity of staining was graded as weak, moderate and strong.
Results: In majority of patients (31/40) we found marked increase of microvessels density, which correlated with the number of VEGF-positive HRS cells. Expression of CD34 was almost twice lower in BM than in LN in majority of patients. We observed that mean vessels count per hpf in LN was 12.0, but in BM this count was 7.5/hpf. The intensity of VEGF expression in HRS cells was usually strong in LN and moderate in BM infiltrate of the same patient. Immunohistohemical expression of CD44 both in LN and BM was high in HRS cells in majority of patients (35/40), but in this group of 35 cases, in 4 cases HRS cells lost CD44 expression in BM infiltrate.
Conclusion: Our findings suggest that neoangiogenesis in BM infiltrates by Hodgkin's lymphoma was extensively increased. Therefore, the density of microvessels and expression of VEGF may provide useful prognostic information. The results of CD44 expression might suggest causal involvement of this marker in the progression of Hodgkin's lymphoma, especially nodular sclerosis type.

BRAZIL

Introduction: Hodgkin Lymphoma (HL) is a monoclonal neoplasm in which the neoplastic cells, named Hodgkin-Reed&Sternberg (H-RS) cells, bear somatic mutations in immunoglobulin genes, inactivating immunoglobulin production. Unlike normal B lymphocytes, which suffer apoptosis when failing to produce immunoglobulins, H-RS cells, by mechanisms not fully understood, are capable of escaping apoptotis. Nitric oxide (NO), a molecule involved in multiple steps of carcinogenesis, is produced by a family of enzimes known as the nitric oxide synthases (NOS), which have been shown to be overexpressed in many human tumors. NOS expression and NO production in HL have not been described yet. Objective: This study analyzed the role of NOS and apoptosis-related proteins expression in HL, to test the hypothesis that NOS expression and NO production are involved in the defective apoptotic program of HL. The role of EBV on NOS expression and NO production was also studied. Finally we investigated the influence of NOS expression on the clinical outcome of HL's patients. Material and methods: 171 cases of HL were retrieved from the archives of the Departamento de Patologia do Hospital do Câncer A C Camargo. Relapse biopsies and HIV-associated HL were excluded. Immunostains with antibodies against NOS1, NOS2, nitrotyrosine, bcl-2, bax, p53, fas, fasL and LMP1 were performed. Cases were also tested for EBV status using in situ hybridization for EBER-1. Results: NOS1 and NOS 2 expression were detected in 42.1% and 55% of the cases, respectively. Nitrotyrosine expression was observed in 18.7% of the cases. Bcl-2, bax, p53, fas, fasL and LMP1 expression were positive in 35.1%, 44.4%, 44.4%, 93,6%, 5.8% e 49.7% of the cases, respectively. EBER-1 was detected in 46.8% of the cases. Significant associations were established between bax and p53 (p=0.036), bax and fasL (p=0.046), NOS1 and p53 (p=0.006), bax and NOS2 (p=0.022); and between bcl-2 e NOS2 (p=0.034). An inverse correlation was observed between EBV (LMP-1) and NOS2 (p=0.018), and between EBV and bcl-2 (LMP-1, p=0.002; EBER, p=0.006). NOS2 expression was associated with a shorter overall survival (p=0.0098). It also predicted a poor prognosis in cases treated with MOPP/ABVD (p=0.0003). Conclusions: H-RS cells express NOS and produce NO, which appear to play a role in the defective apoptotic program of HL. NOS2 may be involved in bcl-2 overexpression in EBV-negative HL. NOS2 expression is associated with a poor outcome in HL.

P 88

FREQUENT ASSOCIATION OF BOB-1 AND MUM-1 IN EBV INFECTED EGYPTIAN CLASSIC HODGKIN LYMPHOMA

H. Abd El All, P. Gaulard

Background: Previous studies concerning the expression of Bob-1, MUM-1 and Bmi-1 in classic Hodgkin lymphoma (CHL), confirmed the expression of Bmi-1 and MUM-1 in Hodgkin/Reed-Sternberg (H/RS) cells, while almost all the researchers agree on the lack of Bob-1 expression pointing out to a defect in transcription machinery associated with lack of immunoglobulin gene expression. Objectives: To study the expression of Bob-1, MUM1 and Bmi-1 proteins in Egyptian CHL and to correlate this expression with EBV viral load. Methods: Paraffin sections of randomly selected 24 CHL cases were included: 3 lymphocyte rich (LR), 6 mixed cellularity (MC), 13 nodular sclerosis (NS) and 2 lymphocyte depletion (LD). Results: All the cases except five (two MC and three NS) were positive for EBV by in-situ hybridization and immunostaining for LMP-1. Unexpectedly, strong to moderate nuclear Bob-1 expression was observed in 94% of cases ranging from 25-100% of the neoplastic cells. Moderate MUM-1staining, observed in 94% of cases, was nuclear, nucleolar and cytoplasmic. The percentage of MUM-1+ cells ranged from 25-75%. Mild to moderate nuclear bmi-1 positivity was observed in 56% of cases; few to 25% of bmi-1+ cells were identified. There was a frequent co-expression of Bob-1/MUM-1 in all the cases ($p<0.005$). This expression parallels the EBV positive H/RS cells. Conclusion: These findings concerning the expression of Bob-1, MUM-1 and Bmi-1 in the Egyptian population are different from the Western ones denoting different genetic and environmental factors. Does this difference should be taken into

consideration in the treatment strategy? A point under consideration.

P 89

CLINICOPATHOLOGIC PROFILE OF HODGKIN DISEASE IN A MOROCCAN CENTRE. ABOUT 269 CASES

L Jabri*, F. Marnissi*, A. Madani**, S Zamiati*, A Iraqi*
*Central Department of Pathology,
**Hematology and pediatric oncology department Ibn Roshd University Hospital, Casablanca, Morocco

Epidemiological distribution of Hodgkin disease (HD) show in developping countries two peaks occurence, one in childhodfor boys and another in older adults. The subtype of HD that occurs most often in this countries is cellularity mixed. In developping countries ther is a bimodal age specific incidence rate with early peak in adulthood and another in advanced age.
In order to define epidemiologic and histoprognosis aspects of the Hodgkin disease, we conduct a retrospective study on 269 cases recorded at the departement of Pathology, Ibn Rochd University Hospital, Casablanca, between 1997 and 2001. The mean age of our patients is 40 [04-84 years]. The sex-ratio is 1,5. Incidence according to age finds a peak between 17 and 35 years, without bimodal repartition. Actually, 74,3% of our patients are less than 40, 17% only are under 14. The predominant histologic type is the sclerosisnodular (SN) (70,5%) versus 26,8% for the cellularity mixed subtype (CM) . The SN subtype is predominant without regard of age (< 14 years, 14-40 years and >40 years). The bone morrow biopsy showed invasion in 30% . The immunohistochemistry study was realised in 80 cases (29,7%). CD15 was positive in 84,4 % and CD 30 in 93,7% . Stage III et IV constitute 64,43%. The rate of complete remission is 69,5%. This rate is 89% for the under 40 years old and only 64,4% for the more 40 years old.
Factors that influe on the complete remission rate are : the advanced age (the rate of complete remission of the patients <40 ans is 89>% versus 64,4 % for patients under 40 years old; the histologic subtype, but we find that complete remission in mixed cellularity subtype is higher than sclerosis nodular subtype.
The absence of bimodal distribution according to age, predominance of the SN subtype and the diffuse stages are the main characteristics of our study.

NODULAR LIVER INVOLVEMENT IN A PATIENT WITH MULTIPLE MYELOMA

I.D.Venizelos1, E.Mandala2, Z.A.Tatsiou1, I.Paradias2, L.Kampas1 , D.Sioutopoulou1

1 Department of Pathology, Hippokration Hospital, Thessaloniki
2D' Department of Internal Medicine, Aristotelian University of Thessaloniki, Hippokration Hospital, Thessaloniki, Greece

Multiple myeloma (MM) is a malignant plasma cell disorder characterized by the production of a monoclonal immunoglobulin. Recurrent infections, anemia, osteolytic lesions and renal insufficiency are the typical clinical manifestations. Liver involvement in the form of solitary or multiple nodules is extremely rare.

We report the case of a 42-year –old male, who presented in our hospital due to pathologic fracture of his right femur. From the hematological examination, bone marrow aspiration and biopsy, the diagnosis of IgG-k MM was made. The patient was treated with oral melphalan and prednisone. Three years later, at the time of reevaluation, it was found pancytopenia, multiple lytic bone lesions, diffuse osteopenia, renal function impairement, but normal liver function. Bone marrow biopsy showed an hypocellular marrow and infiltration by plasma cells (30%). He was treated with VAD regimen for only one cycle, because of severe cardiac complications, and pulse dexamethasone. Whole blood cell counts and renal function improved, but he developed progressive impairment of liver biochemical parameters. A CT scan revealed multiple hypodense liver lesions. A fine needle CT-guided biopsy of a liver nodule was performed to rule out metastasis of another origin. Histological examination showed infiltration of the liver by plasma cells which were positive for CD138 and k-light chain. A bone marrow biopsy at the same time showed plasma cell infiltration (60%). The patient underwent treatment with proteasome inhibitor bortezomib, showing improvement of renal function but progressive hepatic failure with portal hypertension and ascites.

We present this case because liver involvement by MM in the form of multiple nodules is extremely rare in living patients. Conclusively, liver infiltration should be suspected in a case of nodular liver lesions in patients with known MM.

MYELODYSPLASTIC LESIONS IN THE BONE MARROW OF PATIENTS WITH MULTIPLE MYELOMA AT FIRST DIAGNOSIS.

Hadjileontis C1, Zervas K2, Papaioannou M2, Papadimitriou C1, Kaloutsi V1.
Technicians1: Tsatsaroni A, Avgoloupi A.
1. Pathology Dept, Medical School, Aristotle University of Thessaloniki, Greece.
2. Haematology Clinic, Theagenion Cancer Hospital of Thessaloniki, Greece.

INTRODUCTION: The myelodysplastic lesions (MDL) in the bone marrow (BM) of patients with multiple myeloma (MM) that are more widely known are the ones related to the therapeutic treatment. Studies on MDL as a result of the toxicity that myeloma cells may have on the haemopoietic BM and are present at first diagnosis have not until now been reported.
PATIENTS AND METHODS: We investigated the presence of MDL in BM biopsies (H+E stains) as well as in BM and peripheral blood imprints (May Gruenwald Giemsa stains) of 80 patients with newly diagnosed MM. Each case was evaluated by two observators. The presence of MDL was statistically correlated with the percentage of infiltration for each case (paired t-test) and the survival of the patients (Spearman's and Kruskal-Walis's tests).
RESULTS: MDL were present in 35% of the patients and they were similar to those observed in myelodysplastic syndromes, but of less severity. They concerned mainly the red cell line (33,75%), secondarily the granulocytic line (10%) and less often the megakaryocytic line (6,25%), while MDL from two of the three lines were found in 10% of the cases and from all the three lines in 3,75% of the cases. Statistical analysis brought up a significant correlation between the presence of MDL and the percentage of MM infiltration ($p<0,01$), as well as between MDL and patients' survival ($p<0,01$).
CONCLUSIONS: We demonstrate the prognostic value and therefore the diagnostic significance of the presence of MDL in the BM of patients with MM. Due to the absence of other relevant data in the current literature more research should be performed.

P 92

BONE MARROW FIBROSIS IN PATIENTS WITH MULTIPLE MYELOMA

Janusz Dzieciol, Dorota Lemancewicz, Janusz Kloczko, Katarzyna Zietara

Bone marrow fibrosis is a reactive process that results from an increased stimulation of fibroblast proliferation and collagen synthesis. Multiple myeloma (MM) is a malignant neoplasm characterised by the increase of clonal plasma cells in bone marrow. The levels of cytokines, which are responsible for fibrosis, are raised in patients with MM as compared to healthy patients. Histopathological examination of bone marrow by bone marrow trephine biopsy (BMT) makes possibility for evaluation of the degree of reticulin fibrosis (an increasing number of argentophylic fibres) and collagen fibrosis (an increasing number of collagen fibres). BMT is also used for the assessment of bone marrow involvement by plasma cells. The aim of the study was to determine the degree of bone marrow fibrosis in patient with multiple myeloma. The specimens were obtained by BMT from 82 patients with multiple myeloma, as initial examinations prior to any treatment, from the postero-superior iliac spine using the Jamshidi needle. Bone marrow tissue was carried out in Oxford solution and paraffin embedding. Hematoxylin and eosin, Gomori's, AZAN staining was applied. The degree of bone marrow fibrosis using Kundel criteria with Bauermeister modification was determined. The morphometric tests were done using the image analysis (DP 12) for evaluation the percentage of plasma cells infiltration. Nodular and diffuse patterns of infiltration in bone marrow by plasma cells were observed in 67 patients. In the most of patients the marrow was infiltrated in diffuse pattern. The infiltration was accompanied by an increase in the number of reticulin fibres. The frequency of reticulin fibrosis was positively correlated with advanced clinical stage according to the classification of Durie and Salmon. Collagen fibrosis was found in 13 patients. BMT is a useful method for assessing the degree of myelofibrosis in MM. It has prognostic value, because when the collagen fibrosis is present, only partial regression after treatment is possible.

P 93

PLASMABLASTIC MICROLYMPHOMA ASOCIATED WITH A MULTICENTRIC CASTLEMAN DISEASE IN A HIV+ PATIENT

DE PINIEUX Isabelle,MOLINIE Vincent, BALATON André, HOMSI Toufik, departement of pathology
AUPERIN Isabelle, departement of internal medicine
hospital Saint Joseph, 182 rue R. Losserand, 75014 Paris

Multicentric Castleman's disease (MCM)in HIV+ is associated with human herpes virus 8 (HHV8)infection. Most of the patients present a mixed histological pattern : hyaline-vascular variant and plasma cell variant. HHV8 infected cells are plasmablasts localized within the mantle zone or organized in small sheets of large plasmablastic cells or in a microlymphoma toward aggressive NHL.
Aim of the study: evaluation of HHV8 antibody in a plasma cell variant of MCM in a HIV+ 34 year's old man who presented cervical polyadenopathy with night sweats, fever and inflammmatory biological abnormalities.
Materiel and methods: immunostaining were performed on formol fixed, paraffin embedded 3microns sections on a Dakostainer with CD3(1/75),CD20(1/150), CD68(1/500),CD138 (1/50), CD15(1/200), CD30(1/200), EMA(1/50), HHV1 et 2 (2/2500), kappa (1/15000), lambda (1/15000) Dako;CMV(1/300)Biosoft and HHV8(1/25)Novocastra.
Results : histological evaluation of one of these adenopathy revealed atrophic lymphoid follicles with small germinal centers and peripheal onion lymphoid arrangement, hyaline vascular proliferation, mixed with regular plasma cells sheets in the interfollicular zone. In small foci, the peripheral sinus exhibites small sheets of large lymphoid cells with atypical nuclei and prominent nucleoli. These atypical cells were HHV8+ whereas plasma cells were negatives. These large cells were also CD138+. They didn't exhibit any immunostaining with CD20, CD3, CD30, CD15 and EMA antibodies. The diagnosis of a plasmablastic micro lymphoma associated with a MCM was retained in presence of a restricted monotypic phenotype IgMlambda.
Conclusion : In case of lymphadenopathy in a HIV+, the HHV8 staining is helpful to detect plasmablastic microlymphoma and even aggressive NHL.

P 94

IN VIVO WNT-SIGNALING ANTAGONIST SFRP3 EXPRESSION IN MULTIPLE MYELOMA: ANOTHER POTENTIAL PATHWAY IN MYELOMA BONE DISEASE.

Raynaud Pierre(1), Poizat Flora (1), Rigau Valérie (1), Baldet Pierre (1), Klein Bernard (2), Costes Valérie (1).
(1) Laboratoire d'Anatomie Pathologique, CHU de Montpellier, France.
(2) Institut de Recherche en Biothérapies, CHU de Montpellier, France.

Multiple myeloma (MM) is commonly associated with lytic bone lesions. Although the mechanisms of increased osteoclast activity are partially understood, comparatively little is known about the mechanisms that lead to the observed decrease in osteoblast number and activity.
Wnt glycoproteins comprise a family of extracellular signaling ligands that play essential roles in cell proliferation and differentiation during normal developmental processes. Recently, secreted frizzled-related proteins (sFRPs) have been identified as possible modulators of the Wnt signal transduction pathway, based on their ability to bind and sequester the Wnt ligands. The sFRP3 glycoprotein suppress osteoblast cell number, acting as a decoy receptor for Wnt proteins that promote osteoblast proliferation.
Methods: Using a double-immunostaining (CD138/sFRP3) on tissue microarrays (TMA), we analysed plasma cells (PCs) sFRP3 expression in 59 fixed paraffin-embedded bone marrow samples (BMS) from patients with newly diagnosed MM (according to International Myeloma Working Group criteria (2002)) versus 43 control normal BMS.
All BMS were Bouin's (alcohol-based) fixed, decalcified in EDTA and paraffin embedded. The TMA consisted of 2 cores (2mm in diameter) from each BMS.
The percentage of CD138/sFRP3-positive PCs was determined by counting all PCs in normal samples to 400 PCs in MM samples in areas with the impression of highest expression ("hot spot") at low magnification.
Results: Depending on sample, the percentage of positive PCs varied from 0% to 100%.
We found consistent, uniform cytoplasmic sFRP3 expression for an average of 80% of the PCs (mean: 90%) in MM samples, versus 19% (mean: 16.4%) of the PCs in normal BMS (p-value < 0.0001).
If we considered as positive for sFRP3 expression, BMS with more than 50% of PCs sFRP3/CD138+, 88.1% of MM samples were positive as opposed to 11.6 % of normal samples ($p<0.001$).
Conclusion: Using bone marrow TMA for the first time, we observed, by double-immunostaining, significant differences in the relative expression of sFRP3 between PCs of newly diagnosed MM and normal BMS. The production and secretion by myeloma cells of sFRP3, which is an inhibitor of osteoblast proliferation, is a new potential pathway in myeloma bone disease. We propose that sFRP3 inhibits the proliferation of osteoblasts and shift the balance between osteoblasts and osteoclasts, thereby diminishing bone formation and enhancing the development of lytic lesions.

P 95

PLASMA CELL MORPHOLOGY AND PROLIFERATION FRACTION IN MULTIPLE

MYELOMA ASSESSED IN TREPHINE BIOPSIES: RELATION TO CLINICAL STAGE

BAYKOV Vadim
Dept pathology, St Petersburg medical university

Multiple myeloma (MM) is a haematologic malignancy, built of terminally differentiated B-cells with morphological features of plasma cells and their predecessors. Morphological presentation of the tumour is well known, but little data exist on cellular architecture assessed in paraffin sections and related to clinical stage and proliferation rate.
The OBJECTIVE of the study was to evaluate cellular composition and proliferation fraction of the tumour in different clinical stages.
The study was based on 62 trephine biopsies (TB), containing myeloma clone. TB were taken from patients (aged 47-78) for diagnostic and follow-up purposes with informed consent. 9 patients were in Durie stage I, 24 – in stage II and 29 in stage III. Routinely HE and Romanovsky-Giemsa stains were performed, as well as immunostaining for CD138 and Ki-67 (Dako Cytomation, Denmark). CD138 immunoreactivity contributed greatly to recognition of abnormal or immature plasma cells and in some cases increased the total myeloma cell count up to 30% as compared to HE stain alone. The cell sub-classification protocol, proposed by J.E.Goasguen et al. (1999) for cytological purposes, was applied to histological sections. It appeared possible to put over 85% of myeloma cells into four groups - plasmablastic, proplasmacytic I and II and plasma cell using "positive selection" methodology. Statistically significant increase in plasmablastic cells was documented in patients in stage III of the disease in comparison with those in stage I (14% against 2%), accompanied by concomitant decrease in mature plasma cells (30% against 68%). Proliferation index was 0,9 in stage I and 9,5 in stage III. Values in stage III showed substantial variation, entirely because of 3 cases included in the group with predominantly blastic morphology. These cases taken separately showed plasmablastic cell count 39% and proliferation index of 40%. Interestingly, plasmablastic cell count performed in aspirate smears showed mean of 22%.
WE CONCLUDE that blastic cell count and proliferation rate assessed in bone marrow TBs correlate with clinical stage of MM. In bone marrow sections plasmablastic cell count is higher than reported in smears - possibly due to differential ability of mature and immature bone marrow cells to get aspirated.

P 96

CD20 ABERRANT EXPRESSION OF MULTIPLE MYELOMA

M. Melachrinou, V. Zolota, P. Matsouka*, T. Kourelis*, I. Xagoraris, P. Aroukatos, D. S. Bonikos.
Departments of Pathology and *Internal Medicine, Division of Hematology, University of Patras Medical School, Patras, Greece.

Introduction It is well known that reactive and neoplastic plasma cells may express various hematopoietic and non-hematopoietic antigens. However, there are few reports that correlate the aberrant immunophenotype of multiple myeloma (MM) with the survival of patients. The aim of this study was to investigate whether the expression of particular B-cell antigens by myeloma cells is suggestive of a more aggressive phenotype.
Material and method A total of 102 routinely processed bone marrow biopsy specimens from untreated MM patients were immunostained with anti-LCA (CD45), L26 (CD20), anti-CD79a and anti-syndecan-1 (CD138) monoclonal antibodies using Envision detection kit.
Results All the specimens showed a strong positive immunostaining for CD138 in almost 100% of neoplastic cells. CD20- and CD79a-expression (>5% of myeloma cells) was detected in 24.5% and 43.1% of cases, respectively. The great majority to 100% of the myeloma cells were reacted with anti-CD20 and anti-CD79a antibodies in 14 (13.7%) and 15 (14.7%) cases, respectively. Overall survival of patients was not associated with CD20 and/or CD79a expression by myeloma cells ($p = 0.30$). A significant percentage of CD45 positive neoplastic plasma cells was observed in only two specimens.
Conclusions Syndecan-1 appears to be a reliable marker for plasma cells. A positive CD20-immunostaining does not exclude the possibility of a plasma cell tumor, especially in the case of an extramedullary neoplasm (e.g. plasmacytoma). CD20 and/or CD79a expression by myeloma cells does not seem to be of significant value in predicting survival. Myeloma cases with a strong CD20 expression may respond to treatment with anti-CD20 monoclonal antibody, in combination with the standard therapy.

P 97

EXPRESSION OF PI3K/PTEN/AKT-HIF-1 SIGNALING PATHWAY PROTEINS, THEIR RELATION WITH CELL PROLIFERATION AND CLINICAL OUTCOME IN PATIENTS WITH MULTIPLE MYELOMA (MM)

KAYGUSUZ Gulsah [1], KUZU Isinsu [1], CEKIN Nilgun 3, BEKSAC Meral [2], TOPRAK Selami K [2], SOYDAN Ender [2], KIZIL Merih [2], SAHIN Fikret 4, ELHAN Atilla H 5
Departments of Pathology[1], Haematology2, Microbiology4, Biostatistics5, School of Medicine and Biotechnology Institude3, University of Ankara, TURKEY

The factors related with the expansion of the malignant clone in MM, are enhanced proliferation and resistance to apoptosis. Recent studies have focused on different related pathways stimulating proliferation or suppressing apoptosis. The phosphotidylinositol-3-OH kinase (PI3K) signal pathway integrates receptor tyrosine kinase signaling which could be the major candidate regulating the apoptotic cascade related to the survival and proliferation of myeloma cells. One mediator of PI(3)K signaling is the Akt/protein kinase B, which phosphorylates multiple downstream effectors that ultimately regulate a variety of cell functions including glucose metabolism, cell proliferation and survival. mTOR and HIF-1 are among these mediators. And tumor suppressor protein PTEN is one of major inhibitors of Akt phosphorylation.
In this study we aim to examine the expressions of the phosphorylated proteins PI3K/PTEN/Akt, related downstream proteins mTOR, HIF-1 on bone marrow biopsy specimens of MM patients and to analyze their relation between the proliferative activity and survival.
PATIENTS AND METHODS:
Fourty seven myeloma patients diagnosed in our department between 2002-2004, aged 54(33-77), whose bone marrow biopsy specimens could be retrieved were included in this study. All patients were treated with VAD or MP as first line treatment.
Immunohistochemical staining was performed using monoclonal antibodies against phospho- PTEN (Cell Signaling Tech), phospho-Akt (Cell Signaling Tech), phospho-mTOR (Cell Signaling Tech), HIF1 alpha (abcam) and Ki67 (Labvision) with Zymed ABC Px Kit manually or Ventana Benchmark automated immunostainer for secondary visuilisation. Negative control was present in each experiment.

CONCLUSIONS:
Loss of PTEN expression (10 of 35 patients) was correlated with high proliferative activity examined by Ki67 staining ($p=0.014$, Mann-Whitney U test).
Akt activation was seen in 20% of the cases which was not correlated with the survival.

There were no correlations between survival, proliferation status of the myeloma cells and expressions of the proteins involved in PI3K/PTEN/Akt, HIF-1 pathway.
The cases having loss of PTEN expression by immunohistochemistry did not show increased Akt expression. It seems that Akt activation on the way of proliferation may be related to the other stimulating factors rather than the negative control of PTEN.

P 98
EXPRESSION PROFILES OF CYCLIN A, D1, D2, D3 AND CYCLIN DEPENDENT KINASE INHIBITORS (CDKI) P16 AND P21 IN PATIENTS WITH MYELOMA ON BONE MARROW SPECIMENS
KUZU Isinsu [1], KAYGUSUZ Gulsah [1], BEKSAC Meral [2], TOPRAK Selami K [2], SOYDAN Ender [2], KIZIL Merih [2], ELHAN Atilla H 3
Departments of Pathology[1], Haematology2 and Biostatistics3, School of Medicine, University of Ankara, TURKEY

INTRODUCTION
Cyclins are expressed during specific phases of the cell cycle and are controlled by cell cycle dependent kinase inhibitors (CDKI). p16 and p21 control Cyclin D and Cyclin A, respectively. The sequential role of Cyclin A and p21 has not been determined yet. We aimed to analyze the cyclin and CDKI's in marrow plasma cells by immunohistochemistry.
PATIENTS and METHODS
Fourty five myeloma patients diagnosed in our department between 2002-2004, aged 54(33-77), M/F:21/13 whose bone marrow biopsy specimens could be retrieved were included in the study. All patients were treated with VAD or MP as first line treatment.
Immunohistochemical staining was performed using monoclonal antibodies: Cyclins A, D1, p16, p21(LabVision), Cyclin D3(DAKO), Cyclin D2 (Santa Cruz) and Ki67 (Labvision) with Zymed ABC Px Kit manually or Ventana Benchmark automated immunostainer for secondary visuilisation. Negative control was present in each experiment.
CONCLUSION
We could not find any correlation between the expression profiles of Cyclins A, D1, D2, D3, p16, p21, Ki67 and survival. But there was an inverse correlation between p16 and cyclin A expressions as expected.

Cyclins and their inhibitors can be expressed in different combinations by plasma cells. A decreased expression of cyclin A or D and a relevant CDKI's increased expression was evaluated as a low proliferative situation (P min).
P min was observed 5/45 of the patients, resulted with 80% overall response and 100%survival at 5 years.
On the contrary P max patients (high Cyclin and low CDKI expressing patients) were observed more frequently(19/45). 10/19 of these patients responded and performed 57% Survival. Pmax and P interm patients responded (7/17) and survived similarly.
Prognostic factors such as age, B2MG and CRP were similar between Pmin, P max or P interm groups thus did not influence the response and survival effect.
Cyclin-CDKI patterns are associated with bone disease: P max patients had bone lesions more frequently (11/14) whereas P min patients had none(p=0.008). The role of bone disease as a prognostic factor has been shown before by other investigators. This association supports the prognostic role of cell cycle regulators and inhibitors.

P 99
MUC1 EXPRESSING PLASMA CELLS IN BONE MARROW EXHIBITING INVOLVEMENT BY PLASMA CELL MYELOMA
BALDUS Stephan E., PALMEN Christine, THIELE Jürgen
Institute of Pathology, University of Cologne, Kerpener Str. 62, D-50931 Cologne

Introduction: MUC1 represents a mucin molecule expressed in various epithelial tissues and neoplasms as well as normal haematopoietic cell lines. Additionally, its presence could be demonstrated in diffuse large B cell lymphomas as well as plasma cell myelomas. However, a thorough analysis of the clinical as well as pathological importance of MUC1 positive plasma cells in bone marrow involved by plasma cell myeloma was not performed up to now.
Purpose: In the present study, we tried to evaluate the expression of MUC1 in a larger series of bone marrow specimens with plasma cell myeloma involvement in order to evaluate possible correlations with histopathological parameters as well as survival data.
Material and methods: Trephine biopsy specimens with involvement by plasma cell myelomas derived from 105 patients were investigated immunohistochemically visualizing syndecan-1 (CD138) and MUC1 positive myeloma cells. Initially, the percentage of CD138 positive plasma cells was determined. Additionally, MUC1-specific monoclonal antibodies (mabs), anti-epithelial membrane antigen (EMA) as well as HMFG-2 were applied. The rate of MUC1 positive plasma cells was evaluated semiquantitatively. Possible correlations with pathological variables (grade, fibre content, pattern of infiltration) as well as survival were analysed statistically applying chi square tests as well as survival analyses.
Results: About 55 % of the cases showed EMA expression and 47 % HMFG-2 immunoreactivity in more than 5 % of the plasma cells in the bone marrow. In cases exhibiting a so-called packed marrow, EMA immunoreactivity was reduced. However, MUC1 positivity as assessed semiquantitatively did not show a statistically significant correlation with the cytologic grade of differentiation or the fibre content, respectively. Correlations with survival probability could also not be observed.
Conclusions: About 50 % of the cases with plasma cell myeloma involvement of the bone marrow exhibited an expression of MUC1 in plasma cells. This observation may be of special interest with regard to recently published data. For example, enrichment of MUC1-specific T cells or MUC1 vaccination may represent new aspects in the therapy of plasma cell myeloma and MUC1 expression in plasma cell myeloma may be regulated by interleukin 7. However, MUC1 expression by bone marrow-infiltrating plasma cells did not correlate with most histomorphological parameters or patients' prognosis according to our results

EXTRANODAL LYMPHOMA : A CLINICOPATHOLOGIC STUDY OF 87 CASES
AYADI Lobna, BAHRI Ibticem, GHARIANI Mekki, GOUIAA Naourez, MNIF Hela, SELLAMI Ahmed, BOUDAWARA SELLAMI Tahya

Introduction:
Primitive extranodal lymphomas (PENL) constitute 25 % of whole non Hodgkin lymphomas. They are defined as localised lymphomas which appear in extranodal tissue with or without invasion of regional nodes.
Objectives:
The purpose of this study is to specify the clinicopathologic and immunohistochemical characteristics of the principal locations of extranodal lymphomas and to discuss their prognosis.
Patients and methods:
Our study is retrospective relating to 87 cases of PENL diagnosed in the period between January 1995 and December 2000 at the Pathologic Department of Habib Bourguiba Hospital (Sfax –Tunisia). This study is based on the

clinicopathologic and immunohistochemical findings. All cases were analysed and reclassified using the latest WHO (2000) classification.
Results:
The mean age of patients was 45 years (extreme: 3 and 84 years). There was a male prevalence with a ratio of 1,7. Primitive lymphomas of the digestive tract (PLDT) were the most common (44 cases : 50,6%) followed by Waldeyer's ring lymphoma (17 cases : 19,5%), cutaneous lymphomas (9 cases : 10,5 %), lymphomas of the central nervous system (6 cases: 6,9 %), centrofacial lymphomas (5 cases : 5.8 %), osseous lymphomas (2 cases : 2,3 %), splenic lymphoma, thymic, orbital, and salivary glands lymphoma (one case for each location : 1,1 %). The association of a digestive lymphoma to a lymphoma of the ring of Waldeyer were observed among 4 patients (9 % of PLDT). The most common histologic type was diffuse large B-cell lymphoma (56 cases : 64,4 %) followed by MALT- lymphoma (10 cases : 11,6%). Treatment policies adopted as well as the outcome were documented for each location
Conclusion:
The PENL represent a very hetregenous group of neoplasms . They are not always easily identified on routinely stained sections and their diagnosis need immunohistochemical analysis and even molecular biology. Their outcome is variable depending on the site and the histological type.

P 101
ABSENCE OF MICROSATELLITE INSTABILITY IN GASTRIC LYMPHOMA : AN IMMUNOHISTOCHEMICAL STUDY OF HMLH1 AND HMSH2 PROTEIN EXPRESSION
CUILLIERE-DARTIGUES Peggy, FABIANI Bettina, DUMONT Sylvie, COPIE-BERGMAN Christiane, COUVELARD Anne, MOLINA Thierry, FLEJOU Jean-françois

Defective DNA mismatch repair results from genetic or epigenetic alterations that most frequently inactivate the genes hMLH1 and hMSH2. This pathway is known to be involved in the pathogenesis of a subset of solid neoplasm, most prominently encountered in hereditary non polyposis colorectal cancer (HNPCC) syndrome, characterized by microsatellite instability (MSI). However its role in lymphomagenesis is not well established. In gastric lymphoma of mucosa-associated lymphoid tissue (MALT) type, contradictory results concerning the prevalence of MSI have been reported in few studies using molecular testing.
The aim of this study was to identify tumours with a mutator phenotype by detection of abnormal MMR gene protein expressionin a large series of gastric lymphoma.
Immunohistochemestry was performed in 111 low grade MALT lymphomas and in 44 diffuse large B cell lymphomas using two monoclonal mouse antibodies that react against hMLH1 and hMSH2 protein. In all cases with contributive immunohistochemestry (80), tumours showed nuclear expresion of both proteins.
These results suggest that defects in DNA mismatch repair, due to inactivation of hMLH1 and hMSH2, do not seem to contribute significantly to the molecular pathogenesis of gastric MALT lymphoma.

CASTLEMAN'S DISEASE OF THE HEAD OF THE PANCREAS: UNUSUAL ASSOCIATION WITH ADENOMATOUS HYPERPLASIA OF THE PAPILLA VATERI
COSIC MICEV Milena 1, MICEV Marjan 1,2, TODOROVIC Vera 2, MILICEVIC Miroslav 1, DOJCINOV Stefan 3
1 Institute of Digestive Diseases, Clinical Centre of Serbia, Belgrade, Serbia and Montenegro
2 Institute for Medical Research, Belgrade, Serbia and Montenegro
3 Department of Pathology, University Hospital of Wales, Heath Park Cardiff, UK

INTRODUCTION: Castleman's disease has been described in a variety of anatomical sites including the peripancreatic retroperitoneum. We present a case of its unusual intrapancreatic presentation associated with simoultaneous hyperplasia of the papilla Vateri.
A CASE PRESENTATION: A 54 years old female patient suffered back pain, abdominal discomfort and short interval intermittent jaundice. The ultrasound finding suggested cystic lesion and after CT scan examination pancreatic mass was diagnosed in the head of the pancreas. There were no other significant or conclusive laboratory findings. Intraoperative surgical examination found well circumscribed tumor occupying the posterior part of the head of the pancreas and peripancreatic fat in the proximity of obstructive enlargement of the papilla Vateri. Frozen section biopsy was misinterpreted as non-representative peripancreatic lymph node and Whipple's cephalic pancreatico-duodenectomy was performed.
METHODS AND RESULTS: Gross examination revealed well circumscribed mass measuring 64 mm in greatest diameter in the head of the pancreas with small part extruding to peripancreatic fat. Histologically, nodular architecture of lymphoid infiltrate was composed of follicle-like structures with hyalinised and vascularised centres and onion skin-like distribution of surrounding small lymphoid cells. Immunostaining showed B-cell phenotype (CD20+, CD5-, CD10-, CD43-) with CD21+ rich dendritic cell networks, focally mantle zone-like areas (focal expression of CD10+ and bcl-6+) and a lack of bcl-2 immunoexpression in germinal centres, but CD3+/CD5+ positive small T lymphocytes among polymorphous interfollicular lymphoid infiltrate. PCR analysis with Biomed 2 primers (FR1, FR2, FR3) showed a polyclonal pattern. In addition, slight fibrotic ampullary stenosis and adenomatous hyperplasia of the papilla Vateri were found, not accompanied with epithelial atypia or simoultaneous myomatous hypertrophy. In 14 months follow-up there was no relapse or any signs of the disease.
CONCLUSION: Very unusual anatomical presentation of Castleman's disease with profound ingrowth of the lymphoid proliferation within the head of the pancreas associated with obstructive adenomatous hyperplasia of the papilla Vateri was initially misunderstood as pancreatic cancer. This broadens differential diagnosis of obstructive periampullary and pancreatic lesions.

CHEMOKINE RECEPTOR EXPRESSION IN NONGASTRIC MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT)-TYPE LYMPHOMAS
AIGELSREITER Ariane (1), DEUTSCH Alexander (2), STEFAN Martina (3), BEHAM-SCHMID Christine (1), BEHAM Alfred (1), LANZER Gerhard (4), STELZL Evelyn (5), LINKESCH Werner (2), SCHAIDER Helmut (3) and NEUMEISTER Peter (2)
1 Department of Pathology, 2 Division of Hematology, 3 Department of Dermatology
4 Department of Blood Group Serology and Transfusion Medicine, 5 Institute of Hygiene, Medical University Graz, Austria

Introduction: Chemokine receptors mediate the migration and activation of lymphocytes through binding of their ligands. Several recent studies have revealed important contributions of chemokine receptors and their ligands to the development and progression/dissemination of hematopoietic neoplasms. By promoting tumor dissemination CXCR3 has recently been

identified as a major contributor in the pathogenesis of mucosa-associated lymphoid tissue (=MALT) lymphomas. Little is known about the chemokine receptor expression profile of nongastric MALT lymphomas.
Purpose: The aim of our study was to identify the expression pattern of all 17 currently known and characterized chemokine receptors in nongastric MALT-lymphomas in comparison to normal, surrounding tissue.
Material and Methods: 10 extragrastric MALT lymphomas of the parotid gland were selected from the archives of the Department of Pathology, Medical University Graz. As control specimens 5 pooled non-malignant parotid glands were included.
Makrodissected tissue containing >80% lymphoma cells from paraffin embedded MALT lymphomas of the salivary gland were processed for RNA isolation. Semiquantitative Real Time PCR was performed on a GeneAmp® 5700 Sequence Detector. Peripheral blood from healthy donors served as calibrator, due to the broad expression of all chemokine receptors investigated. Expression of 17 chemokine receptors was determined in triplicate and the number of cycles was compared to the reference gene HPRT and peripheral blood, based on calculations of 2-deltadeltaCT.
Results: Compared to normal tissue we demonstrated de novo expression of CCR4 and CCR8.
As opposed to non-malignant control tissues, receptor upregulation occurred in CCR5, CCR6, CCR7, CCR9, CXCR3, CXCR4, CXCR5 and XCR1. Equal expression could be observed in CCR1, CCR2, CCR3, CXCR1, CXCR2 and CX3CR1, whereas the chemokine receptor CCR10 was down-regulated. In the CC receptor family the most pronounced upregulation could be attributed to the family members CCR6 (57,6 times) and CCR7 (31,8 times), whereas CXCR4 (20 times) was highest expressed in the CXC receptor family group.
Conclusion: Hence, our data support a model of the etiopathogenesis of extragastric MALT lymphomas involving a complex interplay of multiple interacting signals mediated by chemokine receptors, where differentially regulated members of the CXC as well as CC receptor family might play a crucial role in the dissemination/homing of malignant B-cells.

INDUCIBLE NITRIC OXIDE SYNTHASE AND APOPTOSIS IN HUMAN B CELL LYMPHOMAS

* ATÝK Esin, **ERGÝN Melek, **ERDOĐAN Þeyda, **TUNCER Ýlhan
(*)Department of Pathology, Mustafa Kemal University, Faculty of Medicine, Antakya-Hatay / Turkey
(**) Department of Pathology, Çukurova University, Faculty of Medicine, Adana/ Turkey

Purpose: Nitric oxide synthases (NOS) are isoenzymes that catalyse the synthesis of nitric okside (NO). NO plays both pathological and physiological roles depending on its rate of synthesis and concentration in cellular source and microenvironment.
Apoptosis is an important biological factor in lymphomas.
This study evaluates expression of inducible nitric oxide synthase (iNOS) in human lymphomas and its relation with apoptosis.
Material and Methods: This study comprised 46 cases of B-cell lymphoma. The lymphomas were classified as 3 mantle cell, 5 marginal zone, 4 follicular, 2 Burkitt, 25 diffuse large cell, 2 anaplastic large cell, 3 lymphoblastic, 2 lymphoplasmacytic according to WHO classification of lymphoid neoplasms. .
Hematoxylin eosin slides of the cases were reviewed and immunoperoxidase technique was performed iNOS and Caspase monochlonal antibodies to selected sections of each case. Antigen staining was carried out with iNOS and Caspase proteins and Ultravision Polyvalent, Rabbit, HRP-AEC kit (Neomarkers- Biogen USA).
For the evaluation of iNOS and Caspase, tumor areas with a high density of expression were chosen. Positive stained cells were counted in 5 different areas at a magnification X40 by an Olympus BX51 microscope in each case.
The iNOS and Caspase expressions were independently recorded by two pathologists and the results were averaged.
Results: Our study revealed that there is a positive relation between iNOS expression and apoptosis (p= 0.032 spearman correlation). This relation might be promising new agents in therapeutic protocols.

SYNCHRONOUS PRESENTATION OF NON-HODGKIN'S LYMPHOMA AND MALIGNANT MELANOMA

I.D.Venizelos1, Z.A.Tatsiou1, L.Kampas1, D.Sioutopoulou1, V.Perifanis2, V.Garipidou2

1 Department of Pathology, Hippokration Hospital, Thessaloniki
2B Department of Internal Medicine, Aristotelian University of Thessaloniki, Hippokration Hospital, Thessaloniki, Greece

The association of malignant melanoma (MM) with different neoplasias is uncommon but not exceptional. Over the past 2 decades, both MM and non-Hodgkin's lymphoma (NHL) incidence rates, have increased substantially. Several epidemiological studies have suggested an association between MM and NHL and an interaction between genetic and environmental factors in the pathogenesis of these tumors.

We report the case of a 72-year-old man who presented in our hospital due to enlarged, not painful cervical, axillary and inguinal lymph nodes, persisted for 6 months. On physical examination it was found peripheral lymphadenopathy with no hepatosplenomegaly. Hematological examination was normal. CT scan of the chest and abdomen revealed generalized lymphadenopathy, with no hepatosplenomegaly. An inguinal lymph node was excised and histological examination showed morphological and immunohistochemical features of B-cell small lymphocytic lymphoma (SLL). At the same time, a melanocytic lesion on the frontal region of the head was excised due to recent enlargement and change of the colour. Histological examination of the lesion showed features of superficial spreading MM, Clark's level IV and Breslow's depth of invasion 2,5 cm, for which he received no further treatment. The patient received 10 courses of systemic chemotherapy with mabthera, 1 course with fludarabine, decadron and mitoxantron for SLL, and remained in partial remission. One year later he presented with neurological signs due to brain metastasis, and multiple skin nodules on the tract. Histological examination of an excised skin nodule showed the features of MM. One month later he died due to complications of CNS involvement.

In the present study we report a rare case of synchronous presentation of NHL and MM. Although it is rare, we should suspect this association and make the correct diagnosis using the appropriate immunohistochemical stains.

P 106

MORPHOIMMUNOHISTOCHEMICAL DIFFERENTIAL DIAGNOSTICS OF "GREY ZONE" LARGE LYMPHOMAS.

Kovrigina A, Probatova N.

INTRODUCTION: Overlape between Hodgkin's lymphoma and large-cell lymphomas creates the difficult task for morphological diagnostics. At the last time "grey zone" is

complicated for the account of T-cell/histiocyte-rich B-cell lymphoma (TCRBCL), anaplastic variant of diffuse B-cell large lymphoma (DBCL), primary mediastinal B-cell lymphoma (PMBL), anaplastic large-cell lymphoma.
Purpose of study was to investigate group of "grey zone" lymphomas.
MATERIALS AND METHODS. We have studied 143 lymph nodes biopsies of "grey zone" lymphomas using immunohistochemical method with wide panel of monoclonal antibodies: CD3, CD4, CD8, CD10, CD15, CD20, CD21, CD23, CD30, CD43, CD45, CD57, Granzyme B, ALK, EMA, bcl-2, bcl-6.
RESULTS: We have diagnosed 21 cases of TCRBCL (m:f 0,7:1,0; mediana 47 years, range 16-67). Diffuse growth was marked in 20 cases and nodular growth in 1 case, that demands differential diagnostics with nodular lymphoid-predominant of Hodgkin's lymphoma. PMBL was diagnosed in 35 pts (m:f 1,0:3,5, mediana 31,5 years, range 16-62) with immunophenotype of neoplastic cells: CD45-positive and CD20-positive (all cases), CD30 (75%), CD23 (48%), bcl-6 (33%) and all cases were IgM-negative. 2 cases of anaplastic variant DBCL were revealed. ALCL was diagnosed in 39 pts (mediana 22 years, m:f 1,0:1,0; range 4-79).
ALK-positive cases were observed in 58% (till 40 years) but any case in 40 years and more senior. The others cases were referred toHodgkin's lymphoma (mixed cellularity, NS II subtypes).
CONCLUSION: "Grey zone" lymphomas may be diagnosed only by using wide panel of antibodies. ALK-negative with 0-immunophenotype cases of ALCL are generated

P 107
CYTOTOXICITY OF THE SMALL MOLECULE BCL-2 ANTAGONIST, HA14-1, AND SELECTED ANTICANCER DRUGS IN FOLLICULAR LYMPHOMA B-CELLS.
Joanna Skommer (1), Donald Wlodkowic (1), Mikko Mattö (1), Mine Eray (2), Jukka Pelkonen (1,3)

The Bcl-2 overexpression is a hallmark of follicular lymphoma (FL). Since patients with FL often suffer from progressively resistant to chemotherapy refractory disease, the development of new regiments is required. In this study we analyzed for the first time the effects of a Bcl-2 antagonist, HA14-1, alone and in combination with antineoplastic agents commonly used against follicular lymphoma, in human FL cell lines with t(14;18). The cell lines were established from patient samples send for PAD analysis and earlier analysed in detail. All cells were sensitive to HA14-1 induced cytotoxicity (the LC50s of 4.5 to 12.6μM) and apoptosis. Moreover, HA14-1 enhanced dexamethasone and doxorubicin mediated (in schedule independent and dependent manner, respectively) cytotoxicity and apoptosis, but antagonized with vincristine, in all FL cells. Together these findings warrant further in vivo studies and provide conceptual basis for therapeutic intervention in follicular lymphoma.

P 108
TUMORS OF HEMATOPOIETIC AND LYMPHOID TISSUES IN CHERNOBYL CLEAN-UP WORKERS (1996-2004)
GLUZMAN Daniel, SKLYARENKO Lilia, NADGORNAYA Valentina, ZAVELEVICH Michael, SIMONET Marie-Laurence
R.E. Kavetsky Institute of Experimental Pathology, Oncology and Radiobiology, National Academy of Sciences of Ukraine, Kyiv, Ukraine
French-Ukrainian Center "Children of Chernobyl"

The role of ionizing radiation as a causative factor of various biological types of leukemias and lymphomas after Chernobyl is still controversial. Different predictive models on the incidence of hematopoietic malignancies in Ukrainian Chernobyl clean-up workers have been suggested up to present. Nevertheless, the actual data are still lacking mainly because of the inconsistency in the primary findings preventing the precise diagnosis of hematopoietic malignancies.
The aim of the study was to characterize in details the major forms and cytological variants of oncohematological diseases in Chernobyl clean-up workers exposed in 1986-1987 to radiation at a dose within the range of 7.5-25 cGy.
The data on 200 consecutive cases of malignant diseases of hematopoietic and lymphoid tissues in Chernobyl clean-up workers diagnosed in Reference Laboratory of R.E. Kavetsky Institute of Experimental Pathology, Oncology and Radiobiology in 1996-2004 on the basis of up-to-date techniques of cytomorphology and immunophenotyping in accordance with novel WHO classification have been summarized. The specimens were analyzed using immunocytochemical techniques (PAP, APAAP, ABC) and panel of monoclonal antibodies to differentiation antigens of leukocytes employed for immunophenotyping of leukemic cells. The patterns of the main forms of hematopoietic malignancies in Chernobyl clean-up workers have been compared with that in general population.
Practically all the main forms of malignant diseases of hematopoietic and lymphoid tissues were revealed in the group of Chernobyl clean-up workers under study. The comparison of relative distribution of the particular forms of hematopoietic malignancies in the patients diagnosed among Chernobyl clean-up workers demonstrates increasing multiple myeloma rate and the tendency to increasing non-Hodgkin's lymphoma and CML rates as compared to general population.
The peculiar feature of AML in clean-up workers under study consists in the development of leukemia on the background of preceding myelodysplastic syndromes in 50% of all AML cases studied. 4 cases of large granular lymphocyte leukemia were recorded among clean-up workers. Strongly alkaline phosphatase-positive villous cells identified in bone marrow stroma in clean-up workers suffering from malignant as well as non-malignant diseases of hematopoietic and lymphoid tissues seem to represent a response to incorporation of the osteotropic heavy metals including radionuclides.

P 109
EBV ASSOCIATED EXTRA-NODAL NK CELL LYMPHOMA NASAL TYPE OF THE BREAST IN BEHCET DISEASE: A CASE REPORT
L. Jabri, S. Zamiati, M. Karkouri, A. Iraqi
Central Department of Pathology, Ibn Roshd University Hospital, Casablanca, Morocco

Primary non Hodgkin lymphoma of the breast is uncommon. Most are of B-cell phenotype, with only rare cases showing a T-cell phenotype, NK-cell lymphomas are extremely rare, only 2 cases are reported so far in the literature. The association of Behcet's disease with malignancies has rarely been reported. Only 6 cases of lymphoma have been reported, of whom one is a nasal NK-cell lymphoma.
We report a case of NK-cell lymphoma extranodal nasal type of the breast
It is a 20 year-old woman followed up for Behcet disease under immusuppressive treatment for 4 years. She presented with a mammary nodule of 3 cm.The biopsy of the lesion revealed the infiltration of medium to large sized lymphoma cells with necrosis and angiocentric pattern. The cells were positive for cytoplasmic CD3, CD56, CD8, TiA1 and Granzyme B, negative for surface CD3. Analysis of T-cell receptor fails to show clonal rearrangement. EBV studies show clonal episomal integration of EBV (EBER-1 positive). She underwent chemotherapy and radiotherapy and achived complete remission.

To our Knowledge this case report is the first to describe NK-cell lymphoma of breast arising in Behcet disease.

REAL-TIME QUANTITATIVE PCR DETECTION OF FUSION GENE ALK/NPM IN PATIENTS WITH ALCL: RESIDUAL DISEASE MONITORING AND A CORRELATION WITH THE DISEASE STATUS

KALINOVA Marketa, KRSKOVA Lenka, HILSKA Irena, KOPECKA Pavla, KODET Roman
Department of Pathology and Molecular Medicine, 2nd Faculty of Medicine, Charles University in Prague, Czech Republic

Introduction: Anaplastic large cell lymphoma (ALCL) represents a heterogeneous group of malignant lymphoproliferative diseases. Most of the cases are of T cell origin. ALCL is frequently associated with t(2;5)(p23;q35)coding for NPM/ALK fusion gene - anaplastic lymphoma kinase (ALK) gene is fused with nucleophosmin (NPM) gene. The NPM/ALK chimeric gene encodes a constitutively activated tyrosin kinase that has been shown to have potent oncogenic properties. The NPM/ALK fusion protein is found in up to 75% of pediatric ALCL.
Purpose: To monitor residual disease using real-time quantitative reverse-transcription PCR (RQ-RT-PCR) of NPM/ALK fusion gene.
Methods: RQ-RT-PCR is a recently developed technique for nuclear acid quantification. We developed an assay using RQ-RT-PCR for the quantitative assessment of minimal residual disease (MRD) in childhood ALCL by using a hydrolysis probe for quantification of NPM/ALK and hybridization probes for quantification of housekeeping gene (Beta-2 microglobulin gene), which was used as internal cDNA quality and quantity control. We constructed plasmid standards with NPM/ALK fusion gene and Beta-2 microglobulin gene. Normalized expression of NPM/ALK (NPM/ALKn) was determined as a ratio between NPM/ALK and Beta-2 microglobulin levels assessed by RQ-RT-PCR.
Results: We analysed NPM/ALK expression levels at diagnosis and/or relapses (cryopreserved and/or paraffin-embedded tissues) from affected lymph nodes and residual samples during the treatment in a group of 6 patients (4 – 19 years). All of them presented hyperexpression of NPM/ALKn (median 17321 copies) suitable for the MRD detection. Combined analysis of NPM/ALKn levels, qualitative RT-PCR NPM/ALK (1st vs 2nd round positivity) and the course of disease in 49 residual samples (bone marrow, peripheral blood) showed a clear correlation.
Conclusion: RQ-RT-PCR-based analysis of NPM/ALK expression is a promising and rapid approach for monitoring MRD in patients with ALCL. The impact of NPM/ALK various levels found during monitoring the residual disease on the treatment and prognosis needs further clarification.

MOLECULAR CHARACTERIZATION OF COMPOSITE MANTLE CELL AND FOLLICULAR LYMPHOMA

ZAMÒ Alberto (1), ZANOTTI Roberta (2), LESTANI Maurizio (1), OTT German (3), KATZENBERGER Tiemo (3), SCARPA Aldo (1), PIZZOLO Giovanni (2), MENESTRINA Fabio (1) and CHILOSI Marco (1)
(1) Department of Pathology, University of Verona, Verona, Italy
(2) Department of Haematology, University of Verona, Verona, Italy
(3) Department of Pathology, University of Würzburg, Würzburg, Germany

Introduction. Composite lymphomas are rare associations of two distinct lymphoma types at the same anatomical sites. Reporting of such cases is important since they pose major biologic, diagnostic and therapeutic dilemmas. Purpose of the study. We describe the third reported case of Mantle Cell and Follicular lymphoma. Methods. We performed accurate immunohistochemical, FISH and molecular studies in order to verify molecular hallmarks of the two components and to define the mono- versus bi-clonal nature of this neoplasm. We used both manual and LASER-capture microdissection combined to multiple molecular approaches for clonality determination, including detection of heavy and light chain recombination, as well as presence of kappa /Kde recombination. Results. By immunohistochemistry and FISH we confirmed the presence of two distinct lymphoma types characterised by specific translocations (namely, t(11;14) and t(14;18)), while by molecular techniques we demonstrated two distinct and not clonally related cell populations. Conclusions. Composite lymphomas are a diagnostic and pathogenetic dilemma, that should be investigated using multiple combined approaches. Care should be taken in the definition of mono- vs bi-clonality. The light chain approach, and particularly the kappa /Kde recombination detection, proved very useful for solving the clonality issue.

P 112
CUTANEOUS T-CELL LYMPHOMA, FLOW CYTOMETRIC IMMUNOPHENOTYPING AND ASSESSMENT OF CYTOKINE PRODUCTION

MANDAKOVA Petra, CAMPR Vit, KORTANKOVA Hana, MACHOVCOVA Alena*
Department of Pathology and Molecular Medicine, *Department of Dermatology, Charles University, 2nd Medical Faculty, Prague, Czech Republic

Background: The diagnosis of cutaneous T-cell lymphoma (CTCL), a tumor predominantly of T-helper cell origin (Th, CD4+), may be facilitated by flow cytometry (FC). If the precise immunophenotype of tumor cells is known, it is possible to study the cytokine production, which may help in explanation of interrelationships between neoplastic and tumor infiltrating cells (TIL). It is known, that Th1 and Th2 cytokines have distinct roles in proliferation and elimination of tumor cells. Th1 cells producing e.g. INF gamma or IL2 may activate cytotoxic T lymphocytes (CTL), but Th2 cells producing e.g. IL4 may inhibit antitumor CTL.
Purpose: The purpose of this study was to assess a contribution of FC to the diagnosis of CTCL and elucidate the relationships between TIL/CTL and tumor cells in CTCL. We presumed that tumor cells might produce the Th2 cytokines and thus inhibit TIL/CTL.
Patients and methods: 20 skin biopsies from 17 patients with the clinical suspicion of primary CTCL were examined. The suspension of lymphocytes for FC was prepared by enzymatic digestion of skin biopsy. After an immunophenotyping with a standard panel of antibodies the spontaneous and induced (by ionomycin and PMA i.e. phorbol 12-myristate 13-acetate) production of IL2, INF gamma and IL4 by tumor lymphocytes was examined.
Results: The suspension of lymphocytes was obtained in 70% of the cases. In this group the aberrant immunophenotype of T-cells was found in 70% and the findings were conclusive for T-cell lymphoma. Tumor cells produced IL2 only. No production of IL4 or INF gamma even after activation by ionomycin and PMA was showed.
Conclusion: If the lymphocytic infiltrate of the skin is not dense (as assessed from a frozen section) and only sporadic tumor cells are present, obtaining a representative sample is problematic. In such cases FC does not seem to be a diagnostic method of choice. Inconclusive results of FC may be caused by an absence of aberrant immunophenotype on

tumor cells and/or because of "masking" of the tumor cells by prevailing populations of TIL.
Furthermore, our results did not confirm our hypothesis, that tumor cells produce Th2 cytokine. Tumor cells produced mainly IL2. It is possible, that they may locally activate themselves by autocrine loop and may contribute to the tumor cell proliferation.

P 113
IMMUNOHISTOCHEMICAL DETECTION OF STAT1 AND TRAF1 IN MEDIASTINAL LARGE B-CELL LYMPHOMA
CAMPR Vit, MRHALOVA Marcela, NERADOVA Marie, PYTLIK Robert*
Department of Pathology and Molecular Medicine,
Charles University, 2nd Faculty of Medicine and Teaching Hospital Motol;
*Department of Internal Medicine, Charles University, 1st Faculty of Medicine;
Prague, Czech Republic

Background: Mediastinal large B-cell lymphoma (MLBCL) is a subtype of diffuse large B-cell lymphoma (DLBCL) defined by its clinicopathological features. Recent studies on the gene expression profile identified a molecular link between MLBCL and classical Hodgkin's lymphoma (cHL). These two tumors share similar pathogenetic mechanisms different from those of most non-mediastinal DLBCLs, with a decreased expression of B-cell receptor signalling cascade components, with an increased expression of cytokine pathways components, and an activation of NF-kappaB pathway. The tumor cells were shown to express among other proteins STAT1 (signal transducer and activator of transcription-1) and TRAF1 (tumor necrosis factor receptor-associated factor-1).
Purpose of the study: The aim of our study was to analyze the immunophenotype of MLBCL focusing on STAT1 and TRAF1 expression and to compare it with cHL and non-mediastinal DLBCL.
Patients and methods: Formalin fixed and paraffin-embedded tissue from 27 cases of MLBCL with a classical immunophenotype (18 females and 9 males, age 21 - 64, average 33 y, median 29 y) and a set of mediastinal nodular sclerotic subtype of cHL and non-mediastinal DLBCL was investigated. The expression of STAT1 (BD Biosciences) and TRAF1 (Santa Cruz) was evaluated by a standard immunohistochemical technique.
Results: The expression of STAT1 and TRAF1 was detected in most MLBCL tumor cells in all cases, the positivity was strong, cytoplasmic. Tumor cells of cHL were also strongly positive. The cells of DLBCL also expressed both proteins, but the positivity was in most cases moderate. Small T cells revealed a weak cytoplasmic positivity and stromal cells were negative.
Conclusion: Our study confirms that MLBCL and mediastinal cHL are characterized by a strong expression of STAT1 and TRAF1. However, the expression of these proteins does not discriminate reliably between MLBCL and non-mediastinal DLBCL which are positive as well, though the positivity of the latter group is weaker.
Supported by Research Project FNM MZO 00064203 and IGA NR 8231/3.

P 114
BONE MARROW BIOPSY FINDINGS IN T-CELL LARGE GRANULAR LYMPHOCYTIC LEUKEMIA (LGL): REPORT OF 4 CASES
BOVERI Emanuela (1), RIBONI Roberta (1), ARCAINI Luca (2), PASSAMONTI Francesco (2), INVERNIZZI Rosangela (3), IPPOLITI Giovanbattista (4), CASTELLO Alessandro (1), MAGRINI Umberto (1)
(1) Institute of Surgical Pathology, (2) Institute of Haematology, (3) Institute of Internal Medicine, IRCCS Policlinico San Matteo and University of Pavia, Pavia (Italy); (4) Division of Internal Medicine, Ospedale Civile, Voghera

Introduction: T cell large granular lymphocytic leukemia (T-LGL) is a rare disease, with indolent clinical course, often associated with autoimmune conditions (rheumatoid arthritis), hematological disorders (myelodisplastic syndromes, aplastic anemia) or neoplasias (hairy cell leukemia, myeloma). Diagnosis can be made on marrow aspirate and peripheral blood by cytological, immunophenotypical and molecular findings (assessment of T cell receptor/TCR rearrangement). However, presenting features can overlap with other low grade lymphomas and a bone marrow biopsy (BMB) is performed.
Purpose of the study: to describe the clinico-pathologic findings in 4 cases of T-cell LGL.
Patients and methods: 4 patients (M : F= 3:1; mean age: 56 years, range 48-70) presented cytopenia (particularly, neutropenia), lymphocytosis (4/4) and hepatosplenomegaly (2/4); in all cases, the clinical picture had been present relatively unchanged for more than 1 year before BMB (range: 1-24 years); one patient showed associated pulmonary hypertension. Paraffin embedded BMBs were used for morphological and immunophenotypical studies; flow cytometry and molecular assessment of the TCR rearrangement were performed on peripheral and/or marrow blood.
Results: in all cases, the hemopoietic matrix was partially (20-40%) replaced by an interstitial lymphoid population of medium-sized cells, with clear cytoplasm. By immunostains, underscoring a constant sinusal involvement, these cells had a T (CD2+, CD3+, CD5+, CD7+, CD20-) activated cytotoxic phenotype (CD8+, CD4-, CD57+, CD56-, TIA1+, granzyme B+, perforin+); they were TCR alpha-beta+, gamma-delta- by flow cytometry and carried a monoclonal TCR rearrangement by molecular analysis. A decreased leuco-erythroblastic ratio and a mild diffuse fibrosis were seen. In 1 patient, sequential BMBs, after therapy, at 1 and 2 years from diagnosis, showed overlapping morphofunctional features, with a mild decrease of lymphoid infiltration.
Conclusion: T-cell LGL is a rare diagnosis in hematopathologist's practice; its distinction from other lymphoproliferative diseases both of B (hairy cell leukemia, splenic marginal zone lymphoma) and T cell origin (hepatosplenic T cell lymphoma) is of paramount importance, as these entities carry a worse prognosis and require specific or more aggressive therapy. In our cases, the final diagnosis could be reached only by combining different techniques, thus underlining the need of a multidisciplinary approach.

P 115
RETROPERITONEAL FOLLICULAR DENDRITIC CELL SARCOMA
ALEXANDROU Paraskevi, LIAPIS George, TZIRAKIS Mixalis, GIASLAKIOTIS Konstantinos, ANDROULAKI Athina. Affiliations: Department of Pathology, Laiko Hospital, University of Athens

Follicular dendritic cell sarcoma (FDCS) is an extremely rare neoplasm with only a few reported cases in the literature reviewed, arising from antigen-presenting immune accessory cells in nodal and extranodal sites. It is considered to be an intermediate grade malignancy with a significant recurrent and metastatic potential. We report a case of excisional biopsy of a retroperitoneal mass performed in a 33 years old woman. The tumor tissue was gray to tan, 5cm in the greatest dimension. On microscopic examination, the prominent histological feature was the presence of sheets, fascicles and trabeculae formed by spindle to ovoid cell with indistinct cell borders, oval nuclei, dispersed chromatin and inconspicuous

nucleoli. There were also scattered multinucleated cell forms and marked necrosis. Striking lymphocyte and plasma cell infiltrations with increased focal vascularity were also present. The neoplastic cells showed positive reaction to vimentin, CD21, CD23 and negative to CD1a, HMB-45 and cytokeratins, an immunoprofile consistent with FDCS. There is an overlap of the immunoprofile among various dendritic cell lesions, which makes the differential diagnosis complicated. The combination of CD21 and CD23 markers is found primarily in FDCS, thus it is of great importance in the diagnostic distinction.

COMPARISON OF FASCIN TO DF3/MUC-1 EXPRESSION IN RELATIONSHIP TO TCR-¦Ã CLONALITY, NPM/ALK CHIMERIC PROTEIN EXPRESSION AND 2P23 REARRANGEMENT FINDINGS IN ANAPLASTIC LARGE CELL LYMPHOMAS

BOBOS Mattheos, KOSTOPOULOS Ioannis, KOTOULA Vassiliki, KARAYANNOPOULOU Georgia, PAPADIMITRIOU S. Constantine
Department of Pathology, Aristotle University Medical School, Thessaloniki, 54006, Greece

Introduction.Fascin is expressed in almost all cases of Hodgkin disease (except lymphocyte predominance type) and in a high percentage in anaplastic large cell lymphomas (ALCLs) and peripheral T cell lymphomas. DF3/Muc-1 mucin-like glycoprotein is aberrantly overexpressed in most adenocarcinomas and in a variety of hematopoietic cell malignancies as T and B-cell lymphomas and myelomas. It is also frequently expressed in ALCL. The aim of this study is to investigate the expression of fascin and DF3/Muc-1 in ALCL in comparison with other markers used in these neoplasms.
Material and Methods. A total of 52 cases of ALCL (46 of T-cell and 6 null-cell type) from various sites (39 systemic ALCL, 10 primary cutaneous [C-ALCL] and 3 HIV-related ALCL) were analyzed for fascin and DF3/Muc-1 expression by immunohistochemistry (IHC). Molecular assessments PCR and RT-PCR) and cytogenetic investigation (FISH) were performed in 42 and 43 cases respectively. Tissue sections from 11 ALCL and tissue microarray blocks containing 41 cases of ALCL were used for IHC and FISH. Chi-Square (¦Ö2) tests of significance were performed using the statistical software SPPS 12.0.
Results. Fascin was expressed in the cytoplasm of tumor cells in 41/52 (78,8%) cases; 34 systemic and 7 C-ALCL, (p¡Ü0,001); 37 of T-cell and 4 of null-cell phenotype. Fourteen out of 15 (93,3%) ALK+ and 27/37 (72,9%) ALK- tumors, as well as all ALCL bearing ALK rearrangements were positive for fascin. The majority of ALCL positive for TCR-¦Ã stained for fascin (20/21) (95,2%).
Cytoplasmic and membraneous expression of DF3/Muc-1 was detected in 18/52 (34,6%) of ALCL cases; 15 systemic ALCL and 3 C-ALCL; 15 of T-cell and 3 of null-cell type. Muc-1 was positive in 60% ALK+ and in 24,3% ALK- tumors ($p<0,05$). Ten out of 21 (55,6%) cases with clonal rearrangement and 5/12(41,7%) cases with 2p23 region rearrangement showed Muc-1 expression. Seventeen out of 18 cases with Muc-1 expression were also positive for fascin ($p<0,05$).
Fascin and/or DF3/Muc-1 were detected 42 (80,8%) cases. The two antibodies were also expressed in the majority of systemic (34/39) or C-ALCL (8/10), (p¡Ü0,001) cases. None of the HIV-related ALCL cases was positive for fascin or DF3/Muc-1.
Conclusion. Fascin is widely expressed in ALCL, in contrast to DF3/Muc-1. Up-regulation of fascin protein and its clinical usefulness in these tumors have not yet been determinated. It seems that this aberrant expression is more common finding in ALK+ ALCL

PROGNOSTIC SIGNIFICANCE OF THE APOPTOSIS-RELATED PROTEINS BAX, BAK, BCL-2, MCL-1, CASPASE 3, ACTIVATED CASPASE 3 AND CASPASE 9 IN ACUTE MYELOID LEUKEMIA

ZOLOTA Vassiliki, SIRINIAN Chaido, TSAMANDAS Athanassios, A. KOURAKLIS-SYMEONIDIS Alexandra*, SYMEONIDIS Argyrios*, MELACHRINOY Maria.
Department of Pathology and *Hematology Division, Department of Internal Medicine, University of Patras, Medical School, Rion, Patras, Greece.

Background: Acute myeloid leukemia (AML) is an aggressive disease with generally poor prognosis. Common mechanisms of resistant disease are defects in apoptotic pathways. Apoptosis is regulated by i) mitochondrial-mediated and ii) receptor-mediated pathways. This study investigates the expression of mitochondrial related apoptotic genes bcl-2, bax, bak and mcl-1, and the apoptosis enzymes caspase-3 and caspase-9 in AML and their potential correlation with patients' outcome.
Material and methods: Paraffin-embedded sections of 40 bone marrow biopsies, from equal number of patients with newly diagnosed AML (34 de novo not otherwise categorised AML cases classified as follows: M0(n=1), M1(n=9), M2(n=8), M3(n=2), M4(n=10), M5(n=4), AML following MDS(n=6)) were analyzed immunohistochemically using antibodies against bcl-2 (Dako), bax (Dako), bak (Dako), mcl-1 (Neomarker), caspase 3 (Neomarker, epitope not determined), activated caspase 3 (Chemicon, cleaved p17 fragment) and caspase 9 (Neomarker, middle fragment of caspase molecule). Patients were followed up for 0-78 (mean14.45) months.
Results: The mean indices for bax, bak, bcl-2, caspase 3 and caspase 9 were: 52.45 (15-100), 47.1 (11-90), 39.26 (5-88), 27.5 (0-95) and 39 (0-90) respectively. In all cases, activated caspase 3 was detected in a very small percentage of tumor cells (mean 2.9%-range 0-5). Mcl-1 was detected only in 4 cases. Bax/bcl-2 ratio mean index was 2.36 (0.26-9.00). A direct correlation was recorded between i) caspase 3 and caspase 9 expression ($p<0.01$) ii) bax, bak and caspase 3 expression ($p<0.05$ respectively) and iii) bax/bcl-2 ratio and caspase 3 expression ($p<0.05$). No significant relationship was observed between the expression of the above markers and disease free or total survival. Cases expressing bax/bcl-2 ratio >1.5 showed longer total survival compared with those expressing bax/bcl-2 <1.5 but this was not statistically significant. Histologic subtyping showed no correlation with any of the markers studied.
Conclusions: Overexpression of bax and bak as well as increased bax/bcl-2 ratio suggest that the apoptotic pathway mediated by mitochondria seems to be activated in AML. However, failure of caspase 3 activation seems to exist and results in accumulation of uncleaved caspase-3 in leukemic cells. Whether this deficit is sufficient to block bax-induced cell death or apoptosis signal may be mediated by other pathways, remains to be evaluated.

P 118

INTERDIGITATING DENDRITIC CELL SARCOMA OF THE TONSIL

ALEXANDROU Paraskevi, LIAPIS George, TZIRAKIS Mixalis, GIASLAKIOTIS Konstantinos, ANDROULAKI Athina. Affiliations: Department of Pathology, Laiko Hospital, University of Athens

Interdigitating dendritic cell sarcomas (IDCSs) derive from antigen-presenting cells of the lymph node paracortex and deep cortex, the splenic periarteriolar lymphoid sheaths and the interfollicular space of mucosa-associated lymphoid tissue. They are extremely rare, generally occur in adults with male predominance and usually show an aggressive course.

We report a case of a 55 years old male presented with a painless enlargement of the right tonsil, having no past medical history. A bilateral tosilectomy was performed. The affected tonsil exhibited a polypoid mass measuring 15 X 15 X 6 mm. On light microscopy, the normal architecture of the tonsil had been replaced by a diffuse infiltration of large irregularly shaped histiocytoid cells with clumped chromatin and indistinct cell borders. Spindle shaped, polylobated and multinucleated forms were also present. The tumor cells were moderately to strongly immunoreactive for vimentin, S-100, CD1a and lysozyme. Other immunostains including cytokeratin, actin, desmin, HMB-45, B-cell markers and T-cell markers, CD30 and follicular dendritic cell markers including CD21 and CD35 were negative. Based on morphological and immunohistochemical profile a diagnosis of IDC was suggested. Ultrastuctural study eliminated the minor possibilities of misdiagnosis. The IDCSs exhibit significant overlap with other malignancies such as undifferentiated metastatic carcinoma, primary and metastatic sarcoma, malignant melanoma, anaplastic large cell lymphoma and histiocytic-dendritic cell proliferations. The phenotypic heterogenity of the IDSCs renders the combination of a thorough pathological and clinical investigation necessary for an accurate diagnosis.

1I Clinic of Pediatrics, Pomeranian Medical University, Szczecin, Poland, 2Dept. of Pathology, Pomeranian Medical University, Szczecin, Poland, 3Clinic of Pediatrics, Hematology and Oncology, Medical University, Warszawa, Poland, 4Clinic of Pediatrics, Hematology and Oncology, Collegium Medicum UMK, Bydgoszcz, Poland

BACKGROUND: Decreased apoptosis associated with overexpression of endogenous inhibitors of apoptosis, e.g. survivin (SUR) may be responsible for treatment failure in children with acute lymphoblastic leukemia (ALL). This study aimed to assess time resolved changes of SUR expression and its intracellular distribution (nucleus versus cytoplasm) in peripheral blood mononuclear cells, collected prior to and after 6 and 12 hours of prednisone administration as well as the relation between expression of SUR and other prognostic factors (age, risk factor group, peripheral blood leukemic cell count at the diagnosis and immunophenotype).
METHODS: The study comprised 26 children with de novo ALL. Cytospin preparations of mononuclear cells isolated on density gradient were stained with mouse anti-SUR antibody followed by goat anti-mouse antibody conjugated with APC. Cellular DNA was counterstained with PI/RNase A. SUR–associated long red fluorescence excited by HeNe (633nm) was measured simultaneously over the nucleus and the rim of cytoplasm (2 pixels width) by laser scanning cytometer (CompuCyte).
RESULTS: Expression of SUR measured: (1) over the nucleus and over cytoplasm before and after 6 and 12 h from prednisone administration was significantly higher in children in medium/high risk groups then in standard risk group ($p<0.005$), (2) over the nucleus before and 12 h after treatment was significantly higher in children with peripheral blood leukemic cell count more then 20 000/uL ($p<0.05$), (3) over the nucleus before treatment was higher in ALL-T then ALL-B ($P<0.05$).
CONCLUSION: The association of high expression of SUR and poor prognostic factors in ALL suggest that SUR may be responsible for higher rates of treatment failures in children with ALL. Further studies are needed to confirm this preliminary observation.

INTRODUCTION: Mantle cell lymphoma (MCL) is a rare and aggressive B-cell lymphoma and has never been fully characterized in Taiwan.
PURPOSE OF THE STUDY: We conducted this multi-institutional study in an attempt to have a better understanding of MCL in Taiwan.
METHODS: Retrospective study with morphology, immunohistochemistry, and real time RCR for cyclin D1 mRNA using paraffin sections.
SUMMARY OF RESULTS: A total of 21 cases, all male patients, were identified with a median age at 61.0 (mean, 60.7; range, 41-75). The most common organs of involvement at diagnosis were lymph node (19 patients, 90.5%), bone marrow (15, 71.4%), spleen (8, 38.1%), and gastrointestinal tract (5, 23.8%). Four patients (19.0%) developed multiple lymphomatous polyposes including 3 at diagnosis and 1 at disease progression. Eighteen (85.7%) were at high-stage disease. The 1- and 5-yr survival rates were 77.8% and 16.7%, respectively. The most common growth pattern in non-marrow tissue was mixed nodular (mantle zone) and diffuse patterns (9/20, 45%); while in the marrow, interstitial pattern (12/13, 92.3%). Cytologically, 18 (85.7%) cases were of classic variant; and 3, blastoid. The tumor cells expressed CD20, Bcl2, and IgM (in 100% cases), cyclin D1 (95.2%), CD5 (85.7%), CD43 and IgD (61.9%), CD52 (60.0%), and Bcl6 (5%). No tumor expressed CD23. There was no statically significant impact of p21, p27, and p53 expression and Ki67 labeling index on survival. Real time PCR for cyclin D1 mRNA was performed on 11 cases. One case was not amplifiable; the single cyclin D1-negative case showed a low level of mRNA while the remaining 9 cyclin D1-positive cases showed extremely high levels.
CONCLUSION: We confirm that the usual morphologic variants and aberrant immunophenotype of MCL in the West occur in Taiwan and this disease carry a poor prognosis. Real time PCR for cyclin D1 mRNA is a useful adjunct for surporting the diagnosis of cyclin D1-negative MCLs.

ANGIOGENESIS IN CHRONIC MYELOPROLIFERATIVE DISEASES DETECTED BY CD34 EXPRESSION.

K. Panteli (1) , N. Zagorianakou (2), A. Goussia (2), A. Zioga (2), A. Katsaraki (2), K. Bourantas (1), N. J. Agnantis (2), M. Bai (2)
Department of Hematology (1) and Department of Pathology (2), Medical Faculty, University of Ioannina, Greece.

Increased bone marrow angiogenesis estimated as bone marrow microvessel density (MVD) or as serum angiogenic factor levels and/or immunohistochemical expression of these

factors in bone marrow biopsy has been demonstrated in a variety of hematological disorders including chronic myeloproliferative diseases (MPDs).
The aim of this study was to investigate the MVD in 25 cases of myelofibrosis with myeloid metaplasia (MMM). MVD was estimated by CD34 immunohistochemical expression in bone marrow biopsies. A control group of 27 patients without bone marrow disease, eight cases of polycythemia vera (PV), 41 cases of essential thrombocythemia (ET) and nine cases of chronic myeloid leukemia (CML) were also studied. Moreover, in cases with MMM and cases with ET, MVD was correlated with clinical, laboratory, histological parameters and the outcome of the patients.
Our study confirmed a significantly higher degree of angiogenesis in MMM, PV, ET and CML compared with controls ($P < 0.001$, $P = 0.0007$, $P < 0.001$ and $P = 0.0008$, respectively). Angiogenesis was higher in MMM than PV, ET and CML cases ($P < 0.001$, $P < 0.001$ and $P = 0.008$). Increased angiogenesis was correlated with hypercatabolic symptoms in MMM patients ($P = 0.009$). No correlation with other clinicopathological parameters or clinical outcome was found. In ET cases, increased angiogenesis was not correlated with clinical, laboratory, bone marrow histopathological parameters or clinical outcome.
Definitive conclusions regarding the prognostic value of increased angiogenesis may require additional follow-up and a larger group of patients.

P 122
ASSOCIATION BETWEEN MEDIASTINAL GERM CELL TUMOR AND ACUTE MYELOÏD LEUKEMIA
CAMPARO P (1), DESANGLES F (2), MOSSAFA H (3), SOULEAU B (4), BRANQUET D (5)
Laboratoire d'histologie pathologique (1) Laboratoire de cytogénétique (2); HIA du Val de Grâce, 74 boulevard Port Royal Paris. (3) Laboratoire CERBA, (4) Service d'Hématologie Clinique, (5) Laboratoire d'Anatomie Pathologique, HIA Percy

Introduction : Acute myeloïd leukemia (AML) in the follow up of other malignant tumors are usually chemotherapy-induced and may present treament specific chromosomic alterations. We report a case of AML occuring in the short follow up of a mediastinal germ cell tumor (MGCT) that was not therapy-induced, but cytogenetically proved to originate from the germ cell tumor.
Observations : A mediastinal tumor was discovered in an asymptomatic 24 years old man. Histologically, this tumor consisted of a mixed germ cell tumor associating seminoma and teratoma with some foci of myeloïd differenciation. It was first treated by chemotherapy. Ten months later the remaining mediastinal tumor was partially removed by surgery while a myelemia occured (35000 WBC). No Phi chromosome was observed on blood cell cultures (myelodysplasic syndrom MDS/MPS). Because of bad general condition, second chemotherapy was delayed and four months later the MDS/MPS transformed into AML (110 000 WBC with 28 % of blast cells). The patient died two month later.
Discussion : 60 cases of such an association between mediastinal germ cell tumor (MGCT) and AML have been discribed. The leukemia is usually of M7 type accordind FAB classification (our case). It occurs during the 5 years following the diagnosis of the germ cell tumor, a too short period for a chemotherapy-induced leukemia. The germ cell tumor is usually mixed with seminoma and yolk sac components.
The proof of a commun ancestor between germ cell tumor and leukemia is made by cytognetic analysis that shows the specific germ cell tumors i(p12) in both tumors, while others genetic alterations commonly observed in induced leukemia are absent (7q32-35 or 11q23). Only ten of such cases have been fully documented.
Conclusion : Association between GCT and AML is rare. The link between the two tumors is proved by cytogenetic analysis. These patients show poor clinical outcome with death occuring in the year following the acutisation.

P 123
B-CELL PROLYMPHOCYTIC "LEUKEMIA" (B-PLL): A HETEROGENEOUS DISORDER WITH EMPHASIS IN ITS CLINICAL, HISTOLOGICAL AND GENETIC CHARACTERISTICS
LOME-MALDONADO Carmen 1, MARTÍNEZ-BENÍTEZ Braulio 1, LARA César 1, VELA-CHAVEZ Teresa 1, QUINTANILLA-MARTÍNEZ Leticia 2, FEND Falko 2, ÁNGELES-ÁNGELES Arturo 1.
1 Pathology, Instituto Nacional de Ciencias Médicas y Nutricion "Salvador Zubirán", Mexico City, Mexico and 2 Institute of Pathology, Technical University, Munich, Germany.

Background: B-PLL is an infrequent disease, defined by the WHO as an aggressive lymphoid neoplasia, characterized by splenomegaly without lymphadenopathy and peripheral lymphocytosis with > 55% prolymphocytes.
We report 3 cases with morphologic and immunohistochemical features of B-PLL with unusual clinical and genotypic features shared by mantle cell lymphomas. Based on these findings we consider the wider term B-cell prolymphocytic leukemia/lymphoma more appropriate and discuss its use.
Design: Retrospective, descriptive.
Results: Patient 1: 51year-old male with splenomegaly and cervical lymphadenopathy, lymphocytosis (>55%),infiltrated bone marrow.
Patient 2: 54 year-old female with fever and generalized lymphadenopathy. CBC without lymphocytosis, infiltrated bone marrow.
Patient 3: 59 year-old male with fever and generalized lymphadenopathy. CBC without lymphocytosis, bone marrow without infiltration.
Lymph nodes in all cases had prolymphocytic differentiation.
All three patients had the next immunophenotype in lymph nodes: CD20+, IgM+, CD5-, CD23-, CD43-, cyclin D1-, with variable expression of Ki-67(5-50%), and p53(5-70%).
Genotyping studies using FISH probes showed t(2;8)(p12;q24) in patient 1. Patients 2 and 3 showed t(11;14) in 20% and 40% of the analyzed cells respectively.
Discusion: B-cell prolymphocytic lymphoproliferations constitute a heterogeneous group of disorders in which c-myc rearrengement can be present in very few cases. However, direct involvement of c-myc specifically affecting 8q24 has been proposed as an important factor in B-PLL pathogenesis, as detected in patient 1.
Patients 2 and 3 correspond to a B-cell prolymphocytic lymphoproliferation with isolated lymph node involvement without leukemic component. To our knowledge, this presentation is very uncommon, and is not part of the WHO classification scheme. Although it has been considered that some cases of B-PLL could represent a variant of mantle cell lymphoma, our cases were CD5 and cyclin D1 negative, partially ruling out this possibility. However, using FISH we documented t(11;14) in both patients. Our clinical and genetic data support the idea that these B-prolymphocytic disorders can be considered as B-cell prolymphocytic lymphoma/leukemia they shares a broad and still undefined genetic spectrum.

P 124
CD56 EXPRESSION WITH OR WITHOUT CYTOTOXIC PHENOTYPE IN T-CELL NON-HODGKIN INTESTINAL LYMPHOMAS
LARA César, MARTÍNEZ-BENÍTEZ Braulio, VALERIO Juan Carlos, VELA-CHAVEZ Teresa, ONTIVEROS

Patricia, LANGUREN Marisol ÁNGELES-ÁNGELES Arturo, LOME-MALDONADO Carmen.
Instituto Nacional de Ciencias Médicas y Nutrición "Salvador Zubirán", México.

In the WHO classification two major neoplasms derived from mature NK/T cells are recognized; the nasal/nasal-type T/NK-cell lymphoma and the aggressive NK cell leukemia lymphoma. Recent papers have documented the expression of CD56 in non-Hodgkin T-cell lymphomas in a variety of anatomic locations, like cutaneous lymphomas, where CD56 expression has been associated with a poor prognosis. The aim of our study is to identify the cases of NH-T cell intestinal lymphoma in our institution, describe in detail their morphologic features and to classify them according to their CD56 expression.
Material and methods: Paraffin blocks from 9 cases of T-cell intestinal NHL were evaluated, by clínical, morphological, immunophenotypical (CD3, CD20, CD4, CD8, CD7, CD5, CD 56, granzyme, LMP-1, and EBER-ISH), and molecular biology analysis (TCRg and IgH by PCR) in most of them.
Results: We identified 67 intestinal lymphomas from 1980-2004; 46 of them were B-cell lineage and 21 of T-cell lineage. Nine cases had available material for immunohistochemical studies. Of these, 6 cases were NK-(CD56-); one with expression of citotoxic granules (granzime +) and two without it. Three cases were NK + (CD56+); one with expression of citotoxic granules and 2 negative. A variable expression of CD4 and CD8 markers was found, showing no correlation with either CD56 or cytotoxic phenotype. Epstein-Barr virus presence was detected in all NK – (CD56-) cases and in none of NK + (CD56+) cases.
Discussion: We describe herein three unusual cases of intestinal large NK/like T-cell lymphomas with or without cytotoxic phenotype and without evidence of enteropathic damage. These cases had morphologic characteristics similar to those described in nasal and nasal-type NK-T cell lymphomas as angiocentric lesions and necrosis. Interestingly, EBV infection was not documented in our CD56+ cases. The particularly aggressive behavior of our cases was confirmed by clinical follow-up.
Conclusions: Our results demonstrated that T-cell intestinal NHL represent a heterogeneous group of neoplasms in which expression of CD56 can be present, with an apparent poor clinical prognosis. Theses cases could be considered as part of the group of NK-T cell nasal type lymphomas or as a particular group of CD56 + (cytotoxic or not) intestinal NHL.These items are open to future investigations with larger series of cases.

Introduction: Central nervous system (CNS) involvement is an extremely rare complication of chronic lymphocytic leukemia (CLL). We reviewed 26 autopsy cases of CLL with special attention on pathological findings in CNS.
Patients: The study group consisted of 18 males and 8 females aged 45-75 years (average 62 years). The diagnosis of CLL was obtained on review of the hematoxylin and eosin-stained slides and immunophenotype data.
Results: Leukemic infiltration of CNS was evident clinically and grossly in two cases. The first patient was 53-years-old man with CLL of 3 years' duration, who developed a sensomotoric aphasia with right-sided hemiplegia six weeks prior to death. At autopsy, a large (6x6x4cm) ill-defined tumor mass was found in the temporo-occipital region of the left cerebral hemisphere with temporal herniation. Histologically, tumor tissue was very cellular, composed of large cells with vesicular nuclei, prominent nucleoli and occasionally giant and Reed Sternberg-like cells admixed with a small number of mature lymphocytes. Immunohistochemically, both types of malignant proliferation (small and large cells) stained positively for CD20 (pan-B marker). The diagnosis of cerebral diffuse large cell lymphoma in CLL (Richter syndroma) was obtained. The second patient was 70-years-old man with CLL of one year's duration, who developed a polyradiculoneuropathia one month prior to death. At autopsy, infiltration of spinal roots and cranial nerves as well as diffuse leptomeningeal dissemination ("leukemic meningitis") were found. Histologically, peri- and endoneural leukemic infiltration, leukostasis and perivascular leukemic infiltration (prevalent in the brainstem and spinal cord) and meningiosis were presented. Histopathological findings (without evidence of a mass lesion) in 2/26 CLL cases without neurological signs were in the form of petechial hemorrhages with leukostasis and perivascular leukemic infiltration, localized in the white matter of the cerebral hemispheres. In all other cases of CLL (22/26, 84,6%) cerebral leukemic infiltration was not present.
Conclusions: The clinicopathological features of these cases indicate that, despite of rarity of CNS involvement in CLL, any neurological manifestation in CLL patients should be aware of the possibility of this complication.

EXPRESSION LEVEL OF CASPASE-3 IN DIFFUSE LARGE B-CELL LYMPHOMA: CORRELATION WITH GERMINAL CENTRE EXPRESSION PROFILE.
PANDELEON Barbara, KATIKOS Evangelos, VAMVOUKA Chrysanthi, STEFANAKI Kalliopi, PAPPA Vasiliki, ECONOMOPOULOS Theofanis, HARHALAKIS Nikolaos, RONTOGIANNI Demetra.
Departments of Pathology and Hematology, Evangelismos Hospital, and Second Department of Internal Medicine-Propaedeutic Clinic, Athens University.

Background: Abnormalities in programmed cell death frequently induce drug and/or radiation resistance in non-Hodgkin's lymphoma (NHL). Caspase-3 is an enzyme crucial to the apoptotic process and is activated in both major apoptotic pathways, including stress-induced pathway and a cell surface death receptor signalling pathway, leading to final execution of apoptosis. Recent study showed that the expression of caspase-3 in NHLs can reflect proper functioning of apoptotic pathways. Diffuse Large B-Cell Lymphomas -DLBCLs- are a group of tumours with heterogeneous clinical, morphological, immunophenotypic, cytogenetic and molecular features.
Purpose of the study: In order to elucidate whether good prognosis of germinal centre cell DLBCLs is related to well functioned caspase apoptotic pathway, we studied the expression of active form of caspase-3 (activated CCP32) in 46 cases of DLBCLs which were classified in four groups according to bcl-6 protein, CD10 and MUM-1 antigen expression: I) bcl-6 positive 16/46, II) bcl-6 positive, CD10 positive, germinal centre cell immunophenotype 14/46, III) bcl-6 positive, MUM-1 positive 10/46 and IV) bcl-6 negative 6/46. Chi-square was used as the statistical test.
Results: 1) Group I -bcl-6 positive- showed significantly higher expression of caspase-3 than the group IV -bcl-6 negative-. 2) Group II -bcl-6 positive, CD10 positive- showed significantly higher expression of caspase-3 than the groups I -bcl-6 positive-, and III -bcl-6 positive, MUM-1 positive-.
Conclusions: Our results indicate that DLBCLs with germinal cell immunophenotype maintain well functioning apoptotic

pathway which can explain good response to current chemotherapeutic agents.

5-"Sfanta Maria" Clinical Hospital, Bucharest, Romania
6-Dept of Pathology, "Fundeni" Clinical Institute, Bucharest, Romania

T/null Anaplastic Large-Cell Lymphoma (ALCL) is a very rare Malignant Lymphoma (~5% incidence), frequently with extranodal determination. 45 cases of systemic ALCL diagnosed in ours laboratories were studied, and a pathological and clinical study was performed. The 45 patients(M/F = 2.75, 66% T-cell ALCL and 33% null ALCL, 56.5% expressing ALK)presented extranodal disease in 42% of cases. Only in 3 cases the first presentation was extranodal (bone-1 case and digestive-2 cases). The most frequently sites were: bone (8 cases), cutaneous (6), bone marrow (4), digestive (4), pulmonary(4), hepatic (4), central nervous system (3). Four patients presented more than 3 extranodal determinations. The pediatric population presented particularly cutaneous and bone marrow infiltration. The phenotype of the malignant cells was more frequently T-cell (28% of the T-ALCL and 18% of the null-ALCL). More than 50% of the ALCL ALK negative presented extranodal disease (half of the cases with more than 2 localizations), and only 38% of the ALCL expressing ALK. The presence of extranodal disease in ALCL is an important characteristic of these malignancy and, sometime, pose problems of diagnosis and treatment.

P 128
IMMUNOHISTOCHEMICAL ANALYSIS OF T-CELL RECEPTOR SIGNALING ACROSS THE SPECTRUM OF CELIAC DISEASE ASSOCIATED LYMPHOCYTIC PROLIFERATIONS

KELLER, Christian, College of Physicians and Surgeons, Columbia University, New York, USA, CATTORETTI, Georgio, College of Physicians and Surgeons, Columbia University, New York, USA, VAKIANI, Efsevia, College of Physicians and Surgeons, Columbia University, New York, USA, GREEN, Peter, College of Physicians and Surgeons, Columbia University, New York, USA, BHAGAT, Govind, College of Physicians and Surgeons, Columbia University, New York, USA

Background: Small bowel biopsies with increased intraepithelial lymphocytes (IELs) are commonly seen in patients with celiac disease (CD). In individuals with refractory CD (RCD) the IELs display an abnormal phenotype, persist despite gluten withdrawal and are often clonal, possibly representing cryptic enteropathy associated T-cell lymphomas (EATLs) in a subset. We evaluated for possible dysregulation of the T-cell receptor (TCR) associated signaling proteins as well as mediators of the NF-kappa B pathway across the spectrum of CD associated IEL proliferations to determine whether any differences exist between IEL expansions in active CD, RCD, and EATL.
Material and methods: Immunohistochemical (and in a subset immunofluorescent) staining of duodenal biopsies from patients with active CD (n=2), RCD with polyclonal IELs (n=2), RCD with clonal IELs (n=1), EATLs (n=4), normal individuals (n=2), and suitable controls was performed with antibodies against Zap-70, Bcl-10, CD25, c-REL, p65, and junB by immunohistochemistry. IELs were also phenotyped by staining for the pan-T-cell antigens, CD30, and TIA-1.
Results: IELs in all cases were ZAP-70+, CD25-, c-REL-, p65-, and junB-; Bcl-10 staining was equivocal in a few cases. One EATL was CD4+ TIA-1-, while the remaining 3 were CD4- CD8- TIA-1+, 2 of these were also CD30+, CD25+, and Bcl-10+. All EATLs were ZAP-70+. None of the EATLs stained with c-REL and p65. Both the CD30+ EATLs showed intense nuclear junB staining while CD30- EATL showed only scattered junB+ cells.
Conclusions: We did not observe any differential expression of TCR associated proteins in CD associated IEL expansions. A lack of CD25 expression by the IELs suggests the role of cytokines besides IL-2 in cell survival and proliferation. No detectable elevation in proteins of the classical NF- kappa B pathway in EATLs suggests the possible role of other signaling pathways. Lastly, nuclear accumulation of junB in a subset of EATLs appears to be the consequence of CD30 activation, as has been demonstrated for other subsets of T-cell lymphomas.

P 129
STUDY OF TRANSLOCATION T(11;18)(Q21;Q21)(API2/MLT1) AND EXPRESSION OF BCL10 IN PRIMARY CUTANEOUS MARGINAL ZONE B-CELL LYMPHOMAS

V.Baena1, C.Barranco1, F.Gallardo1, B.Belosillo1, S.Boluda1, M.Jimeno1, M.Iglesias1, N. Juanpere1, M. Garcia1, R. Esgueva1, A. Ariza2, F.Solé1, R. Pujol1, J. Lloreta1, S.Serrano1. Pathology and Dermatology Departments. Hospital del Mar-IMAS1. Pathology Department. Hospital Universitari Germans Trias i Pujol2.

Background
Primary cutaneous marginal B-cell lymphoma (C-MZL), an usually benign low-growth fraction neoplasm, is probably the most frequent form of primary B-cell lymphoma of the skin. API2/MLT1 fusion transcripts due to (11;18)(q21;q21) and aberrant bcl10 nuclear expression have been described in some noncutaneous marginal zone lymphoma subtypes, but little is known about cutaneous-MZL genetic alterations. Our aim was to evaluate a possible implication of API2/MLT1 fusion transcripts and bcl10 expression in primary cutaneous-MZL.
Design
A total of 42 patients diagnosed with cutaneous-MZL on the basis of WHO/EORTC criteria were studied. Skin biopsies from every patient were routinely tested with a wide panel of monoclonal antibodies. Additionally, MLT1 fusion transcripts were performed in 21 instances.
Results
Aberrant nuclear bcl10 expression, demonstrated in 15 cases, was related to a more aggressive clinical behaviour. Translocation t(11;18)(q21;q21) was absent in all evaluated samples.
Conclusion
The API2/MLT1 fusion, strongly associated with extracutaneous MALT lymphomas, does not seem to play a role in cutaneous marginal zone lymphoma pathogenesis. However, bcl10 aberrant nuclear expression could be a significant prognostic factor in cutaneous marginal zone lymphoma, signalling a more aggressive clinical course and a higher risk of extracutaneous involvement.

P 130
BCL 2 AND BAX INTERACTION IN PERIPHERAL BLOOD B – LYMPHOCYTES IN PATIENTS WITH CHRONIC LYMPHOCYTIC LEUKEMIA

BRAJUSKOVIC Goran, OROLICKI VUKOSAVIC Slobodanka*, CEROVIC Snezana, USAJ KNEZEVIC Slavica, MARJANOVIC Slobodan**, ROMAC Stanka***
Institute of Pathology and ** Clinic of Hematology, Military Medical Academy, Belgrade, Serbia and Montenegro; * Novartis Research Foundation WRO, Friedrich Miescher Institute, Basel, Switzerland, *** Faculty of Biology, University of Belgrade, Belgrade, Serbia and Montenegro

Chronic lymphocytic leukemia (CLL) is neoplastic disease characterized by the accumulation of morphologically mature monoclonal CD 5+ B cells in the early phase (G0/G1) of the cell cycle. The accumulation of neoplastically transformed B lymphocytes (CLL cells) is primarily the consequence of the blockade of apoptosis in these cells. The Bcl 2 proteins are well-known modulators of this process. Some of these proteins are anti-apoptotic while other are pro-apoptotic. All contain at least one of the four conserved regions called Bcl 2 homology domains (BH1-BH4). Evidence indicates that Bcl 2 and Bax form homo- and heterodimers. The antiapoptotic effect of Bcl 2 protein is based on its possibility to bind Bax protein in the heterodimer form, and in that way blocks forming Bax/Bax proapoptotic homodimers. The ratio of Bcl 2 / Bax represents a cell autonomous rheostat which determinates the type of cell reaction to an apoptotic stimulus. We used the co – immunoprecipition method to determine the level of interaction between these two proteins in CLL cells. Our study included the analysis of 20 peripheral blood speciments from 20 patients with CLL, and 20 peripheral blood specimens of healthy persons who represented the control group. Simultaneously we analysed the level of binding Bcl 2 protein to Bax (IP: Bcl 2 / WB: Bax) and reversed (IP:Bax / WB: Bcl 2). The intensity of Bcl 2 and Bax protein binding compared to the control samples of the peripheral blood of healthy persons, was increased in CLL cells. Results IP: Bax / WB: Bcl 2 showed a high level of »free« Bcl 2 protein which is not bound in the heterodimer form to Bax protein. Simultaneously IP: Bcl 2 / WB: Bax has showen that a higher quantity of Bax protein was bound in the heterodimer form to Bcl 2 protein, than the rest of the potential homodimer bound to bax protein. Further studies involving larger groups of patients are necessary to explore potentional significance of Bcl 2 / Bax protein ratio determination as a prognostic parameter in CLL treatment.

P 131

AGGRESSIVE SYSTEMIC MASTOCYTOSIS WITH PRIMARY PRESENTATION IN GASTROINTESTINAL TRACT. CASE REPORT

Ugnius Mickys, Auðrinë Barakauskienë
National Centre of Pathology, Vilnius, Lithuania
Chris De Wolf-Peeters, Karel Geboes
Department of pathology, K.U. Leuven, Belgium

Introduction
The WHO classifies mastocytic proliferations into: 1. Cutaneous mastocytosis. 2. Indolent systemic mastocytosis. 3. Systemic mastocytosis with associated other clonal hematological disease. 4. Aggressive systemic mastocytosis. 5. Mast cell leukemia. 6. Mast cell sarcoma. 7. Extracutaneous mastocytoma.
Aggressive systemic mastocytosis is characterized by clonal mast cell proliferation in skin, bones, lymph nodes and the gastrointestinal tract.
Our aim is to report a rare case of primary presentation of aggressive systemic mastocytosis in small and large bowel.
Materials and methods
A 46 years old woman suffered from watery diarrhea, vomiting, abdominal pain, weakness and weight loss for 6 months. No skin lesions were documented. Clinical and other investigations revealed ascites, massive edema of the legs, leucocytosis, anemia, hypoproteinemia and patchy erosive lesions in the large and small bowel (endoscopically). Small and large bowel biopsies, cytological smear of ascitic fluid and a bone marrow biopsy were evaluated with routine staining (haematoxylin and eosin), histochemical stainings (PAS, Giemsa, Ziehl-Neelsen, Toluidin, Leder). Hmmunohistochemical stainings using antibodies directed against: S-100, CD1a, CD68, mast cell tryptase, CD117 (c-kit) and myeloperoxidase (MPO).
Results
Routine staining revealed an accumulation of large cells with pale cytoplasm in the lamina propria of duodenum and large bowel. PAS, Giemsa, Ziehl-Neelsen and Toluidin blue stainings performed for the identification of these cells were negative. The immunophenotype of the cells was S-100 (-), CD1a (-), MPO (-), CD 68 (+), c-KIT (CD117) (+) and mast cell tryptase (+) which is consistent with mast cells. Infiltrates of mast cells occupied 50% of bone marrow space with collagen fibrosis. Giemsa (+) violet granules and Leder (+) red granules were found in mastocytes. Cytological evaluation of ascitic fluid was negative.
Conclusions
A diagnosis of primary mastocytosis in a visceral localization is very difficult, because this presentation is unusual and it is really a diagnosis of exclusion.
The main clue for the diagnosis of mastocytosis is the detection of mast cell tryptase immunohistochemically. Immunoreactivity of mast cells for CD68, CD117, MPO and positivity for Giemsa and Leder stains histochemically may suggest the diagnosis but the results of these stainings may vary according to the localization and in malignant mast cell proliferations.

P 132

CDK9/CYCLIN T1 EXPRESSION DURING NORMAL LYMPHOID DIFFERENTIATION AND MALIGNANT TRANSFORMATION

DE FALCO Giulia, LEUCCI Eleonora, ONNIS Anna, TILLI Chiara, COCCO Mario, BELLAN Cristiana, GIORDANO Antonio and LEONCINI Lorenzo
Department of Human Pathology and Oncology, University of Siena, Italy

Cdk9 is a member of the CDC2-like family of kinases. Its cyclin partners are members of the Cyclin T family (T1, T2a and T2b) and Cyclin K. Cdk9/Cyclin T1 complex is very important in controlling specific differentiative pathways of several cell types. Limited data are available regarding the expression of Cdk9/Cyclin T1 in haematopoietic and lymphoid tissues. We analyzed the expression of this complex in lymphoid tissue, in order to assess its role in B and T cell differentiation and lymphomagenesis. Cdk9/Cyclin T1 expression was found by immunohistochemistry in precursor B and T cells. In peripheral lymphoid tissues, Cdk9/Cyclin T1 were expressed in germinal center cells and scattered B and T cell blasts in interfollicular areas, while mantle cells, plasma cells and small resting T lymphocytes displayed no expression of either molecule. Therefore Cdk9/Cyclin T1 expression appears to be related to particular stages of lymphoid differentiation/activation.
To monitor the expression level of Cdk9/Cyclin T1 during normal lymphoid differentiation, we isolated different B and T cell populations by magnetic separation, based on their surface antigens, to check the expression levels of the complex at different stages of activation of B and T cells. After isolation, the expression levels of the Cdk9/Cyclin T1 complex was monitored by RT-PCR in Real Time. We observed that the expression level of Cdk9/Cyclin T1 seems to increase in activated cells, compared to un-stimulated ones. Differentiation is achieved through the direct involvement of proteins of the basic helix-loop-helix family, which are specifically activated during differentiation. Different members of this family are involved in different

differentiation systems. In lymphoid cells the E2A gene products, E12 and E47, are specifically activated during differentiation. We investigated whether Cdk9 was able to promote lymphoid differentiation by interacting with E12 and E47. Our results showed that Cdk9 interacts, with the E2A gene products, both in vitro and in vivo, thus suggesting an active role for the Cdk9/Cyclin T1 complex during lymphoid differentiation, through physical binding with E12 and E47.
These preliminary results suggest that the Cdk9/Cyclin T1 complex may affect the activation and differentiation program of lymphoid cells. However, through which molecular mechanism Cdk9/Cyclin T1 complex is altered in malignant transformation still needs to be elucidated.

P 133
THE VASCULAR CHANGES IN LYMPHADENOPATHIES

MIHAILOVICI Maria-Sultana, TELEMAN Sergiu, FERARIU Dan, DANCIU Mihai, BUTCOVAN Doina, TERINTE Cristina, CIOBANU Delia
Pathology Department, University of Medicine and Pharmacy "Gr. T. Popa", IASI, ROMANIA

Disorders primarily affecting the lymph node vessels are certainly uncommon in comparison with those that primarily involve lymphoid tissue. The vascular changes are commonly manifest, either in ischaemic lesions in the nodal parenchyma, or in vascular proliferation and modify the histopathological appearances in both reactive and neoplastic lymphadenopathies.
Aims: We conducted a study to establish vascular lesions from lymph nodes with valuable signification in the positive or differential diagnosis of reactive, inflammatory and neoplastic lymphadenopathies.
Material and methods: Our study included lymph node biopsies from 1701 patients, using histological and immunohistochemical techniques.
Results: Histopathological aspects of 1701 specimens of lymph nodes evidenced: 568 (33.4%) reactive lymph nodes, 969 (57.2%) neoplastic lymphadenopathies; 164 (9.4%) were biopsies that didn't contain lymphoid tissue. The neoplastic lymphadenopathies were primary NHL (432 cases – 25.4%), HL (207 cases - 12.2%) and metastatic neoplasm (330 cases – 14.4%). In the reactive lymphadenopathy cases, we observed a variety of vascular lesions as: diffuse vasodilatation, vascular granulation tissue formation, vascularization of lymph node sinuses, capillary vascular proliferation, post-capillary venule proliferation, vasculitis and total or subtotal, segmental or focal infarction, vasoproliferation in reactive states (angio-immunoblastic lymphadenopathy) or marked proliferation of small blood vessels in Castleman's disease and angiomatosis/haemangiomatoids in axillary lymph nodes draining breast carcinomas. Vasoproliferation in malignant neoplasms was evident whether the lymph nodes were occupied by malignant lymphomas of metastatic tumor.
Conclusions: Vascular transformation of sinuses is a pattern of fibrosis formation in chronic lymphadenitis with atrophy of lymphoid tissue. Reactive proliferation of blood vessels is one of the central features of hyperimmune angiofollicular and plasmacytic polyadenopathy, and angio-immunoblastic lymphadenopathy. Primary vascular lesion of lymph node was infarction with various intensity degrees, mainly in NHL. Capillary proliferation in primary malignant lymphadenopathies was present in Hodgkin's lymphoma, in lymphoplasmacytic neoplasms while in T cell NHL we saw a marked proliferation of post-capillary venules. In latter condition, differetial diagnosis with hyperplasia and stimulation of the paracortical areas is needed.

P 134
EXPRESSION OF TELOMERASE COMPONENTS IN NEUTROPHILS.

LEPREUX Sébastien (1,2), DOUDNIKOFF Evelyne (1), BIOULAC-SAGE Paulette (1), BLOCH Bertrand (1,2), MARTIN-NEGRIER Marie-Laure (1,2).
(1) Laboratoire d'Histologie-Embryologie, UFR II, Université Victor Segalen Bordeaux 2, France (2) Service d'Anatomie Pathologique Hôpital Pellegrin, 33076 Bordeaux Cedex, France.

Backgrounds and aims: Human telomerase comprises an RNA subunit (hTR) and a catalytic protein subunit with reverse transcriptase activity (hTERT). Telomerase extends chromosome ends in compensation for the attrition of the telomeres during replication. Telomerase is normally expressed in germinal or stem cells during the adult life and during cellular immortalisation and tumorigenesis in pathology. Even though hTERT protein is a key component controlled the telomerase activity, some data indicate that hTERT protein expression level did not always correlate with telomerase activity. In this work, we explore the expression of hTR and hTERT protein in neutrophils, which are highly differentiated cells without hTERT mRNA expression and telomerase activity.
Materials and methods: We investigated the expression of hTR and hTERT protein, respectively by in situ hybridization with a S35-labeled specific probe and immunohistochemistry with two different antibodies, in neutrophils of the stroma in 10 cases of bladder carcinomas. hTERT protein expression was also studied by immunoelectronmicroscopy in neutrophils of non-neoplastic liver tissues with "surgical hepatitis" in 3 cases of partial hepatectomy.
Results: Like others non-tumoral cells, neutrophils expressed hTR. hTERT protein was strongly expressed in the cytoplasm of neutrophils with the 2 antibodies. The ultrastructural study showed that the gold particles were not associated with specific organelles but scattered in the cytosol. No significant nuclear labeling was observed in neutrophils.
Conclusions: This study demonstrates that hTERT protein is expressed in the cytoplasm of neutrophils. We hypothesize that complex qualitative changes, i.e. post-traduction modification, compartimental protein sequestration could be of importance in the enzyme activity level control. The functional significance of cytoplasmic hTERT protein without telomerase activity remains to be elucidated.

P 135
ULTRASONIC DECALCIFICATION IS RAPID AND SUITABLE FOR FISH ANALYSIS

T. Reineke, B. Jenni, P. Zubler, S. Frigerio, H. Moch, M. Tinguely
Institute of Clinical Pathology, University Hospital Zurich, Switzerland

Aim
In haematopathology, the requisite analyses on bone marrow biopsies are increasing; in addition to morphology and immunohistochemistry (IHC), molecular analysis (MA) like FISH is now demanded in order to improve diagnostic accuracy. Certain chromosomal alterations in particular, are known to be of prognostic or predictive value. In some circumstances, e.g. surgical biopsy, "packed marrow", only formalin fixed, bone-containing tissue is available for MA. Since the various decalcification procedures can impair DNA quality, there is an urgent need for standardized decalcification protocols allowing FISH analysis on these materials. Our aim was to set up a routinely applicable protocol to optimise the MA method whilst preserving morphology and IHC results.
Materials and Methods
Bone marrow specimens were fixed in 4% buffered formalin. The decalcification procedures were carried out in an EDTA solution (Usedecalc, Medite, Burgdorf, Germany) with or without the use of an ultrasonic decalcifier (USE33, Medite,

Burgdorf, Germany). Decalcification solutions containing either formic or acidic acid were compared. The decalcification times varied from one and a half hours up to 24 hours. Thereafter, the ultrasonic decalcified tissue was dehydrated, paraffin embedded and, depending on the sample size, again incubated in the EDTA solution. Samples were stained with H+E and Giemsa, and IHC for nuclear (Mib1, Glycophorin A) and cytoplasmic markers (CD20, CD3, CD61, MPO) was performed. Interphase FISH analysis with a double colour, double fusion probe (Abbott Molecular Diagnostics, Illinois, USA) specific for the translocation t(11;14) was applied according to the manufacturers instructions.

Results

Ultrasonic decalcification allows reduction of the decalcification time. Overall, the best results for morphology, IHC and FISH analysis were obtained by 3-5 hours of ultrasonic decalcification using an EDTA solution. Of interest, FISH analysis was successfully applied only on samples positive for Mib1 IHC, thus being predictive for DNA quality of the sample.

Conclusion

The combination of ultrasound and EDTA for decalcifying bone-containing tissue samples is a rapid and easy method resulting in an excellent morphology comparable to plastic embedded bone marrow trephines. Most importantly, the same protocol permits successful interphase FISH analysis. Current investigations will reveal whether this decalcification approach is also suitable for PCR studies.

HEDGEHOG SIGNALLING IN B-CELL DIFFERENTIATION

BLAAS Leander, KOLLMANN Karoline, ALINGER Beate, REGL Gerhard, ABERGER Fritz, DIETZE Otto, HAUSER-KRONBERGER Cornelia

Department of Pathology, Gerneral Hospital Salzburg and Department of Molecular Biology, University of Salzburg, Austria

The Hedgehog signalling pathway plays a crucial role in embryonic tissue development and differentiation and has also been shown to function in adult self-renewing tissues.

Apparently, the pathway is also involved in the development of the hematologic system. It has been published that the ligand Sonic hedgehog (Shh) is involved in development of primitive human hematopoietic cells and T-cells. Together with the receptors Patched (Ptch) and Smoothened (Smo) Shh also ensures survival of germinal center B-cells.

Recently published findings showed expression of Shh by follicular dendritic cells and expression of the pathway receptors Ptch and Smo by germinal center B-cells.

Lately, we could show that the Hedgehog signalling pathway is involved in differentiation of human B-cells. Especially the transcription factor Gli2 is expressed in B-cells of the bone marrow.

In the present study we examined the expression of members of the Hedgehog pathway in normal and malignant B-cell development. Formalin-fixed and paraffin-embedded tissues of normal bone marrow and secondary lymphatic tissues were immunohistochemically analyzed using antibodies against ligands, receptors and transcription factors involved in the Hedgehog pathway. Non-Hodgkin's lymphomas and B-cell leukemias were investigated as each disease entity shows an increased proliferation of specific stages of B-cell development.

Lymphatic tissues displaying Precursor B-lymphoblastic lymphoma/leukemia (n=5), Precursor B-cell acute lymphoblastic lymphoma/leukemia (n=5), B-cell chronic lymphatic leukemia/small lymphocytic lymphoma (n=5), B-cell prolymphocytic leukemia (n=5), Lymphoplasmacytic lymphoma (n=5), Plasma cell myeloma/Plasmacytoma (N=5), Extra-nodal marginal zone B-cell lymphoma of MALT type (n=5), Follicular lymphoma (n=5), Diffuse large B-cell lymhoma (n=5), Burkitt's lymphoma (n=10), and Hodgkin's lymphomas (n=10) were examined. By using CD markers in double fluorescence stainings cells with an active pathway were assigned to their hematopoietic lineages.

The results showed pathway activity in several stages of B-cell development. CD79a positive B-cells showed strong expression of Ptch and Gli2. Additionally, only a small minority of plasma cells showed pathway activity. In conclusion, active Hedgehog signal transduction plays a role in the differentiation of B-lymphocytes.

P 137

STUDY OF EC CELLS IN PATIENTS WITH PERNICIOUS ANEMIA

MAÈUKANOVIÆ-GOLUBOVIÆ Lana, KATIÆ Vuka, RANÈIÆ Gorana,MILENOVIÆ Mladen,MARJANOVIÆ Goran,VUKIÈEVIÆ Tomislav,ÈOJBAŠIÆ Irena,GOLUBOVIÆ Ivan,DJORDJEVIÆ Goran

Enterochromathophine (EC) cells are the members of diffuse neuroendocrine system and are classified according to ultrastructure characteristics as ECl-intestinal type; EC2-duodenal type and ECn-gastric type. Gastric type EC cells are argirophylic and argentaphylic in 10-20%.They are localized in antral and corporal gastric mucosa. In pathologic conditions EC cells can change their number, morphology and cytochemical characteristics, so as a functional properties.

The aim of this study is to investigate presence, type and granularity EC cells in patients with pernicious anemia(PA).

During the period from l977 to 2005(Clinic of Hematology-Niš), 78 patients with PA were examined as well as 30 patients with dyspeptic syndrome(control group).Classical (HE) histological method was used for pathological evaluation of gastric mucosa.Grimelius(argyrophilic) and Massons(argentaphilic) methods were used for the identification of EC cells.

Hyperplasia, metaplasia and hypergranularity of EC cells were found in corporal mucosa of PA patients. The number of EC cells was increased proportionally to the changing of gastric mucosa and the grade of intestinal metaplasia(22 to 43 cells per field). Sometimes, EC cells hyperplasia is of so high grade that resemble intramucous carcinoidosis. EC cells were transformed from close type to the open type: they become triangle shape and high amount of serotonin in them.

These results can confirm that new formed, intestinal type of EC cells secrete high quantity of serotonin increasing permeability and inducing the retrograde diffusion of H ions in gastric mucosa. In the way, H ions induce acidosis and inhibit cellular metabolism, leading to citolysis of all attached cells. Serotonin stimulates synthesis of acid mucins and has an inhibition effect on HCL secretion.

Hyperplasia and metaplasia of EC cells could be important for the cancer genesis through serotonine effects.

P 138

D2-40 - SELECTIVE MARKER OF LYMPHATIC ENDOTHELIUM AND A PUTATIVE FOLLICULAR DENDRITIC CELL MARKER.

Assia Bassarova, Jahn M. Nesland, Jan Delabie

Department of Pathology, The Norwegian Radium Hospital, University of Oslo, Oslo, Norway

Introduction: M2A antigen is an oncofetal antigen associated with germ cell neoplasia, present in testis on fetal gonocytes and re-expressed on carcinoma in situ (CIS) and germ cell tumours. It was shown that the antigen is an O-linked sialoglycoprotein containing a simple mucin-type carbohydrate epitope. A specific monoclonal antibody named D2-40 (IgG1) against the antigen was developed. It was then

observed that D2-40 is a selective marker of lymphatic endothelium.
Purpose: The aim of the study was to examine the expression of D2-40 in various haematopoietic and lymphatic tissues.
Materials and methods: The study was performed on 60 cases, distributed as followed: 34 lymph node samples, 14 spleens and 8 bone marrow specimens. Half of the lymph nodes were involved by metastatic carcinoma and half were involved by various lymphoma types – 1 small lymphocytic lymphoma, 2 mantle cell lymphomas, 2 marginal zone lymphomas, 4 follicular lymphomas, 4 diffuse large B cell lymphomas, 2 with peripheral T cell lymphoma and 3 lymph nodes with angioimunoblastic T cell lymphoma. Most of the spleen specimens (8) were with reactive changes, 3 were affected by lymphoma. Bone marrow was predominantly with reactive changes and 2 with lymphoma infiltration. The expression of D2-40 was evaluated immunohistochemically. Except for that on several specimens double immunofluorescence with D2-40 and CD21 was performed.
Results and discussion: All metastatic lymph nodes showed specific D2-40 expression in the preserved lymphoid follicles. In all specimens positive reaction was observed in both lymphatic vessels and follicular dendritic cells. In lymphomas the staining intensity in the follicular dendritic cells was generally weaker. In the spleen no immunoreactivity was detected. The same pattern was observed in the bone marrow. Except for a specific marker for lymphatic endothelium M2A antigen, detected by D2-40 monoclonal antibody detects also a subset of follicular dendritic cells. Further investigations should to be performed to clarify the function and significance of this marker in reactive conditions and lymphoproliferative diseases.

P 139
FATAL NECROTIZING HERPES SIMPLEX VIRUS LYMPHADENITIS IN A PATIENT WITH CHRONIC LYMPHOCYTIC LEUKEMIA AND SEVERE HYPOGAMMA GLOBULINEMIA

B.Chibaudel (1), T.Hanslik (1), F. Rosenberg (2), F. Le Deist (3), J.Prinseau (1), A.Baglin (1), J.F.Emile (4).
(1)Service de médecine interne, Hôpital Ambroise Paré, Faculté de médecine PIFO, Boulogne, (2)Service de virologie, Hôpital Saint Vincent de Paul, Paris, (3)Service d'immunologie et hématologie pédiatrique, Hôpital Necker, Paris, (4)Service d'anatomie pathologique, Hôpital Ambroise Paré, Faculté de médecine PIFO, Boulogne, France

Necrotizing lymphadenitis is a rare manifestation of herpes simplex virus (HSV) infection. We report a 80-year-old patient with fever, retroperitoneal necrotic lymphadenopathy and thrombosis of the lower vena cava, revealing a lymphocytic leukemia and a necrotizing HSV lymphadenitis mimicking Richter's transformation. Lymph node biopsy revealed a diffuse necrosis, with an infarct like pattern. Necrosis contained karyorrhectic bodies and numerous cells with Cowdry A inclusions. HSV was detected within a lymph node biopsy by immunohistochemistry. HSV type II DNA was detected within blood and bone marrow samples by PCR. The patient had a severe hypogammaglobulinemia and normal T cell repertoire. No skin nor mucosal lesion were present. Clinical and biological symptoms improved rapidly with acyclovir and immunoglobulins, however the patient died with pulmonary embolism. HSV lymphadenitis may be misdiagnosed with Richter's transformation. Humoral immunity seems to be the main defense in human against severe HSV infections.

P 140
APOPTOSIS AND PROLIFERATIVE ACTIVITY OF HUMAN TROPHOBLAST CELLS IN SPONTANEOUS ABORTIONS WITH NORMAL AND PATHOLOGIC KARYOTYPES

I.N. Voloschuk, J.V. Gorbacheva, M.A. Paltsev

Introduction. Apoptosis and proliferation are interrelated processes, that supply normal implantation of an ovum and development of pregnancy. Disturbances of these processes in cases of spontaneous abortions (SA) may reflect the pathogenesis of pregnancy loss. From this point of view it is interest to compare the apoptotic and proliferation rates in SA caused by chromosomal aberrations and in SA with normal karyotype.
Materials and methods. Proliferation and apoptosis in villous and extravillous trophoblast was estimated in SA with pathologic karyotype (15 cases), SA with normal karyotype (15 cases) and in normal early pregnancy (20 cases of elective abortions). Proliferative activity (PA) was determined as the rate of Ki-67-positive cells. Estimation of apoptotic index (AI) was performed using the ApoTag Peroxidase Kit ("Biotech", USA).
Results. In normal early pregnancy specimens Ki-67 was strongly expressed in villous cytotrophoblast (VCT) and extravillous trophoblast (EVT). Syncytiotrophoblast (ST) was negative for proliferation marker. Signs of apoptosis were mainly observed in ST, syncytial knots, VCT, some villous stromal cells and in EVT. PA of VCT was low in both groups of SA as compared to control group. The significant differences in rate of apoptosis between SA with normal and pathologic karyotypes was revealed. The rate of villi with apoptotic VCT was significantly higher in SA with pathologic karyotype (26.20 %) than that in SA with normal karyotype (7.6%) and normal first trimester pregnancies (16.65 %). AI of EVT was also higher in group of SA with pathologic karyotype (7.67±3.31) as compared to SA with normal karyotype (2.78±2.56). Furthermore, SA with pathologic karyotype showed uncorrelation between AI and PA in EVT: the level of AI was the highest whereas PA was minimal. The highest frequency of apoptosis in combination with minimal proliferative activity of EVT in SA caused by chromosomal pathology indicates active invasion restriction of chorion with pathological karyotype.

P 141
HUMAN PLACENTA AND FETAL IUGR AT 20-22 WEEKS OF GESTATION

RESHETNIKOVA Olga, KONONENKO Olga, MOROZOV Sergiy
Dept. of Pathologic Anatomy, Medical University, Lugansk, Ukraine.

It is reported that some adult diseases has intrauterine 'programming' mechanism. Disproportions and restrictions of placental and fetal growth could be the marker for the high risk group of newborns.
The aim of the present study was to identify which organs are principally affected in cases of fetal growth restriction (FGR) at 20-
22 weeks of gestation.
Methods: 8 cases with fetal growth restriction (FGR) and high (0.41±0.04) placenta/fetal weight index (PFI) were compared with 10 controls (PFI= 0.26±;0.01) in cases of induced abortions for psychotherapeutic reasons at 20-22 weeks of gestation. Weights of placenta (PW) and fetus (FW), fetus length (FL), head (Ch), chest (Cch), abdominal (Ca) circumferences, fetal kidneys (KW), pancreas (Pn W), liver (LW) and heart (HW) as well as some indices were recorded.
Results: FGR group had smaller parameters of FW (390+2.0 vs 610+2.6 g, $p<0.001$), FL (26+0,9 vs 30+0,6 cm, $p<0.001$), Cch (15+0.6 vs 18+0.4 cm, $p<0.001$), Ch (18+0.04 vs 22+0.4 cm, $p<0.001$), Ca (13+0.4 vs 15+0.3 cm, $p<0.001$). All FGR cases had decreased LW (16+0.2 vs 29+0.2 g, $p<0.001$); PnW (0.2+0.01 vs 0.4+0.07 g, $p<0.001$); KW (4+0.3 vs 6+0.2 g, $p<0.001$); HW (2.1+0.2 vs 3.4+0.2 g, $p<0.001$). PW was unchanged (160+12 vs 160+8 g, $p>0.05$).

Conclusions: these results suggest that the discrepancy between fetal and placental growth at 20-22 weeks of gestation is associated with fetal kidneys, pancreas, heart and liver growth retardation. Pathological alterations of organs could be a structural basis of adult pathologies.

P 142

HISTOLOGIC AND PLACENTAL ABNORMALITIES CORRELATE WITH SEVERITY OF PREECLAMPSIA AND ITS COMPLICATIONS

STANEK Jerzy, WENG Eric, LEVIN Linda. Department of Pathology and Laboratory Medicine and Environmental Health, University of Cincinnati College of Medicine, Cincinnati OH, U.S.A.

We have previously reported that the frequency and severity of placental lesions in preeclampsia (PE) are gestational age-dependent. This analysis was undertaken to identify the clinical and placental factors that are associated with severity of PE and its complications

In years 1994-2004, 332 consecutive placentae from patients with PE with gestational age at delivery of 20 weeks or more were examined (7.9% of all placentae examined). 112 women had mild PE (Group 1), 172 severe PE (Group 2), 36 HELLP syndrome (Group 3), and 12 eclampsia (Group 4). Univariate contingency table analyses were carried out to assess associations between possible risk factors and PE groups. When cell frequencies were sufficiently large, ordinal and nominal factors were analyzed using Mantel-Haenszel and likelihood ratio Chi-square statistics, respectively. For small sample sizes, 2-by-2 tables were analyzed using Fisher's exact test.

Statistically significant differences were found in the following 8 of 14 maternal/fetal clinical risk factors and outcomes, and 7 of 27 gross and microscopic placental features in Groups 1-4, respectively: average gestational age at delivery (36,33,30,30 weeks), maternal diabetes mellitus (14,7,5,0%), abnormal fetal heart rate (26,24,6,8%), meconium-stained amniotic fluid (12,3,3,0%), fetal weight (2594,1822, 1456,1250 gm), one (7,6,5,4) and five minute (8,7,7,5) apgar scores, cesarean sections (45,64,83,67%), placental weight (439,311,274,265 gm), hyperplastic decidual arteriolopathy (20,36,36,33%), decidual atherosis (10,27,44,41%), villous infarctions (29,55,56,58%), maternal floor trophoblastic giant cells (18,40,44,25%), diffuse villous hypoxia (23,32,36,33%), and meconium staining on histology (29,15,16,8%).

The significant overlap of frequencies of various clinical and placental factors in mild and severe PE and its complications indicates that they represent a spectrum of essentially the same process. While the frequency of abnormal maternofetal factors in general decreased from Group 1-4, possibly in relation to increasing frequency of cesarean sections, the frequency of decidual vascular lesions and placental hypoxic changes, except for the histologic evidence of meconium staining, increased from Group 1-4. Therefore, placental examination is a useful tool for retrospective evaluation of PE confirming the important role of uteroplacental hypoxia in fetal distress in PE.

LETHAL OSTEOCHONDRODYSPLASIA: A FETOPATHOLOGICAL STUDY OF 31 CASES

A.Lahmer*, M.T.Yacoubi*, S.Hmissa*, A.Ben Abdelkader*, L.Belaid*, S.Hidar**, M.Mokni*, S.Korbi*
*Department of pathology
*Department of gynecology
F.Hached Hospital
Sousse Tunisia

Introduction:

Skeletal dysplasia is a large heterogeneous group of diseases characterized by malformation, disproportionate growth and deformation of the skeleton or of individual bones or groups of bones. They are common birth defects. Their prevalence differs between populations and in various studies. Lethal osteochondrodysplasia is generally tracked down during the third or the fourth month of pregnancy, or during the antenatal ultrasonography.

Materials and methods:

Our study is retrospective and descriptive of 31 cases of lethal osteochondrodysplasia: 22 foetuses, 6 new-born and 3 dead-born.

Cases were brought from 6 hospitals of the center of Tunisia during a period of 13 years from 1991 to 2004. Foetopathological examination was done for all cases including autopsies, radiography of skeleton and histological examination of bone.

Results:

Mothers were aged between 20 and 39 years. Consanguinity was found in 6 cases. The disorder was revealed on antenatal ultrasonography in 24 cases and showed micromelia in all cases, narrow trunk in 5 cases and spina-bifida in 3 cases. Correlation between radiographics and fetopathological examination, identified 8 cases of achondrogenesis type I, 3 cases of achondrogenesis type II, 9 osteogenesis imperfecta, 4 thanatophoric dwarfism, 4 schneckenbecken dysplasia, 2 short-rib dysplasia with polydactyly (Majewski-type) and one case of asphyxiating thoracic dysplasia (Jeune).

Conclusions:

Severe ostéochondrodysplasia seems more frequent in the center of Tunisia. Correlation between radiographic and histological data must be undertaking for the management of these bone anomalies in order to make adequate genetic counselling.

P 144

ISOLATED OLIGOMEGANEPHRONIC HYPOPLASIA OF THE FETAL KIDNEY: A RARE CAUSE OF FETAL ANAMNIOS

M.T.Yacoubi*, M.Mokhtar*, W.Stita*, A. Ben Abdelkader*, S.HMissa*, A. Achach* L.Belaid*, S.Hidar**, A.Trabelsi*, M.Mokni*, S.Korbi*

* Departement o gynecology and Obstetrics
F.Hached Hospital, Sousse, Tunisia

Oligomeganephronic hypolasia of the kidney is a rare condition leading to anamnios.

We report the first case diagnosed in our department.

It was a 28 week - old- aged female fetus.

The pregnancy was interrupted for anamnios and fetal hypotrophy objectivated by ultrasonography.

External fetal examination showed a diffuse oedema with deformartive sequence caused by the anamnios.

At the visceral examination, the kidneys were hypoplastic weighting 2g together.

The histological study confirms the hypoplastic feature of the kidneys with a reduced number of the nephrons, which are hyerptophic.

These signs support the diagnosis of the ologomeganephronic hypoplasia of the kidney.

Than, we discuss the morphological feature of this anomaly, the embryological and the genetic hypothesis.

P 145

BNOS EXPRESSION IN EARLY ENDOUTERINE FETAL DATH: AN IMMUNOHISTOCHEMICAL STUDY ON PARAFFIN-EMBEDDED PLACENTAS

RESTA Leonardo, SANGUEDOLCE Francesca, PISCITELLI Domenico, SBLANO Sara*, MARZULLO Andrea, GESUALDO Loreto°

DAP-Department of Anatomic Pathology, and * Institute of Forensic Medicine, University of Bari° Institute of Nephrology, University of Foggia, ITALY

Nitric oxide (NO) is a free radical that modulates vasodilatation, smooth muscle relaxation, inhibition of platelet aggregation and functions as an immune system mediator; during pregnancy there are increased levels of NO, partly due to autocrine secretion by feto-placental structures. It is the substrate of the nitric oxide synthase (NOS) enzyme, which is also present in endothelial cells from umbilical cord and placental resistance vessels, but not in term villi.
The aim of the present study was to evaluate the presence of the constitutive isoform of NOS (brain NOS or bNOS), mainly expressed in human nervous tissue, also in early pregnancy (first trimester) endometrium and placenta.
We examined 39 cases of early endouterine death and 5 control specimens of induced abortion. Formalin-fixed paraffin-emebedded tissues were submitted to heat-mediated antigen retrieval and immunohistochemistry with anti bNOS monoclonal antibody.
bNOS was detectable in endometrial decidua (both glands and stromal cells) and villous syncytiotrophoblast. In particular, its expression was reduced in syncytiotrophoblast and increased in deciduas from pathological cases in comparison to controls.
In conclusion, we demonstrated that immunohistochemistry with bNOS antibody can be performed also on paraffin-embedded material, by a proper antigen retrieval system. The difference between the two groups would suggest that early miscarriages may have a vascular pathogenesis.

P 146
CAUSES OF PERINATAL DEATH AT OSIJEK CLINICAL HOSPITAL, 1995-2004

MARJANOVIC Ksenija*, DMITROVIC Branko*, BLAZICEVIC Valerija*, BARTOLIC Kristina**, IVANOVIC Marko**, MARJANOVIC Mirjana***.
*Department of Pathology, Osijek Clinical Hospital, Osijek, Croatia.
**Faculty of Medicine, J. J. Strossmayer University, Osijek, Croatia.
***Health Center Beli Manastir, Beli Manastir, Croatia.

AIM. Perinatal mortality and the causes of perinatal death as determined by autopsy and by placental biopsy at the Osijek Clinical Hospital in the period 1995 – 2004 are presented.
METHODS. The data were collected at the Department of Pathology: the autopsy reports and the placental biopsy reports were reviewed. The causes of death were classified into 10 categories: intrauterine hypoxia and birth asphyxia, congenital malformations, infection, abnormal pulmonary function, intracranial hemorrhage, immaturity, other diseases, macerated fetus with no signs of asphyxia, tumors, and violent death. The asphyxia was later subdivided into 3 categories: failure of blood to become oxygenated in the placenta, obstruction to circulation through the cord, and of unknown cause. Descriptive statistics are presented.
RESULTS. There were 23.860 deliveries at the Osijek Clinical Hospital in the period 1995 – 2004. In this period, there were 540 children deaths, and the autopsy was performed in 534 cases (98.89%). Perinatal mortality values were: 21.31‰ (1995), 17.47‰ (1996), 12.73‰ (1997), 17.75‰ (1998), 13.23‰ (1999), 11.90‰ (2000), 7.97‰ (2001), 13.81‰ (2002), 13.35‰ (2003), and 10,38‰ (2004). The majority of deaths were in fetuses and infants who showed evidence of asphyxia (58.33%): 71.43% of those cases was attributed to the failure of blood to become oxygenated in the placenta, 9.21% to the obstruction to circulation through the cord, and the rest 19.36% were of unknown cause. Congenital malformations (11.49%) ranked second, abnormal pulmonary function (9.26%) third, both immaturity and macerated fetus (6.29% each) fourth, and other conditions were far behind. In the group of 66 congenital malformation, the most common were multiple organs malformations (50%), followed by central nervous system malformations (16.67%), and heart and large blood vessel malformations (12.12%). In the early perinatal period, the most common causes of death were intrauterine hypoxia (53.62%), immaturity (14.01%), and macerated fetus with no signs of asphyxia (13.52%).
CONCLUSIONS. Whether death should be attributed to one cause or another is often subject to variable opinion because of the much overlap among groups. Most of the deaths attributed to asphyxia were explained by placental biopsy report. The placental biopsy report must be an integral part of a autopsy report in the cases of the perinatal death.

P 147
COMPLETE TRISOMY 9: PRESENTATION OF TWO AUTOPSY STUDIES

FERRERES Joan C, TORAN Nuria, VENDRELL Teresa*, PEG Vicente, SALCEDO M Teresa, ESPINOZA Paul.
Departament of Pathology and Genetics Unit*.
Hospital Vall d'Hebron. Universitat Autònoma de Barcelona. Barcelona, Spain

Objective: To present the autopsy study of two cases of complete trisomy 9 (CT9). This is a very infrequent chromosomal abnormality, which in most cases results in spontaneous abortion during the first 3 months of the pregnancy. To our knowledge only about 30 cases have been reported previously.
Case 1: A 35-year-old gravida III woman was referred for amniocentesis at 20 weeks' gestation (wg) because ultrasonography showed a lumbosacral neural tube defect, malposition of hands and micrognathia. A genetic study revealed a karyotype of 47,XY,+9 in all the amniocytes. The pregnancy was terminated at 22 wg. The foetus body weight was 290 g.
Case 2: A 25-year-old primigravida woman was referred to our hospital for evaluation at 32 wg because of an ultrasonographic Dandy-Walker malformation suspicion. The patient underwent amniocentesis with the result of 47,XX,+9 in all the cells. A 1934 g stillborn infant was delivered at 37 wg after spontaneous labour.
Autopsy findings: Both foetuses presented multiple congenital anomalies. In both cases we observed similar craniofacial anomalies: bulbous nose, enophtalmus, small mouth, retromicrognathia, microglosia, a short and thick neck and low-set malformed ears; clenched hands with two oblique palm folds, dysplastic nails (small with triangular form and profound implantation), absence of intergluteous fold, bilobed right lung, agenesis of dorsal pancreas, hypoplastic thymus and hypoplastic adrenal glands. Additional findings: Case 1: Intrauterine growth restriction, microstomia, anterior rotation of shoulders, dorsal cyphosis, small penis, myelomeningocele lumbosacral with Arnold Chiari malformation, diaphragmatic elevation with lung hypoplasia, liver calcification, agenesis of gallbladder, polylobed spleen, horseshoe kidney, atrial left isomerism and atrial septal defect. Case 2: anteroflexed right ankle, club feet, sacral pit, palatal pit, type II truncus arteriosus, aortic right arch, calcification in myocardial vessels, portal venous anomaly (esplenic and inferior mesenteric veins with drainage directly at cava inferior vein), pyeloureteral bilateral stenosis, three supernumerary spleens and Dandy Walker malformation.
Conclusion: Foetuses with CT9 have multiple anomalies and can be identified prenatally with sonographic studies. Some of these abnormalities have not previously been described. The CT9 diagnosis is always done through a genetic study, but some autopsy findings can suggest this diagnosis.

P 148

THE SIGNIFICANCE OF COLLAGEN IV STEREODYNAMICS IN METANEFROGENESIS. IMPLICATIONS IN PATHOLOGY

Dragoi G. S., Trasca T.E., Monica Banita, Catalina Pisoschi, Maria Magdalena Nuta
Academic Hospital Filantropia Craiova Romania
University of Medicine and Pharmacy from Craiova

Introduction. The collagen type IV, an important extra cellular matrix element greatly contributes to the building of reticular nets from lamina basalis of the metanefros structures.
Purpose of the study. The purpose of the study is to establish the stereo and topographic dynamics of the type IV collagen evolution in definitive kidney genesis.
Materials and methods. Renal fragments from 3 human embryos, 2 fetuses and 3 new born have been prepared using microanatomical techniques. The visualisation of the extracellular matrix elements was achieved by means of PAS, Gomori and Van Giesons stains.
Results. The knowledge of the type IV collagen stereo and topographic dynamics is possible by its identification inside tubular and vascular nefron micro anatomic structures. Corroborating the data observed on the differentiating kidney sections we noticed a variable distribution of glicosaminoglicans and type IV collagen inside lamina basalis. The determinant factor of type IV stereo and topographic dynamics is the existence of the reciprocal induction phenomena between urethral bud derivates and metanefrogen mesenchyma derived structures. In pediatric pathology the type IV collagen intervenes in the initiation of the glomerulosclerosis processes.
Conclusions. The type IV collagen is cause and effect in metanefrogenesis processes. It determines the mesenchyma cells migration for the establishment of the nefron structures. Its stereodistribution has as effect the differentiation of the lamina basalis inside tubular and vascular nefron structures.

P 149

VASCULOGENESIS – A DETERMINANT FACTOR IN THE TIME AND SPACE EVOLUTION OF THE METANEFROS STRUCTURES. IMPLICATIONS IN PATHOLOGY

Dragoi G.S., Rodica Silca, E.T. Trasca, P.R. Melinte, Nuta Maria Magdalena
Academic Hospital Filantropia Craiova Romania
University of Medicine and Pharmacy from Craiova

Introduction. The genesis and the evolution of the metanefros structures are multi factorial dependent. A determining factor of the renal glomerulus morphogenesis is represented by the phenotype transformation of the metanefrogen mesenchymal cells in order to achieve the sanguine capillaries.
Purpose of the study. Our purpose was to visualize the time and space apparition of glomerulus vascular structures from the metanefrogen mesenchyma and its integration in the forming stages of the glomerulus basal membrane.
Materials and methods. We used fragments from 3 human embryos (7 weeks old) and tissue fragments from 3 human fetuses (28 weeks old). The serried sections were stained using Hematoxilin Eosine, Van Gieson, Gomori and Giemsa methods.
Results. By analyzing the 300 serried sections through human embryos and the 200 serried sections through human fetus kidney we noted that the glomerulus structures genesis is based on the metanefros vasculogenetic mesenchyma. These elements appear between the proximal sinusoid vessels of the primordial contort tube. The process of the capillary genesis is determined by the presence of the primordial podocytes derived from the nefrogen mesenchyma and of the mezangiocytes from the vasculogen mesenchyma. The three newly formed structures establish contiguity relations for the formation of the plasma filtration structures.
Conclusions. The phenotype transformation of the metanefrogen mesenchymal cells and their integration inside the glomerulus structures represent the basis of the complex mechanisms of the renal glomerulus capillaries vasculogenesis.

FETAL THROMBOTIC VASCULOPATHY (FTV)

BALAN Raluca*, AMALINEI Cornelia*, SOCOLOV Razvan**, GHEORGHITA Vlad**,COTUTIU Coriolan*
*Department of Morphology, University of Medicine and Pharmacy "Gr.T.Popa" Iasi, Romania
**Department of Obstetrics and Gynecology, University of Medicine and Pharmacy "Gr.T.Popa" Iasi, Romania

Occlusion of a large fetal artery on the chorionic plate or of a fetal stem artery create a pattern of clustered avascular villi which is called fetal thrombotic vasculopathy (FTV). We report 3 cases of FTV. The chorionic plate vessels were grossly enlarged, distended, and hard. One case was associated with the rupture into the amniotic cavity. Microscopically, the downstream villi were avascular with densely collagenized, hyalinized stroma, and the nuclei of the syncytiotrophoblast cells were clustered into syncytial knots. The larger fetal stem vessels distal to the thrombus underwent septation and fibromuscular sclerosis, characterized by medial hyperplasia and intimal proliferation with eventual luminal obliteration. FTV diagnosis by histopathologic examination is important as it may be correlated with thrombotic lesions in the newborn.

P 151

OSTEOGENESIS IMPERFECTA TYPE 2: A FETAL CASE REPORT

A. Altavilla, A. Martinelli*, L. Resta, G. Caruso
Department of Pathological Anatomy. University of Bari. Italy
* Department of Radiology. Policlinico. Bari. Italy

Introduction
Osteogenesis Imperfecta, also known as brittle-bone disease, is a heritable disorder characterized by low bone mass, propensity to fracture, blue sclerae, hearing loss, loose joints, and growth deficiency, caused by a quantitative or qualitative defect in collagen synthesis. The underlying defect is a dominant negative mutation affecting COL1A1 or COL1A2 alleles, which encode the proA1 and proA2 chains of type I collagen, a protein of paramount importance for normal skin and bone development. On the basis of clinical presentation and bone architecture the disease is currently classified into seven types. We present a case of post-mortem diagnosis of osteogenesis imperfecta of a 22 weeks-old fetus with skeletal anomalies. The purposes of this paper are to describe this typical example of osteogenesis imperfecta and to value the importance of prenatal and post-mortem diagnosis in managing pregnancy and delivery.
Methods
On a female fetus with skeletal anomalies, the decision of pregnancy termination was based on ultrasound examination. A post-mortem radiographic study and autopsy were carried out. Placenta examination was also performed.
Results
The fetus presented short trunk, blue sclerae, small nose, micrognathia, hypertelorism, low set ears, scoliosis, arthrogryposis, and smallness for gestational age. Post-mortem radiographs showed mild angulation and shortening of long bones due to multiple intrauterine fractures, irregular callus formation, a barrel-shaped rib cage, and a poor ossification of the calvaria with a poor mineralization of the skull. Bone histology revealed a marked decreased in both cortical thickness and trabecular bone, and growth plate showed disorganization. In the fractured areas, the bony

spicules were disorderly arranged and associated with fibrosis and callus formation. Placenta histology showed the presence of hydropic villi and altered Hofbauer cells suggesting a genetic defect.
Conclusions
The wide spectra of clinical, imaging, grossly and hystologic features of the case studied led us to make the diagnosis of osteogenesis imperfecta type II. The differential diagnosis was made with hypophosphatasia, achondrogenesis, thorax dystrophy, osteosarcoma and battered child syndrome. Osteogenesis imperfecta is one of the commonest skeletal disorders with an incidence about one in 10,000 and it is often silent cause of adult osteoporosis for that reason is very important prenatal diagnosis.

P 152
FIBROBLASTIC POLYP OF THE COLON: CLINICOPATHOLOGIC ANALYSIS OF 10 CASES OF A NOVEL TYPE OF BENIGN COLORECTAL POLYP.
Gabriel M. Groisman, Sylvie Polak-Charcon, Henry D. Appelman
Departments of Pathology: Hillel Yaffe Medical Center, Hadera, Israel, Sheba Medical Center, Tel-Hashomer, Israel and University of Michigan, Ann Arbor, Michigan, USA.

Background: Benign fibroblastic polyp (FP) is a recently described, histologically distinctive type of colonic mucosal polyp. Herein we present the clinical, histological, immunohistochemical and ultrastructural features of a series of FP with the goal of further characterizing this entity.
Methods: Ten cases of FP were identified. Clinical and histologic features were reviewed. Immunohistochemistry was performed on formalin fixed paraffin embedded tissue using antibodies against vimentin, actin, desmin, CD-68, cytokeratin AE1/3, S-100 protein, COX-2, c-Kit and CD34. Ultrastructural examination was performed in two cases.
Results: All patients were asymptomatic adults (seven women, three men) with ages ranging from 44 to 63 years (median 59). Polyps ranged in size from 0.2 to 0.4 cm. Eight were located in the sigmoid colon, one in the descending colon and one in the ascending colon. Five cases were associated with hyperplastic polyps and two with tubular adenomas. Histologically, FP were characterized by a proliferation of uniform, bland spindle cells with focal periglandular or perivascular concentric arrangement. Five cases also showed superficial bundles of spindle cells arranged parallel to the surface. Eight lesions contained serrated (hyperplastic) crypts admixed with the fibroblastic cells and represented mixed fibroblastic/hyperplastic polyps (or FP with serreated crypts). Immunohistochemically, the spindle cells reacted to vimentin only. Ultrastructural examination revealed features supportive of fibroblastic differentiation.
Conclusions: 1) FP is a distinctive type of benign colorectal mucosal polyp characterized by its distal colorectal location, small size, frequent association with hyperplastic polyps, distinct morphologic appearance and typical immunonegativity for markers of specific differentiation. 2) FP with serrated crypts (mixed fibroblastic/hyperplastic polyp) represents a frequent variant of this polyp. 3) Pathologists should recognize FP and discriminate it from other types of colorectal polyps.

P 153
CLINICOPATHOLOGICAL STUDY ON CARCINOID TUMOR OF THE RECTUM - MAINLY ON COMPARISON OF CASES WITH METASTASIS AND THOSE WITHOUT METASTASIS
Seiji Haraoka, Akinori Iwashita*, Ikuko Iwashita**
*Department of Pathology, Chikushi Hospital, Fukuoka University, **Nishifukuoka Hospital, Fukuoka, Japan

Epidemiologic studies in Japan have found that gastrointestinal carcinoid tumors most commonly occur in the rectum. An increase in the size of rectal carcinoid tumors is associated with metastasis to regional lymph nodes and distant organs. Invasion to the muscularis propria or deeper also is a risk factor for metastasis. However, malignancy criteria of rectal carcinoid tumors remain to be established. The aim of our study is to clarify the clinicopathological factor relevant to the malignant potential of this disease.
Cases of rectal carcinoid tumor were divided into group A (12 lesions in 12 cases with metastasis) and group B (15 lesions in 14 cases without metastasis), and a comparative study was carried out from the clinicopathological standpoint. Nine of twelve cases of group A had metastasized to the regional lymph nodes at the time of surgery, and four of these cases metastasized to the liver. In seven cases of group A, the tumor had involved the liver.
There were significantly more cases in group A who manifested large tumor size, central depression and/or ulcer formation, deep infiltration, positive vascular invasion, a moderately elevated mitotic index, a moderately elevated Ki-67 labeling index, and appearance of P53 positive cells. Histologically, approximately 80 percent of cases of both group A and B showed Soga• fs classification type B and mixed type (type A+B), and there was no distinct difference between the two groups. From these results it could be pointed out that the findings of tumor size (more than 1.0cm), depth of invasion (muscularis propria or beyond), central depression and/or ulceration, mitotic index (>2/10HPF), vascular invasion and Ki-67 labeling index (>2%) are useful predictive criteria in the assessment of the malignant nature of these neoplasms. In addition, as a result of multivariate analysis of the above factors it was found that only tumor size was an independent and significant factor. Thus, it was concluded that the most important malignancy criterion of this neoplasm is tumor size.

CLINICOPATHOLOGIC CHANGES IN TATTOO OF COLONIC NEOPLASM WITH STERILE CARBON COMPOUND
DINARÈS Maria Carme, ORELLANA Ruth, BRULLET Enric*, CASALOTS Àlex, FERNANDEZ Sara, BELLA Maria Rosa, PARRA Tamara, ESCODA Maria Rosa, REY Mercè.
Corporació Parc Taulí, Pathology Dep, UDIAT-CD. Sabadell, Barcelona. Spain. *Corporació Parc Taulí, Endoscopy Unit. Sabadell, Barcelona. Spain.

BACKGROUND: Endoscopic marking of intestinal lesions, 'colonic tattooing', is used as a guide for the intraoperative identification of polypectomy sites and follow-up examinations. Many dyes, such as India ink and methylene blue, have been employed but may cause serious tissue injury and clinical complications, which must be recognised in pathological examination. Recently, a new sterile carbon compound (SPOT) has been used.
AIMS: To determine the histologic changes, safety and effectiveness of SPOT
METHODS: During the last year colonic tattooing with SPOT was performed in 20 cases of colonic polyps. Six of them turned out to have an infiltrating carcinoma in endoscopic polipectomy and underwent surgical resection. Clinical data and pathological findings were collected.
RESULTS: Six surgically resected specimens (5 sigmoid colon/ 1 rectum) were reviewed. The average age ranged from 52 to 86 years (mean, 70). The interval from endoscopic injection to pathologic examination varied from 1 to 48 days. No clinical complications ocurred. The SPOT was clearly

observed on gross examination in all cases during surgery. Tattoo was observed in submucosa (3 cases), submucosa and muscularis propia (1 case) and transmural (2 cases). No mucosal lesion was detected. Carbon particles were localized mainly in macrophages of the submucosa (5 cases) or as free particles involving the wall (1 case). Inflammatory infiltrate was predominantly neutrophilic and eosinophilic in 4 cases, and lymphocytic and histiocytic in 2 cases. Giant cell reaction was not observed. Areas of submucosal edema (2 cases), necrosis (2 cases) and fibrosis (2 cases) were noted (4 of them with haemorrhagic focus). The vascular injury observed was: endothelial hyperplasia (1 case), neovascularization (4 cases) and fibrinoid necrosis (1 case).
CONCLUSIONS: SPOT is a safe and effective marker for use in colonoscopy when surgical resection is required. It is also useful for endoscopic follow-up of patients who have not undergone surgery. There was no evidence of short-term clinical or histological complications although histologic changes were observed. Fibrosis was detected in cases with greater interval between injection and surgery. To determine long-term safety of colonic tatooing with SPOT, a longer follow-up studies should be performed.

**Department of Gastroenterology, Colentina Universitary Hospital
***Department of Surgery, Colentina Universitary Hospital
Bucharest, Romania

Peutz Jeghers (PJ) polyps are rare hamartomatous tumors of the gastrointestinal tract frequently associated with skin and mucosal pigmentation. Despite their benign nature there is a certain increased risk of progression to malignancy in some cases, justifying a sustained follow-up of the patients.
We present 6 cases of Peutz Jeghers polyposis (PJP) diagnosed in our hospital during the last year on gastrointestinal specimens obtained by endoscopy and by opened surgery. We analyzed different degrees of dysplastic changes, epithelial intussusception, association with other types of polypoid lesions and others various aspects that might be related with disease progression. Clinico-pathological correlations were made.
Two of these cases consisted in two women, mother and daughter; both of them were operated in another hospital for small bowel tumors with a subsequent diagnosis of adenocarcinoma. The daughter (28 years old) was referred to our hospital for endoscopic follow-up; a small polyp of the transverse large bowel was excised by colonoscopy with a histopathologic diagnosis of PJ polyp; a careful histopathologic reevaluation of the both specimens of enterectomy (slides and paraffin blocks) revealed overdiagnosis of cancer due to the epithelial cystic dilatation and pseudoinvasion in both patients.
The other 4 cases showed diagnostic changes of PJP and also various aspects of hyperplastic (1 case) and adenomatous polyps (3 cases), one of them with mild and moderate dysplastic changes.
When a PJ polyp is diagnosed, the possibility of pseudoinvasion should be kept in mind, in order to avoid malignancy overdiagnosis; also, due to the fact that the malignant transformation of a PJ polyp is still on debate (hamartoma – dysplasia – carcinoma progression versus malignant transformation of an adenomatous aria of a hamartoma versus coincidental association of a digestive cancer due to genetic aberrations of PJP), all the other associated microscopic aspects of the lesion should be carefully analyzed.

P 156
ALTERATIONS IN THE EXPRESSION OF MUCIN ANTIGENS IN COLONIC ADENOMAS HARBORING INVASIVE CARCINOMAS
AHISKALI Rengin, EREN Funda, OZKAN Naziye
Marmara University School Of Medicine Department of Pathology, Istanbul, Turkey

Alterations in the synthesis of mucin glycoproteins have been shown to be related to both neoplastic transformation and malignant progression. We studied the expression patterns of four gastrointestinal mucins in colonic adenomas harboring invasive carcinomas with the aim of establishing the alterations that correlate with malignant progression.
MATERIAL METHODS
Immunohistochemical staining for muc1, muc2, muc5AC, muc6 were performed on 44 cases of colorectal carcinomas arising in adenomas. For each mucin antibody, nonneoplastic mucosa, adenoma and carcinoma areas were evaluated for the percentage of epithelial cells with mucin expression and for the staining intensity semi quantitatively. Qualitative changes of mucin expression in different areas of the same tumor were also evaluated.
RESULTS
Adenomas and carcinomas had aberrant expression of mucin antigens which are not normally synthesized in colonic mucosa. When compared to normal mucosa both adenomas and carcinomas had highly significant alterations of all four mucin types($p<0.01$). Although there is no correlation between the expression patterns of non-neoplastic mucosa and neoplasms, adenomas and carcinomas had a significant correlation($r=.6-.7$). Intratumoral heterogeneity of mucin expression were detected in all the neoplastic components. Although there were differences of mucin distribution patterns in adenomas and coexisting carcinomas it did not reach statistical significance.
COMMENTS
The high correlation of alterations in mucin expression patterns of adenomas and invasive carcinomas may be useful for the detection of adenomas which are more likely to develop invasive carcinomas.

P 157
ADENOCARCINOMA OF SIGMOID COLON WITH CHORIOCARCINOMATOUS DIFFERENTIATION.
NADIA KOURDA, ILHEM BETTAIB, ZERMANI RACHIDA, SOUMAYA RAMMEH , BALTAGI BEN JILANI SARRAH Service d'anatomie et cytologie pathologiques,
Hôpital Charles Nicolle BOULEVARD 9 AVRIL 1006 TUNIS

Colorectal carcinomas presenting with choriocarcinomatous differentiation are exceedingly rare; only six prior cases have been reported. We report a new case of carcinoma with germ cell differentiation developed in de novo ulcerative colitis after renal transplantation in a 42-year-old woman. Clinically, the patient presented ulcerative colitis 8 years after renal transplantation, developed colon cancer with liver metastasis 2 years after diagnosis and died one month after operation. Histologically, the removed tumor was composed of two distinctive elements consisting of an adenocarci,noma and a choriocarcinoma. The metastatic foci in the liver were exclusively composed of choriocarcinoma. Identification as choriocarcinoma was made on the basis of typical histologic appearance, immunohistochemical demonstration of human chorionic gonadotropin (hCG) in the tumor cells and the high hCG level in patient's serum, unrelated to trophoblastic disease.

In this report, pathogenesis is briefly discussed and clinical conditions are reviewed.

P 158
ATHOLOGICAL REPORTS OF COLORECTAL CANCER SPECIMENS ON A NATIONWIDE SCALE IN FRANCE: IMPACT OF A CONSENSUS CONFERENCE.
Jean-François Fléjou, Jean-Yves Scoazec, and the members of Committee n°5 “Digestive tract”, working on behalf of AFAQAP (French Association for Quality Assurance in Pathology).

The pathological assessment of surgical specimens is a crucial issue in the management of patients with colorectal cancer (CRC). Tumour stage and lymph node (LN) status are major prognostic factors, circumferential margin is a predictor of local recurrence in rectal cancer, and the presence of LN metastasis is the only criterion to indicate adjuvant chemotherapy. Several studies have demonstrated regional differences in practices in various countries including France. A consensus conference on colon cancer was held in France in 1998, with recommendations on the features that have to be included in pathological reports.
The aim of this study was to evaluate practices in France regarding the reporting of CRC, before and after the consensus conference. All the reports made by pathologists from 82 laboratories throughout the country from June to December 1997 and 2000 were collected, and the items recommended were systematically recorded. The mean number of reports per structure was 30 in 1997 (range 2-158) and 34 in 2000 (6-130). The stage of tumour invasion was present in 99.9% (1997) and 100% (2000) of reports. The longitudinal margins were specified in 94.1% (1997) and 97.1% (2000) of reports. In rectal cancer, the circumferential margin was present in 12.8% (1997) and 51.7% (2000) of reports ($p<0.001$). The number of sampled and metastatic LN was specified in 99.8% (1997) and 99.5% (2000) of reports ($p<0.05$). The pTNM stage was indicated in 19.2% and 80.9% (2000) of reports ($p<0.001$). The mean number of LN per report increased from 9.67 in 1997 to 12.1 in 2000 ($p<0.05$). The percentage of reports with less than 8 sampled LN decreased from 45.65% in 1997 to 26.04% in 2000 ($p<0.05$).
In conclusion, this study suggests that practices have improved in France regarding the reporting of CRC after a consensus conference held in 1998. However, there are still reports with insufficient data, especially regarding the number of LN sampled and the circumferential margin in rectal cancer. These features may be improved by the use of standardized report forms.

P 159
FEATURES OF COLORECTAL CANCERS ARISING ADJACENT TO SESSILE SERRATED ADENOMA
Markus J. Mäkinen, Karoliina Tuppurainen, Susannah M. Harrison, Tuomo J. Karttunen
University of Oulu, Department of Pathology, Oulu, Finland.

Background: Sessile serrated adenoma (SSA) is a novel subtype of colorectal polyps. It has been shown to be temporally associated with microsatellite instable colorectal cancer, but direct evidence on its neoplastic nature and malignant conversion is not well established.
Aims: To find out the prevalence and features of colorectal cancers associated with SSAs.
Materials and methods: Altogether 466 colorectal cancer cases were included in the study. SSA component was sought immediately adjacent to cancer tissue as previously described.
Results: Six colorectal cancers associated with SSA were discovered, with 1.3% prevalence in this study. In addition, 29 other serrated adenocarcinomas were detected (prevalence 6.2%) Four of SSA-associated carcinomas were found from female patients, four of them were located in the proximal colon, and DNA microsatellite instability was present in three cases. SSA component was characterized by a large slightly elevated tumor composed of hyperplastic-like epithelium. Cellular atypia was evident in all cases. Carcinomatous component consisted of serrated clear or slightly eosinophilic serrated epithelial proliferation with a great resemblance to the adenomatous component. Colorectal cancers associated with SSA were more often mucinous than conventional colorectal cancers (67% vs. 8%; P=0.001), but did not differ from other serrated adenocarcinomas (67% vs. 38%, P=0.36). However, they were less often well differentiated than other serrated adenocarcinomas (0% vs. 50%; P=0.017).
Conclusions: SSA is a rare precursor of colorectal cancer. It shares both clinical and morphological features with serrated adenoma and commonly represents MSI. As SSA has been proposed to be more frequent than serrated adenoma, lower frequency of SSA-associated cancers in this study could indicate less frequent malignant conversion rate for SSAs compared to serrated adenomas.

P 160
IS THERE A ROLE OF INFLAMMATION IN SPORADIC COLORECTAL CANCER? A STUDY OF COMMON POLYMORPHISMS IN INFLAMMATORY RESPONSE-RELATED GENES
NONNI Aphrodite1, THEODOROPOULOS George2, GAZOULI Maria2, GAKIOPOULOU Hariklia1, LAZARIS Andreas1, THOMOPOULOU Georgia1, BRAMIS John2, PATSOURIS Efstratios1
Depts of Pathology1 and Biology2, Medical School, University of Athens, GREECE

Epidemiological observations suggest that environmental and host immunological factors could significantly contribute to the initiation and the progression of colorectal cancer (CRC). Genetic polymorphisms can play a role in determining how individuals respond to various environmental factors. Although rather limited, evidence exists linking common polymorphisms in immune system related genes and CRC tumorigenesis.
The aim of the study was to investigate the association between common single nucleotide polymorphisms (SNPs) in the inflammatory response related genes interleukine (IL)-6, IL-8, tumor necrosis factor á (TNFá), peroxisome proliferators-activated receptor ã (PPARã), and intercellular adhesion molecule-1 (ICAM-1) and the risk of colorectal cancer in a group of Greek patients.
The study group consisted of 222 CRC patients and 200 healthy controls. Genotyping was performed using allele-specific PCR of PRC-RFLP and the results were confirmed by sequencing. We have studied the association of SNPs in the IL-6 (-174G>C), IL-8 (-251T>A), TNFá (-308G>A), ICAM-1 (R241G and K469E), and PPARã (Pro12Ala) genes and the risk of CRC.
The IL-6 -174G, R241 and K469 alleles are associated with increased risk of CRC (OR = 1.927 [CI95%: 1.508 to 3.336], OR = 1.833 [CI95%: 1.235 to 2.719] and OR = 1.546 [CI95%: 1.174 to 2.034], respectively). The IL-8 and the TNFá polymorphisms had no effect. Whereas the PPARã Ala12 genotype was associated with reduced risk of disease (OR = 0.588 [CI95%: 0.416 to 0.832]).
The association between common SNPs in immunologic response related genes with CRC is reported in the present study. Apart from shedding light on the mechanisms of malignancy initiation and progression, SNPs may improve appropriate screening for risk sub-population.

P 161
MORPHOLOGICAL FEATURES OF HEREDITARY NON-POLYPOSIS COLORECTAL CARCINOMAS COMPARED TO OTHER EARLY ONSET AND

SPORADIC COLORECTAL CARCINOMAS IN THE WESTERN CAPE, SOUTH AFRICA.

H Holm, P de la M Hall, N Allie, R Ramesar.* Divisions of Anatomical Pathology and Human Genetics* University of Cape Town and Groote Schuur Hospital NHLS

Background:
Families with hereditary non-polyposis colorectal carcinoma (HNPCC) are not uncommon along the West-Coast of South Africa. These patients present with early onset carcinomas, mostly colorectal, predominantly in the right colon. They may develop tumours of other organs, including uterus, breast, stomach and skin.
Objectives:
1. To evaluate and compare the microscopic characteristics of three groups of colorectal carcinomas (HNPCC, early onset colorectal carcinomas and sporadic colorectal carcinomas).
2. To determine the features most characteristic of the HNPCC group in the South African population.
Methods:
Coded sections of formalin-fixed paraffin-embedded tissue from patients with
(1) sporadic colorectal carcinomas (58 cases)
(2) early onset (<45 years) colorectal carcinomas (93 cases) and
(3) HNPCC (30 cases) are evaluated and graded on the following features:
intratumoral lymphocytes (TL),
stromal lymphocytes (SL),
lymphoid aggregates in the vicinity of the tumour (LA),
presence and type of necrosis (Ne),
percentage of mucin (Mo = 0%, M1 = <25%, M2 = 25-50%, M3 = 50-75%, M4 = >75%) and
histological grade based on the standard criteria of gland formation (G1 to G4).
Results and conclusions:
Intratumoral lymphocytes and lymphoid aggregates are fairly sensitive markers for HNPCC, the former being more specific than the latter. Stromal lymphocytes are a third, even more sensitive marker for HNPCC, but less specific than the other two. The other parameters tested are of no help in the differential diagnosis except for presence of necrosis which is more typical of sporadic and early onset colorectal carcinoma than of HNPCC.

* Post-graduate Medical School in Anatomic Pathology, University of Milan, Milan, Italy.

Introduction. Oncocytes are granular, eosinophilic cells, with mitochondria occupying more than 40% of the cytoplasm. Tumors composed mainly of oncocytes are distributed in many organs, although thyroid and kidney are the most frequent. Oncocytic modifications have been reported after radiotherapy in salivary glands. To date few data are available on oncocytic modifications in adenocarcinomas of the colon-rectum.
The purpose of the study was to evaluate whether oncocytic modifications are present before radiochemotherapy (RCT) and if oncocyte-rich rectal carcinomas are resistant to RCT.
Materials and methods. 17 cases of advanced rectal carcinoma, treated preoperatively and simultaneously by 5-fluorouracil (200-225 mg/m2) and 46 Gy in 23 fractions were studied. All patients were biopsied before RCT and underwent surgery within six weeks after RCT. Specimens were routinely processed, stained with hematoxylin and eosin (H&E) and immunohistochemistry was performed using anti-mitochondria antibody (clone 113-1; dilution 1:500; Biogenex). In two cases, both pre and post RCT tissues were examined at ultrastructural level.
Results. All tumors were adenocarcinomas. Pre-RCT features: oncocytic changes were difficult to find on H&E, while at immunohistochemistry, anti-mitochondria antibody stained 5 to 100% of neoplastic cells (mean 59%). Post RCT features: Oncocytic cells were detected in all 17 cases on H&E and constituted 10 to 100% of the residual neoplastic population (mean 61%). With immunohistochemistry, the anti-mitochondria antibody confirmed the oncocytic changes, highlighting a larger number of neoplastic cells (range from 5 to 100%, mean 73%). Ultrastructural examination revealed large and bizarre mitochondria in tumor cells in both pre and post RCT tissues.
Conclusion. The present data suggest that rectal carcinomas can be “mitochondria rich” tumors. After pre-operative RCT, residual neoplastic cells may acquire a definite oncocytic phenotype. It is likely that the mitochondria enhance neoplastic cell survival.

(4)Department of Histopathology, Silesian Center for Heart Diseases, Zabrze, Poland

Introduction Pre-operative radiation(RT) and chemotherapy (CRT) improve outcome in patients with rectal adenocarcinoma (ACA).
Aim Analysis of histological features in residual rectal carcinoma following preoperative RT or CRT and their prognostic significance.
Materials and methods Resection specimens from 54 patients with T1-T4 advanced rectal ACAs treated with RT and CRT before surgery were analyzed for the following features:
tumor treatment response (pPR1, pPR2, pPR3), histological architecture structures
(cribriforme, tubular, papillary, cystic), degree of cytological alteration, extent of damaged tubular structures(0-30%, 30-60%, >60%), inflammatory or histiocytic reaction in the tubular structures, microfoci of carcinoma, tumor necrosis, mucus degeneration of stroma, inflammatory or fibroinflammatory reaction of stroma, cytoplasmic eosinophilia , cytoplasmic basophilia, neoplastic or post-irradiation ulceration. The data obtained were statistically analyzed using ANOVA, Kruskal-Wallis method, median test, ch^2 test and Mann Whitney test.
Results There were no significant correlations between the histological architecture structures and other features.

There was correlation between 30% extent of damaged tubular structures and RT type (42-60Gy) p=0.022; type of ulceration and microfoci of carcinoma (p=0.036), sex (ch^2 test p=0.045) and treatment response (ch^2 test p=0.0001); cytoplasmic basophilia with the time of recurrence (p=0.024); sex and time of recurrence onset of relapse?) (p=0.024).
Conclusion In our study we characterized histomorphology of post-irradiated rectal ADAs and report morphological features associated with the time of recurrence.

P 164
PROGNOSTIC VALUE OF THE CLASSIFICATION OF FIBROTIC STROMA IN COLORECTAL CANCER
Sanei Mohammad Hossein MD, Nooshin Afsharmoghadam MD
, Department of pathology, Isfahan university school of Medicin, Isfahan

Abstract:
Introduction:
Various factors influence prognosis of colorectal cancer including local extension, lymph node involvement, tumoral growth pattern and lymphocytic infiltration at the tumor margin. There is controversy about the role of amount of fibrotic stroma but there are a few studies on the type of stroma. The aim of this study is evaluating the prognostic value of classification of stroma by means of Astlre and coller staging system.
Materials & Methods :
Ninety two cases of colorectal cancer were examinated.we classified fibrotic stroma in front of tumor extension based on Uneo and colleague criteria to three category:typA,multiple fine and mature fiber were stratified ;typeB,broad hyalinized collagen(keloid-tyoe) were intermingled;type C,myxoid stroma.we exited cancers were superimposed on IBD and familial polyposis.Then the data were analyzed by chi-square test..
Results:
45% of cases had typeA stroma, 18% type B stroma. And 37% type C.
The prevalence of type A stroma in the various stages of tumor was such:A=100%,B1=68%,B2=26%,C1=60%,C2=33% and the prevalence of type C stroma in the various stages of tumor was such: A=0, B1=16%, B2=49%, C1=40%, C2=48%.
In order to identify amount of correlation we employed pearson index (R=0.43).
Discussion:
The results showed a decreasing in type A stroma when the stage of disease increase (stage A=100%, stage B1-68%, stage B2= 27%, stage C1=60%, stage C2=33%) and increasing in type C(stage A=0, stage B1=16%, stage B2=49%, stage C1=40%, stage C2=48%).
The result was statically significant and classification of stromal pattern had independent prognostic value same as lymph node involvement, lymphocytic infiltration and growth pattern.
Keywords:
Colon cancer, fibrotic stroma, Collagen, myxoid stroma

RESPONSE TO PREOPERATIVE CHEMORADIOTHERAPY ON RECTAL ADENOCARCINOMA: HISTOPATHOLOGICAL EFFECTS AND RELATIONSHIP WITH LEVEL OF P53 AND PCNA EXPRESSION.
RAMOS Paloma*, DIEZ Manuel**, OLMEDILLA Gabriel*, RUIZ Antonio* and ALVAREZ Isabel***.
*Dpt. of Pathology, Principe de Asturias University Hospital, Alcala de Henares, Madrid, Spain.
**Dpt. of General Surgery, Principe de Asturias University Hospital, Alcala de Henares, Madrid, Spain.
***Dpt. of Pathology, Ramon y Cajal University Hospital, Madrid, Spain.

INTRODUCTION: Adjuvant chemoradiotherapy delivered before surgery has been used to improve control and to reduce the likehood of local recurrence in selected patients with rectal cancer. Although the status of p53 gene and the expression of Proliferating Cell Nuclear Antigen (PCNA) has been widely studied in these tumors, little is known about their value to predict responsiveness of rectal cancer to chemoradiation.
AIMS: To assess effects of preoperative chemoradiation in advanced rectal adenocarcinoma.
METHODS: We examined the histopathologic effects of chemoradiotherapy on 73 rectal tumors and correlated the efficacy of treatment with the level of p53 and PCNA proteins expression in pretreatment biopsies.
RESULTS: Three patients showed no primary tumor in the resection specimen. Another eight carcinomas showed a good response to chemoradiation with only small nests of viable tumor cells. Grouping these two categories, we considered that the tumor response had been total or subtotal in 11 cases (15%). Nuclear accumulation of p53 protein was detected in 53 (72%) specimens. Thirty five tumors showed a high PCNA index (48%). No obvious relationship seemed to exist between pretreatment p53 immunostaining and response to chemoradiotherapy. Tumors with high PCNA index were more likely to respond to chemoradiation: 8/35 (72%) versus 3/38 (43%)(p=0.07).
CONCLUSIONS: Knowledge of proliferative activity of rectal cancer, as determined by PCNA immunostaining, should be useful in predicting the likehood of response to preoperative chemoradiation.

P 166
THE CHANGES OF THE TYPES OF COLONIC MUCINS IN THE BENIGN ,PREMALIGNANT AND MALIGNANT LESIONS
Dr.Ibrahim Ghada(M.B.CH.B,F.I.C.Pathology), supervised by professor dr .Alkaptan Ikbal (F.R.C.Path.,M.r.c.Path)

the aim of study
To clarify the changing pattern of colonic mucins in colonic tumours, and to evaluate the benefit of the staining methods in diagnosis and prognosis of colorectal lesions ,for early detection of premalignant changes and compare this mucin pattern with western researches.
materials and methods
95 biopsies were selected and stained with haematoxylin and eosin,PAS stain ,Alcian blue ph(2.5) and Shikata`s modified orcein/alcian blue
Results
sulphated mucin is the predominant mucin in normal colon.Mucin pattern in adenoma is variable. Adenoma with mild dysplasia mucin pattern is similar to normal.,these with moderate to severe dysplasia and carcinoma in situ,mucin production is decreased or absent and if it is present it is amixture of sialo and sulphated mucin (sialomucin is more predominant)
in ulcerative colitis with dysplastic changes mucin also is vairiable according to the degree of dysplasia
ie in mild and moderate dysplasia mucin pattern is close to normal (both types is present however sulphated mucin is predominant) while in Ulcerative colitis with severe dysplasia the mucin pattern is differ as the amount of mucin is decrease and pattern is change predominantly to sialomucin
In all carcinomas,reduction of mucin is evident,less marked in well differentiated adenocarcinoma in which three types of mucin is present(sialo ,sulphated and neutral mucin)

In Moderately differentiated carcinoma mucin is mainly (intraluminal)sialomucin.In poorly differentiated carcinomas, mucin is scanty or absent.
Conclusion
The study of mucin pattern of colon is rewarding in detection of early malignancy ,classification of polyps.assesment of their malignant potential ,(increased sialylation is important in transition from adenoma to carcinoma and for determining prognosis in patients with colorectal cancer

COLONIC PSEUDOCARCINOMA-CASE REPORT
Simona Mocan1, Simona Stolnicu2, Doina Milutin1, Doinita Radulescu3
1Department of Pathology, County Clinical Hospital Targu Mures, Romania
2Department of Pathology, University of Medicine Targu Mures, Romania
3Department of Pathology, University of Medicine Iasi, Romania

Aims. Misplaced epithelium within an adenoma (pseudocarcinoma) is a rather common findings but currently there are no clinical or endoscopic methods available in differentiate adenomas with epithelial misplacement from those with adenocarcinoma.
Material and methods. We present the case of a 64-year-old female presented with bright red blood per rectum. Previous medical history was not significant. Upon colonoscopy, two pedunculated polyps were identified in the lower sigmoid, which were excised endoscopically and submitted to pathology for evaluation. The tumors were excised, fixed in formaline, embedded in paraffin and the sections were stained with H-E, PAS-ALCIAN blue. We performed also immunohistochemical staining: with Cytokeratin, Vimentin, Collagen IV and p53.
Results. The gross appearance was similar for both polyps. The histological features were different. An adenomatous polyp, with tubulo-villous architecture and misplaced epithelium in the submucosa stalk, mucinous pools lined, represented one of the polyps by dysplastic epithelium similar to that seen at the surface of the polyp. The second polyp was represented by an adenomatous polyp with villous architecture and high-grade dysplasia, focally with irregular, variably sized crypts, without lamina propria, with irregular mucous pools containing floating malignant cells within the stalk of the polyp. The immunohischemical results were different in the two cases.
Conclusions. The most common differential diagnosis of adenomas with epithelial misplacement are adenomas that contain invasive adenocarcinoma, but several other entities may on occasion, be confused with the former lesions, such as solitary rectal ulcer syndrome-associated polyps, Peutz Jeghers polyps, hyperplastic polyps. Unfortunately, the diagnosis it cannot be made just based on the histologic appearance.

P 168
ANALYSIS OF CYCLOOXYGENASE-2 EXPRESSION IN COLON CANCER AND NORMAL COLON USING TISSUE MICROARRAY
Díez A1, García R2, Acuña MJ1, Pajares R1, Ibarrola C2, Lopez-Alonso G2, Sánchez-Verde L1, and Ballestín C2.
Histology & Immunohistochemistry Unit, Biotechnology Program, Spanish National Cancer Center (CNIO), Madrid, Spain1, Department of Pathology, Hospital 12 de Octubre, Madrid, Spain.2

Introduction:
Recent studies have shown that cyclooxygenase (Cox-2) may be involved in colorectal carcinogenesis.
Cyclooxigenase-2 is an inducible enzyme involved in the response of cells to growth factors, tumour promoters, and cytokines that induce its expression. Given its role in synthesizing prostaglandins, Cox-2 is therefore of interest in studying immune response regulation. Is also induced by a wide variety of other stimuli and was initially identified as an immediate-early growth response gene.
Aims: To analyse expression of COX-2 in colorectal carcinomas, and to compare this expression between normal and tumoral colon cells in a series of 35 patients.
Material and Methods:
Tissue samples of primary sporadic colorectal carcinoma and adjacent normal mucosa samples from 35 patients were included in a Tissue Microarray.
Cox-2 expression was first evaluated in a Tissue Microarray with normal tissue samples (thyroid, placenta, tonsil, mammary gland, colon mucosa, appendix, spleen, liver, kidney and lung) in order to establish the best protocol, using Immunohistochemical staining in 3um Tissue Microarray sections, with Cox-2 antibody from Neomarkers. This protocol was then applied to the tumoral and normal colon Tissue Microrrays.

The specimens were graded based on the intensity and extent of staining as follows:
1+: 30% positive cells
2+: 30%-60% positive cells
3+: 60%-100% positive cells
Also the homogeneity and heterogeneity of the staining were validated.
Results:
From a total of 35 patients included in the study, the expression of COX-2 was:
· Normal samples were (3+) homogeneous positively with a very strong level of positivity
· From 35 tumour samples, one sample was not evaluated
17 cases (50%) 3+ homogeneous and with strong intensity
3/34 cases (8.8%) 3+ homogenous and weak expression
5/34 cases (14,7%) 2+ homogenous and weak expression
2/34 cases (5,8%) 1+ homogenous and weak expression
5/34 cases 14.7% heterogeneous expression
2 cases were completely negative
Conclusions:
1.- The data presented in our study show that Tissue Microarrays are a useful tool for identifying expression profiles and expression changes of proteins, allowing comparisons between normal and tumoral regions.
2.-Cox-2 is expressed intensively and homogeneously in normal mucosa colon
3.- Colorectal cancer shows lower intensity in number of cells compared with their normal mucosa colon counterpart
4.- Some tumours show

P 169
CYCLOOXYGENASE-2 (COX-2) EXPRESSION IN POLYPS AND CARCINOMAS OF HEREDITORY NON-POLYPOSIS COLORECTAL CARCINOMA (HNPCC) AND SPORADIC COLORECTAL CARCINOMAS IN THE WESTERN CAPE, SOUTH AFRICA.
H Holm, P de la M Hall, N Allie, R Ramesar*
Division of Anatomical Pathology and Human Genetics,*
Groote Schuur Hospital/University of Cape Town, South Africa

Background:
COX-2 inhibitors are being used as chemoprevention in familial adenomatous polyposis. If COX-2 is also expressed in HNPCC there might be a role of COX-2 inhibitor treatment for patients with a known mismatch repair gene defect - either

to inhibit progression of tumours or to prevent the onset of carcinogenesis.
Objectives:
1. To evaluate COX-2 expression in colonic adenomas and carcinomas in patients with genetically proven HNPCC.
2. To compare COX-2 expression in HNPCC cases with that in sporadic tumours.
Methods:
Coded sections of formalin fixed paraffin embedded tissue from patients with known hMLH1 or hMSH2 mutations (6 polyps and 12 carcinomas) and sporadic tumours (5 polyps and 39 carcinomas) where immunohistochemically stained with an antibody to the COX-2 (Santa Cruz). Expression of COX-2 in the tumours was scored on both intensity and distribution and compared to the adjacent normal epithelium.
Results:
Normal colonic epithelium does not express COX-2. HNPCC: 1/6(17%) polyps and 5/12(42%) carcinomas express COX-2. Sporadic tumours: 3/5(60%) polyps and 26/39(67%) carcinomas express COX-2.
Conclusions:
COX-2 is generally more expressed in sporadic compared to HNPCC tumours. Furthermore COX-2 expression is more often expressed in infiltrating lesions compared to the expression in polyps. Chemoprevention is probably indicated in a selected number of HNPCC individuals.

P 170
EPIDERMAL GROWTH FACTOR RECEPTOR STATUS IN PRIMARY VERSUS METASTATIC SITES OF COLORECTAL ADENOCARCINOMAS

DURZYNSKA Monika, OLSZEWSKI Wlodzimierz T, KRZAKOWSKI Maciej.
Departament of Pathology, Departament of Thoracic and Lung Tumor
The Maria Sk³odowska – Curie Memorial Cancer Center and Institute of Oncology, Warsaw

The epidermal growth factor receptor (EGFR) is expressed in 40% to 80% of colorectal cancers. It is well known that EGFR expression in tumor cells is not early event and it changes in time in opposition to HER2 status. Data from literature have shown different EGFR status comparing primary and metastatic lesions. Relation between EGFR status and respons to specific treatment is still under investigation.

The aim of our study was to compare EGFR status on primary colorecatal tumors with corresponding metastases to determine whether assesment EGFR status in primary tumor is reliable for planing EGFR - targeted therapy.

Patients and Methods: EGFR expression was evaluated by immunohistochemistry in primary tumors and related metastases in 50 pacients with colorectar adenocarcinomas. In 35 (70%) cases metastatic sites were lungs and in 15 (30%) – liver. EGFR status was evaluated as positive if the percentage of membrane stained tumor cells was > or = 1% of all tumor cells.

Results: 33 (66%) of 50 specimens from primary tumor were EGFR positive. In 9 (27%) specimens from related metastses EGFR status was negative. 3 (17%) specimens from metastatic sites were EGFR positive whereas corresponding primary tumor specimens were negative.

Conclusion: Our data suggest that due to differences in EGFR expression on primary and metastatic sites of colorectal adenocarcinomas, for planning EGFR - targeted therapy EGFR status should be evaluated on specimens taken from at the moment exisiting tumor focus - metastates or recurrent lesions.

EXPRESSION OF EGFR IN COLON CARCINOMAS AND THEIR CORRELATION WITH

POPOVSKA Savelina, MARKOVA Elena, BETOVA Tatyana.
Department of General and Clinical Pathology
Medical University, Pleven

Background: Epidermal growth factor receptor (EGFR) is commonly overexpressed in a number of epithelial malignancies and is often associated with an aggressive phenotype advanced stages of cancer and a poor prognosis for the patient.
Aims: The expression of EGFR was analyzed in 50 cases of colon carcinoma, using immuhistochemical technique of paraffin sections. A correlation was made between the EGFR expression in primary tumour and the following clinicopathological parameters: histological type, histological grade and stage of the disease.
Methods: The patients had undergone curative surgical resection at the Oncology Centre in University Hospital - Pleven. EGFR expression was examined by immunohistochemistry using the Dakocytomation's EGFR PharmDx (Dako Cytomation) in paraffin-embedded colon tumors and graded as percentage of cells stained. The correlation statistical analisys was used.
Results:EGFR immunoreactivity was detected in 34 (68%) cases of colorectal carcinomas.
High levels of EGFR protein were observed in 10/50 (20 %) samples. Thirteen (26%) show moderate of EGFR expression in tumor cells and 11/50 (22 %) show slight level of EGFR expression. Sixteen of tumors were totally negative (32%).
Most of the cases showed complex and heterogenous patterns of EGFR-expression.
No association was found between the expression of studied EGFR protein and histological grade and type of primary tumor. Similarly, no correlation was detected between EGFR immunostaining and stage of colorectal adenocarcinoma.
Conclusions: Prospective multicentric studies should be conducted to confirm overexpression of EGFR as a prognostic factor.
Key words: EGFR, colorectal adenocarcinoma

Abstract
Aims:Colon cancer is a prevalent human malignancy.HER2/neu is an important oncogene in breast cancer,but its prevalence and significance in colon cancer have been poorly documented.
Aim of our study is to determine the rate and pattern of HER2/neu expression in colon carcinoma by immunohistochemistry(IHC).
Material and Methods:Sixty-nine archival ,paraffin wax embedded colon carcinoma specimens were chosen.IHC for HER2/neu was performed.Clinicopathologic data and IHC results were analyzed.
Results : Most of the carcinoma cases were well differentiated and located in the left side .There is positive

HER2/neu staining in a high percent of cases (41 Cases ,59.4 %) with both cytoplasmic (27cases.65.9%) and membranous-cytoplasmic (14cases,34.1%) staining .
In higher stages , the rate of positive staining were decreased but there was higher rate of strong membranous staining .Also, in higher grades , the rate of HER2/neu staining was decreased (P=0.04) and there was more membranous staining .
There were no correlation between HER2/neu expression and age , sex, site and type of tumor .
Conclusion : The rate of HER2/neu expression in colon carcinoma is high. Because of more prominent membranous staining in higher stages and grades,the Herceptin therapy could be helpful in patients with lymph node or distant metastases.
Keywords: coloncarcinoma, HER2/neu, immunohistochemistry

IMMUNOHISTOCHEMICAL ASSESSMENT OF EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR) EXPRESSION IN PRIMARY COLORECTAL CARCINOMA AND THEIR RELATED METASTASES. A COMPARATIVE STUDY ON TISSUE SECTIONS AND TISSUE MICROARRAY
BIBEAU frédéric1, BOISSIERE florence 1, SABOURIN jean-christophe 2, GOURGOU sophie 1, PENAULT-LLORCA frédérique 3, ROCHAIX philippe 4, ARNOULD laurent 5, BRALET marie-pierrre 6, AZRIA david 1, YCHOU marc 1 and the GETCO group. 1 Val d'Aurelle Cancer Center Pathology, Biostatistics and Oncology Departments, Montpellier, 2 Pathology, Institut Gustave Roussy, 3 Pathology, Centre Jean Perrin, 4 Pathology, Institut Claudius Regaud, 5 Pathology, Centre Georges-François Leclerc, 6 Pathology, Institut Paul Brousse and Le Groupe d'Etude des Thérapeutiques Ciblés en Oncologie, France.

Introduction: Recently approved new EGFR-targeted treatment (Cetuximab®) in metastatic colorectal carcinoma (CCR), requires an immunohistochemical assessment for patient eligibility. Controversial and limited data are available on the EGFR status in distant metastases.
Purpose: Because of clinical implications, we studied EGFR expression of primary CCR and their related metastases, to assess whether EGFR status was equivalent on both sites.
Methods: EGFR immunohistochemistry (IHC) on tissue sections was retrospectively assessed from primary tumors and related synchronous metastatic sites in 32 CCR patients (colon: 21; rectum: 11). Metastatic sites analyzed were liver (31) and ovary (1). IHC standardized assay was used (EGF-R pharm Dx, DakoCytomation) and EGFR positive status (EGFR +) was defined by a percentage of stained cells >1%, displaying a membranous pattern. In addition to tissue sections, EGFR was assessed on two triple core tissue microarrays (TMA), in order to find out if this high throughput technique was valuable for EGFR screening (diameter of the core: 0,6 mm, punched in the deepest region of the tumor invasion known to contain the strongest immunoreactivity).
Results: EGFR + tissue sections were observed in 84% of the primary cases (27/32) and 94% of the metastases (30/32). All patients displayed an EGFR + status either in the primary site (2/32), in the metastasis (5/32) or both (25/32). Discordant cases (i.e primary positive/ metastasis negative and inversely) were not statistically significant (p=0.453). Additionally, the number of EGFR + cells in the primary site was significantly correlated with that observed in their metastasis (r^2= 0.616, p= 0.0002). EGFR status on TMA was significantly under-evaluated on both sites, when comparing with tissue sections (p=0.0001 and p=0.0015 for primitive and metastatic sites, respectively). Moreover, using the TMA technology, we failed to find any correlation of EGFR expression between both sites.
Conclusion: Our results suggest that EGFR expression is frequent and equivalent on both primary and metastatic sites. Moreover, all patients exhibit an EGFR + status when combining EGFR status from the primary and from the metastatic site. Consequently, patient exclusion for Cetuximab® therapy should not be based on EGFR negativity from one single site. Our results also demonstrated that TMA is not a suitable tool for EGFR assessment in CCR, since it significantly underestimates its status.

P 174
Â-CATENIN, E-CADHERIN AND CYCLIN D1 EXPRESSION AT THE INITIAL STAGES OF THE ADENOMA-CARCINOMA SEQUENCE
AKMAN Hatice, DEMIRKAN Nese, DUZCAN Ender

Introduction and aims:
Most of the colorectal carcinomas originate from adenomatous polyps and this process is known as adenoma-carcinoma sequence. â-Catenin play an important role at Wnt signaling pathway and E-cadherin-catenin complex is essential at the maintenance of normal tissue architecture. An alteration of any of the components of E-cadherin-catenin complex are believed to result in the loss of cell-cell adhesion and to contribute to carcinogenesis. This study aimed to determine expression and cellular distribution of E-cadherin, â-catenin, and its target gene cyclin D1 and c-myc during tumor progression and malignant transformation in colon and to reveal its diagnostic or prognostic usefulness.
Methods:
Following histopathological examination, immunohistochemical staining of E-cadherin, â-catenin, cyclin-D1 and c-myc were performed at each section of 60 tumor samples and 31 polyp samples taken from 61 patients diagnosed as colorectal carcinoma and/or adenomas.
Results:
At polyps, the frequent loss of membraneous expression of E-cadherin was found at high dysplastic lesions however it was not significant (p: 0,07). Cytoplasmic and/or nuclear expression of â-catenin and nuclear expression of cyclin D1 was correlated with the degree of dysplasia (p: 0,01, p: 0,003, respectively).
At the tumors; the membraneous expression of E- cadherin was negatively correlated with lymph node metastasis (p:0,04). Nuclear cyclin D1 was expressed more at well differentiated tumors and at early stage (p:0,02, p:0,04, respectively). The increase of nuclear cyclin D1 positivity was correlated with cytoplasmic â-catenin positivity (p:0,034). Tumors of less than 5 cm diameter have more cytoplasmic and/or nuclear â-catenin positivity than tumors of more than 5 cm diameter (p: 0,039). No specific expression pattern were detected at c-myc expression related to adenoma-carcinoma sequence.
Conclusion:
This study demonstrated a significant loss of membraneous expression of E-cadherin during tumor progression at colon carcinomas. We hypothesized that loss of membrane staining of E-cadherin might be an indicator of worse prognosis at colon carcinomas. We propose to use nuclear expression of â-catenin as a marker of invasiveness in adenomas. As the overexpression of cyclin D1 is an early event in adenoma-carcinoma sequence, cyclin D1 may account for good prognostic parameter in colon carcinomas.

E-CADHERIN EXPRESSION PATTERN IN PRIMARY COLORECTAL CARCINOMAS AND THEIR METASTASIS REFLECT DISEASE OUTCOME
Adam Elzagheid 1,2,Riyad Bendardaf 1, Hanan Lamlum 1,Yrjo Collan 2, Kari Syrjanen1, Seppo Pyrhonen 1.

1Department of Oncology and Radiotherapy, Turku University Hospital, Savitehtaankatu 1 PB 52, FIN-20521, Turku, Finland,
2Department of Pathology, University of Turku, Kiinamyllynkatu 10, FIN-20520, Turku, Finland,

Aim: We using immunohistochemistry to examine the levels of E-cadherin expression in primary tumours and their metastasis from a series of 42 colorectal cancer (CRC) patients. Material and Methods: E-cadherin expression was separately analysed in membrane and cytoplasmic location by calculating two indices (MI and CI) in a series of 42 CRC and their metastases. Univariate and multivariate survival analyses were used to assess the value of these two E-cadherin indices as predictors of both disease-free (DFS) and disease-specific (DSS) survival.
Results: E-Cadherin MI was significantly higher in primary tumours as compared to their metastasis (p=0.0001), whereas CI did not show such a difference. Both MI and CI in the primary tumour were higher among patients who developed subsequent metastasis (p=0.022 and p=0.007, respectively). Interestingly, both indices were higher in metastasis of the liver than in those at other anatomic sites (p=0.034 and p=0.022), respectively. In univariate analysis, CI in the primary tumour was a significant predictor of DFS (p=0.042), and retained its predictive power also in multivariate Cox model, with a strong inverse correlation between CI and DFS (p=0.006). In the multivariate model, MI in the primary tumour proved to be a significant independent predictor of DSS, higher indices being associated with more favourable outcome (p=0.016).
Conclusions: The examining E-cadherin expression and distribution in colorectal tumours can be extremely valuable in predicting disease recurrence. The observation that aberrant cytoplasmic expression of E-cadherin can predict disease recurrence is obviously of great importance for both the patient and the clinician and affects significantly decisions concerning patient therapy and management.

P 176
EXPRESSION OF E-CADHERIN IN BUDS AT THE INVASIVE FRONT OF COLORECTAL CANCER (CRC) IN ASSOCIATION WITH LYMPH NODE INVOLVEMENT.

Katarzyna Guzinska-Ustymowicz, Mariusz Gryko, Andrzej Kemona, Jolanta Czyzewska
Department of General Pathomorfology, Medical University of Bialystok,Poland

Introduction:
Tumor budding refers to microscopic clusters of undifferentiated cancer cells just ahead of the invasive front of the carcinoma. It has been suggested that dysfunction E-cadherin-mediated cell adhesion is associated with tumour invasion and metastasis.
That why the aim of this study was to evaluate the relationship of tumour budding to chosen anatomoclinical features of colorectal cancer, and to E-cadherin expression in the main tumour mass, lymph node metastases and in the buds.
Methods: Tumors from 55 patients with colorectal cancer (CRC) were assessed by immunohistochemistry. Tissue sections were fixed in 10% buffered formaldehyde solution, embedded in paraffin and stained immunohistochemically with anti-human E-cadherin and â-catenin antibody.
Results:
It has been found that loss of membrane E-cadherin expression at the invasion front of primary tumour and tumour budding correlate with lymph node involvement. A different location of E-cadherin expression was also observed in buds. A statistically significant correlation between localization of E-cadherin expression in buds and presence of lymph node metastases ($p<0.01$) was found. We also noted a statistically significant correlation between changes at the site of E-cadherin expression in primary tumor, buds and localization of E-cadherin expression in lymph node metastasis.
Conclusion: These date suggest that different aggressiveness of tumors may depends of changes at the location of E-cadherin expression in buds at the invasion front of colorectal cancer.

P 177
EXPRESSION OF E-CADHERIN, BETA-CATENIN AND CD44V6 IN COLON CANCER: CORRELATION WITH CANCER METASTASIS.

Delektorskaya V.V., Perevoschikov A.G., Kushlinsky N.E.
N.N.Blokhin Russian Cancer Research Centre RAMS,Moscow,Russia.

Adhesion molecules are closely involved in the development and growth of metastatic tumours. The aim of the present study was to invastigate the level of expression and cellular distribution of E-cadherin, beta-catenin and CD44v6 and to assess the role of proteins in progression of colon carcinoma. Immunohistochemical analysis for E-cadherin, beta-catenin and CD44v6 was carried out on formlin-fixed paraffin-embedded sections of colon cancer tissues by streptavidin-biotin immunoperoxidase method. We examined the expression patterns of these molecules in 84 primary colon, 92 liver and 35 lymph node metastatic tumours, obtained from 84 patients and 45 non-metastatic colon carcinomas as control. The presence of membranous, cytoplasmic and mixed staining for E-cadherin were found in tumour tissues. Loss of normal membranous staining and reduced E-cadherin expression were detected more freqwently in the primary tumour with liver metastasis (64/84,76%), than in those without secondaries(14/45,31%)(p=0,014). In addition, the expression of E-cadherin had an inverse relationship with level of differentiation of the tumour.The expression level of E-cadherin was markedly decreased in the cancer cells of metastasis in lymph nodes and liver. Beta-catenin immunoreactivity was increased with cytoplasmic accumulation and nuclear translocation in more than 80% of the neoplasms with distant metastasis and in metastasis in lymph nodes and liver. Nuclear localization of beta-catenin was significantly higher in the invasive magin of some tumours in metastatic group (70/84,83%) when compared with the localized one (15/45,33%) (p=0,01). No significant difference in beta-catenin' expression was found between primary tumours and their lymph node and hepatic metastasis. There was no correlation between the expression of CD44v6 and lymph node involvement or liver metastasis of colon carcinoma. Expression of CD44v6 in metastasis showed no consistent relationship to that in the primary tumours.These results indicate that decreased expression of E-cadherin and nuclear accumulation of beta-catenin in colon cancer tissues are closely related to liver metastasis. There may be no association between CD44v6 expression and metastatic ability of colon carcinoma. In conclusion, our study suggest that both E-cadherin and beta-catenin play an important role in invasion and metastasis of colon cancer and may become a significant prognostic markers for tumour behaviour.

P 178
ASSOCIATION BETWEEN PRESENCE OF TUMOUR BUDDING AND EXPRESSION OF CATHEPSIN B AT THE INVASION FRONT OF COLORECTAL CANCER (CRC).

Katarzyna Guzinska-Ustymowicz, Andrzej Kemona, Mariusz Gryko, Jolanta Czyzewska
Department of General Pathomorphology, Medical University of Bialystok, Poland

AIM: Recent studies concerning the prognostic factors in colorectal cancer (CrC) have paid attention to tumor budding

as a prognostic factor. Cathepsin B play an important role in cancer invasion and metastases by degrading extracellular matrix components and basement membrane. However, the correlation between cathepsin B and presence of tumor budding at the invasion front of colorectal cancer has not yet been presented. The aim of this study was to clarify the association between the expression of cathepsin B in main mass of tumor, budds, and lymph node metastases, and presence of tumor budding at the invasion front of CRC, and lymph node involvement.
METHODS: A standard avidin-biotin immuno-peroxidase method (ABCu-NCL) staining technique was performed on 4im paraffin-embedded tissue section with a mouse anti-human cathepsin B monoclonal antibody (Novocastra/NCL-CATH-B).
RESULTS: A tumor budding was observed in 78.2% cases out of 55 colorectal adenocarcinomas. It has been observed that tumor budding at the invasion front was strongly associated with lymph node metastases. Positive immunohistochemical staining for cathepsin B was observed in 52.7% cases. Statistically significant correlation was found between expression of cathepsin B in main mass of tumor and lymph node involvement ($p<0.01$). The expression of cathesin B in primary tumor was also associated with tumor budding and vascular invasion ($p<0.01$)

CERBB2 AND P53 OVEREXPRESSIONS ARE POOR PROGNOSTIC PREDICTORS IN PATIENTS WITH COLORECTAL CARCINOMA
ERDAMAR Sibel, DOGUSOY Gulen, GOKSEL Suha, DIRICAN Ahmet,Aydin Ovgu
Cerrahpasa Medical College Pathology Deparment, Istanbul

Aim and background:To assess biological markers of primary colorectal carcinima (CRC) that may improve clinical staging and provide useful information for the application of novel therapeutic strategies, we investigated the protein product of the c-erb B2/HER-2 oncogene and p53 expression.
Method: Formalin-fixed paraffin embedded histopathological samples from 41 patients with CRC treated radical surgery in different stage were analysed to determine HER-2 and p53 protein expression by immunohistochemistry using Avidin-Biotin complex. Spearman Rank correlation test and Kaplan Meier survival tests were used in statistical analyses.
Results: Follow-up period was 12-84 months (mean; 27,6 ms) in study group. It's found that there was Lymph node metastases (LN met) in 21 cases (51,2%), perineural invasion (PI) in 13 cases (31%). There was not any expression of HER-2 in 10 cases (24%). There was Her-2 expression (+):n=5, 12%; (++): n=13, 31,7%; (+++): n=13, 31,7%. Expression of Her-2 was correlated with poor prognosis ($p<0.05$). P53 expression was less than 15% in 21 cases, whereas it was 15% or higher in 20 cases. Overexpresion of p53 was found poor prognostic indicator. Both markers were correlated with LD met.
Conclusion: Our study suggest that analysis of cerb B2/HER2 and p53 expression may provide relevant prognostic information about CRC patients that should be added in our pathology reports.

P 180
CLINICAL SIGNIFICANCE OF P53, K-RAS, DCC GENE ALTERATIONS AND EXPRESSION OF P53, RAS P21 ONCOPROTEIN IN THE EARLY STAGE COLORECTAL CANCERS
Mustafa Akkiprik*, Cigdem Ataizi Celikel**, Fikret Dusunceli***, Ozgur Sonmez*, Bahadir Gulluoglu***, Aydin Sav**, Ayse Ozer*
Marmara University School of Medicine, Departments of Medical Biology1, Pathology2 and Surgery3

Genetic alterations of p53, K-ras and DCC genes have a pivotal role in the colorectal colorectal tumorigenesis. Clinical significance of these genetic changes includes contradictory results. The aim of this study was to clarify the association between point mutation of K-ras oncogene codon 12/13, p53 aberrations, DCC loss of heterozygosity (LOH) and p53, ras p21 immunoexpression with the patient outcome and tumor characteristics in the early stage colorectal cancer patients.
Fifty-three stage I-II colorectal cancer patients who underwent surgical treatment with no postoperative adjuvant therapy were included in the study. Follow-up data were available for 43 patients with a median follow up 76 months (range, 6-168). Mutations in exons 5-8 of the p53 gene and codon 12 and/or 13 of the K-ras gene were assayed by PCR-SSCP and then confirmed by DNA sequencing. DCC LOH was studied by PCR-RFLP. p53, using the monoclonal antibody DO7 and ras p21 expression were evaluated by using immunohistochemistry on paraffin-embedded tissue sections.
Mutations of the p53 and K-ras genes were found in 15 and 5 tumors, respectively. DCC LOH was found in 5 cases. The most common combination of these alterations was DCC and p53, whereas p53 and K-ras was extremely rare. Cases with mutation of guanine to thymine (Gà T) which occurred in K-ras codon 12 and DCC LOH were found to be more aggressive than other cases with codon 12 mutations and DCC wild-type phenotype. Fourteen patients developed recurrence, 7 of whom had tumors with p53 or K-ras mutations or DCC LOH. K-ras gene mutations were found mostly in presence of a mucinous component within the tumor ($p=0.06$).
Nuclear staining of p53 was found in 54 % of the cases. Overexpression of the ras p21 were detected in 76% of the tumors. Ras p21 overexpression did not correlate with any of the clinicopathological parameters examined. Many tumors with p53 overexpression were localized at the left site ($p=0,005$). The 5-year disease free and overall survival rates indicated that no significance exists between the patients with or without these genetic alterations.
In conclusion, although none of these genetic alterations showed a significant prognostic value, specific mutation of K-ras gene and DCC LOH phenotype might have a predictive prognostic implication in colorectal cancer. Furthermore, distinct genetic patterns might be involved in the tumoregenesis of the left and right colon and mucinous colorectal adenocarcinomas.

P 181
DNA FLOWCYTOMETRIC ANALYSIS AND CYTOGENETIC ABERRATIONS DETECTED BY FLUORESCENCE IN SITU HYBRIDIZATION (FISH) OF COLORECTAL CARCINOMA
RAAFAT Amira,Professor of Pathology ,National Cancer Institute- Cairo University , Egypt; SHOMAN Soheir,Professor of Patholgy ,National Cancer Institute, Cairo Univ.,Egypt;
MOSTAFA Naglaa , Assistant Lecturer of Pathology, National Cancer Institute, Cairo Univ. Egypt and ABOULELA Mounir, Professor of surgery , National Cancer institute,Cairo Univ. Egypt

Colorectal cancer is one of the leading cancer sites in developed countries. It is also one with high mortality rates. Inspite of the utilization of numerous histopathologic and tumour markers, the clinical behaviour of colorectal cancer is highly variable with unpredictable prognosis.New prognostic markers and increased biologic understanding of the growth of the tumour are therefore needed which would help to identify patients at risk of recurrence and therefore aid in improving treatment strategies. This study was conducted on

45 cases of Egyptian colorectal carcinoma. Detection of DNA content and calculation of S-phase fraction (SPF)was performed by flowcytometry(FCM). Also, detection of numerical chromosomal aberrations of chromosomes 7, 17and 18 using FISH technique was done.It was found that 56.7%of cases were aneuploid, 52.9% in the hypotetraploid range , 23.5% in the near diploid and 11.8% for each of triploid and tetraploid ranges.SPF had a mean of 15.59%, ranging from 3.3% to 37.8%. Aneuploidy correlated with tumour size, grade, lymph node (LN) state and there was a tendency for aneuploid cases to be of metastatic Dukes C/D and to be distally located.Cases with high SPF tended to be more in distal tumours,metastatic Dukes C/D and in cases with more than 3 LNs and correlated significantly with tumour size.Aneusomy for at least 1 of the investigated chromosomes were present in 63.3%, being 53.3%, 26.7% and 43.3% for chromosomes 7, 17 and 18 respectively. Statistically significant correlation existed between chromosomes 7, 17,18 and LN deposits, chromosomes 7,17 aneusomies and tumour size and grade with high tendency of metastatic Dukes C/D to harbour high number of aneusomies.Statistically significant correlation existed between ploidy as detected by FCM and chromosomal aneusomies as detected by FISH and between chromosomes 7,17 and SPF.In conclusion, FCM is a rapid, sensitive and accurate method in evaluating thousands of nuclei for their DNA content and proliferative activity. Ploidy state correlated with tumour size, grade and number of LNs. Also, FISH is a more sensitive technique than classic cytogenetic ones, allowing rapid and straightforward result interpretation. The use of these techniques ,thus can help in improving treatment strategies for patients with colorectal carcinoma.

P 182
DNA PLOIDY, S PHASE FRACTION, P53 EXPRESSION AND CHROMOSOME # 17 COPY NUMBER ANEUSOMY IN COLORECTAL CARCINOMA IN EGYPT.

SHOMAN sohair,ABOU EL-ELA mounir, RAAFAT amira.
Departments of Pathology and Surgery, NCI, Egypt.

INTRODUCTION:
In Egypt high proportion of colorectal carcinoma(CRC) occurs below the age of 35 years and are associated with advanced disease at presentation .
AIM OF THE STUDY:
DNA ploidy, S-phase fraction (SPF), p53 Immunohistochemistry (IH) and chromosome # 17 aneusomy studied in a series of 30 patients below 35 years undergoining resective surgery for primary operable CRC to investigate whether these alternations have any clinical value in predicting CRC patient's prognosis.
METHODS:
DNA ploidy & SPF performed on tumour frozen tissues by flow cytometer (FMC) FAC scan B-D, chromosome copy number changes using non-radioactive fluorescent Insitu hybridization (FISH) using centromer specific DNA probe (D17Z1) for chromosome # 17 and p53 over expression by IH (M3566 –Dako cytomation) on paraffin embedded tissues. The median follow up time was 36 months.
RESULTS:
The majority of cases were males (79%) , distal colon in 46.6% with tumors > 5 cm in 70% of patients. DNA ploidy was associated with high Histologic grade (G3) ($p<0.05$), high SPF (>15.6) in 43 %, lymph node metastases ($P<0.01$), advanced Duke's stage (C&D) ($P<0.01$), lymph node metastases ($P<0.01$) and distal tumours ($P<0.001$). FISH showed chromosome #17 aneusomy in 26.6 %, (20 % deletion and 6% gain) while p53 over expression by IH in 59.4 %. No association detected between chromosome #17 aneusomy by FISH and p53 expression by IH.
CONCLUSIONS:
DNA aneuploidy, high SPF, p53 over expression are the hallmark of CRC in young Egyptian patients and are predictors of poor outcome.

P 183
EXPRESSION OF FASCIN PROTEIN IN COLORECTAL CARCINOGENESIS; RELATIONSHIP TO DECREASED EXPRESSION OF E-CADHERIN PROTEIN

Jin Hee Sohn, Seoung Wan Chae, Min Kyung Kim, Eo-Jin Kim
Department of Pathology, Kangbuk Samsung Hospital, Sungkyunkwan University School of Medicine, Seoul, Korea

Background: Fascin is an actin-bundling protein that induces cell membrane protrusions and increased motility, and is highly expressed in various transformed cells, and in specialized normal cells including neuronal, endothelial and dendritic cells. Methods: We evaluated the expression of fascin by immunohistochemistry in normal colonic mucosa, tubular adenomas and colorectal carcinoma, and investigated its relationship with E-cadherin expression and the various clinicopathologic factors. Results: Overall, variable fascin immunoreactivity was detected in 0% of 13 normal colonic glandular epithelium, and weakly in 52.6% of 16 adenomas, and weak to strongly in 40.9% of 115 colonic adenocarcinomas under study. Fascin immunoreactivity was high in poorly differentiated group compared with well to moderately differentiated group ($p<0.01$). And right side colon cancer showed slightly increase of fascin expression than left side one. Interestingly, fascin expression was inversely correlated with E-cadherin expression ($p<0.01$). And there was no significant correlation with the tumor size, metastasis or pathologic staging. Conclusions: In the multistep pathogenesis of colonic adenocarcinoma, fascin overexpression seemed to be a late event, and was associated with down-regulation of E-cadherin protein.

P 184
EXPRESSION OF TGF-Â2 AND SMAD4 IN COLON CARCINOMAS

Kouvidou Ch.(1), Karatapanis S.(2), Latoufis C.(3), Lianou E.(1), Kouvatseas G.(1), Anagnostakis D.(1), Vrettou-Aravani V.(1)
Departments of Pathology(1), Gastroenterology(2) and Oncology(3), "ELPIS" Hospital, Athens, Greece.

INTRODUCTION: TGF-â2, a potent natural antiproliferative agent, is believed to play an important role in suppressing tumorigenicity. This effect is mediated through Smad4, a tumour-suppressor gene, at chromosome 18q21.1, that affects gene transcription and controls cell growth.
PURPOSE: To study the expression of TGF-â2 and Smad 4 in colon carcinomas and to correlate them with pathological parameters and patient's survival.
MATERIALS AND METHODS: Formalin-fixed paraffin embedded tissue from 50 cases of colon carcinoma was stained by immunohistochemistry for TGF-â2 and Smad4 protein. Statistical analysis was performed using the Fisher's exact test, Kaplan-Meier method and log-rank test.
RESULTS: Smad4 nuclear and cytoplasmic staining was absent or reduced in 29/50 (58%) colorectal carcinomas, while in the remaining 21 (42%) Smad4 expression comparable with colonic mucosa was observed. A subset of poorly differentiated and mucinous carcinomas revealed normal Smad4 expression. TGF-â2 cytoplasmic staining expressed in all colon carcinomas and was overexpressed in 25/50 cases. We observed a tendency for a relationship between Smad4 and TGF-â2 in a subset of poorly differentiated and in advanced stage carcinomas. No statistical relationship between the above markers and survival was detected.

CONCLUSIONS: In poorly differentiated carcinomas the normal Smad4 protein expression may be linked to TGF-â2 overexpression, findings that may represent activation or dysregulation of the TGF-â2 signalling pathway. Inactivation of TGF-â2 gene occurs at an early stage of colorectal carcinogenesis, while inactivation of Smad4 is likely to be a late event.

P 185

HISTOLOGICAL AND IMMUNOHISTOCHEMICAL STUDY OF SPORADIC POORLY DIFFERENTIATED COLORECTAL ADENOCARCINOMAS

DANCIU Mihai*, IVAN Luminita**, FLOREA Niculina***, FERARIU Dan***, PLAMADEALA Petru*, MIHAILOVICI Maria-Sultana*
* Pathology Department, University of Medicine and Pharmacy "Gr. T. Popa", Iasi, ROMANIA
** Pathology Department, Armed Forces Hospital, Iasi, ROMANIA
*** Pathology Derpartment, Universitary Hospital "Sf. Spiridon", Iasi, ROMANIA

Sporadic poorly differentiated adenocarcinoma of colon and rectum are unusual findings. Although, TNM or Dukes systems of stages are the most important in establishing the five-year survival rate, the prognostic depends also on the histological type of the tumor. Hence, the necessity of distinction between these carcinomas and other variants (neuroendocrine carcinoma, large cell carcinoma).
Aims: Our purpose was to analyze the histological and immunohistochemical pattern of sporadic poorly differential colon carcinomas, in order to find reliable additional criteria in differentiating them from other types.
Material and methods: We studied eight cases of sporadic poorly differentiated enteric type colon adenocarcinomas. Selection of these cases was made considering histological aspects. All tumors were routinely processed (paraffin embedded, HE, van Gieson and Alcian blue staining). Immunohistochemical labeling included antibodies to Cytokeratin (cocktail), Chromogranin A and Neuron Specific Enolase and was considered to be positive if present in at least 10% of the tumor cells.
Results: Macroscopically, seven tumors were exophytic, large (mean size of 5.4 cm), ulcerated, infiltrating the subserosa of the colon. Only one tumor, localized in cecum, was 7 cm large, circumpherential, infiltrating the colon wall and penetrating an ileal loop situated at about 30 cm from ileo-cecal valve. Microcopically, all tumors were poorly differentiated, enteric type adenocarcinomas: large atypical tumor cells disposed in irregular cords or nests, with reduced glandular formation (under 10% of tumor mass). Immunostaining for Cytokeratin cocktail was largely positive in all tumors. The intensity of immunoreaction was similar in areas with reduced differentiation, glandular formation and in adjacent mucosa (with or without dysplasia). On the contrary, immunoreactivity for Chromogranin A and Neuron Specific Enolase was negative in these areas for all studied cases. Localization of the tumor, age and sex of the patient had no influence on immunoreactivity intensity.
Conclusions: Chromongranin A and Neuron Specific Enolase are important immunohistochemical markers helpful in distinguishing between poorly differentiated colorectal adenocarcinomas (with no neuroendocrine differentiation) and neuroendocrine carcinomas, when histological aspects are similar.

HYPOXIA INDUCIBLE FACTOR - 1Á INFLUENCES ANGIOGENESIS AND PROGNOSIS IN LOCALLY ADVANCED RECTAL CANCER

GAKIOPOULOU Hariklia1, THEODOROPOULOS George2, THOMOPOULOU Georgia1, LAZARIS Andreas1, NONNI Aphrodite1, PANOUSSOPOULOS Dimitrios2, BRAMIS John2, PATSOURIS Efstratios1
Depts of Pathology1 and Surgery2, Medical School, University of Athens, GREECE

Hypoxia-inducible factor 1á (ÇIF-1á) is a critical regulatory protein of cellular response to hypoxia and is closely related to the triggering of the angiogenic process through activation of the vascular endothelial factor (VEGF) gene. The disruption of apoptosis, which is mainly regulated by the bcl-2 anti-apoptotic gene and the death promoting p53, causes loss of programmed cell death and tumour progression. We investigated the relationship between hypoxia, angiogenesis and apoptosis and their prognostic impact in patients with advanced rectal cancer.
HIF-1á tissue immunostaining, assessment of angiogenesis profile, quantitation of apoptosis (apoptotic index) and expression of p53 and bcl-2 were carried out in formalin-fixed paraffin-embedded tumour tissue samples retrieved from 92 patients with locally advanced rectal cancer (T3,4/N+).
HIF-1á high reactivity was noted in 47.8% of the examined cases and its expression correlated significantly with lymph node metastasis ($p< 0.001$), low rectal location ($p = 0.016$), infiltrative growth pattern ($p = 0.039$), absence of peritumoural lymphocytic infiltration ($p = 0.037$), depth of invasion (pT4) ($p = 0.04$) and vascular invasion ($p = 0.001$). VEGF positive expression was detected in 44.6% of tumour samples. VEGF expression and microvessel density were associated with lymph node involvement ($p<0.001$). VEGF was found more frequently in larger in size and low-lying rectal carcinomas ($p = 0.003$ and $p = 0.029$). HIF-1á expression was directly correlated with VEGF up-regulation ($r = 0.64$, $p < 0.001$) and MVD ($r = 0.41$, $p<0.001$). VEGF expression was also closely interrelated with MVD ($r = 0.75$, $p<0.001$). In univariate analysis advanced grade, low rectal location, infiltrative pattern of tumour growth, vascular invasion, positive lymph node status, HIF-1á expression, VEGF upregulation and p53 accumulation were related to decreased disease-free survival. Regarding overall survival, all aforementioned variables, except for tumour location and p53 status, were proved to be statistically significant negative prognosticators. In multivariate analysis only high HIF-1á reactivity and positive lymph node status were emerged as independent variables of adverse prognostic significance.
HIF-1á and VEGF may play an important predictive and prognostic role in patients with locally advanced rectal cancer. HIF-1á may serve as a prognostic marker of

Introduction: Colorectal cancer is the second most common neoplasia in men and women and the second most deathful cancer in the west world.
Up to date, the most important variable in the outcome from colorectal cancer is the stage of disease at diagnosis (Dukes or TNM stage). Nevertheless, those classifications are not helpful enough to predict the prognosis of patients, mainly when intermediate levels of disease appear (Dukes B and C stage). In order to solve this issue, it is very important to identify molecular markers clearly associated to the outcome of patients.
Material and methods: With this objective, we analysed 198 (52% Dukes B and 48% Dukes C stage) colorectal carcinomas selected from the archives of 3 different Spanish hospitals. All cases were removed between 1997 and 1998. After the surgery 47% were treated with adjuvant chemotherapy (5-FU) while 53% of patients did not receive any additional treatment. Sixty two out of the total amount of the patients have developed metastasis after surgery. After a 5-year follow-up period, 47% of patients had died and 53% were still alive.
Four tissue microarrays (TMA) were constructed with paraffin embedded tissue samples. Thirty molecular markers were examined by inmunohistochemistry, including markers of apoptosis, cell cycle, proliferation, signalling, adhesion, repair genes and immunologic response. Conventional histopathological features of colorectal cancer were also evaluated.
Results: In the univariate analysis, most of molecular markers did not show any significant association with survival or metastasis. However, the over-expression of p21 and cyclin B1 were related with recurrent disease (p= 0,028 and p=0,039), and the loss of expression of p16 was also linked to distance metastasis (p= 0,007).
In addition, the over expression of cyclin D1 was associated with shorter survival (p= 0,037).
However, in current study the presence of lymphovascular invasion was considered the most relevant risk factor for disease recurrence, distal metastasis and survival in general (p<0,0001).
Conclusion: As a conclusion, this inmunohistochemical study of B and C Dukes stage of colorectal carcinoma on TMA reveals that the expression of p21, p16, cyclin B1 and Cyclin D1 could be used as prognostic markers of metastasis or survival.

P 188
PROGNOSTIC EVALUATION OF CD44 EXPRESSION IN CORRELATION WITH BCL-2 AND P53 IN COLORECTAL CANCER
ZIZI-SERBETZOGLOU Adamantia, ZAVRlDIS Harris, KATSAMAGOU Eleftheria,PAPATHEOFANIS Ioannis,ELEMENOGLOU Ioannis
Department of pathology, Tzaneio General Hospital, Piraeus, Greece

Colorectal cancer results from a series of genetic events which disorder the normal mechanisms controlling cell growth. The aim of this study was to investigate the expression of CD44 in colorectal carcinoma and examine its association with clinicopathological features,bcl-2,p53 and long term outcome.
MATERIALS and METHODS:A series of 100 patients underwent surgical resection of primary colorectal carcinoma at the III Department of Surgery , Tzanneio Hospital of Piraeus between 1995 and 1999.Colorectal cancer cases in non-inherited polyposis in adenomatous polyposis and in ulcerative colitis were not included in this study.Colorectal cancer cases which death occured in the immediate postoperative period were also excluded.
Paraffin embedded specimens from 61 patients with Dukes stage B and 39 patients with Dukes stage C colorectal adenocarcinoma were assessed. We determined the expression of CD44,bcl-2,P53 with 5year follow up.
RESULTS:ln our study low CD44 expression‹10%)was present in 30%,moderate CD44 expression (10%-50%) in 30% and extensive CD44 expression(>50%)in 40% of cases.Expression of CD44 was unrelated to patient sex and age but was related to tumor differentiation(p=0.0295),tumors stage (p=0.009)and tumor site. No significant association was demonstrated between CD44 and bcl-2 status. However there was significant evidence of an association between CD44 and P53 status in the 66 cases in which P53 had previously been assessed.When entered into a multivariate analysis model, which also included bcl-2 and P53,CD44 staining emerged as prognostic indicator variable.
CONCLUSSIONS: CD44 expression may be an indicator of poor prognosis in colorectal cancer patients.

P 189
PROGNOSTIC SIGNIFICANCE OF NUCLEOLAR ORGANIZER REGIONS (AGNORS) IN ADENOCARCINOMAS OF THE RECTUM
RADULESCU Doinita*, AMALINEI Cornelia*, STOLNICU Simona**, MOCAN Simona***
*Department of Pathology, University of Medicine and Pharmacy Iasi, Romania
** Department of Pathology, University of Medicine Targu-Mures, Romania
***Laboratory of Pathology, Municipality Hospital Targu-Mures, Romania

The prognostic significance of silver-binding nucleolar organizer regions (AgNORs) was evaluated in tissue sections of biopsies from 45 primary adenocarcinomas of the rectum prior to their curative resection. AgNOR index was correlated with five-year survival rate and various morphological parameters of the primary tumors such as malignancy grade, tumor and lymph node stage. A significant correlation between five-year survival rate as well as pT categories and the mean AgNORs number per tumor cell was found. There was no significant relationship between AgNORs content and grade of malignancy or pN categories. The most valuable variable to predict a poor prognosis were pN, pT, and mean AgNORs index. The analysisi of AgNORs may represent a useful pretherapeutic evaluation of the aggressiveness of the rectum adenocarcinoma.

P 190
RACK1 OVEREXPRESSION ASSOCIATES WITH HIGH GRADE AND LYMPH NODE METASTASES IN COLORECTAL CARCINOMAS
CUATRECASAS Miriam, ESPINOZA Paul, IGLESIAS Carmela, ROJO Federico, ALLENDE Helena, DE TORRES Ines, JIMENEZ Jose, TABERNERO Jose*, RAMON Y CAJAL Santiago
Pathology and Oncology* Departments, Vall d'Hebron University Hospital, Barcelona. Spain.

Introduction: The receptor for activated C kinase 1 (RACK1) is a protein kinase C-mediated (PKC) signaling enzyme. RACK1 is an adaptor protein that contains many domains that mediate protein-protein interactions, anchors activated PKC isozymes and other signaling enzymes and regulates cell growth. The function and levels of expression of RACK1 may help elucidate signaling pathways leading to carcinogenesis and could result in the identification of novel therapeutic targets.
Purpose of the Study and Methods: RACK1 expression was evaluated in 116 colorectal carcinomas between 2001 and 2003 in a prospective study, to asses the clinical utility of the levels of expression of RACK1 protein. Tissue microarrays (TMAs) representative of normal mucosa and colorectal carcinoma of all cases were performed, including areas from

the centre and infiltrative margin of the tumor. When present, additional TMAs from metastatic lymph nodes or adenomas where done. In order to assure the representativity of the areas we included 3 cores of 1,2 mm of each selected zone. Positivity was scored using the Hscore (range from 0 to 300) resulting from multiplying the intensity (0 to 3) by the percentage of positive staining. RACK1 levels were determined by immunohistochemical staining, using a monoclonal antibody (BD610177). Results were correlated with clinical, histopathological parameters, and survival. In a subset of cases Western-blot was also performed.
Results: RACK1 overexpression was observed in 61'2% (71) cases. Overexpression of RACK1 correlated with poor differentiation (grade) p=0.036 and presence of lymph node metastases (p=0.049). No differences were observed between RACK1 expression and tumor localisation, stage or depth of tumor infiltration. Interestingly RACK1 expression in adenomas showed only 16'6% overexpression (2/12), compared to 70% in concomitant carcinomas (p=0.010). No differences in RACK1 immunostaining were observed between the centre of the tumor and the infiltrative margin, neither between the primary tumor and metastatic lymph nodes (p=0.927). Western-blot analysis confirmed the high levels of the protein. Disease-free survival was not related to RACK1 expression (p=0.356).
Conclusions: We have found significant differences in expression of RACK1 in high grade and lymph node metastatic colorectal carcinomas. We propose that RACK1 expression can be a potential marker of worse prognosis in colon carcinoma and be used as a novel therapeutical marker.

P 191
SCREENING FOR ASSOCIATION OF HEREDITARY NON-POLYPOSIS COLORECTAL CANCER (HNPCC) WITH GENOMIC REARRANGEMENT IN HMSH2 OR HMLH1 GENES USING LEUKOCYTE-DERIVED GENOMIC DNA FROM PATIENTS
R. Salehi, M. Salehi, M. Mousazadeh, A. Karimi
Department of Genetics and Molecular Biology, School of Medicine, Isfahan University of Medical Sciences, Isfahan Iran

Background & Objectives:
Hereditary non-polyposis colorectal cancer (HNPCC) is an autosomal dominant disease due to germline mutations of human mismatch repair genes (MMR), mainly hMLH1 and hMSH2. Colorectal cancers associated with the HNPCC syndrome usually present in younger patients, show loss of mismatch repair (MMR) gene expression, and exhibit microsatellite instability (MSI). About 12% of sporadic colorectal cancers also show MMR loss and MSI.
Methods & Materials:
To evaluate the status of genetic lesions in hMLH1 and hMSH2 MMR genes in the peripheral lymphocytes of the patients and find out a prognostic criteria for detection of those who are at high risk to develop the disease in future, 25 individuals diagnosed with HNPCC included in this study.
A DNA sample isolated from peripheral blood leukocytes obtained from each of these probands was examined for genomic rearrangement using the multiplex ligation-dependent probe amplification (MLPA) method. The probe mixture included probes for each of the 19 exons of the hMLH1 gene as well as for each of the 16 exons of the hMSH2 gene.
Results:
Seventy percent of the individuals (18/25) were shown to have a genomic rearrangement resulting in the deletion of one or more exons of one of these two genes. Family cancer histories predictive of a high risk of HNPCC significantly associate with a genomic rearrangement in hMSH2 or hMLH1.
Conclusions:
Based on our results it is concluded that using MLPA to identify genomic rearrangements in the above mentioned genes could be considered an economic first step in screening for HNPCC as an initial assessment of gross genomic integrity in leukocyte-derived genomic DNA. This would be especially valuable when individuals undergoing testing are identified by clinical history to be at high risk, as this approach would bypass the logistical difficulties of tumor analysis (assessment of microsatellite instability and immunohistochemistry.

P 192
THE ROLE OF P53,C-ERB-B2 AND BCL2 IN COLORECTAL TUMORS
Suhail N Abdullah Al-Salam
Pathology department, Faculty of medicine and health sciences, United Arab Emirates University, Alain, UAE.
P.O.17666

Introduction
Colorectal carcinoma is the most common gastrointestinal malignancy and one of the three most common causes of cancer death in western industrialized societies. An important role for P53 gene mutation and c-erb-B2 and bcl2 genes overexpression in the development of colorectal carcinoma had been described .Difficulties in the diagnosis of superficial endoscopic biopsies from papillary rectal neoplasms do exist and this study admits a suggested tool to help the pathologists in making their decision on these lesions.
Objective
The aim of the study is to evaluate the use of immunohistochemical stains of p53, c-erb-B2 , and bcl2 in the diagnosis of papillary colorectal tumours in endoscopic biopsies and
to determine their roles in the pathogenesis of colorectal carcinoma.
Materials and methods
Seventy endoscopic biopsies of colorectal tumours were selected . Fifty biopsies were colorectal adenocarcinomas, 10 were villotubular adenomas, and 10 were villous adenomas .Another 10 biopsies of normal and chronic inflammatory bowel disease were also selected . 4 – micrometer sections were prepared and stained with streptavidin –biotin immunohistochemical method using monoclonal antibodies against P53,c-erb-B2,and bcl2 (DAKO).One section of each biopsy was stained with H&E stain. Suitable positive and negative controls were used. Diaminobenzidine (DAB) was used as a chromogen.
The results were compared with surgical specimens of total colectomy and proctocolectomy .
Results
Forty two(84%)biopsies of colorectal carcinomas , one tubulovillous adenoma (10%) and two villous adenomas (20%)showed positive staining for P53 while no case of chronic inflammatory bowel disease or normal mucosa showed any staining for P53.
Forty eight (96%) biopsies of colorectal carcinoma ,6(60%) tubulovillous adenomas,7(70%) villous adenomas,3 (60%)of the chronic inflammatory bowel disease biopsies and 2 (40%)biopsies of normal colonic mucosa showed positive staining for c-erb-B2. Twenty eight (56%) biopsies of colorectal carcinomas , 4 (40%)tubulovillous adenomas,6(60%)villous adenomas ,2 (40%)chronic inflammatory bowel disease biopsies showed positive staining for bcl2.While no stain for bcl2 was noticed in normal intestinal mucosa biopsies.
Conclusions
P53 immunostaining is an important tool in the differentiation between benign and malignant papillary colorectal neoplasms in endoscopic biopsies especially when combined with c-erb-B2 and bcl2 .

P 193
THYROID TRANSCRIPTION FACTOR-1 IMMUNOREACTIVITY IN COLORECTAL CARCINOMA
MICHALAK Sophie, KOFFI Emmanuel, JOSSELIN Nicolas, TRIAU Stéphane, SAINT-ANDRE Jean-Paul
Department of Pathology, University Hospital, 4 rue Larrey, 49933 ANGERS cedex 09, France

Introduction : Metastatic adenocarcinoma of unknown primary origin is a common but perplexing problem. Among the useful immunohistochemical markers, thyroid transcription factor-1 (TTF1) has revealed to be a sensitive and specific marker for adenocarcinomas of lung and thyroid origin. Two patients with a multinodular liver without known malignancy underwent liver biopsies at Angers Hospital ; the liver specimens showed an adenocarcinoma CK7- CK20+ TTF1+. A colorectal cancer (CRC) was discovered in each patient but no lung tumor. The aim of this study was to investigate TTF1 immunohistochemical expression in CRC.
Methods : We studied TTF1 immunoreactivity of 53 consecutive cases of CRC diagnosed between may to December 2004 on coloscopic biopsies (8 cases), surgical resections (34 cases) or both (11 cases).
Results : A nuclear TTF1-reactivity was observed in 5 cases (9%) : 2 cases with strong reactivity in more than 50% of cells, 3 cases with weak and focal reactivity in less than 5% of cells. When biopsies and tumor were evaluated for the same patient, the immunophenotype was the same.
Conclusion : TTF1 is a useful but not specific marker for lung and thyroid cancer. It must be used with other immunohistochemical markers to guide the clinician toward the primary tumor.

P 194
TUMOR HYPOXIA AND ACIDITY DRIVE STROMATOGENESIS AT THE INVADING TUMOR EDGE OF COLORECTAL CARCINOMAS
A Giatromanolaki(1), Ch. Charalampidis(1), MI Koukourakis(2), E Sivridis(1)
1Department of Pathology, Democritus University of Thrace Medical School, Alexandroupolis, Greece.
2Department of Radiotherapy/Oncology, Democritus University of Thrace Medical School, Alexandroupolis, Greece.

Stromatogenesis, i.e. the formation of new stroma at sites of tumour invasion for tumour invasion itself, occurs in complicity with host's peritumorous fibroblasts (Sivridis et al, 2004 Int J Surg Pathol 12: 1-9); it is a phenomenon of utmost importance for tumour growth and progression. In this study, we investigated the activation status of host's fibroblasts at the invading tumour edge, assessed as MIB1 proliferation index and thymidine phosphorylase (TP) expression. Our results were related to vascular density (VD), and certain qualities expected to occur in invading cancer cells, such as MIB1 proliferation activity, expression of TP, expression of endogenous markers of hypoxia (hypoxia inducible factor-1á or HIF-1á) and acidity (lactate dehydrogenase 5 or LDH5). Standard immunohistochemical techniques were applied in a series of 150 colorectal adenocarcinomas. Normal fibroblasts confronting the tumour edge showed a median MIB1 index of 2%, significantly more than the 0.3% growth fraction found in normal submucosal fibroblasts and significantly less than the median MIB1 index of 40% estimated in cancer cells. Normal peritumorous fibroblasts with a proliferation rate above median were virtually loaded with TP and supported by an increased vascular network. Cancer cells confronting these fibroblasts were characterized by a high MIB1 proliferative index, high HIF1á and LDH5 reactivity, and a clear trend to extramural extension. All these associations were statistically significant. It is suggested that an activated fibroblastic status at the invading tumor front, sets the stage for stromatogenesis and new blood vessel formation, facilitating deep transmural invasion in colorectal adenocarcinomas. This complicity of peritumorous fibroblasts in the overall aggressiveness of the colorectal tumours, occurring within the framework of cancer-stromal cell interactions, is apparently favoured from the altered micro-environmental conditions of hypoxia and acidity.

P 195
HEDGEHOG PATHWAY IN COLONIC LESIONS
ALINGER Beate, KRENNBAUER Stefan, DATZ Christian, ESTERBAUER Harald, ABERGER Fritz, BLAAS Leander, KOLLMANN Karoline, DIETZE Otto, HAUSER-KRONBERGER Cornelia

Colorectal cancer is one of the major forms of cancer in industrialized countries. About 10% of the colorectal cancer cases have a hereditary basis, including defined syndromes like familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC). The remaining 90% of colorectal cancers occur sporadic by spontaneous mutation of single genes.
Hedgehog signaling is a main regulation cascade in embryonic differentiation of the whole gastrointestinal tract and mutations of some components have been associated with birth defects like gut malrotation, imporforate anus or intestinal transformation of the stomach. In addition to their function in the embryo, the Hedgehog pathway members are present in postnatal and adult tissues including stomach, pancreas, small intestine and colon. Therefore unusual expression of Hedgehog components has been associated with benign and malignant lesions of stomach and pancreas, leading to our current investigations.
In the present study we examined the presence of the Hedgehog pathway in normal human colon using immunohistochemical methods. The antibodies used are directed against the majority of the components involved in the Hedgehog signaling cascade, including the ligands Sonic, Indian and Desert Hedgehog, the transcription factors Gli1, Gli2 and Gli3 as well as the receptor Patched. Additionally, 14 cases of benign and 14 cases of malignant lesions of the human colon have been investigated to prove alteration of the expression pattern. Malignant lesions of the colon mostly comprise adenocarcinoma and benign lesions comprise tubular, villous and tubulo-villous adenoma and hyperplastic polyps. Up- or down-regulation of the Hedgehog pathway has been examined.
In the normal colon tissue we detected expression of the ligands Sonic (Shh) and Desert Hedgehog (Dhh) within the lining epithelium, as well as the receptor Patched and the transcription factors Gli1 and Gli2 along the whole colonic crypts. Within all benign lesions a positive staining of Shh, Dhh, Gli1, Gli2 and Ptch was detected, but expression was not consistently distributed within the lesions than rather restricted to single cell aggregates. Some malignant lesions also displayed the same unique staining pattern, though Hedgehog activity was not detected in all malignancies examined. We conclude that the Hedgehog signaling cascade may be involved in the normal physiological renewing process of the colonic lining.

APPLICATION OF SPECIFIC ANTI-SENSE OLIGONUCLEOTIDS AGAINST HUMAN TELOMERASE RNA (HTR) ON CCL-247 COLON CANCER CELL LINE
Mansoor Salehi and Rasoul Salehi
Dept. Of Genetics and Molecular Biology
Medical School
Isfahan University of medical Sciences

Isfahan
Iran

Background & Objectives: Inhibition of telomerase activity is one of the most promising targets for cancer therapy, because telomerase activity is present in most malignant cells but undetectable in most normal somatic cells. Unlike an ordinary enzyme, telomerase has RNA and a protein component that are both necessary for telomerase activity. We targeted the RNA component, the telomerase RNA (HTR), which contains the template for the telomere sequence. It is shown that the majority of gastric cancers express high levels of HTR that is essential for cellular survival. In this study, we evaluated the ability of anti sense oligonucleotides against HTR (anti-HTR) to inhibit telomerase activity in human colon cancer cells.
Methods & Materials: Thio-phosphoramidated anti-sense oligonucleotides against HTR were transfected into the CCL-247 colorectal cancer cell line using FUGENE6-mediated DNA transfection technology. Different concentration of anti-HTR was applied and cell growth and cell cycle parameters were analyzed. Telomerase activity was measured by TRAP assay and the apoptotic features were studied by PI and Hoechst 33258 staining. Control oligonucleotides and normal fibroblast were used as control.
Results: Anti-sense oligonucleotides against HTER were successfully transfected to the cells and reduced the cell viability to 28%. This treatment also inhibited the telomerase activity of the cells by 70%, in a dose-dependent manner. The apoptotic cells rate was also increased to 33%.
Conclusions: Our results demonstrated that application of anti-HTR is a powerful approach that can inhibit telomerase activity in colon cell line and therefore probably have the potential to be considered for anti-cancer therapy.

LABEL-FREE ANALYSIS OF MICROSATELLITE INSTABILITY IN COLORECTAL CARCINOMA BY ON-CHIP ELECTROPHORESIS.

BARTA Nora, BALDUS Stephan E., DIENES Hans Peter, SALOWSKY Rüdiger*, and ODENTHAL Margarete.
Institute for Pathology, University Clinic Cologne, and
*Agilent Technologies Waldbronn Germany

Microsatellite instability (MSI) is caused by a failure of the DNA mismatch repair system and occurs frequently in various types of cancer. Since sporadic MSI are associated with approximately 10 to 15% of colorectal, gastric or endometrial carcinoma and impact clinical prognosis, MSI analysis is an important tool in clinical research and molecular diagnostics.
Aim: Given that conventional techniques used for MSI detection – e.g. polyacrylamide gel electrophoresis (PAGE) or capillary electrophoresis - turned out to be laborious or expensive, this study aimed to develop a simple and efficient procedure of MSI detection.
Methods: Forty cases with no (26 cases) or with MSI (14 cases) were selected out of a panel of 150 patients with colon carcinoma. Amplicons derived from areas of non-tumor (N) and tumor (T) tissues were analyzed by microfluidic based on-chip electrophoresis on the Agilent 2100 bioanalyzer.
Results: The results presenting a pattern of five microsatellite loci were compared with the findings obtained by fluorochrome-associated PAGE technology. In all cases, label-free microfluidic separation of the PCR amplicons resulted in highly resolved, distinct patterns of each of the five microsatellite loci. Detection of MSI could be demonstrated by microsatellite loci-associated, well defined deviations in the electropherogram profiles of tumor and non-tumor material and confirmed the classification of the MSI cases performed by conventional technology (95% concordance rate).
Conclusion: The presented data demonstrate that microfluidic chip technology is a simple, reliable and robust technology for MSI detection, which allows label-free analyses of microsatellite amplicons within 30 minutes.

ANTIBIOTIC-ASSOCIATED HEMORRHAGIC COLITIS CAN BE INDUCED BY KLEBSIELLA OXYTOCA IN AN IN VIVO RAT MODEL

Cord Langner1, Christoph Hoegenauer2, Eckhard Beubler3, Thomas A. Hinterleitner2
1Institute of Pathology, 2Department of Internal Medicine and 3Institute of Experimental and Clinical Pharmacology, Medical University of Graz, Austria

Introduction
Antibiotic-associated hemorrhagic colitis (AAHC) is a serious side effect of antibiotic treatment occurring mainly with broad-spectrum penicillins. Its cause is unknown, however, Klebsiella oxytoca can be found in the stool of affected patients, whereas Clostridium difficile is absent. Concomitant intake of non-steroidal anti-inflammatrory drugs (NSAIDs) by patients is common.
Methods
A strain of K. oxytoca resistant to amoxicillin-clavulanate (AC) was isolated from the stool of a patient with AAHC. Sprague Dawley rats received either K. oxytoca, AC and indomethacin [A], AC and indomethacin [B], K. oxytoca and AC [C], K. oxytoca [D], indomethacin [E] or AC [F]. Four days after exposure to K. oxytoca the animals were sacrificed and the colon was analyzed for presence of inflammation, epithelial damage, mucosal hemorrhage, submucosal edema and erosions applying an arbitrary histological score (0-3 points).
Results
Histological changes were most prominent in the right-sided colon while changes in the distal colon were less severe. Inflammation was seen only in group [A] and [C] animals with median scores of 1.4 and 1.0, respectively. Marked epithelial damage was seen in group [A] and [C] animals with median scores of 1.7 and 1.3, respectively, whereas the animals in the other four groups showed only focal epithelial alteration (median scores 0.2-0.3). Mucosal hemorrhage was again noted in group [A] and [C] animals only with median scores of 1.0 and 0.6, respectively. Submucosal edema was prominent in group [A] and group [E] animals with median scores of 2.2 and 2.3, respectively. However, mild changes were also seen in groups [B], [C] and [E] with median scores of 0.5-1. Finally, severe erosive changes were detected in group [E] animals (median score 2.5), and group [A] animals (median score 1.4), while in groups [B] and [C] mild changes (median scores 0.1-0.2) were found.
Conclusions
K. oxytoca isolated from a patient with AAHC induces a predominantly right-sided hemorrhagic colitis in an in vivo rat model. The administration of NSAIDs enhances the severity of disease.

P 199

INVESTIGATION OF CMV INFECTION AND ANGIOGENESIS IN PATIENTS WITH REFRACTORY CHRONIC ACTIVE ULCERATIVE COLITIS

Hadjileontis C, Fericean A, Kardasi M*, Alexopoulou E., Gerovassilis F*
Technicians: Assimori B, Apostolou G
Pathology and Gastroenterology* Departments
"Achillopouleion" General Hospital, Volos, Greece

OBJECTIVE: A number of cases with chronic ulcerative colitis (UC) are resistant to therapy. Cytomegalovirus (CMV) infection has been reported to be a cause of it. Besides, angiogenesis has also been reported to have a potent role in the course of the disease. This pilot study investigates the

impact of both CMV infection and angiogenesis in patients with refractory UC.
PATIENTS AND METHODS: Twenty patients with UC were studied (ten with chronic active and ten with chronic quiescent form). Six of the cases were resistant to steroid, 5ASA and/or azathioprine therapy. All cases were investigated for the presence of CMV both morphologically and immunohistochemically. Angiogenesis was evaluated quantitatively by measuring the number of newly formed vessels expressing CD34 and VEGF in sections of the bioptic material. Measurements were performed through an ocular millimetric grid at 400X magnification, by two different observers and were expressed as microvessels per square millimeter. Ten intestinal biopsies with normal findings were used as a control group for the above investigation.
RESULTS: There were no viral inclusions in H&E stained sections nor was the presence of CMV detected immunohistochemically in any of our cases. Microvessel density (MVD) was increased in all the cases with chronic active disease compared to both the quiescent form and the control groups ($p<0.05$). Furthermore all patients with refractory UC showed higher MVD within the lamina propria of the inflamed mucosa compared to the responding to therapy cases.
CONCLUSIONS: The above results do not indicate that CMV infection is responsible for resistance to therapy in our cases of refractory UC. We however suggest that a deficient response to therapy in chronic active UC may be due to increased angiogenesis which, together with other factors, seems to play an important role in the mechanism of tissue inflammation, ulceration and regeneration in UC

P 200
DIFFUSE ENDOCRINE SYSTEM AND LYMPHOCYTE SUBSETS IN COLONIC MUCOSA IN ULCERATIVE COLITIS
Botina AV, Solovyeva OI*, Rybakova MG (Dept pathology, St Petersburg state medical university; *Dept therapy, St Petersburg medical academy postgraduate study)

The diagnostics of ulcerative colitis (UC) is based on a complex of methods with obligatory colonoscopy and colon biopsy. The diagnostics is difficult, UC remains largely the diagnosis of exclusion. So, thorough evaluation of all the components of the mucosa could make the diagnostics more reliable. Cellular lining of the mucosa carries out multiple functions including antigen transfer to MALT of the gut and certain endocrine activity. Little attention has been paid to possible role of APUD elements of the mucosa in progression of the disease and their interaction with lymphocytes of the lamina propria.
THE OBJECTIVE of the present investigation was to study the lymphocyte subsets and endocrine cells in the colonic mucosa with special reference to EC-cells.
MATERIAL, METHODS AND RESULTS. 141 colon biopsies (3 from each of 47 patients with UC - from macroscopically inflamed and non-inflamed bowel) were studied by means of conventional morphology, morphometry and immunohistochemistry. Patients were placed in 3 groups, varying from remission to exacerbation, according to the degree of activity of the inflammation, judged by lymphocyte and leukocyte count. Endocrine cells were revealed by argyrophilic reaction as well as with antibodies against chromogranin A, serotonin (Dako Cytomation, Denmark). Differential lymphocyte subset count was performed in slices immunostained for CD20, CD8 (Dako Cytomation, Denmark), CD3, CD4 (Novocastra Lab, UK).
The total population of endocrine cells was increased in inflamed bowel, especially in exacerbation, with EC-cells comprising the majority of the population (up to 70%). T/B ratio showed considerable decrease, CD4/CD8 appeared to be slightly decreased. Statistical analysis showed negative strong correlation between total lymphocyte count and total population of endocrine cells in remission, in exacerbation the correlation was strong and positive. CD8+ lymphocyte count was high in both inflamed and non-inflamed bowel in exacerbation of UC.
IN CONCLUSION we speculate that endocrine cells of the bowel may be involved in the pathogenesis of UC.

RADIATION COLITIS: A DETAILED HISTOPATHOLOGIC STUDY AND CORRELATION WITH ENDOSCOPIC FINDINGS
Panelos I1, Batistatou A1, Katsanos KH2, Briasoulis E3, Tsekeris P4, Economou M2, Christodoulou DK2, Bai M1, Capizzello A2, Karavasilis V3, Tsianos EV2, Agnantis NJ1
1Department of Pathology, 2Hepato-Gastroenterology Unit (1st Department of Internal Medicine), 3Department of Oncology, 4Department of Radiotherapy, University Hospital of Ioannina, Ioannina , Greece

Introduction: Ionizing radiation is known to cause radiation colitis (RC). The histopathological features of irradiation-induced early and late changes in bowel mucosa have not been analyzed in detail
Aim: The aim of the study was to characterize the histopathologic features of radiation-induced colitis and to correlate them with the endoscopic findings.
Patients-Methods: Twenty-three patients (12 females, 11 males; median age 63 years), suffering from rectal, cervical or prostate cancer were enrolled in the study and were followed up for a median of 13.5 months (range 6-32 months). All patients were treated by a linear accelerator (6 MV, box technique), with a median daily radiation dose of 1.9 Gy and a mean number of fractions, 28. They also underwent three endoscopies (sigmoidoscopies): before initiation of radiotherapy, immediately after the end of radiotherapy and at least six months after the end of radiotherapy. During sigmoidoscopy at least three colonic mucosa biopsies were taken. A new endoscopic grading system based on the RTOG/EORTC late radiation morbidity scale for large intestine and on endoscopic grading systems for inflammatory bowel disease was used for endoscopic grading of bowel mucosa. Clinical diagnosis of RC was based on patient symptoms, on sigmoidoscopy findings and on laboratory tests.
Results: Based on the histological features noted, the cases were allocated to one of four groups: no changes, acute injury, early regenerative changes and late regenerative changes. In total 12/23 patients (52.2%) were diagnosed with radiation colitis (RC). Acute radiation colitis was diagnosed in 4/23 patients (17.4%). None of these cases exhibited "eosinophil crypt abscesses." The correlation of histologically defined phases of RC and clinical/endoscopic findings was poor.
Conclusion: Radiation colitis is very frequent in patients irradiated in the pelvic area. The discordance between clinical/endoscopic and histopathologic findings could reflect the absence of relation between the presence and extend of histologically-defined radiation colitis and radiation-induced morbidity and mortality. Furthermore, it strengthens the need for a more global concept of radiation-induced bowel injury, incorporating bowel symptoms, performance status, radiation characteristics (dose-duration-timing), a new endoscopy grading system, a detailed histological analysis, laboratory tests and hospitalization.

FULMINANT CYSTIC FORM OF PNEUMATOSIS COLI ASSOCIATED WITH KAPOSI'S DISEASE IN A MAN WITH A KIDNEY GRAFT.
BARDIER-DUPAS A (1), HOANG C (1), MOUQUET C (2), TURRIN N (3), MENEGEAUX F(3), CAPRON F (1)

(1) Department of surgical pathology, (2) Anesthesia-intensive care unit, (3) Department of digestive surgery, Hôpital de la Pitié – Salpêtrière, 91 bd. de l'hôpital 75634 Paris cedex 13.

We report a first case of fulminant cystic form of pneumatosis coli associated with Kaposi's disease. A 57 year-old-man with Kaposi's disease (skin and lymph nodes), who had a kidney transplantation five years before because of nephroangiosclerosis, suffered from a pyelonephretic syndrome. TDM revealed a wide parietal pneumatosis coli. A right ileocolectomy was performed. Grossly, pneumatosis coli appeared as round, polypoid lesions covered by normal mucosa. It was associated with several black spotty maculas. Microscopic analysis demonstrated multiple empty spaces in the submucosa lined by histiocytes. The maculas were Kaposi's lesions anti-HHV8 +.

Pneumatosis is primary in only 15% of cases. The other cases are secondary to various predisposing conditions. The fulminant form of pneumatosis coli rarely occurs in adults, in whom it is associated with drugs, chemotherapy or with ischemic and pseudomembranous enterocolitis. Pneumatosis coli is also described in acquired immunodeficiency syndrome (AIDS). Such cases have been reported to follow a benign course, even when associated with infectious colitis. Benign form of pneumatosis coli resolves spontaneously in up to 50 % . Rare cases of pneumatosis coli require immediate surgery.

Introduction: Lamivudine is an effective drug for the treatment of CHB. Its long term effect on the activity and stage of CHB is still under investigation as it may induce viral mutations responsible for drug resistance and recurrence of inflammation.
Purpose of the study: A multicenter clinicopathological study of three years duration was undertaken in order to assess the long term effect of Lamivudine in patients with Hbe neg- anti Hbe pos CHB.
Materials: 137 patients entered the study (115• ‰, 22• Š) age 46.7+/- 11.7 years . A liver biopsy was performed at zero time (124/137), 12 months (109/124) and 36 months (39/124). HBV DNA serum levels were annually investigated.
Methods: Histological grade and stage were diagnosed using Ishak• fs classification system. Hbs and Hbc antigens were immunohistochemically detected, their topography was assessed and a semiquantitative method was used for evaluating the extent of their expression in hepatocytes. Statistical analysis was performed with the Wilcoxon Signed Rank Test and Mc Nema• fs chi Square statistic for alterations of grade, stage, Hbc, Hbs and serum HBV-DNA at zero time, 12 and 36 months (ms).
Results: Low HBV-DNA levels were sustained in 77% of patients at 36 ms (p=0.003) and they were unrelated to grade, stage or Hbs expression but with the extent of Hbc expression. There was statistically significant reduction of grade at 12 ms (p=0.0001) which was not altered at 36 ms. The stage of the disease remained steady throughout the study period with the exception of 3 cases with cirrhosis at 12 ms which returned to stage 3-4. There was marginal statistical significance of Hbc and grade (p=0.067) at zero time, which became significant at 12 and 36 ms (p=0.035, p=0.006 respectively). The quantity of Hbs expression was not altered throughout the study but an increase in submembranous localization was observed at 12 ms (p=0.035) with subsequent stabilization.
Conclusion: Lamivudine is a very effective drug for the treatment of CHB patients. It reduces the necroinflammatory response (grade), stabilizes the fibrotic process (stage) and results in sustained low HBV-DNA serum levels.

Needle biopsy of liver as reliable method in evaluation of disease activity with serological markers of Hepatitis B infection enable more detailed realization of histopatologic diagnosis. This study includes light microscopy (LM) and electron microscopy (EM) analyses of needle biopsy of 101 patients with Hepatitis B. Results of this analysis were compared with the level of serologic markers and antigens of HBV infection, which were collected contemporary with the biopsy. Analyzing of biopsy specimens demonstrated further types of lesions in liver tissue: minimal lesion (ML) in 10 biopsies and acute hepatitis (AH) in 17; chronic persistent hepatitis (CHP) in 51 biopsies; chronic active hepatitis (CAH) in 20 biopsies and cirrhosis (CH) in 3 biopsies. By recognition of pathohistological finding and correlation with serological markers of HBV infection we found that histology findings with advanced (high grade) necrosis in AH and CAH most frequently demonstrated the presence of HBeAg in distinction to the other antigens and antibodies of HBV infection, which were present with significantly lower quantity. In addition, the EM analysis in these morphologic categories most distinct demonstrated the ultrastructural lesions, particularly affection of the nucleoli of hepatocytes in the presence of HBeAg. This serological marker represents the viral infectivity factor and manifests the viral replication and hepatocyte destruction. This study confirms a direct proportion between hepatocyte necrosis, presence of HBeAg and changes in hepatocyte nucleoli, and therefore it contributes the recognition of pathogenesis of virus B hepatitis.

P 205

CORRELATION BETWEEN TGF-BETA1, VEGF, HGF, EGF, TGF-ALPHA AND FGF SERUM LEVELS AND NECROIMFLAMMATORY ACTIVITY AND FIBROSIS IN CHRONIC HEPATITIS C.

E. Janczewska-Kazek1, B. Marek2, D. Kajdaniuk 2
1. Department of Infectious Diseases, Medical University of Silesia, Chorzów
2. Department of Pathophysiology, Medical University of Silesia, Zabrze

Introduction: Liver fibrosis can be a result of chronic inflammatory processes of different etiology. The meaning of fibrosis is the accumulation of extracellular matrix components in liver parenchyma. This process is the result of disturbed balance between extracellular matrix protein

synthesis and degradation. It is supposed that growth factors taking part in classic 'wound healing' reaction may play the meaningful role in the similar process in the liver and their serum levels may reflect the intensity of liver lesions.
Aims: The aim of the study was evaluation of the mutual correlation between TGF-beta1, VEGF, HGF, EGF, bFGF, TGF-alpha levels and inflammatory activity grade and fibrosis stage, as an attempt to assess the role of growth factors in chronic hepatitis and fibrosis formation.
Methods: Study group included 100 chronic hepatitis C (CHC) patients (52 men and 48 women, mean age 42) with fibrosis (Scheuer score: inflammatory activity 1-4 points, fibrosis 1-4 points). Control group consisted of 30 HCVAb positive subjects (16 men and 14 women, mean age 41) with normal ALT level, none or minimal necroinflammation (Scheuer: 0 points) and without fibrosis (Scheuer: 0 points). Serum levels of TGF-beta1, VEGF, HGF, EGF, bFGF, TGF-alpha were measured by immunoenzymatic method. Correlation between studied growth factors levels and inflammatory activity grade and fibrosis stage was evaluated.
Results: Levels of TGF-beta1, HGF and TGF-alpha were significantly higher in study group than in control group (TGF-beta1 35,89 vs 32,37 ng/ml, p=0,023; HGF 1506,34 vs 1017,11 pg/ml, p=0,034; TGF-alpha 1,85 vs 0,26 pg/ml, p=0,0001). The significant negative correlation between VEGF, bFGF and TGF-alpha serum levels and the grade of inflammatory activity was observed (VEGF R=-0,40, p<0,01; bFGF R=-0,40, p<0,05; TGF-alpha R=-0,34; p<0,05). Only VEGF level correlated negatively with the stage of fibrosis (R=-0,30, p<0,05).
Conclusions:
1) HGF and TGF-alpha may play the role in chronic inflammation and liver fibrosis formation as well as TGF-beta1, which is well known fibrogenetic factor.
2) Increasing inflammatory activity is connected with decrease of VEGF, bFGF and TGF-alpha levels. All these factors have angiogenetic potential. It may suggest that liver tissue inflammation is connected with impaired angiogenesis. Levels of VEGF were also lower in patients with advanced fibrosis and cirrhosis.

The development of the liver carcinoma during chronic Hepatitis C is barely known. Mice transgenic for the full Hepatitis C Virus (HCV), which we have bred, develop hepatocarcinoma without immune disease. That suggest that HCV proteins are sufficient to induce the liver carcinogenesis. The aim of this work was to study the role of hepatocytic proliferation in carcinogenesis during infection with HCV. The liver is the only organ that can regenerate by multiplication of hepatocytes after hepatectomy at least 70%. Materials: 16 C57Bl6 male mice transgenic for the full HCV open reading frame (FL-N/35 lineage): HCV+, and 15 control mice: HCV-, were used. 27 animals underwent hepatectomy of 75% (12 HCV+, 15 HCV-) and were compare to 4 mice which underwent a white laparotomy. The anaesthesia used was an association of Ketamine-Rompin (1mg/kg). Animals were sacrified at 4 points of kinetic (1, 4, 18 and 48 hours after hepatectomy). The evaluation of hepatocytic proliferation was analysed by 3 methods: a-quantification of the weight of liver after death of mouse compared without weight considered left in place after hepatectomy. b-Immunochemistry detection of BrdU after nuclear incorporation. c-transcriptional analysis by Dot blot technical of 9 genes whose expression during hepatic regeneration is known (early expression: cfos, cmyc, MKP1; delayed expression: p53, p21, mdm2, gadd45; late expression: cyclin A and E). Results: liver regeneration were incomplete 48 hours after partial hepatectomy in the mice HCV+ and HCV-. The liver weight quantification and nuclear marking with BrdU reveals a delay of regeneration of HCV+ hepatocytes. Cyclin A, 48 hours after hepatectomy, is the only gene to have been activated in HCV+ hepatocyte compared to control mice and HCV- mice. The difference transcriptional expression of cyclin A between HCV+ and HCV- animals is compatible with an entry of HCV+ hepatocyte delayed in phase S. Discussion: The delay of liver regeneration in mice HCV- observed in our study is different from the data in the literature. That can be explained by the hepatotoxicity of anaesthesia. Indeed we observed an early transitory toxic microvacuolar steatosis in all mice. No excessive proliferation of hepatocyte were observed in HCV+ mice. Besides our results suggest delay of liver regeneration in HCV+ animals. These results could be the direct consequence of HCV proteins expression in liver.

P 207
THE POTENTIAL ROLE OF STELLATE CELL ACTIVATION IN LIVER BIOPSIES WITH HEPATITIS C COMPARED WITH HEPATITIS C/DIABETES MELLITUS
AC Tsamandas, D Dimitropoulou*, A. Liava, C Gogos*, CD Scopa.
Departments of Pathology and *Internal Medicine University of Patras Greece

Background: Hepatits C virus (HCV) infection is a major cause of chronic liver disease. Steatosis is a common finding both in HCV and in diabetes mellitus (DM). Hepatic stellate cell activation, manifested by the expression of smooth muscle actin (áSMA), is a major factor responsible for fibrosis and its progression in chronic liver disease. In this study we assessed and compared the degree of stellate cell activation in liver biopsies of patients with HCV alone and in patients with HCV/DM.
Patients and Methods: A total of 50 liver biopsies were evaluated: HCV (n=35), and HCV/DM (n=15). All biopsies were immunostained with the antibody for smooth muscle actin (áSMA). A grading system on a scale of 0-3 was applied reflecting the percentage of stellate cell activation which occurred in each zone of the hepatic lobule. Statistical analysis (t-test and Wilcoxon rank-sum test) was implemented to determine if stellate cell activation differed at a given stage of fibrosis, grade of inflammation and steatosis in comparing the aforementioned groups.
Results: The mean stage of fibrosis for the HCV/DM and HCV group were 2.8 and 1.6 respectively (p<.0001). The mean grade of inflammation for the HCV/DM group and HCV group were 1.9 and 1.5 respectively (p=0.03). The mean grade of steatosis for the HCV/DM and HCV group were 1.1 and 0.5 respectively (p=0.01). The average grade of stellate cell activation for all zones for the HCV/DM group and HCV group was 1.3 and 1.2 respectively (p=.39). However, in both diagnostic groups combined, a significant stellate cell activation was observed in periportal areas (zone 1) and portal tracts for higher stages (>2) vs lower stages (<2) of fibrosis (p<0.0001). In addition, a statistically significant increase in stellate cell activation was observed in zone 1 for the HCV/DM group (mean=1.5) as compared to the HCV group (mean=1.2) regardless of stage of fibrosis (p=0.02).
Conclusions: The results of this study imply that the activated stellate cells are predominantly present in periportal areas (zone 1), which correlates with advanced stages (>2) of fibrosis. Periportal stellate cell activation is significantly

increased in the HCV/DM group as compared to the HCV group.

P 208

THE ROLE OF SIGNALING PROTEINS STAT, JAK, SOCS AND PIAS IN RESPONSE TO COMBINED INTERFERON THERAPY FOR CHRONIC HEPATITIS C.

Jiøí Ehrmann jr. 1, Kvìtoslava Aiglová 2, Jiøí Ehrmann 2
1 Laboratory of Molecular Pathology & Department of Pathology, Faculty of Medicine, Palacký University, Olomouc, Czech Republic
2 IInd Department of Internal Medicine, Faculty of Medicine, Palacký University, Olomouc, Czech Republic

The currently used standard treatment for chronic hepatitis C using a dual combination of IFN alpha/RBV is only successful in 50% cases. With the exception of some clinical and biochemical factors, degree of inflammation (grading) and degree of fibrosis (staging), there are no other known markers which may serve as valid predictors of response to therapy. Interference of HCV with signaling pathways modulated by JAK-STAT, ERK1/2, NF-kappa B and MAP proteins is one mechanism which may influence the interaction between HCV and interferon. These proteins regulate different cell processes such as activation of cytokines, activation of apoptosis, regulation of cell proliferation etc. Therefore, it is possible that impaired signaling or inhibition/dysregulation of some of these proteins by HCV infection may cause resistance to IFN alpha treatment.
The aim of study was immunohistochemical assessment and analysis of expression of STAT 2, 3 proteins, their inhibitors SOCS 2, 3 and PIAS 3 and proteins JAK 1 and ERK1/2 in liver biopsies of 23 patients with chronic hepatitis C treated by dual combination IFN alpha/RBV and subsequent correlation of the results of immunohistochemical analysis (histoscore) with histological picture and clinical response to treatment.
The results show increased expression of STAT 3, STAT 2 and ERK 1 proteins and decreased expression of SOCS 3 and SOCS 2 in hepatocytes of patients with more marked inflammation and fibrosis. In patients with sustained virological response there was increased expression of SOCS 3 and JAK 1 and decreased expression of SOCS 2. Relapse was associated with increased expression of SOCS 3 and PIAS 3. However, owing to the small sample size, the results only approximated statistical significance, but we suggest that proteins of STAT family and their inhibitors SOCS and PIAS probably play an important regulatory role during response to treatment for chronic hepatitis C

P 209

SPECTRUM AND INCIDENCE OF SYSTEMIC MANIFESTATIONS IN CHRONIC HEPATITIS C OF LOW ACTIVITY.

T.P.Nekrasova,S.Yu.Karpov,P.E.Krel,T.N.Lopatkina,T.N.Krasnova,S.Yu.Milovanova

The aim of the present study is to evaluate extrahepatic manifestations of chronic HCV-infection with low grade and stage. In 58 patients with chronic hepatitis C (CHC) liver biopsy tissue specimens were histologically investigated. The spectrum of changes from mild piecemeal necrosis in few portal areas, mild or moderate lobular necrosis to mild or moderate portal inflammation and fibrous portal expansion was defined. Grading was done according to Knodell scoring system, and staging - according to Scheuer system. The histology activity index fell between 3 and 8. The stage was 1 in all cases. Systemic manifestations were observed in 23 patients. In 12 of them they were associated with cryoglobulinemia. Systemic manifestations included cryoglobulinemic vasculitis with skin and joint involvement, cryoglobulinemic glomerulonephritis, arthralgia without cryoglobulinemia. Independent risk factors for development of systemic disorders in CHC of low activity comprised gender, age over 45, the disease duration and presence of cryoglobulinemia. CHC with low activity is characterized by high occurrence of systemic manifestations primarily associated with cryoglobulinemia.

P 210

ULTRASTRUCTURAL EVIDENCES OF THE LYMPHOCYTE APOPTOSIS IN CASE OF HEPATITIS C VIRUS INFECTION

Valerie Groma (1), Valda Zalcmane (1), Natalja Makarova (1), Faina Nigmatjanova (2), Baiba Rozentale (2)
1 - Laboratory of Electron microscopy, Institute of Anatomy and anthropology, Riga Stradins university, Riga, Latvia
2 - Latvian Center of Infectology, Riga, Latvia

Recent studies do not provide a definite answer on whether the effect of hepatitis C virus infection (HCV), with respect to other etiologic factors of liver damage, is more an up- or a down-regulation of apoptotic process. An electron microscopy still remains a significant contributor to the study of events in apoptosis. Cell membrane blebbing and nuclear chromatin changes are hallmarks of the apoptotic cell death. This study aimed an ultrastructural characterization of the intralobular lymphocyte involvement in apoptotic process along the course of an acute HCV.
The liver tissue biopsies obtained from patients (11) with an acute HCV were processed for conventional transmission electron microscopy and further analysis of apoptotic events taking place within the liver lobule. The intrahepatic lymphocytes distributed within the sinusoids lumen, sinusoidal wall, perisinusoidal space, and along the intercellular space between the hepatocytes were selectively estimated in this study.
A prominent condensation of lymphocyte nuclear chromatin, compaction of cytoplasmic organelles, blebbing, and fragmentation into a great number of rather small apoptotic bodies were constantly present within the lumen of sinusoids. Macrophages detected ultrastructurally and using an appropriate (CD 68) immunohistochemical marker were detected in the close vicinity to the apoptotic bodies. Paired lymphocytes were rather often in the perisinusoidal space. Lymphocytes apoptotic changes were much more less common in this area comparing with the sinusoids lumen. Lymphocytes invading the intercellular spaces between the hepatocytes were single and paired, in some cases invading lymphocytes extended deep enough toward the bile canaliculi. Many of them caused a prominent depression on the hepatocyte surface, and expansion of the intercellular space. Some of these lymphocytes showed a prominent nuclear chromatin condensation, compaction of cytoplasm, and blebbing. Detection of the hepatocyte apoptosis was rare, and was restricted to the cell cytoplasmic shrinkage.
We can conclude that electron microscopy used in this study provides the evidences on the cellular behavior during apoptosis, and reveals the peculiarities in the lymphocyte distribution, type of invasion and cell death events along the acute HCV.

P 211

IMPACT OF APOPTOSIS ON THE SEVERITY OF CHRONIC HEPATITIS C

Akl M*., Zakaria S**., El Hindawi A.***, Hammam O*., Yehia H.**, El Raziky M.**,
Ibrahim R#, Fakhry S.#, El Behairy N#
Pathology* , Tropical Medicine# , Electron Microscope** Departments ,Theodor Bilharz Research Institute. Tropical Medicine** and Pathology ***Departments, Faculty of Medicine, Cairo University.

Realizing that chronic hepatitis c (CHC) is one of the important health problems in Egypt, this work is designed to study the impact of apoptosis on the parameters concerned with the severity of the disease. The study involved 57 patients diagnosed as pure CHC, according to full clinical history , examination and laboratory investigations to exclude any other associated pathology. All patients were subjected to pelvi-abdominal sonography, upper endoscopy, rectal snips, liver needle biopsies, serological tests for viral markers and liver functions . Immunohistochemical (IHC) studies using both the monoclonals; anti-fas and anti p53 mutant gene were performed on liver sections. Five control cases were included. Electron microscopic (EM) study for a sample of 8 cases was performed.

Apoptosis was focally demonstrated in liver sections by Hx and E stain and via IHC technique by detecting the localization and distribution of Fas antigen (for apoptosis) within the liver tissue. Pathologically patients were classified according to the grades of inflammatory activity into 3 classes; patients with mild inflammatory activity (Gr 1); 38.6%, patients with moderate inflammatory activity (Gr 2); 29.8% and those with severe inflammatory activity (Gr 3); 31.6%, Clinicopathologically; significant elevation of ALT and AST levels were detected with Grs 2 and 3 inflammatory activity compared to both control and Gr 1, inflammatory groups. Fas positivity within hepatic tissue sections was found significantly correlated with the increasing grades of inflammatory activity, stages of fibrosis, serum ALT, AST, ALP, Albumin and HCV-RNA viremia levels in all the studied patients. EM study identified early and advanced ultrastrctural hepatocytic apoptotic changes . P-53 was over expressed in 29.8% of the studied liver cases and showed significant direct correlation with the increase in inflammatory activity.

It was concluded that apoptosis through Fas antigen is a main mechanism of liver cell injury in Egyptian pattern CHC and is in parallel correlation with its biological markers and grades of inflammatory activity. Hepatocytes in variable stages of apoptosis could be localized in periportal areas by fas antigen, light microscope and EM. Mutant p53 is over expressed in the precocious stages of CHC-related liver damage before carcinogenesis. We suggest the term: “apoptotic activity” instead of 'necro-inflammatory' activity, in describing CHC interface areas.

P 212

HEPATIC EXPRESSION OF ENDOTHELIAL NITRIC OXIDE SYNTHASE (ENOS) AND VASCULAR ENDOTHELIAL GROWTH FACTOR (VEGF) IN CHRONIC HEPATITIS C AND SCHISTOSOMAL LIVER DISEASE

BADAWY Afkar, and HAMMAM Olfat.
Department of Pathology, Theodor Bilharz Research Institute. Cairo, Egypt

Immunohistochemical hepatic tissue expression of endothelial nitric oxide synthase (eNOS) that has important function in inflammation and vasoregulation, and vascular endothelial growth factor (VEGF) which plays a role in new vascularization in liver tissue of patients with chronic hepatitis C (n=25),schistosomal liver disease (n=6) ,and mixed schistosomal and chronic hepatitis C infection (n=7) were semiquantitated and correlated to hepatic histological features of inflammation and fibrosis. Control liver tissue (n=5) were collected during cholecystectomy. In control liver eNOS and VEGF were expressed in endothelial cells lining sinusoids and portal vessels and in hepatocytes. Hepatic tissue with chronic hepatitis C or Schistosomal liver disease over expressed both eNOS and VEGF, this over-expression was insignificant versus control group and between each other. Hepatic tissue with concomitant chronic hepatitis C and Schistosomiasis had significant endothelial over-expression of eNOS versus livers with chronic hepatitis C ($p > 0.05$) and control liver ($p > 0.01$) ,and of VEGF versus livers with chronic hepatitis C ($p > 0.05$). Endothelial expression of eNOS and hepatocytic expression of VEGF significantly raised in higher degree of inflammatory activity and in higher fibrotic stage ($p > 0.05$) in hepatic tissue of chronic hepatitis C (with or without Schistosomal co-infection) .

In conclusion: endothelial NOS and VEGF over expressed in chronic hepatitis C and in Schistosomal liver disease without definite correlation between their expression suggesting different regulatory mechanisms. Endothelial NOS is expressed mainly by endothelial cells and to a lesser extent by hepatocytes which are the main cells expressing VEGF. Co-incidence of Schistosomiasis with chronic hepatitis C accentuates over expression of both eNOS and VEGF proteins indicating that Schistosomiasis is a risk factor for haemodynamic disturbance in chronic viral hepatitis.

POSITIVE CORRELATION BETWEEN IGF-IR EXPRESSION AND EXTENSION OF PARENCHYMAL LESIONS IN CHRONIC HEPATITIS C

Stefano JT 1, Correa-Giannella ML 1 , Ribeiro CMF 2, Alves VAF 1, Massarollo PCB 1 Machado MCC 1, Giannella-Neto D 1
University of Sao Paulo School of Medicine 1
Santa Casa de Misericordia de Sao Paulo 2

The Insulin-Like Growth Factor (IGF) system is an attractive target of study, since it may be modified by liver diseases and, reciprocally, it might play a relevant role in the evolution of some hepatic diseases. This system is comprised of two ligands, IGF-I and IGF-II, their specific receptors, IGF-IR and IGF-IIR, and the IGF-binding proteins. IGFs are peptides involved in proliferation, differentiation and inhibition of apoptosis of several cell types. IGF-IR was shown capable to mediate both IGF-I and IGF-II signalling, whereas IGF-IIR is only able to decrease the bioavailability of IGF-II. Although increased IGF-IR gene expression has been reported in hepatocellular carcinoma and in human hepatoma cell lines, studies assessing IGF-IR in chronic hepatitis C (CHC) and cirrhosis are scarce.

The objective of this study was to evaluate the hepatic expression of IGF-IR in patients with CHC. Thirty five patients with CHC were selected according to clinical, serological, and biochemical criteria. IGF-IR expression was determined by semi-quantitative RT-PCR and by immunohistochemical analysis of liver fragments obtained before treatment. In ten patients, liver biopsy was performed within one month after the end of combined treatment with *f*Ñ-2a or *f*Ñ-2b interferon and ribavirin for 48 weeks.

An increase of IGF-IR mRNA content was observed in hepatic tissue from all patients in comparison to normal liver. The immunohistochemical findings suggested these raises in mRNA content are related to increased IGF-IR expression in hepatocytes. There was a positive correlation between IGF-IR mRNA expression and the extension of parenchymal lesions. A statistically significant decrease in IGF-IR mRNA content was observed in patients who achieved sustained virological response after therapy with interferon-*f*Ñ and ribavirin, suggesting an improvement in hepatic damage. Previous studies demonstrated that normal hepatocytes in vitro do not proliferate in response to IGF-I probably due to downregulation of IGF-IR promoted by locally produced IGF-I. The finding of increased IGF-IR expression in hepatocytes in CHC raises the question whether IGF-I, together with other growth factors such as HGF and TGF*f*Ñ, directly participate in liver regeneration in this condition. It remains to be elucidated if IGF-IR upregulation results from direct activation of IGF-IR gene by HCV or if it is a consequence of chronic aggression to hepatic parenchyma.

POST-TRANSPLANT RECURRENT HEPATITIS C - IMMUNOHISTOCHEMICAL DETECTION OF HCV CORE ANTIGEN AND POSSIBLE PATHOGENIC IMPLICATIONS

Mario G Pessoa, Venancio A F Alves, A Wakamatsu; G Maertens, B van der Borght, Joaquim Guanaes; Linda Ferrell, Teresa Wright
Sao Paulo University, Sao Paulo, Brazil; InnoGenetics, Ghent, Belgium; University of California, San Francisco, CA

Background: The mechanisms by which severe cholestatic hepatitis develops after liver transplantation are not fully understood. Reports on immunohistochemical distribution of HCV antigens are still scarce, but recently, HCV immunostaining was suggested for early diagnosis of cholestatic forms of recurrent hepatitis C in liver grafts. Design: After purification, Rb246 pab anti-core (aa1-68) yielded specific, granular cytoplasmic staining in hepatocytes. Signal amplification through Peroxidase-anti-Peroxidase avoided endogenous biotin. Rb246 was applied to liver samples of explants of 14 transplant recipients, 7 with the most severe form of posttransplantation recurrence (group 1) and 7 with mild recurrence (group 2). We also detected immuno-reactivity at 2 time-points posttransplantation (6 mos and 2 years) in both groups. HCV-core Ag was semi-quantified from 0 to 3+ in each time-point. HCV-RNA was also measured on the different time-points by branched DNA. Results and Conclusions: In the early post-transplant time-point, 1 patient had a mild staining (1+) and 2 patients had a moderate staining (2+) in group 1, compared to 6 patients with no staining (0) and 1 patient with mild staining (1+) in group 2. Late post-transplant liver samples were not available in all patients, but only 2 had a mild staining in group 1, compared with no patients in group 2. Strikingly, on the pre-transplant samples, HCV immunostaining was strongly positive in group 1 and mildly positive in group 2. HCV-RNA was significantly higher in group 1, on both time-points post-transplantation. HCV-core Ag was not direct associated to HCV-RNA on the different time-points. These preliminary results suggest that strong HCV immunostaining in the explant is predictive of more severe disease recurrence.

GRANULOMAS IN LIVER BIOPSIES OF CHRONIC HEPATITIS C VIRUS.

MULARCZYK Marius (1), THEBAULT Sophie (1), DANJOUX Marie (2), CUZIN Lise (3), BARANGE Karl (4), KAMAR Nassim (5), VALMARY Sèverine (2), SELVES Janick (2).
1: Service de Médecine Interne, 2: Service d'Anatomie Pathologique, 3: Service des Maladies Infectieuses, 4: Service d'Hépatologie, CHU Purpan, place du Dr Baylac, 31059 Toulouse. 5: Service de Néphrologie, CHU Rangueil, Avenue J Poulhès, 31403 Toulouse.

Introduction : Granulomas are well known findings in the liver biopsies of hepatitis C Virus (HCV)-infected patients. Frequency of those lesions is variously appreciated, from less than 1 to more 10%. The prevalence of granulomas and their relation to the severity of the liver disease will be discussed.
Methods : Between 01/01/2000 and 31/12/2003, 1654 liver biopsies were done in HCV-infected patients and read in a single pathology university laboratory. All results were retrospectively analysed in search for granulomas.
Results : Sixty four biopsies (4%) showed granulomas. Among those, 34 were steatosis-associated lipogranulomas, and 30 corresponded to true epithelioid granulomas. Only the 30 epithelioid granulomas were included in further analysis. They were classified in 3 groups. Group 1 consisted of 13 biopsies, showing granulomas surrounding exogenous inclusions (9 from patients undergoing dialysis and 4 drug-induced granulomas). Group 2 consisted of 7 biopsies with known aetiology: 2 sarcoidosis, 2 tuberculosis, 2 primary biliary cirrhosis (PBC), and 1 atypical mycobacterial infection in an HIV-positive patient. Group 3 consisted of 10 biopsies (0.6% of 1654) with no evident aetiology apart from HCV-infection. Two out of these were portal tracts' epithelioid granulomas surrounding biliary ducts, with associated cirrhosis. These patients had negative anti-mitochondrial antibodies (AMA). The last 8 presented with small and lobular epithelioid granulomas, with moderate fibrosis (less or equal to F2 for METAVIR score) excepted in one patient who had cirrhosis.
Conclusion: In our study, HCV-related granulomas without any other known aetiology were rare (0.6%) and of mild severity. Nevertheless, we found 2 isolated cases with particular pathological features consisting of cirrhosis with portal epithelioid granulomas surrounding biliary ducts in patients with negative AMA. These histological lesions evoke "PBC-like" disease.

Introduction: Liver steatosis plays a central role in the pathogenesis and disease progression of chronic hepatitis C. Evidence has shown that HCV genotype 3 infection is associated with higher rates of steatosis and this is due to a cytopathic viral effect. The aim of the present study was to correlate the occurrence and severity of liver steatosis with the presence or absence of co-factors in chronic HCV genotype 1 and 3 infection.
Material and Methods: We have retrospectively assessed steatosis in biopsy specimens from 239 patients with chronic hepatitis C. Biopsies were divided in a) Group A: 125 biopsies from patients with no metabolic co-factors and Group B: 114 biopsies from patients with metabolic co-factors (alcohol intake, type II diabetes, obesity, lipidemia). Our results were further analyzed according to HCV genotype.
Results: Group A: Steatosis was found to be present in a significantly higher rate in patients with HCV-3 infection (70.7%) compared to 56.2% of patients with HCV-1. In both HCV-1 and 3 infection steatosis was mainly of low grade (HCV-3: grade 1, 44.8%, grade 2, 12.2%, grade 3, 8.6% HCV-1: 37.5%, 12.5%, 6.3% respectively). Group B: The results were similar to those of Group A (57.1% for HCV-1, 70% for HCV-3). However, higher grades of steatosis were noticed, mainly in HCV-3 infection (HCV 3: grade 1, 25%, grade 2, 21.7%, grade 3, 23.3%. HCV-1: 31.4%, 29% and 5.7% respectively).
Conclusions: Our results show that a) HCV-3 infection is more frequently associated with the occurrence of hepatocyte steatosis b) Steatosis is mainly related to a viral effect and c) Metabolic factors aggravate steatotis produced by the virus itself.

LIVER CELL APOPTOSIS AND PROLIFERATION IN HCV INFECTED RENAL TRANSPLANT PATIENTS

Ioanna Delladetsima1, Paraskevi Alexandrou1, Mina Psichogiou2, George Nikolopoulos2, Alkiviadis Kostakis3, Angelos Hatzakis2, John Boletis3

1Dept of Pathology, Laiko General Hospital, 2Dept of Hygiene and Epidemiology, National Retroviral Center, Athens University Medical School, 3Transplantation Center, Laiko General Hospital, Athens, Greece.

Background-Aims: The role and prognostic significance of hepatocellular apoptosis and regeneration in liver disease of HCV infected renal transplant patients (RTx) remain unclear. In the present study hepatocellular apoptosis and proliferation activity (PA) were assessed in liver biopsies (LBs) of RT patients with HCV infection and were correlated with hepatitis-necroinflammatory activity (grade and stage), disease outcome, viremia and genotype.
Methods: Ninety liver biopsies including 31 follow up biopsies were examined histologically. DNA fragmentation was detected by TUNEL assay and PA by immunohistochemical ki67 expression. Apoptotic index (AI) and PA were defined by the number of positive hepatocytes per 10 High Power Fields (1000 cells)and were classified in three categories ranging from 0-5 cells and from 0-1,35 cells respectively. HCV RNA levels and genotype were also determined.
Results: Histological evaluation revealed no significant changes in 8 (13,6%), acute hepatitis in 2 (3,4%) and chronic hepatitis in 49 (83%) cases. A low apoptotic index (AI) (0-2,5) was observed in 31 (52, 5%) and a high (>5) in 12 (20,3%) cases. There was no PA in 22 (37,9%) cases whereas it was >1,35 in 17 (29,3%). By univariate analysis the AI showed a significant correlation with viral load, resulting in 1 log10 higher HCV RNA levels in those patients with high number of apoptotic cells (p=0,003). This finding was verified by multivariate analysis (OR=6,67, 95% CI 1,4-30,9, p=0,015). Both variables did not show any significant correlation with hepatitis grade and stage, disease progression and genotype, whereas a significant positive correlation was observed between AI and PA (p=0,03).
Conclusions: Apoptotic cell death seems to be pathogenetically associated with high viral load probably through a direct cytopathic pathway. The low PA points towards a suppressed liver cell proliferation, which may be linked to viral effects and/ or the immunosuppressive therapy.

P 218
A STANDARDIZED AND COMPUTERIZED PATHOLOGICAL REPORT FOR CHRONIC HEPATITIS C : A SIX YEARS EXPERIENCE.
LE BAIL Brigitte, BIOULAC-SAGE Paulette

Since 1999, we have been using a standardized and computerized pathological report (SCPR) for liver biopsies with chronic hepatitis C in our department of Pathology, with annual revision of its content. Here we present the initial SCPR, its evolution, and the evaluation made by clinicians and pathologists.
The SCRP was developed by one of us in May 1999 on Diamic ® laboratory sofware (Infologic, France), based on a Word interface. It consists in a basic text with missing items to be filled using a panel of predetermined and preregistered answers, with either simple or multiple choice; after that, modifications/addition of data can be made. At first, the basic text and the answers were stricly based on the grid and the algorithm for histological evaluation published by the METAVIR group.
For 6 years, 1718 reports were made by 3 pathologists. They used the SCPR immediately and systematically. This adhesion was favored by the previous use of a paper form for METAVIR grid. Further changes included the introduction of new answers, the development of multiple choice items and of an arborescence of answers, all resulting in more accuracy and flexibility in the description of histological parameters, and in the conclusion, possibility to notify the degree of diagnostic fiability, and to add a secondary diagnosis with clinical consequences, such as steatohepatitis, auto-immune hepatitis, iron overload, or liver cell dysplasia. As a mean, the SCPR is now one full page, 400 words, and 31 lines. During the last revision based on 200 consecutive SCPR, we found 149 (74.5%) reports to be strictly conform to the bible text; for the remaining 25.5%, the small variations observed had to do with the evaluation of fibrosis: difficulties in establishing the stage of fibrosis (n=22) or quantification of peri-centrolobular/-cellular fibrosis, which lead us to the last modifications.Clinicians find this SCPR very well adapted for the diagnosis, prognosis and follow up of patients with hepatitis C, either isolated or associated with other hepatopathies. Pathologists appreciate the quickness of the making the report (120 seconds as a mean), and its didactic and pedagogic values. Furthermore, all necessary data are present and ready for statistical evaluation without reexamination of the slides.
In conclusion, the SCPR for hepatitis C reporting appears as a simple, quick, systematic, reproductible and flexible tool adapted to the clinicians and pathologists needs.

P 219
CORRELATION BETWEEN INTRAHEPATIC EXPRESSION OF HLA-DP / DR, INTERCELLULAR ADHESION MOLECULES AND T HELPER LYMPHOCYTES IN CHRONIC VIRAL B AND C HEPATITIS
BUTUR Georgeta 1, CEAUSU Mihai 1, VASILESCU Florina 1, IOSIF Cristina 1, FLOREA-GRAMADA Zenaida 1, ANDREI Florin 1, ARDELEANU Carmen 1
1 – "Victor Babes" National Institute of Pathology, Bucharest, Romania

The specific cellular immune response in the liver against HBV and HCV chronic infections requires the cooperation between professional and occasional antigen presenting cells (APC) e.g.: Kupffer cells, macrophages, hepatocytes, endothelial cells and lymphocytic subpopulations.
The aim of the study was the assessment of HLA-DP / DR expression and intercellular adhesion molecules on hepatocytes, correlated with activated level of CD4 helper T cells in chronic viral hepatitis.
Indirect tristadial immunohistochemical ABC method was performed on liver biopsies taken from 20 patients with single and double infections, using HLA-DP, HLA-DR, CD54, CD44, CD4 antibodies.
Using regressive biostatistic analysis, a positive direct correlation between HLA-DP/DR and CD44 was observed ($r = 0.46$) with statistical significance ($p = 0.04$). In double infections ($n = 5$ cases), HLA-DP/DR expression had a positive correlation with CD4 ($r = 0.56$), but without statistical signification ($p = 0.3$). In HCV infections, a positive correlation statistically highly significant, between CD44 and CD54 was found ($r = 0.78$, $p = 0.002$). Between CD44 expression and CD4+ infiltrating cells, a negative correlation statistically significant was established ($r = - 0.6$, $p = 0.008$). Activated level of CD4+ lymphocytes assessed by CD44 had a negative relationship ($r = -0.44$), statistically significant ($p = 0.04$).
During hepatic chronic viral infections, decreasing of T helper cells number in inflammatory infiltrate is associated with a significant activation degree of the same lymphocytes and with an increased expression of accessory molecules on hepatocytes, suggesting a by-pass of professional APC which can maintain a necro-inflamatory microclimate.

Background and Aims: Chronic hepatitis C virus (HCV) is a major health problem in Egypt, where genotype 4 is the most prevalent. There is increasing evidence, from recent studies, suggesting that liver damage in chronic HCV genotype 1 and 3 is mediated by the induction of apoptosis. The aim of this study were to assess hepatocytic apoptosis in chronic HCV patients, correlate it with disease severity, and to identify possible mechanisms of apoptosis induction.
Methods: The study included 57 selected patients diagnosed on clinico-pathological and virological basis as chronic HCV , in addition to five control cases. Liver specimens were studied according to the grade of inflammation, stage of fibrosis and extent of steatosis. Immunohistochemical (IHC) studies using both the monoclonals; anti-Fas and anti-p53 mutant gene were performed. Electron microscopic (EM) study for 8 cases were done.
Results: Apoptosis was focally demonstrated in routinely stained liver sections and intensely by detecting Fas antigen expression in 84.2% of patients compared to no expression in controls. A positive correlation was observed between Fas expression and grades of inflammation , stages of fibrosis, serum alanine amino-transferase (ALT), aspartate amino-transferase (AST), alkaline phosphatase (ALP) , and viral load. p53 was over expressed in 29.8% of patients, showing significant direct correlation relative to the grades of activity, stages of fibrosis, serum albumin and bilirubin levels, ALP and viral load. Significant direct correlation were detected between hepatic steatosis and both Fas and p53 positivity. EM study identified the ultrastructural features of apoptotic changes within hepatocytes.
Conclusions: Hepatocyte apoptosis through Fas antigen expression is significantly increased in Egyptian patients with chronic HCV and correlates with disease severity. We suggest the term "apoptotic activity" instead of "necroinflammatory activity" in describing chronic HCV interface areas. Mutant p53 is over expressed in the precocious stages of HCV related liver damage before carcinogenesis indicating close follow-up.

HISTOPATHOLOGICAL STUDY OF CHRONIC HEPATITIS C: EVALUATION OF PERISINUSOIDAL FIBROSIS AND COMPARISON OF SCORING SYSTEMS

CELIKEL Cigdem Ataizi*, AKPULAT Sertac*, TIFTIKCI Arzu**, AVSAR Erol**
Marmara University School of Medicine, Departments of Pathology* and Gastroenterology**

Background/Aims: Needle liver biopsy has been shown to be the "gold standard" in assessing the histopathological degree of liver damage which is essential for the routine care of patients with chronic hepatitis C virus (HCV) infection. Several scoring systems have been proposed to standardize the morphological features seen in HCV. Although it is a characteristic feature for steatohepatitis, it is well known that perisinusoidal fibrosis may also be seen in viral hepatitis. In this study, our aims were to determine 1) the interobserver reliability of the different scoring systems, 2) the correlation between the scoring systems, 4) the correlation of necroinflammatory activity in different scoring systems with the serum transaminase levels, 3) the incidence of pericellular fibrosis in HCV and its relation with different histopathological features. Methods: Liver biopsies stained with H&E and trichrome from 96 chronic HCV cases were re-examined and scored by two independent pathologists using Knodell, METAVIR, Scheuer, and Ishak systems. Pericellular fibrosis was scored semiquantitatively according to Brunt et al. (0= no fibrosis, 1= <33%, 2= 33-66%, 3= >66%). The results were analysed using Kappa statistics and chi-square test. Results: While all the systems used produced moderate agreement when necroinflammatory score (NIS) was assessed, the ISHAK system produced slightly higher (k=0.64) values. NIS showed poor correlation with serum transaminases in all systems (k< 0.30) except Ishak score which was moderate (k=0.47). Concordance between the different scoring systems is good for NIS, and excellent for fibrosis score. Perisinusoidal fibrosis was present in 54.2 % of the cases and no correlation could be identified with any of the histopathological features including degree of steatosis and pericentral necrosis. Conclusions: While all systems produced reasonable agreement, this was greater in the Ishak system, especially concerning NIS. Perisinusoidal fibrosis was not a rare morphological change which had no relation with any of the histopathological features examined and its role in the prognosis of HCV patients needs to be determined with prospective studies.

P 222
CORRELATION BETWEEN IFN-MEDIATED SIGNAL PROTEINS EXPRESSION LEVELS IN LIVER TISSUE AND THE PREVALENCE OF HCV INFECTION.

Dolores Bautista*, Alicia Millan* and Elena Baixeras§.
*Department of Pathology and §.Fundación IMABIS. Hospital Regional Universitario Carlos Haya. Málaga. Spain.

Hepatitis C virus (HCV) affects to 2% of occidental population. Interferon (IFN) is the main antiviral agent. At present, patients with chronic hepatitis C are treated with recombinant IFNa in combination with ribavirin. However, only 30% of patients are responders to this therapy. The molecular mechanisms of HCV and IFNa interactions are not fully solved. IFNa subtypes constitute a family of 13 polypeptides coded by different genes that interact with the same receptor while eliciting distinct antiviral and antiproliferative actions. Recently, in vitro data demonstrated that HCV is able to counteract the IFN signal at very early stages affecting Jak/STAT pathways. Thus, it suggests that HCV bypasses endogenous IFN-mediated signal probably making useless the current therapies with IFN in the majority of patients. In the present study we focus our interest on the expression of proteins involved in IFNa mediated signalling pathways in tissue liver samples from HCV patients and control donors. We sought to determine the correlation between the presence of HCV and the physiological expression levels of STAT proteins and their protein activation modulators (SOCS) that could explain the failure of IFN treatment in the majority of HCV patients. To this aim, we have developed tissue arrays technology and analysis by microscopy. We found robust and higher expression levels of STAT1 and STAT2 in HCV patients when compared with healthy donors. Moreover, expression of these proteins are restricted to nuclear localization in hepatocytes, thus indicating that at least the early-IFN response is functional in these patients. SOCS protein expression were also investigated and results are discussed.

Bright liver is not an uncommon abdominal ultrasonographic finding in the daily medical practice. Objectives: This study aims at evaluation of the clinical, laboratory and pathological aspects of cases presenting with Simple Steatosis (SS) and Non Alcoholic Steato-Hepatitis (NASH) in Egypt.
Methods: Seventy five subjects with bright liver by abdominal ultrasonographic examination were enrolled for this study. According to their virological markers they were selected so as: 60 subjects were sero- negative for chronic hepatitis B(HBV)and chronic hepatitis C (HCV), whereas 15 subjects were anti- HCV sero- positive. All patients were subjected to full clinical and laboratory investigations with special emphasis on risk factors of hepatic steatosis, and to needle liver biopsy.
Results: Hepatic Steatosis is a disease of both sexes, female: male ratio is 1.9:1. It occurs mostly in the fourth and fifth decades of life. Risk factors are: obesity, diabetes mellitus, hypertriglyceridemia. Main complaints are easy fatigue, right hypochondrial pain. On histopathological assessment: NASH was present in 60% of the studied patients among whom mixed micro and macro vesicular hepatocytic steatosis was noted with moderate and severe affection. Eighty-seven percent of patients with SS had a micro steatotic pattern with minimal to mild degree of affection. Chronic hepatitis C patients exhibited micro vesicular pattern in 46.7% and mixed pattern in 53.3% of biopsies. ALT and triglycerides were significantly higher in NASH than SS with positive correlation between their levels and histopathological scoring of hepatic steatosis. AST/ALT ratio was <1 in 90% of cases.
Conclusion: NASH is an emerging disease entity in Egypt which might be a cause of progressive chronic liver disease.

Introduction. Prognosis of chronic HCV infection depends on fibrosis progression in the liver. Previous data concerning rate of fibrosis progression and results of HCV therapy show possible significance of virus genotype and necroinflammatory grade. Semi quantitative assessments of fibrosis and necroinflammation are currently regarded as a routine procedure, but it is obvious that these methods are subjective. Alternative method is comparative morphometrical analysis of repeat liver biopsies.
Aim. The aims of this study were to assess rate of fibrosis progression by investigation of primary and repeat liver biopsy HCV-infected patients and to identify factors, connected with prognosis.
Methods. Paired liver biopsies from 60 patients (age 26-45 years) with chronic HCV were studied. RT-PCR was used for detection of HCV-RNA and its genotype. Patients were non-treated before primary biopsy, 20 patients were treated by _ interferon/riboverin in standard dose between biopsies. The same pathologist scored paired biopsies from the same patient, applied V.J.Desmet (1994) and R.G.Knodell (1981) semi quantitative assessments. Software SigmaScan Pro 5.0 was used for morphometrical analysis. Sections were stained by Masson Trichrome method. Fibrosis index (FI) was calculated as collagen area divided all section area.
Results. Our results showed that 66,6% of patients had 1b genotype of HCV. Genotypes 2a and 3a were found rarely (12,5% and 37,5%). 12,5% of patients were with mixed genotype 1b-3a. Investigation of primary liver biopsy showed predominantly mild and moderate necroinflammation and fibrosis of liver in case of 1a or 1b HCV genotype, without significant difference (Knodell 5, Desmet 1-2, IF 0,01-0,03). Significantly marked necroinflammation (Knodell 9 and more) were in the biopsies from patients, that were infected 3a or mixed 1a-3b HCV genotype. Liver fibrosis stage (IF, Desmet) did not correlate to inflammation degree. Morphometrical investigation of paired biopsies showed that the majority of treated patients showed no progression of fibrosis (invariable IF, or moderate reducing from 0,03 to 0,01). Our data indicated fibrosis progression in repeat biopsy if patients were older than 40 years or had marked fibrosis (Desmet 3, IF 0,1) in primary liver biopsy.
Conclusion. Our results suggest good correlation between histological activity and HCV genotype. Success of therapy depends on fibrosis range and age of patients at the time of primary biopsy.

LIVER HISTOLOGY IN PATIENTS WITH SPORADIC ACUTE HEPATITIS E : A STUDY OF 11 PATIENTS FROM SOUTH-WEST FRANCE.

MISSOURY Réda (1), POIRSON Hélène (2),PERON Jean-Marie (2), VINEL Jean-Pierre (2),MANSUY Jean-Michel(3), BUREAU Christophe (2), IZOPET Jacques(3), BROUSSET Pierre (1), SELVES Janick(1).
1: Service d'Anatomie Pathologique, 2: Service d'Hépato-gastro-entérologie, 3: Laboratoire de virologie, CHU Purpan, Place du Dr Baylac, 31059 TOULOUSE

Hepatitis E virus (HEV) is responsible for acute hepatitis predominantly in developing countries. Sporadic cases have been described in industrialized countries but information on hepatic histology in these cases is scarce. We describe a series of 11 patients with sporadic acute hepatitis E and a liver biopsy. Methods: Liver biopsy was performed because of clinical suspicion of underlying chronic liver disease or uncertain etiology of the acute episode of hepatitis despite though diagnostic evaluation. HEV IgG antibodies were detected using an immuno-enzyme assay. HEV RNA was detected in the serum and feces with a real time PCR. All serums were negative for hepatitis B virus antibodies and DNA, hepatitis C virus RNA and antibodies, immunoglobulin-M class to hepatitis A virus, CMV and EBV. Anti-nuclear, anti smooth-muscle and anti LKM antibodies were also negative. Toxic and drug induced hepatitis were ruled out on anamnesis. Results: Eleven patients, 3 females and 8 males diagnosed with acute hepatitis E from march 1997 to march 2004 had a liver biopsy. Mean +/- SD age was 61 +/- 13. Overall 45% of the patients had an exaggerated alcohol consumption. Liver biopsy was transjugular in 5 cases. Five patients had confirmed histological micronodular cirrhosis. Four had exaggerated alcohol consumption on anamnesis (> 40 g/d). Two of these had lesions of acute alcoholic hepatitis including Mallory bodies, neutrophil infiltrates and steatohepatitis. The other 2 had mild steatohepatitis without Mallory bodies. All the other patients (1 with cirrhosis, 1 with mild fibrosis and 5 without fibrosis) had important spotty necrosis of hepatocytes with polymorph inflammation in the lobule. Anisocaryosis was present in most patients. Ballonisation was observed in only one case. No viral inclusions or epithlioïd granuloma were observed. In portal tracts, inflammation was marked with numerous neutrophils in almost all cases and moderate piecemeal

necrosis in only 2 cases. Bile duct damage was mild and ductular proliferation various. Cholestasis was observed in 4 cases. There was no phlebitis. Conclusion. Cirrhosis and alcohol consumption was frequent in this population of patients hospitalized for acute hepatitis E raising the question of their interaction. Characteristic pathology signs of acute hepatitis E were hepatocyte intralobular necrosis, polymorph inflammation and neutrophils in portal tract.

P 226

THE SIGNIFICANCE OF SMAD4 EXPRESSION IN THE PROGNOSTIC EVALUATION OF THE CHRONIC HEPATITIS

Esra Erden, Aysegul Yalcinkaya, Berna Savas, Hulya Cetinkaya, Hakan Bozkaya, Cihan Yurtaydýn
Ankara University, Medical Faculty, Department of Pathology and Department of Gastroenterology,Turkey

Introduction and Objective: We aimed to compare SMAD4 expression and fibrosis in the pre and post-treatment hepatic biopsies
in cases with chronic hepatitis B, chronic hepatitis C and chronic hepatitis D.
Materials and Methods: We examined the hepatic biopsies of thirty one chronic hepatitis C and 40 chronic hepatitis B cases, 4 chronic D hepatitis which were diagnosed at our department. The cases were reexamined, staged and graded according to modified Ishak and Metavir scoring systems. Immunohistochemistry was performed using antibody against SMAD4 and nuclear SMAD4 staining in perisinusoidal cells having oval nuclei and sprouting vacuolar cytoplasm was accepted as positive.
Results: When SMAD4 cut-off value 0,263 was chosen, 89 percent of the patients having SMAD4 expression below this level showed regression in fibrosis. Patients having SMAD4 expression more than 0.263 cut-off value showed fibrosis progression. This progression was calculated as 77,7 percent when the cases evaluated according to Metavir system and 81 percent when they were evaluated according to the modified Ishak. In cases with SMAD4 cut-off value below 0,184 the stage decreased in 96 percent of the patients. Median SMAD4 expression was found significantly higher in cases with chronic hepatitis C.
Conclusions: Our results showed a significant correlation between SMAD4 expression and fibrosis. Therefore, we conclude that it is necessary to observe the SMAD4 expression in pretreatment hepatic biopsies while defining the prognosis of the cases with chronic viral hepatitis.

**Department of Infectious Disease, Matei Bals Institute
***Department of Gastroenterology, Colentina Universitary Hospital
Bucharest, Romania

Hepatitis D virus (HDV) chronic hepatitis (which is frequent in Romania) shows no specific histopathologic lesions comparing with other viral etiologies.
MATERIAL AND METHODS: We studied 58 cases of HBV-HDV chronic hepatitis and 355 cases of HBV chronic hepatitis diagnosed in our department in 14 months; we analyzed various histopathologic parameters (portal and lobular inflammation, interface hepatitis, spotty necrosis, confluent necrosis, apoptosis, fibrosis, ground glass cells, large cell dysplasia, ductal lesions) using Ishak semicantitative score to assess necro-inflammatory activity and fibrosis; the results were compared with a group of 355 cases of HBV chronic hepatitis; a statistical analysis was performed – CHITEST, FISCHER and STUDENT tests were used with a level of statistical significance (P) of 0.05.
RESULTS: In HBV-HDV chronic hepatitis there were significant more abundant lobular inflammation (P=0.004), interface hepatitis (P=0,002), spotty necrosis (P=0,005), steatosis (P=0.025), Kupffer cells hyperplasia (P=0.007), necro-inflammatory activity (P=2,25428x10-07) and fibrosis (P=9,83716x10-07); the portal inflammatory infiltrate and ballooning degeneration were more prominent in HBV-HDV chronic hepatitis but P values were outside of the confidence range (P=0.052 and P=0.057); there was more hepatocytic hemosiderin deposition, less polymorphic inflammatory infiltrate, more prominent ductal lesions and large cell dysplasia. No significant differences were recorded in matter of sex, age, number of ground glass cells, distribution of portal inflammatory infiltrate or confluent necrosis.
CONCLUSIONS: Based on our data (higher necro-inflammatory activity with an elevation of all histopathologic parameters of necrosis and inflammation except confluent necrosis, higher hepatocytic degeneration (ballooning degeneration and steatosis), higher fibrosis) a more aggressive histopathologic appearance is recorded in HBV-HDV chronic hepatitis.

P 228

IMMUNOHISTOCHEMICAL CHARACTERIZATION OF HEPATIC DUCTULAR REACTION IN WILSON'S DISEASE

NAGY Peter
Semmelweis University, Ist Dept. of Pathology and Experimental Cancer Research, Budapest, Hungary

The so called ductular reaction is a misterious histological response of the human liver. It occurs in a wide variety of hepatic diseases, but its origin and importance is still debated. In the present study the immunophenotype of the ductular cells was investigated in three livers from patients of Wilson's disease.
The immunohistochemistry was performed on paraffin embedded liver tissue by ABC technique using diaminobenzidine as chromogen.
The ductular cells were cytokeratin(CK)7+/19+/14- and were surrounded by smooth muscle actin positive stellate cells. Occasionally, large polygonal, hepatocyte like cells were present in the ductules, which lost CK7 staining but gained nuclear hepatocyte nuclear factor 4 (HNF 4) positivity. Ki 67 staining was confined exclusively to the ductular structures, but copper/orcein positive granules were present only in hepatocytes. Alfa-fetoprotein, deleted in malignant brain tumor-1 (DMBT-1) reactions were negative, CD 34 antibody decorated only the endothelial cells.
These results suggest that the ductular reaction in Wilson's disease represents a stem cell derived regenerative response and shows certain similarity to the oval cell proliferation in the rat liver.

HISTOPATHOLOGICAL SCORING OF THE NECRO-INFLAMMATORY ACTIVITY AND FIBROSIS IN AUTOIMMUNE HEPATITIS: A COMPARISON OF TWO SCORING SYSTEMS

K.Ghaffarzadegan M.D.*, M.Sotoudeh M.D. **, MH. Derakhshan M.D. **, M. Mohammadzadeh M.D. *, S. Haghazali M.D. **, H. Saadatnia M.D. *, H. Vossoghinia M.D. *, S. Amoian M.D. *, L. Kafami M.D. *, A. Mehrnami M.D. **, N. Rakhshani M.D. **, B. Abedi-Ardakani M.D. **, R. Malekzadeh M.D.**
*Mashhad University of Medical Sciences, Mashhad, Iran

**Digestive Diseases Research Center (DDRC), Tehran University of Medical Sciences, Tehran, Iran

Background and Aims:
Histopathological scoring of grade of necro-inflammatory process and stage of fibrosis is widely used for chronic viral hepatitis and the same scoring systems are also applied to the biopsy samples of patients with autoimmune hepatitis. We aimed to compare the results of scorings by Modified Histological Activity Index (HAI) and the METAVIR systems and their validity for determination of severity of disease in Iranian patients with autoimmune hepatitis.
Materials and Methods:
Blind histological examination of 20 liver biopsy slide sets from patients with autoimmune hepatitis was performed by two independent pathologists. Grades and stages of the liver lesions were determined according to the HAI and METAVIR systems. The correlations of the scores of the two systems were determined by weighted kappa analysis. Correlation of necroinflammatory activity and fibrosis with serum levels of aminotrasferases was analyzed by the Spearman's rho test.
Results:
There was moderately well to good correlation between grades and stages obtained by the two systems (weighted kappa 0.58 and 0.56 respectively). However, the scores of none of the two systems showed a significant correlation with serum levels of aminotransferases.
Conclusion:
Concordance between HAI and METAVIR scoring systems is good for the histological grading and staging of autoimmune hepatitis. However, neither of the two systems proved to be valid for determination of the activity of the disease when compared to the levels of serum aminotranferases. We conclude that HAI and METAVIR systems give comparable results in autoimmune hepatitis but a more valid system has to be devised for histological scoring of this group of liver diseases.
Key words:Autoimmune hepatitis,Scoring,Metavir,Modified HAI

EFFECT OF SPLENECTOMY ON LIVER FIBROGENICITY IN PORTAL HYPERTENSION PATIENTS
Zeinab S. Omran, M.D.***, El Batanouny M.M.D.**, Mohamed M. Essawy, M.D.*, Abdel-Rahman Elbee, M.D.**, Hussein Ezzat, M.D.*, Mohamed Abbas, M.D*, Mona M. Nosseir, M.D.***, and Iman A. Khaled, MD.****
*General Surgery, ***Pathology and ****Hematology Departments, Theodor Bilharz Research Institute and **General Surgery Department of Kasr El-Aini, Cairo University, Egypt.

This study was designed to assess the role of the spleen on the presence and localization of liver fibronectin, to measure the amount of hepatic collagen and serum level of fibronectin and procollagen III in cases of portal hypertension.
The study was performed on 40 patients divided into two groups: Portal hypertension group (20 patients) included one pure schistosomal hepatic fibrosis, three mixed schistsomal and virus C cirrhosis, ten virus C hepatic cirrhosis, two virus B hepatic cirrhosis and four mixed B&C infections. Control group (20 patients) presented with different splenic insults without hepatic affection. In the first group, through clinical examinations and sonographic findings revealed hepatosplenomegaly and grade III & IV varices with history of injection sclerotherapy in 65% of cases.
Preoperatively, marked hepatic fibronectin deposition in portal tracts and around blood vessels raised the stage of fibrosis. This was accompanied by decrease in plasma level of fibronectin and increase of serum level of procollagen III in relation to the control group.
Six months post-operatively, tissue fibronectin, collagen content and serum procollagen III were insignificantly decreased. However, plasma level of fibronectin was increased significantly.
These results denoted that fibronectin is one of the predominant early fibrogenic components in chronic liver diseases, stimulating further collagen deposition. It is concluded that the role of the spleen in the development of hepatic fibrosis seems ancillary. Multifactorial influences, including etiology, timing of splenectomy, hepatic vascular adjustment, and factors associated with the biology of extracellular matrix of the liver, probably play a more significant role. Further studies were recommended to assess the role of splenectomy on liver fibrogensis at different stages of fibrosis. Intervention with splenectomy could improve or reverse fibrogenic activity at early stages.
Key words: Splenectomy, fibrogenicity, fibronectin, procollagen III, liver fibrosis, portal hypertension.

P 231
PRIMARY SCLEROSING CHOLANGITIS SIMULTANEOUSLY WITH ANCA-ASSOCIATED VASCULITIS
Honsova E, Kostolna E, Trunecka P, Jaresova M.

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by inflammation and fibrosis of the intra- and/or extrahepatic bile ducts. Anti-neutrophil cytoplasmatic antibodies (ANCA) are a heterogeneous group of autoantibodies directed against cellular components of the polymorphonuclear leucocyte. ANCA directed to proteinase 3 (PR3-ANCA) or myeloperoxidase (MPO-ANCA) are closely associated with systemic necrotizing vasculitis. Atypical anti-neutrophil specific antibodies (atypical p-ANCA) are detected in the majority of patients with PSC.
Methods: Retrospective analysis of patients with diagnosis of PSC between the years 2002-2004.
Results: A total of 38 patients in whom ERCP features of PSC and liver biopsies were evaluated - 25 (65,8%) men, 13 (34,2%) women. Of the 38 patients, 26 (68,4%) suffered from inflammatory bowel disease. 3 patients (2 men, 1 woman) had skin palpable purpuric rash, and underwent skin biopsy with morphological diagnosis of vasculitis. Simultaneously positive ANCA antibodies directed to proteinase 3 were detected in the sera of all of them. All of these patients had been suffering from migrating polyartralgia. None of them had any renal abnormalities.
Conclusion: The underlying pathophysiology of PSC is unknown but genetic and immunological mechanisms may play a role. Patients with PSC can have positive tests not only to atypical pANCA but also to PR3-ANCA. Some of the extrahepatic complications of PSC can be associated with systemic vasculitis, and these patients need more extensive monitoring of the disease and especially adequate therapy to prevent a more serious course of the disease.

P 232
CELL REACTION OF PERISINUSOIDAL FIBROSIS DURING NONALCOHOLIC STEATOHEPADTIS.
Petrov S.B., Kiyasov A.P., Odintsova A.

Nonalcoholic steatohepatitis (NASH) is characterized by perisinusoidai fibrosis, which develops on early stages of the disease. The cellular sources of fibrillar collagens and other matrix proteins are endothelial cells (EC), hepatic cells and mainly hepatic stellate cells (HSC) which proliferate after liver injury and undergo activation to a myofibroblast - like phenotype. Capillarization is a process in which the liver sinusoid became consecutive capillaries with evident basement around and it is followed by expression of CD34 by EC.

Aims: To determine the connection between the development of perisinusoidal fibrosis, activation of HSC and capillarization of sinusoids during NASH. Methods: 36 liver biopsies from the patients with NASH were studied. We analyzed correlation between grade of disease activity and stage of the disease and expression of a- SMA (activation of HSC) and CD34 (capillarization). Results: Perisinusoidal fibrosis is revealed in all stages of NASH and followed by activation of HSC. Expression of CD34 arises on the basis of perisinusoidal fibrosis, activation of HSC and correlates with the grade of activity. Conclusion: Perisinusoidal fibrosis is the result of HSC activation, leads to capillarization and to change of EC phenotype and expression of CD34.

P 233

BETA-AMINOISOBUTYRIC ACID ALLEVIATES STEATOHEPATITIS IN A MURINE MODEL OF DIABETES AND OBESITY.

ABBEY-TOBY A.(1,2), BEGRICHE K.(2), IGOUDJIL A.(2), LETTÉRON P.(2), DUBOIS S.(1), FROMENTY B(2).
1-Service d'Anatomie Pathologique, Hôpital Beaujon, 100 Bd du Général Leclerc, CLICHY, France
2-Inserm U-481, Faculté de Médecine X.Bichat, PARIS, France.

Non-alcoholic fatty liver diseases (NAFLD) are characterized either by isolated steatosis or by steatosis associated with necroinflammation, thus constituting non-alcoholic steatohepatitis (NASH). NASH can evolved toward more severe liver diseases such as fibrosis, cirrhosis and hepatic carcinoma. NASH is mainly observed in metabolic diseases such as type 2 diabetes and obesity.
Background: we previously reported that administration in lean (Swiss) mice of 100 mg/kg/d of beta-aminoisobutyric acid (BAIBA, a natural catabolite of thymine) for 6 weeks was associated with increased hepatic fatty acid oxidation (FAO) and decreased body fat mass (BFM). In genetically obese and diabetic ob/ob mice this dose of BAIBA stimulated FAO at a lesser extent and did not decrease BFM.
Aims: the first goal of the study was to determine whether higher doses of BAIBA and/or a longer exposure could decrease BFM in ob/ob mice. In addition, we asked whether BAIBA could improve liver function and lesions and oxidative stress in this model of obesity. Lastly, we wished to know more regarding the mechanisms whereby BAIBA is able to increase hepatic FAO.
Materials and Methods: 100 or 500 mg/kg/d of BAIBA were administered to ob/ob mice for 4 months. BFM was assessed by DEXA before and at the end of the experiment. ALT and LDH were determined in plasma and liver histology was performed with standard stains (hematoxylin-eosin, Masson trichrom, picrosirius). In addition, apoptosis was assessed with a TUNEL assay. mRNA expression of 2 mitochondrial FAO enzymes (L-CPT-1, MCAD) was assessed with a RiboProtection Assay. Finally, hepatic glutathion and lipid peroxidation were measured.
Results: we showed that administration in ob/ob mice of high dose of BAIBA for 4 months did not decrease BFM. Although hepatic steatosis was not decreased in ob/ob mice, periportal and perisinusoidal fibrosis and necroinflammation and apoptosis were alleviated by BAIBA. This histologic improvement was associated with a trend toward lower ALT and LDH. Hepatic expression of L-CPT-1 and MCAD was increased and oxidative stress was lessened.
Conclusion: although the natural compound BAIBA does not decrease fatness in ob/ob mice, it improve liver function in this model. However, despite increased expression of FAO enzymes, steatosis in ob/ob mice was not decreased suggesting that a compensatory de novo lipogenesis may occur in liver. BAIBA is being tested in other models of dysmetabolic diseases.

HEPATIC DYSFUNCTION IN ANOREXIA NERVOSA: CLINICAL, HISTOLOGICAL, ULTRASTRUCTURAL AND PROGNOSTIC ANALYSES

D Cazals-Hatem, PE Rautou, G Feldmann, C Francoz, G Arcangelli, A Grodet, F Durand, D Valla, P Bedossa.
Departments of Pathology and Hepatology, Hôpital Beaujon, 92118 Clichy, France

Liver tests abnormalities have been described in anorexia nervosa. However, the mechanisms of liver dysfunction in this context are not well established and histological reports are rare.
Aims: To analyze the clinical, pathological and prognostic features of hepatic dysfunction observed in patients with severe anorexia nervosa.
Patients & methods: 9 patients with anorexia nervosa (7 females, 2 males, mean age: 27.3) were investigated in Hôpital Beaujon because of acute liver failure. The clinical and biological parameters were recorded. Liver biopsy was performed in every patient with electron microscopy study in two cases.
Results: At admission, the mean BMI was 11.3 ± 1 kg/m2, (range 9.6 – 13.2). Transaminase ranged from 18.1-105.5N; prothrombin time was below 50% in all patients. Five patients were hospitalized because of hypoglycaemic coma and cardiac explorations revealed cardiac dysfunction in 4 out of the 5 patients (left ventricular ejection fraction below 50%). Hepatic gradient was normal in all patients who underwent a transjugular biopsy (8/9).
Liver biopsies performed days 2 to 9 after admission showed swelling and clear hepatocytes in all cases, corresponding to spongiocytic steatosis as proven by Soudan red staining in only 1 case. Periodic acid-Schiff staining showed decrease glycogen amount in all cases and abundant ceroid pigments in hepatocytes of the centrilobular zone, associated with hepatocytic atrophy and inconspicuous sinusoidal fibrosis in 4 of the 9 cases. Centrilobular necrosis without inflammation or congestion was observed in one case. Ultrastructurally, hepatocytes displayed a low density of glycogen particles and few organelles. Endoplasmic reticulum was slightly altered. Phagolysosomes with dense osmiophilic bodies were prominent. Clinico-pathological confrontations showed a higher proportion of centrilobular lesions in patients with cardiac dysfunction and/or severe hypoglycemia. The patient with microvesicular steatosis presented with recurrent vomiting before admission. After glucose therapy, complete normalization of prothrombin time was achieved in all patients. Only one patient with cardiac dysfunction needed dobutamine therapy.
Conclusion: Severe hepatic abnormalities may occur in anorexia nervosa with favorable evolution after glucose infusion. Microscopically, fatty deposit was infrequent but hepatocytic lesions were common but mild, possibly related to hypoglycaemic coma and/or cardiac dysfunction.

P 235

HISTOLOGICAL STUDY OF POLYCYSTIC LIVER DISEASE REVEALS SIGNIFICANT VASCULAR CHANGES IN NON-CYSTIC LIVER PARENCHYMA.

L Catherine (1), M Ronot (2), C. Francoz (3), O. Farges (4), F. Durand (3), J. Belghiti (4), P. Bedossa (1), V Vilgrain (2), V Paradis (1).
(1) Pathology Dpt, (2) Radiology Dpt, (3) Hepatology Dpt (4) Liver surgery Dpt, Beaujon hospital, Clichy France.

Background : Polycystic liver diseases are made of heterogeneous entities associated with specific genetic mutations. Histological analysis focused on liver cysts' characteristics and failed to describe morphological aspects of non-cystic parenchyma. The aim of this study was to assess

histological changes of the non-cystic parenchyma, which could explain the pejorative clinical evolution of some cases.
Patients and Methods: Forty-six liver resections obtained from patients with polycystic liver disease were retrospectively examined. The sex ratio was 41 women / 5 men, with a mean age of 50 years + 9 (range: 33-66). The liver resection consisted in a left hepatectomy (n=19), a right hepatectomy (n=12), or a total hepatectomy performed in the context of liver transplantation (n=15). Twenty-two patients had also kidney polycystic disease involvement. Histological analysis evaluated the following features in a semi-quantitative assessment: portal fibrosis (0: absent, 1: mild enlargement of portal tracts, 2: few fibrotic septa, 3: numerous fibrotic septa, 4: cirrhosis), centro-lobular fibrosis (0: absent, 1: discrete perisinusoidal fibrosis around the centrolobular vein, 1: perisinusoidal fibrosis involving < 1/3 of the lobule, 2: perisinusoidal fibrosis involving > 1/3 of the lobule), sinusoidal dilatation and congestion (0: absent, 1: few foci, 2: extensive areas), regenerative nodular hyperplasia (incomplete or complete). The presence of venous thrombosis, venular portal dilatation or other parenchyma anomalies were also noted.
Results: In addition to the presence of numerous cysts disseminated throughout the liver, 40 cases (87%) displayed significant morphological changes in the non-cystic parenchyma. All patients had bilobar disease and 32 of them have complicated cysts (28 hemorrhagic cysts, 9 infected cysts). Significant portal fibrosis (> score 2) and centrolobular fibrosis (score 2) were noted in 16 (34.7%) and 25 (54.3%) cases, respectively. In 18 cases (39%), both sinusoidal dilatation and congestion were extensive. Venous thrombosis was present in 12 cases and venular portal dilatation in 41 cases. Architectural disorders, including regenerative nodular hyperplasia-like and regenerative nodular hyperplasia, were observed in 16 cases (34.7%). Peliosis and steatosis were reported in 12 and 7 case, respectively.
Conclusion: This study shows that non-cystic parenchyma of polycystic liver disease display significant morphological disorders, especially vascular changes, including regenerative nodular hyperplasia, and also fibrosis in at least 1/3 of cases. Such modifications, potentially induced by the secretion of cytokines and growth factors by the liver cyst epithelial cells, may be involved in the progression of the disease.

P 236
EVALUATION OF THE ANTI-SCHISTOSOMAL ACTIVITY OF THYMOQUINONE IN MURINE SCHISTOSOMIASIS MANSONI: INFLUENCE ON NITRIC OXIDE, ICAM-1 AND COLLAGEN
.SAMIRA SALEH, MADIHA MAHMOUD1, HANAN E1-ABHAR, ZEINAB OMRAN2
Department of Pharmacology and Toxicology. Faculty of Pharmacy. Cairo University: Kasr El-Aini st. 11562 Cairo. Egypt. Department of 1Pharmacology and 2Pathology, Theodor Bilharz Research Institute. Imhaba, Giza 12411 Egypt

We have proved previously that Nigella Sativa oil reduced Schistosoma mansoni (S. mansoni) induced hepatic fibrosis, the total worm burden, egg load and granuloma formation. Therefore, we aimed here to study the possible antischistosomal effect of one of its active constituent's thymoquinone (TQ). The drug was given to S. mansoni infected mice in two dose levels (5 and 10 mg/kg, p.o.) for two weeks, and its effect was compared to that of the standard antischistosomal drug, praziquantel (PZQ). Two weeks later, the following parameters were estimated, viz., worm load and distribution, oogram changes, egg load in liver and intestine, granuloma diameter, collagen deposition and intercellular adhesion molecule-1 (ICAM-1) expression. Moreover, serum levels of L-alanine aminotransferase (ALT) and nitric oxide (NO), as well as NO hepatic level were estimated. Mice treated with TQ showed a significant reduction in total number of worm burden, both in liver and portomesentric blood vessels. The oogram pattern recorded a decrease in immature and mature ova, and an elevation in dead ova. Tissue egg load was reduced in both liver and intestine. In infected mice treated with TQ, the elevated serum ALT activity leveled off. However, neither serum NO level was altered, nor in the infected group nor in those treated with TQ or PZQ. In liver homogenate, infection decreased NO level, which was not corrected with PZQ, but in-groups treated with TQ, a further reduction was reported. TQ caused shrinkage in granuloma diameter, and a diminution in collagen deposition. On the other hand, PZQ failed to reduce collagen deposition. Both TQ and PZQ decreased ICAM-1 expression in Kupffer and inflammatory cells. However, neither TQ nor PZQ affected it in endothelial cells. These results point to a possible antischistosomal role of TQ, which may be correlated with modulation in the immune system.
Key words: schistosomiasis mansoni; nitric oxide; granuloma; intercellular adhesion molecule-l (ICAM-l), collagen; thymoquinone; praziquantel.

Faculty of Medicine of Ribeirão Preto, University of São Paulo, Ribeirão Preto, SP, Brazil

Hepatic schistosomiasis (SCH) frequently results in liver fibrosis, but in the most of cases without functional loss of the liver. Chronic hepatitis C virus hepatitis (HCV) often curses with cirrhosis and liver failure. The hepatic stellate cells (HSC) are involved in both disease, but it is not clear if the proportion of quiescent or activated HSC and their rates of proliferating can be associated with the clinical outcomes. The present study intends to verify if exist difference in quiescent and activated hepatic stellate cells and their proliferating capacity, between SCH and HCV. The liver biopsies were reviewed and the diagnoses were confirmed. It was performed a immunohistochemistry study, with double staining for proliferating cell nuclear antigen and glial fibrillary acid protein (for detection and quantification of proliferating quiescent HSC), and double staining for proliferating cell nuclear antigen and smooth muscle á-actin (for detection and quantification of proliferating activated HSC). In SCH patients, there was observed a lower number of activated HSC than in HCV patients ($p<0.05$), without any difference considering the quiescent HSC ($p>0.05$). The rates of proliferating, both to quiescent and activated HSC were similar in SCH and HCV patients ($p>0.05$). Thus, the activation state of HSC is more important than proliferating rates. The HSC are important to SCH fibrosis, but, the activated HSC profile, the more proliferating, is predominant in cirrhosis. Probably, the evident inflammatory stimuli present in HCV can activate a higher number of HSC than in SCH, that present a mechanical mechanism of fibrogenesis and curses with lower fibrosis and less important clinical repercussion.

P 238
PULMONARY EPITHELOID HAEMANGIOENDOTHELIOMA (IVBAT)
Fillinger J.,Soltész I.,Kerényi A.,
Marosi M.,Molnár É.,Agócs L.

In our Institute four cases were diagnosed by the authors,they also review the clinicopathologycal features, differential diagnostic problems and the literature.The epitheloid haemangioendothelioma (EHE)can occur everywhere in the human body, most often in liver, soft tissue, bone and lung.In the literature mentiones occurences in central nervous system, mamma, head- neck region and lymph nodes. The opinions are divided but the mostly accepted is that EHE is a low grade sarcoma. The tumors that are normally progressing from soft tissue and bone are more agressive than the ones of other origin.
Pulmonary origin is relatively rare.Patientes are usually without complaint and the condition is dicovered accidentally. Occurence in women is four times more frequent.The average age is under forthy.
In pulmonary EHE on X-ray and CT scan shows most often subpleural soliter or multiplex nodules. Nodules can reach 2 cm in diameter but most are under 1 cm.Radiomorphology shows metastatic tumor progression.Nevertheless repetedly scans can not show any progression.The differential diagnostic approach needs to considers multiplex benign tumors,vasculitis, bronchiolitis and granulomatous diseases.
Survival of patientes are variable from a few month to 15 years and depends on the site of tumor.Pulmonary origin with pleural and lymph node spreading indicates poorer outcome.Therapy is variable, can only be observation or chemotherapy too.

LUNG OSTEOMA – A NEW BENIGN LUNG LESION

Eva Markert, Ulrike Gruber-Mösenbacher, Christian Porubsky, Helmut H. Popper
Institutes of Pathology, Medical University of Graz and Teaching Hospital Feldkirch, Department of Thoracic and Hyperbaric Surgery, Medical University of Graz, Austria

Introduction: The most common benign neoplasm's' of the lung are hamartomas. A primary osteoma in the lung has never been reported. Within its differentials hamartoma with osseous foci, osseous metaplasia, secondary ossification, and nodular amyloidosis have to be discussed.
Material and Methods: A 38 year-old man presented with a solitary well limited tumor in the right middle lobe. He was treated with chemotherapy and interferon because of multiple myelomas and got a bone marrow transplantation 2 years and a few months before this lesion appeared. The patient underwent surgical resection. Usual routine pathologic work-up followed.
Results: The tumor presented with a well defined fibrous capsule and consisted of mature bone. Within the tumor a fatty tissue was seen much as it would be seen in mature bone. Focally most often at the edges small bone spicules could be discerned, most probably the area of new bone formation and appositional growth. There was no amyloid deposition, no immature epithelial tubules as in hamartomas, and no normal lung structure within the tumor, such as in osseous metaplasia.
Discussion: We have named this lesion osteoma, because it looks like any other extrasceletal osteoma. For comparison with similar lesions to be excluded, nodular amyloidosis, hamartomas, and various forms of osseous metaplasias will be exemplarily shown. To the best of our knowledge, this is the first case of osteoma arising in the lung.

P 240

LYMPHOEPITHELIOMA-LIKE CARCINOMA OF THE LUNG: REPORT OF TWO CASES

KASAI Kiyoshi
Divison of Basic and Clinical Medicine, Department of Nursing,
School of Health Sciences, Sapporo Medical University, Sapporo, Japan

Introduction The term lymphoepithelioma-like carcinoma (LELC) has been proposed for histologically unique neoplasms characterized by an undifferentiated malignant epithelial neoplasm with a markedly prominent lymphoid infiltrate. LELC of the lung is a rare lung tumour and is classified as a variant of large cell carcinoma. The aim of the present study is to describe the histopathological features of 2 LELCs and to analyze the association with EBV of LELC.
Materials and methods I report two patients (females) with LELC, who underwent surgery. Tumor specimens were routinely fixed and processed. Deparaffinized sections were stained by HE and examined immunohistochemically with cytokeratin, EMA, CEA, LMP-1 and ZEBRA protein expression. For the detection of EBV, non-radioactive DNA-RNA in situ hybridization for EBV-encoded small RNAs (EBER-1) was carried out.
Results Tumor cells of the 2 lobectomy specimens showed a syncytial growth pattern of undifferentiated cells. Cancer cells consisted of oval nuclei with a clear to vesicular chromatin pattern and a few prominent nucleoli. The neoplastic epithelial cells were accompanied by an intense lymphoid infiltrate and admixed intimately with small lymphocytes. Some areas of squamous differentiation in the form of well-defined cell borders and focal keratinization were observed within the tumors. The tumor cells of both cases stained positive for cytokeratin and EMA but not for CEA. EBER1 expression was intense and was present in most tumor cells of both cases. No expression of EBV-related proteins (LMP-1 and ZEBRA) was detected in tumor cells.
Conclusion I believe that careful histopathological examination of the large cell carcinomas of the lung may help to establish the exact diagnosis of LELC. Although the typical LELC of the lung consists of undifferentiated carcinoma, EBV-infected LELC in Asians is not restricted to undifferentiated carcinoma and includes more differentiated carcinomas

UNDIFFERENTIATED ' LYMPHOEPITHELIOMA - LIKE 'CARCINOMA OF THE LUNG A DISTINCT ENTITY WITH BETTER PROGNOSIS

HAMEL Nadia*, ASSELAH Fatima*, CAPRON Frédérique**
* Departement of pathology CHU Mustapha Algiers- Algeria
**Departement of pathology Hopital de la Pitié Paris- France

BACKGROUND
lymphoepithelioma – like carcinoma (LELC) is a large cell carcinoma histologically similar to nasopharyngeal lymphoepithelial carcinoma with nests of large malignant cells in a lymphoid rich stroma. LELC of the lung is very rare in western countries, but not in southeast Asia where it is frequently associated with Epstein-Barr virus. Algeria is endemic for Epstein-Barr virus infection and nasopharyngeal carcinoma and Burkitt lymphoma are relatively frequent in our population.
OBJECTIVE
to attempt to identify cases of LELC from a large series of lung cancer and to asses their association with Epstein-Barr virus and their particularities.
METHODS
A total of 70 cases of poorly differentiated lung carcinoma reviewed. EBV research was performed by in situ hybridation technique (IHS) using EBER arrays associated with immunohistochemical (IHC) technique for expression of LMP-1 protein.
RESULTS
10 cases of LELC identified (08 squamous carcinomas and 02 undifferentiated carcinomas with lymphoid stroma).The patients were aged 45 to 79 years (median, 52 years), ratio M/F= 5. All the mens were smokers.

We found a high expression of LMP-1 by IHC and EBER-1 by HIS in the two cases of undifferentiated carcinomas with lymphoid stroma. The two patients are females, 60 years old and non smokers. LELC of the lung occurring in Asians is an EBV-associated neoplasm ; it also associated with young age, a history of not smoking, high bcl-2 immunoreactivity, and better survival rate (Fen Fen Chen,1998)
IN SUMMARY
These are the first cases of LELC associated to EBV reported in Algerians. The role of EBV in the oncogenesis is poorly understood. LELC is histologically and biologically distinct entity with a better prognosis.

Abstract:
We report the second case of Low-grade fibromyxoid sarcoma of the mediastinum, a very rare tumor, in a 55-year-old woman presented with dyspenea. Chest X-ray and computed tomography (CT) on admission showed a 30cm mass in the anterior mediastinal space, compressing the lungs and adhered to chest wall. A diagnosis of benign peripheral nerve sheate tumor was established by a CT-guided percutaneous needle biopsy. Systemic examination revealed no metastasis to the contralateral pleural cavity or other distant organs, and the mediastinal mass was resected. Tumor cells were positive for vimentin and negative for actins, EMA, CD34, keratins, and S-100 protein .Pathological and immunohistochemical analyses confirmed a diagnosis Low-grade fibromyxoid sarcoma. The patient is alive without recurrence 10 months after his operation
Key word ; Low-grade fibromyxoid sarcoma- mediastinum

LEIOMYOMA OF THE BRONCHUS: A CASE REPORT AND REVIEW OF LITERATURE
MAEDA Mitsuhide, HARADA Hiroshi, KANEYUKI Utako, YOSHIMURA Junko, KOJIRO Masamichi
Department of Pathology, Kurume University School of Medicine, Kurume, Japan

Leiomyoma of the lower respiratory tract is a rare benign neoplasm and only limited numbers of cases have been described in the English literature. We recently encountered a case arising in the intrapulmonary bronchus of a Japanese young adult and present clinical and histological summary with breif literature review. A 33-year-old woman complained of old pneumonia and persistent cough for three years and was referred to our hospital in late 2004. Chest computed tomography showed a well circumscribed and enhanced mass lesion as well as a dilation of the distal bronchus and pneumonia. The mass was measured 15 mm in the largest dimension and was located in the eighth segment of the left bronchus. Bronchoscopy demonstrated a smooth whitish mass, which obstructed left basal bronchus. The left lower lobulectomy was performed and gross specimen included a polypoid lesion 21• ~11• ~10 mm in dimension, which was covered by the intact bronchial mucosa. Histological examination revealed a spindle cell tumor with bland cellular morphology and readily recognized fascicular arrangement. Nuclei showed typical bland-end shape and rare mitosis. Neither destructive growth nor infiltration into surrounding tissue was observed. Immunohistochemically, the tumor cells were positive for myogenic markers such as desmin, alpha-smooth muscle actin, HHF35, calponin and h-caldesmon. Post-operative course is not eventful for six months after operation. Leiomyomas of the lower respiratory tract are uncommon and account for less than 2% of all benign tumors of the lung. They were subdivided into three anatomical varieties: parenchymal, bronchial, and tracheal leiomyomas. As far as we know, less than 75 cases have been reported with female predominance of 1.5:1, and are found rarely in the aged or in children. Bronchial obstruction with atelectasis, pneumonia and hyperlutency are common symptoms as seen in the present case. Outcome is generally excellent.

P 244
INFLAMMATORY MYOFIBROBLASTIC TUMORS – LUNG NEOPLASMS WITH UNPREDICTABLE BEHAVIOUR
STOJSIC Jelena, RADOJICIC Jelena, MILENKOVIC Branislava, ADZIC Tatjana,
TODOROVIC Vera, DRNDAREVIC Neda
Institute for Lung Diseases and Tuberculosis, Belgrade, Serbia, Institute for Medical Research, Belgrade, Serbia

Background: Inflammatory myofibroblastic tumor (IMT) is a mesenchymal lung neoplasm accoding to a recent WHO classification of lung tumors. Methods: We analysed biological behavior of 20 IMTs diagnosed in last ten years on operated tissue obtained as segmental resection, lobectomy or pneumonectomy. Results: 17 IMTs were solitar nodules without necrosis and 3 IMTs were multinodular with one central, large nodule surrounded by a few smaller ones. Some of “satellite” nodules involved mediastinal pleura, penetrating in mediastinal fat tissue. Morphologicaly, tumor contained spindle cells arrayed in fascicles with or without mild nuclear pleomorphism and seldom mitoses. Spindle cells showed myofibroblastic differentiation, histochemicaly by van Gieson, Masson – trichrome and Periodic –Acid – Shiff (PAS) caracteristic stains and immunohistochemically by desmin and vimentin positivity. After surgery 17 solitar IMTs didn’t recidive. Three multinodular, agressive IMTs were treated as malignant mesenchimal tumors with adequate oncologic therapy. Conclusion: IMTs are mesenchimal neoplasms with benign or locally invasive, malignant growth pattern. The criteria for IMTs malignancy, despite cellular pleomorphism and mitoses, are their multinonodular, agressive growth pattern accompanied with presence of necrosis. Postsurgery oncologic treatment was required in such cases. It means that IMTs are truly neoplasms not pseudotumors.

P 245
GRANULAR CELL TUMORS OF THE LUNGS-THREE CASES
Tatjana ADZIC, Jelena STOJSIC
Institute for lung diseases and tuberculosis, Clinical Center of Serbia, Belgrade, Serbia and Montenegro

Background: Granular cell tumors (GCT) are rare tumors most often located in oral cavity, skin or subcutaneous tissue. The occurrence of this tumor in the tracheobronchial tree is extremely rare.
Methods: We describe three cases of GCT found in our institution during fiftheen years
period (1990-2004). At all three cases biopsies of tumors were obtained, microscopically examined and pathohistologicaly diagnosed.
Results: In the first patient, male, 45-years old, the diagnosis was confirmed, after recurrent bronchopneumonias by

bronchological examination, with endoscopic pendular tumor in the left upper lobe.
In the second patient, female, 63-years old, after hemoptysis, the diagnosis was established by bronchological examination, with tumor in the proximal wall of main left bronchus.
In the third patient, male, 84-years old, the diagnosis was confirmed, after fine needle aspiration biopsy.
The histopathologic study of the specimens, supported by histochemical and immunohistochemical techniques, determined the lesions to be a GCT. In all three cases on pathohistological examination large cells with acidophilic cytoplasm were found. In the first case a mild nuclear pleomorphism was present. Tumor cells showed histochemicaly extremely PAS sensitivity and immunohistochemicaly S-100 positivity.
All patients were treated locally, with complete remission in two patients.
One year after resection, the first patient developed malignant GCT, with metastatic diseases in the left parietal bone and in the left suprarenal gland and was treated with chemotherapy.
Conclusion: Pathohistological examination of each lung tumor is requested because of adequate oncologic treatment, especcialy in cases of rarity as GCT. Endobronchial granular cell tumors are in the majority of cases a benign tumors with a good prognosis. Local treatment gives the best results.

P 246
CONGENITAL CYSTIC LUNG DISEASE AND LUNG CANCER
Titl:
L.Shestakova,PhD; A.Charny,PhD, E.Kogan,MD and M.Paltsev, MD. Central Hospital N1 RGD,
Moscow Medical Setchenov's Academy, Moscow, RUSSIA.

BODY: A retrospective study was carried out on 642 cases. 81 cases / 13%/ were malignant lung tumors arising within congenital malformation areas. There were 72 males / 89%/ and 9 females /11%/ with ages ranging from 23 to 65 years. In 18 cases /22%/ congenital lung malformations were revealed 1-15 years earlier lung cancer development. Morphologic analysis revealed two groups:58 cases were different grade squamous cell carcinoma inside hypoplasia,
congenital cystic adenomatoid malformations of the lungs;23 cases were malignant carcinoid or adenocarcinoma or bronchioloalveolar multifocal cancer inside hypoplasia with congenital cystic disease of the lung, introlobar sequestration or congenital bronchioloectatic emphysema.

(7)Service de pneumologie, Centre Hospitalier Intercommunal, Creteil, France
(8)Service d'anatomie pathologique, Hôpital Europeen Georges Pompidou, Paris, France

Light chain deposition disease (LCDD) is a rare entity that very uncommonly affects the lung. We report 3 cases of LCDD presenting as a bilateral cystic lung disorder with severe outcome leading to lung transplantation. In all cases, a presumptive diagnosis of lymphangioleiomyomatosis or Langerhans'cell histiocytosis was proposed based on clinical and radiological data. The diagnosis of LCDD was finally established in 2 cases, on an open lung biopsy specimen, and in 1 case, on the explanted lungs.
In these cases, the disease was characterized by progressive dyspnea associated with numerous joining cysts, diffusely distributed in both lungs. Nodules were also observed in 1 case. Lung function tests showed an obstructive pattern. The histological examination demonstrated an amorphous eosinophilic Congo red negative material located in the alveolar walls, small airways and vessels. It was most often surrounded by multinucleated giant cells. Emphysematous changes were present at the edge or at distance from these deposits. Many small airways were also dilated. Immunofluorescence disclosed staining for ê but not for ë light chains within abnormal deposits and basement membranes. Electron microscopy revealed coarsely granular electron-dense deposits in the same localizations. No other extrapulmonary deposition was ever found except for 1 case in minor salivary glands. No immunoproliferative disorder could be evidenced.
In summary, this report demonstrated that LCDD may 1) primarily affect the lungs, 2) present as a cystic disease resembling lymphangioleiomyomatosis and Langerhans'cell histiocytosis on radiological grounds, and 3) lead to severe respiratory failure.

THYROID TRANSCRIPTION FACTOR-1 EXPRESSION IN LUNG CANCER
R. Tringidou, K. Papadopoulou, P. Kalkandi, J. Vamvakaris,M. Apostolidou, M. Fotinou
Pathology Dpt., Athen's General Hospital for Thoracic Diseases - Greece

Introduction: It is known that tissue-specific transcription factors control cell determination and differentiation. TTF-1 is a tissue specific transcription factor expressed in the epithelial cells of thyroid gland and the lung.
Aim: In this study we detected the expression of TTF-1 in normal human lung and in lung adenocarcinomas primary or metastatic, by immunohistochemistry, in order to find its diagnostic value, if TTF-1 can be used to distinguish between lung and nonlung origin of a tumor.
Methods: Using AvidinBiotin-Complex / Alkaline Phosphatase immunohistochemical technique method and TTF-1 MAb clone 8G7G3 (DAKO) for the detection of TTF-1 in a retrospective study from our laboratory material (177 adenocarcinomas, 64 diagnosed in biopsies tissue, and 113 in surgical specimens, 20 NE neoplasms and 40 small cell lung carcinomas / SCLCs).
Results: (1) TTF-1 was detected in normal human lung with nuclear immunoexpression in bronchial and alveolar epithelial cells (2) Nuclear immunoreaction of TTF-1 was detected in the majority of lung adenocarcinomas (157/177) (3) TTF-1 was not expressed in neoplasms having a NE cell origin (4) Expression of TTF-1 was identified in 35 cases of SCLCs.
Conclusions: TTF-1 immunoreaction was absent in 20 cases of metastatic lung tumor with clinical or histological suspicion (from colon, breast, renal cell adenocarcinoma) and this finding supports the potential diagnostic value of this marker in lung and nonlung origin of a tumor.

P 249

CONGENITAL CYSTIC ADENOMATOID MALFORMATION OF THE LUNG AND BRONCHIOLOALVEOLAR CARCINOMA IN A YOUNG WOMAN

MUKENSNABL Petr, PESEK Milos, SPIDLEN Vladimir, MINARIK Marek, HADRAVSKA Sarka, CHUDACEK Zdenek
Medical Faculty Hospital, Plzen, Czech Republic
Genomac International, Prague, Czech Republic

Introduction: Congenital cystic adenomatoid malformation (CCAM) is a hamartomatous mass of lung tissue that has varying degree of cystic changes. CCAM is a relatively uncommon pulmonary lesion that presents mainly in neonates, rarely this lesion manifests in older children and adults. There are on records only a few patients with CCAM or history of CCAM who has developed bronchioloalveolar carcinoma.
Case report: A 29-year-old nonsmoking woman was admitted to Department of pulmonary diseases because of persisting fever, cough and the left chest pain suspicious of chronic pneumonia in the last several months. On the chest X-ray paracardial consolidation of the left lung was found. Physical examination was unremarkable. Chest CT-scan revealed a picture suspicious of intralobar pulmonary sequestration. However, the chest and abdominal aortography did not confirm the diagnosis. Lung functions were within normal limits and bronchoscopy did not reveal any abnormality of bronchial tree, or other pathology.
Results: Resection of the left lower lobe was performed. Grossly and histologically there was found a congenital cystic adenomatoid malformation in the excised tissue containing areas with numerous mucinous cells, which in some foci had transitions to mucinous bronchioalveolar carcinoma. Molecular genetic investigation revealed a deletion mutation located on the exon 19 of EGFR gene. Patient recovered without major complaints after surgery. In the follow-up period, the chest X-ray and CT-scan did not show progression of tumor.
Conclusion: CCAM with transition to bronchioalveolar carcinoma is an extraordinary rare disorder. The presence of mucinous epithelium in CCAM may led to the suspicion, that this epithelium is premalignant. Mutation of EGFR gene is currently recognized as a marker of early phase of cancerogenesis in this lesion. Because this type of tumor becomes growth factor-dependent, it typically shows a good response to biological therapy and the prognosis of such patients, who undergo radical surgery, is usually favourable.

COMBINED AND SYNCHRONOUS PULMONARY TUMOURS-CASES REPORT

VASILESCU Florina 1,2 DUMITRESCU Marius 1, FLOREA – GRAMADA Zenaida 2, LUCA Lacramioara 1, TOMA Liana 1, BULATA Rodica 1, CUREA Marius 1.
1- Military Hospital of Bucharest
2- Victor Babes Institute of Pathology

We report two cases of rare lung tumours. The first case is a 51-years-old-male which on CT of the chest had a single centro-hilar tumour. The bronchoscopy revealed a polypoid intrabronchial mass infiltrating the lung parenchima. On bronchoscopic biopsy the histologically diagnosis was typical carcinoid. Also, on frozen sections, the right tracheobronchial lymph node has shown micrometastases of typical carcinoid. The surgery specimen, represented by the middle lobe of the right lung, had a tumour of 5 cm in the main diameter. On routine stain (H&E), we diagnosed two different histo-pathological patterns: typical carcinoid (IHC positive diffuse for chromogranin and synaptophysin) and squamous cell carcinoma (IHC negative for neuroendocrine markers). The second case is a 59-years-old-male which presented in the superior lobe of the left lung two tumours: the first one was a polypoid intrabronchial mass of 2.5 cm which at light microscope had a basaloid scuamous cell carcinoma apearance. The second one was a peripheral mass measuring 3 cm in diameter which microscopically proved to be an adenocarcinoma. The two cases of combined and synchronous lung tumours are rare occurrence. The clinical significance of these types of tumours are uncertain.

PRIMARY LYMPHOID NEOPLASMS OF THE LUNG

KAVANTZAS Nikolaos 1, KORKOLOPOULOU Penelope 1, AGROGIANNIS George 1, THYMARA Irini 1, ZACHILAS Dimitrios 2, ADAMOPOULOU Marina 2, ANASTASIOU Nikolaos 2, PATSOURIS Efstratios 1
1.Department of Pathology, School of Medicine, National and Kapodistrian University of Athens, Athens, Greece
2.Department of Thoracic Surgery, 1st IKA Hospital, Athens, Greece

Introduction: Primary lymphoma of the lung is a rare clinical entity (0.5-1% of the primary malignancies of the lung). Less than 100 cases of primary Hodgkin disease of the lung have been reported in the literature, worldwide. We present five cases of primary lymphoid neoplasms of the lung.
Patients and Methods: Over a 6 years period, 5 patients (3 men, 2 women, mean age: 70.6 years) were admitted with symptoms of bronchial occlusion and/or signs of parenchymal disease. Minimal invasive diagnostic techniques were performed to all patients. Radiologically, 4 patients demonstrated signs of diffuse nodular lesions, while 2 of them had concomitant pleural effusion. Lower lobe atelectasis was demonstrated in one patient. Bronchoscopy was performed in one patient, Medical Thoracoscopy (MT) in one patient and Video-assisted Thoracic Surgery (VATS) in 3 patients. In all cases histological examination of the excised specimens was followed.
Results: Primary non-Hodgkin lung lymphoma was diagnosed in 3 patients (one patient with solitary endobronchial lesion). Primary Hodgkin disease of the lung was diagnosed in 2 patients. All patients received appropriate treatment. One patient with non-Hodgkin lung lymphoma died 4 months after the diagnosis, due to treatment complications, while the other 2 patients with non-Hodgkin lung lymphoma died 12 and 13 months respectively, from non disease-related causes. Two patients with primary Hodgkin disease of the lung are disease-free 9 and 10 months respectively from the time of diagnosis.
Conclusions:
The tremendous progress in the fields of histopathology and immunochemistry along with the advent of minimally invasive diagnostic techniques (MT, VATS) have facilitated the diagnostic approach to the primary lymphoid lung neoplasms. With the use of these minimally invasive techniques by which large sized biopsy specimens can be obtained, unnecessary diagnostic thoracotomies can be avoided.

P 252

SCLEROSING HEMANGIOMA OF THE LUNG: REPORT OF 5 CASES WITH IMMUNOHISTOCHEMICAL AND CLINICOPATHOLOGICAL FINDINGS

OZLUK Yasemin(*), GULLUOGLU Mine G.(*), TOKER Alper(**), KALAYCI G(**), YILMAZBAYHAN Dilek(*)
(*) Istanbul University, Istanbul Faculty of Medicine, Department of Pathology
(**) Istanbul University, Istanbul Faculty of Medicine, Department of Thoracic Surgery

Sclerosing hemangioma of the lung (SHL) is a rare tumor which is thought to be benign. Although the differentiation of tumor cells has been controversial, it is believed to be

originated from fetal pulmonary epithelial cell. Also, with various histological patterns, it leads to diagnostic difficulties having no specific immunohistochemical marker.

The aim of this study is to demonstrate the immunohistochemical profile of SHL in addition to the analysis of clinicopathological features.

The clinicopathological features of 5 SHLs were reviewed and analyzed. Immunohistochemical analysis could be performed in 3 cases for antibodies TTF-1, Surfactan protein-B, NSE, Chromogranin A, Synaptophysin, CD31, CD34, estrogen and progesteron receptors, Cytokeratin 7, EMA, p53 and Ki67.

All patients were female with an average age of 54.4 years (36-65). The tumor size ranged from 2 to 5 cm with a mean of 3.7 cm. The combination of observed histological patterns was different in each case. Four cases revealed papillary pattern, 1 case revealed sclerotic pattern, 4 cases revealed solid pattern and 3 cases revealed hemorrhagic pattern. No mitotic activity was detected in all cases. Ki-67 proliferation index ranged from 1.4 to 2.2% with an average of 1.8%. Both the surface and round stromal cells were diffusely positive for EMA and TTF-1 in two cases, whereas NSE was demonstrated focally in all. Only in one tumor TTF-1 and Surfactan protein-B were detected to be weakly focal positive, but EMA was diffusely strong positive. None of the tumors exhibited positivity for endothelial markers. Cytokeratin7 and Surfactan protein-B were both positive in only surface cells. Progesteron receptor was detected both in surface and round stromal cells but estrogen receptor was negative.

SHL is most probably a benign tumor of primitive pulmonary epithelium with various histological patterns. There is no specific immunohistochemical marker for SHL but EMA, TTF-1 and Surfactan proteins are helpful in differential diagnosis. This entity must always be kept in mind in the diagnosis of solitary pulmonary nodules because of its similarity to the histology and immunophenotype of the primary and metastatic pulmonary tumors. Positivity for progesterone receptor antibody may be associated with the female predominancy of SHL. However, this suggestion is needed to be studied on large series of SHL.

P 253

TTF-1 IMMUNOHISTOCHEMISTRY AS AN INTRA-OPERATIVE DIAGNOSTIC TOOL AT FROZEN SECTION FOR DISTINCTION BETWEEN PRIMARY AND SECONDARY LUNG TUMOURS

BUTCHER David, GOLDSTRAW Peter, LADAS George, DUSMET Michael, SHEPPARD Mary, NICHOLSON Andrew.
Departments of Histopathology and Thoracic Surgery, Royal Brompton Hospital, Sydney Street, London SW3 6NP, UK.

Although undertaking frozen sections is a well established, diagnostically accurate procedure in intra-operative lung cancer diagnosis, differentiation of primary from metastatic carcinomas remains problematic. This study assesses the value and practicality of undertaking immunohistochemistry (IHC) for thyroid-transcription factor-1 (TTF-1) at the time of frozen section when faced with this clinical situation.

Thirteen patients presented with a mass in the lung and a history of previous carcinoma (colon n= 8, renal n= 1, breast n=3, thyroid n=1). Specimens were taken during operation for confirmation of malignancy and at this time additional sections were taken for intra-operative localisation of TTF-1. The antigen was visualised using the Envision® System with abridged methodology. Slides were assessed as positive, equivocal or negative. Conventional IHC was then repeated both on the paraffin block from the frozen section and a separate tumour block from the resection specimen for comparison.

Of 13 cases, seven cases were positive for TTF-1 at frozen section, one of which was metastatic thyroid carcinoma. The remaining six were either positive (n=5) or equivocal (n=1) on the subsequent paraffin section and positive on resection specimen (n=6) and felt morphologically to be primary pulmonary adenocarcinomas. Six cases were negative on frozen section. However, one case of colonic carcinoma showed focal staining for TTF-1 on sections from subsequent paraffin block and resection. IHC confirmed metastatic disease in the resection specimens (colonic carcinoma (n=5), cytokeratins (CK)20 +ve, CK7 –ve TTF-1 –ve; renal cell carcinoma (n=1), TTF-1 -ve with clear cell morphology). The average time above that of the basic frozen section was 24 minutes per frozen section. The extra cost per test was £32 per slide.

Frozen section IHC using TTF-1 shows specificity and sensitivity similar to those seen for fixed tissues, and appears feasible within the time frame of a thoracotomy. However, its practice should be properly planned within an operative procedure as liberal usage will likely have significant staff and cost implications.

P 254

COX-2 EXPRESSION IN NEUROENDOCRINE TUMOURS OF THE LUNG

Tötsch M, Krzysik M, Schmid KW.
Department of Pathology, University of Essen, Westgerman Tumour Centre, Germany

Background:
Recent studies have highlighted the role of COX-2 in human cancers and the protective effect of COX inhibitors. Cox-2 can be found in a large proportion of lung adenocarcinoma and squamous cell carcinoma. However, little is known about the frequency of COX-2 expression in neuroendocrine tumours of the lung.
Materials and Methods:
Paraffin-embedded material from 64 neuroendocrine tumours were retrieved from the archives. Immunohistochemistry showed COX-2 staining in all twelve carcinoids (100%), in two of four atypical carcinoids (50%) and in 13 of 48 small cell carcinomas (27%). While a dense and intensive cytoplasmic COX-2 staining (++ - +++) could be seen in carcinoids, the findings in the two positive cases of atypical carcinoids were weak respectively moderate. In SCLC, seven cases showed a weak (+) expression of COX-2, four cases presented a moderate staining (++). Normal bronchial epithelium showed an apical staining, pneumocytes II were positive in regions with chronic inflammation.
Conclusion:
This study is one of the first to investigate systematically the expression of COX-2 in neuroendocrine tumours of the lung. It demonstrates that the different entities of these tumours show a very distinct immunohistochemical pattern. The clinical impact of these findings has to be further investigated.

P 255

EXPRESSION AND PROGNOSTIC IMPLICATIONS OF APOPTOSIS-RELATED PROTEINS IN LOCALLY ADVANCED NON-SMALL CELL LUNG CANCERS.

FOKKEMA, Eelco 1, TIMENS Wim 2, DE VRIES, Elisabeth G.E. 3, DE JONG, Steven 3, FIDLER, Vaclav4, MEIJER, Coby 3, GROEN, Harry J.M. 1.
Departments of Pulmonary Diseases1, Pathology2, Medical Oncology3, and Biostatistics and Epidemiology4, University Medical Center Groningen, The Netherlands.

Introduction: In advanced lung cancer at present little prameters are available to predict outcome.
Purpose: To evaluate prognostic significance of apoptosis related proteins in locally advanced non-small cell lung cancer (NSCLC).
Patients and Methods: Bronchoscopically procured tumor biopsies of NSCLC patients were stained

immunohistochemically and rated for expression of eight different cellular proteins. Staining ¡Ü 10% of the tumor cells was classified as negative, > 10% was considered as positive. Patients were treated with 60 Gy radiotherapy with or without carboplatin as radiosensitizer.
Results: Apoptotic proteins in tumors that showed positive staining were the highest for Bax (99%), Fas (92%), FasL (87%), Rb (87%), p21(WAF1) (73%), and p53 (70%), and the lowest for c-myc (58%) and Bcl-2 (58%). In the Cox regression analysis stage (stage 3B versus stage 3A, relative risk (RR) = 0.63, 95% CI, 0.43-0.92, p<0.02), the presence of mediastinal lymph nodes (N2 versus N3, RR=1.69, 95% CI, 1.02-2.8, p=0.04) and Bcl-2 positivity (RR=0.61, 95% CI, 0.37-0.98, p=0.04) were predictive for overall survival. Only Bcl-2 staining percentage (RR10 (RR associated with an increase in stained cells of 10%) = 0.93, 95% CI, 0.89-0.99), p53 (RR10=0.94, 95% CI, 0.89-0.99, p=0.027) and FasL (RR10=0.92, 95% CI, 0.86-0.99) were predictive for a longer time to progression. No specific constellation of apoptotic proteins was associated with tumor response except that the loss of Rb expression was associated with the absence of any tumor response.
Conclusion: Bcl-2 expression in tumor tissue of patients with locally advanced NSCLC predicts a better overall survival, while Bcl-2, p53, and FasL expression predict for a longer time to progression.

P 256
EXPRESSION OF SOMATOSTATIN RECEPTORS 2-5 IN NEUROENDOCRINE TUMOURS OF THE LUNG
Tötsch M, Krzysik M, Schmid KW.
Department of Pathology, University of Essen, Westgerman Tumour Centre, Germany

Background:
Somatostatin receptors 1-5 can be found in a large proportion of human tumours. Due to the fact, that receptor-positive tissue can be detected by scintigraphy , several investigations have taken place to demonstrate somatostatin-receptors also at the immunohistochemical level. Recent studies have concentrated mainly on the detection of the Somatostatin receptor type 2 (SSTR2) in small cell carcinoma. We were interested to investigate systematically the presence of SSTR 2-5 by immunohistochemistry in various entities of neuroendocrine tumours of the lung.
Materials and Methods:
Paraffin-embedded material from 45 neuroendocrine tumours were retrieved from the archives. Of twelve carcinoids, 8 expressed SSTR2, three SSTR3. None were positive for SSTR 4 or 5. All four atypical carcinods were negative for SSTR2, in 3 cases a cytoplasmic staining for SSTR3 was found. One case was weakly positive for SSTR4 and two cases for SSTR5. In 10 of 28 small cell carcinoma SSTR2 was found, 13 cases were positive for SSTR3, 3 cases for SSTR4 and one case for SSTR5. The case of large cell neuroendocrine carcinoma was positive for SSTR3 and SSTR4, SSTR2 and SSTR5, however, were negative.
Conclusion:
This preliminary study may help to correlate the findings by receptor autoradiography with immunohistochemical results in various types of lung neuroendocriene tumours. This may provide further information concerning diagnosis as well as therapeutic approach in these tumours.

P 257
PULMONARY METASTASIS SECONDARY TO "BURNED OUT" TESTICULAR TUMOR. A CASE REPORT.

SAINT-BLANCARD Patrick (1), GUIGAY Joel (2)
Department of Pathology (1),
Department of Respiratory Diseases (2)
Hôpital, d'instruction des armées, Percy, 92141 Clamart France.

Metastatic germ-cell tumor of the primary testicular lesion has rarely reported. The majority of cases described described in the literature have occured in patients with retroperitoneal metastasis. The autors present a case of pulmonary metastasis with complete regression of the primary testicular tumor.
A 34-year-old Caucasian man presented with a 3-month history of chronic cough. The chestX-ray and the thoracic computed tomography scan showed a 10x14 cm mass in the lower lobe of the left lung without lymph node involvement. The flexible bronchoscopic examination revealed an obstructive mass in the upper segment of the left lower lobe. Histological examination proved the mass to be a malignant germ-cell tumor containing embryonal carcinoma elements. Serum ƒÒ-human chorionic gonadotropin and ƒÑ-fetoprotein were elevated. Ultrasonography visualized a heterogeneous testicular mass. Histological examination of the testicular tumor showed stromal fibrohyalinosis with no evidence of a tumor. The patient was successfully treated with orchiectomy, chemotherapy and lung surgery. Four years later, he remains disease free.
Confronted with a young man presented an isolated pulmonary tumor and apparently normal testes, the physician should suspect a metastatic malignancy, especially metastatic germinal germ-cell tumor with regression of the primary testicular tumor. Tumor marker assays and ultrasonography should be performed and in-deph histological examination of the testis in essential when lesions are identified.

P 258
THYROID TRANSCRIPTION FACTOR-1 (TTF-1) IN THE DIFFERENTIAL DIAGNOSIS OF THE PRIMARY AND METASTATIC LUNG CANCER. OUR 4-YEAR FOLLOW-UP STUDY.
Jäckel,M1., Moldvay,J2., Bogos,K3., Soltész,I3., Agócs,L3., Kovács,G3. and Schaff,Zs4.:
1Central Hospital of Hungarian Defence Forces, Department of Pathology , Budapest , 2County Hospital of Pulmonology, Torokbalint, 3National Institute of Pulmonology, Budapest, 4Semmelweis University Budapest, 2nd. Department of Pathology, Hungary

Introduction: Lung adenocarcinoma is very frequent in adult population. The tumor may be primary, but metastasis from malignancies of other organs often appears as a solitary nodule. From the treatment's point of view it is very important to know if the tumor is of primary or metastatic origin. TTF-1 is a sensitive marker for pulmonary and thyroid adenocarcinomas.
Material and methods: In order to determine the usefulness of TTF-1 in distinction between primary and metastatic lung adenocarcinoma we have examined the expression of TTF-1 in 100 solitary pulmonary nodules. They included 50 stage I. peripheral primary bronchial adenocarcinomas and 50 metastatic pulmonary adenocarcinomas of different origin such as breast, colon, rectum, kidney, stomach and thyroid gland. TTF-1 was performed on formalin-fixed and paraffin-embedded tissues. All primary adenocarcinomas were diagnosed in 2000. In November, 2004 follow-up study was performed. We investigated the correlation between the strong and the weak nuclear immunostaining and the survival of patients.
Results: We found immunopositivity in 46/50 cases, among them 30 cases showed strong nuclear immunostaining. In the remaining four cases the immunopositivity was localized to the cytoplasm. All metastatic adenocarcinomas were negative, apart from the 2 thyroid carcinoma metastases that showed strong immunopositivity. Follow-up data were available in 49/50 patient. There was no tumor recurrence in 27 cases (12 strong immunopositivity), in 6 cases the disease progressed (5

strong immunopositivity), and 14 patients died (9 weak immunopositivity). Kaplan-Meier survival analysis and chi square test showed strong correlation between strong immunopositivity and free survival time (p=0.03)
Conclusion: Our results confirm, that the TTF-1 immunohistochemistry is a very sensitive and highly specific method in the differential diagnosis of primary and metastatic lung adenocarcinomas and should be used in the everyday routine practice. Moreover, TTF-1 immunopositivity proved to be a good prognostic factor in stage I lung adenocarcinomas.

P 259
TISSUE MICROARRAY IMMUNOPHENOTYPING OF PRIMARY NSCLC AND BRAIN METASTASES
PÁPAY Judit,1 MOLDVAY Judit,2 KRENÁCS Tibor,3 TAMÁSI Anna,1 STELKOVICS Éva,3 FURÁK József,4 KOPPER László1
1Department of Pathology and Experimental Cancer Research, Semmelweis University, Budapest, 2County Hospital of Pulmonology, Törökbálint, 3Laboratory of Tumor Pathology and Molecular Diagnostics, Bay Zoltan Foundation for Applied Research, Szeged, 4Department of Surgery, University of Szeged, Szeged, Hungary

Introduction. A proportion of non small-cell lung cancers (NSCLC) form metastases almost exclusively into the brain irrespectively of their primary sizes. Purpose. To identify markers which can predict metastatization of NSCLC into the brain. Methods. Twenty one squamous cell carcinomas and 5 adenocarcinomas of the lung with brain metastases using immunohistochemistry with a selected panel of antibodies were tested. Twenty squamous cell carcinomas and 15 adenocarcinomas with no brain involvement were used as a control. Tissue cores of 2 mm in diameter were incorporated into 24-sample microarray blocks resulting in 117 samples in 5 paraffin blocks using duplicate samples in most cases. Tested antibodies were specific for molecules of cell adhesion (e.g. BP180/Collagen XVII, CD44, E-Cadherin, b-Catenin), cell growth (e.g. Akt1, EGFR, nm23) cell cycle regulation (e.g. Cyclin D1, -D3; Ki67, p16, p21waf1/Cip1, p27kip1, DNA repair (Topoisomerase IIa) and apoptosis (e.g. Bax, Bcl-2, CAS, Caspase-3, -8,-9, FAS, p53). The results were assessed by 2 independent observers a 4-scale scoring system (0 negative, 1 weak, 2 moderate, 3 strong), where cut-off levels were based on literature data considering the patho/biological role of the given marker. The concensus based final scores were converted using the TMA-Deconvoluter software. Non-supervised hierarchical clustering was applied for all data and for selected data groups, which then were visualized using the TreeView program. Results. Phenotypic marker expression of primary NSCLC and their brain metastases showed very similar profile without major loss or gain of any marker. None of the exclusive groupings of markers, i.e. analyzing cell cycle, apoptosis or cell adhesion associated markers grouped separately, resulted in obvious clustering of our cases. However, when the expression profile was set up combining immunoreactions for Cyclin D1, Cyclin D3, Ki67, p16, Collagen XVII/BP180 molecules, the majority of brain tumors clustered with a high positive correlation (0.86) with these markers. Conclusion. Based on tissue microarray analyses, the metastatic capacity of NSCLC cases into the brain seems to be associated with cell cycle activation and the upregulation and delocalization of the hemidesmosomal Collagen XVII/BP180 antigen. Analyses of further restricted combinations involving the expression of a few more marker molecules are still under way.

P 260
STROMAL TUMOR OF THE ILEUM WITH PULMONARY METASTASIS.
SAINT-BLANCARD Patrick (1), JANCOVICI Rene (2), Department of Pathology (1) and Department of Thoracic Surgery (2), Hôpital d'instruction des armées, Percy, 92141 Clamart, France.

Gastrointestinal stromal tumors (GISTs) constitue the largest category of primary non-epithelial neoplasms of gastrointestinal tract. Extra-abdominal metastases of GISTs occur in less 10 percent of patients.
A 34-year-old Caucasian man was admitted for abdominal pain, anorexia, nausea vomiting occur, weight loss of 10 kg. No abdominal mass was found. The endoscopic findings were not specific. Abdominal computed tomography scan showed multiple intramural masses of jejunum and ileum. Thoracic CT scan showed a right hilar mass with small mediastinal lymph nodes. The intestinal masses were resected by laparotomy and hilar mass by mediastinoscopy. Histological and immunohistochemical studies on the surgical resection specimens revealed a GIST with pulmonary metastases. The patient died after 2 years.
GISTs are rare and represent the 0.2% of all malignancy of this site. They occur predominantly in older individuals over 40 years of age with equal sex incidence. They are most common in stomac (60-70%), followed by small intestine (20-30%), colon and rectum (5 %), oesophagus (*f*¬ 5 %), and occasionnally in omentum and mesentery. Recent work has indicated that the interstitial cells of Cajal, which exhibit both myoid and neural features, could be candidates for tumor histogenesis.
20-30 % of GISTs show malignant behavior, including peritoneal dissemination and hematogenous metastases. Metastases are often present at the time the primary tumor is discovered. The most common metastatic sites are the peritoneal surfaces and liver, following by retroperitoneal soft tissues. Lymph nodes, bone and lung metastases are rare. The survival rates at 5 years of malignant tumors vary of 19 to 54 %.

P 261
UNUSUAL METASTATIC PATTERN OF A RADIATION INDUCED ANGIOSARCOMA OF THE SKIN – A CASE REPORT
KNOLLE Jürgen, HEGE Stefanie, SCHREIBER Christel, SCHREIBER Jens
Municipal Hospital Dessau, Academic Teaching Hospital, Institute of Pathology and Dept. of Pulmonology, 06847 Dessau, Germany

We report on a 67 year old female patient in whom hysterectomy and oophorectomy as well as adjuvant telecobalt radiation were performed 27 years ago. 25 years later multiple tumours occurred in the abdominal wall. Histological examination of these tumours showed an epitheloid neoplasm with vascular proliferation and a fine framework of reticular fibres. Immunohistochemistry (pancytokeratin, cytokeratin 8/18, CA125 and CD45 negative, vimentin and CD31 positive, CD34 focally positive) revealed angiogenic differentiation and an angiosarcoma was diagnosed. It was treated surgically.
Another two years later the patient was admitted to hospital with severe dyspnoea. Chest x-ray and CT-scans showed abundant bilateral predominantly interstitial infiltrates in both lungs. Bronchoscopy revealed a diffuse thickening of the bronchial mucosa. Bronchoalveolar lavage, biopsies of the bronchial mucosa and transbronchial lung biopsies were performed. A malignant small round blue cell tumour was identified in all specimens. Immunohistochemistry (cytokeratin and CD45 negative, CD31 intensely positive) confirmed metastases of the angiosarcoma.
Post-mortem examination revealed relapse of the angiosarcoma in the abdominal wall as well as metastases in the lungs, which showed a predominantly interstitial and

peribronchial growth pattern. Further metastases were found in the lymph nodes, in the myocardium, in the abdominal fatty tissue and additionally in a synchronous renal cell carcinoma. Radiation induced angiosarcoma is very uncommon. Furthermore the metastatic pattern with the clinical presentation as an interstitial lung disease on the one hand and with a metastasis in another malignant tumour, which occurred independently, on the other hand are extreme rarities.

P 262
ASSOCIATION BETWEEN MALIGNANT MESOTHELIOMA OF THE PLEURA AND OTHER MALIGNANCIES

Claudio Bianchi, Tommaso Bianchi, Lucia Ramani
Center for the Study of Environmental Cancer, Italian League against Cancer, Hospital of Monfalcone, 34074 Monfalcone, Italy

The association between malignant mesothelioma and other primary tumors has repeatedly been described. In such reports, however, a denominator is frequently not available. In the present study, a series of 169 malignant pleural mesotheliomas, examined at necropsy at the Hospital of Monfalcone, Italy, in the period 1980-2002, were reviewed.The group included 139 men and 30 women. All mesotheliomas were classified as asbestos-related. The co-existence of mesothelioma with other malignancies had been detected in 33 cases (19.5%). Four different tumors were seen in two cases. A 77-year-old men showed, besides mesothelioma, a lung carcinoma, a small carcinoma of the kidney, and a small carcinoma of the prostate. A 85-year-old woman showed three carcinomas of the large bowel.Triple malignancies were observed in 6 cases; in particular, non-Hodgkin lymphoma or leukaemia were associated with mesothelioma in three cases, and prostate adenocarcinoma in two. Double tumors were observed in 25 cases, with prostate adenocarcinoma (5 cases), bladder carcinoma (4 cases), and hepatocellular carcinoma (3 cases), being the most frequent additional malignancies. Of the four non-Hodgkin lymphomas observed in the whole series, two were extra-nodal. In some of the present cases the co-existence of different tumors was a cause of major difficulties in the clinical diagnosis. Only small percentages of people exposed to asbestos develop mesothelioma. The analysis of the cancer varieties associated with mesothelioma may furnish information about the background, in which mesothelioma develops, and/or about the co-factors playing a role in the genesis of asbestos-related mesothelioma. The co-existence of mesothelioma with non-Hodgkin lymphoma or with hepatocellular carcinoma may suggest a role of immune impairment in the genesis of mesothelioma.

P 263
CELL PROLIFERATION RATE AND TELOMERASE ACTIVITY IN THE DIFFERENTIAL DIAGNOSIS BETWEEN BENIGN AND MALIGNANT MESOTHELIAL PROLIFERATIONS

CAKIR Caglar, GULLUOGLU Mine G., YILMAZBAYHAN Dilek.
Istanbul University, Istanbul Faculty of Medicine, Department of Pathology

The differential diagnosis of malignant mesothelioma (MM) from benign mesothelial proliferations (BMP) based on histopathologic criteria is sometimes not satisfying and causes diagnostic problems for the histopathologists. We investigated whether the immunohistochemically determined cell proliferation rate and telomerase activity, using Ki-67 and hTERT immunohistochemistry, respectively, are useful in the differential diagnosis of MM from BML. Sixty six cases of MM (33 epithelioid, 30 biphasic and 3 sarcomatoid) and 22 cases of BML (15 reactive mesothelial proliferations and 7 fibrous pleuritis/pericarditis) were included in this study. The mean value of Ki-67 proliferation index (pi) in MMs was significantly higher than that of BMLs. Biphasic MMs have higher Ki-67pi than epithelioid and sarcomatoid types. Ki-67 immunohistochemistry has the sensitivity of 86%, specificity of 74% and positive predictive value of 94% in detecting MM. hTERT immunohistochemistry detected MM with sensitivity and specificity of 68%. Furthermore, the sensitivity and specificity of hTERT for detecting MM among the cases with low Ki-67pi were 58% and 78%, respectively. As a result, being cheap and simple methods, Ki-67 and hTERT immunohistochemistries can be used in differentiating malignant and benign mesothelial lesions in routine formalin-fixed, paraffin-embedded material.

P 264
DIAGNOSTIC VALUE OF PSEUDOINCLUSION IN THYROID PAPILLARY CARCINOMA AND HASHIMOTO'S LYMPHOCYTIC THYROIDITIS

Dr Ezatollah Rafie Alavi,Dr Amir Khashayar Varkoohi,Samira Roshani

Objectives and background:Papillary carcinoma is the most common malignant tumor of the thyroid.
Intranuclear inclusions(pseudoinclusions)that represent an invagination of the cytoplasm into the nucleus are frequently seen in papillary carcinoma ,and in fact this is one of characteristic features.
Chronic lymphocytic thyroiditis(Hashimoto's);is one of the thyroid diseases that could be present with thyroid cold nodule and FNA is recommended for evaluation.
Materials & Methods:This is an experimental study .In this study 33 cases of patients with cold nodules or diffuse enlargment of one or both lobes of thyroid were candidated for FNA.In clinical studies, these 33 cases were diagnose as suggested for malignancy or Hashimoto's thyroiditis. All prepared smears were staine with papanicolao and geimsa,and studied.
.Findings: In all cases showed nuclear pseudoinclusion in papanicolao and geimsa stain.
Cytologic findings in 16 smears included variable degrees of lymphocytic infiltration with some hurthle cells in scanty colloid background and diagnosed chronic lymphocytic thyroiditis(Hashimoto's thyroiditis).17 of them were diagnose as suggested for papillary carcinoma,due to seen pseudoinclusion,but in histologic study of them showed hashimoto's thyroiditis and the result of TPO test in these 17 cases was positive
As a result , pseudoinclusion showed clearly in smears stained with papanicolao.
Conclusion: Most of cytomorphologic findings in FNA of papillary carcinoma are not specific ,for example ;papillae could be seen in papillary hyperplasia,nuclear features ,so ground-glass chromatin,longitudinal folds or nuclear groove,although are important for papillary carcinoma ,but are neither constant nor specific.Psammoma bodies are observed in a small number of cases which are not specific to papillary carcinoma of the thyroid, because they also have been described in other lesions such as toxic diffuse goiter and Hashimoto's thyroiditis. In contrast to previous reports,nuclear pseudoinclusion are not characteristic for papillary carcinoma of thyroid and it could be seen in Hashimoto's thyroiditis

Place: Department of Pathology, Shahid Beheshti Hospital, Babol, Iran.
* Correspondence author.

Introduction: FNAC has become accepted as a cost-effective procedure in the assessment of thyroid nodules and is an important first-line diagnostic test for the evaluation of goiter and the single most effective test for the preoperative diagnosis of a solitary thyroid nodule. To evaluate the accuracy of FNAC in the diagnosis of thyroid nodules did this study.
Material & Methods: This study was carried out at Shahid Beheshti Hospital in Babol Medical University during the period of 1998 and 2003. There were 745 FNACs of which 98 had definite histology after thyroidectomy. FNAC was correlated with histology and sensitivity, specificity, accuracy with NPV and PPV were calculated.
Results: The overall sensitivity of FNAC detecting thyroid neoplasia was 86.84%, specificity 73.3% and accuracy 78.57%. NPV and PPV were 89.79%, 69.38%, respectively. There was no false positive malignant FNAC. 32 malignant cases were detected, that of 22 males, 13 (59%) had malignancy compared with 19 of 76 females (25%).
Conclusion: FNAC is a useful test in assessment of solitary thyroid nodules especially in males who have high index of suspicion of thyroid cancer. Malignant or suspicious for malignancy cytology are absolute indicators for thyroidectomy.
Keywords: Solitary thyroid nodule, FNAC, Thyroid neoplasia, Accuracy.

HISTIOCYTOID-LIKE CELLS IN FINE-NEEDLE ASPIRATION BIOPSY (FNAB)OF THE THYROID
ORELLANA Ruth1, BELLA Maria Rosa1, COMBALIA Neus1, FERNÁNDEZ Sara1, GIMÉNEZ Gabriel2, CASALOTS Alex1, ESCODA Maria Rosa1, DINARÈS Maria Carme1, REY Mercé1.
1Corporació Parc Taulí, Pathology Dep. Sabadell, Barcelona. Spain
2 Corporació Parc Taulí, Endocrinology Dep. Sabadell, Barcelona. Spain

INTRODUCTION: Histiocyte-like cells, characterised by vacuolated cytoplasm without classic nuclear changes of papillary carcinoma (PC), isolated or in clusters, have been described recently as highly specific for PC in thyroid FNAB specimens.
AIMS: Immunohistochemical study and cytohistologic correlation in cases with histiocyte-like cells at FNAB without classic features of PC.
MATERIAL AND METHOD: 327 FNA of thyroid were performed in our Hospital last year. Cases with histiocyte-like cells observed isolated in both smears and cell blocks were selected; Cytokeratin 19 (CK-19) (Novocastra, b170), Galectin 3 (Gal-3) (Novocastra, 9C4) and CD-68 (DAKO, PG-M1) were performed on the cell block; histologic correlation with surgical specimen was made.
RESULTS: Of 327 FNAB, only in 3 cases histiocyte-like cells were identified in both smears and cell block. These cells were immunoreactive for CK-19 and Gal-3, and were negatives for CD-68. All resection specimens correspond to nodular hyperplasia (NH), showing at microscopic level cystic follicles lined by follicular cells with histiocytic appearence like those identified in cytologic samples.
CONCLUSIONS: Histiocyte-like cells are a rare finding. Although these cells present the same immunohistochemical profile as PC cells, they are not pathognomonic, raising a potential pitfall for the interpretation of thyroid FNAB. These cells could be altered follicular cells from the cyst lining, in NH, with repair-like features or scamous metaplasia based on their immunoreactivity.

P 267
OUR EXPERIENCE IN THE EFFECT OF FINE-NEEDLE ASPIRATION ON THE PAPILLARY THYROID CARCINOMA SCAN
SOPTA Jelena., TATIC Svetislav , HAVELKA Marija., ATANACKOVIC Mirjana., MARKOVIC Ljiljana

Papillary carcinoma represents approximately 75-85% of all thyroid malignancies. We report comparative analyses: fine-needle aspiration (FNA) cytology before operation and definitive histopathology undergo surgical excision in evaluation of it.
During the last 2 years in 600 exanimate thyroid aspirates 19 cytological diagnosis of papillary carcinoma was made. These diagnostic guidelines were used: so-called “tumor cellularity” of smears, papillary arrangement of cells, tumor cells are larger then normal follicular cells with slight anisocytosis, ground-glass nuclei, presence of intranuclear inclusions and scanty or absent colloid. Tumor was more frequent in females in 74%. The middle ages (51,2) was older then expected. Classic cytological characteristics had 89% aspirates. One papillary carcinoma contained psammoma body. In 26,3% degenerative changes (hemorrhage and necrosis) were presented. In 2 smears papillary carcinoma were associated with Hashimoto`s thyroiditis and oxyphilic lesion.
Definitive histopathology undergo surgical excision was confirmed papillary carcinoma (15, or 79%), Hashimoto`s thyroiditis with degenerative changes (2), nodular goiter with degenerative changes (1) and oxfphilic lesion (1).
We conclude that FNA cytology has a high sensitivity and specificity for the diagnosis of papillary carcinomas. Significant number of thyroid papillary cancers could be detected by fine-needle aspiration before operation.

FINE NEEDLE ASPIRATION CYTOLOGY IN THE BREAST SCREENING PROGRAM IN VERONA. FIVE YEARS OF EXPERIENCE.
Manfrin E 1 , Mariotto R 2, Reghellin D1, Remo A1, Dalfior D1, Eccher A1, Bonetti F1.
1 Department of Pathology, University of Verona (Italy), 2 Breast Screening Unit ULSS 20 Verona (Italy)

Introduction: Fine needle aspiration cytology (FNAC) is a quick, low expensive diagnostic technique widely used in the management of breast lesions both in screening programs and clinical senology. Efficacy of cytology is variable in different experiences. A European standard system of reporting the classification of cell samples (C1-C5) is now used to perform quality assurance statistics in cytology units. This system allows to compare results between units with different experience. Purpose of the study: To evaluate the cytology quality standard in Breast Screening Program (BSP) in first five years of activity according to the European guidelines.
Material and methods: Compared with the “classic” screening, the Verona program has a different organization, similar to that of a Breast Clinic, and operates in a building exclusively devoted to the BSP. First level mammograms and all second level exams (US, FNAC, core biopsy, mammotome) are performed in the same structure by a staff composed of two radiologists, two cytopathologists, four technicians and two nurses. All women are submitted to a double projection mammography with real time analysis of mammograms by Radiologists. Results are immediately communicated. Negative patients are dismissed after

reassurances; suspicious patients are immediately submitted to second level examination. FNAC is evaluated in real time for adequacy and a diagnostic report is immediately given to the Radiologist. Results: 1374 FNAC have been performed; the cytology diagnosis was C1: 10.8% (149 cases); C2:51.7% (710cases); C3:6%(83 cases); C4: 9.2% (124cases); C5:22.3% (308cases). Absolute sensitivity was 73%, Complete sensitivity:95.4%, Specificity (full):75.2%, PPV:99%, False positive rate:0.4%, False negative rate:2.1%, Inadequate rate:10.8%, Inadequate rate from cancers:2.4%, Suspicious rate:15%. Conclusions: In the Verona BSP all thresholds for FNAC quality performance are within the preferable value suggested by European quality guidelines for screening programs. From our results it seems that FNAC can be highly effective particularly within a screening program with real time microscopic analysis coupled with multidisciplinary consult between radiologist and pathologist.(Supported by Fondazione Cassa Risparmio VR-VI-BL-AN.Bando 2004.Progetto Cr.Mammella)

CLINICAL AND CYTOLOGIC FEATURES OF PAPILLARY NEOPLASMS OF BREAST

CHOI Yoo-Duk, *GONG Gyung-Yub, *KIM Mi-Jung JUNG, KIM Hyun-Joong, LEE Ji-Shin, NAM Jong-Hee, JUHNG Sang-Woo, CHOI Chan
Department of Pathology, Chonnam National University Medical School, Gwangju, South Korea
*Department of Pathology, Asan Medical Center, University of Ulsan, Seoul, South Korea

INTRODUCTION: The cytologic pattern of papillary neoplasm of the breast is described as a cellular aspirate with complex papillary fronds and a variable number of single, high, columnar epithelial cells. Differentiating a benign papillary lesion from an atypical or malignant one is difficult using fine needle aspiration cytology owing to their overlapping cytologic features.
OBJECTIVE: To compare the cytologic features of benign and malignant papillary breast lesions.
STUDY DESIGN: We reviewed the clinical and cytologic features in 29 cases of intraductal papilloma and 26 cases of atypical papilloma or papillary carcinoma that had been diagnosed by histologic examination. The diameter of the mass was examined as a clinical feature. The cytologic features evaluated were as follows: bloody background, row of tall columnar cells, naked bipolar nuclei, hemosiderin-laden macrophages, myoepithelial cells, single scattered atypical cells, cellularity, nuclear atypia, nuclear grade, apocrine metaplasia, eosinophilic cytoplasmic granules, papillary clusters, small papillae, cell balls, and large sheets.
RESULTS: Of the features evaluated, the diameter of the mass, naked bipolar nuclei, and cell ball differed significantly between benign and atypical or malignant papillary neoplasm. The average diameter of a benign papillary neoplasm was 1.8 cm, and that of an atypical or malignant papillary neoplasm was 2.2 cm (p=0.042). Naked bipolar nuclei were found in 27 cases of benign papillary neoplasm (93.1%) versus 19 cases of atypical or malignant papillary neoplasm (73.1%) (p=0.050). Cell balls were found in 14 (48.3%) and 21 (80.8%) cases, respectively (p=0.012). All six cases in which cell balls were present and naked bipolar nuclei were absent proved to be atypical or malignant papillary neoplasm. Of 17 cases where cell balls were absent and naked bipolar nuclei present, 13 (76.5%) were benign papillary neoplasm.
CONCLUSION: Most of the cytologic features overlap in benign and atypical or malignant papillary neoplasm. Although they were not pathognomic, naked bipolar nuclei and cell balls were cytologic features that differed significantly between benign and atypical or malignant papillary neoplasm. When papillary neoplasm of the breast is suspected in a cytologic smear, the combination of clinical examination, mammography, and cytologic features should be considered to make the correct diagnosis.

P 270
THE ROLE OF FINE NEEDLE ASPIRATION CYTOLOGY (FNAC) IN CLINICAL DECISION MAKING FOR PATIENTS WITH ADVANCED BREAST CANCER

Chiara Casadio*, Mara Lusiardi*, Anna Cardillo°, Giuseppe Renne*

Background: Fine needle aspiration cytology (FNAC) is a well established procedure for the diagnosis of primary tumor, recurrence, and metastasis. Biomarkers of breast cancer cells (hormone receptor status and Her-2 oncogene expression) play a key role in the prognosis and treatment response. These biomarkers can become modified during progression of disease (PD).
Purpose: To demonstrate the utility of FNAC to confirm the clinical diagnosis and to re-evaluate the biomarker status in recurrent disease.
Materials and Methods: From January 2003 to April 2005, fine needle aspiration was performed on 98 cutaneous nodules or lymph nodes from 86 women. Smears were alcohol fixed (95%) and/or air-dried and stained with hematoxylin and eosin (H&E), Papanicolaou stain, or May-Gruenwald Giemsa. In 42 cases, the remaining specimen was rinsed in a 50% alcohol solution prior to preparation in a paraffin-embedded cell block. Slides from the cell block were submitted for H&E, and when necessary, immunohistochemistry (IHC) and fluorescent-in situ hybridization-dual colour (FISH) were performed. Cytomorphology, IHC, and FISH results were compared with those of the primary tumour, when possible.
Results: The majority of FNAC were positive (76 cases) for recurrent disease. 14 cases were negative and 8 were unsatisfactory for evaluation. 56 of the 76 positive cases were re-assessed for biomarker status. There was an 83.9% concordance in biomarker status (hormone receptor status and Her-2 expression) in the recurrent tumour when compared to the primary tumour. The discordant rate was 16.1% giving rise to the hypothesis that in a few cases one tumour cell clone has dominated and metastasized.
Conclusions: FNAC is a well-tolerated procedure that is easy to perform and less invasive. A well managed cytologic specimen is sufficient for establishing a diagnosis and biological characterization. IHC and FISH can be easily performed on FNAC and facilitate the management of breast cancer patients with PD.

CYTOLOGICAL FEATURES OF PROSTATIC INTRAEPITHELIAL NEOPLASIA

Alexander Valdman. Department of Urology, Karolinska Hospital, Stockholm, Sweden.
Sara Jonmarker. Department of Pathology and Cytology, Karolinska Hospital, Stockholm, Sweden.
Peter Ekman. Department of Urology, Karolinska Hospital, Stockholm, Sweden.
Lars Egevad. Department of Pathology and Cytology, Karolinska Hospital, Stockholm, Sweden.

INTRODUCTION. Fine needle aspiration cytology (FNAC) is an acknowledged method for diagnosing prostate cancer. Although core biopsies have become more common, FNAC is still useful in elderly men and in patients with advanced disease. False positive results are uncommon but concerns have been raised that prostatic intraepithelial neoplasia (PIN) could be misinterpreted as carcinoma. PURPOSE. The aim of this study was to describe cytological features of PIN.
METHODS. Macroscopically normal areas of peripheral zone in 177 radical prostatectomy specimens were sampled by scraping cells from cut surfaces. The obtained material was

smeared, air-dried and Giemsa-stained. Histological slides from these areas were reviewed and 17 samples with high-grade PIN and no invasive cancer were selected. An equal number of smears from invasive cancer were randomly chosen for comparison. The cytological specimens were reviewed without knowledge of the histological diagnosis.
RESULTS. Cancer smears showed high cellularity and dissociation, while PIN smears only contained a few clusters of atypical cells. Pronounced nuclear atypia, prominent or multiple nucleoli and mucin were more often seen in cancer than in PIN. Crystalloids, cytoplasmic granules and size of atypical clusters did not distinguish between PIN and cancer.
CONCLUSION. PIN should not be diagnosed by FNAC alone. However, a highly cellular smear with pronounced nuclear atypia seems to preclude PIN.

URINE CYTOLOGY IN THE PREVENTION OF NEPHROPATHY BY POLYOMAVIRUS IN PATIENTS WITH RENAL TRANSPLANTATION.
ALVAREZ M. (1), GONZALEZ-OBESO E. (1), RUIZ E. (1), LOPEZ-FERRER P. (2), VICANDI B. (2), VIGUER J.M. (2).
(1) Trainee resident; (2) M.D.

INTRODUCTION: The polyomavirus (PV) is a member of the papovavirus family; two strains are associated with disease in humans: BK virus and JC virus. It has a small size (45 nm. diameter), it is not enveloped, and it contains a double-stranded DNA genome. Primary infection occurs in childhood, having an asymptomatic course, and residing in a latent state that can be activated without clinical consequences. 0.3% of the inmunocompetent individuals have asymptomatic virurias, 3% of the pregnant women, and 30-40% of the recipients of a renal allograft. In this last group the reactivation can lead to nephropathy and allograft rejection.
PURPOSE OF THE STUDY: We aim to demonstrate the usefulness of urine cytology in the detection of reactivation of PV infection in patients with renal allograft.
MATERIALS AND METHODS: The 26 transplanted patients in the study were randomly asigned into two groups: group A with 17 patients with monthly control cytologies and group B with 9 patients without urine cytological studies. A cytology was considered to be positive when PV-infected intranuclear inclusion cells (decoy cells) were found. When positive, an additional cytology was made 15 days later, and, if positive too, the inmunosuppression treatment of the patient was reduced. Besides, if renal dysfunction was found a biopsy was performed.
RESULTS: 11% of the patients of group B developed PV nephropathy, while none of the patients of group A developed it, in spite of having 29% of positive urine cytologies.
CONCLUSIONS: The repeated detection of decoy cells in urine cytologies of patients with renal transplantation allows the modulation of the inmunosuppression treatment in order to control the viremia and to prevent the nephropathy that could lead to the loss of the renal allograft. As a consequence, in our hospital the patients with a renal allograft follow periodic urine cytology controls.

P 273
FNAB OF LYMPH NODES – IS IT WORTH USING THIS DIAGNOSTIC METHOD?
Székely Eszter dr., Istók Roland dr., Szabó Ildikó, Hegedûs Ágnes, Járay Balázs dr.
Semmelweis University, II. Department of Pathology

Introduction: Although lymph node examination by fine needle aspiration biopsy (FNAB) is a quick and cost-effective method, which is well tolerated by the patient, it is not widely used by hematologists. In our opinion, it is partly due to misapprehension and bad local experience.
Our purpose was to give a non-aligned statistical proof of the efficacy of this diagnostic method, based on our data.
Method: Between 1st of January 1995 and 31st of December 2004, 2796 ultrasound (US) guided lymph node FNABs were performed in the neighbouring US laboratories, that were examined by our cytological team. (734 aspirations were performed by radiologists, the rest by cytopathologist). The smears were wet fixed with ethanol, stained with H&E.
The results are the following: lymphadenopathy – 1334, metastatic disease-880, unsatisfactory for diagnosis - 307 , (264 of them were performed by the clinician, the rest by the cytopatologist), hematological malignancy: 152 cases, „other" 119 (the latter are cases, in which the smears are staisfactory, but the result cannot be pushed into either of the above-mentioned categories. 76 of the hematological malignancies were non Hodgkin lymphomas (NHL), and found 18 HL. 17 of the 18 HL diagnosed by FNAB, were histologically confirmed. In further 58 cases, the cytological examination raised the possibility of a hematological malignancy, which was confirmed in 41 patients. (No more data in 9 patients). In 8 cases, the histological examination proved no malignancy (fals postitive by cytology). In this series of 2796 lymph node FNAB, one single false negative case was found.
Conclusion: our data prove, that FNAB of enlarged lymph nodes is a very efficient method in the diagnosis of different hematological and non- hematological diseases in experienced hands . The examination can be repeated in case of the suspicion of false negativity. We suggest the use of this easy, cost effective and quick method, by which unneaded operations might be avoided, and based on the quick diagnosis many patients can benefit. We would like to share some of our „favourite cases" with the audience.

P 274
EFFECT OF VITRIFICATION ON FERTILIZING CAPACITY OF SPERMATOZOA IN FERTILE AND INFERTILE MEN
FASLI Hassan, GHAFFARI NOVIN Marefat, PEIROVI Tahmineh, SOLEIMANIRAD Jafar
Department of Reproductive Endocrinology and Embryology, Reproductive Biology and Biotechnology, Infertility Center, Tehran, Iran
Department of Histology, Urimia University of Medical Sciences, Urimia, Iran
Infertility Center, Tabriz University of Medical Sciences, Tabriz, Iran

Cryopreservation is widely used in Assisted Reproductive Techniques to maintain male fertility. Evaluation of the acrosome and its disruption and motility are important tasks within the diagnostic tests of male infertility to predict the fertilizing capacity of sperm. The aim of the present study was to evaluate the effect of vitrification on acrosome reaction and motility of sperm in fertile and infertile men. Semen samples were collected from ten fertile and twenty infertile men after a minimum of 3 days of sexual abstinence. After seminal liquefaction, a routine semen analysis was performed using Semen Analyzer Quality to determine sperm concentration and motility according to World Health Organization specifications. This was immediately followed by the evaluation of acrosome quality by triple staining technique. The remainder of each sample was immediately cryopreserved by vitrification method and thawed after two weeks. Analyses of concentration, motility and acrosome quality were performed after thawing and the results were statistically analysed by paired t-test.
After vitrification, the percentage of live spermatozoa with intact acrosome was significantly decreased from 33.37 ± 4.07 to 9.87 ± 2.97 ($p<0.002$) in fertile and from 26 ± 3.64 to 11.16 ±1.82 ($p<0.001$) in infertile groups. The percentage of sperm progressive motility (a + b) were significantly

decreased from 60 and 35 to 40 and 20 in fertile and infertile groups after vitrification, respectively. It is concluded that vitrification impairs fertilizing capacity of sperm in fertile and infertile men.

SECONDARY TUMORS TO THE PANCREAS. STUDY OF 17 CASES WITH FINE NEEDLE ASPIRATION CYTOLOGY

Manfrin E°, Capelli P°, Zamboni G*, Eccher A°, Remo A°, Reghellin D°, Dalfior D°, Bonetti F°, Menestrina F°.
° Department of Pathology, University of Verona.
* Anatomina Patologica, Ospedale Sacro Cuore Don Calabria, Negrar Verona

Introduction: Secondary tumors to the pancreas are inusual and in most cases part of an advanced metastatic disease. They account for 3-16% of all pancreatic malignancies. They present as solitary or multiple lesions, sometimes with clinical and radiological features that can be confused with a primary pancreatic adenocarcinoma. Fine needle aspiration cytology (FNAC) is a quick, low-expensive technique that allows a rapid identification of metastatic carcinoma and the patient's management in pre-surgical diagnostic phase.
Purpose: To report the clinical and cytological findings of secondary tumors to the pancreas observed in the Department of Pathology of Verona University.
Methods: Between January 1990 and December 2004, we studied 17 secondary tumors to the pancreas diagnosed by FNAC.
Summary: The mean age of patients was 62 years. 10 patients were males (59%) and 7 females (41%). In 16 cases (94%) FNAC was performed with ultra-sonography guide on outpatients and in 1 case FNAC was performed during abdominal laparothomy for suspected pancreatic adenocarcinoma.. The metastatic lesion involved the head of the pancreas in 41% of cases (7/17) and the body-tail in 35% (6/17). In 24% of cases (4/17) the anatomic site of pancreatic metastasis was not available. Radiological imaging showed in 94% of cases (16/17) a suspicious solitary mass and in a single case multiple lesions; the diameter of suspicious nodules ranged from 2 to 8 cm. The histotype of metastasis was renal cell carcinoma, classic type: 35%(6/17), large bowel carcinoma: 18%(3/17), gastric carcinoma 6%(1/17), breast carcinoma: 4%(1/17), prostate carcinoma: 6%(1/17), carcinoma of the lung:6%(1/17). In 24% of cases the primitive site of neoplasia could not be assessed. The clinical history was available in all cases of renal cell carcinoma with a mean interval of 13 years between the primitive renal carcinoma and the pancreatic metastasis.
Conclusion: Most secondary tumors to the pancreas occur as a solitary lesion, both on the head and tail of pancreas, simulating a primary pancreatic carcinoma. The most frequent metastatic tumor to the pancreas is renal cell carcinoma, often many years after the primary renal tumor. FNAC allows a distinction between primary pancreatic cancer and secondary tumors and represents an important diagnostic tool in the follow up of oncologic patients.

University of Medicine and Pharmacy Iasi, Romania

Consistent epidemiologic evidence had demonstrated that human papillomavirus (HPV) infection plays a central role in the development of cervical cancer precursors and invasive cervical cancers. Over 20 types of HPV are associated with cervical intraepithelial lesions and cervical carcinomas. The purpose of our study was to analyze viral markers expression in cervical lesions. 105 Pap smears and 84 biopsies were selected as they exhibited viral cytopatic effects. We performed immunohistochemical staining for HPV on both types of preparations, in cases with SIL diagnosis. Cytologic aspects were: koilocytosis associated with diskeratocytes, and parabasal cells (± atypia), low grade squamous intraepithelial lesion (L-SIL) and high grade squamous intraepithelial lesion (HG-SIL). Histology revealed chronic cervicitis, condyloma acuminatum, L-SIL and H-SIL. HPV was detected in 61.1 % of smears, exhibiting a double localisation: nuclear and cytoplasmic and in 65.71 % of biopsies, with a nuclear localisation and an enhanced expression within superficial layers of condylomas. Concluding, HPV may be evidentiated in cytologic and histologic preparations from cervical lesions, the negative preparations being atributed to (co)existence of other infectious agents or to the limited sensitivity of the immunohistochemical method.

COMPARATIVE STUDY OF CONVENTIONAL AND LIQUID-BASED CYTOLOGY IN A POPULATION WITH OPPORTUNISTIC CYTOLOGICAL SCREENING

HADZI-NICHEVA Biljana,1 GRNCHAROVSKA Zlata,1 PRODANOVA Irina,2 YASHAR Genghis,2 KUBELKA-SABIT Katerina,2 POPOVSKA Zora,1 BASHESKA Neli2
1Department of Gynecological Cytology, Clinic of Obstetrics and Gynecology, 2Department of Histopathology and Clinical Cytology, Institute of Radiotherapy and Oncology, Medical Faculty Skopje, Republic of Macedonia

Background: In the last decade the conventional Pap smear (CPS) has frequently been replaced by the liquid-based cervical cytology (LBC) in the routine clinical practice due to improved technical quality and increased efficacy in detecting squamous intraepithelial lesions (SIL) and cervical cancer by LBC.
Aims: The purpose of this study is to report the preliminary results of the performances of LBC versus those of CPS, in a country with an opportunistic cytological screening and a high incidence of cervical carcinoma.
Methods: This comparative retrospective study is an initial part of a wider project, anticipated to assess the validity of the new method and its impact on clinical practice. It includes two groups of women referred to a tertiary centre for gynaecologic care, in different six-month periods. In each group, the Pap smear was taken by one of the methods. Data from unselected, consecutive series of 3,261 LBC tests and of 4,102 CPSs were analysed. Cytological diagnoses were classified using the Bethesda system. The differences in specimen adequacy and the rates of atypical squamous cells (ASC) category between the two groups were compared using *fÓf¢* test. The histological correlation with histopathological findings could be established in 901 patients with the LBC and in 1,408 with the CPSs. Sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and diagnostic accuracy of the findings were evaluated as well.
Results: The improvement in the specimen adequacy for LBC was documented by the more than fivefold reduction of the proportion of unsatisfactory specimens (0.4% for LBC vs. 2.1% for CPS, P<0.001). The rate of ¡§satisfactory but limited by¡¨ was also reduced by 40% for LBC (P<0.001). However, the rate of ASC category was similar in both methods (0.9% for LBC vs. 1.2% for CPS). The performances of LBC for detection of cervical SIL or cancer lesions versus those of CPS, such as sensitivity (94% vs. 79%), PPV (85% vs. 69%) and NPV (90% vs. 66%) were significantly different (P<0.001). There was no statistically significant difference in

specificity between the methods (65% vs. 62%, P<0.15). Ultimately, the diagnostic accuracy was higher in LBC than in CPS (84% vs. 73%, P<0.001).
Conclusions: Our preliminary results suggest that the implementation of LBC significantly improved the technical quality of the smears and resulted in statistically significant improvement of the diagnostic value of the Pap test.

P 278
IMMUNOPHENOTYPING OF CSF SPECIMENS BY SLIDE BASED LASER SCANNING CYTOMETRY
JASTANIA Raid, BOERNER Scott, GEDDIE William

Background:
In cerebrospinal fluid (CSF) cytology analysis of cell surface markers is frequently required for diagnosis or subtyping of lymphoproliferative disorders, but insufficient cells may be present for flow cytometry. Laser scanning cytometry provides a simplified and inexpensive means of immunophenotyping paucicellular samples. We have assessed our experience with this method in CSF samples requiring immunophenotyping over an 18-month period.
Materials and Methods: Cytocentrifugation and rapid Giemsa stain were used for immediate assessment of 521 consecutive CSF samples. Slide based immunophenotyping by Clatch's method was attempted in 60 samples that showed some increase in lymphoid cells. Twenty-five cases had a history of previous hematolymphoid malignancy, and in 12 HIV positive patients neurologic decompensation led to suspicion of CNS lymphoma. 37 samples contained 10,000 cells or less, with the remainder ranging up to 150,000 cells total. In 12 samples with over 60,000 cells a full immunophenotyping panel of 20 antibodies was performed. In the samples with fewer cells at least kappa and lambda light chains and CD19 were initially assessed. By repetitive re-staining of the unfixed cells on the slide more surface antigens could be documented. After fixation and permeabilization intracellular markers could be assessed. All analyses were performed in the cytology laboratory using an LSC (Laser Scanning Cytometer - Compucyte®)
Results: 43 cases showed a reactive immunophenotype and a diagnosis of negative or chronic inflammation was rendered. The 17 remaining cases were diagnosed as suspicious for lymphoma (7) or malignant lymphoma (10). In 3/7 suspicious cases the LSC result was supportive of, but not conclusive for, lymphoma. In the remainder it was not contributory. In the 10 definite lymphoma cases the LSC immunophenotype confirmed B-cell clonality or an abnormal T-cell phenotype consistent with the clinical and morphologic diagnosis.
Conclusions: Slide based cytometry using Clatch's method is useful in the evaluation of CSF samples containing a hematolymphoid population suspicious for lymphoma, allowing specific reactive or malignant diagnoses in a number of cases containing inadequate cells for flow cytometry.

P 279
UTILITY OF CYTOLOGIC IMPRINTS IN INTRAOPERATIVE DIAGNOSIS
Garza-Guajardo Raquel MD FIAC, Mendez-Olvera Nora MD, Ancer-Rodriguez Jesús MD, Barboza-Quintana Oralia MD FIAC
Anatomic Pathology and Cytopathology Service, Universitary Hospital “Dr. José E. González”, UANL, Monterrey, México

Intraoperative diagnosis has been traditionally based on frozen histologic sections because provide architectural information, cytologic smears allow us to evaluate morphology on well preserved cells, without the well-known artifacts associated with freezing. Both methods thus complement each other. However, utilizing only the cytologic technique is possible if performed by experienced hands in special situations.
Material and Methods
We study 416 consecutive specimens submitted for intraoperative biopsies over a two-year period, Imprint cytologies were done on all specimens, and frozen sections were performed on 384 of them. The diagnoses obtained from both methods were recorded and compared with the final diagnosis yielded by the definitive histological sections.

Results
9 of 416 cases (2.2%) were misdiagnosed by IC, and there were diagnostic errors in 8 / 384 (2.1%) cases by frozen sections. Diagnostic accuracy was 97.8% for imprint cytology and 97.9% for frozen sections. Six cases of 416 (1.4%) were misdiagnosed by both imprint cytology and the frozen section. The accuracy rate of both methods used jointly was 98.5%.
Conclusions
Intraoperative imprint cytology is a quick, easy-to-perform, and low-cost technique that provides morphological details on intact cells without the artifacts resulting from freezing. It is therefore a highly valuable adjunct to the frozen section.
The benefits obtained from the use of imprint cytology are unquestionable, particularly under the following situations and considerations: 1) assessment of small specimens; 2) necrotic lesions; 3) to prevent cryostat contamination in infectious processes; 4) to facilitate identification of micro-organisms; 5) no special equipment is required; 6) to preserve material for special studies (ultrastructure, immunohistochemistry, etc.); 7) for the assessment of some specimens for which it is not possible to perform frozen sections, such as bone specimens; 8) it shows cytogenetic characteristics (e.g. parathyroid tissue, cytological type of lymphoma); and 9) experience is gained in cytology.

P 280
THE IMPORTANCE OF P-16’S EXPRESSION CORRELATED WITH KI-67 IN ESOPHAGEAL INTRAEPITHELIAL HPV-INDUCED SQUAMOUSE LESION
Authors : Maria Sajin , Alina Chefani, Anca Lazaroiu, Anca Simona Constantin,Ana-Maria Sajin,
Bucharest Universitary Hospital, Carol Davila Medicine Faculty, Bucharest

BACKGROUND The esophageal malpighian epithelium may be the siege of HPV infections, thus determining intraepitheial squamouse lesions, similar to thoes found at the level of the uterine cervix. P-16 is an cyclin-dependent kinases inhibitor and a key regulator of the G1-S, and check point in the cell cycle. The over-expression of P-16 marker has been observed in CIN and invasive carcinomas, associated with high-risk hPV types.. Ki-67 is a nuclear antigen expressed in g1-S-G2-M phases, also being an agrssivity indicator.
DESIGN A number of 31 esophageal byopsies and 8 esophagectomy specimen material was fomalin-fixed, paraffin embedded , HE stained and analised immunohistochemicaly using speciffic antibodies against Ki-67 and P-16 by ABC immunoperoxidase procedure. Out of thoes 31 byopsies, 7 were showing HPV-induced low grade intraepithelial squamouse lesion ,and 18 were showing high grade intraepithelial squamouse lesions (CIN II-6, CIN III-9, CIS-3) and 6 cases of inavsive carcinoma.
RESULTS :Our study demonstrates that HSIL-s have uniform and diffuse nuclear staining (Ki-67+) 100% (24 cases) and (P-16+) 80% (19 cases) thruout all cell layers of the lesion. None of our 7 LSIL cases showed (+) Ki-67 in the supperficial layer. In the lower third of the epithelium our LSIL cases showed positive staining for both P-16 and Ki-67 but the upper third of the epithelium showed no such staining for either of them.
CONCLUSION Although the classical morphological features are the main diagnostic mean in the case of HPV

infection, the P16 and Ki-67 immunohistochemical markers and their staining patterns are useful in distinguishing between two biologically different groups of esophageal neoplastic lesions.

INTESTINAL METAPLASIA AT THE GASTRO-ESOPHAGEAL JUNCTION: PREVALENCE AND ASSOCIATED CONDITIONS

Fiocca R, Mastracci L, Musizzano Y, Spaggiari P, Savarino V, Zentilin P, Dulbecco P, Mansi C, Conio M.
DICMI, Department of Pathology;
DIMI,Department of Gastroenerology;
University of Genova

AIM: Junctional intestinal metaplasia (JIM) is defined as intestinal metaplastic change found at the esophago-gastric junction and its pathogenesis is controversial. The aim of our study was to determine the prevalence of JIM and the frequency of coexisting esophageal and gastric lesions. METHODS: we studied a continuous series of 485 unselected patients with various digestive symptoms who underwent upper GI endoscopy including multiple esophageal, junctional, and gastric biopsies (body and antrum). All samples were stained with Haematoxylin-eosin, PAS-Alcian blue and Giemsa for H. pylori detection. All the slides were simultaneously revised by two expert GI pathologists who assessed the presence of microscopic esophagitis, Barrett's metaplasia, intestinal metaplasia at the junction and in the stomach and gastritis in accordance with the up-dated Sydney system.
RESULTS: JIM was found in 91/485 cases (18.8%); 11 had complete-type metaplasia, 77 incomplete-type and 3 both types. The male/female ratio was 1,5/1 for cases with JIM and 1/1 in 394 controls without JIM and the median age was 59.5 in the former and 53.3 in the latter group (p=0.0003). The prevalence of associated lesions in cases with and without JIM respectively was as follows: microscopic esophagitis 50.5% vs 58.6%, Barrett's esophagus 31.9% vs 0%, H. pylori gastritis 22.0% vs 23,9%, gastric intestinal metaplasia 27.5% vs 17.3% (p=0.037), no gastro-esophageal lesions 4.4% vs 24.1%. Since numerous patients showed more than one associated lesion the sum of % exceeds 100%.
CONCLUSIONS: both esophageal and gastric lesions may be found in association with JIM with a trend of esophageal lesions to be more frequent in cases with JIM than in controls. The very low prevalence of normal esophageal and gastric findings in cases with JIM as compared with controls suggests that JIM is not an isolated change but esophageal, gastric or combined factors contribute to its pathogenesis.

ESSENTIAL MARKERS FOR THE EVALUATION OF METAPLASIA, DYSPLASIA AND CANCER IN BARRETT'S ESOPHAGUS

Semyon Petrov, Timur Akhmetov, Michael Burmistrov, Eugeni Sigal
Kazan Cancer Center, Kazan State Medical University, Dept. Pathology,
Kazan, Russian Federation

Introduction:The last 20 years are characterized by increased incidence of distal esophageal adenocarcinoma, being considered as a complication of gastroesophageal reflux disease and Barrett's esophagus. The major risk factors for adenocarcinoma are intestinal metaplasia and high grade dysplasia.
The purpose of this study was to select essential markers of dysplasia and metaplasia that could be included in standard panel for diagnostics of precancerous conditions of distal esophagus.
Methods: In 2003 – 2004 we performed an immunohistochemical (IHC) analysis of distal esophagus biopsy specimens (histologically showing features of metaplasia and/or dysplasia) in 42 patients (38 male and 4 female). Our common panel included antibodies to the following proteins: markers of intestinal or cardial differentiation (CK ¹7 and CK ¹20, villin), markers that could be used for evaluation of dysplasia grade (CEA, p53) and marker of proliferation (Ki67). In difficult cases (where cancer is being supposed) we defined additional markers: basement membrane marker - collagen IV, marker of histiocytes - CD 68, vimentin and a wider set of cytokeratins.
Results: The high grade dysplasia and adenocarcinomas were revealed due to the strong uniform cytoplasm reaction for CEA with nuclear reaction for p53 and a higher proliferation index. Using the above mentioned panel of markers we have diagnosed the following cases: 16 (38,2%) - Barrett's esophagus with cardial metaplasia, 8 (19,2%) - Barrett's esophagus with intestinal metaplasia, 7 (16,6%) adenocarcinoma, 7 (16,6%) squamous-cell carcinoma, 2 (4,7%)–poorly differentiated carcinoma and 2 (4,7%) - chronic esophagitis.
We have concluded that the usage of the wider panel of biomarkers could significantly help to diagnose the distal esophagus precancerous conditions and to determine effective treatment.

GLYCOPROTEIN EXPRESSION PATTERNS IN THE BIOPSIES OF GASTROESOPHAGEAL JUNCTION : A PRELIMINARY STUDY

CELIKEL Cigdem Ataizi*, SAVCI Dilara*, ERBARUT Ipek*,OZKAN Naziye*,AVSAR Erol **
Marmara University School of Medicine, Departments of Pathology* and Gastroenterology**

To determine incomplete intestinal metaplasia (IM) in endoscopic biopsies obtained from the gastroesophageal junction or proximal, may represent IM of the cardia (CIM) due to H. pylori (HP) and gastroesophageal reflux disease (GERD) or Barrett's esophagus (BE), which have different clinical implications. In this study, we aimed to determine the glycoprotein expression patterns in BE, CIM (HP and GERD related), multilayered epithelium(ME) and columnar blues (CB) in order to relate their expression to BE development. Archival biopsies and endoscopy reports of 138 patients biopsied from gastroesophageal junction (or proximal) were re-evaluated. CIM was demonstrated in 51% of 64 patients diagnosed as carditis due to GERD. Fifty-eight patients had HP carditis with complete and incomplete intestinal metaplasia in 16% and 27% of the cases, respectively. BE was determined in 16 patients, 3 biopsies revealing dysplasia. ME was detected in 3 BE and 12 GERD associated carditis. CB was identified in 4 HP related carditis, 16 GERD related carditis and 12 BE. Sequencial sections of representative formalin-fixed paraffin-embedded tissue sections in 16 BE, 12 GERD and 8 HP associated CIM were stained by immunohistochemistry for Human Gastric Mucin (HGM), MUC1, MUC2, MUC5AC. Submucosal glands of esophageal mucosa expressed MUC5B, whereas squamous epithelium

MUC1. MUC1 was rarely expressed in BE and CIM compared to ME and CB ($p < 0.05$). All BE cases showed gastric mucin (MUC5AC, HGM), but only 53.4% MUC2 expression. Gastric mucins (MUC5AC, HGM) were detected in all CIM cases, but expression intensity was low in columnar cells and usually HGM staining was limited to goblet cells in HP associated CIM cases. MUC2 expression differed between GERD and HP associated CIM being 45% and 22%, respectively. Gastric mucins (MUC5AC, HGM) with low intensity of staining was limited to basal cytoplasm in CB, but to the superficial columnar cells in ME. Our preliminary results suggests that ME may be a precursor in the development of BE. In regard to mucin expression the specificity of any pattern is insufficient for distinction in individual cases with BE and CIM in GERD are virtually indistinguishable, limiting their use in this differential and raising the question of whether they are biologically related.

IMMUNOHISTOCHEMICAL MARKERS IN THE DIAGNOSIS OF BARRET'S ESOPHAGUS AND ESOPHAGEAL ADENOCARCINOMA

IMMUNOHISTOCHEMICAL MARKERS IN THE DIAGNOSIS OF BARRET'S ESOFHAGUS AND ESOPHAGEAL ADENOCARCINOMA

IMMUNOHISTOCHEMICAL MARKERS IN THE DIAGNOSIS OF BARRET'S ESOFHAGUS AND ESOPHAGEAL ADENOCARCINOMA

A.Kotsev, M.Kamenova, N.Sarbianova, K.Tschernev, Al.Tcherveniakov

Bulgaria, Medical University, Sofia, :Medical Institute of Emergency,Sofia

Introduction: Barrett's esophagus /BO/ is associated with increasing incidence of the adenocarcinoma of the esophagus. Histopathological staging of BO is associated with high inter- and intraobserver variation .There have been many attempts to find adjunctive methods for improving the diagnose.

Purpose: As the progression of Barrett's metaplasia to adenocarcinoma is related to impaired control of cell cycle the question arised whether the application of tumor markers involved in increased proliferation and inhibition of apoptosis could be useful for an exact diagnosis. ..

Material and methods: Tissue samples from 25 patients were examined: eight with BO and seventeen with adenocarcinoma, associated with BO. The tissue pieces for the immunohistochemistry analysis were obtained by endoscopic biopsy or after surgical resections and included in paraffine blocks. Several tumor markers involved in cell proliferation and apoptothic pathways were studied: Ki-67, PCNA, RB, p16, p53, Bcl-2 and Bax .Routine immunohistochemical procedures were applied with antibodies produced from Dako, Denmark.

Results:Expression of the markers for proliferation Ki-67 and PCNA was increased in adenocarcinoma, especially in undifferentiated forms.Mutated tumor marker-p53 was strongly expressed in adenocarcinoma and Barrett's epithelium with high grade of dysplasia.Expression of the proapoptotic marker Bax was increased in adenocarcinoma.The antiapoptotic marker Bcl-2 showed no expression in most of the samples; in some samples the staining was weak in tumor cells and strong positive in immune cells of the lamina propria. Expression of the markers associated with cell cycle-p16 and Rb was increased in adenocarcinoma and high grade Barrett's epithelium .

Conclusion: The results suggest that the investigation of tissue tumor markers may contribute to improve the diagnosis , assessment of the prognosis and risk of progression .

P 286

PROGNOSTIC AND POTENTIALLY PREDICTIVE FACTORS IN EARLY GASTRIC CANCER

Ma³gorzata Malinowska, Anna Nasierowska-Guttmejer

Department of pathology,Oncology Center,Warsaw

BACKGROUND: The incidence of gastric cancer is decreasing worldwide, but the prognosis is still generally poor. It is the second cause of death in men and fourth one in women. Detection of the early gastric carcinoma is the crucial factor to improve the results
of treatment. 5 -year survival rate in T1 stage is 80-95%. Lymph node metastasis are observed in 10.4% of early gastric cancer. The depth of invasion and lymph node metastasis are the most significant prognostic factors in the early gastric cancer. AIM: The E-cadherin-catenin complex is important for cell-cell adhesion of epithelial cells. We analyze the E-cadherin expression with clinicopathological features of the early gastric cancer. METHODS: 39 patients were diagnosed and total gastrectomy with lymphadenectomy was done. Histological report included: location and size of the tumor, surgical margins, histologic type and grade, pTNM stage. Immunohistochemical staining of E-cadherin was performed. Normal membrane E-cadherin staining was observed in control gastric mucosa. RESULTS: Abnormal expression of E –cadherin was demonstrated in 37 cases (94.9%). High (3+) membranous expression of E-cadherin was seen in 2 well differentiated adenocarcinomas (5.1%). Less or absent immunoreactions of E-cadherin was observed in 14 well differentiated adenocarcinomas and all (23) poorly differentiated adenocarcinomas or diffuse type of Lauren classification. Moreover, abnormal expression of E-cadherin occurred more frequently in macroscopic ulcerated type (0-IIc, 0-I II) and was associated with lymph node metastasis. CONCLUSION: We suggest that E-cadherin play an important role in the macroscopic growth as well as microscopic differentiation of the early gastric carcinoma.

HISTOLOGIC CHANGES OF THE GASTRIC MUCOSA ASSOCIATED WITH GASTRIC CARCINOMAS AND PRIMARY LYMPHOMAS

RAMADAN Saime Sezgin, CELIKEL Cigdem

Marmara University School of Medicine, Department of Pathology, Istanbul, Turkey

In order to formulate proper surveillance and therapy protocols in epithelial changes of the gastric mucosa, it is important to determine the frequency and type of preneoplastic lesions in gastric carcinogenesis. For comparative purposes, we evaluated gastric mucosa surrounding 93 gastric adenocarcinomas (GCa), 19 primary gastric lymphomas (PGL) and gastric mucosa of 30 autopsy cases who died of reasons other than gastric malignancies, according to the updated Sydney System and Padova International Classification. In addition, in order to determine the role of G-cell and enterochromaffin-like cell hyperplasia in gastric carcinogenesis, we studied gastrin and chromogranin A (ChrA) immunohistochemistry in the surrounding mucosa of each case. In our study; atrophy, intestinal metaplasia (IM) type I and III, foveolar hyperproliferation (FHP) were all observed in high frequencies in gastric carcinoma cases ($p<0.001$). Hyperproliferative intestinal metaplasia (HIM), low (LGD) and high grade dysplasia (HGD) were only detected in carcinoma cases. When diffuse (n=43) and intestinal (n=50) type of GCa cases were compared, atrophy, IM type III, HPIM, LGD, and HGD were statistically more common in intestinal GCa's ($p<0.05$). High H.pylori density and FHP were recorded mainly in diffuse GCa's. In our study, gastrin and ChrA overexpression were observed in GCa and PGL cases but not in autopsy cases. Gastrin expression was related to intestinal metaplasia ($p<0.05$) but not to the H. pylori

density and atrophy. ChrA expression was related to intestinal metaplasia ($p<0.01$) and atrophy ($p<0.05$) but not to the H. pylori density. G cell hyperplasia corelated well with the lineer and diffuse neuroendocrine cell hyperplasia ($p<0.05$). Our study revealed that FHP and HPIM which comprises inconspicious for dysplasia group in Padova International Classification were associated with carcinoma cases in high frequencies. We think that these lesions could be preneoplastic lesions rather than being a part of a regenerative process. Our results show that although intestinal GCa's develop as a consequence of a sequence of events, some mechanisms acting in the active phase of gastritis could be an important factor in the carcinogenesis of the diffuse type. Our data related to gastrin and ChrA immunohistochemistry gives the idea that both G cell and enterochromaffin cell hyperplasia may be involved in gastric carcinogenesis.

P 288

INTESTINAL AND DIFFUSE TYPES OF GASTRIC ADENOCARCINOMA: CLINICOPATHOLOGIC FEATURES

RAMADAN Saime Sezgin, CELIKEL Cigdem, KULLU Sevgi
Marmara University School of Medicine, Istanbul, Turkey

Gastric carcinoma is classified into intestinal type (IC) and diffuse type
adenocarcinoma (DC) by Lauren histological classification. There are reports that these two types have different prognostic implications according to different clinicopathological factors. We examined 40 DC and 49 IC in radical gastrectomy specimens to determine the importance of factors affecting prognosis within these two groups of carcinomas. Patients' age, sex and tumor localisation were determined from clinicopathologic files. We retrospectively evaluated all the H&E stained
slides of the cases and recorded histological grade,WHO histological types, invasion patern(submucosal, pushing or infiltrative), depth of invasion, venous, lymphatic and perineural invasion, intratumoral and peritumoral lymphocytic infiltration, desmoplasia,metastatic foci in lymph nodes and other organs. In our study, we observed that both types were more common in males and IC was more frequent in elderly. In the literature; lymph node metastases, perinodal, perineural, serosal invasion,surgical margin positivity are features accepted as determinants of poor prognosis and these are all observed in high frequencies in our DC cases. No statistical difference was found between the two groups in respect to WHO histological types but DC mostly had signet ring cell component. In our study, we also found that the two types had different invasion paterns: DC,infiltrative or submucosal; IC, infiltrative or expansile. There were no difference in intratumoral lymphocytic infiltration (including lymphoid agregate and follicle formation) between two histological types. Although no statistical difference could be found in regard to desmoplasia formation between the two groups, the extend of desmoplasia was higher in IC. In summary, factors defined as poor prognostic factors in the literature were more common in DC and we conclude that these altogether bring out the poor outcome in DC.

P 289

HISTOLOGICAL CHANGES IN HYPERPLASTIC POLYPS AND SURROUNDING GASTRIC MUCOSA

ALTINOK Gulcin*, GUREL Bora*, CAKAR Mustafa**, HIMMETOGLU Cigdem*, SOKMENSUER Cenk*, BAYRAKTAR Yusuf**, GEDIKOGLU Gokhan*,
Departments of Pathology* and Gastroenterology**, Hacettepe University School of Medicine, Ankara, Turkey

Introduction: Hyperplastic polyps were considered to represent the regenerative changes in a background mucosa with chronic atrophic gastritis and rarely harbor true precancerous lesions themselves.
Aim: The aim of this study was to determine on which morphological background gastric hyperplastic polyps develop and to assess the frequency of precancerous changes in the hyperplastic polyps and background mucosa.
Material and Method: We studied 73 patients with gastric hyperplastic polyps and characterized endoscopic and histologic features of the polyps (topographic location, multiplicity and the presence of dysplasia and adenocarcinoma) and the background gastric mucosa (intestinal metaplasia, dysplasia, carcinoma, and classification of gastritis). The histopathologic features seen within the hyperplastic polyp and the background mucosa were assessed according to the revised (2004) Vienna classification.
Results: Hyperplastic polyps were most common in the antrum (42.5%) followed by the corpus (27.4%), both antrum and corpus (15.1%) and the site of anastomosis (15.1%). There were multiple polyps in 37% of the patients which were mostly situated in antrum (40.7%), followed by both antrum and corpus (33.3%). Intestinal metaplasia of the polyp was present in 19% and low-grade dysplasia in 9.5% of patients. Only one patient (1.3%) had intramucosal adenocarcinoma within the polyp which also showed adenocarcinoma in the surrounding mucosa. Evaluation of the surrounding gastric mucosa showed intestinal metaplasia in 36% of patients, at least low-grade dysplasia in 12%, and synchronous carcinoma in 9%. Of the seven cases with hyperplastic polyps harboring low grade dysplasia, four also demonstrated low grade dysplasia in the surrounding gastric mucosa. All hyperplastic polyps with dysplasia were located in the antrum and all but one were multiple. Ninety percent of the hyperplastic polyps were associated with various forms of gastritis, most commonly superficial gastritis (44.2%), followed by chronic active H. pylori gastritis (23.1%), chronic atrophic gastritis (21.2%) and chemical gastritis (11.5%).
Conclusion: These results show a strong association between mucosal inflammation and development of hyperplastic polyps. As the frequency of dysplasia and adenocarcinoma in the background mucosa was higher than that of hyperplastic polyps, a meticulous endoscopic examination and multiple biopsies of the surrounding mucosa would reveal early precancerous changes.

P 290

EFFECT OF TRANSFORMING GROWTH FACTOR-BETA (TGF-B) ON PROLIFERATION OF GASTRIC EPITHELIAL CELLS IN CULTURE

GHAINI M.Hosswin, Pathologist

BACKGROUND: Helicobacter pylori has a well-established role in the development of gastric cancer. In vitro studies reveal increased proliferation of the gastric mucosa in the presence of H. pylori infection. It has been also shown that production of some cytokines, such as interleukin-1 beta (IL-1b) is increased in H. pylori infection. In addition, IL-1b increases proliferation of gastric epithelial cell in culture study. In this study, The effect of transforming growth factor beta (TGF-b) on gastric epithelial cell proliferation has been examined.
METHODS: AGS cells were cultured with TGF-b. DNA synthesis was assed by bromo-deoxyuridine (BrdU) test and total viable cell numbers by MTT assay.
RESULTS: TGF-b decreased DNA synthesis and cell numbers. This effect was both time- and dose-dependent ($p<0.05$). Both tests, BrdU test & MTT assay revealed this suppressive effect, but it was more evident in BrdU test. Simultaneous exposure to TGF-b & IL-1b, obliterated the results of each one, alone.
CONCLUSIONS: TGF-b suppresses proliferation of malignant gastric epithelial cells. It appears that modulatin of tyrosine kinase activity is essential to anti-proliferative effect

of TGF-b. This effect is reversed by IL-1b, and it may be due to opposed effects of these cytokines.

P 291

PROGNOSTIC VALUE OF BAX, BCL-2 PROTEINS AND FAS/FASL SYSTEM IN PATIENT WITH GASTRIC AND COLON CANCER.

N.Belushkina, V.Obukhova, A.Samokhvalov, S.Kharnas
Sechenov Moscow Medical Academy, Russian Federation

Background. The inhibition of apoptosis is one of possible mechanism of tumor formation. The family Bcl-2 proteins and Fas/FasL system play the important role in apoptosis regulation. The family Bcl-2 protein includes the proteins-inhibition of apoptosis (such as Bcl-2), and activators of apoptosis (such as Bax). Fas protein is known to induce cell death by apoptosis in susceptible cells. Change of a level gene expression these protein lead to disturbed of apoptosis regulation. The prognostic importance of Bax, Bcl-2 proteins and Fas/FasL system in this tumor is yet to be evaluated.
Aims. To examine the prognostic significance of Bax, Bcl-2 and Fas protein expression in patient with gastric and colon adenocarcinoma.
Methods. The content of proteins Bcl-2, Bax and Fas was definite in fragments of the frozen tissues by immunohistochemical research serial paraffin section both tumor and not transformed tissues along patients (n=15) with the streptavidin-biotin method.
Results. It was establish the modification in level Bcl-2 and Bax protein in gastric and colon cancer. The level of Bcl-2 protein in tumor tissue increase in 1,5 time in comparison with not transformed tissue. The Bax level is increased or remains like not transformed tissue. Is shown, there is the high level of Bcl-2 and Bax in majority of cells in gastric and colon cancer. Fas expression were noted in all cancer specimens and all their noncancerous counterparts. The level of Fas-positive cells was significantly lower in patient without metastasis (by 89%, p=0,04) and then in non cancerous tissue (by 54%, p=0,04)
Conclusion. The increase of synthesis Bcl-2, apparently, is one of mechanisms of apoptosis inhibitors in tumor cells. The increase of Bax level testifies to activation apoptosis-inducing mechanisms in tumor cells. However the determining importance has not a level of protein in a cell, and its ability to carry out the function. By us is earlier shown, that the gene Bax frequently changes at gastric and colon cancer. Expression of Fas in gastric and colon epithelium is progressively reduced during the malignant transformation and is frequently associated with metastasis in gastric and colon adenocarcinoma.

CLAUDIN 1, 3, 4 AND 5 IN GASTRIC CARCINOMA, LOSS OF CLAUDIN EXPRESSION ASSOCIATES WITH THE DIFFUSE SUBTYPE

Y Soini M.D.(1), S Tommola M.D. (2), H Helin M.D.(3), P. Martikainen (2)
Department of Pathology, University Hospital of Oulu and Oulu University, PO Box 5000 (Aapistie 5) 90014 Oulu, Finland (1)
Department of Pathology, Tampere University Hospital, PO Box 2000, FIN-33521, Tampere, Finland (2)
HUSLAB, Division of Pathology, Helsinki University Central Hospital, PO Box 400, FI-00029, HUS, Helsinki, Finland (3)

Introduction: Claudins are tight junctional proteins present in epithelial and endothelial cells.
Purpose of the study: Purpose was to study the expression of claudins 1, 3, 4 and 5 in gastric carcinomas and their significance for tumor behaviour
Methods: 118 cases of gastric carcinoma including additional samples from 50 metastatic lesions were collected. Immunohistochemistry was performed for claudins 1, 3, 4 and 5 Ki67 and E-cadherin. Additionally, cases were studied for apoptosis by the TUNEL method.
Results: Expression of all these claudins could be seen in gastric carcinoma, most prominently for claudin 4 and least expression was found for claudin 5. All claudins showed significantly more expression in gastric carcinomas of intestinal type. Their expression was significantly associated with each other. Expression of claudin 4 and 5 was associated with E-cadherin. Strong expression of claudin 5 was associated with higher cell proliferation and apoptosis. Claudin 3 expression had an association with a better prognosis of the patients, especially in the intestinal type.
Conclusions: The results show that expression of claudins 1, 3, 4 and 5 is lower in diffuse type gastric carcinomas. Possibly they play a role in determining the diffuse phenotype and lowered cohesion of cells in diffuse type of gastric carcinoma in a similar manner as E-cadherin. The loss of their expression does not clearly associate with poorer prognosis of the patients, except for claudin 3 where strong expression was associated with a better outcome of the patients, a feature especially related to intestinal type tumors.

P 293

CYTOKERATIN EXPRESSION PATTERNS OF GASTRIC CARCINOMAS ACCORDING TO LAUREN AND GOSEKI CLASSIFICATION

*Ye°im Gürbüz, *Nur Köse,
*Kocaeli University Medical Faculty Pathology Department

INTRODUCTION: Goseki system is a new gastric carcinoma classification proposal that classifying gastric carcinomas as according to their gland formation and mucin production patterns. In Goseki system, grade I tumors are in intestinal type; grade II tumors correspond to mucinous tumors; grade III tumors include mucin poor, diffuse infiltrating morphology and grade IV tumors contain signet ring cell carcinomas. The signet ring cell carcinoma of the stomach is believed to be originated from superficial foveoler epithelium of the gastric mucosa while mucinous carcinoma is a specific entity originating from goblet cell metaplasia. It seems likely that the main advantage of Goseki classification is to separate signet ring cell carcinomas, mucin poor diffuse infiltrating carcinomas and mucionus carcinomas of the gastric mucosa in to different groups. Cytokeratin 7 (CK7) is observed only in chronically inflamed gastric mucousa and co-exists with incomplete intestinal metaplasia. CK20 can be observed in the superficial foveoler epithelium and mature goblet cells.
PURPOSE: The aim of this study was to examine the cytokeratin expression profiles in gastric carcinomas that are classified according to both Goseki and Lauren systems.
MATERIAL METHOD: CK7, CK8, CK19 and CK20 were applied to the paraffin sections of 66 gastric carcinoma cases. The cytokeratin expression patterns of cases were grouped as CK20(+)/CK7(+), CK20(+)/CK7(-),CK20(-)/CK7(+), CK20(-)/CK7(-).The results were compared statistically with chi-square test.
RESULTS: CK20 immunoreactivity was observed in 18% of the grade I carcinomas, 24% and 31% of grade III and IV case respectively. CK20(+)/CK7(-) pattern was observed in 20% of the grade IV and 66.7% of the grade II carcinomas and was not observed in the grade I or grade III tumors ($p<0,0001$).
CONCLUSION:In conclusion, bouth Goseki grade III and IV carcinomas originate from superficial gastric mucousa but grade III carcinomas are poorly differentiated. Goseki grade II carcinomas have a specific immunophenotype than inthestinal type gastric tumors. Goseki classification seems to be superior in identifying poorly and well differentiated forms of diffuse infiltrating carcinomas and mucinous carcinomas.

P 294
UNEXPECTED TTF-1 EXPRESSION IN GASTRIC CARCINOMA
ONEA Alina, WALTER Paul, MARIN Cristi, LAURENT Camille, CHENARD Marie Pierre.
Hôpital de Hautepierre, CHU de Strasbourg

Background: Thyroid transcription factor 1 (TTF-1) is a nuclear transcription factor selectively expressed in thyroid, lung and diencephalon. Immunoreactivity against TTF-1 in an adenocarcinoma is thought to be highly specific for pulmonary or thyroid origin.
Design: The morphologic characteristics of a case of gastric adenocarcinoma exhibiting strong staining for TTF-1 are reported and relevant literature data is reviewed.
Results: A biopsy specimen from a polypoid lesion of the cardia in a 68-year-old caucasian patient showed neoplastic glands with immunoreactivity against TTF-1 (MAb 8G7G3/1). Exploration of lung and thyroid was unremarkable. After surgical resection, the gastrectomy specimen revealed a mixed diffuse-type and intestinal type adenocarcinoma of the oesocardial junction, with strong nuclear TTF-1 positivity limited to the intestinal-type component. Moreover, TTF-1 staining was also focally present in the surrounding gastric mucosa, within intramucosal glandular cysts partly lined by metaplastic ciliated epithelium. Distant mucosal changes in stomachs resected for carcinoma and especially ciliated metaplasia are common findings in Japanese patients, but are rarely observed in European subjects. Expression of TTF-1 in ciliated metaplasia has never been reported before. Among the numerous studies concerning TTF-1 expression in carcinomas other than those derived from lung and thyroid, positivity in gastric carcinoma has only be shown in two cases, without details of histological data.
Conclusions: We describe a case of gastric carcinoma showing strong nuclear TTF-1 positivity within the tumor cells themselves and in intramucosal glandular cysts partly lined by ciliated epithelium. This finding suggests that the rare gastric cancers with TTF-1 expression may possibly derive from ciliated metaplastic cells. Moreover, detection of TTF-1 in a gastric carcinoma calls into question the absolute specificity of this marker for thyroid or pulmonary cancer.

P 295
RCAS1 EXPRESSION IN GASTRIC CANCER: CORRELATION WITH CLINICOPATHOLOGICAL VARIABLES AND PATIENTS' OUTCOME
THEOCHARIS Stamatios1, EFKARPIDIS Themistocles2, GIANGINIS Konstantinos1, SFINIADAKIS Ioannis1, SPILIOPOULOU Chara1, KOURAKLIS Gregorios2
Departments of Forensic Medicine-Toxicology1 and Propaedeutic Surgery2, Medical School, University of Athens, Athens, Greece

Background-Aims: The tumor associated antigen "receptor-binding cancer antigen expressed on SiSo cells" (RCAS1) inhibits the growth of receptor expressing cells and induces apoptosis. In this study, RCAS1 expression was examined in tumor samples obtained from gastric cancer patients and was correlated with histopathological parameters and patients'survival.
Materials and Methods: RCAS1 protein expression was examined immunohistochemically in paraffin embedded tissue sections from 38 gastric cancer cases. RCAS1 protein positivity, overexpression (positivity in more than 75% of tumor cells) and intensity (mild, moderate, intense) of staining were correlated with patients'age, gender and TNM stage, tumor histological type, grade, proliferative capacity (Ki-67 labeling index), and the patients' final outcome.
Results: RCAS1 protein positivity was noted in all of the examined cases, while in 15 out of 38 (39%) RCAS1 protein was overexpressed. RCAS1 overexpression and intensity of staining were statistically significantly correlated with tumor histological type, being mainly expressed in tumors of intestinal type ($p=0.027$ and $p=0.002$, respectively). The other clinicopathological parameters examined and patients' survival were not correlated with RCAS1 protein overexpression and intensity of staining.
Conclusions: RCAS1 protein is widely expressed in gastric cancer cases and its overexpression is correlated with intestinal type gastric tumors, suggesting the participation of RCAS1 in gastric carcinogenesis.

P 296
RELATION OF NEUROENDOCRINE DIFFERENTIATION TO TGF-ALPHA AND EGFR EXPRESSION IN GASTRIC ADEOCARCINOMAS: THEIR PROGNOSTIC IMPLICATIONS
CELIKEL Cigdem*, EREN Funda*, GULLUOGLU Bahadir**, TURHAL Serdar***
Marmara University School of Medicine
Departments of Pathology*, General Surgery**, and Oncology***

Coexpression of transforming growth factor-alpha (TGF-a) and epidermal growth factor receptor (EGFR) in carcinomas is believed to confer growth advantage to tumor cells. It is well known that TGF-a is one of the products of neuroendocrine cells, but there is no evidence concerning the possible effect of neuroendocrine differentiation (NED) in gastric adenocarcinomas (GCa) on the expression of TGF-a and EGFR. In order to assess this and their role on the survival of carcinoma patients, we analyzed Chromogranin A (ChrA), TGF-a and EGFR immunohistochemistry (IHC) in partial/total gastrectomy specimens of 101 GCa (diffuse type = 41, intestinal type = 60) cases. ChrA IHC was performed on the tissue sections prepared from formalin fixed paraffin embedded tissue blocks containing GCa areas. ChrA IHC was evaluated semiquantitatively (0-4). For each case IHC was performed for TGF-a and EGFR in sequential sections of a representative block selected based on NED. Evaluation of the IHC staining for TGF-a and EGFR was done according both to the intensity (0-2) and quatification of the positively stained areas (0-3). When a total score (sum of the intensity and quantification measurements) was 4 or greater, the tumor was considered positive for either TGF-a and EGFR. According to the results of TGF-a and EGFR staining the carcinomas were scored as 0 if neither TGF-a and EGFR was stained, as 1 if either TGF-a or EGFR was stained, and as 2 if both TGF-a and EGFR were stained. Follow-up data was available in 54 patients. Twenty seven patients was alive, while 27 died of disease with a follow-up of 7-101 and 1-131 months, respectively. NED in GCa's was related to TGF-a expression ($p<0.01$) but not to EGFR expression and TGF-a / EGFR coexpression. The percentage of cases expressing ChrA was higher in diffuse type GCa's, not with statistical significance ($p>0.05$). When the cases were grouped according to Lauren's classification, NED correlated with TGF-a but not with EGFR in both intestinal and diffuse type GCa's. Correlation of NED with TGF-a / EGFR coexpression reached statistical significance only in diffuse type GCa's. Although histologic type, NED, and TGF-a had no effect on survival, EGFR ($p<0.05$) and TGF-a / EGFR coexpression (<0.001) were related to survival. The results of our study suggest that the autocrine mechanism between TGF

P 297
EXPRESSION OF HUMAN GASTRIC MUCUS AND PCNA IN INTESTINAL METAPLASIA ASSOCIATED WITH GASTRIC CARCINOMA: AN IMMUNOHISTOCHEMICAL STUDY AND A PRELIMINARY REPORT

AKBULUT Metin, BIR Ferda, DOGANAVSARGIL Baþak, DEMIRKAN Neþe

Background: Gastric adenocarcinoma is in important cause of cancer related death and historically is known to be frequently associated with intestinal metaplasia (IM). Because IM is an important intermediary in the gastric carcinogenic sequence, understanding how an IM progress to cancer is important. HGM is a well known gastric phenotypic mucus marker that expressed in normal gastric epithelial cells and various carcinomas.To clarify the heterogeneous nature and significance of IM, we have examined the relationship between proliferating cell nuclear antigen (PCNA) and human gastric mucus protein (HGM) expression in areas of IM adjacent to gastric cancer and chronic gastritis.
Methods: In this study, we reevaluated biopsy samples obtained from 110 cases of chronic gastritis associated with IM (CG+IM) and 30 cases of gastric carcinoma associated with IM (GC+IM). We examined PCNA and HGM expression in the proliferating zone, in the areas of IM and tumor separately via immunohistochemically and correlated with each groups of CG+IM and GC+IM. Immunohistochemical study could not evaluated in all of the cases due to technical problems.
Results: The immunohistochemical staining of HGM were positive in normal gastric mucosa adjacent to CG+IM and GC+IM groups. In CG+IM group, HGM expression of the areas of IM was shown lower than GC+IM groups, this was statistically significant according to Mann Whitney-U test (p: 0,005). Although statistically insignificant, PCNA labeling index of the IM areas in GC+IM was higher than in CG+IM (p: 0,07).
Conclusion: The findings suggest that cases of IM with overexpression of HGM and high PCNA labeling index are more commonly observed in GC+IM group. We concluded that, overexpression of HGM and evaluating the PCNA labeling index may be useful for early detection of IM with high risk of gastric carcinoma. But it is necessary to study these parameters within large series to establish the precise decision.

P 298
EXPRESSION OF MUCINS IN GASTRIC CARCINOMA AND THEIR CLINICOPATHOLOGICAL SIGNIFICANCE.

Gursan N1, Gursan MS2,
1Department of Pathology, Ataturk University, Medical Facult, Erzurum,Turkey
2Department of Surgery, Ataturk University, Medical Faculty, Erzurum,Turkey

AIM: To investigate the expression of three types of mucin (MUC1, MUC2, MUC5AC) and in human gastric carcinomas and their clinical significance
METHODS: Tumours were classified according to WHO criteria. The mucin phenotype was determined immunohistochemically using markers for MUC1, MUC2, MUC5AC in 95 cases of human gastric cancer.
RESULT: There were significant correlations between MUC1 and MUC2 expression and types of cancer. MUC1 and MUC2 expression was showed the tendency to lower expression in well and moderately differentiated tubular adenocarcinoma and higher expression in advanced stage cancers (poorly differentiated adenocarcinoma, signet-ring cell carcinoma and mucinous carcinoma) (P>0.05); MUC5AC expression was showed the tendency to higher expression in well and moderately differentiated tubular adenocarcinoma and lower expression in advanced stage cancers (P>0.05);
CONCLUSIONS: MUC1 ve MUC2 is significantly influenced by histological grade,. These findings suggest that MUC1 ve MUC2 expression may be an indicator for prognosis of gastric cancer patients and correlated with early tumorigenesis and initiation of invasive growth in gastric cancer.

HELICOBACTER PYLORI GASTRITIS-UPDATED SYDNEY CLASSIFICATION APPLIED IN OUR MATERIAL

Manxhuka-Kerliu S, Kerliu A, Telaku S, Baruti-Kelmendi A, Pruthi D, Juniku-Shkololli, Maloku I.

Institute of Pathology, Faculty od Medicine, University of Prishtina.

Hp inhabits the stomach more than 50% of humans and is the most frequent cause of chronic gastritis worldwide.
The purpose of this research was to present the importance of combining topographical, morphological and etiological information of diagnostic evaluation on grading gastritis in our material according to Updated Sydney Classification.
There have been investigated 154 cases of gastric mucosa (endoscopic biopsies) which were fixed in buffered neutral formalin and embedded in paraffin. Tissue sections (5mm thick) were cut and stained with H&E, May Grunwald Giemsa and Silver stain.
The biopsy cases were analyzed in attempt to assess the major histopathological features of gastritis. The histopathological variables (Hp density, neutrophil infiltration, mononuclear infiltration, atrophy, intestinal metaplasia and dysplasia were graded on a scale of 3 (mild, moderate and severe). Minor histopathological features were not graded, but simply assessed in case of their presence or absence.
36 (23.37%) cases were positive for Hp (22.2%, 72.2%, 5.5%) . The atrophy was positive in 23 (14.93%) cases with the scale (47.8%; 47.8%; 4.34%). Dysplasia was positive in 13 (8.44%) cases with the scale (84.6%; 7.6%; 7.6%). Intestinal metaplasia was positive 25 (16.2%) with the scale (76%; 20%, 4%).
After eradication of Hp, neutrophils disappeared for 6-8 weeks, but chronic inflammation persisted longer as well as other major Hp features.
There were 6 (3.8%) cases of MZL, which were treated properly.
The presence of H. pylori increases the chances of developing adenocarcinoma and MALT lymphoma; therefore, it is important to look for possible early eradication of H.pylori to prevent the eventual development of gastric cancer. These findings should influence the treatment of gastric cancers.

P 300
COMPARING 200 GASTRIC TOUCH CYTOLOGY STAINED BY GIEMSA AND GRAM METHODS WITH HISTOLOGY STAINED BY H&E FOR HELICOBACTER PYLORI INFECTION

Seyed Mohammad Owji M.D., Mehrbod Karimi M.D.
Pathology Department,Shiraz Univ. Med Sciences,Shiraz-Iran.

Introudction and purpose:
Many observations suggesting that Helicobacter pylori (H.Pylori) to be closely associated with acute gastritis (Type B) and gastric ulcer,and some malignancy of stomach. Multiple tests are available for determining H.pylori infection. Culture is the standard method, but as the histologic examination the result is delayed .Serologic method and phase contrast microscopy is also used for detection of H.pylori.
Among the methods based on endoscopic biopsies only the rapid urease test and cytology may give result available before the patient leaving endoscopy room. The purpose of this study is to compare histologic examination with t ouch cytology stained by Giemsa and gram methods in 200 cases.

Materials and Methods:
For each patients 2-5 biopsies were obtained put into 10% formalin for histologic examination.. Additional single gastric biopsy was transferred from the biopsy forceps to a glass slide then delicately rolled onto the surface of the slide. This technique is called touch cytology. Then the slides were air dried. For each patient one slide stained by Giemsa and another slide stained by Gram method.
Results:
In histologic examination 93 out of 200 cases were positive for H.pylori. In Giemssa method 135 out of 200 cases, and in Gram method 92 cases out of 200 were positive for H.pylori. Additional result consist of 4 cases of Candida albicans with yeast –like organism and pseudohyphea in touch cytology stained by Giemsa or Gram method but not detected in histologic examination.
Conclusion:
We believed that touch cytology method is useful ,simple and rapid in diagnosis of mucosal infection of stomach with H.pylori organism, specially when the level of infection is mild. Touch cytology stained by Giemsa method yield more positive result and easier and faster to screen the smear , but in touch cytology stained by Geram method no advantage obtained over histologic examination. The combination of the histologic examination with touch cytology examination(Giemsa) are the test of choice for detection of H,.pylori and evaluation of inflammation and degree of injury/

P 301
EFFECT OF TRIPLE THERAPY IN HELICOBACTER PYLORI ASSOCIATED GASTRITIS.
C.W. Hsueh, Y.Y. Tsai, S.C. Wen, N.H. Feng, T.M. Lee*.
Depts. of Internal Medicine and Pathology*, Kaohsiung Armed Forces General Hospital, Kaohsiung, Taiwan.

Helicobacter pylori (HP) infection is a cause of gastritis in most of the patients with duodenal ulcer. Clearance of the organism leads to improvement or even total resolution of gastritis.
Aim: To evaluate the histological outcome of gastritis in the patients with duodenal ulcer after HP eradication.
Methods: A total 87 patients with duodenal ulcer with positive HP, were given triple therapy for one week. The gastric antral biopsies were made before and 6 months after the end of treatment. Histological investigation was performed according to the Sydney system on a four-point scale.
Results: The scores of gastritis histological feature before and after HP eradication are as following: 1) 2.1 and 0.9 for inflammatory cells infiltration, 2) 0.7 and 0.4 for atrophic changes, 3) 0.2 and 0.2 for intestinal metaplasia, 4) 0.4 and 0.3 for lymphoid follicles. Gastric mucosa was normalized in 58.6 % (51 / 87) out of the patients.
Conclusions: In this study, HP eradication improved gastritis in the patients with duodenal ulcer. Gastric mucosa normalizes in 58.6 % of the patients, 6 months after triple therapy.

P 302
REGRESSION OF GASTRIC MALT LYMPHOMA AFTER HELICOBACTER PYLORI ERADICATION.
AMIR Zine-Charaf, ASSELAH Fatima
Department of Histopathology, CHU Mustapha Algiers - ALGERIA

Background : Helicobacter pylori (H p) is considered the leading cause of gastric mucosa associated tissue lymphoid (MALT) lymphoma (GL) and the majority (60 – 90%) of low grade gastric MALT lymphoma are reported to regress after eradication of H p (Fischbach, 2004).
Objective: to evaluate the histologic response of low grade gastric MALT lymphoma after eradication of H p.
Methods and results: 186 cases of gastric MALT lymphoma were analyzed at the pathological department during eight years (1996 – 2003). They represent 30, 8% of all gastric cancer diagnosed during the same period. Sex ratio was 0, 97 and median age was 42 years (17 – 80 y). Abdominal pain was the most common presenting symptom (81%); a suspect antral ulceration was the endoscopic finding in 80%.
124 patients (66%) had low grade gastric MALT lymphoma. Hp infection was found in all cases. 61 of them (53%) were treated with triple therapy (amoxicillin, proton pump inhibitor and metronidazol) for seven days. Subsequently, they were followed up by sequential endoscopy and biopsy. Eradication of Hp infection was achieved in all patients; 35 of them were free of lymphoma (complete remission, 28 months median follow up); 03 patients were in partial remission (median follow up, 10 months). 02 patients relapse after 21 and 27 months; they had surgical cure and adjuvant chemotherapy.
Eradication therapy permitted the regression of more than 50% of early low grade gastric MALT lymphoma. Our results are similar to those reported in the literature
Conclusion: Actually, GL therapy isn't well codified. However eradication of Helicobacter pylori in low grade gastric MALT lymphoma is widely accepted as a first line therapy. Although complete Hp eradication is necessary and a long time follow up needed to confirm the regression.

P 303
MOLECULAR DETECTION AND GENOTYPING OF HELICOBACTER PYLORI STRAINS FROM GASTRIC BIOPSY SPECIMENS USING PCR-RFLP
R. Salehi, F. Navabakbar, M. Salehi, AR. Sabahi
Department of Genetics and Molecular Biology, School of Medicine, Isfahan University of Medical Sciences, Isfahan 81744-176, Iran

Helicobacter pylori is a gram-negative microaerophilic organism that colonizes human gastric mucosa. It has been proved that H. pylori is an etiologic agent of chronic gastritis and peptic ulcer diseases and is also a risk factor for gastric cancer. The World Health Organization has classified H. pylori as a class I carcinogen. Epidemiological studies have shown that H. pylori infection occurs world wide at a high prevalence rate.

Recurrence of infection after apparent eradication has also been reported and is associated with recurrence of ulcers. However, it is unclear whether the recurrence of ulcers following H. pylori eradication therapy is due to recrudescence of the previous infection or to exogenous re-infection by another strain. An accurate method for the detection and differentiation of H. pylori strains in patients both before and after therapy is therefore of great importance for diagnosis, monitoring of treatment, and reduction of the long-term consequences of continued but undetected disease.

Attempts to differentiate H. pylori strains have been made using a variety of conventional typing schemes, like haemagglutination, biotyping, cytotoxin activity, plasmid profiles and immunobloting. However, each of these methods due to some inherent difficulties did not gain widespread use for precise differentiation of H. pylori strains.
Gastric biopsy specimens were obtained from 79 patients, 36 women and 43 men. Extracted DNA amplified using primers specific for UreC gene. The amplified products were purified using PCR products purification kit and then digested with 10 U of CfoI, MboI and AluI restriction enzymes separately for at least 3h at 37°C.
Five patterns for MboI, five patterns for AluI and 4 restriction patterns for CfoI were observed. The patterns were classified based on the number of bands detectable by gel electrophoresis.
From our study it is concluded that, the PCR-based RFLP technique is a useful approach for genotyping of specific H. pylori strains. Using this method we can determine

reinfection, infection with new strains, recrudescence or drug resistance in H. pylori infected patients.

P 304

THE POSSIBILITIES OF IMMUNOHISTOCHEMICAL STAINING METHOD FOR DETECTION OF HELICOBACTER PYLORI (HP) INFECTION IN CASES WITH CHRONIC GASTRITIS, ULCERS AND GASTRIC CANCER AND GASTRIC LYMPHOMA

BRACHKOVA Yordanka, MARKOVA Elena

Background: The HP infection affects more than 50% of the human population and plays an important role in the pathogenesis of chronic gastritis, chronic peptic ulcer of stomach and duodenum, gastric cancer and gastric lymphoma. Thus the eradication of HP has definite therapeutic and preventive effect.

Aims: 1. To improve the diagnosis of HP infection putting into practice the immunohistochemical / IHCh/ staining of bacteria on endoscopic biopsies.2. Determine the rate of HP infection in patients with chronic gastritis, chronic peptic ulcers, gastric cancer and gastric lymphoma.

Methods: Two hundred forty endoscopic biopsies prepared with routine histological and histochemical methods (HE, V.G., PAS) are studied retrospectively and analyzed. Two hundred twenty three (92%) are stained with Giemsa for HP and 99 (42%) are tested immunohistochemically with Polyclonal rabbit anti HP antibody (DACO}

Results: Analyzing the material we found that the identification of HP with Giemsa staining was respectively 55% and 58% in cases with chronic gastritis and ulcers and 66% and 69% in the surrounding mucosa in patients with gastric cancer and gastric lymphoma. Immunohistochemically HP was detected in 83% and 93% in chronic gastritis and ulcers and 70% and 77% in gastric cancer and lymphoma. The efficiency of the proposed method in number detection is mostly evident in the group of patients with chronic gastritis, where all the negative and suspicious for HP cases were examinated immunohistochemically. The percentage of cases with identified HP bacteria in this group increased from 55% to 93%. For the group of ulcers the rise is from 58% to 83%, while for gastric cancer and lymphoma cases it was inconsiderable. The reason for this is the lack of appropriate material from the surrounding mucosa in the tissue samples for IHCh staining. Conclusions:The examination with IHCh staining is a reliable method for identification of HP infection in gastric mucosa. By the means of this method we reduce the number of suspicious cases. The increased exposure of HP is due to the detection of the attached to the cell membranes bacteria and the coccoid forms too.

Key Words: HPylory, immunohistochemical detection, gastroscopic biopsies.

P 305

HELICOBACTER PYLORI INFECTION IN CHILDREN: CORRELATION BETWEEN CAGA, ICEA AND VACA GENOTYPES AND HISTOPATHOLOGICAL CHANGES IN GASTRIC MUCOSA

Boštjan Luzar, Mario Poljak*, Matjaž Homan**, Boštjan J. Kocjan*, Gabriela Panter*, Maja Shrestha*, Maja Kveder*, Tina Moèilnik*

Institute of Pathology, Microbiology and Immunology*, Medical Faculty University of Ljubljana, and Department of Paediatrics**, Clinical Centre, Ljubljana, Slovenia

Background

Despite strong association of distinct Helicobacter pylori (HP) genotypes with degree of histological changes in gastric mucosa of adults, such an association is still controversial in paediatric population.

Aims of the study

To analyse correlations between cagA, iceA and vacA HP genotypes and the degree of histological changes in the gastric mucosa in paediatric population.

Material and methods

The entry criteria for the study was a positive rapid urease test, and subsequent detection of ureA and/or ureC genes by polymerase chain reaction (PCR) in the same tissue specimen. Histological changes in gastric mucosa were graded according to the updated Sydney system. The cagA gene, signal (s) and middle (m) regions of vacA gene and iceA gene were determined by PCR in the total DNA, isolated from tissue samples used for the rapid urease test.

Results

Altogether 186 samples of gastric mucosa (158 from antrum and 28 from corpus) from 140 children, aged from 4 to 18 years (mean age 13 years) were analysed histologically. The degree of activity and chronicity in antrum and corpus correlated with the density of HP colonisation ($p<0.05$). A statistically significant decrease in the degree of activity and chronicity after HP eradication was observed only in antral mucosa ($p<0.05$). The HP eradication rate was 69% for antrum and 75% for corpus. cagA was detected in 63% (75 of 119) of samples and correlated with the degree of activity and chronicity in antrum ($p<0.05$). No correlation was found between iceA and histological changes. Regardless of the subtype, a borderline statistical association was present between vacA s and antral intestinal metaplasia ($p=0.05$), and between vacA m and corpus atrophy ($p=0.03$). Co-infection with various HP strains, found in 8% of antral mucosa samples, did not correlate with histological changes.

Conclusions

Our results confirm the need for treatment of symptomatic children with HP infection in order to diminish and/or abolish the damaging effect of acute and chronic inflammation on the gastric mucosa, a hallmark of HP infection. Both have been previously shown in adults to correlate with the subsequent development of atrophy and intestinal metaplasia, possible precursor lesions in gastric carcinogenesis. Finally, it appears that at least the cagA gene influences the degree of activity and chronicity in antral mucosa of children, and that the mechanism of mucosal damage by HP is different in corpus and antrum.

P 306

GASTROINTESTINAL LYMPHOMAS AND HELICOBACTER PYLORI INFECTION – CLINICOPATHOLOGIC STUDY

BRACHKOVA Yordanka, MARKOVA Elena

Medical University of Pleven, Bulgaria

Background: Chronic Helicobacter Pylori /HP/ infection is strongly associated with the development of primary gastric B-cell lymphoma of MALT type. The choice for gastric surgery or stomach concerning treatments, should be based on an accurate histopathological diagnosis, grading and clinical staging. The effect of curing HP infection on the course of a high-grade gastric MALT lymphoma is uncertain.

Aims: 1. To study the primary gastrointestinal lymphomas /GIL/ for the last 5 years, obtained gastroscopically, after surgical treatment or diagnosed on autopsy.

2. To follow up and analyze the effect of HP eradication therapy /HPET/ and chemotherapy on gastroscopic biopsies.

Patients and methods: For the period 2001-2005, 36 patients between 38 and 84 years with primary GIL were studied /32 of the stomach, 3 on small bowel and 1 on large bowel/. Twenty six cases were diagnosed on gastric biopsies, 5 after surgical biopsy and 5 after autopsy. All lymphomas were immunophenotype identificated, graded and clinical staged by Ann Arbor and Musshoff system.

Results: From 36 GIL 35 were classified as B-cell NHL and 1 as high grade T-cell NHL, 28 were high-grade B cell

lymphoma /HGBCL/ or diffuse large B cell lymphoma /DLBCL/ and 7 low-grade B cell lymphoma /LGBCL/. A follow up examination, about 30-36 months, was performed on 7 cases/3 with HGBCL and 4 with LGBCL/. Complete histological remission was found in 2 patients with successful HPET and chemotherapy /CHOP, MABTHERA/ and unsuccessful HPET with incomplete histological remission in 5 cases. Twelve patients /aged 50-57/ with DLBCL were operated in stage IIE -10 gastric and 2 intestinal. Half of them were with large ulcerated lesions. All GIL diagnosed after autopsy were in advanced stage /1 high-grade T-cell and 4 DLBCL/.
Conclusions: Our results revealed that primary GIL were mostly high grade B-cell/DLBCL and in 80% were associated with HP infection. The effect of HPET was not successful in most cases. We found that they were rarely suspected by clinicians and were diagnosed mostly in IIE clinical stage. This settled down the question about revision of HPET and the responsiveness of lymphomas to the therapy.
Key words: Gastrointestinal lymphoma, Low grade MALT, DLBCL, HP eradication, Chemotherapy, Surgical treatment.

3 Institute of Pathology, Medical Faculty, University of Belgrade, Serbia and Montenegro

INTRODUCTION AND AIMS: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract with the stomach as the most common site. CD117/KIT immunoexpression has been accepted as a specific marker for GISTs preferentially used for confirmation of the diagnosis. However, GISTs constitute a group of phenotypically heterogenous mesenchymal neoplasms with uncertain biological behaviour that often coexpress CD34 and/or myoid, neural and other markers.
MATERIAL AND METHODS: We reexamined clinically, histologically and immunohistochemically 121 cases of paraffin-embedded GISTs noted in the Tumor Registry of Clinical Centre of Serbia from the total of 412 patients operated for abdominal mesenchymal mostly visceral tumours between 1992 and 2004. In addition, evaluation of malignancy of GISTs was based on clinico-pathological criteria proposed both by Fletcher in 2002 and Bucher in 2004.
RESULTS: Most of gastric GISTs were composed of spindle cells (73%), epithelioid cells (20%) or both and/or rare cell types (7%), and nearly 30% showed obvious clinical malignant behavior. We present three cases of primary GISTs with similar small round cell morphology, two gastric (in 47 year old male and 56 year old female patients) and one esophageal (63 year-old male patient). In one case, hepatic metastases were resected during primary surgery, in two other cases they developed after 8 and 11 months. None of them were treated with imatinib (Glivec) and only one patient had conservative chemotherapy. Follow-up showed short survival interval (9 to 16 months). All cases expressed only strong vimentin immunoexpression and were preexcluded for other small round cell differentiation. Immunohistochemical examination showed weak cytoplasmic CD117 expression in one case, evident CD34 expression in two of cases (one of them exlusively CD34 positive) and confirmed non-myogenic and non-neurogenic differentiation. In addition, all cases showed Ki-67 index higher than 10% and PCNA higher than 30%.
CONCLUSION: Round cell anaplastic type of GIST might represent small distinct clinically aggressive subgroup of these tumours with incomplete immunophenotypic expression or dedifferentiated type of GISTs different from immunohistochemically similar group of so-called fibroblastic, mostly spindle cell type of GISTs (GIFT).

Abstract
Introduction:The mayority of gastrointestinal tumors (GIST) express c-kit, a growth factor receptor with tyrosine kinase activity .Mutations in the c-kit proto-oncogene may lead to constitutive ligand-independent activation of c-kit and subsequent neoplastic transformation, but alterations in chromosomes 14 and 22 may also play a role in the molecular pathogenesis.The purpose of the study is to distinguish GISTs from the other mesenchymal tumors of the GI tract and specially duodenal tumors,because of differences in natural history, as well as the efficacy of treatments targeting the GIST tyrosine kinase.
On immunohistochemical staining, tumor duodenal cells were positive for vimentin, CD34, CD117(c-Kit), Ki-67 and negative for muscle-specific actin, desmin, S100, neurofilament and keratin.GISTs tumors have a spectrum of clinical behavior at all sites of their ocurrence. Tumors that show low mitotic frecuency (5 or fewer mitoses per 50 HPF) usually have a benign behaviour. However, there is a definite percentage of mitotically inactive tumors that subsecuently metastasize, emphasizing the fact that low mitotic count does not rule out a malignant behaviour. GISTs with mitotic counts over five per 50 HPF are customarily designated as malignant, and tumors over 50 mitoses per 50 HPF are designated as high-grade malignant
The small intestinal tumors and duodenal tumors were more agresive than other localizations, in our cases the tumors shows high risk and malignant potential in comparison with gastric tumors. Tumor size, location,mitotic and proliferation indices, and mutations in the juxtamembrane domain of c-kit (exon 11) appear to correlate with risk of malignant behaviour.
The molecular targeting of the critical pathogenetic mechanism underlying GIST has given patients new hope, and has provided physicians with a highly effective and well tolerated therapeutic option for a disease for which no systemic therapy existed previously.
Moreover GISTs serve as the model solid tumor for a molecular biology-based diagnosis and treatment of cancer.

CLINICOPATHOLOGIC FEATURES AND IMMUNOHISTOCHEMICAL STAINING FOR C-KIT PROTEIN (CD117) IN METASTATIC AND PRIMARY MALIGNANT MELANOMA OF THE GASTROINTESTINAL TRACT
ALTINOK Gulcin*, HIMMETOGLU Cigdem*, GUREL Bora*, SAVAS Berna**, ENSARI Arzu**, DURSUN Ayse***, SOKMENSUER Cenk*, GUNGEN Yucel*, GUNHAN Omer****, GEDIKOGLU Gokhan*

Introduction: Malignant melanoma (MM) is the most common metastatic tumor of the gastrointestinal tract and can present with fairly common constitutional symptoms. The small and large intestines are the most common sites for metastases from cutaneous MM. However, primary MMs in these sites are exceedingly rare. Genuine primary MM of the gastrointestinal tract is a rare, highly malignant anorectal neoplasm of poor prognosis.
Aim: This investigation was performed to determine the clinicopathologic features and immunohistochemical staining for c-kit protein in metastatic and primary gastrointestinal malignant melanomas.
Material and Method: 26 gastrointestinal MM cases were retrieved from the archives of pathology departments of four different medical schools and were evaluated for histologic features. Formalin-fixed, paraffin-embedded tissue sections were immunostained with c-kit protein by the avidin-biotin-peroxidase procedure.
Results: These cases included 17 anorectal, 6 small intestinal, 2 duodenal, and 1 gastric MM. Most of the anorectal MMs (56.2%) were presented with gastrointestinal hemorrhage, whereas small intestinal (SI) MMs with intussusception (44.4%) and acute abdomen. Comparison of gender and tumor size (median, 5.5cm in anorectal MM, and 5cm in SI) showed no significant difference. Patient age at presentation (median, 62 years in anorectal, and 49 years in SI) was not statistically different (p=0.08). Resection materials revealed that anorectal cases were solitary (12/12), whereas small intestinal cases were multiple (4/4), p=0.0005. Histologically, tumor cell (epitheloid and spindle) type (p=0.667), and diffuse and intense cytoplasmic expression of c-kit did not differ significantly in between the anorectal, small intestinal and duodenal MM (p=0.627).
Conclusion: Metastatic MM in the gastrointestinal tract should be suspected in patients with history of melanoma of the skin and acute gastrointestinal symptoms. Other than clinical presentation, location and multiplicity, the clinicopathologic parameters did not differ between primary and metastatic MM. This study also emphasizes on diffuse positive immuno-expression of c-kit protein in gastrointestinal MMs which diminishes the discriminatory value of c-kit protein for differential diagnosis between the cases of gastrointestinal stromal tumor and poorly pigmented malignant melanoma.

Dept. of Pathology, Faculty Hospital in Prešov*

Introduction: The definition of gastrointestinal stromal tumors (GIST) has evolved over time and its true incidence is still unknown, probably underestimated. GIST showing an increasing incidence after molecular discovery (KIT gene) and clinical-pathological diagnostic tools (CD117) represent targets for new treatment by anti-CD117 therapy.
Purpose of the study: Comparation of incidence, morphology and clinical data of GIST of two series: The 1st series representing a retrospective study of 10 years material reported at ESP Congress in Ljubljana (2003) versus (vs) 2nd series of GIST diagnosed during the last 2 years under cooperation with other Slovak departments involved in national program.
Methods used: For both the series, identical methodology and interpretation of the findings based on the criterias of Fletcher et al. (2002) were used. In addition to histological stainings, the immunohistochemical analysis included primary antibodies against vimentin, desmin, actins, S-100 protein and CD117 (all DakoCytomation) and CD 34 (Immunotech). Because of lacking molecular biology examinations, only CD117-positive cases were included to the study.
Summary of results: The 1st series includes 32 and the 2nd 33 cases. The tumors of both the series showed predominant localisation in the stomach (18 vs 13 cases) and small intestine (11 vs 15 cases), while other localisations were rare (colon 1 vs 2 cases, extramural GIST 2 vs 2 cases). One of the 2nd series cases represented a liver metastasis of the case diagnosed previously as „gastric leiomyoma“ 19 years ago, without a possibility for the review. However, both the series showed different distribution of the risk categories: predominance of the lower risk categories in the 1st series (2 cases of very low, 16 of low, 8 of intermediate and 6 of high risk category) vs predominance of high risk categories in the 2nd series (4 cases of very low, 8 of low, 7 of intermediate and 14 of high risk category).
Conclusion reached: In contrast to literary data and results of our 1st series, the intestinal localisation was predominating in the 2nd series. Although both files are relativelly small, the localisation might be related to the increased number of the higher risk categories cases. The study shows first benefits of the program, resulting in a higher „sensitivity“ of the pathologist to recognize the GIST. Therefore the program will continue and should involve molecular diagnostic techniques of GIST diagnosis.

BACKGROUND: Gastrointestinal stromal tumors (GISTs) are mesenchymal neoplasms of the gastrointestinal tract. These lesions have been a source of controversy in regards to classification, histogenesis, differentiation and biologic potential. Recently with the advent of new therapeutic interventions, proper characterization and conceptualization of these tumors has acquired a new meaning, and emphasis is being placed on the role that various diagnostic techniques play in the evaluation of these neoplasms.
PURPOSE OF THE STUDY: We conducted a study to identify true GISTs with known pathological and immunohistochemical criteria from other tumors of the gastrointestinal tract.
METHODS: We selected from clinical records of patients with diagnosis of schwannoma, leiomyoma, leiomyosarcoma and tumor of uncertain biological behavior of the gastrointestinal tract, 79 cases. All the cases studied were surgically treated. To confirm the usefulness of an immunohistochemical panel of antibodies and histological analysis we have been selected 30 cases of GISTs . The antibodies used were : c-kit/CD117, CD34, desmin, smooth muscle actin (SMA), S-100 protein.
RESULTS: Thirty cases of GISTs were identified, based on histological and immunohistochemical analysis. All the confirmed GISTs were positive at immunohistochemistry for c-kit expression and most of them for CD34, desmin and S-100. SMA have only limited value. The two predominantly location of the tumors were the stomach (75%)and small intestine (6%). Various pathological and clinical parameters have been evaluated (size, mitotic rate, invasion into mucosa,

presence or absence of coagulative necrosis, status of surgical margins, location, chronic or acute bleeding).
CONCLUSIONS: Tru GISTs can be recognized from other tumors by histological analysis. Immunohistochemistry to identify c-kit protein expression is useful to certified the diagnosis. For predicting behavior in GISTs, the authors proposed some criteria .

Gastrointestinal stromal tumors (GISTs) are KIT-positive spindle cell or epithelioid mesenchymal tumors (MTs) occurring anywhere in the gastrointestinal (GI) tract or abdomen. The majority of GI-MTs are therefore now considered as GISTs. However, the frequency of GISTs in GI-MTs is not well known and their incidence too. The purpose of this study is to identify GISTs in the Franche-Comté region (eastern France) in a ten year-period (1990-2000) in all primary benign or malignant MTs of the GI-tract and abdomen.
This study includes MTs diagnosed in all Franche-Comté region pathology laboratories as leiomyomas, leiomyosarcomas, leiomyoblastomas, schwannomas, schwannosarcomas, neurofibromas, fibromas, fibromatosis, spindle cells sarcomas, and GISTs. The Franche-Comté (population : 1,200,000) is a region composed of 4 counties in particular the Doubs county (population : 499,062). Over the 10 year-period, 230 cases were retrieved. For each case, a standard morphologic study and an immunohistochemical study using anti-CKIT, CD34 antibodies was carried out. The proliferative index was performed with the Ki67 (MIB-1) antibody. The diagnosis was drawn up according to GIST Symposium 2002 criteria.
Out of the 230 cases, 29 were initially identified as GISTs (13 %). After this second study, 102 / 230 are GISTs (44 %), and 28 / 29 are true GISTs. In stomach 67 / 81 are GISTs (83 %), in small bowel 24 / 40 (60 %), in omentum 4 / 5 (80 %), in mesentery 3 / 9 (33 %), in colon 3 / 53 (6 %), in retroperitoneum 1 / 12 (8 %). In esophagus (21 tumors), in liver (5), in anus (2), in appendix (1) and in gallbladder (1), no GIST was identified. GISTs were developed in stomach in 66 % of cases, in small bowel in 24 %, in omentum and mesentery in 7 %, in colon in 3 % and in retroperitoneum in 1 %. Over 102 GISTs, 47 patients live in Doubs county at time of diagnosis. The mean “floor” limit of the raw incidence rate was estimated at 1 case / year / 100,000 in Doubs county. The proliferative index over 10 % of neoplastic cells stained was correlated with poor prognostic.
The occurrence of GISTs in our study is close to that reported in literature. Stomach and small bowel locations are the most frequent. Furthermore, our study show that 74 benign or malignant GI-MTs were reclassified as GISTs and that GISTs are the most common mesenchymal neoplasm in the gastrointestinal tract.
Supported by grants from the French Research Ministry (PHRC 2003), NOVARTIS, and Ligue Contre le Cancer

P 313
NATIONAL PROGRAM OF A STANDARDIZED BIOPSY DIAGNOSIS OF GASTROINTESTINAL STROMAL AND NEUROENDOCRINE TUMORS OF THE GI-TRACT IN SLOVAKIA
PLANK Lukáš, SZÉPE Peter, KAJO Karol, MACHÁLEKOVÁ Katarína, KVIATKOVSKÁ Zuzana

Introduction: The gastrointestinal stromal and neuroendocrine tumors (GISTs, resp. NETs) of the gastrointestinal tract show unique biological behavior. Their appropriate managment requires a standardized approach and methods used for the biopsy diagnosis.
Purpose of the study: Because of their relativelly low incidence, the experiences of the pathologists with the biopsy diagnosis and differential diagnosis of GIST and NET are limited. Therefore the aim was to develop a national system offering a standardized biopsy examination and interpretation of all the clinical and laboratory results for the patients with GIST and NET.
Methods used: The authors introduced in 2004 a retrospective analysis of previously diagnosed GISTs and NETs and attended the Italian course INTUIT („Identification and New Treatment of Uncommon Intestinal Tumors“). Due to a cooperation of Slovak pathologists and involved clinical specialists, a national network system of a GISTs and NETs biopsy diagnosis based on the accepted regional centralisation and using standardized protocol for all the obtained data was introduced in Jan. 2005. The system includes a second look biopsy examination of the cases at accepted specialized centres in relation to clinical data evaluation. In addition to the unified panel of morphologic and immunohistochemical methods of the GISTs and NETs biopsy diagnosis, all hormonal and necessary prognostic markers may be examined in situ at the coordination centrum of the project.
Summary of the results: The early preliminary results summarizing first months of the project document its first benefits, e.g. increasing number of the bioptically identified GIST cases. An integral part of the project is represented by the educational activities. In association with the traditional IAP meetings of the Slovak pathologist, first two minisymposias discussing the topics of GIST and NET biopsy diagnosis were organized and the project was introduced at the national conference of the gastroenterologists. Next educational activities will involve also other specialists, incl. the participations of the molecular biologists.
Conclusions reached: The described program starts to offer: a./ for clinical practice standardized results representing a good basis for the managment and therapeutical considerations in the cases of GISTs and NETs, incl. their targeted therapy, b./ good outcomes for further optimization of their diagnosis including also molecular biological techniques.

VARIABILITY ASSESSMENT OF IMMUNOPHENOTYPICAL PATTERN OF DIFFERENTIATION IN GASTROINTESTINAL STROMAL TUMORS
CEAUSU Mihai 1,2, ARDELEANU Carmen 1,2, BUTUR Georgeta 2, ANDREI Florin 2, FLOREA-GRAMADA Zenaida 2, CONSTANTIN Laura 1
1 - « Carol Davila » University of Medicine and Pharmacy, Bucharest, Romania
2 - “Victor Babes” National Institute of Pathology, Bucharest, Romania

Gastrointestinal stromal tumors (GIST) are mesenchimal neoplasms of gut with origin in interstitial cells of Cajal which express the tyrozin-kinazic receptor of c-kit (CD117). According to phenotypical features, GIST’s can be classified in tumors with smooth muscle differentiation, neural, mixt or non neuro-muscular diferentiation.

The aim of the study was to investigate and to test the efficiency of a panel of antibodies in immunophenotypical pattern variability analysis of diferentiation in GIST.
The indirect tristadial ABC method was performed on formalin fixed paraffin embedded tissues taken from 13 patients with GIST, using 5 antibodies : CD117, CD 34, vimentin, actin, S-100.
GIST's were immunoreactive to CD117 in 80% cases, to CD34 in 91% cases. Using regresive biostatistics analysis, it was observed a direct positive correlation between CD117 and CD34 ($r = 0.7$) and highly significant ($p = 0.002$). Between CD117 and actin, a positive polynomial relation was found ($r = 0.4$), without statistical signification ($p = 0.6$). Between CD34 and actin, a slightly positive liniar correlation ($r = 0.3$) was observed, as it was between CD34 and S-100 ($r = 0.23$), but none with statistical signification ($p = 0.2$). Tumors with a diffuse stain to CD117 and CD34 shown a focal expression to S-100, actin and vimentin.
The study confirmed the coexpression between the main diagnostic markers of GIST's - CD117 and CD34 ; CD34 high percentage in correlation with actin and S-100 expression, may provide to this heterogen antigenic association, a significant diagnostic value with future therapeutical involvements.

P 315
INFLAMMATORY CELL-RICH GASTROINTESTINAL STROMAL TUMOR IN THE STOMACH: A CASE REPORT
DILEK Fatma Husniye,MD, AKTEPE Fatma,MD, SAHÝN Dursun Ali,MD, DÝLEK Osman Nuri,MD,FACS.

We report the case of a 62-year-old woman with two primary neoplasms: adenocarcinoma of the colon with hepatic metastase and stromal tumor of the stomach, that had unusual histologic findings. Abdominal-pelvic ultrasonography and computed tomography revealed that there was wall widening in the descending colon and posterior wall of the antrum. Preoperative endoscopic examination revealed a hemispheric submucosal tumor in the anterior wall of the antrum. Histologic diagnosis of colon mass was adenocarcinoma and tumor metastased to liver. The tumor of the stomach, which was 3 cm in diameter, was resected by antrectomy. Histologic examination revealed that it was composed of spindle shaped cells with elongated nuclei and no mitoses. Inflammatory cells were intense and patchy throughout the tumor and a peripherial cuff of lymphoid aggregates was observed in the tumor. Tumor cells expressed vimentin, S-100 protein and CD117 strongly and diffusely and neuron-specific enolase weakly and focally. Tumor was uniformly negative for smooth muscle actin, desmin, cytokeratin, CD34, synaptophysin, and chromogranin. A positive reaction for MIB-1 was only a few. This appears to be the first report of the stromal tumor which has a cuff of lymphoid cells in peripheral and dense plasma cells in GISTs.

P 316
C-KIT MUTATIONS ANALYSIS OF A SERIES OF GISTS FROM PORTUGUESE PATIENTS
GOMES Ana 1, BRITO Maria 2, MILANEZI Fernanda 1,3, SCHMITT Fernando 3,4, REIS Rui 1
1- Life and Helath Sciences Research Institute (ICVS), School of Helath Sciences, University of Minho, Braga, Portugal, 2 - Hospital Garcia de Orta, Almada, Portugal, 3 - IPATIMUP, Porto Portugal and 4 - Medical Faculty, Porto University, Porto, Portugal

Gastrointestinal Stromal Tumors (GISTs) are rare primary mesenchymal tumors of the gastrointestinal system. GISTs diagnosis is partially dependent on the immunohistochemistry c-Kit over expression, a type III tyrosine kinase receptor. The majority of GISTs have a constitutively active form of oncogene c-kit, which is the reflex of activation mutations in the extracellular domain (exon 9), juxtamembrane domain (exon 11), and intracellular kinase domains (exons 13 and 17). Approximately 80% of c-kit mutations occur in exon 11, and are clinically important due to their association with high sensitivity and response to Imatinib, a specific kinase receptor inhibitor, when compared to mutations in the other c-kit exons. The reported frequency of c-kit mutations ranges from 20 to 70% of GISTs cases. In Portugal, the incidence of c-kit mutations in GISTs tumors is, to the best of our knowledge, unknown.
The aim of this work was to assess the frequency of oncogene c-kit mutations, in a Portuguese series of GISTs and other mesenchymal tumors, to determine the frequency of patients that would benefit from Imatinib therapy.
DNA was extracted from formalin-fixed and paraffin-embedded tissues of 22 GISTs and 7 mesenchymal non-GISTs tumors (3 Leiomyosarcomas, 1 Malignant Triton, 2 Leiomyomas, 1 Sarcoma). Mutation analysis of c-kit exons 9, 11, 13 and 17 was done by PCR-SSCP. Samples with a SSCP pattern different from the normal blood pattern were further sequenced to confirm the genetic alteration.
Of the twenty-two GISTs cases, eight (36.4 %) contained a mutation in exon 11, one (4.5 %) in exon 9, and no mutation was identified in exons 13 and 17. Mutations in exon 11 included four deletions, two duplications and two base substitutions. The mutation in exon 9 was duplication. All deletions and duplications were in-frame. In total, c-kit mutations were present in 9/22 (41%) of GISTs. No mutation was found in any of the mesenchymal non-GIST cases studied.
We characterized for the first time the occurrence of c-Kit mutations in Portuguese GISTs series. The incidence of c-kit mutation is 41%, in agreement with described range. As previously reported, the great majority (8/9, 89%) of mutations are located in exon 11, and lead to constitutive activation of c-kit kinase activity. No mutations were identified in non-GISTs stromal tumors.

Gastrointestinal study group of HELLENIC SOCIETY OF PATHOLOGY

GISTs are rare neoplasms of the GI tract with unpredictable prognosis, differentiating towards Cajal cells; most GIST express CD117 and carry genetic changes in chromosome 11 which encodes for the c-kit receptor, a tyrosine-kinase transmebrane molecule get involved in cell signaling. An inhibitor of this molecule has been discovered recently, giving rise to new therapies.
The aim of this study is to investigate the incidence of GIST in Greece and analyze the morphological and immunohistochemical characteristics, so as to create a GIST database in Greece.
The mesenchymal neoplasms of GI tract and mesentery diagnosed in 23 laboratories in Greece during a 5-year period (1998-2002) were collected. They were studied by ten couples of Pathologists for morphological subtypes, mitotic activity (50hpf), necrosis, cystic degeneration and atypia in H&E and by immunostaining with CD117 for the staining pattern and the percentage of positive cells (DAKO 1/100,

polyclonal, without pretreatment, using the Ventana automated NeXes system). Follow up the patients for 24 –96 months for overall survivor, partial or complete remission and relapsing in comparison to the morphological and immunohistochemical characteristics of GISTs.
209 out of 311 cases of mesenchmyal neoplasms were positive for CD117 (67.2%). 60.3% of the patients were 61-80 years old, 51% were men and 41% \women (M/F: 1.44). 57.8% of GISTs affected stomach, 28.6% small bowel, 6.6% large bowel and 3% mesentery. 48.2% of neoplasms were measured < 2cm, 36% >2<5cm, 37.6% >5<10 and 21.60% >10cm. Less than <2 mitoses per 50hpf were counted in 48.2% of the cases, 2-5 in 20.3%, >5<10 in 13.7% and >10 in 17.8%. The most common neoplasm was the spindle cell type (52.50%) with moderate atypia (54%). In 51.2% of GISTs 81%-100% of neoplastic cells express KIT protein. A diffuse staining pattern was found in 80.2% of the cases. Since now we follow up 80 patients.
Epidemiology and Histology of GISTs in Greece share the same characters with GISTs worldwide apart from a lower expression of KIT protein, a finding needing further investigation. Follow up of patients is in process and the results should be discussed.

P 318
MULTIPLE GASTROINTESTINAL STROMAL TUMORS IN SMALL BOWEL
SOYUER Isýn,KALA Mehtap,GÜRSOY Sebnem, OK Engin,TURAN Cuneyt,ÖZDEMÝR Mehmet Akif,ÖZKAN Metin, SOYUER Serdar,
Department of Pathology, Department of Gastroenterology,Department of Surgery,Department of Pediatric Surgery, Department of Pediatric Hematology and Oncology,
Department of Oncology,Department of Radiation Oncology, University of Erciyes, Medical Faculty, Kayseri, Turkey

Objectives: In most cases, gastrointestinal stromal tumors (GIST) are sporadic in nature, however, they may occur as multiple lesions in familial forms associated with KIT or PDGFRA germline mutations, but may also develop in the setting of type 1 neurofibromatosis. In these situations, GISTs arise in a background of interstitial cell of Cajal hyperplasia and may be associated with systemic manifestations including skin hyperpigmentation and mast cell disorders. We report four patients with multiple GIST in small bowel and one of them was a child who was diagnosed as a very rare multiple GISTs and gastrointestinal autonomic nerve tumor (GANT).
Methods and Results: We identified four patients with multiple GISTs in small bowel. One of the adult patients has also type 1 neurofibromatosis. Rests of the patients have no type 1 neurofibromatosis and familial disorders. Immunostains for CD117, CD34, desmin, actins, S-100 protein, and keratins were performed on all of the tumors. Patient's ages/genders were 66/M, 65/F, 48/F, 10/M. All of the patients had multiple GISTs in small bowel, large bowel mezothelial surface (operation findings); at least 10 nodules and average 3.0 cm (0.2mm-12cm). First patient also had pancreatic adenocarcinoma, third patient with type 1 neurofibromatosis also had periampullary somatostatinoma. Our child patient had suffered from diarrhea and had familial tuberculosis history. He had multiple (the largest was 12cm diameter) serozal nodules. Tumor cells appear like ganglion cells and immunostains for CD117 was focal positive, NSE, Synapthophysin were diffuse positive,CD34, desmin, actin, myoglobulin were negative.
Our cases had no hepatic metastases. However they had multiple residual tumor nodules, only child patient has been treated with Imatinib Mesylate for two months.
Conclusions : Multiple GISTs are unusual tumors that have been rarely described in children. GISTs require resection and close observation for hepatic metastases.

P 319
REDUCED PROLIFERATIVE ACTIVITY DOES NOT EXPLAIN LOSS OF AVIDITY ON PET SCAN, IN A CASE OF METASTATIC GIST
HEMMINGS Chris*, YIP Desmond#
*Department of Anatomic Pathology and #Department of Medical Oncology, The Canberra Hospital, ACT, Australia

INTRODUCTION
Positron Emission Tomography (PET) is commonly used to monitor disease progression in patients with metastatic Gastrointestinal Stromal Tumour (GIST). We report a case of Imatinib-refractory disease with very low avidity on PET scan.
A malignant GIST was resected from the stomach of a 60 year old woman in 2000. She represented with metastases in the liver and lesser sac in 2001, and was treated with Imatinib. In 2003 further metastases were identified, although tracer uptake on PET was so low that the scan was initially reported as negative. One possible explanation for this could be that the chemotherapy had resulted in a metabolically inactive tumour, which would not take up tracer. A likely result of this would be lower proliferative activity; therefore the pathology was reviewed in an attempt to ascertain whether this could provide an adequate explanation.
METHODS
All slides were reviewed from both the original resection specimen and the subsequently resected metastatic tumour. Mitotic counts were performed on two separate tissue blocks from each specimen, along with immunoperoxidase staining for Ki-67 (MIB-1, Dako). For the mitotic counts, 50 high power fields (hpf)per block were examined, and only definite mitotic figures were counted. Ki-67 staining was assessed by counting the number of positively stained cells per 100 tumour cells, conducting several counts over each slide.
RESULTS
In the original specimen, there weer 55 and 66 mitotic figures (mf) in 50hpf; up to 4mf/hpf and 40mf/10hpf. In the metastatic tumour the counts were 58 and 51mf/50hpf; up to 4mf/hpf and 29mf/10hpf.
Ki-67 staining showed zonal variation in both instances, with staining per centages ranging from 2-58% in the primary tumour and 2-54% in the metastasis. In both cases, the overall average staining rate was estimated at around 40%.
CONCLUSION
There does not appear to be any significant difference in proliferative activity between these tumours, whether assessed by traditional mitotic counts or by staining for Ki-67. Thus differences in proliferative activity do not explain the lack of tracer uptake in this case. It is postulated that Imatinib therapy may have been sufficient to inhibit tracer uptake and/or phosphorylation, but insufficient to inhibit tumour cell proliferation. Regardless of the cause, this loss of avidity has important implications for therapeutic monitoring of patients with recurrent GIST.

P 320
THE HISTOPATHOLOGIC PATTERN OF GASTRO - INTESTINAL STROMAL TUMORS (GIST) AFTER TREATMENT BY IMATINIB.
MICHEJ Wanda, NASIEROWSKA – GUTTMEJER Anna

INTRODUCTION – Mesenchymal neoplasms derived from stroma of gastrointestinal tract (GIST) are restive for classic chemotherapy. These tumors become from Cajal cells and show immunopositivity for tyrosine kinase receptor – CD 117. This reaction is a base to recognize them and allows to treat by Imatinib (Glivec). It is no a predictive factor.
MATERIALS AND METHODS – Thitry patients with GISTs were treated by Imatinib in Cancer Center in Warsaw

between 2001 and 2004 year because of dissemination of neoplasms. Eight cases become from stomach, twelve from small intestine, ten tumors were of unknown origin. The response of treatment was monitorring by computer tomography. The cases with radiologically regression were resected. The resected specimen were fixed in 10% formalin and futher tissue sections were stained with routin hematoxylin and eosin. Immunohistochemical anaysis for CD 117 were also done.
AIM – To show histopathologic curative effects in GISTs treated by Glivec RESULTS – Comlete response appeared in 3 cases, partial response in 20 ones, in others (8) there were no any changes. Grossly: Tumors of diameter from 2 to 6 cm with gelatinous consistensy were present with many haemorrhages and necrotic slough. Microscopically – the cells of neoplasm show a little degree of damage (about 30% of neoplasm volume). The remainder or tumors cells were confirmed by positive reaction CD 117. The results of therapy were: necrosis, haemorrhage, foci of connective tissue, hyaline deposits.
CONCLUSION – Partial or complete regression of GISTs was observed in patients cured by Imatinib. This medicine makes possible to resect non – operative tumors within healthy limits.

IMMUNOHISTOCHEMICAL EVALUATION OF P16, MCM-2, AND KI-67 EXPRESSION AS MARKERS OF TUMOR PROGRESSION IN GISTS BY TISSUE MICROARRAY AND CORRELATION WITH THE RISK CLASSIFICATION OF THE NIH CONFERENCE CONSENSUS

Chien-Feng LI^, Ching-Nan LIN^, Wen-Wei HUANG$, Hsuan-Ying HUANG*
Department of pathology, Chi-Mei foundation Medical Center, Tainan, Taiwan^
Department of Family Medicine, National Cheng Kung University, Tainan, Taiwan$
Departemnt of Pathology, Chang Gung Memorial Hospital, Kaohsiung Medical Center, Kaohsiung, Taiwan*

Introduction: Risk stratification for gastrointestinal stromal tumors (GISTs) is crucial but sometimes remains challenging if based on histology alone. Inactivation of p16 gene is common in human cancers, which results in aberrant loss of its encoding protein and consequently promotes G1/S progression of cell cycle. Minichromosome maintenance protein-2 (MCM-2) is associated with cell proliferation and represents one member of the MCM hexamers that unwind DNA during replication. Few series have addressed the role of dysregulated p16 in disease progression of GISTs with a sufficiently large sample size. Moreover, the prognostic value of MCM-2 has never been examined in GISTs. Purpose: We attempted to elucidate the association between expression of p16, MCM-2, and Ki-67 and disease progression in GISTs by tissue microarrays (TMAs). Methods: Six TMAs were prepared from 343 GISTs conformed by CD117 and/or PKC-£cwith each case punched in quadruplicate. All cases were stratified by NIH consensus criteria and immunostained with p16 (Novacastra), Ki-67 (DAKO), and MCM-2 (Novacastra). Only cases with ¡Ù2 preserved cores were scored for statistic analysis. Results: Of cases with scoring data, aberrant loss of p16 (<15%) was observed in 63% of GISTs: 47/88 (53%) of very low/low-risk (VL/L-R) cases and 134/201(67%) of intermediate/high-risk (I/H-R) GISTs (p=0.032). Overexpression of Ki-67 (¡Ù5%) and MCM-2 (¡Ù10%) was found in 34% and 48% of GISTs, respectively: 15/81 (18%) of VL/L-R cases and 79/192 (41%) of I/H-R GISTs for Ki-67 (p<0.001); 29/82 (35%) of VL/L-R cases and 106/197 (54%) of I/H-R GISTs for MCM-2 (p=0.005). Both Ki-67 and MCM-2 were highly related to mitoses (p<0.0001 for each) and tumor size (p<0.0001 for Ki-67, p=0.017 for MCM-2), but aberrant loss of p16 was not so. Besides, MCM-2 labeling was not only highly correlated with (p<0.0001) but also significantly higher (p<0.0001) than that of Ki-67. However, expression of p16 was inversely associated with MCM-2 labeling alone (p=0.011). Conclusions: I/H-R risk GISTs preferentially express higher MCM-2, higher Ki-67, and loss of p16, indicating their roles in tumor progression. However, aberrant loss of p16 protein still occurs in a considerable proportion of early GISTs, which may contribute to tumorigenesis by promoting G1/S transition with a consequent increase in cell proliferation. MCM-2 may help identify non-high risk GISTs that will behave aggressively because of the higher sensitivity than Ki-67.

P 322

GIST AS UNEXPECTED CAUSE OF DYSPHAGIA IN MULTIPLE SCLEROSIS PATIENT

BULIMBASIC Stela1, NIKOLIC Igor2, KRIZANAC Simun3
1Department of Pathology, General Hospital “Sveti Duh”, Zagreb, Croatia
2Department of Thoracic Surgery, University Hospital “Jordanovac”, Zagreb, Croatia
3Institute of Pathology, Zagreb Medical School, Zagreb, Croatia

Introduction: Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the gastrointestinal tract. Majority of cases arise in stomach and small intestines, while occurrence in other sites is rare. We report a case of GIST causing dysphagia in patient with multiple sclerosis.
Patient and methods: A 50 year old female patient with multiple sclerosis suffered from dysphagia of unknown cause. Preoperative endoscopic and CT procedures discovered large tumor mass in the lower posterior mediastinum. Left posterolateral thoracotomy revealed tumor basis emerging from the esophageal wall. Excided tumor was pathohistologically analyzed using standard HE and immunohistochemical stains against vimentin, S-100, SMA, CD34 and CD117.
Results: Tumor mass measured 9.5 cm in diameter. Cut surface was fleshy with areas of cystic degeneration and necrosis. Histologically tumor consisted of short fascicles of spindled cells mixed with areas of epitheloid cells, both positive for CD34, CD117 and vimentin, while S-100 and SMA were negative. There were 8 mitosis per 50 high power fields.
Discussion: Less than 2% of GISTs occur in the esophagus, mostly in the lower parts, causing dysphagia. High majority of patients are middle-aged males without other symptoms which makes GIST difficult to diagnose. Rareness of such cases explains why there is only one study found in literature that reports 17 patients with GIST of esophageal localization. That survey enabled Miettinen and associates to undoubtedly confirm that size of tumor and high mitotic index are major prognostic factors. According to these prognostic elements, GIST revealed in our patient was characterized with high risk of aggressive behavior. The specific targeted medication therapy was recommended. Postoperative period was uneventful and patient was discharged on the ninth postoperative day.
The occurrence of GIST in patient with multiple sclerosis is considered to be coincidental; tumor symptoms were masked by known neurological disease and proper diagnostic evaluation was delayed. Overall survival will depend not only on response to given therapy but also to concomitant neurological disease.
Conclusion: Although rare, GIST ought to be considered in differential diagnosis of tumor masses in posterior mediastinum. Pathologist should be aware of this possibility because adequate gross and microscopic examination followed by immunohistochemical analysis is essential.

** Service de chirurgie B, ***Service de chirurgie A, Hôpital Charles Nicolle, Tunis

Introduction: Stromal tumors of the digestive tract, or gastrointestinal stromal tumors (GIST), originate from Cajal cell. Small intestinal stromal tumors (SIST) are infrequent tumors. Their worse prognosis compared to other GIST is clearly established. The aim of this study was to report the clinicopathologic features and immunohistochemical characteristics of SIST through a series of 7 cases.
Material and methods: We identified seven cases of c-kit positive SIST from 40 cases of GIST reviewed in our center over a 13-year period (from January 1990 to December 2002).
Results: Three patients were men, four were women and the average patient age was 56 years. Five tumors were located in the ileum, two in the duodenum and one in the jejunum. The presenting clinical symptoms were gastrointestinal bleeding, either acute or occult, in 4 cases and abdominal pain in 2 cases. In the remaining patient, SIST was an incidental finding during abdominal ultrasonography for unrelated condition. Tumour size was ranged from 2 to 10 cm (median: 5.5 cm). Histologically, the majority of tumours in this group (6 cases) were composed of spindle cells with relatively scant amounts of cytoplasm. In all 6 of these tumours, the cells were arranged in a predominant fascicular growth pattern. In one tumour (case 3), the majority of cells had an epithelioid morphology and a focal organoid growth pattern was seen. Nuclear pleomorphism was absent in two cases, moderate in 3 and severe in 2 tumors. Mitotic counts ranged from 0 to 10 mitotic figures per 50 HPF. Treatment options were segmental intestine resection in all cases. None of the patient had lymph node involvement or distant metastasis at time of surgery. Four of five patients on whom there was follow-up information were free of disease. One patient died at 8 days from postoperative complications.
Conclusion: The authors discuss the clinicopathologic features including immunohistochemical staining profile of the SIST and define morphologic criteria which can help the pathologist to distinguish between low and high malignant potential SIST. The SIST express CD117, and mutations of the c-kit gene are central to their pathogenesis and likely the key to effective therapeutic intervention(Gliveec®).

IMMMUNOHISTOCHEMICAL EXPRESSION OF CYCLOOXYGENASE-2 AND CYTOKERATIN 8/18 IN GASTROINTESTINAL STROMAL TUMORS

F. Patakiouta, P. Xirou, D.Tzilves*, N. Vladika, Z. Antonopoulos*, I. Katsos*
Departments of Pathology and Gastroenterology-Oncology*, "Theagenio" Anticancer Hospital, Thessaloniki, Greece

Introduction: Cyclooxygenase (COX) is the key enzyme in the prostaglandins synthesis, catalyzing the conversion of arachidonic acid to PGH2 and exists in two isoforms (COX-1 and COX-2). The inducible form COX-2 plays an important role in tumorigenesis and has been shown that it is expressed in colorectal cancer, as well as in lung, breast and prostate cancer. Little is known about the expression of COX-2 in nonepithelial tumors, such as the gastrointestinal stromal tumors (GISTs). As regards expression of cytokeratin in GISTs, it seems to be very rare.
Purpose: To examine the expression of COX-2 and cytokeratin 8/18 in GISTs.
Materials and Methods: Twenty-six patients (15 females and 11 males, median age: 63.8 years, range: 36-79), with GISTs were evaluated. Paraffin-embedded tumor tissue sections were stained with hematoxylin-eosin. COX-2 and cytokeratin 8/18 expression were determined immunohistochemically.
Results: COX-2 expression was noted in the cytoplasm of tumor cells in 19 of 26 tumors (73,1%), with variable intensity of staining. The expression was stronger in epithelial than in spindle cell tumors and in epithelial areas of mixed tumors. There was no statistically significant difference of the COX-2 expression between benign and malignant tumors, but there was a greater extent of expression in tumors located within the stomach. Cytokeratin 8/18 expression was focally found in tumor cells in 2 gastric tumors (7,7%), one benign and one malignant.
Discussion: COX-2 is upregulated in many epithelial tumors, particularly in those of the gastrointestinal tract. The enzyme is implicated in the process of carcinogenesis and its overexpression has correlated with tumor size, infiltrative growth, local recurrence, haematogenous metastasis and reduced survival. However, up to now little is known about the expression of COX-2 in non epithelial tumors. COX-2 expression has been described in the sarcomatoid component of some uterine tumors, in pleural tumors and in sarcomas of infancy. It is also known that expression of simple epithelial keratin in GISTs is much rarer than that observed in typical leiomyosarcoma and occurs especially in malignant epithelioid tumors.
Conclusions: COX-2 overexpression was noted in the majority of cases of GISTs, suggesting the possible role of the enzyme in the tumor growth and the use of COX-2 inhibitors in treatment. On the contrary, expression of cytokeratin 8/18 in GISTs was very rare.

GASTRITIS IN CHILDREN AND ADULTS : A COMPARATIVE HISTOPATHOLOGIC STUDY.

Bettaieb I, Mrad K, Sassi S, Driss M, Abbes I, Dhouib R, B. Zouari*, Ben Romdhane K.
Pathology department, Institut Salah Azaiez, *epidemiology and medical statistics, Faculty of medicine, 1006, Bab saadoun, Tunis, Tunisia.

Introduction : Helicobacter pylori (HP) is highly associated with gastritis, peptic ulcer, gastric carcinoma and lymphoma. Since HP infection usually occurs in childhood and remains for life unless treated, we compared gastric biopsies in children and adults.
Material and methods : The study was performed on random biopsies from gastric mucosa of 100 patients (50 adults and 50 children). Sex and age were recorded for each patient. Following parameters were evaluated on H&E biopsies according to Sydney system: HP infection (0/1/2/3+), lymphocyte infiltrate (0/1/2/3+), activity (0/1/2/3+), atrophy (0/1/2/3+), and intestinal metaplasia (present/absent). Comparison of histologic variables between two groups (children and adults) was performed using the Fisher exact test or khi-2 analysis, as appropriate.
Results : The male to female ratio was 1.17 in both groups. HP was present in 90% of children biopsies and 82% of adult biopsies (p=0.249). A significant trend toward increased lymphocyte infiltrate in children was detected (p=0.019), but there was no difference in the prevalence of follicular pattern (p=0,838). There was no statistical difference in activity (p=0.58).The mucosa in children (18%) showed significantly less atrophy than in adults (36%) (p=0.043). Intestinal metaplasia was positively correlated with age (22% in adults/2% in children, p=002).
Conclusion : In children, gastritis shows increased lymphocyte infiltrate and less damaged epithelium. In adults,

the immune response seems to be decreased and the capability of epithelium regeneration is altered since atrophy and metaplasia are increased.

IMMUNE RESPONSES INDUCED AFTER MUCOSAL ADMINISTRATION OF THE NON TOXIC CHOLERA B SUBUNIT IN HUMAN VOLUNTEERS: USEFULNESS OF ELISPOT METHOD

CUBURU Nicolas (1), BERTO Frederick (2), TRIPAULT Frederique (2), GAVRIC- TANGA V (2), CZERKINSKY Cécil (1), HOFMAN Paul (1, 2).
(1) INSERM 721 and (2) Laboratory of Clinical and Experimental Pathology, Pasteur Hospital, University of Nice, Nice, France

Oral administration of antigens, including allergens and autoantigens, maybe an efficient way to prevent diseases associated with untoward immune responses to self- and non-self antigens. However, this approach has met with limitations because it usually requires repeated administrations of large doses of antigen. Tolerance induction, based on oral administration of small amounts of antigens conjugated to the B subunit of cholera toxin (CTB), may find broad applications for preventing untoward immune responses. The aim of this study was, by using a commercial CTB (SBL vaccine), 1) to evaluate the CTB-specific systemic and mucosal immune responses after oral, nasal, or sublingual human immunization; 2) to evaluate the predictive markers of immunogenicity. We showed that homing receptor expression profile depends on the site of immunization: 100% of CTB-specific IgA SCs express alpha4 beta7 after oral, nasal and sublingual immunization; 100% of CTB-specific IgA SCs express CD62L after nasal and sublingual immunization, whereas 40% of CTB-specific IgASCs express CD62L after oral immunization. The detection of CTB-specific antibody-secreting cells in blood was performed in cell suspensions par ELISPOT method. According to the route of immunization and systemic or mucosal CTB-specific response, ELISA (IgA2) or search for antibody secreting-cells in blood (IgA and IgG ELISPOT) were performed. Moreover, a selection of cells expressing chemokine receptor or integrin such as CCR9, CCR6, CCR10 and integrin alpha4 beta7 was performed by magnetic cell sorting and detection of antibody secreting-cells in positive and negative fraction was done by ELISPOT.

P 327

GASTRIC MUCOSAL ENDOCRINE CELLS IN THE EXPERIMENTAL BREAST CARCINOGENESIS.AN IMMUNOCYTOCHEMICAL STUDY

Maric Lj.Ivana, Jancic A Slavisa, Rosic L. Gvozden, Jancic A.Snezana
Oncology Clinic,University Medical School,Nis,Serbia and Montenegro
Institute of Pathology and Phisiology,University Medical School,Kragujevac,Serbia and Montenegro

It is well known the role of many regulatory peptides in clinical course of human cancers.However,these are no reported data about endocrine cells of the stomach in the experimental breast carcinogenesis.Because of that,the aim of this report is to study G-,EC-,ECL- and D-gastric mucosal cells,during chemically induced breast carcinogenesis.
We used the female albino Wistar rats,42 days old and 120±10gr. of weight.One miligram of 9,10 dimethyl-1,2 benzanthracene(DMBA) was implanted in the 5-th mammary gland.The experimental group includud 15 rats,as well as control group.The animals were killed after 60 days after the implantation.
Specimens from stomach were taken only from the rats with developed mammary gland cancer.Five micrometer thin sections were routhynly stained with HE and immunocytochemical SAB-method with antibodies against gastrin,serotonin,histamin and somatostatin.Obtained results were statisticaly analysed by Students T test.
We have found a characteristic hyperplasia of endocrine cells,with hyperplastic G,EC and ECL-cells,compared to these cells of control animals.Simultaneously in this study revealed revealed the development of multifocal dysplastic lesions in the antral mucosa.
The authors suggests direct stimulatory effects of DMBA on endocrine cells of the gastric mucosa.It can be concluded that DMBA cause preneoplastical effects on the gastric mucosa in rats.

P 328

AUTOMATED PROLIFERATION/APOPTOSIS DETERMINATION IN GASTROINTESTINAL FRESH FROZEN SECTIONS USING TRIPLE FLUORESCENT LABELLING AND SCANNING FLUORESCENT MICROSCOPY CORRELATES TO IMMUNHISTOCHEMICAL STAINING AND VISUAL COUNTING

BOCSI József *, SIPOS Ferenc, FICSÓR Levente, VARGA Viktor, MOLNÁR Béla, TÁRNOK Attila *
* Children's Heart Center, Uni. Leipzig, Germany
Cell Analysis Lab, II.Dept. of Medicine, Semmelweis Uni, Budapest Hungary

Background: Proliferation/ apoptosis balance is an important information in gastrointestinal ulcerative and malignant diseases. Until now immunhistochemical staining and visual counting was the routine procedure. Recently we reported a new scanning fluorescent technique for automated motorised microscopes (SFM).
Aims: development of triple fluorescent labelling method for proliferating/apoptotic/ resting cells and application of SFM for the automated analysis and counting on gastric biopsy specimen.
Materials and methods: Routine gastroscopy antral biopsy specimen (30) were fresh frozen and 5 um sections were prepared. Proliferation was detected using a PCNA antibody and an antimouse-rhodamine labelling system. Apoptosis was labelled using the TUNEL reaction with FITC bound nucleotids. DAPI nuclear counter staining was applied.
The labelled sections were scanned and digitised in the three fluorescent channel. SFM was modified to detect epithelial surface, glands in the biopsy specimen. Automated nuclei detection, PCNA and Tunnel detection was performed, ratio was calculated. In paralell standard biopsy specimen were labelled with PCNA and AEC labelling . TUNEL reaction was performed also performed.Visual counting was performed upto 1000 epithelial cells.
Results: The mean PCNA labelling in healthy samples were 45,3+12,4%, TUNEL positivity was found in 23,2+ 7,8%. Significant correlation in apoptosis/proliferation ratio between the two methods could be observed ($p<0,05$). The SFM procedure proved to be more time efficient both in the labelling, both in the detection procedures.
Conclusions: Triple fluorescent labelling and automated fluorescent microscopy is an applicable tool for the proliferation, apoptosis determination in fresh frozen samples.

P 329

EXPERIENCES IN AUTOMATIC CLASSIFICATION OF COLON AND GASTRIC DIGITAL SLIDES

FICSÓR Levente, MOLNÁR Béla, TULASSAY Zsolt
Cell Analysis Laboratory, 2nd Department of Internal Medicine, Semmelweis University

INTRODUCTION
Thanks to the fast evolution of digital microscopy new ways have been opened for image analysis on whole histological

tissue slides. Moreover recently new pattern recognition techniques were introduced for cell detection on the complicated histological images working on single field of views.

AIMS

The aims of present study were to adopt new development of image processing algorithm for whole biopsy slides to detect higher structures as gland, epithelium surface and finally to automatically classify gastric and colon samples using digital slide format.

METHODS

Altogether 69 colon (24 normal, 11 aspecific colitis, 25 colitis ulcerosa and 9 crohn disease) and 79 gastric (14 normal, 17 atrophy, 6 gastritis with intestinal metaplasia, 12 gastritis and 30 adenocarcinoma)well oriented mucosal biopsy specimens were selected. To digitalize the selected H/E stained slides Zeiss Mirax slide scanner system was used. Automatic histological evaluation modules were developed in C++. Altogether 45 parameters described the area, cell density and cellular characteristics of the basic tissue components as the surface epithelium, glands, connective tissue and the inflammatory cell compartment. Area and contained cell number ratios of different tissue compartments were calculated which we named to tissue cytometric features.

RESULTS

We could find that that newly developed tissue cytometric features efficiently can be used to classify both gastric and colon digital slides by their disease state. The most important parameter was the ratio of total cell number and cell number in interstitial region (Colon: healthy 1.57±0.17; aspecific colitis 1.34±0.16; colitis ulcerosa 1.18±0.09; Crohn disease 1.28±0.11, $p<0.01$ - Gastritis healthy 1.43±0.12; gastritis 1.23±0.13; carcinoma 1.1±0.05 $p<0.01$).

CONCLUSION

This preliminary study proved again that the development and evaluation of quantitative tissuemetric features can be used in the automated classification of histological colon biopsy specimen.

WEGENER'S GRANULOMATOSIS MASQUERADING AS MASTOIDITIS: REPORT OF AN UNUSUAL CASE

NAGY Pál*, SALAMON Ferenc*, Z. SZABÓ László**, DOMJÁN Gyula***, BALOGH Károly****

*Dept. of Pathology, National Medical Center, Budapest, Hungary

**Dept. of Otorhinolaryngology, National Medical Center, Budapest, Hungary

***Dept. of Medicine, Szent Rókus Hospital, Budapest, Hungary

****Dept. of Pathology, Harvard Medical School, Boston, USA

Introduction: Wegener's granulomatosis is a rare, immunologically mediated inflammatory disease (WHO, 1991). The diagnosis is based on the clinical picture, the presence of cANCA by immunofluorescent microscopy and by biopsy of the affected tissue. Our purpose is to present a case in which the unusual clinical picture and the atypical histologic findings posed a diagnostic problem.

Material and methods: A 27 year old woman was referred to our hospital (NMC) with symptoms of severe mastoiditis. During a period of 7 months she had 7 operations in 4 different hospitals for progressive chronic inflammation of the right mastoid process. Microsopically, all surgical specimens showed nonspecific granulation tissue with chronic inflammation, fibrosis, and once, suppurative granulomatous inflammation. This process also involved adjacent bone, causing focal osteonecrosis. Laboratory tests, including bacteriologic cultures failed to reveal a definite etiology of the progressive, destructive process which later necessitated also resection of a part of the first cervical vertebra. The patient's condition deteriorated and she became critically ill. Consultation was requested and the entire histologic material was reviewed (K.B). Special stains (Gram, PAS) for microorganisms, fungi and parasites, as well as immunohistochemical reactions to exclude differential diagnostic considerations were all negative.

Results: The main features of the reviewed histologic material were

- •Ulcerative granulomatous inflammation with focal fibrosis and destruction of underlying tissues
- •Capillaritis and venulitis without arteritis
- •Confluent, partly well circumscribed histiocytic granulomas with central microabscesses
- •Irregular („geographic") necrosis (in one small area only)

These histologic characteristics and the exclusion of differential diagnostic considerations (infectious granuloma, sarcoidosis, histiocytosis, eosinophilic granuloma) strongly suggested a localized variant (" forme fruste") of Wegener's granulomatosis and was confirmed by the cANCA test, which initially was negative. The patient was treated with steroids and cyclophosphamide and has been in remission for almost two years. Follow-up studies failed to disclose any upper respiratory, pulmonary or renal involvement.

Conclusion: In young or middle age patients "mastoiditis " resistant to conventional medical or surgical therapy may be due to Wegener's granulomatosis.

P 331

A CLINICOPATHOLOGICAL STUDY OF KIMURA'S DISEASE IN THE HEAD AND NECK REGION. A REPORT OF THREE CASES.

Bellefqih S*, Le Pelletier F*, Charlotte F*, Meningaud J-P**, Pitak-Arnnop P**, Barete S***, Bertrand J-C**, Capron F*, Fouret P*.

Dpts of Pathology*, Maxillofacial Surgery**, and Internal Medecine***, Groupe Hospitalier Pitie-Salpetriere, Paris, France.

Background: Kimura's disease (KD) is an uncommon inflammatory disorder of unknown aetiology, primarily seen in young Asian males. Its characteristics are painless subcutaneous masses in the head and neck region, blood and tissue eosinophilia, and markedly elevated serum IgE.

Material and methods: Over a ten-year period, 3 cases of KD of the head and neck region were diagnosed in our department and retrospectively reviewed.

Results: The three male patients (25, 26, and 29 years old at diagnosis) were natives from Madagascar, Cambodia and Mauritius. All had hypereosinophilia and elevated serum IgE with normal renal function. The first patient presented with a parotid localization, while the second had a temporal dermohypodermic nodule with ipsilateral involvement of parotid gland. The third patient showed a preauricular mass. Histologically, the soft tissue and the parotid gland were infiltrated by lymphoid follicles with folliculolysis and eosinophils forming eosinophilic abcesses. There were numerous thin walled vessels with neither epithelioid nor vacuolated endothelial cells. Adjacent lymph nodes also showed hyperplastic follicles with paracortical eosinophilia and folliculolysis. The immunohistochemical studies revealed CD20+ follicles with prominent staining of dendritic reticular cell CD23+, surrounded by numerous interfollicular CD3+ and CD4+ or CD8+ T-cells. CD1a, HHV-8, and LMP1 were negative. In situ hybridization confirmed the lack of EBV infection. FVIII-related antigen and CD34 decorated the thin-walled blood vessels.

Recurrence was observed in the first patient both at original and contralateral sites.

Conclusion: KD is a rare chronic inflammatory disease with genetic predisposition that typically presents as a deep pre-auricular nodule and/or parotid gland involvement. The

immunohistological study confirms its reactive nature. Excision is considered as the treatment of choice, but recurrences can occur even in a prolonged period.

P 332
MORPHOFUNCTIONAL PECULIARITIES OF THE GUM TISSUES AT PATIENTS WITH CHRONIC PERIODONTITIS AND PRE-IMPLANTATION TREATMENT
MUDRAYA Valentina, RESHETNIKOVA Olga
Department of Operative Dentistry and Department of Pathologic Anatomy, Medical University, Lugansk, Ukraine.

Periodontal diseases have high incidence rate worldwide.Quite often treatment plans involving tooth replacement, are used for sites diagnosed with chronic periodontitis (CP). Thus, there is a problem of finding pathogenically based methods of structural changes correction in a gum. Present study was undertaken to help further evaluate gum tissues remodelling with and without pre-implantation treatment of CP.
Methods. 30 volunteers were enrolled while receiving dental care. 10 gums biopsies were taken from patients without CP symptoms (group of comparison), 10- from patients with CP undergoing surgical operation without preoperational therapy (group 1) and 10- from CP patients with pre-implantation treatment by glutarginum and vector-therapy (group 2). Histological slides were stained with H&E, Van Gison, and then stereological evaluation by point count method was performed. The volume fractions of inflammatory infiltrates, vascularity, areas of dystrophy and necrosis of connecting tissue and others were determined. Collagen I and ? type's expression were studied immunohistochemically with the use of specific antibodies.
The results have shown that the increase of volume fractions of inflammatory infiltrates, vessels, foci of periodontal connective tissue dystrophy and necrosis are determined in group I. Immunohistochemical analyses showed that both expression and distribution of the I type collagen was diminished here too. Unlike this, the ? type collagen was registered here more often with increased intensity of expression.
The data in group 2 demonstrate a reduction of hyperemia, vessels number, inflammatory infiltrates and areas of connecting tissue dystrophy. The collagen type's distribution has changed to the mode seen in group of comparison: type I collagen predomination over the ? type collagen.
Conclusion. These findings suggest that chronic periodontitis stimulates the forming of immature connective tissue and persistent inflammation in a gum. On this background there is braking of repair processes, which can unfavorably affect implant osteointegration. The use of glutarginum, possessing antioxidant and membranes protective properties, in conjunction with the mechanical debridement by vector-therapy, allows normalizing gum tissue's metabolism, to recover the normal parameters of collagen stromal components. These seem to be effective in maintaining structure and function of the gums and periodontal tissues at pre-implantation period.

P 333
PRESENCE AND DISTRIBUTION OF MERKEL CELLS IN ORAL MUCOSA.
RIGHI Alberto, MARUCCI Gianluca, **MARCHETTI Claudio,**MONTEBUGNOLI Lucio, FOSCHINI Maria P.
Department of Oncological Sciences, Section of Anatomic Pathology, University of Bologna.
** Department of Oral Sciences, University of Bologna.

Introduction: Merkel cells (MC) are endocrine elements located in the basal layer of epidermis and oral mucosa. MC are difficult to be found by routine light microscopy; but can be visualized by electron microscopy and immunohistochemistry. Cytokeratin 20 (ck20) is a sensitive marker for MC. A few data are available on the distribution of MC in human oral mucosa. The aim of the present paper is to better define the presence and distribution of MC in normal and pathological oral mucosa.
Materials and Methods: 89 surgical consecutive biopsies of oral mucosa were evaluated. Patients age ranged between 3 and 84 years (mean 48). Sections were stained with haematoxylin\eosin and immunohistochemistry applying a monoclonal antibody anti ck20 (Dako, clone KS 20.8, diluted 1:40). Semiquantitative evaluation of ck20-positive cells, consistent with MC, was performed on 300 basal keratinocytes, in the area with higher number of MC. Location (basal or supra-basal) of MC and shape (oval or dendritic) were recorded.
Results: MC Distribution according to the site: the highest number of MC was observed in the gingiva (range 1 to 80 MC, mean 14 MC), palate (range 1 to 40 MC, mean 11 MC) and buccal mucosa (range 2 to 19 MC, mean 11), while MC were rare in the tongue (1 to 8 MC, mean 4 MC), and cheek (no more than 1 MC for biopsy), and were not observed in tonsil mucosa. Distribution according to the histological diagnosis. MC were present in 7\14 biopsies from normal oral mucosa (range 1 to 27 mean 8); 7\14 in acute inflammation with ulceration (range 3 to 18, mean 8); 9\11 chronic inflammation with hyperkeratosis (range 1 to 80, mean 18); 4\6 lichen (range 1 to 14, mean 5); 7\12 epithelium overlying chorion fibrosis (range 1 to 33, mean 13); 12\15 epithelium overlying salivary gland tumours and ameloblastoma (range 1 to 40, mean 13); 3\17 dysplasia and in situ carcinoma (range 1 to 8, mean 5). MC were not localized in the ulcerated or dysplastic epithelium, but when present they were observed in the epithelium adjacent to the lesion. In all cases MC were oval or dendritic in the same proportion., they were mainly located in the basal layer, in two cases only reaching the superficial layers of the epithelium.
In conclusion the present data confirm that MC are mainly localized in gingival, palate and buccal mucosa. In addition their number increases in chronically damaged mucosa, thus suggesting a possible function in reparative processes.

P 334
HPV GENOTYPING BY DNA CHIP STUDY IN AMELOBLASTOMA
Hye-Kyoung Yoon, Mi-Seon Kang, Woo-Hyung Kim
Dept. of Pathology, Pusan Paik Hospital, Inje University, Pusan, Korea

Background: Ameloblastoma is a relatively common tumor, however, the etiologic factor or biologic activity are not clearly defined. This study is designed to determine the relation of ameloblastoma with a possible etiologic factor, human papilloma virus (HPV), and to evaluate the clinicopathologic characteristics of HPV-positive ameloblastoma.
Methods: The materials were 31 formalin-fixed, paraffin-embedded tissue samples from 22 ameloblastoma patients. HPV DNA chip study was done, and clinicopathologic parameters were compared according to the recurrence and HPV status.
Results:
1. In sixteen cases without recurrence, HPV DNA was not detected. However, three of 15 tissue samples from six recurred cases were HPV 16-positive. One of them showed positive for HPV 16 and HPV 40.
2. Nine of 16 cases without recurrence were under 20 years old, in contrast, there was no case under 20 years old in 6 recurred cases.
3. There were no significant differences of sex ratios and tumor locations according to the recurrence.

4. Radiologically three of 16 cases without recurrence was multicystic mass, but four of 6 recurred cases were multicystic. Three HPV DNA-positive cases were also multicystic.
5. Ten of 16 cases without recurrence and five of 6 recurred cases were follicular type histologically, and one recurred cases showed conspicuous cytologic atypia.
6. Two of 3 HPV-positive cases showed relatively rich stromal component, and remaining one case exhibited conspicuous inflammatory reaction.
Conclusion: In the half of recurred ameloblastoma cases, HPV 16 was detected, in contrast, no HPV-positivity in 16 cases without recurrence. The results suggest that HPV could be regarded as a possible etiologic factor of ameloblastoma with a tendency of recurrence. In addition, the risk of recurrence might be increased in cases showing multicystic mass, follicular type with cytologic atypia or rich stromal components and HPV-positivity.

P 335
AMELOBLASTOMA WITH MALIGNANT TRANSFORMATION: A CASE REPORT - 20 YEARS EVOLUTION
PAIVA Geise Rezende, ANDRADE Rodrigo Guimarães, VILELA Rafael Sarlo, PINTO Clóvis Antonio Lopes.
Research and Medical Center Hospital do Cancer, São Paulo, Brazil

INTRODUCTION: Ameloblastomas comprise nearly 1% of the oral tumors. They have slow growth, but they are locally aggressive. Malignant transformation and metastasis occurrence are described in the literature. In 1971 Malignant ameloblastoma was included in WHO's classification of odontogenic tumors.
OBJECTIVE: Report a case of ameloblastic carcinoma in jaw.
CASE REPORT: We present a case of a 30 year-old female patient, with primary ameloblastoma in left jaw, without evidence of metastatic disease to the diagnosis. This patient was submitted to partial resection of the left jaw. The evolution demonstrated local progression, with eight recurrences in jaw, buccinator muscle, infratemporal fossa and cervical area, in 20 years of observation, showing evident maligant transformation in the last three recurrences.
DISCUSSION: The term malignant ameloblastoma and ameloblastic carcinoma have been raising discussions in the literature. Peter et al revising WHO's odontogenic tumors classification (1992) suggests a subdivision of malignant potential ameloblastic tumors, proposing the terms malignant ameloblastoma and ameloblastic carcinoma. The literature demonstrates that the expression of P53 and a high proliferation index is related to a higher tendency of tumor's recurrence and aggressiveness. Morphologically we observed a neoplasia composed of strings or islands of basaloid epithelial cells, with fence appearing outlying cells, intermixed with a reticular colagenized stroma. Pleomorfic cells with atypical and hipercromatic appearing nucleus, beyond numerous mitosis, were observed in the last three recurrences, as well as the high p53 and Ki67 expression. Indeed, it is a highly aggressive tumor with evident malignant transformation, testified by cytological alterations, initial negative expression for p53 protein, which is over expressed in the last three recurrences, and the cellular proliferation index progression (Ki67).
CONCLUSION: The term ameloblastic carcinoma can be applied to our case. It demonstrated malignant cytological alterations, besides the classical ameloblatoma morphology. The morphological and immunohistochemical features of this case can represent a tumoral progression model of the ameloblastic tumors.

P 336
EWING'S SARCOMA OF THE JAW BONES. A REPORT OF THREE CASES.
Bellefqih S*, Gruffaz F*, Handra-luca A*, Couturier J***, Meningaud J-P**, Pitak-Arnnop P**, Bertrand J-C**, Capron F*, Fouret P*.
Dpt of Pathology* and Dpt of Maxillofacial Surgery**, Groupe Hospitalier Pitié-Salpêtrière;
Dpt of Genetics***, Institut Curie, Section Médicale. Paris, France.

Background: Ewing's sarcoma is an uncommon neoplasm usually arising in long bones or pelvis. The involvement of jaw bones is very rare.
Patients and methods: Three patients with Ewing's sarcoma of jaw bones treated between 1996 and 2005 were clinicopathologically reviewed. The diagnosis was based on the histological, immunohistochemical and genetic molecular data.
Results: Two women and one man were 22, 24, and 25 years-old at diagnosis. Two tumours localized in the mandible, while the other was in the maxilla. The dominant symptoms were pain, as well as a rapidly destructive and expansile mass. Histologically, the tumour consisted of sheets of small, round and undifferentiated cells that were PAS-positive. Abundant blood vessels, haemorrhagic foci, and necrotic areas were seen. Immunohistochemical study revealed that the tumour cells were reactive for CD99 (MIC2) and vimentine, but EMA, pancytokeratin, S-100 protein, chromogranine A, and CD45 negative. The Ki-67 proliferation rate was 10, and 80% in two cases. In one case CD117 (c-Kit) was slightly expressed as well as p53 in 30% of cells. MDM2 was negative in each case. EWS rearrangement was evidenced by FISH in one case and RT-PCR in another case. Patients were treated by surgery followed by chemotherapy. One patient had three local recurrences without metastasis during a 5 years follow up.
Conclusion: Ewing's sarcoma is a rare and aggressive tumour of jaw bones that occurs in young adults. Immunohistochemical and genetic molecular analyses are essential for diagnosis. The recurrence is quite common and the prognosis is poor.

P 337
ATYPICAL LIPOMATOUS TUMORS OF THE TONGUE
1Aleš Ryška, 2Thomas Mentzel, 1Helena Hornychová, 1Aleš Kohout
1Department of Pathology, Charles University Medical Faculty and University Hospital, Hradec Králové, Czech Republic
2Dermatopathologische Gemeinschaftspraxis, Friedrichshafen, Germany

Aims: To report 5 cases of rare low grade lesion, atypical lipomatous tumor (ALT) of the tongue.
Patients: The patients were 3 males and 2 females, aged 11-78 years (average 51.2 years, median 65 years). The tumors were in all cases present at the lateral side of the tongue. In one case, there were multiple tumor nodules, localized at both sides of the tongue. Follow up was available in four cases (8-96 months). After surgical excision, none tumor recurred or metastasized.
Results: The size of the tumors ranged from 7 mm to 20 mm (average 11.2 mm, median 10 mm). All cases shared similar microscopic features. They showed infiltrative growth into surrounding structures (skeletal muscle, fibrous tissue). They were of lobular arrangement, composed of adipocytes with slight variation of size and shape. Isolated sparse lipoblasts (both univacuolar and multivacuolar) were present. In two cases, there was prominent interstitial sclerosis and the features thus coped more with the diagnosis of sclerosing ALT, whereas three cases had the features of lipoma-like

o cases, isolated spindle-shaped primitive looking found, presumably of precursor nature. Mitotic s very low, only several typical mitoses were found s examined. Immunohistochemically, the tumor ed positivity of vimentin (4/4), S100 protein (4/4),) and CDK4 (3/4). Proliferative antigen Ki-67 was isolated cells only (less than 0.5 %). Two cases xamined by FISH. Amplification of mdm-2 gene in both cases, whereas amplification of CDK-4 resent in one case only.
s: Atypical lipomatous tumors of the tongue are ver, they have characteristic morphologic features her with typical immunophenotype, enable their agnosis. The herein presented results are in with conclusions of the previously reported series. ve in an indolent fashion; they can recur if y excised, however they virtually never .

GIOPERICYTOMA OF THE OCCIPITAL CASE REPORT

C Ksenija ,DOZIC Branko ,JEZDIC Zoran
t of Oral pathology Faculty of Stomatology
linic for Maxillofacial Surgery Faculty of
y Belgrade,Serbia and Montenegro.

n: Haemangiopericytoma (HPC) a rare neoplasm in somatic soft tissue, or in a central nervous C of central nervous sustem is highly cellular and larised tumour almost always attached to the dura. ty of meningeal haemangiopericytomas can be ut local reccurences are almost inevitable in the while postoperative irradiation appears to delay .
fication 1979 still contained " haemangiopericytic of meningioma, however this concept has now olete.
scull, HPC occurs more often in occipital region, confluens sinuum.
: 69 years old female patient reffers to the Clinic facial Surgery, Faculty of Stomatology Belgrade, f swelling in occipital region. From personal t could be concluded that pathological formation m duration (" since childhood").
c feature tumor was slightly lobulated, firm, cut fleshy and yellow white to red brown, with zones rhage and necrosis.
ogy : Highly cellular lesions with numerous anels (" stag-horn type") surrounded by and thin nests of spindle-shaped cells. The nuclei was imes elongated with moderate chromatin density. r atypia was found as well as prominent mitotic nse reticulin network surrounded individual tumor

efinitive diagnosis was made : pericytoma WHO grade II.

USCULAR MYXOMA OF THE TEMPORAL CASE REPORT

nko, BODLOVIC Ksenija, JEZDIC Zoran,
rko
t of Oral pathology Faculty of Stomatology
Clinic for Maxillofacial Surgery Faculty of
y Belgrade,Institute of Oncology et Radiology
erbia and Montenegro

n : Myxomas are commonly found in the heart, jaw oft tissues of the body; however these lesions are unusual in the soft tissue of the head and neck. The lesion is composed of undifferentiated stellate cells set in a myxoid stroma.
Case report : In june 2000, a 63-year-old male was evaluated for a slowly growing, asymptomatic mass in his left temple region, which had been present for more than 4 years.
Clinical examination showed a ,5x4x2 cm,firm ,smooth,painless,oval mass in the left temporal region.The cup surfaces was yellowich and gelatinos.
Microscopic examination showed a rellativelly well circumscribed lesion. The spindle and stellate cells embedded in an abundant myxoid stroma with a reticulin fiber network. No cellular pleomorphism or mitotic activity was evident. A diagnosis of intramuscular myxoma was made. 3 years after surgery, there was no evidence of reccurence.
Discussion: In the head and neck, intramuscular myxoma is extremely rare, because it commonly arises from large sceletal muscles.
It is difficult to diagnose this lesion before biopsy, because of the lack of typical clinical manifestations or features in radiographic studies. It usually appears as a painless and slow-growing mass.
The basic histology of intramuscular myxoma is indistinguishable from myxoma that occurs elsewhere in the body; however, on close inspection, the delicate fibrous capsule is incomplete, and most of all lesions infiltrate adjacent muscle.
Differential diagnosis of intramuscular myxoma must include malignant tumors such as myxoid liposarcoma, malignant hystiocytoma and myxoid chondrosarcoma.
Treatment for intramuscular myxoma is surgical excision. There is no report of metastasis or malignant changes, but occasionally recurrences resulting from incomplete exccision.

** Service de médecine interne – hôpital la Rabta– Bab saadoun 1007 – Tunis – Tunisie

It has been suggested that defects in the modulation of programmed cell death (apoptose) might lead to autoimmune disease, such as sjögren's syndrome (SS).
OBJECTIVES: The aim of our study is to determine the role of apoptosis in Sjögren'syndrome. MATERIAL AND METHOD: Salivary glands biopsies from 21 patients suffering of primary and secondary SS (Chisholm 3 and 4) were analysed by apoptosis regulators: Bcl-2, Bax, P53 and Fas (CD95) using immunohistochemisty method. Control group had 15 normal subjects. RESULTS: Bcl-2 was strongly expressed in lymphocytic lesions of all cases. Its associated with a bax and a p53 reactivity respectively in 76% (16/21 cases) and 85% (18 cases/21)of acinar and ductal epithelial structures. A fas antibody was detected in 5 cases only in epithelial component and none in lymphocytic area.
CONCLUSION: Present data suggest a lymphoid defective apoptosis, by Bcl2 activation, inducing lymphoid infiltrate. SS salivary epithelial cell death requires the cooperation of both Fas and Bax. However, P53 duct expression may be a defensive mechanism that provides ductal cells with time to repair DNA damage.

STUDY OF B-CELL MONOCLONALITY, HELICOBACTER PYLORI AND BCL-10 EXPRESSION IN SJOGREN'S SYNDROME.

Kouvidou Ch.(1), Piperi E.(2), Chrysomali E.(2), Tsakistou G.(1), Anagnostakis D.(1) and Vrettou-Aravani V(1).

(1) Department of Pathology, "ELPIS" hospital, Athens, Greece
(2) Department of Oral Pathology and Medicine, Dental School, National and Kapodistrian University of Athens, Greece

INTRODUCTION: Sj'gren's Syndrome (SS) is an autoimmune disorder characterized by lymphocytic infiltration and MALT acquisition at the exocrine glands, as well as an increased risk of developing malignant lymphoma, especially extranodal marginal zone lymphoma of MALT type.
Helicobacter pylori (Hp)-gastritis predisposes to the development of acquired MALT and eventually MALT lymphoma, associated in 5% of cases with the mutant form of Bcl-10, while the bacterium is a common habitant of oral microbial plaque and saliva, only rarely investigated in salivary lymphoid tissues in SS.
PURPOSE: To evaluate the presence of acquired MALT and B-cell monoclonality at the labial salivary glands of patients with SS and their possible association with Helicobacter pylori and Bcl-10 expression.
MATERIALS AND METHODS: Formalin-fixed paraffin embedded tissue from 40 cases with SS and 20 control cases with non-specific sialadenitis was stained by immunohistochemistry for CD3, CD20, kappa, lambda, Helicobacter pylori and Bcl-10 protein.
RESULTS: Acquired MALT was observed in 26/40 (65%) cases with SS, while 9/26 (34,6%) showed areas of light chain restriction. 7/26 cases (27%) were positive for Hp, 3 of which were also monoclonal (43%). Cytoplasmic expression of Bcl-10 was observed in lymphoid follicles in all 26 cases, while no nuclear expression was detected. None of the controls showed either MALT and B-cell monoclonality or Hp. and Bcl-10 expression. Acquired MALT, Helicobacter pylori, and Bcl-10 expression statistically significant correlated with the emergence of B-cell monoclonality (p value < 0,05).
CONCLUSIONS: Helicobacter pylori may be linked to MALT acquisition and B-cell clonality in SS, at least in some cases. Adherence to saliva may facilitate lipopolysaccharide (LPS) activation of Toll-like receptors on ductal cells and Bcl-10-mediated NFêÂ antigenic signalling of B-cell receptor (BCR) may result in persistent B-cell proliferation in genetically susceptible individuals, thus predisposing to the emergence of pathologic clones. Alternatively, Hp. presence in the salivary glands may induce MALT accumulation as a result of acquired gastric MALT dissemination, as observed in MALT lymphomas, through á4â7-associated recruitment of gastric memory B-cells. Bcl-10 may be of importance in the interruption of the neoplastic cascade, while further studies are needed to clarify Hp's precise role in SS's pathobiology.

P 342

ROLE OF EPSTEIN BARR VIRUS IN PATHOGENESIS OF SJOGREN'S SYNDROME

K. BELLIL*, I. BEN GHORBAL**, A. MEKNI*, S. BELLIL*, N. KCHIR*, MH. HOUMAN**, MM. ZITOUNA*, S. HAOUET*
* Service d'anatomie pathologique – hôpital la Rabta– Bab saadoun 1007 – tunis – tunisie
** Service de médecine interne – hôpital la Rabta– Bab saadoun 1007 – Tunis – Tunisie

Sjogren's syndrome (SS) is a chronic autoimmune disease characterized by lymphocytic infiltration of salivary and lachrymal glands which results in xerostomia and keratoconjonctivitis sicca. The pathogenesis of this syndrome remains unclear but viral infections have been suggested as a possible aetiologic factor.
OBJECTIVES: The aim of our study is to determine the potential role of Epstein Barr Virus (EBV) in pathogenesis of SS. MATERIAL AND METHOD: Salivary glands biopsies from 35 patients suffering of primary and secondary SS were analyzed to determine the presence of EBV by immunohistochemistry method (LMP, ZEBRA, EBNA-2) and in situ hybridization study with EBV-encoded small RNAs termed EBER1 and early lytic PNA probe. Control group had 15 normal subjects. RESULT: 14 cases were positive for ZEBRA, 17 were positive for LMP and EBNA-2. All cases were EBV positif after in situ hybridization. None case of control group was EBV (+). CONCLUSION: EBV has a strong salivary tropism. Our results suggest that EBV could be implicated in the pathogenesis of SS. Its T-cell responses might contribute to labial salivary gland destruction and could have a role in lymphoid proliferation.

P 343

INVASIVE SPHENOID ASPERGILLOSIS: A CASE REPORT WITH AN UNUSUAL PRESENTATION

Mneimneh W, Cazals-Hatem D, Mosnier I, Bellier C, Sterkers O, Bedossa P
Departments of Pathology, ENT and Internal Medicine, Hôpital Beaujon, 92118 Clichy, France

Backgrounds: Fungal sphenoid sinusitis is rare, and aspergillus fumigatus is the most common pathogen. The invasive form of the disease is usually encountered in immunocompromised hosts with a potentially unfavorable outcome. We report a case of invasive sphenoid aspergillosis with pseudo-tumoral features on imaging, developed in an immunocompetent patient.
Observation: A 51-year-old male patient presented in January 2005 with a right otorrhea. He underwent in November 2004 a total thyroidectomy which revealed a multifocal papillary micro-carcinoma of the thyroid. He presented with an eight-year history of a chronic intermittent headache with a negative complete work up. Physical examination was unremarkable except for a right tympanic perforation, and no neurological defect was noted. A computed tomography revealed a 4x2.7cm mass of the left sphenoid sinus associated with bone erosion and suspicious for metastasis. Biopsies of the mass were performed. Histologic examination showed an extensive granulomatous inflammatory process invading the mucosa and bone, with fungal hyphae, identified as Aspergillus flavus by culture. Serologies for soluble aspergillus antigen and HIV were negative. The diagnosis of chronic invasive aspergillosis of the sphenoid sinus was established, and one-year of voriconazole treatment was started.
Discussion: In addition to immunosuppression states, predisposing factors for sinus invasive mycosis include maxillofacial trauma, drug sniffing and radiotherapy, none of which was present in our patient. The disease is usually symptomatic, most frequently with headache, followed by visual changes, cranial nerve palsies, seizures and pain in the trigeminal distribution. Diagnosis relies on endoscopy, imaging and biopsy for histologic examination and culture.
Conclusion: Sinus invasive aspergillosis is a rare condition, encountered most frequently in immunodeficient patients. We present an unusual case of a pauci-symptomatic sphenoid invasive aspergillosis in an immunocompetent patient with a pseudotumoral aspect. This entity should be kept in mind in the differential diagnosis of pseudo-tumoral lesions of this area.

P 344

THE SIGNIFICANCE OF HISTOLOGICAL ESTIMATION IN FUNGAL INFECTIONS OF THE ORAL AND MAXILLOFACIAL REGION

MAKOS Christos1, NIKOLAIDOU Anastasia2, DIMITRAKOPOULOS John3
1 Registrar, Oral and Maxillofacial Department, General Hospital of Kilkis, Kilkis, 61100 Greece

2 Registrar, Pathology Department, General Hospital of Kilkis, Kilkis, 61100 Greece
3 Associate Professor, Aristotelian University of Thessaloniki, Oral and Maxillofacial Clinic, "G. Papanikolaou" General Hospital, Exohi, Thessaloniki, Greece

Introduction: Mucormycosis (zygomycosis, phycomycosis) is an opportunistic and often fatal fungal infection caused by aerobic saprophytic fungi of the class Zygomyces (Phycomycetes), order Mucorales, family Mucoraceae and most common genera Absidia, Mucor, Rhizopus and Rhizomucor. Different clinical forms are described and most common the rhinocerebral form. Aspergillosis of the maxillary and paranasal sinuses is an endemic disease in countries with hot and dry climate. The causative factor is Aspergillus fungus of Actinomyces race. Recent studies have shown an increasing incidence of the disease in mild and cool climates. The non invasive (localised and allergic) and invasive (benign and fulminant) forms are accepted. Most cases of the non invasive form are prescribed in otherwise healthy individuals imitated an acute, chronic or allergic sinusitis with a remarkable resistance in a classical therapy of sinusitis.

The purpose of this work is to discuss about the significance of histological estimation in relation to diagnosis, treatment and prognosis in cases with these fungal infections.

Methods: The clinical, radiographical and histological pictures in cases with mucormycosis and aspergillosis in oral and maxillofacial area are presented and the particularities in histological sections and stains are referred.

Conclusion: Definite diagnosis in the above mentioned fungal infections is emphasized by histological evidences. The systematic laboratory examination of the excretions, material and tissues of the affected oral and maxillofacial areas is the exclusive method for the earliest diagnosis and a successful treatment of the disease, even if negative clinical and radiographical evidences exist.

P 345

ROLE OF NERVE GROWTH FACTOR RECEPTOR IN ATROPHIC SALIVARY GLAND IN CASE OF SIALOLITHIASIS

Valerie Groma (1), Janis Dumpis (2), Girts Salms (3), Andrejs Skagers (3)

3 - Department of oral and maxillofacial surgery, Riga Stradins University, Riga, Latvia

Involvement of nerve growth factor cell surface receptor p75 (p75) has been shown to be essential in maintaining the integrity of the salivary glands. Furthermore, in human salivary glands no immunoreactivity for the p75 was observed in the serous or mucous acinar cells. This study was undertaken to analyze a possible role of p75 in human submandibular gland atrophy in case of sialolithiasis using immunohistochemistry.

The study was carried out on 14 human salivary glands obtained along sialadenectomy performed because of the presence of intraglandular sialoliths. The salivary glands were morphologically subdivided into two groups on the basis of the presence (9 cases) and absence (5 cases) of parenchymal atrophy. Formalin fixed, paraffin embedded tissue sections were processed for a traditional streptavidin-biotin-peroxidase technique.

p75 immunoreactivity was restricted to the ductal myoepithelial cells and nerve fibers supplying salivary glands. There was a co-localization of p75 and an alpha-smooth muscle actin reactivity within the myoepithelial cells. A ductal p75 expression was much more stronger displayed in cases with a prominent gland atrophy and severe fibrosis. This ductal p75 expression correlated with a degree of ductal wall cell proliferation assessed by routine morphological visualization and proliferating cell nuclear antigen immunohistochemistry.

The present study revealed a strong co-incidence between p75 expression and proliferation within a ductal wall in case of prominent salivary gland parenchymal atrophy. These findings suggest that p75 present on the surface of the myoepithelial cells may be intimately involved in the pathophysiology of salivary gland disturbances in case of sialolithiasis contributing to the interplay of multiple factors that balance homeostasis at the appropriate level.

P 346

P63 EXPRESSION IN SALIVARY GLAND TUMOURS: ROLE OF DELTANP73L IN NEOPLASTIC TRANSFORMATION.

FOSCHINI Maria P., GAIBA Alessia, COCCHI Roberto°, PENNESI Maria G.°, PESSION Annalisa.
Department of Oncological Sciences, Section of Anatomic Pathology , University of Bologna, at Bellaria Hospital, Bologna.
°Department of Maxillo-Facial Surgery, Bellaria Hospital, Bologna.

Introduction: p63 gene has two different functions: TAp63 favours cell differentiation, whereas DeltaN p63 favours cell proliferation. Two new isoforms have been described, Delta4TAp63 and DeltaNp73L, lacking exon 4. DeltaNp73L is present in squamous cell carcinoma, but absent in normal epithelium.

Purpose of the present study was to illustrate the role of p63 and its truncated variants in salivary gland tumours.

Materials and methods: Twenty three consecutive tumours and six normal salivary glands were studied immunohistochemically with anti-p63 monoclonal antibody (NeoMarkers, Freemont, USA, clone 4A4, diluted 1:200) and by RT and Nested PCR to detect p63 isoform expression.

Results: Normal salivary glands: p63 antibody stained basal and myoepithelial cells; by RT and nested PCR, the two main isoforms, TAp63 and DeltaNp63 were present, whereas DeltaNp73L was absent.

Tumours: p63 antibody was positive in 20 out of 23 cases, specifically in Warthin tumour (WT) (3/3), oncocytoma (OC) (1/1), pleomorphic adenoma (PA) (7/7), polymorphous-low-grade adenocarcinoma (PLGA) (3/3), adenoid-cystic carcinoma (ADCC)(3/4), epithelial-myoepithelial-cell carcinoma (EMC)(1/1), myoepithelial-cell carcinoma (MCC)(1/1). By RT and nested PCR all tumours expressed p63 irrespective of their morphological differentiation. Furthermore the DeltaNp73L isoforms were present in neoplastic tissue but absent in normal salivary gland.

In conclusion, p63 antibody stained basal and myoepithelial cells in normal and neoplastic salivary gland tissues. By RT and nested PCR all salivary gland tumours appeared to express at least one isoform of p63. The DeltaNp63 variant lacking exon 4, named DeltaNp73L, was present only in neoplastic lesions, whereas it was lacking in normal salivary gland tissue, a feature that indicates the crucial role of this molecule in neoplastic transformation.

P 347

A CASE OF MUCIN-RICH VARIANT OF SALIVARY DUCT CARCINOMA EX PLEOMORPHIC ADENOMA

Tohru Kaku, Tomoyuki Ohuchi, Masaaki Satoh, Tatsuru Ikeda, Hiroko Asanuma, Kyogo Azuma, Hideki Kobayashi
Department of Oral Pathology, School of Dentistry• @, Health Sciences University of Hokkaido
Department of Clinical Pathology, Sapporo Medical University

Salivary duct carcinoma (SDC) is an established aggressive salivary gland neoplasm resembling intraductal and infiltrative ductal carcinoma of the breast. Diagnostic criteria and concept of SDC have been expanded along with subtype and new entity case reports such as sarcomatoid SDC, minor salivary gland origin SDC, invasive micropapillary SDC, and mucin-rich variant SDC. SDC often occurs as the malignant component of carcinoma ex pleomorphic adenoma.• @ Lewis et al. reported that SDC was many as the malignant component of carcinoma ex pleomorphic adenoma next to adenocarcinoma, not other specified from retrospective study (Hum Pathol 32: 594, 2001). Mucin-rich variant SDC was first reported by Simpson et al. (Am J Surg Pathol 27: 1070, 2003). They reported four mucin Ðrich variant SDC cases. However, there is no report of other mucin-rich variant SDC case after SimpsonÕs description. Here we report a case of mucin-rich variant of SDC ex pleomorphic adenoma arising from submandibular gland.

A 73-year-old Japanese male had noticed a painless swelling at the right submandibular area for about 35 years. This lesion had rapidly increased in size for a period of about 10 months. Macroscopically, the resected tumor was a solid mass with multiple mucinous cysts and necrotic areas in the submandibular gland. Microscopically, large areas of tumor nests infiltrated to normal salivary gland with aboundant fibrous and/or hyalininzing connective tissue. Malignant tumor has many forms, such as, arranged solid, ductal, cribriform, and mucinous (colloid) carcinoma-like patterns. Some nests exhibit Roman bridge-like appearance, central necrosis, and intraductal patterns. In the mucinous carcinoma-like area, irregularly shaped small nests with fibrous connective tissue floated in pools of mucin. In this tumor it was composed of large atypical round to polygonal eosinophilic cells with round shaped nuclei. Most of these tumor cells were positive for diastase-PAS and mucicarmine, and androgen receptor, gross cystic disease fluid protein-15 and Her2/neu, histochemical and immunohistochemical stainings respectively. Immunohistochemistry of this tumor was the same as general SDC. In a small part of tumor, we recognized small bilayered duct and mixed appearance-like regionm,such as resembling pleomorphic adenoma in strongly hyalinized stroma. Furthermore• @this case has a long term history. Finally,we diagnosed this tumor as a mucin-rich variant of of SDC ex pleomorphic adenoma.

LYMPHOEPITHELIAL CA OF PAROTID GLAND. REPORT OF TWO CASES

Tzaida O., Iakovidou J., Valavanis C., Simoulis A., Petridis N.,Arapantoni-Dadioti P.
Pathology Department , METAXA Cancer Hospital Piraeus , GREECE

Two cases of lymphoepithelial Ca, a rare salivary gland malignant epithelial neoplasm, are presented. This neoplasm is also referred to as “malignant lymphoepithelial lesion” and “undifferentiated Ca with lymphoid stroma”.
The patients were males 50 and 61 years old and presented a slowly growing, painless mass located at the left parotid gland, measuring 3 and 2.5 cm, respectively.
In the case of the elder patient a biopsy of a left cervical LN preceded the tumor’s surgical excision. The diagnosis on this material was a metastatic high-grade undifferentiated Ca resembling the nasopharyngeal lymphoepithelioma. A simultaneously performed nasopharynx biopsy was negative.
The microscopical examination of the two subtotal parotidectomies revealed malignant epithelial tumors. The neoplasms consisted of irregular shaped islands of large, anaplastic, eosinophilic, epitheliod cells within a mature type lymphocytic–rich stroma. Presence of epimyoepithelial islands, characteristic finding of benign lymphoepithelial lesion, was also evident. The immunohistochemical study confirmed the epithelial nature of the neoplasms and the concomittant benign lymphoepithelial lesion . EBV infection was revealed by a positive expression to LMP1 .
Particularities of this tumor, problems of differential diagnosis and terminology, are discussed.

EPSTEIN-BARR VIRUS AND WARTHIN TUMOR IN TUNISIA: MOLECULAR AND IMMUNOHISTOCHEMICAL STUDY

TRIMECHE Mounir, ZIADI Sonia, AMARA Khaled, HMISSA Sihem, MESTIRI Sarra, MOKNI Moncef, KORBI Sadok
Laboratoire d’Anatomie et de Cytologie Pathologiques, CHU Farhat Hached de Sousse, Tunisia

Purpose: Tunisia belongs to a zone at high risk for several neoplasms associated to Epstein-Barr virus (EBV), particularly for the nasopharyngeal carcinoma. The salivary glands are considered as one of the major reservoirs of replication and latency of this virus. Warthin tumor of the salivary gland is composed of oncocytic epithelium with a prominent follicular lymphoïd infiltrate. The histogenesis of this tumor is still debated and its association with EBV is controversial. The purpose of this study was to determine the prevalence of EBV in Warthin tumor in Tunisia.
Methods: Nineteen formalin-fixed, paraffin-embedded blocks of Warthin tumors from the parotid gland were examined for the presence of EBV, using polymerase chain reaction (PCR), EBERs in situ hybridization and immunohistochemistry for the detection of LMP1, EBNA2 and ZEBRA.
Results: Thirteen cases were PCR b-globin positive. The EBV was detected by PCR in 2 of 13 cases (15,4%). In the two EBV positive cases, EBERs in situ hybridization showed a positivity in few lymphocytes; these cells does not express LMP1, EBNA2 or ZEBRA.
Conclusions: The low frequency of EBV in Warthin tumor indicate that the virus is not the cause of this tumor, however the possibility that the virus acts as a cofacteur cannot be ruled out.

Mucinous adenocarcinoma is a rare malignant neoplasm characterized by large amounts of extracellular epithelial mucin that contains cords, nests and solitary epithelial cells. It is a tumor analogous to mucinous eccrine carcinoma and mucinous carcinoma of the breast and colon. Few cases of primary salivary gland mucinous adenocarcinoma have been reported and all these cases arose in the major salivary gland.
We report a new case in 41-year-old man presented with an enlarging, painless left submandibular mass. On physical examination, a 6-cm firm mass was noted and no adenopathy was detected. Ultrasonography revealed a 4-cm heterogeneous mass. The patient underwent excision of the submandibular gland and lymph node dissection. Histological study concluded at mucinous adenocarcinoma without lymph node metastasis. After two years, the follow-up has been good.
The aim of this study is to review diagnosis difficulty of this rare entity and differential diagnosis.
