A large nodular growth of atypical melanocytes can arise in the core of a congenital nevus. This usually occurs at birth but may also happen later in childhood. Nodules excised in adulthood are rarer but still possible. In children, such nodules are polypoid and can be ulcerated or bleeding. The clinical diagnosis is often that of a melanoma, but over time, most of these stiff and large nodules evolve in soft and smaller lesions and can also completely disappear. These nodular lesions in the midst of a congenital nevus are called proliferative nodules and are considered benign and must be distinguished from true nodular melanoma developed in the core of the intra-dermal portion of a congenital nevus [126]. Such benign proliferative nodules can have disparate histological features reminding one of any possible nevus variants. Consequently, they can have features of blue nevus [119], Spitz nevus [35, 155], Deep Penetrating nevus and so on [103]. Occasionally, nodules have cytological or architectural aspects that do not fit with any form of nevus and are composed of immature round melanocytes with scant cytoplasm. The latter are called melanoblasts. On rare occasion, nodules have no melanocytic features at all but show, instead, aspects or neural, adipocytic or myoblastic differentiation [49, 82].

As a rule, the nevus hosting these nodules is a large congenital nevus, but occasionally, small proliferative nodular or plaque-like foci are present in medium or even small nevi, which can be not only congenital but also acquired.

In a few cases, especially in very young patients, an atypical melanocytic proliferation can also be present in the epidermis with important pagetoid spread of melanocytes above the junction. Such proliferation is unrelated to the nodule itself, but these aspects can contribute to mislead the diagnosis towards a melanomatous nature of the entire lesion.

Because of their worrying aspects, these nodules can be misdiagnosed as melanoma. Those with Spitz nevus features are the most frequently confused because of the striking cytological details of the nodule. In the differential diagnosis between these Spitz nevus-like nodules and nodular melanoma developed in the dermal portion of a congenital nevus, the following aspects must be taken into account:

- The age of the patient can be crucial. Melanoma in the intra-dermal portion of a congenital nevus usually develops between 2 years of age and puberty. Before this age range, the lesion is most likely benign. In neonates, although the histological features can be highly atypical, the prognosis can still remain good. Congenital melanomas and melanomas in the first 2 years of life are, in fact, exceedingly rare. In adulthood, melanomas on congenital nevi usually develop at the junction and not in the intra-dermal core of the lesion. In an adult, a melanoma on the dermal component of an acquired or congenital nevus is very rare.
- Large benign proliferative nodules arising in the midst of a large congenital nevus are much more frequent than a melanoma in the same site. Therefore, based on pure statistical considerations, a nodule in the core of a congenital nevus is most likely benign, in both children and in adults. This is even truer in very young patients (1 or 2 years old) where benign nodules can have remarkable cytological atypia and a very high mitotic rate. In this group of very young patients, pathologists should always be reluctant in giving a straightforward diagnosis of malignancy despite the striking cellular features.
- Benign proliferative nodules in patients older than 1 or 2 years usually have low mitotic activity, whereas melanomas developed in the dermal portion of the nevus show evident mitotic activity. Finally, in melanomas, mitoses are often atypical, a finding not to be seen in benign nodules.
- In nodules with features of Spitz nevus, cytological details are monomorphous. Cells have atypical characteristics but are uniform in size, shape and cytological features. Per se, the nodules closely resemble a Spitz

nevus. On the contrary, in melanomas developed in the dermal component of a congenital nevus, cells are heterogeneous in size, shape and cytological details. In melanomatous masses, atypia is striking with large-sized nuclei and huge amphopilic macronucleoli and nuclear pseudo-inclusions. In melanomas, the cytoplasm is variable, ranging from cells with abundant cytoplasm to cells with only a rim of pale cytoplasm or 'naked nuclei' [104]. Inside the benign nodules, collagen fibres may be present on the contrary melanoma growths as solid masses of compactly packed cells without interposed collagen. Pathologists should be cautious in judging cytological details when only part of the lesion is available. Frequently, the uppermost portion of the nodule is the most atypical, whereas at the bottom cells mature and blend into the surrounding benign nevus cells.

- At scanning magnification, benign proliferative nodules have a quite clear-cut border; however, at higher magnification, a gradual maturation is seen between the large Spitzian cells of the nodule and the small benign-looking melanocytes of the rest of the nevus [156]. In melanoma, there is a more abrupt border between the atypical proliferation and the rest of the bland nevus tissue without a progressive blending of one cell type in the other. Infiltrative or blurred margins of the nodule are also more consonant with a melanoma arisen in a congenital nevus.
- As regards to the proliferation of melanocytes in the epidermis, which is frequently seen in the area above the benign proliferative nodule (but is unrelated to the nodule itself), the pattern is similar to the pseudo-melanomatous intra-epidermal proliferation seen in congenital and acquired nevi in young subjects. Cells are gathered in irregular confluent nests at the junction and scattered throughout the epidermis but are typical, and they mature (become smaller) when they descend into the papillary dermis.
- Immunohistochemical studies are contraddictory. Herron et al. [60] found that proliferative nodules and the surrounding nevus cells have similar expression for Ki67, p16, p27, bcl-2 and CD95. The cells in the nodules overexpress P53 and c-Kit. The most cytologically atypical nodules overexpress Ki67 and bcl-2.
- Comparative genomic hybridization performed by Bastian et al. [16] showed chromosomal aberration in most of the nodules. The type of these alterations was different from those found on melanoma. In nodules, there were numerical aberrations (i.e. gain and loss of entire chomosomes) without structural aberration (i.e. one or several gains or losses of fragment of chromososme). Structural aberrations were typical of melanoma. Chomosome 7 is more involved in nodules, whereas 9 and 10 are the mutant chromosomes in melanoma. However, the chromosome pattern of melanoma was found also in a lesion that had a benign outcome.

A tightly packed population of small sized, nevus-like melanocytes composes the second most frequent type of benign proliferative nodules that, in our own experience, are likely to be confused with a melanoma in young patients [5]. These lesions are diagnosed as melanoma because of the impressive cellular density; cells have only scant cytoplasm and show occasional mitoses. The nature of these cases is more difficult to be assessed. Judging from the literature, the most objective clues indicating malignancy are the high mitotic rate, the presence of atypical mitoses and the age of the patient [38]. In short, a nodule of these melanoblasts, as such cells are called, is probably benign if it is small, monomorphous, mitotically quiescent and developed in a congenital nevus in a very young patient [21]. Criteria indicating a melanoma are mostly pleomorphism and high mitotic rate with atypical mitoses. Other criteria are the presence of a spindle cell component, a palisading nuclear pattern or other forms of neural differentiation with the presence of hyperchromatic cells. Necrosis is also an ominous sign. Moreover, in melanomas, a few foci of large epithelioid, plainly malignant cells can appear among the uniform population of small melanocytes. Finally, the size of the nodule should be considered: Large and deeply sited nodules are most probably melanoma, whereas, on the contrary, a small, circumscribed and superficial collection of melanoblasts is most likely benign.

As said above, many other histological types of nodules can develop in a congenital nevus. These nodules usually have the features of blue nevi (both common and cellular), deep penetrating nevi or other forms of not easily classifiable nevi. These nodules, having a plain benign-looking architectural or cytological characteristic, are usually easily diagnosed.

The distinction between a nodule with neuromesenchymal differentiation and a melanoma with similar features is more complicated. These cases are very rare and not clearly described in the literature. The presence of neurosarcomatous-like features with atypia and mitoses seems to be the best indication of a malignant neoplasm. Benign nodules with similar differentiation are usually cytologically typical and mitotically quiescent.

Epithelioid blue nevus vs animal-type melanoma

In a few rare cases, melanocytic neoplasms are overwhelmingly hyper-pigmented (Fig. 10). Cells are mostly epithelioid and similar to melanophages, but spindle or dendritic elements are present as well [62, 79, 113, 161]. In these

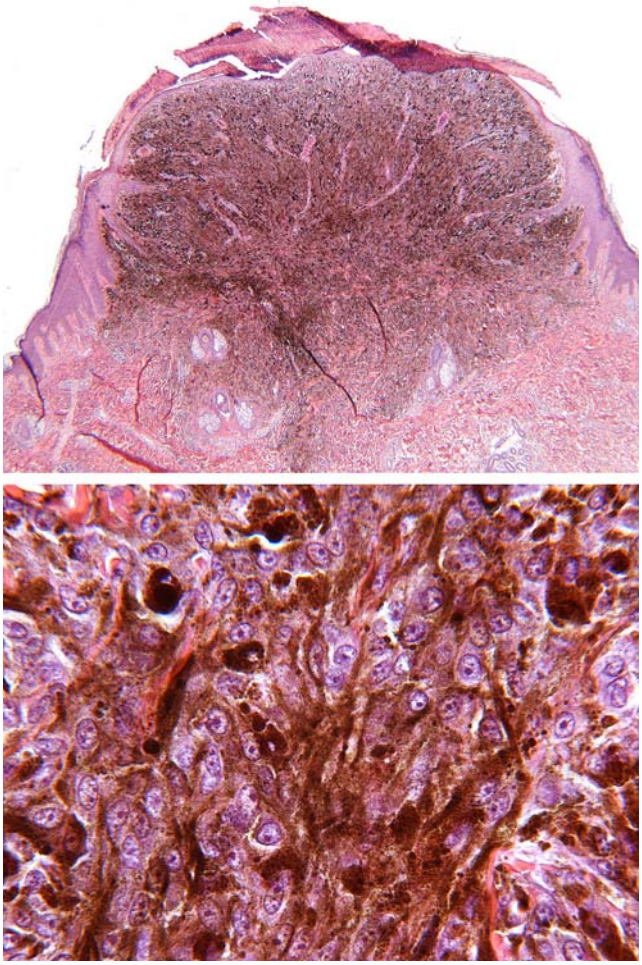

Fig. 10 A diagnosis of pigmented epithelioid melanocytoma is usually provided for this type of neoplasm. Often, the sentinel lymph node contains a small nest of pigmented dentritic melanocytes similar to those illustrated here. Whether this finding represents a true metastasis or a nodal nevus is yet to be established

cases, the differential diagnosis is between heavily pigmented compound (or intra-dermal) nevi and similarly heavily pigmented melanoma. The former has been reported under disparate denominations as epithelioid blue nevus, pigmented epithelioid Spitz nevus, combined nevus with features of blue and Spitz nevus and pigmented benign melanocytoma [6, 151]. Heavily pigmented melanoma is frequently reported as animal-type melanoma or pigment-synthesizing melanoma (probably also melanoma with features of blue nevus have been included in this group) [66, 86, 115, 128]. This group of heterogeneous entities is complex and have in common similar histological features, for these reasons, Mihm proposed to lump them all together under the uncommitted term of pigmented epithelioid melanocytoma, without further indication of the benign or the malignant nature of the neoplasm [161]. I find that pigmented epithelioid (Spitz) nevus, epithelioid blue nevus, and animal-type melanoma deserve to be considered as separate entities that can be distinguished by silhouette and cytology.

Certainly, our knowledge on the matter is incomplete, and studies on large groups of patients with prolonged follow-up is mandatory; however, we can say that in a heavily pigmented epithelioid and dendritic melanocytic neoplasm, a melanoma is very doubtful when the following aspects are present:

- The lesion is small and histologically well circumscribed or wedge shaped.
- Collagen fibres are present among the cells.
- There is a regular epidermal hyperplasia on the lesional epidermis.
- The distribution of the pigment is symmetrical.
- Cells are uniform, and nuclei are vesicular with inconspicuous nucleolus.
- No significant mitotic activity is found.
- Details of a congenital nevus or common blue nevus are present.
- There is an association with Carney syndrome.

In the malignant counterpart (animal-type melanoma or other forms of heavily pigmented melanoma), the cytological features can be deceptively bland, and mitoses are often undetectable, but in the cases reported as metastatic, the following aspects were present:

- The lesion is large: as a rule, more than 1 cm and occasionally of several centimetres in its lateral diameter (although animal-type melanomas inevitably start as small lesions and may be excised at that time [130]).
- The lesion is also many millimetres deep, occupying the entire dermis reaching the sub-cutis.
- The growth is solid with large sheets or nodules of cells without collagen interposed.
- Foci of necrosis are present.

Presence of brisk mitotic activity, nuclear atypia and strong P53 positivity all indicate melanoma, but these findings can be absent.

In this group of lesions, a sentinel node procedure for diagnostic purposes would be advisable. However, one should remember that the presence of melanocytes in the node is not tantamount to metastatic melanoma: Melanocytes gathered in small nests inside the capsule or the septa of the node could be an intra-nodal nevus (with the same features as the cutaneous lesion) and not a metastatic melanoma.

Regressed nevus vs regressed melanoma

Both nevi and melanomas can undergo partial or total regression. Regression implies a dense inflammatory infiltrate causing melanocytic necrosis followed by a

fibrous granulation tissue. The latter partially or completely replaces the regressed melanocytic neoplasm.

In its first phase of dense inflammatory infiltrate, a regressing nevus can be very similar to a regressing melanoma [48, 98, 108], especially when the involved nevus is congenital with large nests. The architecture of the nevus is altered by the inflammatory infiltrate, which gives the lesion an asymmetrical aspect. The presence of large cells with a hyperchromatic nucleus among the melanocytes is most worrisome. Such cells can be easily confused with melanomatous elements. Few mitotic figures are frequent in this setting (although they may belong to the lymphocytes), and few melanocytes are epithelioid. Regressing nevi might have architectural alterations as well: Large confluent nests are present at the junction, and irregularly shaped unusually large and pigmented nests occupy the dermis. However, the differential diagnosis with melanomas [20, 36] is possible considering that:

- In its usual presentation, a regressing nevus has its own clinical setting. It appears in youngsters, usually teenagers, and it is frequently multiple and can be clinically surrounded by a clear halo. A melanoma with extensive regression is a lesion of the elderly, is irregular from a clinical point of view and no clear-cut perilesional whitish halo is evident. A large regressing melanoma is, as a rule, an isolated lesion [91].
- A regressing nevus is a small lesion, while regressing melanoma is large, at least when regression is significant.
- Atypical melanocytes present in a regressing nevus are scattered among typical ones, whereas in melanoma, irregular nodules or masses are composed only of atypical elements. In these masses or nodules, cells have a high nucleus/cytoplasmatic ratio and nuclei are hyperchromatic.
- Mitoses are usually easily found in melanomas but are sparse in nevi. Presence of mitoses in the nodules of atypical cells at the bottom of the lesion is an indication of melanoma (mitoses on the core of inflammatory infiltrate can belong to non–melanocytic cells).
- In a nevus, the inflammatory infiltrate is quite homogeneous throughout the lesion and is sharply circumscribed, with a flat bottom in the deep dermis; on the contrary, a much more disordered infiltrate is present in melanoma, where the peripheral border of the infiltrate is blurred. In a regressing melanoma, plasma cells are more abundant than in nevus.
- A clearer aspect of the lesion usually appears with serial sections, especially in cases of melanomas. In fact, in melanoma, nodules or masses of atypical cells not altered by the inflammatory infiltrate are possible. A pagetoid spread of cells above the junction is indicative of a melanoma.
- The presence of tumoural (nodular) melanosis, i.e. of intra-dermal nodular aggregates of melanophages, is always an indication of melanoma [54].

When the inflammatory process has burnt out and granulation and fibrous tissues supervene, the regressed nevus can be misinterpreted as a regressed melanoma. The nevus in this case shows an area of fibrillary collagen, which occupies the superficial dermis along a line of melanophages. Only residual melanocytes are present. In cases with sub-total or total regression and cicatricial substitution, an ‘absent’ nevus can be reasonably misinterpreted as an ‘absent’ melanoma [61, 91, 99]. In such cases, it is possible to pursue the following diagnostic pathway:

- First of all, ruling out other non-melanocytic-pigmented neoplasms that are also likely to regress or to cause a scarring process rich of melanophages is necessary: Basal cell carcinoma, seborrheic keratosis, lichenoid keratosis, postinflammatory pigmentary alteration from lichen planus in dark-skinned people and mycosis fungoides are all lesions that can leave a fibrillary scar scattered with melanophages [81]. Serial sections and clinical correlation will resolve at least a few of these cases. However, one should never forget that in extreme cases, a definitive distinction from a completely regressed melanoma, a regressed nevus and a regressed lichenoid keratosis is utterly impossible.
- The size of the lesion is crucial: A regressed nevus is usually a small lesion, while a regressed melanoma is a large one (usually larger than 1, 5 cm). Furthermore, the age of the patient is important: An entirely regressed melanoma is exceedingly rare in youngsters.
- Nevus retains, at least for a while, a gently papillated silhouette, whereas melanoma is mostly flat or dome shaped.
- In the case of a regressed nevus, rete ridges are still present or even hyperplasic. In melanoma, the rete ridges are entirely erased.
- The presence of tumoural (nodular) melanosis is indicative of melanoma.
- Small residual melanocytes at the junction or in the dermis are possible in both conditions, while atypical melanocytes indicate a melanoma.
- Severe solar elastosis is an indirect, although precious, hint of melanoma.
- Unlike nevi, where collagen is more delicate and fibrillary with sparse mucin deposits, an entirely regressed melanoma occasionally has a fibrotic dermis.
- Residual plasma cells indicate a melanoma.

There is a very peculiar condition, which, on occasion, can be seen in both nevi and melanomas: the recurrence of the neoplasm on the scar [1]. In melanoma, this phenom-

enon is well known and has been described by McGovern et al. [88] many years ago. Malignant cells surviving the regression reoccupy the epidermis and the dermis. In the epidermis, a lentiginous array of atypical melanocytes substitutes the junction, and atypical melanocytes are scattered in the spinous layer, while in the dermis, large expansive nodules of atypical melanocytes appear. This sort of recurrent melanoma developed on the site of a previously regressed melanoma can be very similar to a regressed nevus in which junctional and dermal proliferation re-appear after regression. In fact, in such nevi, the junctional proliferation has a striking architectural feature with large confluent nests, pagetoid spread and irregular architecture of the dermal component. This sort of regressed nevus with re-grown atypical proliferation is similar to the so-called recurrent nevus with pseudomelanomatous features described by Ackerman and Kornberg years ago [72].

The distinction between this regressed nevus with atypical proliferation from its melanomatous counterpart is mostly based on the size of the lesion and on the cytological details. Nevus is small and cytologically inconspicuous, whereas regressed melanoma with new proliferations is rich with large nodules of atypical cells, which are often in mitosis. Immunohistochemistry can be effective in this quandary: In the nevus, a strong HMB45 positivity is indeed present, but it is restricted to the uppermost portion of the lesion; in melanoma, HMB45-positive cells are scattered all over the area, even in the deepest portion of the lesion.

A careful survey is required in distinguishing between regressing Spitz nevus and regressing melanoma [4, 57, 157]. In these cases of regressing Spitz nevus, the cytological features could be impressive: Cells are large, epithelioid and contain hyperchromatic nuclei. The distinction from melanoma is trusted on the absence of large expansile nodules, the lack of mitotic figures and peculiarly symmetrical distribution of lymphocytes in the lesion. In regressing Spitz nevus, the lymphocytes seem evenly scattered among the Spitzian cells.

Other forms of nevi simulant melanoma

Nevus on special sites

It is now very well known that nevi developed on special sites can have important architectural alterations evoking a form of melanoma [43, 118]. The ‘special sites’ are mostly along the mammary line (axilla, breast, genital area). Other sites are the umbilicus, the ear canal, the knee and the elbow. Recently, this type of nevus has been also seen by us and by other scholars on the scalp of adolescents.

The knowledge of such lesions is today widespread, and they are rarely diagnosed as a melanoma; in fact, the only criterion for the diagnosis of melanoma is peculiar architecture: irregular, large nests haphazardly scattered in the epidermis and in the dermis. Cells, both in the epithelium and in the dermis, show only moderate atypia. These aspects of cytological and architectural atypia reach the climax in the genital skin of young women [32]: Nests are large, confluent and elongated vertically and are scattered in a disordered pattern at the junction and in the corium (Fig. 11). A few nests are also confluent or oriented parallel to the epidermal surface, forming a sort of elongated festoon that can substitute the lowermost portion

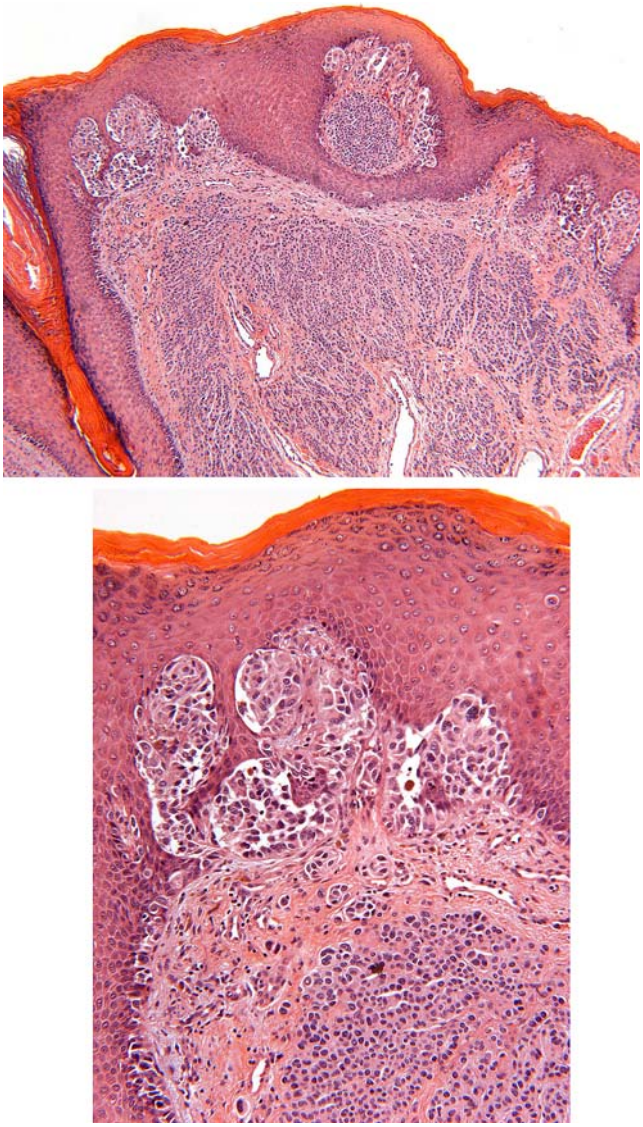

Fig. 11 In genital nevi, a striking cytological and architectural dysplasia is possible, as in this case. Note that the melanoma-like alterations are restricted to the junction, and the intradermal component has obvious benign looking features

of the epidermis. Cells can be large and have hyperchromatic nuclei, but they are monomorphous. In the past, these entirely benign lesions have been diagnosed as melanomas with subsequent vulvectomy and extensive lymph-node dissection. Fortunately, today, pathologists are well aware of these peculiar entities, and catastrophic errors of this kind are no more a part of our profession's medicolegal record.

The main criterion for the differential diagnosis of a melanoma is the fact that melanomas on the genitalia are highly atypical lesions with numerous mitoses, plain nuclear pleomorphism and cellular necrosis.

With the exception of architectural anomalies and mild nuclear hyperchromasia, there are no further indications of the malignant nature of the lesion in atypical nevi of the genitalia (and of other special sites): Cells are, in fact, typical (although they can be hyperchromic) and monomorphous, pagetoid spread is limited in the central portion of the lesion (or altogether absent) and there is no significant mitotic activity.

Congenital nevi with unusual features

A few dramatic cases of congenital nevi or of nevi with histological features of congenital nevi (occasionally called 'tardy' congenital nevi) have been misdiagnosed as a melanoma. Indeed, when arising on special sites, in youngsters or in pregnant women, these nevi can be very atypical and can contain unusual, alarming features.

These lesions are usually taken as invasive melanoma for the following three aspects: pagetoid scattering of cells above the junction, presence of large and confluent nests in the dermis and at the junction and presence of pigment at the bottom of the lesion. The most worrisome aspect is certainly represented by the large intra-dermal nests, which are much larger than the junctional ones and mimic the tumorigenic vertical proliferation (the so-called vertical growth phase) of a melanoma. Moreover, these nodules are scattered asymmetrically in the neoplasm giving a quite inordinate appearance. In fact, these congenital nevi are considered unusual because of their silhouette and of the infiltration's depth, while other aspects are indicative of an entirely benign congenital lesion:

- These bizarre nevi frequently present nests inside the follicular structures or in the eccrine ducts. Cells are occasionally found in and around the vascular and nervous structures. A perivascular cuffing of melanocytes is highly characteristic of these lesions.
- Cells are small and lymphocyte like, with barely detectable mitotic activity. Significant cellular atypia is absent.
- The large intra-dermal nodules, which are particularly worrisome, are roundish, symmetrical and homogeneous in cellular density. They neither compress nor destroy the surrounding nevus nor the dermal structures.
- Mitotic activity is virtually absent.

Deep penetrating nevus

Deep penetrating nevus [47, 117] is a form of melanocytic nevus with peculiar architecture and cytological features. Cells are gathered in nests and cords in a vaguely anastomotic, plexiform pattern, for this reason, Barnhill proposed the term plexiform spindle cell nevus. The entire dermis may be occupied by the nevus, and frequently, the sub-cutis is involved. Although usually wedge shaped and symmetrical, many cases of deep penetrating nevus have architectural asymmetry. Cells are plump, oval or dendritic. Among these cells, a few epithelioid elements are present as well. These large epithelioid cells have abundant clear cytoplasm and a large vesicular nucleus. In a few elements, nuclei can be hyperchromatic or with prominent nucleolus. Mitoses are possible even in the deep portion of the neoplasm. In the lesion, there is no maturation of the melanocytes as they go deeper in the dermis.

Deep penetrating nevus has some architectural similarities with forms of melanoma growing in a plexiform or nested pattern [136]. In this type of melanoma, cells aggregate in small nests scattered throughout the dermis; normal collagen fibres separate the nests. These nests are connected to each other forming a sort of plexiform structure. Despite the fact that the architecture of this form of melanoma is similar to that of deep penetrating nevus, the cytological aspects are completely different. In fact, melanoma cells show a uniform cellular atypia and nuclear pleomorphism; moreover, mitoses are easily found. In doubtful cases, one can consider that in melanoma, there is presence of atypical melanomatous proliferation at the junction, an aspect absent in deep penetrating nevus.

Ancient nevi

Pathologists, which are not familiar with a melanocytic neoplasm, may have some perplexity when facing compound or intra-dermal nevi containing some cells with large, hyperchromatic nuclei and blurred chromatin [67]. Occasionally, these cells are numerous or in clusters. The over diagnosis of these nevi as melanomas can be avoided considering that the atypical cells have indeed hyperchromatic, irregularly shaped nuclei, but no prominent nucleoli and no mitotic figures are seen. Cells are similar to those seen in ancient schwannomas (from the term ancient nevus). In fact, other degenerative or

senescent details are present, i.e. ectasic vessels, dermal sclerosis and fibrin deposits. Moreover, no expansile nodules are present, and the junctional melanocytic component is inconspicuous.

Nevi with occasional intra-dermal mitoses

It has been described decades ago that completely innocent lesions may have a few scattered mitotic figures in their midst [51]. The presence of a background of a common Miescher or Unna nevus easily rules out melanoma. Abundant collagen fibres and large portions of small nevus cells separate the cells in mitosis. Besides, melanoma developed in the core of the intra-dermal portion of a nevus is exceedingly rare in adults.

Polipoyd nevus of pregnancy

During pregnancy, a few alterations are occasionally seen in a compound nevi [41, 53, 84]. In a few cases, cells are large and epithelioid with pale cytoplasm and vesicular clear nuclei. Melanocytic nests become large and confluent. In other cases, nevi show a remarkable or irregularly distributed pigmentation. Sparse mitoses are possible. However, these nevi have no other indication of melanoma, no pagetoid spreading is seen and melanocytes, although large, are not atypical.

Prognostic factors for ampullary adenocarcinomas: tumor stage, tumor histology, tumor location, immunohistochemistry and microsatellite instability

Received: 20 March 2007 / Revised: 5 June 2007 / Accepted: 6 June 2007 / Published online: 26 July 2007

Abstract Prognostic factors for ampullary carcinomas (ACs) are poorly defined. Fifty three resected ACs were analyzed for CDX2, MUC1, MUC5AC, MUC6, MUC2, and for mismatch repair proteins (hMLH1, hMSH2, PMS2, hMSH6) using immunohistochemistry. Microsatellite instability (MSI) status was evaluated by fluorescently labeled PCR using an automated sequencer. Univariate and multivariate analysis was performed for clinicopathological, immunohistochemical and molecular parameters. CDX2 was found in 32 out of 53 (60%) ACs with a significantly higher frequency among intestinal ACs compared with biliopancreatic (BP) ACs. The MUC1, MUC5AC, MUC6, MUC2 apomucins were expressed in 75, 43, 39, and 28% of ACs, respectively, with a significantly higher coexpression of MUC1/MUC5AC in BP ACs. MSI and loss of expression of hMLH1/PMS2 or hMSH2/hMSH6 proteins were observed only in intestinal ACs. Factors significantly correlated with improved survival in the univariate analysis were: low stage, absence of lymph nodes metastases, negative surgical margins (*R*0 status), and presence of MSI. In the multivariate analysis, stage was the only independent prognostic factor of survival. We conclude that stage is the only independent prognostic factor of survival in the multivariate analysis, whereas histological criteria and the immunohistochemical expression of apomucins and CDX2 are helpful in the classification and understanding of the histogenesis of ACs.

Introduction

There are different histological classifications of ampullary carcinomas (ACs) which [2, 3, 20] makes comparison of clinical, therapeutic, and prognostic studies of these tumors difficult. So far, two major histological types of these tumors have been recognized: an intestinal type, arising from intestinal mucosa of the papilla, and a biliopancreatic (BP) type, deriving from the BP ductal epithelium. Nevertheless, conflicting data have been reported about the frequency of these two histological types due to the absence of reliable and consistent histomorphological criteria for differential diagnosis [2, 20, 31]. As patients with intestinal-type ampullary ACs have been reported to have a significantly better prognosis than patients with BP-type ACs [2, 20], the clear differentiation between the two tumor types would have clinical implications.

Although immunohistochemistry has had only limited value to date in unequivocally differentiating BP ACs from intestinal-type ACs, several authors have suggested that knowledge of CDX2 and apomucin expression may be

useful for this purpose and may have a prognostic value [10, 12, 16, 18, 21, 23, 26, 31]. In particular, adenocarcinomas of the ampulla of Vater show positive reactivity for MUC1, MUC2, MUC5AC, and MUC6 [16], and some authors suggested that the prognosis of AC is worse with stronger staining for MUC1 and weaker staining for MUC2 [21, 26].

Human CDX2 is a homeobox gene encoding for an intestine-specific transcription factor [7, 14]. The CDX2 protein regulates normal development and differentiation of the small and large intestine and is expressed in the nuclei of epithelial cells throughout the intestinal tract both in embryonic and in postnatal life. Some authors have suggested that the immunohistochemical analysis of CDX2 expression may be a useful marker for identifying intestinal-type carcinomas with a sensitivity and specificity higher than 90% [5, 30]. In particular, very recently, Hansel et al. [18] reported that CDX2 expression may identify intestinal-type ACs with a favourable prognostic outcome.

Finally, few studies assessed the role of DNA mismatch repair (MMR) in ACs, and discrepant data are available about the frequency of a widespread microsatellite instability (MSI) in these cancers [1, 25, 27]. To date, the largest series of ACs was investigated for MSI status by Scarpa et al. [27] demonstrating the occurrence of MSI in 15% of cases as well as a significant correlation between MSI and a better 5 year survival in these patients compared with the remaining cases.

The aim of this investigation was to evaluate in a large series of ampullary cancers the prognostic value of clinicopathological, immunohistochemical, and molecular parameters such as location, histology, and stage of tumors, MSI status as well as the immunohistochemical expression of the MUC1, MUC2, MUC5AC, MUC6 apomucins and CDX2 protein.

Materials and methods

Histological and immunohistochemical study

Fifty-three cases of surgically resected primary carcinomas of the ampulla of Vater (ACs) were retrieved from the surgical pathology files at the Department of Pathology (University of Insubria, Varese, Italy) and the Ospedale di Circolo (Busto Arsizio, Varese, Italy). The selection of the cases was based on the availability of sufficient tumor samples for histopathological, immunohistochemical, and molecular analysis. Moreover, only patients harboring sporadic tumors were eligible for the study (two cases of ampullary cancers were excluded because of their association with familial adenomatous polyposis and with hereditary nonpolyposis colorectal cancer syndrome, respectively). The ethical consent of each patient was collected according with the rules of the local ethical committee.

Formalin-fixed and paraffin-embedded tissue sections were stained with hematoxylin and eosin (H&E) and Alcian Blue periodic acid Schiff stain (AB-PAS). The slides were reviewed to confirm the diagnosis according to the WHO classification (2001) and to study the extension of the neoplastic disease [17]. In each tumor, we considered both the main histological pattern (intestinal or BP) and a second or a third pattern when present in more than 10% of neoplastic tissue according to the criteria reported by Albores-Saavedra et al. [2]. The macroscopic classification as described by Cubilla and Fitzgerald [11] was used to distinguish the tumors as periampullary (PA), intra-ampullary (IA), and mixed types (MT). Follow-up data were collected by contacting clinicians and/or by consulting the Tumor Registry of the Lombardy region (Italy).

Immunoperoxidase studies were performed on sections prepared from formalin-fixed and paraffin-embedded specimens that were dewaxed and rehydrated using Bio-clear (Bio-Optica, Milan, Italy) and graded alcohols. Endogenous peroxidase was blocked by dipping sections in 3% aqueous hydrogen peroxide for 10′ and antigen retrieval was performed with 10′ microwave treatment in 10-mM citrate buffer, pH 6. The immunostaining was performed with the avidin–biotin–peroxidase complex technique using diaminobenzidine as a chromogen. The sections were incubated overnight at 4°C with mouse monoclonal antibodies against full-length hMLH1 protein (G168-15, PharMingen, San Diego, CA) at 1:100 dilution; carboxy-terminal fragment of hMSH2 protein (FE11, Oncogene Research Products, Cambridge, MA) at 1:200 dilution; hMSH6 protein (44, BD Transduction Laboratories, Europe) at 1:200 dilution; PMS2 (A16-4, BD Biosciences, Europe) at 1:200 dilution. Sections were lightly counterstained with hematoxylin. The normal staining pattern for hMLH1, hMSH2, hMSH6, and PMS2 was nuclear, and a case was considered positive only in the presence of nuclear staining of neoplastic cells. A case was considered negative for expression of hMLH1, hMSH2, hMSH6, and PMS2 when there was a complete absence of nuclear staining of neoplastic cells in the presence of an unquestionable internal positive control, represented by normal epithelial cells, stromal cells, muscle cells, or lymphocytes [8]. Immunoreactive intraepithelial lymphocytes were detected by using a mouse monoclonal antibody anti-CD3 (Biogenex, San Ramon, CA, USA) at 1:100 dilution.

The immunohistochemical study of intestinal transcriptional factor CDX2 was done with monoclonal antibody CDX2-88 (Biogenex) raised against a full-length CDX2 recombinant protein at 1:100 dilution.

Apomucins were studied using mouse monoclonal antibodies against MUC1 glycoprotein (MA695, Novacastra

Lab., Newcastle, UK) at 1:100 dilution, MUC2 glycoprotein (CCP58, Novacastra Lab) at 1:200 dilution, MUC5AC glycoprotein (CLH2, Novacastra Lab) at 1:100 dilution, and MUC6 glycoprotein (CLH5, Novacastra Lab) at 1:100 dilution.

All immunostaining results were evaluated according to the percentage of immunopositive tumor cells ranging from less than 10% of positive cells (+), between 10 and 50% of positive cells (++) and more than 50% of positive neoplastic cells (+++). Cases with no immunoreactive cells were indicated as negative (−).

DNA extraction and microsatellite analysis

The MSI status of all 53 ampullary cancers was determined. Tumor DNA was extracted from archival paraffin-embedded tissues using DNeasy Tissue kit (Qiagen, Hilden, Germany) after a manual microdissection to enrich the neoplastic cellularity of at least 80% in all tumor samples [15]. MSI status was assessed by a fluorescent pentaplex PCR of five quasi-monomorphic mononucleotide repeats (Bat-26, Bat-25, NR-21, NR-22, NR-24) according to the amplification conditions reported by Suraweera et al. [28]. The fluorescently labeled PCR products were electrophoresed on an Applied Biosystems 310 automated DNA sequencer (Applied Biosystems, Milan, Italy). This panel of quasi-monomorphic mononucleotide markers can identify the MSI status of tumors without the need for matching normal DNA. However, the size of all PCR products from tumor DNA were always aligned with normal-sized alleles from a germline DNA sample. A tumor was classified as MSI when allelic size variations were observed in ≥3 out of five markers and as MSS when allelic size variations were observed in ≤2 out of the five markers.

Statistical analysis

The statistical analysis was performed using Fisher's exact test and the χ^2 test with Yates' correction (SPSS 7.5 software). The survival analysis was performed by employing the Kaplan-Meier product limit estimate of probability of survival against time, producing a product limit survival curve for each of the following variables: tumor size, macroscopic localization, histological type, grade, stage, presence of lymph node metastases, immunohistochemical expression of CDX2, MUC1, MUC2, MUC5AC, MUC6, and MSI status.

Multivariate analysis was carried out using the Cox proportional hazard model. Variables with $p<0.15$ in the univariate analysis were entered into the multivariate analysis.

For all the survival analyses, the Survan XL program, version 1.14 (copyright© 1995–1997), was employed.

Results

Histopathological study

The series of patients with ACs included 30 men and 23 women with a mean age at diagnosis of 65.8 years (range 44–82 years). The comprehensive results of the clinicopathological and immunohistochemical study of these tumors are reported in Tables 1 and 2, respectively. According to Cubilla and Fitzgerald's criteria, 11 of 53 tumors (21%) were classified as PA, 35 of 53 (66%) as IA and 7 of 53 (13%) as MT ACs. Histologically, 23 ACs (43.4%) were classified as intestinal (I) type and 30 (56.6%) as BP type (Fig. 1). A second histological pattern (intestinal or mucinous) was detected in eight cases (26.6%)

out of the 30 BP-type ACs (Table 1), whereas seven cases (30.4%) out of 23 intestinal-type ACs were associated with a BP pattern as a second component. Thirty-three tumors were moderately differentiated (grade 2), and 20 were poorly differentiated (grade 3). The T stage distribution was: 11 cases (21%) at T1, 21 (40%) at T2, 16 (30%) at T3, and 5 (9%) at T4. The pancreatic and choledochus resection margins were negative in all the cases. The posterior fat tissue was macroscopically negative in all cases but residual neoplastic disease (microscopically positive margin of resection: R1) was found in ten cases (19.2%). A total of 924 regional lymph nodes were examined, (range 5–49, mean 18.8; median 14). Lymph node metastases were observed in 28 out of the 49 (57%) cases for which the information was available (range 1–32, mean 4.7, median 2). The stage distribution was: 18 cases (37%) at stage 1, 26 (53%) at stage 2, 5 (10%) at stage 3.

Immunohistochemical and molecular study

The immunohistochemical expression of CDX2 and MUC1, MUC2, MUC5AC, and MUC6 apomucins was significantly different in intestinal and BP ACs. In particular, all intestinal ACs showed a nuclear immunoreactivity for CDX2 with 19 out of 23 cases demonstrating a high level of expression (score 3+ in seven cases and 2+ in 12 cases) compared with BP ACs exhibiting CDX2 immunoreactivity in nine out of 30 (30%) of cases (score

2+ in 3 cases and 1+ in 6 cases; $p<0.000001$). Notably, all but one of the BP ACs which were positive for CDX2 showed an intestinal and/or a mucinous component.

A nuclear immunoreactivity for CDX2 was found in 32 out of 53 (60%) ACs with a significantly higher percentage of positive cases among PA and MT ACs compared with IA ACs ($p=0.028$). Considering the grading of the tumors, CDX2 staining was found in 18 of 33 (54.5%) moderately differentiated and, in 13 of 20 (65%), poorly differentiated adenocarcinomas, but no significant correlation was observed.

The MUC1, MUC2, MUC5AC, MUC6 apomucins appeared to be expressed in 75, 43, 39, and 28% of ACs, respectively. A significantly higher frequency of MUC1 and MUC5AC expression was detected in BP than in

intestinal ACs ($p<0.0001$ and $p<0.05$, respectively, for the two antibodies), whereas a significantly higher percentage of positive cases for MUC2 was found among intestinal ACs compared with BP ACs ($p<0.023$). Moreover, a higher frequency of MUC1 immunoreactivity was detected in the IA cancers (86% of tumors) than in PA and MT ACs (63 and 42% of tumors, respectively). No other significant correlations were detected between the immunostaining results for the apomucins and macroscopic classification, histological type, or grading of ACs. MUC6 was rarely expressed in the ACs included in this study, and positive cases showed a focal immunoreactivity.

MSI was observed in five out of 53 ampullary ACs (9.5%) showing allelic size variations in at least three of the five mononucleotide markers (Tables 1 and 3). The remaining tumors were classified as MSS, exhibiting an absence of MSI in all markers or the presence of allelic size variations at two loci (case *N*° 6 in Table 3) or at one locus (cases *N*° 7 and *N*° 8 in Table 3). All five MSI tumors were intestinal-type ACs showing a mucinous component in two cases, a medullary component in two cases and a rich lymphoid infiltrate around the tumor in one case (Fig. 1). Moreover, all five MSI tumors showed a CDX2 immunoreactivity and a variable pattern of immunohistochemical expression of apomucins (Table 1).

To corroborate the MSI data, all eight ACs showing allelic size variations in at least one locus were analyzed for hMLH1, hMSH2, hMSH6, and PMS2 immunostaining (Table 3). All the five MSI ACs showed lack of the immunohistochemical expression of hMLH1/PMS2 proteins (cases 1 and 2) or of hMSH2/hMSH6 proteins (cases 3, 4, 5). By contrast, the three cases classified as MSS displayed an intense nuclear immunoreactivity for all MMR proteins. Figure 2 shows an example of the histological, immunohistochemical, and molecular profile of an AC with MSI.

Survival analysis

Follow-up data were available for 52 of the 53 patients with ACs. Nine patients were excluded from the survival analysis because they died within the first 60 days after tumor resection. Twenty-nine patients (67% of cases) died of disease after a median time of 24.8 months (range: 4–80), whereas 14 patients (33% of cases) are still alive after a median follow-up time of 71.2 months (range: 8–138).

Factors influencing survival in the univariate analysis were (Fig. 3): tumor stage (median survival >49 months for T1–T2 vs 7 months for T3–T4, $p<0.001$), lymph node metastases (median survival >52 months for lymph node negative tumors vs 20 months for lymph node positive tumors, $p=0.0017$), *R* status (median survival >31 months for complete tumor resection with grossly and microscopically negative margins vs 20 months for grossly negative but microscopically positive margins of resections), and presence of MSI (all patients with MSI tumors were alive with no evidence of disease after a median follow-up time of 69 months, $p=0.019$). Although the results were not statistically significant, a longer survival was correlated with the immunohistochemical expression of CDX2, using a nuclear labeling cut-off of >10% cells ($p=0.14$) as well as with an intestinal type of AC ($p=0.08$). No correlation with survival was observed even when considering different cut-offs for CDX2, including ≥25, 30, 40, and 50% nuclear labeling. Finally, no other correlation was observed between patient outcome and clinicopathological parameters including macroscopic localization, size, and grade of the tumor.

A multivariate analysis was performed using the Cox proportional hazard model for all variables which were significant or near to statistical significance in the univariate analysis, and only stage was an independent prognostic factor (Table 4).

Discussion

ACs demonstrate a wide spectrum of biological behavior that probably reflects their different histogenesis, arising from one of the three types of epithelium that converge at this site (duodenal mucosa, pancreatic ductal epithelium, and biliary ductal epithelium). Currently, conflicting data have been reported about the frequency of the two major histological types of ACs (intestinal and BP type) due to the absence of reliable histomorphological or immunohistochemical markers for differential diagnosis [2, 20, 31]. Very recently, Hansel et al. [18] examined a large series of ACs demonstrating that CDX2 expression alone may identify intestinal-type tumors with good prognosis, suggesting that it may be used as an independent marker of outcome at this site.

In this work we evaluated the correlation between the histomorphological classification and the immunohisto-

chemical expression of CDX2 and found a high specificity of the protein for intestinal-type ACs and for the minor intestinal and/or mucinous components of the BP-type ACs (Table 1). Intriguingly, a significantly higher percentage of CDX2 immunoreactive cases was observed among PA and MT ACs compared with IA ACs (p=0.028) in line with the possible origin of these cancers in duodenal mucosa.

As regards the prognostic role of CDX2 expression, our results are in contrast with previously reported data by Hansel et al. [18] showing that CDX2 expression in ACs was the only independent predictor of survival in the multivariate analysis of their AC cases. In the present work, although CDX2 expression showed a trend towards a longer survival in the univariate analysis, no significant prognostic role as an independent marker was demonstrated for this variable in the multivariate analysis.

The univariate analysis showed that, microscopically positive margins of resection (R1), advanced clinical stages, and lymph node metastases were significantly related to a shorter survival, whereas the presence of MSI was a marker of a better outcome. In the multivariate analysis, stage group remained the only significant and independent prognostic factor of survival, as reported in other studies [4, 22, 24].

A widespread MSI as well as loss of the immunohistochemical expression of hMLH1/PMS2 or hMSH2/hMSH6 proteins were observed in five ACs (9.5% of all cases, 22% of the intestinal ACs). All MSI ACs were of an intestinal type, and half were associated with a mucinous or with a medullary component. In one case, a rich lymphoid infiltrate around the tumor was observed. In addition, all MSI ACs were intensely CDX2-positive. This histopathological and immunohistochemical profile appears to be similar to that of gastric and colorectal MSI cancers [6, 9, 13, 19] and confirms the notion that MSI is a peculiar feature of a consistent percentage of intestinal-type ACs [27]. Until now, few and controversial data have been reported about the frequency of a MSI in ACs [1, 25, 29] probably due to different criteria for tumor selection, including cases of not unequivocally ampullary origin and ACs of different types. Our results regarding MSI ACs are comparable with those reported by Achille et al. [1] that indicated a 20% rate of MSI ACs in a series of 25 cases and reported a significant association between MSI and longer patient survival in the univariate analysis.

Finally, differences in the mucin distribution between BP and intestinal ACs were observed. The coexpression of MUC1 and MUC5AC appears to be a peculiar feature of BP ACs, whereas a strong production of MUC2 is associated with an intestinal histology and a CDX-2 positive immunophenotype. These data are consistent with the findings reported by Chu et al. [10] and suggest that the two main immunoprofiles mentioned above are helpful in the differential diagnosis between intestinal and BP types of ACs. However, the composite pattern of apomucin expression often observed in ACs does not allow a clear-cut classification of the two major histological types and suggests only an ancillary use of apomucins in this differential diagnosis. Furthermore, no significant correlation between mucin immunoprofile and survival was observed. Similar results have been reported by using other immunohistochemical markers such as cytokeratin 7 and cytokeratin 20 [10, 31].

In conclusion, this study shows a comprehensive analysis of the main clinicopathological, immunohistochemical, and molecular parameters suggested to have an impact on survival of patients with ACs and proves that a precise stage assessment remains the only independent predictor of survival. The extent of resection appears to be prognostically of great significance, although it is not part of the TNM staging as well as negative lymph nodes, and presence of MSI are significantly correlated with improved outcome for the patients.

Although precise histological criteria and the immunohistochemical expression of apomucines and CDX2 are helpful in the classification of the two major histological types of ACs, no significant correlation between intestinal profiles and improved survival is observed.

Abstract To eliminate the risk of colorectal cancer in patients with familial adenomatous polyposis (FAP), reconstructive proctocolectomy is performed. Although most colonic mucosa is resected during the ileal pouch anal anastomosis, adenomas and carcinomas may develop in the pouch. This may be caused by altered cell kinetics due to intraluminal changes in the pouch. In 32 patients with FAP, biopsy specimens from the mucosa of the pouch and also of the afferent ileal loop were taken. Tissue sections were immunohistochemically processed with the monoclonal antibodies M30 and MIB-1 to assess apoptotic and proliferative indices, respectively. Cell proliferation was also assessed by a modified sign test. There were no significant differences in apoptotic rates between the mucosa of the pouch and the mucosa of the afferent ileal loop. However, cell proliferation was significantly higher in the mucosa of the pouch vs afferent ileal loop, both by using the quantitative (68.3% vs 61.6%, $p=0.001$) and semiquantitative methods ($p<0.05$). Our newly developed semiquantitative approach outperformed previously described methods. The higher cell proliferation in the pouch as compared to the afferent ileal loop may contribute to the increased risk for adenomas and carcinomas in the pouch of patients with FAP and emphasizes the need for regular endoscopic surveillance.

Keywords Familial adenomatous polyposis · Restorative proctocolectomy · Cell proliferation · Apoptosis and carcinogenesis

Introduction

Familial adenomatous polyposis (FAP) is an autosomal-dominant disease with an estimated prevalence of 1 in 5,000 to 1 in 7,500 [5]. It is characterized by the development of hundreds of adenomas in the large intestine. Without surgical intervention, virtually all patients will develop colorectal cancer at relatively young age.

To eliminate the risk of colorectal cancer, a restorative proctocolectomy with ileal pouch anal anastomosis (IPAA) is accepted as one of the surgical treatments of choice in these patients.

In the IPAA procedure, almost all colonic mucosa is resected, thus reducing cancer risk significantly. However in patients with FAP, adenomas are also present in the upper gastrointestinal tract; approximately 5% of the patients having gastric, 60 to 90% duodenal [4], 50% jejunal [14], and 9 to 25% ileal adenomas [14, 23, 34]. Occurrence of ileal adenomas is of special interest because the terminal ileum, which is used to construct the pouch, may already contain adenomas. There is accumulating evidence that adenomas develop in the pouch. The reported incidence after a follow-up of at least 5 years is 8 to 60%, increasing up to 75% in certain subgroups [14, 26, 33, 38], which is much higher as

The experiments performed for this study comply with the current laws of The Netherlands.

compared to the reported incidence of 9–25% in the preoperative ileum of patients with FAP [14, 23, 34]. Therefore, it seems that in the ileal pouch of patients with FAP, the development of adenomas is accelerated. At present, the malignant potential of the pouch adenomas is unclear. However, 13 patients with a carcinoma in the pouch have been recently described in the literature [2, 3, 7, 9, 13, 24, 25, 29, 35–37].

Stasis in the pouch causes a change in the luminal content, which is in close contact with the ileal mucosa. There is an increase in the concentration of short-chain fatty acids to colonic levels [10], an increase in anaerobic bacterial counts resulting in a more colonic type of flora, and an increased deconjugation and dehydroxylation of bile acids by anaerobic bacteria [20, 21]. The intestinal flora could play a role in initiation and promotion of colon cancer by activation of various classes of carcinogens, such as nitrosamines, polycyclic aromatic hydrocarbons, and glycosides [17]. A direct link between intestinal bacterial flora and tumor promotion in the $APC^{Min/+}$ mouse model for FAP has already been established [22].

Therefore, we hypothesize that the intraluminal ecological changes in the pouch are responsible for enhanced tumor formation in the mucosa of the pouch. Alteration of cell kinetics in the mucosa, including a lower rate of apoptosis and a higher rate of cell proliferation, is associated with tumor initiation and promotion. In colorectal cancer, the balance between apoptosis, cell proliferation, and cell shedding is disturbed, and such changes may favor the development of adenomas [30]. Up to now, no data are available on changes in proliferation and apoptosis rates of the ileal mucosa of the pouch after IPAA in patients with FAP.

The aim of this study is to investigate changes in apoptosis and cell proliferation rates, occurring in the mucosa of the pouch of patients with FAP, in comparison with the ileum of the afferent loop. The results may contribute to a better understanding of the enhanced adenoma formation in the pouch compared to normal ileum.

Materials and methods

Patients and tissues

The study was approved by the regional medical ethical commission, and informed consent was obtained from all patients.

Patients with FAP and an IPAA, who were under surveillance in the Radboud University Nijmegen Medical Centre or regional affiliated hospitals, were invited to participate in this study. Thirty-two patients with FAP were included. The diagnosis FAP was based on either a clinical presentation of at least 100 colonic adenomas or a mutation in the APC gene. Data concerning the surgical procedures were obtained from medical records.

From each patient, mucosal biopsy specimens of both the pouch and the afferent ileal loop were obtained during a regular surveillance endoscopy, in the period January 2002 until April 2004. Patients were fasted overnight. On the day of examination, patients were encouraged to drink liberally. No laxatives or cathartic enemas were given. To clear the pouch of fecal ruminants, two 250-ml water enemas were given before the endoscopy.

The endoscopy was performed with an Olympus GIF-1T140 video endoscope. From January 2002 until August 2003, a 2.8-mm diameter biopsy forceps (FB 13K-1 Olympus, Tokyo, Japan) was used, and from September 2003 until April 2004, a 3.0-mm diameter biopsy forceps (B102-C1-30.160 MedWork/Treier Endoscopie GA, Beromünster, Switzerland) was used. The afferent loop was introduced up to 20 cm proximal of the pouch. The mucosa was sprayed with 1% indigo carmine dye (Laboratoires SERB, Paris) at 1:1 dilution with water, where after photographs were taken to evaluate number and size of adenomas present.

For pathological examination, at least four biopsies were taken at random locations from the afferent ileal loop (10 to 20 cm proximal from the pouch), four biopsies from the pouch mucosa (at least 5 cm proximal from the anal verge), and four biopsies from adenomas if present. The biopsies from adenomas were used only for pathological evaluation, i.e., to exclude serious dysplasia in pouch adenomas, and were not used for research purposes. The biopsies were stretched on filter paper to maintain correct orientation of crypts, fixated in formalin, and embedded in paraffin.

Immunohistochemistry

Cell proliferation and apoptosis were measured in the stretched formalin-fixed nonadenomatous tissue. The crypt cell proliferation activity was assessed after staining with the monoclonal antibody MIB-1 (Dako A/S, Glostrup, Denmark), which recognizes the Ki-67 nuclear antigen of dividing cells in formalin-fixed paraffin-embedded tissue [8]. Apoptosis was assessed by staining with the monoclonal antibody M30 (Roche Diagnostics, Mannheim, Germany), which recognizes cleaved cytokeratin 18. Immunoreactivity of M30 is confined to the cytoplasm of apoptotic epithelial cells and is expressed during early apoptosis [18].

Tissue sections of 4-μm thickness were cut from paraffin blocks, mounted on electrostatic slides (Super Frost Plus, Menzel-Gläser, Germany), and dried overnight, followed by drying in a stove at 50°C for 15 min.

Sections were put in xylol for 10 min and taken from xylol through 100% alcohol to water. After deparaffinization, endogenous peroxidase was blocked by treatment with 3% hydrogen peroxide in phosphate-buffered saline (PBS) for 30 min. Pretreatment was performed by heating the tissue sections in citrate buffer (10 mmol/l, pH 6.0) at 180-W power in a microwave oven for 10 min. After cooling at room temperature for 1.5 h, sections were rinsed with PBS. Then, 20% normal horse serum (Vector Laboratories, Burlingame, CA, USA) was applied for 10 min. The sections were then incubated overnight at 4°C with either the mouse monoclonal antibodies MIB-1 at 1:1,000 dilution or M30 at 1:100 dilution.

Thereafter, the sections were rinsed in PBS for 10 min and incubated with biotinylated horse anti-mouse IgG (Vector) for 30 min. After rinsing for 10 min in PBS, incubation with 'avidin and biotinylated horseradish peroxidase macromolecular complex' (Vector) was performed for 45 min. Finally, 5 mg/10 ml diaminobenzidine was used as chromogen, and the sections were put in 0.5% $CuSO_4$/0.9% NaCl for 5 min to intensify the staining. Mayer hematoxylin counterstaining was applied. Sections were dehydrated through 100% alcohol, cleared in xylol, and coverslipped with permount (Fisher Scientific, Fiar Lawn, NJ, USA).

Tissue sections of rectal carcinoma were used as positive controls.

Evaluation of immunostaining results

Investigators were blinded for the origin of the tissue sections, regarding patient and biopsy location.

For evaluation of M30 staining, tissue sections were examined by light microscopy. M30 positivity was identified as brown cytoplasmic staining. M30-positive cells were marked by a first investigator (BvH) and reevaluated by an expert pathologist (IN). In all cases, the complete section was evaluated, and all M30-positive epithelial cells were counted. The apoptotic index was expressed as the number of M30-positive cells per tissue area in square millimeters. Tissue area was assessed by using a Zeiss KS400 computer-aided system.

In each MIB-1-immunostained tissue section, crypts whose entire length could be visualized were photographed under ×400 magnification using a Zeiss KS400 computer-aided system. Crypts were excluded when they did not reach the muscularis mucosae or had multilayered bases.

MIB-1 positivity was identified as brown nuclear staining. The number of MIB-1-positive epithelial cells and the total number of epithelial cells in up to five crypts per tissue section were counted from screen. The labeling index for each crypt was given by the ratio of MIB-1-positive cells and the total number of crypt epithelial cells and is expressed as percentage of total. For each patient, the labeling indices of pouch and afferent ileal loop were expressed as means of three to five counted crypts. If less than three crypts could be photographed for either pouch or ileal loop, the patient was excluded from analysis. The photographed crypts of five randomly selected patients were counted twice by one investigator (BvH) to determine intraobserver variability.

Although great effort was made to obtain well-orientated mucosal crypts when using the quantitative method, however, not all biopsies reached the criteria mentioned above, and therefore, could not be examined. This problem mainly occurred in the biopsies taken from the pouch and might be due to friability of the pouch mucosa. We therefore developed a new semiquantitative scoring system. A representative part of the biopsies showing several complete crypt/villous axes was photographed under ×100 magnification. The photographs were judged pair-wise (pouch vs afferent loop) during which the investigators had to choose from four possible outcomes; one of the two locations showed most MIB-1 positivity. MIB-1 positivity did not differ or no judgement could be made. Judgement was based on relative length of the area of positive cells and the relative size of the stem cell compartment. Five investigators, two pathologists (IN, HvK), two gastroenterologists (PF, FN), and one junior investigator (BvH) independently compared the paired photographs of biopsies of pouch and afferent ileal loop of all patients. When three or more observers agreed in their judgement, this judgement was denoted as consensus judgement. If this criterion was not met, no consensus was reached. If the quality of the tissue sections was poor, no judgment was made. One investigator (BvH) judged the whole series twice for evaluation of intraobserver reliability.

Statistical analyses

Values for apoptosis and cell proliferation in the quantitative study were not expected to be normally distributed; therefore, they were presented as median and range. The Wilcoxon matched-pairs signed-ranks test was used to compare the paired observations in the apoptosis staining and the paired mean labeling indices in the cell proliferation study.

Consensus judgements on the semiquantitative assessment of cell proliferation, favoring either pouch or ileal afferent loop, were compared with a Sign test. To evaluate the reliability of this semiquantitative method to assess cell proliferation, Cohen's kappa was calculated for the first and second series of judgements by the prime investigator to determine intraobserver reliability. Also, for each pair of investigators, a Cohen's kappa was calculated. The mean Cohen's kappa was taken as value for interobserver reliability.

Table 1 Patient characteristics

	Apoptosis	Cell proliferation
Number of patients studied	32	20
Male/Female	19/13	12/8
Median age in years (range)	32 (16–72)	29 (16–62)
Median age at surgery in years (range)	24 (10–55)	20 (10–52)
Median age pouch in months (range)	96 (9–216)	105 (9–216)
IPAA: hand-sewn/double-stapled/ unknown	9/21/2	5/14/1
Carcinoma at surgery	4	0
Patients with adenomas at biopsy: yes/no	24/8	15/5

For quantitative cell proliferation analysis, 12 patients had to be excluded from analysis (right column) due to absence of sufficient evaluable crypts (see under "Materials and methods").

Consensus judgments were compared to the difference in mean labeling index between pouch and ileal afferent loop for each evaluable patient.

A p value less than 0.05 was considered as significant (SPSS for Windows 11.0.1, 2001).

Results

Patient characteristics

Patient characteristics are given in Table 1. The median age of the 32 patients (19 men, 13 women) included in the study was 32 (range 16–72) years.

Twenty-three patients were operated in the Radboud University Nijmegen Medical Centre. The median age at the time of reconstructive colectomy was 24 (range 10–55) years. A mucosectomy with hand-sewn IPAA was performed in 9 patients, and a double-stapled IPAA was performed in 21 patients. For two patients, the information about the performed technical procedure could not be retrieved. At the moment of colectomy, four patients had a colorectal adenocarcinoma localized in the rectum, sigmoid, hepatic flexure, or appendix, respectively.

At the time of endoscopy, the median age of the pouch was 96 (range 9–216) months. The medication used was loperamide by 18 patients, psyllium fibres by 3 patients, and iron, metoclopramide, colestyramine, omeprazole, sulindac, tramadol, tamoxifen, gosereline, nifedipine, metoprolol, furosemide, or losartan each by 1 patient. Thirteen patients were not on medication 3 months before endoscopy.

One patient used sulindac, a nonspecific cyclooxygenase inhibitor, which is thought to influence cell proliferation and especially apoptosis [15, 27]. Exclusion of this patient from analyses had no effect on the results.

Histological examination revealed pouch adenomas in 24 patients (75%).

Apoptosis

In both pouch and afferent ileal loop, M30-positive cells were predominantly detected in the mucosal villi (Fig. 1).

In the 32 pairs of biopsies from pouch and afferent ileal tissue investigated, the median absolute number of apoptotic cells in the pouch mucosa was two per tissue section (range 0–9), which was identical to the values in the afferent ileal loop (2, range 0–19). The median apoptotic index (expressed as number of M30-positive cells per mm^2 tissue section area) did not differ between pouch (median 0.4/mm^2, range 0–2.9) and afferent ileal tissue (median 0.3, range 0–2.7; see Fig. 2).

Cell proliferation

Quantitative comparison

The intraobserver reliability for counting of the photographed crypts (Fig. 3) was r_s=0.855, p=0.002.

In 12 pouch tissue sections, less than three crypts were available for counting, and these samples were therefore excluded from analysis. For the same reason, two afferent ileal tissue sections were excluded. In the 20 pairs of pouch and afferent ileum tissue sections left for comparison, median labeling index (expressed as percentage of MIB-1-positive epithelial crypt cells) was significantly higher in

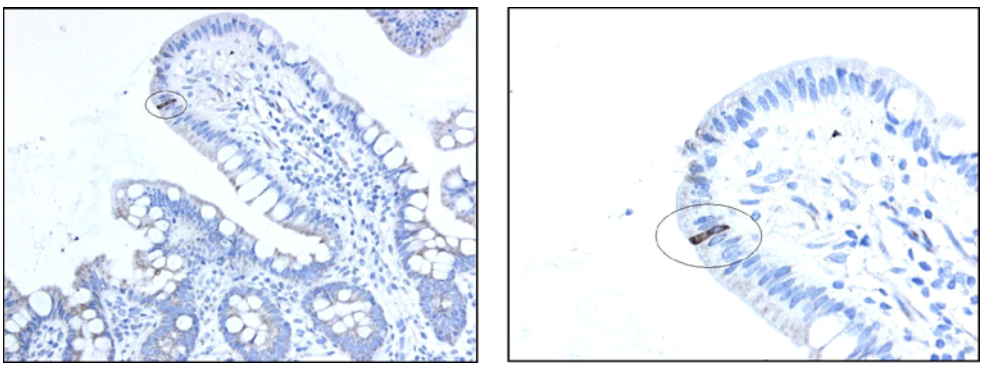

Fig. 1 Apoptotic epithelial cells (*encircled*) using M30 immunohistochemistry. Original magnification ×200 (*left*) and ×400 (*right*)

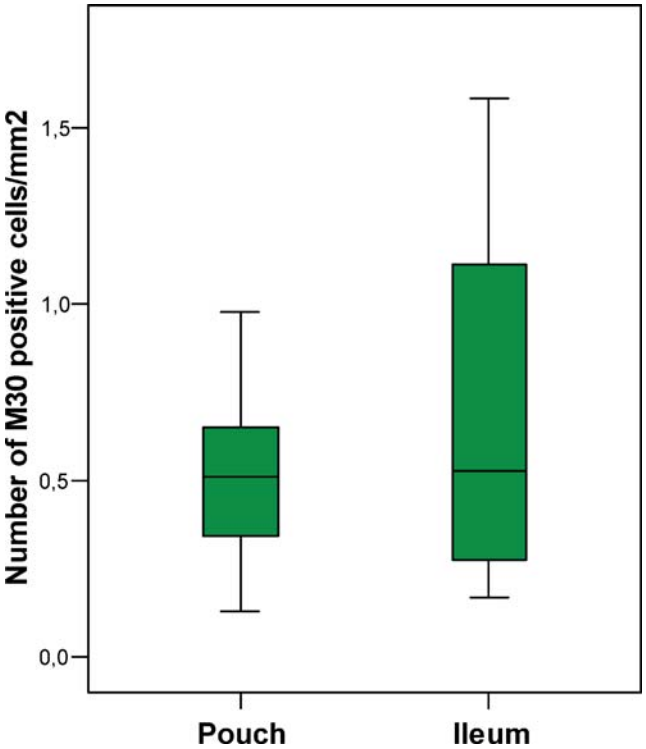

Fig. 2 Box-Whisker plots of apoptosis expressed as number of M30-positive epithelial cells per mm^2 tissue section area of pouch and afferent ileum of 32 patients with FAP. Difference between groups was not significant. Values are given as median (*fat line*), lower to upper quartile (*green box*), and minimum and maximum values (*error bars*)

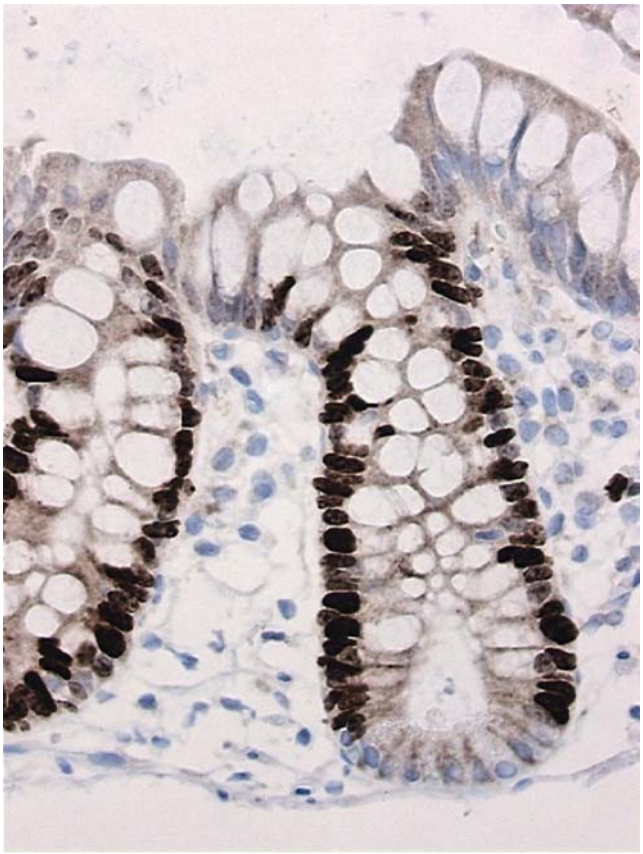

Fig. 3 Detection of proliferating crypt cells with MIB-1 immunohistochemistry. *Brown stained nuclei* are positive. Nonproliferative crypt stem cells are visualized at the base of the crypt. Original magnification ×400

the pouch as compared to the afferent ileum (median 68.3%, range 52.9–79.6% vs median 61.6%, range 38.0–73.9%; Wilcoxon signed-ranks test, $p=0.001$; Fig. 4).

Semiquantitative comparison

The results of the semiquantitative comparison of the photographed tissue sections from the pouch and afferent ileum mucosae (Fig. 5) are visualized in Fig. 6. In 15 patients (47%), the proliferation was higher in the pouch; in 7 patients (22%), there was no difference; in 5 patients (16%), proliferation was higher in the afferent ileal loop; in 2 patients (6%), no consensus could be achieved; and in 3 patients (9%), no judgement was possible due to poor quality of the tissue sections. These differences were significant ($p<0.05$).

Intraobserver reliability was $\kappa=0.87$. Cohen's kappa for each pair of observers ranged from 0.26 to 0.59 with a mean Cohen's kappa of 0.38, which corresponds with "fair agreement" following Byrt's guidelines [6]. Thus, interobserver reliability was acceptable.

In cases in which a labeling index could be assigned to both pouch and afferent ileal loop, consensus judgment was available in 18 cases (Fig. 7). In all cases in which the semiquantitative analyses showed more proliferation in the pouch ($n=11$), this was confirmed by the quantitative method; the median value of the difference in proliferation between pouch and ileum was 0.107 (range 0.032–0.175). In the five cases where no difference was observed with the semiquantitative approach, the median value of the difference in proliferation between pouch and ileum was 0.023 (range −0.096 to 0.120). There were only three cases in which the semiquantitative method showed more proliferation in the afferent loop, and the median value of the difference in proliferation between pouch and ileum in these cases was 0.098 (range −0.021 to 0.262). The Spearman's correlation coefficient between the semiquantitative and the quantitative methods was 0.273 ($p=0.244$).

Discussion

Although both the pouch and its afferent loop contain the same preexisting ileal mucosa, adenomas occur more frequently in the pouch of patients with FAP than in the afferent ileal loop, suggesting an accelerated adenoma formation in the pouch [14, 26, 33, 38]. To investigate the

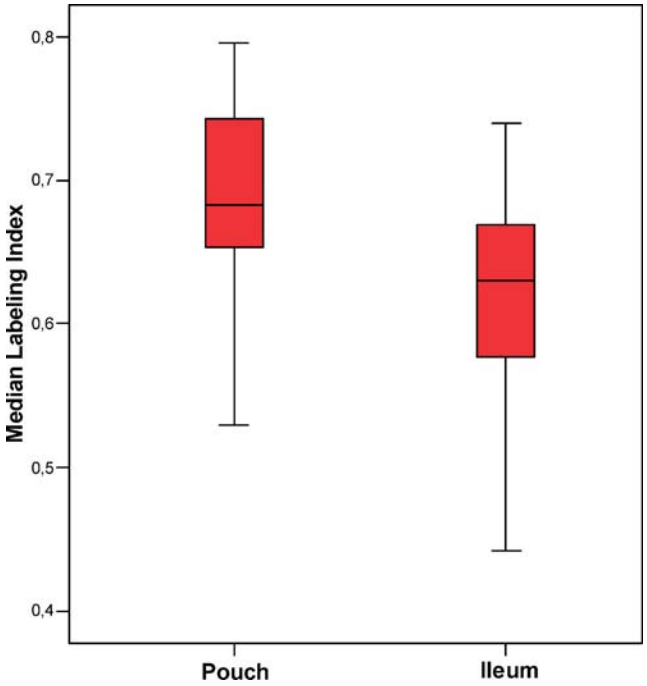

Fig. 4 Box-Whisker plots of cell proliferation expressed as median labeling index (MIB-1-positive crypt cells per total number of crypt cells) of 3–5 crypts in tissue sections of pouch and afferent ileum of 20 patients with FAP. Difference between groups was significant (p= 0.001). Values are given as median (*fat line*), lower to upper quartile (*red box*), and minimum and maximum values (*error bars*)

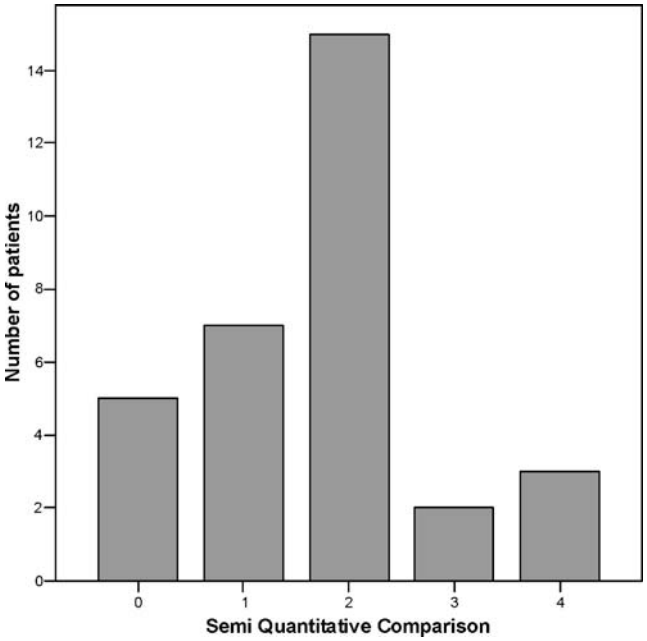

Fig. 6 Histogram of semiquantitative comparison; *0* ileal mucosa shows more cell proliferation than pouch mucosa, *1* no difference in cell proliferation between pouch and ileal mucosae, *2* pouch mucosa shows more cell proliferation than ileal mucosa, *3* no judgement possible, *4* no consensus could be reached

role of cell kinetics as a possible explanation for this observation, apoptosis and cell proliferation rates in the mucosa of the pouch were compared with those of the afferent ileal loop from the same patient to eliminate bias caused by interindividual differences. Cell proliferation was significantly higher in the pouch mucosa in comparison to mucosa of the afferent ileal loop. No significant difference in apoptosis was found in the mucosa of the pouch and afferent ileal loop.

A low amount of apoptotic cells in the pouch as well as in the ileal mucosa was found. This might be caused by the APC mutation-induced apoptotic resistance [16]. Only a trend but no significant difference in apoptosis was found. Taking into account the broad range of apoptotic rates as found in our study samples, a significant difference might be found when a larger group of patients could be studied. There are no clear guidelines for estimation of ileal proliferation. For estimation of colonic proliferation, an accepted method is to count proliferating cells in five colonic crypts. Although most biopsy specimens were stretched and orientated directly after endoscopy, only a lower number of crypts could be counted completely along the longitudinal axis in most patients. For this reason, we accepted three full crypts as the minimal number to assess proliferation. Using this criterion, tissue sections from 12 patients still could not be used to determine the cell proliferation and had to be excluded from the study. Especially in the tissue sections of the pouch, this problem was evident and is possibly caused by a higher fragility of this tissue. In the remaining 20 pairs of tissue sections left

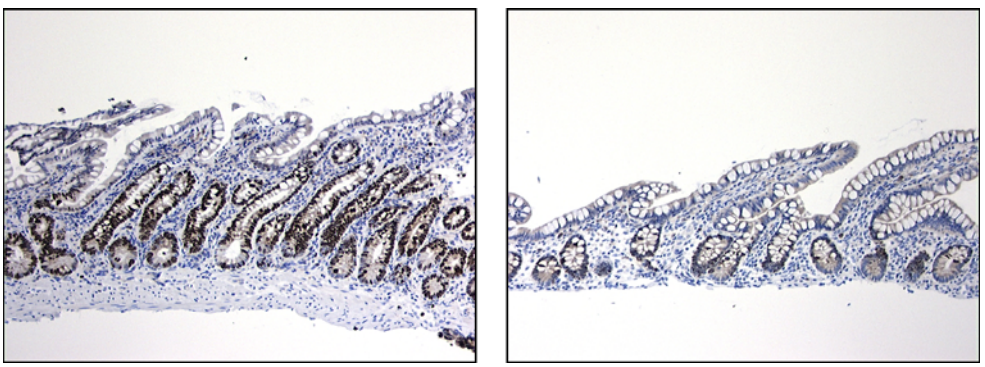

Fig. 5 Photographs used for semiquantitative comparison of cell proliferation in MIB-1 immunohistochemically stained tissue sections of pouch (*left*) and afferent ileal mucosae (*right*; original magnification ×100)

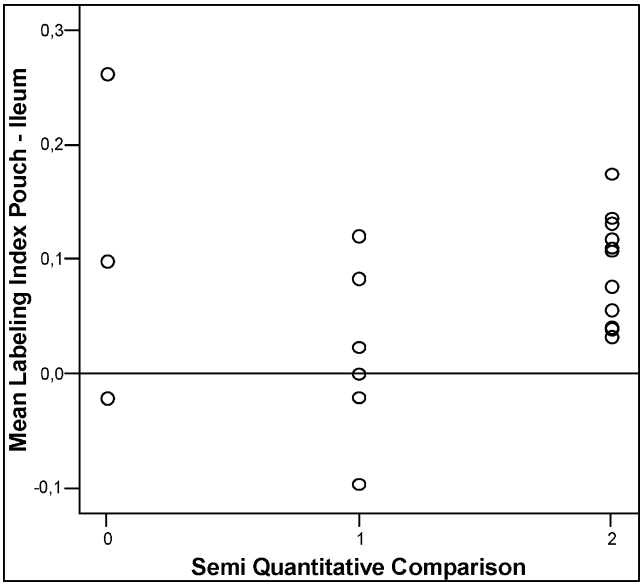

Fig. 7 Semiquantitative comparison vs difference in mean labeling index of pouch minus afferent ileal mucosa; *0* ileal mucosa shows more cell proliferation compared to the pouch mucosa, *1* no difference in cell proliferation between pouch and ileal mucosae, *2* pouch mucosa shows more cell proliferation compared to the ileal mucosa

for comparison, we found a significantly higher median labeling index in the pouch compared to the ileal afferent loop.

To overcome the problem of the relative low number of assessable crypts, another quicker but less quantitative method was applied in which five investigators compared photographs of tissue sections of pouch and ileal mucosae. In accordance with the results of the first method, we found significantly higher cell proliferation in the mucosa of the pouch compared to that of the ileal mucosa. Although no significant correlation could be found in a case-by-case comparison between both methods, in all cases in which the semiquantitative analyses showed more proliferation in the pouch, this was confirmed by the quantitative analyses of crypts. Furthermore, the inter- and intraobserver variability was good.

In addition, the semiquantitative method is far less time-consuming and can therefore give a relatively fast and easy impression of eventual differences in cell proliferation. Evaluation of this method in a larger study may further demonstrate its value.

Data on cell proliferation in ileal mucosa in patients with FAP are limited. Previously, de Silva et al. [11] reported a labeling index of 19.8% in afferent ileal loop mucosa of patients with FAP or ulcerative colitis (UC), far lower than the 61.6% that was found here. Their labeling index for cell proliferation in ileal pouch mucosa (33.6%) was also much lower than in the present study. Only the labeling index of 51.7% as found by them in pouches with pouchitis nears the values we obtained. However, the majority of patients included in the study of de Silva et al. were patients with UC (23 of the 26 patients), so direct comparison with our results therefore seems inappropriate. In addition, Goldberg et al. [12] reported a median labeling index of 34.9% in the ileal pouch of patients with FAP, which is much lower than the 68.3% we found. However, their labeling indices were based on a minimum of three counted crypts, and if this number could not be reached, halves of crypts were included in the analyses. Moreover, their study group consisted of only 5 patients with FAP, whereas in the present study, 3 to 5 whole crypts of 20 patients were counted.

Several studies indicated that cell proliferation of normal-appearing colorectal mucosa of patients with adenomas or carcinomas was 19 to 86% higher compared to colorectal mucosa of healthy persons [1, 28, 30, 32]. These findings strongly suggest an association between the presence of adenomas or carcinomas and an increased mucosal cell proliferation. However, the difference in cell proliferation between pouch and afferent ileal mucosae of 6.7% as found in this study is less pronounced in comparison to the above referred findings. A possible explanation for this relatively small difference in cell proliferation between pouch and ileal mucosae in our study may be that intestinal epithelial cell proliferation is already very high in patients with FAP [19, 31], and these high cell proliferation rates make a further increase less pronounced.

The higher proliferation found in the pouch mucosa in comparison to mucosa of the afferent ileal loop can only be explained by intraluminal changes that occur after construction of the pouch. Whether changes in bacterial flora, bile acid composition, short-chain fatty acids, or other compounds are responsible for this finding remains unclear, but a better understanding of this process is necessary to find a possible treatment for this group of patients.

In conclusion, the increased cell proliferation in the ileal pouch mucosa compared to the mucosa of the afferent ileal loop may contribute to the enhanced risk for adenomas and carcinomas in the pouch of patients with FAP and emphasizes the need for regular endoscopical surveillance of the pouch in these patients. In addition, cell proliferation can be used as an early endpoint marker in chemopreventive studies in these patients.

The applied new method for semiquantitative evaluation of cell proliferation in immunohistochemically stained tissue sections seems promising, as it offers a relatively fast and easy means of assessment.

Abstract We evaluated the usefulness of the tight-junction associated protein Claudin 4 (CL-4) in the diagnosis of mesothelioma and mimickers, analyzing biopsies from 454 tumors, including 82 mesotheliomas, 336 carcinomas of different origin (278 primary, 58 metastatic to serosae), 36 nonepithelial spindle cell neoplasms, as well as 97 cytological samples from reactive effusions (12), mesothelioma (23) and metastatic carcinomas (62). CL-4 was consistently negative in normal and reactive mesothelium, as well as in all 82 mesotheliomas. In contrast, strong reactivity was found in 57/58 serosal metastasis, and in 245/278 primary carcinomas, with uppermost expression (150/153) in those most frequently involved in the differential with mesothelioma (lung, breast, gastrointestinal tract, pancreas, ovary, primary serous papillary carcinoma of peritoneum). On effusions, reactive and neoplastic mesothelial cells were regularly negative, while metastatic tumor cells stained positively in 60/62 (96.8%) cases. Among spindle cell neoplasms, only 2/9 biphasic synovial sarcomas and 4/4 follicular dendritic cell sarcomas stained positively. Results indicate that CL-4 reacts with the majority of epithelial neoplasms that often metastasize to serous membranes, representing a pancarcinoma marker with extremely high sensitivity and specificity. CL-4 may be considered a primary immunohistochemical reagent to rule out the diagnosis of mesothelioma.

Introduction

Mesothelioma is a seemingly rare tumor, and its incidence has increased steadily and progressively over the last 30 years on a worldwide basis [31, 55]. Its recognition is important not only for medical but also for public health reasons in consideration of its relationship to exposure to environmental asbestos and asbestiform minerals [31]. Because mesothelioma can exhibit many histological patterns, its diagnosis and distinction from cancers that most commonly metastasize to serosal surfaces represents a challenging diagnostic problem in surgical pathology, leaving to immunohistochemistry the role of diagnostic discriminator [46, 73]. Unfortunately, despite the large number of studies devoted to the immunohistochemistry of mesothelioma and mimickers [19, 43, 46–49, 76], to date none of the markers used in routine practice is diriment in all the cases. Results obtained in different studies are

conflicting, pointing out how relevant might be the quality of the primary antibodies, the sensitivity of the techniques used for antigen retrieval and signal amplification, and the interpretation of the results [42, 58]. On the other hand, it should be noted that absolute positive and negative markers for mesothelioma are still lacking [73], and even those characterized by very high sensitivity and specificity do not have universal diagnostic usefulness, because they largely depend on individual conditions related to the site involved by tumors (pleural vs peritoneal) and the neoplasm that is primarily considered in the differential [4, 19, 43, 44, 46–48, 73, 76]; furthermore, the diagnostic value of some markers can also depend on the sort of specimens analyzed (histological *versus* cytological samples).

Recently, claudins have been shown to represent new interesting targets for cancer diagnosis [36]. Claudins comprise a multigene family consisting of more than 20 members believed to be major functional constituents of tight junctions [38]. They are present at epithelial and endothelial cell interfaces and contribute to mechanical adhesion, control the paracellular ion flux, maintain cell polarity, and by their capacity to recruit signaling proteins [34], they may regulate cell proliferation and differentiation [36].

The expression of claudins mRNA and protein vary within normal epithelia [9, 15, 17, 22, 40, 60, 62, 63] and is altered in several cancers [68, 69]. However, whereas some of these molecules such as claudin 1 and claudin 7 are downregulated in carcinomas [36], in keeping with the generally accepted idea that tumorigenesis is associated by a disruption of tight junctions, others especially claudin 4, are generally overexpressed during neoplastic transformation [11, 13, 15, 17, 26, 35, 37, 56, 64, 67–69]. Claudin 4, a major modulator of tight junctions [23], identifies neoplasms potentially metastasizing to serosal surfaces, while it is usually not expressed in nonepithelial tumors [68], as claudin 4 is negative in normal mesothelium [17, 63, 71, 77], we investigated its possible diagnostic usefulness in the differential diagnosis between mesothelioma and carcinomas, analyzing claudin 4 protein expression in a large series of histological and cytological samples. The results indicate that claudin 4 is expressed by the majority of epithelial neoplasms with capacity to metastasize to pleura and peritoneum, while is consistently negative in mesothelioma. Claudin 4 is a candidate to be included as a primary reagent in the panel of antibodies to assist the diagnosis of tumors involving serosal cavities.

Materials and methods

Tissue and effusion specimens

The material used in this study was obtained from the files of the Department of Pathology at the University of Brescia and at the Hospital of Mestre, and included histological and cytological samples (Tables 1, 2 and 3) submitted for diagnostic purposes; the study was performed in accordance with Hospital Institutional Ethical Board protocols.

Diagnoses of tissue specimens and site of biopsy are detailed in Tables 1 and 2. They included normal tissues associated with the tumors or removed for different diagnostic purposes (Table 1), as well as 454 neoplastic samples (Table 2). All diagnoses of mesothelioma were based on WHO criteria [74], and confirmed in all instances by clinical, morphological and immunohistochemical data. They included 79 mesotheliomas from the pleura and 3 from peritoneum. Similarly, diagnoses of nonmesothelioma cancers were unequivocal and established on morphological and phenotypical data, as well as on clinical histories. The majority of tissue samples consisted in whole biopsy or

surgical specimens, fixed in neutral formalin, and embedded in paraffin. In addition, tissue microarrays were constructed from representative areas of paraffin blocks obtained from different carcinomas, and assembled using a manual tissue-arraying instrument (Bio-Optica, Milan, Italy), sampling from each case two 2-mm-diameter tissue cores.

Effusions were submitted for routine diagnostic purposes, and samples were centrifuged, fixed in 95% ethanol, and stained with the Papanicolau or hematoxylin-eosin techniques. Diagnoses were established by morphological evaluation of smears, correlation with biopsy samples (if available), clinical information, and in appropriate cases, by the use of a panel of antibodies against carcinoma and mesothelioma antigens [52]. Diagnoses of cytological specimens are detailed in Table 3.

Immunostainings

On 30-μm-thick paraffin sections, endogenous peroxidase activity was blocked with 0.3% H_2O_2 in methanol for 20 min, and epitope retrieval was performed using a slide steamer (DAKO, Glostrup, Denmark, EU) in 1.0 mM ethylenediamine tetraacetic acid (EDTA) buffer (pH 8.0), for 40 min at 98°C. Upon washing in Tris-HCl buffer (pH 7.4–7.6), sections were incubated for 5 min in Tris-HCl buffer containing 5% normal goat serum, followed by mouse monoclonal antibody anti-claudin 4 (clone 3E2C1, Zymed, San Francisco, CA, USA), diluted 1:100, for 60 min. Sections were then washed in Tris-HCl buffer before incubation for 30 min with the antimouse, biotin-free, peroxidase-conjugated polymer ChemMate (DAKO). The reaction was developed using diaminobenzydine as chromogen, and sections were counterstained with hematoxylin. On cytological slides, after coverslip removal by immersion in xylene for 48 h, cells were rehydrated through a scale of alcohols and endogenous peroxidase activity blocked with 0.3% H_2O_2 in methanol for 20 min; cytoplasmic staining was then cleared using a lithium sutured solution in 70% ethanol, and epitope retrieval was obtained by microwave heating in 1.0 mM EDTA buffer (pH 8.0), for 3×5 min, at 750 W. Subsequently, the immunostain followed the same procedure as for tissue sections.

The specificity of the antibody was evaluated using known positive (normal bronchial epithelium) and negative (lymphocytes) controls. Furthermore, omission of the primary antibody was also used as negative control.

In the evaluation, membrane-bound reactivity was considered significant, and positive cases were defined when at least more than 10% of tumor cells were distinctly labeled. On occasion, benign and neoplastic cells of different origin (such

as endothelial cells, mesothelium, fibroblasts, smooth muscle cells) showed single or multiple positive intracytoplasmic dots: although we cannot rule out a binding to a cytosolic claudin 4-related epitope, this reactivity was considered nonspecific and excluded from the evaluation.

Statistic

Diagnostic sensitivity and specificity were calculated using the Bayesian statistical program at the Medical College of Wisconsin website http://www.intmed.mcw.edu/clincalc/bayes.html.

Results

Results on claudin 4 expression on tissue biopsies from normal tissues, pathological samples, and effusions are summarized in Tables 1, 2 and 3, respectively.

Normal tissues

Normal mesothelium was regularly negative for claudin 4. In the abdominal cavity, there is an abrupt transition from the intensely positive fallopian mucosa to the negative epithelium of ovarian surface and peritoneum (Fig. 1a,b). Among claudin 4-expressing cells, the vast majority were decorated along the entire cell membrane; however, in some epithelia such as lung alveoli (Fig. 1c), large pancreatic ducts, as well as endocrine cells of the pancreas and C cells in the thyroid, the reactivity was variable and frequently discontinuous; stomach mucosa showed only occasional positive cells at the base of fundal glands, but even minute foci of intestinal metaplasia were highlighted by strong reactivity for claudin 4. In the thymus, claudin 4 reactivity was restricted to medullary epithelial cells (not shown). Besides epithelia, claudin 4 was uniquely found in follicular dendritic cells of B follicles associated with some tumors. This finding was further supported by the demonstration of strong positivity of follicular dendritic cells occurring in reactive lymph nodes (Fig. 1d) and spleen, as well as in follicular B-cell lymphomas.

Reactive mesothelium and malignant mesothelioma

Similar to normal mesothelium, mesothelial cells, including those showing pronounced reactive features associated with metastases or overlying primary carcinomas, were also negative for claudin 4. No reactivity was also found in mesothelial cells occurring in inflammatory or metastatic effusions (Fig. 2a,e, and g).

All 82 tissue biopsies and 23 cytological samples from malignant mesothelioma resulted negative for claudin 4 (Fig. 2b,c, and d).

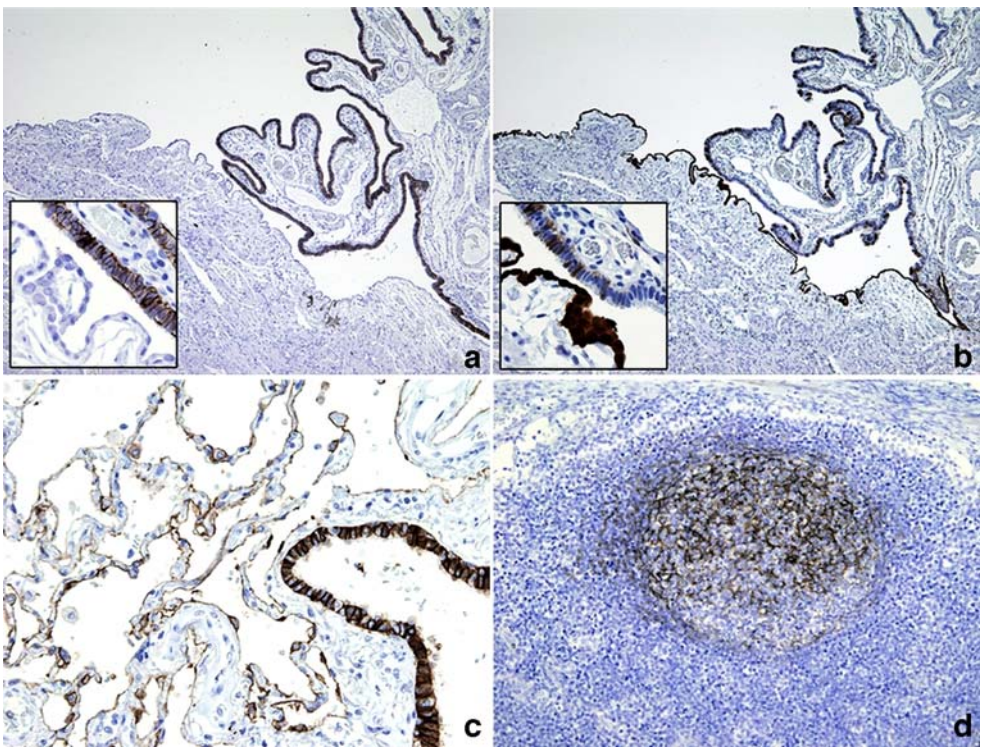

Fig. 1 Claudin 4 reactivity (**a**) compared to calretinin (**b**) in serial section form normal salpinx: note the abrupt transition from the tubal epithelium, strongly positive for claudin 4, to the negative mesothelial layer; in contrast, calretinin is expressed by mesothelium, as well as by scattered cells within the tubal epithelium. Details of claudin 4 and calretinin reactivity are illustrated in the insets. In lung parenchyma (**c**), reactivity for claudin 4 is shown by bronchial epithelium and, less intensely, by alveolar cells. Besides epithelia, claudin 4 is also expressed by follicular dendritic cells occurring in secondary B follicles (**d**). (Immunoperoxidase for claudin 4, counterstained with hematoxylin)

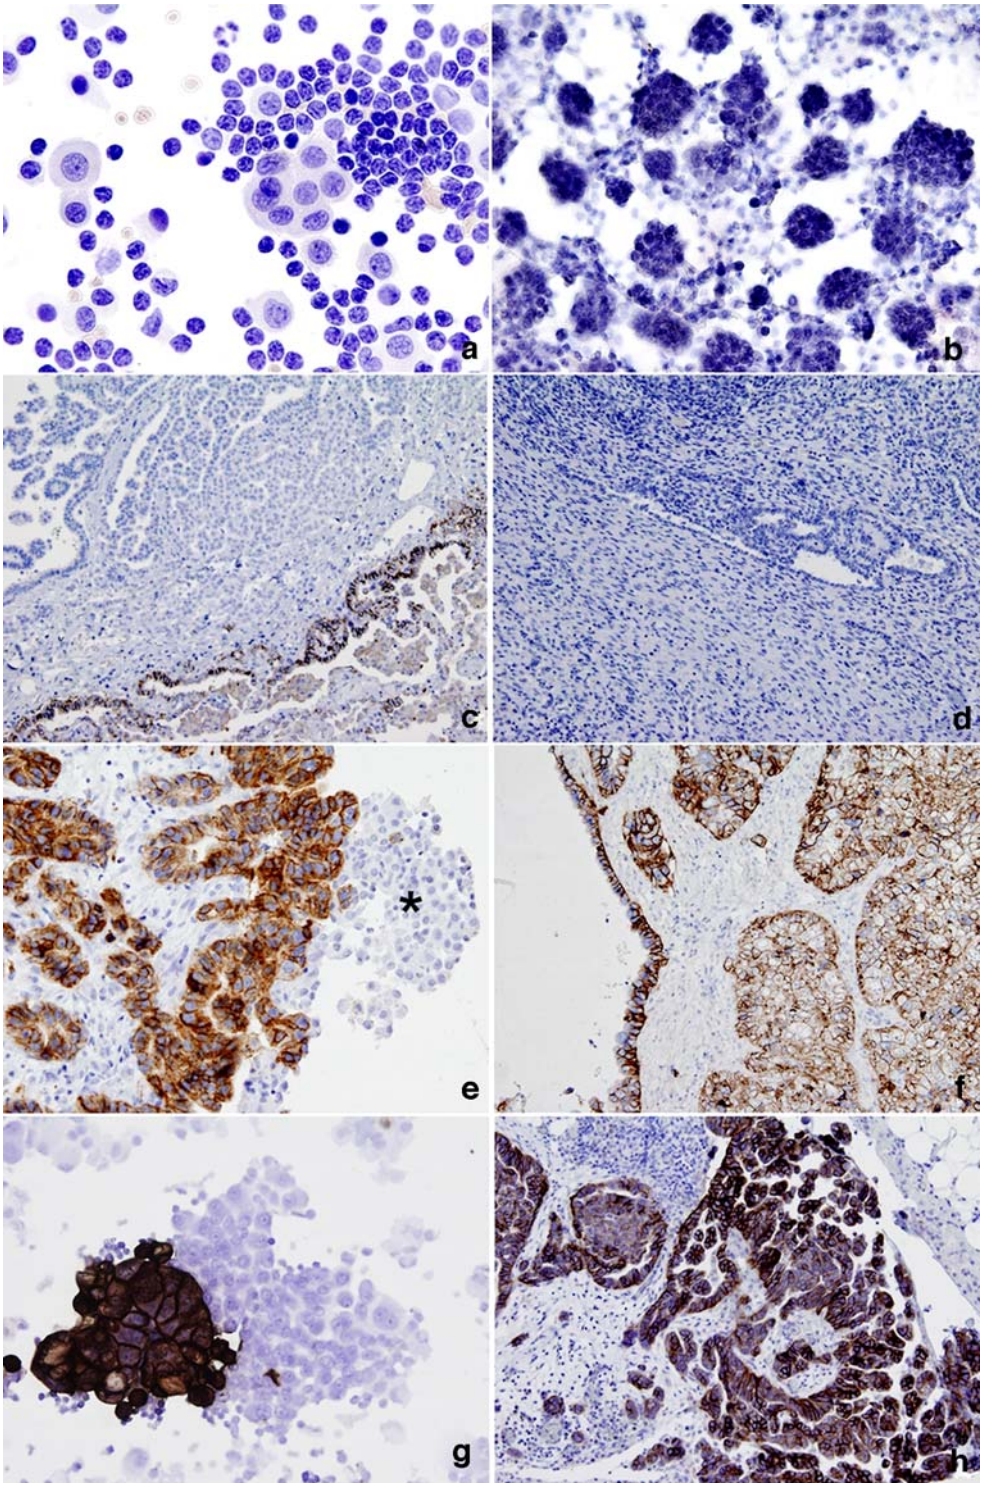

Fig. 2 Claudin 4 expression in mesothelial cells from inflammatory pleural effusion (**a**), mesothelioma (**b**–**d**), and neoplasms involving serous surfaces. Hyperplastic mesothelial cells occurring in a cell smear (**a**) do not express claudin 4. Representative examples of mesothelioma in a pleural effusion (**b**), and epithelioid (**c**) and biphasic (**d**) mesothelioma in pleural biopsies, all completely unreactive for claudin 4. Note the reactivity for claudin 4 on alveolar epithelium infiltrated by the tumor (**c**). Pleural metastases of adenocarcinoma originated from the stomach (**e**) and the lung (**f**) highlight the strong reactivity of tumor cells for claudin 4; positivity is also obvious in the malignant peritoneal effusion from an ovarian carcinoma (**g**). Note in **e** x(*asterisk*) and **g** aggregates of claudin 4-negative hyperplastic mesothelium. Strong and diffuse positivity is shown in a case of papillary serous carcinoma of peritoneum (**h**). (Immunoperoxidase for claudin 4, counterstained with hematoxylin)

Serosal metastases of carcinoma and primary serous papillary carcinoma of the peritoneum

Fifty-seven out of 58 (98.3%) biopsies from serosal metastases of different epithelial origin, as well as eight cases of primary serous papillary carcinoma of the peritoneum were found to express claudin 4 (Fig. 2e,f, and h). In all cases, positivity was strong and diffusely distributed along the cell membrane on most parts of the tumoral proliferation, including scattered neoplastic cells infiltrating the fibrous stroma. Pseudosarcomatous areas in two-pleural metastasis from lung carcinoma were also positive.

On effusions, 60 out of 62 (96.7%) cases originating from various epithelial neoplasms showed strong reactivity on all

tumor cells (Fig. 2g); the two negative samples were represented by a small-cell undifferentiated carcinoma of the ovary, hypercalcemic-type and by a case of hepatocarcinoma.

Primary extra-serosal tumors

Because antigenic properties may vary between primary and metastatic cancers, we extended the study to a series of epithelial neoplasms in their site of origin. Two hundred seventy primary carcinomas were analyzed; 237 (87.8%) resulted positive for claudin 4. It should be noted that positive cases included all epithelial neoplasms that are more frequently involved in the differential with mesothelioma, such as carcinomas of the lung (36 cases) and ovary (28 cases; Fig. 3a,b, and c). The positivity was membranous and occurred along the entire surface of the cells. In most of the samples the staining involved the whole tumor; however, in three cases of pulmonary squamous cell carcinoma, it was stronger at the outer part of large neoplastic aggregates, and in five carcinomas of the breast, positivity was variable throughout the tumor and occurred as both linear and multiple-dots reactivity along the plasma membrane. Because downregulation of claudin 4 expression has been previously recognized in diffuse-type of gastric carcinoma [57, 70], we studied 15 cases and found that the majority of them (12/15) were strongly positive in 50–100% of tumor cells; only a single case expressed claudin 4 in less than 50% of cells, and two cases were weakly positive in 5% of cells. Four cases of hepatocarcinoma and three of renal clear cell carcinoma contained between 20 and 50% of positive cells. We tabulated as negative those specimens with less than 10% of reactive cells, but only seminomas, adrenal carcinomas, and eight hepatocarcinomas completely lacked claudin 4 reactivity. Except for a single-type AB thymoma, which contained numerous positive cells within areas of glandular differen-

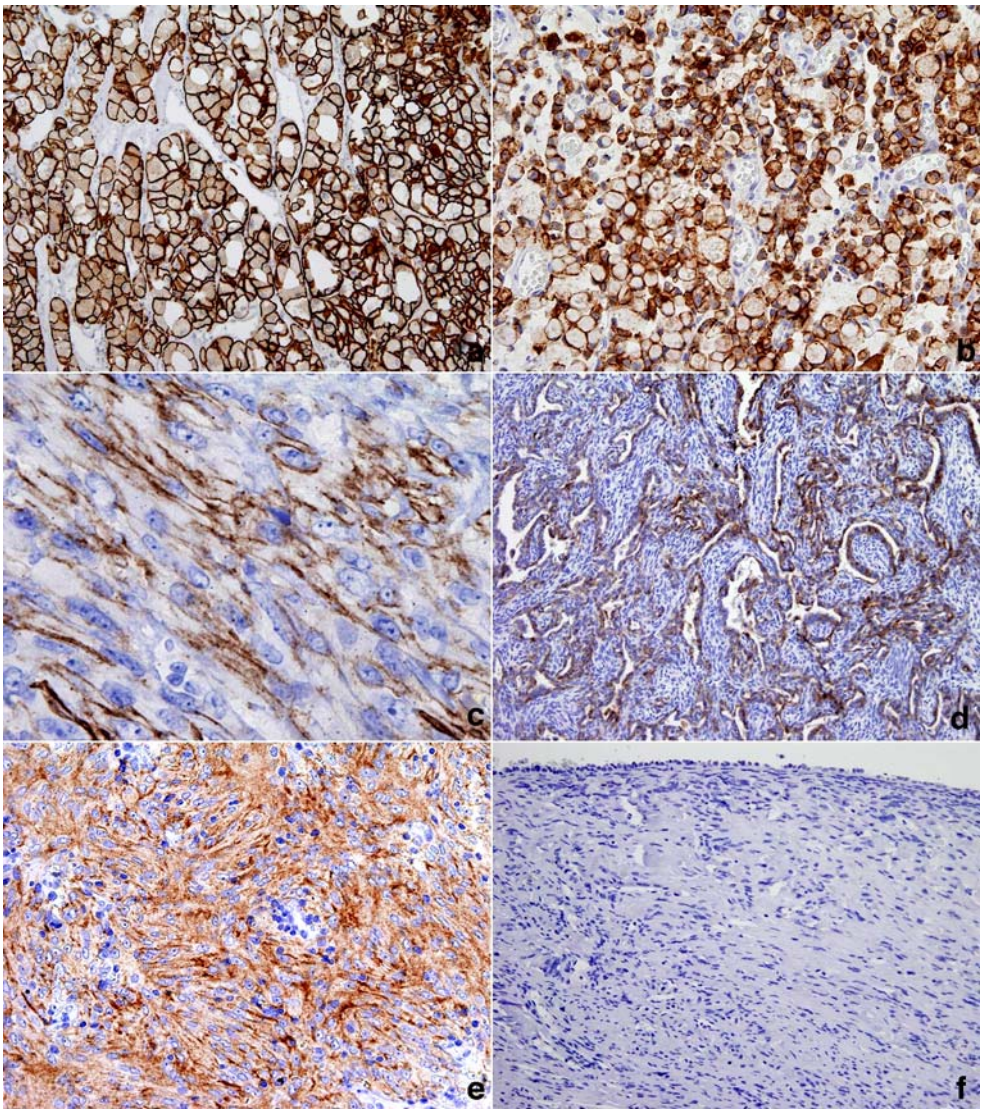

Fig. 3 Examples of primary epithelial (**a**–**c**) and mesenchymal neoplasms (**d**–**f**) stained for claudin 4 Homogeneously strong positivity is shown in a case of renal chromophobe carcinoma (**a**), and gastric carcinoma diffuse-type (**b**), while reactivity is more variable in a case of pseudosarcomatous carcinoma of the lung (**c**). Only the epithelial cell component in a biphasic synovial sarcoma (**d**) reacts for claudin 4, while the spindle cells are completely negative. In keeping with the reactivity of normal follicular dendritic cells, also neoplastic cells from a case of follicular dendritic cells sarcoma are strongly positive for claudin 4 (**e**). No reactivity is evident in a solitary fibrous tumor of the pleura (**f**). (Immunoperoxidase for claudin 4, counterstained with hematoxylin)

tiation, the other eight cases showed only focal scattered reactivity (data not shown). Six synovial sarcomas arising in the soft tissues were also analyzed, two of which revealed reactive cells, that were regularly restricted to areas of epithelial differentiation (Fig. 3d). Melanomas and gastrointestinal stromal tumors were regularly negative, while, in keeping with the reactivity on the normal cell counterpart, all four cases of follicular dendritic cell sarcoma (one spindle and three epithelioid cell-type) showed strong reactivity for claudin 4 (Fig. 3e).

Solitary fibrous tumor of the pleura, and other nonepithelial tumors involving the serous surfaces

Mesothelioma can be simulated histologically by spindle cell tumors, either arising in or metastatic to serosal surfaces, such as solitary fibrous tumor, synovial sarcoma and epithelioid angiosarcoma [4, 24, 29]. We therefore investigated eight cases of solitary fibrous tumor of the pleura (Fig. 3f), three cases of monophasic synovial sarcoma involving the pleura, four metastatic myogenic sarcomas, and a single epitheliod angiosarcoma, all of which lacked any reactivity for claudin 4.

Discussion

In the present study, we analyzed by immunohistochemistry the expression of the tight-junction-associated protein claudin 4 in a large series of normal and neoplastic tissues. Results show that all eighty-two cases of mesothelioma were negative, while strong reactivity was found in 57/58 serosal metastasis of carcinomas, and in 245/278 primary carcinomas of different origin, with uppermost expression (150/153) in those most frequently metastasizing to serosal surfaces or simulating mesothelioma (lung, breast, gastrointestinal tract, pancreas, ovary, and primary serous papillary carcinoma of the peritoneum). Taken together, these data indicate that claudin 4 represents a very robust pancarcinoma marker, with an extremely high sensitivity (90.0%) and specificity (100%) for distinction from mesothelioma.

These data are in keeping with the study by Davidson et al. [12], who demonstrated that claudin 4 gene expression is significantly lower in mesotheliomas compared with ovarian carcinomas; in contrast, Soini et al. [71] found claudin 4 positivity in 8 out of 35 (23%) mesotheliomas; because we used the same anti-claudin 4 primary antibody and similar antigen retrieval techniques, we cannot exclude that the discrepancy with the results of Soini et al. might depend on variability in the quality and preservation of the tissues.

Claudin 4 exhibits several advantages compared with other pancarcinoma markers qualified for optimal specificity and sensitivity (Table 4). Firstly, it was regularly negative in mesotheliomas, while cumulative data from several studies indicate that MOC-31 and carcinoembryonic antigen (CEA) label approximately 5–10% of mesotheliomas [19, 44, 46, 49], and even higher expression rates are reported for BG-8, B72.3, and Ber-EP4 [4, 46, 47, 73]. In addition, claudin 4 demonstrated to be of similar diagnostic usefulness in pleural and peritoneal pathology, because tumors most frequently implicated in the differential with mesothelioma in these locations (respectively, pulmonary carcinomas, and ovarian and peritoneal papillary serous carcinomas) [6, 7, 19, 43, 45, 47, 48, 76] were regularly positive. In contrast, sensitivity of other markers is known to greatly vary according to specific tumor subtypes: CEA is frequently expressed in adenocarcinoma derived from the lung, gastrointestinal tract, and breast but is mostly negative in the ovary and peritoneal serous papillary carcinoma [4, 47, 49]. Similarly, squamous cell carcinoma of the lung frequently lacks CD15 and B72.3 [48], and Ber-EP4 has been reported to be poorly expressed in peritoneal serous papillary carcinoma [4]. The strong and constant reactivity of claudin 4 on a wide range of epithelial neoplasms simplifies the choice of immunohistochemical

Table 4 Data from the literature [1, 5, 14, 19, 25, 27, 30, 39, 41–44, 46–50, 54, 68, 69, 71, 75, 76] on the percentage of reactivity of the most used pancarcinoma markers with mesothelioma and with carcinomas frequently involved in the differential diagnosis, compared with claudin 4 expression as found in the present and previous studies (between brackets)

	Ber-EP4	BG-8	B72.3	CEA[a]	CD15	MOC-31	Claudin 4
Epithelioid mesothelioma	0–88%	3–23%	0–48%	0–5%	0–32%	0–10%	0% (23%)
Lung adenocarcinoma	100%	89–100%	35–85%	25–100%	50–85%	90–100%	100% (100%)[b]
Lung squamous cell carcinoma	87%	80–83%	40–84%	77%	30%	97%	100% (100%)[b]
Ovary/peritoneum serous carcinoma	50–100%	73%	65–100%	0–8%	30–80%	98%	100% (100%)[c]
Kidney carcinoma	35–50%	0%	0%	0%	75–100%	50%	95.5% (50%)
Hepatocarcinoma	8–36%	n.a.	46%	0–11%	n.a.	87–93%	33.3% (0–10%)

[b] Results were not distinguished according to the histological subtype of lung carcinoma
[c] Data are related only to ovarian serous carcinoma.

reagents and avoids tailoring it to the specific circumstances of each case.

Renal carcinomas less commonly metastasize to serosal surfaces, but represent potential mimickers of mesothelioma [44, 46]. The expression of classical negative mesothelioma markers such as CD15, MOC-31 and Ber-EP4 is quite variable in these tumors, and largely depends on the histological subtype [44, 51]. Furthermore, Ordonez [44] found that epithelioid mesotheliomas can express renal carcinoma associated antigens, such as CD10 (38% of cases) and RCC-Ma (8%). In the present study, claudin 4 was positive in 22 out of 24 primary and metastatic renal cell carcinomas; the reactivity was independent from the histological subtype, indicating that this marker has a high negative (0.98) and positive (1.0) predictive value in the differential with mesothelioma.

The choice of immunohistochemical reagents for the diagnosis of sarcomatoid and desmoplastic mesothelioma is challenging, because these tumors frequently loose expression of some of the more common positive markers [73]. Moreover, several spindle cell neoplasms involving the serosal surfaces may mimic mesothelioma, both clinically and histologically [73]. Claudin 4 showed to be useful in the distinction of sarcomatoid mesothelioma from sarcomatoid carcinoma, whereas it was of no value for its differentiation from mesenchymal spindle cell neoplasms that more frequently occur in the pleura [4, 29, 73], as well as thymomas [73], thus confirming the limited role of immunohistochemistry in the differential diagnosis of sarcomatoid compared with epithelioid tumors occurring in serosal surfaces [29, 73]. Interestingly, among mesenchymal cells, claudin 4 showed selective expression on follicular dendritic cells and strongly stained four cases of follicular dendritic cell sarcoma. This observation is not unexpected, considering the presence of ultrastructural (such as desmosomes) and antigenic (epithelial membrane antigen, epidermal growth factor receptor, desmosome-associated proteins) features of epithelial cells in follicular dendritic cells [10, 72].

More than 80% of all mesothelioma patients develop a serous effusion at an early stage of the disease and cytological examination frequently represents the first diagnostic procedure. However, metastasis involving the serosal cavities are by far more frequent than mesothelioma, and the differential diagnosis between metastatic carcinoma and mesothelioma represents a common challenge on cytological specimens from body cavity fluids [53]. Similar to histological diagnosis, this process can be assisted by immunohistochemistry, but individual positive mesothelial markers have been found to be of lower diagnostic value compared to tissue biopsies, and the sensitivity of adenocarcinoma markers (such as CEA, Ber-EP4, MOC-31, and CD15) is extremely variable (43–96.6%) [2, 8, 28, 59, 65, 66]. In the present study, anti-claudin 4 antibody was successfully applied on Papanicolau or hematoxylin-eosin stained cytospins, and strongly labeled 60 out of 62 (96.8%) metastatic adenocarcinomas, while all 23 mesotheliomas and reactive mesothelium were regularly negative (specificity, 100%; sensitivity, 96.7%). The regular negativity for claudin 4 on reactive mesothelium is of particular relevance, considering the common quandary in cytopathology of distinguishing reactive mesothelial cells from metastasis [20, 52, 53].

In keeping with previous observations [11, 13, 15, 17, 26, 35, 37, 56, 64, 67–69], this study shows that claudin 4 is widely expressed in carcinomas from different origin, including those in which the normal epithelial counterpart lacks any significant reactivity, such as stomach, kidney, ovary, as well as endocrine tumors of pancreas and thyroid medullary carcinomas. Mechanisms responsible for the increase in claudin 4 expression in malignant epithelial neoplasms are unknown: epigenetic modifications of claudin 4 promoter occur in ovarian cancer cells [16] and lead to increase survival, motility, and invasion [3]; in contrast, claudin 4 reduces invasiveness of pancreatic tumor cells [33]. In the present study, claudin-4-negative epithelial neoplasms were related either to poor differentiation (such as bladder urothelial carcinoma), or to specific histological types (such as adrenal carcinoma, most germ cell tumors of the testis, thymoma and, as previously reported [25], hepatocarcinoma). These data support the hypothesis that functions of claudin 4 may be highly tissue specific and may depend on the exact molecular circuitry of the cells.

Finally, we cannot disregard the implication of claudin 4 reactivity in the treatment of neoplasms involving the serosal surfaces. Claudin 4 identifies the functional receptor of *Clostridium perfringens* enterotoxin (CPE) [18], and recent studies demonstrated that treatment of xenograft cancer cells with CPE induces necrosis in tumors expressing claudin 4 [21, 32, 61]. Despite the fact that claudin 4 expression in normal epithelia is a cause of concern towards the use of CPE for systemic cancer therapy [36], its absence on normal and hyperplastic mesothelium opens the possibility of intracavitary treatment with CPE or monoclonal antibodies of claudin 4-positive tumors.

In conclusion, data provided by this study indicate that claudin 4 is a pancarcinoma marker with a broad spectrum of reactivity, while it is regularly negative in normal and neoplastic mesothelium; due to its high specificity and sensitivity for carcinomas on both tissue biopsies and cell smears, claudin 4 appears to be an ideal single-shot marker to be applied in a wide range of circumstances to assist the immunohistochemical diagnosis of mesothelioma and mimickers. If claudin 4-targeting drugs will be delivered for humans, the immunohistochemical evaluation of protein expression will be also relevant for selection of patients eligible for treatment.

Abstract L-type amino acid transporter 1 (LAT1), a neutral amino acid transporter, requires covalent association with the heavy chain of 4F2 cell surface antigen (4F2hc) for its functional form. We investigated the importance of LAT1 and 4F2hc expressions to progression in upper urinary tract cancer. We examined their expressions and their relationships to clinicopathologic parameters and clinical outcome in 124 cases. Positive expressions of LAT1 (protein and messenger ribonucleic acid) and 4F2hc (protein) were recognized in 79.8, 89.5, and 87.9% of tumor samples, respectively. In tumor cells, LAT1 protein was detected either as nodular granules within the cytoplasm or diffusely within the cytoplasm and/or on plasma membrane. In the normal urothelium, its expression was detected as nodular granules within the cytoplasm. A correlation with stage was shown for LAT1 protein expression and for a cooperative expression of LAT1 protein with 4F2hc protein (active form of LAT1 protein). Further, in all tumors, a cooperative expression of LAT1 protein and 4F2hc protein was significantly correlated with both overall and disease-free survival rates in the univariate analysis but not in the multivariate analysis. In conclusion, the detection of the active form of LAT1 protein would appear to be of value in informing the risk of progression in transitional cell carcinoma of the upper urinary tract.

Introduction

Facilitated diffusion and active transport are responsible for the transport of substances such as glucose and amino acids, respectively. System L amino acid transport mediates the sodium-independent uptake of nonpolar branched-chain or aromatic neutral amino acids and is the major route by which mammalian cells take up nutritionally essential amino acids from extracellular fluids [2, 3,7, 8]. Indeed, system L amino acid transport plays a critical role in the absorption of amino acids by the intestine, kidney, and placenta. The genes encoding the proteins responsible for this type of transport have now been cloned, and the L-type amino acid transporter 1 (LAT1) was the first member of the system L amino acid transporter family to be identified [9, 15]. LAT1 requires covalent association with the heavy chain of 4F2 cell surface antigen (4F2hc) for its functional expression in the basolateral plasma membrane of epithelial

cells [29]. Previous studies have shown LAT1 to be highly expressed in proliferating tissues, many tumor cell lines, and primary human tumors but to be at barely detectable levels in adult tissues (except brain, ovary, and placenta), while 4F2hc is ubiquitous [2, 3, 7, 8, 10–13, 16, 23, 25–27, 30, 31, 34–36]. Furthermore, overexpression of LAT1 in hepatocytes has been found to enhance their growth [1], leading the authors of that paper to suggest that LAT1 may play an important role in cell growth. However, little is known about how the expression of LAT1 is related to clinicopathological findings or the prognosis of tumors. In transitional cell carcinoma of the upper urinary tract (TCC-UUT), no study has yet been made of the relationship between LAT1 protein expression and either tumor progression or prognosis.

In the present study, we examined the expressions of LAT1 protein and messenger ribonucleic acid (mRNA), 4F2hc protein, and proliferating cell nuclear antigen (PCNA) in 124 cases of TCC-UUT. Our goal was to evaluate the importance of LAT1 expression as a prognostic tool in TCC-UUT.

Materials and methods

The material used comprised 124 surgically resected specimens from patients with primary TCC-UUT. These specimens had been obtained at the Mutual Aid Associations' Hospital, Tachikawa, and National Defense Medical College Hospital, Tokorozawa, between 1970 and 1995. Histopathologic stage was determined according to the criteria proposed by the International Union Against Cancer [32]. Tumor cells were divided histopathologically into two grades using the criteria for urinary bladder tumors laid down by the Armed Forces Institute of Pathology [17].

Immunohistochemistry

We used the polymer-peroxidase method (EnVision+/HRP; Dako Cytomation, Denmark) on deparaffinized sections, employing mouse monoclonal antibodies against LAT1 (1:20; clone no. 4D9; Trans Genic, Kumamoto, Japan) and 4F2hc (1:200; polyclonal antibody; Trans Genic). For LAT1 expression, the sections received autoclave pretreatment with 0.05 M citrate buffer, pH 6.0, for 20 min before immunohistochemistry against the antibody. For the negative control, the incubation step with the primary antibody was omitted.

In situ hybridization

In situ hybridization was performed essentially as previously described [18]. Briefly, sections were treated with 0.2 N HCl for 20 min, then incubated in 2× sodium chloride–sodium citrate (SSC) for 10 min at 37°C, then incubated in 5 μg/ml proteinase K for 10 min at 37°C. Sections were subsequently postfixed in 4% paraformaldehyde for 5 min, then incubated in 0.1 mol/l triethanolamine buffer, pH 8.0, containing 0.25% (vol/vol) acetic anhydride for 10 min to prevent nonspecific binding because of oxidation of the tissue. Hybridization was carried out overnight at 42°C in 50% (vol/vol) deionized formamide, 5× Denhardt's solution, 5% (wt/vol) dextran sulfate, 2× SSC, 0.3 mg/ml salmon sperm deoxyribonucleic acid (DNA), 5 mM ethylenediamine tetraacetic acid (EDTA), and 10 ng/ml biotin-labeled probes. After performing a final stringent wash at 37°C for 20 min, hybridization was detected immunologically. The LAT1 complementary (cDNA) probe used was a 251-bp fragment (obtained from positions 918 to 1,168 in the cDNA of human LAT1) subcloned into the *Eco*RI site of a pGEM-T Easy Vector (Promega, Madison, WI). The antisense probe and the corresponding sense probe were labeled with biotin using SP6 and T7 polymerases, respectively, by means of an RNA-labeling kit (Roche Diagnostics GmbH, Mannheim, Germany).

Evaluation of immunohistochemistry and in situ hibridization

For the analysis of immunoreactivity and in situ hybridization, the extent of staining was scored as "–," indicating negative reaction of tumor cells, "±," less than or equal to 10% of tumor area stained, "+," 11 to 25% stained, "2+," 26 to 50% stained, or "3+," greater than or equal to 51% stained. The tumors in which stained tumor cells made up more than 25% of the tumor were graded as positive. The evaluation was performed twice by one investigator (Nakanishi) who was blind to both tumor stage and grade. PCNA was evaluated immunohistochemically; the technique used and the results obtained in these same patients have been reported elsewhere [24]. For the analysis of PCNA, the percentage of nuclei exhibiting a positive immunoreaction (PCNA index) was determined (on the basis of the immunoreaction in at least 1,000 tumor cells) as previously described [24]. The PCNA index was classified as high if it was greater than or equal to 70.0%, a figure representing the median value for the carcinomas.

Western blotting analysis

For Western blotting analysis, tissue samples were homogenized using a polytron homogenizer (Kinematica AG, Lucerne, Switzerland) for 1 min, then sonicated (UD200; Tomy Seiko, Tokyo, Japan) for 1 min in 500 μl of an ice-

cold homogenizing buffer of the following composition: 20 mM Tris/HCl, pH 7.4, containing 250 mM sucrose, 2 mM EDTA, and protease inhibitor cocktail (Complete Mini, Roche Diagnostics GmbH, Roche Applied Science, Penzberg, Germany). An 800-g crude particulate fraction was discarded, and the supernatant was centrifuged at 100,000×*g* for 60 min at 4°C. The resulting pellet constituted the membrane–particulate fraction, while the supernatant was the cytosolic fraction. The particulate fraction was resuspended in homogenizing buffer containing 0.5% Triton X-100, then centrifuged at 100,000×*g* for 60 min, and the resulting detergent-treated supernatant was the membrane fraction. The protein concentration of each sample was determined by means of a BC protein assay system (Bio-Rad Laboratories, CA). Then, 25 μg amounts of protein extracts, in the absence (nonreducing condition) of 2-mercaptoethanol, were separated by 7.5% sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred to polyvinylidene difluroride membranes (Hybond-N+; Amersham Pharmacia Biotech, Buckinghamshire, England). Membranes were blocked with 5% nonfat dry milk for 60 min at room temperature, then incubated overnight at 4°C with LAT1 antibody (clone no. 4D9; Trans Genic) diluted at 1:20. Finally, after blots had been incubated for 1 h with horseradish peroxidase-conjugated secondary antibodies, they were visualized by enhanced chemiluminescence (Amersham Life Science, Arlington Heights, IL).

Statistical analysis

For statistical analysis, disease-free and overall survival rates were the two main dependent variables tested in this study. "Disease-free survival" was defined as the period between the initial radical operation and the subsequent appearance of recurrence or metastasis. Recurrence was defined as TCC occurring anywhere in the genitourinary tract. The end-point was either recurrence/metastasis of TCC or the closing date of the study, whichever came first. "Overall survival" was defined as the interval between surgery and death; the end point for this variable was either death or the closing date of the study.

Disease-free and overall survival curves for all of the univariate analyses were assessed using the Kaplan–Meier method. Comparisons between two or more survival curves were assessed using Wilcoxon and log-rank tests. Multivariate analysis of the clinicopathologic parameters was performed using the Cox stepwise-regression model. The above analyses were performed using the SAS statistical software package (SAS Institute, Carey, NC) [28]. The comparison in respect of stage in all tumors was performed using the Kruskal–Wallis test. Comparisons in respect of age, sex, grade, pattern of growth, and PCNA index were performed using the Chi-squared analysis.

Results

Clinicopathological findings

The patients' age at diagnosis was within the range of 34 to 84 years, with a median age of 67 years. Twenty-nine of the 124 patients died as a result of their tumors 2 to 132 months after surgery (mean, 24 months; median, 15 months). The remainder survived 0 to 257 months after surgery (mean, 69 months; median 63 months). Among the 124 cases, 53 tumors (42.7%) were in the renal pelvis or calyces, 47 (37.9%) were in the ureter, and 24 (19.4%) were multicentric. Ten patients had simultaneous bladder tumors at the time of diagnosis, 27 had subsequent bladder tumors, and six had an antecedent bladder tumor. In all, 41 (33.0%) patients had an associated bladder neoplasm; of these, six had such a neoplasm at more than one of the above times and thus appear in more than one group. The initial management of the 118 patients who were not treated as having bladder cancer included complete nephroureterectomy with a bladder cuff (88 patients), nephroureterectomy without a bladder cuff (eight patients), nephroureterectomy with total cystectomy (ten patients), and nephrectomy (12 patients). Thirty-two patients received adjacent chemotherapy (21 patients), radiotherapy (seven patients), or both (four patients), in addition to surgery.

The tumors were divided into three groups (A, B, and C) on the basis of tumor stage. There were 47 cases (37.9%) in group A (papillary, noninvasive tumors, pTa), 20 cases (16.1%) in group B (tumors invading the submucosa or muscularis, pT1 and pT2), and 57 cases (46.0%) in group C (tumors invading beyond the muscularis or renal parenchyma or metastasizing the regional lymph node or a distant site, pT3 and pT4). Ten of the 47 patients in group A showed recurrence (seven patients), metastasis (one patient), or both (two patients), but 37 developed neither recurrence nor metastasis within the follow-up period. The mean follow-up for patients with a noninvasive tumor who had a recurrence and/or metastasis was 67 months (median, 48; range, 14 to 124), whereas the mean follow-up for those without recurrence or metastasis was 81 months (median, 86; range, 4 to 203). Of the 20 patients in group B, seven showed either recurrence (four patients) or recurrence with metastasis (three patients), but the remaining 13 developed neither recurrence nor metastasis within the follow-up period. The mean follow-up for group B patients who showed recurrence and/or metastasis was 69 months (median, 66; range, 9 to 175), whereas the mean follow-up for those without recurrence or metastasis was 86 months (median, 33; range, 0 to 257). Of the 57 patients in group C, five either had metastasis at surgery, or the tumor could not be excised totally by surgery. In this group, a total of 33 showed recurrence, metastasis, or both (5, 18, and 10

patients, respectively), but the remaining 24 developed neither recurrence nor metastasis within the follow-up period. The mean follow-up for group C patients who showed recurrence and/or metastasis was 28 months (median, 15; range, 2 to 167), whereas the mean follow-up for those without recurrence or metastasis was 44 months (median, 41; range, 4 to 119).

At the time of diagnosis, tumors were in low grade in 76 of the patients (61.3%) and high grade in 48 (38.7%). Inspection of the pattern of growth of the tumors revealed that 88 cases (71.0%) showed a papillary pattern and 36 cases (29.0%) a nonpapillary pattern (solid tumor). Of the 29 patients who died of their tumors, 11 (37.9%) had a tumor in the renal pelvis or calyces, 13 (44.9%) in the ureter, and five (17.2%) had multicentric tumors. Twelve of the 29 (41.3%) who died had an associated bladder neoplasm. Of these 29, two were in group A, three in group B, and 24 in group C.

Immunohistochemistry and Western blot analysis for LAT1 protein

A positive expression of LAT1 protein was recognized in 99 (79.8%) of the samples. Cells either expressed nodular granules within the cytoplasm (Fig. 1a), or exhibited a diffuse expression within the cytoplasm (Fig. 1b and/or on the plasma membrane, Fig. 1c). Expression of LAT1 protein diffusely within the cytoplasm and/or on the plasma membrane was recognized in 59 of the 99 LAT1 protein-positive samples. In the normal urothelium, its expression was detected as nodular granules within the cytoplasm (Fig. 1d). In our Western blotting analysis, conducted in the absence (nonreducing condition) of 2-mercaptoethanol, LAT1 protein was detected as one band of 125 kDa in the cytoplasm or membrane of both normal pelvic mucosal tissue and tumor tissues (Fig. 2). In normal pelvic mucosal tissues and in the illustrated TCC case 1—in which LAT1 protein was detected as nodular granules within the cytoplasm using immunohistochemistry—LAT1 protein was revealed more strongly in the cytoplasmic extraction than in the membrane extraction. In TCC case 2—in which diffuse cytoplasmic staining and plasma membrane staining was revealed by immunohistochemistry—LAT1 protein was seen as a distinct band for both the membrane extraction and the cytoplasmic extraction.

A positive expression of PCNA was recognized in all tumors, the immunoreactivity being confined to tumor cell nuclei. The PCNA index was within the range of 7.4 to 93.0% (mean and median values, 66.7 and 69.9%, respectively).

In our assessment of whether LAT1 protein expression was related to PCNA index or clinicopathologic findings, a LAT1 protein-positive expression was found to be associated with sex (p=0.018) and stage (p=0.014; Table 1). However, a LAT1 protein-positive expression was not associated with the PCNA index. When LAT1 protein expression was assessed separately for noninvasive and invasive tumors, a significant correlation with a LAT1 protein-positive expression was found for sex (p=0.029) in

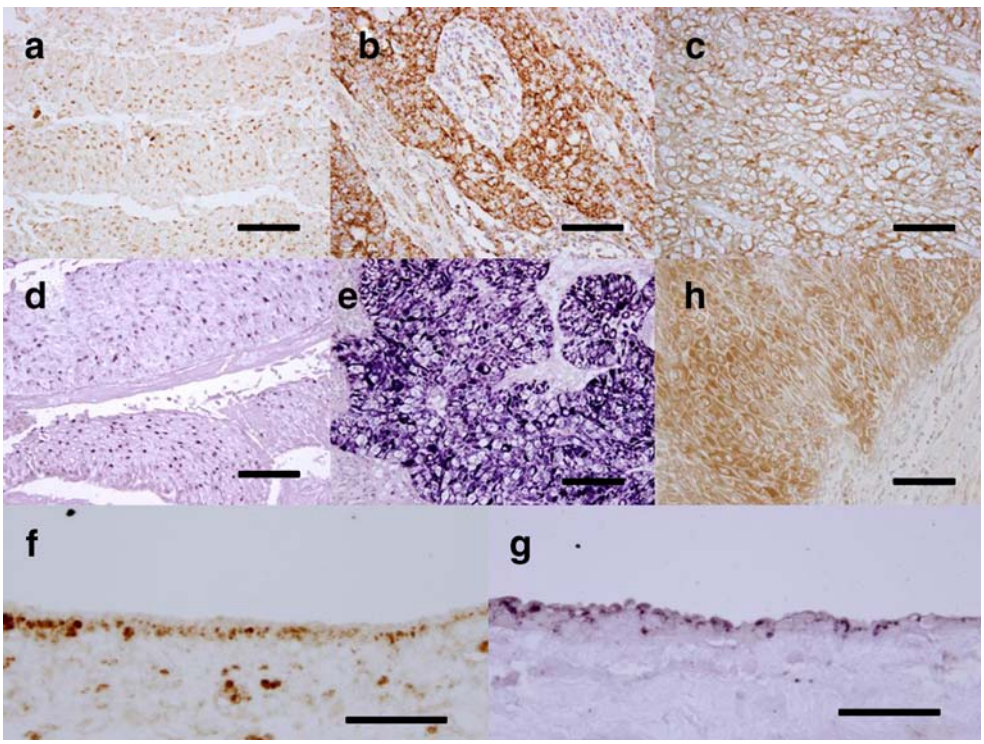

Fig. 1 Expressions of LAT1 (**a**, **b**, **c**, **d**, protein; **e**, mRNA) and 4F2hc (**h**, protein) in normal pelvic mucosa (**d**) and transitional cell carcinoma of the upper urinary tract (**a**, **b**, **c**, **e**, **f**). In the case of LAT1 protein, tumor cells displayed nodular granules within the cytoplasm (**a**) or a diffuse expression within the cytoplasm (**b**) and/or on the plasma membrane (**c**). LAT1 mRNA was displayed by tumor cells within the cytoplasm (**e**). In the normal pelvic mucosa, LAT1 protein was detected as nodular granules within the cytoplasm (**d**). 4F2hc protein was displayed by tumor cells within the cytoplasm (**f**). *Scale bar*=100 μm

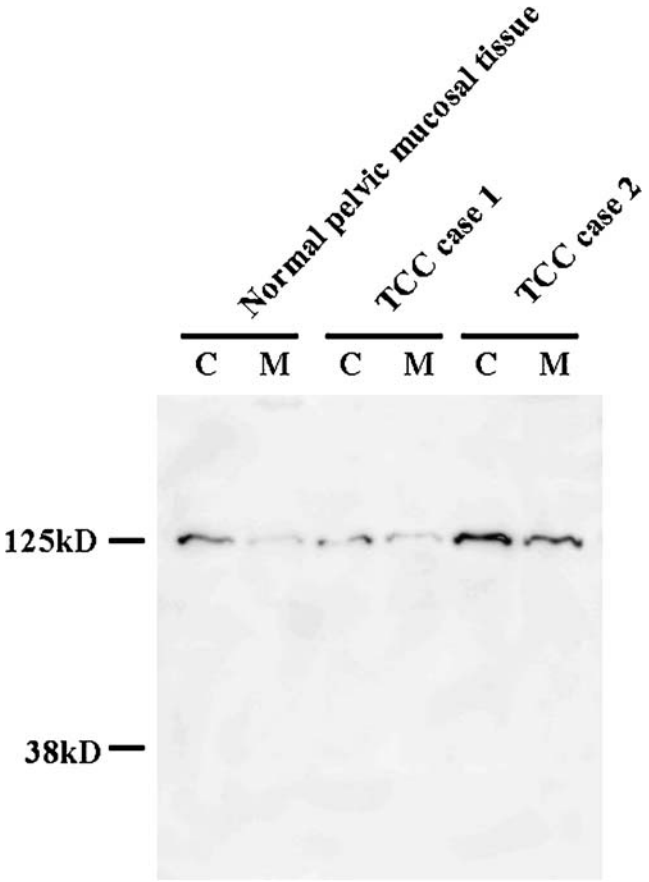

Fig. 2 Western blot analysis performed in the absence (nonreducing condition) of 2-mercaptoethanol for LAT1 in normal pelvic tissue and transitional cell carcinomas (*TCC*). LAT1 protein was detected as one band of 125 kDa in the cytoplasmic extraction (*C*) or in the membrane extraction (*M*) of all three tissues. TCC case 1 displayed nodular granules within the cytoplasm, whereas TCC case 2 displayed diffuse cytoplasmic staining and membrane staining (using immunohistochemistry)

the case of noninvasive tumors and for stage (p=0.019) in invasive tumors (Tables 2, 3).

In situ hybridization for LAT1 mRNA

By in situ hybridization, LAT1 mRNA was detected within the cytoplasm of tumor cells (Fig. 1d). A positive expression of LAT1 mRNA was recognized in 111 (89.5%) of all samples. In the normal urothelium, a moderate expression was detected within the cytoplasm. In our assessment of whether LAT1 mRNA expression was related to PCNA index or clinicopathologic findings in all cases, noninvasive cases, and invasive cases, no significant correlations were found with a LAT1 mRNA-positive expression (Tables 1–3).

Immunohistochemistry for 4F2hc protein

A positive expression of 4F2hc protein was recognized in 109 (87.9%) of samples. The expression of this protein was confined to the cytoplasm of both tumor cells and normal urothelial cells (Fig. 1f). In our assessments of whether 4F2hc protein expression was related to PCNA index or clinicopathologic findings in all cases, noninvasive cases, and invasive cases, no associations were found with 4F2hc protein-positive expression except that it was associated with age (p=0.039) in all cases and with sex (p=0.029) in noninvasive cases (Tables 1–3).

Relationship between LAT1 (protein and mRNA) expression and 4F2hc protein expression

This relationship was examined because it is well known that LAT1 requires 4F2hc for its functional expression. A cooperative expression of LAT1 protein with 4F2hc protein ("LAT1 protein with 4F2hc") was recognized in 89 (71.7%) of all samples. In our assessment of whether simultaneous expression of LAT1 and 4F2hc proteins was related to the PCNA index or clinicopathologic findings, "LAT1 protein with 4F2hc" was found to be associated with sex (p=0.016) and stage (p=0.0013; Table 1). When a cooperative expression of LAT1 and 4F2hc proteins was assessed separately for noninvasive and invasive tumors, a significant correlation with "LAT1 protein with 4F2hc" was found for sex (p=0.033) in noninvasive tumors and for stage (p=0.0071) in invasive tumors (Tables 2, 3).

Cooperative expressions of LAT1 mRNA with 4F2hc protein ("LAT1 mRNA with 4F2hc") was recognized in 99 (79.8%) of the samples. In our assessment of whether cooperative expressions of LAT1 mRNA and 4F2hc protein were related to the PCNA index or clinicopathologic findings, "LAT1 mRNA with 4F2hc" was found to be associated with age (p=0.028; Table 1). When a cooperative expression of LAT1 mRNA and 4F2hc protein was assessed separately for noninvasive and invasive tumors, a significant correlation with "LAT1 mRNA with 4F2hc" was found for age (p=0.016) in noninvasive tumors (Tables 2, 3).

Distant-metastasis-free interval and overall survival rates

Our assessments of distant-metastasis-free interval and overall survival revealed rates for a 5-year disease-free survival and a 5-year overall survival of 60.2 and 73.3%, respectively. In the assessment of disease-free survival, 119 patients who had no metastasis at surgery and in whom the malignant tumor was excised totally by surgery were included in the analysis.In the assessment of overall survival, all 124 patients were included in the analysis. Univariate analyses of disease-free and overall survivals in all patients revealed that "LAT1 protein with 4F2hc," PCNA index, stage, grade, and pattern of growth each had a significant effect on both of the two survival rates in all tumors (Table 4, Fig. 3). In patients with invasive

The tumors were divided into three groups on the basis of tumor stage (A, papillary, noninvasive tumors, pTa; B, tumors invading the submucosa or muscularis, pT1 and pT2; and C, tumors invading beyond the muscularis or renal parenchyma or metastasizing the regional lymph node or a distant site, pT3 and pT4).

[a] Comparisons (for all except stage) were performed using the Chi-squared analysis. The comparison in respect of stage in all tumors was performed using the Kruskal–Wallis test.

tumors, stage had a significant effect on overall survival rate.

In the final models of the multivariate analysis for all tumors, stage was shown to be a prognostic factor for disease-free and overall survivals (for disease-free survival, the value obtained for risk ratio was 8.11 [$p<0.0001$], while for overall survival, it was 7.60 [$p<0.0001$]).

Discussion

In urothelial carcinoma, differences in the anatomy of tumors are associated with differences in survival. Although prognostic significance has been established for both stage and grade [4, 6], it is important to identify prognostic markers that will predict which patients are likely to experience disease progression. Several markers, including epithelial growth factor receptor, p53, E-cadherin, and HIF-1α, are known to be associated with progression and prognosis in TCC-UUT [18–22]. The purpose of our investigation was to look for possible relations between LAT1 (protein and mRNA) expression and PCNA index, clinicopathologic findings, or clinical outcome in TCC-UUT. Our analysis revealed that a LAT1 protein-positive expression was significantly associated with stage in all TCC-UUT cases. When the relationship between LAT1 and 4F2hc was examined (because LAT1 requires 4F2hc for its functional expression), a cooperative expression of LAT1 protein with 4F2hc protein ("LAT1 protein with 4F2hc") was found to be more strongly associated with stage than suggested by a simpler analysis. Further, in all tumors, significant correlations were found between "LAT1 protein with 4F2hc" and both overall and disease-free survival rates in the univariate analysis. Although the expression of the active form of LAT1 protein (cooperative expression of LAT1 protein with 4F2hc protein) was not found to be associated with prognosis in the multivariate analysis, the detection of the active form of LAT1 protein would appear to be of value as a prognostic tool in TCC-UUT.

It has previously been reported that LAT1 is expressed in some normal tissues, including the blood–brain barrier, activated lymphocytes, the basal layer of the skin, the

proximal tubules of the kidney, the placenta, and testis, and also in a variety of tumor cell lines such as hepatoma, leukemia, breast cancer, oral squamous cell carcinoma, bladder carcinoma, and glioma [10–13, 16, 23, 25–27, 29–31, 34–36]. In normal urothelial cells, we found, using immunohistochemistry, that LAT1 protein was expressed within the cytoplasm as nodular granules, an observation indicating nonfunctionality because of their absence from the plasma membrane. In contrast, LAT1 protein was detected in the plasma membrane (which contains the sites of action for LAT1 protein) in about half of the tumor cells. Furthermore, our Western blot analysis revealed that (a) in the normal pelvic mucosal tissues and in a TCC case in which nodular granules were observed by immunohistochemistry, the LAT1 protein expression was stronger in the cytoplasmic extraction than in the membrane extraction, while (b) in a TCC case in which diffuse LAT1 expression was detected in both the cytoplasm and the plasma membrane by immunohistochemistry, a distinct band for this protein was seen in the membrane extraction as well as in the cytoplasmic extraction. Thus, LAT1 protein localized to its sites of action in cells may be present at significantly higher levels in tumors than in normal urothelial tissues.

In an in vitro study, Campbell and Thompson [1]—who transiently overexpressed LAT1 and 4F2hc (either alone or together) in nontransformed mouse hepatocytes—demonstrated (a) that overexpression of LAT1 alone was sufficient to increase system L transport activity significantly in these hepatocytes and (b) that hepatic cells overexpressing LAT1 displayed a growth advantage relative to control cells under conditions involving limited arginine. They therefore proposed that cells in which LAT1 is not normally expressed, such as hepatocytes, may acquire a growth advantage if LAT1 becomes constitutively expressed at some stage. After an examination of human materials, Kim et al. [10]—who looked for expressions of LAT1 and 4F2hc proteins in oral normal mucosa, oral precancerous lesions, and oral squamous cell carcinomas using immunohistochemistry—reported that LAT1 and 4F2hc protein expressions increased progressively from normal mucosa to dysplasia and carcinoma. More recently, we demonstrated (a) that the incidence of positive expressions for LAT1

The tumors were divided into three groups on the basis of tumor stage (A, papillary, noninvasive tumors, pTa; B, tumors invading the submucosa or muscularis, pT1 and pT2; and C, tumors invading beyond the muscularis or renal parenchyma or metastasizing the regional lymph node or a distant site, pT3 and pT4).

[a] Comparisons (for all except stage) were performed using the Chi-squared analysis. The comparison in respect of stage in all tumors was performed using the Kruskal–Wallis test.

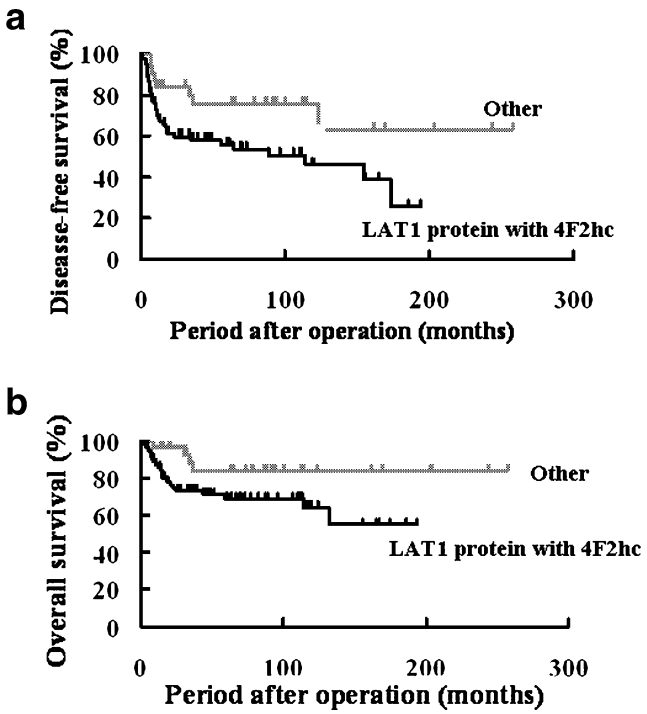

Fig. 3 Disease-free and overall survival curves for all patients with transitional cell carcinoma (subdivided according to presence or absence of cooperative expression of LAT1 protein with 4F2hc protein ["LAT1 protein with 4F2hc"]). **a** Disease-free survival curve for patients displaying LAT1 protein with 4F2hc (n=85) or other expressions (n=34). **b** Overall survival curve for patients displaying LAT1 protein with 4F2hc (n=89) or other expressions (n=35)

protein and LAT1 mRNA increased or tended to increase from low-grade atypical adenomatous hyperplasia (AAH, a precancerous lesion of the lung) through high-grade AAH to early adenocarcinoma of the lung (using immunohistochemistry and in situ hybridization) and also (b) that the labeling index calculated using Ki-67 antibody (which was detected in all stages of the cell cycle except for the G0 period) was significantly higher in LAT1 protein-positive AAH and early adenocarcinoma than in their LAT1 protein-negative counterparts [23]. Furthermore, Kobayashi et al. [13], who examined esophageal carcinoma using immunohistochemistry, reported that LAT1 expression increased as the depth of invasion and the tumor size increased. On the basis of the above evidence, LAT1 has been concluded to be associated with tumor growth, proliferation, and aggressiveness [10, 13, 23]. In TCC cases, to our knowledge, no previous report dealing with LAT1 and 4F2hc has been published. In our immunohistochemical and in situ hybridization examinations, LAT1 protein-positive expression was significantly associated with stage in all cases, indicating an association with the aggressiveness of the tumors. Thus, our findings support the above idea of a relationship between LAT1 and tumor growth and aggressiveness. In our study, however, we failed to find an association between LAT1 expression and PCNA index (cell proliferation index). A similar lack of association (between LAT1 expression and tumor mitosis) was noted in a previous study of colon carcinoma [10]. We are not entirely surprised at this lack of a direct correlation between LAT1 expression and PCNA index because of the diversity of the other biological factors involved in the promotion of cell proliferation.

Concerning tumor prognosis, to our knowledge, no report dealing with LAT1 and 4F2hc has been published. When a tumor exhibits enhanced uptake and transport of amino acids into select metabolic pathways, including those involving LAT1, it would be expected to benefit from the metabolic and regulatory effects of those amino acids and to experience an accelerated rate of growth. Although in our multivariate analysis for all tumors, we failed to find a relationship between LAT1 expression and either disease-free or overall survival rates, significant correlations were found between "LAT1 protein with 4F2hc" and both overall and disease-free survival rates for all tumors in the univariate analysis. On that basis, the expression of LAT1 protein with 4F2hc (that is, the active form of LAT1 protein) may be expected to be one of the tools that can be used to evaluate the prognosis in TCC-UUT. However, this may not result in a direct association being found between LAT1 expression, for example, and prognosis. Therefore, future studies should attempt to elucidate the relationships between such expression(s) and clinicopathologic findings or clinical outcome in several tumors.

In conclusion, the detection of the active form of LAT1 protein (a cooperative expression of LAT1 protein with 4F2hc protein) would appear to be of value as a prognostic tool in TCC-UUT. In the last few years, several investigators have demonstrated that the expressions of ASCT2 and other neutral amino acid transporters are coordinately elevated in a wide spectrum of primary cancers [5, 14, 33]. The suggestion is that these transporters support the "tumor metabolome." Therefore, future studies should examine other neutral amino acid transporters and seek to elucidate the relationship between their expressions and clinicopathologic findings or clinical outcome in TCC-UUT.

Abstract Dedifferentiated chondrosarcoma is a rare, highly malignant variant of chondrosarcoma in which a high-grade sarcoma coexists with a low-grade chondroid tumor. We herein review a case of dedifferentiated chondrosarcoma with an osteosarcoma omit component that occurred in the distal femur of a 38-year-old man. We established the cell line (NDCS-1) from a pleural effusion of the metastatic lung tumor. The cell line was characterized by a the G-banded karyotype, polymerase chain reaction (PCR) single-strand conformation polymorphism analysis, spectral karyotyping, and reverse transcriptase PCR (RT-PCR). The tumor exhibited complex karyotypes and a high frequency of chromosomal amplication with p53 mutation. This tumor revealed an osteoblastic and chondroblastic character in vitro and in severe combined immunodeficiency mice. The expression and phosphorylation of platelet-derived growth factor receptor-β, which seemed to play a major role in the malignant phenotype of chondrosarcoma, was confirmed by RT-PCR and Western blotting. To our knowledge, this is the first report of the establishment of a human dedifferentiated chondrosarcoma.

Introduction

Dedifferentiated chondrosarcoma was first proposed in 1971 by Dahlin and Beabout. They described a high-grade nonhchondroid sarcoma, such as osteosarcoma, rhabdomyosarcoma, fibrosarcoma, and malignant fibrous histiocytoma (MFH), arising within a pre-existing low-grade chondrosarcoma. Dedifferentiated chondrosarcoma is rare variant, accounting for about 10% of all chondrosarcomas. The importance of recognizing this dedifferentiated neoplasm relates its locally aggressive behavior, frequency of recurrence, and ultimately its poor prognosis [10, 14, 15]. Many analyses of dedifferentiated chondrosarcoma are available at the clinico-pathological level, but only few molecular studies have so far been published, and the cell biology of this neoplasm is still not clearly understood. To our knowledge, there has not been any report describing the establishment of cell lines of dedifferentiated chondrosarcoma. We have established this cell line, NDCS-1, derived from a pleural effusion of a metastatic lung tumor that may serve as a useful in vitro and in vivo model for study of the molecular pathogenesis of dedifferentiated chondrosarcoma.

Materials and methods

Source of tumor cells

A 38-year-old man was founded to have a bone tumor on the left distal femur (Fig. 1a, b). The patient underwent wide excision. Histopathological diagnosis was grade I chondrosarcoma. Five years after the surgery, the tumor recurred, and open biopsy revealed it to be dedifferentiated to osteosarcoma (Fig. 1c, d). He was operated on with an above-knee amputation.

The tissue specimen was examined histopathologically. The patient did not react to chemotherapy with cisplatinum, ifosmfamide, and methotrexate and died of lung metastasis after 7 months after the above-knee amputation.

Establishment of cell line

A sample from the pleural effusion of the lung metastasis was seeded in dishes, containing Roswell Park Memorial Institute Tissue Culture Medium (RPMI) 1640 supplemented with 10% heat-inactive fetal bovine serum and 300 mg kanamycin sulfate (Wako Tokyo, Japan). These were maintained in a humidified atmosphere of 5% CO_2 in air at 37°C.

Fig. 1 **a** Plain radiograph of the distal femur at the first operation. The lateral rentogenogram showing a periosteum elevation. **b** MR imaging showing a bone periosteal tumor of the distal femur. **c**, **d** The *arrows* pointed at the recurrent tumor. The tumor invaded the intramedullary space. A sagittal MRI demonstrated the tumor to have spread to the soft tissue and the borders of the tumor were indistinct

Histological examination of the xenografted tumor

Seven-week-old mice with severe combined immunodeficiency (SCID; Icr/SCID purchased from Nihon Clea, Tokyo, Japan) were used. The tumor cells (1×10^{7} cells suspended in 0.2 ml RPIM; the passage number was 20) were subcutaneously implanted into the mice. Three months after the tumor cell inoculation, the mice were killed, and a specimen was obtained. We stained 4-μm-thick sections of the specimen with routine hematoxylin–eosin staining and analyzed with p53 (DO7; DAKO, Japan), platelet-derived growth factor receptor (PDGFR; Lab Vision, CA, USA), and Ki-67(MIB-1; IMMUNOTECH, France) immunohistochemical staining.

Cytogenetic analysis

The Standard trypsin–Giemsa banding technique [51] was performed for cells obtained after 20 passages, and additional slides were made for spectral karyotyping analysis, according to the manufacturer's protocol (Applied Spectral Imaging, Migdal Ha'Emek, Israel) [25, 50, 58]. Clonal chromosomal abnormalities were described according to the International System for Human Cytogenetics (ISCN 1995) [42].

PCR-SSCP analysis

A polymerase chain reaction (PCR) single-strand conformation polymorphism (SSCP) analysis was performed on exons 4–8 of p53. High-molecular-weight deoxyribonucleic acid (DNA) was isolated from the original tumor samples using standard methods [52]. PCR-SSCP was performed [51] and analyzed using the Allele Link software package (Amersham Pharmacia Biotech). Abnormal bands during the SSCP analysis were amplified and sequenced using an autosequencer [52].

Reverse transcriptase polymerase chain reaction

We used Reverse transcriptase PCR (RT-PCR) to detect the expression of the gene-triggering lineage differentiation in mesenchymal cells. The total cellular ribonucleic acid (RNA) was prepared from the following: cultured cell and human osteosarcoma cell lines, NOS-1 [24] and human chondrosarcoma cell line, and OUMS [30]. These were harvested for RNA extraction with guanidine thiocynate/secium chloride gradient centrifugation. The RNA was then reverse transcribed to complementary DNA using 100 U of Moloney murine leukemia virus reverse transcriptase per reaction with an oligo-dT primer (Promega, Madison, USA). The oligonucleotide primers have been described in previous reports (Table 1). Aggrecan was designed in our laboratory, and the specific amplification was confirmed by

the direct sequencing analysis with dideoxy-chain termination methods employed using an ABI Prism 310 genetic analyzer and Big Dye Terminator cycle sequencing ready reaction kit (Perkin Elmer, Foster City, CA). The PCRs were analyzed for these primer sets [3, 16, 18, 22, 29, 48, 59, 61].

Western blotting

A whole-cell lysate was prepared by scraping the cells into Laemmli buffer (62.5 mM Tris, pH 6.8, 2% [w/v] sodium dodecyl sulfate [SDS], 5% [v/v] glycerol, 6 M urea [Fisher: BP169–212] with proteinase inhibitors [Complete: Roche]). The protein concentration was determined by the bicinchoninic acid method (PIERCE) with bovine serum albumin as the standard. The proteins were separated by SDS–polyacrylamide gel electrophoresis and electrophoretically transferred to a nitrocellulose membrane. The membranes were blocked with 5% nonfat dry milk with 0.2% Tris-buffered saline–Tween for 1 h and incubated overnight at 4°C with PDGFR-β antibody (Santa Cruz Biotechnology, dilution 1:200) and phosphorylated PDGFR-β (p-PDGFR-β, Santa Cruz Biotechnology, dilution 1:500). After washing, the membranes were incubated for 1 h with biotin-conjugated second antibodies (anti-rabbit, dilution 1:3000) at room temperature. After washing, the immunoreactivity was visualized with electrochemiluminescence (Amersham Biosciences).

Result

Establishment of NDCS-1 of cell line and doubling time

Spindle-shaped, polygonal tumor cells reached confluence with some piled-up foci of cells (Fig. 2a). This new cell line was designated NDCS-1 and has been maintained in vitro for more than 50 passages (a period of more than 6 months).

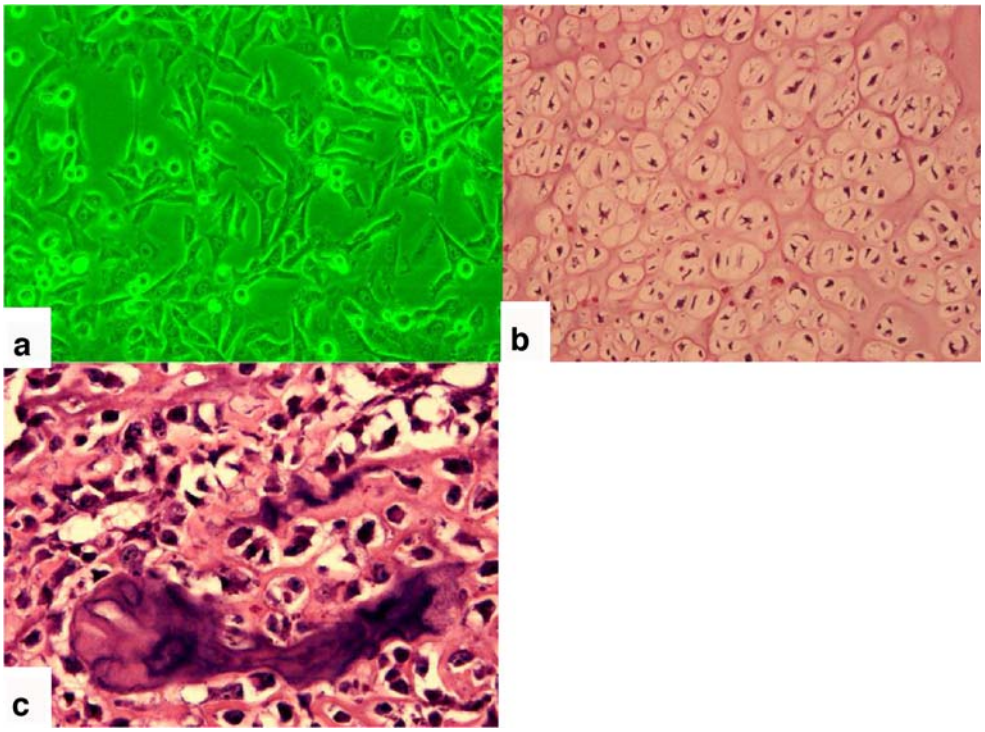

Fig. 2 **a** Light microscopic findings of the NDCS-1 cells in vitro. The NDCS-1 cells were spindle to polygonal in shape, with oval nuclei and extended elongated the cytoplasmic processes (original magnification, 200×). **b** The primary tumor showed low-grade chondrosarcoma (original magnification, 100×). **c** The recurrent tumor had an osteosarcomatous component with abundant bone formation (original magnification, 200×)

The population-doubling time of NDCS-1 cells in the logarithmic growth phase was 30 h. The maximum cell density was approximately 5.0×10^6 cells/cm^2.

Histological examination

The primary tumor showed grade I chondrosarcoma (Fig. 2b). The recurrent tumor showed dedifferentiation component of high-grade osteosarcoma with massive bone formation, and chondroblastic areas were also found (Fig. 2c). The p53 immunoactivities were positive in a recurrent tumor but were hardly seen in the original one. The Ki-67 immunoreactivity rose to 30% at the time of recurrence from 2% of the primary tumor (Fig. 3a, b, c, d). The small elastic hard nodules were first palpable in the mice 2 weeks after implantation. Three months later, the

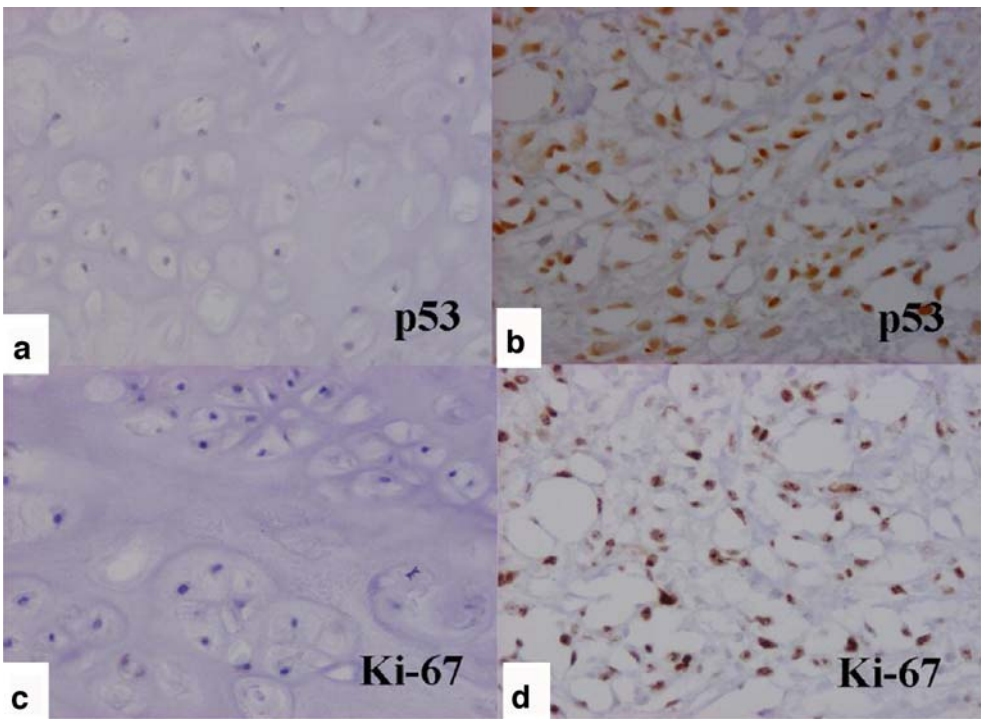

Fig. 3 **a** p53-positive cells were not seen in the primary tumor. **b** There were numerous p53-positive cells in the recurrent tumor. **c** Ki67-positive cells were hardly detected in the primary tumor. The rate of the Ki67-positive cells was only 2%. **d** Ki67-positive cells were 30% in the recurrent tumor, (**a**–**d**, original magnification, 200×)

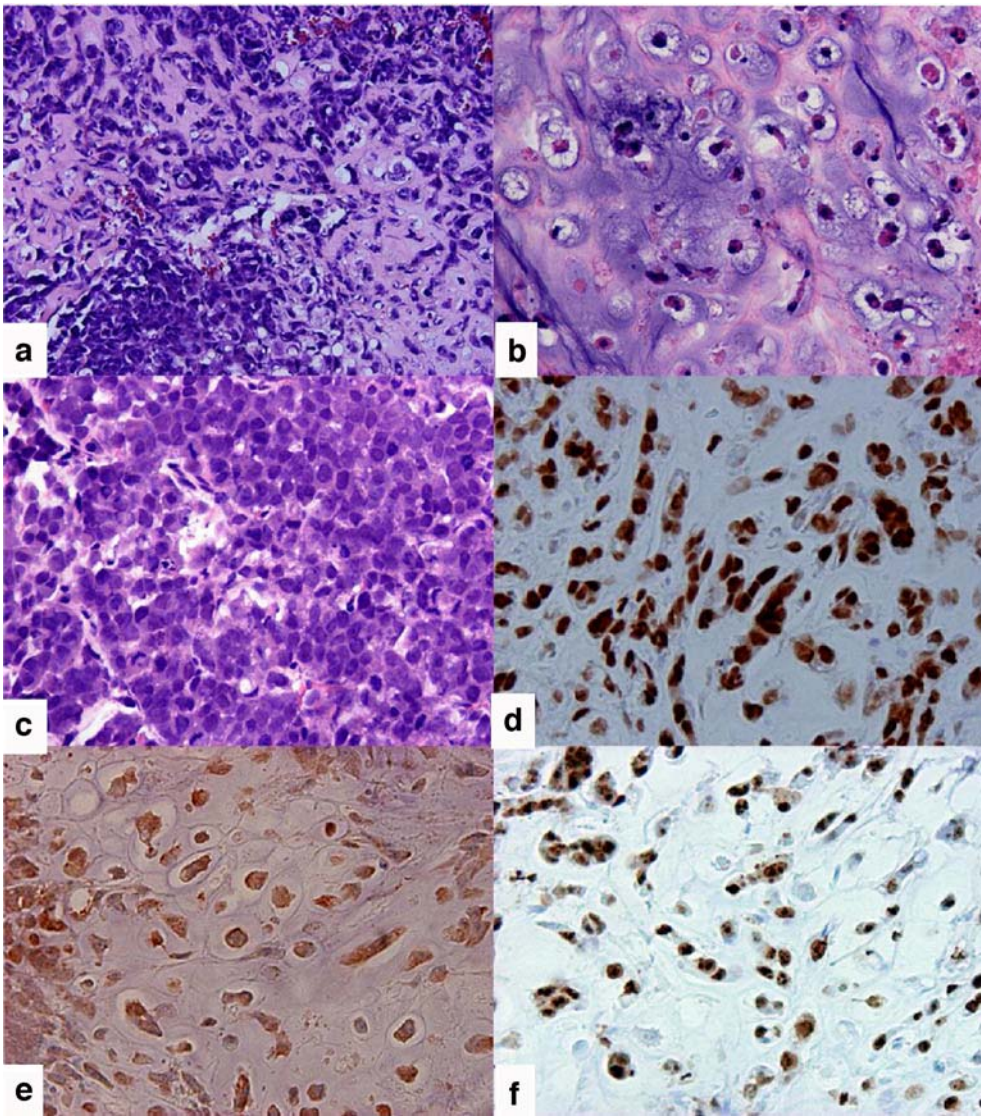

Fig. 4 Light microscopic findings of NDCS-1 cells in vivo. The specimens were from the tumor implanted into the subcutaneous tissue of severe combined immunodeficiency (SCID) mice. **a** Osteoblastic area in the tumor. A lace-like osteoid was observed (original magnification, 200×). **b** Chondroblastic area in this tumor (original magnification, 400×). **c** Anaplastic area in this tumor (original magnification, 400×). Immunoactivities of the p53, PDGFR, and Ki67 proteins. There were strongly p53- (**d**) and PDGFR-positive cells (**e**) in the tumor. The positive rate of the Ki67 protein was 60% in the tumor (**f**; original magnification, 4000)

tumor had grown up to 3.0 cm in diameter. The cut surface of these tumor were solid and white including mineralized areas.The transplanted NDCS-1 cell tumors were composed mainly of three parts: the osteoblastic (immature bone) lesion (Fig. 4a), the chondroid lesion (Fig. 4b), and the anaplastic lesion (Fig. 4c). Based on the immunohistochemistry, the tumor cells were diffusely positive for p53 and the PDGFR, and the positive rate of Ki-67 was 60% (Fig. 4d, e, f).

Cytogenetic examination

The results of the cytogenetic analyses were very complex (Fig. 5). Cytogenetic analyses of ten metaphases were

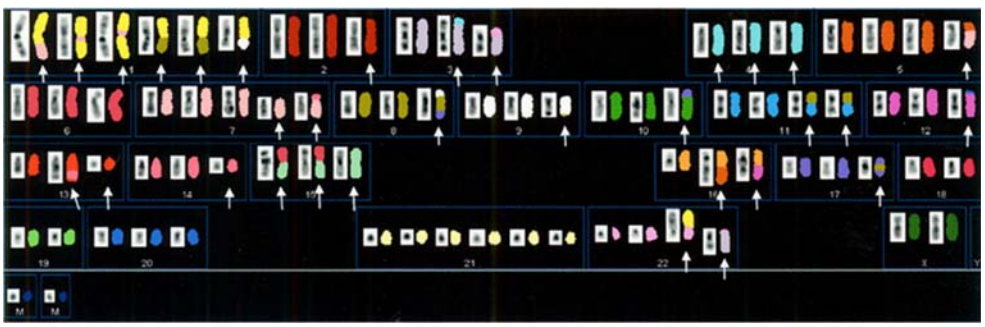

Fig. 5 Representative SKY of the cell line. *Many arrows* point to the abnormal chromosomes

These alterations were all clonal abnormality.

Polymerase chain reaction single-strand conformation polymorphism

The PCR-SSCP sequence analyses of the original tumor and cultured cells revealed a functionally relevant p53 missense mutation from TGC to AGC in codon 242 of exon 7 (T-to-A transvesion).

RT-PCR and Western blotting

As shown in Fig. 6, we performed an RT-PCR analysis to confirm the expression of various mRNAs in NDCS-1, NOS1, and OUMS cells (Table 2). Although NDCS-1 had osteoblastic characterization (Runx2, ALP, Type I collagen, and osteocalcin were positive), chondroblastic characterization had been also present (Type II collagen, Type X collagen, aggrecan, Sox9 were positive). The myogenic master genes, which were MyoD1 and myogenin, were negative. Peroxisome proliferator-activated receptor (PPAR) γ, bone morphogenetic protein (BMP) 2, BMP4, and the BMP receptor were positive. PDGFR-α and PDGFR-β were positive in the RT-PCR. PDGFR-β and

Discussion

Dedifferentiated chondrosarcoma has a very poor prognosis, with a poor 5-year survival rate ranging from 0 to 18% [10, 11, 17, 26, 27, 35, 36, 40, 41, 47]. In addition, the dedifferentiated component usually is a high-grade spindle sarcoma that may respond to chemotherapy, but the response of this tumor to chemotherapy is very poor. In particular, the prognosis of the osteosarcomatous component in the dedifferentiated chondrosarcoma is extremely bad in comparison to other tumors such as MFH and fibrosarcoma [14]. The mechanism of resistance to chemotherapy has not yet been fully understood. Although intensive chemotherapy has been administrated in our case, no significant effect was observed.

This tumor has a strong tumorigenicity and shows chondroblastic and osteoblastic characteristics in vitro and in vivo. The expression of PPAR-γ might have contributed to the multifunctional property of the cell line. This cell line showed extremely complicated karyotype based on cytogenetic analysis. To our knowledge, 15 cases of cytogenetic analysis of dedifferentiated chondrosarcoma have been reported previously. Including that in this case, the cytogenetic findings of dedifferentiated chondrosarcoma were very complex. Although no specific chromosomal abnormality has yet been identified; a part of the chromosome commonly demonstrated a repeated numerical aberration of +7, +8, +20, and +21 [9, 12, 34, 46, 49, 55]. In addition, this cell line shared a part of cytogenetic findings with chondrosarcoma and osteosarcoma. In conventional chondrosarcoma, the most frequent chromosomes having structural aberrations was 1 and 9 [44], and numerical aberration was 7 and 19 [12, 44, 47]. In the loss of heterozygosity studies, the loss of chromosomes or chromosomal regions 1p36, 1p13p~22, 4, 5q13~q31, 6p22~qter, 9p22~pter, 10p, 10q24~qter, 11p13~pter, 11p25, 13q21~qter, 14q24~qter, 18p, 18q22~qter, and 22q13 and the gain of 7p13~pter,12q15~qter,19,20pter~q11, and 21q have been reported [8, 46]. In comparative genomic hybridization studies, the most frequently gained regions were 20q 12~qter (37%), 20q whole arm (32%), 8q24~qter (27%), 20p (24%), and 14q24~qter, while the most common losses were Xcen~q21, 6cen~q22, and 18cen~q11.2 (11%) [28, 30, 33, 35]. The cell line reported herein exhibited a partly shared structural and numerical aberration with the abovementioned cell lines namely, 1p13 and ~22, 10p, 20q.

In osteosarcoma, frequent structural alterations were found in 1p11–13, 1q11–12, 1q21q22, 11p15, 12p13, 17p11–13, 19q13, and 22q11–13 and common numerical abnormalities were at +1 -9, -10,-13, and -17 [4, 19, 32, 54, 56, 63]. This cell line also partly shared a part of structural and numerical aberration in the abovementioned, which were namely, 1q11, 12p13, and 17p11–13.

There is increasing evidence that tumor suppressor gene mutations play a major role in the development, progression, and /or differentiation of tumors, with p53 mutations occurring frequently in the oncogenesis of various mesenchymal neoplasms [1, 2, 6, 7, 13, 20, 57, 60, 62]. This cell line has a p53 point mutation (exon 7,codon 242 [Cys→Ser] [TGC→AGC]) and results in an immunnohistochemistry with strong positivity in high-grade cells with p53 staining. Grade I chondrosarcoma, in this case, did not show immunoreactivity for p53. Simms et al. reported that p53 overexpression was consistently present in dedifferentiated components with accompanied increased proliferative activity and an absence in low-grade cartilaginous component. It has been documented that the overexpression of p53 measured immunohistochemically is usually due to the accumulation of the mutated gene product, which exhibits a longer half-life than the wild-type protein. Recent genetic analyses revealed that p53 mutations were detected exclusively in dedifferentiated components. These evidences of a p53 mutation in the dedifferentiated component may be regarded as at least a cofactor that switched the pre-existing low-grade chondrosarcoma to a highly malignant dedifferentiated tumor [20, 43, 45, 53].

Recent advances in understanding chondrosarcoma development have suggested several molecular targets for the future development of new adjuvant therapy for this chemoresistant neoplasm. Many studies of receptor tyrosine kinase signaling for possible candidates for molecular therapies have been performed [5, 21, 23, 31, 37–39]. Receptor tyrosine kinase inhibitors have recently been developed to block deregulated protein kinase activity and thus slow tumor progression. The expressions of PDGFR-α and PDGFR-β have been detected in conventional chondrosarcoma [31]. Langonigro et al. reported that PDGFR-β seemed to play a major role in the malignant phenotype of chondrosarcoma.

In this cell line, we showed the expression of PDGFR-β in immunnohistochemistry, Western blotting, and RT-PCR. The phosphorylation of PDGFR-β in the cell line offers a rationale for the use of receptor tyrosine kinase inhibitors, alone or in combination with chemotherapy, for dedifferentiated chondrosarcoma. The NDCS-1 cell line appears to maintain the morphological and genetic characteristics of dedifferentiated chondrosarcoma in vitro and in vivo. This cell line may therefore be a useful tool for investigating the biology and molecular target of treatment in dedifferentiated chondrosarcoma.

Abstract The detection and typing of human papilloma virus (HPV) in pathology specimens is gaining increasingly in importance. In the context of the initiative for quality assurance in pathology (QuIP) of the German Society of Pathology and the Professional Association of German Pathologists, four panel laboratories with experience and expertise in polymerase chain reaction (PCR)-based HPV detection were selected to establish an inter-laboratory trial. In a first step, these laboratories performed an internal testing of their own methodologies, which comprised DNA sequencing, multiplex nested PCR and hybridization techniques. Material from 39 samples including paraffin sections and DNA preparations of tissues and plasmids were evaluated by each panel institute according to their own protocols. Despite the different methodologies, a high degree of inter-laboratory reliability was achieved. In this report, we summarise the results. Pretested specimens are available for the external trail and can be ordered from the steering institute via provitro GmbH Berlin (http://www.provitro.de). Supplementary data are online available at http://pathologie-ccm.charite.de (rubric "Forschung"), which includes a web-based photo gallery of HPV-associated lesions and their potential association with specific virus types. The initiative is intended to foster the quality assurance of molecular HPV analysis in pathology and its correlation with morphological changes.

Introduction

Infection with certain types of the human papilloma virus (HPV) is the primary risk factor for the development of cervical cancer and its precursor lesions [53]. In addition, HPV may be associated with other anogenital neoplasias, cancer of the respiratory tract, and in particular, tonsillar carcinomas [50]. More than 100 different HPV types have been identified with about 40 of these infecting the anogenital epithelium. These have been classified as either low-risk (LR) or high-risk (HR) for the development of cervical cancer based upon their identification in cervical tumour samples. A recent analysis of 11 studies has designated 15 anogenital HPV types as HR (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73 and 82), with a further three types designated as probably HR (26, 53 and 66) [3, 9].

Molecular biological detection of HPV has become an important method in gynecology [2, 33]. The relevance is based on the fact that screening for HR HPV types together with cytology can increase considerably the sensitivity for identifying individuals with the propensity to develop high-grade intraepithelial lesions and cervical cancer [4, 7, 10, 15, 31].

Persistent HPV infection is a necessary, although not a sufficient, cause of cervical cancer [3, 32]. It is the only cancer that is almost completely preventable through regular screening. Incorporation of HPV tests into screening programs might identify women who are at risk of developing invasive cervical cancer. Therefore, it is logical that HPV testing could be a useful cervical cancer-screening tool, and its use has been proposed for primary screening, for the triage of equivocal Pap smears and for the follow-up of patients after treatment for cervical intraepithelial neoplasia (CIN). Large-scale controlled trials are currently conducted in Europe using the Hybrid Capture 2 HPV test (HC2, Digene) or HPV-polymerase chain reaction (PCR) [9] examining the performance of HPV testing as a primary screening test. The techniques are widely applied on cytological specimens assisting and/or replacing conventional Pap smear cytology.

Detection and identification of cancer-related genes in surgical pathology specimens, i.e. in biopsies and resections, have gained increasing importance in recent years and are the domain of molecular pathology laboratories. There are certain peculiarities that are related to the use of formalin-fixed and paraffin-embedded (FFPE) tissue imposing several methodological obstacles [8, 18, 19, 36, 49].

As part of a joint initiative of the German Society of Pathology (Deutsche Gesellschaft für Pathologie http://www.mh-hannover.de/institute/pathologie/dgp) and the Professional Association of German Pathologists (Berufsverband Deutscher Pathologen, http://www.bv-pathologie.de) for quality control in pathology (QuIP), we performed an internal comparative inter-laboratory trial in the field of PCR-based HPV detection. Four institutes were selected by both societies because of their expertise and experience in this area [20, 37, 40, 44–46, 50]. Our aim was to compare and to validate methodological variants employed by the four panel laboratories. This study followed the general guidelines in molecular pathology [22] and is similar to another multicentre trial on tuberculosis PCR detection that was recently performed [39, 41].

Despite a number of methodological variations, PCR-based diagnostics of HPV proved to be reliable and reproducible. The specimens tested constitute the first stock of a sample collection that is available for external molecular pathology laboratories to test their methodology and to increase quality assurance.

Materials and methods

Design of study and sample collection

Each panel laboratory contributed between 8 and 13 cases (paraffin sections and/or DNA solutions) that had been previously analyzed in their own laboratory for the presence and type of HPV. The material of each set of cases was sent by the respective laboratory to each of the three other panel laboratories. In total, 39 cases comprising DNA solutions as well as paraffin sections were analyzed by all panel laboratories. The collection consisted of four negative controls (two fetal lungs, two bone marrow aspirates of breast cancer patients), two positive controls (plasmid solutions with defined HPV types) and 33 clinical samples including 18 portio conisations, five uterus hysterectomy specimens without dysplasia, three portio/cervix biopsies, two cervical (neck) lymph node metastases, two portio smears, one lung metastasis, one introitus vaginae biopsy and one penile amputation specimen. The DNA solutions that were sent by the respective panel laboratories had a volume of 10–12 µl and a DNA concentration of about 50 ng/µl. The number of sections of the paraffin samples is listed in Table 1.

Preparation of DNA from paraffin-embedded tissue and cytological swab/smear samples or cervical scrape specimens

A survey on the methodological steps is shown in Fig. 1, and details are listed in Table 1. For the FFPE specimens, all panel laboratories transferred a variable number of sections into reaction tubes for deparaffinization. The panel laboratories A–C de-waxed the paraffin sections according to standard protocols using xylene and ethanol; the number of treatments varied between the laboratories from one to three times. Laboratory D removed the paraffin mechanically after heating and cooling down of the sections in buffer solution. For disruption of the tissue and cell lysis, all laboratories performed proteinase K digestion using standard protocols. Some details in brief:

Laboratory A Extraction of DNA was performed by the use of QIAamp DNA Mini Kit (Qiagen, http://www.qiagen.com) according to the instruction of the manufacturer with the following modifications: The de-waxed tissue or an aliquot of 100 µl of cervical scrape specimens in liquid cytology medium were pre-treated 10 min at 95°C prior the proteinase K incubation step at 55°C. The DNA was eluted in a final volume of 50–100 µl. After determination of the DNA concentration, about 100 ng DNA was used for PCR reaction [41].

Table 1 Comparison of the methodological steps of laboratories A–D

Methodological steps	Laboratory A (Berlin)	Laboratory B (Bonn)	Laboratory C (Tübingen)	Laboratory D (Zürich)
FFPE specimen cutting	3–5×3 μm sections	3×10 μm sections	5×8 μm sections	3–5×10 μm sections
Cytological specimen handling	100 μl cervical swab in ViraPap™ transport solution (Digene) or *PreserveCyt*™ Solution (Cytyc)	200 μl concentrated swab sample in *PreserveCyt*™[46]	Cervical scrape in 400 μl PBS buffer	Gynecological cell suspension
Pre-treatment of FFPE specimens	De-wax with xylene (1×), wash with ethanol (1×), air dried [40]	De-wax with xylene (2×), wash with ethanol (2×), air dried	De-wax with xylene (3×), wash with ethanol (2×), vacuum dried [44, 45]	Boiling 10 min with buffer, centrifugation at 4°C, removing the paraffin lid
Pre-treatment of cytological samples (fresh material)	Nothing	10 ml cervical samples were concentrated 10 min 2,000×*g*	Snap-frozen (1×)	Centrifugation (20 min at 14,000 rpm each) and washing (1×) of the pellet
DNA preparation	Heating of the sample in lysis buffer (10 min), QIAamp DNA Mini Kit	QIAamp DNA Mini Kit	QIAamp DNA Mini Kit, extraction with phenol/$CHCl_3$/Isoamyl alcohol, ethanol precipitation	Proteinase K lysis (15–18 h, 37°C), heat denaturation (10 min), centrifugation [29]
Final extraction volume	50–100 μl	100 μl	100–200 μl	Variable
DNA quality	Pure	Pure	Pure	Crude cell or tissue extract
DNA quantity per PCR	1–5 μl (50–200 ng)	3 μl	100 ng DNA	1–10 μl (~50 ng)
PCR volume	25 μl	20 μl	50 μl	50 μl
DNA quality control	$OD_{260/280\ nm}$	Without	$OD_{260/280\ nm}$	1% agarose gel, comparison with standard DNA solution
DNA integrity control	β globin PCR (268 bp)	β globin PCR (268 bp)	β globin PCR (268 bp)	Duplex versican PCR (268 bp, 589 bp)
PCR and HPV detection method	Electrophoresis (3.3% agarose gel), DIG-PCR/ELISA (Roche) HPV PCR Array (Chipron)	Fluorescence capillary electrophoresis, DNA sequencing, INNO-LiPA HPV assay	Electrophoresis (2% agarose gel), sequencing by dye-deoxy terminator method (377 ABI Prism Sequencer)	Electrophoresis (3% MetaPhor-agarose gel), sequencing

Laboratory B For DNA preparation, 3×10 μm thick slices of the paraffin blocks were used. Isolation of DNA was performed with the QIAamp DNA Mini Kit (QIAGEN, Hilden) according to the manufacturer's protocol. Cytological samples (10 ml) in PreservCyt™ (Cytyc) solution were centrifuged 10 min at 2,000×*g*. After removing the supernatant, 200 μl of the concentrated sample was used for DNA isolation (QIAamp DNA Mini Kit). DNA was eluted from the columns in a volume of 100 μl 10 mM Tris–HCl pH 8.0. [46].

Laboratory C For extraction of total genomic DNA from biopsy specimens, five 8-μm thick sections were cut from each paraffin block for microdissection. The FFPE material was transferred into reaction tubes and de-waxed according to standard protocols. In brief, tissue was vortexed in 1 ml xylene (100%) for 1 min and centrifuged at 13,000 rpm for 5 min. The procedure was repeated three times. Then, samples were washed twice in pure ethanol and vacuum-dried. Proteinase K digestion was carried out in a final volume of 200 μl buffer (50 mM Tris, 1 mM ethylenediamine tetraacetic acid (EDTA), 0.5% Tween-20, pH 8.5) containing 0.2 mM proteinase K at 55°C for 2 h. Total DNA was extracted with phenol/chloroform/isoamyl-alcohol (*v*/*v*/*v*, 25:24:1) and precipitated with ethanol (100%)/LiCl (8 M) as described [44, 45]. Cervical scrapes were transferred in 400 μl phosphate buffer, rigorously vortexed for 1 min and the swab removed. An amount of 20 μl of Qiagen protease stock solution and 400 μl AL buffer were added. The extraction of total DNA was performed using the QIAmp DNA mini kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. The concentration of extracted DNA was determined by spectrophotometry at 280 nm. One hundred nanograms of total extracted DNA was used for PCR amplifications.

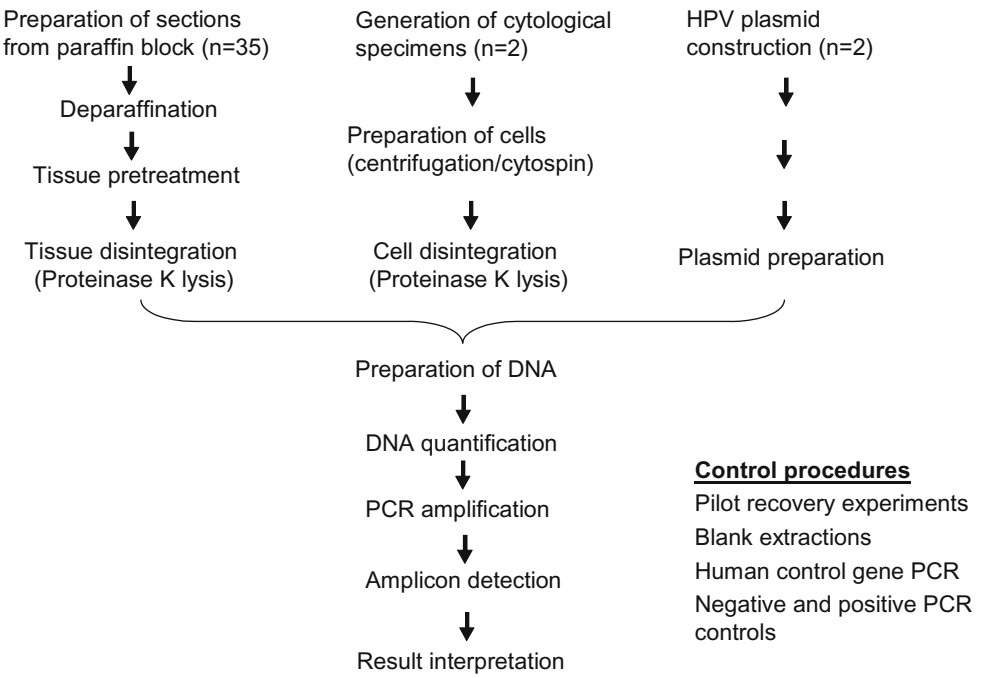

Fig. 1 Methodological steps in PCR-based HPV detection

Laboratory D The paraffin sections (three to five, 10 μm thick) were boiled in 200 μl buffer (50 mM Tris pH 8.5/1 mM EDTA/0.5% Tween 20) with vigorous mixing for 10 min, then centrifuged 30 min full speed in an Eppendorf centrifuge and cooled down to 4°C. The solid paraffin lid was removed immediately using a sterile pipette tip. After addition of 2 μl proteinase K (19 mg/ml stock solution) the incubation was carried out with shaking at 55°C. Cell suspensions of cytological specimens were centrifuged 20 min at 14,000 rpm, the supernatant discarded and the cells were carefully washed with phosphate buffered saline (PBS) and centrifuged again 14 min at 14,000 rpm. The cells were also dissolved in the lysis buffer and treated as mentioned above. After complete lysis of the tissue or the cells, the proteinase K was inactivated for 10 min at 95°C.

DNA quantification control procedures, quality assurance

To standardise the conditions and to estimate the amount of extracted DNA, the concentration of DNA was measured spectrophotometrically and the optical density ratio (260 nm/280 nm) was calculated to obtain information about the purity of the template DNA (laboratories A and C). The integrity and the quantity of the DNA was assessed semi-quantitatively via gel electrophoresis and comparison of the sample with other standard DNA samples by laboratory D. DNA amounts and PCR reaction volumes of each laboratory are specified in Table 1.

To examine whether amplifiable DNA was present in the samples, all panel laboratories assessed the quality of the prepared DNA by control PCR to amplify an appropriate segment of a human gene (Table 2), laboratories A–C used the β globin sequence as target. Laboratory D selected a multiplex PCR to amplify a small and a large amplicon of the CSPG2 (versican) gene, the larger fragment being greater as the largest HPV PCR product [35, 52]. Details of the control PCR are described in the next section.

Other control procedures were blank extractions and the selection of negative controls consisted of tissue samples that could not have had contact with HPV, similar as previously described [41]. Additionally, sterilised water or buffer without DNA were used as standard PCR negative controls, which were included in each run to check the reagents. Positive PCR controls for all amplifications included well-characterized HPV-infected samples, i.e. HPV11 (laboratory A), purified DNA from the HPV16-positive cell line Caski (laboratory B) and HPV16-infected clinical sample (laboratory D). The specificity of the nested PCR used for HPV typing was verified by including plasmid solutions of either HPV16, 33, 35 or 68 as positive controls in the PCR runs (laboratory C).

PCR amplification and HPV detection

Primer sets as well as detection methods for HPV are provided in Tables 2 and 3. All panel laboratories

[a] The degenerate base code is as follows: K=G or T, M=A or C, W=A or T, Y=C or T, R=A or G, N=A;C;G;T

performed consensus PCR for the amplification of variable regions differing between the HPV genotypes. The consensus or general PCR primers were selected to amplify a broad spectrum of HPV genotypes and were mostly located in the L1 open reading frame region of the HPV genome. It is a highly conserved region, and several universal PCR primer sets were described in the literature, most of which were applied by the panel laboratories (Table 2).

Specifically, the MY09/11 primers were used by laboratories A and B, the PGMY09/PGMY11 primers by laboratory D, the GP5+/6+ primers by laboratory B, and a nested PCR which combines the MY09/11 and GP5+/6+ primers was applied by laboratory C (Fig. 2). Commercially available primer mixtures consisted of 125.for/125.rev (LCD-Array HPV 3.1, Chipron, Berlin), which combined a number of distinct forward and reverse primers, aimed at the same position of the L1 gene (laboratory A), and the short PCR fragment (SPF) primers of INNO-LiPA HPV detection/genotyping assay, which yield a short PCR fragment of the L1 region of a broad spectrum of HPV types (laboratory B).

Another consensus PCR targeted the E6 and E7 region by a nested multiplex PCR approach (NMPCR) assay (laboratory C). Using a single consensus forward primer (GP-E6-3F) and two consensus reverse primers (GP-E7-5B and GP-E7-6B), genomic DNA of all known mucosal HPV genotypes were amplified. The PCR products of the first round were the target of four second-round reactions with primer cocktails each containing four to five different primer pairs for the amplification of specific HPV types (Table 3), which were identifiable by the size of the nested PCR amplification product in the gel electrophoreses [44].

The main procedures of HPV amplification and typing used by each laboratory are specified in the following and in Table 3.

Laboratory A All amplifications were performed with the commercially available ready mixture (Reddy Mix™, *Ab*gene,

Table 3 HPV PCR product identification/typing

Lab	Method	Potentialities	Detection of HPV types
A	DIG-PCR/ELISA (Roche)	Screening method to detect the subgroups:	
		"Low risk"	{6, 11, 42, 43, 44}

http://www.abgene.com). The final reaction volume of 25 µl contained: 75 mM Tris–HCl (pH 8.8 at 25°C), 20 mM ammonium sulphate, 1.5 mM $MgCl_2$, 0.2 mM of each deoxynucleotide trisphosphate, 0.01% (*v*/*v*) Tween 20, 1.25 units Thermoprime DNA polymerase, as well as loading buffer and dyes for electrophoresis. For the Digoxygenin (DIG)-PCR, the twofold concentrated kit reagents were complemented by a PCR DIG labelling mix (DIG detection, Roche, http://www.roche.com), final DIG-dUTP concentration of 120 µM and primer concentration of 0.1 µM. The cycle conditions were: 5 min 95°C, 40 cycles with 1 min 94°C, 2 min annealing temperature (see Table 2), 2 min 72°C and a final 7-min extension step at 72°C. PCR products were detected by standard electrophoresis using a 10-µl PCR aliquot and a 3.3% agarose gel containing ethidium bromide.

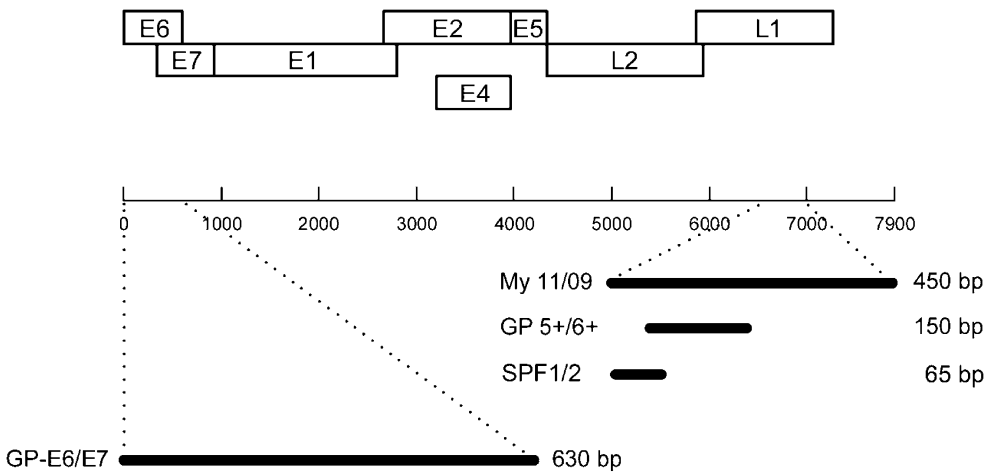

Fig. 2 Diagram of the positions of PCR amplicons used by the panel laboratories. The positions are indicated relative to the HPV-16 genome (modified from Sotlar et al. [44, 45])

In the following enzyme-linked immunosorbent assay (ELISA) detection, two 2.5-µl aliquots containing the digoxygenin-labelled PCR products were hybridized with mixtures of biotinylated probes of HR and LR HPV types (TIB MOLBIOL, Berlin, probe sequences from Bauer et al. [1], Hildesheim et al. [21] and Gravitt et al. [16]), respectively. The hybridization solutions containing DIG-labelled PCR product and biotinylated probe are then subjected onto streptavidin-coated microtiter plates; the unattached DNA strand is removed by washing. The DIG-containing hybrid can be detected and photometrically measured by binding of anti-DIG/enzyme conjugate and the substrate colour reaction as described by the instruction manual (Roche, Penzberg, Germany). This DIG-PCR/ELISA allows the differentiation of HR and LR HPV types and corresponds to the Hybrid Capture 2 analysis (Digene) used for cytological screening.

For HPV typing, a chip-based detection system ("LCD-array HPV 3.1", Chipron GmbH, Berlin) was used according to manufacturer's instructions. In brief, the biotinylated primer mixtures MY09/11 and 125 for/rev were used to generate labelled PCR products from the L1 region of the HPV genome. An amount of 10 µl of PCR products was then hybridized to HPV type-specific capture probes immobilized as two-dimensional arrays on the surface of a transparent polymer support, i.e. the chip/LCD array. Eight identical arrays of capture probes are present on one chip in separated reaction wells. After hybridization (30 min, 35°C) and high stringency washes (5 min, 24°C), the hybridization events were visualized by binding of streptavidin-horseradish peroxidase (HRP) conjugate and the precipitation of a chromogenic substrate (5 min, 24°C). Data analysis was mediated by high-resolution transmission light scanning and software-supported analysis. Specific Probes of 29 HPV types are spotted in duplicate onto the surface of the reaction well (Table 3).

Laboratory B All reactions were performed in a final volume of 20 µl consisting of 3 µl extracted DNA as a template, 2 µl 10× PCR buffer, 1 U Platinum Taq Polymerase (Invitrogen) with 20 pmol of each primer and 0.2 mM deoxyribonucleotide triphosphates (dNTPs). A $MgCl_2$ concentration of 1.5 mM was used for all reactions. The forward primers used in the PCR were labelled with fluorescence dyes: GP5+, MY11, Glob-F with HEX, fluorescein amidite derivate (FAM) and NED, respectively. The conditions were as follows: preheating for 5 min at 94°C was followed by 40 cycles of 20 s at 94°C, 20 s at the annealing temperatures (see Table 2), 40 s at 72°C and a final extension of 5 min at 72°C.

The PCR products were analyzed by fluorescence capillary electrophoresis using an automated ABI 310 Genetic Analyzer (Applied Biosystems). Therefore, 0.8 µl of each of the three PCR products were mixed with 10 µl formamide and 0.5 µl internal standard (Genescan 500-ROX, Applied Biosystems). After denaturation at 90°C for 2 min and cooling, the size of the PCR products were determined using the GeneScan software 2.1.1 (Applied Biosystems, Weiter-stadt, Germany).

The products of positive reactions were purified using the High Pure PCR product purification kit (Roche Diagnostics) according to the manufacturer's instructions and subsequently sequenced with the Big-Dye Terminator sequencing kit (Applied Biosystems) using one of the PCR primers as sequencing primer. The sequencing reactions were also analyzed on the ABI 310 Genetic Analyzer (Applied Biosystems). The obtained sequences were compared with documented virus sequences available in the GenBank databank using the BLAST program. HPV type-specific PCR was performed as described by van den Brule et al. [5] with modifications. All forward primers used in the reactions were labelled with FAM. This allowed the analysis of the PCR fragments by fluorescence capillary electrophoresis as described for the consensus PCR.

In case of negative PCR with the MY09/11 and GP5+/6+ primers or when the capillary electrophoresis showed more than one peak, a third PCR approach with SPF1/2 primers and a line probe assay (INNO-LiPA Genotyping v2 Amplification and Detection, Innogenetics, Heiden, Germany) was applied.

The line probe assay contained multiple probes immobilized as parallel lines (INNO-LiPA HPV Genotyping v2) on membrane strips. The SPF primers [28] amplify a short PCR fragment (65 bp) of a broad spectrum of HPV types in the L1 open reading frame region and allows detection of at least 24 different single HPV types and HPV patterns. The PCR was performed in a final reaction volume of 50 µl, containing 10 µl of the isolated DNA, PCR buffer II (Applied Biosystems), 2.0 mmol/l $MgCl_2$, 200 µmol/l each deoxynucleotide triphosphate, 20 pmol of forward and reverse biotinylated primer and 1.5 U AmpliTaq Gold DNA polymerase (Applied Biosystems). PCR conditions were as follows: preheating for 9 min at 94°C was followed by 40 cycles of 30 s at 94°C, 45 s at 52°C, 45 s at 72°C and a final extension of 5 min at 72°C.

After denaturation of the PCR product, the single biotinylated strand in the liquid phase is hybridized with the multiple oligonucleotide probes of the line probe assay according the manufacturer's instructions. After hybridization and stringent washing, the hybrids can be detected by addition of a streptavidin conjugate and a substrate generating colour as lines which can be visually interpreted. This method permits detection of multiple HPV types in a single step.

Laboratory C HPV detection with primers MY09-MY11 was performed in a final volume of 50 µl. Each PCR mixture contained 50 mM KCl, 10 mM Tris–HCl (pH 8.5), 6 mM $MgCl_2$, a 200 µM concentration of each deoxy-

nucleoside triphosphate, 5 U of AmpliTaq Gold DNA polymerase (Applied Biosystems, Weiterstadt, Germany), 50 pmol of primers MY09 and MY11, 5 pmol of primer HMBB01 (5′-GCG ACC CAA TGC AAA TTG GT-3′) and 5 pmol of primers PC04 and GH20 for the simultaneous amplification of a 268-bp product of the human β globin housekeeping gene [38]. Amplifications were performed with the following cycling profile: activation of AmpliTaq Gold at 94°C for 10 min followed by 40 cycles of 1 min denaturation at 94°C, 1 min annealing at 55°C and 1 min elongation at 72°C at final extension step of 7 min at 72°C. To increase the sensitivity of HPV detection, nested PCRs were performed using MY09-MY11 as outer and GP5+-GP6+ as inner primers. Two microliters of the MY09–MY11 PCR product was used as template for the nested PCR amplification with GP5+-GP6+ primers [44].

To achieve exact typing of the HPV infections, a nested multiplex amplification of the GP-E6/E7 PCR with type-specific primers was chosen (NMPCR). Nested primers were arranged in multiplex PCR which discriminate among a broad spectrum of different HPV genotypes (Table 3). The primers were used in four cocktails, each containing four to five different primer pairs [44]. The identification of each HPV type present was achieved by determining the size of the nested PCR amplification product by gel electrophoresis. For HPV-6 and -11, only one specific primer pair was designed because of their high-sequence homologies and their biological similarity.

The conditions for the reactions with E6 consensus primers were 4-min denaturation step at 94°C followed by 40 amplification cycles at 94°C for 1 min, 40°C for 1 min and 72°C for 2 min for a total. The last step was an additional 10-min elongation at 72°C. NMPCRs with type-specific primers were performed under the following conditions: The first cycle was preceded by a 4-min denaturation followed by 35 cycles of 94°C for 30 s, 56°C for 30 s and 72°C for 45 s step, and the last cycle was a 4-min elongation step. All PCRs were performed in a final volume of 50 μl containing 50 mM KCl, 10 mM Tris–HCl pH 8.3, a 200-μM concentration of each dNTP, 1.5 mM $MgCl_2$, 1 U of thermostable DNA polymerase (AmpliTaq DNA polymerase; Applied Biosystems) and 15 pmol of each primer. Two microliters of the PCR product served as template for the nested PCR. Ten microliters of the amplification products were analyzed by electrophoresis on 2% agarose gels and ethidium bromide staining. With clinical samples, 100 fg of HPV-16, -33, -35 and -68 DNA-containing plasmids were used as positive controls.

For sequencing of PCR products, PCR products were excised from 2% Tris–acetate–EDTA (TAE) agarose gels and purified with a gel-extraction kit (QIAGEN) according to the manufacturer's instructions. PCR products were sequenced by the dye-deoxy terminator method on a 377 ABI Prism Sequencer (PE Applied Biosystems) using 5 pmol of either forward or back primers.

Laboratory D Essentially, PCR protocols of Gravitt et al. [17] and Yoshikawa et al. [51] were followed. The total reaction volume was 50 μl. All PCR mixtures included 1× reaction buffer II (Applied Biosystems), 0.2 mM primers, 0.2 mM dNTPs (Roche) and 2.5 U Amplitaq Gold (Applied Biosystems). In the L1C1/2 reaction, the final magnesium chloride concentration was adjusted to 2.5 mM, while 4 mM $MgCl_2$ was used in the PGMY 09/11 and the versican reactions. Cycling was performed in an Applied Biosystems 9700 thermocycler starting with a enzyme activation step at 96°C for 3 min followed by 40 cycles consisting of 1 min at 95°C, 1 min at 55°C (MY 09/11/Versican-PCR) or 48°C (L1C1/2 PCR), respectively, and 1 min 72°C. After final extension at 72°C at 5 min, samples were cooled to 4°C.

The PCR products were subsequently analyzed by gel electrophoresis on 3% Metaphor agarose (Cambrex Bio Science) and visualized on a UV screen after staining with ethidium bromide. PCR products were excised, purified with a Qiagen MinElute gel extraction kit and directly subjected to sequencing on an ABI 3100 genetic analyzer using Big Dye terminator chemistry (Applied Biosystems). All products were sequenced from both strands. Sequences were analyzed with Sequencher 3.1.1. software (Gene Codes). In some instances, mixed infections were identified by manually calling the secondary sequence.

Statistical analysis

For the nominal attribute infection type and dichotomous attribute HPV, HR HPV and LR HPV, we measured agreement across laboratories by using Fleiss' kappa statistic [14], which is a variant of Cohen's kappa for more than two raters. Kappa was determined by a custom-made program that calculated values in a range of 0 to 1. In accordance with the method of Landis and Koch [30], estimated kappa values below 0.40 were considered poor to fair, 0.41 to 0.60 moderate, 0.61 to 0.80 substantial and 0.81 to 1.00 almost perfect.

The concordance for the attributes and main result were measured pair-wise for all laboratories. For each pair, the ratio of matched cases to the total number of cases was determined, which leads to a range 0 (total disagreement) to 1 (full agreement). Finally, the mean agreement was averaged over all pairs. This alternative concordance measure was used to take the strong imbalance of attribute values (yes/no) into account.

The HPV detection methods were also evaluated for their sensitivity and specificity being defined as follows.

Sensitivity: proportion of true positives among all positive cases, i.e. number of true positive results/(number of true positives+number of false negatives), specificity: proportion of true negatives among all negative cases, i.e. number of true negative results/(number true negatives+false positives). The consensus result among the laboratories was used as "gold standard".

Results

The detailed results of all PCR analyses which were performed in the different laboratories are provided in Table 4. The interpretation of the HPV results and the histopathological diagnosis are presented in Table 5. Scores were established for each positive result corresponding to the number of laboratories, which identified a specific virus type. A consensus HPV type was defined by a positive finding in the majority of the laboratories (score 4 or score 3 cases).

Mono infections

HPV DNA was consistently found in 28 cases. In 22, a single-consensus HR HPV type was found by the majority of the laboratories. These cases were interpreted as mono infections. In two of these (A1, D28), one laboratory using PCR after DNA sequencing failed to find the consensus virus type (score 3). In the remaining 20 cases, the consensus type was consistently found (score 4). However, in three of these (A8, C23, D34), one laboratory using PCR after hybridization found a weak additional signal for HPV16 being distinct from the consensus HR type. All the 22 cases consisted of clinical samples, i.e. 5 invasive carcinomas, 13 cases with severe dysplasia or carcinomas in situ (CIN 3 or VAIN 3), 3 CIN 2 lesions and 1 Pap IIID smear.

Mixed infections

In six cases, the majority of the laboratories detected more than one HPV type. These cases were formally interpreted as mixed infections. Two of these (C24, C26) consisted of a mixture of DNA plasmids representing two distinct HPV types that were included into the collection as positive controls. In these two controls, only one laboratory did not succeed to determine one of the two HPV types correctly. For the four clinical samples, three revealed one HPV consensus type (A2, C21, D35), and one carried two (D29). The fact that the consensus types belonged to the HR group was determined by all laboratories. Additionally, the consensus types were always correctly determined except for two cases (A2, D29) in which one specific HPV type (HPV53) was not covered by detection method of the respective laboratory. Up to four additional types were observed in these clinical samples, which consisted of two CIN 3 lesions, one Pap IIID smear and one cervix biopsy with inflammation and very minor epithelial polymorphism compatible with a CIN 1 lesion.

Negative samples

A negative result in HPV detection and subtyping analysis was only scored if the amplification of control genes for testing the DNA integrity of the tissue gave a positive result. Two fetal lung tissues and two breast cancer biopsies were selected as true negative controls. In one of these four cases, a positive result for HPV6 (LR) and HPV45 (HR) was found by one laboratory using a hybridization detection method, while the others were consistently negative. Additionally, seven clinical samples (two cervix/portio biopsies and five hysterectomy specimens) were analyzed, which were consistently negative (score 4) in two cases, while single positive results (score 3) were detectable in five cases. All these aberrant positive findings were identified by hybridization methods, i.e. one ELISA test indicated a LR infection that could not be further sub-typed (D33), two (A6, D37) LR types (HPV6, HPV11), and in two cases (D30, D39), HR viruses (HPV51, HPV16) were found. In two of these five aberrant positive cases, the finding was only evident in the paraffin sample, while the corresponding DNA solutions were negative. Notably, there were pathological findings on the respective histological evaluations that consisted of squamous metaplasia in two cases (one with CIN 1) and microglandular hyperplasia in one additional case.

Statistical analysis

Sensitivity and specificity of the different methods for detecting HPV DNA and the group of HR types were calculated. In addition, the concordance of detecting specific HPV types was calculated (Table 6). Interestingly, specific methods applied in individual laboratories showed higher values than the most widespread method using the MY09/11 primers.

The statistical analysis of the test results between the four laboratories is represented in Table 7, indicating substantial concordance for the detection of HPV and the discrimination of the infection type. Almost perfect concordance was reached for the detection of HPV HR, while only moderate matching was achieved for HPV LR. The congruence for the detection of the consensus HPV types including only the positive cases was 95%. Overall, the concordance in the detection of the consensus HPV types or a consensus negative result was 89%. In Fig. 3,

Discussion

In this study, we performed for the first time an inter-laboratory trial on PCR based HPV detection in surgical pathology specimens. Previously, only a few studies were published. They were all performed on cytological specimens, some at a much larger scale, mostly using hybridization detection methods and in particular hybrid capture (Digene) [42]. The scope and intention of these trials were manifold; besides validating the sensitivity and specificity of the methodology, an important focus was the applicability of testing in the prevention of HPV-associated disease and the triage of women with increased risk. The hybrid capture technology is a non-PCR based methodology using signal amplification, which is widely used in the analysis of cytology specimens. Importantly, it can detect an HPV infection but can only differentiate between a HR and LR infection [25]. Furthermore, due to the limited number of probes represented by the system and potential cross-hybridizations, it harbours the risk of wrong classifications in a substantial fraction of cases. One study comparing sequencing with hybrid capture identified revealed that about 15% of HPV infections were not found, of which 50% represented HR types [27]. In this study, the hybrid capture technique was not applied.

Our objective was the evaluation of techniques for HPV typing being in daily use at four experienced molecular pathology laboratories and the establishment of a sample collection for an external inter-laboratory trial. In general, we achieved a substantial concordance for the detection of HPV with almost perfect match in detecting a HPV HR infection. Concordance for HPV LR was moderate, which was related to the fact that only two cases were analyzed both harbouring a second HR virus type. The identification of the main HPV type was also achieved with very good concordance (Table 7). However, there was greater variability in the detection of specific virus types (Fig. 3) being related to methodology (detection technique etc.) on the one hand but also to HPV biology (infection type, genome variability etc.) on the other hand.

Methodologically, all laboratories analyzed multiple regions of the HPV genomes, most frequently in the L1 gene. This precaution was taken to minimize false negative results in the consensus PCR. The positive PCR is the

prerequisite for HPV typing, which was performed by all laboratories and was a major endpoint of the analysis.

In general, the sensitivity of DNA detection by PCR is inversely related to the size of the amplimer, as the kinetics of the PCR reaction favour smaller amplimers. Moreover, as the efficacy of PCR also depends on the quality of the DNA extracted from the clinical specimen, detection with small amplimers will be advantageous, especially when using formalin-fixed, paraffin-embedded materials. The PCR products varied between 65 bp (SPF1/2, L1 region), 150 bp (GP5+/6+, L1 region), 450 bp (MY09/11, L1 region) and 630 bp (GP-E6/E7 region). The two negative results of positive samples were indeed achieved with the MY09/11 primers using conventional PCR while these cases were still detectable using nested PCR of the even longer fragment GP-E6/E7. In contrast, the smallest fragment detected additional samples, however, once also resulting in a false positive result of a negative control. Subjecting clinical samples to pre-treatments such as formalin fixation and paraffin-embedding degrades DNA. Consequently, the efficiency of PCR primers generating a small product is considerably higher than primer sets yielding larger amplimers [24, 28].

Typing was performed by DNA sequencing, hybridization techniques and nested multiplex PCR. All methods have certain advantages and disadvantages. While DNA sequencing may be most specific by the capability to detect all virus types, it seems to be less sensitive in the detection of multiple infections. Hybridization and multiplex PCR are more sensitive but they can identify only those virus types that are covered by the assay and may show false positive results by mismatches of primers or probes.

The biology of HPV infection and its potential progression to cancer is complex [13]. One prerequisite seems to be the integration of HPV into the host genome which, being generally found in invasive carcinomas, is uncommon or absent in CIN 1 lesions [23, 48]. Similarly, persistence of HPV HR infection was observed in low-grade dysplasia which showed progression to severe dysplasia (CIN 3) while clearance of up to five different HPV types was seen in 17% of cases with low-grade histologies [6]. The presence of multiple HPV genotypes is a common phenomenon in many patient groups. Up to 35% of HPV-positive samples from patients with advanced cytological disorders contain multiple HPV genotypes, whereas multiple genotypes are less prevalent in carcinoma patients [31].

In view of these observations, it is not surprising that we observed an excellent concordance in cases with HPV HR mono infections while a higher variability was found in cases with mixed infections. Although for the latter there was also a good concordance for the detection of the predominant type, the detection of the additional HPV

Table 6 Statistical analysis of the different PCR-based HPV detection methods

Method	Used by laboratory	Number of analyses	HPV detection		HR detection		Type detection

genomes frequently differed between the laboratories. In this context, it is also important to mention material heterogeneity as a potential factor with influence on the results. Copy number differences and the ratios of the various HPV types being present in the sample can obviously influence the sensitivity of detection. This is particularly true for PCR using consensus primers. Single HPV types may show a better primer affinity than others, and the less frequent genomes may be overlooked by the exponential amplification of the predominant type.

Furthermore, tissue heterogeneity is an inherent problem of our study because we analyzed tissue sections in addition to aliquots of DNA solutions. Particularly, the use of distinct tissue sections may have caused some positive results in our 11 samples of presumably negative cases. These consisted of four most probably HPV-unaffected cases (two bone marrow aspirates and two fetal lungs) as negative controls and seven uterus samples (cervix/portio biopsies and uterus resections) with potential contact to HPV. In addition, these cases carried histological changes (cervicitis, squamous metaplasia, microglandular hyperplasia, CIN 1) indicative for an external irritation which might have been caused by virus infection.

One by-product of our study was the observation of the morphological changes being associated with different HPV types. In our experience, there is some variability in the morphology. This is not surprising, given the limited number of histological patterns (CIN 1, CIN 2, CIN 3, koilocytosis, parakeratosis) linked to HPV so far on the one hand and the existence of more than 100 viral subtypes on the other hand. To enhance our perception and to better correlate morphology with viral subtypes, we initiated a photo gallery of HPV positive cases (see http://pathologie-ccm.charite.de, rubric "Forschung"). We feel that HPV analysis and typing will become an integral part of the molecular pathology diagnostics. There is a demand for the identification of women at risk of developing cervical cancer and an increased public interest in HPV typing due to the introduction of the recently approved vaccines. Therefore, surgical pathologists should also become more aware about potential HPV-related lesions in their daily morphological triage of histological and cytological specimens. Furthermore, specific HPV types may not only carry a different morphology but also distinct risk profiles.

Conclusions

HPV analysis is complex and should be carefully evaluated for its capacity to detect HPV DNA, HR infections and finally the correct virus type. Within our inter-laboratory trial, we tested several methods that showed reliable and consistent results in daily practice. Pretested specimens will be made available for the quality testing of other laboratories and the implementation of an external inter-laboratory trial. The initiative will hopefully increase the quality of the HPV identification and typing in surgical pathology specimens. Together with the web-based photo gallery, it may enhance the perception of the diversity of HPV-induced pathology and its putative association with specific virus type.

Table 7 Statistical analysis of test results of the panel laboratories

Parameter	HPV (yes/no)	Infection type (neg/mono/mixed)	HPV high risk (yes/no)	HPV LR (yes/no)	Main HPV type (yes/no)	Main result (first type/neg)

CASE REPORT

Psammomatous melanotic schwannoma presenting as colonic polyps

Runjan Chetty · Rajkumar Vajpeyi · John L. Penwick

Received: 1 January 2007 / Accepted: 8 February 2007 / Published online: 11 July 2007

Abstract Psammomatous melanotic schwannoma is an uncommon neoplasm that usually occurs in the setting of Carney's complex. They can occur in the gastrointestinal tract with preferential location in the stomach. A 43-year-old female presented with two colonic polyps at routine endoscopy. The patient was asymptomatic and did not have features of Carney's complex. Both polyps were composed of melanin-containing epithelioid and spindle cells with several psammoma bodies. There was no evidence of cytological atypia or necrosis. The tumor was diffusely positive for S-100, and focally for HMB-45 and melan-A. The differential diagnosis includes melanoma, GIST, pigmented neuroendocrine tumor, and epithelioid leiomyoma. The lack of malignant features separates this lesion from melanoma while the immunophenotype of the other lesions is characteristic.

Keywords Psammomatous melanotic schwannoma · Carney's complex · Colon polyp

Introduction

Schwannomas are encountered in the gastrointestinal tract with the most commonly affected site being the stomach [6, 9, 10]. However, cases have also been documented within the colon [8, 11, 13]. The histological spectrum that may be encountered in schwannomas can vary widely but psammomatous melanotic schwannoma is a characteristic lesion that is often seen in association with Carney's complex [2]. Carney first described this unique variant of schwannoma in 1990 which he noted in peripheral and posterior spine nerve roots near the midline, bone, soft tissue, heart, liver, skin, bronchus, retroperitoneum, and the gastrointestinal tract [2].

We wish to highlight an unusual case of psammomatous melanotic schwannoma presenting as an incidental colonic polyp in an asymptomatic patient without stigmata of Carney's complex.

Clinical features

A 43-year-old female presented for routine colonoscopy and was found to have two separate polyps, measuring 0.8 and 0.5 cm in greatest diameter, respectively, at 25 cm. They were pedunculated and thus easily snared and removed in toto. No other lesions were noted endoscopically. The patient did not have any of the clinical manifestations of Carney's complex despite relevant investigations. The patient made an uneventful recovery. The patient has not yet been investigated for germline mutations of the *PRKAR1A* gene.

Materials and methods

The specimens were fixed in 10% buffered formalin and routinely processed, cut, and stained with H&E. In addition, stains for melanin and iron were performed as well as

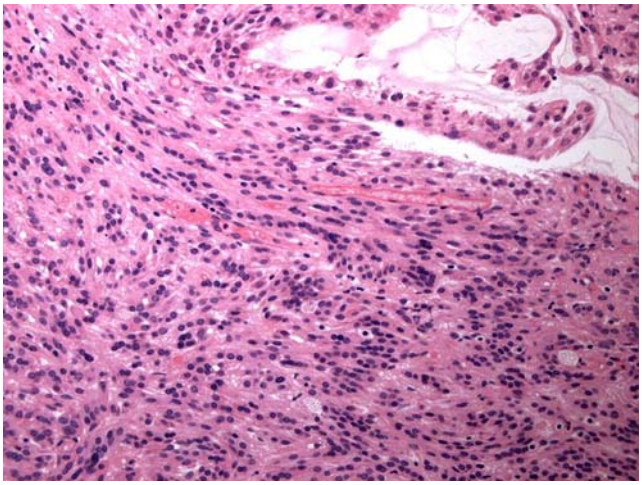

Fig. 1 The lesion composed of epithelioid cells and occasional spindle cells arranged in sheets (H&E×100)

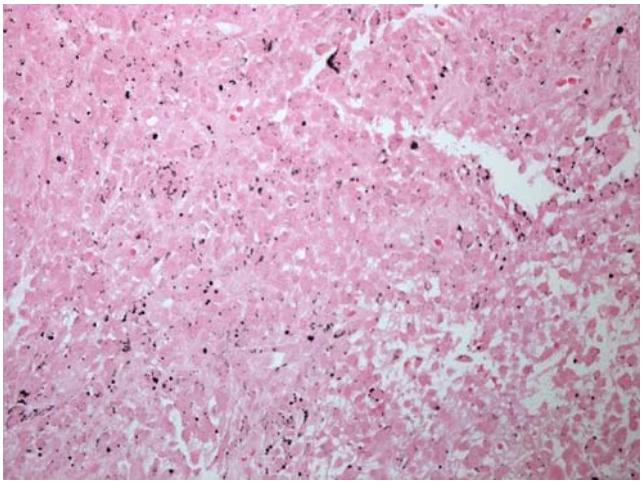

Fig. 3 The pigment was positive for the Masson-Fontana stain for melanin (Masson Fontana×400)

immunohistochemistry for: S100 protein, HMB-45, melan-A, synaptophysin, chromogranin, somatostatin, desmin, actin, CK7, CK20, CD68, CD34, and CD117.

Pathology

Sections from both polyps showed identical histological features. There was focal surface ulceration with fibrin and acute inflammatory exudate. Glands subjacent to the ulceration showed rupture with extravasation of mucin in to the lamina propria and regenerative activity. A cellular proliferation occupied the entire lamina propria and focally extended beyond the muscularis mucosae, creating a polypoid lesion. The tumor was composed of epithelioid cells (mainly) and a component of spindle cells arranged in sheets with focal areas of suggesting palisading and pseudorosette formation around vessels (Fig. 1). Several of the spindle cells had dendritic cytoplasmic processes. The epithelioid cells had abundant eosinophilic cytoplasm and several contained brown nonrefractile pigment (Fig. 2). The brown pigment was positive with the Masson Fontana melanin stain (Fig. 3) and negative for iron. Occasional lipid-laden macrophages were interspersed but obvious fat was not detected within the tumor. The nuclei were uniform with minimal pleomorphism, some contained small nucleoli and many contained intranuclear pseudoinclusions. The mitotic count was extremely low and only one mitotic figure per 10 high power fields was counted. Several multinucleated cells with clustering of nuclei were scattered throughout the lesion (Fig. 4). The stroma varied from fibrillar to oedematous to microcystic. Several psammoma bodies were liberally distributed throughout the lesion (Fig. 5). Foci of hypercellularity and necrosis were not evident.

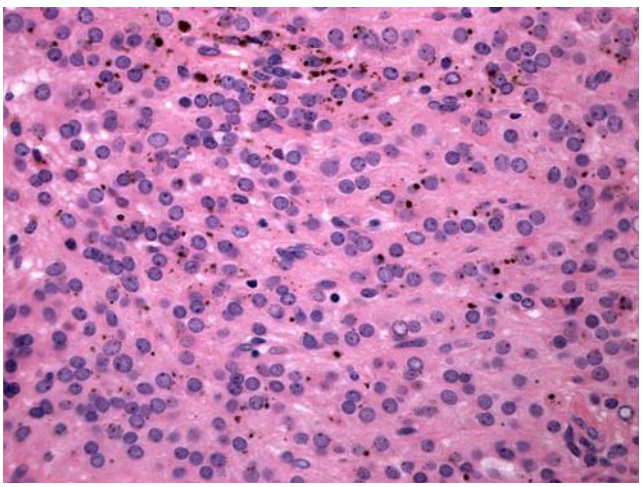

Fig. 2 Several of the tumor cells contained brown, nonrefractile pigment within the cytoplasm (H&E×400)

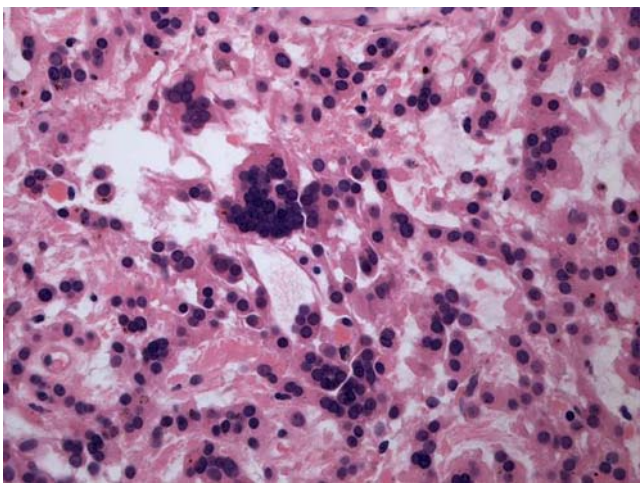

Fig. 4 A prominent finding was the presence of multinucleated giant cells scattered throughput the lesion. The number of nuclei varied from two to in excess of 25 (H&E×400)

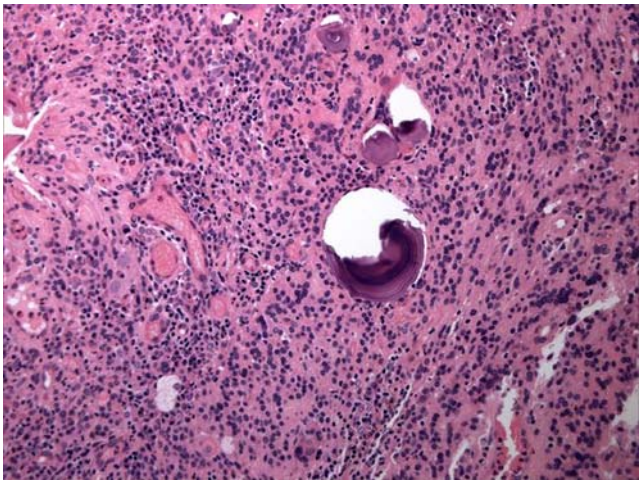

Fig. 5 The other typical and characteristic feature of the tumor was the presence of psammomatous calcification (H&E×400)

The tumor cells were strongly and diffusely positive for S-100 (Fig. 6), and focally for HMB-45 and melan-A. All other markers were negative.

Discussion

In a series of 20 schwannomas of the colorectum, Miettinen et al. noted that there was an equal gender distribution, wide age range (18–87 years; mean 65 years), size ranging from 0.5 to 5.5 cm, most frequently seen in the cecum followed by sigmoid and rectosigmoid, then transverse colon, descending colon, and rectum only [8]. The schwannomas appear as polypoid lesions causing bleeding, obstruction, and abdominal pain. The commonest pattern seen consists of spindle cells with Verocay body formation.

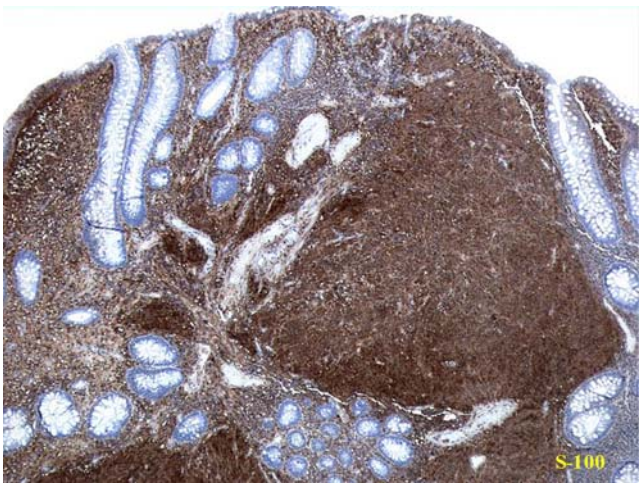

Fig. 6 The tumor cells exhibited strong and diffuse immunoreactivity for S-100 protein (anti-S-100×200)

The epithelioid variant, interestingly, occurred most frequently in the descending and sigmoid colon. These tumors were S100 positive but CD34 and CD117 negative and all behaved in a benign fashion.

Melanin pigment has been described in schwannomas [5] and amianthoid type calcification has also been encountered. The combination of melanin pigment and psammomatous calcification within a schwannoma occurs in two settings. Schwannomas, thus characterized, are associated with Carney's complex, which is named for Aidan Carney who first described the constellation of features attributed to this disease. It is a multiple neoplasia and lentiginosis syndrome of variable expression and nearly complete penetrance [1, 14, 15]. The complex consists of myxomas in the heart, breast, uterus and skin, lentigines, endocrinopathy (Cushing's syndrome from a bilateral pigmented nodular adrenocortical hyperplasia, or acromegaly) and a variety of tumors including psammomatous melanotic schwannoma, growth hormone-producing pituitary adenomas, epithelioid blue nevi, calcifying large cell Sertoli cell tumor of testis, tumors of the thyroid, and ductal adenoma of the breast [3, 4, 12]. In a detailed analysis of 40 psammomatous melanotic schwannomas, Carney noted that several cases occurred without the features of the complex [2]. Those that were associated with Carney's complex tended to be younger with an average age of 20 years, whilst those without the complex were around 33 years of age. There was an equal frequency of tumors in the gastrointestinal tract with or without the complex. He also noted that the tumors may precede the onset of the complex. Within the gastrointestinal tract, these tumors occurred from the esophagus to the rectum with the majority occurring in the stomach [2].

Microscopically, they are composed of solid sheets of spindled, dendritic, and epithelioid cells. The nuclei vary from being fusiform to round with vesicular of hyperchromatic chromatin, small nucleoli, and occasional nuclear pseudoinclusions [2]. In occasional cases, the nuclei may be large and binucleate, trinucleate and even cells with 10, or more nuclei may be encountered. The cytoplasm is generally eosinophilic and melanin is present in variable amounts. Verocay bodies are unusual. The psammomatous calcification tends to be round or oval and occasional mulberry shaped foci are present. The psammoma bodies are scattered relatively uniformly throughout the tumors. Approximately, 50% of psammomatous melanotic schwannomas may also contain areas of fat. Osseous metaplasia and thick walled vessels may also be noted. Overt cytological atypia is not seen and very occasional to rare mitotic figures are noted [2].

The differential diagnosis includes primary or metastatic melanoma, gastrointestinal stromal tumor (GIST), pigmented neuroendocrine tumor, and epithelioid leiomyoma. The absence of cytological atypia (mitoses, large inclusion-like nucleoli, hypercellularity, and foci of necrosis) militates

against a diagnosis of melanoma despite the melanoma immunohistochemical markers being positive. A psammomatous malignant melanoma has been described [7]. These authors reasoned that their lesion (which had neural-like features) was a melanoma on the basis that the lesion arose within an intradermal nevus, displayed a high mitotic rate, showed necrosis and marked pleomorphism in the deep aspects of the tumor [7]. GIST, pigmented neuroendocrine tumor, and epithelioid leiomyoma have a characteristic immunophenotype that allows distinction from a psammomatous melanotic schwannoma.

This case highlights an unusual presentation of a rare tumor, a psammomatous melanotic schwannoma presenting as incidental colonic polyps in an asymptomatic patient who lacked the stigmata of Carney's complex.

Abstract A 44-year-old Japanese man with elevated growth hormone levels and gradual deterioration of mental and renal function was admitted to the hospital. With his deteriorated general condition and renal failure, the patient developed pulmonary thromboembolism and died of respiratory failure. Autopsy examination was conducted, which revealed abnormal accumulation or intracytoplasmic storage of lipid-rich material in the small blood vessels, kidney, heart, and nervous system. After postmortem pathologic studies, including light-microscopic histochemistry, electron microscopy, and biochemical analysis of the stored lipid contents, a final diagnosis of Fabry disease was made. Histopathologic examination revealed a unique vasculopathy characterized by the presence of abnormal intracytoplasmic lipid inclusions and vascular remodeling. With regard to the clinical presentation of acromegaly, hyperplasia but not adenomatous transformation of the acidophils of the anterior pituitary gland with immunohistochemical detection of growth hormone within the cells was noted. In this case, the complication of acromegaly with hyperplasia of the acidophilic cells of the anterior pituitary gland and the unique vasculopathy causing significant organ failure, mainly of the kidney, heart, and central nervous systems, possibly as a result of microcirculatory failure, are considered to be not incidental findings but to be intimately involved in the pathogenesis of Farby disease.

Introduction

Fabry disease is an X-linked recessive hereditary disorder associated with mutation of the *GLA* gene (NM-000169) [2, 14]. In early 1898, Anderson in England and Fabry in Germany separately described the disease as angiokeratoma corporis diffusum [1, 8]. In McCusik's Online Mendelian Inheritance in Man database review, Fabry disease is defined as a congenital lipid storage disease because of the deficiency of the lysosomal enzyme alpha-galactosidase (ceramide trihexosidase; EC 3.2.1.22) [6]. The deficiency of this enzyme causes accumulation of ceramide trihexoside

(trihexosylceramide) and ceramide digalctoside in various tissues of the body [24]. The common clinical phenotype of Fabry disease is characterized by cutaneous angiokeratoma, burning pain in the extremities, sensory and autonomic nervous impairment, and accelerated renal and cardiovascular failure [16, 19, 20]. With wider recognition of the disease, clinical and pathologic heterogeneities have been reported among affected individuals [3, 7, 12]. In fact, a cardiac variant of Fabry disease was proposed in individuals with severe cardiac lesions without other profound lesions. The clinical diagnosis of Fabry disease, therefore, may be difficult without a typical clinical presentation or genetic analysis.

We report a case of Fabry disease that presented with an acromegaly-like appearance and cognitive dysfunction, as well as a unique vasculopathy. The objective of the present report is to (1) emphasize the importance of autopsy for accurate diagnosis and (2) provide information on the clinical and pathologic heterogeneities of Fabry disease.

Clinical history

A 44-year-old Japanese man was found unconscious on the street. He was transferred by ambulance to the emergency room and admitted to our hospital. Clinical information about the patient was limited because the patient had been homeless for a long time. At admission, physical examination revealed generalized hypothermia (29.9°C) and loss of consciousness. Routine laboratory analyses revealed elevation of the blood urea nitrogen and serum levels of creatinine potassium, consistent with renal failure. A chest X-ray revealed cardiomegaly and a homogeneous radiopacity in the right upper lobe. After admission, his renal function and consciousness level continued to deteriorate despite aggressive treatment. When he eventually showed partial recovery, we noticed that he had severe cognitive dysfunction. In fact, his score on the Hasegawa Dementia Scale—Revised was 4 out of 30, suggestive of severe dementia. Based on the limited information, he was diagnosed to possibly have developed acromegaly when he was in his teens. Thickening of the heel pad was observed. Brain computed tomography (CT) revealed multiple cerebral infarcts in the border zone area in the right frontal lobe and showed mild enlargement of the sella tunica without any apparent pituitary mass. However, single-photon emission CT revealed diffuse cerebral hypoperfusion in the cerebral cortex as well as in the brainstem and basal ganglia. Electroencephalography revealed an occasional theta or delta burst. The serum level of growth hormone markedly elevated (16.3 ng/ml, normal value <0.42). However, the serum level of prolactin, adrenocorticotropic hormone (ACTH), free thyroxin, free T3, thyroid-stimulating hormone (TSH), and somatomedin were all normal. Four months after his first admission, the patient died of respiratory failure because of pneumonia.

Family history

His father and mother had died of esophageal cancer and myocardial infarction, respectively. His elder brother had suffered from an episode of acute renal failure and also some sort of cognitive dysfunction. He had committed suicide when he was in his 30s. His younger sister had also been recognized to have some cognitive dysfunction and had reportedly died of bronchial asthma when she was in her 20s. A living younger sister is in good health. No definitive diagnosis of Fabry disease had been made in any of the family members.

Materials and methods

Postmortem study, histology, light microscopy, and immunohistochemistry

Autopsy was carried out 14 h and 30 min after the patient's death. Briefly, after through macroscopic inspection, representative tissue specimens from several organs were obtained, fixed in 15% formalin, embedded in paraffin, and processed using conventional histological techniques. The tissue sections, except for those from the brain and spinal cord, were stained with hematoxylin and eosin (H&E); H&E and luxol fast blue (LFB) staining was performed for the sections of the brain and spinal cord. Immunohistochemical analysis of paraffin-embedded tissue sections of the pituitary gland was carried out using the Envision method (Dako, California), with or without the specified pretreatment [4]. Primary antibodies for growth hormone, TSH, follicle-stimulating hormone, luteinizing hormone, prolactin, ACTH, Kp-1 (CD68), and keratin (KL-1) were used. Frozen sections of some formalin-fixed tissue specimens, including those from the kidney and heart, were stained with Sudan Black B for the detection of lipid.

Electron microscopy

Retrieved heart and kidney fragments from formalin-fixed tissue specimens were refixed in 2.5% glutaraldehyde, postfixed in 1% osmium tetroxide, dehydrated using graded alcohol solutions, and embedded in epoxy resin. Ultrathin sections were stained with uranyl acetate and lead citrate and examined under a transmission electron microscope (JEOL 1200 EXII) [11, 13].

Results

Postmortem study, histology, light microscopy, and immunohistochemistry

The pathologic findings in the present case are summarized in Table 1 (Fig. 1a–e). In regard to the external appearance, the patient was 169 cm in height and only 38 kg in body weight, possibly because of malnutrition. The heart weighed 580 g, and sections of the heart revealed evidence of left ventricular hypertrophy. The kidney revealed marked atrophy (left, 90 g; right, 100 g). Both lungs were congested (left, 510 g; right, 790 g in weight), and a pulmonary thromboembolus was found in the right S9. Some other incidental findings were found in the testes, thyroid gland, and liver (Table 1). The size and weight (0.8 g) of the pituitary gland were within normal limits. Horizontal slices of the cerebrum revealed recent infarcts in the frontal and parietal lobes. Old cystic infarcts were also observed in the same. The findings were consistent with border zone infarction in the region of supply of the anterior and middle cerebral arteries (Fig. 1b). Small infarcts were also seen in the thalamus and putamen.

The most striking feature on microscopic examination was the marked presence of lipid inclusions in various types of cells (Fig. 1a,c). The inclusions were detected, as vacuoles using H&E staining (Fig. 1a,c) showed strongly positive staining with Sudan black B, suggesting lipid deposition. In the vasculature, lipid deposits were observed in the endothelial cells, pericytes, and smooth muscle cells (Fig. 1a,c). In the nervous system, marked lipid deposition was observed in the amygdala, parahippocampus, inferior temporal gyrus (deep cortical layers), hippocampus, subiculum, and the ganglion cells of the posterior spinal cord root ganglia and celiac ganglia. Sparse intracytoplasmic deposits were also seen in the neurons of the substantia nigra and dorsal motor nucleus of the vagus. No deposits were seen in the frontal, parietal, or occipital cortex or in the cerebellum.

Numerous deposits visualized by LFB staining were visualized in the cytoplasm of the smooth muscle cells of the parenchymal and leptomeningeal. Furthermore, lipid deposits were also observed in the histiocytes in the lymph nodes, spleen, liver, bone marrow, and kidney, as also in the epithelial cells of the renal glomeruli and renal convoluted tubules. Lipid deposits were also seen in the smooth muscle cells of the bronchi and renal pelvis, and the cytoplasm of cardiomyocytes (Fig. 1a).

In the anterior lobe of the pituitary gland, the acinar architecture was relatively well preserved. However, hyperplasia of the acidophilic cells of the anterior pituitary gland with positive immunostaining of the cells using antibody raised against human growth hormone was observed (Fig. 1d,e). No lipid accumulation was seen in either the acinar cells or the vasculature of the pituitary gland.

Analysis of the accumulated lipid

A large amount of trihexosylceramide was extracted from the formalin-fixed kidney tissue. This finding was consistent with the diagnosis of Fabry disease [23, 24].

Table 1 Summary of autopsy findings

Findings
1. Fabry disease
Generalized intracytoplasmic accumulation of lipid (trihexosylceramide) in the:
(a) myocardium with cardiac hypertrophy (heart weight, 580 g),
(b) endothelial cells, pericytes, and smooth muscle cells of the body vasculature with multiple small brain infarcts (brain weight, 1425 g),
(c) neurons and ganglion cells in the posterior spinal roots, celiac ganglion, hippocampus, and striatum nigrum,
(d) histiocytes in the lymph nodes, spleen, liver, bone marrow, and kidney,
(e) epithelial cells in the renal glomeruli, renal convoluted tubules, with marked atrophy of kidney (kidney weight: left, 90 g, right, 100 g),
(f) smooth muscle cells in the bronchi and renal pelvis.
2. Acromegaly-like condition
High serum growth hormone level: 16.3 ng/ml (normal level, 0.42 ng/ml), thickened heel pad, hyperplasia of the anterior pituitary gland acidophilic cells containing human growth hormone as confirmed by immunohistochemistry, although the size and weight of the gland were within normal limits (pituitary gland weight, 0.8 g)
3. Pulmonary congestion and edema with pulmonary thromboembolism and pulmonary infarction in the lower lobe (lung weight: left, 510 g; right, 790 g; pleural effusion: left, 20 ml; right, 300 ml)
4. Atrophy of the testis (testis weight: left, 16.3 g; right, 13.8 g)
5. Thyroidal follicular adenoma (small)
6. Hepatic cavernous hemangioma (small)

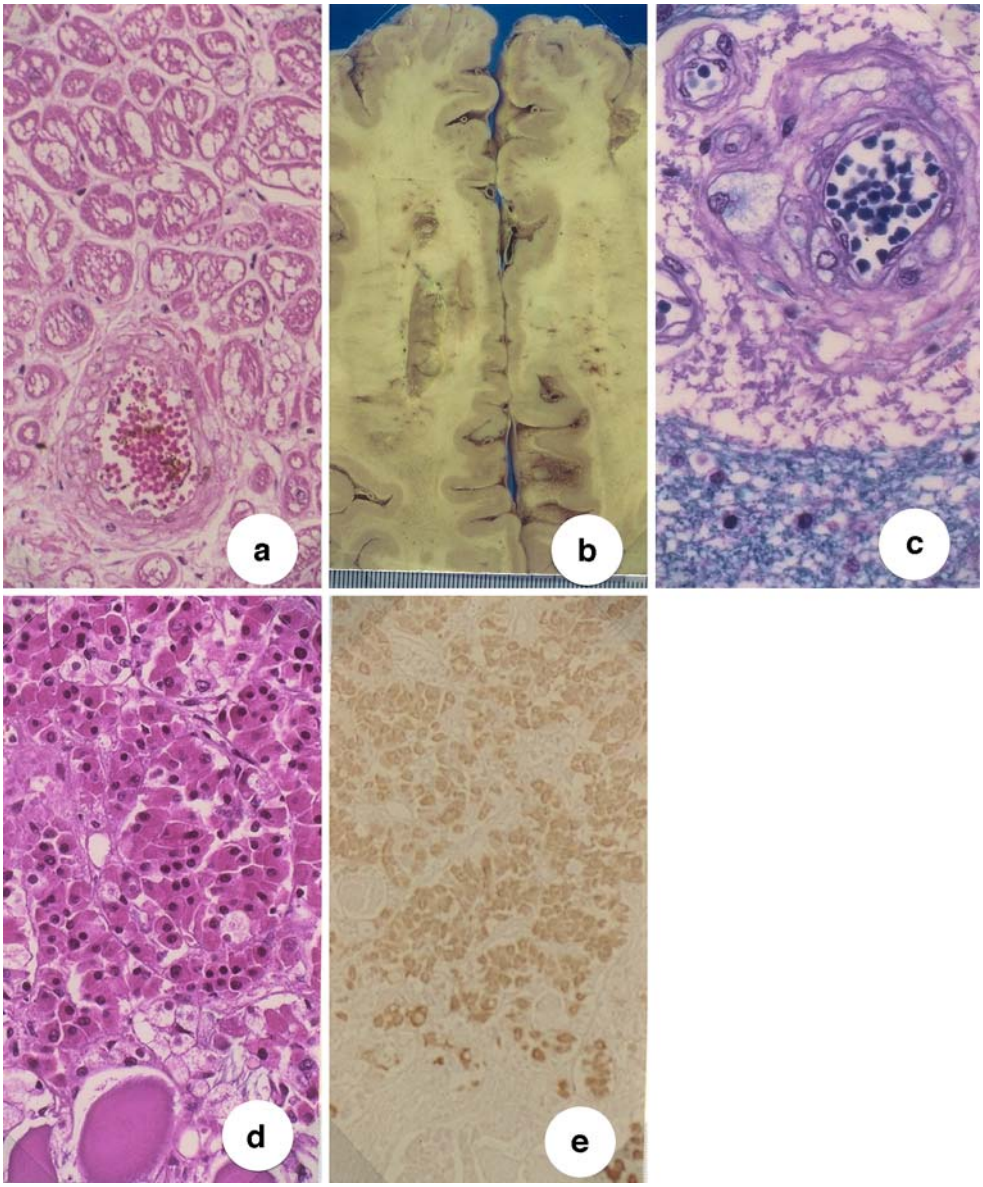

Fig. 1 Photomicrographs of gross and microscopic appearances from several organs. **a** Histological sections of the myocardium. Lipid-rich contents could be extracted during processing from each of the striated cardiac muscle cells showing intracytoplasmic vacuole. Congested vessels with small vacuoles in the endothelial and medial smooth muscle cells are observed. H&E stain, 190×. **b** Macroscopic view of a horizontal (parallel to the computer tomographic scan axis) section of the brain. Many small infarct foci with *gray color* and softening are seen on the cut surface. **c** Histological section of the Virchow Robin space in the brain cortex. Many small vacuoles are seen in the vascular constituent cells. Narrowing of the vascular lumen by the swollen endothelial cells and thickened medial layer and aggregated blood cells. H&E–LFB stain, 190×. **d** Histological section of the anterior (upper part in the figure) and middle part with small Rathke's cysts of the pituitary gland. Predominant acidophil cell proliferation with maintenance of the acinar architecture is; no proliferation of chromophobe or basophilic cells is noted. H&E stain, 190×. **e** Anterior pituitary gland histological and consecutive section used for **d**. Many alveolar cells showed immunopositivity for antibody raised against the human growth hormone. 190×

Electron microscopy of the heart and kidney tissue specimens

In the myocardial tissue specimens, numerous myelinosome like-laminated membranous cytoplasmic bodies or zebra bodies with laminated alternate electron-dense and lucent layers were seen in the cytoplasm of the cardiomyocytes, as well as in the endothelial cells, pericytes, and smooth muscle cells in the vascular wall (Fig. 2).

Furthermore, in the kidney tissue specimens, many myelinosome-like-laminated membranous cytoplasmic bodies or zebra bodies with laminated alternate electron-dense and lucent layers were seen in the cytoplasm of the renal tubular epithelial cells, stromal fibroblasts, macrophages, endothelial cells of the vasculature, and smooth muscle cells in the vascular wall (Fig. 3). Feathery structures with condensed electron-dense layers were seen in some cells in obliterated renal convoluted tubules.

In both the cardiac and renal tissue specimens, small vasculature revealed stenosis or obstruction, possibly because of massive accumulation of intracytoplasmic inclusion, membranous cytoplasmic bodies, or zebra bodies in the endothelial cells (Figs. 2 and 3). Occasionally, liberated free membranous cytoplasmic bodies or zebra bodies were found floating in the vascular lumen, with some aggregation of blood cells (Figs. 2 and 3).

Discussion

We present a case of Fabry disease presenting with an acromegaly-like condition and cognitive dysfunction. A

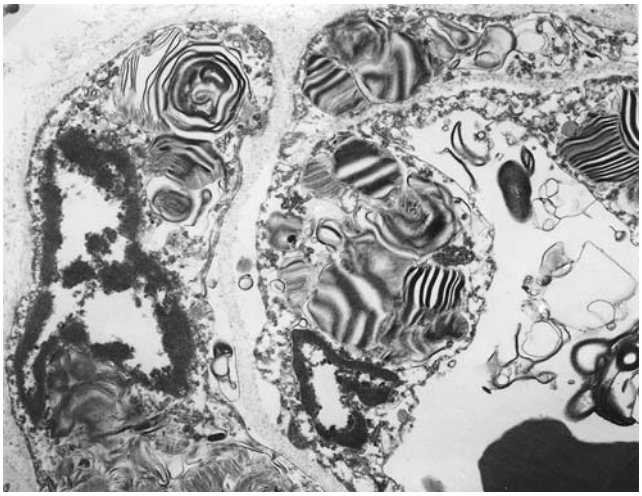

Fig. 2 Electron micrographs of myocardial tissue. High-power view of a small blood vessel of possibly capillary type shown. Many small laminated bodies, myelinosome-like structures, and zebra bodies are scattered in the swollen cytoplasm of the endothelial cells and a pericyte. Note in the lumen, similar small laminated bodies and myelinosome-like structures intermingling with the aggregated red blood cells are seen. 18,000×

unique vasculopathy was observed in several organs. According to the results of autopsy, the patient died of several critical conditions, including severe renal failure, respiratory failure because of pneumonia, pulmonary congestion, and anasarca.

In general, glycosphingolipid accumulation is observed in the endothelial and smooth muscle cells of the body vasculature, cardiomyocytes, epithelial cells of the glomeruli, renal interstitial cells, renal tubular epithelial cells, sweat glands, nervous system (neurons, astrocytes, and ganglion cells of the autonomic nervous system), and cornea [15, 25]. Circulatory disturbance resulting from the lesions in the vasculature is the most common finding in cases of Fabry disease. Vasculopathy is especially frequently reported in the kidney and nervous system, and even vascular dementia has been reported in Fabry disease [15]. Postmortem pathological findings of severe or unique vasculopathy in Fabry disease were recently emphasized again and published by Schiffmann et al. [21] and Schiffmann [22]. Their case with enzyme replacement therapy (ERT; such as intravenous infusions of alpha-galactosidasse A) has been shown to markedly reduce the cellular storage or lysosomal inclusions in vascular endothelial cells [21, 22]. Presently, our ultrastructural study exactly showed similar small structures intermingling with the aggregated red blood cells in the vascular lumen and vascular remodeling. Diagnosis of Fabry disease in the patients' early life and additional or detailed further investigation with clinical attempt of ERT [21, 22] are necessary for their improvement of prognosis.

The living condition of the patient with no immediate relations and the severe cognitive dysfunction would have made the potential clinical diagnosis of Fabry disease extremely difficult in the present case. Recent studies have indicated that some patients may exhibit only the cardiac or renal clinical phenotype of Fabry disease without the typical clinical features [3, 7, 12]. In such cases, it may be difficult to make an accurate diagnosis. In the present case, little clinical information about the patient was available because he lived as a vagrant. He lacked the typical angiokeratoma, severe burning pain in the extremities, and autonomic disturbances. However, careful analyses of the histological sections immediately raised the possibility of some lipid storage disease. In particular, we suspected the diagnosis of Fabry disease in the present case based on the observation of lipid-rich intracytoplasmic inclusions in the heart, kidney, and central nervous system. Further analyses of the accumulated lipid (trihexosylceramide) and electron microscopy of the kidney and myocardial tissue specimens confirmed the diagnosis. This case report thus serves to emphasize the importance of histopathologic examination to confirm the diagnosis in suspected cases.

The present case was diagnosed as having developed acromegaly in his teens. Thickenings of the heel pad and elevated serum growth hormone levels were observed. However, no pituitary adenoma was detected at the time of autopsy. In rare instances, an acromegaly-like condition has been reported without follow-up detailed postmortem examination [5, 9, 10, 26].

In the pituitary gland, some proliferation of acidophilic cells contained the growth hormone, as detected by immunohistochemistry. Histologically, the acinar architecture of the proliferated anterior pituitary gland cells was

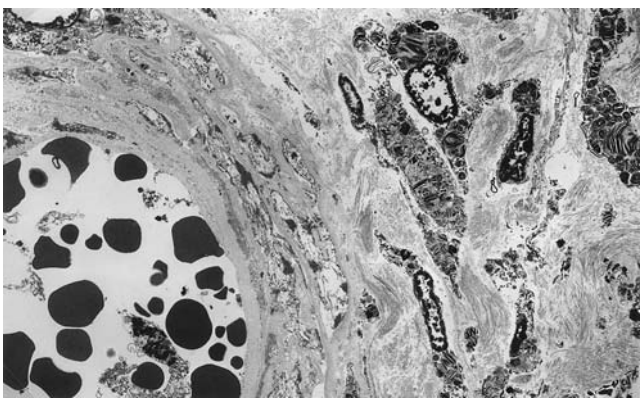

Fig. 3 Electron micrographs of the kidney tissue. Low-power view of the interstitial or stromal tissue of the kidney. Many small laminated bodies, myelinosome-like structures, and zebra bodies are scattered in the cytoplasm of the stromal fibroblastic cells and histiocytes. Similar structures are seen in the medial cells and endothelial cells of the small blood vessels. In the lumen, similar small structures are seen intermingling with the aggregated red blood cells. 3,500×

preserved. Lipid accumulation and the characteristic vasculopathy were inconspicuous in the pituitary gland. The profile of this proliferated anterior pituitary gland cells are suggestive of not adenoma but hyperplasia. Furthermore, the histological characteristics were also suggestive of hyperplasia rather than adenoma or neoplasia. An acromegaly-like condition is extremely rare in Fabry disease in which growth hormone–releasing hormone-producing tumors have not been reported [9, 26]. We speculate that the acromegaly-like condition in our present case was associated with some alterations of the growth hormone regulation pathway and/or vasculopathy in the pituitary gland–hypothalamus axis or in the target organs of growth hormone action (striated muscle, bone, etc.). In fact, the testicular atrophy and thyroidal follicular adenoma observed in our case may also be related to this speculative pathogenic mechanism [17]. Because endocrine abnormalities are considered to be rare, further study may be warranted to investigate the endocrine abnormalities in Fabry disease.

In the present case, direct accumulation of lipids in certain types of cells may be expected to have caused functional deterioration of the cells. A pervious report emphasized the mechanism of luminal narrowing of the blood vessels as being related to the deposition of glycosphingolipids in the vessel walls [15]. In the ultrastructural examination in our study, we found not only intraendothelial deposition of materials (zebra body, myelinosomes, laminated materials—storage material of lipid–sugar compound) but also breakdown materials in the vascular lumen. Noninvasive examination has also suggested endothelial dysfunction in cases of Fabry disease [18]. These pathologic abnormalities might predispose to thromboembolism and stenosis or occlusion of the vascular lumen and ultimately cause failure of the microcirculation in the kidney, heart, and central nervous systems.

CASE REPORT

Basaloid adenocarcinoma. A new variant of pulmonary adenocarcinoma

Valerio Marci · Marco Volante · Susanna Cappia · Luisella Righi · Corrado Novello · Giorgio V. Scagliotti · Elisabeth Brambilla · Mauro Papotti

Received: 5 April 2007 / Revised: 18 June 2007 / Accepted: 18 June 2007 / Published online: 6 July 2007

Abstract The 2004 WHO classification of lung tumours recognised basaloid carcinoma as a variant of squamous and large cell carcinoma. We report a unique case of primary pulmonary adenocarcinoma with a basaloid component. An 82-year-old man underwent pulmonary lobectomy for a 2.8 cm tumour. The patient is disease-free 13 months after diagnosis. Histologically, an invasive carcinoma having a glandular and a solid component was observed. The former was an adenocarcinoma with mucus containing spaces lined by columnar mucinous cells and basaloid cells. The solid component was an organoid proliferation of basaloid-type cells, as in cutaneous basal cell carcinoma. Basaloid cells, but not mucinous cells, were immunoreactive for high molecular weight cytokeratins (CK), CK 7 and, focally, for TTF-1. High Ki67 index, p53 and EGFR expression were also found. This tumour is unique in several respects: (1) The solid areas resemble a conventional basaloid carcinoma, except for the presence of small mucin-containing spaces. (2) The mucinous adenocarcinoma areas contain two layers of columnar and basaloid cells. (3) Both components are neoplastic based on cell morphology, invasive properties and phenotypic profile. These findings indicate that a basaloid variant of adenocarcinoma is also existing in the spectrum of basaloid carcinomas of the lung.

Introduction

Basaloid carcinoma of the lung (BCL) has originally been described by Brambilla et al. [3] as a peculiar type of primary pulmonary neoplasia with a striking morphological resemblance to the more common basal cell carcinomas of the skin, upper aerodigestive tract and anal canal [1, 6]. Although a minority of the originally described cases (3/38) had focal signs of glandular differentiation within the classical solid or lobulated patterns of growth, BCL was regarded as a variant of squamous or of undifferentiated large cell carcinomas of the lung, and as such this tumour type was classified in the recent WHO classification of lung tumours [18]. In this scheme, BCL is listed in both categories of squamous and large cell carcinomas [18]. The described cases with focal glandular differentiation had morphological similarities with adenoid cystic carcinoma, although the pattern of growth was largely solid and small acinar formations were barely detectable in the

solid lobules. In addition, ultrastructural evidence of microvilli formation in the cell surface facing acinar lumina was also provided [3].

The existence of pulmonary and extra-pulmonary tumours with combined (mixed) features of the squamous and glandular lineages is well known, including for example adenosquamous carcinoma, mucoepidermoid carcinoma, mixed squamous carcinoma and adenocarcinoma of the lung [18]. In all such cases, two distinct components are generally growing one aside the other (collision tumour) or intermingled one into the other. However, no case has so far been described in the English literature of a primary pulmonary tumour combining basaloid features with any known type of adenocarcinoma [7, 18]. A single case of such an association was reported in the parotid gland under the heading of basal cell adenocarcinoma [9] and another apparently similar one (though with myoepithelial differentiation of the basaloid cells) was recently described in minor salivary glands [20].

We report a unique case of mucinous adenocarcinoma of the lung having an associated component of BCL, both in the classical form of solid, lobulated growth pattern and—within the glandular component—as layers of neoplastic basaloid cells, lining the dilated mucinous glands externally to the columnar cells. The term basaloid adenocarcinoma of the lung is proposed for this new variant.

Clinical history

An 82-year-old man, heavy smoker (20 cigarettes per day from age 20 to 68), was admitted to the Division of Thoracic Surgery at the University of Turin at San Luigi Hospital in January 2006 due to cough and thoracic pain. He had worked for 40 years as a clerk in a textile industry and is now retired. In the medical history, the patient received surgery for varicocele (1958), sigmoid diverticulosis (1991) and renal cyst (2002). The chest X-rays revealed a pulmonary sub-pleural opacity; subsequently, a chest CT scan confirmed the presence of a 2.8 cm mass in the sub-pleural location of the left lower pulmonary lobe. No mediastinal lymph node involvement was detected at CT scan and major bronchoscopy was negative for endobronchial lesions. The patient underwent pulmonary lobectomy and was discharged 10 days later. No additional post-operative treatment was performed in consideration of the T1N0 surgical stage of the tumour and the age of the patient. After 13 months, the patient is alive and completely disease-free.

Materials and methods

The surgical specimen was fixed in 10% buffered formaldehyde and representative tumour tissue samples embedded in paraffin. Serial 4 μ thick sections were stained with a standard hematoxylin and eosin for conventional diagnostic purposes, and with Alcian blue and periodic acid-Schiff (PAS) reaction (with and without diastase pre-treatments) to reveal mucins. Parallel sections were also used for immunohistochemistry, employing a biotin-free detection system (En-Vision, DakoCytomation, Glostrup, Denmark), after appropriate antigen retrieval procedures based on microwave oven heating in citrate or EDTA buffer solutions. The primary antibodies used, their type and/or clones, working dilutions and sources are listed in Table 1. Appropriate positive and negative controls were introduced for each immunoperoxidase stain.

Fluorescent in situ hybridisation (FISH) for epidermal growth factor receptor (*EGFR*) gene was performed on serial sections of the tumour, which were de-paraffinised, re-hydrated, pre-treated with 0.2 N HCl and then sodium thiocyanate at 80°C for 30 min, and finally incubated with pepsin (25 mg/ml) at 37°C for 10 min (pre-treatment kit, Vysis, Abbott Molecular, IL, USA). After rinsing in 2X SSC (at room temperature for 5 min) and dehydration, the Spectrum Orange LSI EGFR/Spectrum Green CEP7 probe (Vysis) was applied and the hybridisation performed after sealing the coverslip with rubber cement. The slides were incubated at 80°C for 10 min for co-denaturation of chromosomal and probe DNA and were then placed in a humidified chamber at 37°C for 18 h. Then the rubber cement seal was stripped off, the coverslip gently removed and the slides immediately incubated in 2X SSC/0.3% NP-40 buffer at 73°C for 2 min. After rapid washing in 2X SSC at room temperature and air drying in darkness, the section was counterstained with DAPI (4′,6′-diamidino-2-phenylindole), and the slides examined under an Oympus BX41 microscope, equipped with single and dual bandpass filters for spectrum orange, spectrum green and DAPI, and with ×40 and ×100 oil objectives. The procedure and result interpretation followed published protocols [5, 19].

Results

Grossly, a firm peripheral nodule with pleural fibrotic reaction and retraction was detected. On cut surface, a well-demarcated solid grey node was found measuring 2.7×2 cm with colloid areas in the absence of macroscopically evident necrosis or haemorrhage. Histologically, the carcinoma had a double component with totally different patterns, a glandular one and solid/lobulated one, which merged one into the other. Both components were non-capsulated and had an irregular infiltrative margin into the pulmonary parenchyma with a dense fibrotic reaction around the neoplastic islands.

The glandular component represented approximately 60% of the tumour area and superficially resembled

classical acinar adenocarcinomas. Glandular spaces of different sizes, sometimes enlarged as a result of gland confluence with abundant, strongly PAS stain positive, mucus in the lumen were observed (Fig. 1, top right). Well-differentiated, polarised, columnar mucinous cells lined the tubular or micro-cystic structures. In some glands, the mucinous cell layer was interrupted and/or the mucinous cells were rather cuboidal or roundish. Occasional signet ring-shaped cells abutting the luminal prospect of the glands were also present. Such mucinous glands infiltrated the pulmonary parenchyma and residual bronchial and alveolar spaces were traceable within the tumour entrapped in a moderate fibrotic reaction made of lymphocyte-rich dense collagen. At a closer view, however, all neoplastic glands were basally lined by apparent basaloid type cells, arranged in two to four layers within the basal membrane and beneath the columnar mucinous cell layer (Fig. 1e). These cells were polygonal or roundish with a hyper-chromatic nucleus of larger size than that of the columnar cells and—above all—markedly more irregular in shape (Fig. 1f–h). These cells were all similar to those growing in the solid/organoid component (see below). In such basaloid cell layer, some mitoses were present, as opposed to the columnar mucinous cells in which no mitotic figure has been identified.

The second component represented approximately 40% of the tumour area and, at low power, had the lobulated organoid growth pattern typical of basaloid carcinoma of the skin and other locations (Fig. 1, top left and right). Variously confluent islands with peripheral palisading or, more rarely, cords of poorly differentiated, medium size cells with hyper-chromatic nuclei, no visible nucleoli and scant cytoplasm were present throughout in this part of the tumour (Fig. 1a,b). In addition, part of the neoplastic islands had a cribriform appearance, as a result of small cystic or micro-glandular space formations, generally towards the center of the neoplastic nest or lobule. These spaces were irregularly lined by PAS-positive mucinous columnar cells and contained rare histiocytes (Fig. 1c,d), suggesting the possibility that some of these neoplastic nests were glandular spaces overgrown and almost totally replaced by a basaloid cell population. Numerous mitoses were observed in the solid and cribriform component, including occasional atypical mitoses. More or less extensive foci of necrosis, especially at the center of solid neoplastic lobules, were present.

In the whole tumour, a dense collagen reaction with lymphocytic infiltration, areas of hyalinosis and irregularly shaped calcifications was observed. The neoplasia grew contiguous to the visceral pleura, but did not infiltrate the surface. No signs of angioinvasion or infiltration of the bronchial surgical margins were observed. Hilar and mediastinal lymph nodes were free of metastases, and the tumour was staged pT1-N0. The surrounding non-neoplastic

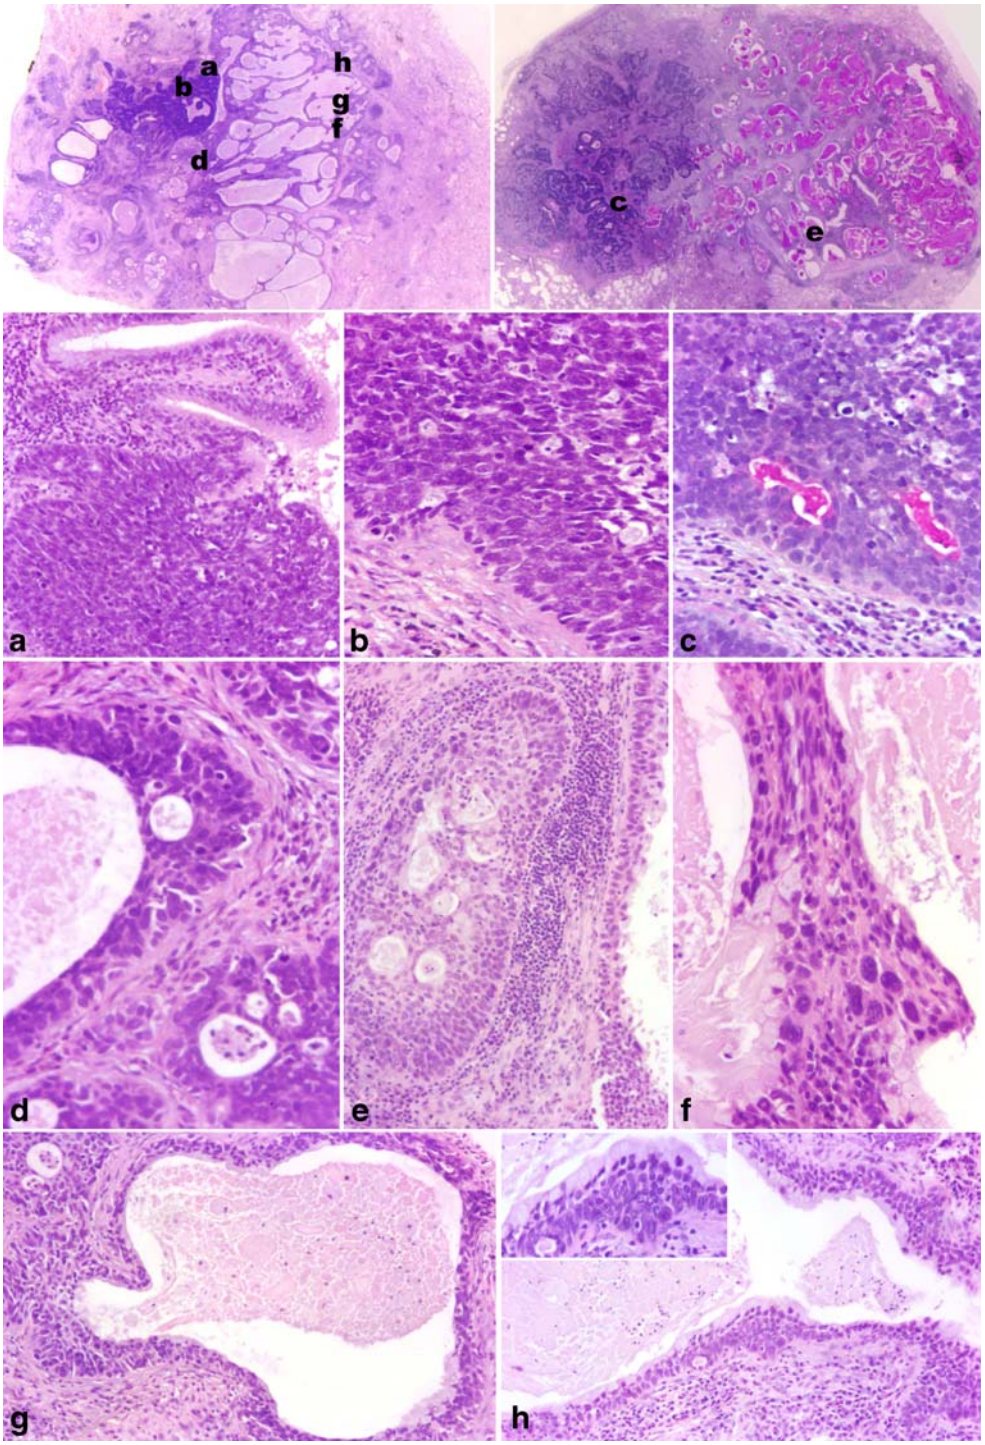

Fig. 1 Basaloid adenocarcinoma of the lung. Whole mounts of the tumour stained with hematoxylin and eosin or with PAS stain (top figures). In both sections, from left to right, a transition from a basaloid component towards a classical mucinous (cysto)adenocarcinoma component is observed. The various patterns of growth are shown in pictures *a* to *h*, and the original location of the representative fields are indicated in the whole mounts by the same letter (**a**–**h**). The basaloid carcinoma ulcerates the bronchial mucosa (**a**) and solid islands with peripheral palisading infiltrate the lung parenchyma causing a fibrotic reaction (**b**). In some areas, small acinar spaces containing PAS-positive material are recognised within the basaloid islands (**c**). Elsewhere, the spaces are dilated and lined by mucinous cells (**d**, **e**). A double component of mucinous and basaloid cells is observed along glandular and mucus-containing cystic spaces (**g**–**h**). The cells of the basaloid layers are larger and more atypical than the well-differentiated polarised mucinous cells (**f**). (**a**, **b**, **d**–**h** hematoxylin and eosin; **c** PAS stain)

pulmonary parenchyma had signs of emphysema and mild respiratory bronchiolitis, probably related to tobacco smoke.

The immunophenotypic profile had some differences between the two components and was consistent with the features of basaloid carcinoma on the one side and of mucinous carcinoma of the lung on the other. Both components were strongly reactive for wide spectrum cytokeratin (CK). The basaloid component also strongly expressed high molecular weight CKs (nos. 1, 5, 10, 14) (Fig. 2a) with this marker also present in the basal cell layer of the glandular component, but absent in the mucinous columnar cell layer (Fig. 2e,f). CK 7 (but not CK 20) was strongly expressed in the basaloid component (Fig. 2b), but in scattered mucinous cells only of the glandular component. Scattered CK 20 reactive cells were seen in the mucinous component. TTF-1 was only focally expressed in

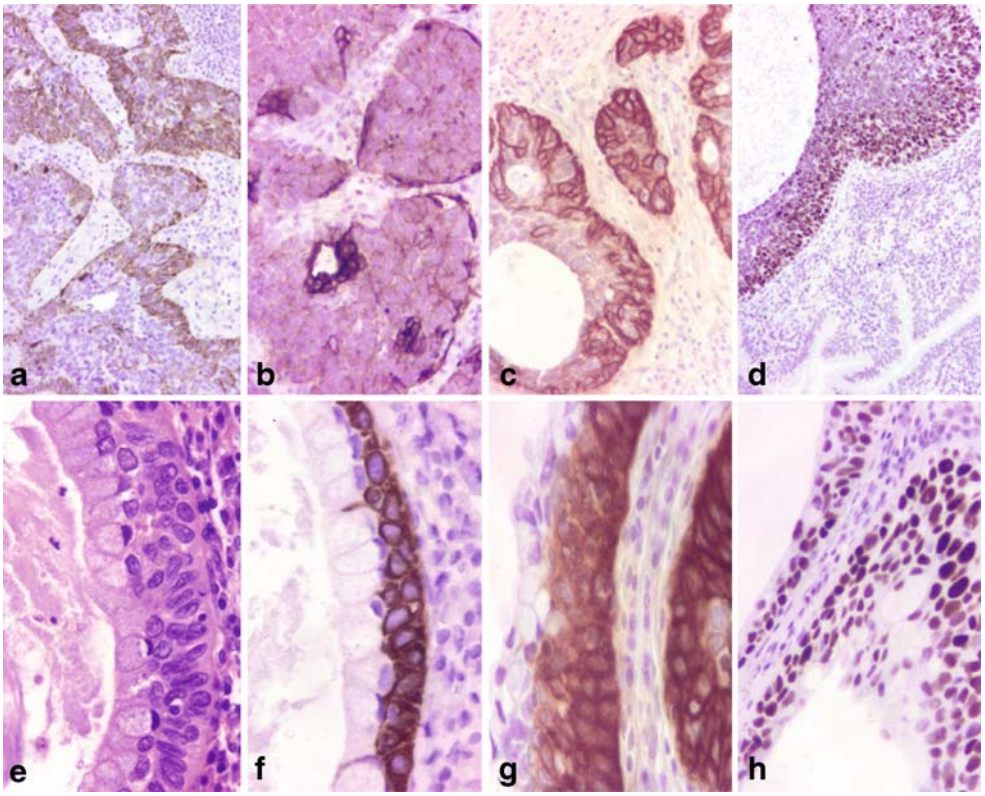

Fig. 2 Basaloid adenocarcinoma of the lung. Immunoprofile of basaloid (**a**–**d**) and glandular (**e**–**h**) components. High molecular weight cytokeratins (**a**) and cytokeratin 7 (**b**) are strongly positive in most neoplastic cells of the basaloid areas. The same cells also express EGF receptor at the cell membrane level (**c**) and most nuclei are positive for p53 (**d**). The glandular component shows a peculiar double layer of inner well-differentiated mucinous cells and of outer basaloid cells (**e**). Only the latter react for high molecular weight cytokeratins (**f**) and EGF receptor (**g**). Conversely, p53 is expressed in the nuclei of both cell types, although the mucinous cells are less intensely stained than the basaloid cells (**h**). (**a**–**d** and **f**–**h** immunoperoxidase stain; **e** hematoxylin and eosin)

the basaloid component and did not stain any mucinous cell. No reactivity for surfactant protein was observed. MUC-1 expression was restricted to the basaloid cells, but absent in the mucinous glands. The neuroendocrine markers chromogranin A, CD56 and synaptophysin were negative. Molecules implicated in invasion and metastatic processes, such as bone sialoprotein, osteopontin and cathepsin K were negative in both neoplastic components. Stromal reactivity for cathepsin K was found, as recently described in the fibrotic stromal tissue of invasive pulmonary adenocarcinoma [15].

Vascular endothelial growth factor (VEGF) was unreactive in the basaloid cells, weakly expressed in mucinous columnar cell and in the intra-tumoural vascular endothelia. Epidermal growth factor (EGF) receptor was strongly positive in peripheral areas of the basaloid carcinoma component (Fig. 2c) and in the basal cell layer of the glandular areas, being mucinous cells completely unreactive (Fig. 2g). Conversely, p53 expression was found in both tumour cell populations, although the glandular cells were weakly expressing p53 in 60% of nuclei (Fig. 2h), as opposed to a strong and diffuse immunoreactivity in most basaloid cell nuclei (Fig. 2d,h). A high proliferative rate was detected by means of Ki67 immunostaining in the basaloid component with approximately 65% of nuclei undergoing cell division, as opposed to the adenocarcinoma component in which the columnar mucinous cells had less than 5% and the basal cell layers approximately 20% of proliferating cells, respectively. FISH analysis of the *EGFR* gene was negative for amplifications and polysomies in both components. It is interesting to note that a low trisomy, according to the definition of Cappuzzo et al. [5] for chromosome 7, was observed in both neoplastic components.

Discussion

In this report, we described the pathological features of a unique primary non-small cell pulmonary carcinoma characterised by basaloid cell growth in both a typical basaloid carcinoma area and within a mucinous adenocarcinoma component having two layers of basal and mucinous columnar cells lining enlarged mucin-laden spaces. We propose the term “basaloid adenocarcinoma” for this particular tumour type.

The tumour is unique in several respects: (1) The solid areas look like a basaloid carcinoma (of the skin or of the lung), except for some cribriform appearance due to the presence of small acinar mucin-containing spaces, in the absence of keratinised squamous cells. (2) The glandular areas represent a well-differentiated mucinous adenocarcinoma, as commonly observed in various locations with columnar mucinous cells lining dilated acinar and micro-cystic formations. (3) In such glandular component, layers of basaloid cells similar to those

described in the basaloid carcinoma component, grow external to the mucinous cell layer and within the basal membrane. (4) Both components are neoplastic based on the cell morphology, invasive properties and the p53/Ki67 profile. These points will be briefly commented on.

Firstly, the basaloid component had an architecture, which at low power was strikingly similar to the classical basaloid carcinoma described as a variant of squamous or large cell lung cancer [18]. Roundish or irregular lobules of basaloid cells having a peripheral palisading were present throughout with an invasive border into the pulmonary parenchyma and immunophenotype described for basaloid carcinoma (including strong expression of high molecular weight cytokeratins). In classical basaloid sub-types of squamous and large cell carcinomas of the lung, the presence or absence of squamous keratinised cells has been indicated as a diagnostic criterion for entering the tumour in one of these sub-types, respectively. No mention is made in the WHO classification to the extent of basaloid differentiation (vs squamous component) required to qualify a tumour as basaloid carcinoma, although in the original report [3] half cases were not pure basaloid carcinomas and the basaloid areas accounted for at least 60% of the tumour. It can be assumed that, in general, basaloid carcinomas have a predominant basaloid growth pattern. The present case was not characterised by the predominance of basaloid features (present in less than half of the tumour area). However, being basaloid cells recognised either in the classical lobulated/solid growth pattern or in a basaloid layer beneath the adenocarcinoma component, it seemed to us that such basaloid component deserved mention in the pathology report. Being relatively extensive, the term basaloid adenocarcinoma was favoured over adenocarcinoma with basaloid differentiation, although this is a largely semantic issue in our opinion. At variance with classical basaloid carcinoma, no squamous keratinised cells were observed and small acinar mucus-containing spaces were present within the basaloid islands, a pattern somewhat similar to that described in Fig. 4 of the original paper of Brambilla et al. on basaloid carcinoma of the lung [3]. These acini contained small amounts of mucins and glandular cells, which were overgrown by the basal cells. This pattern may superficially resemble an adenoid cystic carcinoma (see below). A similar condition was reported in rare basaloid carcinomas of the skin in which focal signs of "duct differentiation" (probably of the sweat gland type) were detected at the center of basaloid islands [10]. No areas of squamous differentiation with keratinisation were traced throughout the tumour, thus excluding that the present tumour was a basaloid variant of squamous carcinoma (code 8083/3 of the WHO classification) [18]. The presence of a well-differentiated adenocarcinoma component also excluded the alternative diagnosis of basaloid variant of large cell carcinoma (code 8123/3 of the WHO classification) [18].

In addition, the basaloid component merged with the glandular component, which showed dual differentiation along mucinous and basaloid cell lineages, both lining the enlarged mucin spaces. The mucinous cells had the typical appearance of mucinous adenocarcinomas as commonly observed in colorectal, ovarian or pancreatic locations and, more rarely, in the lung. The morphological features and the immunoprofile (focal expression of CK 7 and CK 20 and absence of TTF-1) were consistent with those reported in cases of primary pulmonary mucinous adenocarcinoma [16]. External to the mucinous cell layer, a growth of basaloid cells all similar to those described in the basaloid carcinoma component, was regularly represented. These cells were arranged in a few layers apparently confined within the basal membrane, in a pattern superficially resembling the pagetoid spread of breast cancer cells along mammary ducts or the hyper-plastic basal cells of enlarged prostatic ducts [14], except for the fact that such pattern of growth developed in the context of an invasive adenocarcinoma. With regard to the invasive component, a stromal reaction was observed with dense collagen, lymphocytic infiltration, hyalinosis and calcifications. These modifications of the stroma were mentioned, including calcifications [3].

Finally, both cell types had the features of malignant cells. Columnar cells generally maintained the cell polarity and had hyper-chromatic nuclei with minimal atypias. Basaloid cell in both areas had enlarged hyper-chromatic nuclei with occasional highly atypical nuclei and numerous mitoses. The possibility of a hyper-plastic nature of the basaloid cells lining the neoplastic glands was excluded based on the morphology of such cells, the high proliferative index and strong expression of p53. The tumour had an elevated Ki67 proliferative index (65%) in the basaloid component, only. Conversely, p53 was strongly expressed in both cell types and EGFR immunoreactivity was detected in basaloid cells of both component, but not in the mucinous columnar cells. It is interesting to note that the FISH analysis of *EGFR* gene did not reveal any amplification or polysomy, but in both neoplastic components, a low trisomy of chromosome 7 (as defined by Cappuzzo et al.) [5] was observed, suggesting a common genetic background of the different cell populations represented in this tumour.

Despite the presence of worrisome prognostic factors, after radical surgery and in the absence of any additional treatment, the patient is currently free of disease 13 months after the diagnosis. The follow-up is too short for this T1N0 surgically resected tumour to draw any prediction on the intrinsic aggressivity of the disease because 80% of stage IA surgically treated are alive at 5 years and basaloid median survival is about 20 months.

The tumour described in this study may well be the result of a collision between two independent carcinomas of the lung with one component growing into the other. Incidentally, if this were the case, in any event, we would face a currently un-described tumour type ("mixed or combined basaloid carcinoma"?). Although a definite proof of the collision vs divergent differentiation origin of this neoplasm is definitely lacking, there are arguments favouring both hypotheses. The two components of the tumour seem, in part, separate in the low power view of the tumour and merged in the central area. The transition zone shows neoplastic islands containing mucinous cells, which give the impression of being externally overgrown by neoplastic basaloid cells. Such cells have more marked atypias and a higher proliferative potential than the bland-looking tumour cells of the mucinous component. Although all the above features would favour the hypothesis of a collision tumour, other characteristics support the possibility of a divergent differentiation within an adenocarcinoma. These include the fact that basal, reserve cells also exist in the glandular epithelium, and the basaloid tumour cells may be related to these glandular cells, also taking into account the arrangement of basaloid cells along the mucinous cell layer. Such growth pattern along the basal membrane in the glandular component seems to us hard to be interpreted as a merging of two different tumours: the invasive properties of either component would probably have lead to a more irregular infiltration of tumour and stromal areas rather than to an ordered basally located basaloid cell arrangement, recalling the "pagetoid spread-type" of breast cancer. Finally, the presence of single mucin-containing cells in the classical basaloid component, which was already shown in initial basaloid cases description [3], and the similar molecular profile in terms of p53 expression and low trisomy of chromosome 7 (observed in both neoplastic cell populations) better support the hypothesis that the whole tumour is a basaloid variant of adenocarcinoma.

The unique features of this tumour initially raised the suspicion of a metastatic tumour. In fact, no similar tumour had so far been described in the lung. Basaloid variant of squamous or large cell carcinoma was excluded for the above reasons. The described basaloid pattern rather recalled a well-differentiated neuroendocrine tumour [2] and, indeed, the possibility of a combined adenocarcinoma–large cell neuroendocrine carcinoma was originally suggested by morphology alone. Obviously, the absence of neuroendocrine markers (chromogranin A, synaptophysin etc.) immediately excluded this hypothesis. Finally, adenoid cystic carcinoma can be suggested due to the presence of small acinar and cyst formations associated to a more solid growth pattern [2]. The differential diagnosis may be difficult and require immunohistochemistry [8]. The structure of classical adenoid cystic carcinoma, as described for example in the esophagus [12], larynx, uterine cervix [17], salivary glands, mammary gland [4] and prostate [11, 13], and of cloacogenic carcinomas of anal canal [5], is however not exactly overlapping with that of the current tumour, especially with regard to the double-layered glandular spaces lined by mucinous and basaloid cells. Among other possible differential diagnoses, combined squamous and glandular tumours are to be considered; in various organs, these have been described as mucoepidermoid or adenosquamous carcinomas [1, 18]. The currently known tumours of this type typically show a squamous (keratinised) component rather than a pure basaloid cell component, as seen in the present tumour. In addition, so far, published adenosquamous carcinomas are characterised by a mixture of glandular and keratinised cells that either line the lumen of glandular spaces both abutting to the lumen or grow admixed in solid nests. This is not the case of the currently reported tumour in which the adenocarcinoma component has a clear-cut double layer of inner columnar mucinous cells facing the mucin-laden lumen and of outer basaloid-type cells, stratified at the periphery rather than facing the lumen. We are not aware of such a pattern of growth in other adenocarcinomas.

In conclusion, we support the fact that a basaloid variant of pulmonary adenocarcinoma is also existing, thus expanding the currently known spectrum of basaloid carcinomas of the lung. This variant is characterised by the concurrent presence of clear-cut glandular areas, variously admixed with a basaloid cell population. This combination may well represent an example of collision tumour or of dual divergent differentiation. However, the presence of PAS-positive mucin material also within the basaloid areas, the overlapping profile of p53 expression in both components and the low trisomy of chromosome 7 observed in both neoplastic cell populations better support the hypothesis that the whole tumour is an adenocarcinoma with extensive basaloid cell differentiation (that has more or less extensively overgrown the mucinous component in part of the neoplastic glands).

LETTER TO THE EDITOR

Silicotic mediastinal lymphadenopathy can cause left vocal cord paralysis and dysphagia

Ulrich F. Vogel · Christina Pfannenberg · Thomas Renck · Dietrich Müller-Wening · Burkhard Bültmann

Received: 21 March 2007 / Revised: 15 May 2007 / Accepted: 3 June 2007 / Published online: 13 July 2007

Dear Editor,

Left vocal cord paralysis can complicate differential diagnosis, especially when associated with dysphagia. The added presence of cough, hemoptysis, and bronchial stenosis pinpoints the damage in the mediastinum. Despite chest X-ray, bronchoscopy, and bronchial biopsy, a definitive diagnosis may only be possible at autopsy.

Case report

A 71-year-old white woman sought out her physician because of hoarseness and difficulty in swallowing. Her previous history included treatment for lung tuberculosis about 20 years previously and hormone substitution for hypothyroidism. The patient was a non-smoker. Laryngoscopy demonstrated a complete paralysis of the left vocal cord. A barium swallow revealed slow passage time, a hypotonic esophageal wall, irregular peristalsis, dilatation of the esophagus and diverticula next to the tracheal bifurcation. Chest X-rays showed calcification in the left thyroid gland. Computer tomography of the neck and the upper mediastinum revealed a few mediastinal, hilar, and carinal calcified lymph nodes about 1.5 cm in diameter.

Seven years later, the patient was admitted to hospital because of persistent cough with increasing expectoration and hemoptysis. Occupational history revealed that the patient had worked for 10 years in a brick factory in the post-war era with exposure to silica dust. Physical examination showed acral cyanosis and watch glass nails. The Mantoux test was positive. Leukocyte count (15,000/μl) and sedimentation rate test (60/66 mm) were elevated. Chest X-ray and tomograms showed a band-like pneumonic infiltrate in segment 3 of the right upper lobe with a stenosis of the segment 3 bronchus. Bronchoscopy revealed severe stenosis of the segment 3 bronchus by focal black mucosal tissue. A biopsy was taken, which was complicated by massive bleeding. The biopsy revealed a bronchus wall with slight fibrosis, a mild chronic unspecific inflammation, and anthracosis. After a combined antibiotic therapy (gentamycin and ampicillin) with only initial improvement of the chest X-ray, a tuberculostatic triple drug therapy was introduced. Two weeks later, the patient died unexpectedly during the hospital stay.

Autopsy findings

Autopsy revealed silicotic mediastinal lymphadenopathy with destruction of the segment 3 bronchus of the right upper lobe (Fig. 1) and mediastinal nerves like the left recurrent laryngeal nerve (Fig. 2). Histologically, coalesced lymph nodes were found with necrosis, focal calcification, concentric bundles of collagen and macrophages with anthracosis, and numerous silica particles made visible by

polarization microscopy. The lungs demonstrated only small silicotic nodules with adjacent perifocal emphysema. Tuberculous caseation with giant cells could not be found. The thyroid gland was diagnosed with Riedel's thyroiditis. Furthermore, recurrent lung embolism could be detected. The patient died of acute pulmonary embolism leading to right heart failure. The deep veins of the legs were without pathological changes. Reevaluation of the bronchial biopsy with polarization microscopy revealed few silica particles.

Discussion

Silicosis is one of the oldest occupational diseases and still kills thousands of people each year. It is a global phenomenon and is not restricted to low-income countries [16, 26]. This incurable, debilitating, sometimes fatal, yet preventable disease is caused by inhaling respirable crystalline silica dust ($Si0_2$) [3]. Silicosis progresses even after cessation of silica inhalation [15]. Silica dust is released during operations in which rocks, sand, concrete, and some ores are crushed, broken, ground, dispersed, sieved, screened, mixed, stored, or bagged. Therefore, persons in a wide variety of different occupations and workplaces are at particular risk of contracting silicosis (e.g., in mining, quarrying, tunnel construction, sandblasting, bricklaying, masonry, metal casting, ceramics, stone carving, gem working, farming, greenhouse gardening, highway repair, dental laboratories, flax scutching, whetstone cutting) [3, 26]. However, silica exposure is not restricted to the workplace, but can be due to living in silica rich environments (soils) in semidesert or desert climates, as proven by reports on the development of silicate pneumoconiosis and even silicosis in inhabitants of the Himalaya, Saudi Arabia, and the southwestern United States [2, 14, 22]. Moreover, silicate pneumoconiosis and silicosis is not restricted to human beings, but can also be found in animals like hens, pigs, water buffaloes, camels, and other species [2, 8, 19–21]. The form and severity in which silicosis manifests itself depend on the extent of exposure to silica dusts and on the origin, crystallinity, and state of surface of the silicas [7, 26]. Crystalline silica (in the form of quartz or crystobalite) has a particularly strong pathogenic effect and is even classified by the International Agency for Research on Cancer as a group 1 human lung carcinogen [26]. Furthermore, freshly fractured silica, such as that generated during abrasive blasting, is more toxic than aged silica [25]. Crushing silica yields Si and SiO radicals on the cleavage planes that react with water to produce the damaging hydroxyl radical (–OH) [25]. Therefore, the pathogenicity of and biological response to silica is a function of its surface [4]. Besides pulmonary silicosis with simple (nodular) silicosis (with fibrotic nodules up to one centimeter in size), acute silicosis (silicoproteinosis), complicated pneumoconiosis (progressive massive fibrosis with nodules larger than 1 cm), and true diffuse interstitial fibrosis [17], silicosis is associated with a great number of autoimmune disorders such as progressive systemic sclerosis, systemic lupus erythematosus, rheuma-

toid arthritis, dermatomyositis, glomerulonephritis, and vasculitis [24]. The link between these various diseases may be the fact that the pathogenesis of silicosis involves uncontrolled immune processes which may start with the recognition and uptake of silica by alveolar or interstitial macrophages via the MARCO receptor and the subsequent activation of these immune cells [9]. According to Huaux [9], it is now generally accepted that silica-induced pulmonary lesions are modulated and triggered by the immune system and its mediators (macrophages, mast cells, B lymphocytes, TNF alpha). These pathogenic routes may highlight new potential therapeutic targets and strategies [9].

Hoarseness due to paralysis of the left vocal cord with or without associated dysphagia can be caused by diseases of the heart (cardiomegaly, mitral stenosis with gross enlargement of the left atrium), the aorta (aortic arch aneurysm), the esophagus (carcinoma), the thyroid (carcinoma), or the mediastinal lymph nodes (bronchial carcinoma, sarcoidosis, tuberculosis, lymphoma, silicosis) [5, 6, 13, 18]. These pathological processes can destroy, compress or stretch the vagal nerves, the thoracic sympathetic outflow—both nerves necessary to control swallowing—and the laryngeal recurrent nerves. The left laryngeal recurrent nerve in particular is more commonly affected than the right by a pathological mediastinal process owing to its longer intrathoracic course around the aortic arch [23]. Lardinois et al. [10] presented a case of left laryngeal nerve palsy due to encasement of the nerve by scar tissue and a dense, irregularly shaped lymph node. Under videomediastinoscopy, the nerve was carefully dissected with scissors and freed from the scar and lymph node encasement. After 15 weeks of postoperative follow-up, total and lasting recovery of the voice was observed. In our case, however, the aggressive silicotic tissue had already destroyed the mediastinal lymph nodes and adjacent anatomical structures like the segment 3 bronchus of the right upper lobe, the left laryngeal recurrent nerve, and other vagal and sympathetic nerves. This destruction resulted in hoarseness, dysphagia, and bronchial stenosis. As our patient had worked for 10 years in a brick factory in the post-war era (1947–1957) with exposition to silica dust, this combination of occupational history and clinical findings led us to suspect silicosis. In the post-war era, occupational and health safety regulations in Germany were non-existent or much weaker than nowadays. Despite the absence of visible silicotic changes in the parenchyma of the lungs in the chest X-ray and computer tomography, the possibility of silicosis could not be dismissed. Silicotic mediastinal lymphadenopathy can be present even without obvious silicotic fibrosis of the lung parenchyma [11, 12, 18]. It is unclear why in some rare cases silicosis is exclusively extrapulmonary. According to Adamson and Prieditis [1], silica particle translocation to the lymph nodes

may be increased especially during alveolar epithelial injury. This epithelial injury also potentiates fibrosis which, however, could not be detected in such cases. Silicotic mediastinal lymphadenopathy as an isolated phenomenon is probably due to a low exposure to silica over a long period of time. This dose of silica may be too low for a significant inflammation in the lung tissue, but is enough to accumulate a large amount of silica in the lymph nodes. Furthermore, silicosis often becomes manifest 20 to 40 years after the initial exposure [4] because the inflammation and damage due to silica may progress even after cessation of silica inhalation [15]. Whether Riedel's thyroiditis or a similar fibrotic form of thyroiditis is associated with silicosis—like rheumatoid arthritis in Caplan's syndrome—or is only coincident in this special case cannot be established with certainty. Silicotic mediastinal lymphadenopathy has to be considered in the differential diagnosis of left vocal cord palsy with associated dysphagia, especially in a patient with an occupational exposition to silica.

REVIEW AND PERSPECTIVE

Mutation analysis of gastrointestinal stromal tumors: increasing significance for risk assessment and effective targeted therapy

Eva Wardelmann · Reinhard Büttner · Sabine Merkelbach-Bruse · Hans-Ulrich Schildhaus

Received: 17 April 2007 / Revised: 6 July 2007 / Accepted: 6 July 2007 / Published online: 14 August 2007

Abstract Molecular characterization of gastrointestinal stromal tumors (GISTs) plays an increasing role not only for the patient's prognosis but also for treatment options and in the context of resistance to therapy. Several mutational subtypes in *KIT* or platelet-derived growth factor receptor-α (*PDGFRα*) have been identified to be correlated with a different clinical behavior of GISTs. In *KIT* exon 11, deletions in the proximal part are associated with a high metastatic risk, whereas duplications in the distal part lead to a less aggressive phenotype. GISTs of the small bowel with a duplication in *KIT* exon 9 are often high risk tumors. In contrast, *PDGFRα* exon 18 mutated GISTs tend to have a low malignant potential. The authors suggest to include these molecular data together with classical parameters such as mitotic count and tumor size into the risk assessment of GISTs. The first choice for treatment of GISTs is still the surgical resection. In advanced tumors, which cannot be R0 resected, the neoadjuvant treatment with the tyrosine kinase inhibitor imatinib is now well established. Furthermore, an adjuvant treatment of locally R0-resected intermediate and high risk tumors is evaluated in several international clinical trials. For metastatic disease, treatment with imatinib is still the first option, but with new upcoming substances, the molecular characterization of GISTs may become mandatory. Very recently, it has been shown that sunitinib may be especially effective in GISTs with *KIT* exon 9 mutation, whereas these tumors show only an intermediate response to imatinib. A European Organisation for Research and Treatment of Cancer clinical trial randomizing patients according to their mutational status is under preparation. Secondary resistance to imatinib treatment is increasing, at least partly due to secondary mutations in the tyrosine kinase domain of the KIT receptor. Once a lesion has been shown to carry such a mutation, the local excision may be useful, mean while still responding metastases are further controlled by continuing imatinib. Taken together, the molecular characterization of GISTs turns out to play a central role before and during the treatment with tyrosine kinase inhibitors, which have improved the treatment of GIST patients dramatically.

Introduction

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal tumors of the digestive tract. They are characterized by the expression of the type III receptor tyrosine kinase KIT in the vast majority of cases (>90%) [40, 44]. More than 80% of GISTs carry a gain-of-function mutation in the encoding *KIT* gene or—less often—alternatively in the platelet-derived growth factor receptor-α (*PDGFRα*) gene leading to a ligand-independent autoactivation of one of both tyrosine kinases [18, 20, 21]. Approximately, 50% of patients with GISTs seen in cancer hospitals develop recurrences and/or metastases after surgical resection of the primary lesion that are resistant to radio- and chemotherapy [10, 11]. The tyrosine kinase

inhibitor imatinib mesylate (Glivec®, Gleevec®, Novartis, Basel, Switzerland) has revolutionized the treatment of GISTs leading to response rates of up to 75% of patients suffering from advanced GIST disease. Several international clinical trials have proven that, to date, imatinib is the gold standard in treatment of these patients [5, 19, 48].

Diagnosis of GIST

Most GISTs occur in the stomach (about 60%) followed by the small bowel (30%). Rarely, GISTs may present in the esophagus or in the large bowel (<5%), the latter preferentially in the rectum [37]. A small subgroup of GISTs occurs without connection to the tubular gastrointestinal tract and is designated as extra [36]. Histomorphologically, GISTs may exhibit three different phenotypes: the spindle cell type (70%), the epithelioid cell type (10%), or the mixed cell type (20%), the latter with an intermediate cell type or as composition of distinct spindle or epithelioid cell areas (Fig. 1a–d) [14]. Multinucleated tumor giant cells are preferentially identified in the epithelioid cell type [41].

GISTs are thought to derive from the interstitial cells of Cajal or a common precursor as they share the immunohistochemical co-expression of the stem cell antigens cluster of differentiation 34 (CD34) and KIT. Histopathological evaluation including a well-done immunohistochemistry is sufficient in the most instances for making a correct GIST diagnosis. Difficulties in the differential diagnosis may occur preferentially in gastrointestinal tumors with epithelioid phenotype. Immunohistochemical examination has to rule out not only sarcomatoid carcinomas but also other mesenchymal tumors such as clear cell sarcoma, which rarely presents in the gastrointestinal tract [15, 45, 54] and can be identified by its strong expression of S-100 protein and by fluorescence in situ hybridization detection of the characteristic EWS–ATF1 translocation. Furthermore, CD34 is expressed in more than 70% of GISTs, but may also be found in solitary fibrous tumors that may exhibit an epithelioid or spindle cell phenotype [2]. The latter are constantly completely negative for the KIT receptor.

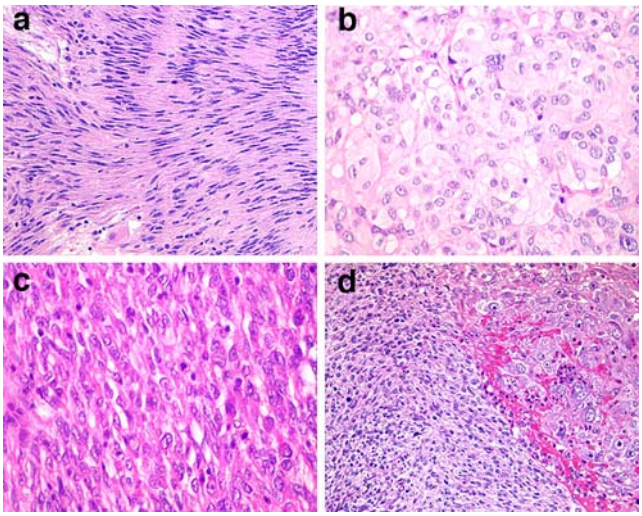

Fig. 1 Histomorphological subtypes of GISTs. **a** Spindle cell type. **b** Epithelioid cell type. **c** Mixed cell type composed of cells with intermediate cell phenotype. **d** Mixed cell type with distinct separated spindle and epithelioid cell morphology (×20 original magnification, H&E)

Less than 5% of GISTs are negative for both CD34 and KIT [25, 42, 47]. Some of the KIT-negative GISTs belong to the subgroup driven alternatively by the PDGFRα receptor (PDGFRA) [18, 22, 33]. Especially in these cases, which may lack immunohistochemical expression of the KIT receptor, molecular characterization is helpful to identify these tumors as GIST. Novel immunohistochemical markers for GISTs have been described, such as protein kinase C (PKC) theta [3, 24] or hypothetical protein spicifically expressed in GISTs named “discovered on GIST-1” (DOG-1) [53]. The first one showed in our laboratory a lower sensitivity than KIT, as only half of all the tumors included in a small immunohistochemical study were immunopositive. DOG-1 is not yet commercially available. Therefore, further studies are required to evaluate the utility of these markers in diagnostic procedures.

Molecular characterization

Mutational analysis should be carried out by using fresh snap-frozen tumor tissue. However, under most circumstances, only formalin-fixed and paraffin-embedded tissue is available, which can also be used. Tumor tissue should be enriched by removal of normal tissues (e.g., mucosa, surrounding connective tissue or liver parenchyma in the case of metastases). All specific polymerase chain reaction products should be sequenced. Screening methods, as single-strand conformation polymorphism, denaturing high-pressure liquid chromatography, or gel electrophoresis, can be used before sequencing.

More than 80% of GISTs carry a gain-of-function mutation in the *KIT* gene or—less often—in the *PDGFR*α gene [38, 39]. These mutations lead to a ligand-independent autoactivation of the encoded type III receptor tyrosine kinases KIT or PDGFRα.

In *KIT*, four hot spots have been identified, i.e., exon 9, exon 11, exon 13, and exon 17 [43]. Exon 11, encoding the juxtamembraneous domain, is affected in up to 65% of all KIT-mutated GISTs [38, 39]. This region is thought to have an autoinhibitory function resulting from its α-helical conformation, which is disrupted by changes in the amino acid sequence [31]. The spectrum of exon 11 mutations

consists of point mutations as well as of large in-frame deletions and insertions. On the protein level, large complex mutations may result in a combination of an amino acid exchange and a deletion of one or more amino acid residues. Exon 9 encodes the fifth extracellular immunoglobuline-like loop probably responsible for proteolysis of the receptor protein and shows mutations in 10 to 15% of GISTs. Mutations in this region are almost always insertions of 6 bp leading to a duplication of the codons A-502 and Y-503 [1, 28]. Genomic changes in one of both tyrosine kinase domains are exceedingly rare with less than 1% of *KIT* mutations. For exon 13 (encoding the tyrosine kinase domain 1), one point mutation (K642E) is most frequent; for exon 17 (encoding the tyrosine kinase domain 2), different point mutations most often occur between codons D-816 and Y-823 [26, 30].

Recently, several groups could show that one third of these GISTs without any *KIT* mutation are driven by an alternative tyrosine kinase very similar to *KIT* [18, 22, 49]. Belonging to the same type III receptor tyrosine family as KIT, PDGFRα shares 35% of the amino acid sequence with KIT and activates nearly the same signal transduction pathways as KIT. The encoding gene is located just beneath the *KIT* gene on the long arm of chromosome 4 (4q12) and consists of 22 exons (one more than *KIT*). PDGFRα mutations are most often located in the tyrosine kinase domain 2 encoded by exon 18 (up to 90% of all *PDGFRα*-mutated GISTs), and point mutations are the most common mutational subtype (predominantly D842V) followed by deletions in the same region of the exon. Less often, mutations are found in exon 12 encoding the juxtamembraneous domain or in exon 14 encoding the first part of the tyrosine kinase domain (Fig. 2) [29].

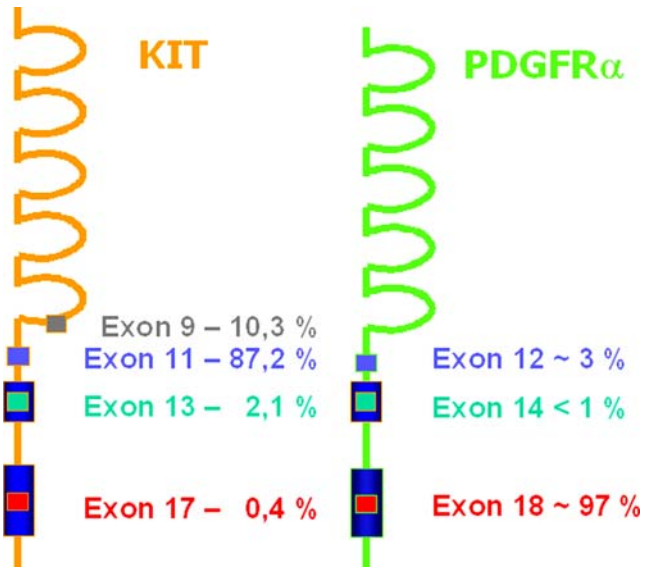

Fig. 2 Mutational hot spots of GISTs in *KIT* and *PDGFRα* gene. Data are given as percentage of all cases mutated in one of both genes

About 15–20% of GISTs carry wild type sequences in all hot spots of *KIT* and *PDGFRA* (wt-GISTs). The pathogenesis of these tumors is still poorly understood.

Prognosis

The prediction of the biological behavior of GISTs is difficult based on pathomorphogical data alone. To date, three parameters are known to be relevant: location of the primary tumor, largest tumor diameter, and mitotic count per 50 high power fields (HPF). The classification system proposed by Miettinen et al. [34] uses all three parameters leading to the three categories: probably benign, uncertain or low malignant potential, and probably malignant (Table 1). Another widely accepted classification [14] considers the risk assessment of an aggressive biological behavior. According to size and mitotic count/50 HPF GISTs are subgrouped into tumors with very low, low, intermediate, and high risk (Table 2). Recently, Miettinen and Lasota [35] modified their risk stratification in a large series of primary GISTs with special regard to the different prognosis of gastric versus small bowel tumors. Table 3 shows which different risk groups could be identified by evaluation of nearly 2,000 GISTs with long-term follow-up. The relevance of the Ki67 index as proliferation parameter has been evaluated by several groups, but its reproducibility is too low to be included as a classification criterion.

Several authors have proven the usefulness of these classifications by correlating the clinical follow-up with subgrouping. However, a part of GISTs behaves unpredictably, leading to the need of further prognostic parameters. Larger actual studies have found that, besides the classical

Table 1 Evaluation of GIST malignancy according to Miettinen et al. [32]

Categories	
Probably benign	
Intestinal tumors	Maximum diameter ≤2 cm and ≤5 mitoses/50 HPFs
Gastric tumors	Maximum diameter ≤5 cm and ≤5 mitoses/50 HPFs
Uncertain or low malignant potential	
Intestinal tumors	Maximum diameter >2 cm but ≤5 cm and ≤5 mitoses/50 HPFs
Gastric tumors	Maximum diameter >5 cm but ≤10 cm and ≤5 mitoses/50 HPFs
Probably malignant	
Intestinal tumors	Maximum diameter >5 cm or >5 mitoses/50 HPFs
Gastric tumors	Maximum diameter >10 cm or >5 mitoses/50 HPFs

Table 2 Risk assessment of an aggressive clinical behavior in GIST according to Fletcher et al. [13]

	Tumor size (cm)	Mitotic count (HPFs)
Very low	<2	<5/50
Low	2–5	<5/50
Intermediate	<5	6–10/50
	5–10	<5/50
High	>5	>5/50
	>10	Any mitotic count
	Any size	>10/50

parameters, molecular typing might give further information concerning aggressiveness of GISTs. They identified special mutational subtypes in exon 11 of *KIT* associated with a high metastatic risk as, for example, the loss of the amino acid residues W-557 and K-558 in exon 11 [32, 50]. Miettinen et al. [38] found in a large series of gastric GISTs that tumors with point mutations in KIT exon 11 behave better than those with deletions. Others describe that duplications in the distal part of *KIT* exon 11 are correlated with a better prognosis [1, 28]. *KIT* mutations in exon 9 encoding the extracellular domain of the receptor protein are found preferentially in GISTs of the small bowel and predict a worse prognosis than GISTs with other *KIT* mutations [1]. On the other hand, GISTs caused by an activating mutation in exon 18 of *PDGFRα* are preferentially located in the stomach and are characterized by a low malignant potential [27, 29, 49]. A comprehensive classification system including the "classical" histomorphological parameters as well as the mutational status is still missing. However, most oncologists already use the mutational status as a predictive parameter for therapy planning. We have included a summary of the most relevant pathomorphologic and molecular parameters for risk assessment in Table 4.

Table 3 Metastatic risk of gastrointestinal stromal tumors (modified according to Miettinen and Lasota [33])

Group	Size (cm)	Mitotic count (HPFs)	Metastatic risk			
			Stomach	Jej./ileum	Duodenum	Rectum
1	≤2	≤5/50	ϕ	ϕ	ϕ	ϕ
2	>2–5	≤5/50	Very low	Low	Low	Low
3a	>5–10	≤5/50	Low	Moderate	High	High
3b	>10	≤5/50	Moderate	High	High	High
4	≤2	>5/50	ϕ*	High[a]	–	High
5	>2–5	>5/50	Moderate	High	High	High
6a	>5–10	>5/50	High	High	High	High
6b	>10	>5/50	High	High	High	High

Based on previously published long-term follow-up studies on 1939 GISTs

– No cases available

[a] Denotes tumor categories with very small numbers of cases

Treatment

The first step in the treatment of GISTs is the surgical resection of the primary tumor. For small tumors, a local excision with clear margins as confirmed by the pathologist is sufficient. In larger tumors with local resectability, the clear margins should measure at least 1 to 2 cm [10, 23]. In metastatic and unresectable GISTs, primary surgery has been shown not to be a sufficient therapy. GISTs are resistant to radio- and chemotherapy. In advanced cases, the gold standard is a targeted therapy with tyrosine kinase inhibitors leading to response rates of up to 80% [12, 19]. Actually, imatinib mesylate (Glivec®) is the first line drug administrated orally (400 mg daily). Imatinib binds to the adenosine triphosphate (ATP)-binding pocket in the tyrosine kinase domain of the KIT receptor thereby inhibiting the ATP binding and thus the enzymatic activity of the receptor [46].

In advanced tumors, an extensive surgical approach with resection of several organs has been shown to be ineffective, as most patients develop early local recurrence with a very unfavorable course. In these cases, a neoadjuvant strategy to reduce the tumor load before surgical resection is under study (for example, NCT00112632, Munich, Germany). Furthermore, several international studies evaluate if an adjuvant treatment with imatinib increases the event-free and overall survival in cases with intermediate or high risk GISTs (for example, the European Organisation for Research and Treatment of Cancer 62024, SSGXVIII, ACOZOG-Z9000, and Z9001).

The molecular status of GISTs turns out to be relevant for the response to targeted treatment with imatinib. Larger clinical studies have shown that tumors with a *KIT* exon 11 mutation respond in a higher percentage than GISTs with an exon 9 mutation. Tumors without *KIT* mutations in these exons often have only low responsivity [8, 17]. *PDGFRα* mutations may lead to a primary resistance to imatinib, especially the point mutation D842V in exon 18, which is the most frequent mutation in this gene. On the other hand, *PDGFRα*-mutated GISTs, in most cases, behave less aggressive than tumors with *KIT* mutation [6, 29].

With new upcoming tyrosine kinase inhibitors other than imatinib, the molecular characterization gets further importance. It has been shown that other drugs such as sunitinib (SU11248, Sunitinib, Sutent®, Pfizer Oncology) are especially effective in GISTs with exon 9 mutation [13]. Furthermore, the mutational status is relevant for the most effective dosage of imatinib. Whereas response rates for

Table 4 Relevant risk parameters of an aggressive clinical behavior in gastrointestinal stromal tumors including molecular data

Parameters	Risk ↓	Risk ↑
Surgery	R0	R1, rupture
Location	Stomach	Small bowel, E-GIST
Size	≤5 cm	>5 cm
Mitotic count	≤5/ 50 HPFs	>5/50 HPFs
Mutated gene	*PDGFRα*	*KIT*
Mutational type (*KIT* exon 11)	Duplication	Deletion (esp. when including codons W557 and K558)

exon 11-mutated GISTs are comparable for 400 mg versus 800 mg/daily, patients with exon 9 mutations show a significant longer progression-free survival when treated with 800 mg instead of 400 mg/daily [9]. Until now, the treatment options throughout Europe are still different. The approval of 800-mg imatinib daily or sunitinib as first line treatments of GIST patients with KIT exon 9 mutation are still missing in several countries. However, most data highlight that, in the future, GISTs with high risk criteria or proven malignant behavior should be characterized molecularly as soon as possible to choose the right treatment regimen.

Novel KIT multi-tyrosine kinase inhibitors such as AMG 706 and AMN 107 (nilotinib) as well as downstream targeting small molecules, as for example, the mTOR inhibitors RAD001 (everolimus) and rapamycin (sirolimus), the PKC inhibitor PKC412, and the vascular endothelial growth factor receptor inhibitor bavacizumab (avastin), are in clinical trials. Lastly, the heat-shock protein-90 inhibitor IPI-540 is also in phase I evaluation in imatinib-refractory patients with GIST. Subgroup analyses will show in the future how these small molecule inhibitors will improve the treatment of GISTs further.

Resistance

With longer duration of imatinib treatment in patients with advanced GISTs, the risk of resistance to therapy increases. Several groups describe an increasing frequency of secondary mutations in *KIT* or rarely in *PDGFRα* [7, 51]. These point mutations are located preferentially in or near the ATP-binding pocket and often involve the known imatinib contact points (Fig. 3). New *KIT* mutations are often found in only some of several lesions, whereas other metastases only carry the primary mutation and are still responding to imatinib [51, 52]. Several different new mutations in addition to the primary mutation may occur indicating polyclonal resistance as already shown in chronic myelogenic leukemia under imatinib treatment [4, 16]. This observation may lead to a surgical approach even in

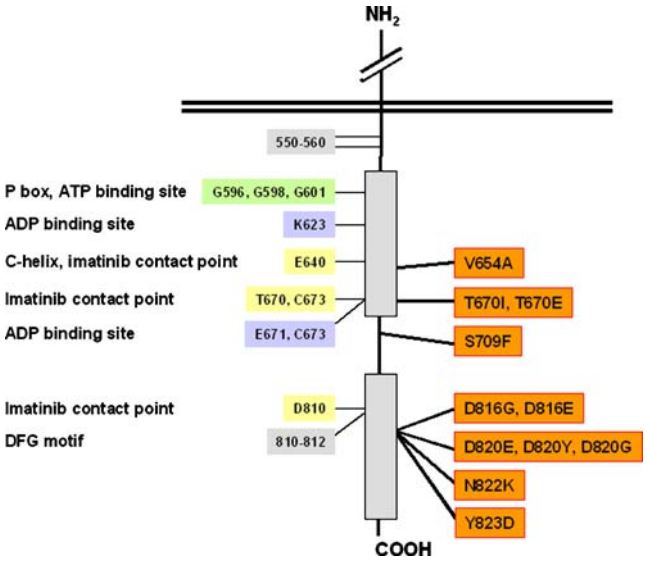

Fig. 3 Co-localization of imatinib binding points and secondary *KIT* mutations under imatinib treatment of GISTs leading to secondary resistance

advanced GIST disease. In these cases, functionally active metastases suspective for secondary mutations may be resected while other still responding lesions do not require surgery while the imatinib treatment is continued [23]. Several novel tyrosine kinase inhibitors that may be even more effective in GISTs resistant to imatinib are in clinical trials as mentioned above.

Several other mechanisms for secondary resistance are still under research, as for example, gene amplification or activation of other tyrosine kinase pathways. Exact data of these issues are still missing.

Conclusions

The treatment of gastrointestinal stromal tumors has changed dramatically since the past few years due to new insights into the molecular mechanisms responsible for prognosis, treatment response, and resistance against therapy. The surgical R0-resection of a localized GIST is still the first choice of treatment. In unresectable, R1-resected, or metastatic GISTs, targeted treatment with the tyrosine kinase inhibitor imatinib is the gold standard. With newly developed small molecule inhibitors such as sunitinib and everolimus, novel stratification criteria might be needed especially regarding GISTs becoming resistant. The molecular characterization of GISTs is not only helpful for diagnostic purposes in cases with low or no KIT receptor expression but might also help to predict clinical prognosis as several subgroups with different risk of aggressive clinical behavior can be identified. Tumors with high risk criteria can be treated individually on the basis of their molecular background. In the future, the molecular

analysis of GIST in the hot spot regions of *KIT* and *PDGFRα* will be a further parameter that has to be determined in addition to the established pathomorphological criteria, at least, in high risk lesions. It might also help to clarify the optimal treatment regimen especially in cases of secondary resistance.

RECOMMENDATION

Recommendations for the reporting of prostate carcinoma

Jonathan I. Epstein · John Srigley · David Grignon · Peter Humphrey · Christopher Otis

Introduction for ADASP reporting guidelines

It has been evident for decades that pathology reports are very variable even within a single institution. Standardization of reporting is the optimal way to insure that information necessary for patient management, prognostic and predictive factor assessment, grading, staging, analysis of outcomes, and tumor registries are included in pathology reports.

The Association of Directors of Anatomic and Surgical Pathology (ADASP) has chosen a pathologist expert in each field to assemble a group from within the pathology community (with clinician input if desired) to write specific cancer protocols. These were then approved by the ADASP council and subsequently by the membership. The American College of Surgery (ACS) Commission on Cancer (COC) accredits cancer centers in the USA. Recently, the COC decided to require elements, deemed as essential by the College of American Pathologists (CAP), to be described in all pathology reports in their accredited cancer centers as of January 2004. Importantly, they do not require that the specific CAP protocols or synoptic reports be utilized. ADASP has updated all of its protocols to comply with the COC requirements in the form of uniform checklists. The checklists use the staging criteria sited in the American Joint Committee on Cancer (AJCC) 2002 staging manual (sixth edition) but include a variety of other references listed in each of the checklists. Moreover, the checklists are formatted for ease of use. They may be used as templates for uniform reporting and are designed to be compatible with voice-activated transcription.

The different elements in these revised ADASP Diagnostic Checklists have been divided into Required and Optional. The term Required in this context only signifies compliance with the COC guidelines. ADASP realizes that specimens and practices vary and it will not be possible to report these elements in every case. However, ADASP hopes that pathologists will find these checklists to be useful in daily clinical practice while facilitating compliance with the new COC requirements.

The checklists are in standard PDF file format and may be easily downloaded from the ADASP Web site. They are not to be reproduced, altered, or used for commercial purposes without consent from ADASP.

I. Features the Association recommends to be included in the final report because they are generally accepted as being of prognostic importance, required for therapy, and/or traditionally expected [1–8].

A. Gross Description

1. Description of Specimen Received—Fresh, in formalin, intact, cut, margins inked, or not, etc.
2. Specimen Labeling—Labeled with (name, number), designated as prostate, and procedure (core biopsy, transurethral biopsy, transurethral resection, enucleation, radical prostatectomy, radical cystoprostatectomy, other)
3. Size—Theoverall size of the excised specimen should be measured in three dimensions: TURP specimens should be weighed; needle biopsy cores should be counted and measured in length (state if multiple small fragmented cores without need for measuring)
4. Additional Organs Attached—(e.g., seminal vesicles, vasa deferentia, bladder neck in radical prostatectomy specimens).
5. Tumor Description
   - Presence of lesion(s) or absence of lesion(s)
   - Location of the lesion(s) (e.g., in radical prostatectomy: posterior, posterolateral, lateral, anterior and apex, mid, base)
   - Size of the lesion(s) (greatest diameter if radical prostatectomy)
   - Consistency of the lesion(s) (e.g., firm, fleshy)
6. Lymph Nodes—Number and appearance of lymph nodes if received
7. Frozen Section—Whether a frozen section was performed and the diagnosis that was made

B. Diagnostic Information

1 Histological Type

- ___Adenocarcinoma (acinar, not otherwise specified)
- ___Prostatic duct adenocarcinoma
- ___Mucinous (colloid) adenocarcinoma
- ___Signet-ring-cell-like carcinoma
- ___Adenosquamous carcinoma
- ___Small cell carcinoma
- ___Sarcomatoid carcinoma
- ___Undifferentiated carcinoma, not otherwise specified
- ___Other (specify): _____

2 HistologicalGrade. All acinar adenocarcinomas should be graded using the Gleason grading system [9, 10]. Ductal adenocarcinomas are typically assigned a Gleason score $4+4=8$ yet are diagnosed as "ductal adenocarcinoma (Gleason score $4+4=8$)" to convey the unique clinical and pathological features of this tumor. There is no consensus as to the grading of mucinous carcinomas. Approximately one-half of urological pathologists grade them as Gleason pattern 4 (e.g., Gleason score $4+4=8$ if pure mucinous tumor). The remaining experts grade the tumor based on the underlying tumor architecture, mentally subtracting away the mucin. Regardless of the method used to grade mucinous carcinomas, the majority of these tumors end up being assigned a Gleason score $4+4=8$. True signet-ring-cell carcinomas containing vacuoles of mucin that are primary in the prostate are exceedingly rare. Rather, there exists signet-ring-cell-like carcinomas, which contain clear vacuoles without mucin. These tumors are graded by their underlying architecture. Small cell carcinomas are not graded as they have unique clinicopathological features and most importantly are treated differently than Gleason pattern 5 adenocarcinoma. The carcinomatous component of sarcomatoid carcinoma and adenosquamous carcinoma should be assigned a Gleason score.

For all types of specimens (needle, TURP, enucleation, radical prostatectomy), when there is a minor secondary component (<5% of tumor) and where the secondary component is of higher grade, the latter should be reported. For instance, a case showing >95% Gleason pattern 3 and <5% Gleason pattern 4 should be reported as Gleason score $3+4=7$. Conversely, if a minor secondary pattern is of lower grade, it need not be reported. For instance, where there is >95% Gleason score 4 and <5% Gleason 3, the score should be reported as Gleason score $4+4=8$. These aggressive cases with only a few glands of Gleason pattern 3 should be distinguished from cases with a more prominent secondary Gleason pattern 3, which are assigned a Gleason score of $4+3=7$.

In needle biopsy specimens, it is recommended that separate Gleason scores be assigned for each specimen container. This is most critical for the situation where the grade for the tumor in one container is Gleason score $4+4=8$ and the others are of lower grade. In these cases, the tumor behaves according to the highest grade (e.g., Gleason score $4+4=8$) and not the composite (overall) score, which would be lower. Further support for assigning separate Gleason scores for different containers is that the Gleason grade factored into currently existing tables and nomograms (e.g., Partin tables, Kattan nomograms), which predict the stage and prognosis of prostate cancer, utilized the highest Gleason score in a case and not the composite (global) score. Providing a global or composite score reflecting the overall Gleason score in the entire specimen is optional.

In needle biopsy specimens where more than two patterns are present and the worst grade is neither the predominant nor the secondary grade, the predominant and highest grade should be chosen to arrive at a score (e.g., 75% pattern 3, 20% pattern 4, and 5% pattern 5) is assigned

a Gleason score $3 + 5 = 8$. It is assumed that a minor component of high-grade cancer on needle represents a sampling artifact, where it is likely that there will be a significant amount of the high-grade cancer in the prostate.

In TURP or enucleation specimens where one cannot identify separate tumor nodules, only one Gleason score is assigned. In radical prostatectomy specimens, each dominant tumor nodule is assigned a separate Gleason score. It is not necessary to assign a separate score to each small, multifocal, low-grade cancer focus in the setting of a larger higher-grade dominant nodule. In the case where there is no dominant tumor nodule, it can be stated that there are multifocal tumor nodules with a comment as to their grades. In TURP, enucleation, and radical prostatectomy specimens, the Gleason score is based on the primary (most common) and secondary (next most common) pattern. If there is a third pattern or if the second pattern occupies less than 5% of the specimen, then this pattern is reported as a tertiary pattern.

3. Tumor Extent. In core biopsies, the absolute number of involved cores should be reported out of the total number of cores received. In cases with fragmented cores where one cannot accurately derive the number of involved or total number of intact cores, one can merely state the overall percentage of the fragmented specimen involved by cancer. In addition, one should provide one other more detailed measurement of cancer, such as the linear extent of involvement in millimeters (either per core or total) or the percentage of cancer in each involved core. There is no consensus whether one should give the linear extent or percentage of involved core by either counting gaps of uninvolved tissue in the measurement or by "collapsing" the tumor by ignoring the intervening gaps of benign tissue. As different foci of cancer along a core most likely represent the same tumor as opposed to multifocal cancer, it is preferred to record the tumor extent including the uninvolved tissue in the measurement as it more accurately represents the minimal extent of the cancer in the prostate. To distinguish small discontinuous foci from continuous cancer, one can report the following: "Small foci of cancer discontinuously involving *X*% of the length of the core", where "*X*" is measured from one end of the cancer to the other on the core regardless of intervening benign tissue.

In TURP and enucleation specimens, the percentage of tissue involved by carcinoma is reported, with 5% the cut-off between T1a and T1b disease.

There is no uniform data that tumor volume in radical prostatectomy specimens is an independent predictive parameter of prognosis once other standard parameters are recorded. Nonetheless, it is recommended that some measurement of tumor volume be recorded even if it is a subjective quantification of "minimal, moderate, and extensive." If more precise measurements are required by the clinician, an "eyeball" estimate of the percentage of the specimen involved by cancer is sufficient.

4. Margins of Resection—The entire surface of a radical prostatectomy specimen should be inked to evaluate the surgical margins. Usually, surgical margins should be designated as "negative" if tumor is not present at the inked margin and as "positive" if tumor cells touch the ink at the margin. When tumor is located very close to an inked surface but is not actually in contact with the ink, it is considered negative. Positive surgical margins should not be interpreted as extraprostatic extension. Intraprostatic margins are positive in the setting of capsular incision (so-called pT2+ or pT2x disease). The specific locations of the positive margins are useful to report, and there should be some indication of the extent of margin positivity [e.g., unifocal versus multifocal or focal versus extensive or number of positive sites (blocks) or linear extent in millimeters].

The apical and bladder neck surgical margins should be submitted entirely, preferably with a perpendicular sectioning technique. Microscopic involvement of bladder neck muscle fibers in radical prostatectomy specimens should not be equated with a pT4 designation. The latter generally requires gross involvement of the bladder neck. A recent study has shown that patients with microscopic bladder neck involvement have recurrence rates similar to patients with seminal vesicle involvement (pT3b).

5. Extraprostatic Extension (EPE). This is the preferred term for the presence of tumor beyond the confines of the prostate gland. Tumor abutting on or admixed with fat constitutes EPE and, in general, is the only method to reliably diagnose EPE on needle biopsy. However, if one relies on the identification of tumor in fat to diagnose EPE on radical prostatectomy specimens, EPE will be underdiagnosed. One should also diagnose EPE when tumor extends beyond the condensed smooth muscle of the prostate to involve the looser connective tissue and thinner less compact smooth muscle outside of the prostate. One can also use the overall scanning magnification to assess whether tumor has extended beyond the normal contour of the gland. Reporting EPE at the apex is controversial as the boundaries of the prostate gland in this region are vague; benign prostatic acini are seen admixed with skeletal muscle in this region. One option is merely to state whether tumor is present and whether the margins are positive or negative in the apical region while not attempting to determine if tumor is organ-confined in this area.

The other option is to assume that the urologist has gone as wide as possible and the inked margin at the apex is outside of the prostate. Tumor not extending to the ink is considered organ-confined and tumor at the inked margin is considered as showing EPE, unless benign prostatic glands are also seen at the inked margin whereby capsular incision is diagnosed. The specific location(s) of EPE are useful to report. Descriptors of EPE (unifocal versus

multifocal or focal versus nonfocal or focal versus extensive or linear millimeters or number of blocks) may be used.

6. Lymph Node Status. Indicate the number of nodes involved and the total number of nodes evaluated.

7. Angiolymphatic Invasion. This finding is independently predictive of prognosis in radical prostatectomy specimens and should be recorded. The Association does not recommend the routine use of immunohistochemical stains to detect intravascular invasion.

8. Perineural Invasion. Perineural invasion in needle biopsy cores has been associated with EPE in most correlative radical prostatectomy studies, although its value as an independent prognostic factor has been questioned. Perineural invasion has been found to be an independent risk factor for predicting an adverse outcome in patients treated with external beam radiation. As it is easily measured and appears to have prognostic significance on biopsy, regardless of whether it is an independently prognostic parameter, its presence should be recorded on needle biopsy specimens. Perineural invasion has no prognostic significance in radical prostatectomy specimens and should not be mentioned in the pathology report.

9. Prostatic Intraepithelial Neoplasia (PIN)—Generally, low-grade PIN is not reported. The presence of isolated high grade PIN (HGPIN) should be reported in all biopsy specimens. The risk of cancer on repeat biopsy within 1 year of a needle biopsy diagnosis of HGPIN is not sufficiently different from the risk of cancer on repeat biopsy after a benign diagnosis on needle biopsy [11]. Consequently, immediate repeat biopsy after a needle biopsy diagnosis of HGPIN is not necessary. Whether and when a repeat biopsy should be performed remains to be studied. The reporting of HGPIN in prostatectomy specimens is optional.

10. Staging—It is necessary to provide the TNM staging for radical prostatectomy specimens. The subdividing of pathologically organ-confined disease whether the tumor involves <1/2 of one lobe (pT2a), involves >1/2 of one lobe (pT2b), or involves both lobes (pT2c) has been criticized [12, 13]. This aspect of the staging system will be changed in future revisions, and many urological pathologists do not subdivide pT2 tumor using the current system. Adenocarcinoma of the prostate is multifocal in more than 85% of cases. In many of these cases of bilateral and/or multifocal tumor, the other tumors are small, low-grade, and clinically insignificant. Consequently, the distinction between pathologic stages T2a and T2c may reflect several very different conditions: (1) a large single tumor nodule involving both sides; (2) separate large tumor nodules on each side; (3) dominant nodule on one side with multifocal minute tumor on the other side; or (4) bilateral minute multifocal tumor. Prognostically, there are no differences between the subdivisions of pT2 [12, 13]. Stage pT2b tumor almost never exists, as it is almost impossible for a tumor to involve greater than one-half of the lobe without involving the other lobe [12]. However, using the current staging system for subdividing pT2 tumor remains an option. It is now recommended by the American College of Surgeons, and will be updated in the new TNM Staging System such that pathologists do not fill in a "pM" (metastasis) category, as that is the domain of the clinician.

11. Submission of Tissue for Microscopic Evaluation in TURP and Radical Prostatectomy Specimens [14]. TURP specimens should be sampled with eight cassettes. In a younger man (e.g., <65 years old), consideration should be given to more extensive sampling. Some experts suggest submitting additional cassettes based on the weight of the TURP. In general, random chips are submitted. If an unsuspected carcinoma is found in tissue submitted and it involves 5% or less of the tissue examined, the remaining tissue is generally submitted for microscopic examination, especially in younger patients.

Radical prostatectomy specimens may be totally submitted or partially sampled in a systematic fashion. For partial sampling in the setting of a grossly visible tumor, the sections with visible tumor along with the entire apical and bladder neck margins and samples from the base of each seminal vesicle should be submitted. If there is no grossly visible tumor, a number of systematic sampling strategies may be used. One that yields excellent prognostic information involves submitting the posterior aspect of each transverse slice along with a mid-anterior block from each side. The anterior sampling detects tumors that predominantly involve the transition zone. The entire apical and bladder neck margins and base of each seminal vesicle should also be submitted.

Appendix

ASSOCIATION OF DIRECTORS OF ANATOMIC AND SURGICAL

Final Anatomic Diagnosis Checklist
Prostate Carcinoma
(Ver 1.4, 12-06)

Accession No.:	**Part No(s).**	**Date:**
Patient Name:		
ORGAN,	**SITE,**	**OPERATION:**
Prostate Gland		Radical Prostatectomy
Prostate Gland		Radical Prostatectomy with right and left pelvic and wlymphadenectomy
Other		

-Primary Tumor Diagnosis: *Required*

- Adenocarcinoma (not otherwise specified)
- Mucinous adenocarcinoma
- Prostatic duct adenocarcinoma
- Small cell carcinoma
- Adenosquamous carcinoma
- Transitional cell carcinoma
- Squamous cell carcinoma
- Other:_____

A. Gleason Score: ____+ ____ = ____/10 with tertiary pattern ____ (if present)

Gleason Grading System

1 Single, separate, closely packed, uniform fairly large glands with a margin delineating the edge of tumor

2 Single, separate fairly large glands that are less uniform and more loosely arranged, with a less definite margin

3 Single, separate, but variably sized and shaped glands that may be widely separated and have a poorly delineated margin
Sharply circumscribed, rounded tumor with a cribriform pattern of the same size as normal glands

4 Fused glands
Poorly formed glands
Irregular or large cribriform glands
Hypernephromatoid pattern

5 Single cells
Sheets of cells
Cords of cells
Tumor with central comedonecrosis

NOTE: It is required that only the dominant tumor nodule is assigned a Gleason score with an option to assign a Gleason score to other major tumor nodules. The dominant nodule is typically the largest tumor, which is also the tumor with the highest stage and highest grade. In the unusual occurrence of a non-dominant nodule (i.e. smaller nodule) that is of higher stage or highest grade, one should also assign a grade to that nodule.

B. Location of Tumor: Required

- Tumor predominantly involves the _____ lobe (specify laterality)
- Tumor involves both lobes.

NOTE: Only dominant tumor(s) should be categorized. Small multifocal tumor foci should not be factored in unless they are the only or highest grade or highest stage tumor in the prostate

C. Extent of Tumor

- Tumor is confined to the prostate (lacks extra-prostatic extension),
- Tumor demonstrates extra-prostatic extension with
  - unilateral extra-prostatic extension (specify laterality) .
  - bilateral extra-prostatic extension.
- Tumor invades into muscular wall of the seminal vesicle(s) (specify laterality)
- Extra-prostatic extension cannot be determined since the outer border of the prostate is microscopically not intact (capsular incision is present, _____ specify laterality)

-Margins of Excision: Required

(specify status of bladder base, apical margins, vas deferens margins, and peripheral margins)

- Bladder base margin is free of tumor
- Apical margin is free of tumor
- Bladder base and apical margins are free of tumor
- Vas Deferentia margins are free of tumor
- Tumor is present at the apical margin
- Tumor is present at the bladder base margin
- Tumor is present at left/right vasa deferens margin
- Tumor is present at the peripheral margin in an area of extra-prostatic extension at aspect of specimen (specify site (s) of involvement such as anterior, posterior, left, right, etc)
- Tumor is present at the peripheral margin in an area of capsular incision at aspect of specimen (specify site(s) of involvement such as anterior, posterior, left, right, etc)

NOTE: All of the following lymph node groups will not be identified in most cases. However, appropriate designations are provided below.

-Lymph Nodes, right pelvic:

A. Number examined _____
B. Number positive _____
C. Comment _____

-Lymph Nodes, left pelvic:

A. Number examined _____
B. Number positive _____
C. Comment _____

-Lymph Nodes, right obturator:

A. Number examined _____
B. Number positive _____
C. Comment _____

-Lymph Nodes, left obturator:

A. Number examined _____
B. Number positive _____
C. Comment _____

-Additional Tumor Features: Optional

A. **Tumor involves approximately _____ %** of the prostate gland (alternate measurements of tumor volume can be used).
B. **Vascular invasion:** Identified Not Identified
C. **Extent of extra-prostatic spread:** Focal Non-focal
D. **Extent of margin positivity:** Focal Non-focal

-Addition findings and comments:

- Prostatic Intraepithelial Neoplasia (PIN), high grade
- Adenosis
- Basal cell hyperplasia
- Atrophy
- Treatment related changes
- Other:

-Ancillary Studies: Optional

Special stains are performed, the results are as follows:

A. _____
B. _____
C. _____
D. _____

Interpretation _____

Immunohistochemical studies are performed, the results are as follows:

A. _____
B. _____
C. _____
D. _____

Interpretation:_____

-pTN Stage: Required

A. **Primary Tumor:**

pT2	Tumor confined within the prostate
pT2x (or pT2+)	Tumor is organ confined except in an area of capsular incision where it cannot be determined
pT3	Tumor extends out of the prostate
pT3a	Tumor demonstrates extra-prostatic extension without seminal vesicle invasion
pT3b	Tumor demonstrates extra-prostatic extension and invades seminal vesicle
pT4	Tumor is fixed or invades adjacent structures other than the seminal vesicles such as: bladder neck (grossly), external sphincter, rectum, levator muscles and/or is fixed to the pelvic wall

NOTE: A microscopically positive bladder neck margin is pT3

NOTE: If surgical margin(s) are positive for carcinoma, this should be indicated by the designation R1 in the pT stage: e.g., pT3(R1).

B. **Regional Lymph Nodes**:

PNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in regional lymph node or nodes

Abstract Criteria for the staging and grading of neuroendocrine tumors (NETs) of midgut and hindgut origin were established at the second Consensus Conference in Frascati (Rome) organized by the European Neuroendocrine Tumor Society (ENETS). The proposed tumor–node–metastasis (TNM) classifications are based on the recently published ENETS Guidelines for the Diagnosis and Treatment of gastroenteropancreatic NETs and follow our previous proposal for foregut tumors. The new TNM classifications for NETs of the ileum, appendix, colon, and rectum, and the grading system were designed, discussed, and consensually approved by all conference participants. These proposals need to be validated and are meant to help clinicians in the stratification, treatment and follow-up of patients.

Background

Based on recognized differences in morphology, function and clinical behavior [1, 2, 21, 30], the current WHO classification provides a prognosis-oriented definition of gastroenteropancreatic neuroendocrine tumors (GEP-NETs) [3, 5, 8, 12, 13, 34].

All GEP-NETs probably have a malignant potential, but their biological behavior differs from tumor type to tumor type [9, 10, 14–17, 22, 25, 26, 36]. Given their rarity [10, 14–17], correct diagnosis and appropriate treatment are often difficult in nonexpert settings and even for appendiceal "carcinoids," probably the best known GEP-NETs with the most benign behavior [31]. Recent data on ileal, appendiceal, and rectal carcinoids, also indicated several variables influencing survival and prognosis [6, 15, 29, 35].

Guidelines for the management of patients with GEP-NETs were developed by the recently established European Neuroendocrine Tumor Society (ENETS) [23, 37]. In two separate meetings a consensus was sought on these guidelines. The papers deriving from the first conference dedicated to foregut tumors, including a detailed tumor–node–metastasis (TNM)/staging and grading proposals, have been published meanwhile [4, 27]. The "Consensus Conference on the ENETS Guidelines for the Diagnosis and Treatment of Neuroendocrine Gastrointestinal Tumors, Part 2: Midgut and Hindgut Tumors" was held in Frascati (Rome, Italy) from November 1 to 4, 2006. In this paper, we present the TNM staging and grading proposals for pure NETs of the lower jejunum/ileum, appendix, and colon/rectum.

Materials and methods

Fifty-seven experts in the field of GEP-NETs from 18 different countries attended the consensus conference. The attendees represented all medical branches involved in managing patients with GEP-NETs. They formed four working groups according to their specific clinical expertise: (1) pathology and genetics (11 participants, all listed as

Table 1 Proposal for a TNM classification for endocrine tumors of lower jejunum and ileum

	TNM
T-primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor invades mucosa or submucosa and size ≤1 cm
T2	Tumor invades muscularis propria or size >1 cm
T3	Tumor invades subserosa
T4	Tumor invades peritoneum/other organs
For any T add (m) for multiple tumors	
N regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M	Distant metastasis
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1[a]	Distant metastasis

[a] M1 specific sites defined according to Sobin LH, Wittekind C [32].

Table 2 Disease staging for endocrine tumors of lower jejunum and ileum

Stage Disease stages	T-primary tumor	N-regional nodes	M-distant metastasis
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
Stage IIB	T3	N0	M0
Stage IIIA	T4	N0	M0
Stage IIIB	Any T	N1	M0
Stage IV	Any T	Any N	M1

coauthors), (2) surgery (8 participants), (3) imaging and radiology (7 participants), (4) medicine and clinical pathology (31 participants, including the coauthor B.W.). Most of the participants also attended the first consensus conference held in Frascati in November 2005.

The conference was divided sequentially into five sessions devoted to specific topics on an anatomical basis (ileal well-differentiated NETs; appendiceal well differentiated NETs; colorectal well differentiated NETs; NETs metastatic to the liver; poorly differentiated neuroendocrine carcinomas of midgut and hindgut origin).

A working booklet with the ENETS guidelines text [23] and specific queries had been prepared in advance by the organizing committee. The work was organized as previously detailed [4, 27]. This procedure was followed for all five sessions. The TNM staging proposal was prepared by the pathology and genetics working group and amended and approved by the plenary session of the consensus conference. The grading system was mainly discussed and defined by the pathology and genetics working group.

Results and discussion

The consensus guidelines have been reported elsewhere. The TNM staging proposal for NETs of midgut and hindgut origin together with a grading system is intended to reflect, like its forerunner for the NETs of the stomach, duodenum and pancreas [27], the prognostic assessment by the pathologist. The intestinal NETs were separated into lower jejunum/ileum, appendix, and colon/rectum, but were not distinguished according to specific functional activity, main tumor cell type, or genetic background.

TNM staging proposal

The currently published TNM format was adopted as working template (see Tables 1, 2, 3, 4, 5, and 6) [32].

Tumor There is no proposed definition for in situ endocrine tumor of the jejunum, ileum, appendix, colon and rectum, because no specific precursor lesion has been described in the literature so far. For the lower jejunum and ileum, the size limits indicated for T1 and T2 are those defined for tumors of "benign behavior" and "uncertain behavior," respectively, according to the WHO site-specific clinico-pathological correlations [5, 8, 34]. For the appendix and colon and rectum tumors, lower size limits were defined for T1 and T2 based on current data [6, 15, 29]. For colon and rectum tumors, T1 was divided into T1A and T1B based on current information on the biology of tumors below 1 cm in size and between 1 and 2 cm [6].

Deeply invasive and large tumors are included in the T3 and T4 categories, taking into account site-specific features. For any T definition, the maximum tumor size should be reported and, in the case of multiple lesions, the largest one. The use of T3 category subdivision (pT3a, b, c, and d) according to distance below or higher than 5 mm from *muscularis propria* as proposed for the adenocarcinoma [33], could be of value. Its application could be implemented once data on endocrine carcinomas will be generated.

Lymph nodes N1 indicates the presence of any single or multiple metastases in the regional lymph node group, according to TNM rules. A minimum of 12 nodes should be identified in a surgical specimen, assessed and, when possible, named according to their location in relation to tumor. Although regional lymph node metastases are a negative prognostic factor in GEP-NETs [11], the signifi-

Table 3 Proposal for a TNM classification for endocrine tumors of the appendix

TNM	
T-primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤1 cm invading submucosa and muscularis propria
T2	Tumor ≤2 cm invading submucosa, muscularis propria and/or minimally (up to 3 mm) invading subserosa/mesoappendix
T3	Tumor >2 cm and/or extensive (more than 3 mm) invasion of subserosa/mesoappendix
T4	Tumor invades peritoneum/other organs
N-regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M-distant metastasis	
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1[a]	Distant metastasis

[a] M1 specific sites defined according to Sobin LH and Wittekind Ch [32].

Table 5 Proposal for a TNM classification for endocrine tumors of colon and rectum

TNM	
T-primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor invades mucosa or submucosa
	T1a size <1 cm
	T1b size 1–2 cm
T2	Tumor invades muscularis propria or size >2 cm
T3	Tumor invades subserosa/pericolic/perirectal fat
T4	Tumor directly invades other organs/structures and/or perforates visceral peritoneum
For any T add (m) for multiple tumors	
N-regional lymph nodes	
NX	Regional lymph node status cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M-distant metastases (subspecification as in small bowel)	
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1[a]	Distant metastasis

[a] M1 specific sites defined according to Sobin LH and Wittekind Ch [32].

cance of the number of metastatic nodes is not yet known. Therefore, similar to the previous foregut TNM proposal, the N1 status in stage IIIB in Tables 1, 2, 3, 4, 5, and 6 has to be specified with regard to the number of lymph nodes involved to allow validation.

Distant metastasis M1 indicates the presence of any single or multiple metastases at any distant anatomical site (including nonregional nodes). As extrahepatic bone metastases are a negative prognostic factor [7, 21], it is recommended to specify the anatomical site of the metastasis according to the TNM classification rules (PUL, pulmonary; HEP, hepatic; OSS, osseous; etc.) [32].

Staging Stage I encompasses the T1 NETs with limited growth. Stage II identifies tumors that are larger in size or more invasive, either T2 or T3, although always in the absence of metastasis. At stage III, the increased malignancy refers either to invasion into surrounding structures (Stage IIIA) or to the presence of regional node metastases (Stage IIIB). Stage IV always implies the presence of distant metastases.

Table 4 Disease staging for endocrine tumors of the appendix

Stage Disease stages	T-primary tumor	N-regional nodes	M-distant metastasis
Stage I	T1	N0	M0
Stage IIA	T2	N0	M0
Stage IIB	T3	N0	M0
Stage IIIA	T4	N0	M0
Stage IIIB	Any T	N1	M0
Stage IV	Any T	Any N	M1

Grading proposal

Grading Studies on well-differentiated NETs of midgut and hindgut origin have shown the usefulness of a grading system (see Table 7) [6, 35, 36]. Well-differentiated endocrine tumors with proliferative activity greater than 2%, but below that usually found in poorly differentiated endocrine carcinomas, may have a prognosis intermediate between the "2% NETs" and poorly differentiated carcino-

Table 6 Disease staging for endocrine tumors of colon and rectum

Stage Disease stages	T-primary tumor	N-regional nodes	M-distant metastasis
Stage IA	T1a	N0	M0
Stage IB	T1b	N0	M0
Stage IIA	T2	N0	M0
Stage IIB	T3	N0	M0
Stage IIIA	T4	N0	M0
Stage IIIB	Any T	N1	M0
Stage IV	Any T	Any N	M1

Table 7 Grading proposal for (neuro)endocrine tumors of ileum, appendix, colon and rectum

Grade	Mitotic count (10HPF)*	Ki-67 index (%)**
G1	<2	≤2
G2	2–20	3–20
G3	>20	>20

* 10 HPF (High Power Field)=2 mm^2, at least 40 fields (at 40× magnification) evaluated in areas of highest mitotic density; ** MIB1 antibody; % of 2000 tumor cells in areas of highest nuclear labeling.

mas [18–20, 23, 24]. We decided to follow the same grading system proposal as that devised for foregut tumors, with the aim of distinguishing G2 from G1 and G3 GEP-NETs. The three tumor categories are defined as follows: G1, <2 mitoses per 2 mm^2 (10 high-power fields, HPF, 40× magnification) and/or Ki-67 index ≤2%; G2, 2–20 mitoses per 2 mm^2 and/or Ki-67 index between 3% (intended as >2%) and 20%; G3 with 21 or more mitoses per 2 mm^2 and Ki-67 index >20%.

The G1 and G2 well-differentiated NETs usually display diffuse and intense expression of the two general immunohistochemical neuroendocrine markers, chromogranin A and synaptophysin [28]. Punctate necrosis is per se indicative of a more aggressive tumor and points to a G2 or G3 status, which is then determined by the mitotic count and the proliferation fraction. G3 indicates a poorly differentiated neuroendocrine carcinoma with high mitotic counts/Ki-67 index, fields of necrosis, significantly reduced chromogranin A expression and intense staining for synaptophysin, meeting the current WHO histological criteria [5, 8, 34].

Mitotic count and Ki-67 index As for the foregut proposal, mitoses should be counted on hematoxylin and eosin stained slides in at least 40 HPF when possible. The mitoses should be assessed in areas where they are most frequent after a general slide survey. For Ki-67 assessment, the MIB1 antibody is recommended at the conditions that have been established at the laboratory in question. The Ki-67 index should be assessed in 2,000 tumor cells in areas where the highest nuclear labeling is observed (often but not exclusively at the tumor periphery).

Concluding remarks

The TNM staging system proposed here for midgut and hindgut NETs closely follows its forerunner for foregut tumors [27]. It has the same basis, i.e., the current WHO classifications of GEP-NETs, and results from a consensus conference held by specialists and practicing physicians involved in the management of patients with GEP-NETs. The grading system described here is substantially identical to that proposed for foregut NETs and again attempts to close the gap between the advances of the most recent WHO classifications and the need for a better prognostic assessment of NETs. These proposals, as well as those already published, await confirmation by clinicopathologic work.

ORIGINAL ARTICLE

Value of staining intensity in the interpretation of immunohistochemistry for tumor markers in colorectal cancer

Inti Zlobec · Luigi Terracciano · Jeremy R. Jass · Alessandro Lugli

Received: 9 May 2007 / Accepted: 27 June 2007 / Published online: 3 August 2007

Abstract The purpose of this study was to determine whether staining intensity in conjunction with the percentage of positive tumor cells should be used as an indicator of protein expression detected by immunohistochemistry. A tissue microarray of 1,197 colorectal cancers was immunostained for p53, Her2/neu, epidermal growth factor receptor (EGFR), adenomatosis polyposis coli (APC), and β-catenin. Immunoreactivity was described by the percentage of positive tumor cells (percent positivity) and by the staining intensity (weak, moderate, strong). The interobserver reproducibility of both was evaluated by two pathologists. The association of T stage, N stage, tumor grade, vascular invasion, and survival with percent positivity, staining intensity, and the combination of both was assessed. In univariate analysis, protein expression assessed by percent positivity resulted in 11 significant associations between the proteins and clinico-pathological features. Eight of these 11 were also demonstrated using only the degree of staining intensity. However, more than half of the associations identified by percent positivity alone were lost when staining intensity was also analyzed in combination with the percentage of positive tumor cells. A scoring method based on percent positivity, rather than on staining intensity, for p53, Her2/neu, EGFR, APC, and β-catenin is reproducible and appears to be sufficient for establishing associations of the selected tumor markers with most clinico-pathological features.

Introduction

Diagnosis and research in colorectal cancer (CRC) routinely relies on the interpretation of protein expression detected by means of immunohistochemistry (IHC). The lack of standardized IHC scoring systems has led to a variety of unvalidated methods used to assess immunoreactivity. Scoring systems for tumor markers in CRC are usually based on a measure of the proportion of positive tumor cells and are often combined with a degree of staining intensity [3, 9, 12, 29]. It is recognized that the interpretation of staining intensity is not only highly subjective but may be affected by storage time, variation in protocols, and fixation procedures [2, 13]. Despite these concerns, staining intensity has become an integral component of many IHC scoring methods for tumor markers in CRC [7, 8, 10, 12, 23, 25–27].

We have recently shown that a descriptive, semiquantitative scoring system for IHC based on the percentage of immunoreactive tumor cells (percent positivity) provides a more complete assessment of the predictive and prognostic value of several tumor markers in CRC when compared to an evaluation system using "negative/positive" [16–19]. Additionally, we have studied the interobserver variability of this semiquantitative method among pathologists for several proteins namely, epidermal growth factor receptor

(EGFR), vascular endothelial growth factor, p53, Bcl-2, and apoptotic protease-activating factor 1 (APAF-1), in tumor biopsies and tissue microarray (TMA) punches and have shown that it is reproducible [30, 31, 34].

One of the most important advantages of a semiquantitative scoring method is that it allows the investigator to establish more biologically or clinically relevant cutoff scores for positivity for the protein and the outcome under study rather than relying on an often arbitrary threshold value, such as 10%, to describe a tumor as "positive." Such a method to ascertain cutoff scores has been recently proposed using receiver operating characteristic (ROC) curve analysis and has been applied, along with several other tumor markers, to EGFR and APAF-1 [32–34].

The purpose of this study was to determine whether staining intensity in conjunction with percent positivity should be used as an indicator of protein expression detected by IHC. The associations of p53-, Her2/neu-, EGFR-, adenomatosis polyposis coli (APC)-, and β-catenin-staining intensity with a range of clinico-pathological features, notably T stage, N stage, tumor grade, vascular invasion, and survival, were evaluated in 1,197 mismatch repair (MMR)-proficient CRC.

Materials and methods

Tissue microarray construction

A TMA of 1,420 unselected, nonconsecutive CRCs was constructed [24]. Briefly, formalin-fixed, paraffin-embedded tissue blocks of CRC resections were obtained. One tissue cylinder with a diameter of 0.6 mm was punched from morphologically representative tissue areas of each donor tissue block and brought into one recipient paraffin block (3×2.5 cm) using a homemade semiautomated tissue arrayer. The resulting TMA set comprised three slides.

Clinico-pathological data

The clinico-pathological data for all patients included T stage (T1, T2, T3, and T4), N stage (N0, N1, and N2), tumor grade (G1, G2, and G3), vascular invasion (presence or absence), and survival time [19].

Immunohistochemistry

Four-micrometer sections of TMA blocks were transferred to an adhesive-coated slide system (Instrumedics, Hackensack, NJ). Standard indirect immunoperoxidase procedures were used for IHC (ABC-Elite, Vector Laboratories, Burlingame, CA). One thousand four hundred and twenty CRCs were immunostained for mutL homolog (MLH)1 (clone MLH-1; dilution 1:100; BD Biosciences Pharmingen, San Jose, CA), MSH2 (clone MSH-2; dilution 1:200; BD Biosciences Pharmingen, San Jose, CA), and MSH6 (clone 44; dilution 1:400, Transduction Laboratories). After dewaxing and rehydration in deionized H_2O, sections were subjected to heat antigen retrieval in a microwave oven (1,200 W, 15 min) in 0.001 mol/L ethylenediamine tetraacetic acid at pH 8.0 for MLH1 and MSH2 and in 0.01 mol/L citrate buffer (pH 7.0) for MSH6. Endogenous peroxidase activity was blocked using 0.5% H_2O_2. The sections were incubated with 10% normal goat serum (Dako Cytomation, Missassauga, Canada) for 20 min and incubated with a primary antibody at room temperature (Her2/neu clone PN2A, DAKO, Denmark; p53 clone DO-7, 1:100; DAKO; clone β-catenin-1, dilution 1: 200; Dako Cytomation, APC clone C20, dilution 1:50; Santa Cruz, CA). Subsequently, sections were incubated with secondary antibody (K4005, EnVision+ System-HRP (AEC); Dako Cytomation) for 30 min at room temperature. For visualization of the antigen, the sections were immersed in 3-amino-9-ethylcarbazole+substrate-chromogen (K4005, EnVision+ System-HRP (AEC); Dako Cytomation) for 30 min and counterstained with Gill's hematoxylin. IHC for EGFR was performed using an automated stainer (EGFR clone 3C6, 3 mg/mL; Ventana Medical Systems, Tucson, USA) according to the manufacturer's instructions. TMA slides for each protein were stained on the same day under identical conditions.

MMR results

The 1,420 CRCs were stratified according to MMR status: (1) MMR-proficient tumors expressing MLH1, MSH2, and MSH6, (2) MLH1-negative tumors, and (3) presumed hereditary nonpolyposis colorectal cancer (HNPCC) cases demonstrating loss of MSH2 and/or MSH6 at any age or loss of MLH1 at age less than 55 years [11]. In population-based studies, the mean age of diagnosis of Lynch syndrome is around 55 years. By contrast, sporadic high-level microsatellite instability (MSI-H; MMR-deficient) CRC is far more age-related with a mean age of onset of around 75 years and few cases occurring younger than 60 years. A cutoff of 55 years was set as a reasonable compromise for distinguishing CRCs with loss of MLH1 into likely HNPCC syndrome vs likely sporadic. These immunohistochemical groupings showed a good fit with the known clinicopathological features associated with these subsets of CRC. Particularly, the MLH1-negative group was associated with advanced age, predilection for women and the proximal colon, large tumor size, and poor differentiation. The presumed HNPCC group was young and showed no gender difference, and there was a predilection for the proximal colon as compared with the MMR-proficient group. While it is possible that a small proportion of presumed sporadic MSI-H and HNPCC

cases were incorrectly assigned, the overall findings are likely to be valid in view of the large numbers of samples and the good fit with clinico-pathological features. Only MMR-proficient tumors were included in the study to ensure a homogeneous sample of tumors (N=1,197, 84.4%).

IHC evaluation

Immunoreactivity was evaluated in all 1,420 punches by one experienced pathologist. TMA punches with insufficient tissue or tumor for analysis were excluded from the study. Protein expression was scored in the nucleus for p53 and β-catenin and in the cytoplasm for APC. EGFR and Her2/neu positivity were scored in both cell membrane and cytoplasm. Immunoreactivity was assigned a score based on the proportion of positive tumor cells over total tumor cells (percent positivity) ranging from 0 to 100%. Staining intensity was evaluated as 0=negative, 1=weak, 2=moderate, and 3=strong. If the staining intensity was heterogeneous, then scoring was based on the greatest degree of intensity. MLH1, MSH2, and MSH6 were scored in the nucleus as negative (0%) and as positive (>0%).

Statistical analysis

Interobserver reproducibility of scoring percent positivity and staining intensity

To determine the interobserver reproducibility of percent positivity and staining intensity, a minimum of 100 CRC punches was evaluated by a second pathologist. The intraclass correlation coefficient (ICC) defined as the ratio of the between-subject variance over the between-subject+within-subject variances was used to determine the reliability of percent positivity for each protein. The ICC has previously been used to assess the agreement of IHC scores [14, 31]. An ICC of 0.7 or greater is considered sufficient to establish reproducibility [14]. The interobserver agreement of staining intensity (negative, weak, moderate, and strong) was determined using the kappa coefficient (κ) [15]. The overall κ coefficient measures the reliability of categorical data while taking into account the probability that both observers achieved the same scores by chance [1]. The weighted κ may be used as a measure of inter-rater agreement for ordinal variables and quantifies the relative difference between them. The greater the difference is between the scores, the lower the weighted κ. The interpretation of κ is commonly made as follows: values between 0.81 and 1.0 represent "almost perfect" agreement, 0.61 and 0.80 "substantial" agreement, 0.41 and 0.60 "moderate" agreement, 0.21 and 0.40 "fair" agreement, and 0 and 0.20 "slight" agreement [15].

Univariate analysis

Logistic regression analysis was used to determine the association of percent positivity or staining intensity with T stage (early=T1+T2/late=T3+T4), N stage (absence [N0] or presence [>N0] of lymph node involvement), tumor grade (low=G1+G2/high=G3), and vascular invasion (absence or presence). Survival analysis was carried out using Cox proportional hazards regression.

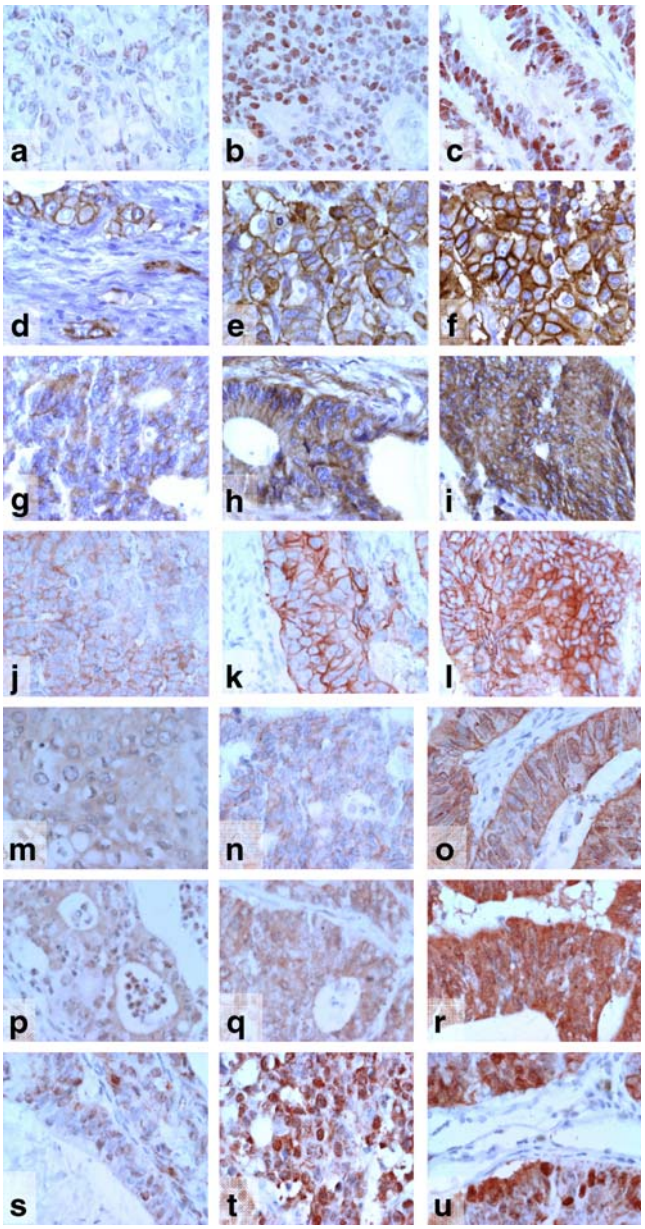

Fig 1 **a**–**l** Weak (*left*), moderate (*center*), and strong (*right*) staining intensity of nuclear p53 (40×; **a**–**c**), membranous EGFR (40×; **d**–**f**), cytoplasmic EGFR (40×; **g**–**i**), and membranous Her2/neu (40×; **j**–**l**). **m**–**u** Weak (*left*), moderate (*center*), and strong (*right*) staining intensity of cytoplasmic Her2/neu (40×; **m**–**o**), cytoplasmic APC (40×; **p**–**r**), and nuclear β-catenin (40×; **s**–**u**)

Multivariate analysis

Staining intensity and percent positivity were entered into a multivariate logistic regression model for all binary outcomes, whereas multiple Cox proportional hazards regression was performed for survival analysis. Adjusted *P* values for percent positivity and staining intensity were obtained.

P values less than or equal to 0.05 indicate a significant association of percent positivity or staining intensity with the outcome. All analyses were carried out using SAS version 9.1 (The SAS Institute, Cary, NC).

Results

Interobserver reproducibility of percent positivity and staining intensity

The reproducibility of scores expressed as percent positivity was very strong for p53 (ICC=0.91). The ICCs for APC (ICC=0.85), β-catenin (ICC=0.78), and membranous Her2/neu (ICC=0.71) suggest excellent consistency of scores between observers. The interobserver agreement for cytoplasmic Her2/neu scores was only slightly lower than for its membranous counterpart (ICC=0.68). However, the reliability of membranous and cytoplasmic EGFR expression was only moderate to low. The same observers independently re-evaluated EGFR expression a second time by scoring the number of immunoreactive tumor cells without regard to localization of staining (i.e., by scoring either membrane and/or cytoplasmic EGFR). The interobserver agreement was significantly increased (ICC=0.86) [33].

The agreement of staining intensity between observers using the overall κ coefficient was only moderate for APC (κ=0.41) and membranous and cytoplasmic Her2/neu (κ=0.53 and 0.57, respectively). The reproducibility of staining intensity for β-catenin was determined to be fair (κ=0.34) while that of membranous or cytoplasmic EGFR was poor (κ=0.11 and 0.12, respectively). Analyses with the more generous weighted κ did little to improve these findings (Fig. 1; Table 1).

Association of protein expression with clinico-pathological features

Univariate analysis of percent scores

The evaluation of percent positivity with the clinico-pathological features identified significant associations between p53 and T stage (*P*=0.007) and tumor grade (*P*=0.005), membranous EGFR expression and T stage (*P*=0.005), N stage (*P*=0.002), tumor grade (*P*=0.014), and survival (*P*<0.001), and cytoplasmic EGFR expression and survival (*P*=0.01). APC expression was correlated with T stage (*P*=0.023) and β-catenin expression with tumor grade (*P*=0.035), vascular invasion (*P*=0.008), and survival (*P*=0.004). There were no associations of Her2/neu with any of the clinico-pathological features (Table 2).

Univariate analysis of staining intensity

All eight significant associations of staining intensity with the clinico-pathological features were previously established by percent positivitiy. The associations of membranous EGFR and tumor grade, β-catenin, vascular invasion, and survival were not present (Table 3).

Multivariate analysis of percent positivity and staining intensity

The combined analysis of percent positivity with staining intensity identified five associations between the proteins and clinico-pathological features that were previously found using only the percentage of positive cells. In addition, the remaining associations found to have statistical significance in univariate analysis of percent positivity (p53 with T stage, membranous EGFR with T stage, N stage, and tumor grade, APC with T stage, and β-catenin with tumor grade) were no longer observed in combination with the degree of intensity. In only 1 of the 35 analyses (2.8%) did staining intensity provide additional information about the association of the protein with the outcome (β-catenin with N stage; Table 4).

Discussion

The results of this study confirm that the evaluation of percent positivity for nuclear p53, cytoplasmic APC, nuclear β-catenin, and membranous and cytoplasmic Her2/neu expression is highly reproducible among pathologists. The assessment of EGFR expression resulted in strong interobserver agreement when cytoplasmic and/or membranous immunoreactivity were scored together rather than in their separate localizations. The intensity of staining was not reproducible for the proteins in this study.

In the univariate analysis, protein expression assessed as percent positivity resulted in 11 significant associations between the proteins and clinico-pathological features. Eight of these 11 were also demonstrated using only the degree of staining intensity. However, more than half of the associations identified by percent positivity alone were lost when staining intensity was also analyzed.

Scoring systems for tumor markers in CRC are typically based on some measure of the number of positive tumor cells and often combined with a degree of staining intensity. However, Atkins et al. [2] demonstrated using an anti-EGFR antibody in head and neck cancer, non-small cell lung carcinomas, and colorectal adenocarcinoma that the degree

[c] Gain of significance with the addition of staining intensity

of staining intensity varied by tumor type, was partially influenced by the choice of fixatives, and was inversely correlated with storage time of the unstained tissue sections. These factors in addition to the variation in IHC protocols inevitably contribute to the subjective nature of staining intensity. Contradictory results from different reports on the same tumor markers may be partially explained by this subjective assessment of immunoreactivity [23, 26].

We have previously demonstrated that a descriptive, semiquantitative scoring system based on the percentage of positive tumor cells (percent positivity) is reproducible and has several advantages over standard scoring methods based on predetermined cutoff scores [17–19]. First, this scoring system allows a more thorough assessment of the predictive or prognostic significance of tumor markers by evaluating the entire range of protein expression levels (from 0 to 100%). Moreover, by quantifying protein expression at the outset, more biologically and clinically relevant cutoff scores for tumor positivity can be established by, for example, performing ROC curve analysis [34]. This method has been used to select cutoff scores for tumor markers macrophage stimulating factor 1, Raf-1 kinase inhibitor protein, receptor of hyaluronic acid-mediated motility (RHAMM), APAF-1, EGFR, as well as for several others involved in transforming growth factor β signaling in CRC [4, 20, 21, 32, 33]. Additionally, the correlations between various proteins can be assessed. We have recently shown using this scoring method that the percentage of pERK-positive tumor cells is strongly associated with increases in RHAMM expression supporting the hypothesis of a RHAMM–mitogen-activated protein kinase interaction in MMR-proficient CRC [17]. By percent scoring, we have also described how classification and regression tree methods could be used to select proteins playing a role in predicting rectal tumor response to preoperative radiotherapy [30]. Finally, this descriptive scoring method avoids an often complex and interpretative composite scoring system based on the intensity of staining. One such method includes a four-tier scoring of the intensity of staining (0, 1+, 2+, 3+) coupled to either the mean percentage of positive tumor cells or to a categorical measure of the percentage of positive tumor cells (for example, 1–10%, 10–50%, and >50) [3, 6, 9, 12, 29]. A graded scoring system has also been used where the percentage of positive tumor cells is categorized (0=no positivity, 1=1–25%, 2=25–50%, 3=>50%) and multiplied by the degree of intensity (0, 1, 2, 3) to obtain a score that is then dichotomized into “low” or “high” expression (low=score<6 and high=score≥6) [26]. Others have reported only the degree of staining intensity regardless of the proportion of immunoreactivity or considered only staining intensities of 2+ or 3+ as positive for protein expression [24].

The purpose of this study was not to evaluate the prognostic significance of several tumor markers in CRC but rather to determine whether staining intensity is a useful indicator of immunoreactivity in colorectal tumors. In addition, the study focused on whether staining intensity provides independent information on the association of the protein with clinico-pathological features beyond that which can be obtained from the semiquantitative assessment of immunoreactivity. The markers included in this study are well established and/or of current interest as prognostic factors. They were selected to provide a range of subcellular localizations for scoring purposes (cytoplasm, cell membrane, nucleus) as well as representing both tumor suppressors (p53 and APC) and oncogenes (β-catenin, Her2/neu, and EGFR).

TMA technology allowed us to analyze more than 1,000 CRCs using only three slides. One tissue sample (0.6 mm) per tumor was obtained. Although it is argued that a single tissue core may not be representative of the whole tumor, results using one sample appear to approximate those from larger tissue sections as more samples are analyzed. In fact, even larger tissue sections may contain only a small fraction of the entire tumor mass (1/10,000) [24]. Goethals et al. [9] reported that four core biopsies are sufficient to account for tumor heterogeneity. Because the inclusion of several punches per tumor is not always possible, a larger series of tumors should compensate for tumor heterogeneity as was the case in this study. Several studies have shown well-established associations between molecular features and clinico-pathological endpoints in TMAs using only one spot per tumor [5, 22, 28]. Most importantly, evaluating a single tumor punch may lead to a more reliable analysis of interobserver agreement for both percent positivity and staining intensity, as precisely the same area of tumor is scored by each observer [24].

The results of our study suggest that staining intensity is not an independent measure of protein expression for the markers in this study. Additionally, the evaluation of immunoreactivity using a semiquantitative scoring method appears to be sufficient for establishing associations of the selected tumor markers with most clinico-pathological features.

MAD1 (mitotic arrest deficiency 1) is a candidate for a tumor suppressor gene in human stomach

Abstract Mitotic arrest deficiency 1 (MAD1) is a component of the spindle checkpoint factors that monitor fidelity of chromosomal segregation. We previously confirmed that the level of MAD1 protein was decreased in gastric carcinoma compared with non-tumoral mucosa by conducting proteome-based analyses (Nishigaki R, Osaki M, Hiratsuka M, Toda T, Murakami K, Jeang KT, Ito H, Inoue T, Oshimura M, Proteomics 5:3205–3213, 29). In this study, an immunohistochemical analysis was performed to examine MAD1 expression histologically in gastric mucosa and tumor. MAD1 was detected in the supranuclear portion of normal epithelial, intestinal metaplasia, and adenoma cells, but its expression was not restricted to any specific area in carcinoma cells. Lower levels of expression were noted in 16 (47.1%) of 34 adenomas and in 52 (60.5%) of 86 carcinomas, whereas all normal mucosae and intestinal metaplasias were grouped into cases with higher level of expression. Moreover, the expression of MAD1 was significantly lower in advanced carcinomas than early carcinomas and in intestinal than diffuse type, respectively ($P<0.05$). Exogenous expression of wild-type MAD1, but not the mutant MAD1, inhibited cell proliferation and resulted in G2/M accumulation in MKN-1, a gastric carcinoma cell line. Taken together, our findings suggest that the *MAD1* gene could be a candidate tumor suppressor gene and that down-regulation of MAD1 expression contribute to tumorigenesis in human stomach.

Introduction

Gastric carcinoma remains one of the major causes of cancer-related death worldwide [7], especially in Japan [37]. Although many studies have found various genetic and molecular alterations in patients with gastric cancer [36], the precise mechanisms behind the development and progression of this disease remain unclear. Recent advances in proteomic science have led to a better understanding of the molecular mechanisms of gastric carcinogenesis and its progression. The comprehensive analysis of protein expression profiles, proteomics is one approach in identifying novel diagnostic and/or prognostic markers. Previously, we identified various up- or down-regulated proteins specific to gastric carcinoma by proteomic analysis using human-

resected stomach tissue [29]. Of these proteins, mitotic arrest deficiency 1 (MAD1) was identified as a cancer-specific down-regulated protein. MAD1 is a component of the spindle assembly checkpoint (SAC), which includes other microtubule-interacting proteins (BUB family proteins, CENP family proteins, MAD2, Mps1, Nuf2, HEC1, Zwint-1, ZW10, etc…). SAC proteins preferentially localize to kinetochores of unaligned chromosomes and contribute to the production of a diffusible signal that inhibits mitotic cell cycle progression from metaphase to anaphase [3, 11, 31]. This signal delays anaphase by inhibiting the activity of the anaphase-promoting complex/cyclosome (APC/C), a multisubunit E3 ubiquitin ligase required for the degradation of securin and subsequent activation of separase, which is necessary for the cleavage of cohesin and the separation of sister chromatids [3, 30, 41]. Therefore, it stands to reason that a down-regulation of MAD1's function might be associated with carcinogenesis in human stomach via chromosomal instability. As yet, little has been reported regarding the functions of MAD1 in human cancers. Moreover, the expression and distribution of MAD1 in gastric carcinoma remain unclear.

In this study, we examined the histological expression and distribution of MAD1 in human gastric non-neoplastic mucosae, adenomas, and carcinomas. In addition, we also investigated the mechanism by which MAD1 expression suppressed cell proliferation and verified whether *MAD1* has functions as a tumor suppressor gene in human gastric carcinoma cells.

Materials and methods

Clinical samples

Histological examinations were performed on 86 surgically resected gastric adenocarcinomas and 34 gastric adenomas obtained by endoscopic mucosal resection. In all cases, histological type was classified according to the criteria of the Japanese Gastric Cancer Association [16]. All specimens were extracted from the files of the Division of Organ Pathology, Faculty of Medicine, Tottori University and affiliated teaching hospitals. Approval for the study was obtained from the Institutional Review Board of the Faculty of Medicine, Tottori University (approval number 283). All specimens were fixed with 10% formalin and embedded in paraffin. Three-micrometer thick sections were examined using immunohistochemistry.

Immunohistochemistry

Dewaxed paraffin-embedded sections were immunostained using the streptavidin–biotin peroxidase complex (SAB) method with a HISTOFINE SAB-PO (M) Immunohistochemical Staining Kit (Nichirei) [12]. As primary antibodies, a mouse monoclonal antibody raised against MAD1 [18] and a goat polyclonal antibody raised against γ-tubulin (Sigma) were used. Immunoreactions were visualized with diaminobenzidine and the sections were counterstained with hematoxylin. MAD1 immunoreactivity was classified into two groups: lower and higher levels of expression. A tumor was judged to have a higher level of expression when at least 10% of the tumor cells or epithelia were immunoreactive. The correlation between MAD1 expression and each histological factor was evaluated using Mann–Whitney's *U* test. $P<0.05$ was considered as statistically significant.

Cell culture

Seven human gastric carcinoma cell lines (MKN-1, MKN-7, MKN-28, MKN-45, MKN-74, TMK-1 and KATO-III) were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 100 U/ml penicillin, 100 μg/ml streptomycin, and 292 μg/ml L-glutamine at 37°C in 5% CO_2.

Trichostatin A (TSA, Sigma) and 5-aza-2′-deoxycytidine (Aza, ICN Biochemical) were kept as a 3.3-mM stock solution in ethanol and a 1 mM stock solution in water, respectively, and added to the medium at a final concentration of 500 nM and 1 μM, respectively.

RT-PCR single-strand conformation polymorphism

Mutations in the coding regions of *MAD1* were examined in the seven gastric carcinoma cell lines. Total RNA was isolated and cDNA was synthesized as described previously [9]. The polymerase chain reaction (PCR)–single-strand conformation polymorphism (SSCP) and direct sequencing were performed as described previously [39].

Detection of MAD1 mRNA expression by RT-PCR

The expression level of MAD1 messenger RNA (mRNA) after treatment of Aza or TSA was examined in the seven gastric carcinoma cell lines. Total RNA was isolated, and complementary DNA (cDNA) was synthesized as described previously [9]. The sequences of primers were 5′-ggagaaaatgcagatggagctgagt-3′ and 5′-gagatcctcccttcagtgc-3′, and 28 cycles of PCR were performed. The annealing temperature was at 60°C, and PCR products were confirmed by 2% agarose-gel electrophoresis, followed by ethidium bromide staining.

SDS-PAGE and Western blot analysis

Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and Western blotting were performed as described previously [9]. The membranes were blotted with

the anti-MAD1 monoclonal antibody (1:2,000) [18] or with the anti-β-actin monoclonal antibody (1:2,000; AC-15, Sigma). Signals were visualized with an enhanced chemiluminescence system (ECL Detection System; Amersham Pharmacia Biotech).

Immunoprecipitation

MKN-1, MKN-28, and MKN-45 cells were lysed in immunoprecipitation buffer (25 mM Tris pH 7.5, 100 mM NaCl, 2 mM EDTA, and 0.5% Triton X-100) with protease inhibitors (1 mM PMSF, 10 μg/ml Leupeptin, and 10 μg/ml Aprotinin). The extracts were immunoprecipitated with anti-MAD1 polyclonal antibody [18] or with anti-γ-tubulin monoclonal antibody (Sigma). The precipitates were examined by SDS-PAGE and Western blotting using the two antibodies described above.

Plasmid vector and generation of stable cell lines

To generate mammalian expression vectors for enhanced green fluorescent protein (EGFP)-tagged MAD1, N-terminus-deleted MAD1 (MAD1 ΔN) and C-terminus-deleted MAD1 (MAD1 ΔC), cDNAs encoding a full-length MAD1 (1–718aa), the C-terminus only (295–718), and the N-terminus only (1–303) were produced by PCR from human MAD1 cDNA obtained from ATCC (Fig. 1). The primer sequences used in the constructions are available upon request. Fragments of the wild-type or mutated MAD1 were inserted into pEGFP-C3 (Clontech) at the *Bgl*II and *Eco*RI sites.

MKN-1 cells expressing stable levels of the above genes were generated by transfection with the plasmid vectors using Trans IT-LT1 Polyamine Transfection Reagents (TaKaRa) according to the manufacturer's instructions. Cells were selected for 2 weeks in the presence of 500 μg/ml G418 (Nakarai Tesque).

Cell viability and flow cytometry

Cell viability was measured using Cell Counting Kit-8 (Dojindo) according to the manufacturer's instructions. Results are presented as the mean±SD. Comparisons were made using Student's *t* test. $P<0.05$ was considered statistically significant. To analyze the DNA content, a flow cytometric analysis for EGFP and propidium iodide fluorescence was performed using an EPICS-ELITE 4.0 (Coulter) as described previously [13]. Proportions of cells in the G1, S, and G2/M phases of the cell cycle were determined with the WinMDI 2.8 software program (freeware).

Immunofluorescence microscopy

MKN-7 cells were grown on chamber slides and were fixed with 4% paraformaldehyde at 4°C for 20 min followed by 0.5% Triton X-100 in phosphate-buffered saline (PBS) at 4°C for 20 min. The slides were then incubated with the primary antibodies: rabbit polyclonal anti-MAD1 antibody [18], mouse monoclonal anti-γ-tubulin antibody (sigma), mouse monoclonal anti-GM130 antibody (BD Biosciences), and mouse monoclonal anti-KDEL antibody (Stressgen); followed by flourescein isothiocyanate (FITC)-conjugated goat anti-rabbit IgG antibody (Vector Laboratories) and Alexa594-conjugated goat anti-mouse IgG antibody (Molecular Probes). The MKN-7 cells were viewed under a Leica confocal microscope (TCS SP2), and software (Leica confocal software) was used to produce images.

Results

Expression of MAD1 protein in normal gastric mucosa, intestinal metaplasia, adenoma, and carcinoma

Immunohistochemistry was performed to examine the histological expression of MAD1 in human gastric mucosae and carcinomas. In the normal gastric mucosa, frequent MAD1-positive cells were distributed among surface mucous cells and isthmus cells, but such cells were rare in fundic and pyloric glands, especially in deeper zones. Immunoreactivity of MAD1 protein was noted in the

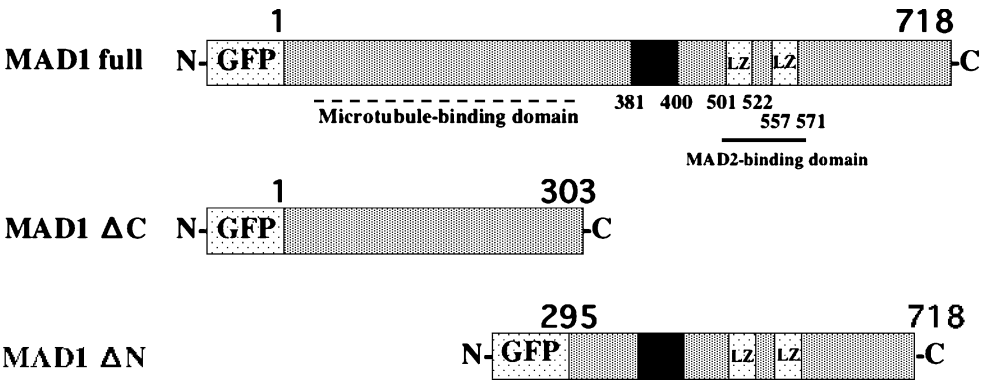

Fig. 1 Schematic representation of full-length MAD1 (MAD1 full), C-terminus-deleted MAD1 (MAD1 ΔC) and N-terminus-deleted MAD1 (MAD1 ΔN). *GFP* Green fluorescent protein, *NLS* nuclear localizing signal, *LZ* leucine zipper

supranuclear portion of the cells in these areas (Fig. 2a), as well as in intestinal metaplasia and adenoma cells (Fig. 2b,c). On the other hand, the subcellular distribution of MAD1 was not restricted to a specific area in carcinoma cells (Fig. 2d). In addition, little immunoreactivity was seen in mesenchymal cells including lymphocytes.

Table 1 shows the frequency of lower expression levels of MAD1 in gastric adenomas and carcinomas. The frequency was significantly higher in carcinomas than in adenomas ($P<0.05$). Moreover, the frequency was significantly increased in the 57 advanced carcinomas than in the 29 early carcinomas and in the 46 intestinal types than 40 diffuse types, respectively ($P<0.05$). On the other hand, none of the normal gastric mucosae or intestinal metaplasia lesions were classified as having lower expression levels (data not shown). These findings suggest that a down-regulation of MAD1 expression is associated with tumorigenesis and cancer progression in human stomach.

Subcellular distribution of MAD1 in gastric epithelia and carcinoma cells

Next, we wished to identify the subcellular distribution of MAD1 in gastric epithelial cells and carcinoma cells. We wanted to do this because the histological studies revealed that MAD1 protein was located in the supranuclear portion of epithelial and adenoma cells, while the immunoreactivity pattern was altered in carcinoma cells. We surmised that the distribution of MAD1 in gastric epithelial cells could be at centrosome, Golgi apparatus, or endoplasmic reticulum (ER) based on the histological findings. To define localization more precisely, γ-tubulin, GM130, and KDEL were used as characteristic markers for centrosome, Golgi apparatus, and ER, respectively. Endogenous expression of these proteins was detected and visualized by dual-colored fluorescent immunocytochemistry using specific antibodies. As shown in Fig. 3a, MAD1 was detected as green and γ-tubulin was detected as red, respectively. All of the green signals were concordant with the red signals when the two were merged. A few red signals (γ-tubulin) were observed alone, although no green signal was detected alone. By contrast, the immunoreactive pattern of MAD1 was discordant with that of GM130 or KDEL (data not shown). These cytological findings suggested that MAD1 forms a complex with γ-tubulin at the centrosome.

To confirm the above hypothesis biochemically, immunoprecipitation and immunoblotting were performed using antibodies against MAD1 and γ-tubulin. MAD1 protein

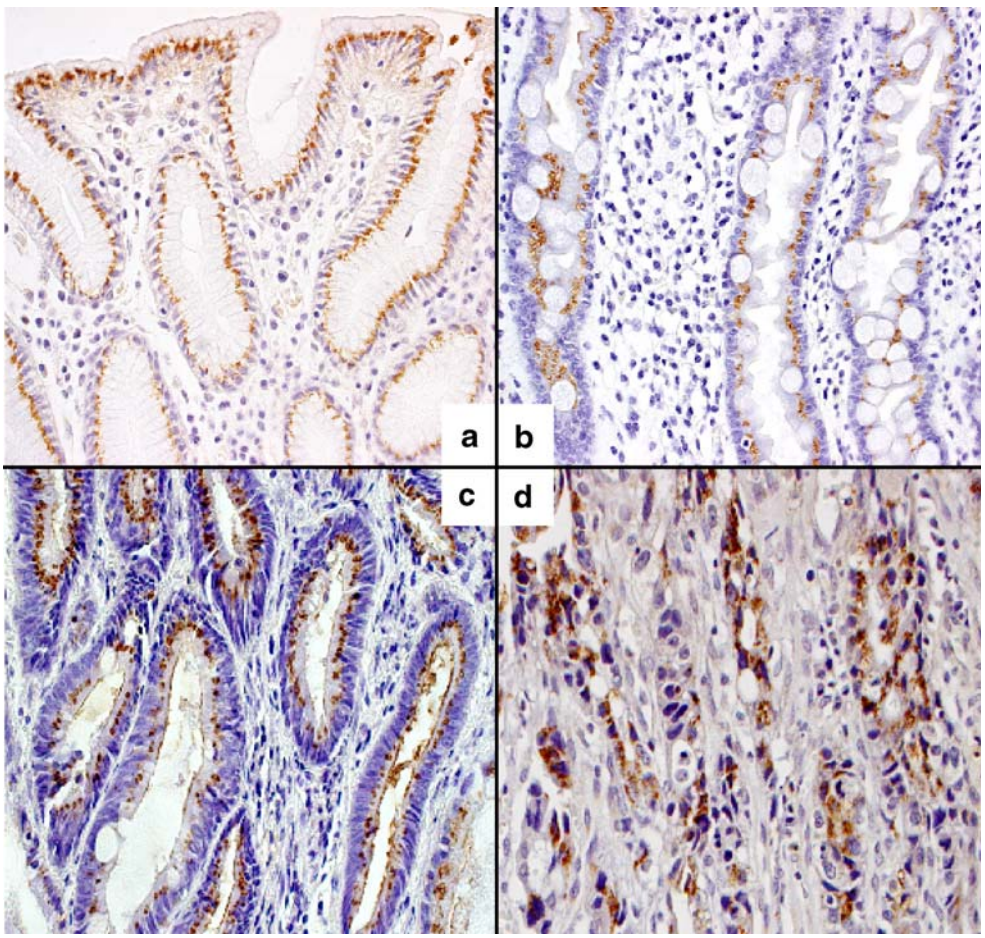

Fig. 2 MAD1 expression in normal gastric mucosa (**a**), intestinal metaplasia (**b**), adenoma (**c**), and adenocarcinoma (**d**). Immunoreactivity of MAD1 is noted in the supranuclear portion in **a**, **b**, and **c**. Immunoreactivity of MAD1 is not restricted to a specific area in carcinoma cells (**d**)

Table 1 Expression of MAD1 in gastric tumors

	Lower expression cases	*P* value
Adenoma (*n*=34)	16 (47.1%)	0.05
Carcinoma (*n*=86)	52 (60.5%)	
Early (*n*=29)	14 (48.3%)	0.05
Advanced (*n*=57)	38 (66.7%)	
Intestinal type (*n*=46)	32 (69.6%)	0.05
Diffuse type (*n*=40)	20 (50.0%)	

was revealed to coprecipitate with γ-tubulin protein, and vice versa in MKN-1, MKN-28 and MKN-45 cells, respectively (Fig. 3b). These results are consistent with MAD1 localization at centrosome not only in gastric carcinoma cell lines but also in non-neoplastic epithelia. Immunohistochemistry was performed to reveal the distribution of MAD1 and γ-tubulin using serial sections of resected stomach. Interestingly, most of the immunoreactivity was found with γ-tubulin in both gastric epithelial and carcinoma cells (Fig. 3c).

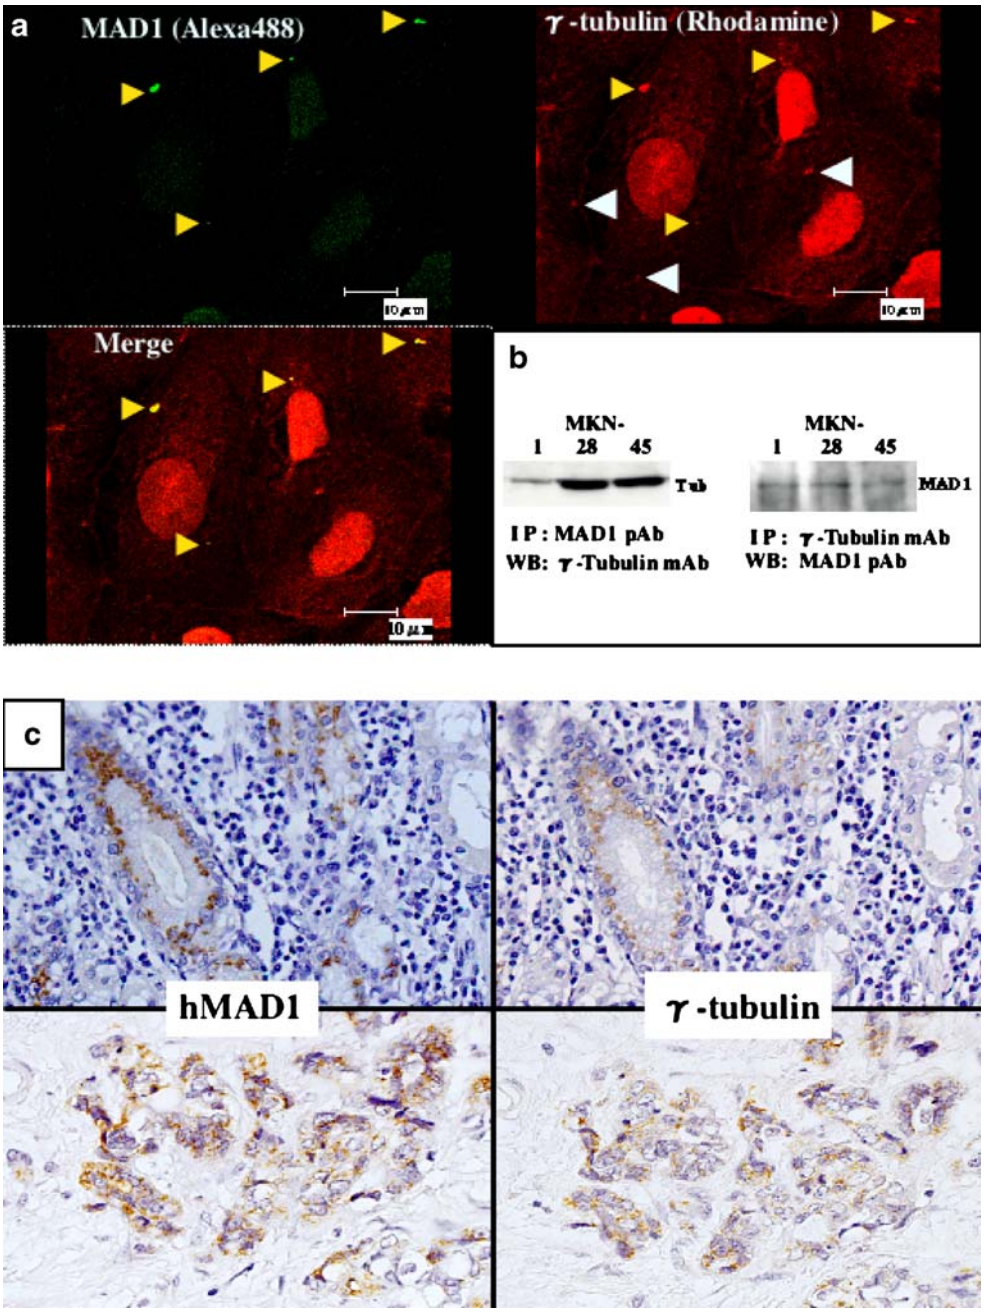

Fig. 3 Association of MAD1 with γ-tubulin. **a** Colocalization of MAD1 and γ-tubulin assessed by confocal microscopy in MKN-7 cells. Immunostaining with anti-MAD1 antibody (*green*) and with anti-γ-tubulin antibody (*red*), areas of colocalization are in yellow (*arrows*). A few red signals (γ-tubulin) are observed alone (*arrowheads*), whereas no green signal (MAD1) is detected alone. **b** Association of endogenous MAD1 with γ-tubulin in cells. Lysates of MKN-1, MKN-28 and MKN-45 cells were subjected to immunoprecipitation with anti-MAD1 pAb or anti-γ-tubulin mAb, fractionated by SDS-PAGE, and immunoblotted with anti-γ-tubulin mAb or anti-MAD1 pAb, respectively. **c** Immunohistochemical analysis of MAD1 and γ-tubulin in non-tumoral gastric mucosa (*upper panels*) and gastric carcinoma (*lower panels*) using serial sections

Genetic vs epigenetic alteration of the MAD1 gene in human gastric carcinoma cell lines

To determine whether human gastric carcinoma cell lines bear mutations within the *MAD1* coding region, seven cell lines were screened by SSCP and direct sequencing. We found a C to T transition at position 663C; this change is without an amino acid alteration (His to His) in MKN-1 cells, and we observed a G to A transition at position 1673G in which arginine 558 was converted to histidine in MKN-1, MKN-45 and MKN-74 cells. These genetic changes, however, are established polymorphisms and do not represent mutations specific for cancer, according to a previous report [39].

Then, we next focused on epigenetic changes as explanations for reduced MAD1 expression. Epigenetic silencing of gene expression can be due to hypermethylation of the gene promoter and/or acetylation of chromatin-associated histones. Aza, an inhibitor of DNA methyltransferase, and TSA, an inhibitor of histone deacetylase, can reactivate gene expression when hypermathylation of CpG islands in the MAD1 promoter or acetylation of gene-associated histones is the cause of reduced expression [1]. As shown in Fig. 4a, the expression of MAD1 protein was consistently reactivated by treatment with either Aza or TSA in all seven cell lines compared to non-treated counterparts. The expression of MAD1 mRNA was also clearly up-regulated by these treatments in MKN-28 and MKN-74 (Fig. 4b). These results suggest that both DNA methylation and histone acetylation normally participate in regulating *MAD1* gene expression.

Exogenous expression of MAD1 suppresses MKN-1 cell proliferation

The cell cycle regulatory activity of MAD1 was examined next using a cell proliferation assay. Using MKN-1, we selected for the stable expression of several MAD1-expressing cell lines. In G418 selected clones, the number of proliferating cells was monitored by Cell Counting Kit-8. As shown in Fig. 5a, proliferation of MKN-1 cells expressing wild-type MAD1 (MKN-1/MAD1 full) was significantly slowed compared to the other clones ($P < 0.01$). The growth curve of MKN-1/MAD1 ΔN was similar to that of the control clone (MKN-1/GFP). Although the growth rate of MKN-1/MAD1 ΔC was slightly suppressed compared to that of MKN-1/GFP or MKN-1/MAD1 ΔN, no significant difference was ascertained.

To understand the mechanisms of MAD1's growth suppression, DNA contents were examined by flow cytometry. Figure 5b shows that exogenous expression of wild-type MAD1 apparently increased cells that accumulated in the G2/M phase. Induction of apoptosis generally results in an accumulation signal in the sub-G1 peak. In our experiments, no evidence of apoptosis was induced by MAD1 expression in MKN-1 cells.

Discussion

In this paper, we report that MAD1 expression was observed in epithelial cells and tumor cells but not in mesenchymal cells including lymphocytes. Hence, the

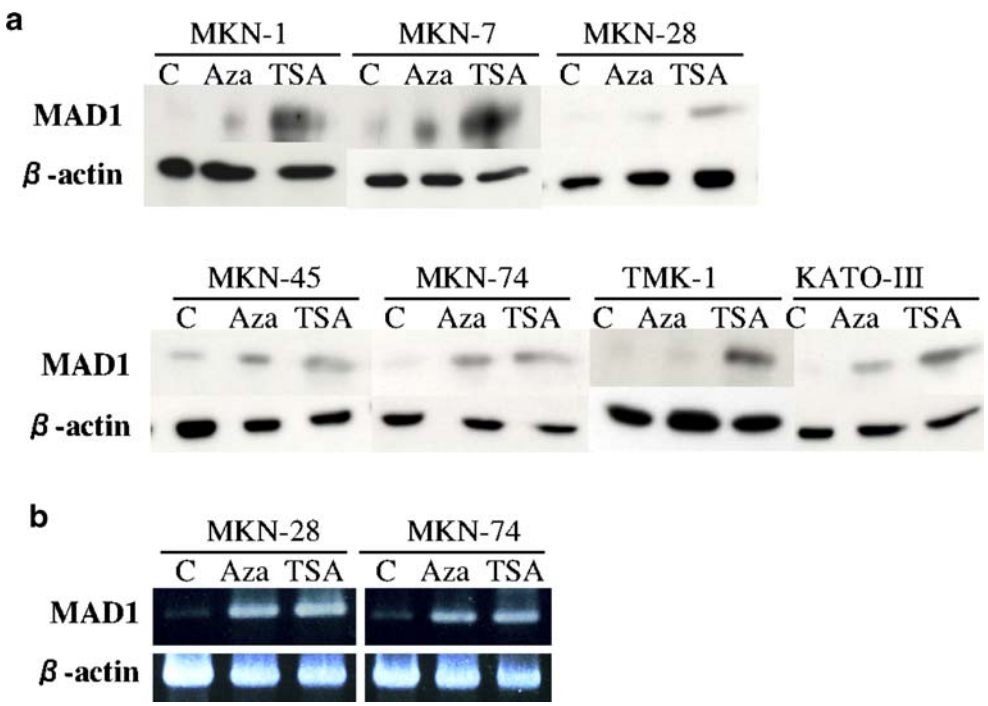

Fig. 4 Expression of MAD1 protein (**a**) or mRNA (**b**) were reactivated by treatment with Aza or TSA in human gastric carcinoma cell lines. Cells were cultured for 48 h in the presence of Aza (500 nM 5-aza-2′-deoxycytidine treatment) or TSA (1 μM Trichostatin A treatment). **c** Untreated control

Increased cell accumulation in G2/M phase (indicated by *arrow*) was observed in MKN-1 cells transfected with the wild-type *MAD1* gene

down-regulation of MAD1 expression identified by proteomics indicates that the expression level of MAD1 was obviously reduced in the gastric carcinoma cells compared to non-neoplastic epithelial cells. All of our non-tumor mucosae were classified as higher MAD1 expression cases, while about half of the gastric adenomas and two-third of the carcinomas fell into the lowered expression category. In addition, MAD1 expression was lower in advanced carcinomas compared to early carcinomas. There have been reports that MAD1 is required to recruit MAD2 to kinetochores and that a MAD1–MAD2 complex at kinetochores is important for SAC function [2, 4, 18, 26, 27, 35]; thus, our observed the down-regulation of MAD1 expression could explain one reason for tumorigenesis and cancer progression in human stomach.

Histological examinations also revealed that more MAD1 protein was present in the diffuse type than in the intestinal type carcinomas. Kienitz et al. [21] reported that partial repression of MAD1 resulted in chromosomal aneuploidy in a human colon cancer cell line, indicating that a reduction in MAD1 function contributes to chromosomal numerical aberrations. Recently, Iwanaga et al. [14] have shown that mice heterozygously knocked out for one MAD1 allele have high incidence of constitutive tumors. Several reports have also described that intestinal type gastric carcinomas had a significantly higher rate of aneuploidy than diffuse type carcinomas [17, 22, 23, 24, 32]. Taken together, the findings collectively support an interpretation that chromosomal instability in gastric carcinoma cells might be attribute, in part, to reduced MAD1 expression. It would be informative in future studies to elucidate how loss of function in spindle checkpoint proteins, including MAD1, leads prospectively to in vivo aneuploidy.

Our present work contributes to an understanding of reduced MAD1 expression in human gastric carcinoma cells by examining genetic and epigenetic regulation. To date, no data are available on genetic or epigenetic disorder of *MAD1* gene in human stomach. Based on direct sequencing, we found that four nucleotide transitions resulting conserved, H221H, and non-conserved, R558H, amino acids were detected in coding region of MAD1 protein in MKN-1, MKN-45, MKN-74 cells. These genetic changes have been reported as polymorphisms and are unlikely to be cancer-specific alterations [39]. Interestingly, Iwanaga et al. [15] previously identified a single nucleotide polymorphism at codon 558 located within the second leucine zipper in MAD1 in human cells. They reported that MAD1H558 was less proficient than MAD1R558 in binding MAD2 and in enforcing mitotic arrest. Therefore, a polymorphism such as R558H in MAD1 might be an at-risk form that contributes to attenuate spindle checkpoint function in human gastric epithelial cells.

The sequencing analyses revealed no causal mutations reducing MAD1 expression in human gastric cell lines. We, therefore, examined whether epigenetic disorders could explain reduced MAD1 expression. Because *MAD1* was reactivated by Aza or TSA treatment, we inferred that MAD1 expression could normally be under epigenetic control. Recently, it has been reported that a number of tumor suppressor genes, such as *RUNX3* [25], *p16* [38], *DCC* [33], *hMLH1* [6], *DAP kinase* [19], *RASSF1A* [5], *TSLC1* [10], among others are silenced by promoter hypermethylation in gastric carcinoma. Our findings suggest that MAD1 could also have tumor suppressor function and may be similarly regulated as other tumor suppressors through epigenetic mechanisms.

One of our additional salient observations is that MKN-1 cell proliferation was inhibited by exogenous expression of wild-type MAD1 resulting in accumulation in the G2/M phase. Tunquist et al. [40] showed that the microinjection

of MAD1 protein into *Xenopus laevis* embryos caused metaphase arrest. Thus, the suppression of cell growth by the transduction of wild-type MAD1 might be explained by M phase arrest due to activation of the spindle checkpoint function. Because little growth arrest function was seen with N- or C-terminus-deleted MAD1 in MKN-1 cells, these results suggest that full-length MAD1 is required for spindle checkpoint function.

Our present study revealed preferential subcellular distribution of MAD1 at centrosome in the interphase non-neoplastic epithelia and carcinoma cells. Shah et al. [34] reported that MAD1 protein and the other spindle checkpoint factors, is located at kinetochores in prometaphase, and MAD1 is released from kinetochores and relocalized to spindle poles after prometaphase. These results suggest that MAD1 protein found at centrosome in interphase presumably inactive for function. Further studies are needed to elucidate the relationship between sequential subcellular localization and MAD1's SAC activity.

We note with interest that the subcellular distribution of MAD1 in gastric carcinoma cells is extremely different from that in normal epithelial cells. A supranuclear localization of MAD1 protein was noted in normal epithelial cells, intestinal metaplasia, and adenoma. Normal cells generally have one centrosome, duplicated in S phase. By contrast, numerical and distributional abnormalities of the centrosomes have been reported in a variety of solid tumors [8, 20, 28, 42]. The altered immunoreactive MAD1 pattern in gastric carcinoma cells might reflect numerical and distributional abnormalities in the centrosomes. We infer these findings to support that (1) a down-regulation of MAD1 expression might be associated with a disruption to the distribution and/or function of the centrosome, which can contributed to gastric tumorigenesis, and (2) the histological examination of MAD1 protein might assist in distinguishing between gastric adenoma and carcinoma.

In conclusion, our histological examination revealed that the expression of MAD1 protein is down-regulated in gastric tumors probably via epigenetic alteration. This is the first report linking MAD1 abnormality with gastric carcinomas. Because exogenous expression of MAD1 suppressed the proliferation of MKN-1 cells, we suggest that the *MAD1* gene exhibit tumor suppressor-like activity in human stomach.

Morphologic features in the regenerating liver—a comparative intravital, lightmicroscopical and ultrastructural analysis with focus on hepatic stellate cells

Received: 31 January 2007 / Accepted: 6 July 2007 / Published online: 3 August 2007

Abstract Different cell types play a role in the liver regeneration. The present study reveals morphological key steps of liver regeneration by correlating intravital, light, and electron microscopic with immunohistochemistry results focusing on hepatic stellate cells (HSCs). In Lewis rats, liver regeneration was induced by a 2/3-hepatectomy. Animals (n=7 each) were killed after 0, 1, 2, 3, 4, 7, and 14 days. Morphological features were investigated by light microscopy, immunohistochemistry [α-smooth muscle actin (α-SMA), Desmin, vascular endothelial growth factor (VEGF)/VEGF receptor, Ki-67, ssDNA], intravital microscopy (sinusoid density, number of hepatocytes, and HSC), and electron microscopy focussed on cell-to-cell interactions. During liver regeneration, HSC were activated at day 3 showing a loss of autofluorescence and simultaneously an increased α-SMA expression and direct cell contact to hepatocytes. HSC activation was followed by increasing VEGF expression and sinusoid density. After 14 days, liver architecture and ultrastructure was restored and HSCs were deactivated showing decreased α-SMA expression as well as increased apoptosis and no more direct cell contact to hepatocytes. HSCs play a central role in the regenerating liver by governing angiogenesis and extracellular matrix remodeling. A direct cell contact to hepatocytes seems to be essential for HSC activation, whereas deactivation is accompanied by loosening of hepatocyte contact and increased apoptosis.

Introduction

The liver has the remarkable capability to regenerate representing the precondition for modern liver surgery [11, 13]. After tissue loss of the liver, growth factors, cytokines, and protease promote and control the temporal and spatial proliferation and migration of the various cells to efficiently reconstitute liver mass. The most important findings of liver regeneration were gained from the model of 70% partial hepatectomy by Higgins and Anderson [11]. Hepatocyte proliferation starts about 24 h after resection in the areas of the lobules surrounding the portal triads and then proceeds to the pericentral areas by 36–48 h. The hepatocytes leave their quiescent state and enter the proliferative stadium of the cell cycle. After 72 h, the replication of the hepatocytes is completed. Most nonparenchymal liver cells enter the DNA synthesis 24 h after the hepatocytes, with a peak activity at 48 h, for example, hepatic stellate cells (HSCs) and Kupffer cells [11]. On the other side, sinusoidal endothelial cells (SECs), the open, fenestrated, discontinuous endothelial cells that line the vessels

supplying the parenchymal plates, do not initiate DNA synthesis until 48–72 h after resection. The DNA synthesis of the SECs is peaking on fourth day and continue to proliferate at least until 8 days after partial hepatectomy. This chronological order of cell proliferation results in the formation of avascular hepatic islands, also called hepatocyte clusters, throughout the liver lobule. Subsequent proliferation and migration of the sinusoidal endothelium into the hepatocyte clusters are driven by the release of various angiogenetic growth factors, including vascular endothelial growth factor (VEGF) synthesized by hepatocytes [1, 7]. It seems that not only hepatocytes play an important role in regulating the vascularization of the hepatocyte clusters but also other cells of the liver like HSCs [1, 5].

Surprisingly, very little is known about the role of HSCs in the liver regeneration. HSCs represent a distinct cell type engaged in several important functions under both physiological and pathological conditions. HSCs occur in "quiescent" and "activated" morphologically distinguishable forms. The quiescent HSCs are found in the space of Disse, especially at the branching of sinusoids where they wrapped sinusoidal cells with their long cytoplasmic processes. The quiescent HSCs possess the highest capacity to store vitamin A. In the quiescent state, HSCs are characterized through a low proliferation rate. In response to liver injury, HSCs change their phenotype from quiescent to activated. In the activated state, HSCs lose vitamin A and synthesize a large amount of extra-cellular matrix components. The HSCs are found to be congregating around the avascular hepatocyte islands and adhering to the hepatocytes [9, 14, 16].

In the present study, we investigated the liver regeneration in close intervals by correlating different morphological methods, e.g., light, electron, intravital microscopy, and immunohistochemistry with special reference to the role of HSCs.

Materials and methods

Animals and study design

All operations and handling procedures were in accordance with local animal welfare regulations and approved by the veterinary district administration of Muenster.

In 49 Lewis-rats, liver regeneration was induced by a 2/3 hepatectomy [13]. Animals (n=7 each) were killed after 0, 1, 2, 3, 4, 7, and 14 days. All procedures were carried out under nitrous oxide/isoflurane anesthesia ($N_2O/O_2 = 2:1 + 1.5\%$ isoflurane). Preoperatively, the rats had to fast for 24 h but had free access to water. Postoperatively, animals received water and food ad libitum.

Intravital microscopy

Intravital microscopy was performed with a fluorescence microscope, Zeiss Axioscope, integrated in the Multi-Purpose Microscope system [100 W/2 HBO mercury lamp; eyepieces: 10×/20; objective Zeiss Achroplan 20×/0.5 w Ph 2 for water immersion; zoom lens 0.5–2.0; filter combinations of 450–490/515–565 nm (excitation/emission) for sodium fluorescein and 330–390/>430 nm for bisbenzamide and vitamin A autofluorescence] in epi-illumination technique [9]. Sodium fluorescein (2 μmol/kg body weight i.v., Sigma) was used to enhance contrast for assessing the sinusoid density. Hepatocyte nuclei were identified by admission of Hoechst 33342 (Ho342, 20 μmol/kg b.w., Sigma). HSCs were identified using their inherent vitamin A autofluorescence.

Intravital microscopy was performed under constant conditions of anesthesia and temperature by an adjustable heating system integrated into the table. A polyethylene catheter was inserted into the carotid artery for measurement of arterial blood pressure. For investigation of the liver regeneration, the lower surface of the left liver lobe was used. In the first, sodium fluorescein was injected via the central venous catheter. In the next step, half an acinus was visualized using the filter for sodium fluorescein to identify the sinusoids and to measure the width of the hepatic cord in the later off-line analysis. Then the filters were switched from the filter for sodium fluorescein to the filter for vitamin A autofluorescence and also for bisbenzimide to study the HSCs. It is very important to firstly focus on the acinus during the investigation of the sinusoids for immediately having a sharp picture of HSCs owing to their rapid photobleaching characteristics. Six to ten acini were randomly selected and recorded for the analysis of sinusoid density, hepatic cord width and number of HSC [2, 5, 18]. After the hepatocytes were studied because the same filter had to be used for the hepatocytes as for the HSCs and the fluorescence of the hepatic nuclei illuminated the vitamin A autofluorescence of the HSCs. Also 6–10 acini were randomly selected and recorded for the analysis of the hepatocytes.

All parameters were quantified off-line by a frame-to-frame analysis of video-recorded microscopic images via the computer-assisted image analysis system AnalySIS (SIS, Muenster, Germany). A final magnification of ×750 was employed for assessment of the liver regeneration. The following parameters were analyzed: The number of hepatocyte nuclei were counted per area ([n/mm^2]). The hepatocytes were identified by their regular, circular shape and enduring nature of their Ho342-related fluorescence. The hepatic cord width ([μm]) was measured ten times per acinus. The sinusoid density was defined as the number of sinusoids per half acinus ([n/mm^2]). HSC frequency per area was calculated by counting the number of photo-

bleaching sites per half acinus ([n/mm^2]). HSCs were identified as intense areas of fluorescence, which faded within 10–20 s of epi-illumination. HSCs were counted in the first second of UV epi-illumination because of its rapidly photobleaching characteristics.

Light microscopy

For histological evaluation, all liver specimens were fixed for at least 2 days by immersion in 4% paraformaldehyde phosphate-buffered solution (pH 7.4) and were subsequently dehydrated and embedded in paraffin wax to process sections at a thickness of 10 μm that were conventionally stained by Hematoxylin & Eosin and examined under a Zeiss lightmicroscope by an experienced morphologist. Histological criteria of evaluation were focussed on cell swelling, mitosis, immigration of sinusoidal cells into hepatic clusters, and endothelium structure. For documentation, photomicrographs were taken from the periportal and the pericentral zones of liver lobules belonging to the control group (sham operation) and to the six postoperative groups.

Electron microscopy

For transmission electron microscopy, liver specimens were immersed in 2.5% glutaraldehyde solution for 24 h (0.1 m

PBS, pH 7.2), postfixed with 1% OsO_4 in cacodylate-buffer for 1 h (0.1 m PBS, pH 7.2), dehydrated, embedded, and polymerized in epoxy resin (Epon 812) for 24 h. Ultrathin sections were contrasted with uranyl acetate and lead citrate and observed under a transmission electron microscope (CM-10, Philips, Germany). Criteria of ultrastructural investigation were focussed on cell–cell membrane contacts between hepatocytes and nonparenchymal cells.

Immunohistochemistry

The monoclonal antibody, MIB-5 (DakoCytomation, Hamburg, Germany), is specific for the rat homologue of the Ki-67 cell-cycle-associated nuclear antigen and detects cells outside the G0 stage of the cell cycle. MIB-5 was diluted 1:20 and visualized on paraffin sections using the immuno-alkaline phosphatase (APAAP) method with fuchsin as the chromogen. The hepatocellular mitotic index, i.e., the proportion of MIB-5 decorated nuclei per 100 hepatocellular nuclei, was assessed by counting a grid defined field containing approximately 1,000 hepatocytes and nonparenchymal cells per section.

Immunohistochemical assessment of apoptosis was performed on paraffin sections using the labeled streptavidin–biotin immunoperoxidase technique (Streptavidin Alexa Fluor 488, Molecular Probes Eugene, USA) with a rabbit

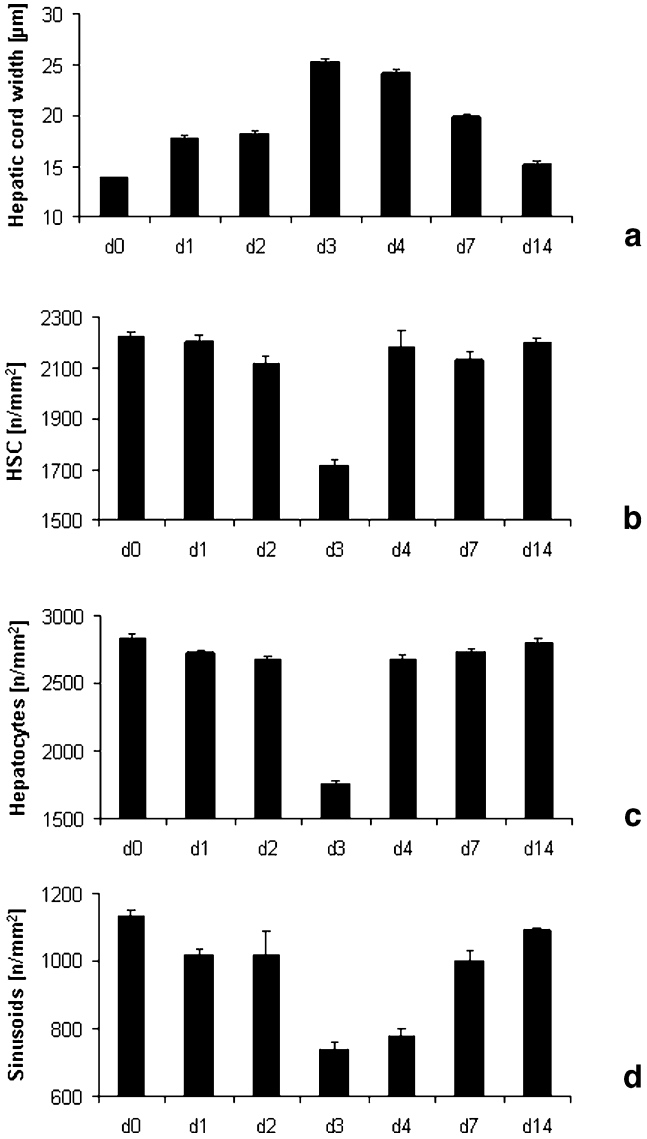

Fig. 3 Intravital microscopic features of liver regeneration. **a** Hepatocyte cord width (µm); **b** number of HSC (n/mm^2); **c** number of hepatocytes (n/mm^2); **d** sinusoid density (n/mm^2). *d* Day after induction of liver regeneration by partial hepatectomy

polyclonal antibody against ssDNA (IBL, Japan) at a 1:2,000 dilution and a biotinylated anti-rabbit antibody (Vector Laboratories, USA) at a dilution of 1:500. Nuclei were stained with DAPI (Sigma Chemical, USA) at a dilution of 1:10,000. Apoptosis index, i.e., the proportion of ssDNA decorated nuclei per 100 hepatocellular nuclei, was semiquantified as described above.

Immunohistochemical detection of VEGF and its receptor (VEGFR) as markers for angiogenesis was performed on paraffin-sections with an anti-VEGF antibody (ab2992, Abcam) and an anti-VEGFR antibody, respectively, and visualized as described above. The immunostaining intensity of VEGF and VEGFR was evaluated according to a four-grade score: 0=negative, 1=partially (<25%) weak-positive stained cells, 2=partially (<25%) moderate or diffuse (>75%) weak-positive cells, 3=diffuse (>75%) moderate or strong positive cells, 4=diffuse strong positive cells.

Immunohistochemical detection of desmin as marker for HSCs and α-smooth muscle actin (α-SMA) as a marker for activated HSCs was performed on paraffin sections with anti-desmin antibody (clone D33, mouse monoclonal) and anti-α-SMA antibody (clone 1A4, Rabbit monocloncal, both DakoCytomation, Hamburg, Germany) using the staining detection as described above. The percentage of nonactivated and activated HSCs was assessed as described above.

Results

Light microscopy

All specimens of the first group showed a regular liver histology with a normal hepatocellular structure and stainability. One day after induction of liver regeneration, tissue specimens displayed hepatocyte swelling and intracellular vesicular steatosis predominantly in the periportal zone. On the postoperative days 2 and 3, numerous mitotic figures in hepatocytes and nonparenchymal cells as well as clusters of small hepatocytes were visible, which were surrounded by sprouts of patent capillaries on day 4. On day 7, liver tissue appeared to be normally structured apart from the occurrence of enlarged lobules compared to the control specimens. Some persisting clusters of small hepatocytes were noticed to be immigrated by aluminal endothelial cell strands. On day 14, the regenerative liver showed a regular liver histology with a normal hepatocellular structure (Fig. 1).

Electron microscopy

One day after liver resection, hepatocyte vesicular steatosis and endothelial cell damage of adjoining sinusoids was most obvious. The cell membrane of the endothelial cell displayed desquamation (see Fig. 2 d1). On the postoperative day 2, mitotic figures of hepatocytes were apparent. On days 3 and 4, hepatocytes often appeared to have developed membrane contacts to adjoining nonparenchymal cells (see Fig. 2 d3a). These cells were situated alongside of the endothelial cells within the space of Disse and presumably belong to the stellate-type cell due to their cell protrusions extending from the central cell body with the nucleus, whereas hepatocytes were identified by their cuboidal shape, their microvilli covering, and their numerous mitochondria. At higher magnification, cell membrane of hepatocytes and HSCs revealed a linear type of contact over an estimated distance of around 1.0 µm (see Fig. 2 d3b). In the sham operation group and on the 7th and the 14th postoperative day, such types of cell contact could not

be observed by electron microscopy (see Fig. 2 d7a and d7b). At the 7th and the 14th postoperative day, all specimens showed hepatocytes with regular ultrastructure without occurrence of vesicular steatosis. Likewise, endothelial cells appeared as cells with morphological features corresponding to the control specimens and HSCs reobtained loose contact to hepatocytes.

Intravital microscopy

Intravital microscopic features of liver regeneration started at day 0 with continuous columns of hepatocytes (2,836.2±29.5/mm^2) with a narrow cord width (13.9±0.3 μm), extended sinusoids (1,135.1±15.4/mm^2), and HSCs (2,221.7±16.6/mm^2) located around all sinusoids. Hepatic cord width increased to a maximum on day 3 (25.3±0.3 μm). The number of hepatocytes and autofluorescent HSCs decreased to a minimum on day 3 (Hepatocytes, 1,760.6±18.1/mm^2, HSC: 1,751.9±20.2/mm^2). Particularly, a strong drop of HSCs was recorded between the second and third day. In contrast to day 0, HSCs were arranged in clusters on the third day. From day 4 onwards, the number of hepatocytes and HSCs continuously increased reaching their original number on day 7. The sinusoid density decreased to a minimum on the third day. On the fourth day, the sinusoid density remained low and recovered on the seventh day. After

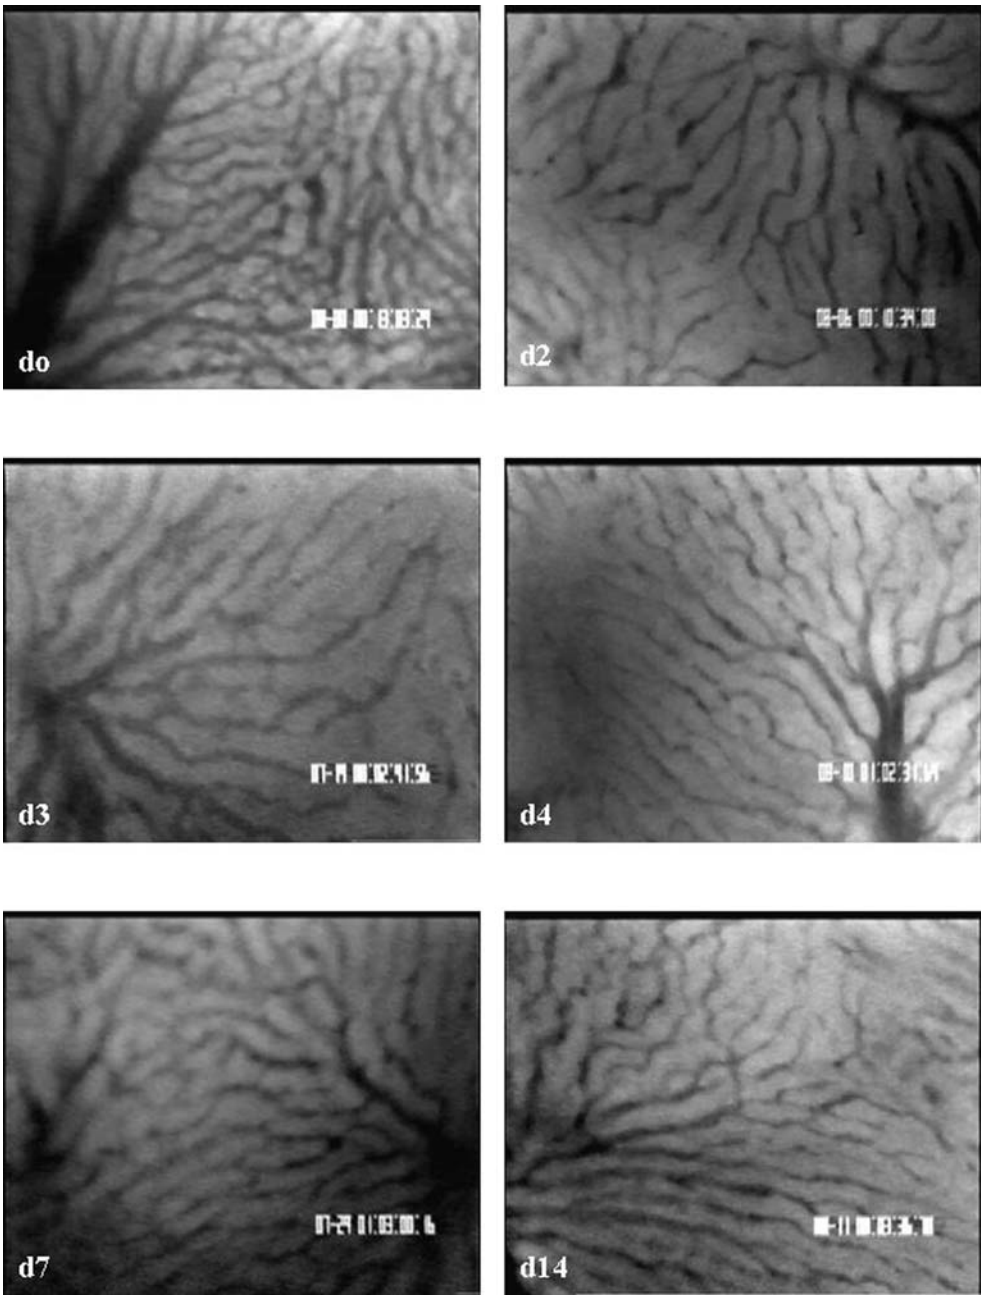

Fig. 4 Intravital microscopical image of sinusoid density and hepatic cord width at days 0, 2, 3, 4, 7, and 14. The sinusoid density decreased to a minimum on the third day and the hepatic cord width increases to a maximum. On the fourth day, the sinusoid density remained low and recovered on the seventh day. The *dark lumen* are representing the sinusoids. *d* Day after induction of liver regeneration by partial hepatectomy

14 days, the original intravital microscopic liver morphology was regained (Figs. 3, 4, 5, and 6)

Immunohistochemistry

Two days after induction of liver regeneration, hepatocyte proliferation—as shown by the Ki-67 expression—increased up to the fourth day. Proliferation of nonparenchymal cells proceeded with a delay of 24 h. On the seventh day, Ki-67 expression showed original values for hepatocytes and nonparenchymal cells. Expression of VEGF (Fig. 8) and its receptor showed a strong increase on the third, fourth, and seventh day. Whereas desmin expression of HSC remained almost constant during liver regeneration, HSCs showed an increased α-SMA expression starting from day 2 to a maximum between days 3, 4, and 7. Hepatocyte apoptosis was increased at day 7, whereas the nonparenchymal cells showed an increased apoptosis at day 7 and 14 in comparison to day 0 (Fig. 7; Table 1).

Discussion

This study demonstrates that HSCs were activated at day 3 during liver regeneration by loosing their autofluorescence and showing an increased α-SMA expression and direct cell

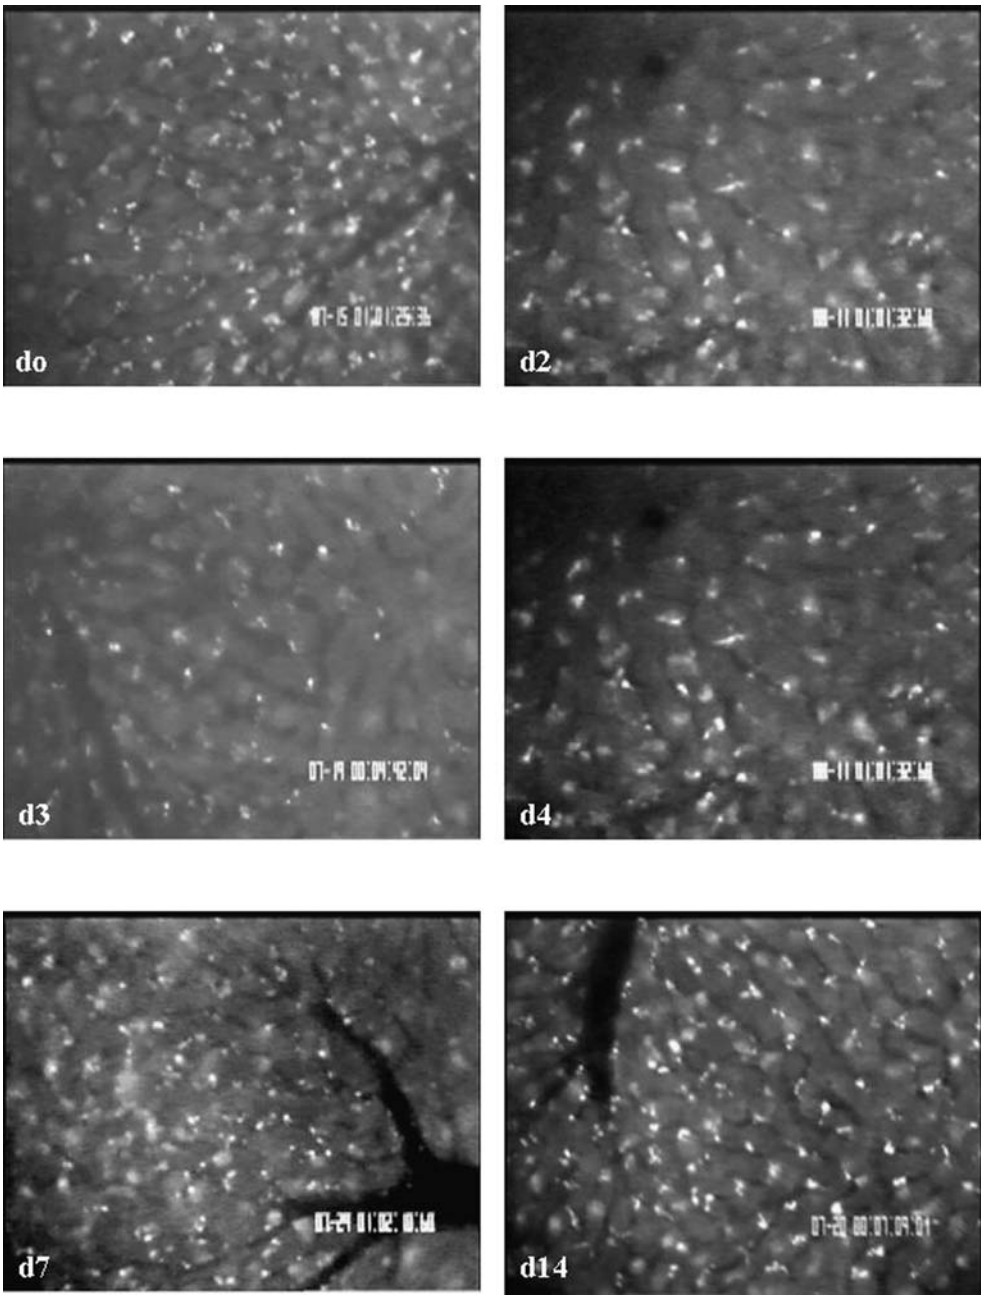

Fig. 5 Intravital microscopical image of hepatic stellate cells at days 0, 2, 3, 4, 7, and 14. The number of autofluorescent HSCs decreased to a minimum on day 3, with a strong drop between the second and third day. In contrast to day 0, HSCs were arranged in clusters on the third day. From day 4 onwards, the number of HSCs continuously increased reaching their original number on day 7. HSCs were identified using their inherent vitamin A autofluorescence (*white spots*, HSCs). *d* Day after induction of liver regeneration by partial hepatectomy

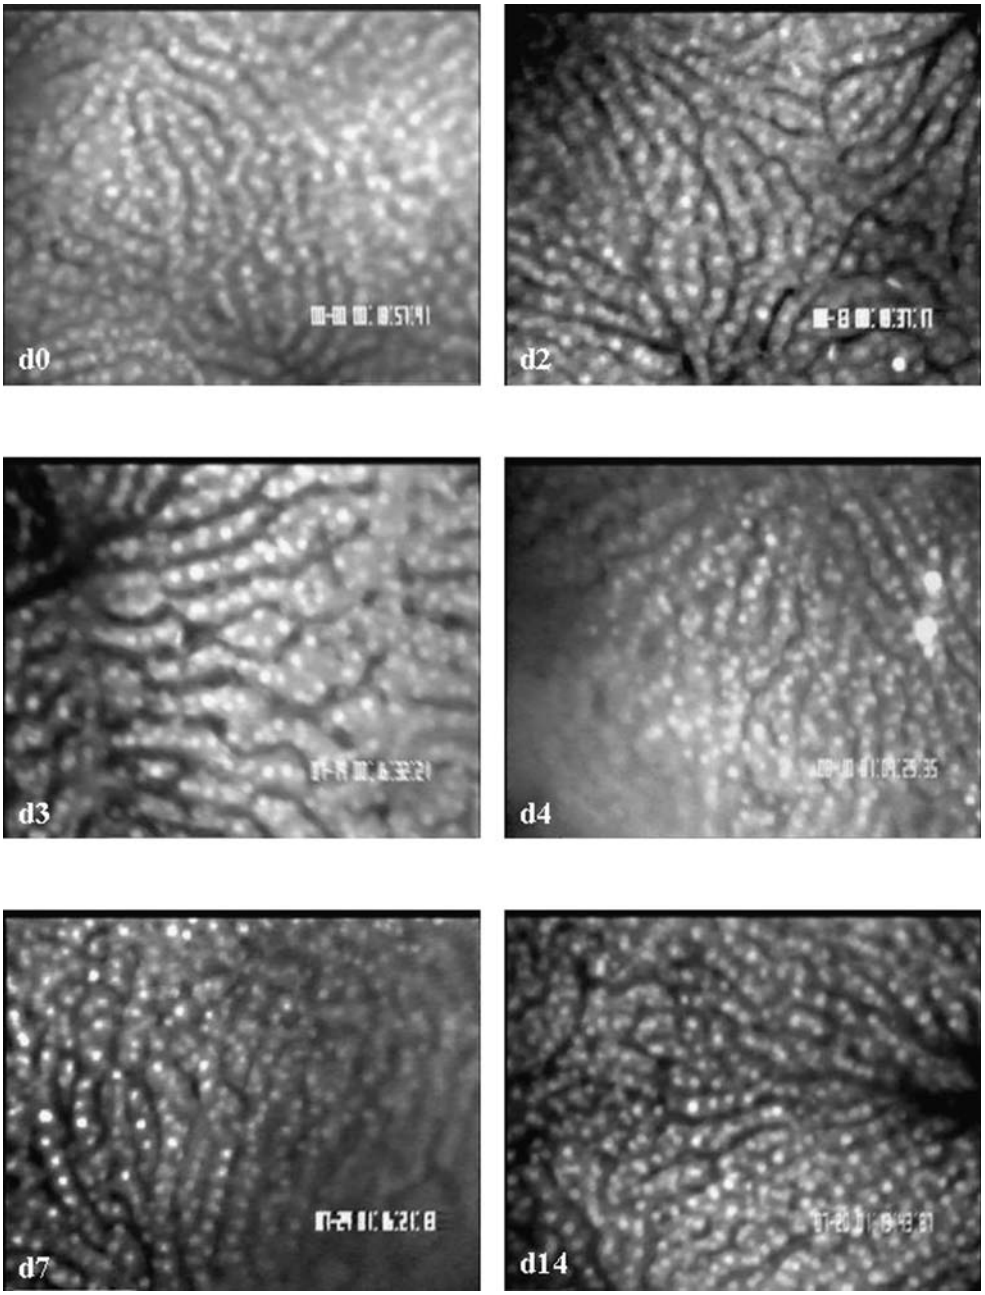

Fig. 6 Intravital microscopical image of hepatocyte at days 0, 2, 3, 4, 7, and 14. The number of hepatocytes decreased to a minimum on day 3. The number of hepatocytes continuously increased from day 4 reaching their original number on day 7 (*white spots*, hepatocytes). *d* Day after induction of liver regeneration by partial hepatectomy

contact to hepatocytes. HSC activation was followed by an increased expression of VEGF and its receptor and sinusoid density. After 7 days, angiogenesis was not completed as shown by solitary hepatocyte clusters, increased VEGF and VEGFR expression, and activated HSCs. After 14 days, liver architecture and ultrastructure was restored and HSCs were deactivated showing decreased α-SMA expression as well as increased apoptosis and no more direct cell contact to hepatocytes (Fig. 8).

Intravital microscopy represents an innovative tool for simultaneous and serial analysis of morphological features in the regenerating liver, particularly for the investigation of HSCs characteristics [9]. In healthy livers, HSCs represent around 5–8% of all liver cells. With the help of the intravital microscopy, HSCs can be specifically visualized because of their unique capability to store vitamin A, which possesses the characteristic of autofluorescence [2, 5, 18]. Precisely, only nonactivated HSCs are able to store vitamin A. Zhang et al. [18] and Bauer et al. [2] demonstrated in their studies that the number of visible vitamin A particles corresponds to the number of existing HSCs. By means of the intravital microscopy, it is therefore possible to investigate the chronological course of HSC-storing vitamin A during liver regeneration after partial hepatectomy in correlation to the angiogenesis represented by the sinusoid density. Activated HSCs could furthermore be immunohistologically identified by detection of α-SMA.

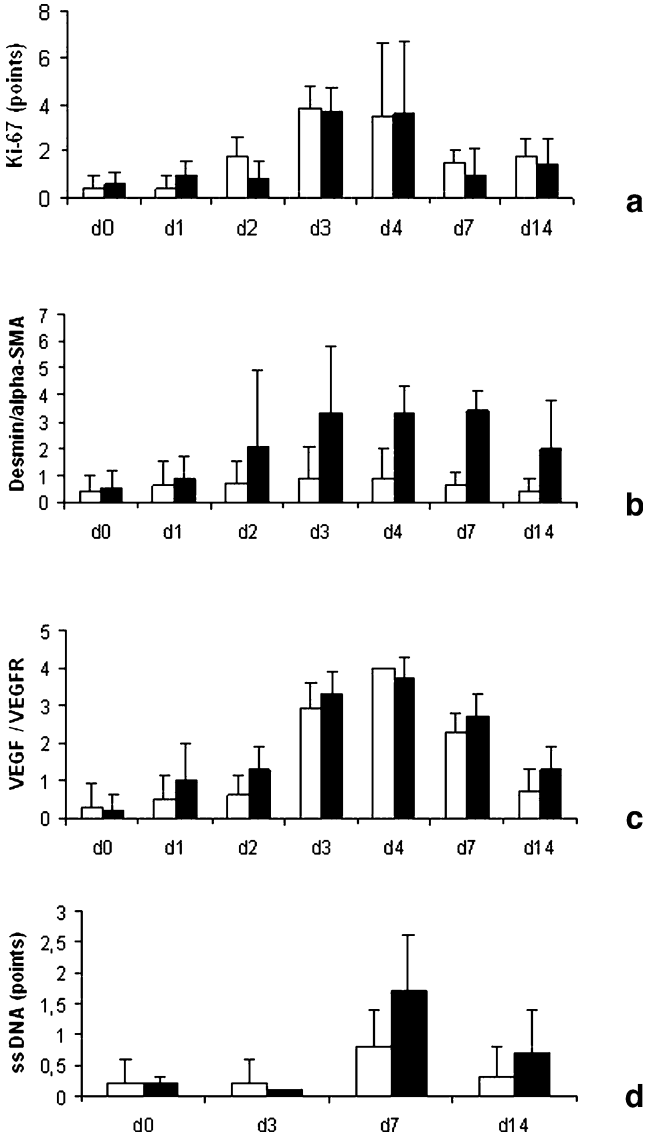

Fig. 7 Immunohistological features of liver regeneration. **a** Proliferation rate by Ki-67 expression of hepatocytes (*white box*) and nonparenchymal cells (*black box*); **b** HSC function by desmin (*white box*) and aSMA (*black box*) expression; **c** VEGF (*white box*) and VEGFR (*black box*) expression as markers for the angiogenesis; **d** ssDNA detection as an apoptosis index for hepatocytes (*white box*) and nonparenchymal cells (*black box*). *d* Day after induction of liver regeneration by partial hepatectomy

In this study we observed a discrepancy between intravital microscopy and immunohistology concerning the number of hepatocytes on the third day which was significantly lower by intravital microscopy while already increased by Ki-67 staining. Although at this time the total number of hepatocytes—as detected by bisbenzamide staining using intravital microscopy—was the lowest during the

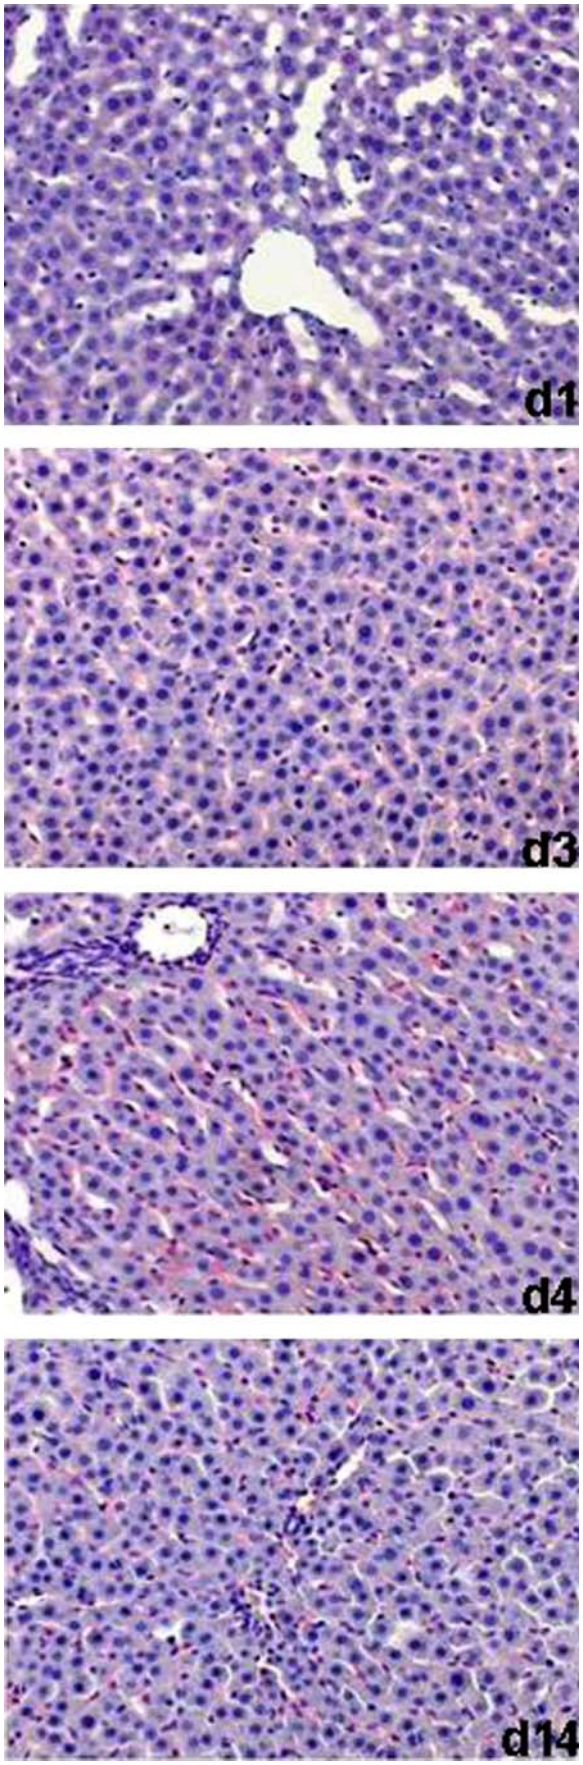

Fig. 8 VEGF expression in the regenerating liver. After liver resection, ▶ animals showed an increasing expression of VEGF between days 3 and 4 that dropped at day 7 reaching almost preoperative levels at day 14. *d* Day after induction of liver regeneration by partial hepatectomy

Table 1 Key steps of liver regeneration seen in light, electron, and intravital microscopy

Day	Light microscopy	Electron microscopy	Intravital microscopy
0	Regularly liver histology	Regularly ultrastructure of liver	Normal
1	Swelling and vesicular steatosis	Vesicular steatosis of hepatocytes and damage of the endothelial membrane	Increasing hepatic cord width
2	Mitotic figures in hepatocytes and nonparenchymal cells	No cell–cell contact between hepatocytes and HSCs, some mitotic figures in hepatocytes and nonparenchymal cells	Begin of drop of hepatocytes
3	Clusters of hepatocytes	Increased cell–cell contact between hepatocyte and HSCs	Drop of hepatocytes and HSCs, minimum sinusoid density
4	Hepatocyte clusters surrounded by endothelial cells	Signs of cluster vascularization, increased cell–cell contact between hepatocytes and HSCs	Increasing hepatocyte number and normalization of HSC number
7	Normally arranged liver histology with enlarged lobules	Normal hepatic ultrastructure, no damage of endothelial cells, no increased cell–cell contact between hepatocyte and HSCs	Increasing sinusoid density
14	Regularly liver histology	Regular ultrastructure of liver	Normal

whole course of liver regeneration, the proportion of hepatocytes which have already entered the G1-phase—as detected by Ki-67 staining—has been already increased. Additionally, we observed a compensatory swelling of hepatocytes between the first and third day after induction of liver regeneration as represented by the increased hepatic cord width which might also explain the decreased number of hepatocytes at the third day.

There is a growing body of evidence that HSCs represents the key cells in the regenerating liver [1, 4, 5, 12]. HSCs have several important functions like retinoid storage and homeostasis, regulating the width of the sinusoid lumen by contraction and dilatation in response to endothelin, angiotensin, thromboxane, and prostaglandins, remodeling of extracellular matrix by production of collagens, matrix metalloproteinases (MMPs), growth factors, and cytokines [8, 15]. During liver regeneration nonparenchymal cells like HSCs and SECs enter the DNA synthesis 24 h later than hepatocytes and proliferate and migrate into the hepatocyte clusters at the fourth day before the normal sinusoidal architecture has been restored [4, 17]. In this study, the ratio between HSCs and hepatocytes was about 0.78 corresponding to other studies [9]. Regeneration led to a shift of the ratio in favor of HSCs on the third day with a ratio of 1, loss of vitamin A particles, and increase in α-SMA, normalizing in the later course [5, 9]. Parallel to the increase in HSC/hepatocyte ratio, angiogenesis started which was accompanied by an increased VEGF expression in hepatocytes showing the interdependence between the activation of HSCs and VEGF expression. Furthermore, activated HSCs modulated the extracellular matrix. Most activated HSCs have been found near the hepatic clusters and possibly contributed to synthesis and deposition of ECM into the avascular islands to aid infiltration of sinusoid endothelial cells [10].

The initiation for HSC activation is still unclear [6, 8, 15]. In this study we showed by electron microscopy that a cell-to-cell contact between hepatocytes and HSCs represents the precondition for HSC activation. A direct cell-to-cell contact between hepatocytes and HSCs has been found on day 3 and 4, whereas under normal conditions, HSCs have a close contact with SEC through incomplete basement membrane components but only a loose contact to hepatoctyes by interstitial collagen fibers and nerve fibers run through the space of Disse. The above-named temporal interdependence between HSC activation and VEGF expression demonstrated in this study could be explained by the release of several growth, matrix, and chemotactic factors, e.g., TGF-β1 and PDGF, which are known to have potent fibrogenic and proliferative properties as well as increase VEGF expression [3, 7]. Relating to the direct cell-to-cell contact, several studies provided evidence that HSCs require the basement membrane components for their normal, nonactivated function, and remodeling of the ECM by MMPs, like MPP-1, MPP-2, MPP-3, MPP-9, MPP-11 and TIMP-1 and TIMP-2 which can also be released by hepatocytes [10]. This could also explain the release of MMPs and TIMPs in the first hours after liver resection, when HSCs are not yet activated. Furthermore, it has not yet been resolved how activation of HSCs will end, e.g., by apoptosis or simple conversion in a

deactivated state [6]. In this study we showed by intravital microscopy that the number of nonactivated HSCs—identified by their autofluorescence—has already normalized at day 4 which was accompanied by an increased apoptosis rate and α-SMA expression. Additionally, electron microscopy revealed that from day 7 on the HSCs reobtain a loose contact to hepatocytes suggesting that several pathways for HSC deactivation may exist.

In summary, the synthesis of intravital, light, and electron microscopic analysis of the regenerating rat liver demonstrated the central role of HSCs in governing angiogenesis and ECM remodeling. Due to the recent identification of several receptors at the surface of activated HSCs, e.g., endothelin-A-receptor, angiotensin-1-receptor, and PDGF receptor, new treatment approaches for modulating HSC function in the regenerating liver are available that warrant more extensive preclinical studies [6].

Association of progressive structural changes in the bronchial epithelium with subepithelial fibrous remodeling: A potential role for hypoxia

Received: 20 April 2007 / Accepted: 3 July 2007 / Published online: 3 August 2007

Abstract In airway remodeling that occurs in association with chronic obstructive pulmonary disease (COPD), the relationship between the subepithelium and structural changes of the bronchial epithelium is not well defined. To investigate whether the subepithelium and epithelium undergo remodeling as an integrated unit, we performed morphological examination of 55 bronchial biopsy specimens obtained from explanted or resected lungs from tobacco smokers with COPD. Our results indicate that reticular basement membrane (RBM) thickness is increased and the subepithelial microvascular bed is reduced in association with progression from the normal epithelium to squamous metaplasia. Subsequent bronchial epithelial transformation to dysplasia is characterized by differential subepithelial remodeling with normalization of RBM thickness and subepithelial blood vessel density. Because fibrous remodeling of the subepithelium could limit delivery of nutrients and oxygen to the epithelium, we assessed expression of hypoxia-inducible factor-1α (HIF-1α) and carbonic anhydrase IX (CA IX) as markers of cellular hypoxia. The number of HIF-1α-positive epithelial cells increased with progression of epithelial structural changes, RBM thickness, and reduction in blood vessels in the subepithelium. These findings suggest that the HIF-1α pathway is activated in response to subepithelial remodeling and contributes to progressive premalignant epithelial lesions in the airways of tobacco smokers with chronic airway inflammation.

Introduction

Airway remodeling comprises a spectrum of structural changes in conducting airways such as smooth muscle hypertrophy and hyperplasia, thickening and fibrosis of

subepithelial reticular basement membrane (RBM), enlargement of submucosal bronchial glands, and structural alterations of the bronchial epithelium [21, 39]. Together, these processes cause significant thickening of airway walls (especially respiratory bronchioles) with narrowing and/or distortion of the airway lumen [19]. While subepithelial and epithelial structural changes have been identified in airways of patients with chronic obstructive pulmonary disease (COPD), it is not clear whether these changes occur in concert as an integrated unit or represent separate, localized responses to injurious stimuli or ongoing inflammation. Understanding the relationship between progressive structural changes of the airway epithelium and subepithelial remodeling in tobacco smokers could shed light on factors that regulate progression of airway inflammation and remodeling and predispose to premalignant transformation of the bronchial epithelium.

According to the World Health Organization grading, neoplasia of the bronchial epithelium develops sequentially from the normal epithelium to basal cell hyperplasia, squamous metaplasia, and dysplasia to carcinoma in situ and microinvasive squamous cell cancer [4, 13]. The development of the squamous phenotype and accumulation of mutations in key cell regulatory genes are two major factors contributing to airway epithelial malignant transformation [5, 36]. Squamous metaplasia and dysplasia are considered as preneoplastic lesions, and their development increases the risk of epithelial malignancy [4, 13], and both are found in airways of patients with COPD [37, 38]. Therefore, factors that control epithelial structural changes could directly impact progression toward malignant transformation. In this study, we hypothesized that in airways of patients with COPD, the epithelium and subepithelium form an integrated unit that undergoes remodeling in a coordinated fashion in response to chronic exposure to tobacco smoke. Further, subepithelial fibrous remodeling contributes to progressive epithelial changes by altering the local microenvironment. To evaluate this hypothesis, we undertook histological, morphometric, and immunohistochemical (IHC) investigations of bronchial biopsy specimens from 55 current or former tobacco smokers with COPD and chronic bronchitis. Our initial findings indicated that subepithelial fibrous remodeling and capillary loss correlated with progressive structural changes in the overlying epithelium. These findings suggested that remodeling of inflamed subepithelium could reduce delivery of oxygen and nutrients to the bronchial epithelium, contributing to progressive epithelial structural changes. Prior studies have found that cellular hypoxia can increase genetic instability and lead to overexpression of key growth factors and their receptors [3, 7]; therefore, identification of hypoxic responses in the bronchial epithelium could help clarify mechanisms linking airway remodeling in COPD with epithelial structural changes and development of lung cancer. For assessment of hypoxic signaling in bronchial specimens, we identified the ubiquitously expressed oxygen-sensitive transcriptional regulator, hypoxia-inducible factor-1α (HIF-1α) [2, 9, 43]. HIF-1α is unstable in normal oxygen tension but becomes stabilized under hypoxic conditions and translocates to the nucleus to function as a transcriptional regulator. HIF-1α is responsible for the regulation of a broad array of hypoxia-responsive genes, whose products are involved in promotion of angiogenesis [10, 32] and regulation of energy metabolism [14, 24]. We also evaluated another widely used marker of cellular hypoxia, carbonic anhydrase IX (CA IX), a transmembrane protein that catalyzes the reversible hydration of carbon dioxide to carbonic acid, thus regulating pH in hypoxic cells [45, 47]. Using IHC techniques, we found upregulation of these markers in the altered bronchial epithelium, suggesting a mechanistic link between microenvironmental changes in the subepithelium and progressive structural abnormalities in the bronchial epithelium.

Materials and methods

Clinical material Surgical bronchial biopsy specimens from segmental or subsegmental bronchi from 55 current or former smokers with COPD were selected retrospectively from the pathology tissue banks of Vanderbilt University Medical Center (Nashville, TN, USA) and Novosibirsk City Thoracic-Surgical Hospital (Novosibirsk, Russia). In 18 cases, bronchial biopsy specimens were received from explanted lungs of patients with COPD undergoing lung transplantation. In 37 cases, bronchial biopsy specimens were obtained from patients who underwent lobectomy or pneumonectomy for lung cancer (15 squamous cell carcinoma, five adenocarcinoma), chronic lung abscess (ten), or

bronchiectasis (seven). In cases of lung cancer, tissue specimens were obtained as remote from the tumor as possible. All subjects had smoked greater than 10 years and had a clinical diagnosis of COPD or symptoms of chronic bronchitis. Table 1 summarizes demographic and clinical characteristics of these patients. This study was approved by the institutional review board of Vanderbilt University School of Medicine and the ethical committee of Novosibirsk City Thoracic-Surgical Hospital.

Light microscopic examination Tissue specimens were fixed in 10% solution of neutral-buffered formalin for 24 h and after dehydration were embedded in paraffin. For primary light microscopy, tissue sections (4–5 μm thickness) were stained with hematoxylin and eosin (H&E) and the periodic acid-Schiff (PAS) reaction for detection of mucin.

Morphometry Thickness of the RBM, epithelial height (L_{ep}), blood vessel density (total number of blood vessels per 1 mm^2, N_{cap}), and blood vessel volume density (VV_{cap}) of the lamina propria, the space between RBM and smooth muscle layer, were estimated. VV_{cap} was defined as the percentage of the lamina propria area occupied by blood vessels. RBM thickness and L_{ep} were quantified by measuring 100 sites (spaced 20 μm apart) on ten subse-

quent tissue fields along the length of the epithelium in each tissue section with measurements in a line perpendicular to the epithelial layer. For each field, the bronchial epithelial structure was determined (normal structure, altered pseudostratified, stratified, squamous metaplasia, dysplasia), and mean RBM thickness associated with each structural variant was recorded. N_{cap} and VV_{cap} were measured on ten nonoverlapping tissue fields of lamina propria for each tissue specimen. As above, bronchial epithelial structure was determined for each field, and N_{cap} and VV_{cap} associated with each structural variant of the overlying epithelium was recorded. All measurements were made by calibrated image analysis using Image-Pro Express software (Media Cybernetics, Silver Springs, MD). Thickening of RBM and L_{ep} were measured in H&E-stained tissue sections in 400× magnification, whereas N_{cap} and VV_{cap} were measured in PAS-stained tissue sections at 200× magnification, which gave better contrast to endothelial cells.

Electron microscopic analysis Electron microscopy (EM) was performed according to a previously described protocol [38]. A small component of each of 24 biopsy specimens selected for EM was fixed in 4% paraformaldehyde in phosphate-buffered saline (PBS), then in a 1% solution of OsO_4 in PBS, and, after dehydration, embedded in a mixture of Epon and Araldite (Electron Microscopy Sciences, Fort Washington, PA). Semithin sections were stained with Toluidine blue and analyzed by light microscopy. Ultrathin sections were stained with uranyl acetate and lead citrate.

Immunohistochemical analysis Of the 55 biopsies, tissue was available for additional unstained sections on 38. IHC studies were performed on these 38 tissue specimens using techniques as previously described [28, 29]. IHC was performed on two serial tissue sections for detection of active HIF-1α or CA IX using polyclonal antibodies (Santa Cruz Biotechnology, Santa Cruz, CA) followed by a standard immunoperoxidase/avidin–biotin complex protocol (Vectastain ABC kit, Vector Laboratories, Burlingame, CA). Immunostained tissue sections were analyzed in a blind fashion. The percentage of HIF-1α-positive cells was calculated on ten sequential, nonoverlapping tissue fields using 400× magnification, which represented the score for the specimen.

Statistical analysis Statistical analysis was performed with GraphPad Instat (GraphPad Software, San Diego, CA) using a Kruskal–Wallis test (nonparametric analysis of variance) with a Dunn's multiple comparisons test for individual variables ($p<0.05$ considered significant). Correlations were calculated using Spearman's rank test.

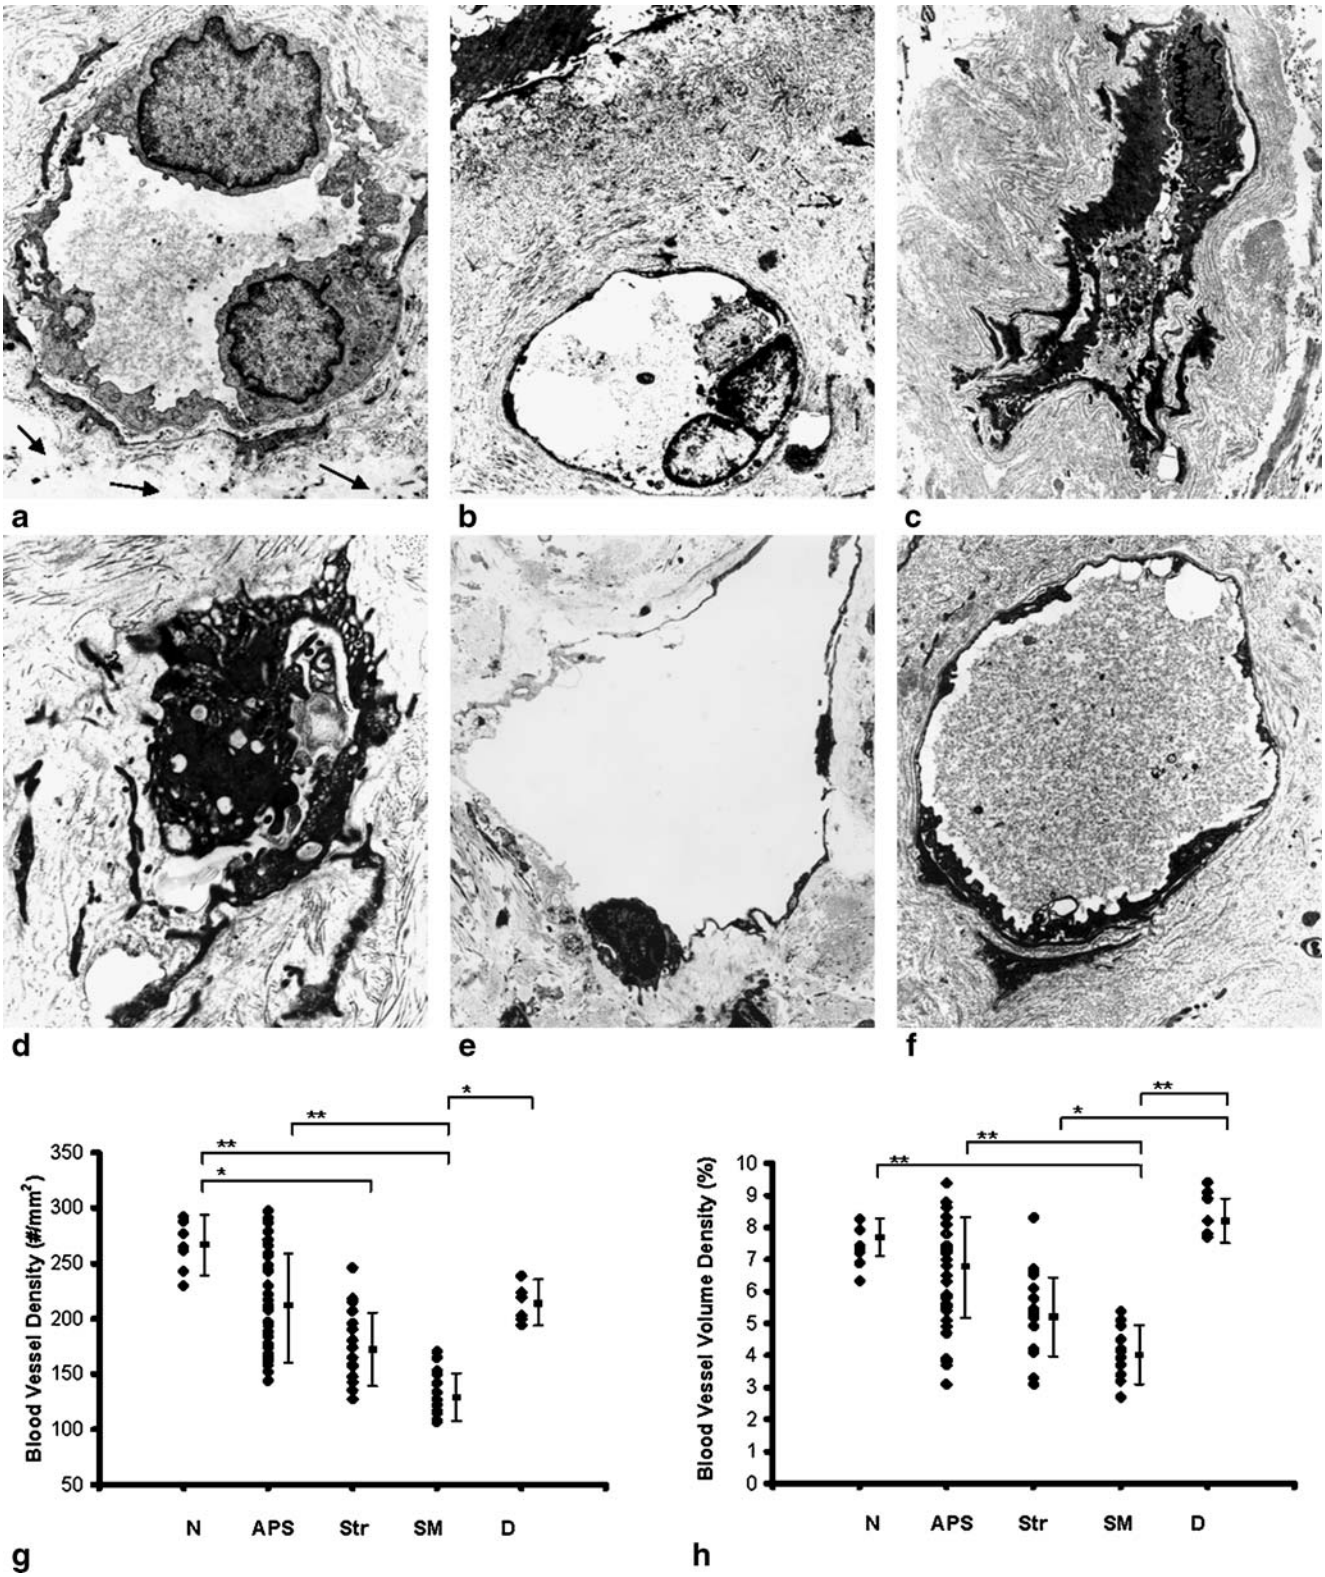
Results

Comparison of bronchial epithelial structural alterations with parameters of subepithelial remodeling

To characterize structural changes of the bronchial epithelium, we used a previously described classification that includes the bronchial epithelium with normal-appearing structure and four basic pathological states: altered pseudostratified epithelium (or hyperplasia of basal and/or goblet epithelial cells), stratified epithelium (or immature squamous metaplasia), squamous metaplasia, and dysplasia [4, 23, 38].

The distribution of pathological variants of epithelial remodeling was mosaic, and more than one pattern of epithelial structural change was frequently observed in the same bronchial cross-section (Fig. 1a–c). Epithelial height varied widely, and both hyperplasia of basal cells and enlargement of epithelial cells contributed to increased epithelial height. Of the 55 bronchial biopsy specimens analyzed, areas of normal bronchial structure were identified in only seven, underscoring the widespread nature of epithelial structural alterations in this patient population. Other epithelial states were characterized by variable manifestations of basal and/or goblet cell hyperplasia, incomplete differentiation, or epidermoid metaplasia/dysplasia. An altered pseudostratified epithelium was identified in 39 specimens. Areas of stratified epithelium were identified in 18 specimens. In those areas, hyperplasia of basal epithelial cells was characterized by focal formation of at least four epithelial cell layers, consisting of proliferating basal epithelial cells and uniform surface cells without clear differentiation into ciliated or goblet cells. Surface cells of the stratified epithelium lose contact with basement membrane but do not undergo flattening as in squamous metaplasia [38]. Areas of squamous metaplasia or dysplasia were found in 14 and 6 biopsies,



respectively. Of the six biopsies with dysplasia, four cases were mild, and two were moderate in severity.

In the lamina propria, prominent fibrosis of the bronchial wall was present. RBM alterations included collagen deposition and increased thickness. RBM thickness was variable and could be significantly different within the same tissue specimen (Fig. 1a–c). In areas without significant subepithelial remodeling, the RBM had a structural organi-

zation consisting of finely organized collagen fibers, with RBM thickness usually less than 5–7 μm (Fig. 1d). In contrast, areas with prominent subepithelial fibrosis showed abundant collagen deposition within the RBM and increased RBM thickness, usually more than 10–12 μm. Collagen fibers were packed in rough bundles with longitudinal orientation (Fig. 1e). Intermediate variants were characterized by accumulation of fibroblasts and freshly synthesized bundles of collagen fibers in the RBM.

To characterize the association between structural alterations of the bronchial epithelium and subepithelial fibrosis, we performed morphometric analysis of RBM thickness and correlated this parameter with the state of the overlying epithelium. As shown in Fig. 1f, RBM thickness increased with severity of epithelial structural lesions from normal structure to basal cell hyperplasia, stratification, and squamous metaplasia. However, RBM thickness returned towards normal in areas of dysplasia, suggesting that additional matrix remodeling accompanies progression from squamous metaplasia to dysplasia. This normalized RBM thickness was observed only in areas with epithelial dysplasia, whereas areas with less prominent epithelial changes in the same bronchial biopsy specimens always had increased thickness of RBM.

Microvascular disorders were observed in most specimens and included structural alterations of blood vessels and fibrous remodeling of perivascular connective tissue. In normal-appearing blood capillaries, no inflammatory cells or proteinaceous aggregates were observed, and collagen accumulation was not observed in the pericapillary connective tissue (Fig. 2a). However, most capillaries showed significant ultrastructural alterations with damage to endothelial cells. Such capillaries, especially those localized subjacent to the epithelium, showed evidence of structural damage, including damage to endothelial cells with clarification of nuclear matrix (Fig. 2b). Capillaries localized deeper in the subepithelium were characterized by variable structural alterations ranging from insignificant changes to total destruction. The lumen of most capillaries was packed with fragments of destroyed cells, clarified red cells, or proteinaceous aggregates. In areas of prominent subepithelial fibrosis, rough bundles of collagen fibers with circular orientation were found around most capillaries and postcapillary venules (Fig. 2c). Some capillaries appeared to be destroyed and unlikely to participate in the microcirculation (Fig. 2d). The overwhelming majority of lymphatic capillaries were distended, forming thin-walled cavities (Fig. 2e), whereas some showed signs of lymphostasis (Fig. 2f), a finding that increased in parallel with fibrous remodeling.

The described ultrastructural manifestations of blood vessel damage increased with fibrous remodeling of the subepithelium, and we investigated whether these manifestations correlated with the severity of bronchial epithelium alterations. Morphometric analysis of N_{cap} and VV_{cap} in subepithelial connective tissue showed that these parameters inversely correlated with progressive structural alterations of the bronchial epithelium from normal to squamous metaplasia (Fig. 2g,h). These findings indicate that in addition to subepithelial fibrosis and RBM thickness, microcirculatory changes in the subepithelium correspond to epithelial structural alterations. As with RBM thickness, N_{cap} and VV_{cap} normalized in areas of dysplasia, suggesting that a differential remodeling process is activated in the progression from squamous metaplasia to dysplasia. However, most of the blood vessels localized beneath foci of epithelial dysplasia were structurally abnormal. The endothelial cells lining these blood vessels usually had significant structural damage, and the basement membrane was interrupted or totally absent.

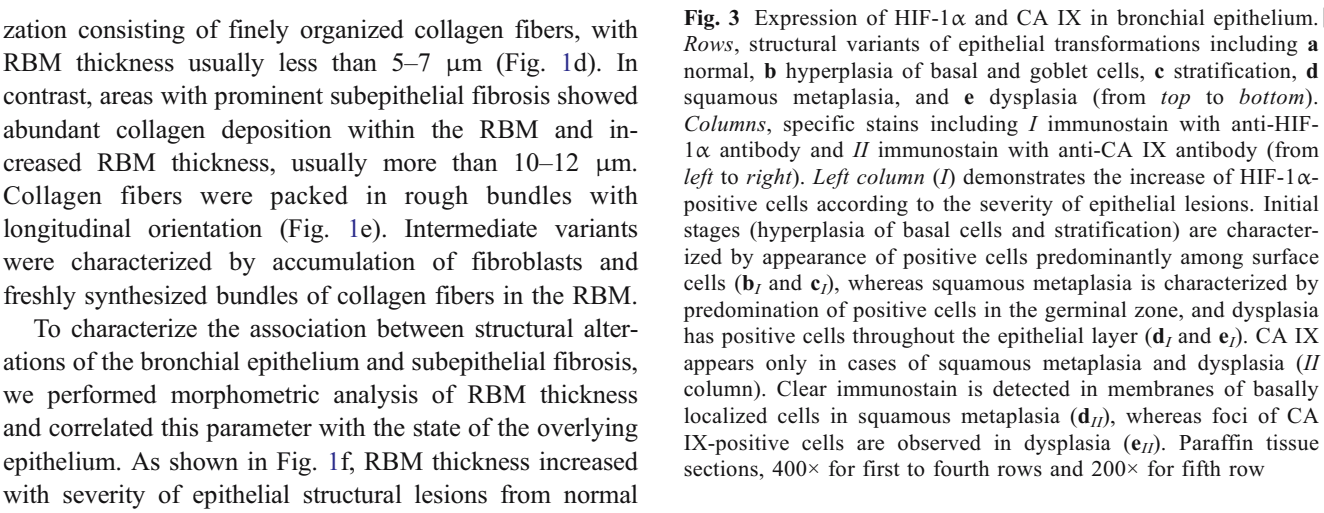


Fig. 3 Expression of HIF-1α and CA IX in bronchial epithelium. *Rows*, structural variants of epithelial transformations including **a** normal, **b** hyperplasia of basal and goblet cells, **c** stratification, **d** squamous metaplasia, and **e** dysplasia (from *top* to *bottom*). *Columns*, specific stains including *I* immunostain with anti-HIF-1α antibody and *II* immunostain with anti-CA IX antibody (from *left* to *right*). *Left column* (*I*) demonstrates the increase of HIF-1α-positive cells according to the severity of epithelial lesions. Initial stages (hyperplasia of basal cells and stratification) are characterized by appearance of positive cells predominantly among surface cells ($\mathbf{b}_I$ and $\mathbf{c}_I$), whereas squamous metaplasia is characterized by predomination of positive cells in the germinal zone, and dysplasia has positive cells throughout the epithelial layer ($\mathbf{d}_I$ and $\mathbf{e}_I$). CA IX appears only in cases of squamous metaplasia and dysplasia (*II* column). Clear immunostain is detected in membranes of basally localized cells in squamous metaplasia ($\mathbf{d}_{II}$), whereas foci of CA IX-positive cells are observed in dysplasia ($\mathbf{e}_{II}$). Paraffin tissue sections, 400× for first to fourth rows and 200× for fifth row

Identification of markers of cellular hypoxia in structurally altered bronchial epithelium

In this part of the study, we hypothesized that loss of functional subepithelial capillaries with fibrosis and increasing RBM thickness could lead to reduced delivery of oxygen and nutrients to the epithelium, contributing to progressive epithelial structural changes. We performed IHC on bronchial biopsy specimens to identify induction of HIF-1α. In these studies, HIF-1α was not expressed in pseudostratified epithelium with normal structure (Fig. $3a_I$). All pathological states of the bronchial epithelium were accompanied by increased HIF-1α expression in both cytoplasm and nuclei of epithelial cells with specific patterns of localization. In the altered pseudostratified epithelium and stratified epithelium, HIF-1α expression was mostly observed in intermediate and surface cells (Fig. $3b_I$,c_I). In contrast, the epithelium with squamous metaplasia was characterized by a predominance of HIF-1α-positive cells in the germinal zone

of the epithelial layer (Fig. 3d_I). When IHC was performed for CA IX, this marker was detected in bronchial epithelial cells in areas of squamous metaplasia and dysplasia (Fig. 3, column II). In squamous metaplasia, CA IX was expressed in membranes of most basal epithelial cells (Fig. 3d_{II}). In both mild and moderate dysplasia, HIF-1α-positive cells were observed throughout the epithelial layer (Fig. 3e_I), and CA IX was detected not only in cell membranes but also in nuclei and cytoplasm (Fig. 3e_{II}). Foci of extensive immunostained cells were also seen.

Quantification of HIF-1α immunostaining showed that the percentage of HIF-1α nuclear-positive cells increased with severity of epithelial alterations (Fig. 4). As seen in Figs. 1f and 2g,h, RBM thickness, blood vessel density, and blood vessel volume density were altered along the spectrum from normal to squamous metaplasia. Analyzing these epithelial states, correlations between HIF-1α expression and morphometric parameters reflecting subepithelial fibrous remodeling showed that the percentage of HIF-1α-positive epithelial cells significantly increased with thickness of the RBM (Fig. 5a), with reduction in blood vessel number (Fig. 5b) and with increased epithelial height (Fig. 5c).

Discussion

Our data indicate that chronic airway inflammation in tobacco smokers with chronic bronchitis and/or COPD is accompanied by structural changes of bronchial epithelium and subepithelial stroma. Specifically, we detected fibrosis and thickening of the RBM and disorders of the subepithelial microvasculature, including reduction in blood vessel density, severe perivascular fibrosis, and structural damage to endothelial cells. Microvascular disorders were identified in both blood and lymphatic microcirculatory systems. Quantitative parameters of subepithelial remodeling, including RBM thickness and blood vessel density, correlate with severity of bronchial epithelial structural lesions. These findings suggest that the epithelium and subepithelium are remodeled as an integrated functional unit. Fibrous remodeling of the subepithelium may alter the physiological balance between the epithelium and underlying stroma

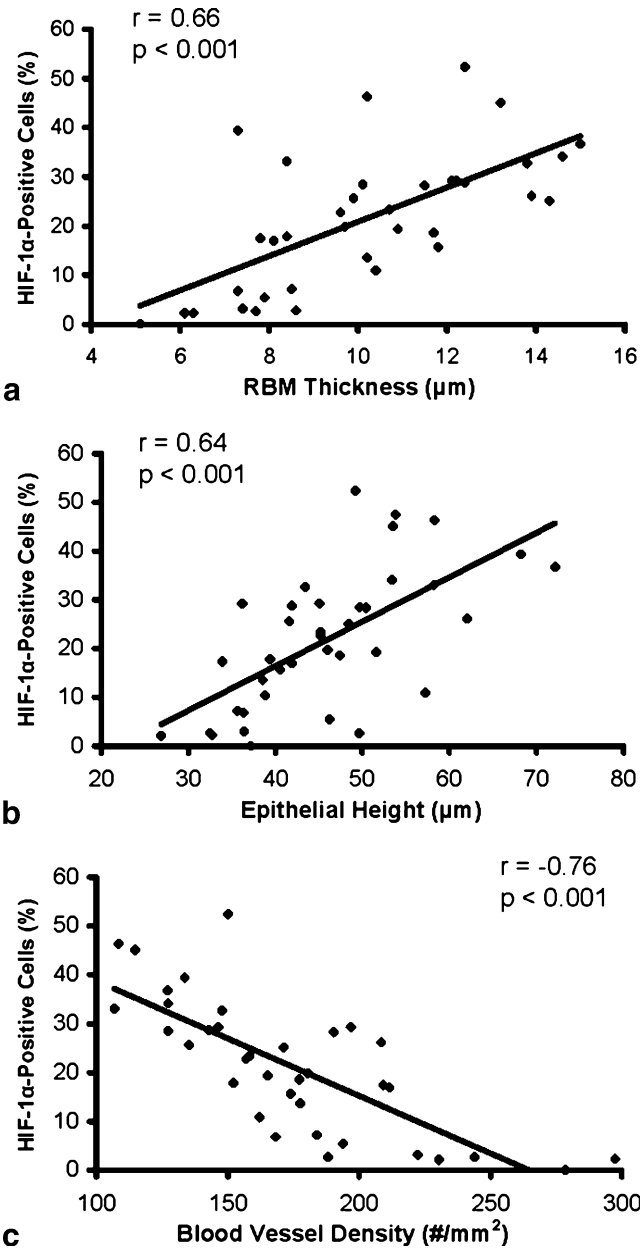

Fig. 5 Correlation of HIF-1α-positive cells with structural changes in airway epithelium and parameters of subepithelial remodeling. **a** Graph showing association between number of HIF-1α-positive cells and RBM thickness. **b** Graph showing association between number of HIF-1α-positive cells and blood vessel density in the lamina propria. **c** Graph showing association between number of HIF-1α-positive cells and epithelial height

and create favorable conditions for development of squamous metaplasia/dysplasia, which are considered as early premalignant lesions. Detection of increased expression of HIF-1α and CA IX in the bronchial epithelium indicates that hypoxic signaling is induced in association with epithelial and subepithelial structural changes.

Prior studies have shown a significant association between tissue hypoxia measured by oxygen microelectrodes and expression of HIF-1α and CA IX [16, 48]; therefore, IHC detection of HIF-1α with nuclear localization and CA IX within cellular membranes in airway epithelial cells indicates the presence of hypoxia. The principal mechanism of HIF-1α regulation is its post-translational modification and subsequent degradation under normoxia or stabilization under hypoxia [2, 9, 43]. Both HIF subunits, HIF-α and HIF-β, are constitutively transcribed and translated; however, the α subunit has a very short lifespan under normoxic conditions and is usually undetectable. Under hypoxic conditions, HIF-1α rapidly stabilizes then translocates to the nucleus and acts as a transcriptional factor [2, 9, 43]. While hypoxia is a major stimulus governing the regulation of HIF activity, several other factors can also stimulate low-level HIF activity including growth factors (such as epidermal growth factor and platelet-derived growth factor) and cytokines (such as tumor necrosis factor-α and interleukin-1β) that can increase HIF-1α expression [15, 50]. However, the amplitude of HIF induction is much lower than hypoxic activation, and only hypoxia leads to HIF-1α stabilization [1]. CA IX is a transmembrane protein, and its expression is closely associated with hypoxia development [45, 47]. Thus, both HIF-1α and CA IX may be considered as endogenous markers of cellular hypoxia.

Although somewhat surprising, given the proximity of airway epithelium to the relatively high oxygen tension of the airway, our results suggest that subepithelial fibrotic remodeling and increased epithelial thickness result in induction of HIF-1α signaling in the airway epithelium. Airway fibrous remodeling with RBM thickening and reduction in effective microvasculature could impair oxygen delivery via the bronchial circulation. In addition, increased epithelial height in areas of structural change could increase diffusion length from the airway lumen. A combination of these factors could lead to insufficient oxygen supply to portions of the bronchial epithelium. Therefore, despite contact between the luminal surface of the bronchial epithelium and inhaled air, our findings suggest that hypoxia of bronchial epithelial cells occurs in areas of airway remodeling.

We observed HIF-1α expression more often than CA IX, which was expressed only in germinal zones of the epithelium with squamous metaplasia or dysplasia. These differences in expression of HIF-1α and CA IX may be associated with the degree of cellular hypoxia that is necessary for HIF-1α stabilization and CA IX expression. The degree of hypoxia required to induce HIF-1α is lower than that required to induce expression of CA IX [25, 45]. Thus, colocalization of both HIF-1α and CA IX in germinal zones of the epithelium with squamous metaplasia or dysplasia may represent bronchial epithelium foci with the greatest degree and/or duration of hypoxia.

Hypoxia has been proposed to be a key microenvironmental factor involved in the development of genetic instability, enhanced mutagenesis, and functional impairment of deoxyribonucleic acid repair pathways [3]. The consequences of hypoxia-induced or hypoxia-repressed gene expression have important implications in disease progression, especially in chronic inflammation and tumor development. While HIF-1α plays a major role in controlling the transcriptional response to hypoxia [2, 9, 43], a number of other transcriptional factors may also be activated either directly or indirectly. Some of the most important pathways involve activation of nuclear factor kappa-B, the cyclic adenosine monophosphate response element-binding protein, and activating protein-1 [7], resulting in the mediation of the global cellular response to hypoxia. Thus, epithelial cellular hypoxia may be an important factor in driving progressive bronchial structural changes and ultimately the development of premalignant and malignant transformations of the bronchial epithelium.

It has been shown that overexpression of the epidermal growth factor receptor and its ligands can develop because of hypoxia-dependent activation of HIF-1α [44, 46], and in turn, this overexpression may lead to epithelial hyperplasia and squamous metaplasia [8]. Thus, the development of epithelial cellular hypoxia might initiate this pathway leading to epidermoid metaplasia. Our data show that squamous metaplasia is associated with maximal fibrous remodeling of underlying subepithelium, reduction in subepithelial microvasculature, and substantial HIF-1α activation. At the same time, established cellular hypoxia in basal layers of epithelial cells in squamous metaplasia may initiate other hypoxia-dependent signaling pathways that can be critical for secondary remodeling in the subepithelium. As noted in this study, RBM thickness decreases and subepithelial vascularity increases within areas of dysplasia, while cellular hypoxia remains prevalent based on HIF-1α and CA IX immunostaining. We speculate that this increased subepithelial vascularity in dysplasia is associated with initiation of angiogenesis via the vascular endothelial growth factor (VEGF) pathway [10, 27, 32] while the reduction in RBM thickness is due to extracellular matrix degradation via matrix metalloproteinase pathways [12, 35]. However, because of severe abnormalities of these newly formed blood vessels and damage to their lining endothelial cells, this secondary stromal remodeling does not restore normal microcirculation.

Our working hypothesis for progressive bronchial epithelial transformation is that epithelial injury initiates airway inflammation and results in fibroblast and myofibroblast activation, leading to fibrous remodeling of the subepithelium [26, 41]. Progressively increased remodeling of the subepithelial connective tissue in turn affects the bronchial epithelium microenvironment and creates conditions for progression to squamous metaplasia. The structurally altered epithelium is unable to sustain the normal functions of the pseudostratified epithelium such as mucociliary clearance, mucosal immune host defense, and modulation of bronchial smooth muscle tone. As a result, airways with altered epithelial structure lose important functional abilities, contributing to subsequent progression of airway inflammation [26, 38]. The formation of this pathological cycle results in progression of airway inflammation and remodeling. The development of epithelial cellular hypoxia and activation of hypoxia-dependent signaling pathways within this pathological cycle may play central roles in carcinogenesis, predisposing to the development of a squamous phenotype of bronchial epithelium and enhancing genetic instability.

The association between inflammation and cancer has been illustrated in many epidemiologic and clinical studies [6, 30, 36, 42]. The specific cellular and molecular pathways that link inflammation to lung cancer are associated with recruitment and activation of inflammatory cells and the subsequent respiratory burst that releases free radicals. Free radicals peroxidate lipids and induce genetic mutations, thus contributing to malignant transformation [6, 18, 22, 30]. The accumulation of mutations in key cell regulatory genes eventually leads to malignant transformation, whereas active proliferation of injured epithelial cells contributes to selection of genetic mutations specific for preneoplastic and neoplastic transformations of the bronchial epithelium [11, 17, 20, 31, 34]. An inflammatory microenvironment enriched with multiple cytokines and growth factors creates good conditions for tumor growth and progression [40, 49]. This pathway is generally assumed as a working hypothesis, whereas our study reveals an alternative pathobiological mechanism that also may contribute to epithelial neoplasia because of changes in the epithelial cell microenvironment and formation of local foci of epithelial cellular hypoxia.

In this study, we demonstrate a close relationship between subepithelial remodeling and structural changes in the bronchial epithelium. We also suggest that the activation of HIF-1α signaling may be an important part of the bidirectional epithelial and mesenchymal interactions that drive airway remodeling. Our findings create a basis for future studies to better define interactions between the airway epithelium and underlying stroma that impact ongoing remodeling. Combined with the results of prior studies showing that VEGF, which is induced by HIF-1α, is increased in bronchial dysplasia [27, 33], our results suggest that hypoxic signaling is a potential therapeutic target to prevent progression of epithelial structural abnormalities, neoangiogenesis, and ultimately the development of squamous cell lung cancer in high-risk individuals with chronic bronchitis and COPD.

Abstract Testicular germ cell tumours (TGCT) exhibit remarkable ability to differentiate into virtually all somatic tissue types. In this study, we investigated changes in mucin-type *O*-glycosylation, which have been associated with somatic cell differentiation and cancer. Expression profile of simple mucin-type *O*-glycans (Tn, sialyl-Tn, T), histo-blood group H and A variants and six polypeptide GalNAc-transferases (T1–4, T6, T11) that control the site and density of *O*-glycosylation were analysed by immunohistochemistry during human testis development and in TGCT. Normal testis showed a restricted pattern; gonocytes expressed abundant sialyl-Tn and sialyl-T, and adult spermatogonia were devoid of any glycans, whereas spermatocytes and spermatids expressed exclusively glycans Tn and T and the GalNAc-T3 isoform. A subset of mature ejaculated spermatozoa expressed an additional glycan sialyl-T. The pattern found in testicular neoplasms recapitulated the developmental order: Pre-invasive carcinoma in situ (CIS) cells and seminoma expressed fetal type sialylated glycans in keeping with their gonocyte-like phenotype. Neither simple mucin-type *O*-glycans nor GalNAc-transferase isoforms were found in undifferentiated nonseminoma, i.e. embryonal carcinoma, whereas teratomas expressed them all to some extent but in a disorganized manner. We concluded that simple mucin-type *O*-glycans and their transferases are developmentally regulated in the human testis, with profound changes associated with neoplasia. The restricted *O*-glycosylation pattern in haploid germ cells suggests a role in their maturation or egg recognition/fertilization warranting further studies in male infertility, whereas the findings in TGCT provide new diagnostic tools and support our hypothesis that testicular cancer is a developmental disease of germ cell differentiation.

Introduction

Testicular germ cell tumours (TGCT) are a good model for studying cell differentiation because of the unusual features, such as embryonic pluripotency and phenotypic heterogeneity. TGCT occur predominantly in young adults and

originate from a common precursor, carcinoma in situ (CIS) cell [38]. CIS cells morphologically resemble primordial germ cells/gonocytes (fetal pre-spermatogonia), and both cell types share expression of a number of genes; therefore, we have proposed that CIS cells are transformed fetal germ cells that have been arrested in their differentiation [23, 32, 33, 39]. More recent studies have demonstrated that CIS cells express several genes that are necessary for maintaining pluripotency in embryonic stem cells, e.g. *POU-5F1* (OCT-3/4) and *NANOG* [1, 18, 20, 28, 34]. After puberty, CIS cells transform into overt tumours, which can be divided into two main histological types, seminoma or nonseminoma. Seminomas retain the CIS cell morphology (germ cell-like), whereas nonseminomas can exhibit a broad spectrum of phenotypes from undifferentiated embryonal carcinoma (EC) to highly differentiated teratomas, which may contain all types of somatic tissues. In contrast to TGCT, somatic cell tumours, e.g. Leydig cell-derived, are very rare in the testis.

Mucin-type *O*-glycans are found in high density on mucins as well as in glycoproteins, and they play numerous important biological roles, including modulation of protein structure and protease resistance, intracellular sorting of glycoproteins, cell–cell adhesion, microbial interactions and cell maturation. The initial step in mucin-type *O*-glycosylation involves the transfer of GalNAc from UDP-GalNAc to selected serine and threonine residues in proteins. A large family of homologous UDP-GalNAc, polypeptide *N*-acetylgalactosaminyltransferase isoforms (GalNAc-transferases), catalyse the transfer, and these isoforms are differentially expressed in cells and have different specificities for acceptor peptide sequences [12, 19]. GalNAc *O*-glycans are normally subsequently further elongated by other glycosyltransferases forming a variety of structures usually terminated by sialic acid or fucose. The simple mucin-type *O*-glycans, designated Tn (GalNAcα1-*O*-Ser/Thr), sialyl-Tn (NeuAcα2-6 GalNAcα1-*O*-Ser/Thr) and T (Galβ1–3GalNAcα1-*O*-Ser/Thr) antigens (Fig. 1), represent the most immature *O*-glycans in the *O*-glycosylation pathway. These are not generally expressed by normal cells but are abundant in many types of neoplasia and are considered pan-carcinoma markers [41]. The changes in glycosylation during neoplastic transformation are interesting, viewed both from a biological and therapeutical perspective, as the resulting immature carbohydrate structures frequently reflect developmental phenotypes and may be recognised as antigens by immunological defence mechanisms as well as be considered targets for immunological drug design [14, 16].

A large number of studies have investigated 'histo-blood group' antigens and glycolipids in testicular tumours [3, 4, 13, 27, 31, 45]. By contrast, very little is known about the expression of simple mucin-type *O*-glycans Tn, T and sialyl-Tn and sialyl-T as well as GalNAc-transferases that initiate *O*-linked glycosylation and form the Tn antigen

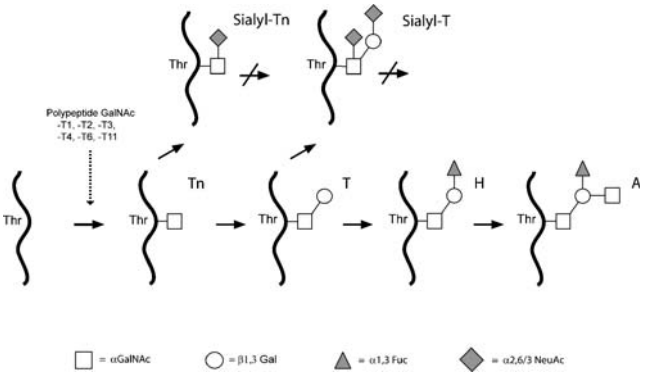

Fig. 1 Schematic depiction of simple mucin-type *O*-glycosylation. GalNAc-transferase enzymes and glycan structures investigated in the present study are indicated. The most immature *O*-glycans Tn, sialyl-Tn and T are considered pan-carcinoma markers

within the testis, and even less is known about their function. *O*-glycans have been implicated as involved in sperm maturation [11]. In addition, a recent study indicated that polyunsaturated, fucosylated glycosphingolipids are essential for spermatogenesis [35]. The mechanism by which spermatozoon binds the egg has not yet been completely elucidated, but there is a consensus that this interaction is carbohydrate-mediated and initiated by glycan-binding molecules (reviewed in [44]).

It has not yet been established to what extent *O*-glycosylation patterns change during germ cell differentiation and maturation in the human testis, nor is it known whether any changes of this pattern occur during malignant progression of CIS to TGCT. Identification of these changes, in particular, possible differences between seminomas and nonseminomas, would shed some light on the pathogenesis and malignant progression in germ cells. Therefore, in this study, we analysed for the first time the expression of cancer-associated mucin-type *O*-glycans Tn, sialyl-Tn and sialyl-T, as well as GalNAc-transferase isoforms that are responsible for *O*-glycosylation during development of normal human testis and in a large series of testicular neoplasms. We demonstrate that simple mucin-type *O*-glycans and their transferases are developmentally regulated. The expression profile in pre-invasive CIS and seminomas mirrored the phenotype of fetal gonocytes, while differentiated nonseminomas had a pattern only partially similar to that in somatic cells, with important pathogenetic and diagnostic implications.

Materials and methods

Tissue and cell samples

The use of human tissue samples for the study was approved by a local Medical Research Ethics Committee.

A series of 94 samples of TGCT and adjacent testicular tissues (which in most cases contained CIS) were obtained from patients who had undergone orchidectomy in three collaborating hospitals. After gross pathological evaluation, small tissue fragments were either frozen or fixed in Stieve's fluid or formalin and paraffin-embedded. The diagnosis of TGCT was confirmed by experienced pathologists after histological evaluation of all samples. The specimens selected for this study included a representative spectrum of histological types, classified as normal testis parenchyma with ongoing spermatogenesis, carcinoma in situ (CIS), seminoma, EC and immature or mature teratomas with variable somatic tissue components. Among specimens containing CIS (n=24), eight samples were adjacent to a seminoma, eight samples in vicinity to nonseminomas, five to combined tumours (containing both a seminoma and a nonseminoma in one testicle), and three specimens were true pre-invasive CIS, without the presence of an overt tumour. All samples with CIS were examined for the expression of sialyl-Tn because the antibody (3F1/TKH2) was suitable for all types of fixatives in paraffin-embedded samples, while a representative selection was stained with all other antibodies. In addition to TGCT, two testicular tumours derived from somatic cells—one Leydig cell tumour and one B cell lymphoma—were also included. A few paraffin-embedded tissue blocks with anonymous fetal tissues left from a previous study of CIS markers [23] were included to study the glycosylation profile during early testis development. The samples were from fetuses autopsied after abortions at the gestational age of 12–20 weeks when there are still numerous gonocytes present. We had no access to frozen fetal tissues. The fetal samples thus were only studied for the glycan profile, and not for the transferases, because antibodies for the latter were not suitable for paraffin-embedded specimens.

In addition, a few anonymised fresh semen samples (N=5) were investigated. These samples were obtained with informed consent from young healthy volunteers who were enrolled into a concurrent prospective study of reproductive health in the Danish population [24]. The staining was performed on leftover smears collected for the assessment of sperm morphology in these subjects.

Finally, a human teratocarcinoma-derived cell line, NTERA2 (NT2/D1) was examined before and after retinoic-acid-stimulated differentiation, as first described by Andrews [2]. Retinoic acid (RA, Sigma) was added to the medium (final concentration of 10^{-5} M) for 3 weeks until cells have differentiated. Immunostaining was performed on formalin-fixed cytospins of untreated and RA-treated cells, as described below.

Antibodies

A panel of well-characterized mouse monoclonal antibodies to simple mucin-type *O*-glycans and human polypeptide GalNAc transferases were used in this study. We have previously raised most of these antibodies and validated their specificity [6–8, 29, 30, 37]. Table 1 below lists all antibodies, their targets and the tissue preparation method.

Immunohistochemistry

For most antibodies, except 3F1, TKH2 and HH8 (after neuraminidase pre-treatment), frozen tissues or cultured

Table 1 The list of antibodies (all murine monoclonal) used in this study

Target antigen, protein	Antibody name/symbol	Tissue preparation recognised	Source
Simple mucin-type *O*-glycans			
Tn	5F4	Paraffin-embedded	Copenhagen University
Sialyl-Tn	3F1 or TKH2	Paraffin-embedded	Copenhagen University
T	HH8	Cryo-preserved	Copenhagen University
Sialyl-T	Neuraminidase +HH8	Paraffin-embedded	Copenhagen University
Histo-blood group variants			
H-type 3	HH14	Cryo-preserved	Copenhagen University
A-type 3	HH5	Cryo-preserved	Copenhagen University

GalNAc-T11	1B2	cryo-preserved	Copenhagen University
Testicular germ cell tumour (TGCT) markers			
Placental-like alkaline phosphatase	PLAP	Paraffin /cryo-preserved	DAKO-Cytomation
TRA-1-60 embryonic antigen	TRA-1-60	Paraffin /cryo-preserved	Dr. P. W. Andrews

cells were used. Frozen tissues were cut into 6-μm-thick sections. Cultured cells were dispersed on microscopic slides by centrifugation (Cytospin, Shandon, Pittsburgh, PA, USA). Subsequently, the sections or cytospins were fixed in 4% buffered formalin (15 min at 4°C) and rinsed in Tris-buffered saline (TBS). Paraffin sections were cut into 4-μm-thick sections, dewaxed in light petroleum and rehydrated in a series of ethanol solutions. For detection of sialyl-T, the sections were pre-treated for 2 h in 0.1 U/ml type VI neuraminidase in acetate buffer (Sigma, USA) to remove sialic acid and subsequently stained with HH8 antibody (which without this pre-treatment recognises T). If T was not present, but a sample appeared positive with HH8 antibody after neuraminidase treatment, we could conclude that sialyl-T was expressed. Endogenous peroxidase activity was blocked by 30-min pre-incubation with 1% H_2O_2. Pre-diluted non-immune goat serum (Zymed Laboratories, S. San Francisco, CA, USA) was used to decrease unspecific staining. The incubation with primary antibodies was carried out overnight at 4°C. For all our own monoclonal antibodies, we used 'neat' hybridoma supernatants, without any further dilution. Incubations with the second (link) antibody (biotinylated goat-anti-mouse IgG) and the colour development (a streptavidin-peroxidase conjugate followed by aminoethyl carbazol, AEC, or diaminobenzidine, DAB, and H_2O_2) were performed at room temperature, according to the instructions of the manufacturer (Zymed, Histostain System). The positive reaction manifested as a red (AEC) or brown (DAB) stain. The sections were counterstained in Mayer's haematoxylin. A serial section from each specimen was processed with a dilution buffer substituted for the primary antibody, as a negative control. For positive controls, all specimens were stained for two established germ cell tumour markers, PLAP [22] or TRA-1-60 [3]. The stainings were evaluated by two primary evaluators (ERM and SP), with additional examiners consulting (AG, UM), if needed. Entire specimens of substantial size (approximate average size was 5× 5 mm) were examined; in many cases, two to three sections from the same tissue sample were examined, often in separate staining experiments. Because of heterogeneity of staining in some cases, additional semi-quantitative estimation was added, as indicated in the footnotes to Table 2.

For some tissue sections and cell cytospins, especially spermatozoa, immunofluorescence was used. The protocol was essentially the same as described above for immuno-

Table 2 Summary of the expression of simple mucin-type *O*-glycans and GalNAc-transferases in the human testis and testicular neoplasms

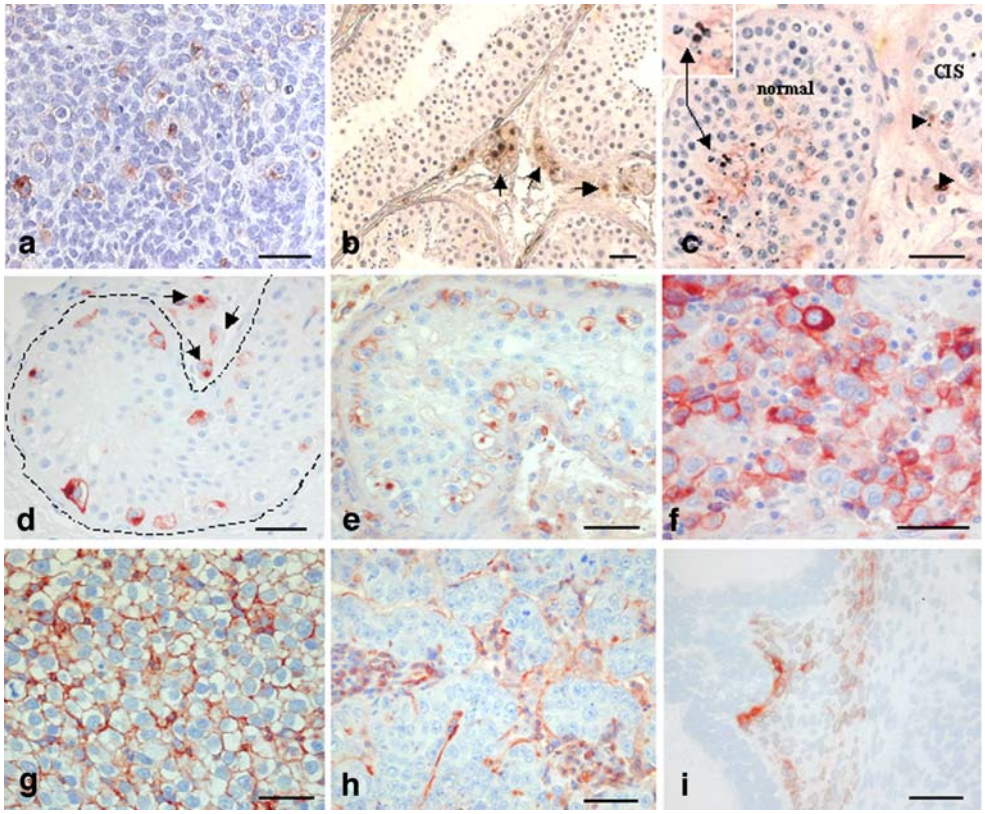

Fig. 2 Examples of immunoexpression of simple mucin-type *O*-glycans in normal human testis (**a**, **b**, **c**), pre-invasive CIS (**c**, **d**, **e**) and overt tumours (seminomas, **f** and **g**, and nonseminomas, **h** and **i**). Sialyl-T antigen is present in fetal gonocytes (**a**), absent in spermatogonia of the adult testis, but present in Golgi apparatus in spermatocytes and acrosomal structures of spermatids (**c**, magnified in the inset; see also Fig. 4) as well as in CIS cells (**c**, marked by *arrowheads*; **e**) and seminoma (**g**) but not in the undifferentiated EC component of teratomas (**h**) where is also present in vascular endothelium. Sialyl-Tn is completely absent from the normal adult seminiferous epithelium (**b**), but it is expressed in Leydig cells (**b** and **d**: *arrows*), heterogeneously in CIS cells (**d**, red-stained cells inside an outlined tubule) and seminoma cells (**f**), while in nonseminomas, it is not present in undifferentiated components but only in rare somatic components of teratomas. Only some somatic elements of non-seminomas express Tn (**i**). Magnification bar=50 μm

peroxidase, except that at the end, instead of a streptavidin-peroxidase conjugate, an FITC conjugate (rabbit anti-mouse IgG, F-261, DAKO-Cytomation or goat anti-mouse IgG1; Southern Biotech) giving a bright light-green signal or an Alexa fluor 594 conjugate (goat anti-mouse IgM; Molecular Probes) giving a light-red signal was used. The sections were counterstained with DAPI and subsequently visualized under a fluorescent microscope.

Results

Normal adult testis

We first established the pattern of expression of simple mucin-type *O*-glycans and GalNAc-transferases in the normal testicular tissue. A summary of the results is given in Table 2, and representative examples are shown in Figs. 2 and 3. The studied glycans were absent from spermatogonia and appeared first in spermatocytes, i.e. T was seen in spermatocytes and spermatids, whilst Tn was first found in spermatids. Ejaculated spermatozoa expressed Tn in >50% of the cells in all cases and T and sialyl-T in a subset of cells (Fig. 4). Sialyl-Tn was not detected in the normal adult germ cells. The A variant was seen in spermatocytes and spermatids only in a subset of samples (presumably in individuals with A blood type), and the H variant was negative in all samples (not shown). As presented in Fig. 3b, germ cells (except spermatogonia) expressed exclusively GalNAc-T3, which appeared first in spermatocytes (>50% in 16 of 17 cases) and was most intense in round and late spermatids. The GalNAc-T3 isoform was also the only GalNAc-transferase that was expressed in ejaculated spermatozoa (>50% in five of five cases; Fig. 4d). The sub-cellular pattern of expression of Tn, T and GalNAc-T3 was very characteristic: Spermatocytes had staining localised to a perinuclear rounded organelle (Figs. 3b and 4d, inset), whereas ejaculated round spermatids and mature spermatozoa displayed a ring-shaped equatorial staining consistent with the edge of acrosome (Fig. 4a, b, d). Sialyl-T, on the other hand,

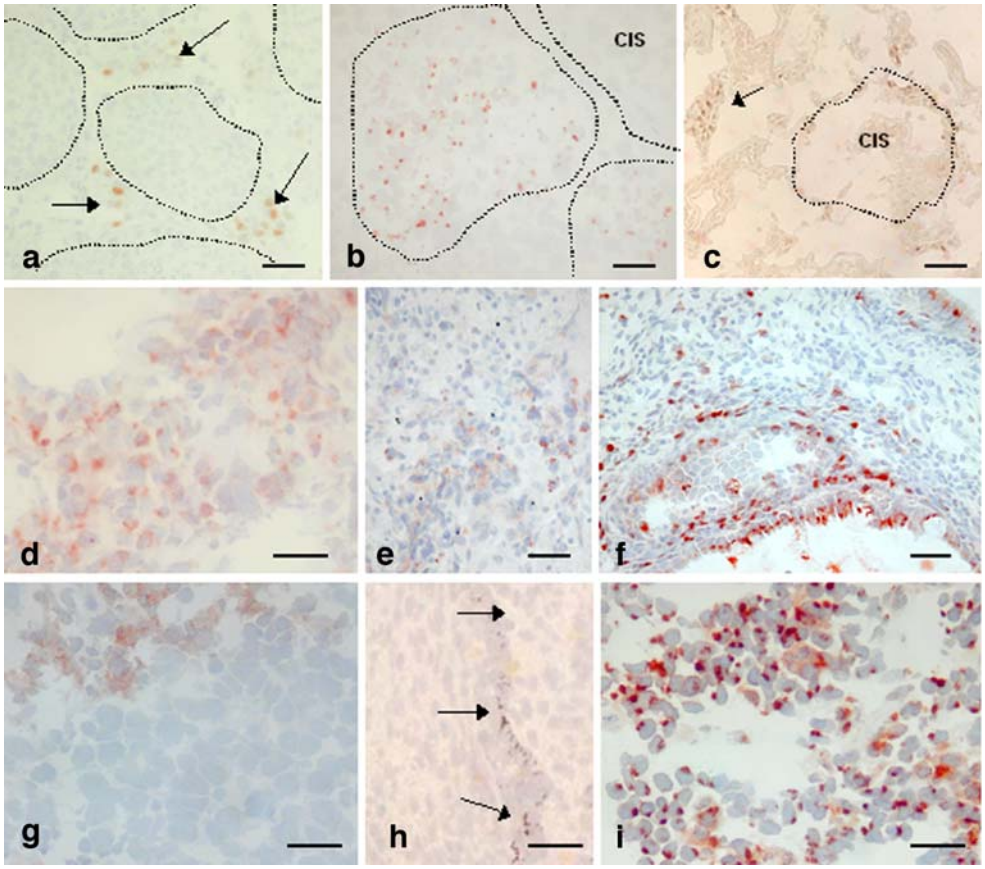

Fig. 3 Immunoexpression of GalNAc-transferases in human testis and testicular neoplasms. Note that all images show frozen tissue samples, where tissue morphology is inferior to paraffin-embedded specimens; thus, seminiferous tubules need to be outlined (**a**–**c**) to delineate their boundaries. GalNAc-T2 is not present in normal adult germ cells, but it is detectable in normal Leydig cells (**a** and **c**, marked with *arrows*), whereas only a very weak staining is seen in a subpopulation of CIS cells in some samples (**c**). GalNAc-T2 is also detectable in seminomas (**d**) and in some tissue element of teratomas and teratocarcinomas (**e**). GalNAc-T3 in normal adult testis appears in spermatocytes and round- and late-spermatids (**b**), but it is absent in pre-meiotic spermatogonia and CIS cells (**b**), while some epithelium-like structures are focally stained in teratomas (**h**, *arrows*). Other GalNAc-transferases shown are: GalNAc-T4 in some components of teratomas (**f**), GalNAc-T6 in the inflammatory infiltrate but not in seminoma cells (**g**) and GalNAc-T1, which is strongly positive in Golgi-like structures of B cell testicular lymphoma cells (**i**). Magnification bar=50 μm

localized to the whole spermatozoa including both the acrosome area and the tail (Fig. 4c).

Leydig cells preferentially expressed sialyl-Tn and GalNAc-T2 (Figs. 2b and 3a) and weakly expressed Tn, GalNAc-T1 and GalNAc-T4. Sialyl-Tn was also present in the endothelium of the blood vessels and present in some of the peritubular myoid cells. In addition, sialyl-T was strongly expressed in endothelial cells of blood/lymphatic vessels.

Expression pattern in testicular neoplasms

We then investigated the expression pattern of simple mucin-type *O*-glycans and GalNAc-transferases in testicular tumours, with special emphasis on the germ-cell-derived neoplasms. We found a completely different pattern of expression in malignant germ cells (Table 2). CIS and especially seminomas expressed sialyl-Tn and sialyl-T, in contrast to Tn and T that characterized the normal testis (Fig. 2). CIS cells demonstrated a weak and heterogeneous expression of GalNAc-T2 in 10 of 13 cases (Fig. 3c) and rarely GalNAc-T1 and GalNAc-T4. The observed pattern was the same in all samples of CIS, regardless of the type of the adjacent tumour. GalNAc-T3, GalNAc-T6 and GalNAc-T11 were not detected in CIS at all (Fig. 3b). This pattern was mirrored by seminomas, i.e. a large number of the seminoma cells expressed GalNAc-T2 (11 of 11; Fig. 3d), GalNAc-T1 and GalNAc-T4 in only 4 of 10 cases, and GalNAc-T6 and GalNAc-T11 were not expressed. GalNAc-T6 was present in a subset of lymphocytic infiltrates associated with seminomas (Fig. 3g). The undifferentiated form of nonseminoma, EC, was practically devoid of any staining, except for a trace of GalNAc-T3 in one sample and focal expression of Tn in a few cells. Teratomas, however, which are differentiated forms of nonseminoma, displayed a focal expression of nearly all the simple mucin-type *O*-glycans and GalNAc-transferases in some epithelial and glandular elements (Table 2, Fig. 3e,f).

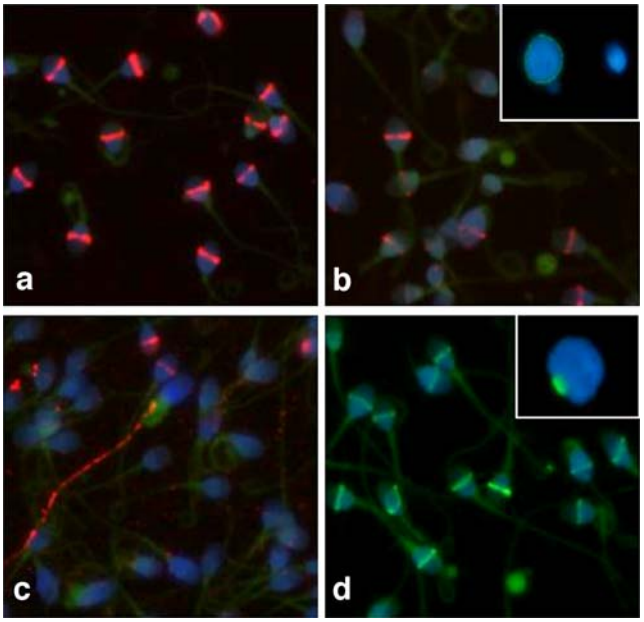

Fig. 4 Examples of immunofluorescence with monoclonal antibodies to simple mucin-type *O*-glycans **a** Tn (marked in *red*), **b** T marked in *red* or *green* (*inset*), **c** sialyl-T (*red*) and **d** GalNAc-T3 (*green*) on ejaculated spermatozoa. In all images, cell nuclei are counterstained with DAP (*blue*). Tn, T and GalNAc-T3 as a ring-shaped staining consistent with the beginning of acrosome formation (**a**, **b**, **d**). Note that Tn and GalNAc-T3 stained most cells and T only few cells. In the *inset* in **b**, T antigen is shown as a round halo in an ejaculated round spermatid, and no staining is seen in the adjacent spermatozoon. Sialyl-T (**c**) is visible on the surface of the tails of spermatozoa, while the heads most probably show the expression of T. GalNAc-T3 (**d**) is visible in the equatorial position of the spermatozoon's head; the GalNAc-T3 expression first begins in spermatocytes in the Golgi apparatus (*inset*)

To further explore the changes of expression during differentiation of nonseminomas, an EC cell line (NT2/D1) was examined for expression of simple mucin-type *O*-glycans, and GalNAc-transferases before and after differentiation triggered in vitro by retinoic acid [2]. Both undifferentiated and differentiated cells expressed Tn and T as well as only two of the GalNAc-transferase isoforms, i.e. GalNAc-T1 and GalNAc-T2. Sialyl-Tn, T and the A and H variants could not be detected.

Somatic cell tumours in the testis demonstrated again a completely different pattern of expression. In one Leydig cell tumour, we could only detect sialyl-Tn and also only one of the GalNAc-transferase isoforms, i.e. GalNAc-T2. A specimen of B cell lymphoma was characterised by very strong expression of sialyl-T and GalNAc-T1 (Fig. 3i), weak expression of GalNAc-T2 and GalNAc-T6 and no trace of other simple mucin-type *O*-glycans or GalNAc-T3 or GalNAc-T4.

Mucin-type antigens in fetal gonocytes

Having observed the marked difference in expression of simple mucin-type *O*-glycans between CIS/seminoma cells and normal adult germ cells, we investigated the pattern of expression of mucin-type *O*-glycans in fetal germ cells, which resemble CIS to a much greater extent than adult germ cells [33]. The majority of fetal samples demonstrated the presence of sialyl-Tn and sialyl-T in early fetal gonocytes (Fig. 2a), similar to CIS and seminoma cells and different from the normal adult testis and EC, which expressed Tn and T.

Discussion

Changes in the expression pattern of mucin-type *O*-glycans are associated with malignant transformation in cancer, and in the present study, we demonstrated marked changes in *O*-glycans and key enzymes involved in *O*-glycan biosynthesis in testicular cancer in comparison to the normal adult testis. We found also distinct changes during differentiation and maturation of normal germ cells. The pattern of expression in germ-cell-derived neoplasms recapitulated closely developmental changes in germ cells, with a notable exception of teratomas, which exhibited peculiar changes in *O*-glycan configuration and GalNAc-transferases, apparently caused by their partial somatic differentiation.

In the normal testis, we found a very restricted pattern of *O*-glycans, combined with expression of only one transferase (GalNAc-T3) in the maturing post-meiotic germ cells. The expression of this transferase was not detected in spermatogonia and was first present at the more mature spermatocyte stage, in a perinuclear area resembling Golgi apparatus. With cell maturation to round spermatids and later to spermatozoa, the protein formed a round equatorial ring at the base of the acrosome. This finding is consistent with our earlier studies that reported the presence of GalNAc-T3 in normal sperm [8, 29]. GalNAc-T3 thus appears to have a specific function in spermatozoa, which may be related to sperm maturation, oviduct attachment or to the adhesion of spermatozoa to the zona pellucida of an egg. GalNAc-T3 was postulated to initiate *O*-glycosylation of zonadhesin, a mucin molecule evolutionarily related to von Willebrand factor [17], as previously shown by in vitro studies of the substrate specificity [8]. Zonadhesin is a testis-specific protein, known to bind the zona pellucida; therefore, we hypothesise that GalNAc-T3 may play a role as an additional mediator of sperm–egg binding, such as, for example, recently identified mouse SED1 [15].

Loss of expression of GalNAc-T3 due to a mutation of the *GALNT3* gene was associated with familial tumoral calcinosis [21, 42, 43]. This rare disease manifests in childhood or early adolescence; therefore, it is presently unknown if familial tumoral calcinosis has implications for fertility. Recently, however, a family was reported with a nonsense mutation in GalNAc-T3, and one affected adolescent boy

exhibited testicular calcium deposits (microlithasis) and oligozoospermia [10]. We hypothesize that lack of GalNAc-T3 expression may impair maturation of spermatozoa and are currently investigating males with fertility problems.

In TGCT, the pattern of expression of simple mucin-type *O*-glycans and GalNAc-transferases was markedly different than in the normal testis. The most striking features were an abundance of sialyl-Tn and sialyl-T, a complete lack of GalNAc-T3 and appearance of GalNAc-T2 in CIS and seminoma. Sialyl-Tn was not detectable in normal adult germ cells, and we have thus shown that sialyl-Tn is a new marker for their neoplastic counterparts in adult men. On the other hand, the practical use of this marker in routine diagnosis is limited because of the presence of sialyl-Tn in Leydig cells and endothelial cells of vessels in the interstitial compartment of the testis.

Accumulation of Tn and sialyl-Tn antigens has been described in other cancers, e.g. breast cancer cells [9, 41], and sialyl-Tn has been implicated as a factor reducing cell interactions, thus promoting migratory and invasive phenotype of cells [25]. Of particular interest is that sialyl-Tn was also detected in fetal gonocytes. This may have something to do with the ability of gonocytes to move inside the tubules from the central parts of seminiferous cords toward the basal membrane. When gonocytes reach the membrane, they mature to spermatogonia, downregulate pluripotency markers and lose sialyl-Tn. The presence of sialyl-Tn (and sialyl-T) in gonocytes is also consistent with similarity between the antigenic phenotype of CIS cells and gonocytes and supports our hypothesis that gonocytes are the cell of origin for CIS [23, 33, 34, 39].

We noticed that, in the neoplastic specimens, sialyl-T displayed a pattern of staining strikingly similar to that of D2-40 antibody, which recognises a tumour-associated antigen, M2A, but does not require sialic acid residues [5]. M2A was recently identified as podoplanin/Aggrus [36, 40]; thus, we hypothesise that in immature testes and TGCT, sialyl-T is associated with podoplanin molecules, while in post-meiotic germ cells, this glycan is bound to another protein, perhaps specific for haploid cells. The reported presence of a sialylated *O*-glycan on the podoplanin/Aggrus molecule supports our hypothesis [26].

The current study focused on the analysis of germ cells. However, we noticed that sialyl-Tn and Tn as well as GalNAc-T1, GalNAc-T2 and GalNAc-T4 were present in Leydig cells. This localisation suggests a possible role in the synthesis or secretion of testicular hormones produced in Leydig cells. In addition, the ability of nonseminomas to somatic differentiation diverted also our attention from germ-cell-specific to somatic patterns of mucin-type *O*-glycosylation. Interestingly, we observed a marked difference between EC, an undifferentiated component of nonseminomas, and differentiated teratomas. Nearly all studied *O*-glycans and GalNAc-transferases could be found focally in small components resembling somatic cells within teratomas. The presence in teratomatous somatic components of simple mucin-type *O*-glycans, which are not usually detectable in normal cells, suggests that these elements still have abnormal pattern of glycosylation, which is one of the hallmarks of cancer cells. These findings could be confirmed only partially by the analysis of NT2/D1 cells differentiating in vitro after retinoic acid treatment. A likely explanation for the lack of expression of the entire panel of studied *O*-glycans and GalNAc-transferases in the differentiated NT2/D1 cells is that their phenotype is largely limited to two somatic cell types: neuron-like elongated cells and flat unclassified cells [2].

In summary, this study has established a complete profile of simple mucin-type *O*-glycans and GalNAc-transferases that control *O*-glycosylation in the human testis and testicular tumours, thus providing a solid reference for further studies. The observed restricted *O*-glycosylation pattern in post-meiotic male germ cells suggests a possible role in their maturation or egg recognition/fertilization and warrants further studies in male infertility. Our findings in testicular tumours demonstrate that malignant germ cells display specific changes in mucin-type *O*-glycosylation and in the initiators of *O*-glycosylation, the polypeptide GalNAc-transferases. Some of these changes reflect the immature phenotype of malignant germ cells, thus providing additional evidence that testicular cancer is a developmental disorder of cell differentiation. In addition, we detected specific changes in the expression pattern associated with differentiation of nonseminomas, which involves transformation from embryonic and partially germ-cell-like phenotype into phenotypes resembling variable somatic lineages. These changes may have an auxiliary diagnostic and prognostic value, as they allow to delineate the somatic-like lineages that retain partially transformed cancerous phenotype.

Acknowledgement The authors thank Professor P. W. Andrews for a generous gift of NT/D1 cell line and TRA-1-60 antibody, Dr N. Jørgensen for fetal tissue specimens, the pathologists at several pathology departments in the Greater Copenhagen area for assistance in obtaining tissue specimens and L. Andersen, H. Kistrup and T. Adelfest for skilful technical assistance. This work was supported by grants from the Danish Cancer Society, the Svend Andersen Foundation, the Vissing Foundation, the Kirsten and Freddy Johansen Foundation, the Willumsen Foundation and the Danish Medical Research Council.

Abstract Ligneous conjunctivitis (LC) is a rare disease characterized by wood-like pseudomembranes developing on the ocular and extraocular mucosae secondary to plasminogen (PLG) deficiency. In this paper, we report two cases of LC in two sisters of 57 and 62 years of age that presented with recurrent, bilateral pseudomembranes on conjunctiva and a history of consanguinity and deafness. Pseudomembranes showed superficial and/or subepithelial deposits of eosinophilic amorphous hyaline, amyloid-like material with a variable proportion of granulation tissue, and inflammatory cells. The eosinophilic deposits were negative for Congo red stain, immunoreactive for fibrinogen, and consistently negative for amyloid A component, transthyretin, β_2-microglobulin, albumin, fibronectin, collagen type IV, vimentin, and cytokeratins. Among inflammatory cells, a percentage of positivity of roughly 60% for lymphocytes T (CD3+) and 40% for lymphocytes B (CD8+), with a relation of cytotoxic/helper (CD8/4) T cells of 3:2, was found. In one case, nasal polyps and recurrent gastric peptic ulcer were also characterized by the same subepithelial hyaline deposits. A novel homozygous point mutation c.1856 C>T was found in exon 15 of the *PLG* gene in both patients. Amniotic membrane transplantation was done in one case with promising results.

Introduction

The term ligneous conjunctivitis (LC) was coined in 1933 by Borel [4] to describe a rare form of chronic, bilateral, recurrent conjunctivitis characterized by the development of firm fibrin-rich, woody-like pseudomembranous lesions mainly on the upper tarsal conjunctivae, and less frequently in the lower eyelid and the bulbar conjunctive [38]. LC was first described by Bouisson [5] as early as 1847, and the microscopic appearance of pseudomembranes presented as inflammatory fungus-shaped masses first reported in 1924 [19]. Because similar lesions can occur on other mucous surfaces indicating a systemic disease, Mingers et al. [23] proposed the term pseudomembranous disease for this entity; the same group [22] also demonstrated severe inherited type I plasminogen (PLG) deficiency as the cause of this disease in 1994. Familial occurrence was also reported [4, 38], and distinct homozygous and compound-heterozygous mutations in the *PLG* gene have been demonstrated by Schuster et al. [35, 39] and other groups since 1997.

Extraocular lesions were reported occurring in the oral cavity (mainly gingiva) [14, 40], the upper gastrointestinal tract [38], the ear (including temporal bone) [7, 15], the nasopharynx, larynx, tracheobronchial tree, and lung [10,

27], the female genital tract (sometimes with infertility) [8, 17, 28], and the renal collecting system [37]. A new syndrome or a coincidental association of non-Hodgkin's lymphoma, auricular hypoplasia, and juvenile colloid milium with LC were recently noted [16]. In very rare cases, congenital occlusive hydrocephalus has been associated with the more severe forms of the disease and may even precede LC [1, 10, 36]. More recently, the report of a single patient with extensive woody deposits in her eyes, hydrocephalus, gingival hyperplasia, otitis media, sinusitis, and genital tract involvement exemplified the various manifestations of the pseudomembranous disease characteristic of severe PLG deficiency [21].

In 1998, it was shown that repeated infusions of PLG could resolve ligneous pseudomembranes [34], and effective treatment with topical PLG was reported in 2002 [47]. More recently, amniotic membrane transplantation has shown promising results in conjuntival reconstruction in difficult-to-manage cases of LC [2, 3].

In this paper, we report the clinicopathological, immunohistochemical, and genetic data of two sisters that presented with LC in adulthood, one of whom was treated with amniotic membrane transplantation.

Clinical history

Two sisters of 57 (Case 1) and 62 (Case 2) years of age were referred to the Clinical University Hospital with a diagnosis of bilateral epidemic conjunctivitis and unsatisfactory responses to different treatments. Consanguinity and moderate deafness were found in both patients. In Case 2, there had been a previous history of deafness at age 32, recurrent gastric peptic ulcer at age 57, and recurrent nasal polyps at age 60. No other additional relevant data were found in the clinical records of the two patients. The patients showed abundant mucopurulent secretions with wood-like pseudomembranes on the upper and lower tarsal conjunctiva, with *Staphilococcus epidermidis* in culture.

A putative diagnosis of LC was made based on recurrences during the previous 6 months to 1 year period (in both cases) and on the clinical appearance of the lesions (Fig. 1a and b). Surgical excision of pseudomembranes with a thorough cleaning of the surgical field using 5,000 IU/ml heparin eye drops was carried out. Pathological examination of the removed tissue supported a diagnosis of LC, and a PLG deficiency was confirmed with a level of 0.061 U/ml in Case 1 and of 0.045 U/ml in Case 2 (normal range, 0.80–1.20). After surgery, both patients underwent topic treatment with dexametasone at 0.1% every 4 h, cyclosporine A at 2% every 6 h, heparin 5% eye drops every 2 h, and ofloxacine every 6 h until complete epithelization was achieved. Unfortunately, topical PLG drops were unavailable. Six weeks later, both patients presented with a new recurrence of pseudomembranes, and similar surgical and medical treatment was undertaken. Twelve weeks later, the Case 1 patient presented again with serious lesions in tarsal and nasal conjunctiva of both eyes with no corneal involvement. Excision of all inflamed tissue

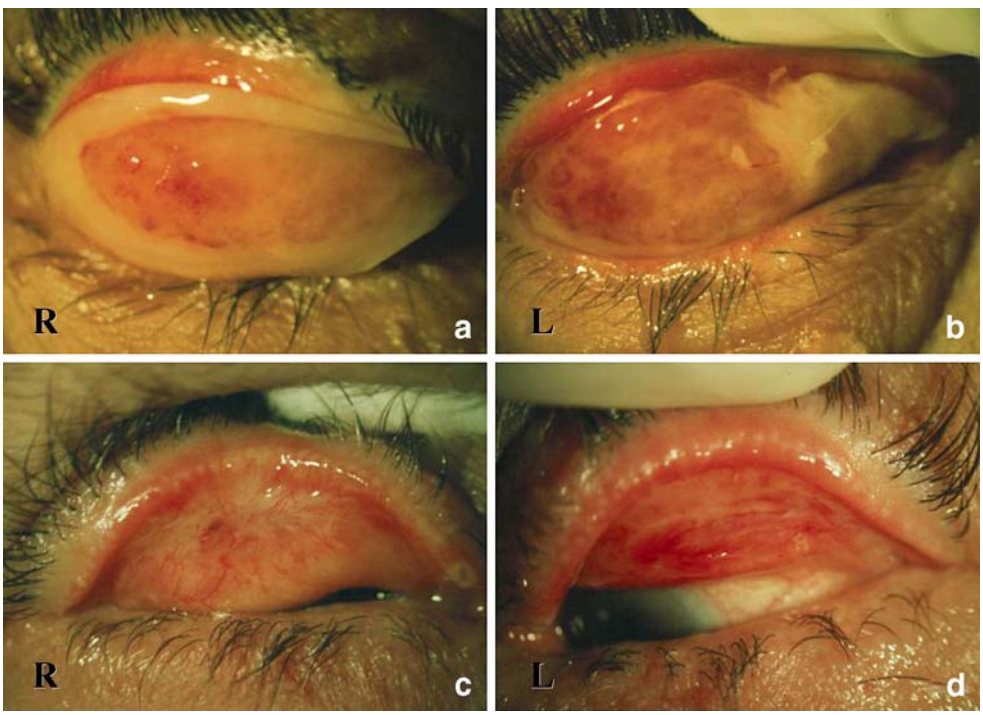

Fig. 1 LC. **a**–**b** A thick membrane covers the upper palpebral conjunctiva in both eyes (Case 1). **c**–**d** Postoperatively, amniotic membranes have disappeared, and there are no pseudomembranous lesions

together with amniotic membrane transplantation for conjunctival reconstruction under local anesthesia was decided upon. Previous to surgery, the ethics committee of our institution approved treatment, and the patient gave her written informed consent. The human amniotic membrane was prepared according to the method of Tseng et al. [46]. The corneal surface was covered by a therapeutic contact lens to prevent abrasion, and the amniotic membrane epithelium was secured up to the conjunctival edge with interrupted sutures. Perioperative topical treatment with intensive (every 30 to 60 min) heparin (5,000 U/ml) was carried out. The patient received dexamethasone and tobramicine eye drops four times daily for 6 weeks, heparin (5,000 U/ml) eye drops gradually tapered down from six times daily over 3 months, and topical cyclosporine A (2%) every 6 h daily for 6 weeks. Two months postoperatively, the amniotic membranes had dissolved, and the conjunctiva appeared free of pseudomembranous lesions (Fig. 1c and d). The patient has been examined monthly by the same ophthalmologist, and no recurrence of membranes has occurred in 39 months. Case 2 patient was lost on follow-up due to death caused by an ovarian poorly differentiated adenocarcinoma.

Materials and methods

Histological, histochemical, and immunohistochemical analyses

The surgical specimens were fixed in buffered formaldehyde and routinely embedded in paraffin. The 4-μm-thick sections were stained with hematoxylin and eosin and Congo red stain. Immunohistochemical studies were also performed on paraffin sections using a universal second antibody kit that utilized a peroxidase-conjugated labeled-dextran polymer (Dako EnVision Peroxidase/DAB; Dako, Glostrup, Denmark), to avoid misinterpreting endogenous biotin or biotin-like activity in tissues [9] as positive staining. The following antibodies were used: amyloid A component (clone mc1, dilution 1:50, Novocastra, Newcastle upon Tyne, UK), transthyretin (polyclonal, 1:1,000, antigen retrieval water bath, Dako, Glostrup, Denmark), β_2-microglobulin (polyclonal, 1:2,000, Dako), fibrinogen (polyclonal, 1:200, microwave, Dako), albumin (polyclonal, 1:2,000, BioGenex, San Ramon, CA, USA), fibronectin (polyclonal, 1:10,000, water bath, Dako), collagen type IV (CIV, 1:10, microwave oven and EDTA), vimentin (V9, 1:5,000, microwave oven, BioGenex), cytokeratins (AE1–AE3, 1:20, water bath and proteinase K, Dako), immunoglobulin A (IgA; polyclonal, 1:10,000, microwave oven, Dako), IgD (polyclonal, 1:1,000, water bath, Dako), IgG (polyclonal, 1:10,000, microwave oven, Dako), IgM (R1/69, 1:500, microwave oven, Dako), light chains kappa (polyclonal, 1:50,000, water bath, Dako), light chains lambda (polyclonal, 1:50,000, water bath, Dako), CD3 (SP7, 1:50, water bath and EDTA, Master Diagnóstico, Granada, Spain), CD4 (4B12, 1:4, water bath and EDTA, Master Diagnóstico), CD8 (4B11, 1:20, water bath and EDTA, Novocastra), and CD20 (L26, 1:50, water bath, Dako). Negative control samples (the primary antibody was replaced by nonimmune mouse serum) and positive tissue samples were included in each slide run.

Mutation analysis

Informed consent was obtained for this study, which was conducted according to the Spanish law including adherence to the Helsinki Principles of 1975, as revised in 1983. For Case 1, genomic DNA was extracted from peripheral white blood cells by standard methods. For both cases (Case 1 and Case 2), to confirm our results, genomic DNA was extracted from paraffin-embedded tissue using QIAamp DNA Kit and QIAamp DNA Blood Mini Kit (QIAGEN: www.qiagen.com), following the manufacturer's instructions. Thereafter, all coding regions and exon/intron boundaries of the *PLG* gene were amplified by polymerase chain reaction (PCR). To prevent the coamplification of homologous genes, we used primers and strategy described in Siboni et al. [41]. After the amplification, PCR products were purified. Both strands were subjected to cycle sequencing with the same PCR primers that covered the complete gene, both exons and introns, using the BigDye terminator kit and run in the 3730 xl DNA Analyser (Applied Biosystems, Foster City, CA, USA).

Results

Pathological and immunohistochemical findings

Histological examination revealed similar findings in both patients. Pseudomembranes showed superficial and/or subepithelial deposits of eosinophilic amorphous hyaline, amyloid-like material with a variable proportion of granulation tissue, and inflammatory cells, mainly plasma cells and lymphocytes (Fig. 2a). Ulceration and hyperplastic changes in the residual epithelium were observed. The eosinophilic deposits were negative for Congo red stain, immunoreactive for fibrinogen (Fig. 2b), and consistently negative for amyloid A component, transthyretin, β_2-microglobulin, albumin, fibronectin, collagen type IV, vimentin, and cytokeratins. A similar proportion of immu-

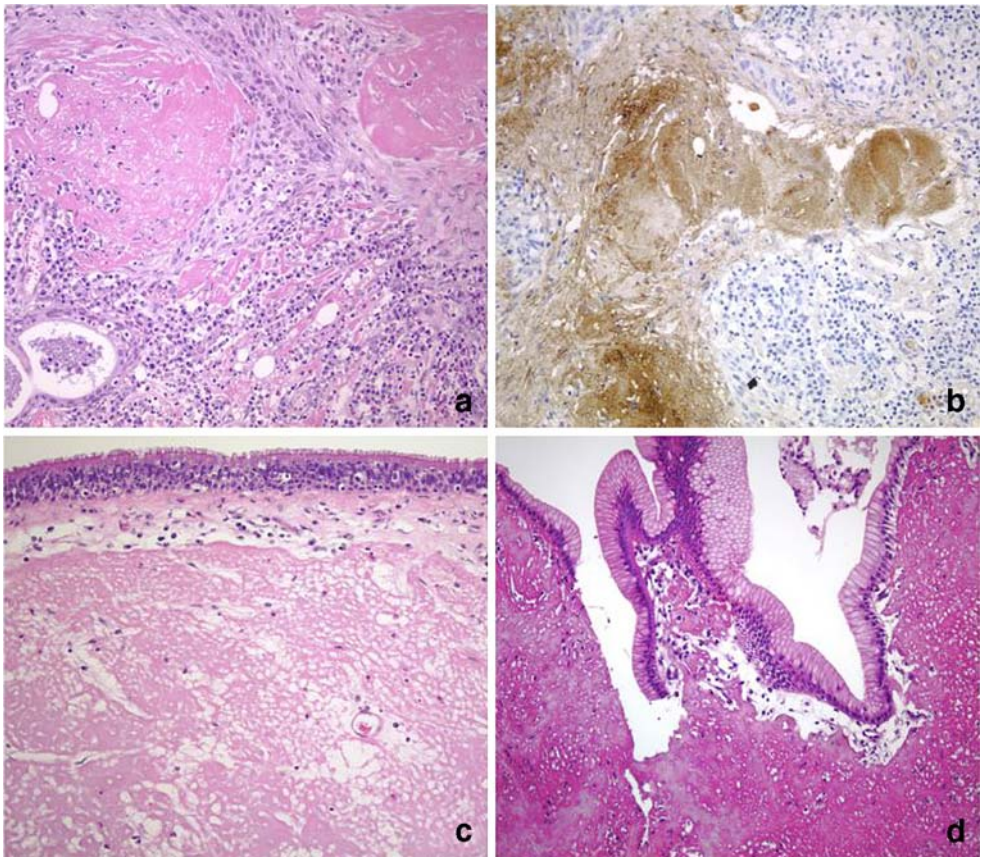

Fig. 2 Ligneous disease (**a**–**d**). An inflammatory cell component with amyloid-like material is noted in the histological section of the conjunctiva (**a**). Immunohistochemical analysis of the deposits demonstrates positive localization of fibrinogen (**b**). Subepithelial deposits of amorphous eosinophilic material in nasal polyp (**c**) and in gastric mucosa (**d**)

noreactivity for light chains was found in plasma cells, but no stain was found in the hyaline material. Among inflammatory cells, a percentage of positivity of roughly 60% for lymphocytes T (CD3+) and 40% for lymphocytes B (CD8+), with a relation of cytotoxic/helper (CD8/4) T cells of 3:2, was found.

Reevaluation of biopsies in Case 2 showed both exuberant granulation tissue and subepithelial fibrin deposits in gastric biopsies (Fig. 2d) and in metastatic vaginal lesions from the ovarian adenocarcinoma. The nasal polyps were also composed of subepithelial deposits of amorphous eosinophilic material instead of the loose mucoid stroma characteristic of nasal inflammatory polyps (Fig. 2c).

Genetic analysis

Direct sequencing of both single strands of PLG exon 15 from patient 1 showed a homozygous point mutation c.1856 C>T (using GenBank X05199 as reference sequence and starting with +1 at the A of the ATG translation initiation codon), which leads to an amino acid change ACT (Thr) to ATT (Ile) at position 600: p.Thr600Ile (the amino acid residues are numbered starting with the amino-terminal glutamic acid residue of the mature PLG as number +1) (Fig. 3). This mutation lies in the beta chain of PLG, 39 amino acids downstream of the Arg561-Val562 cleavage site that is necessary for the conversion of PLG to plasmin [29]. The same mutation was also present in homozygous state on the paraffin samples of the patient and her deceased sister.

Discussion

According to the excellent revision of Shuster and Seregard [38], the diagnosis of LC is based on the clinical picture (pseudomembranous lesions), the typical histological findings, and eventually on a positive family history. All of these criteria were present in the two patients here presented, with some unusual features that deserve consideration.

The prevalence of LC may be roughly estimated in the range of 1.6 per 1 million people [38], at least in Europe, but in countries where consanguinity is more frequent, the prevalence of LC may be higher [10]. Although most cases of LC are sporadic, some familial cases have been reported with an autosomal-recessive pattern [4, 38]. In most cases, infants and children are affected, but late onset manifestation of LC may occur, as in our patients, ranging from birth to 85 years [18, 38]. Both eyes are affected in up to 51% of cases, and corneal involvement, a complication that may lead to blindness, occurs in 20–30% of cases [38]. Systemic signs and symptoms may precede or concomitantly occur with the ocular disease.

Histopathological findings of the ocular and extraocular lesions in LC are identical. The excessive depositions of fibrinogen in LC should be differentiated from very rare cases of amyloidosis of the eye [20]. While amyloid deposits are positive with the Congo red stain, fibrinogen is negative. It must be noted that, in some extraocular biopsies, the nature of the disease may be overlooked by the pathologist, particularly if there is no clinical suspicion of LC, as occurred in our Case 2. Immunohistochemical studies for fibrinogen can definitively confirm the nature of the eosinophilic material in LC as occurred in our biopsies.

PLG plays an important role in fibrinolysis and wound healing. In patients with LC, wound healing in mucous surfaces is impaired and seems arrested at the stage of granulation tissue [30, 38]. Histopathological and immunohistochemical findings indicate that fibrinogen is the major constituent of the membranes in LC. As was referred to in the literature, and as we confirmed in our patients, severe type I PLG deficiency (hypoplasminogenemia) is a major cause of LC [23, 24, 38]. The observation of cases of LC developed during treatment with tranexamic acid, an antifibrinolytic drug, also supports this idea [12].

Several mutations have been detected in the *PLG* gene of patients affected with LC [10, 33, 38, 43, 45]. PLG is the proenzyme of the serine protease plasmin and is a 791-amino-acid residue single-chain glycoprotein with a molecular weight of 93 kDa [26]. Its gene spans approximately 52.5 kb on chromosome 6q26–27 and consists of 19 exons [11]. The proteolytic activity of plasmin contributes to the digestion of the insoluble fibrin clot and thrombi by which normal recanalization and tissue repair can be accomplished [31]. The mutation p.Thr600Ile of the PLG gene is very close to His-603, one of the three amino acid residues that constitute the serine protease triad. Moreover, p.Thr600Ile is next to p.Ala601Thr, a mutation present in 2–4% of Japanese subjects that predisposes them to thrombophilia and is known as Plasminogen Tochigi [25]. But, as stated for ligneous conjunctivitis [35], the mutation found in our patients does not predispose them to thromboembolic episodes [6]. In these patients, however, the risk of thrombotic occlusions of implanted catheters may be markedly increased [21, 38]. To the best of our knowledge, this is the first report of this mutation described in patients with LC.

LC has also been reported in different animal species [38]; mice in which both PLG genes have been knocked out (PLG-deficient mice, $Plg^{-/-}$ mice) will develop conjunctival lesions indistinguishable from human lesions [13]. The clinical phenotype in $Plg^{-/-}$ was reported to differ from that in humans with LC, in that, in humans, gastric, colon, and rectal ulcers, rectal polyps, and liver involvement have not been reported so far. We believe, however, that our Case 2 patient is, as far as we know, the first description of recurrent gastric ulcer and LC.

Shuster and Seregard [38] and Tefs et al. [44] concluded that a potentially useful initial approach for LC is the topical application of a PLG concentrate, possibly in combination with a PLG activator (uPA or tPA), which may soften the pseudomembranes and facilitate removal. To prevent recurrence, manipulations of the conjunctiva should be kept to a minimum, and treatment with heparin and corticosteroids should be undertaken, sometimes combined with topical cyclosporine A [3, 38, 44]. Topical and subconjunctival fresh frozen plasma may also help in the prevention of membranes in susceptible PLG-deficient patients [42]. Therapy with intravenous infusion of lys-plasminogen was favorable in one case [34], but impossible as a long-term solution due to the short half-life of the preparation, the risk of intravascular fibrinolysis activation, and the high costs [3]. In rare cases, LC may resolve itself spontaneously [38]. Amniotic membrane transplantation is effective in some corneal and conjunctival lesions because of production of antiangiogenic and antiinflammatory proteins; Barabino and Rolando [2, 3] has proposed this as a promising therapy for LC. Although other experimented researchers [44] have not found this procedure adequate, we have had no recurrences of pseudomembranes in our patient for 39 months after amniotic membrane transplantation nor did any appear in the patient reported by Barabino and Rolando [3] for at least 3 years. Oral contraceptive therapy deserves attention as an alternative therapy in selected cases of LC [32].

In summary, the present paper, describing two cases of LC shows that LC is a rare disease characterized by wood-

like pseudomembranes developing on the ocular and extraocular mucosae secondary to PLG deficiency. Pseudomembranes are subepithelial deposits of amorphous eosinophilic material (fibrinogen) with a variable proportion of granulation tissue and inflammatory cells. The same subepithelial deposits occurred as nasal polyps and recurrent ulcers in gastric mucosa. A novel homozygous point mutation c.1856 C>T in exon 15 of the *PLG* gene was found in both patients, and amniotic membrane transplantation was done in one case with promising results.

Acknowledgment We thank Ms. Elena Couso Folgueiro for her technical assistance.

Abstract The pathogenesis of Fabry disease is poorly understood. We used a variety of immunohistological techniques to localize globotriaosylceramide, the main glycolipid that accumulates in Fabry disease. Globotriaosylceramide immunoreactivity in a heterogenous pattern was present in all organs examined of a patient on long-term enzyme replacement therapy. In the brain, immmunopositivity was found only in the parahippocampal region. Globotriaosylceramide immunostaining was present in the cell membrane and cytoplasm of endothelial cells, even in the absence of lysosomal inclusions. In kidney tissue, globotriaosylceramide colocalized with lysosomal, endoplasmic reticulum, and nuclear markers. Pre- and post-embedding immunogold electron microscopy of skin biopsies and untreated patient cultured skin fibroblasts confirmed the presence of globotriaosylceramide in the cell membrane, in various cytoplasmic structures, and in the nucleus. Control organ tissues and cultured fibroblasts from five unaffected subjects were uniformly negative for globotriaosylceramide by immunohistochemistry and immunogold electron microscopy. We conclude that a substantial amount of lysosomal and extralysosomal globotriaosylceramide immunoreactivity remains in cells and tissues even after years of enzyme replacement therapy in Fabry disease. These findings are crucial for the understanding of the disease mechanism and suggest the usefulness of immunostaining for globotriaosylceramide as a means to assess response to novel, specific therapies.

Introduction

Fabry disease, a systemic disorder caused by a deficiency of the lysosomal enzyme α-galactosidase A, results in a failure to catabolize α-D-galactosyl moieties and a systemic deposition of glycosphingolipids particularly globotriaosyl-

ceramide (Gb_3) [5]. The accumulation of Gb_3 in virtually all cell types causes a progressive disorder that consists of a painful small fiber neuropathy, cardiac disease, chronic renal insufficiency, and a high propensity for cerebrovascular strokes [6]. Gb_3 is assumed to be the main offending metabolite, although the mechanism by which its accumulation leads to the multisystem disorder of Fabry disease is not known. It has traditionally been stated that Gb_3 is stored only in lysosomes and that mechanically or by some other process these lipid-laden lysosomes cause disease [8, 15]. However, studies of the mechanisms of the vasculopathy of Fabry disease suggested increased production of reactive oxygen species invoking dysfunction of other cellular components such as endothelial nitric oxide synthase, which is associated with the cell membrane [1, 27]. Research into other lysosomal disorders pointed toward interaction of the accumulating glycosphingolipid with distinct ion channels or transporters that are mostly located in the endoplasmic reticulum (ER) [22, 34, 35, 44]. Similar interactions may occur for the accumulating substrate in Fabry disease. To gain insight into potential abnormal interactions between Gb_3 and molecular components, we studied the cellular and tissue localization of Gb_3 in patient cell culture, skin biopsies, and autopsy samples in the context of long-term enzyme replacement therapy. We hypothesized that Gb_3 is present in extralysosomal cellular compartments in Fabry disease.

Materials and methods

The study materials consisted of autopsy tissue sampled from a previously published 47-year-old patient with the classic form of the disease who died of a myocardial infarction after 2.5 years on agalsidase beta treatment (patient 1) [39]. This patient demonstrated the virtual absence of lysosomal inclusions in vascular endothelial cells. Non-Fabry autopsy control tissues from three patients who died from an acute myocardial infarction and a fourth who died from a cholecystitis and sepsis (complicated by an acute myocardial infarction) were used for immunohistochemical studies. Skin biopsies were obtained from a 28-year-old patient with the classic form of Fabry disease (patient 2) who has been treated with agalsidase alpha for 7 years at a dose of 0.2 mg/kg every 2 weeks and from a healthy control volunteer subject, and analyzed by immumohistochemisty and immunogold electron microscopy. Immunohistochemistry of cultured skin fibroblasts from two patients with classical Fabry disease (patients 2 and 3) and healthy controls were also studied. All subjects who had skin biopsies gave their written informed consent on a study protocol approved by the institutional review board of the National Institute of Neurological Disorders and Stroke.

Light microscopy

Formalin-fixed sections (5 μm thick) were stained with hematoxylin and eosin, Luxol fast blue, and toluidine blue. A pair of slides were selected from each organ for Gb_3 immunohistochemistry. Slides were deparaffinized, rehydrated, and then quenched at room temperature for 30 min in 0.03% hydrogen peroxide. All slides were then washed for 5 min in phosphate-buffered saline (PBS), immersed in 2.5% Horse serum (Vector Laboratories, Burlingame CA) for 20 min, incubated with anti-Gb_3 monoclonal antibody (1:400 in PBS, Seikagaku, Tokyo, Japan, clone BGR-23 [19]) washed for 5 min with PBS, and incubated with ready-to-use secondary antibody (Vectastain kit, Vector Laboratories). Adjacent sections were stained with the secondary antibody only. Slides labeled with the secondary antibody were washed with PBS for 5 min and incubated with avidin/biotinylated horseradish peroxidase (Elite Rabbit IgG Vectastain ABC kit,PK-6101,Vector Laboratories). 3,3′-Diaminobenzidine tetrahydrochloride was used as chromogen and hematoxylin was used as counterstain.

Immunostaining of cultured cells

Cultures of primary skin fibroblasts were derived from explant cultures of skin biopsies taken from patients affected with Fabry disease who have α-galactosidase A mutations K240X or R356W. The cells were maintained in antibiotic-free Alpha-Minimum Essential Medium culture medium (Invitrogen, Carlsbad, CA) supplemented with 10% cosmic calf serum (Hyclone, Logan, UT). Cells were used for staining before the tenth passage.

For immunolocalization studies by light microscopy, fibroblasts were seeded on 12-mm glass coverslips in growth medium and cultured until confluent (7 days). Cells were fixed with 2% paraformaldehyde for 20 min, incubated with blocking buffer (2% bovine serum albumin [BSA] in PBS) for 60 min at room temperature, and then incubated overnight at 4°C with anti-Gb3 mouse monoclonal antibody (Seikagaku America, Falmouth, MA; 1:200 in blocking buffer). After extensive washing, antibody binding was visualized by incubating the coverslips with Alexa 594-labeled goat anti-mouse IgG antibody (1:200 in blocking buffer) for 30 min at room temperature. The coverslips were washed and mounted on glass slides with FluorSave mounting medium (Calbiochem, San Diego, CA). Samples were imaged with a 40× objective and using a rhodamine filter set (excitation 546/emission 590) on a Zeiss Axioplan fluorescent microscope equipped with a Spot RT Slider digital camera.

For immunostaining and immuno-electron microscopy, Fabry or normal fibroblasts were seeded on glass 12-mm-

diameter glass coverslips in the growth medium and incubated for 3 days without additional feeding.

Immunogold electron microscopy

Pre-embedding and post-embedding techniques were used on different samples from the same subjects.

Pre-embedding technique Skin biopsy or cell culture material was immersion fixed in freshly made 4% paraformaldehyde in PBS for 1–12 h. Then, biopsies were cut with a vibratom (100-μm-thick slices) and fixed with 4% glutaraldehyde in 0.1 N sodium cacodylate buffer overnight for electron microscopic examination or processed for pre-embedding immunogold labeling. The immuno-labeling procedure was done as previously described [43] with steps carried out at room temperature unless otherwise indicated. Briefly, vibratomed slices were washed in PBS, blocked, permeablized with saponin (0.1% in PBS with 5% normal goat serum) for 1 h, treated with mouse anti-Gb_3 monoclonal antibody (1:400; Seikagaku America) for 1–2 h, washed, treated with secondary antibody conjugated with 5-nm gold particles (Nanogold from Nanoprobes, 1:250, Yaphand, NY) for 1 h, and silver enhanced for 10–20 min with the HQ kit from Nanoprobes. Slices were then treated with 0.2% OsO_4 in phosphate buffer for 30 min, mordanted en bloc with 0.25% uranyl acetate overnight at 4°C, dehydrated with ethanol, and flat embedded in epoxy resin. Thin sections were counterstained with uranyl acetate and lead citrate.

Post-embedding technique Each skin biopsy (Fabry and control) was fixed in glutaraldehyde (2.5% in PBS 0.1 M pH 7.3, overnight), dehydrated in a graded series of increasing ethanol concentrations, and embedded in Spurr low-viscosity epoxy using flat molds at 70°C for 18 h. Semi-thin sections (0.5 μm) were stained with 1% toluidine blue and then sectioned (500–700 Å) and placed on square mesh nickel (300 mesh), thin-bar, high-definition grids for the post-embedding immunogold reaction [3, 30, 41]. For antigen retrieval, grids were immersed in sodium citrate (0.1 M, pH 6.0, 95°C, 10 min), washed, and incubated with blocking solution (1% BSA in 0.1 M PBS, with 0.05% Tween 20) for 30 min at room temperature [42]. Sections were incubated with mouse anti-Gb_3 monoclonal antibody (1:200 in PBS) for 90 min at room temperature, washed, and incubated with a secondary goat anti-mouse antibody labeled with 15-nm gold particles or protein A polygold 15 nm (1:25 dilution of blocking solution Polysciences, Warrington, PA) for 1 h at room temperature. After an additional wash, sections were stained with uranyl acetate in distilled water for 20 min. Samples incubated with PBS instead of the first antibody (mouse anti-Gb_3) were used as controls. Samples were analyzed using a Philips CM100 EM electron microscope at 80 kV from the Biomedical Instrumentation Center, Uniformed Services University of the Health Sciences.

Immunofluorescence staining

Paraffin sections were melted (60°C), hydrated, and then put in Tris–ethylenediamine tetraacetic acid (EDTA) buffer PT Module™ Buffer 4 (100× Tris–EDTA Buffer, pH 9.0) TA-050-PM4X (Lab Vision, Fremont CA) for antigen retrieval. Sections were then rinsed once in 1× Tris-buffered saline (TBS) Tween (Lab Vision) for 5 min and incubated in peroxidase block (Biocare Medical, Concord, CA) for 15 min followed by a rinse in TBS Tween for 5 min. Sections were blocked using Background Sniper (Biocare Medical, Newport Beach, CA) for 15 min followed by incubation with the primary monoclonal antibody marker of lysosomes (anti-lysosome-associated membrane protein 1, BD Biosciences, San Jose CA) diluted in DaVinci Green (Biocare Medical) for 2 h at room temperature or overnight

Table 1 Results of immunohistochemical staining with anti-Gb_3 antibody viewed by light microscopy

Tissue	Region	Gb_3 detected	
		Fabry	Normal
Heart	Myocardium	Yes	No
	Endocardium	Yes	No
	Coronary arteries	Yes	No
	Intracardiac nerves	Yes	No
	Vasanervorum	Yes	No
Kidney	Distal tubules	Yes	No

ND Not done

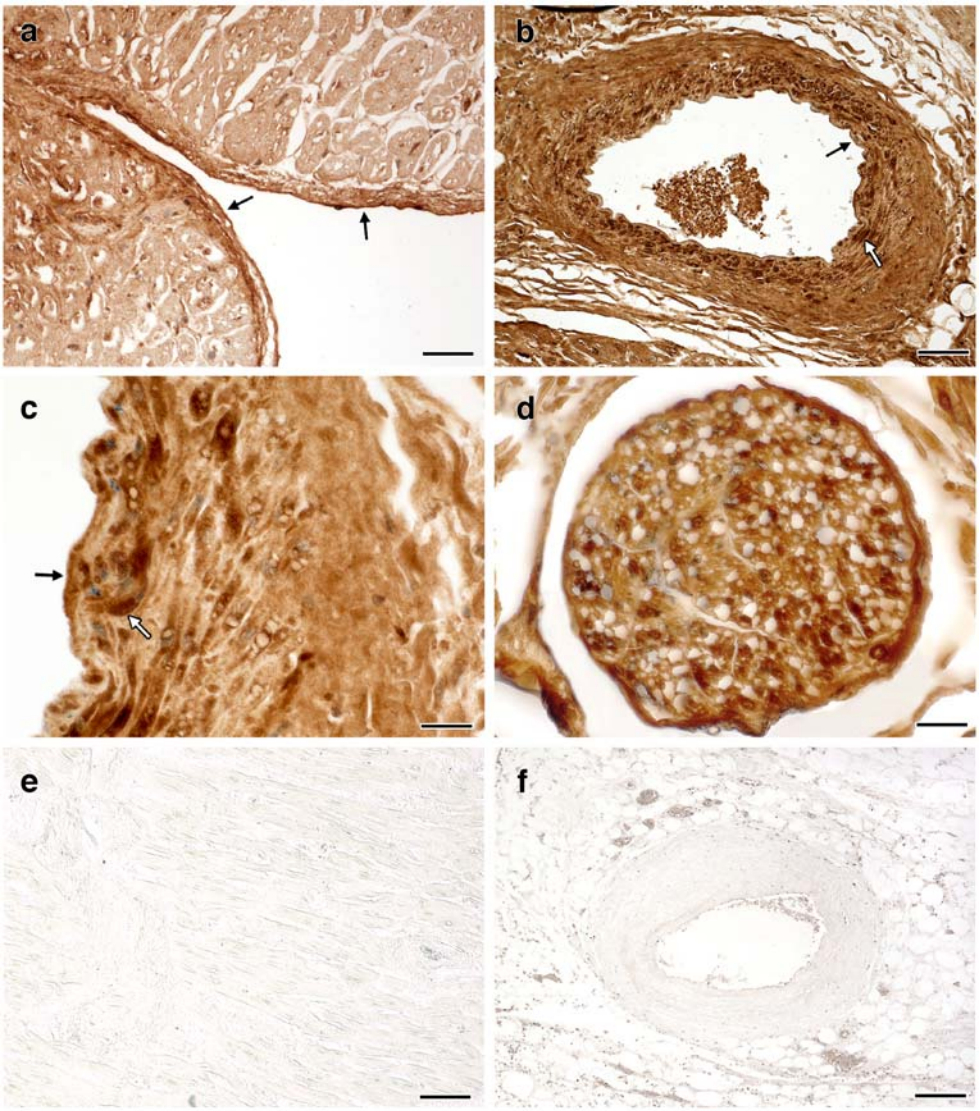

Fig. 1 Gb_3 immunohistochemistry in the heart of Fabry patient 1 shows extensive staining of the coronary artery, myocardium, and endocardium as well as intravascular and intracardiac nerves but no staining in normal tissue. **a** Staining of the myocardium and endocardium (*arrows*, original magnification 20×, *scale bar*=50 μm). **b** Coronary artery showing endothelial (*black arrow*) and vessel wall staining (*white arrow*, original magnification 10×, *scale bar*=100 μm). **c** Higher magnification of the same coronary vessel wall (original magnification 40×, *scale bar*=25 μm). **d** Staining of an intracardiac nerve showing Gb_3 in Schwann cells and endoneurium (original magnification 40×, *scale bar*=25 μm). **e** Staining or Gb_3 staining in a non-Fabry patient's heart with a myocardial infarction shows no reactivity (original magnification 10×, *scale bar*=100 μm). **f** Absence of staining of a coronary artery in a non-Fabry patient (original magnification 5×, *scale bar*=200 μm)

at 4°C. After three 5-min rinses in TBS Tween, slides were incubated in Envision secondary anti-mouse/rabbit (Perkin Elmer, Wellesley, MA) for 1 h at room temperature and then treated with Cy3 tyramide (1:50 in amplification buffer, Perkin Elmer) for 10 min. Subsequently, this procedure was repeated with a cocktail of primary antibodies for Gb_3 (Seikagaku Corp, 1:400) and anti-calreticulin (Stressgen, San Diego, CA) in DaVinci Green and incubated for 2 h at room temperature or overnight at 4°C. Slides were then incubated in Alexa Fluor secondary antibody (Molecular Probes, Carlsbad, CA) diluted in Envision mouse/rabbit (Perkin Elmer) for 1 h in the dark treated with Cy5 tyramide (1:50 in amplification buffer) for 10 min, mounted with Prolong anti-fade with diamidinophenylindole (Invitrogen), and allowed to dry overnight.

Results

Immunohistochemistry for Gb_3 in normal and Fabry patient 1 tissues

Results are summarized in Table 1. The strongest staining for Gb_3 was present in the heart and the kidney of the Fabry patient (Figs. 1 and 2). A diffuse pattern of Gb_3 staining was observed in the myocardium and endocardium, even in the absence of visible inclusions (Fig. 1a). Coronary arteries showed a strong endothelium staining pattern with virtually every cell in the vessel wall staining positive for Gb_3 (Fig. 1b,c). Intracardiac nerves and vasa-nervorum fibers stained positive in a heterogeneous pattern (Fig. 1d). No Gb_3 staining was seen in the myocardium

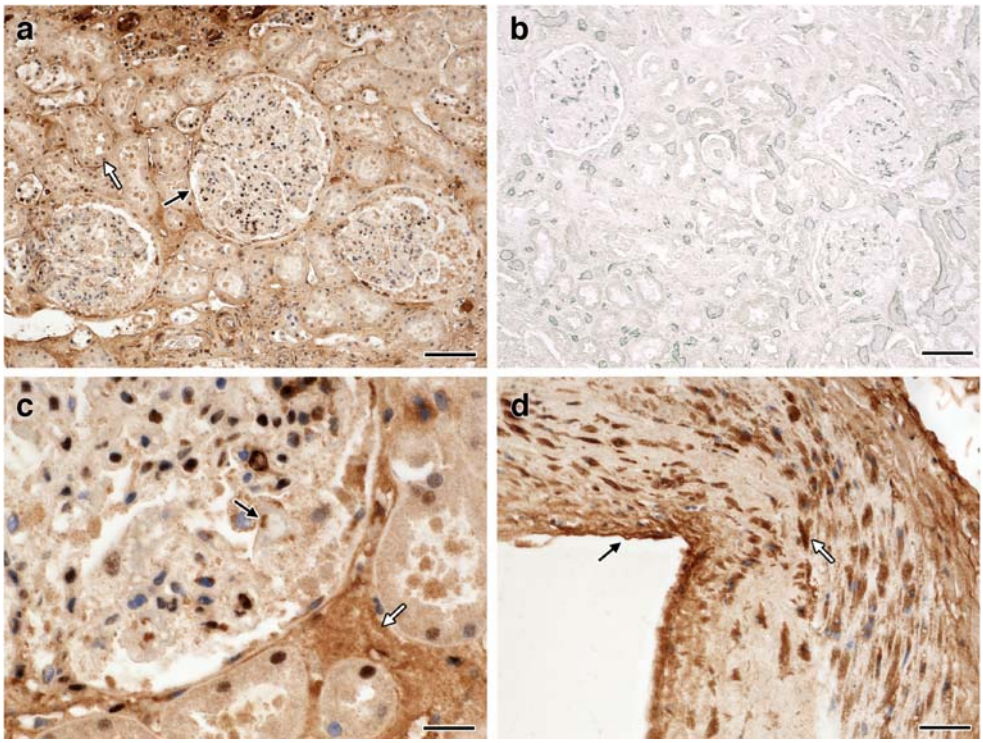

Fig. 2 Gb_3 staining in the kidney of Fabry and non-Fabry subjects showing variable immunopositivity in virtually all cell types (patient 1). **a** A glomerulus (*black arrow*) surrounded by tubules (*white arrow*, original magnification 10×, *scale bar*=100 μm). **b** No positive immunostaining for Gb_3 seen in a kidney of a non-Fabry control patient (original magnification 10×, *scale bar*= 100 μm). **c** A higher magnification of one glomerulus in the same field showing staining in a capillary endothelial cell or podocyte (*black arrow*) and interstitium (*white arrow*, original magnification 40×, *scale bar*= 25 μm). **d** A small renal artery showing Gb_3 immunostaining in endothelial cells (*black arrow*) and smooth muscle cells (*white arrow*, original magnification 20×, *scale bar*=50 μm)

(Fig. 1e) and coronary arteries (Fig. 1f) of a non-Fabry control. In non-Fabry controls, there was no difference in staining between sections with anti-Gb_3 and those when the secondary antibody only was used (data not shown). Gb_3 staining was present throughout the kidney of the Fabry patient but to a variable degree. Renal tubuli and most or all glomerular cells were immunopositive (Fig. 2a, c), although staining was relatively weak, while no Gb_3 could be detected in the normal control kidney (Fig. 2b). Interstitial kidney tissue (Fig. 2c) and renal blood vessels, including the endothelial cells, also stained positive for Gb_3 (Fig. 2d),

The areas of the brain we studied were largely negative for Gb_3. Staining was positive almost exclusively in the meningeal, meningothelial, and cerebral blood vessels (Fig. 3a–c). Neuronal staining was detected only in the parahippocampal gyrus (Fig. 3e) while no Gb_3 immunostaining was present in the non-Fabry brain (Fig. 3f).

In the adrenal gland, immunostaining for Gb_3 was present in the vasculature of the adrenal gland capsule (Fig. 4a), glomerulosa (Fig. 4c,e,f), and reticularis (Fig. 4h), but almost no staining was observed in the fasciculata region of the adrenal gland cortex (Fig. 4g). In the glomerulosa, Gb_3 stained distinct round structures that resemble lipid vacuoles (Fig. 4e,f). Heterogeneous staining was present in the adrenal medulla of the Fabry patient (Fig. 4i,j). No staining was seen using the secondary antibody only (Fig. 4b,d).

Subcellular localization of Gb_3

To identify the subcellular localization of Gb_3 in kidney cells from Fabry subjects, Gb_3 was colocalized with a combination of markers specific for the ER, lysosomes, and nucleus in a section of kidney tissue from patient 1 (Fig. 5a–j). We found that Gb_3 partially colocalizes with lysosomal, ER, and nuclear markers in renal cells of the Fabry patient (Fig. 5a–j). Staining for Gb_3 was much stronger in the patient compared to normal non-Fabry control (Fig. 5k,l).

We further studied Gb_3 localization in the skin. Using light microscopy; immunopositivity for Gb_3 was found mainly in the dermal blood vessels of patient 2 (Fig. 6a–c). Typical lysosomal inclusions were only detected in a small number of skin blood vessels (Fig. 6d), as detected by toluidine blue staining. However, pre- and postembedding immunogold electron microscopy showed Gb_3 labeling in a number of cellular areas, including lysosomal and non-lysosomal membrane structures, seemingly not membrane associated and in the nucleus (Fig. 6e–g). No labeling was present in normal control skin (Fig. 6h). Gb_3 immunogold

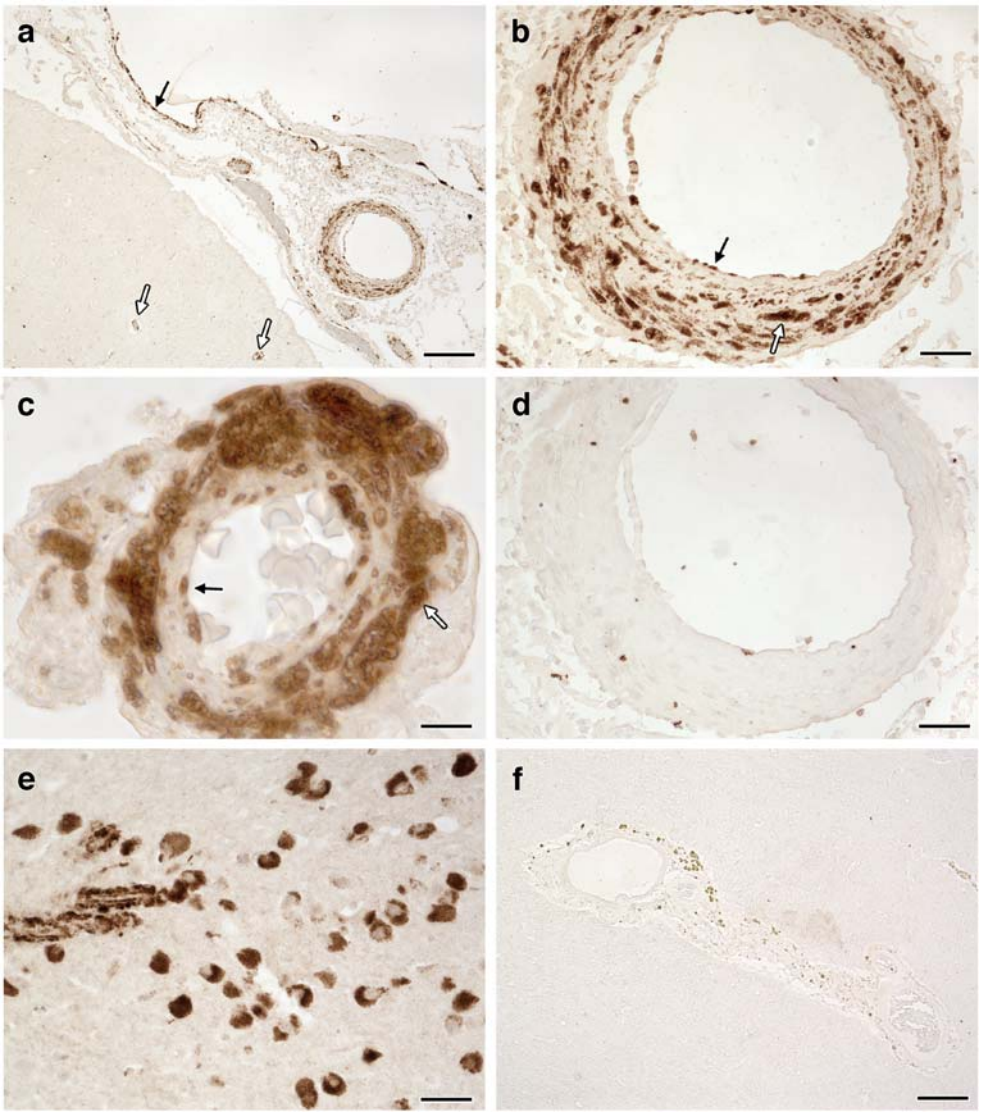

Fig. 3 Gb_3 staining of the brain of Fabry patient 1. **a** Brain and meninges of the Fabry patient includes staining of leptomeningeal membrane (*black arrow*) and parenchymal capillaries (*white arrows*, original magnification 5×, *scale bar*=200 μm) **b** A higher magnification of a meningeal artery showing endothelial (*black arrow*) and smooth muscle cell staining (*white arrow*, original magnification 20×, *scale bar*=50 μm). **c** A high magnification of a small intracerebral blood vessel showing staining in endothelial cells (*black arrow*) and smooth muscle cells (*white arrow*, original magnification 100×, *scale bar*= 10 μm). **d** Secondary antibody only of the image in **b** (*scale bar*=50 μm). **e** Parahippocampal gyrus showing Gb_3 neurons (original magnification 20×, *scale bar*=50 μm). **f** Normal brain immunostained for Gb_3; only hemosiderin pigments are seen around a blood vessel (original magnification 5×, *scale bar*=200 μm)

labeling was present even in capillaries devoid of lysosomal inclusions with toluidine blue staining (Fig. 6i).

Cultured skin fibroblasts showed variable staining by light microscopy (Fig. 7a) and also showed immunogold labeling of Gb_3 in cytoplasmic vacuoles, lamellar bodies, plasma membrane, and within the nucleus (Figs. 6f and 7b–d). Again, normal cultured fibroblasts from a non-Fabry subject showed no Gb_3 labeling (Fig. 7e).

Discussion

Using various forms of immunodetection, this study demonstrates that in Fabry disease, Gb_3 is not only present in lysosomes but is rather widely distributed in other cellular structures including the ER, cell membrane, and nucleus. Such distribution of Gb_3 was observed in cultured skin fibroblasts from patients with the classic form of the disease as well as in organs of patients on long-term enzyme replacement therapy, even in cells that were free of classic lysosomal inclusions [39]. Enzyme replacement therapy in Fabry disease has been shown to slow the progression of kidney disease and improve peripheral nerve function and sweating [2, 38, 40]. Another remarkable feature is the heterogeneity of Gb_3 distribution and accumulation at the organ, cellular, and subcellular levels. Although immunohistochemistry is not typically quantitative, the most intense staining was observed in the heart and kidney, organs that are known to accumulate the greatest amounts of Gb_3 [25, 37]. Among specific organs/tissues

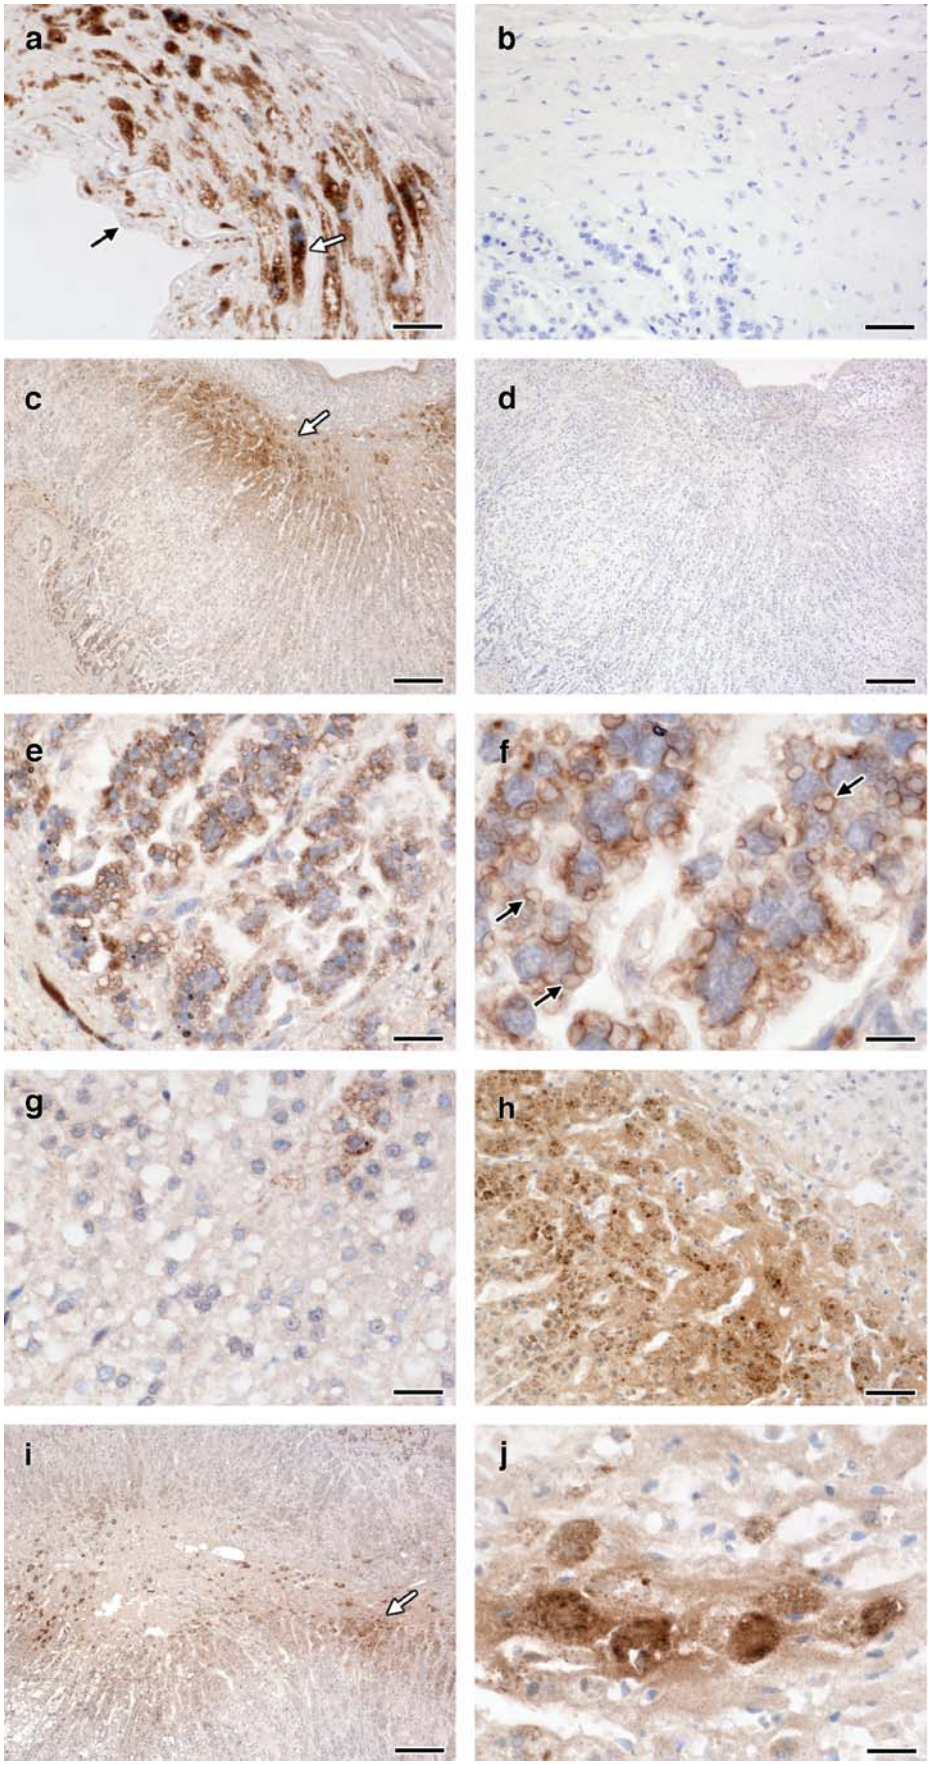

Fig. 4 Staining for Gb_3 in the adrenal gland of patient 1 on ERT for 2.5 years and a non-Fabry control. **a** Capsular artery showing endothelial (*black arrow*) and smooth muscle staining (*white arrow*, original magnification 40×, *scale bar*= 25 μm). **b** Adrenal gland capsule with secondary antibody only (original magnification 20×, *scale bar*=50 μm). **c** Overview of the capsule and the glomerulosa region (*arrow*) of the adrenal gland cortex (original magnification 5×, *scale bar*=200 μm). **d** Adrenal cortex with secondary antibody only (original magnification 5×, *scale bar*=200 μm). **e** Glomerulosa region of adrenal cortex (original magnification 40×, *scale bar*=25 μm). **f** Higher magnification of glomerulosa region with staining of round intracellular structures (*arrows*, original magnification 100×, *scale bar*= 10 μm). **g** Fasciculata adrenal cortical region (*arrows*, original magnification 40×, *scale bar*= 25 μm). **h** Adrenal reticularis showing greater Gb_3 staining than the fasciculate adrenal cortical region (original magnification 20×, *scale bar*=50 μm). **i** Overview of adrenal medulla (*arrow*) showing greater Gb_3 than surrounding areas (original magnification 5×, *scale bar*= 200 μm). **j** Higher magnification of medulla (original magnification 40×, *scale bar*=25 μm)

These two images were obtained using the same conditions. The images were acquired at 40× using the PM-2000™ and AQUA® technology

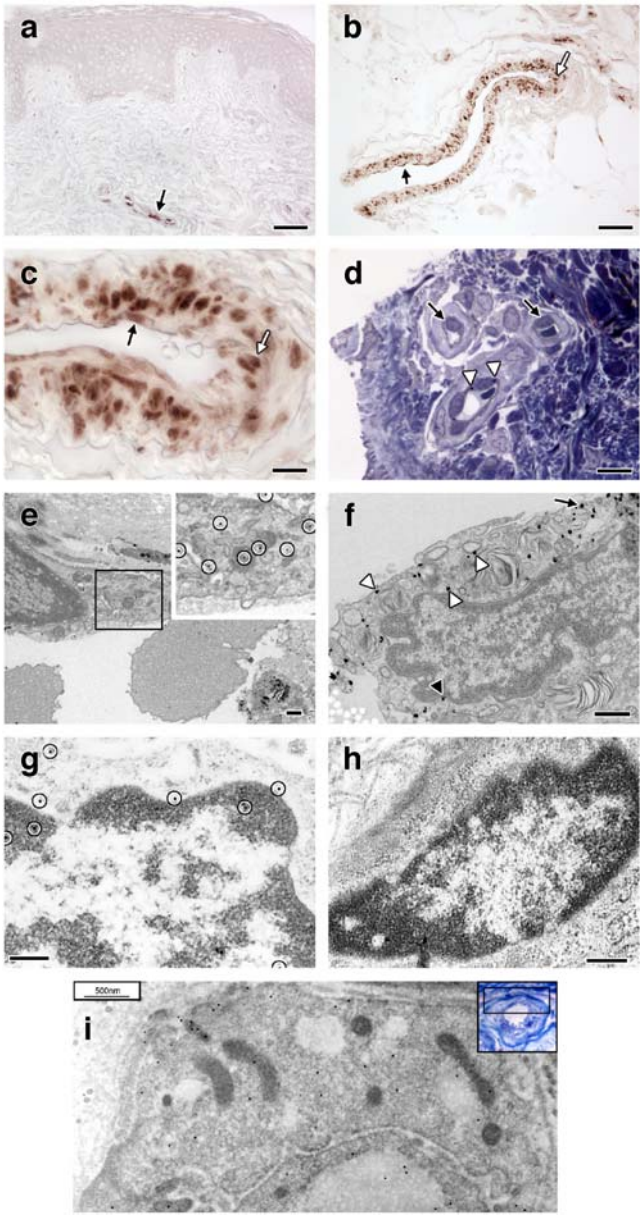

Fig. 6 Gb_3 immunolocalization in the skin of Fabry (patient 2) and non-Fabry subjects. **a** Overview of skin biopsy showing staining of dermal blood vessels (*arrow*, original magnification 20×, *scale bar*= 50 μm). **b** A dermal arteriole with endothelial (*black arrow*) and smooth muscle staining (*white arrow*, original magnification 20*arrow*50 μm). **c** Details of the same arteriole (original magnification 100×, *scale bar*=10 μm). **d** 1-μm section of skin stained with toluidine blue showing dermal vessels. Two capillaries have no lysosomal inclusions (*arrows*) while another capillary has two inclusions (*arrowheads*; original magnification 100×, *scale bar*= 10 μm). **e**, **f** Pre-embedding immunogold electron microscopy for Gb_3. **e** Labeling of a dermal blood vessel using 5-nm gold particles (19,000×, *scale bar*=500 nm). *Digital insert*: *black circles* surround gold particles. **f** A dermal fibroblast showing labeling of the cell membrane (*arrow*), cytoplasmic structures (*white arrowhead*), and probably the nuclear membrane (*black arrowhead*, 38,000×, *scale bar*=500 nm). **g**–**i** Post-embedding immunogold labeling for Gb_3. **g** Fibroblast showing labeling of the nucleus, associated preferentially with heterochromatin fibrils (39,000×, *scale bar*=266 nm). **h** Normal control skin fibroblast showing no labeling (17,000×, *scale bar*= 500 nm). **i** Dermal capillary endothelial cell with no lysosomal inclusions on toluidine blue staining (*insert*) is labeled for Gb_3 throughout the cell (21,000×)

such as arteries or the adrenal gland, staining patterns were especially heterogeneous. Staining of vascular endothelial cells varied from cell to cell. In the adrenal gland cortex, staining of cells within the glomerulosa region produced a specific intracellular vacuolar-like pattern while Gb_3 immunoreactivity was diffuse in reticulata cells. This heterogeneity suggests that the various cellular metabolic needs, including possibly the cell cycle stage, interact differently with the α-galactosidase A-deficient state. The finding of Gb_3 immunoreactivity only in the parahippocampal region

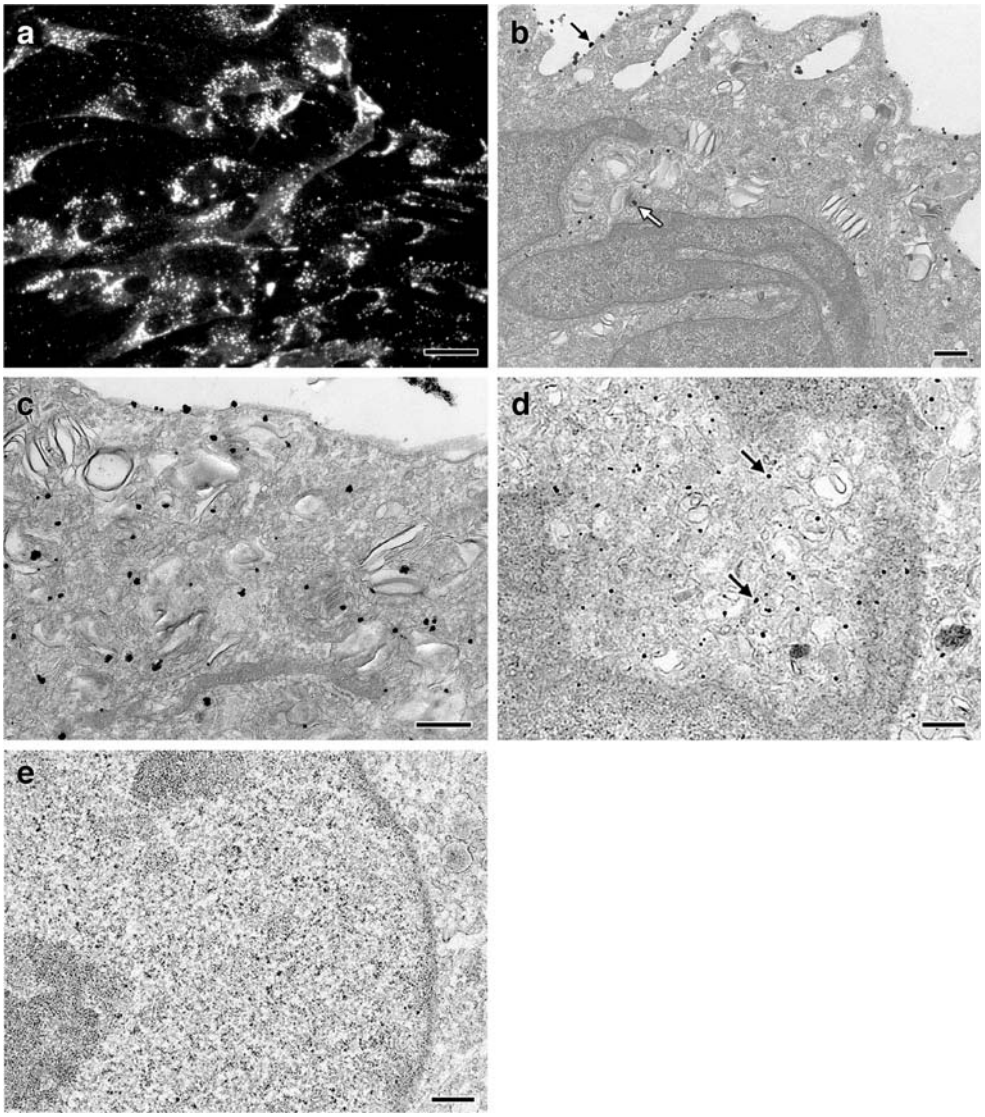

Fig. 7 Gb_3 immunolocalization in the skin of Fabry and non-Fabry subjects. **a** Light microscopic image of cultured fibroblasts from patient 3 showing cell-to-cell variation in immunoreactivity (40×, *scale bar*= 25 μm). Immunogold electron microscopy using the pre-embedding technique of cultured cells of patient 2. **b** A cell showing membranous (*black arrow*) and cytoplasmic labeling (*white arrow*, original magnification 4,000×, *scale bar*= 500 nm). **c** A higher magnification showing labeling of the cell membrane and various cytoplasmic structures (10,000×, *scale bar*=500 nm). **d** Membranous cytoplasmic (*arrows*) and nuclear labeling in another fibroblast (6,000×, *scale bar*= 500 nm). **e** Nucleus of a normal cultured fibroblast showing no Gb_3 labeling (6,000×, *scale bar*=500 nm)

fits well with previous quantitative analysis of this glycolipid in various brain regions showing marked regional heterogeneity [17].

In this study, we used a monoclonal antibody against Gb_3 that has been extensively characterized and used in a number of publications [9, 13, 16, 19, 36]. While this may be the first detailed study into the extralysosomal localization for Gb_3 in Fabry patients, examination of previously reported electron microscopy photographs support our current findings [16]. Although a difference in technique can account for the different findings, examination of previously reported immuno-electron microscopy photographs suggests extralysosomal labeling. Similarly, inspection of images published in an ultrastructural lectin histochemical analysis shows rather extensive labeling of Gb_3 in a number of cellular structures including the mitochondria [15]. Gb_3 has also been detected on the surface of vascular endothelial cells [33] and erythrocytes and has been described as a P^k blood group antigen [24]. Gb_3 is present in normal human cells [29]; therefore, the absence of immunopositivity in non-Fabry tissue likely reflects the relative insensitivity of the anti-Gb_3 antibody we used. For example, another possibly more sensitive but also somewhat less specific monoclonal antibody has been shown to identify Gb_3 in a variety of normal tissues including the kidney, stomach, and vascular endothelial cells [31].

The propensity of Gb_3 to localize in the cell membrane and nucleus in Fabry disease may be related to its physiologic function [21] or to unknown biological functions. The subcellular pattern of Gb_3 localization in cells from patients with Fabry disease could be a result of

retrograde transport from the lysosome to the ER, plasma membrane, and nucleus [20]. Studies with verotoxin have demonstrated that Gb_3 can be distributed throughout the cell via retrograde transport. Gb_3 is a receptor (also known as CD77) for verotoxin at the cell surface of certain B cells present in the germinal center of lymph nodes [12]. In such CD77+ lymphocytes, Gb_3 appears to be critical for both the receptor-mediated endocytosis and the transport to the nucleus of the CD19 protein, as well as for its ability to induce increased production of reactive oxygen species and apoptosis [18, 45]. Gb_3 is also an antigenic target of natural killer cells in antimicrobial defense, as an alternative to lipopolysaccharide for innate recognition [23].

It is likely that Gb_3 disrupts biological interactions by interacting with other lipids or proteins or by altering the composition of lipid rafts (or microdomains) and endocytic trafficking [32]. For example, the enhanced atherosclerosis in apoE knockout mouse is associated with a marked increase in Gb_3 [11]. This atherosclerotic process is further enhanced when α-galactosidase A is also deficient [4]. In cells from Gaucher, GM1 gangliosidosis, and GM2 gangliosidosis, it has been demonstrated that accumulation of glycosphingolipids in the ER disrupt specific Ca^{2+} homeostatic mechanisms [34, 35, 44], further supporting the existence of glycosphingolipid trafficking between the organelles of the endosomal pathways and the ER [10]. Increasing evidence suggests that ganglioside accumulation is a stress inducer resulting in ER stress and mitochondria-elicited cell death pathways [7]. Gangliosides or other glycoshingolipids were immunolocalized in cellular regions outside of the primary storage material in the mucopolysaccharidoses suggesting that they are extralysosomal in nature [47]. Additionally, GM2 ganglioside has been shown to be associated with the presence of ectopic dendrites in the cerebral cortex [46]. In Fabry disease, there is a suggestion that the clinical abnormalities are caused by perturbations of extralysosomal functions. Excess amounts of Gb_3 in the cell membrane may interfere with the function of caveolae/rafts that are known to contain glycosphingolipids and a number of important signal transduction proteins such as endothelial nitric oxide synthase (eNOS) [26]. There is evidence of increased reactive oxygen species in Fabry disease, possibly in relation to eNOS [1, 4, 27], as well as an abnormality of the fibrinolytic system [28].

This study has demonstrated that Gb_3 accumulates in nonlysosomal cellular compartments and membranes and that further studies are needed to investigate the natural functions of Gb_3 as well as the mechanisms of toxicity associated with its accumulation. In addition to helping us understand the pathogenesis of Fabry disease, the cellular localization of Gb_3 may be a clinical outcome measure to assess the effect of novel therapies that are designed to further reduce the amount of Gb_3 in Fabry disease [14].

Acknowledgments We thank the NINDS EM facility for expert technical help in the pre-embedding immunogold technique. This study was funded by the Intramural Program of the National Institute of Neurological Disorders and Stroke and the National Cancer Institute. The authors do not have financial conflict of interest that is relevant to this study. Dr. Brandon A. Wustman is employed by Amicus Therapeutics that develops pharmacological chaperones for the treatment of lysosomal diseases.

CASE REPORT

Primary epithelioid sarcoma of the oesophagus

Francesca Maggiani · Maria Debiec-Rychter · Nadine Ectors · Antoon Lerut · Raf Sciot

Received: 13 March 2007 / Revised: 22 May 2007 / Accepted: 3 June 2007 / Published online: 12 July 2007

Abstract Epithelioid sarcoma is a rare soft tissue tumour presenting two main variants: the 'classical' distal type and the more recently described proximal type. The latter is distinguished from the former by occurrence in elderly patients, more axial and deep location, prominent atypical and pleomorphic appearance and eventually aggressive clinical behaviour with poor outcome. To date, only few perivisceral epithelioid sarcomas have been described, and they are mainly related to the colon and bladder in pelvic and perineal sites. We report a hitherto undescribed epithelioid sarcoma of the distal oesophagus and discuss the relevance of molecular cytogenetics.

Introduction

Epithelioid sarcoma is an uncommon mesenchymal tumour of unknown histogenesis with a predominant epithelial differentiation, showing reactivity for both epithelial and mesenchymal markers, such as cytokeratin, epithelial membrane antigen (EMA), vimentin and CD34. The 'classical' epithelioid sarcoma, first described as a distinct clinicopathological entity by Enzinger in 1970 [2], usually occurs in the distal extremities of young adults, mainly in the hand and around the wrist and presenting as a slowly progressive, solitary or multinodular tumour with a superficial or subcutaneous location and frequently associated with ulceration of the overlying skin. Three morphological variants are recognized: the more common granuloma-like, a fibroma-like and an angiomatoid-like variant. In 1992, a clinically more aggressive entity, the large-cell 'proximal type' epithelioid sarcoma has been described by Guillou et al. [3], which differs from the 'classical type' by a multinodular growth pattern, a more proximal/axial distribution and a deep seated location, mainly but not exclusively involving the pelvic, genital and perineal area in elderly patients [4]. It is not well known if the reduced survival of this type is more related to the histotype by itself or to the lesser resectability because of the deeper location, the proximal distribution and/or the bigger size at the diagnosis. Microscopically, this proximal type consists of a proliferation of large epithelioid cells with copious eccentric cytoplasm, arranged in multiple nodules. Tumoural necrosis is a common finding but usually without the granuloma-like aspect.

We report a hitherto undescribed case of epithelioid sarcoma arising at the gastro-oesophageal junction and infiltrating the visceral wall, with multiple local lymph node metastases. Because visceral locations have not been reported, the diagnostic value of molecular cytogenetics is highlighted.

Clinical features

A 64-year-old man presented with a painful, ulcerating, not-obstructive lesion of the gastro-oesophageal junction, measuring 5×3 cm at endoscopic examination. Magnetic resonance imaging showed enlarged lymph nodes at the hepatophrenic, hepatogastric and oesophagophrenic ligaments. A staging laparoscopy was performed, and one of the oesophagophrenic lymph nodes was removed for histological examination. In addition, a partial oesophagogastrectomy with local and regional lymph node dissection was performed.

Materials and methods

A part of the samples was snap frozen in liquid nitrogen-cooled isopentane, while the largest part was fixed in 4% formalin followed by conventional processing and embedding in paraffin wax. Sections were cut and stained with haematoxylin and eosin. Immunohistochemical stainings were performed with a panel of antibodies using the avidin–biotin peroxidase complex technique. The antibodies used include anti-epithelial membrane antigen (EMA; DAKO, Glostrup, Denmark, dilution 1:50), Prekeratin (Serotec, Oxford, UK, dilution 1:200), Keratin AE1/AE3 (Forlab, Brussel, Belgium, dilution 1:100), carcinoembryonic antigen (CEA; DAKO, dilution 1:1000), Chromogranin (DAKO, dilution 1:200), S-100 protein (DAKO, dilution 1:300), CD34 (Becton Dickinson, Franklin Lakes, NJ, dilution 1:10), CD31(DAKO, dilution 1:1000), CD30 (DAKO, dilution 1:20), CD45 (DAKO, dilution 1:500), HMB45 (DAKO, dilution 1:1000) and beta-catenin (Santa Cruz Biotecnology, Santa Cruz, CA, dilution 100).

Chromosome preparation of tumour cells was obtained after an overnight culture of the lymph node metastatic lesion. G-Banded chromosomes were evaluated and classified according to the International System for Human Cytogenetic Nomenclature (2005). Fluorescence in situ hybridization (FISH) utilizing either biotin- or digoxigenin-labelled BAC's RP11-742c19 and RP11-71G19 deoxyribonucleic acid probes, specific for the *PDGFB*/22q13 and *SMARC-B1*/22q11.2 genes, respectively, was performed on frozen sections of tumour specimen according to standard procedures.

Results

Gross pathology

At the level of the gastro-oesophageal junction, along the small curve, a nodular haemorrhagic and necrotic mass was observed. The cut surface showed a 5-cm greyish white nodule extensively infiltrating the muscularis propria, without evident serosal involvement. In addition, a 4-cm-large lymph node adhering to the stomach wall was reported (Fig. 1).

Light microscopy

Microscopically, the tumour was composed of a multinodular proliferation of large polygonal cells mainly arranged in discohesive sheets, merged with necrotic areas and inflammatory cells. The neoplasia infiltrated the mucosa, submucosa and muscularis propria and subserosa. Prominent perineural invasion was seen but no evidence of vascular invasion. The neoplastic cells showed an abundant, often eccentric eosinophilic cytoplasm, with well-defined cellular margins. The nuclei were atypical, vesicular and characterized by prominent, central nucleoli (Fig. 2a). Brisk mitotic activity and numerous apoptotic figures were easily observed (37 mitoses/10 high power fields). The residual mucosa did not display any signs of atypia (Fig. 2b). Immunohistochemical stainings showed positivity for EMA and beta-catenin and no reactivity for the other antibodies. The enlarged local lymph nodes

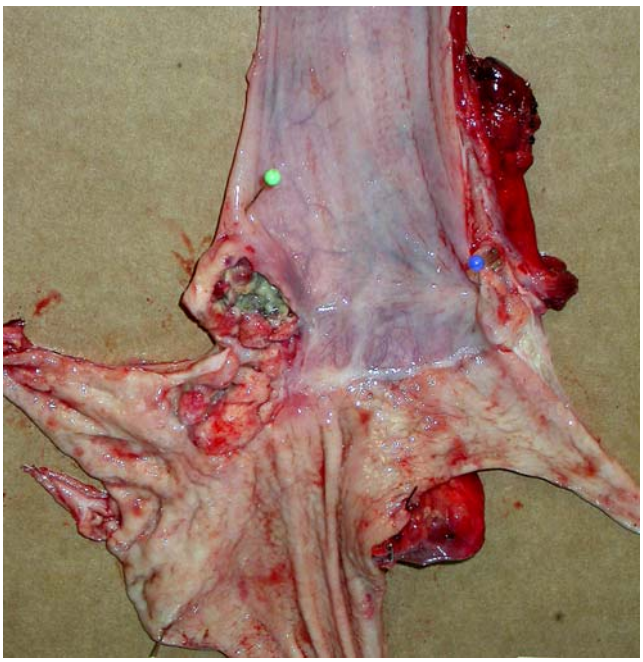

Fig. 1 Evidence of the tumour on the surgical specimen

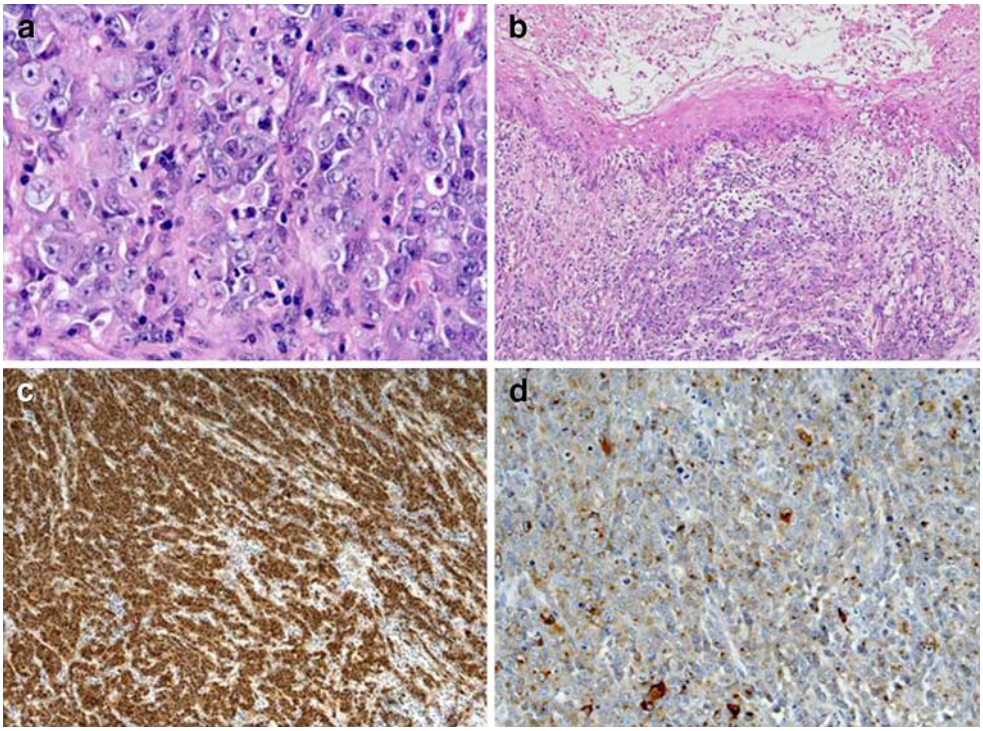

Fig. 2 **a** Neoplastic cells showing large vesicular nuclei, prominent nucleoli and brisk mitotic activity. **b** Tumour cells intermingled with inflammatory cells, infiltrating the mucosa, the epithelium of which shows no signs of atypia. **c** Diffuse positivity to beta-catenin immunostaining. **d** Focal positivity to EMA immunostaining

contained metastatic disease, whereas no peripheral nodal metastases were documented.

Cytogenetic analysis

Cytogenetic analysis revealed 45–46,XY,t(9;13)(p22;q34),-22[3][cp6]/46,XY[11] karyotype (data not shown). Dual-color interphase FISH analysis showed loss of *SMARC-B1*/22q11.2 in reference to control *PDGFB*/22q13 loci in 87% of nuclei (Fig. 3), with 31% cells showing nullisomy for the *SMARC-B1* gene.

Discussion

Epithelioid sarcoma is an uncommon malignant neoplasia of soft tissue with unknown lineage, characterized by a local recurrence rate of up to 70% and a median time to recurrence after surgery ranging from 6 to 82 months [10]. It often culminates in regional lymph nodes or lung metastases, occurring in up to 45% of patients [10]. Nevertheless, an overall 5-year survival up to 70% is reported.

The more common sites reported so far are distal extremities for the classical 'distal' type and proximal extremities or limb girdles for the 'proximal' variant. Chest wall, trunk, back and perineum have been reported as possible locations for the latter, more aggressive type, but no visceral primary tumour has been described so far.

The morphology of the reported lesion was in agreement with the features of epithelioid sarcoma, either the nodular pattern or the epithelioid/rhabdoid-like cells nests alternating with necrotic areas, but the gastrointestinal location associated with the lymph node involvement and the nodular appearance prompted more common diagnoses,

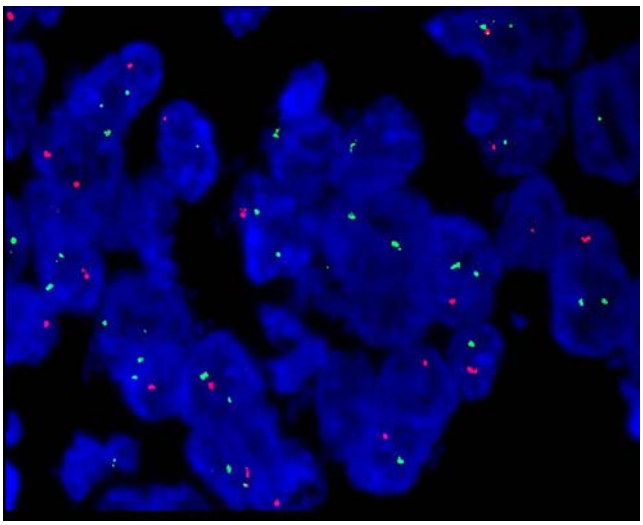

Fig. 3 Dual-color interphase FISH on frozen tumour sections using a biotin-labelled BAC RP11-742C19 (*green signals*) and digoxigenin-labelled RP11-71G19 (*red signals*) DNA probes, which map to *PDGFB*/22q13 and *SMARC-B1*/*INI1*/22q11.2 loci, respectively. Over-representation of green hybridization signals in reference to red signals indicates loss of *SMARC-B1* loci, with many cells being nullisomic for the gene. Nuclei are counterstained with DAPI

such as undifferentiated carcinoma, diffuse large B cell lymphoma on a pre-existing extra-nodal marginal zone B cell lymphoma and primary or metastatic melanoma. Nevertheless, the lack of reactivity for all the epithelial markers, except for EMA, lymphoid markers, S-100 protein and melanocytic markers, such as HMB-45 and Melan A, definitely excluded these hypotheses [6].

Epithelioid-appearing malignant mesenchymal tumours such as synovial sarcoma could be included in the differential diagnoses because the tendency for lymph node metastases is well known, and gastrointestinal locations have been reported in at least ten cases (nine of them in the oesophagus and one in the gastric antrum). The EMA positivity could be in line with this diagnosis but by cytogenetic analysis did not show the characteristic t(X;18) translocation. Two other entities presented a morphologic and immunohistochemical profile compatible with our case: extra-renal rhabdoid tumour and epitheliod sarcoma, whose features usually overlap. Extra-renal rhabdoid tumour is a highly aggressive neoplasia, typically occurring in infancy and histologically characterized by large "rhabdoid" cells, presenting juxtanuclear, globular and amphophilic inclusions and vesicular nuclei with prominent nucleoli [9]. The wide variety of topographic locations of this neoplasia includes the gastro-oesophageal tract. The most consistently expressed immunohistochemical markers are EMA and cytokeratin, but S100 and neuroectodermal antigens can be displayed as well. CD34, expressed in 50% of epithelioid sarcoma, is usually negative. An immunohistochemical study on adhesion molecules expression in epithelioid sarcoma and extra-renal rhabdoid tumour showed different expression of beta-catenin, with striking positivity in 11 of the 15 epithelioid sarcomas examined (73%) and no staining in all the six extra-renal rhabdoid tumours. Our case exhibited a diffuse membranous and cytoplasmatic staining for beta-catenin.

Previous studies revealed striking similarity between malignant rhabdoid tumour and proximal-type epithelioid sarcoma on the cytogenetic and molecular level, e.g. rearrangements or deletions of chromosome 22q11.2, which have been associated with a bi-allelic inactivation of a tumour suppressor gene implied in the oncogenesis [1, 5, 7, 8]. The later was identified as the *hSNF/INI1/SMARC-B1/BAF47* gene, a member of the SWI/SNF chromatin-remodelling complex [5]. However, the spectrum of somatic *SMARC-B1/INI1* mutations in epithelioid sarcomas seems to be restricted to deletions and not to include point mutations frequently observed in malignant rhabdoid tumours. Our oesophageal tumour presented the translocation t(9;13) (p22;q34), so far not associated with any specific mesenchymal neoplastic entity, and loss of chromosome 22 in a subset of cells. By FISH analysis, the latter was associated with the cryptic 22q11.2 microdeletion that resulted in homozygous loss of both *SMARC-B1/INI1* gene copies in 31% of the examined cells. This finding supports the diagnosis of epithelioid sarcoma rather than extra-renal rhabdoid tumour (although it does not exclude the latter completely). Furthermore, additional factors such as the age of the patient and the diffuse beta-catenin expression in tumour cells are in favour of an epithelioid sarcoma diagnosis. Altogether, this case again underscores the value of molecular genetics in establishing the correct diagnosis.

CASE REPORT

Clear cell sarcoma of the ileum: report of a case and review of literature

Camilla E. Comin · Luca Novelli · Daniela Tornaboni · Luca Messerini

Received: 28 February 2007 / Accepted: 6 March 2007 / Published online: 18 July 2007

Abstract Clear cell sarcoma (CCS) is a high grade soft tissue sarcoma with a distinct molecular profile and with morphological features resembling those of melanoma. CCS has been rarely described in other locations other than the soft tissues, including the gastrointestinal tract. In this study, we report a case of CCS arising in the ileum of a 31-year-old woman. Histologically, the tumor involved the entire thickness of the intestinal wall. Tumor cells were polygonal or fusiform, with clear or eosinophilic cytoplasm, arranged in a uniform nested to fascicular growth pattern. Immunohistochemical studies revealed strong positivity for vimentin and S-100 protein. HMB-45, Melan-A, tyrosinase, cytokeratins, EMA, smooth muscle actin, CD34, CD31, CD117, CD99, synaptophysin, chromogranin A, CD56, and NSE were negative. Fluorescence in situ hybridization analysis demonstrated the presence of a t(12;22)(q13;q12) translocation, the diagnostic hallmark of CCS of soft parts. The present case, together with a detailed review of the literature on this topic, demonstrates that the gastrointestinal tract is a possible site of CCS of soft tissues and that making a reliable diagnosis of this tumor requires cytogenetic or molecular diagnostic investigations.

Introduction

Clear cell sarcoma (CCS) (also known as malignant melanoma of soft parts) is a soft tissue sarcoma of adolescents and young adults with melanocytic differentiation typically involving tendons and aponeuroses. The distal extremities, in particular foot and ankle regions, are the main sites of involvement. The prognosis is poor, owing to a high percentage of regional and distant metastasis. The immunoprofile of CCS is characterized by the strong expression of S-100 protein and of more specific melanoma markers, mainly HMB-45 [8]. The presence of melanosomes has also been well documented by ultrastructural studies [8]. Although gene expression profiles have demonstrated CCS to be a subtype of melanoma [26], the two entities are also genetically distinct: CCS lacks BRAF mutations [21], so common in melanoma, and shows a distinct and recurrent chromosomal translocation, t(12;22)(q13;q12), in which the 5′ region of the EWS gene on chromosome region 22q12 recombines with the 3′ region of ATF1 on 12q13 [30].

Beyond the soft tissues, CCS has also been described in a wide range of other anatomical sites such as the ear, bone, penis, kidney, pleura, pancreas, and gastrointestinal tract [1–6, 9, 10, 13, 16, 17, 19, 22, 24, 25, 27–29]. This latter site is extremely rare. To date, 15 genetically confirmed cases of gastrointestinal CCS have been reported, of which seven where located in the ileum [1, 2, 4, 5, 9, 10, 13, 17, 22, 27–29]. In this study, we report an adjunctive case of CCS arising in the ileum and discuss the tumor diagnosis approach, the importance of molecular genetics in tumor

diagnostics, along with a review of the literature on the clinicopathological characters of this rare tumor.

Clinical history

A 31-year-old female was admitted for a weight loss of 8 kg in a 3-month period and symptoms of intestinal obstruction such as abdominal pain and vomiting. Her past medical history was unremarkable. No laboratory abnormalities were present. A computed tomography scan revealed a segmental thickening of the distal ileum. At laparotomy, a single stenotic lesion of the ileum, 3 cm in diameter, was found. No other tumor deposits in the abdominal cavity or liver metastasis could be observed. A partial resection (20 cm) of the small bowel was performed and regional mesenteric lymph nodes were removed.

Materials and methods

The specimen was fixed in neutral, phosphate-buffered, 10% formalin and routinely processed with tissue sections embedded in paraffin and stained with hematoxylin and eosin. Immunohistochemical studies were performed on representative sections of the tumor. Prediluted antibodies were used for AE1/AE3, CAM 5.2, CK20, EMA, HMB45, Melan-A, tyrosinase, vimentin, smooth muscle actin (clone 1A4), CD34, CD31, CD99, synaptophysin, chromogranin, CD56, and NSE (all from Ventana Medical Systems, Tucson, AZ). The other antibodies tested were S-100 protein (1:500; DAKO, Carpinteria, CA) and CD117 (1:500; DAKO). The reaction product was detected with 3,3-diaminobenzidine chromogen. Appropriate positive and negative controls were employed throughout.

Sections from the same paraffin-embedded blocks used for immunohistochemistry were processed for fluorescence in situ hybridization (FISH) analysis which was performed according to the manufacturer's instructions and laboratory protocol using the EWS (22q12) dual-color, break-apart probe (Vysis, Downer's Grove, IL, USA). A positive result was reported when greater than 10% of the tumor nuclei had evidence of an EWS rearrangement. Only tumor nuclei with all four signals present were evaluated, whereas overlapping cells with indistinguishable separate nuclei were excluded from the analysis. A total of 100 tumor nuclei were examined.

Results

Grossly, the resected segment of ileum was centered by a superficially ulcerated, well-defined firm, circumferential tumor involving the entire thickness of the intestinal wall extending into the subserosa. Cut section showed a gray-white mass measuring 2.8 cm in maximum diameter. On microscopic examination, the tumor was found to be based mainly in the muscularis propria and to have invaded the submucosa, the mucosa, and subserosa (Fig. 1). Tumor cells were arranged in a uniform nested to fascicular pattern of growth. Fibrous septa divided the fascicles and nests of tumor cells. The cells were polygonal or fusiform with abundant clear or eosinophilic cytoplasm. The nuclei were vesicular, round to oval with prominent nucleoli (Fig. 2). The mitotic activity was low (two mitosis per ten high-power fields; one high power field: 0.174 mm^2). Neither melanin pigment, nor multinucleated tumor cells, nor osteoclast-like multinucleated giant cells were present. Metastasis to 2 of 14 mesenteric lymph nodes were identified. The ileal resection margins were free of disease.

The tumor cells were strongly immunoreactive for vimentin and S-100 protein (Fig. 3). HMB-45, Melan-A, tyrosinase, cytokeratins, EMA, smooth muscle actin, CD34, CD31, CD117, CD99, synaptophysin, chromogranin A, CD56, and NSE were all negative.

Dual-color FISH analysis revealed hybridization signals in 95% of the nuclei. In 85 out of 100 nuclei examined, the applied probe yielded one juxtaposed red and green signal (one per nucleus), indicating the normal EWS allele in one chromosome, and split, single red and green signals, indicating the presence of an EWS (22q12) gene rearrangement, in the second chromosome, thus allowing a definite diagnosis of CSS.

Discussion

Originally described by Enzinger in 1965 [7], CCS is an unusual type of sarcoma that shows features of melanocytic

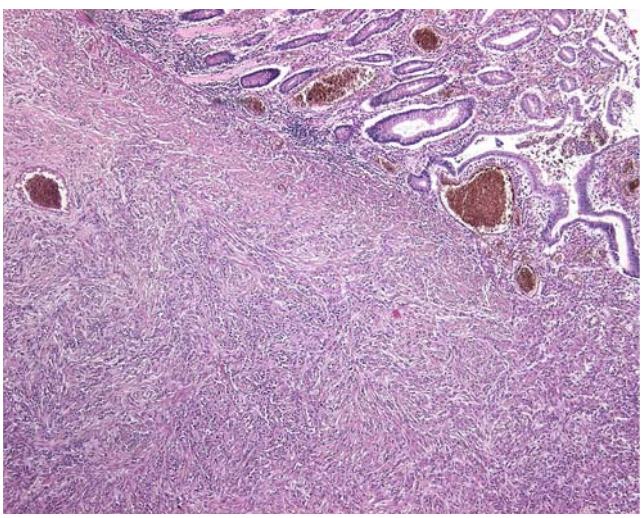

Fig. 1 Low power view of the tumor diffusely infiltrating the mucosa and submucosa of the ileum

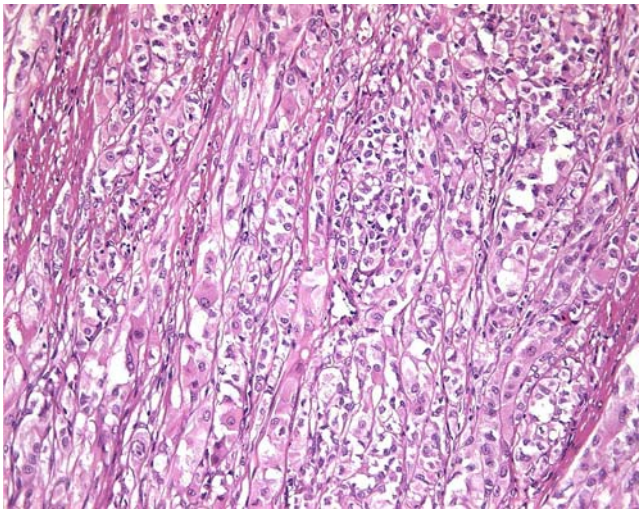

Fig. 2 Nests and fascicles of tumor cells separated by fibrous septa. The cells are polygonal or fusiform with abundant eosinophilic or clear cytoplasm. The nuclei are vescicular, round to oval, with prominent nucleoli

differentiation and that affects predominantly adolescents and young adults [8]. The neoplasm typically presents as a slow-growing tumor arising in the deep soft tissues of the lower extremities close to tendon, fascia, and aponeuroses. Recent data from the literature have shown that CCS may arise at a variety of other sites, including the viscera [1–6, 9, 10, 13, 16, 17, 19, 22, 24, 25, 27–29]. Gastrointestinal involvement is extremely rare [1, 2, 4–6, 9, 10, 13, 17, 22, 27–29]. Some of the most peculiar clinicopathological features of previously genetically confirmed reported cases, together with the present case, are shown in Table 1. As observed within soft tissue lesions, there is a slight female predominance. The median age is 39 years (range: 15–85 years) and the most common site within the gastrointestinal tract, appears to be the small bowel, in particular, the ileum. Most tumors are relatively small (median size: 5 cm; range: 1.8–8.7 cm), just like soft tissue lesions. The majority of the tumors are described as ulcerated masses involving all the layers of the intestinal or gastric wall, deep into the serosa. About half of the cases have already spread to the regional lymph nodes and/or to the mesentery at the time of diagnosis. The overall clinical behavior seems to be aggressive, with a high percentage of regional and distant metastasis. Most patients develop liver metastasis; intraperitoneal spread, pancreatic spread, lung, and mediastinal lymph node metastasis have been reported in few cases as well.

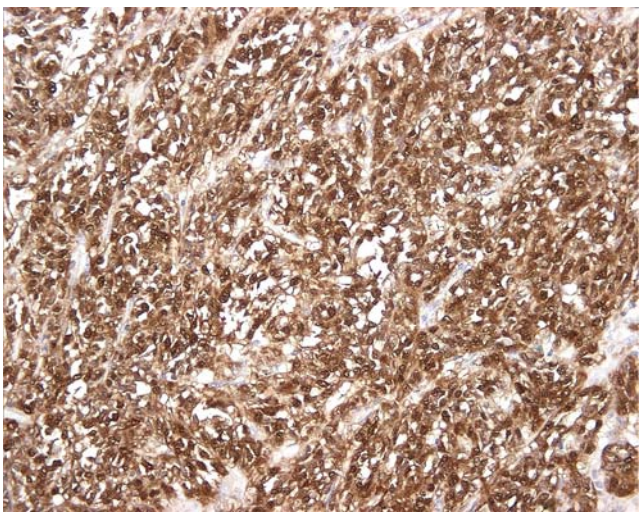

Fig. 3 Strong and diffuse nuclear and cytoplasmic S-100 protein immunoreactivity

Microscopically, a common feature of CCS of the gastrointestinal tract is its infiltrative growth pattern: the tumors are mainly centered in the submucosa and muscularis propria and extend into the mucosa and into the subserosal fat. The histologic features closely resemble those of its soft tissue counterpart. The tumor discloses a rather uniform pattern composed of nests or fascicles of rounded, polygonal, or fusiform cells with abundant clear or eosinophilic cytoplasm, delineated by thin to dense fibrous septa. The nuclei are typically vescicular with prominent nucleoli. Within genetically confirmed CCSs, the presence of CD68-positive osteoclast-like multinucleated giant cells has been reported in four [2, 9, 13, 29] of 16 cases, whereas multinucleated HMB-45-positive tumor cells, which are commonly seen in soft tissue CCS, were described only in one case [4]. At this point, it is worthwhile to mention the description of a major number of gastrointestinal neoplasms containing CD68-positive osteoclast-like multinucleated giant cells with morphological features resembling those of CCS lacking molecular confirmation. Six cases of osteoclast-rich tumors of the gastrointestinal tract resembling CCS were reported by Zambrano et al. [29] (only one case was studied by cytogenetics) and a further case was described by Huang et al. [17]. All reported cases, including those with cytogenetic/molecular studies, were found to be vimentin- and S-100 protein-positive and negative for other melanocytic markers, thus giving rise to the question whether these osteoclast-rich CCS-like tumors of the gastrointestinal tract should be considered a entity separate from classic S-100 protein-positive, HMB45-positive CCSs of soft tissues [23]. If we analyze the immunoprofile of all gastrointestinal tumors with features resembling CCS with or without osteclast-like giant cells (see below), and with or without molecular confirmation, it seems evident that the expression of melanocytic markers is only rarely described. Thus, the lack or low expression of melanocytic differentiation could be related mainly to the gastrointestinal location and not to a new osteoclast-rich entity. Moreover, intracellular melanin pigment has been

Table 1 Clear cell sarcoma of the gastrointestinal tract (review of genetically confirmed cases)

observed in less than half of the reported cases, thus supporting the recent observation [2] that most of these tumors have somehow lost the potential to differentiate along the melanocytic lineage, as more clearly evidenced by immunohistochemical results (see below).

Concerning the immunohistochemical profile, whereas most soft tissue CCSs express melanocytic markers, a high percentage of these tumors in the gastrointestinal location do not. Among genetically confirmed CCSs (Table 1), melanocytic markers were found to be positive only in four cases. Conversely, positive immunostaining for S-100 protein has been reported in all published cases; the expression of other neuroectodermal markers, such as NSE, CD56, and synaptophysin has been encountered in only few cases.

The distinctive cytogenetic character of CCS is the recurrent t(12;22)(q13;q12) translocation, resulting in the EWS-ATF1 fusion, first described in soft tissue cases [30]. This translocation has never been observed in any other neoplasm until very recently [14, 15]. In fact, fusion of the EWS and ATF1 genes has been described in three cases of angiomatoid fibrous histiocytoma; however, this latter tumor type lacks the melanocyte-specific splice form of the MITF gene [14, 15]. We now know that although CCS carries a recurrent distinctive translocation and lacks mutations of the BRAF gene, which are so common in melanoma, immunohistochemical, and ultrastructural studies suggest that it is, like melanoma, a neuroectodermal tumor with melanocytic differentiation. The melanocytic differentiation has been demonstrated by a microarray-based gene expression profiling study by Segal et al. [26], which showed that CCSs do not cluster with other high grade soft tissue sarcomas but with melanoma, thus representing a distinct genomic subtype of melanoma. Moreover, the up-regulation in most CCSs of genes, such as MITF and SOX10, involved in melanocytic differentiation, was also confirmed by the same authors [26].

In the recent study by Antonescu et al. [2], a novel recurrent variant fusion involving the EWS gene, EWS-CREB1, has been demonstrated in a series of three CCSs of the gastrointestinal tract. CREB1 is a gene that encodes another CREB family member closely related to ATF1. The three cases with EWS-CREB1 fusion showed only low or absent expression of melanocytic differentiation genes thus suggesting that evidence of melanocytic differentiation in CCS with EWS-CREB1 fusion is either absent or much less than in classic CCS with EWS-ATF1 fusion, suggesting the notion that melanocytic features are not a necessary finding in this type of sarcoma.

The above-reported findings on EWS-CREB1-positive CCS, together with the inconsistent immunohistochemical expression of melanocytic markers observed in both EWS-CREB1-positive and EWS-ATF1-positive gastrointestinal CCS cases, may once more suggest that the gastrointestinal location, rather than the fusion transcript type, might determine the lack of melanocytic differentiation [2]. The lack or low expression of melanocytic differentiation in either EWS-CREB1-positive and EWS-ATF1-positive CCSs of the gastrointestinal tract support the concept of a common histogenesis of these tumors from a gastrointestinal neuroectodermal precursor cell that might have lost the capacity to differentiate along the melanocytic lineage, in contrast to the neuroectodermal precursor cell of CCS of soft tissues [2].

Because of its unusual site of presentation, together with the inconsistent expression of melanocytic markers, the diagnosis of CCS of the gastrointestinal tract may be difficult. In view of its location and mesenchymal appearance, an obvious consideration is that of gastrointestinal stromal tumors (GISTs), which account for most of mesenchymal tumors at this site. These tumors usually arise within the gastric wall and the small intestine and are less frequently seen within the colon and rectum. Most GISTs are CD117-positive and CD34-positive and although CD117-negative cases have been reported, an overwhelmingly strong S-100 protein-positivity makes this hypothesis unlikely. Based on morphology, and particularly on immunohistochemical stains (strong positivity for S-100 protein), the most intriguing possibility to be ruled out is that of a metastatic melanoma. Metastatic spread of melanoma of the skin and eyes to the gastrointestinal tract has been reported. The differential diagnosis between CCS and melanoma is of particular importance, in spite of different therapeutic modalities. An extensive systemic examination, together with the lack of metastasis in other sites, could exclude a melanoma, although cases of metastatic melanoma of unknown origin have been reported. The immunohistochemical profiles of CCS and melanoma overlap, providing no aid to the differential diagnosis between these neoplasms. It has been recently stressed that CD117-positivity may prove useful in differentiating deep soft tissue or visceral lesions with melanocytic differentiation, as positive staining results would exclude CCS, but are compatible with metastatic melanoma [11]. Nonetheless, in these instances, a firm diagnosis of CCS relies mainly on cytogenetics or molecular diagnostic investigations by the demonstration of the EWS-ATF1 or EWS-CREB1 fusions and the lack of BRAF gene mutations. Among other neoplasms that may enter the differential diagnosis, strong positivity for S-100 protein excludes the hypothesis of a leiomyosarcoma whereas more challenging is the differential diagnosis with the epithelioid variant of malignant peripheral nerve sheet tumor (MPNST) which shows strong S-100 protein immunoreactivity. This latter eventuality may be ruled out mainly by molecular diagnostic investigations, as the expression of neural markers (other than S-100 protein)

has been reported in few cases of CCS [2, 22], whereas, no translocation involving the EWS or ATF1 gene locus has been found to date in MPNST. Another differential diagnostic alternative that may be considered is the rare clear cell tumor known as PEComa, of which few cases have been described in the gastrointestinal tract [12, 20]. This last entity is immunohistochemically characterized by the expression of both melanocytic markers and muscle markers, in particular smooth muscle markers, whereas S-100 protein is typically negative. When melanocytic differentiation is not evident, various types of tumors, including neuroendocrine tumors, poorly differentiated carcinomas, paragangliomas, and the rare renal-type clear cell sarcoma, of which one case has been described in the terminal ileum [18], should be distinguished mainly by immunohistochemical studies.

In summary, CCS of the gastrointestinal tract is a rare entity, with most cases affecting the small bowel. The clinical behavior of this tumor seems to be aggressive with an overall high incidence of local (regional lymph nodes, peritoneum, and mesentery) and distant (more frequently liver) metastasis. The morphology of these tumors, with or without osteoclast-like giant cells, closely resembles that of CCS of soft tissue, and their common histogenesis is confirmed by the presence of the typical EWS-ATF1 transcript fusion. In view of the rarity and unusual site of this tumor, and since most cases at this location lack the immunohistochemical expression of melanocytic markers, we emphasise the pivotal role of cytogenetics and/or molecular techniques for the correct evaluation of these lesions.

CASE REPORT

Mucinous carcinoma of thyroid gland. Report of a primary and a metastatic mucinous tumour from ovarian adenocarcinoma with immunohistochemical study and review of literature

Antonio D'Antonio · Maria Addesso · Gianfranco De Dominicis · Amedeo Boscaino · Guiseppina Liguori · Oscar Nappi

Received: 16 April 2007 / Revised: 4 June 2007 / Accepted: 16 June 2007 / Published online: 18 August 2007

Abstract Mucinous carcinoma of the thyroid gland is an uncommon tumour that from the histological point of view, resembles mucinous carcinoma of others sites. Although a mucinous appearance has sometimes been reported in association with cases of typical thyroid carcinoma, true mucinous carcinoma is exceptionally rare. We describe two cases of thyroid tumours with mucinous differentiation studied with immunohistochemistry. Both cases disclosed a similar histological appearance, with small nests and sheets of malignant epithelial cells associated with extensive extracellular mucin that substituted and entrapped the follicular parenchyma of the thyroid. Thyroglobulin and focally thyroid transcription factor (TTF) 1 were positive in one case. From these findings, we classified this tumour as primary mucinous thyroid carcinoma. Thyroglobulin and TTF-1 were negative in tumour cells of second case; on the contrary, positivity to the carcinoembryonic antigen and CA-125 was strong and generalized. However, successfully, the patient presented ascites associated to right ovarian mass. In this case, thyroid tumour represents the first clinical sign of an ovarian mucinous adenocarcinoma, and it has not been previously described in literature. Both patients died after few months to diagnosis. In conclusion, primary and secondary mucinous carcinoma are rare and unusual tumours of the thyroid gland that can be a cause of pitfall in differential diagnosis. In these cases, for a correct diagnosis, a complete clinical history, restricted histological criteria and immunohistochemical panel are necessary.

Introduction

Mucinous thyroid tumours are very rare and sometimes can occur in association with a typical thyroid carcinoma (follicular and papillary) but does not represent a true primary thyroid carcinoma [1, 2, 6, 8, 10]. This latter is exceptionally rare, with only six cases reported in literature, and histologically are indistinguishable from mucinous carcinoma of others sites [3, 5, 7, 9]. We describe two cases of a mucinous tumour of the thyroid where one is a primary carcinoma as demonstrated by immunohistochemistry and the second represents a first clinical manifestation of a mucinous carcinoma of the ovary.

Case reports

Case 1

A 62-year-old female patient, presented in January 1999 with fever, weight loss, odynophagia and a rapidly enlarging

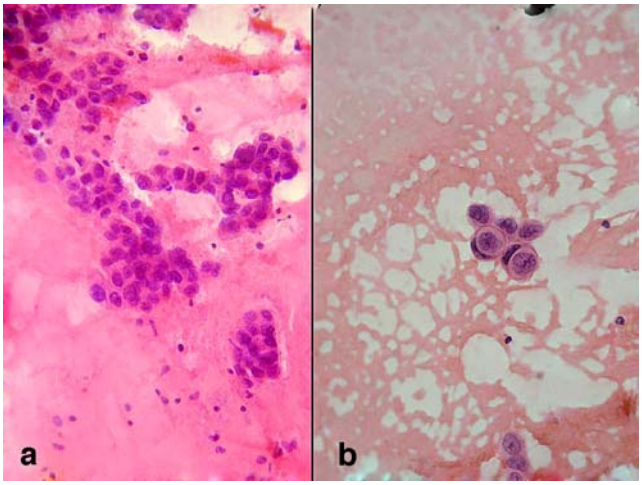

Fig. 1 FNA (case 1) shows scant amount of colloid material containing cohesive groups of malignant epithelial cells (**a**); an additional feature was the presence of malignant cells with features of signet ring cells (**b**) (hematoxylin–eosin, 40×)

mass of thyroid region. She was euthyroid, and ultrasonography confirmed a solid mass involving both lobes of the thyroid and bilateral lymph nodes. A fine-needle aspirate (FNA) of the mass and of the bigger lymph node was performed, which suggested poorly differentiated thyroid carcinoma. The patient underwent total thyroidectomy with resection of lymph nodes. Post-operative tomography revealed a metastatic lymph node at the right side of the neck and at the mediastinum. It was negative for lung metastasis. The adenopathy was irresectable because it was adherent to the vessels. Six months later, the patient died of disease, and the autopsy did not reveal others sites of disease.

Case 2

A 59-year-old woman had first sought medical attention in March 2004 when she was noted to have several enlarged thyroid glands. Ultrasound examination of the anterior region of the neck showed a diffuse enlargement of the thyroid gland associated with cervical lymph nodes. FNA was performed in our Department of Pathology using a standard technique followed by total thyroidectomy for malignancy. Over the next 3 months, the patient had developed subclavian, deep cervical lymph nodes and ascites.

The serum level of CA125 and carcinoembryonic antigen (CEA) were elevated. Computed tomography showed a right adnexal mass with peritoneal implants and retroperitoneal lymph nodes; no other mass is identified in the abdominal cavity. The patient died 4 months later. Autopsy was not allowed.

Material and methods

In both cases, FNA of the thyroid gland was performed using a 23-gauge needle under ultrasonographic control. The cytological smears were air dried and stained with May–Grunwald–Giemsa. Others slides were fixed in ethanol and stained with the Papanicolau method and hematoxylin–eosin.

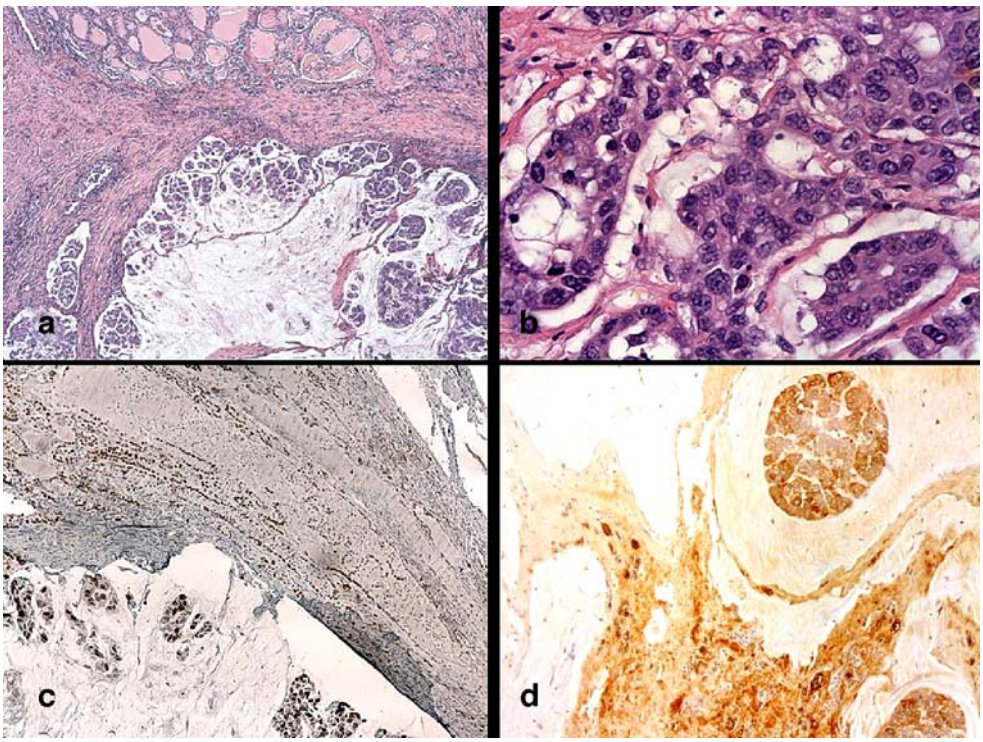

Fig. 2 **a** A large pool of extracellular mucin (hematoxylin–eosin, 10×). **b** Solid areas of poorly differentiated carcinoma with glandular differentiation (hematoxylin–eosin, 40×). **c** Tumour cells were immunoreactive with TTF-1 (immunoperoxydase, 20×) and **d** thyroglobulin (immunoperoxidase, 40×)

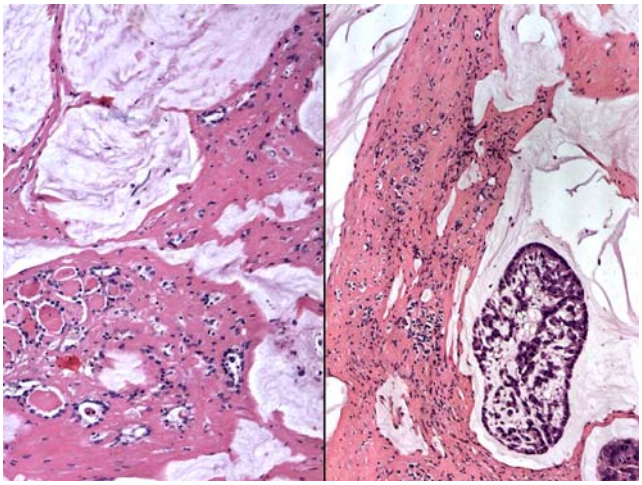

Fig. 3 In case 2, the tumour was predominantly composed of areas of large amount of paucicellular mucus (*left*), sometimes extracellular mucin entrapped residual atrophic thyroid follicles (*right*) (hematoxylin–eosin 20×)

In case 2, cytological effusion from ascites was used for cytological smears like previously reported, and after clearing of the supernatant from the cell pellet, the cell deposit was fixed in formol sublimate for processing into cell blocks.

Both surgical specimens were fixed in 10% buffered formalin and embedded in paraffin; 4-μm-thick, formalin-fixed, paraffin-embedded tissue sections of both cases were stained with hematoxylin–eosin, mucicarmine, Alcian blue and periodic acid-Schiff (PAS) before and after diastase treatment for light microscopic examination.

For immunohistochemical studies, consecutive sections were stained with antibodies to thyroglobulin, CK7, CK20, CK MNF116, Thyroid transcription factor 1(TTF-1), CEA, calcitonin and Ki67/MIB 1 (Dako, Carpinteria, CA) in case 1 and CA-125 (Dako) in case 2.

Results

Thyroid aspirates of case 1 were moderately cellular, with scant amount of colloid material containing cohesive groups of variable size of malignant epithelial cells (Fig. 1a); an additional feature was the presence of small groups of mucin-producing cells also with features of signet ring cells (Fig. 1b).

In case 2, FNA showed large streaks of mucin with small aggregates or sheets of malignant epithelial cells.

Some groups of neoplastic cells showed a papillary-like finding, but there was no evidence of a central vascular core.

Grossly, in both cases, the tumours were described grossly as firm to soft, solid mass and adherent to surrounding structures. The cut surface was smooth or slightly bulging also with a ‘fish-flesh’ or a focal gelatinous appearance.

Histologically, both cases disclosed a very similar appearance, with areas of abundant extracellular mucin around strands, small solid nests and trabeculae of epithelial malignant cells, an image similar to that of mucinous carcinoma of the breast. The mucus was positively stained for mucicarmine, Alcian blue and PAS before and after diastase treatment.

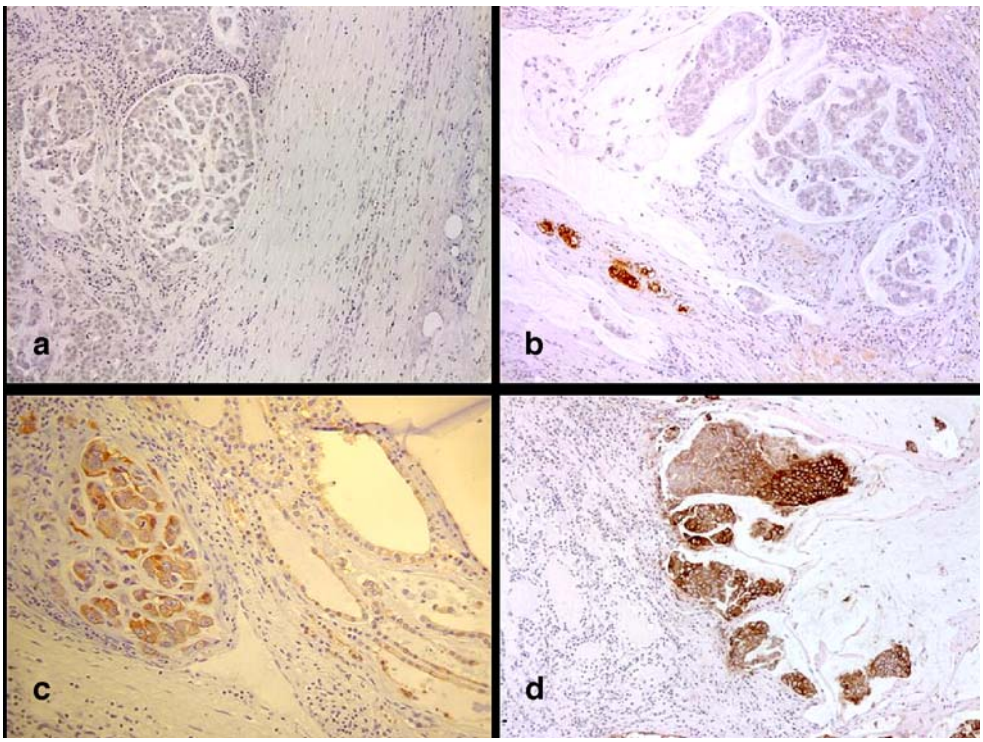

Fig. 4 Immunohistochemically, neoplastic cells are negative for **a** CK20 and **b** thyroglobulin but show strong reactivity for **c** CEA and **d** CA125 (immunoperoxidase, ×20)

Table 1 Summary of previous cases

Authors	Age	Sex	Immunochemistry	Follow-up
Diaz-Perez et al.	44	M	ND	AWD 8 Yr
Sobrinho-Simoes et al.	–	–	Thy+	–
Mizukami Y et al.	58	M	Thy+	Cervical and axillary metastases
Kondo T et al.	82	F	Thy+, TTF1+	DOD 4 Yr
Present case	62	F	Thy+, TTF1−/+	DOD 4 Yr

M male, *F* female, *Thy* thyroglobulin, *ND* no data, *AWD* alive without disease, *Yr* year, *DOD* died of disease

In case 1, large pool of extracellular mucin (Fig. 2a) progressively merged with loose nests of carcinoma with mucinous stroma and solid areas of poorly differentiated carcinoma also with glandular differentiation (Fig. 2b). The tumours grew in an aggressive manner and invaded the neighbouring cervical structures and skeletal muscle of the neck. There were no areas of typical thyroid carcinoma noted.

In this case, there was immunoreactivity to epithelial markers (CK MNF116, CK7), focally to TTF1 (Fig. 2c) and thyroglobulin (Fig. 2d) but not to calcitonin and CK20.

A diagnosis of primary thyroid mucinous carcinoma was made.

In case 2, the tumour was predominantly composed of areas of a large amount of paucicellular mucus and focally of mucin-containing gland-like structures, sometimes extracellular mucin entrapped residual atrophic thyroid follicles (Fig. 3). Vascular invasion was also evident. Immunohistochemically, neoplastic cells showed a positive reaction for cytokeratin (CK MNF116), CA-125, CEA and CK7 but did not show reactivity for CK20, epithelial membrane antigen, calcitonin, thyroglobulin and TTF-1 (Fig. 4).

Furthermore, malignant epithelial cells in cytological smears from cell blocks of ascites showed a consistent positivity for CA-125 and CK7 but was negative for CK20.

A diagnosis of thyroid metastasis from a mucinous adenocarcinoma of the ovary was made.

Discussion

Mucin production in thyroid gland is an unusual event but can occur in a wide variety of thyroid lesions (follicular neoplasm, papillary carcinoma, anaplastic and medullary carcinoma) [1, 2, 6, 8, 10]. Generally, in these cases, the tumour appears characterized by a pool of mucin, often extracellular and admixed with areas of typical thyroid carcinoma. These tumours do not represent a true primary thyroid mucinous carcinoma. In fact, this latter is extremely rare (only four cases reported), and histologically, it is indistinguishable from a mucinous carcinoma at other sites [3, 5, 7, 9]. In these case, areas of papillary or follicular carcinoma are not always evident. Among five cases studied, all are thyroglobulin and/or TTF-1 positive (Table 1).

Furthermore, in our case (case 1), the tumour was composed of nests of epithelial cells also with glandular differentiation that progressively merged with neoplastic areas of mucinous stroma and a pool of extracellular mucin, in the absence of findings of typical thyroid carcinoma. Tumour cells were positive for thyroglobulin and focally for TTF-1. Finally, follow-up examination has not demonstrated another neoplasm in others sites. From these features, we classified this tumour as primary mucinous thyroid carcinoma.

In the presence of neoplastic epithelial clusters or glands accompanied by a large mucus pool involving thyroid parenchyma, a metastasis from a mucinous adenocarcinoma arising in others sites should be considered in differential diagnosis. Generally, in this case, a correct diagnosis is easy because the metastatic cells are often associated with obvious widespread metastatic disease elsewhere.

Uncommonly, metastatic carcinoma in the thyroid gland can represent the first manifestation of the systemic disease [4].

In our case 2, we describe a previously unreported case of metastatic mucinous adenocarcinoma of the thyroid gland that represents the first evidence of an ovarian carcinoma. Furhtermore, in this case, the tumour was composed of strands and small nests of malignant epithelial cells with

Table 2 Criteria for differential diagnosis in primary and secondary mucinous thyroid carcinoma

	Histology	Immunohistochemistry	Clinical history
Primary MTC	Mucus pool with transition to solid and glandular areas	Thy+ and/or TTF-1+	Local recurrences
Secondary MTC	Large mucus pool with small clusters of epithelial cells	Thy−, TTF-1−	Tumour in others sites, lymph nodes and visceral metastasis
Other type	Mucus pool and typical thyroid carcinoma	Thy+, TTF-1+	Not relevant

extensive extracellular mucin. The presence of mucinous features in a thyroid mass in the absence of a previous history of a primary tumour in the other side may represent an even greater cytological and histological challenge to the pathologist. In fact, this tumour was first recognized as a primary mucinous carcinoma of the thyroid. A key feature that can help in the differential diagnosis is the absence of solid or glandular areas that progressively merged with areas of mucinous stroma and a pool of extracellular mucin, such as case 1. If a primary thyroid tumour is suspected, an immunohistochemical study on the histological specimens or on the aspirate material is necessary to provide a final diagnosis.

In fact, in our case, a negative immunostaining for thyroglobulin and TTF1 but positive for CA125 and CEA favour metastatic ovarian carcinoma over the primary thyroid adenocarcinomas. Then, the result of the diagnosis was confirmed by successive appearances of ascitis with an ovarian mass. In conclusion, mucinous carcinoma are rare and unusual tumours of the thyroid gland that can be a cause of pitfall in differential diagnosis. For a diagnosis of primary carcinoma-restricted histological criteria, an immunohistochemical panel and a complete clinical history are necessary. Particularly, from the histological point of view, the presence of solid and glandular clusters of neoplastic cells that progressively merge with areas of mucin deposition in the stroma and with a large pool of mucus, in the absence of areas of typical thyroid carcinoma, should favour a diagnosis of primary mucinous carcinoma (Table 2). Nevertheless, also in the absence of a history of metastatic disease or distant primary carcinoma, the possibility of a secondary thyroid involvement in mucinous adenocarcinoma could be considered.

For this motive, in the presence of uncommon and/or rare thyroid tumours, for it to be defined, diagnosis could only be established after the careful immunohistochemical study.

CASE REPORT

Primary retroperitoneal mucinous cystadenoma with sarcoma-like mural nodule

A case report and review of the literature

R. F. R. Bakker · J. H. M. B. Stoot · P. Blok · J. W. S. Merkus

Received: 29 June 2007 / Revised: 10 July 2007 / Accepted: 15 July 2007 / Published online: 10 August 2007

Abstract Primary retroperitoneal cystadenomas are extremely rare. This is the first report in literature to describe a primary retroperitoneal cystadenoma with a sarcoma-like mural nodule. A 45-year-old woman complained of a left-sided abdominal mass. A computed tomography scan revealed a cystic mass with a mural nodule, which seemed to originate from the tail of the pancreas. At laparotomy the cyst was not adhered to the pancreas but localized retroperitoneally. Histologic examination showed a mucinous cystadenoma with only foci of borderline malignancy with a mural "sarcoma-like" nodule. In view of the surgical and histopathological findings, the mucinous cystadenoma was regarded as primary retroperitoneal. This case demonstrates that in the era of radiological preoperative refinement, pathological diagnosis remains of utmost importance, especially for rare cases.

Keywords Retroperitoneum · Mucinous cystadenoma · Mural nodule

Introduction

Mucinous cystadenomas of the ovary are clinically and histopathologically well-established and common tumors. Primary retroperitoneal mucinous cystadenomas are extremely rare. Such tumors are histologically similar to ovarian mucinous cystadenomas. Their histogenesis is still unclear. We report a case of primary retroperitoneal mucinous cystadenoma with foci of borderline malignancy containing a mural "sarcoma-like" nodule.

Case report

Clinical history

A 45-year-old, para 2, woman presented at the emergency room with a 3-week history of left-sided abdominal pain. She had felt a mass in the left lower quadrant 2 days before. Her clinical history included endometriosis and a car accident. The mass was progressive but not painful. Apart from the palpable mass of 15 cm in the left lower abdomen, physical examination was unremarkable. Ultrasonography demonstrated a 15-cm cystic mass with a 3.8-cm nodule in its wall. The uterus was normal in size, and internal ultrasonography showed small ovaries. Carcinoembryonic antigen, cancer antigen (CA) 125, and CA 19-9 levels were within normal limits. The next day, a contrast-enhanced computed tomography scan of the abdomen revealed a 15-cm left-sided cystic mass, which seemed to originate from the tail of the pancreas (Fig. 1a). The cystic mass showed a 4-cm nodule in its wall (Fig. 1b) and was suspected for a cystic papillary adenocarcinoma. At laparotomy, the cyst was not adhered to the pancreas and could be easily separated from its location near the tail without opening the pancreatic capsule. Vascularization appeared to arise from the mesentery of the left colon. It was localized in the retroperitoneal space extending caudally from the spleen to the lower abdomen with medial displacement of the left colon. Total resection of the cyst was performed, and the specimen was sent for histopathological examination.

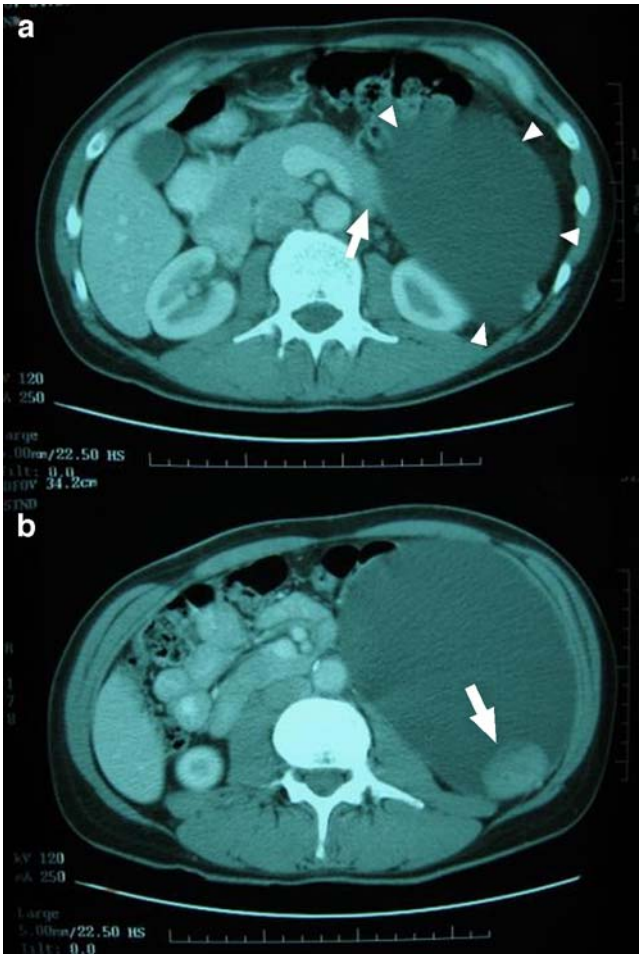

Fig. 1 Contrast enhanced CT scan shows images of a pancreatic cyst (*arrowheads*) originating from the tail of the pancreas (**a**) and a mural nodule within the wall of the cystic mass (**b**)

Further inspection showed two normal ovaries. Her postoperative recovery was uneventful. One year after surgery, the patient was without signs of recurrence or metastasis.

Materials and methods

The specimen was fixed in 4% buffered formalin. Representative samples were routinely processed and embedded in paraffin blocks. Four-micrometer-thick sections were stained with hematoxylin and eosin and with parallel routine immunohistochemical procedures. The antigens tested by immunohistochemistry were: pan-keratin, keratin Cam 5.2, cytokeratin 7, cytokeratin 10, cytokeratin 18, cytokeratin 20, epithelial membrane antigen, vimentin, desmin, actin, myosin, CD34, CD68, CD99, CD117, S-100 protein, and bcl-2.

Pathological findings

The specimen consisted of a unilocular cyst measuring 20×11 cm with a smooth surface. The content was a watery mucinous material. The wall was thin with a smooth gray-white inner surface and contained a circumscribed bean-shaped solid mural nodule of 3.5×3.5×2.5 cm, which showed a brown-yellow and focally hemorrhagic cut surface. Microscopically, most of the cyst was lined by single-layered tall columnar cells, abundant clear cytoplasm, and small basally located nuclei (Fig. 2a).

Occasionally (over less than 1% of the surface), the epithelium showed slightly atypical proliferation with

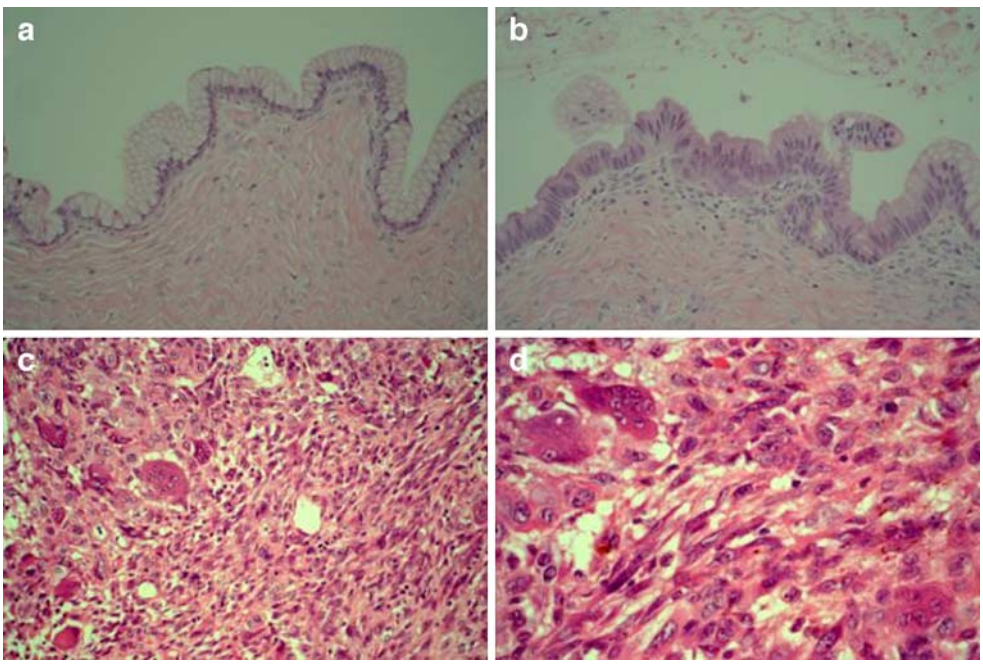

Fig. 2 Cyst wall with typical tall columnar mucous-secreting epithelium and fibrous wall (**a**). Low cellular proliferation with some stratification of the cells and slight nuclear atypia (**b**). Heterogenous proliferation of pleomorphic cells, spindle cells, osteoclast-like giant cells, and some mononuclear cells with some pigment (**c**). Detail of sarcoma-like nodule (**d**)

glandular budding, tufting of the epithelium, decreased cytoplasmic mucin, some stratification of slightly irregular nuclei, and an occasional mitoses (Fig. 2b). There was no infiltrative growth but foci of borderline malignancy. The nodule was well circumscribed without vascular invasion and consisted of a heterogenous population of spindle-shaped cells, pleomorphic cells with bizarre nuclei, mixed mononuclear inflammatory cells, benign osteoclast-like giant cells, and foci of hemorrhage. There were mitotic figures, including some atypical forms (Fig. 2c and d). The sarcoma-like cells proved to be keratin negative (Table 1).

Discussion

Mucinous cystadenomas can be located in the ovaries, pancreas, and in the retroperitoneum. The mucinous cystadenoma presented was localized retroperitoneally near the pancreas but was clearly not adhered to it. Because normal-appearing ovaries were found, the cystadenoma was thought to be primary retroperitoneal.

According to the literature, symptoms are nonspecific, and most patients complained of an abdominal distension or mass with or without pain [9]. Mucinous cystadenomas were relatively large, varying from 10 to greater than 20 cm in diameter, which is large enough to cause symptoms like abdominal fullness [9]. Preoperative diagnosis is very difficult, not because the tumors are often overlooked in the differential diagnosis but also because no sensitive methods or reliable markers are available [2]. As retroperitoneal mucinous cystadenomas are histologically similar to mucinous cystadenomas of the ovary, the ultrasonographic image pattern is in general of no help in distinguishing between ovarian and retroperitoneal origin. In our case, the diagnosis of the retroperitoneal mucinous cystadenoma could not be established preoperatively by ultrasonography or computed tomography. Although ultrasonography, computed tomography, or magnetic resonance imaging can detect retroperitoneal cysts, the diagnosis of mucinous cystadenoma is seldomly made preoperatively. The usual preoperative differential diagnosis consists of ovarian cyst, cystic mesothelioma, cystic lymphangioma, nonpancreatic pseudocyst, and renal cyst [4, 9, 18]. Although aspiration is a good method for delineating the nature of the cyst, cytologic analysis of the aspirated fluid frequently fails to reveal the type of epithelial cells lining the cyst. Therefore, exploratory laparotomy with complete excision of the cyst is usually indicated both for diagnosis and treatment [2].

Retroperitoneal mucinous cystadenomas are histologically similar to mucinous cystadenomas of the ovary. The histogenesis of these tumors is still unclear. Four main hypotheses have been proposed [2, 14]. According to the first three hypotheses, the tumor arises either from ectopic ovarian tissue, although ovarian tissue was only rarely found [14], from a teratoma in which the mucinous epithelium has overgrown all other components or from urogenital remnants. The most widely accepted theory suggests coelomic metaplasia as the causal agent, whereby tumors arise from invagination of the peritoneal mesothelial layer that undergoes mucinous metaplasia with cyst formation [3, 9]. Such origin rather than from ectopic ovarian tissue is supported by the occurrence of such a tumor in a male patients [5, 8, 10, 17].

Primary mucinous tumors of the retroperitoneum are very uncommon. These tumors can be classified into three clinicopathologic types: mucinous cystadenoma, mucinous cystic tumor of borderline malignancy, and mucinous cystadenocarcinoma. Our case was diagnosed as a primary retroperitoneal mucinous cystadenoma with only foci of borderline malignancy and a mural “sarcoma-like” nodule.

Mural nodules have been described in ovarian and pancreatic mucinous cystic tumors [7, 16]. Mural nodules may be malignant representing anaplastic carcinoma, containing a predominant population of cytokeratin-positive cells with high-grade malignant nuclei, or a genuine soft tissue-type sarcoma [7, 15, 16]. Benign pseudosarcomatous mural nodules are composed of a heterogeneous cell population of epulis-type giant cells, atypical spindle cells with bizarre nuclei and mitotic figures, mixed inflammatory cells, and signs of hemorrhage and necrosis. In these cases, immunohistochemical staining shows a weakly or focally cytokeratin positivity in the pseudosarcomatous cells.

We performed a literature review using Embase and Medline starting in 1966 and identified approximately 45 cases of retroperitoneal mucinous cystadenoma and 25 cases of mucinous cystadenocarcinoma. Only eight cases of mucinous

cystadenoma with borderline malignancy have been reported (Table 2). Thus, our case is the ninth case of a retroperitoneal mucinous cystadenoma of borderline malignancy. By our knowledge, however, combination with a mural "sarcoma-like" nodule has not been described earlier in the literature. The patient should be followed. However, in this case, long-term follow-up seems not warranted regarding the only focal aspect (<1% of the surface) of borderline malignancy of the cyst and the benign reactive nature of the mural nodule.

Appendix

Article Précis

A 45-year-old woman complained of a left-sided abdominal mass, which turned out to be a primary retroperitoneal cystadenoma with mural nodule.

LETTER TO THE EDITOR

The neonatal Fc receptor (FcRn) expression in the human skin

Petru Cianga · Corina Cianga · Petru Plamadeala · Daciana Branisteanu · Eugen Carasevici

Received: 20 March 2007 / Revised: 7 June 2007 / Accepted: 1 July 2007 / Published online: 3 August 2007

The neonatal Fc receptor, FcRn, has a wide expression within the human body, including adult cells; however, it is not ubiquitously expressed (reviewed in [2]). The receptor is involved both in IgG transcytosis as well as recycling, being able to bind both free and antigen complexed IgG molecules (reviewed in [4]).

Cauza et al. [1] have shown that the neonatal receptor is present in the human epidermal keratinocytes, using both biopsies and cultivated keratinocytes. Furthermore, they were able to demonstrate that most of the FcRn molecules are expressed intracellularly, in acidified vesicles [1], and that the receptor is functional within these cells. However, the FcRn role in keratinocytes in terms of recycling, transcytosis, or perhaps both remains speculative.

In this paper, we show by immunohistochemistry that FcRn expression in human skin is not restricted only to keratinocytes but has a wider expression.

Tissues were obtained from five human cadavers (harvested in an interval of 24 h from the time of death), and a surgical biopsy was performed for diagnostic purposes (nevus). Immunohistochemistry was done on consecutive skin sections as previously described [2]. The epithelial cells were evidenced with an antihuman cytokeratins antibody (clone MNF116, Dako). As expected, the antibody stained the epithelial cells of the hair follicles and sebaceous glands and the keratinocytes (data not shown). The FcRn-staining pattern proved to be more complex. The epithelial structures, evidenced by the cytokeratins targeting, proved to be positive as well for the Fc neonatal receptor (Fig. 1). Furthermore, we were able to show that the cytokeratin-negative, S-100-positive melanocytes (data not shown) [3] express also this receptor (Fig. 2). Histiocytes and dendritic cells were also shown to be FcRn positive by others [1, 5]. The characterization of the exact nature of the cells scattered throughout the investigated tissues was beyond the goals of this study. However, we can speculate that the isolated FcRn-positive cells in our skin sections are histiocytes and dendritic cells.

The presence of FcRn in endothelial cells was investigated by labeling sequential sections with anti-FcRn and respectively anti-CD34 II (clone QBEnd, Dako) antibodies, as well as double labeling with HRP/DAB (brown) for FcRn, and Alkaline Phosphatase/FastRed (Dako, Denmark) (red) for CD34 II. Consistent with the results obtained on human mammary gland sections [2], blood vessels are either negative for the neonatal Fc receptor or express this molecule at a level that is undetectable by the immunohistochemical method (Fig. 3).

IgG is the main antibody isotype in the extravascular body spaces. Hence, the wide expression of the neonatal Fc receptor throughout the organism, including in various cell types of the skin, does not come as a surprise. Although the receptor was proven to be functional in keratinocytes [1], the FcRn function (recycling, transcytosis, or both) in the skin structures remains to be elucidated. On the other hand,

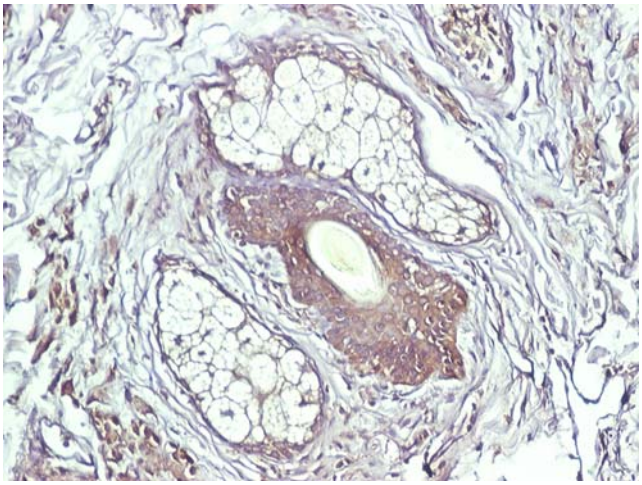

Fig. 1 Normal hair follicle and sebaceous gland. Positive staining for FcRn (200×)

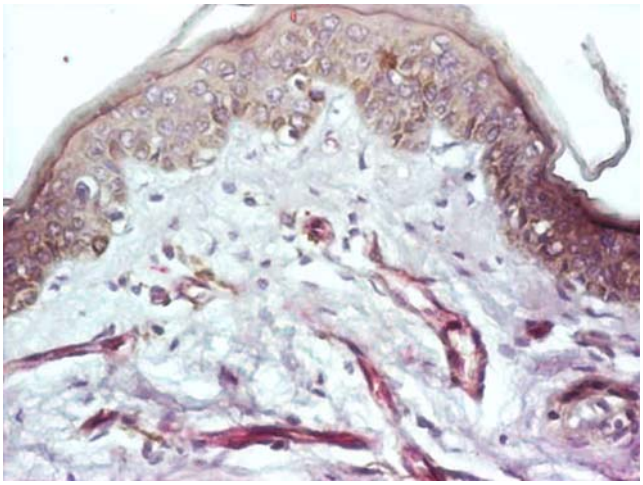

Fig. 3 Normal skin. Double labeling for FcRn (*brown precipitate*) and CD34 II (*red*; 200×)

given the fact that we were unable to identify the presence of the neonatal Fc receptor in the endothelial cells, we raise the question of potential alternative mechanisms capable of transporting IgG antibodies across the blood vessel walls.

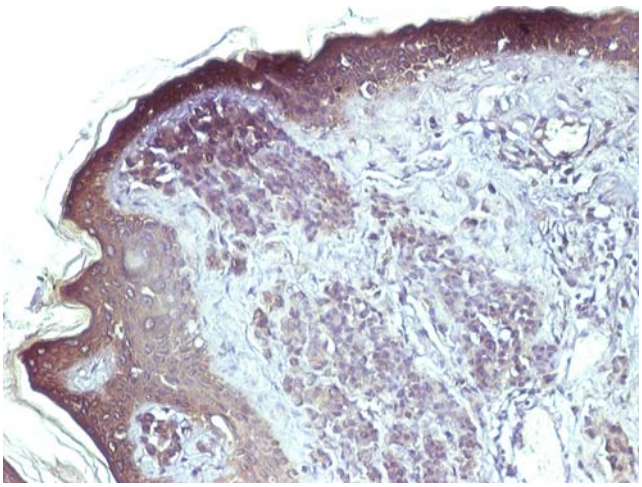

Fig. 2 Skin with nevus. Positive staining for FcRn both in keratinocytes and melanocytes (100×)

REVIEW AND PERSPECTIVE

Pancreatic intraductal papillary-mucinous neoplasms: a new and evolving entity

Snezana Andrejevic-Blant · Markus Kosmahl · Bence Sipos · Günter Klöppel

Received: 2 August 2007 / Revised: 6 September 2007 / Accepted: 6 September 2007 / Published online: 27 September 2007

Abstract For a long time, intraductal tumors of the pancreas were neglected because they were misdiagnosed as mucinous cystadenocarcinoma, ordinary ductal adenocarcinoma, or chronic pancreatitis. Only in recent years have they been recognized as clinical and pathological entities. Most common are the intraductal papillary-mucinous neoplasms. Although they show an adenoma-carcinoma sequence, they have proved to have a more favorable prognosis than ductal adenocarcinoma, when resected in a preinvasive state. Recently, it has become clear that they constitute a heterogeneous group with at least four subtypes. Their stratification reveals that the various intraductal papillary-mucinous neoplasm subtypes have different biological properties with different prognostic implications.

Historical notes and a rising incidence

The pancreatic tumors that are characterized by an intraductal origin and growth pattern include intraductal papillary-mucinous neoplasms [3, 24, 41], intraductal tubular carcinomas [22, 45], intraductal tubular adenomas of the pyloric type [6], and intraductal acinar cell carcinomas [15]. Most common are the intraductal papillary-mucinous neoplasms (IPMNs). They are mucin-producing epithelial tumors that usually show a papillary architecture and are associated with dilatation of the ducts. Before 1990, these tumors were thought to be rare. They first started to be recognized approximately 20 years ago [31, 36, 39], when the many different names given to the tumor in the 1980s were replaced by the term IPMN [41]. This name was also introduced in the classification of exocrine pancreatic tumors propagated by the World Health Organization (WHO) [24] and the fascicles of the Armed Forces Institute of Pathology [44]. Since then, IPMNs have been reported with increasing frequency (Table 1) and currently account for about 7% of clinically diagnosed pancreatic neoplasms and up to 16% of surgically resected pancreatic neoplasms and for almost 50% of pancreatic cysts found incidentally [8, 17]. When only the cystic tumors of the pancreas are considered, IPMNs take first place, with a frequency of 24% [26].

The new incidence data on IPMNs raise the question whether their increase in number is real or not. Of course, it is difficult to accept that IPMNs might have been overlooked in the past, not only clinically but also morphologically. There are good reasons, however, to believe that IPMNs did always exist and did not really increase in frequency. One reason is related to the rapid improvements in modern imaging techniques, which enable more precise recognition of cystic lesions, even if they are small and

Table 1 Incidence data on intraductal papillary-mucinous neoplasms

Author	Period 1	Number of incidence	Period 2	Number of incidence
Sohn et al. [43]	1987–2001	58	2001–2003	78
Wada et al. [47]	1988–2000	63	2001–2003	37
Our series	1981–2000	55	2001–2007	50

asymptomatic. Another is connected with the decreasing risk of pancreatic surgery. The most important fact, however, may be that until 1999, the distinction between IPMNs and mucinous cystic neoplasms (MCNs) was unclear, so that many IPMNs were classified as MCNs [50] or regarded as ductal adenocarcinomas or chronic pancreatitis.

Adenoma-carcinoma sequence

In IPMNs, the normal ductal epithelium is replaced by mucin-producing columnar cells showing papillary proliferations and variable degrees of cellular atypia, even within an individual neoplasm. They are graded according to the most atypical area as IPMN with low grade dysplasia (adenoma), IPMN with moderate dysplasia (borderline), and IPMN with high grade dysplasia (carcinoma in situ). An invasive component may be found in 38–50% of the cases [7, 26, 40, 43]. Progression from adenoma to carcinoma is estimated to occur at about 5 years [43]. IPMNs therefore provide a model of neoplastic progression from a benign intraductal neoplasm through increasing grades of dysplasia to invasive carcinoma.

Prognosis after resection

Between 80 and 90% of IPMNs are surgically resectable. For these IPMNs, a 5-year survival rate of 77–100% was reported, provided the tumors did not have an invasive component (Table 2). By contrast, IPMNs with an invasive component had a 3- to 5-year survival rate of only 36–46% [12, 16, 43] (Table 2). Interestingly, the survival rate did not appear to be dependent on the grade of dysplasia in the IPMN if there was no invasive component [12, 16, 43, 47]. These data imply that the overall outcome of IPMNs therefore largely depends on the presence of an invasive component. If the tumor is already invasive, criteria for a poor outcome are lymph node involvement, vascular invasion, and bilirubin elevation [13]. A comparison of the prognosis of all patients with invasive IPMNs with that of patients with ductal adenocarcinoma reveals that patients with IPMNs survive longer than those with ductal adenocarcinomas [29, 40, 43].

Several studies have reported recurrences after resection of noninvasive IPMNs, some of which revealed only moderate dysplasia [12, 43, 47, 48]. The recurrences were either local or metastatic (Table 2). To explain the recurrences, particularly the local ones, it has to be assumed that either tumor tissue was overlooked at the pancreatic resection margin, or an invasive component remained undetected in the resected specimen, or there was multifocal disease. The last possibility has to be considered if the surgical margins were negative and the recurrence occurred in the pancreatic remnant. This has been observed only in a few cases [40]. When metastatic recurrences occur, it is most likely that they resulted from inadequate sampling that failed to detect an invasive component. Regarding the impact of a positive resection margin on IPMN recurrence, it is interesting to note that it has been reported that even IPMNs with positive margins did not recur during a median follow-up period varying from 19–40 months [13, 48]. The reason for this phenomenon might be that the growth of the remaining intraductal tumor tissue is so slow that clinical symptoms

Table 2 Five year survival rate and recurrence in 349[a] intraductal papillary-mucinous neoplasms

	Noninvasive 77–100%	Invasive 36–46%
No recurrence	93–98.7%	52–70%
Recurrence	1.3–7%	30–48%
Local	up to 6%	8–48%
Distant (metastases)	1%	12%
Both	0%	10–48%

Invasive (35%)	*n*=7 (26%)	*n*=22 (38%)	*n*=4 (57%)	*n*=4 (28%)

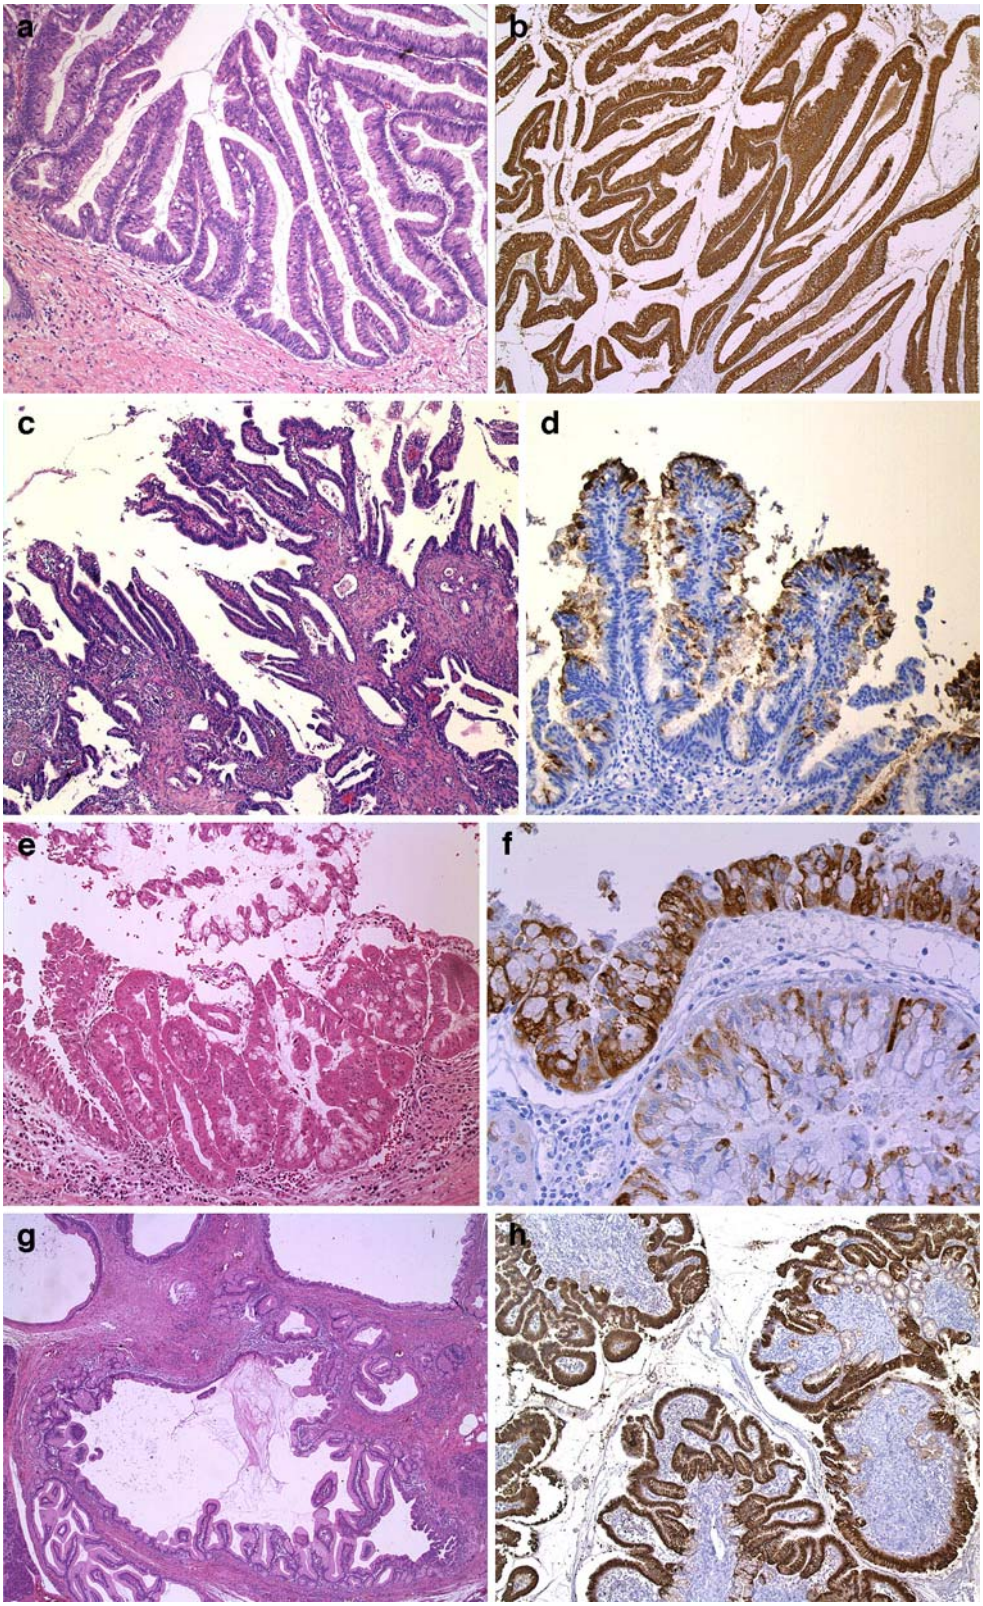

Fig. 1 Histological subtypes of intraductal papillary-mucinous neoplasms of the pancreas and their usual mucin pattern. **a**, **b** IPMN of the intestinal type positive for MUC2; **c**, **d** IPMN of the pancreatobiliary type positive for MUC1; **e**, **f** IPMN of the oncocytic type showing scattered positivity for MUC2; **g**, **h** IPMN of the gastric type, positive for MUC5

only appear after a follow-up period of 2 to 3 years. However, even if intraductal recurrences may take a long time to become clinically apparent, a positive margin in any IPMN case should lead to further tissue resection.

Histological type and prognosis

In 1991, it was reported that the invasive component of IPMNs corresponded either to an ordinary ductal adeno-

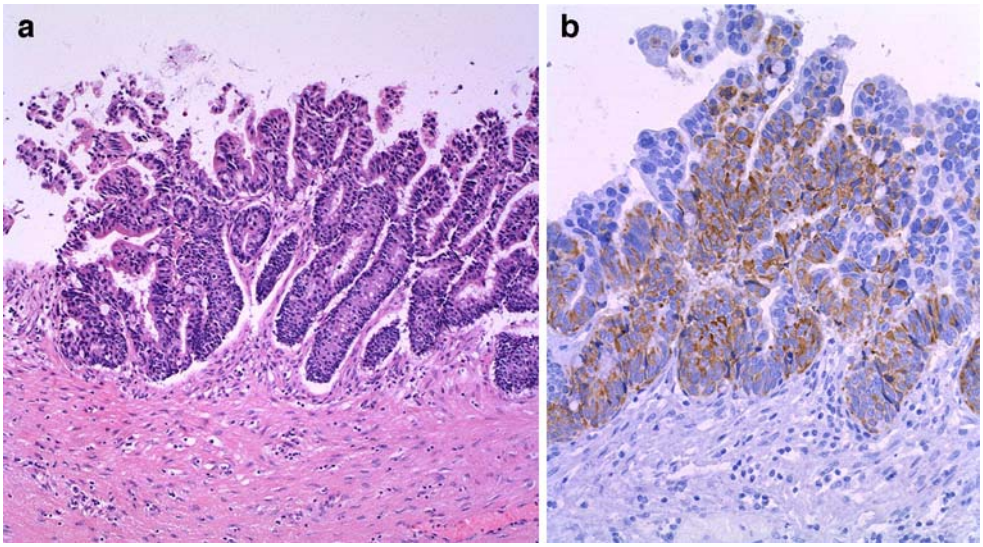

Fig. 2 IPMN of the gastric type showing severe cellular atypia and MUC5 positivity

carcinoma or, more frequently, to that of a mucinous (colloid) carcinoma [49]. This observation suggested that IPMNs form a group of heterogeneous neoplasms. A further argument for the heterogeneity of IPMNs was the detection of IPMNs in branch ducts rather than in the main duct, where most of the IPMNs are found. Finally, it was recognized that IPMNs differ in their histological and cytological features and in their mucin profile [3, 4, 18, 28, 32, 33]. Currently, four subtypes of IPMN can be distinguished: an intestinal type, a pancreatobiliary type, an oncocytic type, and a gastric type [18].

The most common type of IPMN is the intestinal type (Table 3). It usually occurs in the main duct of the pancreatic head [9] and shows a villous growth pattern similar to that of villous adenoma in the colon. It also expresses MUC2 and CDX2 but not MUC1 (Fig. 1a,b). When this IPMN type becomes invasive, the invasive component resembles mucinous (colloid) carcinoma [5, 28], a tumor of which at least 80% is composed of pools of extracellular mucin containing single cells or strands of neoplastic glandular epithelium or even a small component of signet ring cells. Patients with colloid carcinoma have a 55% 5-year survival rate after resection [5]. These tumors therefore seem to be much less aggressive than ordinary ductal adenocarcinomas.

The pancreatobiliary type of IPMN is much rarer than the intestinal type IPMN (Table 3). It shows complex arborizing papillae and expresses MUC1 only (Fig. 1c,d). Its invasive component usually corresponds to a conventional ductal adenocarcinoma. The prognosis of this type of IPMN, if invasive, seems to be similar to that of ductal adenocarcinoma and therefore poorer than that of the intestinal type of IPMN [4].

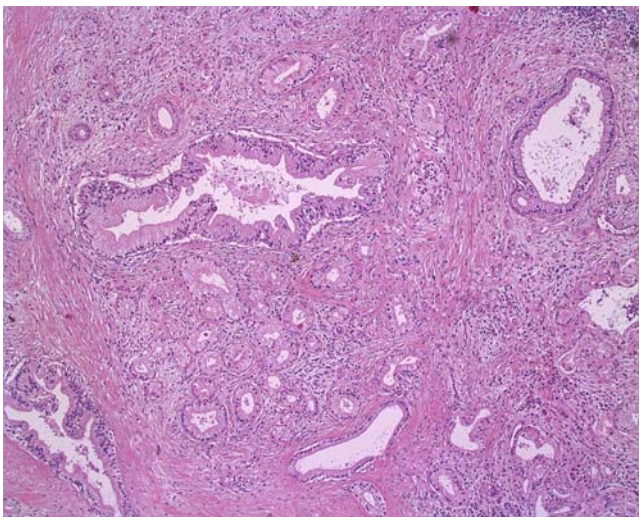

Fig. 3 PanIN-1 lesion associated with lobular fibrosis

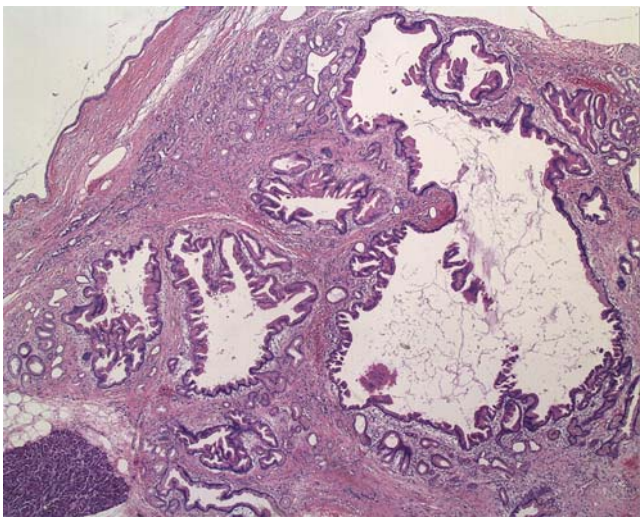

Fig. 4 Small multicystic duct-associated lesion in the periphery of pancreatic tissue suggestive of an IPMN of the gastric type but difficult to distinguish from a large PanIN-1 lesion

The oncocytic type of IPMN (also called intraductal oncocytic papillary neoplasm [2]) shows the same complex papillae as the pancreatobiliary type, but the lining cells reveal strongly eosinophilic cytoplasm. In addition, there are often numerous goblet cells. The tumor cells express MUC1 and MUC2 inconsistently (Fig. 1e,f). With fewer than 20 cases reported in the literature to date [2, 20, 34, 35, 37, 38, 42], the clinical and pathological behavior of this type is still unclear. Most of the cases (94%) were diagnosed as carcinoma, some of them with an invasive component or even distant metastases [37]. As the follow-up in this patient group is very short, no relevant data are available yet on survival and outcome.

The gastric type of IPMN exhibits papillary projections lined by epithelial cells resembling gastric foveolar cells and shows pyloric gland-like structures at the base of the papillae. These cells express MUC5 (Fig. 1g,h), while MUC1, MUC2, or CDX2 positivity is only occasionally observed. The gastric type of IPMN corresponds to the branch duct type, which occurs in the periphery of the pancreatic parenchyma, most often in the uncinate process, where it usually presents as a multicystic lesion with cysts no larger than 3 cm [9]. The gastric type seems to be less aggressive, i.e., less invasive, than the other IPMN subtypes [10, 25, 33, 46] but may show severe cellular atypia in a few cases (up to 25%) [46] (Table 3, Fig. 2) The size of the lesion was unrelated to the grade of cellular atypia [46].

Interestingly, pancreatic intraepithelial neoplasia (PanIN)-like complexes are frequently observed next to gastric type IPMNs. This raises the question whether IPMNs of the gastric type are a focal accentuation of a diffuse disease rather than a localized lesion. They might therefore also be related to the small peripheral cystic changes described by Kimura et al. [21] in non-neoplastic pancreata or the patchy lobular fibrosis associated with PanIN-1B lesions described by Detlefsen et al. [14] (Fig. 3). If this were the case, IPMNs of the gastric type would actually be large PanIN-1 lesions. An argument for this assumption is that both IPMNs of the gastric type and PanIN-1 lesions stain for MUC5 in the absence of MUC1 and MUC2 positivity. This assumption would also explain why it is difficult to distinguish PanIN lesions from some IPMNs [27] (Fig. 4), despite a consensus definition of both lesions [19].

Although the malignant potential of IPMNs of the gastric type seems to be rather low, it has to be pointed out that the fibrocystic changes that have been described in pancreata removed from patients with a strong family history of pancreatic cancer [11, 30] are similar, if not identical, to IPMNs of the gastric type and their associated PanIN lesions. This implies that IPMNs of the gastric type/PanIN-1 lesions are not innocuous lesions but have a malignant potential.

Summary and perspectives

The significance of IPMNs among the pancreatic tumors has increased greatly in recent years because of their improved recognition, both clinically and histopathologically and their much better prognosis than ordinary ductal adenocarcinomas. Moreover, they appear to fall into four subtypes that have special biological properties with prognostic implications. Of particular interest in relation to the development of ductal adenocarcinomas is the fact that the so-called gastric type IPMNs seems to occur in pancreata from patients with a strong family history of pancreatic cancer. Furthermore, it is of interest that the pancreatic IPMNs have their counterparts in IPMNs of the biliary duct system, where the same subtypes may occur [1, 23, 51, 52]. The treatment of choice is resection, but future trials may reveal that the extent of resection could depend on the IPMN subtype.

REVIEW AND PERSPECTIVE

Lymphatic vessels are present in phosphaturic mesenchymal tumours

K. Williams · A. Flanagan · A. Folpe · R. Thakker · N. A. Athanasou

Received: 30 April 2007 / Revised: 5 July 2007 / Accepted: 6 July 2007 / Published online: 3 August 2007

Abstract Oncogenic osteomalacia (OO) is an acquired form of hypophosphataemic osteomalacia, which is associated most commonly with the development of a benign phosphaturic mesenchymal tumour mixed connective tissue type (PMTMCT). PMTMCTs are generally well vascularised tumours, and many have in the past been classified as haemangiomas and haemangiopericytomas. Although these tumours show some morphological variation, it has been proposed that they represent a distinct histopathological entity. Our aim in this study was to determine by immunohistochemistry the vascular profile of PMTMCT. Using monoclonal antibodies directed against several vascular markers, including the lymphatic endothelial cell antigens LYVE 1 and podoplanin, we found that PMTMCTs, in contrast to haemangiomas and haemangiopericytomas, contain lymphatic vessels. Taken with previous observations that PMTMCTs over express FGF23 and other gene products, this finding provides further evidence that most osteomalacia associated mesenchymal tumours represent a discrete pathological entity.

Introduction

Oncogenic osteomalacia (OO) is a rare syndrome characterised by hypophosphataemia that occurs in association with a number of tumours, particularly mesenchymal tumours of soft tissue and bone [5, 21, 22]. In this syndrome, there is increased phosphate excretion, decreased plasma 1,25 dihydroxy vitamin D_3 levels and osteomalacia, which does not respond to vitamin D therapy. These biochemical and clinical abnormalities resolve when the tumour, which may be very small, is resected [5, 7].

OO may occur at any age and has been reported to occur in association with a variety of different tumour types. Most cases are associated with mesenchymal neoplasms of soft tissue or bone, but a few cases have been reported in association with other tumours, such as carcinomas and lymphomas, as well as in association with neurofibromatosis, polyostotic fibrous dysplasia and epidermal naevus syndrome [1, 7, 10, 13, 14]. The various types of mesenchymal tumour associated with OO have been categorised into four distinct morphological patterns [22]: (a) a primitive appearing mixed connective tissue tumour, (b) an osteoblastoma-like tumour, (c) a non ossifying fibroma-like tumour and (d) an ossifying fibroma-like tumour. The most common of these tumour types is the mixed connective tissue variant, which is generally designated as phosphaturic mesenchymal tumour, mixed connective tissue type

(PMTMCT). OO-associated mesenchymal tumours have common histopathological features and have been shown to over-express fibroblast growth factor 23 (FGF23), a protein that inhibits renal tubular epithelial phosphate transport [8, 9]; on this basis, it has been proposed that these tumours constitute a single pathological entity.

Although malignant tumours associated with OO have been reported, most PMTMCTs are benign tumours [7]. PMTMCTs exhibit some morphological variation but generally contain a proliferation of spindle shaped mesenchymal cells that lie in a well vascularised connective tissue matrix; this matrix may contain areas of calcification, cartilage and bone formation as well as scattered osteoclast like giant cells [21, 22]. The vascular component of PMTMCTs is often very prominent, and many of these lesions have in the past been classified as a type of vascular tumour, usually a haemangiopericytoma or some benign form of haemangioma [7].

To examine whether the vascular profile of PMTMCT is unique, we analysed the antigenic phenotype of endothelial cells in eight cases of PMTMCT and compared it with that of haemangiomas and haemangiopericytomas. As it has previously been shown that lymphatic vessels are not typically found in haemangiopericytomas and (capillary, cavernous or epithelioid) haemangiomas [23], we were particularly interested in determining whether PMTMCTs contain lymphatic vessels, which we identified in this study by expression of two highly specific lymphatic endothelial cell markers, LYVE 1, a novel homologue of the CD44 glycoprotein, which is a receptor for hyaluronan [3] and podoplanin, a heavily O glycosylated glycoprotein that plays a role in cell and matrix adhesion [4].

Materials and methods

Eight cases of PMTMCT, five cases of capillary haemangioma, five cases of cavernous haemangioma and five cases of haemangiopericytoma were obtained from the archives of the Histopathology Departments of the Nuffield Orthopaedic Centre, Oxford, the Royal National Orthopaedic Hospital, London, and Emory University, Atlanta. Clinical details of the PMTMCT cases are shown in Table 1; four of these cases have previously been reported and were found to be FGF23 positive by immunohistochemistry [8]; the remaining four cases had elevated serum FGF23 levels. Paraffin embedded sections (5 μm) were cut onto silane-coated or charged slides and incubated at 37°C for 24 hours before staining.

All immunohistochemical staining was performed using an indirect immunoperoxidase technique (ChemMate Envision, Dako, UK). Tissue sections were dewaxed and re hydrated by successive immersion in xylene, graded ethanol and water. Antigen retrieval was performed by microwave treatment (700 W, 2×4 min) in Target Retrieval Solution (Dako). Endogenous peroxidase was blocked by 0.2% (*v*/*v*) hydrogen peroxide in 80% ethanol and protein block serum before 30-min incubation with a mouse anti-human LYVE 1 monoclonal antibody, which was generated against a soluble LYVE 1 Fc fusion protein [3]. Sections were also stained with a monoclonal antibody to the lymphatic endothelial cell marker, podoplanin [4]. Tumour sections where also stained immunohistochemically against the blood vessel endothelial cell markers, Factor VIII related antigen/von Willebrand factor (vWf), CD31 and CD34 using respectively a polyclonal antibody to vWf and the monoclonal antibodies JC70 and QBend10 (Dako). Antigens were detected by incubation with labelled polymer and diaminobenzidine (Dako). The sections were then counterstained with haematoxylin, dehydrated, cleared and mounted.

Normal sections of skin and lymph node were used as positive control tissue; these contained both lymphatic and blood vessels. Negative controls consisted of sections stained with primary antibody diluent alone or substitution of an appropriate irrelevant antibody for the tumour under investigation [e.g. MNF116 anti-cytokeratin antibody (Dako) for primary neoplasms and non-neoplastic lesions of bone].

Table 1 TMCT cases analysed in this study

Case no.	Age (years)/ sex	Site	LYVE 1/podoplanin staining
1	53 Female	Foot	+/+
2	60 Female	Femur	+/+
3	54 Male	Groin	+/+
4	48 Male	Thigh	+/+
5	58 Male	Popliteal fossa	+/+
6	52 Male	Bone	+/+
7	30 Female	Ilium	−/−
8	37 Female	Wrist	+/+

Results

All eight cases of PMTMCT showed a number of common histological features. The tumours were composed of a proliferation of spindle shaped tumour cells, which showed minimal to moderate nuclear pleomorphism and little or no mitotic activity (Fig. 1). All the tumours were highly vascular; there were numerous prominent thick or thin-walled vessels, some of which were dilated and had a haemangiopericytoma like appearance. Tumour cells lay in a fibrous matrix, which focally showed a variable degree of

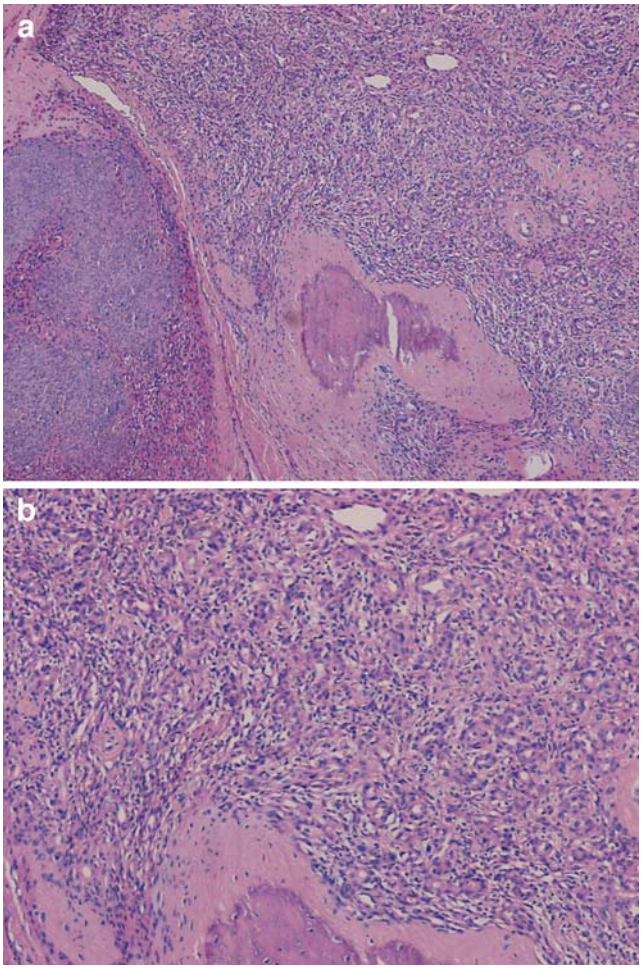

Fig. 1 **a** Low and **b** high-power photomicrographs of a representative PMTMCT of soft tissues showing a well-vascularised spindle cell tumour in which there is focal ossification. The bone trabeculae have a prominent osteoid seam

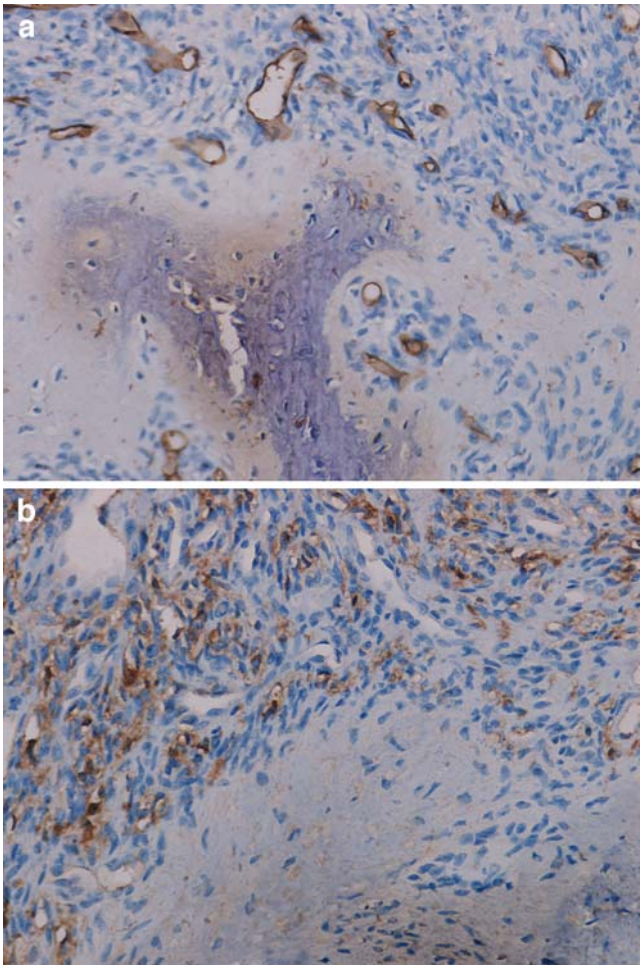

Fig. 2 **a** LYVE-1 staining of endothelial cells lining lymphatic vessels and **b** CD34 staining of endothelial cells lining vascular channels in a PMTMCT of soft tissues in which there is focal ossification

mucinous or myxoid degeneration. Some tumour contained focal areas of ossification with formation of bone trabeculae, some of which were covered by wide osteoid seams (Fig. 1).

The five cases of soft tissue PMTMCT contained numerous vessels, which were lined by endothelial cells that stained for CD34, CD31, and vWf. These tumours also contained scattered LYVE 1^+/podoplanin$^+$ lymphatic vessels (Fig. 2); these vessels also reacted variably for CD34, CD31 and vWf. Spindle shaped mesenchymal tumour cells, giant cells and other cells not lining vascular spaces did not express LYVE 1 or podoplanin.

The number of LYVE 1^+/podoplanin$^+$ lymphatic vessels in the PMTMCTs examined varied depending on the degree of vascularity seen in these tumours. In general, the more vascular the PMTMCT, the more lymphatics were observed. LYVE 1^+/podoplanin$^+$ lymphatic vessels were most numerous in two haemangioma-like lesions, which contained many capillary sized blood vessels as well as scattered dilated vascular spaces lined by endothelial cells which were LYVE 1^-/podoplanin$^-$ but vWf$^+$, CD31$^+$ and CD34$^+$. Examination of serial sections revealed that some LYVE 1^+/podoplanin$^+$ endothelial cells also expressed vWf, CD31 and CD34 to a variable extent. The remaining three soft tissue PMTMCTs contained mainly a proliferation of spindle shaped mesenchymal tumour cells amongst which were scattered small capillary sized vessels, including some lined by LYVE 1^+/podoplanin$^+$ endothelial cells; these vascular channels did not contain red cells and stained for CD34 as well as variably for CD31 and vWf.

Three cases of PMTMCT arose in bone. Two of the tumours contained capillary sized and larger thin walled vessels, which did not contain red cells, and were lined by LYVE 1^+/podoplanin$^+$ endothelial cells (Fig. 3). These tumours contained focal areas of bone formation and dystrophic calcification associated with the presence of reactive osteoclast like giant cells. Endothelial cells lining the vascular channels containing red cells were positive for CD34 and showed variable staining for CD31 and vWf. The remaining bone PMTMCT was a spindle cell tumour in

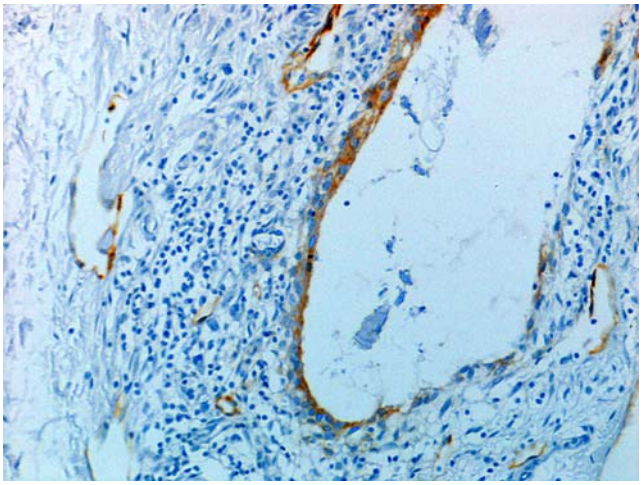

Fig. 3 Podoplanin staining of lymphatic endothelial cells lining a dilated lymphatic vessel in a PMTMCT of bone

which there were scattered small vessels that were $CD34^+$, $CD31^+$ and vWf^+ but LYVE 1^-/$podoplanin^-$.

In positive control lymph node and skin tissues, endothelial cells lining lymphatic vessels were positive for LYVE 1 and podoplanin; these vessels showed variable staining for CD31, CD34 and vWf. Endothelial cells lining blood vessels also expressed CD31, CD34 and vWf. These antigens were also expressed by endothelial cells in capillary and cavernous haemangiomas, as well as haemangiopericytomas; there was no staining of vessels for LVYE 1 or podoplanin in these lesions.

Discussion

Identification of lymphatic endothelial cell markers has led to a re-assessment of the histogenesis of several tumours, such as Kaposi's sarcoma and angiosarcoma [4, 23]. In this study, we have shown that, in contrast to capillary/cavernous haemangiomas and haemangiopericytomas [23], most PMTMCTs contain lymphatic vessels as demonstrated by expression of the specific lymphatic endothelial cell markers, LYVE 1 and podoplanin.

PMTMCT is the most common type of osteomalacia associated tumour, which occurs in soft tissues [7, 22]. This tumour behaves in a benign fashion (although malignant forms have been reported) and is often small, slow growing and difficult to localise. It is characterised by the presence of variable numbers of primitive appearing mesenchymal stromal cells that lie in a well vascularised connective tissue stroma that may contain scattered osteoclast like giant cells. It is thought that mesenchymal cells in these tumours are the source of the hormonal factor that causes the osteomalacia. Immunohistochemical studies have not found evidence of epithelial, neural or neuroendocrine differentiation in the mesenchymal cells of this tumour, and in the present study, we found that PMTMCT mesenchymal cells did not express lymphatic endothelial cell markers. The vascularity of OO-associated PMTMCTs is often very prominent, and on this basis, many of these lesions have in the past been categorised as a type of vascular tumour [7, 21, 22]. Most of the vascular elements in the eight PMTMCTs studied in our series were lined by blood vessel endothelial cells that expressed CD31, CD34 and vWf; these antigens are expressed by lining endothelial cells in benign and malignant vascular tumours (including haemangiomas and haemangiopericytomas) [23]. CD31, CD34 and vWf are also known to be expressed by lymphatic endothelial cells [11, 16, 20], and we found that LYVE 1^+/$podoplanin^+$ lymphatic vessels in PMTMCTs also expressed these antigens. Our finding of lymphatic vessels expressing these antigens in most PMTMCTs shows that these tumours have a distinct vascular profile, which distinguishes them from morphologically similar vasoproliferative tumours; this observation is in keeping with the hypothesis that PMTMCTs represent a discrete pathological entity.

FGF23, a gene known to be mutated in autosomal dominant hypophosphataemic rickets, is abundantly expressed in PMTMCT as shown by protein and mRNA expression. Increased levels of FGF23 have been found in patients with OO and polyostotic fibrous dysplasia [15, 19] and were noted in four of the PMTMCT cases we studied. Although the precise relationship between FGF23 expression in PMTMCTs and OO is not certain, many (but not all) of these tumours are clearly distinguished by over expression of this gene product. FGF23 is expressed in mesenchymal tumour cells and not in endothelial cells in PMTMCTs [8]. FGF23 is degraded by PHEX, a membrane - bound endopeptidase mutated in X linked hypophosphataemia. It has been suggested that OO-associated mesenchymal tumours may produce sufficient FGF23 to overwhelm native PHEX levels. The precise role of FGF23 in the pathogenesis of OO is uncertain, but most FGFs are potent stimulators of angiogenesis in vitro and in vivo [2]. It is not known if the presence of lymphatic vessels in PMTMCT is associated with over expression of FGF23, but several FGFs or their receptors are known to influence lymphangiogenesis. Fibroblast growth factor receptor 3 (FGFR3) expression is upregulated in lymphatic endothelial cells by PROX1, a transcription factor which is essential for the development of the lymphatic system [18]. FGF1 and FGF2 have also been shown to promote the proliferation, migration and survival of lymphatic endothelial cells in vitro [6, 12].

In addition to FGF23, tumours that cause OO are distinguished from other mesenchymal tumours by expression of a number of gene products, which are related to bone matrix formation (DMP 1 and fibronectin), mineralisation (MET) and mineral ion transport (Pit 1/Glvr 1 and Ank A)

[6]. Some OO-associated tumours also show increased expression of several genes involved in tumourigenesis and/or inflammation, including factors associated with matrix adhesion such as CD44 and osteopontin [6, 17]. Expression of these factors is of interest as both LYVE 1 and podoplanin play a role in cell/matrix adhesion. LYVE 1 is a well characterised homologue of the CD44 glycoprotein, which acts as a receptor for cell/matrix hyaluronan [3]. It is possible that in PMTMCTs mesenchymal tumour cells over express a number of gene products, which promote the generation of matrix components that induce the proliferation of lymphatic vessels, a feature which distinguishes these tumours from typical haemangiomas and haemangiopericytomas.

Abstract The aim of this study was to evaluate protein expression of Karyopherin alpha 2 (KPNA2) in invasive breast cancer and matched ductal carcinoma in situ (DCIS) and to correlate it with clinicopathological data, including patient survival. KPNA2 protein expression was assessed by immunohistochemistry in breast tissue samples, containing invasive carcinomas, DCIS, and adjacent histologically benign breast tissues. A polyclonal goat KPNA2 antibody was used for immunostaining of 83 clinicopathologically characterized cases. For statistical analysis, staining of at least 10% of nuclei was considered KPNA2 positive. Immunohistochemical detection of KPNA2 in invasive carcinoma showed a significant correlation with higher tumor stage, positive lymph node status, higher tumor grade, and negative ER status. Concordantly, KPNA2-positive tumors (31.3%) showed significantly shorter disease-free survival times (69 months vs 118 months; $p=0.007$). KPNA2 protein expression was also detected in DCIS (21.3%) adjacent to invasive tumor and correlated with nuclear grade ($p=0.013$). Expression of KPNA2 in invasive breast cancer correlates with conventional prognostic parameters and shorter disease-free survival. Additionally, KPNA2 is overexpressed in DCIS, particularly high grade lesions, which emphasizes its potential role in carcinogenesis of invasive breast carcinomas.

Introduction

Breast cancer is the most common malignant neoplasm of women in the Western world, with an estimated number of 178,480 new cases of breast cancer among US women in 2007 [4]. Recent diagnostic and therapeutic advances are encouraging, but at the same time, increasingly detailed prognostic information is required, which should exceed conventional prognostic parameters, i.e., age, nodal status, tumor size, tumor grade, tumor type, and receptor status. This condition seems to be met by several promising molecular markers like Kallikrein 5 [20], urokinase plasminogen activator and its inhibitor [9], tissue inhibitor of metalloproteinase 1 [10], Ep-CAM [17], osteopontin [12],

CD24 [8], SFRP1 [7], survivin [13, 16], and Karyopherin alpha 2 (KPNA2) [2, 15, 19].

Several gene expression profiling studies demonstrated overexpression of KPNA2, a member of the karyopherin alpha protein family, in breast cancer tissue [2, 15, 19]. Proteins of the karyopherin alpha family play a central role in nucleocytoplasmic transport. They act as an adaptor in the nuclear import of macromolecules by binding cargoproteins, which contain a classical nuclear localization signal, thereby linking them to the transport protein karyopherin beta. A strong nuclear KPNA2 immunoreactivity was observed in breast cancer cells compared to a weak or absent staining in normal breast tissue by Dahl et al. [2]. They also demonstrated an independent negative correlation between nuclear KPNA2 protein expression in the primary tumor and overall survival of breast cancer patients.

So far, no data on KPNA2 protein expression in preinvasive lesions of the breast are available. We, therefore, aimed to investigate the expression of KPNA2 immunohistochemically in a cohort of clinically characterized breast cancer samples and matched peritumoral ductal carcinoma in situ (DCIS) to verify the prognostic properties in invasive cancer and to focus on KPNA2 expression in adjacent DCIS.

Materials and methods

Patients

The study included 83 patients with breast cancer, diagnosed at the Institute of Pathology, University Hospital Charité, Berlin, between 1991 and 1997. Patient age at the time of diagnosis ranged from 30 to 80 with a mean of 58 years. Clinical follow-up data, including overall survival and disease-free survival, were available for all cases. The median observation time for overall survival was 78 months for patients still alive at the time of analysis (range 3–162 months). Fourteen patients (16.9%) died during follow-up, and 31 patients (37.3%) experienced disease progression, defined by either metastatic disease or local recurrence.

The selection of cases for this study was based on availability of tissues. Patients with systemic disease (pM1) at the time of diagnosis were excluded. Histological typing of tumors was carried out according to the criteria of the World Health Organization. Tumor stage was determined according to the guidelines of the UICC [14]. Tumors were graded according to Bloom and Richardson in the modification of Elston and Ellis [3]. Data regarding the estrogen receptor (ER) status, the expression of Her-2/neu (c-erbB2), and the proliferative fraction (Mib-1) were gathered from the archival pathology reports. The clinicopathological data of the cases are described in Table 1.

Immunohistochemistry

Immunohistochemistry (IHC) staining was performed using formalin-fixed, paraffin-embedded archival tissues. After sectioning, tissue sections were applied to slides, deparaffinized with xylene, and gradually rehydrated. Antigen retrieval was performed using a microwave oven (10 min at 250 W). The primary antibody anti-KPNA2 (goat polyclonal SC6917, Santa Cruz Biotechnology; dilution 1:200) was incubated at room temperature for 1 h. Detection was carried out using an avidin–biotin peroxidase method with 3,3′-diaminobenzidine as chromogen (ChemMate detection kit, DAKO, Glostrup, Denmark). Brief nuclear counterstaining with hematoxylin completed the procedure.

While normal testicular tissue served as a positive control for KPNA2 IHC, unspecific binding of the secondary antibody was excluded by omitting the primary antibody.

Evaluation

Evaluation of the immunohistochemical stainings was independently carried out by two pathologists who were

unaware of the outcome of the disease. Areas of invasive carcinoma, DCIS, and adjacent histologically benign breast tissue were considered separately. KNPA2 positivity was defined as strong nuclear staining in at least 10% of cells.

Statistical analysis

Data were analyzed using the software package SPSS, version 13.0. Spearman's rank correlation was calculated, and Fisher's exact test and χ^2 test were applied to evaluate the statistical significance of association between expression of KPNA2 and clinicopathological variables.

For univariate survival analysis, cumulative survival curves were calculated according to the Kaplan–Meier method. Differences in survival were assessed with the log-rank test. The impact of KPNA2 positivity, patient age, histologic tumor type, pT status, pN status, tumor grade, ER status, and cerbB2 status on overall survival time and disease-free survival time was analyzed.

Results

KPNA2 immunostaining showed a predominantly nuclear staining pattern, restricted to epithelial cells of normal breast glands, DCIS, and invasive breast cancer (Fig. 1). Additionally, a weak-to-moderate cytoplasmic staining was seen in some cases, but was not subjected to further analysis. Connective tissue cells, blood vessels, and inflammatory cells did not display KPNA2 immunoreactivity.

KPNA2 immunostaining in normal breast tissue

Normal breast tissue adjacent to tumor was present and evaluable in 78 (94%) patients. Nuclear staining was only seen in ten (12.0%) samples. As the stained nuclei never exceeded 1%, all samples were considered KPNA2 negative.

KPNA2 immunostaining in intraductal carcinoma

Seventy-five (90.4%) invasive breast cancer specimens contained peritumoral DCIS, of which 40 cases (53.3%) were of non-high grade and 35 (46.7%) were of high grade. Staining of KPNA2 in at least 10% of nuclei was detected in 16 samples (21.3%), whereas 59 samples (78.7%) were KPNA2 negative. High-grade DCIS displayed KPNA2 staining in at least 10% of nuclei significantly more frequently (n=12, 34.3%) than non-high-grade DCIS (n=4, 10.0%; p=0.013). According to this, 23 samples of high-grade DCIS (65.7%) and 36 samples of non-high-grade DCIS (90.0%) were KPNA2 negative. KPNA2 immunoreactivity in DCIS correlated with KPNA2 expression in adjacent invasive carcinomas (cc=0.725; p<0.001).

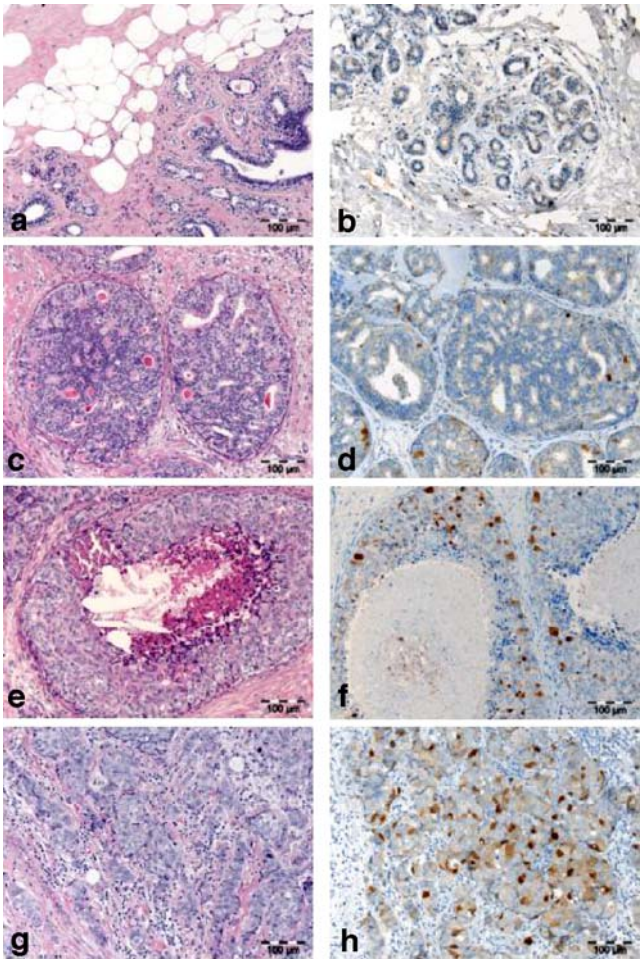

Fig. 1 Hematoxylin and eosin staining and KPNA2 immunohistochemistry. **a** Normal glandular breast tissue (HE). **b** Normal glandular breast tissue displaying luminal epithelium with only single KPNA2-positive nucleus and weak-to-moderate cytoplasmic staining. **c** Non-high-grade DCIS (HE). **d** Few KPNA2-positive nuclei and weak cytoplasmic staining in non-high-grade DCIS. **e** High-grade DCIS (HE). **f** High-grade DCIS with markedly increased nuclear KPNA2 staining. **g** Invasive ductal carcinoma (HE). **h** Strong nuclear KPNA2 staining and moderate cytoplasmic staining in invasive ductal carcinoma. **a**–**h** Original magnification ×200

KPNA2 immunostaining in invasive breast carcinomas

KPNA2-positive immunostaining was seen in 26 (31.3%) invasive carcinomas, the median percentage of positive nuclei being 15%, with a maximum of 40%. KPNA2 positivity of invasive carcinoma revealed a statistically significant correlation with higher pT status, nodal status, histological grade, and a negative ER status (Table 2).

KPNA2 immunoreactivity in invasive carcinomas and univariate survival analysis

Patients with KPNA2-positive breast carcinomas (≥10%) had an estimated mean disease-free survival time of 69 months (95% confidence interval, 47–92 months)

compared to 118 months (95% confidence interval, 100–135 months) in patients with negative KPNA2 staining (<10%; $p=0.007$; Fig. 2). For overall survival, no significant differences were noted (data not shown).

Discussion

Nucleocytoplasmic transport mechanisms have been the target of numerous studies for they are involved in many cellular processes, such as gene expression, cell-cycle progression, and signal transduction [1]. Regulating the subcellular distribution of macromolecules, nuclear transport mechanisms may also control their functions. There is increasing evidence that these mechanisms may contribute to malignant cell transformation, which makes their elements interesting targets for further evaluation [11]. One of these elements is KPNA2, an adaptor protein, which mediates the nuclear import of macromolecules with a classical nuclear localization signal. Linking a cargoprotein and Karyopherin beta, KPNA2 initiates the transport through the nuclear core complex. Thakur et al. [18] demonstrated that one of the proteins whose subcellular distribution may be influenced by KPNA2 is BRCA1, thereby connecting KPNA2 expression with breast carcinogenesis.

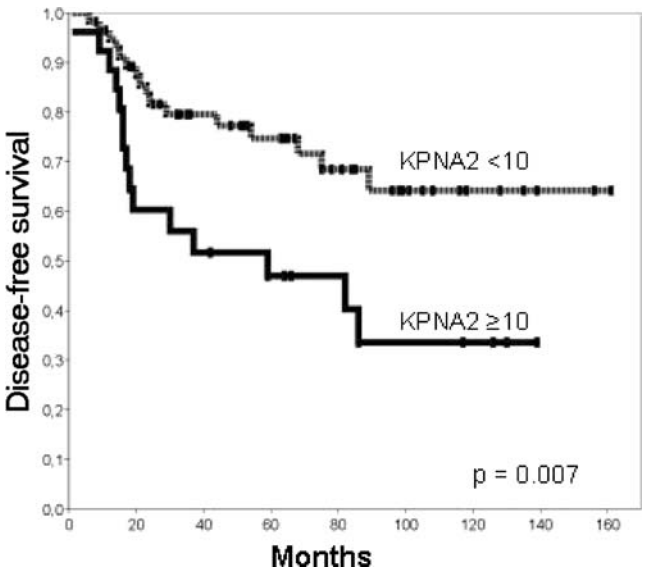

Fig. 2 Survival analysis. Kaplan–Meyer curves regarding disease-free survival of patients with KPNA2 expression in less than 10% of nuclei (*dashed line*) vs patients with KPNA2 expression in at least 10% of nuclei in invasive carcinomas (*bold line*)

Another cargoprotein of KPNA is TP53. Kim et al. [5] identified a truncated form of KPNA in a breast cancer cell line and showed that overexpression of this truncated form results in cytoplasmic accumulation of TP53, whereas overexpression of intact KPNA leads to a transactivation of TP53-responsive genes in the nucleus.

Several gene expression profiling studies reported overexpression of KPNA2 in breast cancer [2, 15, 19]. Sotiriou et al. [15] found an association of KPNA2 overexpression with higher histologic tumor grade, which matches our findings on protein level. Dahl et al. were the first to evaluate KPNA2 protein expression in breast cancer and observed a strong nuclear immunohistochemical staining in breast cancer cells compared to a weak or absent staining in normal breast tissues. They also demonstrated an independent negative association between KPNA2 expression in the primary tumor and overall survival in breast cancer patients which was particularly valid in the group of node-positive cases. Importantly, KPNA2 expression appears to be characteristic of the basal-like subtype of breast cancers, which has an immediate impact on adjuvant therapy planning [2].

The present study confirms our former results in an independent and well-characterized breast cancer cohort, using the cutoff value applied by Dahl et al. [2]. KPNA2 expression in at least 10% of nuclei was seen in 31% of invasive carcinomas, whereas none of the matched normal tissues was KPNA2 positive. Nuclear KPNA2 staining was significantly correlated with higher tumor stage, lymph node status, higher tumor grade, and negative ER status. Consistent with the results reported by Dahl et al., survival analysis revealed that patients with KPNA2-positive breast carcinomas had significantly shorter disease-free survival times, which clearly validates the prognostic value of KPNA2 in breast cancer.

Further investigation of KPNA2 expression in preinvasive lesions of the breast appears mandatory to establish the time point of KPNA2 upregulation in the multistep process of mammary carcinogenesis. To our knowledge, the present study includes the first description of KPNA2 protein expression in matched DCIS and invasive lesions of the breast. Staining of KPNA2 in at least 10% of nuclei was detected in 21% of patients with DCIS. KPNA2 immunoreactivity in DCIS and invasive carcinomas correlated significantly. The portion of KPNA2-positive cases increased successively, comparing adjacent benign tissues (0%), DCIS (21.3%), and invasive carcinomas (31%). This indicates, that upregulation of KPNA2 may be an early

event in carcinogenesis, which is also assumed by Klein et al. [6], who found KPNA2 upregulated early in a mouse model of breast cancer. This hypothesis is corroborated by the fact that samples showing positive KPNA2 staining in at least 10% of nuclei were significantly less frequent in the group of low-grade DCIS (10%) compared to those cases displaying adjacent high-grade DCIS (34.3%). The portion of KPNA2-positive cases in the latter group was almost equivalent to the portion of KPNA2-positive invasive carcinomas, which suggests that KPNA2 overexpression is preceding invasion. Clearly, further studies are needed to clarify the functional role of KPNA2 in breast carcinogenesis.

Abstract Uniform management of flat DIN 1 (flat epithelial atypia) on core needle biopsy (CNB) concerning surgical excision or clinical follow-up are lacking. In a retrospective review of 1,751 CNB over an 8-year period, we found 63 cases with flat DIN 1 as the most advanced lesion; follow-up was available in 55 cases. Of the 63 patients, 24 had a subsequent biopsy for 15 days to 10 years after the initial CNB, an infiltrating carcinoma was found in nine (14.3%) patients, seven (11.1%) in the ipsilateral, and two (3.2%) in the contralateral breast. Five underwent an excisional biopsy of the ipsilateral breast within less than 3 months of the initial CNB; none had either an invasive or intraepithelial carcinoma. Based on our findings, we consider flat DIN 1 a marker of slightly increased risk for subsequent development of invasive breast carcinoma. When flat DIN 1 is found on CNB as the most advanced lesion after mammographic correlation, an excisional biopsy is not mandatory; however, close follow-up is advised with repeat mammograms for early detection of any clinically occult carcinoma in the vicinity of flat DIN 1 that may have been missed by the CNB.

Keywords Flat epithelial atypia · Flat DIN 1 · Core needle biopsy · Breast carcinoma · Ductal intraepithelial neoplasia

Introduction

Flat epithelial atypia is an intraductal alteration characterized by replacement of the native epithelial cells by a single or three to five layers of mildly atypical cells. The ducts involved are variably distended and often contain intraluminal microcalcifications or secretory material [33]. Azzopardi, using the term "Clinging carcinoma, monomorphous type," provided a thorough description of this lesion in 1979 [1]; however, the lesion remained widely unrecognized and/or ignored, until recent years when its neoplastic nature was confirmed at the molecular level [18]. Because of the often subtle cytologic atypia and absence of architectural alterations, it can be easily mistaken for normal breast tissue and has been misinterpreted as a component of fibrocystic changes, as blunt duct adenosis and normal breast for many years. Over the past 5–6 years, there has been a surge of interest in flat epithelial atypia with the increasing frequency of its detection in breast biopsies performed for mammographically detected microcalcifications. A number of reports have referred to this lesion by a wide variety of terms including columnar alteration with prominent apical snouts and secretion [10], atypical cystic lobules [14, 23], columnar cell change with atypia, and columnar cell hyperplasia with atypia [29]. Genetic evidence supports the idea that flat epithelial atypia represents one of the earliest recognizable neoplastic alterations in the breast [18, 30]. These genetic findings coupled with the frequent finding of this alteration as the milieau in which micropapillary and cribriform ductal carcinoma in situ (DCIS) develop further supports its inclusion in the ductal intraepithelial neoplasia (DIN) classification. The rationale and advantages in the use of the DIN classification have been previously stated [32, 36]. As we have used the DIN classification proposed by one of the authors, modifications to the DIN 1 group of lesions as described in the World Health Organization (WHO) 2003 classification [33] have been incorporated into the DIN classification (Table 1). The modified classification that we currently use applies the designation of flat DIN 1 for flat

Table 1 DIN (ductal intraepithelial neoplasia) and traditional terminology in the classification of intraductal proliferative lesions

DIN classification (currently used by the authors)	DIN classification (2003 WHO) [33]	Traditional terminology [33]
Low risk DIN	Usual ductal hyperplasia	Usual ductal hyperplasia
Flat DIN 1	DIN 1a	Flat epithelial atypia
DIN 1 (lesion ≤2 mm)	DIN1b	Atypical ductal hyperplasia (ADH)
DIN 1 (lesion >2 mm)	DIN 1c	DCIS grade 1
DIN 2	DIN 2	DCIS grade 2
DIN 3	DIN 3	DCIS grade 3

epithelial atypia. Despite the increasing recognition of this lesion, the clinical significance and management of flat DIN 1, particularly when found on core needle biopsy (CNB), are unknown, and uniform management guidelines for surgical excision or clinical follow-up are lacking. The current study presents the follow-up and frequency of subsequent invasive breast carcinoma among patients with pure flat DIN 1 discovered in a retrospective review of 1,751 CNB over an 8-year period.

Materials and methods

The files of the Yale University Department of Pathology were searched for breast CNB evaluated between January 1992 and December 1999. CNBs showing other than invasive carcinoma, DCIS, lobular intraepithelial neoplasia (LIN), and/or fibroadenomas were retrieved from the files, and all initial diagnostic hematoxylin-and-eosin-stained slides were reviewed. The 2003 WHO definition of flat epithelial atypia as a change "characterized by replacement of the native epithelial cells by a single layer of mildly atypical cells often with apical snouts, or proliferation of a monotonous atypical cell population in the form of stratification of uniform, cuboidal to columnar cells generally up to 3–5 cell layers with occasional mounding" was used [33]. Flat epithelial atypia, with even a single arcade or micropapillary formation, was considered as atypical ductal hyperplasia (ADH) and excluded.

Cases with pure flat DIN 1 as the most advanced lesion on CNB were included. Medical records were reviewed to verify the absence of any history of ipsilateral breast carcinoma or clinically evident malignancy at the time of biopsy. Follow-up was obtained from the medical records, and the pathology files were searched for subsequent surgical procedures, and hematoxylin-and-eosin-stained slides from subsequent breast biopsies were also retrieved and reviewed.

The number of cores/core fragments present in the initial CNB and the extent of flat DIN 1 was recorded. The cases were grouped according to the extent of flat DIN 1 present in the fragments examined, in those having less then five ductules (or only one terminal duct lobular unit [TDLUs]) involved, five to ten ductules (two TDLUs) involved, and greater than ten ductules (greater than two TDLUs) involved.

Results

A total of 1,751 CNB were performed and evaluated in the period selected. After excluding biopsies with the diagnosis of invasive carcinoma, DCIS, LIN, and/or fibroadenomas, a total of 736 CNB were retrieved and reviewed.

Among 736 CNB reviewed, 63 (8.5%) qualified as flat DIN 1 and met the inclusion criteria. The patients, all women, ranged in age from 39 to 75 with a median age of 52 years. The mammographic abnormalities leading to CNB included calcifications in 49 cases (76%) and density/mass in 14 cases (24%). Follow-up was available in 55 patients. Mean follow-up was 6.2 years (range 1–11 years; Figs. 1 and 2).

The average number of cores/fragments received for pathologic examination was 13 (range 4–26). In 14 (22%) cases, less than five ductules (only one TDLU) were involved, in 20 (32%) cases, five to ten, and in 29 (46%) cases, greater than ten ductules were involved.

Of the 63 patients, 24 had a subsequent breast biopsy (core or excision), 16 in the ipsilateral and four in the contralateral breast, and four in both the ipsilateral and contralateral breasts (Table 2). The interval between the initial CNB and subsequent biopsy was 15 days to 10 years. An infiltrating carcinoma was found in nine (14.3%) patients in a subsequent biopsy, seven (11.1%) in the ipsilateral breast, and two (3.2%) in the contralateral breast (Fig. 3). The mean interval between the initial CNB and the invasive carcinoma was 3.7 years (range 2–9 years) for the ipsilateral tumors. Both cases with contralateral tumor were found 7 years after the initial CNB. In one patient, DIN 2 (DCIS grade 2) was found in the contralateral breast 2 years after the initial CNB.

The mean age of the patients who developed subsequent invasive carcinoma in the ipsilateral breast was 53 years (range 39–63 years) at the time of diagnosis of flat DIN 1, and both women who developed invasive carcinoma in the contralateral breast were 51 years of age.

Among the seven patients who developed subsequent ipsilateral invasive carcinoma, five (71%) had greater than ten ductules (greater than two TDLUs) involved by flat DIN 1 in the initial CNB; the number of fragments in these cases was five in two cases and 7, 12, and 16 in the remaining three. In the other two patients (29%) who had

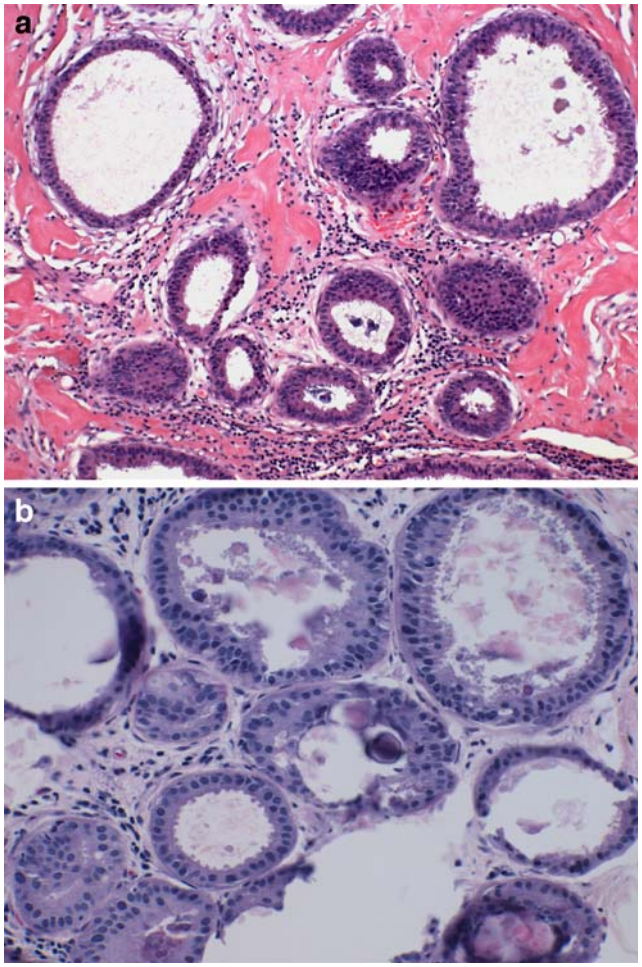

Fig. 1 **a** Case 32, flat DIN 1 on CNB, variably distended acini lined by one to three layers of monotonous cells. No evidence of breast carcinoma in 8 years of available follow-up. **b** Case 42, flat DIN 1 with microcalcifications, no evidence of breast carcinoma in 3 years of available follow-up

four and six core fragments for evaluation, less than five ductules (less than one TDLU) were involved.

All the subsequent ipsi and contralateral infiltrating carcinomas were of ductal type. Five were moderately differentiated and two well differentiated in the ipsilateral breast; in six of the seven cases, flat DIN 1 was present associated with the invasive carcinoma or in the surrounding tissue. Both contralateral invasive carcinomas were moderately differentiated; flat DIN 1 was present in the adjacent breast tissue in both cases. Flat DIN 1 was also present in the subsequent excision showing DIN 2 in the contralateral breast of a third patient.

Two of the seven patients who developed a subsequent ipsilateral invasive carcinoma (cases 15 and 20) had an "interval" biopsy showing DIN 1 (ADH) in between the initial CNB and subsequent invasive carcinoma. Case 15 had two subsequent excisional biopsies, 1 month and 3 years after the initial CNB with the last biopsy 5 years before the invasive carcinoma. Case 20 had a subsequent CNB followed by an excisional biopsy 2 years after the initial CNB and 3 years before the invasive carcinoma.

Five of the 24 women underwent an excisional biopsy of the ipsilateral breast within less than 3 months of the initial CNB; one 15 days later, three 1 month later, and one 2 months later (cases 9, 13, 14, 15, and 63); none of these patients had either an invasive or intraepithelial carcinoma in their excision. The reason for the excisional biopsy after the CNB in these cases was the finding of a radial scar on CNB in one case and the presence of a mass or density on mammography unexplained by the CNB findings. The findings in the excisional biopsy ranged from concurrent flat DIN 1 and LIN in two cases (cases 9 and 63), DIN 1 less than 2 mm (ADH) and a radial scar in one case (case 14), DIN 1, less than 2 mm (ADH) in one case (case 15), and familial colorectal cancer with calcifications in the remaining case (case 13).

Five (7.8%) of 63 women with flat DIN 1 on core biopsy developed subsequent ipsilateral invasive carcinoma without any intervening biopsies that contained a more advanced process (ADH or DCIS).

Discussion

This study is based on a retrospective assessment and identification of 63 examples of flat DIN 1 as the most advanced lesion in core biopsies performed before the widespread recognition of this lesion. Although limited by its retrospective nature and relatively small number of cases, it offers insight into the natural history of these lesions. Because flat epithelial atypia was not recognized as a pathologic

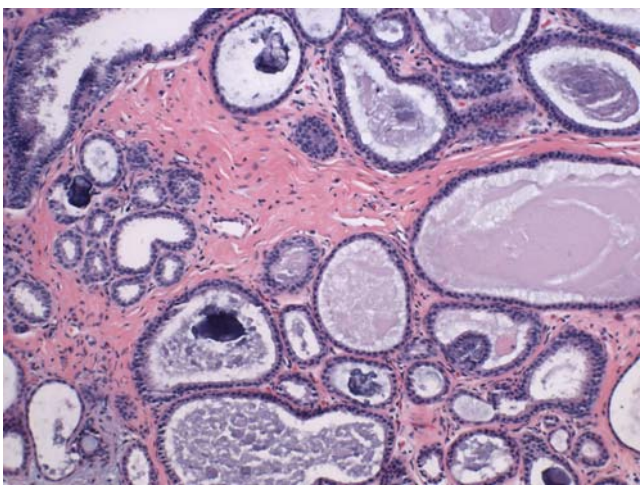

Fig. 2 Flat DIN 1 (case 41), terminal duct lobular unit with distended acini lined predominantly by a single layer of monotonous cells. Luminal calcifications are a frequent finding in flat epithelial atypia leading to mammographic detection. Lifting of the epithelium by stromal calcifications can occur as seen here in the *lower right* (*arrow*) and should not be considered as epithelial tufts or arcades

Table 2 Summary of clinicopathologic data of patients who underwent subsequent breast biopsy after initial CNB

alteration at the time of initial review, no immediate (within 3 months) excisional biopsy was performed in 58 of the 63. Follow-up was available for 55 of the women.

Flat DIN 1 as the most advanced lesion was identified in 3.6% of CNB (63 of a total of 1,751), but this percentage is likely to be higher in current practice as a result of the widespread use of mammography as a screening tool and more abundant sampling (increased number of cores removed per case).

In 73% of the cases, flat DIN 1 was identified in biopsies performed for the evaluation of microcalcifications found on screening mammogram. The frequent association of flat epithelial atypia with microcalcifications is well documented in the literature [10, 25].

There is limited knowledge concerning the bilaterality and multifocality of flat epithelial atypia. Flat DIN 1 was identified in the contralateral breast in six of the eight cases (75%) in which a subsequent biopsy of the contralateral breast was performed, including two associated with invasive carcinoma and three with more advanced intraepithelial lesions (ADH and DCIS; Fig. 4). This finding seems to indicate that flat DIN 1 is often bilateral. In 29 (46%) of the CNB greater than ten ductules showed flat DIN 1, and in the excision specimens, flat DIN 1 was seen in a multifocal

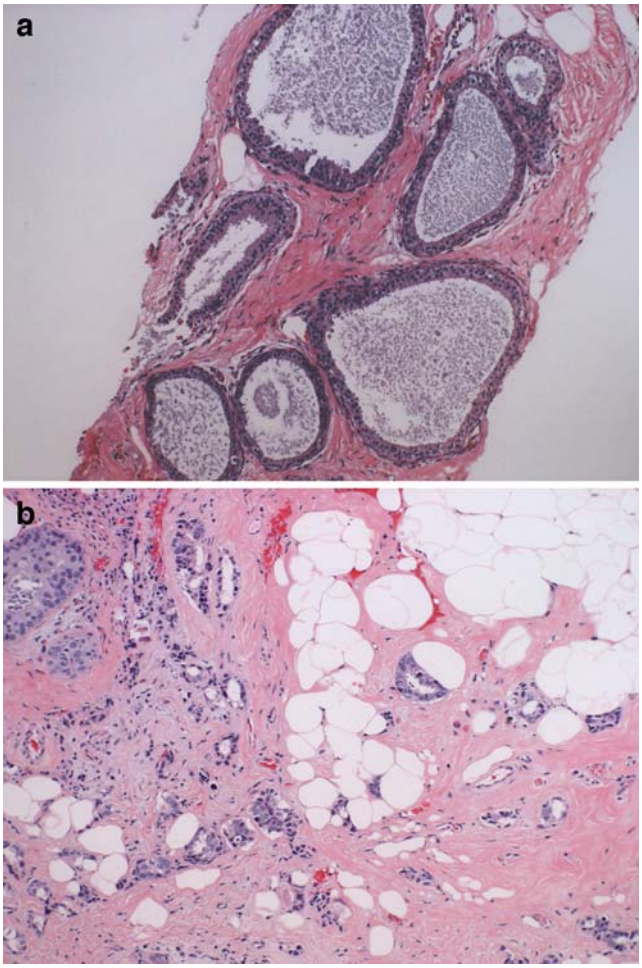

Fig. 3 **a** Flat DIN 1 on CNB, distended acini lined by one to two cell layers of monotonous mildly atypical cells, containing secretory material (case 20). **b** Ipsilateral infiltrating duct carcinoma 5 years after initial the CNB

distribution. The high frequency of bilaterality and multifocality noted for flat DIN1 is quite similar to that observed with lobular intraepithelial neoplasia.

Flat DIN 1 was found adjacent to invasive carcinoma in eight of the nine subsequent invasive carcinomas and in the case of contralateral DIN 2. Flat DIN 1 is often noted in the background with gradual transition to micropapillary and cribriform DIN 1 (DCIS grade 1) illustrating an increase in cell volume with progression but no change in the cytologic features [1, 10, 11, 24, 28]. This observation has been proposed as morphologic evidence for flat DIN 1 representing a precursor lesion of invasive and in situ carcinoma [21, 29]. Moinfar et al. [18] identified the same genetic alterations (loss of heterozygosity) in flat DIN 1 and adjacent in situ and infiltrating carcinoma; this has been confirmed in subsequent studies [30]. The morphologic findings confirmed at the molecular level indicate that flat DIN1 reflects a neoplastic alteration with the potential—often unrealized—to progress slowly to a more advanced process and ultimately a low-grade invasive carcinoma.

Studies with follow-up information on biopsies with only flat DIN 1 as the most advanced atypia, whether in excisional or core biopsies, are limited. Eusebi et al. [9] identified 21 cases of "clinging carcinoma" in a retrospective review of more than 4,000 breast biopsies initially diagnosed as benign between 1965 and 1971. However, the study makes no distinction between clinging carcinoma of the monomorphous type (flat DIN 1) and more proliferative micropapillary DIN 1 or a pleomorphic variant (unequivocal and higher-grade DCIS). Of these 21 patients, two died of breast cancer: One presented several years after the initial biopsy with advanced ipsilateral breast cancer and died 12 years after the biopsy, and the second patient presented with invasive duct carcinoma 6 years after the initial biopsy and died 4.9 years later. Another two were found to have persistent clinging carcinoma, one in the ipsilateral breast 9 years later and the other in the contralateral breast 11 months later. Bijker et al. [2], analyzing the data of the European Organization for

One duct has a cribriform proliferation of monotonous mildly atypical cells similar to the cells lining the ducts in the areas of flat epithelial atypia

Research and Treatment of Cancer trial 10,853 (excision with or without radiotherapy), reported no recurrences among 59 women with well-differentiated DCIS with clinging architecture after a median follow-up of 5.4 years.

Of the 63 patients identified as having flat DIN 1 on CNB retrospectively in this study, seven developed an invasive carcinoma in the ipsilateral breast indicating an absolute risk of 11.1%. The absolute risk was higher in the ipsilateral breast compared to 3.2% in the contralateral breast, with a mean follow up of 6.2 years available for 55 of the 63 patients. The results from the study by Eusebi et al. [9] indicate an absolute risk of 9.5% with a mean follow-up of 16.7 years, but this study was inclusive of lesions beyond flat DIN 1. Although available data do not permit assessment of the precise level of risk of developing subsequent carcinoma, they appear to indicate an increased risk of developing carcinoma compared to the absolute risk in women with intraductal hyperplasia (IDH), reported as 2.6% in the study by Tavassoli and Norris [34] and 4% by Dupont and Page [8], and perhaps closer to that of ADH. In the study by Tavassoli and Norris [34], 9.8% of women with ADH developed invasive carcinoma with a mean follow-up of 12.4 years; however, the development of subsequent invasive carcinoma after a diagnosis of ADH varies in the literature from 3.7 to 22% [3, 7, 15]. In patients with ADH, 25 [33] to 44% [26] of subsequent invasive carcinomas occur in the contralateral breast; in comparison, the percentage of contralateral invasive carcinoma in patients with flat DIN 1 is lower, 3.2% in our study. It should be pointed out that all previous studies cited here for flat DIN 1, IDH, and ADH were based on the assessment of excisional biopsy samples; therefore, disease extent as well as absence of more advanced pathology was more definitively established compared to core biopsies.

There is limited available data regarding the significance of flat DIN 1 detected on CNB and its management. Most of the data regarding flat epithelial atypia in core biopsies are limited to abstracts that looked at the findings in subsequent excisions [4, 5, 12, 16, 20]. Based on this limited data, a subsequent excision showed a more advanced lesion, (DCIS or invasive carcinoma) in approximately one third of cases. It should be noted, however, that given the variation in terminology used to designate this lesion and the inclusion in many of these studies of more advanced lesions with arcades, epithelial tufts, and cribriform architecture in addition to flat epithelial atypia (in essence inclusion of ADH among flat lesions), it is difficult to determine how many of the reported cases are truly pure flat epithelial atypia and how many represent atypical IDH. In five of the cases in our study, the initial core biopsy was followed by an excisional biopsy within less than 3 months, and none of these patients had either an invasive or intraepithelial carcinoma in the excision, but ADH was present in two cases; in these cases, lack of correlation between findings in the core and imaging may have prompted the excisional biopsy.

Because most published follow-up studies on flat epithelial atypia include ADH among the studied cases, the results are of limited value. Routine performance of excisional biopsy after the identification of flat epithelial atypia on CNB has been suggested by some authors [13, 21, 29] based on studies that have included ADH among the cases of flat epithelial atypia. Given the rather high frequency of flat epithelial atypia and lack of general familiarity with the lowest threshold for this lesion, attachment of undue clinical significance to this lesion could lead to an explosion of excisional biopsies for a lesion of still unknown consequence.

The current recommendation is that a surgical excision should be performed in cases showing ADH on a core biopsy, based on the reported finding of carcinoma in 33–87% of the subsequent excisional biopsies [6, 13, 27]. However, the frequency of subsequent carcinoma varies according to the method of biopsy used being lower with the use of the Mammotome compared to the automated biopsy gun and gauge of the needle. The current use of the Mammotome and the larger 8-ga needle provide a larger and/or more adequate sampling of the mammographically detected abnormalities. In our practice, when we encounter pure flat DIN 1 on CNB and is the only explanation for the mammographically detected abnormality, we perform three additional levels, beyond the usual three initial levels, to exclude a more advanced lesion deeper in the block. If arcades or micropapillae become apparent, the lesion should be diagnosed as ADH, and an excisional biopsy should be performed. This is a logical approach that many pathologists utilize intuitively when encountering early or borderline lesions (i.e., to evaluate areas suspicious for microinvasion). This is a minor additional step in the evaluation of a lesion of unknown biologic significance that has the potential of identifying a more advanced lesion, in which case an excision would be recommended, rather than recommending an excision in all cases. In our opinion, if additional levels fail to reveal a more advanced lesion, an excisional biopsy is not mandatory, but close follow-up is advised with repeat mammogram every 6 months for 2–3 years for early detection of any clinically occult invasive carcinoma or more advanced DIN (DCIS) in the vicinity of flat DIN 1 that might have been missed.

To get a true assessment of the clinical significance of flat DIN 1, only cases of pure flat lesions uncontaminated by more advanced proliferations in the form of focal arcades, micropapillae, and cribriforming should be studied, and standardization of the morphologic criteria and terminology are crucial to understand its biological significance and establish therapeutic guidelines.

Incorporation of the "columnar cell" in the designation of this lesion is misleading, and the value of grading or subcategorizing "columnar cell lesions" further is doubtful. The mature mammary epithelium varies from cuboidal to low columnar and columnar in shape with or without apical snouts in its many normal physiologic variations. Furthermore, flat epithelial atypia also varies from cuboidal/low columnar to columnar and from a single to multiple cell layers. Therefore, it is not clear what is accomplished by inclusion of "columnar" in the terminology or grading of these lesions. It is actually misleading as it may imply that only lesions with columnar cells should be placed in this category, although flat epithelial atypia also consists of cuboidal cells. Furthermore, the presence of cells with columnar morphology lining the ducts with unequivocal ADH can result (and has resulted) in incorrect inclusion of ADH in the category of flat DIN 1. The term "flat" refers to the overall architecture of the proliferation, which lacks any intraluminal protrusions in the form of arcades, bridges, or micropapillae and is essential in distinguishing this lesion from ADH.

Within the DIN classification system for intraductal proliferative lesions, flat epithelial atypia is designated as flat DIN 1. The common findings of flat epithelial atypia in association with ADH, low-grade DCIS, and well-differentiated infiltrating carcinoma, particularly tubular carcinoma, and the similarities in their cytologic features and genetic alterations have led to the concept that flat epithelial atypia represents one of the earliest morphologically recognizable intraepithelial neoplastic alteration of the breast [18] supporting its inclusion into the DIN classification and within the DIN 1 group; the cytologic features of the cells in the spectrum of DIN 1 (flat epithelial atypia, ADH, and low-grade DCIS) whether flat, forming partial, or complete duct involvement by micropapillae, arcades, or cribriform growth patterns in one or 30 ducts are identical.

The diagnosis and identification of flat epithelial atypia remains a diagnostic challenge in current practice with inter and intraobserver variability [22, 31]. Those lesions characterized by the presence of three to five cell layers are more readily recognizable (Fig. 5); those consisting only of a single layer are more difficult. Immunohistochemistry for high-molecular-weight cytokeratins CK-34betaE12 (CK903) and CK5/6 as used in the evaluation of problematic intraductal proliferations of the breast [17, 19] and estrogen receptors (ER) could be useful when considering the diagnosis of flat epithelial atypia. Negative immunoreaction for CK-34betaE12 (CK903) or CK5/6 along with intense and diffuse positivity for ER, as is often seen in flat epithelial atypia [35], would be in favor of the diagnosis; however, the final interpretation should be made on the overall morphologic features and not on the immunohistochemical findings alone. When in doubt, it is better to underdiagnose. It is also important to differentiate flat epithelial atypia from DIN 2 and 3, flat type (high-grade DCIS). Lesions with flat architecture but showing high-grade cytologic atypia with high nuclear pleomorphism (nuclear grades 2 and 3) with or without frequent mitotic figures should be designated as DIN 2 or 3 (DCIS grade 2 or 3) and excluded from the category of flat DIN 1 (flat epithelial atypia).

On the other hand, blunt duct adenosis, a form of adenosis characterized by mild distention of the ducts and generalized hypertrophy of all components of the TDLU (epithelial cells, myoepithelial cells, and often stroma) should be distinguished from flat epithelial atypia. In blunt duct adenosis, the myoepithelial cell layer is commonly prominent resulting in the impression of a proliferative lesion; however, there is only a single epithelial cell layer without any atypia. This distinction may be difficult, and in the past, not uncommonly, flat epithelial atypia was misinterpreted as blunt duct adenosis.

The use of standardized criteria for the diagnosis and common terminology is essential in establishing the significance and determining guidelines for management of this lesion, particularly on CNB. As we continue to study the biology of this lesion and more data emerge in the literature, we propose performing three additional levels, beyond the usual three initial levels, when flat DIN 1 is found as the most advanced lesion on CNB. If additional levels fail to reveal a more advanced lesion, an excisional

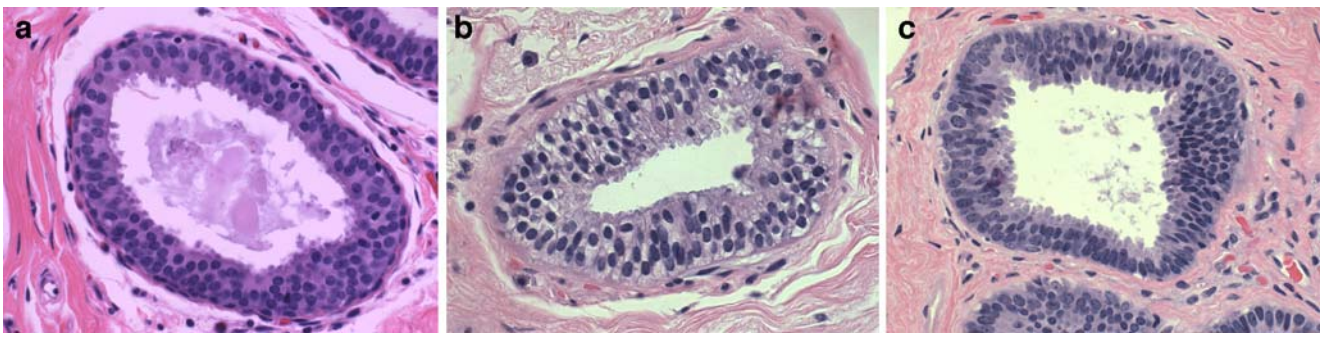

Fig. 5 **a**, **b**, **c** Three examples of multilayered Flat DIN 1, characterized by replacement of the native epithelial cell layer by two to four cell layers of monotonous mildly atypical cells

biopsy is not mandatory if there are no mammographic features of concern. Because clinically occult, more advanced DIN and low-grade carcinomas may be missed, close follow-up is advised with repeat mammogram every 6 months for 2–3 years for early detection of any such invasive carcinomas in the vicinity of flat DIN 1. Finally, after assessment of additional levels and the immunoprofile, if there remains doubts about the presence of flat DIN 1, it is better to underdiagnose this lesion or refrain from diagnosing.

Conclusion

Flat DIN 1 found on CNB is often in the setting of a biopsy performed for the evaluation of microcalcifications identified on screening mammogram. Cognizant of the retrospective nature of the study, based on our findings, flat DIN 1 is a marker of slightly increased risk for subsequent development of invasive breast carcinoma. However, follow-up studies of flat DIN 1 as the most advanced lesion are needed to better understand the significance of this lesion and establishing uniform guidelines in its management.

Abstract The designation lobular neoplasia (LN) of the breast includes atypical lobular hyperplasia and lobular carcinoma in situ. Estrogen receptors (ER) play a significant role in breast carcinogenesis. In the present study, ER-alpha and ER-beta status are evaluated in 30 breast tissue specimens from patients whose main lesion was LN. A standard immunohistochemical procedure, using monoclonal antibodies for ER-alpha and ER-beta, was applied to the lesion and the adjacent normal breast tissues, the latter serving as control. In all cases, both receptors were expressed in LN as well as in normal breast ducts and lobules. Concerning ER-alpha, the Allred score and the percentage of ER-alpha-positive cells were significantly higher in LN than in the adjacent normal breast tissue. On the contrary, regarding ER-beta, the Allred score and the percentage of ER-beta-positive cells were significantly lower in LN compared with normal adjacent breast tissue. Greater increase in the percentage of ER-alpha-positive cells was associated with a smaller reduction in the percentage of ER-beta-positive cells and vice versa (Spearman's rho=−0.5044, p=0.001). In conclusion, upregulation of ER-alpha and downregulation of ER-beta may represent two discrete molecular events in LN pathogenesis. Of notice, a mutually limiting interaction may exist between the two events.

Introduction

The term lobular neoplasia (LN), including the designations atypical lobular hyperplasia and lobular carcinoma in situ (LCIS), refers to the entire spectrum of atypical epithelial proliferation originating in the terminal duct-lobular unit, with or without pagetoid involvement of terminal ducts. Nowadays, it is widely known that LN represents a risk factor and a nonobligatory precursor for the subsequent development of invasive carcinoma in either breast, of either ductal or lobular type [10, 14, 17].

Estrogen receptor (ER) upregulation is a hallmark of cancer progression, at nearly all stages of breast carcinogenesis [25]. Two ERs exist: ER-alpha, located on chromosome 6q25.1, and ER-beta located on 14q22-24. A great number of isoforms/splice variants of ER-beta have been identified. Of notice, ER-beta seems to exhibit a pattern inverse to ER-alpha, declining during the progression from normal breast tissue to atypical ductal hyperplasia, ductal carcinoma in situ, and invasive ductal carcinoma [15, 18]. The ER-beta/ER-alpha ratio has emerged as an important risk factor; a low ER-beta/ER-alpha ratio seems to predict progression to carcinoma in nonatypical epithelial hyperplasia [19]. It is interesting to note that ER-beta gradual reduction has been reported to be more pronounced in invasive ductal than in invasive lobular carcinomas [20].

To date, there is scarcity of data with respect to the evaluation of ER-alpha and ER-beta status in patients whose main lesion is LN. To our knowledge, this is the first study focusing on the immunohistochemical expression of ERs alpha and beta in LN cases.

Materials and methods

Tissue specimens were taken from 30 patients with LN. The patients' age at operation ranged between 38 and 67 (median age=51 years). The diagnosis of LN was established by vacuum-assisted breast biopsy or by excisional breast biopsy. The cases of LN coexisting with atypical ductal hyperplasia, ductal carcinoma in situ, invasive lobular carcinoma, or invasive ductal carcinoma were excluded.

The ER-alpha and ER-beta receptors were immunohistochemically detected with the commercially available ER6f-11 and ER-beta (clone EMRO2; Novocastra supplied by Menarini) antibodies and visualized using an avidin–biotin detection system. Antigen retrieval was achieved in 0.001 M citrate buffer (pH=6.0) at 85°C for 18 h. Immunohistochemical assessment of ER-alpha and ER-beta was performed both in the lesion and the adjacent normal breast ducts and lobules, serving as control.

As far as ER-alpha and ER-beta evaluation is concerned, (1) Allred score was calculated [1], and (2) the percentage of positive cells (nuclei) was separately analyzed. In all cases, the area of maximum staining intensity was preselected on each slide and a minimum of 100 cells were evaluated in the designated area. The immunohistochemical evaluation was performed independently by two consultant histopathologists (AN and AL).

Statistical analysis was performed with STATA 8.0 statistical software. The statistic performed at each case is mentioned in parentheses in the text.

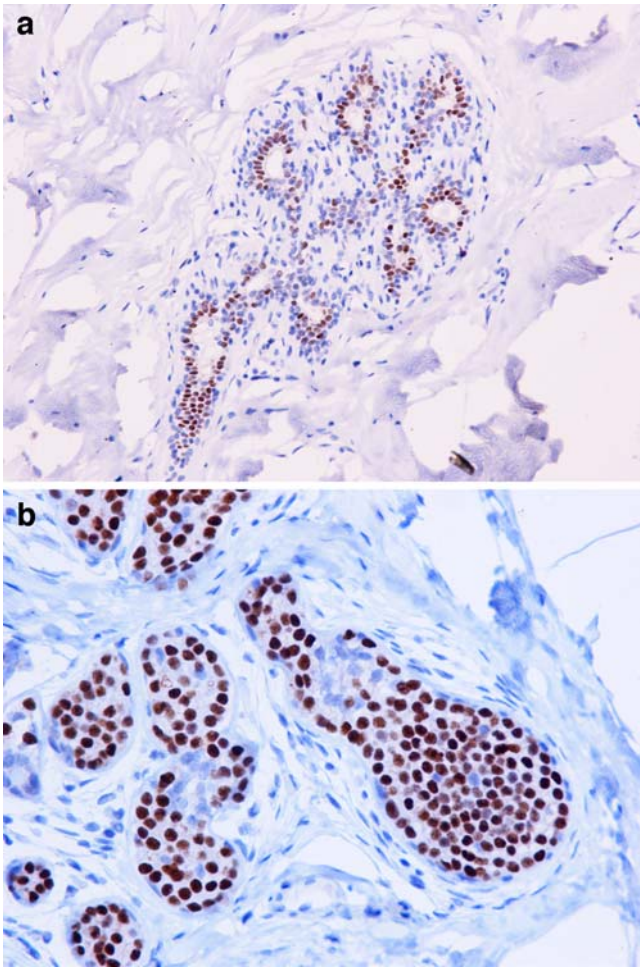

Fig. 1 Immunohistochemical nuclear expression of ER-alpha in normal breast (**a**; ×200) and in lobular neoplasia (**b**; ×400)

Results

Apart from the nuclear ER-alpha and ER-beta immunoreactivity in epithelial cells of normal ducts and lobules and in LN, some lymphocytes and myoepithelial cells were also stained (Fig. 1a,b, and 2a–c).

Concerning ER-alpha, Allred score was significantly higher in LN than in the adjacent normal ducts and lobules (mean ± SD=6.85±0.98 vs 6.24±1.04, respectively; p=0.003, Wilcoxon matched-pairs signed-ranks test). On the other hand, regarding ER-beta, Allred score was lower in LN than in the adjacent normal ducts and lobules (mean ± SD=6.95±0.67 vs 7.26±0.63; p=0.007, Wilcoxon matched-pairs signed-ranks test; Fig. 3).

The percentage of ER-alpha-positive cells was significantly higher in LN than in the adjacent normal ducts and lobules (mean ± SD=67.8±17.2 vs 59.7±18.6%, respectively; p=0.039, Wilcoxon matched-pairs signed-ranks test). On the contrary, the percentage of ER-beta-positive cells was lower in LN than in the adjacent normal ducts and lobules (mean ± SD=69.9±17.1 vs 80.7±12.0%; p<0.001, Wilcoxon matched-pairs signed-ranks test; Fig. 4).

Subsequently, the increase in ER-alpha percentage was calculated (percentage of positive cells in LN−percentage of positive cells in normal breast tissue), together with the decrease in ER-beta (percentage of positive cells in normal breast tissue−percentage of positive cells in LN). It interesting to note that the greater increase in ER-alpha expression was associated with a smaller reduction in ER-beta expression and vice versa (Spearman's rho=−0.5044, p=0.001). Accordingly, the increase in ER-alpha Allred score and the decrease in ER-beta Allred score were calculated, but the respective association did not reach statistical significance (Spearman's rho=−0.074, p=0.648).

Discussion

ER positivity is a well-established feature of LCIS [6, 13], but the profile of ER subtypes has not been evaluated in detail. This is the first study focusing exclusively on LN lesions and demonstrating a significant ER-alpha upregulation and ER-beta downregulation therein. The diptych ER-

alpha upregulation/ER-beta downregulation has become evident after the calculation of the Allred score and, more specifically, after the assessment of the percentage of ER-alpha- and ER-beta-positive cells.

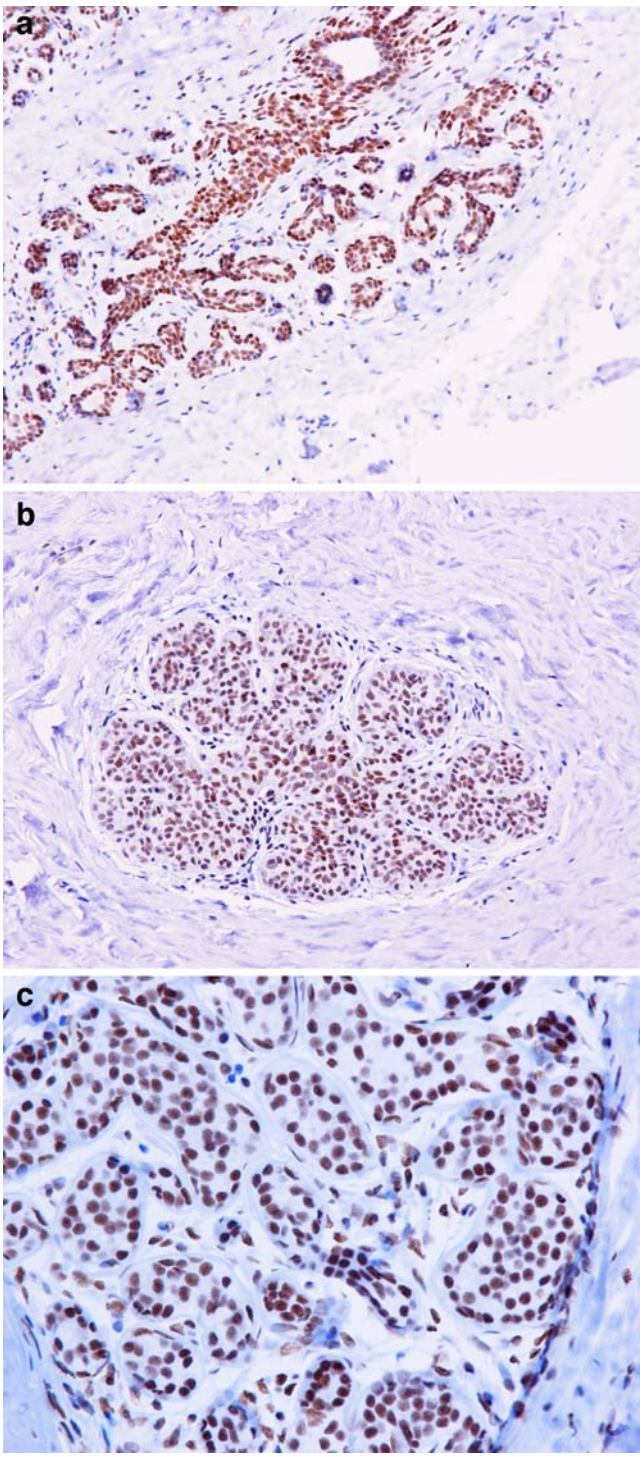

Fig. 2 Immunohistochemical nuclear expression of ER-beta **a** Strong intensity in normal breast (×200). **b** Decreased percentage of positive cells in lobular neoplasia, in comparison to the adjacent normal breast tissue (×200). **c** Strong intensity in lobular neoplasia (×400)

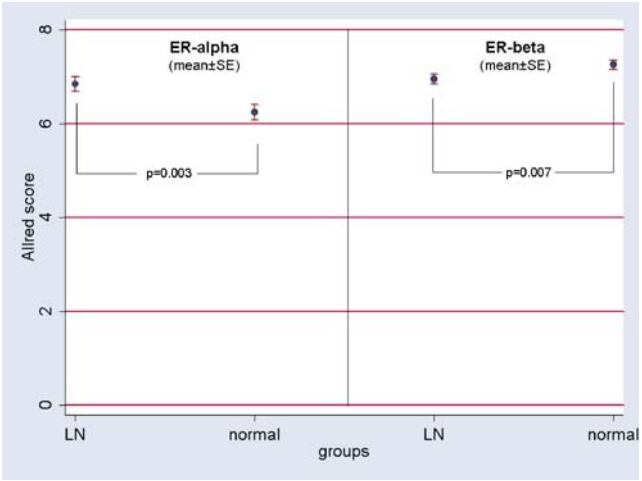

Fig. 3 Allred score in LN and normal adjacent breast tissue

The present finding has multivalent physiological implications. ER-alpha and ER-beta are two distinct receptor subtypes, differing in their transcriptional activity and putatively mediating differential estrogen effects [3]. As mentioned above, the importance of the ER-beta/ER-alpha ratio has been reported in the context of breast cancer [11]; ER-beta has been associated with favorable features in breast cancer [9] and may have a generally protective role [8]. Thus, the increase in ER-alpha expression together with ER-beta downregulation might represent an advantage of LN cells, pointing to a putative subsequent malignant transformation.

Concerning ER subtypes in LN, a hint dates back to 2001, when the decreased ER-beta/ER-alpha ratio was demonstrated in proliferative benign breast disease with atypia and in carcinomas in situ [15]. Of notice, however, that study did not make the distinction between ductal and lobular lesions, putatively because of the relatively small

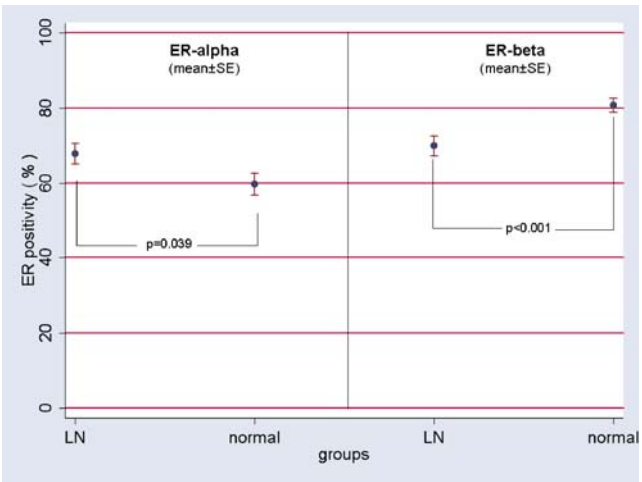

Fig. 4 Percentage of ER-alpha and ER-beta positivity in LN and normal adjacent breast tissue

sample size, and thus the ER subtype status in LN remained an undiscovered field.

Additionally, a rather striking finding emerged in our sample: A greater increase in ER-alpha positivity was associated with a smaller reduction in ER-beta positivity and vice versa. It seems thus that there is a mutually limiting link between the two molecular events, i.e., ER-alpha upregulation and ER-beta downregulation, at the phase of LN. This mutually limiting effect could prevent excessive, aberrant proliferation, which might have occurred in case of disproportionate ER-alpha upregulation or extreme ER-beta downregulation. Indeed, a sole event (concerning ER-alpha or ER-beta expression) may be needed at the phase of LN.

However, when the Allred score was calculated, the respective, mutually limiting, association did not reach statistical significance. This might be due to the fact that the intensity of the staining (a major constituent of the Allred score) is measured in a rather limited, confined 0–3 scale. Such a confined scale-range may render difficult to document statistically significant changes and may thus blur the association detected when the absolute percentage of positive cells was evaluated.

It would be of particular interest to evaluate whether the mutually limiting effect vanishes or persists in invasive lobular carcinoma. Despite controversial reports [12], marked ER positivity is an important feature of invasive lobular carcinoma, vis-à-vis invasive ductal carcinoma [2, 5, 7, 16], but the inter-relationships between ER-alpha and ER-beta therein have not been fully elucidated. For the future, it is also tempting to anticipate the evaluation of ER-beta isoforms in LN tissues because to date ER-beta isoforms have only been studied on breast cancer and breast cancer cell lines [23].

An interesting observation was that ER-beta was also expressed on some lymphocytes and myoepithelial cells. The expression of ER-beta on myoepithelial cells has been also reported in the past [4, 21]. Concerning lymphocytes, ERs have been found occasionally expressed in breast tissue lymphocytes [21]; ER-beta have been also identified in intraepithelial lymphocytes in human oviducts [24] and human cervix [22]. The significance of such findings remains to be fully elucidated in the future.

In conclusion, ER-alpha upregulation and ER-beta downregulation represent two discrete molecular events in LN pathogenesis. The mutually limiting interaction between the two events seems to characterize LN. Automated procedures involving quantification of ER-alpha and ER-beta expression, as well as the evaluation of ER-alpha and ER-beta messenger ribonucleic acid expression are needed to confirm the present findings.

Mesometrial smooth muscle as an origin of female retroperitoneal (pelvic) leiomyomas

Kazuo Watanabe · Mizuko Tanaka · Takashi Kusakabe · Shu Soeda

Received: 18 May 2007 / Revised: 1 August 2007 / Accepted: 13 August 2007 / Published online: 6 September 2007

Abstract Retroperitoneal (pelvic) leiomyomas have recently come to be recognized as distinctive lesions. Retroperitoneal leiomyomas occur almost exclusively in women, and past studies on these invariably emphasized a striking similarity between their histological features, with those of uterine leiomyoma, whereas their origin remains unknown. In this study, we took notice of mesometrial smooth muscle, which has been little known either clinically or pathologically, as a possible origin of tumor. Anatomically, the mesometrial smooth muscle was an accumulation of thin bundles (approximately 1 mm in thickness) that ran parallel to the oviduct. It was connected broadly with the lateral wall of the uterine body and ended in the pelvic floor. The mesometrial smooth muscle was present just beneath the serosal surface of the anterior aspect of the mesometrium and continuously transited from the smooth muscle bundles of the outer layer of the uterine myometrium. The muscle cells were immunopositive for smooth muscle cell markers and estrogen/progesterone receptors. In all of the six female retroperitoneal leiomyomas examined, hormone receptor-positive nontumorous smooth muscle layers were present in the periphery of the tumors, seemingly representing the mesometrial smooth muscles. In conclusion, we believe most retroperitoneal (pelvic) leiomyomas in females arise from the mesometrial smooth muscle.

Introduction

Retroperitoneal (pelvic) leiomyoma is a rare but distinctive lesion. Although it was traditionally believed that most smooth muscle cell tumors of the retroperitoneum (which include a number of gastrointestinal stroma tumors) were malignant [13, 15], recent follow-up studies by Billings et al. [3] and Paal et al. [12] clarified the presence of benign smooth muscle tumor in the retroperitoneum and abdominal cavity. Characteristically, retroperitoneal leiomyomas occur almost exclusively in women in contrast to gastrointestinal, cutaneous, and somatic deep leiomyomas [8], which exhibit no difference between genders, and past studies on retroperitoneal leiomyomas invariably emphasized the striking similarity of their histological features with those of uterine leiomyoma [3, 12]. Some investigators called them "parasitic uterine leiomyoma," which means an implantation or detachment of uterine leiomyoma, but this idea dose not have any scientific basis [6, 18]. Thus, the cellular origin of retroperitoneal leiomyomas has not been elucidated.

The mesometrium is the largest part of a broad ligament that is attached to the uterus, ovarian ligament, and pelvic floor. The mesometrium includes a broad bundle of smooth muscle cells just beneath the thin peritoneal membrane, but this fact is not generally known. In the present study, we noted the mesometrial smooth muscle as an origin of retroperitoneal (pelvic) leiomyoma and studied the anatomical and immunohistochemical characteristics of mesometrial smooth muscle with an analyzation of retroperitoneal leiomyomas experienced in our laboratory. We believe that

most retroperitoneal leiomyomas in females seem to arise from the mesometrial smooth muscle, which belongs to an identical cell lineage of those of uterine myometrial cells.

Materials and methods

Gross and microscopic examination of the mesometrium was performed using autopsy cases from nine women aged 46 to 79. To examine the expression of estrogen and progesterone receptors in smooth muscle cells, various organs were sampled from a 72-year-old man who had died of pulmonary carcinoma and a 62-year-old woman who had died of polycystic kidney disease. The tissues sampled included the lung, stomach, urinary bladder, ureter, prostate, testis, seminal duct, uterus, ovary, oviduct, and vaginal wall. A piece of scrotum wall was obtained from a surgical specimen of a 58-year-old-man who underwent wide resection for primary squamous cell carcinoma of the scrotum.

Six retroperitoneal and two parauterine leiomyomas were retrieved from the surgical file of the Pathology Division of the Fukushima Medical University Hospital.

All tissues were processed routinely and embedded in paraffin. Sections that were 3 to 4 μm thick were cut and stained with hematoxylin–eosin. Immunohistochemical staining of formalin-fixed and paraffin-embedded sections was performed using the streptavidin–biotin method (LSAB kit, Dako Japan, Kyoto, Japan). The primary antibodies and their final dilutions were: α-smooth muscle actin (1A4, Dako Japan, 1:100), desmin (D33, Dako Japan, 1:50), *h*-caldesmon (h-CD, Dako Japan, 1:50), estrogen receptor-α (ER1D5, Immunotech Japan, Tokyo, Japan, 1:50), and progesterone receptor (1A6, Immunotech Japan, 1:20).

Results

Anatomy of the mesometrial smooth muscle

Grossly, the mesometrial smooth muscle was an accumulation of light tan-colored thin bundles covered by the surface serous membrane, when observed from the anterior aspect of the uterus. The bundles ran parallel with the oviduct and were connected broadly with the lateral wall of the uterine body (Fig. 1), and ended in the lateral to posterior pelvic wall involving the pararectal region.

Histologically, the mesometrial smooth muscle was present just beneath the serosal surface of the mesometrium (Fig. 2). It continuously transited from the smooth muscle bundles of the outer layer of the uterine myometrium and preserved an almost uniform thickness in the anterior aspect of the mesometrium (approximately 1 mm in thickness; Fig. 3a,b). Although uterine myometrium also transited to the posterior aspect of the mesometrium, smooth muscle cells soon became sparse in this region, unlike with the anterior mesometrial smooth muscle. The mesometrial smooth muscle was composed of an accumulation of rather loosely arranged small bundles of smooth muscle cells in the

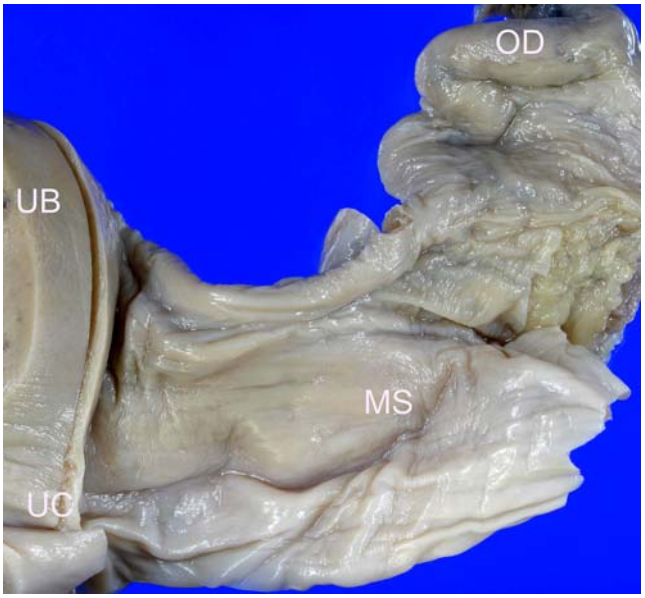

Fig. 1 Gross features of anterior aspect of the broad ligament including mesometrium (left side of 46-year-old female, autopsy case). Mesometrial smooth muscle (*MS*) was formed by an accumulation of light tan-colored thin bundles covered by the surface serous membrane, which ran parallel to the oviduct (*OD*). They were connected broadly with the lateral wall of the uterine body (*UB*). The right margin of the mesometrium was cut near the pelvic wall. *UC* Uterine cervix

Although scattered smooth muscle cells (*asterisk*) were present in the posterior aspect, they were almost restricted near the uterus. There were rich blood vessels and nerve fibers between these. *A* Anterior aspect, *P* posterior aspect, *MS* mesometrial smooth muscle. *Asterisk*, Scattered smooth muscle cells

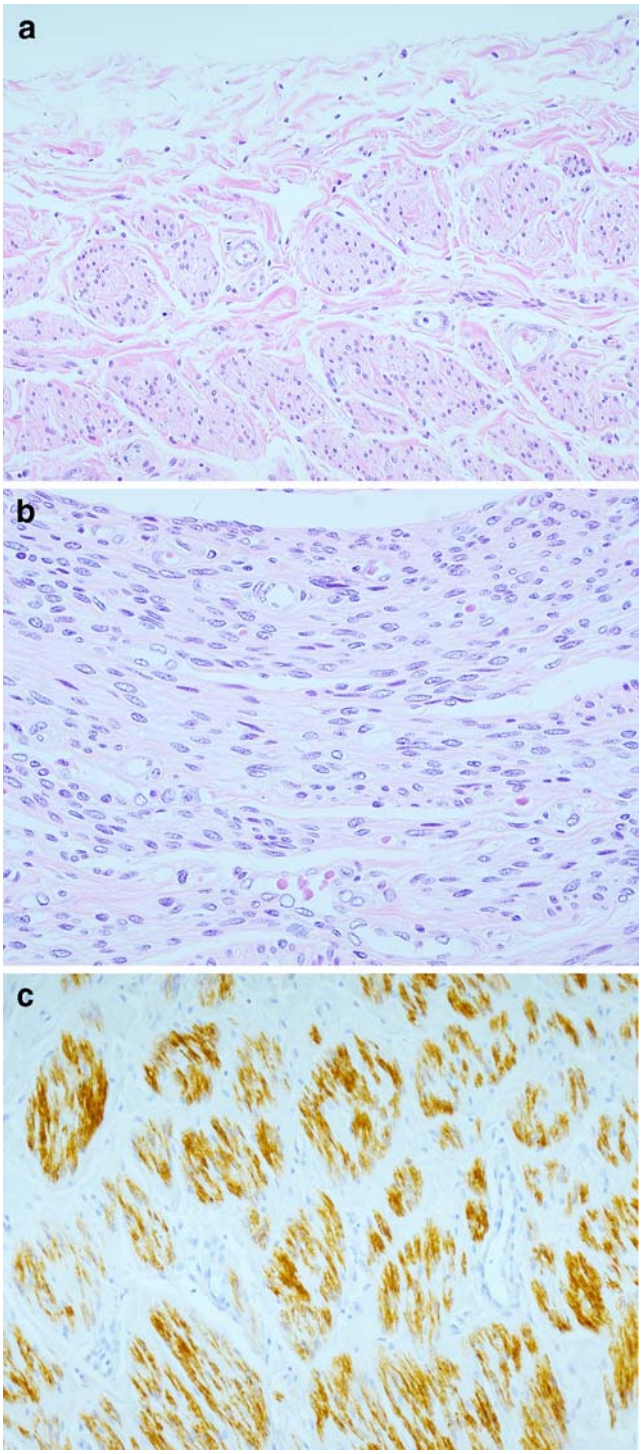

Fig. 3 High-power fields of the mesometrial smooth muscle cells. Cross-section (**a**) and longitudinal section (**b**). The cellular features were indistinguishable from those of myometrial smooth muscle cells. The cells were immunopositive for smooth muscle markers (**c** *h*-caldesmon)

sagittal section and showed a longitudinal arrangement almost parallel to the oviduct. Immunohistochemically, the smooth muscle cells were intensely positive for α-smooth muscle actin but were rather less intensely positive for *h*-caldesmon (Fig. 3c) and desmin. They consistently express estrogen/progesterone receptors to various degrees (Fig. 4).

Retroperitoneal and parauterine leiomyomas

Clinical information and histopathological features are summarized in Table 1. The age of patients ranges from 21 to 58. All but one case had a past history of uterine leiomyoma, and three patients had undergone a simple hysterectomy in the past. Four of the eight tumors were beyond 10 cm in size, and the minimum tumor size was 3.7 cm. The preoperative diagnosis was ovarian tumor in five cases, and the remaining three cases were diagnosed as retroperitoneal tumors.

Histological features of both retroperitoneal and parauterine leiomyomas were indistinguishable from those of uterine leiomyoma. The tumors often exhibited varying degrees of myxoid change, which was extensive in two tumors (cases 1 and 2). Extensive hyalinous change was observed in one case (case 7). Case 5 was a cellular type, and case 6 had rich lipomatous elements (lipoleiomyoma). In all of the retroperitoneal leiomyomas and a parauterine leiomyoma arising from the broad ligament, nontumorous smooth muscle layers were present in the periphery of the tumors (Fig. 5). Immunohistochemically, all retroperitoneal and parauterine leiomyomas and nontumorous muscle layers were positive for antibodies against estrogen/progesterone receptors.

Estrogen/progesterone receptors in the normal smooth muscles

Estrogen/progesterone receptor-positive smooth muscle cells were present in the uterine myometrium, stroma of the ovary, muscle layer of the oviduct, muscle bands of the

broad (mesometrial smooth muscle) and round ligaments, and in the wall of the vagina. The vascular smooth muscle cells in these regions were consistently negative for hormone receptors. Smooth muscle cells included in the lung, stomach, urinary bladder, ureter, prostate, testicle, seminal duct, and scrotum were all negative for estrogen/progesterone receptors.

Discussion

Generally, leiomyoma preferentially arises from organs where rich smooth muscle cells are originally present. As is well known, the uterus is the most common site of leiomyoma, followed by the gastrointestinal tract and skin. In contrast, the origin of retroperitoneal leiomyoma remains unclear. Although there have only been a few large-series studies on retroperitoneal leiomyomas, these reports [3, 12] describe their distinctive clinicopathological features: (1) Retroperitoneal leiomyomas almost exclusively occur in women in contrast to gastrointestinal, cutaneous, and somatic deep leiomyomas, which exhibit no difference between genders; (2) They show a striking resemblance in their histology to uterine leiomyomas and immunohistochemically express estrogen/progesterone receptors. These characteristics of retroperitoneal leiomyoma strongly suggest an intimate relation to uterine leiomyomas. In contrast, it is noteworthy that retroperitoneal leiomyoma can occur in patients who have previously undergone a hysterectomy. Although retroperitoneal leiomyomas rarely arise in men, histological features for these are different from those of women, and the hormone receptor is negative [12]. Thus, retroperitoneal leiomyomas of men are thought to be different entities from those of women.

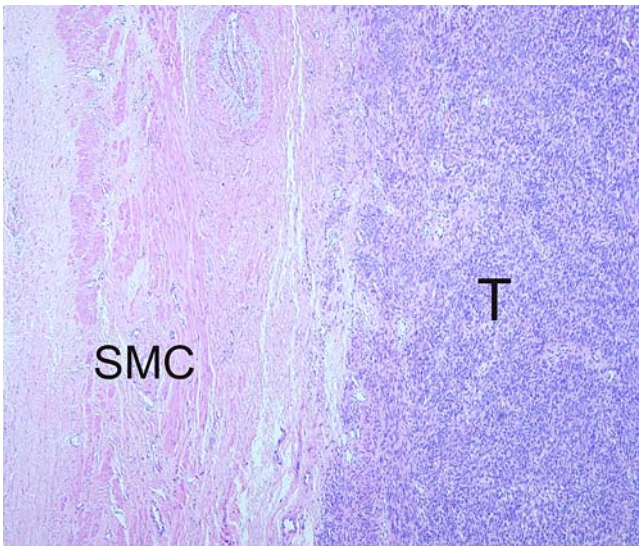

Fig. 5 In the periphery of cellular leiomyoma (*T*), a thin layer of smooth muscle cells (*SMC*) were seen, presumably mesometrial smooth muscle. Case 5

The purpose of the present study is to clarify the origin of retroperitoneal leiomyomas in women. The first clue to make us take notice of the mesometrial smooth muscle was the presence of a seemingly nontumorous, thin, smooth muscle layer adjacent to the tumor tissue in a case of retroperitoneal leiomyoma. Consequent analysis revealed that thin smooth muscle layers were identified adjacent to tumor tissue in all six retroperitoneal leiomyomas and in a parauterine leiomyoma. Moreover, observation of the female pelvis of autopsied cases clarified that the mesometrial and myometrial smooth muscles are a continuous structure with similar cellular characteristics including the expression of hormone receptors. The hypothesis that retroperitoneal leiomyomas originate from the mesometrial smooth muscle well explain the indistinguishable similarity of retroperitoneal and uterine leiomyomas. It can be accepted that the retroperitoneal leiomyomas exclusively

occur in female. Furthermore, retroperitoneal leiomyoma can occur in patients who have undergone hysterectomy, as the mesometrium is preserved through the various gynecologic surgeries. Although we could not explain the origin of intraabdominal leiomyomas located far from the pelvic cavity, we believe that most of pelvic leiomyomas, if not all, seem to arise from the mesometrial smooth muscle.

To date, descriptions of human mesometrial smooth muscle are rarely found and have been limited in literature either the anatomy or of reproductive medicine using animal models. Mossman [11] described in an anatomical study of the mammalian uterus that the development of mesometrial smooth muscle varies greatly between mammalian groups and that in some species, as in the porcupine, mesometrial smooth muscle forms a very conspicuous band. Liebgott [9] first studied the mesometrial smooth muscle systemically in the mouse and reported that the outer longitudinal myometrial layer extends onto the mesometrium as a bilaminar extension. This description corresponds to our observation in humans, while the mesometrial smooth muscle seems to be more developed in mice than humans [9]. As expected, uterine myometrium and mesometrial smooth muscle are intimately related, but they do not appear identical. Several studies using animal models reported that the effect of estrogen or prostaglandins administration was different between uterine myometrium and mesometrial smooth muscle [1, 10, 17].

Traditionally, parauterine leiomyomas including paracornual, parametrial, and parasalpingeal types has been distinguished from retroperitoneal leiomyoma [4, 5, 7]. Honore [7] defined parauterine leiomyoma as follows: (1) Their juxtauterine borders were easily separated from the uterus, (2) they were not covered externally by perimetrium directly continuous with that overlying the normal adjoining uterus, and (3) histologic study of the interface showed no direct continuity between the outer myometrium. Based on the observation of 22 parauterine leiomyomas, he reported that none were found in the distal perisalpinx or mesovarium [7]. Interestingly, Honore [7] mentioned that "It appears that smooth muscle in parauterine connective tissues, whether anatomically orthotopic or representing heterotopic myometrial rest, behaves oncologically like the myometrium, the closer it is to the uterus," while he seemed not to be aware of the mesometrial smooth muscle itself. It is likely that some parametrial leiomyomas arise from the mesometrial smooth muscle. Thus, retroperitoneal and parauterine leiomyomas are thought to be analogous tumors with close, if not identical, cell lineage.

In the present immunohistochemical study, it was confirmed that normal smooth cells with expression of hormone receptors were restricted in the reproductive and genital organs of women and that male smooth cells completely lacked hormone receptors in any organs examined immunohistochemically. This result correspond well to a description in a past report on the leiomyoma of deep soft tissues, in which no somatic leiomyomas, whether in men or women, expressed hormone receptors [3]. It seems certain that the smooth muscle cells and their neoplasm of female genital organs including the uterus and parauterine tissues, vagina, and vulva have different characteristics from those of other organs, e.g. gastrointestinal tract, skin, and soft tissue, and the former tumors often exhibit various secondary changes, high cellularity, and atypia as commonly seen in uterine leiomyomas. Therefore, leiomyomas of female genital organs should be distinguished from those arising from other organs. Although the origin of retroperitoneal and intra-abdominal leiomyomas in men has been unknown, these may originate from vascular smooth muscles.

Although most retroperitoneal leiomyomas are correctly diagnosed without difficulty, some cellular or atypical tumors may be problematic. Paal and Miettinen [12] said that well-differentiated retroperitoneal smooth muscle tumors that lack atypia and coagulation necrosis and have less than three mitoses/50 high power fields can be classified as at least probably benign. Criteria for these are principally based on an excellent study on uterine smooth muscle tumors carried out by Bell et al. [2]. Recently, more simplified criteria was proposed to differentiate problematic uterine atypical leiomyoma from leiomyosarcoma based on the differences in their cellular origin [16]. The expression of hormone receptors was thought to be the most easily recognizable characteristics of uterine leiomyomas and was exceedingly rare in the leiomyosarcomas of either the uterus or soft tissue [14, 19]. It seems that the criteria can be applicable to the retroperitoneal smooth muscle tumor in women. Paal and Miettinen [12] also argued that the immunostaining of hormone receptors is essential to the diagnosis because the 11 retroperitoneal leiomyosarcomas examined were all negative. In contrast, other criteria should be applied for tumors of men, because their cellular origin seems to differ from those in women.

In summary, mesometrial smooth muscle, which has been little known to date, was described with anatomical, histological, and immunohistochemical observations. It was clarified that mesometrial smooth muscle was continuous and that it had a structure intimately related to uterine myometrium. We believe most retroperitoneal leiomyoma in women originate from mesometrial smooth muscle.

ORIGINAL ARTICLE

Tubulocystic carcinoma of the kidney: a new entity among renal tumors

Sandy Azoulay · Annick Vieillefond · François Paraf · Dominique Pasquier · Olivier Cussenot · Patrice Callard · Mathilde Sibony

Received: 24 April 2007 / Revised: 20 July 2007 / Accepted: 23 July 2007 / Published online: 5 September 2007

Abstract Tubulocystic carcinoma is a tumor entity, which is not yet included in the WHO-classification of renal tumors. We report a series of 11 cases of this tumor, 6 of which were examined in by immunohistochemistry using a panel of five antibodies (CK7, CK34βE12, CK19, CD10 and P504S). All patients were men. Each had renal tumor stage of pT1N0M0, with a diameter of 1.7 to 7 cm (mean, 3.3 cm). None of the patients presented with recurrence or metastases. Grossly, tumors were microcystic masses with a bubble-wrap appearance. Histological features included cysts and small tubules, separated by delicate septa and lined by flat to columnar or hobnail cells. The cyst and tubule epithelium showed immunohistochemical characteristics of both proximal and distal tubules. Tubulocystic carcinoma is a distinctive kidney tumor, with noteworthy macroscopic and microscopic characteristics, which can be distinguished from other cystic kidney tumors, including cystic nephroma, multilocular cystic renal cell carcinoma and some solid tumors with extensive cystic changes. More cases are needed to ascertain its prognosis. Tubulocystic carcinoma should be considered as a new subtype of renal cell carcinoma in the next revision of the WHO classification.

Introduction

Tubulocystic carcinoma (TCC) of the kidney is a very recently described entity [10], which was not illustrated in the last WHO 2004 classification [6].

This rare tumor has been described over the last few decades as a variant of collecting duct carcinoma. In 1956, Masson [11] described a cystic tumor located in the central region of the kidney, with cysts lined by "hobnail cells"; he proposed the denomination "epithelioma bellinien". Thus, in the literature, such a tumor related to the Bellini ducts was translated as a collecting duct (or Bellini duct) carcinoma. In the third series of the AFIP fascicle, published in 1994, collecting duct carcinomas were illustrated either by multicystic tumors or by a number of high-grade solid tumors [13]. Since then, this tumor has been considered to be, and has been published as, a "low-grade collecting duct carcinoma" by McLennan et al. [9], Amin et al. [1], Srigley and Eble [16] and Farah et al. [7].

In 2004 at the USCAP meeting, Amin et al. [2] presented a series of 29 such tumors and renamed them "tubulocystic carcinomas of the kidney". They described a tumor with a very specific aspect. Macroscopically, tumors

M man, *pN* partial nephrectomy, *pN** diagnosis on preoperative biopsy, *N* total nephrectomy

had a spongy-like cut surface; microscopically, they displayed a tubulocystic architecture. Four cases with ultrastructural and immunohistochemical studies were added to the previous series and presented at the 2005 USCAP meeting [14]. The authors showed that cells exhibited characteristics of proximal convoluted tubule cells (brush border, expression of CD10 and P504S) and of intercalated cells of the collecting duct (short microvilli, cytoplasmic interdigitation, expression of CK19 and parvalbumin), therefore indicating the absence of a relationship with collecting duct tumors.

Finally, at the end of 2005, McLennan and Bostwick [10] reconsidered their initial series of 13 cases published in 1997 and reported it in a large review entitled "recently described rare renal tumors". They divided it into two separate entities: five cases of mucinous tubular and spindle cell carcinoma and eight cases of TCC, which belonged partly to the series of Amin et al. [2].

Less than 40 cases of TCC have been reported in the literature. Our series comprises 11 cases of TCC of the kidney and includes, for 6 of them, an immunohistochemical study.

Materials and methods

Cases were personal cases or consultation cases (AV) and were reviewed by three pathologists (SA, MS and AV). The diagnostic criteria used were based on the description by Amin et al. [2] in 2004 and MacLennan and Bostwick [10] in 2005. A total of 11 cases of TCC were diagnosed over a period of 11 years (1995–2006). Clinical findings were obtained for all patients and follow-up was conducted for only six of them, with a mean time of 23 months (range 3–72 months). Tumors were staged and graded according to the TNM 2002 classification and Fuhrman's classification.

An immunohistochemical study was performed in six cases. The panel of markers included the following: CK7 (M7018, 1/50, Dako), CK34βE12 (M0630, 1/50, Dako),

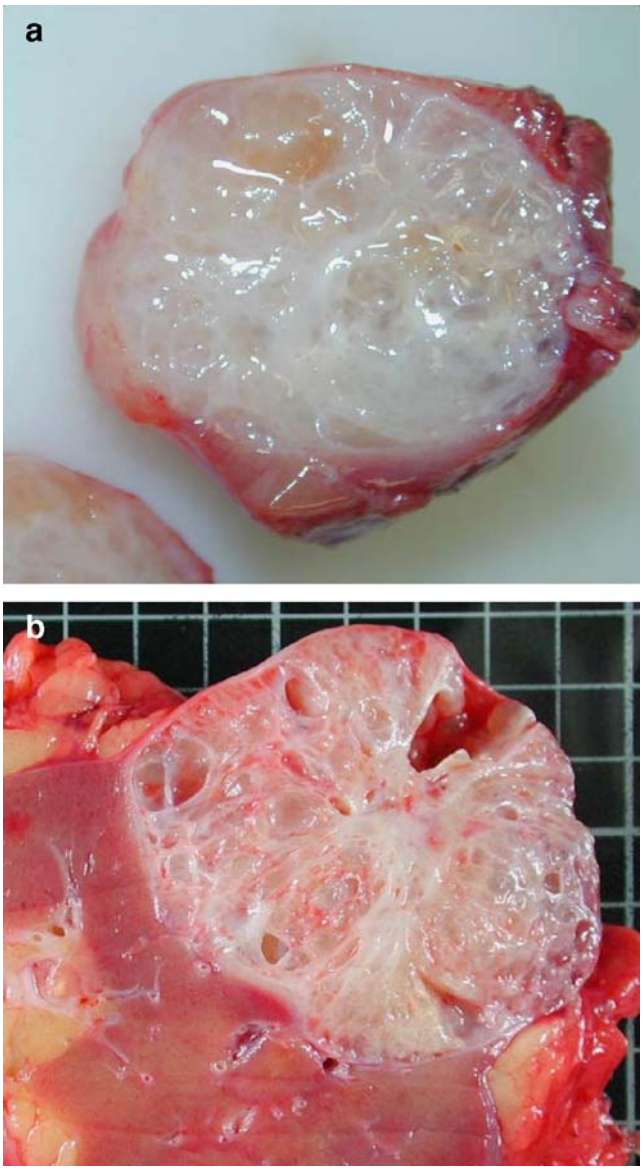

Fig. 1 **a** and **b**: Macroscopic aspect of two different cases of tubulocystic carcinoma of the kidney with both a similar white "bubble-wrap" appearance

CK19 (M0888, 1/25, Dako), CD10 (NCL-CD10-270, 1/10, Novocastra) and P504S (CP200C, 1/20, Biocare-Menarini). Two independent observers (SA and MS) graded the staining on all sections. Grading was as follows: − (no staining), ± (positive and focal staining) and + (positive and diffuse staining).

Results

Clinical findings

Clinical findings are listed in Table 1.

All patients were men, with ages ranging from 30 to 80 years (mean: 56.8 years). Each presented a unilateral renal tumor of 1.7 to 7 cm in diameter (mean: 3.3 cm). For two of them, the diagnosis was made on a pre-operative renal biopsy. All tumors were stage pT1N0M0. The treatment consisted of partial nephrectomy for six patients and total nephrectomy for five patients. No patient received adjuvant therapy. In our series with a mean follow-up of 23 months, none of the six patients presented with recurrence or metastases.

Pathologic features

All tumors showed remarkable uniformity in macroscopic aspects (Fig. 1). They were well delineated from normal parenchyma. The cut surface had a "bubble-wrap" appearance. All consisted of a white and spongy mass made of thin-walled translucent cysts that contained clear watery fluid. No solid components or hemorrhagic or necrotic areas were identified. The mass was confined to the kidney, with no renal capsule penetration or vascular invasion.

Microscopically, tumors were limited but not encapsulated (Fig. 2a). They were entirely composed of cyst structures of variable size and of small tubules (Fig. 2b). They were separated by delicate septa or by fibrotic stroma. The tubules and cysts were lined by flat to columnar eosinophilic epithelial cells (Fig. 2c), producing, in some areas, a "hobnail" appearance (Fig. 2d). Nuclei were regular, round or oval with some prominent nucleoli. Fuhrman nuclear grade was 2 in nine cases and 3 in two cases. No necrosis was seen, and mitotic figures were extremely rare. Neither clear cell areas, papillary projections or "ovarian-like" stroma were identified in any of the cases. All tumors were classified as pT1 (pTNM 2002).

Immunohistochemistry

Immunohistochemical staining results are summarized in Table 2.

Immunohistochemistry showed strong positivity for CK19, CD10 and P504S in all cases. The expression of CK7 was either weak or heterogeneous or both. Five cases were CK34βE12 negative, and in one case (case no. 8), a

few cells were marked with this high molecular weight cytokeratin (Fig. 3).

Discussion

The present study illustrates a distinctive group of tumors renamed "tubulocystic carcinoma" in 2004 by Amin et al. [2].

It is a very rare tumor; to our knowledge, less than 40 cases have been described in the literature. Amin et al. [10], in their series of 29 patients, reported a strong male predominance (6/1). We found the same tendency: All our patients were men. These tumors seem to have a favourable prognosis. In the Amin series, follow-up was obtained for 22 of them, and the authors reported only two cases of metastases (bone and liver metastases). Interestingly, however, the two metastatic tumors displayed areas of clear cells. In our study, follow-up obtained for 6 out of 11 patients showed no recurrence or metastases, with a mean time of 23 months (range, 3–72 months).

In the past, TCC was considered to be a tumor of collecting duct origin and was sometimes confused with collecting duct (Bellini duct) carcinoma, an aggressive infiltrative solid tumor with poor prognosis. Therefore, an "evolving concept" of collecting duct carcinomas was proposed, and low-grade collecting duct carcinoma at the beginning of the spectrum corresponded to the current TCC [9]. However, immunohistochemical and ultrastructural studies demonstrated the poor relationship between TCC and collecting duct tumors [14]. These tumors show expression of proteins of proximal convoluted tubules (CD10 and P504S), distal tubules (CK19) and intercalated collecting duct cells (parvalbumin). Ultrastructurally, they display abundant microvilli with brush border organization as proximal convoluted tubule cells, but with short microvilli and cytoplasmic interdigitation, similar to intercalated cells of the collecting duct [14]. Those observations led to the conclusion that TCC epithelial cells show aberrant renal tubular differentiation. This coexistence of proximal and distal tubules characteristics has been reported in several renal tumors [3, 4, 8, 15] indicating that aberrant tubular differentiation may be a common occurrence in renal neoplasms regardless of their nephron origin. All reported cases present a homogeneous macroscopic and cytoarchitectural appearance: they have a spongy "bubble-wrap" appearance due to small to interme-

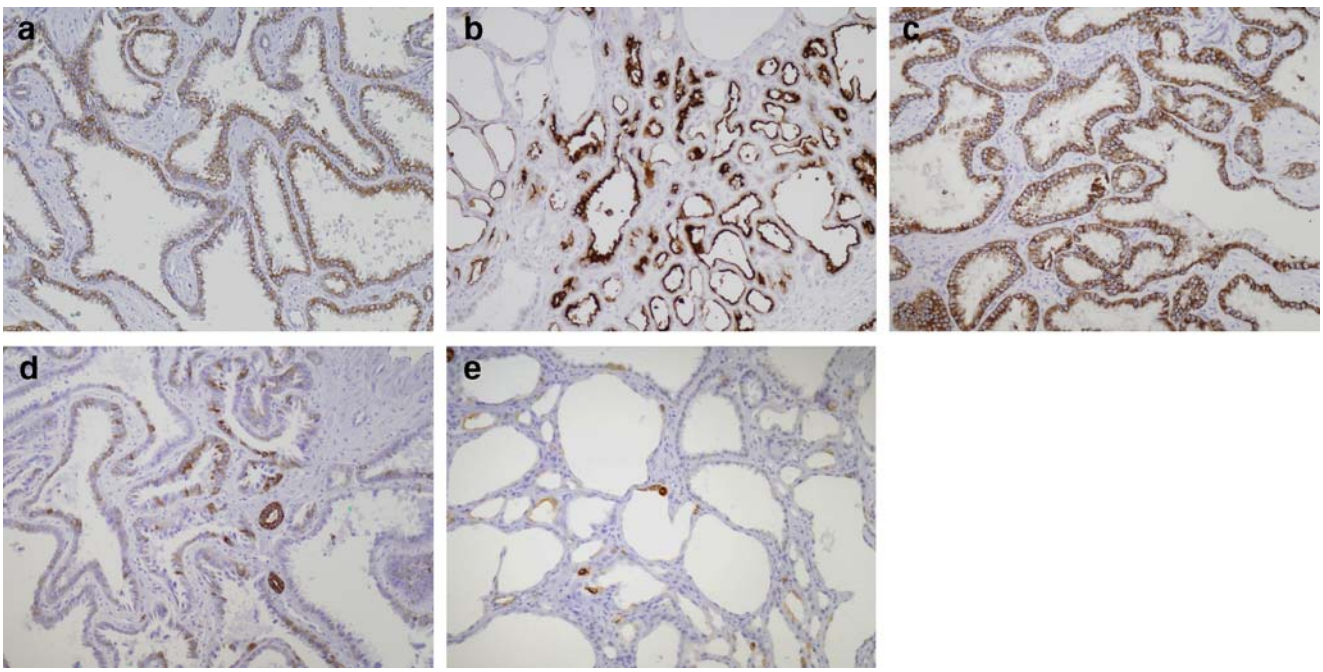

Fig. 3 Immunohistochemical features: strong positivity for CK19 (**a**), CD10 (**b**) and P504S (**c**), weak and heterogeneous positivity for CK7 (**d**) and heterogeneous positivity of few cells for CK34βE12 (**e**)

diate (and occasionally large) cystic structures dispersed within a thin fibrotic stroma.

Two main differential diagnoses among cystic renal neoplasms must be considered: cystic nephroma and multilocular cystic renal cell carcinoma. TCC and cystic nephroma are both composed of multiple cysts lined by a single layered cuboidal epithelium of eosinophilic cells with some areas of hobnail cells. In cystic nephroma, however, cysts are usually larger and contain neither tubules nor epithelial cells in the septa. Of interest, cystic nephroma shows a striking female predominance (8:1), whereas TCC occur more often in men [12].

Low-grade multilocular cystic renal cell carcinoma was described in the WHO 2004 classification as a new entity [6]. This tumor is a variant of clear cell carcinoma displaying large cysts lined by clear cells, separated by fibrous septa containing nests of clear cells [5]. Moreover, some chromophobe carcinomas and some oncocytoma may be entirely cystic with no solid areas, but cysts are lined, respectively, by chromophobe cells or, oncocytic cells. In the later, oncocytic cells are usually cuboidal with round central nuclear and are classically CD10 and CK7 negative by immunochemistry [17, 18].

In conclusion, TCC are a distinctive group of kidney tumors with a male predominance and noteworthy macroscopic (bubble-wrap appearance) and microscopic (cysts lined by hobnail cells and separated by a thin fibrotic stroma) characteristics. The examination of more cases is warranted so as to better understand the biology of this tumor, to ascertain its prognosis and to choose appropriate treatment. It is suggested that TCC will be described in the next revision of the WHO classification.

Acknowledgments We thank Drs. I. Abd-Al-Samad, E. Auberger, Baylac (Angouleme), C. Guillaubey (Saint Etienne) and J.M. Romeo (Paris) for providing some of the cases.

We thank Anita Rodenas for technical assistance.

ORIGINAL ARTICLE

Contraction of tubulointerstitial fibrosis tissue in diabetic nephropathy, as demonstrated in an in vitro fibrosis model

Keisuke Ina · Hirokazu Kitamura · Shuji Tatsukawa · Takashi Miyazaki · Hirokazu Abe · Yoshihisa Fujikura

Received: 26 April 2007 / Revised: 29 August 2007 / Accepted: 6 September 2007 / Published online: 25 September 2007

Abstract Tubulointerstitial fibrosis in diabetic nephropathy (DN) was investigated using an in vitro tissue model of remodeling, to determine the pathogenic mechanism of fibrosis that leads to renal atrophy, i.e., renal failure. The remodeling model consisted of a renal fibroblast-populated collagen lattice (FPCL). The overexpression of transforming growth factor (TGF)-β1 in the diabetic kidney gave rise to FPCL contraction. FPCL relaxation was induced by the subsequent addition of cytochalasin D. The FPCL failed to contract when exposed to TGF-β1 plus Y27632, a Rho kinase inhibitor. TGF-β1 induced the phosphorylation of myosin light chains, and Y27632 blocked this activity. TGF-β1-induced FPCL contraction was suppressed by the addition of 2,3-butanedione monoxime, a myosin ATPase inhibitor. As shown in the video, the contraction rate of the projections of the cells in the FPCL was significantly greater in the TGF-β1 group than in the control group. Collectively, these results indicate that TGF-β1-induced FPCL contraction is attributable to actin–myosin interactions in the fibroblasts through the activation of Rho kinase, the phosphorylation of myosin light chains, and the subsequent activation of myosin ATPase. We propose that via these mechanisms, tubulointerstitial fibrosis generates tissue contraction that leads to renal atrophy and renal failure in DN.

Introduction

Diabetic nephropathy (DN) is one of the most serious complications in diabetic patients. DN results in chronic renal failure. Morphologically, it is well known that glomerulosclerosis, which includes glomerular basement membrane thickening and mesangial expansion, and tubulointerstitial fibrosis occur at the early stages of DN. It has recently been demonstrated that the development of tubulointerstitial lesions is more closely correlated with a progressive decline in renal function compared to glomerular lesions [5, 40]. Tubulointerstitial fibrosis ultimately leads to renal failure through renal atrophy in DN. The mechanism by which fibrosis leads to renal atrophy has not yet been determined.

Transforming growth factor (TGF)-β1, which is a profibrogenic cytokine, is overexpressed in the DN kidney, especially in the interstitial cells and proximal tubular epithelial cells that are involved in tubulointerstitial fibrosis [29, 47, 52]. It is well known that TGF-β1 causes fibrosis in various disorders [6]. TGF-β1 stimulates the production of extracellular matrix (ECM), including type I collagen, by fibroblasts and myofibroblasts. In addition, TGF-β1 attenuates the degradation of ECM deposits, thereby promoting ECM accumulation. The inhibition of ECM degradation results from the reduced production of matrix metalloproteinases and the increased production of tissue inhibitor of metalloproteinase-1 and plasminogen activator inhibitor-1 by infiltrating cells and other types of cells [14,

32, 39]. TGF-β1-mediated intracellular signaling occurs mainly via the Smad pathway. TGF-β1 binds to the type II receptor, which as a consequence recruits and phosphorylates the type I receptor. The activated type I receptor then phosphorylates Smad2 and Smad3. Activated Smad2 and Smad3 form heteromers with the common partner Smad4 and then translocate into the nucleus to regulate target gene expression [11, 57].

On the other hand, it has been demonstrated that TGF-β1 evokes the contraction of granulation tissues [19, 44] or fibrotic tissues [28]. TGF-β1-induced tissue contraction has been revealed to occur via activation of the small G protein Rho, using an in vitro granulation or fibrosis tissue model that consists of a fibroblast-populated collagen lattice (FPCL) [51]. Although the pathway through which TGF-β1 activates Rho has not been clarified, it appears to be independent of the Smads [13, 33]. Activation of Rho induces the formation of stress fibers and focal adhesions [1, 49]. Rho also activates Rho kinase [30, 41, 42], which in turn gives rise to actomyosin contraction through phosphorylation of the myosin regulatory light chain (MLC) [2, 9]. Phosphorylation of MLC occurs in different ways depending on the cell type. In smooth muscle cells, the increased level of intracellular Ca^{2+} plays a dominant role in contraction. An increase in the level of intracellular Ca^{2+} activates Ca^{2+}-dependent MLC kinase, which is followed by the phosphorylation of MLC [25, 34, 53]. In nonmuscle cells, such as fibroblasts [8, 46, 50] and endothelial cells [20], cell contraction is predominantly generated in a Ca^{2+}-independent manner. MLC is directly phosphorylated by Rho kinase in these cells, independently of MLC kinase. For both MLC kinase-dependent and Rho kinase-dependent MLC phosphorylation, the phosphorylation site is Ser-19. In addition, Rho kinase phosphorylates the myosin-binding subunit of MLC phosphatase, resulting in the inhibition of MLC phosphatase activity [37]. As a consequence, contraction is induced through increased phosphorylation of MLC. In addition, several reports have shown that Rho kinase induces TGF-β signaling [10, 36, 48], leading to the positive feedback system. Ultimately, after contraction of the FPCL, the fibroblasts undergo apoptosis [12, 22, 54, 56].

To the best of our knowledge, the present study is the first to investigate the mechanism of fibrosis tissue contraction in DN using renal fibroblasts (NRK 49F cells) populated in a collagen lattice, in the form of an in vitro model of fibrosis tissue. Grinnell [21] has previously described that contraction of floating FPCL gives rise to a mechanically relaxed tissue whose cells have morphological and proliferative features resembling dermis or scar, whereas FPCL anchored to the bottom of a culture dish develop into a stressed tissue resembling granulation tissue. Miura et al. [43] showed contraction of the floating collagen lattice with the cells as a model of contraction of fibrous tissue. Anchored FPCL, a model of fibrosis tissue as well as granulation tissue, could also contract in the direction of top and bottom. We use these models to determine whether cell contraction actually occurs during FPCL contraction, and we show that TGF-β-induced contraction is generated by activation of the Rho kinase pathway, leading to the activation of myosin ATPase.

Materials and methods

Materials Materials and chemicals were purchased as follows: type I collagen solution (Nitta Gelatin, Osaka, Japan), recombinant human TGF-β1 (R&D Systems, Minnesota, USA), cytochalasin D (Sigma Chemical, Missouri, USA), the specific Rho kinase inhibitor Y27632 (CalBiochem, California, USA), and hydroxyfasudil, a potent and selective Rho kinase inhibitor, and 2,3-butanedione monoxime (BDM), an inhibitor of myosin ATPase activity (Sigma-Aldrich, Missouri, USA). Rabbit polyclonal antibody against phospho-MLC (Ser19) was purchased from Santa Cruz Biotechnology (California, USA). Rhodamine-conjugated phalloidin (Cytoskeleton, Colorado, USA) was used to stain actin filaments.

Cell culture Normal rat kidney fibroblasts (NRK 49F cells) were obtained from the RIKEN Cell Bank (Tsukuba, Japan). Cells were maintained in Dulbecco's Minimal Essential Medium (D-MEM; Nissui Pharmaceutical, Tokyo, Japan) that contained 100 IU ml^{-1} penicillin, 100 μg ml^{-1} streptomycin, and 10% fetal bovine serum (FBS; JRH Biosciences, Kansas, USA) at 37°C in a humidified, 5% CO_2 atmosphere. Cells from passage 3 to passage 8 were used in the experiments described below.

FPCL contraction assay A collagen solution (7 ml of 3 mg ml^{-1} stock) was gently mixed with 2 ml of fivefold-concentrated D-MEM on ice. The mixture was adjusted to pH 7.4 with 1 ml of 200 mM hydroxyethyl piperazineethanesulfonic acid plus 2.2% $NaHCO_3$ in distilled water. This collagen mixture was blended with 1 ml of NRK 49F cell suspension (2.5×10^6 cells ml^{-1}). The resultant mixture (0.4 ml) was added to each well of a 24-multiwell plate (Becton-Dickinson Labware, New Jersey, USA), and the formation of the collagen gel (FPCL) was induced by incubation for 30 min at 37°C. After gelatinization, 1 ml of D-MEM that contained 10% FBS was added to each well. The FPCLs were then detached from the lateral wall and bottom of each well with a microspatula and used for the experiments. The diameter of the FPCL was measured with a ruler at the indicated time points, to assess FPCL contraction after treatment with reagents.

Fluorescence microscopy After the contraction experiments, the FPCLs were fixed in 4% paraformaldehyde in 0.1 M phosphate-buffered saline (PBS; pH 7.4) for 10 min. After rinsing, the cells in the collagen lattices were permeabilized with 0.5% Triton X-100 in PBS for 20 min, washed with PBS, and stained with rhodamine-phalloidin for 30 min. After staining, the lattices were rinsed with PBS and observed and photographed using an Olympus BX 60 microscope equipped with epifluorescence optics. FPCLs anchored to the bottoms of two-well Labtek chamber slides (AS ONE, Osaka, Japan) were also subjected to the experimental procedure mentioned above. To determine the phosphorylation level of MLC in NRK 49F cells after treatment with TGF-β1, a monolayer culture of the cells (1×10^4 cells ml^{-1}) was grown in a two-well Labtek chamber slide. After stimulation of the monolayer culture, the cells were fixed in 4% paraformaldehyde in 0.1 M PBS (pH 7.4) for 10 min. After rinsing, the cells were permeabilized with 0.5% Triton X-100 in PBS for 20 min and washed with PBS. The cells were then incubated with the primary antibody against phospho-MLC for 2 h at room temperature (RT). After washing, they were incubated with goat anti-rabbit fluorescein isothiocyanate-conjugated secondary antibody (Wako Pure Chemical, Osaka, Japan) for 1 h at RT. After staining, the cells were rinsed with PBS, observed, and photographed. As a negative control, the primary antibody was replaced with mouse or rabbit nonimmune serum.

Transmission electron microscopy After the contraction experiments, the FPCLs were cut into pieces. The pieces were fixed in twofold-diluted Karnovsky's fixative [35] for 10 min at 4°C and then washed with 0.1 M cacodylate buffer and postfixed in 2% osmium tetroxide–0.05% potassium ferrocyanide for 30 min at 4°C. The specimens were dehydrated in an ascending series of ethanol and embedded in epoxy resin. Ultrathin sections were cut on an ultramicrotome (LKB 2088 Ultrotome V; LKB, Bromma, Sweden), mounted on copper grids, and stained with methanolic uranyl acetate and lead citrate. The sections were observed and photographed under a transmission electron microscope (TEM-1200 EX II; JEOL, Tokyo, Japan) at 80 kV.

Analyses of cell projection movements FPCLs were anchored to the bottoms of glass-bottomed dishes (Matsunami, Osaka, Japan). Under phase-contrast microscopy, cell contraction, which was exhibited as expansion and contraction of the projections of NRK 49F cells in the anchored collagen lattice, was monitored with time lapse video microscopy for 24 h from 16 h after treatment. The video camera linked to the TE-2000-E microscope (Nikon, Tokyo, Japan) was controlled using the Luminavision software (O-kumashokai, Fukuoka, Japan). Images were acquired at 5-min intervals, stored on a computer, and analyzed by Dipp-Motion 2D (DITECT, Tokyo, Japan).

Statistical analysis The experimental data are presented as mean ± SD. Statistical analyses were performed with the Student's *t* test. Differences were considered to be statistically significant at $p<0.05$.

Results

TGF-β1 enhances collagen lattice contraction by NRK 49F cells

Under control conditions, although the FPCLs did not contract fully on day 1 (Fig. 1a), they contracted progressively over the 5-day culture period. FPCL contraction was

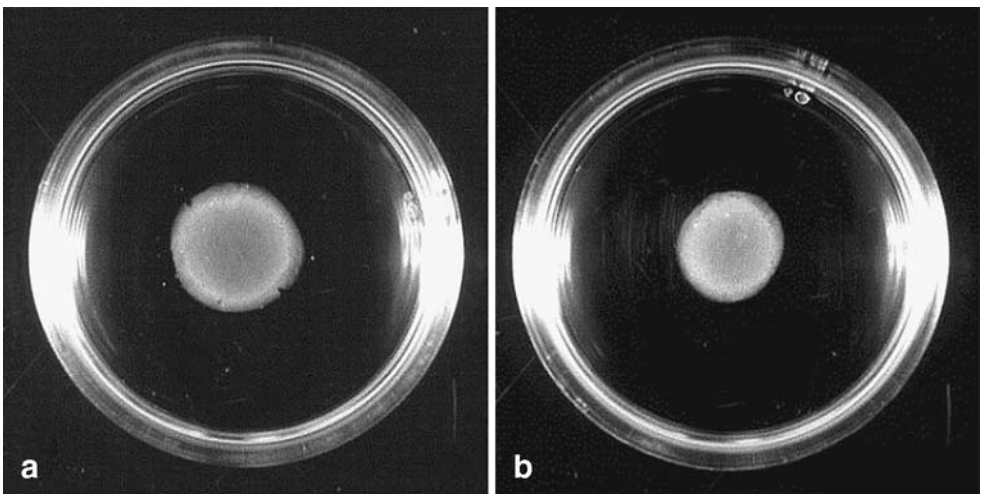

Fig. 1 FPCL contraction produced by TGF-β1. FPCLs were cultured for 1 day in 10% FBS/D-MEM (control, **a**) or 10% FBS/D-MEM that contained 5 ng/ml TGF-β1 (**b**). Photographs show FPCL contraction induced by the addition of TGF-β1 (**b**) but not by the control medium (**a**)

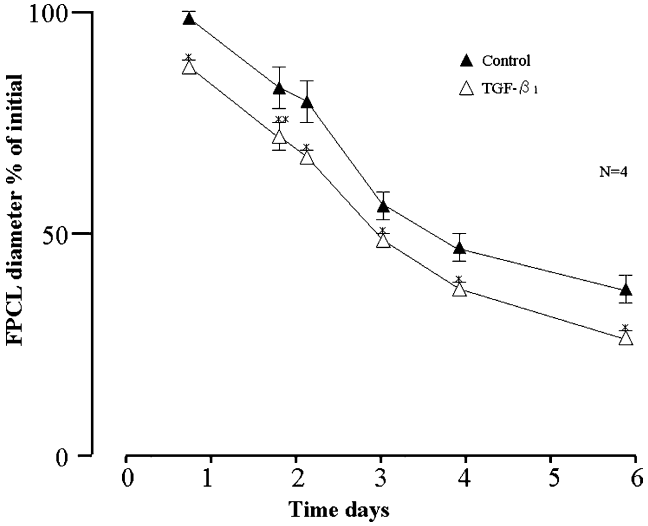

Fig. 2 Time course of FPCL contraction caused by TGF-β1. The FPCL was cultured in 10% FBS/D-MEM in the absence (*closed triangles*) or presence (*open triangles*) of TGF-β1. TGF-β1 significantly enhances FPCL contraction compared to the control over the entire 6-day incubation period. Results are presented as mean ± SD. *Asterisk*, $p<0.001$ and *double asterisk*, $p<0.01$ vs control at each time point

significantly enhanced by the addition of 5 ng ml^{-1} TGF-β1 over the entire 6-day incubation period starting on day 0 (Figs. 1 and 2). On day 1, the diameter of a FPCL treated with or without TGF-β1 was 86.3±1.1 or 99.3±1.1% of the initial FPCL diameter, respectively ($p<0.001$).

TGF-β1 does not affect the formation of stress fibers during FPCL contraction

Electron microscopy identified bundles of actin microfilaments, the so-called stress fibers, in the cytoplasm of NRK 49F cells in the collagen lattices from both the TGF-β1-treated group and the control group. However, there were no differences in the numbers of bundles between the two groups on day 1 (Fig. 3). Under fluorescence microscopy, rhodamine-phalloidin staining of filamentous actins was detected in the cytoplasm of the cells in the FPCL on day 1 (Fig. 4). Microfilaments were present with similar numbers and distributions in cells with and without TGF-β1 treatment.

Inhibition of actin polymerization by cytochalasin D relaxes TGF-β1-induced FPCL contraction

To confirm the participation of intracellular actin microfilaments in FPCL contraction, cytochalasin D, which is an inhibitor of actin polymerization, was used. The FPCL contracted to 74.1±1.7% of its initial diameter after treatment with TGF-β1 for 2 days and relaxed significantly to 79.7±1.2% of its initial diameter 5 h after the addition of 6 μM cytochalasin D ($p<0.001$) (Fig. 5). On the other hand, the FPCL contracted to 71.1±1.1% of its initial diameter without cytochalasin D in the same time period. FPCL recontracted after the removal of cytochalasin D and retreatment with TGF-β1 after FPCL relaxation. Rhodamine-phalloidin staining demonstrated that the microfilament

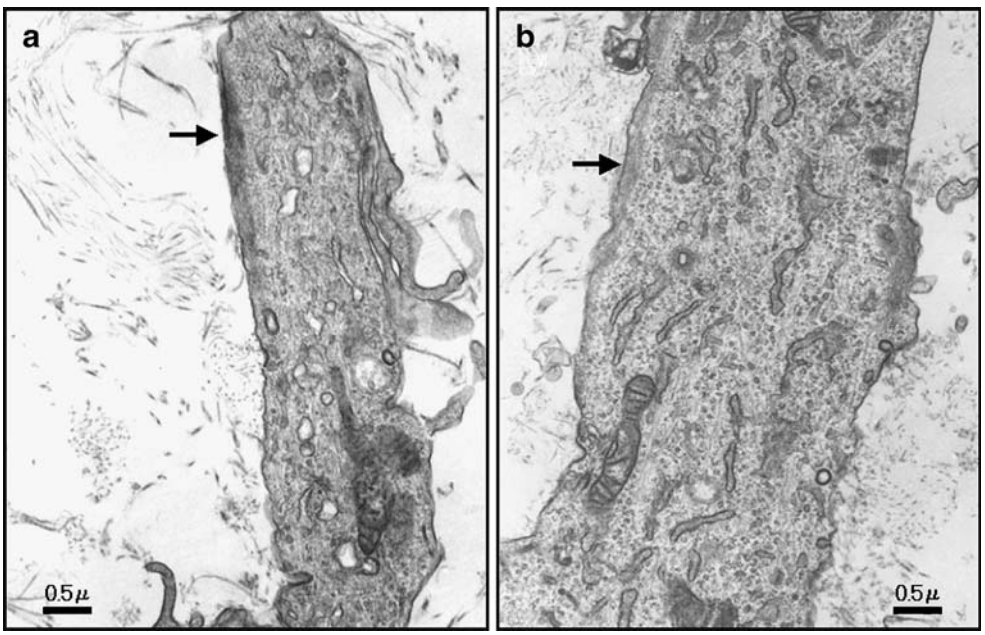

Fig. 3 TEM of bundles of cellular actin microfilaments. The FPCL was cultured in medium with (**b**) or without (**a**) TGF-β1 for 1 day. Bundles of actin microfilaments are present with similar numbers and distributions in cells with and without TGF-β1 treatment. *Arrows* show bundles of actin microfilaments. *Bar*, 0.5 μm

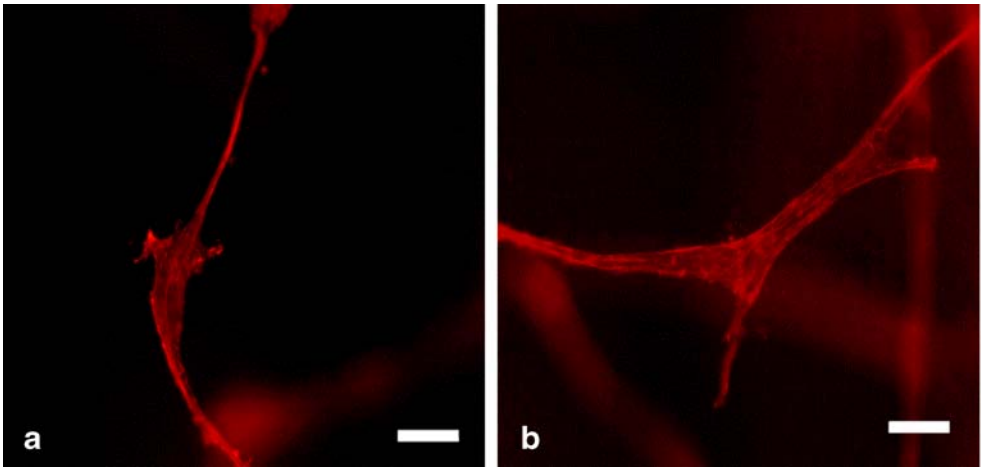

Fig. 4 Effect of TGF-β1 on the fluorescence of rhodamine-phalloidin. Filamentous actin is visualized by staining with rhodamine-labeled phalloidin. **a** Control, **b** TGF-β1-treated FPCL on day 1. There are no differences in the numbers and distributions of actin bundles between the two groups. *Bar*, 20 μm

structures were disrupted in the cells of the FPCL that were relaxed by cytochalasin D and that the cells were assuming a rounded shape (Fig. 6). After the removal of cytochalasin D, cell shape, as well as contractile activity, was restored (data not shown).

Contribution of Rho kinase pathway to TGF-β1-induced FPCL contraction

To determine whether Rho kinase activation is required for TGF-β1-induced FPCL contraction, two structurally different Rho kinase inhibitors, Y27632 and hydroxyfasudil, were used. FPCL contraction was assayed after culture in medium with or without 5 ng ml^{-1} TGF-β1 in the presence or absence of 10 μM Y27632 or 20 μM hydroxyfasudil for 1 day. The stimulatory effect of TGF-β1 on FPCL contraction

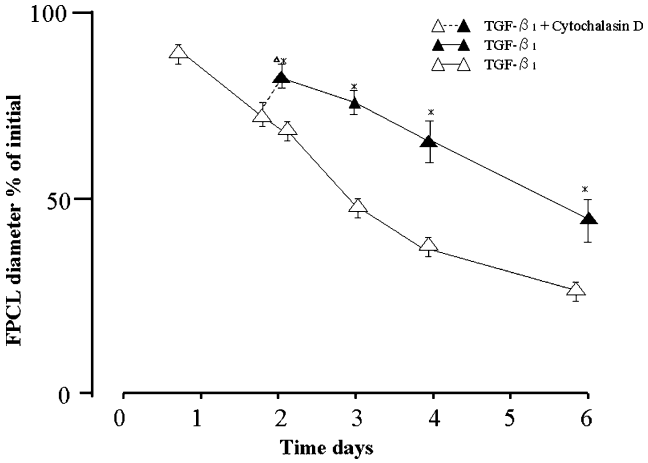

Fig. 5 Effect of cytochalasin D on TGF-β1-induced FPCL contraction. Cytochalasin D (6 μM) was added to medium that contained TGF-β1 on day 2. FPCL diameter was measured 5 h after the addition of cytochalasin D. Cytochalasin D induces the relaxation of FPCL that contracted with TGF-β1 treatment. After FPCL relaxation, the removal of cytochalasin D and retreatment with TGF-β1 leads to FPCL recontraction. Results are presented as mean ± SD. *small open triangle*, $p<0.001$ vs FPCL just before the addition of cytochalasin D; *asterisk*, $p<0.001$ vs FPCL with TGF-β1 alone at each time point

was completely blocked by Y27632 or hydroxyfasudil (Fig. 7). On the other hand, there were no differences in cell shape and rhodamine-phalloidin staining between the control, TGF-β1, and TGF-β1 plus Y27632 groups in floating FPCLs (Fig. 8). In anchored FPCLs, the major part undergoing contraction also revealed no differences in cell shape and phalloidin staining between the three groups. Those morphological features were similar to those in floating FPCLs. Cells with conspicuous stress fibers were sparsely observed in the control group as well as the TGF-β1 group near the part of FPCL attaching to the bottom of the culture dish (data not shown).

TGF-β1 activates Rho kinase leading to the phosphorylation of MLC

To examine whether phosphorylation of MLC is involved in TGF-β1-induced FPCL contraction, immunostaining for phospho-MLC was performed. On day 1, TGF-β1 augmented phospho-MLC immunostaining in the cytoplasm of NRK 49F cells in monolayer culture. Furthermore, Y27632 downregulated phospho-MLC immunostaining that was enhanced by TGF-β1 (Fig. 9).

Actin–myosin interaction via myosin ATPase activation in TGF-β1-induced FPCL contraction

The myosin ATPase inhibitor BDM was used to investigate the contribution of myosin ATPase activation as the final step leading to cell contraction by actin–myosin interaction. BDM suppressed TGF-β1-stimulated FPCL contraction in a dose-dependent manner after 4 h of incubation (Fig. 10).

Accelerated cell contraction during collagen lattice contraction

In the filmed study, anchored FPCL was attached exclusively to the bottoms of the dishes. Because FPCL was not

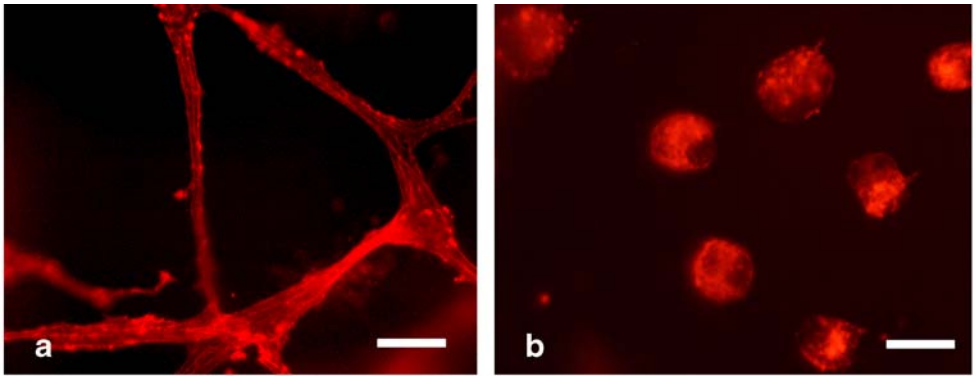

Fig. 6 Effect of cytochalasin D on the fluorescence of rhodamine-phalloidin. Rhodamine-phalloidin staining was performed 5 h after the addition of cytochalasin D. **a** TGF-β1 alone, **b** TGF-β1 plus cytochalasin D. Cytochalasin D disrupts the microfilament structures and makes the cells assume a rounded shape (**b**). *Bar*, 20 μm

attached to the lateral walls of the dishes, the FPCL could only contract in the directions of top and bottom. FPCL contracted in response to TGF-β1 on day 1, with the cells that were in focus at the beginning of the movie becoming gradually more blurred. The cells in the FPCL that was incubated with control medium remained in focus from the beginning to the end of the culture period. The cell motility movie sequence revealed that cell projections extended in every direction and contracted in turn. In the control FPCL, a projection (arrow) of the cell was observed to elongate from 0 to 390 min (Fig. 11a). Another projection (arrowhead) of the cell extended from 50 to 185 min and contracted at the rate of 0.49 μm min^{-1} until 390 min (Fig. 11a). On the other hand, two projections (single arrow and double arrow) contracted more rapidly at 1.41 (single arrow) and 1.38 μm min^{-1} (double arrow) in the TGF-β1-stimulated FPCL than in the control FPCL (Fig. 11b). Another projection of the cell (closed arrowhead) both branched and extended (Fig. 11b). One (open arrowhead) of the branches elongated and subsequently underwent intensive contraction at 2.00 μm min^{-1} from 340 to 390 min (Fig. 11b). Thus, the expansion and contraction of cell projections were repeated in the collagen lattice for a 24-h period from 16 h after the beginning of the culture (Fig. 11). The total distance by which the cell projections contracted for 17 h was significantly longer in the collagen lattice treated with TGF-β1 than in the control lattice, i.e., 267±61 and 131±51 μm, respectively ($p<0.01$; Fig. 12). Collagen fibers in the background were observed to move concomitant with the extension and contraction of the cell projections, although this movement could not be measured in detail.

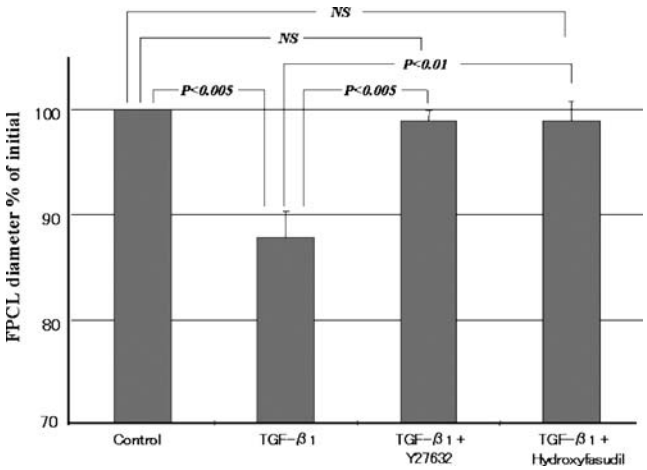

Fig. 7 Effect of Rho kinase inhibitor on TGF-β1-induced FPCL contraction. Y27632 (10 μM) or hydroxyfasudil (20 μM) was added to the FPCL in 10% FBS/D-MEM with TGF-β1 at the beginning of the culture period. FPCL diameters were measured on day 1. TGF-β1-induced FPCL contraction is fully blocked by each of the two Rho kinase inhibitors. Results are presented as mean ± SD

Discussion

TGF-β1 produced greater FPCL contraction than the control treatment during the experimental period. This result is compatible with those of a number of studies reported to date [17, 19, 44, 55]. Although FPCL contraction occurred in response to TGF-β1 on day 1 but not in the control medium, there was no difference in the morphology of the bundles of actin microfilaments between the TGF-β1-treated and control groups, as shown by transmission electron microscopy and fluorescence microscopy. The number of cells in the FPCL is known to affect FPCL contraction [4, 23, 24]. There were no differences in cell numbers between the TGF-β1-treated and control groups on day 1 (data not shown). The FPCL contracted by TGF-β1 expanded in response to cytochalasin D. Fluorescence microscopy revealed few bundles of actin microfilaments, and the cells in the FPCL became rounded. The change in actin microfilaments was reversible. These

Rhodamine-phalloidin staining was performed on day 1. **a** Control; **b** TGF-β1 alone; **c** TGF-β1 plus Y27632. There are no differences of rhodamine-phalloidin staining between the three groups. *Bar*, 20 μm

results suggest that the formation of filamentous actin is necessary for FPCL contraction.

We investigated whether TGF-β1-induced FPCL contraction was mediated by the Rho kinase pathway. The addition of two structurally different Rho kinase inhibitors, Y27632 and hydroxyfasudil, completely blocked FPCL contraction induced by TGF-β1 on day 1. However, in contrast to cytochalasin D treatment, the addition of the Rho kinase inhibitor did not affect the formation of actin microfilament bundles. There was no difference in actin bundle formation between the control and TGF-β1-treated groups and the TGF-β1 plus Rho kinase inhibitor groups. Furthermore, there was no difference in cell numbers between the three groups (data not shown). The inhibitory

effect of Y27632 has been reported to be specific for Rho kinase at 10 μM [31]. TGF-β1 causes FPCL contraction via Rho kinase pathway in NRK 49F cells. The Rho kinase pathway has been demonstrated to play a pivotal role in the contraction of granulation tissues [19, 44] and fibrous tissues [28]. In renal tissues, Rho kinase has been reported to contribute to the development of renal tubulointerstitial fibrosis in various disorders [10, 36, 45, 48]. With regard to FPCL contraction and renal cells, TGF-β1 has been shown to produce contraction of a mesangial cell-populated collagen lattice [38]. However, that report did not include any information regarding the intracellular signaling pathway of TGF-β1-induced contraction. To the best of our knowledge, the present study is the first to demonstrate that TGF-β1 causes the contraction of a renal FPCL via the Rho kinase pathway. It is well known that TGF-β1 transdifferentiates fibroblasts and epithelial cells into myofibroblasts,

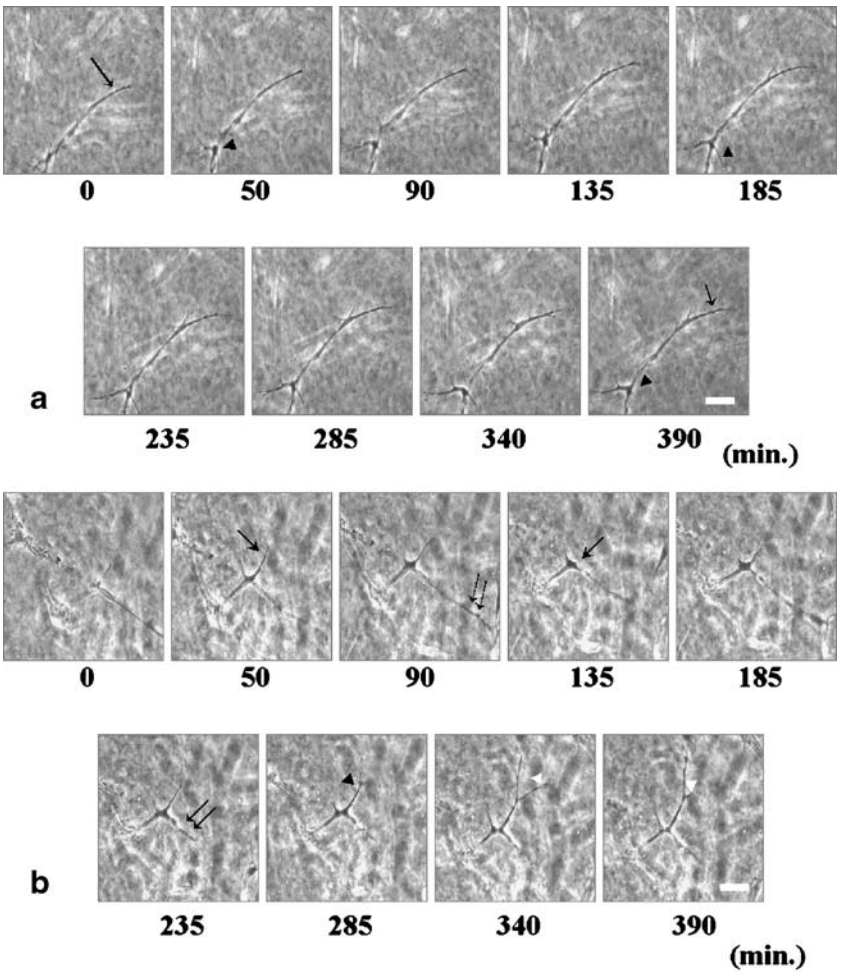

Fig. 11 Motilities of cell projections in the FPCL. Under phase-contrast microscopy, the movie shows the expansion and contraction of cell projections in the FPCL for 390 min from 16 h after initiation of the culture. **a** Control; **b** TGF-β1-treated FPCL. The *arrow* in **a** shows a projection that is elongating slowly. The *arrowhead* in **a** indicates a projection that is elongating and that subsequently contracts. The *single arrow* and *double arrow* in **b** show contracting projections. The *closed arrowhead* in **b** reveals a branching projection. The *open arrowhead* in **b** shows the rapid extension and contraction of a branched projection. *Bar*, 100 μm

which are characterized by the expression of α-smooth muscle actin [16, 29]. Myofibroblasts contribute to the progression of fibrosis. In addition, it has been reported that this response to TGF-β1 is mediated by the Rho kinase pathway [26]. However, whether or not myofibroblast transdifferentiation contributes to TGF-β1-induced FPCL contraction remains a controversial issue [3, 15]. Furthermore, TGF-β1 increased phosphorylated MLC in the cytoplasm of NRK 49F cells, as shown by immunohistochemistry on day 1. Y27632 downregulated MLC phosphorylation induced by TGF-β1. These results suggest that Rho kinase evokes the phosphorylation of MLC, after the activation of Rho kinase by TGF-β1. TGF-β1-induced FPCL contraction could have taken place via Rho kinase-dependent MLC phosphorylation. Furthermore, we examined whether myosin-based contractility is essential for FPCL contraction. BDM, which is an inhibitor of myosin ATPase activity, repressed FPCL contraction induced by TGF-β1. It seems likely that phosphorylated MLC activates myosin ATPase, leading to actin–myosin interaction and subsequent cell contraction.

In the filmed sequence, the relationship between collagen lattice contraction and cell motility was examined. The expansion and contraction of cell projections were repeated in a collagen lattice. The rate of cell projection contraction per hour was significantly higher in the FPCL contracted by stimulation with TGF-β1 than in the noncontracted control FPCL. This result suggests a close relationship between the FPCL and cell motility. Cell–matrix interactions would be required for FPCL contraction after cell contraction. Cell–matrix interactions are thought to include cell extension, the formation of focal adhesions at the tip of the cell, intracellular force generation through actin–myosin interaction, and the breakdown of the focal adhesions. In the current study, cell extension and actin–myosin interaction were associated with FPCL contraction. In our preliminary study, focal adhesions were observed to be enlarged to a greater extent in response to TGF-β1 in the monolayer culture on a plastic plate compared to the control (data not shown). The significance of this finding remains to be defined. It may reflect the fact that stronger cell–matrix adhesion is required for more intensive contraction of the cell–matrix complex by TGF-β1 than by the control. Thus, cell contraction is considered to lead to FPCL contraction. In the present study, it appears that DN results in the contraction of fibrotic tissues through fibroblast contraction.

In a previous study, it was reported that collagen lattices contraction was prevented by the formation of advanced glycation endproducts (AGEs), which are produced through the Amadori arrangement from nonenzymatic glycation in the diabetic milieu [27] and occur in diabetic complications [18]. In that study, collagen lattices were exposed to the reducing glucose glucose-6-phosphate at doses greater than or equal to 50 mM for 5 days. High concentrations of glucose evoked cross-linking of collagen fibers by nonenzymatic glycation, as reported by Brownlee et al. [7]. The cross-linked collagen fibers stabilized the collagen lattices and resulted in decreased collagen lattices contraction. Our results are incompatible with this previous report. The discrepancy may be a function of different diabetic milieus. We used TGF-β1 instead of AGEs as a factor that leads to diabetic complications. Our preliminary study showed that TGF-β1-induced FPCL contraction on day 6 was reversible, as evidenced by the results of cytochalasin D treatment. The prevention of contraction by AGE was irreversible. It is likely that FPCL is reversibly contracted at the early stage, while FPCL contraction becomes irreversible at the later stage.

In conclusion, our results suggest that TGF-β1-induced FPCL contraction is the consequence of Rho kinase activation and subsequent phosphorylation of MLC, leading to the activation of myosin ATPase. This mechanism is considered to account for renal atrophy and renal failure in DN, although there is a difference in time required for the limit of tissue contraction between FPCL and diabetic kidney, more than several days and more than several years, respectively. Hydroxyfasudil, a Rho kinase inhibitor, is already in clinical use as a treatment for cerebral vasospasm. It may be of great benefit to patients with DN. Further studies are required to elucidate the detailed mechanism of actin–myosin interaction in fibroblasts.

Acknowledgments We are grateful for the excellent secretarial assistance of Ms. Yukari Goto.

Abstract Myxoinflammatory fibroblastic sarcoma (MIFS) is a rare low-grade sarcoma of the distal extremities characterized by a myxohyaline stroma, a dense inflammatory infiltrate and virocyte- and lipoblast-like giant cells. Up to now, only two cases have been investigated cytogenetically, showing complex and heterogeneous karyotypes, in part with supernumerary ring chromosomes. We characterized two further cases of MIFS immunohistochemically and performed comparative genomic hybridization as well as DNA image cytometry analyses. Both tumors showed the characteristic histomorphological pattern of MIFS and were positive for Vimentin and CD68. Moreover, both cases presented aberrant karyotypes including distinct DNA copy number changes involving chromosome 7 and disclosed DNA aneuploidy.

Introduction

In 1998, Montgomery et al. [14] first described inflammatory myxohyaline tumors of the distal extremities with virocyte or Reed-Sternberg-like cells as a distinct tumor entity with unique histologic features. In the same year, Meis-Kindblom et al. coined the shorter term acral myxoinflammatory fibroblastic sarcoma (MIFS) for the same lesion, usually presenting as poorly circumscribed multinodular mass of the distal extremities ranging from less than 1 to 8 cm in size [2, 12]. Patients typically report a history of slowly growing and painless tumors that only occasionally are associated with pain or decreased mobility [2]. Histologically, MIFS exhibit a dense inflammatory infiltrate, predominantly consisting of lymphocytes and plasma cells, embedded in an alternating myxoid and hyaline stroma. Three main types of neoplastic cells can be distinguished, namely spindle-shaped cells, bizarre virocyte, or ganglion-like cells with enlarged nuclei and often huge, inclusion-like nucleoli and multinucleated lipoblast-like cells of variable size. Tumor cells are

dispersed through the myxohyaline stroma as single cells or form coherent nodules [2, 9, 12–14, 17, 18]. The rates of local recurrences range between 22 and 67%, probably depending on differences in surgical treatment, whereas distant metastases are exceedingly rare (<2% of all reported cases) [2, 12, 14, 17].

Cytogenetic data on chromosomal aberrations of MIFS are scarce, and up to now, only two cases have been investigated so far. One of them revealed a complex karyotype with a reciprocal translocation t(1;10)(p22;q24) in addition to the loss of chromosome 3 and 13, while the other exhibited supernumerary ring chromosomes and a derivate chromosome 13 with additional material on the short arm [9, 11]. In this paper, we report two further cases of MIFS investigated by immunohistochemistry, comparative genomic hybridization (CGH), and DNA image cytometry.

Materials and methods

Immunohistochemistry

The biopsy specimens were formalin-fixed, routinely processed, paraffin-embedded, and stained with hematoxylin and eosin. The panel of applied primary antibodies, dilutions, and different methods of tissue preparation and pretreatment, respectively, are listed in Table 1. All primary antibodies were diluted in a 1% solution of bovine serum albumin in phosphate-buffered saline (pH 7.4) and incubated for 30 min at room temperature. After incubation with the biotinylated secondary antibody, the avidin–biotin–peroxidase complex was applied for 30 min, and color development was performed using diamino-benzidine (DAB). The slides were counterstained with hemalaun, dehydrated, and mounted.

Comparative genomic hybridization

For CGH, tumor DNA was isolated from formalin-fixed and deparaffinized tumor tissue by proteinase K digestion (2 mg/ml final concentration; Roche, Mannheim, Germany) followed by spin column purification (Qiagen, Hilden, Germany). Labeling of tumor DNA with biotin-16-dUTP (Roche, Mannheim, Germany) and normal reference DNA with digoxigenin-11-dUTP (Roche) was performed by standard nick translation. The denatured DNA probe containing 2 μg of tumor DNA, 1.5 μg of reference DNA, and 80 μg of COT-1 DNA was hybridized for 3 days to normal metaphase spreads on glass slides (15×15 mm cover glass area). The slides were then washed, blocked with bovine serum albumin solution, and incubated with fluorescein-conjugated avidin (Vector Laboratories, Burlingame, CA) and rhodamine-conjugated antidigoxigenin (Roche). Finally, the slides were washed and mounted in antifade solution (Vector Laboratories) containing 2.5 μg/ml of 4,6-diamino-2-phenylindole (DAPI) counterstain. Image acquisition was performed on a Zeiss Axioskop fluorescence microscope (Zeiss, Göttingen, Germany) equipped with three separate bandpass filters (DAPI bandpass, Green single bandpass, Red single bandpass) and a high sensitive monochrome charge coupled device camera (Photometrics, Tuscon, AZ). For each analysis, the averaged chromosome-specific green to red fluorescence ratios and their 95% confidence intervals (CI) from at least ten well-selected metaphases were plotted using the Quips CGH software (distributed through Applied Imaging, Newcastle, UK). Relative copy number changes were interpreted as gains when the average green-to-red ratio exceeded 1.2 or 2 (high-level amplification), and

Table 1 Antibodies used in the study

Antibody specificity	Source	Type	Dilution	Pretreatment
Vimentin	Novocastra (Nunningen, Switzerland)	mm	1:50	Microwave

as losses when the corresponding ratio was less than 0.8. Exceptionally, in cases with only trends not reaching the aforementioned thresholds, deviations from normal were classified as gains or losses when the 95% CI varied beyond the ratio of 1.0. An event was defined as a gain or a loss of (part of) a chromosomal arm. Chromosomal regions 1p32-pter, 13p, 14p, 15p, 19, 21p, 22p, telomeres and constitutive heterochromatic regions at 1q, 9q, 16q, and Yq reported to produce false results by CGH were excluded from all analyses [7].

DNA image cytometry

The specimens were evaluated with the semiautomatic AUTOCYTETM cell analytical system (Carl Zeiss AG, CH 8706 Feldmeilen) using a Zeiss AxioplanTM microscope. On average, 135 (104–153) of the most abnormally looking tumor cells were selected as test cells, whereas 50 nuclei of lymphocytes were measured as internal standard.

The histograms were analyzed following the recommendations of the European Society for Analytical and Cellular Pathology (ESACP) [3, 4]. Both stemlines and single events were considered. The key data of DNA cytometry, i.e., integrated optical density and nuclear area, were transferred to the server EUROQUANTTM (http://euroquant.med.tu-dresden.de) at the Institute of Pathology, Technical University/Dresden, which is available free of charge to any user for quality assurance [5]. There, the data were standardized and evaluated on the basis of statistic models, by which, the number of stemlines, their position on the ploidy axis, and their coefficient of variation are determined. EUROQUANT delivers the modal DNA values of peaks and the coefficient of variation (CV) value of stemlines and calculates several quality parameters defined by the ESACP (e.g., parameters for a control of measured glare factors and of the homogeneity of measurement) and compares them to established limit values. Single events were directly analyzed on the basis of the AUTOCYTE data. Ploidy classes were defined as follows: euploid/diploid: 1.8–2.2 c; tetraploid/polyploid: 3.6–4.4 c; octaploid: 7.2–8.8 c; aneuploid: stemline outside of a euploid region (2 c, 4 c, 8 c, etc.), single events >8.8 c.

Results

Clinical findings

Clinical features of the two cases are summarized in Table 2. One patient noticed a slowly growing painless mass in the right index finger and was treated surgically by local excision (case 1). The other patient suffered from pain in the right popliteal fossa and observed a slowly growing tumor that turned out to be located inside the tibial nerve (case 2). After histologic diagnosis, treatment consisted in isolated limb perfusion with tumor necrosis factor alpha (TNF-α) and Melphalan followed by neoadjuvant percutaneous radiotherapy and local excision without destruction of major fascicles. On histologic examination, no viable tumor was detectable anymore, and the patient did not sustain sensory or motor deficits (Fig. 1). At initial surgery, both tumors showed a myxoid aspect with no signs of necrosis or hemorrhage on cut section. Patient 1 developed local recurrence 5 months after initial resection and underwent re-excision followed by another recurrence 16 months later. The second patient is still free of disease (follow-up 14 months).

Microscopical and immunohistochemical findings

Light microscopy showed cell-rich tumors containing myxoid and hyaline areas and zones of fibrosis (Fig. 2). Tumor cells revealed pronounced nuclear polymorphism, including differences in nuclear size and form. Some cells were rather small and spindle-shaped, while others revealed big vesicular nuclei and prominent nucleoli, focally resembling ganglion cells or virocytes (Fig. 2f). Additionally, multinucleated cells and lipoblast-like cells with multiple intracytoplasmatic mucin-containing vacuoles were present in all cases (Fig. 2a–c). The inflammatory infiltrates were dense and particularly prominent in the fibrotic and myxoid areas of the tumors. Immunohistochemically all tumors were strongly positive for vimentin and focally positive for CD68 (not shown). Expression of CK22, CD15, CD30, epithelial membrane antigen (EMA), S100 protein, or desmin could not be detected in any of the two cases.

Table 2 Clinical features

Case	Sex/age	Location	Size	Follow-up

Case	Results
1	0.20: rev ish enh(3p11p12, 7q31q32) trend enh(1p, 18), dim(6q14qter)
2	0,20: rev ish enh(5pterq32, 7p15p21, 14q12q21)

Comparative genomic hybridization

DNA copy number changes were identified in both cases (Table 3, Fig. 3). The number of changes ranged from two (case 1) to three (case 2). There were no specific common gains or losses, but both investigated cases showed gains at chromosome 7.

DNA image cytometry

All tumors revealed aneuploid stemlines and additional aneuploid single events. Modal DNA value of peaks ranged between 2.54 c and 2.72 c (mean 2.63 c). The CV varied between 7.31 and 7.36% (mean 7.34%).

Discussion

Myxoinflammatory fibroblastic sarcomas are rare low-grade tumors typically presenting as painless and slowly growing masses of the distal extremities. According to the Medline database, 133 cases have been reported up to now, including

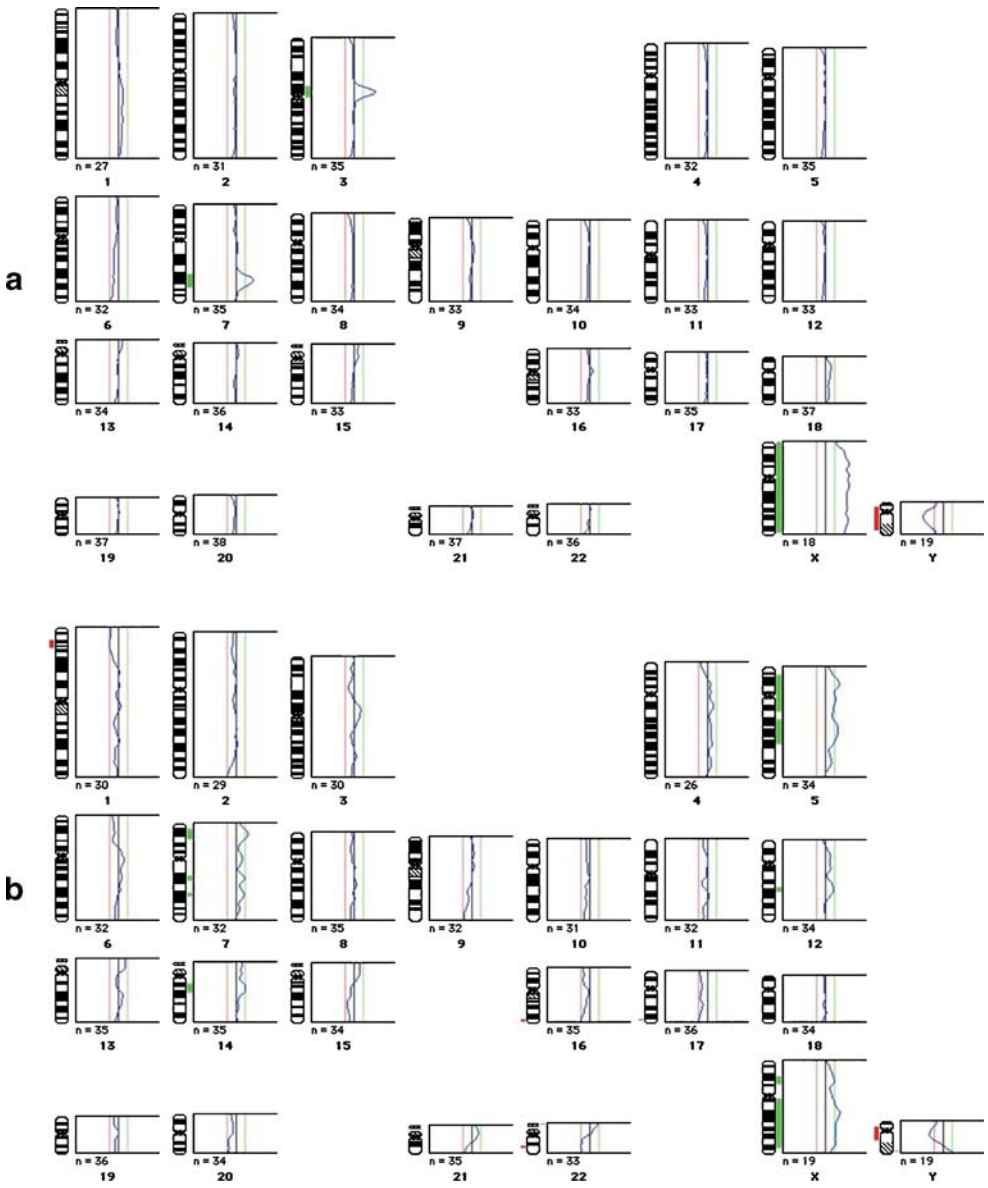

Fig. 3 a–b Comparative genomic analyses of cases 1–2

several tumors of the proximal extremities as well (upper arm, thigh) [1, 6, 8–10, 12–17]. Both investigated cases revealed the characteristic histomorphological and immunohistochemical pattern of MIFS. Besides the alternating and confluencing myxoid and hyaline stroma containing a predominantly lymphoplasmocytic inflammatory infiltrate, all tumors exhibited intermixed spindle cells, large polygonal and partially bizarre ganglion-like cells with huge inclusion-like nucleoli and bubbly multinucleated cells resembling lipoblasts (Fig. 2). Immunohistochemically, the tumor cells stained positive for Vimentin and CD68.

Cytogenetic data on chromosomal aberrations on MIFS are limited. To our knowledge, only two cases have been investigated by conventional cytogenetic and fluorescence in situ hybridization analyses so far. One case showed a derivate chromosome 13 with additional material on the short arm and supernumerary ring chromosomes, while the other exhibited a complex karyotype with a reciprocal translocation t(1;10)(p22;q24) and losses of chromosomes 3 and 13 [9, 11]. The two cases of the present study also revealed aberrant karyotypes involving gains at several different chromosomal regions. Although no specific common aberration was observed, both cases shared gains at chromosome 7. Losses of chromosomal regions were not detected. Furthermore, no chromosomal alterations were shared with the previously investigated two MIFS [9, 11]. DNA image cytometry revealed both tumors of our series to be DNA aneuploid, which has never been investigated so far.

In conclusion, the two MIFS of the present study show considerable genetic diversity, which is in keeping with the two previously investigated cases. However, no single marker or profile of DNA copy number changes characterizing all tumors could be detected. Further, cytogenetic or CGH analyses have to be awaited to define specific cytogenetic profiles of MIFS and possible separate subtypes of MIFS, respectively.

Abstract Disseminated trichosporonosis is known to be a severe opportunistic mycosis and has a high mortality rate. In autopsy cases, it is often difficult to diagnose as trichosporonosis because the causative *Trichosporon* species are pathologically similar to other fungi, especially the *Candida* species. Immunohistochemical analysis is essential for the differential diagnosis, but an antibody to *Trichosporon* is not available commercially. In the present study, we investigated the supplemental utility of nested polymerase chain reaction (PCR) for the pathological diagnosis of trichosporonosis from formalin-fixed and paraffin-embedded tissues. Total DNA was purified from 30 major organs in three autopsy cases, and *Trichosporon* DNA was specifically amplified by nested PCR using three sets of primers. Of 22 organs in which Grocott's stain was positive for fungal infection, 170- and 259-bp PCR products were detected in 20 (91%) and 12 (55%) organs, respectively. In short-term fixation (about 1 day), these bands were highly detected in ten (100%) and nine (90%) organs, whereas the detection efficiency tended to decrease after long-term fixation and decalcification. No PCR product of 412 bp was detected in any organs. These findings suggest that nested PCR from short-term-fixed tissues is useful for supportive pathological diagnosis of disseminated trichosporonosis.

Introduction

Trichosporon species are recognized as significant peccant fungi in opportunistic mycoses. These are currently reclassified into more than 30 individual species by DNA sequence analysis [26]. *Trichosporon asahii*, *T. dermatis*, *T. montevideense*, *T. mucoides*, and *T. ovoides* are related with summer-type hypersensitivity pneumonitis [21, 26, 28], whereas *T. asahii*, *T. asteroids*, *T. cutaneum*, *T. inkin*, *T. loubieri*, *T. mucoides*, and *T. ovoides* are associated with superficial and disseminated infections to the human organs [16, 18]. Of these species, *T. asahii* and *T. mucoides* are major causative species for acute-onset disseminated trichosporonosis.

Acute trichosporonosis generally disseminates to multiple organs and is highly fatal in immunocompromised hosts. Most of the patients had received chemotherapy for hematological malignancies or solid malignant neoplasm, as well as treatment with immunosuppressants after bone

marrow transplantation or organ plantation [1, 5, 8, 12, 14, 15]. The attributable mortality rate is higher than that of other fungemia [14]. Thus, it is important to identify *Trichosporon* species from patients' blood at an early stage. Unfortunately, however, patients occasionally rapidly die before detection of *Trichosporon*, and an autopsy is often performed to determine the causative pathogen.

In autopsy cases, the pathological diagnosis of trichosporonosis is usually derived from the characteristic structures of species; (1) oval or square spores in the core of the fungal colonies; (2) slender or occasional curled hyphae in the periphery of the colonies; and (3) presence of both separate hyphae and pseudohyphae. However, *Trichosporon* lacking these features is occasionally confused with other fungi such as the *Candida* species. Some reports of disseminated trichosporonosis are diagnosed by immunohistochemical examination using in-house antibodies to *Trichosporon* [7, 10, 11, 20], but these antibodies are now limited to a few laboratories. Therefore, we tried to investigate the usefulness of nested polymerase chain reaction (PCR) for the pathological diagnosis of disseminated trichosporonosis in formalin-fixed and paraffin-embedded tissues.

Materials and methods

Samples and pathological investigation

Three autopsy cases in which *Trichosporon asahii* was routinely identified premortem by blood culture and sequent VITEK® 2 compact system (Japan BioMérieux, Tokyo, Japan) were used for this investigation. All autopsy samples were fixed in 20% formalin. Bone marrow samples were treated with Plank-Rychlo solution [25] (7 g of $AlCl_3 \cdot 6H_2O$, 5 ml of 86% formic acid, 8.5 ml of 12N HCl) for 15 h, and they were neutralized with 5% Na_2SO_4 for 12 h. Paraffin-embedded sections (4 μm) were performed with hematoxylin and eosin (HE) and Grocott's stains. Positive results with these stains microscopically determined fungal infection.

DNA extraction and nested PCR

Three 8-μm tissue sections were deparaffinized in xylene and rinsed in ethanol. Tissues were suspended with 200 μl of DNA lysis buffer [100 mM Tris–HCl (pH 8.0), 100 mM NaCl, 25 mM EDTA, 0.5% sodium dodecyl sulfate, and 1 mg/ml proteinase K] and incubated at 55°C for 16 h. After addition of 100 μl of phenol and 100 μl of chloroform-isoamyl alcohol (24:1), the solution was mixed well with vortex and centrifuged at 12,500×*g* for 2 min. The supernatant was mixed with 100 μl of 7.5 M ammonium acetate, 0.05 mg/ml glycogen, and 400 μl of ethanol, and the resulting suspension was incubated at −20° C for 2 h. DNA was trapped in the glycogen by centrifugation at 12,500×*g* for 20 min at 4°C and finally resuspended with 10 μl of TE buffer.

Specific PCR primers for the *Trichosporon* species were used for amplification of different product sizes as shown in Table 1 [19, 27, 29]. All primers were synthesized by Tsukuba Oligo Service (Tsukuba, Japan). The amplification

reaction was performed in a PCR buffer containing 50 mM KCl, 10 mM Tris–HCl (pH 8.3), 1 mM $MgCl_2$, 2.5 μM dNTP, 2 mM primers, 0.5 U Taq DNA polymerase (Ampli Taq Gold™; Applied Biosystems, Tokyo, Japan), and 2 μl of extracted DNA template. The reaction mixture was amplified in an automated thermal cycler (ASTEC PC808; ASTEC, Fukuoka, Japan). An initial denaturation at 95°C for 5 min was followed by 40 cycles consisting of denaturation at 95°C for 1 min; annealing at 55°C for 2 min (TB26-1 and TB26-2), 56°C for 2 min (TRF and TRR) or 57°C for 1 min (TAAF and ITS4R); and extension at 72°C for 2 min. Final extension was performed at 72°C for 7 min. In the nested PCR step, 2 μl of the first amplification product was added to a new reaction mixture with inner primers and reamplified with 40 cycles as described above, except for the annealing step at 60°C for 2 min (TB26-9 and TB26-10) and 65°C for 1 min (TAAF and S2-2). Amplified PCR products were separated by electrophoresis on 2% agarose gel and visualized by staining with SYBR Green I (Molecular Probes, Eugene, OR, USA).

[a] Slight bands were detected.
[b] Slightly longer band than 259 bp was observed.

Immunohistochemistry

Immunohistochemical analysis was performed by Dr. Hotchi using specific antibodies to *Trichosporon*, *Candida*, and *Aspergillus*. These in-house-produced antiserum and control specimens were as previously reported [7, 10].

Results

We detected *Trichosporon* by both conventional pathological examination and nested PCR analysis to elucidate the utility of nested PCR for the diagnosis of disseminated trichosporonosis. In a total of 30 organs, fungi were observed in 20 (67%) and 22 (73%) organs under HE and Grocott's stains, respectively (Table 2). HE staining showed numerous fungal colonies composed of basophilic and segment-like fungal bodies, but detailed fungal structures were unclear (Fig. 1). On the other hand, Grocott's staining revealed clearly dark brownish or blackish fungal hyphae (2 to 4 μm in diameter). In a few colonies, careful observation revealed slightly large and oval spores (up to 10 μm in diameter), as well as terminal slender hyphae. Despite the presence of these fungal structures being highly suspicious of *Trichosporon* infection, we could not definitively conclude that these fungi were *Trichosporon* species. In nested PCR using specific primers, 170- and 259-bp *Trichosporon* DNA was amplified in a total of 21 (70%) and 13 (43%) samples, respectively (Fig. 2). In the 22 organs that were positive for Grocott's staining, 170-bp PCR products were highly detected in 20 (91%) samples, while 259-bp bands were observed in 12 (55%) samples (Table 3). In the total of eight samples that were negative for Grocott's staining, only one sample (13%) was positive for both 170- and 259-bp bands. In ten samples that were positive for Grocott's staining in the short-term fixation (about 1 day), both 170- and 259-bp bands were highly amplified in ten (100%) and nine (90%) samples, respectively. However, in 12 samples which were Grocott's stain-positive in long-term fixation (6 to 21 days), these bands were decreasingly detected in ten (83%) and two (17%) samples. In two bone marrow samples positive for fungal colonies with Grocott's staining, only the170-bp band was detected in one sample (50%). On the other hand, in no sample was the band of 412 bp detected.

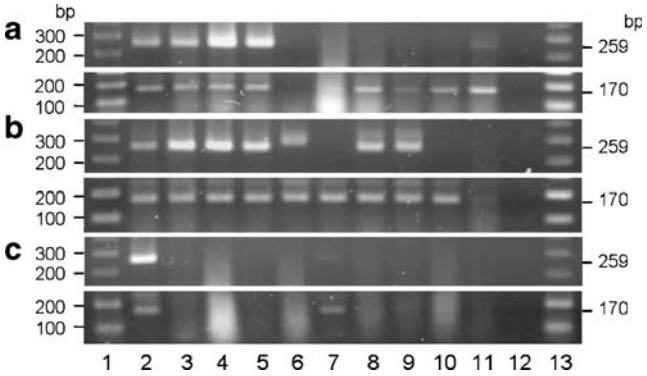

Fig. 2 Detection of *Trichosporon* DNA by nested PCR. The specific 259- and 170-bp bands for *Trichosporon* are detected in multiple organs (**a**–**c**, cases 1–3). **a** *Lanes 2* through *11* are shown as follows: ileum, spleen, liver, lung (1-day fixation), bone marrow, pancreas, kidney, urinary bladder, heart, and lung (9-day fixation). **b** *Lanes 2* through *11*: liver, spleen, heart, lung, bone marrow, urinary bladder, kidney, brain, adrenal gland, and pancreas. **c** *Lanes 2* through *11*: lung, liver, spleen, bone marrow, kidney, urinary bladder, colon, heart, thyroid gland, and adrenal gland. Negative controls (no template) are indicated in *lane 12*. Molecular weight markers are shown in *lanes 1* and *13*

To confirm whether the infected fungi were *Trichosporon* species, an immunohistochemical analysis using a specific anti-*Trichosporon* antibody was performed (Fig. 3). The fungi were positive for anti-*Trichosporon* antiserum, but no reaction occurred with antibodies to either *Candida* or *Aspergillus*. In the control specimens for *Candida*, hyphae and round spores were strongly positive for the anti-*Candida* antibody. Meanwhile, the antibody to *Aspergillus* revealed the characteristic 45° angle branch of *Aspergillus*. Thus, the disseminated fungi were immunohistochemically identified as being of the *Trichosporon* species.

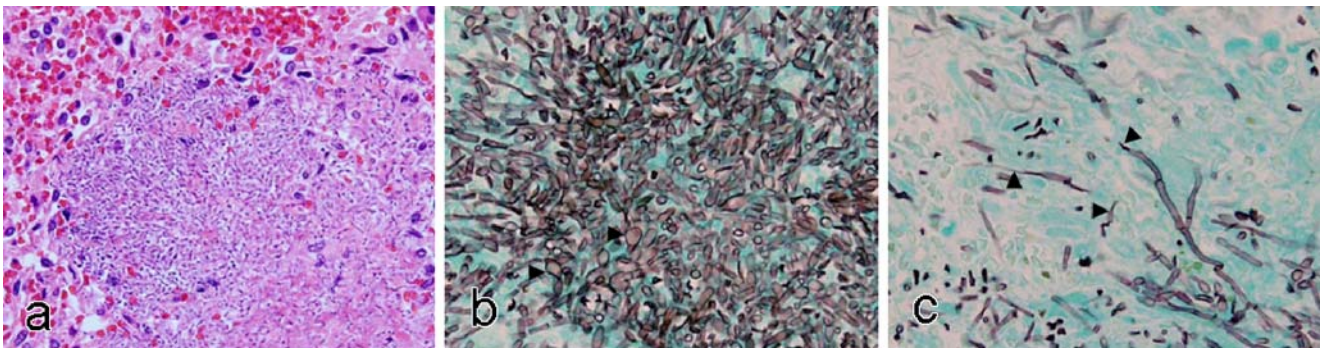

Fig. 1 Histopathological findings of disseminated trichosporonosis. Fungal colonies composed of numerous filamentous hyphae are observed (**a**, HE stain). High-power view under Grocott's stain showing the fungi have slightly large oval spores in the core of the colony (*arrowheads*, **b**) and slender hyphae in the periphery (*arrowheads*, **c**)

Table 3 Detection of *Trichosporon* using Grocott's staining and nested PCR

Samples	Grocott's stain, *n* (%)		Positive for nested PCR[a]		
			170 bp, *n* (%)	259 bp, *n* (%)	412 bp, *n* (%)
Total samples	Positive	22 (73)	20/22 (91)	12/22 (55)	0/22 (0)

[a] Of Grocott's stain-positive or -negative samples, nested PCR-positive samples are shown.

Discussion

Although disseminated trichosporonosis is a lethal mycosis, the causative *Trichosporon* species are often pathologically confused with other fungi. In this paper, we demonstrated that nested PCR analysis was useful for pathological diagnosis of disseminated trichosporonosis even in formalin-fixed and paraffin-embedded tissues. However, we should consider the possibility of false positive results due to contamination by superficial and resident *Trichosporon* species. In some reports, *Trichosporon* species are isolated from skin, sputum, urine, and stools [1, 2, 9, 18, 30], but it is difficult to identify the causative species of disseminated trichosporonosis from these materials. In our analysis, *Trichosporon* DNA was amplified in the urinary bladder and gastrointestinal tract, but we should refrain from pathological diagnosis of disseminated trichosporonosis based on the results of skin, urinary bladder, and gastrointestinal tract, in addition to the trachea and bronchi. Meanwhile, identification of *Trichosporon* species from blood culture and sequent biochemical analysis is routinely essential for clinical diagnosis of disseminated trichosporonosis. Sugita et al. [27] reported on the usefulness of nested PCR analysis from patients' sera. In autopsy cases, however, sera are probably unsuitable for nested PCR due to possible fungal translocation after the destruction of the

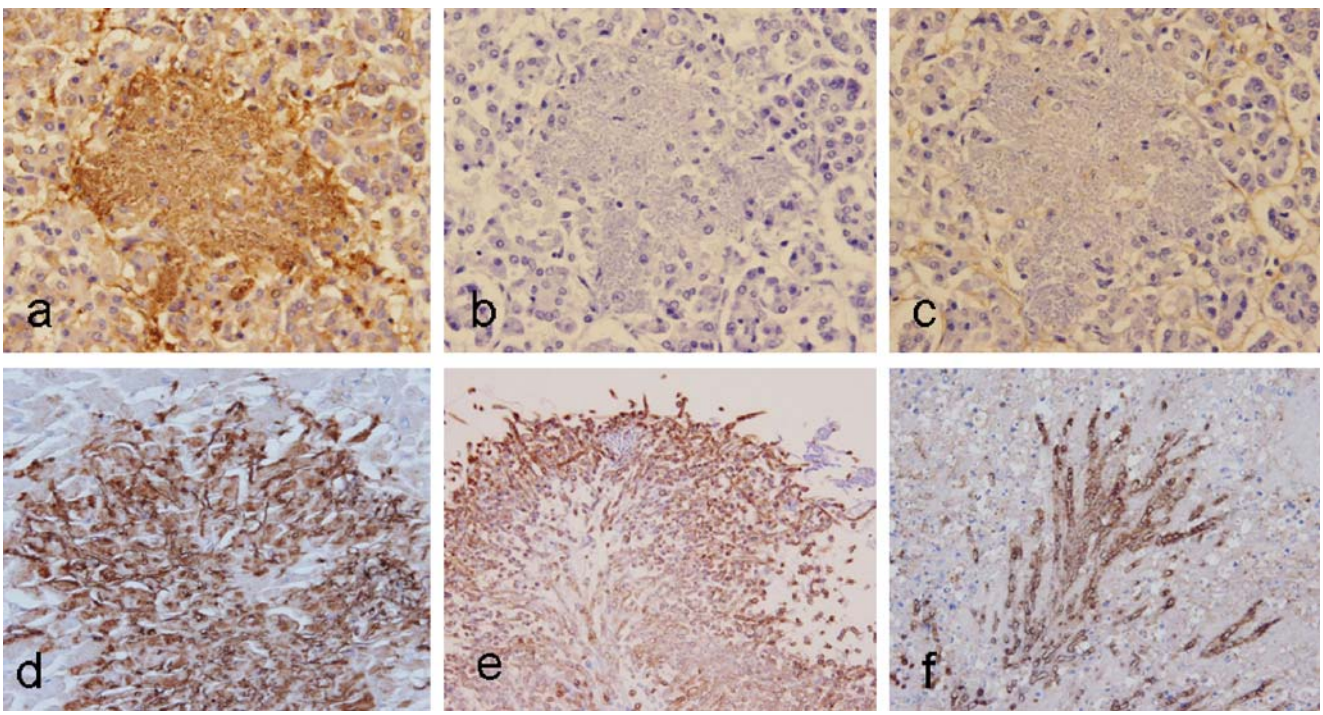

Fig. 3 Immunohistochemical confirmation of trichosporonosis. Fungi are positive for anti-*Trichosporon* antibody (**a**), but are negative for antibodies to *Candida* (**b**) and *Aspergillus* (**c**). Control specimens for *Trichosporon* (**d**), *Candida* (**e**), and *Aspergillus* (**f**) are detected with these antibodies

gut mucosal barrier after death. Thus, nested PCR should be performed on specimens from visceral organs with the exception of some materials as described above.

We should also pay attention to false negatives in nested PCR results that have been caused by DNA degradation. Generally speaking, DNA is known to be unstable for formalin and acidic solutions. In our investigation, the detection efficiency of nested PCR tended to decrease after long-term fixation in formalin and decalcification with a solution containing formic acid and hydrochloric acid. In addition, fungal hyphae were observed under Grocott's stain in the thyroid gland of case 3, but nested PCR revealed no reaction. HE staining showed disappearance of basophilic fungal structures with a massive abscess. It is possible that the fungal DNA degraded after administration of antifungal agents or long-term fixation. Therefore, appropriate sampling from short-term-fixed materials is significant for effective and accurate nested PCR analysis. In addition, the pathological diagnosis of disseminated trichosporonosis should be determined carefully with consideration of the results of nested PCR in combination with the histopathological findings under HE and Grocott's stains.

Disseminated trichosporonosis cases have recently been increasing and are associated with a poor prognosis [8, 12, 13, 17]. Although some reports suggest that an antifungal agent voriconazole is effective for *Trichosporon* compared to other fungi in vitro [6, 22] and in vivo [3, 4], *Trichosporon* is generally less susceptible to the usual antifungal agents such as amphotericin B or micafungin [17, 23, 31]. In addition, the possible air contamination of *Trichosporon* by removal of the catheter has been reported [24]. Thus, an accurate pathological diagnosis of disseminated trichosporonosis even in postmortem patients is significant as a warning sign to prevent hospital-acquired infection.

Trichosporon species have not been detected with nested PCR from formalin-fixed and paraffin-embedded tissues. Therefore, the methods in our present study would be helpful for the pathological diagnosis of trichosporonosis in both autopsy and biopsy materials such as the cutaneous white piedra or cystitis caused by *Trichosporon* infection, thereby leading to determination of antifungal agents.

Abstract Tubulo-interstitial fibrosis in dogs may result from primary injury to the interstitium or develop secondary to other renal diseases. As in human renal pathology, tubular epithelial cells (TEC) are believed to actively participate in the mechanisms of renal fibrosis. In this study, we examined the changes in the tubular epithelial component in two specific canine diseases. Immunohistochemistry showed the expression of the epithelial marker cytokeratin, the smooth muscle marker α-SMA, the mesenchymal marker vimentin and PCNA in 20 dogs with membranous glomerulonephritis and membrano-proliferative glomerulonephritis. Results showed that the loss of the epithelial marker in TEC was directly correlated to the grade of tubulo-interstitial disease present and independent of the type of glomerulonephritis. Varying degrees of vimentin positivity were detected in tubular epithelium in areas of inflammation, and low numbers of scattered α-SMA-positive cells were also observed. Immunohistochemistry showed that epithelial tubular cells lose their cytokeratin staining characteristics and transdifferentiate into cells exhibiting key mesenchymal immunophenotypic feature of vimentin-positive staining in both diseases investigated. The integrity of the tubular basement membrane is likely to be fundamental in maintaining the epithelial phenotype of TEC. Animal models provide opportunities for investigating the pathogenesis of renal fibrosis in humans.

Introduction

In dogs, membranous and membrano-proliferative glomerulonephritis are acknowledged to have a variety of aetiologies. Protozoal, bacterial and viral infections are the best-described causes, whilst yet other cases are considered idiopathic. As the glomerular lesions progress, the tubulo-interstitial (TI) compartment becomes involved, and TI damage (TID) is a common outcome of all chronic progressive renal diseases regardless of aetiology or site of primary injury [12, 14]. Histologically, these end stage lesions are characterized by interstitial fibrosis with inflammatory cell infiltrates and loss of peritubular capillaries, whilst tubules undergo concurrent degenerative, atrophic and regenerative changes [4]. Decline in renal function (reduced glomerular filtration rate) in chronic renal disease appears to be correlated more closely with

interstitial lesions than with glomerular damage [8, 15]. Interstitial fibrosis is linked to a pathological imbalance between extra-cellular matrix deposition and degradation, which is stimulated by a variety of cytokines and growth factors [13]. The fibrogenic response and the inflammatory infiltrates progressively reduce the number of functional nephrons leading to renal failure [9].

Previous studies carried out on kidneys from humans, rats and cattle have shown that, during renal injury, tubular epithelial cells (TEC) are able to acquire features typical of mesenchymal cells [16, 20, 22]. This process has been named epithelial–mesenchymal transition (EMT). EMT has been demonstrated in lung fibrosis as well as in some type of tumours, and it is considered a physiologic process in embryogenesis [21]. Renal tubular EMT, by definition, is a process in which tubular cells lose their epithelial phenotype and acquire characteristic features of mesenchyme [7] such as the expression of vimentin, the characteristic cytoskeleton protein of mesenchymal cells. Proteinuria and chronic hypoxia both appear to play significant roles in EMT, and several authors have suggested the importance of reduced local oxygen tension, resulting from peritubular capillary destruction, in development of the process [5, 11].

This current study aims to use immunofluorescence and immunohistochemical techniques to detect and quantify phenotypic changes in TEC undergoing EMT during the course of two specific canine glomerular renal diseases.

Materials and methods

Tissue samples

Twenty cases exhibiting renal lesions of one of two specific glomerular diseases were selected from archives of the Department of Animal Pathology (University of Turin) from a period spanning 4 years (2003–2007). The glomerular diseases chosen were membranous glomerulonephritis and membrano-proliferative glomerulonephritis as defined in the WHO classification of glomerular diseases. Kidney tissue samples were obtained by renal biopsy (Trucut method) in routine diagnostic cases (eight biopsies), whilst the remaining tissue was collected from dogs subjected to post-mortem examination (12 dogs). Controls were five young dogs (age range 2–6 years). These dogs were strays from dog shelters that were euthanised for aggressive behaviour. No significant lesions in systemic organs were found. Renal clinical examinations were normal. Signalment and clinical data from the dogs considered in the study are shown in Table 1.

[a] Autopsy
[b] Biopsy

Histology

Renal samples for histological examination were fixed in 10% buffered formalin and embedded in paraffin. Sections were cut at 4 μm in thickness and stained with: haematoxylin–eosin, periodic acid-Schiff (PAS), acid–fuchsin orange G, Masson's trichrome and phosphotungstic acid haematoxylin.

To quantify the interstitial changes in the two forms of glomerulonephritis, the severity of TID was graded. Interstitial fibrosis and inflammation were assessed at ×200 magnification and scored as follows: normal tubulointerstitium (score=0), mild tubular atrophy and interstitial oedema or fibrosis affecting up to 25% of the field of view (score=1), moderate TI fibrosis affecting 25–50% of a given field (score=2), severe TI fibrosis >50% of a field

(score=3). Score data are shown in Table 1. The samples were scored by a veterinary pathologist and a human renal pathologist in a blinded fashion.

Immunofluorescence

For immunofluorescence staining, unfixed renal tissue was OCT-embedded, snap-frozen in liquid nitrogen and stored at −80°C. Six-micrometer-thick sections were fixed with acetone for 15 min. After washing with PBS (two passages), slides were incubated with fluorescein isothiocyanate-labelled anti-goat IgA, IgG, IgM and complement C3 antibodies specific for the dog (Bethyl Laboratories, Montgomery, AL, USA). Primary antibodies were omitted as negative controls.

Immunohistochemistry

Immunoperoxidase staining was performed on renal sections of formalin-fixed, paraffin-embedded renal samples. An immunohistochemical panel was performed to assess changes to the epithelial tubular cells. Antibody against cytokeratin (CK) AE1/AE3 (Dako, Glostrup, Denmark) was used to detect cells expressing an epithelial phenotype. Mesenchymal markers were stained with antibodies against vimentin (Dako) and α-smooth muscle actin (α-SMA, Dako). Proliferation cell nuclear antigen (PCNA; Clone PC10, Dako) was used as index of cellular proliferation.

Double immunohistochemical staining

On selected representative cases, CK AE1/AE3 and vimentin double antigen-immunoperoxidase labelling was performed using a commercial kit (Vector Laboratories, Burlingame, CA, USA), according to manufacturer's instructions. Peroxidase activity was demonstrated firstly by DAB+Ni^{2+} (grey to black chromogen reaction) for Vimentin and secondly by 3-amino-9-ethylcarbazole (AEC, red chromogen reaction) for CK AE1/AE3.

Quantification of immunohistochemistry and statistical analysis

Quantification of results in each case was achieved by counting the numbers of TEC per ten high power fields (HPFs, ×200) that expressed cytoplasmic staining for the mesenchymal marker. Loss of cytoplasmic staining for the epithelial marker CK was evaluated by counting the number of negative-stained cells per HPFs. Data were analysed using Minitab 14, and results were expressed as means, standard deviations and the numbers of TEC for each fields. To demonstrate that CK and vimentin expression were statistically correlated to the TID grade, a number of paired comparisons were performed.

Results

Tubular-interstitial damage was a common finding in membranous and membrano-proliferative glomerulonephritis (Fig. 1d). All three different grades of TID were present amongst the samples examined. The quantitative analysis data corresponding to the grade of TID are summarized in Table 1. Renal samples, independent of the diagnosis, showed variable intensity of positive immunostaining in the TEC for all markers.

A diffuse and statistically significant increase (p=0.001) in the number of PCNA-positive cells was noted in nuclei of tubules within foci of nephritis (3.5±1.5 TEC/field in TID grade 3; Fig. 1c).

In control kidneys, TEC exhibited strong and uniform cytoplasmic expression of the epithelial marker CK (98.7±1.3 TEC/field in controls; Fig. 1a). In contrast, expression of CK was reduced in tubules associated with mild or severe interstitial fibrosis and completely lost in atrophic regions (54.5±4.8 TEC/field in TID grade 3; Fig. 1b).

The mesenchymal markers (vimentin and α-SMA) showed no staining in TEC from control kidneys. However, expression of vimentin was demonstrated in TEC of degenerate, atrophic tubules and tubules within areas of inflammation (39.5±13.9 TEC/field in TID grade 3; Fig. 2a,d). Some α-SMA-positive myofibroblasts were found in contact with intact tubules both in areas with no interstitial inflammation and in areas of severe TID (0.5± 0.1 TEC/field in TID grade 3). In fibrotic regions, within areas of inflammation, there was occasional positive staining of α-SMA in cells considered to be peritubular myofibroblasts. Both the size and the number of capillaries, next to the zone of cortical interstitial fibrosis and tubular atrophy, were subjectively reduced. Vimentin-PAS immunohistochemical staining showed thickening of the tubular basement membrane (TBM) with occasional multifocal membrane rupture. A high percentage of the tubules with vimentin positivity exhibited preservation of TBM integrity (Fig. 2c).

Statistical results

A linear regression model was generated using the TID grade as predictors and CK and vimentin as dependent variables (Fig. 3). The Pearson correlation coefficient confirmed the existence of a linear relationship. The two

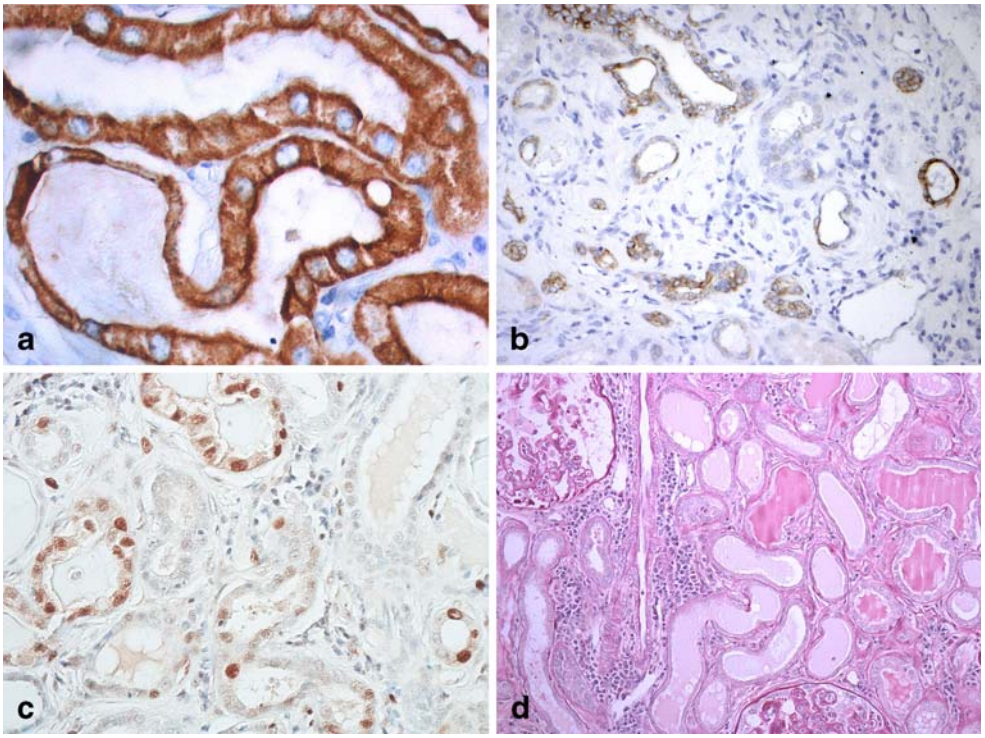

Fig. 1 **a** Normal CK expression in the cytoplasm of TEC in control kidney (×500). **b** Loss of CK expression in most of tubular cross sections inside the inflammation, TID grade 2 (×200). **c** Positive expression of scattered nuclei in epithelial tubular cells inside the inflammation, TID grade 2 (×300). **d** Area of interstitial nephritis, characterized by inflammatory cells (lymphocytes and plasma cells), tubular atrophy and minimum extent of fibrosis, TID grade 3 (PAS, ×200)

lines, with the confidence band at the level 95%, exhibited the behaviour between the indices: as the TID grade increases, the proportion of CK-positive TEC reduces (in fact, the slope is significantly negative); as the TID grade increases, the proportion of vimentin-positive TEC increases (the slope is significantly positive).

Discussion

The present results suggest that TEC are able to lose the typical cytoskeletal intermediate filament of epithelial cells (CK) and transdifferentiate into cells exhibiting the typical cytoskeletal intermediate filament of mesenchymal cells

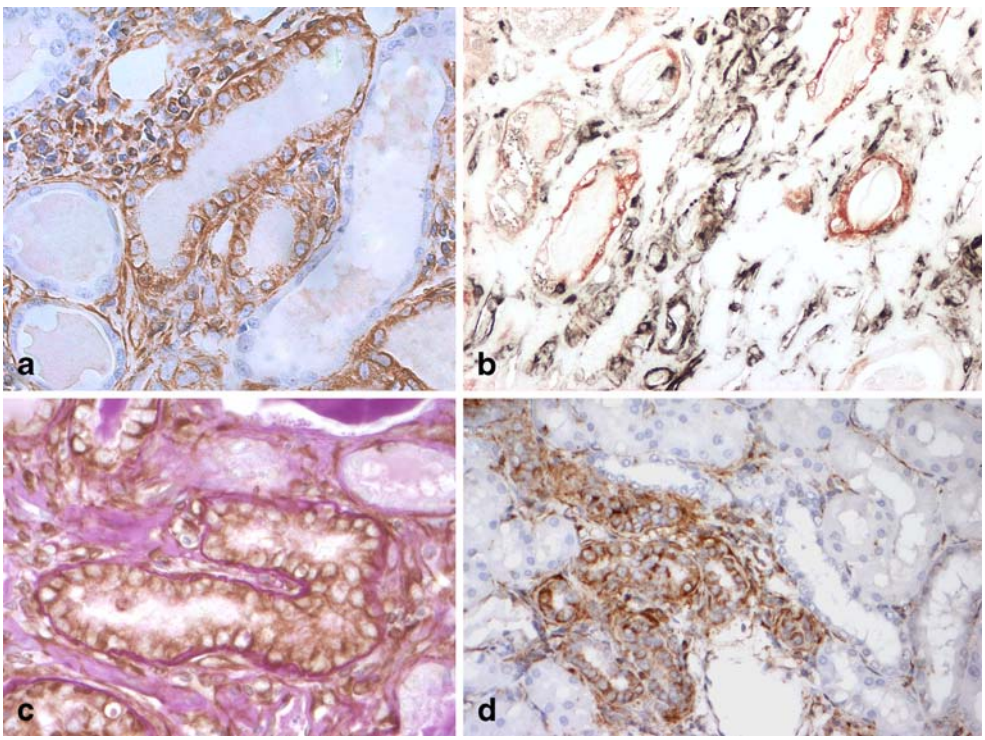

Fig. 2 **a** Diffuse expression of vimentin marker in TEC inside the inflammation, TID grade 2 (×400). **b** Atrophic-degenerating TEC in area of severe TID predominantly express vimentin (black chromogen reaction) and only in few tubules co-localization with CK (red chromogen reaction) is still present (×200). **c** Vimentin expression in tubules associated with thickening of PAS-positive TBM, TID grade 2 (×500). **d** Positive vimentin expression in TEC inside the area of inflammation and negative vimentin expression in tubules not involved, TID grade 1 (×200)

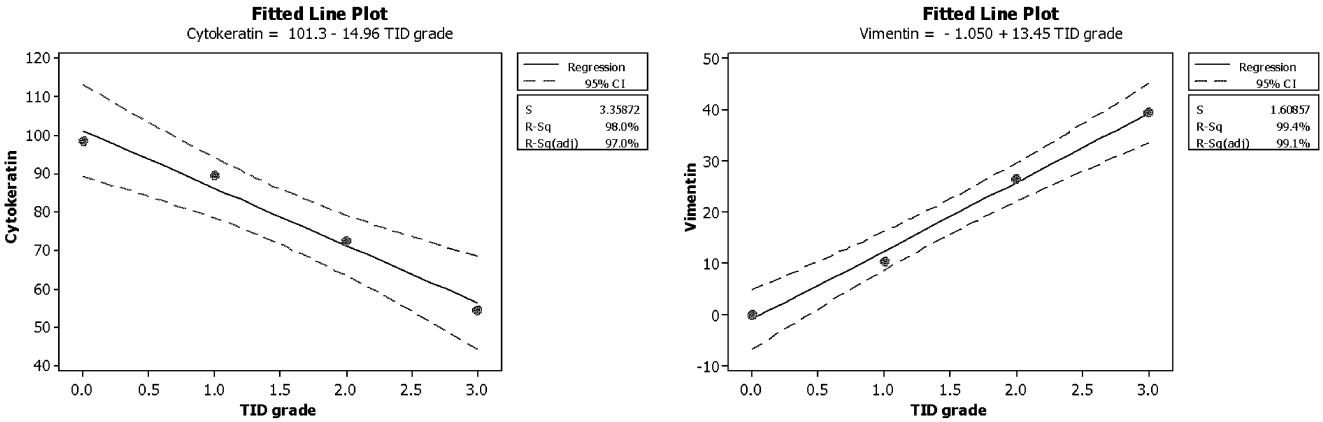

Fig. 3 Linear relationship between TID grade and CK loss (*left*) and vimentin expression (*right*)

(vimentin). This change in the cytoskeletal components named EMT was observed in both the canine renal conditions considered in this study. The process of cell shifting between epithelial and mesenchymal phenotype has long been known to play an important role in cellular transdifferentiation during organ fibrosis and tumour progression in human pathology [21] as well as in cases of interstitial nephritis in animals [16]. During TID, TEC are probably capable of these radical changes in cytoskeletal phenotype expression because of their embryonic metanephrogenic mesenchymal origin [13].

Studies carried out in human renal pathology and in experimental models in laboratory animals have confirmed that TEC actively participate in the mechanisms of injury within the interstitial compartment. These modifications act at different steps including proliferation and phenotypic changes, to eventually lead to synthesis of extracellular matrix. Furthermore, in humans as well as in dogs, the expression of class II major histocompatibility complex molecules in TEC in interstitial nephritis has been demonstrated, drawing attention to the possible role of TEC in the development of TI disease [19]. The present work focuses on the modification of TEC in the two most common canine renal diseases, membranous glomerulonephritis and membrano-proliferative glomerulonephritis. The association between the thickening of the TBM (depicted by the PAS staining) and vimentin expression by TEC suggests that direct interactions between the TEC and the extracellular matrix of the interstitium could be important in the induction of the transdifferentiation process. Other researchers have hypothesised that the critical features of EMT are the ability of epithelial cells to lose polarity, to disassemble cell adhesion systems and their strict relation with the basement membrane [1, 2, 17, 21]. The integrity of the TBM is thus likely to be fundamental in maintaining the epithelial phenotype of TECs [18].

In this study, we have described the first steps in the pathogenesis of renal fibrosis in two of the most common disease resulting in renal failure in dog. Renal tubular EMT is a phenotypic alteration that occurs after chronic injury and results in increased numbers of interstitial mesenchymal cells. As such, EMT may be involved in the initiation of renal scar formation. However, activation of resident interstitial fibroblasts would also be expected to occur after injury as part of normal wound healing by which the injured kidney attempts to repair and to recover [10]. The variable intensity of vimentin-positive staining in TEC suggests the existence of different steps in phenotype transition with the proportion of TECs undergoing transition related to the grade of TI inflammation (see Table 2). Double immunostaining demonstrated the co-expression of CK and vimentin markers within TEC in TID (Fig. 2b).

Table 2 Summary of immunohistochemical results

	Control		TID grade 1		TID grade 2		TID grade 3		*p* value
	Mean	SD	Mean	SD	Mean	SD	Mean	SD	
Cytokeratin	98.7	1.3	89.6	2.3	72.6	4.8	54.5	4.8	0.0012
Vimentin	0.0	0.0	10.5	3.2	26.5	8.3	39.5	13.9	0.0010
α-SMA	0.0	0.0	0.3	0.1	0.5	0.1	0.8	0.2	0.0084
PCNA	0.7	0.3	1.2	0.6	2.6	0.9	3.5	1.5	0.0010
Number of cases	5		7		10		3		

Results are reported as percentage of positive TEC.

Vimentin, the intermediate filament protein specific for mesenchymal cells [6], from our work appears to be the most suitable marker for the defining the process of EMT in the kidney. In our study, PCNA staining results showed an increase in the proliferation index of TEC within the TI compartment directly correlated with the severity of TID. This could be considered further evidence of the suggested multi-potential capacity of tubular cells in repairing damage [23]. EMT features were totally absent in the control kidneys, suggesting a link between TI inflammation and phenotypic transition of epithelial tubular cells. Histological studies of human kidneys and animal models have also shown that TI injury is associated with damage to renal arterioles and loss of peritubular capillaries [3, 5]. In our work, the mild increase in number of α-SMA-positive cells recorded in TID correlated with a minimal myofibroblasts proliferation. Glomerular inflammation and scarring have the potential to compromise blood flow in downstream peritubular capillaries and thereby result in ischemic injury to tubule cells. This mechanism may be intimately involved with EMT, with hypoxia activating fibroblasts and altering the extra-cellular matrix metabolism of resident renal cells. Within areas of fibrosis, small arteries may remain constricted causing anoxia and perpetuating the vicious cycle of TI disease, through further fibroblasts activation [11].

In summary, the crucial loss of the epithelial phenotype in EMT in dogs can be demonstrated by CK and vimentin co-expression in double immunostaining, whilst the process of EMT may contribute to the pathogenesis of fibrosis in the canine kidney. The importance of EMT in canine TI disease remains to be fully elucidated. The canine model can be used to define the evolution of the lesions, and sequential screening of the progression of the renal fibrosis at different times would be helpful in understanding the mechanism of transition.

Abstract FOLFOX-4 (*fol*inic acid/5-*f*luorouracil/*ox*aliplatin) chemotherapy is used to treat patients with colorectal liver metastases. We aimed to assess hepatic histopathological responses to neoadjuvant FOLFOX-4 chemotherapy in patients with colorectal liver metastases. We selected all patients (n=54) treated with FOLFOX-4 for colorectal liver metastases between June 2002 and June 2005. Only 25 underwent hepatectomy and formed the study group. Histological responses were assessed in the study group and a matched control group (n=25) that did not receive neoadjuvant chemotherapy. The median (IQR) body mass index in the study and control groups was 24 (22–26) and 24 (23–25) kg/m^2, respectively, (P = NS). Complete histological resolution of tumour occurred in six (24%) patients in the study group. Median residual tumour cellularity was less (35 vs 70%) and fibrosis greater (50 vs 5%) in patients in the study group when compared with controls (P<0.001). The liver surrounding the tumour was steatotic in 17 (68%) patients in the study group and five (20%) controls (P= 0.001). Hepatic sinusoidal dilatation was more pronounced in patients in the study group than in controls (P<0.001). The response to FOLFOX-4 was associated with tumour necrosis, fibrosis and inflammation. More than two thirds of patients undergoing hepatectomy after FOLFOX-4 had steatosis despite being non-obese.

Introduction

Oxaliplatin (trans-l-diaminocyclohexane oxalatoplatinum), is a platinum derivative with a high level of in vitro and in vivo activity against colorectal cancer cells [9]. Oxaliplatin-based chemotherapy alters the natural history of unresectable colorectal liver metastases by downstaging the disease, allowing operability and prolonging survival in some patients [1–3, 5, 11].

Hepatic sinusoidal abnormalities have been shown to be present in up to 78% of patients receiving oxaliplatin [12]. Changes range from sinusoidal dilatation to sinusoidal obstruction and perisinusoidal fibrosis leading to veno-occlusive disease of the liver. Patients with colorectal liver metastases treated with oxaliplatin or irinotecan-based

neoadjuvant chemotherapy can also develop what is termed chemotherapy associated steatohepatitis [7, 14]. It has also been shown that steatosis is associated with neoadjuvant irinotecan chemotherapy (20% of patients) and sinusoidal dilatation with neoadjuvant oxaliplatin chemotherapy (19% of patients) [13]. Patients who developed steatosis in this study had a significantly higher 90-day postoperative mortality compared with those who had liver resection without chemotherapy [13]. In contrast, two studies have shown no significant increase in risk of steatosis in patients receiving oxaliplatin-based chemotherapy compared to patients receiving no chemotherapy [4, 8].

The aim of this study was to evaluate the histological responses in patients undergoing hepatectomy for colorectal liver metastases after neoadjuvant chemotherapy exclusively with FOLFOX-4 (*fol*inic acid/5-*f*luorouracil/*ox*aliplatin) and to compare these responses with those in patients who did not receive neoadjuvant chemotherapy.

Materials and methods

Study design

The study was a retrospective comparative one set in a university teaching hospital.

Study groups

All patients who received neoadjuvant FOLFOX-4 chemotherapy for colorectal liver metastases between June 2002 and June 2005 were identified from a prospectively maintained oncology database. The study group comprised patients who underwent hepatectomy after treatment with FOLFOX-4. A control group of patients who underwent hepatectomy without neoadjuvant chemotherapy was selected from our Liver Unit database by matching for age, sex, Dukes' stage of the primary tumour and body mass index (BMI). While selecting controls, the investigators were blind to the operative outcome and histological findings.

Interventions

Study group The group was composed of patients undergoing neoadjuvant FOLFOX-4 chemotherapy and hepatectomy. On the first day of each cycle, patients received folinic acid (200 mg/m^2) and oxaliplatin (85 mg/m^2) as intravenous infusions over 2 h. They also received an intravenous injection of 5-fluorouracil (400 mg/m^2), followed by an intravenous infusion of 600 mg/m^2 over 22 h. The same doses of folinic acid and 5-fluorouracil were repeated on day 2. There was no treatment from days 3–14 and the next cycle was started on day 15. Hepatectomy was performed 5–7 weeks after the last cycle of chemotherapy.

Control group This group was composed of patients who did not receive neoadjuvant chemotherapy but underwent hepatectomy for colorectal metastases.

Assessment of response

Clinical case notes were reviewed along with computed tomography scans before and after chemotherapy. Histology was reviewed by one pathologist (AMZ) in all those who underwent hepatic resection, and histological responses were graded objectively.

Three sections of tumour and non-tumoural liver from one large block of the resected specimen were sampled to evaluate pathological changes. Tumour regression, fibrosis, vascular changes, inflammatory response and steatosis were recorded.

Tumour regression was graded according to the percentage area of fibrosis in the residual tumour (or tumour area in control group) into five grades according to the method proposed by Dworak et al. [6]: *Grade 0*: no regression, *Grade 1*: dominant tumor mass with obvious fibrosis and/or vasculopathy, *Grade 2*: dominantly fibrotic changes with few tumor cells or groups (easy to find), *Grade 3*: very few (difficult to find microscopically) tumor cells in fibrotic tissue with or without mucous substance, and *Grade 4*: no tumor cells, only fibrotic mass (total regression or response). The mitotic index was assessed by determining the mean of the number of mitotic figures in the tumour in 20 random high power fields (×40 magnification) per resected specimen.

The degree of inflammatory response was characterised into three main grades, *Grade 0*: no inflammatory response, *Grade 1*: mild or minimal response (characterised by the presence of small percentage of inflammatory cells - <10% in the field) and *Grade 2* moderate or marked response (characterised by the presence of ≥10% inflammatory cells in the surrounding area of the tumour).

Sinusoidal dilatation was graded according to the system described by Rubbia-Brandt et al. [12]: *Grade 0*: absent, *Grade 1*: mild (centrilobular involvement limited to one third of the lobular surface), *Grade 2*: moderate (centrilobular involvement extending to two thirds of the lobular surface) and *Grade 3*: severe (complete lobular involvement). Presence of pericellular/perisinusoidal fibrosis was also noted.

Steatosis was assessed in the peri-tumoural liver, and the presence of macrovesicular and microvesicular steatosis was noted [15]. The degree of steatosis in the liver not involved with tumour was classified into five grades: *Grade 0*: no

steatosis, *Grade 1*: characterised by the presence of steatosis in <10% of the parenchymal area, *Grade 2*: characterised by the presence of steatosis in ≥10% but <30% of the total parenchymal area, *Grade 3*: steatosis present in ≥30% but <60% of the parenchymal area and *Grade 4*: steatosis present in ≥60% of the parenchymal area.

Statistical analysis

The data were analysed with SPSS for Windows™ Release 14.0 software (SPSS, Chicago, USA). The Mann–Whitney *U* test was used to compare the percentage responses, and the χ^2 test was used for categorical data. Differences were considered significant at $p<0.05$.

Ethics

The Ethics Committee of Nottingham University Hospitals approved the study.

Results

Over the study period, 54 patients (Table 1) received a median (IQR) of six (four to eight) cycles of neoadjuvant FOLFOX-4 chemotherapy for colorectal liver metastases. Twenty-nine of the 54 patients (53.7%) did not undergo liver resection because of extrahepatic disease (13), locally advanced disease (2), poor response to chemotherapy (11) and medical reasons (3). The study group consisted of the 25 patients who underwent hepatectomy after FOLFOX-4. The control group was well matched for age, sex, BMI and Dukes' stage of the colonic primary with the study group (Table 1).

Operative morbidity and mortality

Operations performed in the study and control groups, respectively, were right hepatectomy ($n=13$ and 12), right trisectionectomy ($n=2$ and 2), left hepatectomy ($n=2$ and 3) and segmental resection ($n=8$ and 8). Eight patients in the study group developed postoperative complications, which included a bile leak (2), liver failure (2), sepsis (2), bilioma (1) and hepatic duct stricture (1). Four patients in the control group developed postoperative complications—wound infection (1), pulmonary embolism (1), atrial fibrillation (1) and pneumonia (1). There was no statistical difference in the type of operation and rate of complications in the two groups. There were no deaths within 30 days in either group, but one patient in the study group who underwent a left hepatectomy died of fulminant liver failure 3 months later.

Histological response

The histological responses in the resected liver (Figs. 1 and 2) are summarised in Table 2. The interface between the tumour and the surrounding normal liver showed a marked inflammatory response in the FOLFOX-4-treated group compared to control group (Table 2).

Sinusoidal dilatation was more pronounced in the study group than in controls (Table 2, Fig. 2). However, pericellular/perisinusoidal fibrosis was present in only three patients in the study group and two in the control group ($P=0.49$).

Steatosis in the tumour-free liver (Fig. 2) was more frequent and more pronounced in FOLFOX-4-treated patients than controls (Table 3). There was no relation between the development of steatosis and BMI (Table 3).

Table 1 Profile of the study and control groups

	Patients who received FOLFOX-4 ($n=54$)	Hepatectomy after FOLFOX-4: Study group ($n=25$)	Hepatectomy without neoadjuvant chemotherapy: Control group ($n=25$)
Median (IQR) age (years)	65 (61–72)	65 (61–72)	64 (60–70)
Sex ratio (M/F)	33:21	16:9	16:9
Dukes' stage of the primary (A/B/C)	3:2:49	3:0:22	2:4:19
Median (IQR) body mass index (kg/m^2)	25 (23–28)	24 (22–26)	24 (23–25)
Median (IQR) number of metastases	3 (2–4)	2 (1–2)	2 (1–2)
Median (IQR) diameter (cm) of largest metastasis	4.9 (2.7–7.0)	3.5 (2.5–6.5)	4.0 (2.8–7.0)

Differences between the groups were not statistically significant.

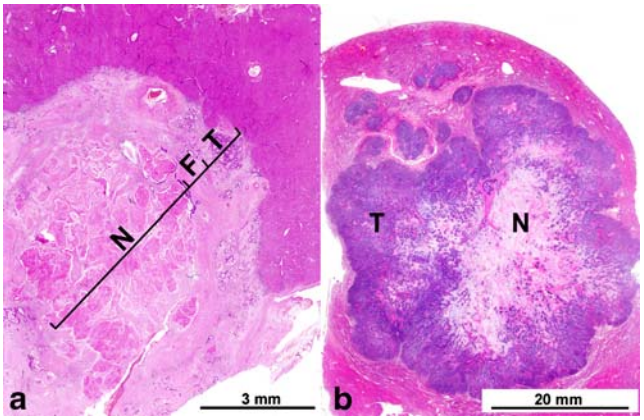

Fig. 1 **a** Haematoxylin & eosin-stained section of liver (×1) demonstrating a moderate response to chemotherapy with three zonal changes: central zone of necrosis (*N*), mid zone of fibrosis (*F*) and outer zone of residual tumour (*T*). **b** Haematoxylin & eosin stain (×1) of a tumour nodule from a patient who did not receive neoadjuvant chemotherapy showing two zones: central zone of necrosis (*N*) and outer zone of tumour (*T*)

Discussion

The present study has shown that the histological response to FOLFOX-4 is through a fibrotic process, replacing the tumour nodule. This desmoplastic reaction was negligible in the control group. There also was a marked inflammatory response within the tumour and in the interface between the tumour and surrounding liver parenchyma. Both the treated and the control groups had central tumour necrosis, but this was much more pronounced in the treated group. Histologically, three zones could be identified in a FOLFOX-4-treated liver nodule—a central zone of necrosis, an intermediate zone of fibrosis and a peripheral zone of inflammation.

The liver not involved with tumour showed steatotic change in 68% of patients treated with FOLFOX-4 compared to 20% of controls. None of these patients with steatosis had a history of alcohol dependence or diabetes mellitus nor were they on medications likely to cause steatosis, implicating FOLFOX-4 therapy as a potential causative agent of steatosis. This finding gains prominence in the context of the more extensive liver resections being carried out after neoadjuvant FOLFOX-4. However, the limiting factor in liver resections is an adequate functional liver volume to prevent postoperative liver failure. Chemotherapy-induced steatosis can potentially compromise function of the remnant liver.

A large series of 325 liver resections in patients with steatosis showed an increased rate of postoperative infective morbidity, but no effect on mortality when compared with 160 matched controls without steatosis [10]. However, these patients developed steatosis from varying aetiologies, with chemotherapy being just one of them [10]. Yedibela et al. [14] studied 64 patients who underwent hepatectomies for colorectal cancer metastases (neoadjuvant chemotherapy, 32; no chemotherapy, 32) and found that chemotherapy can induce a steatotic change in the non-tumour liver in 6% of treated patients compared to 1% of controls. However, the authors did not specify the chemotherapeutic agent used or grade the steatosis. The term "chemotherapy associated steatohepatitis" (CASH) was coined by Fernandez et al. [7] when they demonstrated a frequent occurrence of steatohepatitis in patients receiving oxaliplatin/irinotecan-based chemotherapy for colorectal liver metastases (n=14) compared to those receiving 5-fluorouracil (n=10) and controls (n=13) who did not receive chemotherapy. They also showed that a BMI >30 kg/m^2 was a risk factor [7]. Vauthey et al. [13] have recently demonstrated that steatosis occurred in irinotecan- rather than oxaliplatin-based regimens and was strongly linked to irinotecan-treated patients irrespective of BMI. However, oxaliplatin-treated patients in this study had a stronger association with sinusoidal dilatation than steatosis [13]. Despite the relatively large numbers of patients in the Vauthey study, the treated and control groups were not matched for comparing histology and clinical outcome [13]. Aloia et al. [4] studied a cohort of 92 patients, 75 of whom underwent hepatectomy after different chemotherapy regimes (5-FU + folinic acid or FOLFOX) and 17 after no chemotherapy. Although two thirds of patients in the chemotherapy group received oxaliplatin, they did show an increased rate of steatosis. In a similar study, Karoui et al. [8] demonstrated that although neoadjuvant chemotherapy was associated with sinusoidal dilatation, hepatocyte atrophy or necrosis, there was no significant difference in steatosis, inflammation and fibrosis in the normal liver in the chemotherapy-treated group compared to controls. However, both these studies [4, 8] had similar biases of the study group being treated with different chemotherapeutic regimes and the study and control groups not being matched. In contrast to these, our

	Grade 2: moderate (centrilobular involvement extending to two thirds of the lobular surface) [n (%)]	8 (32%)	0	
	Grade 3: severe (complete lobular involvement) [n (%)]	3 (12%)	0	

comparative study demonstrates a strong link between FOLFOX-4 therapy and steatosis in a series of patients uniformly treated with FOLFOX-4, compared with matched controls. Steatosis occurred more frequently and was more pronounced in FOLFOX-4-treated patients compared to those who did not receive chemotherapy. However, there was no correlation with BMI, suggesting that the development of steatosis may be independent of obesity. Two patients in our study had postoperative liver failure. Both these patients had ≥60% steatotic change in the hepatic parenchyma. Histological examination of other resected specimens clearly demonstrated that liver not involved with tumour was steatotic to varying degrees.

It may appear that steatosis induced by FOLFOX-4 may be a reasonable trade-off for down staging of metastases and operability. On the other hand, we cannot ignore the fact that significant steatosis was responsible for two cases of liver failure (one death) in our series. The risk of steatosis should be carefully assessed before planning a major hepatectomy after neoadjuvant chemotherapy with FOLFOX-4. Biopsy of the liver not involved with tumour may be of value in assessing this risk preoperatively, and

[b] Both patients developed postoperative liver failure and one died.

preoperative portal vein embolization may have to be considered in some patients who may have insufficient hepatic reserve after resection.

Sinusoidal dilatation complicated by perisinusoidal fibrosis has been documented after oxaliplatin-based chemotherapy [4, 8, 12]. It has been suggested that these changes may result in impairment of liver function and limit the regenerative capacity of the liver [12]. In contrast to this, we showed only hepatic sinusoidal dilatation without significant perisinusoidal fibrosis in the FOLFOX-4-treated group.

We conclude that FOLFOX-4 therapy is an independent risk factor for the development of hepatic steatosis. Further studies of the development, progression and resolution (if it occurs) of hepatic steatosis and its temporal relationship to the cycles of chemotherapy may help time post-chemotherapy liver resections prudently. The presence of steatosis and the degree of the steatotic change may be critical in assessing the risk of postoperative liver failure. As steatotic livers are more prone to ischaemia-reperfusion injury, avoidance of hypoxia during surgery is advisable.

Conflict of interest None of the authors has a conflict of interest to declare.

Abstract Primary and metastatic so-called malignant fibrous histiocytoma/undifferentiated high-grade pleomorphic sarcoma (MFH) is rare in the gastrointestinal (GI) tract with ≈50 primary and five metastatic cases reported so far. We evaluated two primary gastric and three metastatic intestinal high-grade pleomorphic sarcomas with features of storiform-pleomorphic MFH. Gastric tumours occurred in a 79-year-old man and a 68-year-old woman. One patient died post-operatively, and the other was disease-free at 6 months. Three patients presented with GI metastasis 24, 60 and 0 months after diagnosis of MFH of the heart (n=1) and the thigh (n=2). Metastases were located in the small (n=1) and large bowel (n=2) and were characteristically pedunculated and polypoid with oedematous haemorrhagic stroma. Concurrent metastases (brain, lung, bone) were present in all three cases. Tumours expressed α-smooth muscle actin (four of five), platelet-derived growth factor receptor (PDGFR) α (three of three) and PDGFRβ (two of three) but were negative for CD117, CD34 and other lineage-specific markers. Ultrastructural examination revealed myo/fibroblastic features. Both gastric MFH were wild type for *KIT* and *PDGFRα*. In conclusion, primary and metastatic MFH of the GI tract commonly express PDGFRα and show a myo/fibroblastic phenotype. They should be distinguished from a variety of primary and metastatic pleomorphic neoplasms, in particular high-grade sarcomatous GI stromal tumours (GIST), pleomorphic leiomyosarcoma, sarcomatoid carcinoma and other mimics.

Introduction

Once the most commonly diagnosed soft tissue sarcoma (STS) in adults [43], the existence of 'malignant fibrous histiocytoma' (MFH) as a diagnostic entity has been questioned in the recent years [15, 16]. This dramatic shift in the diagnosis and classification of STS was the result of recent studies showing that the majority of pleomorphic STS formerly called 'MFH' could be classified into one of the well-characterized sarcoma types, if ancillary diagnostic tools are applied [15, 16, 18, 24, 29]. More importantly, the clinical relevance of this sub-classification could be confirmed in several studies [16, 24]. Adult high-grade pleomorphic sarcomas with myogenic differentiation (leiomyosarcoma, rhabdomyosarcoma and myofibrosarcoma) are characterized by a poor outcome compared to other pleomorphic sarcoma types [16, 24]. However, no significant difference in the prognosis was observed among the various sub-types of adult pleomorphic myogenic sarcomas [16, 24]. The term 'undifferentiated high-grade pleomorphic sarcoma/MFH' has been

adopted by the latest World Health Organization (WHO) classification of soft tissue tumours for pleomorphic STS showing no specific line of differentiation [17]. MFH most commonly involves the deep soft tissue of the extremities (mainly the thigh) with a predilection for men [17, 43]. Metastases occur predominantly in the lung (82%), lymph nodes (32%), liver and bone (15% each) and other rare sites [43].

Primary and metastatic MFH is rare in the gastrointestinal (GI) tract with ≈50 primary [33, 41, 42, 44] and five metastatic cases reported from different parts of the GI tract, usually as single case reports [1, 6, 9, 22, 33, 39–42, 44]. In this study, we describe and compare the clinicopathological and immunohistochemical features of two primary gastric MFH and three metastatic MFH involving the small and large bowel and discuss their broad differential diagnosis with a reference to myofibroblastic differentiation.

Materials and methods

Cases were retrieved from routine surgical pathology files of the Nuremberg Medical Center (a large community-based hospital). One case has been reported previously [2]. At least ten paraffin blocks were available in cases with large neoplasms. Immunohistochemical stains were performed by the avidin–biotin-peroxidase complex method on fresh-cut sections using a Dako Envision+ autostainer and an Envision+ kit (K5007, Dako, Lot 29661). The following antibodies were applied: vimentin (Vim 3B4, 1:50, Linaris, Wertheim-Bettingen, Germany), α-smooth muscle actin (α-SMA; 1A4, 1:200, Dako), desmin (D33, 1:250, Dako), *h*-caldesmon (h-CD, 1:75, Dako), S-100 (polyclonal, 1:2,500, Dako), CD117 (anti-Human c-kit proto-oncogene product, polyclonal antibody, 1:200, Dako), CD34 (BI-3C5, 1:200, Zytomed), fibronectin (polyclonal antibody, 1:2,000, Dako), HMB45 (1:50, Dako), pan-keratin (KL-1, 1:300, Immunotech), Ki-67 (MiB-1, 1:150, Dako), myogenin (F5D, 1:50, Dako), platelet-derived growth factor receptor (PDGFR) α (polyclonal, 1:50, New England Biolabs) and PDGFRβ (Clone 28E1, 1:100, New England Biolabs). In brief, tissue sections were mounted on poly-L-lysine-coated slides, incubated at 37°C for 30 min, deparaffinized and washed, followed by microwave antigen retrieval in target buffer (pH 6.0, Dako, no. S1699; Lot 6859) for CD117, α-SMA, desmin, CD34, S100 and Ki-67. Alternatively, for PDGFRα and PDGFRβ slides were incubated in a pressure cooker at 120°C, and primary antibodies were incubated overnight at 4°C. Endogenous peroxidase was blocked by applying a peroxidase-blocking solution (Dako, S2023, Lot 29772) for 8 min at room temperature. Appropriate positive and negative controls were used in each case. At least three paraffin blocks per case were evaluated for CD117, CD34, desmin, α-SMA and *h*-caldesmon.

Mutation analysis of *KIT* and *PDGFRA*

Genomic tumour DNA from both gastric neoplasms was extracted from formalin-fixed paraffin-embedded tissue by microdissection and investigated for presence of *KIT* exons 9, 11 and 13 and *PDGFRα* exons 12 and 18 mutations using polymerase chain reaction amplification and direct sequencing as previously described [4, 20].

Ultrastructural studies

Only formalin-fixed paraffin embedded tissue was available. Tissue samples of 2 mm^2 were punched out from tumour blocks in cases 1, 2 and 3, deparaffinized and processed for electron microscopy as previously described [5].

Results

The five cases represented 2% of all primary and metastatic mesenchymal GI neoplasms in our routine case material and 24% of 21 non-GIST sarcomas primary or metastatic to the GI tract exclusive of retroperitoneal liposarcoma and other intra-abdominal sarcomas secondarily involving the GI tract.

Clinical features

Primary tumours

These were found in a 79-year-old man and a 68-year-old woman. Tumours arose in the gastric fundus and greater curvature. Clinical symptoms were non-specific. Endoscopic biopsy was performed in case 1 and was consistent with MFH. Treatment was total gastrectomy and two-thirds-gastrectomy (Billroth II), respectively. The first patient died 2 weeks post-operatively of pulmonary embolism, but autopsy was not performed. The other was alive and well at 6 months (Table 1).

Metastatic tumours

Patient ages at time of diagnosis of GI metastasis were 30, 54 and 61 years. All patients presented with abdominal pain and/or signs of GI bleeding. Time to GI metastasis was 24, 60 and 0 months from initial diagnosis of the primary sarcoma. Involved GI sites were the small bowel, left colon and rectum (one each). The site of primary sarcoma was the heart (left atrium; $n=1$) and the proximal thigh ($n=2$). Two patients received curative surgery for their primary sarcoma

Table 1 Clinicopathologic features of primary and metastatic MFH in the GI tract (n=5)

Number	Age/sex	Site	Symptoms	Size	Gross features	Other metastasis outcome
Primary MFH						
1	79/M	Stomach fundus	Non-specific, large ulcer	8×7.5×5 cm	Polypoid ulcerated and intramural, whitish	Died 2 weeks post-operatively of pulmonary embolism, no concurrent MTS
2	68/F	Stomach greater curvature	Weight loss, Abdominal mass	12×9×6 cm	Extramural, gastric wall infiltrated, cystic areas, fleshy whitish-yellow	No MTS, NED at 6 months
Metastatic MFH						
3	30/M	Small bowel	Abdominal pain, lower GI bleeding	4 cm	4 cm pedunculated polyp, 1.4 cm intramural nodule	Cerebral MTS 12 months before GI manifestation GI metastasis 24 months from diagnosis of left atrial MFH
4	54/F	Descending colon	Non-specific, +ve haemoccult	3.5 cm	3.5 cm pedunculated polyp	Multiple lung MTS concurrent with GI MTS 60 months from diagnosis of thigh MFH
5	61/M	Rectum, probably Rt. Flexure, cecum	non-specific	3 mm	3 mm polyp, small shallow ulcers in Rt flexure +cecum	thigh MFH with concurrent femur, pleuropulmonary cerebral and GI MTS DOD at 5 weeks

MTS Metastasis, *NED* no evidence of disease, *DOD* died of disease

with no evidence of local recurrence at the time of GI metastasis. The patient with left atrial MFH received, in addition, percutaneous radiotherapy. The third patient had an inoperable 20×14-cm deeply seated intramuscular soft tissue mass in the proximal right thigh with pathological fracture of the femur. Diagnosis was achieved by core biopsy. Synchronous rectocoloscopy revealed multiple shallow ulcers and polypoid lesions measuring up to 5 mm in the cecum, right flexure and the distal rectum. He died of respiratory failure because of extensive pleuropulmonary metastases 5 weeks from initial diagnosis. Multiple further organ metastases were diagnosed before or concurrent to GI metastases in all patients (cerebral metastases in case 3, pulmonary metastases in case 4, pleuropulmonary, cerebral and osseous metastases in case 5; Table 1).

Pathological findings

Primary tumours

Representative gross and histological features are depicted in Fig. 1. Tumours measured 12 and 8 cm in maximum diameter and revealed a fish-flesh-like to grey-whitish focally whorled cut surface (Fig. 1a,b). The deep margins were irregularly infiltrating into the subserosal tissue. Histologically, both tumours consisted of large highly pleomorphic plump spindled to epithelioid cells arranged in intersecting sheets with an occasional storiform pattern (Fig. 1c). In some areas, the tumour cells were reminiscent of myofibroblasts with stellate and wavy nuclei and copious pale eosinophilic to amphophilic cytoplasm that gradually merged with the surrounding stroma (Fig. 1d). Osteoclast-like giant cells were prominent in case 2 (Fig. 1e) and were typically associated with stromal haemorrhage. Mitoses ranged from 17 to 50 in ten high-power fields (average, 31). Scattered entrapped adipocytes were seen near the exterior border of the tumour in case 2 (Fig. 1f). Immunohistochemistry (Table 2) showed a strong reactivity for vimentin in both lesions. α-SMA was expressed in 80 and 20% of tumour cells, respectively (Fig. 1g). Osteoclast-like giant cells were strongly reactive for CD68-KP1 (Fig. 1h). Both cases stained with PDGFRα with a moderate to strong cytoplasmic and membranous staining in ≥70% of the cells (Fig. 1i). In addition, case 1 stained weakly for PDGFRβ. Tumours were consistently negative for CD117, CD34, *h*-caldesmon, protein S100, pan-keratin, HMB45, desmin, myogenin and ALK-1. Case 1 revealed a weak reactivity in scattered cells for MDM2.

Metastatic tumours

The surgical specimen from cases 3 and 4 harboured 4- and 3.5-cm pedunculated polyps with a dark red soft cut surface (Fig. 2a,b). In addition, a 1.4-cm intramural nodule was submitted from case 3 separately. In case 5, minute

endoscopic biopsies from colorectal lesions were submitted. Histological examination showed essentially similar microscopic features with a higher nuclear pleomorphism and a remarkably oedematous and haemorrhagic angiomyxoid stroma (Fig. 2c). Ulceration was more extensive, and no more than minimal involvement of the inner muscularis propria was seen, except for the smaller intramural nodule in case 3. The latter showed focal epithelioid areas with cytoplasmic vacuoles reminiscent of epithelioid GIST (Fig. 2d) but was predominantly highly pleomorphic in other areas. The rectal biopsy from case 5 revealed metastatic sarcoma, but colonic biopsies were negative for tumour. Immunohistochemistry revealed a similar profile as for cases 1 and 2 with a strong expression of α-SMA in cases 3 and 4 (Fig. 2e). Case 3 stained strongly with PDGFRα (Fig. 2f). All other markers were negative. Primary MFH from the thigh and left atrium were all of the storiform-pleomorphic type.

Molecular findings

Both primary gastric tumours (cases 1 and 2) were examined and were wild type for *KIT* exons 9, 11 and 13 and *PDGFRα* exons 12 and 18.

Ultrastructural features

Tissue preservation was generally poor. Tumour cells (cases 1, 2 and 3) revealed features of fibroblastic/myofibroblastic differentiation with spindle to plump vesicular indented nuclei and abundant dilated rough endoplasmic reticulum (Fig. 3). Peripherally located microfilaments with focal

densities and rare cell-to-matrix connections were present in case 2 (Fig. 4) (Table 3).

Discussion

This represents the first study combining primary and metastatic MFH of the GI tract from a single institution. Previously, reported primary MFH of the GI tract involved the small and large bowel more frequently and only rarely the stomach [22, 33, 41, 42, 44]. As the majority of them have preceded the era of sub-classifying pleomorphic STS, it is likely that a considerable fraction of previous reports might have represented pleomorphic variants of other specific sarcoma types. The clinical features and the biological course of primary GI MFH are comparable to their soft tissue counterparts [33, 41, 42]. Symptoms were generally non-specific, but signs of GI bleeding are common. Rare cases presented initially with pulmonary

metastases [44] and intussusception [22]. In a previous review [41], 24% of patients with a mean follow-up of 15 months died of disease 2–48 months post-operatively (mean, 15). Metastases/local recurrence developed in 35% of cases.

Intra-abdominal metastasis from non-visceral STS is rare and affected only 0.9% of STS patients in one large study [7]. Myxoid liposarcoma was the most frequent histological type, and only 2 of 19 were MFH [7]. GI metastasis from STS usually presents months to years after diagnosis but may be present initially as in the current study. In our cases, GI metastasis occurred with almost equal frequency as primary GI MFH. This contrasts with previous reports (≈50 primary vs 5 metastatic MFH), possibly suggesting under-recognition of GI metastasis from MFH or over-diagnosis of primary GI MFH. It is of interest that one of our cases (case 3) was initially diagnosed as a GI primary because of lacking clinical information. On preparing this study, we discovered that this patient had a storiform-pleomorphic MFH of the left atrium treated by surgery and radiotherapy 2 years ago with subsequent cerebral metastasis. Distinguishing primary and metastatic MFH in the GI tract is mandatory for appropriate patient treatment. An occult or previously resected STS should be excluded by appropriate clinical and imaging procedures before rendering a diagnosis of primary MFH in the GI tract. However, subtle differences exist between primary and metastatic GI MFH. A predominantly polypoid pattern combined with a remarkable stromal oedema and haemorrhage argue for metastatic disease, as does multi-focal occurrence. Primary polypoid GI sarcomas limited to the mucosa/submucosa are exceedingly rare with only three unequivocal examples reported previously [3, 36, 46], where two of them were multi-focal [3, 46].

The differential diagnosis of MFH/undifferentiated high-grade pleomorphic sarcoma encompasses a wide range of pleomorphic neoplasms and is a matter of exclusion [17]. Pleomorphic leiomyosarcomas reveal, at least focally, typical areas that permit diagnosis. Their cells show a brightly eosinophilic cytoplasm and blunt-ended nuclei by light microscopy with a common expression of desmin and *h*-caldesmon [30, 32]. Ultrastructurally, they possess diffusely distributed cytoplasmic myofilaments and a well-developed external lamina [11, 18]. A sub-set of MFH expressing smooth muscle markers represented unusual variants of leiomyosarcoma and could be re-classified as such using ancillary methods [15, 16, 19, 29, 32]. It is interesting to note that a subset of MFH revealed similar cytogenetic features as leiomyosarcoma suggesting a common pathogenetic pathway [38].

'Myofibrosarcomas' show histological and ultrastructural features intermediate between fibrosarcoma and leiomyosarcoma. They are characterized by a pale eosinophilic to amphophilic cytoplasm, fusiform-tapered indented or plump nuclei, prominent dilated rough endoplasmic reticulum, modestly developed peripherally located myofilaments with focal densities, sub-plasmalemmal attachment plaques and specialized cell-to-matrix connecting structures (fibronexus junctions or microtendons) [11, 12, 18, 31]. The latter was considered by some authors essential for

myofibroblastic differentiation [11, 12]. However, based on the degree of differentiation in individual cases, these features may be less well developed and focal. The strong and peripherally accentuated expression of α-SMA in some of our cases (in particular in case 2) together with the cytomorphological and ultrastructural features and the lack of *h*-caldesmon all argue for a myofibroblastic phenotype. Admittedly, ultrastructural evaluation on formalin-fixed paraffin embedded tumour tissue was largely limited by poor tissue preservation. Thus, a diagnosis of 'pleomorphic myofibrosarcoma' could not be definitively confirmed. Ultrastructural myofibroblastic differentiation in MFH has been documented in several studies but carried no prognostic significance [31]. Although the occurrence of low-grade myofibroblastic sarcoma was recognized by the current WHO classification of soft tissue tumours [28], the concept of 'pleomorphic myofibrosarcoma' is not generally accepted. The nature and significance of the myofibroblast-like phenotype seen in MFH and other pleomorphic neoplasms (specific line of differentiation vs a common final pathway for undifferentiation) is still controversial [13, 31]. Likewise, cutoffs for minimal criteria for diagnosing 'pleomorphic myofibrosarcoma' and the potential clinical relevance of such a diagnosis remain to be defined.

Dedifferentiated liposarcoma (DDL) follows a more favourable clinical course and should be separated from MFH [25]. Intra-abdominal DDL is typically a retroperitoneal neoplasm with a well-differentiated lipogenic component or a history of atypical lipomatous tumour. However, rare cases may present initially as DDL, and a minor lipogenic component may be missed on sectioning. A majority of retroperitoneal MFH represented DDL in a recent retrospective study [10]. Nuclear staining for MDM2 and CKD4 is sensitive in detecting DDL, but both markers lack absolute specificity and may be rarely seen in a subset of high-grade sarcomas [8]. The presence of pleomorphic lipoblasts in an 'MFH-like' background is characteristic of pleomorphic liposarcoma. Entrapment of fatty tissue in MFH, as in the current study, may mimic pleomorphic liposarcoma.

KIT-negative GISTs are generally cellular and monotonous throughout and have a prominent epithelioid component, and a majority of them harbour mutations in PDGFRα exons 18 and 12 [26]. PDGFRα and PDGFRβ have emerged as additional immunomarkers in identifying KIT-negative GIST [34, 35, 37], but results have been contradictory. While one study reported a strong reactivity for PDGFRα in KIT-negative epithelioid GISTs but in none of KIT-expressing GISTs [37], another reported co-expression of both proteins in KIT-mutated GISTs [34]. Furthermore, 25% of non-GIST neoplasms [35] and 27% of desmoid tumours [37] stained with PDGFRα. None of four sarcomas tested expressed PDGFRα [35]. A remarkable pleomorphism comparable to MFH is exceptional in GISTs and may indicate dedifferentiation, but this rare phenomenon is usually focal, and a conventional component is evident (own unpublished data). Conversely, focal epithelioid areas in MFH may mimic GIST, but more typical areas are usually easily detectable. *h*-Caldesmon is commonly expressed in GISTs and in leiomyosarcoma but not in MFH or myo/fibroblastic sarcomas [14, 30]. The biological significance of PDGFRα/β staining in MFH in the current study is not clear. This might indicate a non-specific neoexpression, but a potential role for these receptor tyrosine kinases in the pathogenesis and progression of a subset of MFH, similar to desmoid tumours [23], cannot be excluded, meriting future investigation of more cases.

Sarcomatoid carcinoma usually shows evidence of origin from a mucosal surface with a detectable epithelial component in most cases (at least dysplastic or carcinoma in situ changes). Expression of keratins may be helpful in equivocal cases. The polypoid pattern adopted by many sarcomatoid carcinomas may mimic metastatic pleomorphic sarcoma.

Osteoclast-like giant cells (as in one of the current cases) have been described as a rare non-specific finding in a variety of neoplasms [21, 27] and as an integral component of a recently described clear cell sarcoma-like GI neoplasm [45]. The latter rare entity reveals a strong reactivity for S100 combined with absent expression of melanocytic markers and KIT. Some of the cases harboured the characteristic t(11;22)(q13;q12) translocation [45].

Other more common pleomorphic intra-abdominal and retroperitoneal sarcomas, metastatic genital tract sarcomas,

pleomorphic rhabdomyosarcoma, pleomorphic epithelioid angiomyolipoma/malignant PEComa with high-grade features, follicular dendritic cell sarcoma, sarcomatoid mesothelioma, melanoma and other miscellaneous primary and metastatic GI sarcomas may mimic and be mistaken for MFH, if not thought of and should be excluded by careful analysis of architectural and cytomorphological features, assisted by appropriate use of ancillary methods.

In summary, we documented five cases of primary and metastatic MFH in the GI tract demonstrating myofibroblast-like features and expressing PDGFRα. Before rendering a diagnosis of primary MFH in the GI tract, a variety of primary and metastatic 'MFH-like' neoplasms and a concurrent or previously excised STS should be excluded by appropriate morphological and clinical evaluation. Similarly, extensive sectioning to detect or exclude a better differentiated minor component would help establish a correct diagnosis in liposarcoma, pleomorphic leiomyosarcoma, dedifferentiated pleomorphic GISTs and others.

Abstract Desmocollin 3 (Dsc3) and desmoglein 3 (Dsg3) are both transmembrane glycoproteins that belong to the cadherin family of calcium-dependent cell adhesion molecules. β-Catenin is a member of the cadherin–catenin complex that mediates homotypic cell–cell adhesion and is also an important molecule in the wnt signaling pathway. In this study, we examined the simultaneous expression level of Dsc3, Dsg3, and β-catenin in oral squamous cell carcinomas (OSCCs) and normal oral epithelia using immunohistochemistry. There was a significant correlation ($p<0.05$) among the following variables in OSCCs: reduced or loss of expression of Dsc3, Dsg3, and β-catenin compared to normal oral epithelium, reduced or loss of expression of Dsc3 and histological grade (moderately or poorly differentiated), and reduced or loss of expression of β-catenin and lymph node metastasis. Furthermore, a positive correlation was found between reduced or loss of β-catenin staining and reduced or loss of Dsc3 staining in lymph node metastatic cancer tissue ($r=0.734$, $p<0.05$). These results suggest an abnormal expression of Dsc3, Dsg3, and β-catenin induced in the progression of oral carcinomas and that the Dsc3 expression level might be related to the regulation of β-catenin in lymph node metastasis and cell proliferation in OSCCs.

Introduction

Desmosomes are intercellular junctional apparatuses that connect intracellular intermediate filaments to the cell surface and mediate strong cell–cell adhesion [5]. Malignant transformation is often characterized by major changes in the organization of the cytoskeleton, decreased adhesive strength, and aberrant adhesion-mediated signaling [5, 6]. Disruption of normal cell–cell adhesion in transformed cells may contribute to enhancement of tumor cell migration and proliferation, leading to invasion and metastasis [6].

The main components of desmosomes consist of the products of three gene superfamilies: The desmosomal

cadherins, the armadillo family of proteins, and the plakins family of cytolinkers [11, 12, 38].

Desmosomal cadherins are divided into two subfamilies: desmogleins (Dsg) and desmocollins (Dsc). There are four main types of epidermis-specific Dsg proteins, Dsg1, Dsg2, Dsg3, and Dsg4, and three major Dsc proteins, Dsc1, Dsc2, and Dsc3, each cadherin subtype being encoded by a unique gene [12]. They belong to the cadherin family of calcium-dependent cell adhesion molecules. Plakoglobin belongs to the armadillo family and binds directly to the cytoplasmic tail of both Dsg and Dsc [27, 26] and is closely related to the adherens junction molecule β-catenin [39].

β-Catenin interacts with the cytoplasmic tail of the calcium-dependent cell–cell adhesion molecule and through the association with plakoglobin creates a link between cadherin and the actin cytoskeleton [39]. More specifically, β-catenin is involved in the Wingless/Wnt signaling pathway [2] and interacts with epidermal growth factor receptor [16], the adenomatous polyposis coli protein product [35], and proto-oncogene c-ErbB2 [25]. β-Catenin also interacts with the two nuclear transcription factors, lymphoid-enhancing binding factor-1/T cell factor-4 [24].

Many studies have demonstrated a reduction in or loss of cell surface desmosomal cadherin expression, β-catenin membranous expression, and β-catenin mutation, which correlated with esophageal carcinoma [23], oral carcinoma [37, 18], and other carcinomas in systemic organs [29, 19, 1]. It was also shown that downregulation of desmosomal protein and abnormal β-catenin expression was associated with invasion and cell proliferation in pharyngeal [9], oral [9, 34], hepatocellular [7], and pancreatic [31] carcinomas.

In this study, we examined the simultaneous expression levels of Dsc3, Dsg3, and β-catenin in both oral squamous cell carcinomas (OSCCs) and normal oral epithelia using immunohistochemistry. We analyzed the relationship between clinicopathological findings, especially metastasis or cell proliferation and Dsc3, Dsg3, and β-catenin expression levels. We also examined the intracellular localization of Dsc3, Dsg3, and β-catenin expression.

Materials and methods

Human samples and clinicopathologic data

Between January 2001 to December 2003, we collected 48 formalin-fixed, paraffin-embedded human primary OSCC biopsy specimens (without previously treated), which included 24 cases without lymph node metastases and 24 cases with lymph node metastases, and 26 normal oral epithelia from the patients admitted to Tokyo Medical and Dental University Hospital, Japan. The patients with OSCC consisted of 20 women and 28 men with an age range of 28–82 years and an average age at the diagnosis of 59 years. Tumors were located in the tongue in 20 cases (41.7%), in the gingiva in 12 cases (25%), in the floor of the mouth in nine cases (18.8%), and in the buccal mucosa in seven cases (14.6%). Clinical details of each patient included age, gender, tumor size, clinical stage, lymph node status, and histological grade of tumor differentiation. Histological grading was done according to the World Health Organization (WHO) classification [8, 28].

Serial sections of 4 μm thick were cut from the paraffin-embedded tissue blocks and mounted on silanized slides. One section was stained with hematoxylin–eosin and examined to confirm the original diagnosis and tumor grade, and the other sections were submitted to immunohistochemical staining.

Immunohistochemical analysis

Anti-β-catenin (1:100, E-5, mouse monoclonal, Santa Cruz Biotechnology, Santa Cruz, CA) antibody, Dsc3 (U-114, mouse monoclonal, ready to use, Progen Biotechnik, Germany) antibody, and Dsg3 (1:25, 5G11, mouse monoclonal, Zymed, Berlin, Germany) antibody were used for all specimens. After deparaffinization and rehydration, endogenous peroxidase activity was blocked by immersing the sections into methanol containing 0.3% hydrogen peroxide at room temperature for 20 min. For antigen retrieval, histological sections were heated twice in 10 Mm citrate buffer (pH 6.0) for 10 min each time in a 500-W microwave oven, and sections were subsequently incubated with 10% normal rabbit serum to block nonspecific immunological reactions for 30 min. Each section was incubated with primary antibody overnight in a moist chamber, followed by incubation with biotinylated anti-mouse IgA+G+M secondary antibody and streptavidin–peroxidase complex (Nichirei, Tokyo, Japan). Finally, 3,3'-diaminobenzidine was used as a chromogen to visualize labeling. Nuclei were counterstained with methyl green. Negative controls were prepared by substituting the primary antibody with phosphate-buffered saline.

Scoring of immunostaining

The adjacent normal oral epithelium was used as an immunopositive control for Dsc3, Dsg3, and β-catenin staining that is normally seen at cell–cell junctions. A grading system was devised to obtain a semiquantitative evaluation of the distribution of each protein in the tissue slides. Scores were awarded according to Alazawi et al. [1] as follows: 0, negative staining throughout the epithelium, I, minimal membrane staining, II, patchy nonpericellular membrane staining, III, pericellular staining in one third of

Table 1 Comparison of immunohistochemical staining score of β-catenin, Dsc3, and Dsg 3 in normal oral mucosa and OSCCs

[b] *OSCC* Oral squamous cell carcinoma

the epithelium, IV, pericellular staining in two thirds of the epithelium, and V, pericellular staining in all three thirds of the epithelium.

Statistical analysis

The statistical data was stored and analyzed by SPSS 13.0 for Windows software (SPSS). The Chi-squared test was used to analyze the association between clinical parameters (age, gender, T status, clinical stage, regional lymph node status, and histopathological grade) and immunohistochemical staining results. The relationship between the expression of β-catenin and Dsc3/Dsg3 were analyzed using Pearson's coefficient of correlation method. A p value less than 0.05 was accepted as statistically significant.

Results

Immunohistochemical examination showed Dsc3, Dsg3, and β-catenin expressions in all samples as follows.

Expression of Dsc 3

As shown in Table 1, Dsc3 membranous immunoreactivity was confined to the basal and spinous cells of normal oral epithelium (15 cases scored V points, ten cases scored IV points, and only one case scored III points, Fig. 1a), and intracytoplasmic expression was not observed. On the other hand, the reduced or absent membranous expression of Dsc3 was found in the OSCC cases (30 of 48 cases showing 0–II scores) with only 18 cases showing III–IV

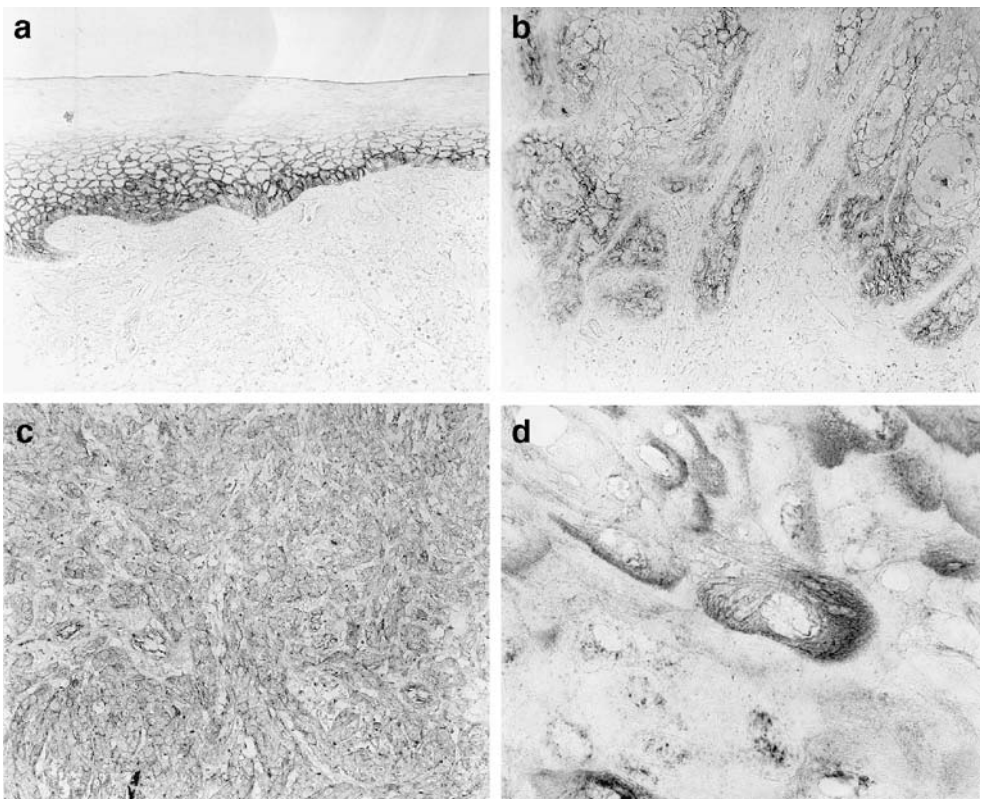

Fig. 1 **a** Dsc3 immunohistochemical staining in normal oral epithelium showing strong linear membranous expression (150×). **b** Dsc3 immunohistochemical staining showing partially reduced membranous and cytoplasmic expression in moderately differentiated OSCC (150×). **c** Dsc3 staining is completely absent in poorly differentiated OSCC (150×). **d** Abnormal Dsc3 immunohistochemical localization in the cytoplasm of tumor cells (750×)

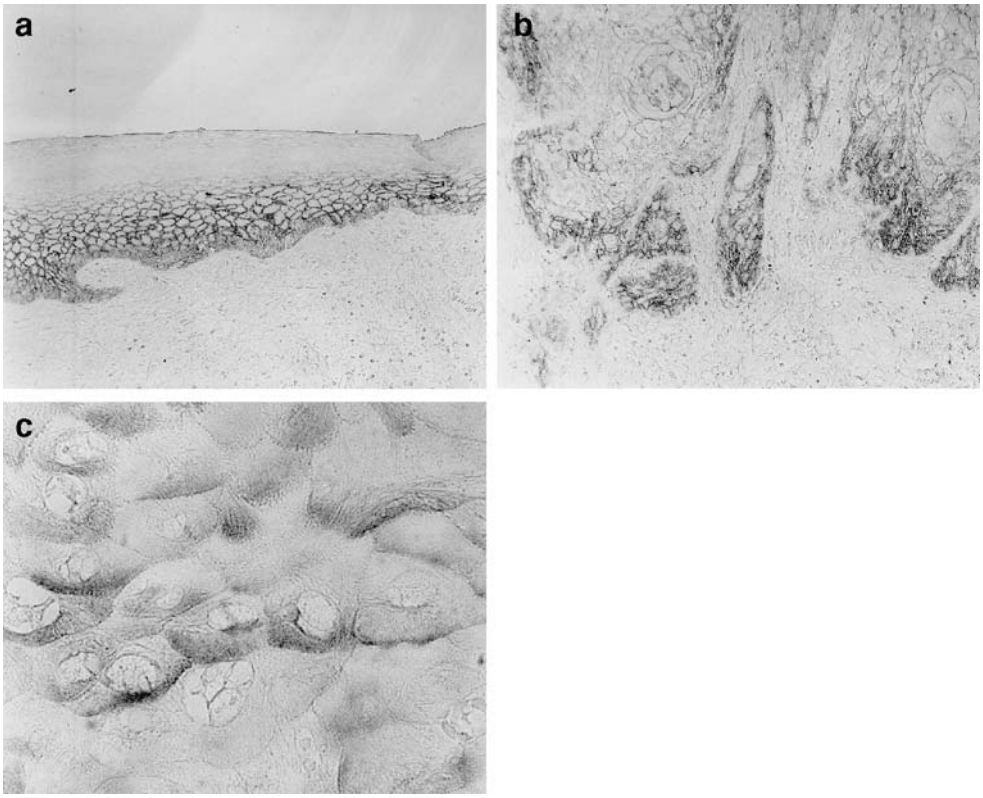

Fig. 2 **a** In normal oral epithelium, immunohistochemical staining of Dsg3 shows strong linear membranous expression (150×). **b** Dsg3 immunohistochemical staining showing partially reduced membranous and cytoplasmic expression in moderately differentiated OSCC (150×). **c** Abnormal Dsg3 localization in the cytoplasm of tumor cells (750×)

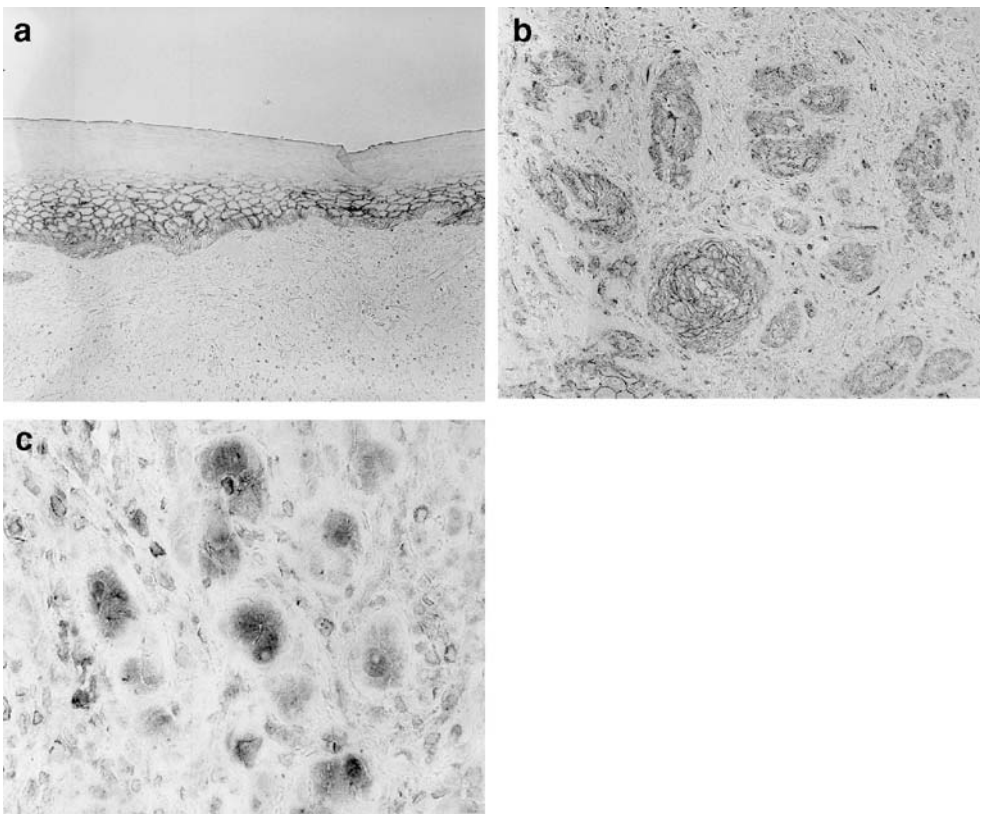

Fig. 3 **a** In normal oral epithelium, β-catenin shows normal membranous expression (150×). **b** Peripheral loss of membranous of β-catenin in well differentiated OSCC (150×). **c** Nuclear β-catenin expression in tumor cells of OSCCs (750×)

scores (Fig. 1b,c). The scores of Dsc3 expression were significantly lower in OSCCs than in normal oral epithelium ($p<0.01$). In addition, Dsc3 exhibited diffuse intracytoplasmic immunostaining, and nuclear staining was not observed in OSCC tumor cells (Fig. 1d).

Expression of Dsg 3

The staining results of Dsg3 are summarized in Table 1. Dsg3 membranous staining was located in the basal and spinous cells of normal oral epithelium (15 cases scored V points, eight cases scored IV points, and only three cases scored III points, Fig. 2a), and cytoplasmic expression was not observed, whereas reduced or absent membranous staining of Dsg3 was found in OSCCs (32 of 48 showing 0–II scores, 16 of 48 showing III–V scores, Fig. 2b). The staining score of Dsg3 was significantly lower in OSCCs than in normal oral epithelium ($p<0.01$). In addition, intracytoplasmic accumulation of Dsg3 was observed in OSCC tumor cells (Fig. 2c).

Expression of β-catenin

The expression of β-catenin in normal oral epithelia and OSCCs is presented in Table 1. Among 26 specimens of normal oral epithelium, β-catenin expression was showed as a strong, linear membranous pattern (11 cases scored V points, 11 cases scored IV points, and four cases scored III points, Fig. 3a). Faint staining was detected in the cytoplasm, but no nuclear staining was found, whereas reduced or absent membranous expression of β-catenin was recognized in OSCCs (32 of 48 showing 0–II scores) with only 16 cases with score III or IV (Fig. 3b). There was a statistically significant difference in low expression level of β-catenin between OSCCs and normal oral epithelium ($p<0.01$). In addition, β-catenin exhibited

cytoplasmic and nuclear immunoreactivity in OSCC tumor cells (Fig. 3c).

Relationship between clinicopathological features and expression of Dsc3 Dsg3 and β-catenin in OSCCs

The variety of Dsc3, Dsg3, and β-catenin expression in relation to clinicopathological features are presented in Table 2. No correlation was found between the reduced or loss of membranous staining of Dsc3, Dsg3, β-catenin and clinical parameters such as age, sex, T status, and clinical stage ($p>0.05$, respectively). Whereas, the statistical analyses showed a positive correlation between reduced or loss of membranous staining of β-catenin and lymph node metastasis ($p<0.05$) and also between reduced or loss of membranous staining of Dsc3 and histological grade (moderately or poorly differentiated; $p<0.05$).

β-Catenin expression levels correlate with decrease in Dsc3 and Dsg3 expression levels in lymph node metastasis in OSCC

The reduced or absent expression of β-catenin had a positive correlation with reduced or absent expression of Dsc3 showing scores 0, I, and II in 24 cases with lymph node metastasis ($p<0.05$, Table 3). There was no significant correlation between the expression of Dsc3/Dsg3 and β-catenin/Dsg3 revealing scores 0, I, and II in 24 cases with lymph node metastasis ($p>0.05$, respectively, Table 3). However, there were no correlations among the decrease in β-catenin/Dsc3, β-catenin/Dsg3, and Dsc3/Dsg3 expression levels exhibiting scores III, IV, and V in 24 cases with lymph node metastasis ($p>0.05$, respectively, Table 3). It is also showed in Table 3 that no correlation among the decrease in β-catenin/Dsc3, β-catenin/Dsg3, and Dsc3/Dsg3 expression levels exhibiting scores 0, I, and II and scores III, IV, and V in 24 cases without lymph node metastasis ($p>0.05$, respectively).

Discussion

Desmosomes are intercellular junctional apparatuses that provide membranous anchors for intermediate filament cytoskeleton. A reduced number of desmosomes would represent reduced intercellular adhesiveness, which, in turn, would be expected to promote invasive and metastatic ability [34]. In this study, we used immunohistochemistry to examine the cellular expression of Dsc3, Dsg3, and β-catenin in OSCCs and normal oral epithelium. We analyzed the relationship between clinicopathological features, especially metastasis or cell proliferation and Dsc3, Dsg3, and β-catenin expression levels. We also assessed intracellular localization of Dsc3, Dsg3, and β-catenin.

Desmosomal proteins are well established markers of epithelial differentiation [10]. Our results showed that Dsc3 and Dsg3 are strongly expressed in the basal and lower spinous layers in normal oral epithelium. Moreover, our results also demonstrated that a reduction in or absence of expression of Dsc3 and Dsg3 was significantly higher (30 of 48 and 32 of 48 cases showing 0–II scores, respectively) in OSCCs than in normal oral epithelium. The results are generally in agreement with previous studies [1, 34, 15, 22].

Hynes [17] reported that adhesion molecules transduce signals across the cell membrane both inward and outward and that such signals can modulate cell behavior, proliferation, and gene expression. A relationship between suprabasal misexpression of Dsc3 and cell proliferation/early terminal differentiation is suggested by Hardman et al. [14]. Dsc and Dsg misexpression has been examined and founded in actinic keratoses, Bowen's disease, and squamous cell carcinoma (SCC) of the skin and oral cavity formerly [22, 34], this study furthers our understanding by showing that there was a definite relation between the reduction in or absence of expression of Dsc3 and histological differentiation (moderately or poorly differentiation) in OSCCs. The results of the present study suggest that desmosomes may have a possible role in suppression of cell proliferation in OSCCs.

It was reported that normal oral epithelium showed only membranous staining for β-catenin and membranous staining was lost or reduced with an increase in cytoplasmic staining in oral carcinoma [18]. In basal cell carcinomas of the skin, oral SCC and breast cancer, nuclear and diffuse intracytoplasmic staining of β-catenin was observed without membrane signal reinforcement [18, 19, 32]. Thus, membranous staining may be lost or markedly reduced according to the cytoplasmic internalization/nuclear staining of β-catenin. Our results showed that a reduction in or absence of membranous β-catenin staining was significantly different in OSCCs (0–II scores in 32 cases) from normal oral epithelium (III–V scores in 26 cases). These results are supported by other studies showing a similar correlation between β-catenin and the progression of oral cancer [36] and skin tumor [3].

Hiraki et al. [15] and Kurzen et al. [22] had recently reported an association between the abnormal expression of β-catenin at the time of invasion/metastasis and progression in oral cancer and skin tumor. The current study promotes our understanding by showing that β-catenin is also significantly associated with lymph node metastasis in OSCCs, but no correlation was found between the expression or absence of β-catenin and clinicopathological parameters such as age, gender, T status, clinical stage, as well as histological differentiation.

Dsc also plays an important role in epidermal integrity and differentiation. Dsc3 expression might be more compatible with keratinocytic proliferation and dynamic cell–cell adhesion. Plakophilin 2 binds β-catenin in vitro, and experimental upregulation enhances β-catenin signaling; at the same time, plakophilin 2 is also expressed in the basal cell layer of epidermis, where it should interact with Dsc3 [4]. Aberrant expression of Dsc3 in the epidermal suprabasal layers regulated epidermal differentiation and affected β-catenin expression [14, 13]. Hardman et al. [14] have reported a correlation between Dsc3 and β-catenin stability, providing further evidence for the integration of desmosomal cadherins and cell-signaling pathways fundamental to epidermal proliferation and differentiation programs. A study regarding the relationship between β-catenin, Dsc3, and Dsg3 expression in 24 cases with lymph node metastases showed that while there was a significant positive correlation between the reduction in or loss of β-catenin and the reduction in or loss of Dsc3 (Pearson's correlation coefficient $r=0.734$, $p<0.05$), no correlation was found between β-catenin and Dsg3 and between Dsc3 and Dsg3 expression showing scores 0, I, and II. In other words, our results showed that the decrease in Dsc3 expression levels positively regulates β-catenin expression levels in lymph node metastasis in OSCCs. The research on relation between desmosomal components and β-catenin signaling have been carried out, where it was shown that Dsc3 regulated β-catenin in suprabasal keratinocytes [14] and human odontoblasts [33], by inducing β-catenin stabilization and altering signaling.

Additionally, our results also showed that a diffuse perinuclear cytoplasmic internalization of Dsc3 and Dsg3 and a cytoplasmic and nuclear staining pattern of β-catenin were found in OSCC tumor cells. This change of distribution was accompanied by a reduction in membranous expression in most tumors and significantly correlated with disease progression in accordance with other studies [18, 20, 21, 32, 30]. Thus, a reduction in or absence of membranous pattern of cadherin proteins and β-catenin, together with internalization to the cytoplasm, may be associated with tumor progression.

Conclusion

We have shown that there was a significant correlation between loss of or reduction in β-catenin staining and loss of or reduction in Dsc3 staining in lymph node metastasis in OSCCs. Our observations suggest that the abnormal expression of Dsc3, Dsg3, and β-catenin were correlated with the progression of oral carcinomas. Dsc3 expression levels might be related to the regulation of β-catenin in metastatic activities and cell proliferation in OSCCs, and internalization of Dsc3, Dsg3, and β-catenin may also be associated with progression of OSCCs.

Abstract The immunoglobulin superfamily protein MUC18 is involved in transendothelial migration and signal transduction, and is expressed in malignancies including cutaneous melanoma. Recent in vitro studies showed evidence of increased MUC18 protein in some uveal melanoma cell lines with an increased potential for invasion. We assessed seven uveal and three metastasis-derived melanoma cell lines for the expression of MUC18 mRNA and protein by RT-PCR, and immunoblotting and immunocytochemistry, respectively. We also examined the expression and distribution of MUC18 in paraffin sections of primary uveal melanomas (n=23; 5/23 spindle; 18/23 mixed and epithelioid) and normal eyes (n=3) using a polyclonal goat anti-human antibody to MUC18 visualized with peroxidase and Vector NovaRED. Distribution and intensity of immunostaining was graded semi-quantitatively (grade 0 to 3) by 2 independent observers. All cell lines expressed MUC18 mRNA and protein (~130 kDa), and showed punctate cell membrane MUC18 immunostaining. Primary melanomas displayed heterogeneous cell membrane and cytoplasmic MUC18, with moderate to strong immunolabelling (≥grade 2) in ~70% of tumours. Vasculature in tumours and in retina and choroid of all melanoma-affected and normal eyes showed intense MUC18 immunostaining. These observations further suggest a role for MUC18 in uveal melanoma growth; moreover, interactions between MUC18-positive melanoma cells and vasculature may be important for the hematogenous spread of cells during metastases.

Introduction

Uveal melanoma, affecting iris (3%), ciliary body (5–10%) and choroid (~90%), is the most common primary adult eye cancer with an incidence of 8 per million per year in Caucasians [43, 53, 55]. Metastatic disease can develop after a prolonged disease-free period, does not respond well to therapy and advances rapidly to be often fatal within 12 to 15 months after diagnosis [15, 16, 24, 41]. More aggressive uveal melanomas display a predominantly epithelioid histopathology, with vasculature and a complex extravascular matrix pattern (vasculogenic mimicry) clearly seen using periodic acid Schiff (PAS) stain [14]. PAS+ closed loops and networks are seen in more aggressive choroidal and ciliary body melanomas, in liver metastases and secondary metastatic sites [14], and in other tumors including cutaneous melanoma, and prostate and breast carcinomas [11, 12, 19, 31].

Mucin isotype 18 (MUC18/CD146), melanoma cell adhesion molecule (MelCAM/MCAM) or S-Endo 1-associated antigen is a transmembrane immunoglobulin (Ig) superfamily cell adhesion molecule normally expressed in vascular endothelium, activated T-lymphocytes, myofibroblasts, smooth muscle, Schwann cells and ganglion cells [6,

49]. Cell–cell adhesion *via* MUC18 occurs through an as yet unidentified heterophilic ligand [50]. MUC18 expression is also strongly up-regulated in malignant cutaneous melanoma compared to benign nevi, particularly in metastatic lesions [21, 27, 28]. In tissue microarrays of cutaneous melanomas, MUC18 immunostaining is reported to be a highly significant independent prognostic marker inversely correlated with survival of patients [37]. In vitro and in vivo studies in cutaneous melanoma also indicate that MUC18 antibody can target both MUC18-positive melanoma cells and vascular endothelium, with possible inhibitory therapeutic effects on cutaneous melanoma growth and metastases [30, 32, 34].

Recent studies using 2D gel electrophoresis also found MUC18 protein expression in several uveal melanoma cell lines [38, 39]. Cell lines with increased levels of MUC18 protein generally displayed an increased potential for in vitro invasiveness, suggesting an association between MUC18 and tumor growth [39]. Pre-conditioning of collagen I matrix by aggressive metastatic (MUM2B) uveal melanoma cells also induced expression of MUC18 (and other genes) in poorly aggressive (OCM-1A) uveal melanoma cells, suggesting a role for MUC18 in uveal melanoma growth [45]. In the present study, we extend these in vitro observations to a series of uveal and metastasis-derived cell lines, and describe the distribution of MUC18 protein expression in primary human uveal melanomas and normal eyes.

Materials and methods

Uveal melanoma and metastasis-derived cell lines

Cell lines

Uveal melanoma (OCM-1, OCM-3, OCM-8, 92.1, Mel202, C918, OCM-1A) and metastasis-derived (OMM-1, MUM2B, MUM2C) cell lines were grown in either RPMI-1640 medium (OCM-3 and OCM-8, Mel202, 92-1, C918, MUM2C, MUM2B) or Dulbecco's Modified Eagle's Medium (DMEM; OCM-1A, OCM-1 and OMM-1) supplemented with 10% heat inactivated fetal bovine serum (FBS), 2 mM glutamine, 50 IU/ml penicillin and 50 μg/ml streptomycin (Thermo Electron, USA).

RNA extraction and reverse transcription-PCR

Total RNA was extracted from melanoma cells using Trizol (Invitrogen Australia Pty, Australia) and reverse transcribed to cDNA (SuperScript III First-Strand Synthesis System for RT-PCR, Invitrogen) following manufacturer's instructions. PCR analyses were performed to identify MUC18 transcripts under the following conditions: 35 cycles of denaturation at 94°C for 35 s, annealing at 60°C for 35 s, and elongation at 72°C for 60 s, followed by a 5 min extension at 72°C. Primers used for MUC18 (accession no. M28882.1) amplification were:

- Forward: 5′-ACCCTGAATGTCCTCGTGAC-3′
- Reverse: 5′-TCTCTGTGGAGGTGCTGTTG-3′ (amplicon 209 bp)

PCR products together with a 100 bp DNA ladder (Invitrogen) were run on 1.5% agarose gels and visualised with ethidium bromide using a BioRad GelDoc system and WinFast Software. Products were subsequently extracted and purified from agarose gels, and verified by dye-determination DNA sequencing of both strands.

Immunoblotting

Melanoma cells were seeded in 35 mm dishes (Nunc A/S, Denmark) and cultured to semi-confluence in RPMI or DMEM growth medium for 24 h at 37°C. Growth medium was removed and cells were quickly rinsed in sterile PBS, then lysed in CellLytic™-M Mammalian Cell Lysis/Extraction Reagent (Sigma-Aldrich Pty, Australia) supplemented with protease inhibitor cocktail (Complete Mini Tablets, Roche Products Pty, Australia) for 20 min on a shaking table on ice. Lysed cells were collected and centrifuged for 15 min at 15,000×*g*, after which supernatants were collected and stored at −80°C until used. Protein concentration of cell lysates was determined using the Bio-Rad DC Protein Assay (BioRad Laboratories, Sydney Australia). Equal amounts of protein (15 μg) were diluted in 5× loading buffer [Tris–HCl 300 mM pH 6.8, glycerol 50% (*v*/*v*), bromophenol blue 0.04%, sodium dodecyl sulfate (SDS) 10%, β-mercaptoethanol 5%], denatured at 95°C for 10 min, then loaded onto 10% SDS-acrylamide gels and separated by SDS-PAGE under reducing conditions. Resolved proteins were electrophoretically transferred to 0.45 μm Invitrolon PVDF membranes (Invitrogen) in Tris–glycine/methanol buffer at 250 mA for 3 h.

The membranes were blocked with 5% skim milk powder in 0.05% Tween 20/TBS [20 mM Tris (pH 7.5), 0.5 M NaCl] (TTBS) at 4°C overnight. After rinsing in TTBS, membranes were incubated overnight at 4°C overnight in goat polyclonal anti-MCAM (C-20, MW ~130 kDa; sc18942, Santa Cruz Laboratories, CA, USA), followed by HRP-conjugated anti-goat IgG antibody (Bethyl Laboratories, TX, USA; 1:12,500 dilution in 1% BSA/TTBS) for 2 h. After washing in TTBS and finally in TBS, immunolabelled proteins were visualized with ECL (SuperSignal West Dura Extended Duration Substrate, Pierce Biotechnology, IL, USA) followed by exposure to X-OMAT film (Kodak) and photographic development. To

confirm equal loading of protein lysates, immunoblots were stripped (Restore Western Blot Stripping Buffer, Pierce) and re-probed using mouse GAPDH mAb (0.5 μg/ml, Ambion, Applied Biosystems, VIC, Australia) and then processed as above. Immunoblots (n=3) were visualized using a Syngene G:Box, Chemi XT 16 Camera and GeneSnap (Syngene) software. The average sum of intensities of MUC18 bands and GAPDH bands for each cell line were analysed using GeneTools [Syngene; Ver. 3.07(g)] Software and the ratio of MUC18/GAPDH band intensity calculated.

Immunocytochemistry

We also immunolabelled cultured cells as described previously [26], to assess the cellular distribution of MUC18 protein. Briefly, all melanoma cell lines were grown on glass coverslips, fixed in 2% paraformaldehyde in 0.1 M phosphate buffer with 0.9% sodium chloride (PBS, pH 7.4), and immunolabelled with either polyclonal goat anti-human antibody to the extracellular domain of MUC18 (MCAM, R&D Systems, MN, USA; 2 μg/ml), or goat immunoglobulins (Ig; 2 μg/ml) as a non-specific control, diluted in 2% normal rabbit serum (NRS)/PBS. Antibody binding was visualized using rabbit anti-goat Alexa 488 (1:1000; Invitrogen), nuclei were stained with Hoechst 33342, and cells were examined using a Zeiss LSM 5 Pascal confocal microscope.

Primary uveal melanomas

Specimens

This study was performed under the tenets of the Declaration of Helsinki and with approval from the Human Ethics Committee, University of Sydney. Eyes enucleated for uveal melanoma (n=23 age range: 41 to 85 years) were routinely fixed in 10% neutral buffered formalin (NBF) and paraffin embedded. The specimens included 18 untreated melanomas and 5 I^{125}-treated melanomas, and the majority of tumors were located in the choroid posterior to the equator. Normal human eyes (n=3; aged 39, 50 and 78 years), provided by the Lions NSW Eye Bank with consent and ethical approval, were fixed in 10% NBF, paraffin embedded, and used as controls. Paraffin sections were cut at 8 μm and collected on Super-Frost Plus (Menzel-Glaser) slides.

Tumor histopathology: H&E and periodic acid Schiff staining

Sections were dewaxed and rehydrated through alcohols to water, before staining with hematoxylin and eosin (H&E) according to standard protocols. A separate series of slides was prepared similarly but stained with PAS reagent according to standard protocols. The stained sections were subsequently dehydrated through alcohols and xylenes, then coverslipped in DePeX (BDH Pty), and examined using a Leica light microscope.

From H&E stained sections, tumors ranged from 5 to 24 mm maximum diameter and 2 to 14 mm maximum height, and tumor cell type was classified as spindle, mixed or epithelioid. Extracellular matrix (ECM) patterns in PAS-stained sections were classified as described previously [13, 14], with the following patterns observed: vessel lumens only, straight channels, incomplete loops and complete loops and networks. Complete loops and networks appeared only in epithelioid tumors, while spindle melanomas showed vessel lumens, straight channels or occasionally incomplete loops. From these observations, tumors were graded as follows: 1=spindle; 2=mixed; 3=epithelioid.

Immunohistochemistry

Sections were dewaxed, rehydrated and rinsed in 0.1 M PBS (pH 7.4). For antigen retrieval, sections were incubated in 0.01 M citrate buffer (pH 6.0) at 80°C for 15 min, cooled to 40°C, before rinsing in PBS for 10 min. This was followed by immersion in 5% H_2O_2 in water for 10 min to inhibit endogenous peroxidase activity, then rinsing in PBS. Sections were incubated at room temperature (RT) in 10% NRS for 30 min followed by incubation for 48 h at 4°C in a polyclonal goat anti-human antibody to the extracellular domain of MUC18 (MCAM) at 2 μg/ml in 2%NRS/PBS. After rinsing in PBS, sections were incubated for 1 h at RT in biotinylated rabbit anti-goat antibody (Zymed, San Francisco, USA) diluted 1:200 in PBS, rinsed, then further incubated for 1 h at RT in ExtrAvidin peroxidase (1:200, Sigma Aust. Pty). Antibody binding was visualized using Vector NovaRED substrate (Vector Labs Pty), and a constant time for color development was used for all specimens. After counterstaining in hematoxylin for 10–15 s, sections were dehydrated through alcohols and xylenes and coverslipped in DePeX. Non-specific controls were incubated in 2 μg/ml goat Ig instead of the primary antibody, and processed identically as for the MUC18 antibody.

Immunostaining was graded in masked fashion by 2 independent observers using a semi-quantitative scale where 0=none, 1=weak (low intensity staining of tumor cells regardless of percent, and medium intensity staining of ≤20% cells); 2=moderate (medium intensity staining of >20% tumor cells, high intensity staining of ≤20% tumor cells), and 3=strong (high intensity staining of >20% tumor cells). Differences in grading were resolved by joint review and if necessary, consultation with a third independent

observer. The grading of the two observers was significantly correlated ($P<0.001$; Kendall's rank correlation). Nonparametric linear regression analysis was used to test for a relationship between tumor cell type, maximum tumor height (in mm) and MUC18 immunostaining.

We also assessed the distribution and intensity of MUC18 in retina overlying tumors, and in regions of choroid and retina without melanoma, as well as in normal choroid and retina.

Results

MUC18 in uveal and metastasis-derived cell lines

RT-PCR showed MUC18 mRNA expression in seven uveal and three metastasis-derived melanoma cell lines (Fig. 1). Immunoblotting showed a positive band at ~130 kDa for all cell lines, with variable expression of MUC18 protein between cell lines (Fig. 2a). Membranes re-probed with GAPDH antibody showed a consistent band at ~35 kDa in all samples, confirming that equal amounts of protein were loaded (Fig. 2a). The mean ratio of intensities of MUC18 and GAPDH bands (from three separate immunoblots) showed high levels of MUC18 protein in OCM-3, OCM-8, 92-1, Mel202 and OCM-1A cell lines, relatively less MUC18 protein in OCM-1, OMM-1 and MUM2C cell lines and much reduced MUC18 protein in C918 and MUM2B cell lines (Fig. 2b). All cell lines showed punctuate cell membrane MUC18 immunolabelling, with no immunostaining for goat Ig control (Fig. 2c).

MUC18 in primary uveal melanoma

Immunohistochemical analysis for MUC18 expression was performed on primary uveal melanoma specimens. Overall ≥grade 2 immunolabelling was observed in 60% (3/5) of I^{125}-treated and 78% (14/18) of untreated melanomas. For untreated melanomas, we found a significant relationship between tumor cell type and average MUC18 immunostaining grade ($P=0.031$, nonparametric regression; Fig. 3), with more MUC18 immunostaining in mixed and epithelioid tumors compared to spindle cell tumors. No relationship between maximum tumor height (mm) and MUC18 immunostaining was found for untreated tumors ($P>0.05$). As tumor specimens were collected over a recent period, the relationship between MUC18 expression and survival could not be analysed.

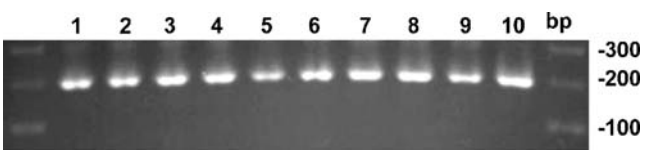

Fig. 1 Diagnostic RT-PCR showing MUC18 mRNA expression in uveal (*lanes 1–7*) and metastasis-derived (*lanes 8–10*) cell lines (accession number M28882.1: Amplicon 209 bp; *Lane 1*=OCM-1, *2*=OCM-3, *3*=OCM-8, *4*=92-1, *5*=Mel202, *6*=OCM-1A, *7*=C918, *8*=OMM-1, *9*=MUM2B and *10*=MUM2C)

In approximately 50% (9/18) of untreated melanomas, cells at the tumor edges showed moderate to strong cell membrane and cytoplasmic MUC18 immunostaining (Fig. 4a; inset). Within tumors, heterogeneous regions of MUC18 membrane and cytoplasmic immunolabelling of tumor cells were observed (Fig. 4b–e). Blood vessels within all tumors showed intense MUC18 immunostaining of vascular endothelium, and often lumen contents (including erythrocytes; Fig. 4a,e; Fig. 5a). We did observe some areas with patterns of MUC18 immunolabelling (Fig. 5b) similar to PAS+ loops and networks; these were seen in 28% (5/18) of untreated specimens (predominantly epithelioid tumors; Fig 5d). PAS+ vessel lumens were also seen in spindle cell and mixed tumors (Fig. 5c).

Blood vessels in the retina and choriocapillaris showed intense MUC18 immunostaining in all specimens (melanoma-affected and normal eyes; Fig. 6a,b). Large retinal vessels and the inner and outer retinal vascular plexus were intensely immunolabelled for MUC18 in normal and melanoma-containing eyes (Fig. 6a,b). No obvious immunostaining of tumor cells or blood vessels, including luminal erythrocytes, was observed in sections when goat IgG (Fig. 6c) was used in place of MUC18 antibody (Fig. 6d).

Discussion

In the present study we found that all melanoma cell lines (primary and metastasis-derived) expressed MUC18 mRNA and protein (western blot and immunocytochemistry). Compared to the other melanoma cell lines, C918 and MUM2B showed reduced levels of MUC18 protein in western blots; C918 uveal melanoma cells and MUM2B metastasis-derived cells are both considered to be highly aggressive [46]. Recent in vitro studies also described variable levels of MUC18 protein in uveal melanoma cell lines [38, 39]. In these studies, two uveal melanoma cell lines with low and moderate levels of MUC18 protein, respectively, displayed similar in vitro invasiveness. However, it was concluded that MUC18 expression was generally associated with an increased potential for in vitro invasiveness [38, 39]. Variable expression of MUC18 protein has also been found in western blots of ovarian carcinoma cell lines and primary cells, with an overall association between tumor progression, and poor prognosis [1]. MUC18 gene expression has also been reported in uveal melanoma cell lines and in primary uveal melanoma

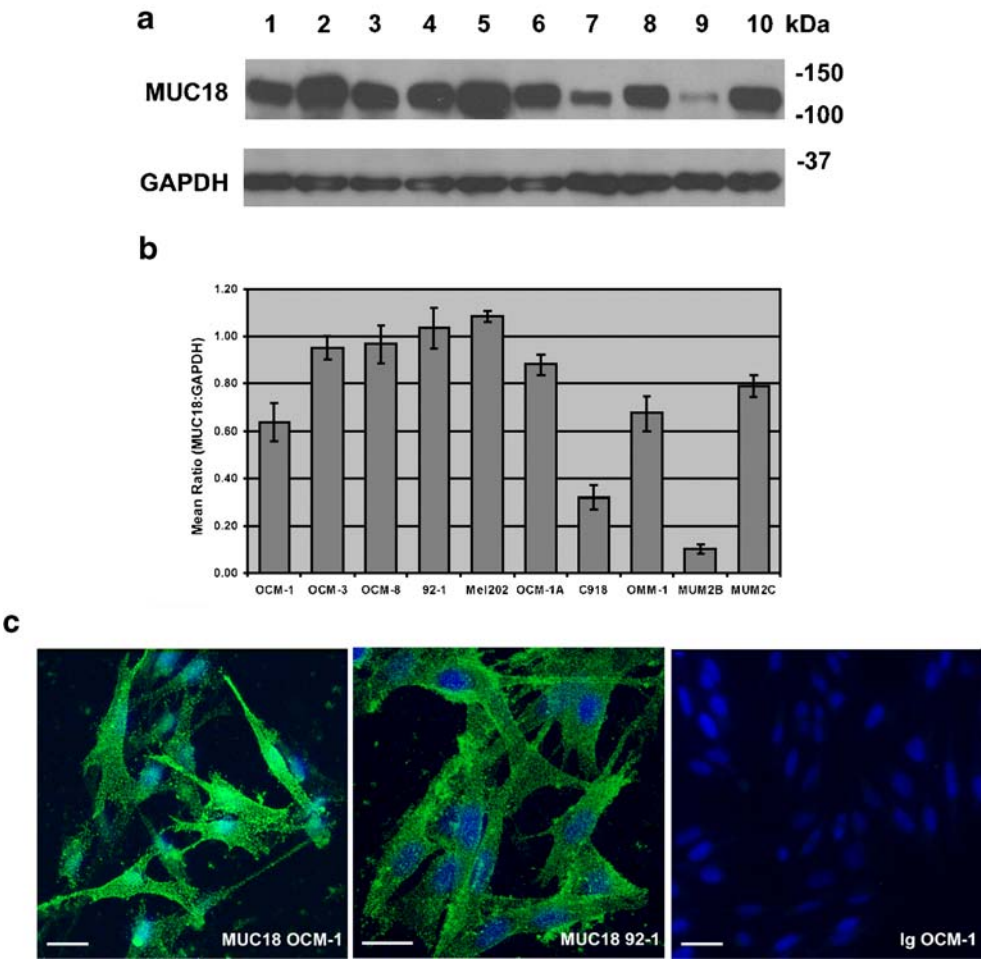

Fig. 2 **a** Representative immunoblot showing a band at ~130 kDa consistent with MUC18 protein expression in uveal (*lanes 1–7*) and metastasis-derived (*lanes 9–10*) cell lines. Reprobing of the membrane with GAPDH antibody showed a consistent band at ~35 kDa for all cell lines. Molecular mass markers (kDa) are shown on the right. (*Lane 1*=OCM-1, *2*=OCM-3, *3*=OCM-8, *4*=92-1, *5*=Mel202, *6*=OCM-1A, *7*=C918, *8*=OMM-1, *9*=MUM2B and *10*=MUM2C). **b** Histogram of the ratio of the average intensities of MUC18 and GAPDH bands calculated from three separate immunoblots. **c** Examples of MUC18 punctate cell membrane immunolabelling of OCM-1 and 92-1 cell lines, and OCM-1 cells with control goat Ig showing no immunolabelling. Nuclei are stained with Hoechst 33342 (*blue*); Bar=15 μm

specimens in gene array studies. *MUC18* was found to be upregulated in a primary uveal melanoma cell line compared to two metastasis-derived melanoma cell lines [56]. In contrast, for primary uveal melanomas, *MUC18* was downregulated in class 2 primary uveal melanomas (associated with epithelioid morphology, monosomy 3 and poor prognosis) compared with class 1 uveal melanomas (spindle morphology with good prognosis) [36]. These findings may reflect the involvement of tumor-stromal cell interactions in regulating gene expression in primary melanomas. The differences in gene and protein expression observed in cell lines and primary tumors most likely suggest that while MUC18 is important for uveal melanoma growth and invasiveness, more than one signalling pathway contribute to these processes as proposed by Pardo et al. (2005, 2006) [38, 39], and discussed below.

Over-expression of MUC18 in primary cutaneous melanoma cells has been reported to enhance adhesion between tumor cells themselves, increased tumor cell invasiveness, as well as greater interactions between tumor cells and endothelial cells, and decreased tumor cell adhesion to laminin; these effects were reversed by anti-MUC18 (MCAM) monoclonal antibody [59]. This study also

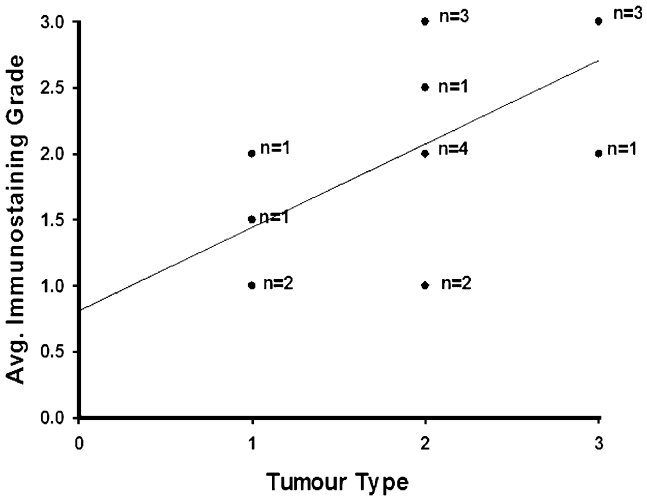

Fig. 3 Tumor type vs Average MUC18 immunostaining for untreated melanomas (n=18; nonparametric regression, P=0.031). Tumor type: (*1*) spindle; (*2*) mixed and (*3*) epithelioid. Average Immunostaining Grade of 2 independent observers: 0=none, 1=weak (low intensity staining of tumor cells regardless of %, and medium intensity staining of ≤20% cells); 2=moderate (medium intensity staining of >20% tumor cells, high intensity staining of ≤20% tumor cells), and 3=strong (high intensity staining of >20% tumor cells)

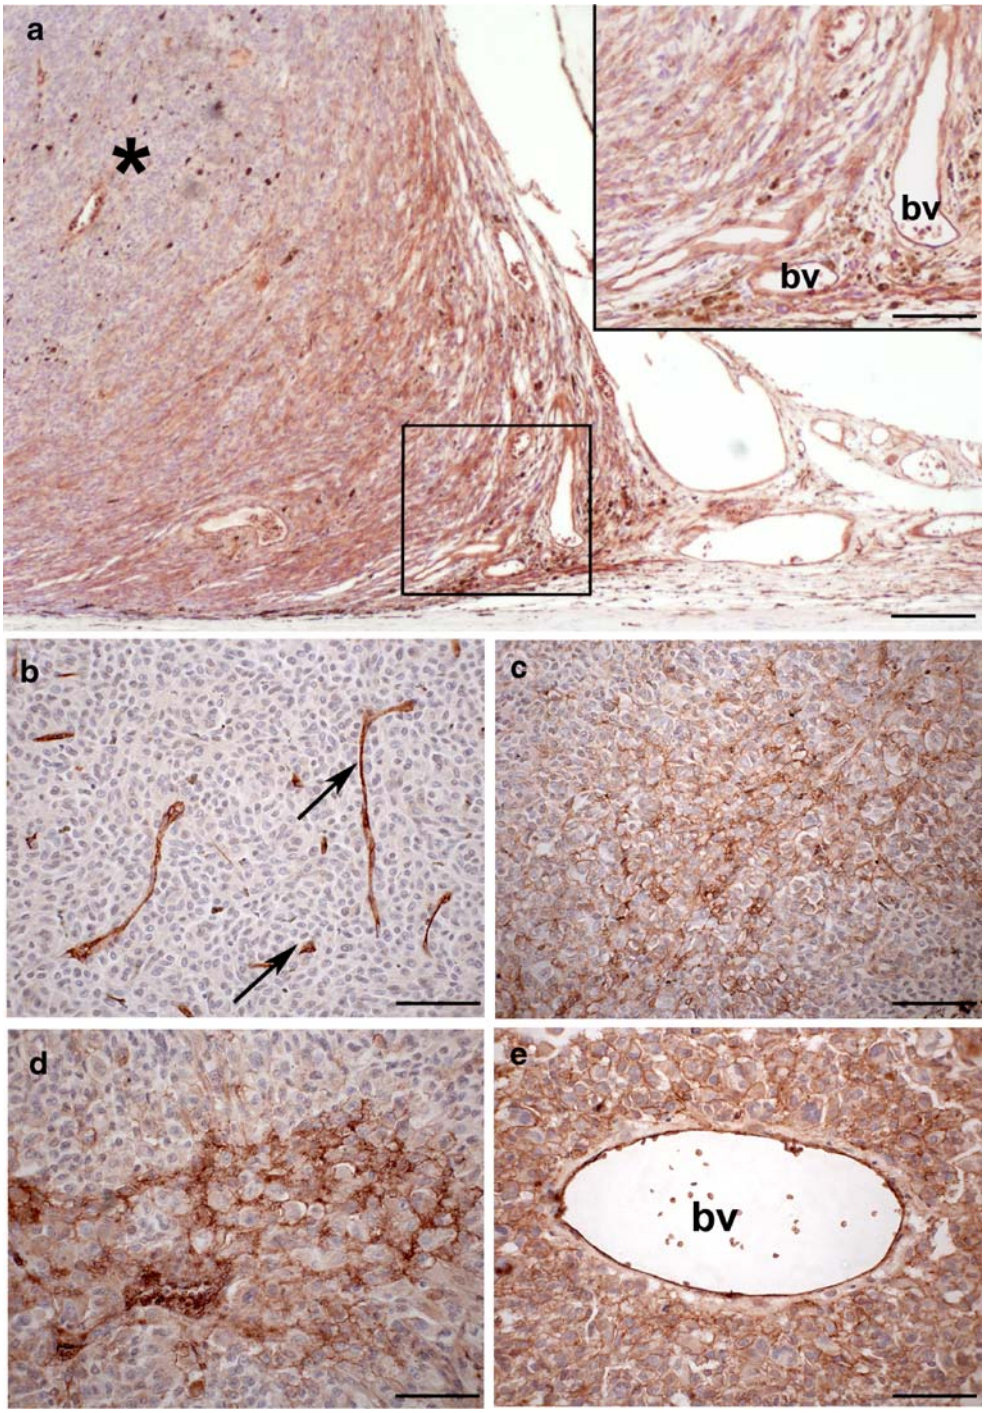

Fig. 4 MUC18 immunostaining in uveal melanoma. **a** Low power micrograph showing MUC18 expression at the tumor edge, where cells display membrane and cytoplasmic MUC18 immunoreactivity (see inset). The more central regions of the melanoma (*asterisk*) show lower levels of MUC18 compared to the tumor edge. Blood vessels (*bv*) in the tumor and adjacent choroid display strong MUC18 immunostaining (bar=100 μm; inset bar=30 μm). **b** Grade 1 (low) MUC18. Blood vessels show intense MUC18 immunolabelling (*arrows*; bar=35 μm). **c**–**e** Areas of moderate to intense (≥Grade 2) cell membrane MUC18. observed increased collagenase production in MUC18 transfected cells, contributing to increased tumorigenicity [59]. MUC18 over-expressing cutaneous melanoma cells induced tumor growth and metastases in nude mice that could be reversed using anti-MUC18 (MCAM) monoclonal antibody [59]. Further evidence for involvement MUC18 in cutaneous melanoma growth comes from recent in vitro and in vivo studies using antibodies to MUC18 to inhibit melanoma cell tumorogenesis and subsequent metastasis; a therapeutic application for MUC18 antibodies in controlling cutaneous melanoma growth is currently being investigated [30, 32, 34]. Although these studies indicate a major role for MUC18 in cutaneous melanoma growth, other cell adhesion and signaling molecules, for example, N-cadherin, integrins, RAS/ERK and PI3K, are also important for tumor growth [33]. A recent gene and tissue microarray study reported a significant correlation between progression of cutaneous melanoma and expression of N-cadherin and β3 integrin, but not MUC18 [57]. However, MUC18 (and β3 integrin) were implicated in cutaneous

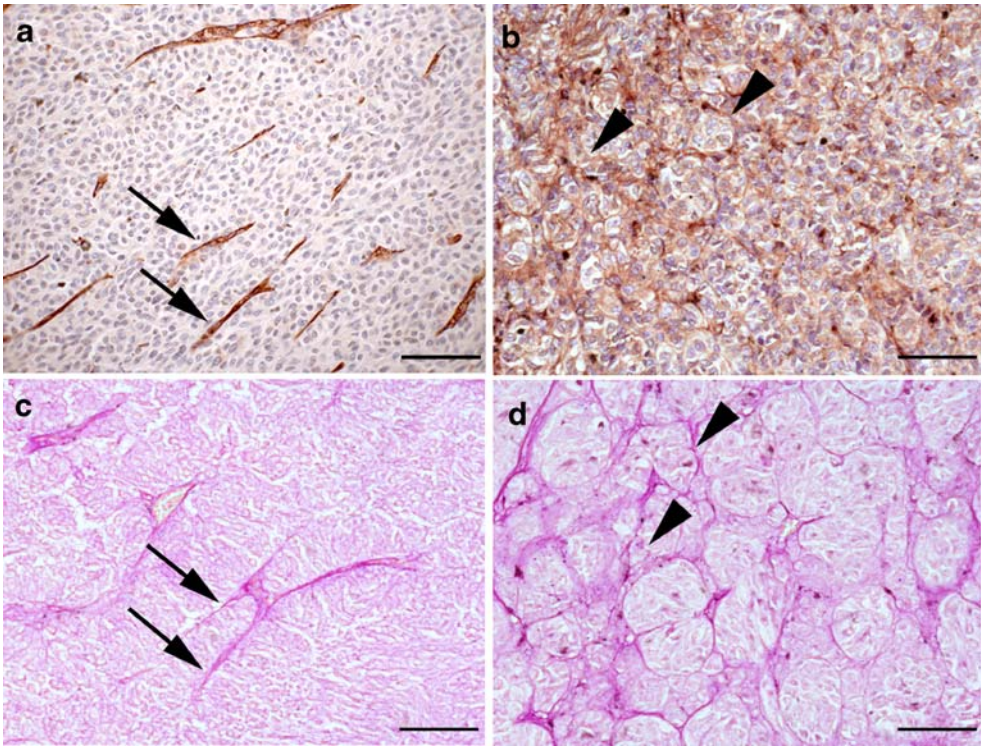

Fig. 5 **a** MUC18 immunostaining (*arrows*) and **c** PAS staining (*arrows*) of tumor blood vessels, with no apparent immunostaining of tumor cells (**a** and **c**: bar= 35 μm). **b** Areas of MUC18+ immunostaining (*arrowheads*) in an epithelioid melanoma appear similar to **d** PAS+ loops and networks (*arrowheads*; **b** and **d**, bar=25 um)

melanoma cell migration and invasion [57]. Overexpression of MUC18 has been associated with tumor progression in prostate and ovarian carcinomas [51, 48, 58]; however, this is not the case for all tumors, as seen for example in breast carcinoma where loss of MUC18 occurs with progression [48]. Furthermore, MCF-7 breast cancer cells transfected with *MUC18* produced smaller tumors when grown in immune-compromised mice, suggesting that in breast cancer, at least, MUC18 increased tumor cell cohesion and reduced the potential for spread into neighbouring tissues [50].

Binding sites for transcription factors including activator protein (AP)-2α, Sp1 and CREB/ATF-1 have been found on the MUC18 promoter [29], and loss of the transcription factor AP-2α has been shown to be involved in progression of several tumors including malignant melanoma [4], breast and prostate cancers [8, 42] and gliomas [18]. Highly metastatic (AP-2α-negative, MUC18-positive) cutaneous

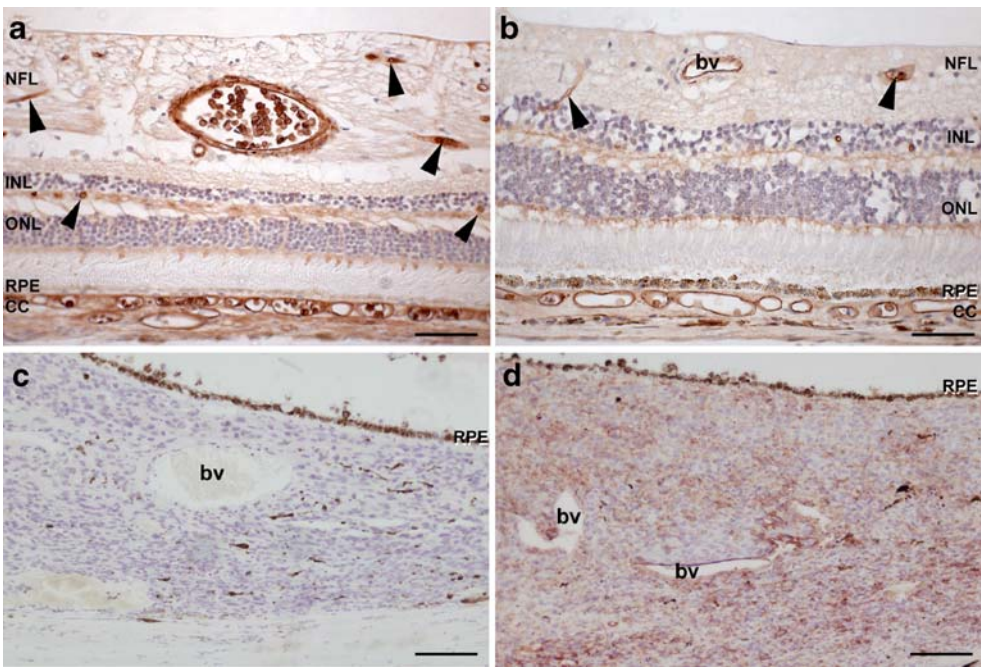

Fig. 6 **a** and **b** MUC18 immunostaining of retina and choriocapillaris (*CC*). Blood vessels (*arrowheads*) display strong MUC18 expression, with both the inner and outer retinal vascular plexus clearly seen in **a** melanoma-containing and **b** control eyes. In **a**, a large vessel also shows MUC18 immunoreactive perivascular cells. **c** No immunostaining of tumor cells or blood vessels (*bv*), including lumen contents, is seen with goat IgG control, compared to **d** MUC18 immunostaining in the same specimen (*NFL*, nerve fibre layer; *INL*, inner nuclear layer; *ONL*, outer nuclear layer; *RPE*, retinal pigmented epithelium; bar=40 μm)

melanoma (A375SM) cells transfected with AP-2α displayed greatly reduced levels of MUC18 mRNA and protein compared to parental cells [20]. These cells also displayed suppressed tumorigenicity and metastatic potential in nude mice that was suggested to be related to AP-2α down-regulation of MUC18 gene expression [20]. However, other transcription factors, including Sp1, have been found to be involved in regulating *MUC18* expression [22, 23, 35]. Other AP-2α-regulated genes important for tumor cell proliferation and apoptosis, invasion and angiogenesis including *c-kit*, *E-cadherin*, *MMP-2* and *PAR-1* have also been found to contribute significantly to cutaneous melanoma growth and metastases [17, 20, 29, 54]. The expression of transcription factors including AP-2, Sp1 and CREB/ATF-1, their role in regulating *MUC18* and other genes, and their relationship to uveal melanoma phenotype and progression remains to be established.

As discussed above, a major role for MUC18 in the growth and metastases of cutaneous melanomas has been proposed, and MUC18 expression has been reported to be strongly up-regulated in malignant melanomas of increasing vertical thickness, especially in metastatic lesions [9, 21, 25, 27, 28]. One study has observed a correlation between MUC18 expression and tumor thickness, associated with the transition of cutaneous melanoma from the radial to the vertical growth phase [59]. We observed heterogeneous areas of moderate to intense MUC18 immunostaining, particularly in mixed and epithelioid tumors; however, no relationship between MUC18 expression and maximum tumor height was established in this series of uveal melanomas.

All vascular endothelium, regardless of location or vessel size, constitutively express MUC18 [5, 7], and consistent with this we observed strong MUC18 immunolabelling of tumor vasculature, and of retinal and choriocapillaris blood vessels in both normal and melanoma eyes. MUC18 has been found localized at endothelial cell junctions, although outside *adherens* junctions, and associated with actin filaments in the endothelial cytoskeleton, suggesting an important role in endothelial cell cohesion [5, 52]. Several studies also show that MUC18 binding in endothelial cells can regulate intercellular permeability, inducing phosphotyrosine-kinase-dependent outside-in signaling associated with proteins including $p59^{FYN}$, $p125^{FAK}$ and paxillin [2, 3]. MUC18-mediated adhesion between melanoma cells and endothelial cells, *via* an unknown heterophilic ligand, may be important for the movement of melanoma cells in and out of the tumor vasculature [34, 47, 50, 59]. Activated peripheral T lymphocytes also express MUC18, with an increased capacity to bind endothelial cells that contributes to T-cell extravasation and/or homing [10, 40, 44]. Overall these observations indicate that interactions between MUC18-positive tumor cells and endothelial cells (and activated T-lymphocytes), may play an important role in (cutaneous and uveal) melanoma hematogenous spread and immunoregulation.

In conclusion, we observed variable expression of MUC18 protein in uveal and metastasis-derived melanoma cell lines. In primary mixed and epithelioid tumors, however, the extent and intensity of MUC18 immunostaining was significantly increased compared to spindle cell tumors. These findings suggest that while MUC18 is important for uveal melanoma growth, its expression may not be essential for invasion and metastasis, consistent with findings in other tumors. The role of transcription factors including AP-2a and the signaling pathways involved in regulating MUC18 expression and activity in uveal melanoma remain to be defined. Finally, interactions between MUC18-positive melanoma cells and vasculature, via an as yet unidentified ligand, may be important for the hematogenous spread of tumor cells during metastases.

CASE REPORT

Heterotopic respiratory mucosa in the rectum: A first case report

Kunimitsu Kawahara · Hideyuki Mishima · Shin-ichi Nakamura

Received: 10 May 2007 / Revised: 5 September 2007 / Accepted: 6 September 2007 / Published online: 25 September 2007

Abstract A 50-year-old Japanese woman consulted our hospital complaining of hematochezia. Colonoscopic examination showed Borrmann type 1 rectal carcinoma in the lower rectum, which was later demonstrated to be mucinous adenocarcinoma of Dukes' class A. Along with carcinoma, there was a small sessile polyp with a central depression that mimicked a submucosal tumor. Histologically, the polyp demonstrated tubular structures that coursed from the top of the polypoid surface to the deep submucosa. The tubular structure was 6 mm in length and showed abortive dichotomous branching. It was mainly lined by ciliated pseudostratified columnar to more cuboidal epithelium. Along with the tubular structure, there were bundles of smooth muscle cells and lobules of seromucinous glands. There was no cartilage. The pathological diagnosis was heterotopic respiratory mucosa (HRM) arising in the rectum. To our knowledge, this is the first reported case of HRM in the rectum.

Keywords Heterotopia · Respiratory epithelium · Rectum

Introduction

The term heterotopia (or choristoma) is applied to microscopically normal cells or tissues that are present in abnormal locations [5]. Previous reports have described heterotopic gastric epithelium (HGE) [6, 7, 9], salivary gland tissue [2, 8], and pancreas [4] in the rectum. However, heterotopic respiratory mucosa (HRM) has not been reported in the literature at any site along the gastrointestinal tract including the rectum. In this report, we describe the first case of HRM arising in the rectum and discuss the possible pathogenesis.

Clinical history

A 50-year-old Japanese woman consulted at our hospital complaining of hematochezia persisting for 5 months. There was no significant past history. Regarding family history, the patient's father died of pulmonary cancer. Colonoscopic examination showed that the patient had a Borrmann type 1 tumor and a coexisting small sessile polyp in the lower rectum. The polyp had a smooth surface covered by normal rectal mucosa with a small depressed area at the top (Fig. 1a). There was no apparent erosion or ulcer on the polyp. There were no evidence of inflammation or polyposis of the large intestine. Endoscopic findings suggested that the polyp was a submucosal tumor. Endoscopic biopsies showed that the Borrmann type 1 tumor was histologically adenocarcinoma, but in the polyp sample, there was only a rectum mucosa without pathological changes. Routine laboratory tests, including serum CEA and CA19–9, were within normal limits. Under a tentative diagnosis of coexisting advanced rectal adenocarcinoma and submucosal benign tumor, low anterior

The polyp had a smooth surface covered by normal colonic mucosa with a small depressed area (*arrow*) at the top. **b** Surgically resected specimen showing the Borrmann type 1 carcinoma and a small benign-looking polyp (*arrow*)

resection of the rectum and lymph node dissection were performed. The postoperative course was uneventful, and the patient has remained disease free for 7 years after surgery.

Pathologic findings

Macroscopic findings

Macroscopically, a Borrmann type 1 adenocarcinoma, measuring 3.7×2.9 cm, was observed in the surgically resected rectum. A small polyp measuring 1.2×1.3 cm was located 2 cm from the carcinoma (Fig. 1b).

Microscopic findings

From the mucosal surface to the deep submucosa in the polyp (Fig. 2), there were tubular structures with abortive dichotomous branching (Fig. 3a). The proximal segments of the tubular structures, near the rectal mucosa, were lined by pseudostratified columnar epithelium with ciliated cells. There were no goblet cells (Fig. 3b). Deeper in the rectal submucosa, the lining cells demonstrated a low columnar appearance. Around the distal tubular structures, numerous salivary-type glands containing both serous and mucinous cells appeared to mimic respiratory submucosal seromucinous glands (Fig. 4a, b). Smooth muscle bundles were occasionally recognized around the proximal tubular structures. The transition between the colonic epithelium and ciliated epithelium was abrupt. There was no gastric epithelium present in numerous sections examined. Taken together, the pathological diagnosis was HRM arising in the rectum. The Borrmann type 1 carcinoma was diagnosed as mucinous adenocarcinoma of Dukes' class A type. Colonic mucosa in the background demonstrated a slight elongation of the glands surrounded by a proliferation of smooth muscle fibers from the muscularis mucosae, suggesting mucosal prolapse syndrome.

Immunohistochemical studies

Immunohistochemical studies showed that paratubular seromucinous glands were positive for smooth muscle actin (Dako, Glostrup, Denmark), suggesting a myoepithelial cell component (data not shown). CA19-9 (Zymed, South San

Francisco, CA, USA) and CEA (Dako) were positive in a small number of cells lining a limited area of the tubular structure. TTF-1 (Dako), Chromogranin A (Dako, CA, USA) and NSE (Dako) were negative.

Discussion

"Heterotopia", a term derived from Greek, implies "other place." It refers to the finding of normal tissues in abnormal locations [5]. Heterotopia in the rectum is relatively rare, but HGE [6, 7, 9] and salivary gland heterotopia (SGH) [2, 8] are well known. HGE is more commonly seen. Wolff [9] reviewed 87 cases of HGE throughout the alimentary tract. Through their clinicopathological analysis, they also divided HGE in the alimentary tract into the following three types: (1) developmental errors of positioning from failure of the stomach to descend between the fourth and seventh weeks of gestational life; (2) dysontogenetic error in the differentiation of the fetal entoderm at that site, rather than error of positioning; and (3) abnormal acquired regenerative process after the destruction of pre-existing mucosa. The

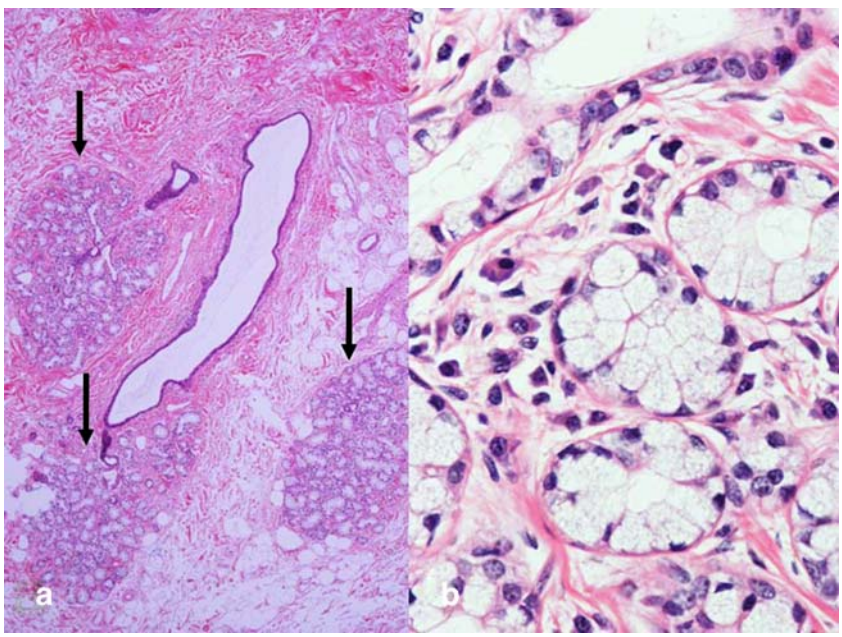

Fig. 4 **a** Lobules of glands (*arrows*) around the distal tubular structure (×40). **b** Lobules composed of seromucinous glands with a duct (×600)

second edition of Gastrointestinal Pathology edited by Cecilia M. Fenoglio-Preiser [3] indicates that: "rectal HGE may coexist with ectopic respiratory epithelium, presumably representing the equivalent of heterotopic foregut" and "gastric heterotopias result from developmental failure of the descent of the foregut, adhesion of ectoderm in the 3- to 4- week-old embryo, a differentiation error of fetal rectal endodermal cells, or proliferation of pleuripotential cells." A unifying concept of foregut heterotopia seems appealing, and the present case could demonstrate one of the expressions in the spectrum of this abnormality. A case of heterotopic pancreas [4] in the rectum was previously described.

Srinivasan et al. [7] reported two HGE cases in the rectum showing a sessile polypoid shape similar to that in our case. In these two cases, there was no endoscopically distinctive feature of HGE as in our case, but endoscopic biopsies of the rectal lesions histologically demonstrated the presence of heterotopic tissue, which differed from our case.

Weitzner [8] first reported a case of SGH in the rectum composed of salivary gland tissue alone. In two previously reported cases of SGH, ectopic gastric mucosa was concomitant [4, 7]. In Weitzner's article, he reported a lesion composed of mixed salivary gland tissue (lobules of serous and mucinous glands and ducts) typically of the submaxillary glands, minor salivary glands, and glands of the respiratory tract. Downs-Kelly et al. [2] reported the fourth case of submucosal SGH in the rectum in a 31-year-old man complaining of rectal bleeding and postulated that SGH may be a form of metaplasia or a developmental abnormality in which undifferentiated stem cells inadvertently migrate to a rectal location and then differentiate into salivary gland tissue. On histology, our case somewhat mimicked SGH arising in the rectum, but the presence of ciliated lining cells was not compatible with SGH [2, 3, 8] because pseudostratified epithelium with ciliated cells is confined to the respiratory tract, which includes nasal mucosa, paranasal sinus, larynx, pharynx, trachea, and bronchus. In the normal salivary gland, the cell surface of the duct system usually contains scattered short microvilli, not cilia.

In the differential pathologic diagnosis, monodermal teratoma (endodermal variant of mature cystic teratoma [1]) was another possibility. Philip et al. first reported a case of endodermal variant of mature cystic teratoma of the ovary [1]. Their ovarian lesion was a multilocular cyst divided by thin fibrous septa without a solid area. The cystic space and occasional smaller gland-like spaces were lined by well-differentiated histologically benign ciliated psuedostratified columnar epithelium with goblet cells, closely resembling normal respiratory epithelium. There was no other teratomatous tissue present. On histology, the lesion in this case was not a teratoma-like cyst or solid mass and lacked goblet cells.

Based on the preoperative endoscopic biopsy specimen in our case, we could not establish a pathological diagnosis of heterotopia because most of the tubular structures were located under the rectal mucosa. Therefore, obtaining an adequate pathologic specimen was very difficult by the standard biopsy sampling method. To establish a final diagnosis, endoscopists should confirm the orifice of the characteristic tubular structure at the depressed area and obtain an adequately deep sample.

In conclusion, to our knowledge, this case of HRM in the rectum arising in a 50-year-old woman is the first such case to be reported. Endoscopists and pathologists should be aware of the rare occurrence of HRM and bear it in mind when considering the differential diagnoses of a submucosal mass in the rectum.

LETTER TO THE EDITOR

A case of nephroblastoma histologically mimicking rhabdomyosarcoma

Junji Takeyama · Mika Watanabe · Atsushi Sato · Yutaka Hayashi

Received: 26 March 2007 / Revised: 12 July 2007 / Accepted: 13 July 2007 / Published online: 14 August 2007

Keywords Rhabdomyosarcoma · Nephroblastoma · Renal tumor

Sir:

We herein report a case of pediatric renal tumor that was difficult to differentiate whether monophasic nephroblastoma or rhabdomyosarcoma (RMS). Although RMS is one of the common malignant tumors in infants and children, RMS of the kidney is extremely rare [2, 3, 5]. There is still controversy as to whether renal RMS is a distinct entity or a variant of nephroblastoma.

A 2-year-old girl presented with a large abdominal mass. Radiological examination showed giant tumor (16×15×11 cm) arising from the left kidney. No distant metastasis was detected. It was clinically diagnosed as nephroblastoma, and left radical nephrectomy was performed. At surgery, the capsule was ruptured and dissemination was suspected. On cut section, the tumor almost occupied the excised kidney and had areas of degeneration, hemorrhage, and necrosis. Histologically, the tumor was composed entirely of sarcomatous elements and contained neither epithelial cells nor structures indicative of blastema (Fig. 1a). Mitotic figures were frequently seen. Anaplastic cells with bizarre nuclei and multipolar mitosis were observed as scattered (Fig. 1b and c). Additionally, atypical rhabdomyoblasts with plump eosinophilic cytoplasm were sporadically found. Cross-striations were not apparent. Many of the tumor cells were immunohistochemically positive for myogenin, MyoD1, desmin, and myoglobin (Fig. 1d). Immunostaining for cytokeratin (AE1/3) was entirely negative. No lymph node metastasis was detected. Ultrastructural, genetic, and molecular examinations were not performed. The patient was treated with chemotherapy using vincristine, actinomycin D and adriamycin, and radiation therapy according to the regimen for nephroblastoma with diffuse anaplasia stage III (according to the National Wilm's Tumor Study). She has no evidence of recurrence 3 years after completion of therapy.

The unique histologic feature of this case was monomorphous proliferation of sarcomatous cells with rhabdomyogenic differentiation. From histological aspects alone, this case was also compatible with embryonal RMS. Although rhabdomyogenesis often occurs in nephroblastoma, predominant proliferation of malignant rhabdomyoblasts is extremely unusual. This case was not compatible with fetal rhabdomyomatous nephroblastoma, as it did not contain the typical triphasic nephroblastoma [4]. Additionally, the histological feature was not reminiscent of fetal rhabdomyomatous tissue. Differential diagnosis includes clear cell sarcoma of the kidney, malignant rhabdoid tumor of the kidney, cellular mesoblastic nephroma, and primary renal synovial sarcoma [1]. They were excluded by the

result of immunohistochemical study showing positive staining for rhabdomyogenic markers. Argani et al. [1] suggest that skeletal muscle differentiation is so sufficiently distinctive as to be a criterion to distinguish nephroblastoma from other primary renal sarcoma.

We diagnosed and treated this case as monophasic nephroblastoma based on the clinical diagnosis and the fact that renal RMS is extremely rare. At present, it remains unclear whether renal RMS in childhood is a distinct entity or in the spectrum of monophasic nephroblastoma. Therefore, there is no criterion for diagnosis and treatment of such cases. The number of reported cases is now limited [2, 3, 5], and further investigations are required to clarify the biological behavior of such renal tumor.

Absence of mismatch repair deficiency in gastric lymphoma: an immunohistochemical study of mlh1 and msh2 protein expression

P. Cuilliere-Dartigues · B. Fabiani · S. Dumont · C. Copie-Bergman · A. Couvelard · T. Molina · A. Duval · J. F. Flejou

Received: 8 June 2007 / Revised: 3 August 2007 / Accepted: 13 August 2007 / Published online: 12 September 2007

Sir,

A subset of cancers exhibit ubiquitous microsatellite instability (MSI-H) due to mismatch repair deficiency (MMR). These tumors are characterized by improved survival and a better prognosis. Because MLH1 or MSH2 knock-out mice, i.e. the two main MMR genes, often develop lymphoid neoplasms [3], several groups have looked for the presence of MSI in human non-Hodgkin lymphomas (NHL), retrieving contradictory results. Gastric mucosa-associated lymphoid tissue (MALT) lymphomas run an indolent course, but transformation to diffuse large B-cell lymphoma (DLBCL) is responsible for decreasing 10-year survival rate from 90 to 45%. In such a subset of NHL, contradictory results concerning the prevalence of MSI have been reported so far in studies based on molecular testing of these tumors with nonconsensual markers for MSI analysis and biological materials deriving from either frozen or paraffin embedded tissue. International criteria have now been established for MSI testing, saying that it can be detected using a PCR-based molecular assay or by immunohistochemistry (IHC) of MLH1 and MSH2 MMR proteins. To evaluate the contribution of MSI in gastric lymphomagenesis, we thus analyzed MLH1 and MSH2 protein expression by IHC in a retrospective series of 122 MALT NHL and 51 DLBCL. Cases originated from the pathology files of Beaujon, Henri Mondor, Hôtel Dieu, and Saint Antoine hospitals, and from a variety of private laboratories. IHC assay was processed on 48 formalin, 78 Bouin, and 47 Acetic Acid/Formalin/Alcohol (AFA)-fixed specimens, on 162 freshly cut slides from paraffin-embedded tissue and on stored unstained slides that were only available in 11 cases. Immunohistochemical labelling was performed as described [4] with mouse antihuman monoclonal antibodies to MLH1, MSH2, and Ki67. Complete absence of nuclear expression in tumor cells for one MMR protein was considered indicative of an MMR defect. 85 cases were excluded because of absent nuclear signal in tumor and normal cells, related to fixation (100% inconclusive cases with AFA and near 50% with Bouin), and to prolonged slide storage. Using this approach, we failed to find out loss of MMR protein expression in the 88 cases tested (58 MALT NHL and 30 DLBCLs). Of interest, MMR staining was weak and heterogeneous in MALT lymphomas, showing the same intensity in tumor cells compared to internal control cells (Fig. 1), whereas strong nuclear signal with a widespread immunostaining of more than >80% of positive tumor cells was observed in DLBCLs (Fig. 2). Generally, MMR protein expression paralleled the proliferation rate assessed by Ki67 IHC.

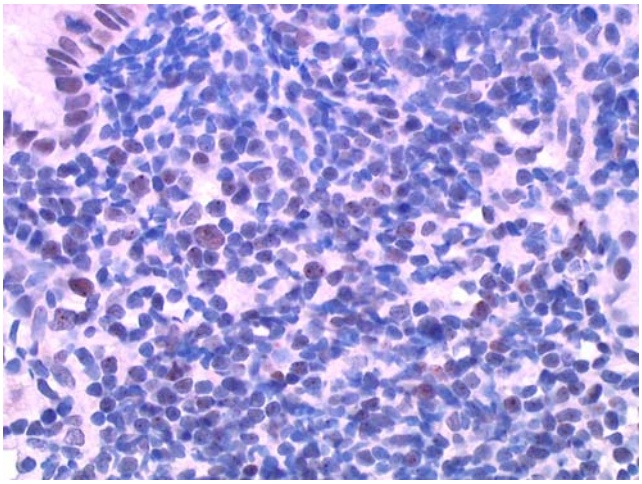

Fig. 1 Expression of MLH1 protein: low and heterogenous nuclear staining in gastric low-grade marginal-zone B-cell lymphoma of MALT-type (×40)

Although IHC has been validated as an accurate technique to identify MMR deficient tumors, MMR protein expression in gastric MALT lymphomas has never been reported. Retained expression of MLH1 and MSH2 has been observed in 31 cases of gastric DLBCLs, which showed a strong nuclear expression of both proteins that parallels the proliferation rate, as reported here [5]. As also reported previously, some technical factors may affect the assessment of IHC, e.g., slide storage (which alters antigenicity), fixative type (which was responsible for 85 inconclusive cases in our study). These technical limits have to be considered when using IHC as a diagnostic test for MSI in unselected series of tumors, as already shown in other tumor subtypes [1].

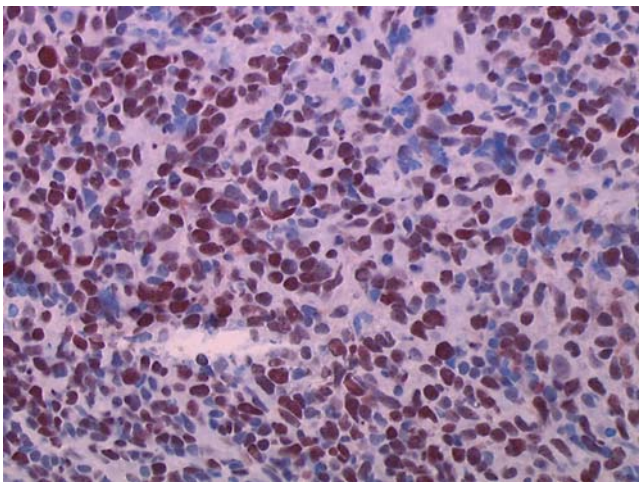

Fig. 2 Expression of MLH1 protein: strong and widespread positivity in a gastric diffuse large B-cell lymphoma (×40)

Consequences of the DNA mismatch repair inactivation pathway is not well established in lymphomagenesis. Our study supports previous reports about the minor role of defects in DNA mismatch repair mechanism in the pathogenesis of gastric MALT lymphoma. It appears, therefore, that MSI only plays a role in NHL occurring in immunodeficient patients, i.e., posttransplant lymphoproliferative disorders and HIV-related NHL, as demonstrated by our group [2].

LETTER TO THE EDITOR

Early pulmonary manifestations of yellow nail syndrome: a case report

Sarah Liptrot · Geoffrey Hulks · Fiona Roberts

Received: 27 June 2007 / Revised: 3 August 2007 / Accepted: 16 August 2007 / Published online: 6 September 2007

Dear Editor,

Bronchiectasis with lymphatic obstruction and pleural effusions are well recognised pulmonary manifestations of the yellow nail syndrome. We describe bronchiectasis associated with markedly dilated lymphatic channels in an open lung biopsy from a patient with onycholysis and yellow discoloration of the nails. Although pleural effusions were absent in this patient, we propose that these changes represent the early pulmonary manifestations of yellow nail syndrome.

This 47-year-old man presented with recurrent chest infections and at least a 2-year history of recurrent cough productive of green sputum. His symptoms transiently responded to antibiotics but recurred soon thereafter. He also admitted to mild exertional dyspnoea. Two months before his presentation to the Chest Clinic, a heavy growth of *Pseudomonas aeruginosa* had been isolated from his sputum, and thereafter, his symptoms improved after a course of high dose oral Ciprofloxacin. He admitted to 5-kg weight loss in the previous year, which had since stabilized. The main symptom bothering the patient at the time of presentation was a yellow/green discoloration of his finger and toe nails that were growing very poorly, indeed one thumb and toe nail had come off in whole pieces.

The patient was a lifelong non-smoker with no history of childhood chest disease. He had been investigated for halitosis in 1995 and when he was thought to have a low grade sinusitis. There was no relevant family history or occupational history.

G. Hulks
Respiratory Medicine, Raigmore Hospital,
Inverness, UK

On examination, all his finger and toe nails were abnormal with a yellowish discoloration, onycholysis and nail thickening (Fig. 1a). There was an increased curvature along their long axis and loss of cuticles. He was slightly built with a body mass index of 19.9. His chest was clear to auscultation, and physical examination was otherwise unremarkable. Spirometry demonstrated a forced expiratory volume in 1 s/forced vital capacity of 2.95:4.15 l (predicted 3.70:4.54). Routine biochemistry, haematology and CRP were normal. Serum immunoglobulins were within normal limits and electrophoresis negative. Aspergillus and micropolyspora precipitins were negative. Nail slicings taken for mycological examination were negative.

His initial computed tomography scan showed some peripheral consolidation in the right middle lobe and lingula and also the left base with some small patchy areas of air space consolidation throughout both lungs (Fig. 1b). Interlobular septal thickening was also noted. The appearances were not considered to be specific but were consistent with infective or inflammatory change.

Video-assisted thoracoscopic biopsy was taken from the right middle lobe and left lower lobes. Histology showed bronchiectasis and organising pneumonia most prominent in the lower lobe biopsy (Fig. 1c). In addition, markedly dilated lymphatics filled with fluid were identified in the interlobular septa and visceral pleura (Fig. 1d). These were considerably more marked than those associated with inflammatory conditions such as bronchopneumonia particularly in the middle lobe where the inflammatory changes were minimal. After discussion, it was considered that these findings in conjunction with the abnormal nails would be consistent with the early pulmonary manifestations of yellow nail syndrome.

The yellow nail syndrome is a relatively rare disorder usually occurring in middle-aged patients and characterized by yellowish, deformed nails, peripheral lymphoedema and recurrent pleural effusions [3, 6]. In addition, a significant number of patients also have sinusitis, bronchiectasis and

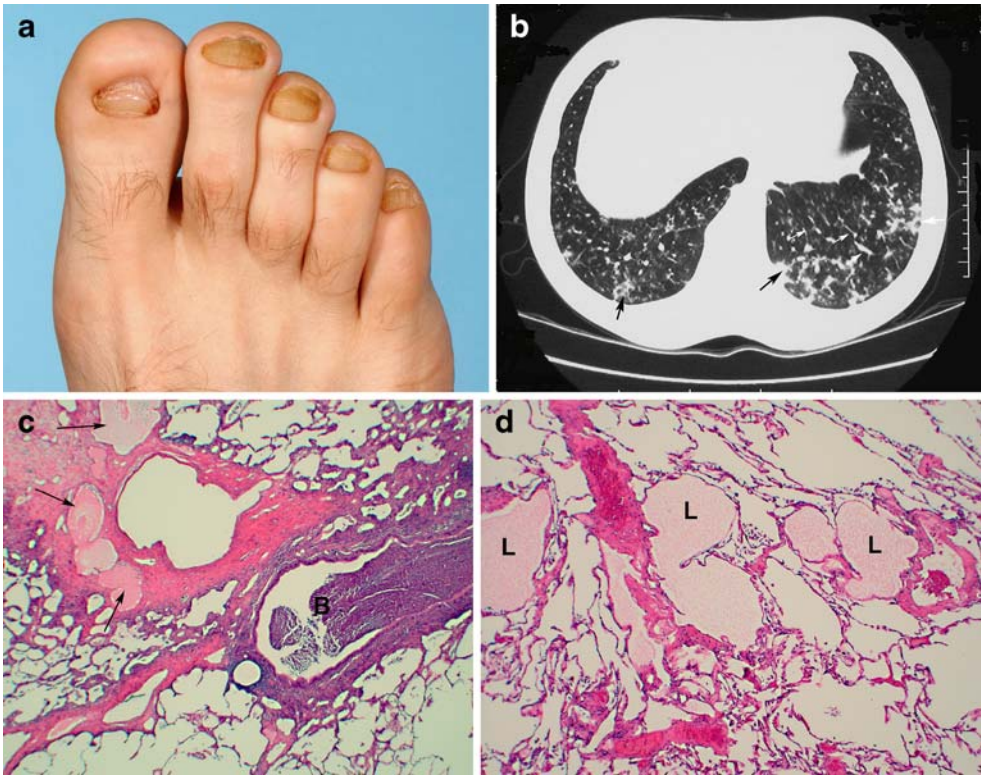

Fig. 1 **a** Discoloration, dystrophy and onycholysis of nails. **b** High resolution computed tomography of chest showing patchy air space consolidation (*black arrows*) and prominent vascular structures (*white arrows*). **c** Histological section of open lung biopsy from the lower lobe showing an ectactic bronchiole (**b**) filled with pus. In the adjacent septa, there are dilated lymphatics (*arrows*) containing eosinophilic fluid. (H&E, ×40 magnification). **d** Histological section of open lung biopsy from the middle lobe showing dilated lymphatics (L) without associated bronchiectasis. (H&E ×40 magnification)

lower respiratory tract infections. The underlying defect in yellow nail syndrome is unclear. Lymphangiography has shown hypoplastic lymphatics in some but not all sufferers [6]. Furthermore, dilated lymphatics have been described in subpleural tissues and small intestines [2, 4, 5]. Lymphoscintigraphy, however, supports a functional rather than an anatomical lymphatic defect [1].

The pulmonary pathology of yellow nail syndrome is not well described with only occasional case reports in the literature. Edwards et al. [2] described one case of yellow nail syndrome where there were characteristic dilated subpleural lymphatics in addition to inflamed bronchioles. Sacco et al. [5] reported the presence of dilated lymphatic channels in the subpleural tissue in association with cystic lung disease with changes of airway obstruction and ongoing inflammation. These latter authors postulated that respiratory infections may damage a previously inadequate lymphatic drainage and result in persistent pleural effusions. In our case, dilated lymphatics were evident both in areas with evidence of bronchiectasis and ongoing infection but also in the middle lobe where inflammation was minimal. The lack of inflammation in the middle lobe biopsy in our case lends support to this theory that there is a pre-existing lymphatic abnormality, which presumably predisposes to recurrent infection and bronchiectasis. Damage from recurrent inflammation may explain the later appearance of pleural effusions in some cases [3, 6].

The treatment of yellow nail syndrome remains largely symptomatic. Currently, our patient's clinical condition is stable, and although he continues to expectorate a little tenacious mucoid phlegm, the overall quantity has decreased and no further pathogens have been isolated from his sputum. The discoloration of his nails appears less, but their morphology remains very abnormal.

Acknowledgements We are grateful to Professor Andrew Nicolson, Brompton Hospital, London for his comments on the pathology of this case.

REVIEW AND PERSPECTIVE

Pseudoneoplastic lesions of the testis and paratesticular structures

F. Algaba · G. Mikuz · L. Boccon-Gibod · I. Trias · Y. Arce · R. Montironi · L. Egevad · M. Scarpelli · A. Lopez-Beltran

Received: 3 July 2007 / Revised: 31 July 2007 / Accepted: 15 August 2007 / Published online: 6 September 2007

Abstract Pseudotumors or tumor-like proliferations (non-neoplastic masses) and benign mimickers (non-neoplastic cellular proliferations) are rare in the testis and paratesticular structures. Clinically, these lesions (cysts, ectopic tissues, and vascular, inflammatory, or hyperplastic lesions) are of great interest for the reason that, because of the topography, they may be relevant as differential diagnoses. The purpose of this paper is to present an overview of the pseudoneoplasic entities arising in the testis and paratesticular structures; emphasis is placed on how the practicing pathologist may distinguish benign mimickers and pseudotumors from true neoplasia. These lesions can be classified as macroscopic or microscopic mimickers of neoplasia.

Keywords Testis · Paratesticular structures · Pseudotumor · Tumor-like · Benign mimics

Introduction

There are many lesions that can simulate a neoplasm in the testis or paratesticular structures. Their incidence among tumors arising within the scrotal sac varies according to different series from 6 to 30% [16, 32]. These pseudoneoplastic lesions can be divided into those that only macroscopically imitate neoplasia (Table 1) and those that microscopically imitate neoplasia, regardless of whether they form a macroscopic mass (Table 2). The latter group causes more problems to the practicing pathologist in terms of the correct classification of a giving lesion. Hereby, we summarize main tumor-like lesions and benign mimickers that may be seen in the testis and paratesticular coverages, with emphasis on morphologic criteria for the differential diagnosis from true neoplasia.

This publication is made under the auspices of the Uropathology Working Group (European Society of Pathology, ESP).

Amyloidosis
Polyorchididm
Sclerosing lipogranuloma

Macroscopic mimickers (pseudotumors) of testicular and paratesticular neoplasia

This group of lesions refers to those that macroscopically imitate a neoplasia. Frequently, these lesions affect both compartments and are therefore difficult to establish if one or both are affected. For this reason, we classify the tumor-like lesions according to their etiology.

Vascular lesions

The majority of the vascular disorders of the male gonad are not confused with a tumor because, in addition to causing acute symptoms, they usually affect the entire gonad. However, in the rare situation in which the vascular lesion is segmental, it can simulate neoplasia, as follows:

1. Intratesticular hemorrhage, which occurs spontaneously [24] or in the context of anticoagulation treatment [15], may simulate a tumor at ultrasound examination.
2. Segmental testicular infarction, a lesion clinically characterized by slight local pain unrelated to any acute episode [20], may be related to isolated or systemic vasculitis [43, 103] with morphology of polyarteritis nodosa [21], giant cell vasculitis [94], or Wegener granulomatosis [45]. Up to year 2000, 81 cases of systemic vasculitis with testicular tumor-like lesion have been recorded [45]. Other cases are seen in the context of a hematological disease (sickle cell anemia) [53] or associated with nonspecific perivascular fibrosis. Any of the phases of an infarction can be observed from acute (with hemorrhage) to healing stage (Fig. 1). Currently, the clinical diagnosis can be suspected with Doppler sonography [81], avoiding orchiectomy.
3. Organized testicular hematocele and other hemorrhages in the tunica vaginalis are rarely confused with a neoplasia [89], but this can happen occasionally in long-standing cases because of fibrous thickening with cholesterol granuloma formation in the tunica vaginalis (Fig. 2) [61] Exceptionally, a true testicular neoplasia presents clinically with a hematocele [86].

Inflammatory lesions

Similar to what was stated for vascular tumor-like lesions, inflammation that simulates a neoplasia usually has atypical clinical features; these entities can be grouped as follows:

1. Nonspecific infectious inflammatory lesions with a tumor-like presentation are frequently chronic processes causing

Table 2 Microscopic mimickers of testicular and paratesticular neoplasia

Testicular
Inflammatory-reactive lesions
Lymphocitic orchitis (Testicular pseudolymphoma)
Rosai-Dorfman disease
Sertoli cell hyperplasia

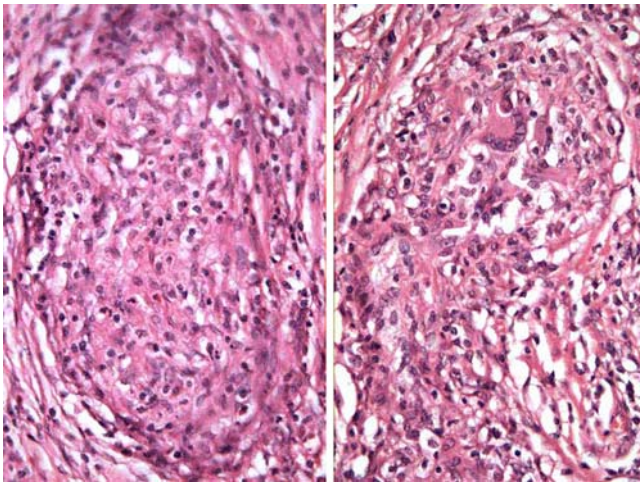

Fig. 3 Idiopathic granulomatous orchitis characterized by tubular granulomas (tubular orchitis)

progressive fibrosis, which may clinically [38] or sonographicaly [23] simulate neoplasia. Rarely a testicular, epididymal, or vas deferens abscess can look like a neoplasia [84]. Very occasionally, testicular neoplasia can clinically imitate an acute inflammatory process [44].

2. Specific infectious inflammatory lesions. The entities of this group that most often have been confused with neoplasias are granulomatous inflammation in tuberculosis [87], brucellosis [49], syphillis [5], fungal infections [42], and parasite diseases [9]. These lesions are usually not problematic for the pathologist.
3. Noninfectious inflammatory lesions. This group of tumor-like lesions include different entities among which can be highlighted:

(a) Idiopathic granulomatous orchitis, probably of autoimmune aetiology, of which around 230 cases have been published [4], is characterized by tubular granulomas (tubular orchitis; Fig. 3) or interstitial granulomas (interstitial orchitis). The presence of intratubular giant cells differentiate this entity from infectious granulomatous orchitis [70]. Diffuse testicular hypoechoic involvement with only peripheral low-resistance flow on color Doppler sonography is a typical but not pathognomonic pattern [72].

(b) Malakoplakia. This lesion is secondary to a mononuclear decrease in cyclin–guanine monophosphate that impairs the killing of bacteria. Fusion of the phagolysosomes with bacterial rests produces the characteristic Michaelis–Gutman bodies in the cytoplasm of the macrophages (von Hansemann cells) [1] (Fig. 4). Giant cells are occasional or absent. Testicular involvement represents only 12% of genital malakoplakia with around 388 cases in the literature [19, 56]; exceptionally, it may affect the epididymis only [31]. It has been related to idiopathic granulomatous orchitis [56, 57] and chronic xantogranulomatous inflamma-

tion of testis [85, 109, 110]; this last also reported in the spermatic cord [64, 100].

(c) Sarcoidosis. Testicular involvement in a systemic sarcoidosis [39] is exceedingly rare, and its presentation as the primary form is even rarer; in these cases, the epididymis is affected more with the testicle being involved by contiguity [83].

4. Meconium periorchitis. This is an infrequent lesion (around 30 cases being reported) that typically presents in the first months of life; most times there is a clinical history with obstetric problem that has caused the passing of meconium toward the testicular surrounding structures [29]. The macroscopic appearance is a myxoid material with calcified pearls resulting from the calcification of the remains of squamous cells or lanugo hairs [107] (Fig. 5). Suspicion of neoplasia, although very uncommon in this period of life, may be caused by a scrotal mass or sonographically detectable calcifications [6]. Clinically, the peritesticular and spermatic cord enlargement can simulate a paratesticular rhabdomyosarcoma.
5. Sperm granuloma. As its name indicates, this granulomatous lesion with few giant cells is the consequence of extravasation of spermatozoa generally postvasectomy (40% of vasectomized men and 2.5% of general population) [108]. When it produces a tumor-like lesion, it is usually located in the deferent duct or the epididymis [22] with firm nodules of 0.7 to 4 cm with occasional cysts formation.

Cysts

The majority of the cysts with a tumor-like appearance are paratesticular structures, but the testicle may occasionally have some cystic lesions that can be confused with a neoplasia.

1. Testicular cysts occur in approximately 8–10% of patients with a lump in the testis, including those of the tunica albuginea or the parenchyma [33].

(a) Tunica albuginea cysts do not usually cause any diagnostic problem, unless if they are complex cysts [74].

(b) Parenchyma testicular cysts can be more difficult to distinguish from a neoplasia and if there is the slightest suspicion of an intracystic content, one must suspect a malignant neoplasia [107]. Special consideration deserves the testicular Epidermoid cyst, which must only be lined with squamous epithelium (Fig. 6). It is recommended that the specimen is examined "in toto" to avoid underdiagnosis of any area of teratoma (especially among postpuberal patients) or intratubular germ cell neoplasia, as sonographically it is not possible to distinguish between these lesions [54, 106]. Epidermoid cysts represent 1% of the masses of the testes. Recent genetic studies have shown that there is no chromosome 12p abnormality [14], thus supporting its distinction from teratoma.

(c) Tubular ectasia of the rete testis secondary to obstruction and generally located in the mediastinum area of the testes (Fig. 7) [69], is usually bilateral and very different from cystic dysplasia of the rete testis, a congenital lesion with complete testicular parenchyma substitution [68].

2. Epididymal cysts and spermatoceles are relatively frequent and the majority are in relation to the inflammatory processes. The differential diagnosis with other entities are related to its size, and similar to the other cystic formations a true neoplasia must be considered in case of observing any content in its interior [108].

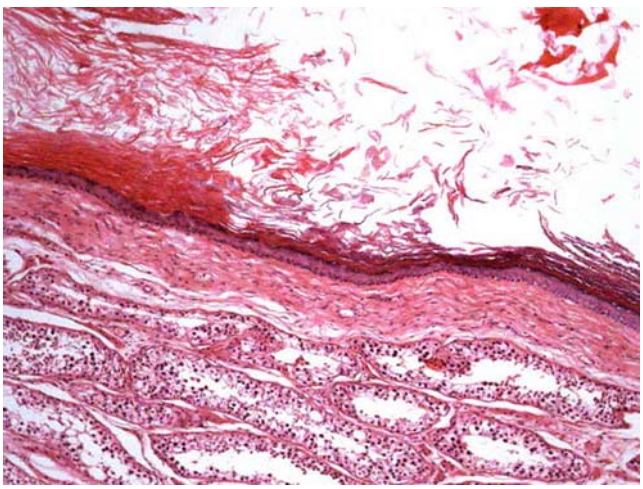

Fig. 6 Epidermoid cyst, which must only be lined with squamous cell epithelium (H&E)

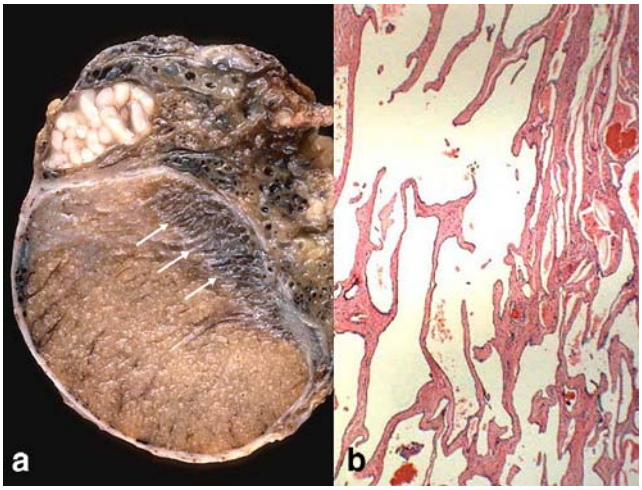

Fig. 7 **a** Tubular ectasia of the rete testis located in the mediastinum area of the testes (*arrows*). **b** Microscopic aspect (H&E)

3. Spermatic cord cysts. The majority of these cysts do not cause any diagnostic doubts, only the occasional Epidermoid cysts [46, 105] can simulate a neoplasia. These cysts can be unilocular or multilocular depending on their origin [65], and the multilocular must be distinguished from the exceptional cystadenomas of probably Müllerian origin [55].

Ectopic tissues

1. Ectopic adrenocortical tissue is relatively frequent in the tunica albuginea, rete testis, epididymis, and spermatic cord and occasionally reaches the size to be symptomatic. Its incidence ranges from 2.5 to 15% [17, 102]. It is made up of adrenal cortical nodes surrounded by a connective tissue band and of about 5 mm in diameter on average (Fig. 8); for which reason, they are not clinically palpable. Only in cases of congenital adrenal hyperplasia or Cushing syndrome, ectopic adrenocortical tissue can be prominent and appear as a tumor-like lesion [90].
2. Splenic–gonadal fusion, as its name indicates, is the fusion of spleen and gonad. It is more frequent on the left side, with about 148 published cases [41]. Morphologically, the ectopic splenic tissue can be in close relation to the head of the epididymis or the upper pole of the testis (Fig. 9) or being separated from it; likewise, there may or may not be a structural continuity between the normal spleen and the ectopic tissue [30]. The same alteration has been described in women, but it is much less frequent that in men, probably because it is much easier to find it clinically in men. In about 30% of the cases, it is associated with complex malformations such as micrognathia, peromelia, or phocomelia (absence of upper portion of a limb) [30, 60, 95]. In three of the reported cases, the fusion was associated with a germ cell tumor of the testis [41].
3. An exceptional hepato-gonadal fusion is reported [26].

Testicular appendages

There are five testicular appendages, but for the surgical pathologist, only three can be of interest (appendix testis or hydatid of Morgagni, appendix epididymis, paradidymis or organ of Giraldes; Fig. 10). These structures are not usually the origin of a tumor-like lesion, but in rare cases of large-sized cysts, it may presents as a paratesticular mass [93]. A case of ectopic epididymal tissue in an appendix testis [101] has recently been reported.

Miscellaneous other lesions

1. Fibrous pseudotumors. This name refers to a fibrosis phenomenon with paucicellular hyalinized collagen (Fig. 11) presenting as nodular (single or multiple) or diffuse lesion of the testicular tunics [96, 71]. Sometimes, a node can be free (scrotal mouse) [108]. This broadly considered spectrum of lesions has received diverse names: chronic periorchitis, fibromatous periorchitis, nodular periorchitis, fibrous proliferation of the tunica, nonspecific paratesticular fibrosis, granulomatous periorchitis, nodular fibrous pseudotumor, fibrous pseudotumor, inflammatory pseudotumor, fibroma, reactive periorchitis [108], indicating its controversial pathogenesis. Some cases have been reported preceded by trauma or infection, and on occasion, an inflammatory component can be observed and granulation tissue suggesting the possibility that there might be the healing of an inflammatory pseudotumor, (which will be described later on) [10]. Although radiologically, it is not difficult to recognize, upon occasion, an intraoperative frozen section becomes necessary.
2. Amyloidosis. It is usually bilateral and present in a patient with a prior history of amyloidosis [34]; more rarely, it is a primary form that by being a cryptorquidic patient simulates a testicular tumor [13].
3. Polyorchidism or supernumerary testes is a rare condition, which is easy to recognize. However, the sonography can occasionally be different from that of the normal testis, and the condition may then be tumor suspicious [79].

Microscopic mimickers of testicular and paratesticular neoplasia

Lesions or cellular changes that microscopically imitate a neoplasia are included under this category, whether or not they make a clinical mass. These changes are closely related to the structure of the organ in which they arises, as follows.

Testicular

Inflammatory-reactive lesions Some lesion, already described above such as xantogranulomatous orchitis, idiopathic granulomatous orchitis and malakoplakia could be considered under this category; their microscopic confusion with a neoplasia (seminoma for example) is not currently a usual event; therefore, we preferred to include them in the macroscopic mimickers (pseudotumors).

The situation is different with lymphocitic orchitis or testicular pseudolymphoma [2, 3], which is characterized by a lymphocytic and plasmocellular reaction that may be

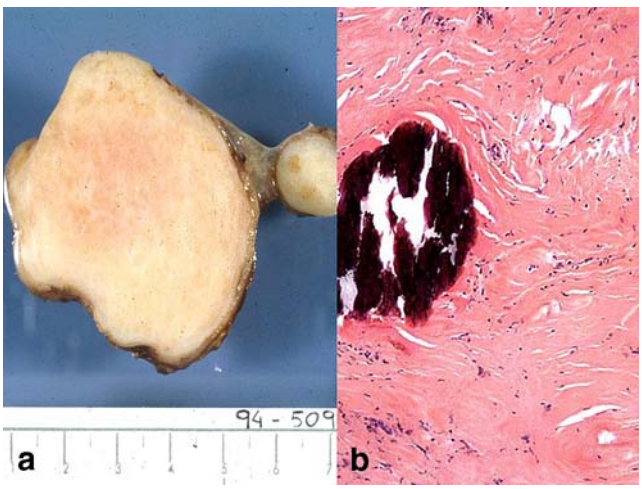

Fig. 11 Fibrous pseudotumor. **a** Well outlined fibrous-like nodule. **b** Paucicellular hyalinized collagen with calcification

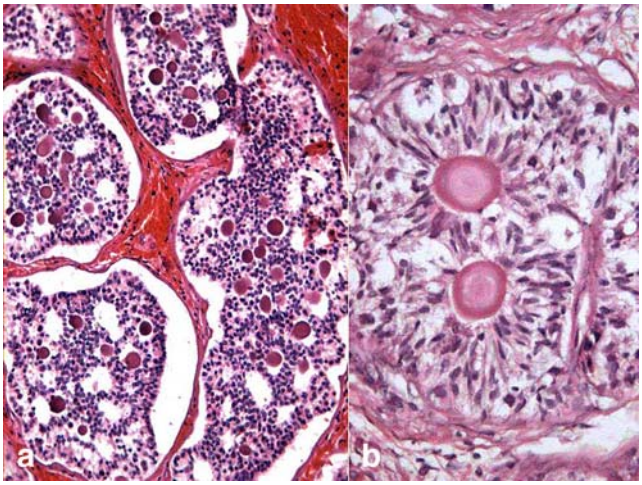

Fig. 13 Sertoli cell hyperplasia. **a** Nonencapsulated nodules of Sertoli cells (Pick's adenoma). **b** Sometimes there are areas that mimic Call–Exner bodies

confused with a lymphoma, but immunohistochemistry will show that the cellular infiltrate is polyclonal (Fig. 12). Among these idiopathic lesions, we can include Rosai–Dorfman disease; histological examination of the testicular mass reveals an inflammatory lesion comprising lymphocytes, plasma cells, and sheets of pale staining histiocytes, some containing lymphocytes within their ample cytoplasm, suggestive of emperipolesis. The histiocytes stained positive for CD68, S100 by immunohistochemistry and negative for CD1a, while ultrastructural examination confirmed emperipolesis [25].

Sertoli cell hyperplasia In a series of situations, nonencapsulated nodules of Sertoli cells can be found, especially known in cryptorchid testes as Pick's adenomas (Fig. 13a) [77]. Because of their appearance, these should be distinguished from the actual Sertoli cell tumors that generally are larger and sometimes there are areas that mimic Call–Exner bodies (Fig. 13b) A differential diagnosis with a yolk-sac tumor is not usually in the scope, but the immunohistochemistry study with AFP, calretinin, α-inhibin, and CD 99 can help [40].

A special consideration merit the androgen insensitivity syndrome or testicular feminization (male pseudohermaphrodism, caused by a failure of androgen receptor binding) that in 63% of cases can have tubular hamartomas (tubules lined by immature Sertoli cells) [82] that must be differentiated from the Sertoli cell adenomas and sex cord tumor with annular tubules [76].

Interstitial cell hyperplasia In testicles with marked tubular atrophy, such as in the Klinefelter's syndrome, it is possible to see Leydig cell nodules that must be distinguished from Leydig cell tumors. An interstitial growth without expansive pattern favors hyperplasia (Fig. 14) [62].

Nodules of eosinophilic cells appearing to be Leydig cells are found in the patients with adrenogenital syndrome [18, 48] and Nelson's syndrome (adrenocorticotropic hormone-secreting pituitary adenoma after bilateral adrenalectomy), some of this last syndrome with excessive testosterone production [91]; proof that these interstitials cells are not only morphologically similar to Leydig cells but also have the functional property of these cells. These nodules are usually bilateral and of a large size with cellular pleomorphism and pigmentation. The clinical history and a complete endocrinological profile avoid an unnecessary orchiectomy [78] because only one case of aggressive behavior is published [18].

Hyperplasia of the rete testis The normal rete testis epithelium is flat, but in some hyperestrogenic situations (treatment or hepatic dysfunction), the epithelium may become columnar and rarely a micropapillary growth of bland cells can be observed. The diagnosis of rete testis hyperplasia is subjective, and adenomatous lesions are rarely seen [35, 63]. In some cases, there are intracytoplasmic hyaline eosinophilic globules resembling a yolk sac tumor, but the negative stains of α-fetoprotein or placental alkaline phosphatase help to rule this differential diagnosis [99].

Pseudohyperplasia of the rete testis and epithelial reaction in case of germ cell invasion and cryptorchidism must be differentiated from real hyperplasia of the rete testis [62].

Epididymis

Benign microscopic mimickers of cancer in the epididymis are very rare. Cysts may occur but do not resemble tumors microscopically. However, some cases of adenomatoid hyperplasia of the rete testis can involve the epididymis, and occasionally, they may become macroscopically apparent [93].

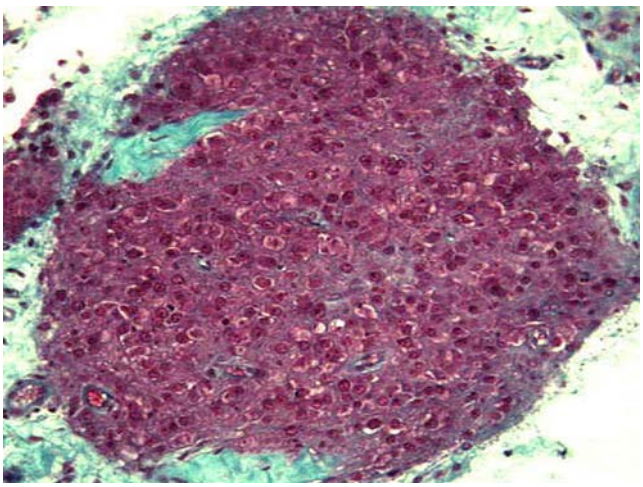

Fig. 14 Leydig cell hyperplasia

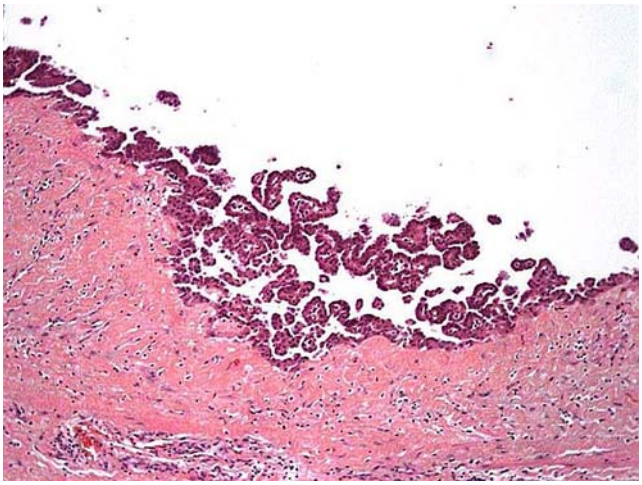

Fig. 15 Mesothelial hyperplasia. The bland nucleus, no true invasion and associated inflammatory elements, can be useful to distinguish from malignant mesothelioma

Tunica albuginea and vaginalis

Non-neoplastic mesothelial lesions involving the paratesticular region include mesothelial cysts and reactive mesothelial hyperplasia [73].

Mesothelial hyperplasia is the most important benign mimicker of the testicular tunics. It is present as a reactive lesion in hydrocele or hernia but may also be found microscopically in older men [80]. The mesothelial proliferation has an epithelial appearance, and rarely, a spindle cell proliferation can be present. In the differential diagnosis with mesothelioma, the bland nucleus, no true invasion, and associated inflammatory elements can be useful (Fig. 15) [11, 98]. Recently, a case was published with "atypical" mesothelial hyperplasia on one side and "well differentiated" mesothelioma on the contalateral [97]. This case is an example of the subjective interpretation of some mesothelial proliferative lesions because some malignant mesotheliomas lack cellular atypia. In these cases, an extensive confluence or prominent infiltration favors a malignant diagnosis. Unfortunately, the immunohistochemical expression of benign and malignant mesothelial proliferations are similar (low- and high-molecular-weight cytokeratins and vimentin) [11, 28], and only the metastatic neoplasias can be differentiated by the CEA, Ber-EP4, and B72.3 expression [27]. Only deoxyribonucleic acid ploidy can distinguish some borderline lesions [28].

Spermatic cord

The vas deferens and the soft tissues of spermatic cord can have benign mimickers.

1. Vasitis nodosa is a ductular proliferation, generally after vasectomy [36], although it can be seen following other trauma on that area, [75]. It has a microglandular morphology (Fig. 16) with mild nuclear atipia and perineural growth [7] or benign vascular invasion [8] that may be mistaken for malignancy [104]. The frequent hyperplasia of nerve fibers in the adventitia can explain the painful symptoms in some patients [36]. The coincidence with microscopic sperm granulomas and inflammatory reaction can help in the correct diagnosis. An analogous epididymal lesion also occur [88].
2. Proliferative funiculitis is the inflammation of the spermatic cord usually the result of an extension of vasitis. The soft tissues of the spermatic cord are also the most common site of an inflammatory pseudotumor in the male genital tract [37, 50, 58]. The lesion is ill defined, myxoid with white-gray color, and a moderate cellular proliferation with loose collagen fibers and irregular infiltration of inflammatory cells. An exceptional case has been reported that was largely infiltrated by mast cells [92]. In some cases, a prominent spindle cell proliferation mimics a sarcoma (pseudosarcomatous myofibroblastic proliferation), but low mitotic index, a capillary pattern, inflammatory cells, and absence of atypical mitoses speak against a diagnosis of sarcoma. Unfortunately, immunohistochemistry is only partly helpful because the cells express actin and vimentin, less strongly desmin and exceptionally cytokeratin. Two cases of this lesion in epididymis [12, 51] and one in the rete testis [47] have been reported.

Embryonic remnants

Although ectopic tissue usually is more problematic for constituting a mass, some of them can cause microscopic diagnostic doubts for which reason they can be included in

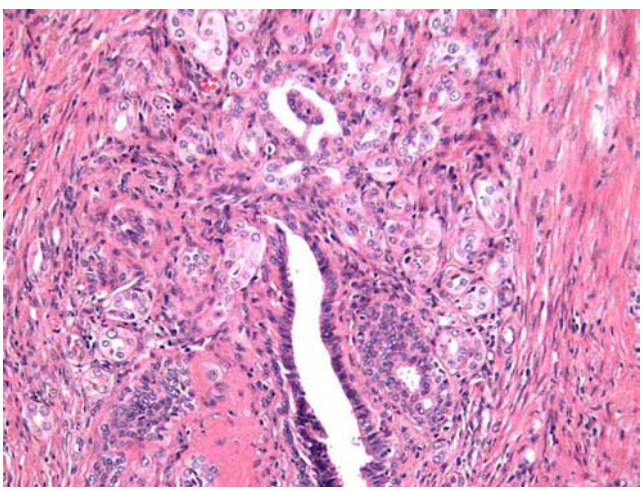

Fig. 16 Vasitis nodosa. Ductular proliferation with a microglandular morphology

this group of benign mimics. The presence of seminiferous tubules within the tunica albuginea [67], Leydig cells in rete testis, albuginea, spermatic cord, or within sclerotic tubules [59, 66], prostate gland in the epididymis [52], and special circumstances with muscular rete testis hypertrophy [27] can mimic a neoplasia.

The lesions described constitute a large heterogeneous group, without etiological or pathogenic relations among them or with true neoplasias. However, in spite of that, the patient with one or more of these tumor-like and/or benign mimickers can have a concomitant or ulterior true neoplasm.

Abstract Ezrin is a cytoskeleton linker protein that is actively involved in the metastatic process of cancer cells. We have searched for a prognostic value of ezrin and some of its partners: α-smooth muscle actin and CD44H in 37 patients with an osteosarcoma. Automate immunohistochemistry (IHC) with anti-ezrin, α-smooth muscle actin and CD44H antibodies was performed in 66 specimens: 37 biopsies before chemotherapy, 16 resected tumours of "poor" responders and 13 metastases. The messenger RNA (mRNA) levels of ezrin of 13 frozen biopsies and 4 metastases were evaluated by real-time quantitative reverse transcriptase polymerase chain reaction (RT-PCR). All results were correlated to the following clinical data. Ezrin expression by IHC was found in 62% of 37 biopsies in the different histological subtypes. A good correlation was found between positive or negative samples by IHC and mRNA levels. Ezrin expression was recorded in 84.5% of metastastic samples. The mean expression of ezrin was higher in metastases than biopsies ($p=0.024$). In multivariate analysis, ezrin was an independent prognostic marker for event-free survival and overall survival (OS) with $p<0.001$ and $p=0.003$, respectively, and α-smooth muscle actin for OS only ($p=0.024$). Our findings suggest that ezrin and α-smooth muscle actin are predictive IHC prognostic markers for patients with an osteosarcoma.

Introduction

Prognosis of patients with an osteosarcoma has improved during the last two decades with the use of multiagent adjuvant chemotherapy leading to a 5 years disease-free survival of nearly 70% [20, 24]. One of the most powerful prognostic factors in osteosarcoma is the histological response to preoperative chemotherapy evaluated on the resected specimen after surgery [29, 31, 32]. No clinical, pathological or molecular parameter is predictive of the response to chemotherapy. In addition, the use of more intensive preoperative chemotherapy has increased the percentage of patients with good histological response but has not improved outcome, as the event-free survival rate has not changed. At the time of diagnosis, the most important prognostic factor is the presence or absence of metastasis [23]. About 20% of patients present with a metastatic disease and have an extremely poor prognosis with a long-term event-free survival of usually less than 10% [2, 9]. In the group of patients with localised disease, few prognostic factors have been reported such as age of onset of the disease, sex, location and size of tumour [3, 36]. To date, no genetic or molecular prognostic factor can be routinely used to stratify patients into high risk or low risk of metastasis. The finding of novel molecules variably expressed among osteosarcomas cells might provide insight into the mechanisms of tumour progression and could serve to identify tumours with more or less aggressive behavior.

Recently, overexpression of ezrin protein has been correlated to the metastatic potential of several cancers [11, 12, 41]. Ezrin belongs to the ezrin/radixin/moesin (ERM) protein family, which act as membrane organizers and linkers between plasma membrane and cytoskeleton [21]. ERM proteins occur in the cytoplasm in an inactive closed conformation with N- to C-terminal associations within the protein or with the other ERM members. Upon threonine and tyrosine phosphorylation, ezrin assumes an active open conformation, moves to the cell membrane and tethers F-actin directly or indirectly to the cell membrane [37]. Ezrin, also known as cytovillin or villin2, is a component of cell-surface structures, which are involved in cell adhesion to the extracellular matrix and in cell–cell interactions, receptor tyrosine-kinase signalling (cmet/HGF pathway), signal transduction through Rho GTPase and interactions with the Akt-mediated cellular apoptotic machinery. Khanna et al. [13], using sets of cell line variants of osteosarcomas with low or high metastatic properties, found that *vil2* gene mapped to chromosome 6q25–26, was consistently overexpressed in the metastatically capable clones. More recently, they also showed that stable transfection with full length anti-sense ezrin diminished experimental and spontaneous metastases in mice. High expression of ezrin in dog osteosarcomas was also associated with early pulmonary metastases, and a significant association with high ezrin expression and poor outcome was also found in a small cohort of pediatric osteosarcomas [14]. CD44 is a family of cell surface glycoproteins implicated in the invasiveness and metastasis [22]. Ezrin directly interacts with the cytoplasmic tail of the CD44 gene product, the hyaluronic-acid receptor [37]. Increased expression of CD44 potentially leading to increased functional activation of ezrin has also been shown to correlate with increased invasion in osteosarcomas [28]. Shiratori et al. [34] reported that lung metastasis was accelerated by up regulation of CD44 in an osteosarcoma cell line: POS-1. Weber et al. also showed that disruption of CD44 gene led to aborted metastasis formation in osteosarcoma [21]. However, prognostic value for the standard CD44 form (CD44H) or variants in osteosarcomas remains controversial [18, 28, 40].

To further evaluate the prognostic value of the expression of ezrin and CD44H in osteosarcomas, we performed automated immunohistochemistry in 66 specimens of conventional osteosarcomas: a series of 37 biopsies of osteosarcomas before chemotherapy, 13 metastases, 16 resected tumour specimens of "poor responders" and correlated them to patients' outcome. We also investigated messenger RNA (mRNA) level of ezrin in 13 frozen biopsies of osteosarcomas and 4 metastases. As ezrin is a protein that links cell surface glycoprotein such as CD44H to the actin cytoskeleton and as in conventional osteosarcomas, α-smooth muscle actin expression has been variably reported [10, 39, 42]; we also studied α-muscle actin expression by immunohistochemistry (IHC) in the same specimens.

Materials and methods

Patients and tumour specimens

Thirty-seven patients treated for an osteosarcoma at the La Timone hospital between 1993 and 2004 in the pediatric and adult oncological departments were included in this study. All tumours arose de novo. All patients received preoperative and postoperative chemotherapy derived from T10 regimen [33] or SFOP OS94 regimen [19]. All patients received high-dose Methotrexate and had wide conservative surgery (except one case of amputation) with microscopically complete resection (R0). The response to preoperative chemotherapy was assessed on resected specimens according to Rosen's protocol [31]. Good responders were defined by no more than 5% viable tumour. Surgical biopsies of osteosarcomas made before chemotherapy were available for all patients. Histological diagnosis was conventional osteosarcomas type in all cases. They encompassed

osteoblastic subtype in 17 cases (45.9%), pure chondroblastic subtype in 2 cases (5.4%), telangiectatic subtype in 2 cases and mixed subtype (mainly osteoblastic and chondroblastic or fibroblastic and osteoblastic) in the 16 remaining cases (43.2%).Thirteen metastases from 13 patients were also available for immunohistochemistry. For seven patients, biopsy and metastasis were both available for immunohistochemistry study. The location of the metastases was lung in 11 cases and brain in 2 other cases. Total RNA extraction was performed for 13 frozen biopsies (10 was positive and 3 negative for ezrin by IHC) and 4 metastatic specimens (all positive for ezrin by IHC).

Immunohistochemistry

Tumour specimens were fixed in 4% formalin. Fleshy tissue was separated from calcified areas in biopsy specimens to avoid unuseful decalcification and then parafin embedded. Resection specimens were decalcified in a solution of 22% acid formic about 2 or 3 weeks. Sections of 4-μm thickness were prepared from one representative block of the 37 biopsies before chemotherapy, 16 resection specimens after chemotherapy (among the 19 poor responders) and 13 metastases. Automated immunohistochemistry was performed with avidin–biotin–peroxidase complex on a Ventana 320 Device (Tucson, AZ) with Ventana kits (Strasbourg, France) including AEC reagent. Sections were counterstained with hematoxylin and mounted in glycergel (Dakocytomation).The following antibodies were used: ezrin (sigma, clone 3C12, diluted to 1/250) and CD44H (RD system, clone 2C5, diluted to 1/2,000). Heat antigen retrieval was used for both with citrate buffer (pH 6). For α-smooth muscle actin immunohistochemistry, the antibody was purchased from Dako (clone 1A4) and used prediluted without heat pre-treatment. For ezrin immunohistochemistry, paraffin sections from a placenta collected after birth were used as external positive control. Lymphocytes in biopsies or bronchial epithelium in pulmonary metastasis served as internal positive controls. An anaplastic oligodendroglioma served as external positive control for CD44H, and vessels served as internal positive control for α-smooth muscle actin [4]. Slides incubated without antibodies were performed for negative controls. Immunohistochemistry was recorded as positive for ezrin when a membranous and/or cytoplasmic staining was observed. For CD44H, the staining was membranous only, and for α-smooth muscle actin, the staining was cytoplasmic. More than 1% of the cells was the arbitrary cut-off to accept positivity. A mean percentage of stained cells was scored for each positive case in representative cellular areas avoiding necrosis and abundant matrix. One hundred cells were counted in the most stained areas.

RNA preparation

Total RNA extraction was performed using the acid guanidinium isothiocyanate/phenol/chloroform procedure [6] and analysed on both nanodrop spectrophotometer and Agilent 2100 bioanalyzer (Agilent Technologies, France). Only samples with 28S/18S ratio of >1.5 and no evidence of ribosomal degradation were included. Before use, RNA samples were treated with 10 U ribonuclease-free deoxyribonuclease (Promega, France) at 37°C for 15 min.

Real-time quantitative RT-PCR

Real-time quantitative reverse transcriptase polymerase chain reaction (QPCR) was used to accurately detect the changes of Ezrin and ribosomal 18S gene copies. Total RNA (1 μg) DNA-free was reverse transcribed into complementary DNA (cDNA) using 1 μg of hexamers (Pharmacia Biotech, Orsay, France) and M-MLV reverse transcriptase (Invitrogen Life Technologies, France). Human Ezrin and 18SrRNA were amplified, detected and quantified in real-time using the Light Cycler Detector System (Roche Applied Science, Meylan, France) using the following primers: for ezrin, EZS1, 5′CGAAACCAAT CAATGTCCG3’ and EZAS2, 5′GGGCAGACACCTTCT TATC3′ and for 18S rRNA, 18SS, 5′CTACCACATCCAA GGAAGGCA3′ and 18SAS, 5′TTTTTCGTCACTACCT CCCCG3′. The QPCR conditions for 18SrRNA expression level analysis have been previously described [7, 30]. The amplification mixture contained cDNA derived from 50 ng of total RNA, 0.2 μM of primer and mix from Light Cycler Fast Start DNA Master Sybr Green I kit (Roche Applied Science) in a final reaction volume of 20 μl. For ezrin, a three-step PCR was performed for 40 cycles as follows: denaturation at 95°C for 10 s, annealing at 56°C for 5 s and elongation at 72°C for 15 s after one cycle of denaturation/activation at 95°C for 15 min. A melting curve was performed at the end of amplification cycles to verify the specificity of the PCR products, and each amplicon was sequenced to validate the assay. All determinations were performed in duplicate.

Efficiencies (E) were calculated from the given slopes in the Light Cycler software using dilutions of total RNA prepared from renal cDNA samples.

The relative expression ratio (R) of the target gene transcript and reference gene transcript (18SrRNA) was calculated from the QPCR efficiencies (E) and the crossing point (Cp) deviation of a tumour sample vs the renal cDNA used as control:

$$R = \frac{\left(E_{\text{target}}\right)^{\Delta Cp\ (\text{control}-\text{sample})}_{\text{target}}}{\left(E_{\text{ref}}\right)^{\Delta Cp\ (\text{control}-\text{sample})}_{\text{ref}}}$$

Statistical analysis

Correlation between quantitative covariates was analysed by Pearson correlation test or non-parametric Spearman correlation test when Pearson correlation test assumptions was not verified. Relations between quantitative and qualitative covariates was analysed by ANOVA or non-parametric Kruskall–Wallis test when analysis of variance assumptions was not verified.

Overall survival and event-free survival (survival without local relapse or metastasis) were both analysed. Survival analysis was first provided using Kaplan–Meier estimation and Log-rank test for covariate selection, with the usual level of significance of 0.25 [8]. Secondly, multivariate analysis was provided using Cox proportional hazard model with forward stepwise based on likelihood ratio. The IHC parameters were recorded as a continuous variable. As the presence of initial metastasis and preoperative chemotherapy response are known as prognostic factors [2, 9, 29, 31, 32], the model was adjusted (as usual) for these two confounder covariates. Furthermore, because ezrine and α-smooth muscle actin expressions were biologically related, the model was also adjusted for interaction between these two covariates. The level of significance for the multivariate model was set at 0.05. The association of the results of QPCR with IHC parameters was assessed by the no parametrics Spearman test. Data analysis was performed using SPSS version 11.5.1. (SPSS, Chicago, IL) software.

Threshold value of ezrin/18S/rRNA ratios was determined by receiver operator characteristic (ROC) curve using the Analyze-It software (Excel™, Microsoft).

To compare ezrin expression by IHC (mean percentage of positive cells) of biopsies and metastases, we used non parametrics Wilcoxon test.

Results

Patients

Data are summarised in Table 1. Mean age was 15 years. Seventy-five percent of patients were younger than 17 years. Thirty-one patients were treated in the paediatric unit and six in the adult unit. Sex ratio was 62.2% male and 37.8% female. The tumour was located in long bones except for one case where it was located in a rib. Tumour size varied from 3.5 to 25 cm. The duration of preoperative symptoms ranged from 2 weeks to 7 months. Two patients had lung metastases at the time of diagnosis. There were 18 "good" responders to preoperative chemotherapy and 19 "poor" responders. The median of follow-up was 4.5 years (minimum, 10 months; maximum, 150 months). At the end of the follow-up 8 patients had died of disease, and 13 had developed metastases (11 lung metastasis, 1 bone metastasis, and 1 node metastasis). The median of metastasis onset in our cohort was 21 months (minimum, 4 months; maximum, 78 months). One patient developed local recurrence and then metastases. Event-free 3-year survival rate for good responders was better: 72 vs 48% for poor responders.

Table 1 Clinical data

Clinical characteristics	Values
Number of patients	37
Median age at diagnostic (years)	15 (6.7; 54.2)
Male (%);	62.2%
Female (%)	37.8%
Patients of medical pediatric oncology	31 (83.7%)
Patients of medical adult oncology	6 (16.3%)
Histologic response, number of patients	
Good responders	18 (48.6%)
Poor responders	19 (51.4%)
Metastatic disease at diagnosis, number of patients	
Absent	35 (94.6%)
Present	2 (5.4%)
Preoperative chemotherapy, number of patients	
Polychemotherapy or monochemotherapy with Methotrexate	37
Surgical treatment, number of patients	
Wide conservative surgery	37
Amputation	1
Limb salvage	36
Microscopically complete resection (R0)	37
Histological diagnosis and subtype, nb. of patients, %	
High grade osteosarcomas of central "conventional" type	37
Osteoblastic	17 (45.9%)
Chondroblastic	2 (5.4%)
Telangiectatic	2 (5.4%)
Mixed subtype	16 (43.2%)
Tumor localisation, number of patients

Median of metastasis onset	21 months
Event-free 3-years survival rate	
Good responders	72%
Poor responders	48%

Ezrin, CD44H and α-smooth muscle actin expression in biopsies of osteosarcomas before chemotherapy

Among the 37 patients, 23 biopsies were positive for ezrin (62%), 23 for CD44H (62%) and 15 for α-smooth muscle actin (40%) (Table 2). No statistically significant correlation was seen between each of the three IHC parameters and histological subtypes. The positivity for ezrin IHC was mainly cytoplasmic with sometimes a membranous signal (Fig. 1a). Atypical multinucleate giant cells and mononuclear cells were both positive for ezrin in telangiectatic osteosarcomas (Fig. 1b). However, positivity with ezrin antibody was present in chondroblastic areas (Fig. 1c) and in osteoblastic or fibroblastic areas.

Quantification of Ezrin mRNA with 18S rRNA reference gene transcript confirmed higher Ezrin mRNA levels in biopsies positive for Ezrin in IHC compared with negative samples (Fig. 2). The mean level of Ezrin mRNA expression was 0.698±0.404 in positive samples vs 0.173±0.116 in negative samples. Statistical correlation was found between ezrin expression by IHC scored as a continue variable and the QPCR (p=0.003). The correlation coefficient was 0.75.

Ezrin, CD44H and α-smooth muscle actin expression in residual tumour of "poor responder" osteosarcomas

Of the 19 cases of osteogenic sarcomas that were "poor responders" to chemotherapy, 16 resection specimens were available for IHC analysis. For 13 cases that were immunoreactive for ezrin before chemotherapy, only 2 maintained their immunopositivity after chemotherapy. For CD44H, 11 cases were positive: 9 both on biopsy and resection and 2 on resection only. For α-smooth muscle actin, four cases were positive both on biopsy and resection.

Ezrin, CD44H and α-smooth muscle actin expression in metastases

Among the 13 metastatic specimens, 11 were positive for ezrin (Fig. 1d,e), 11 for CD44H and 5 for α-smooth muscle actin (Table 2). Mean ezrin expression (percentage of cells positive by IHC) was 38.1% (95% CI, 21.4–54.7) in metastases vs 17.3% (95% CI, 7.6–27.1) in biopsies (p=0.024). Mean CD44H expression was also statistically higher in metastases than in biopsies 60.8% (95% CI, 42.9–78.6) vs 27.1% (95% CI, 15.2–39; p=0.004). However, for α-smooth muscle actin expression, no significant difference was observed (p=0.88).

Table 2 Immunohistochemistry data

	Biopsy: positive samples, number (%)	Metastasis: positive samples, number (%)	Tumour on resected specimen: positive samples, number (%)
Ezrin	23/37 (62%)	11/13 (84.5%)	2/16 (12.5%)
α-smooth actin	15/37 (40%)	5/13 (38.5%)	4/16 (25%)
CD44H	23/37 (62%)	11/13 (84.5%)	11/16 (68.7%)

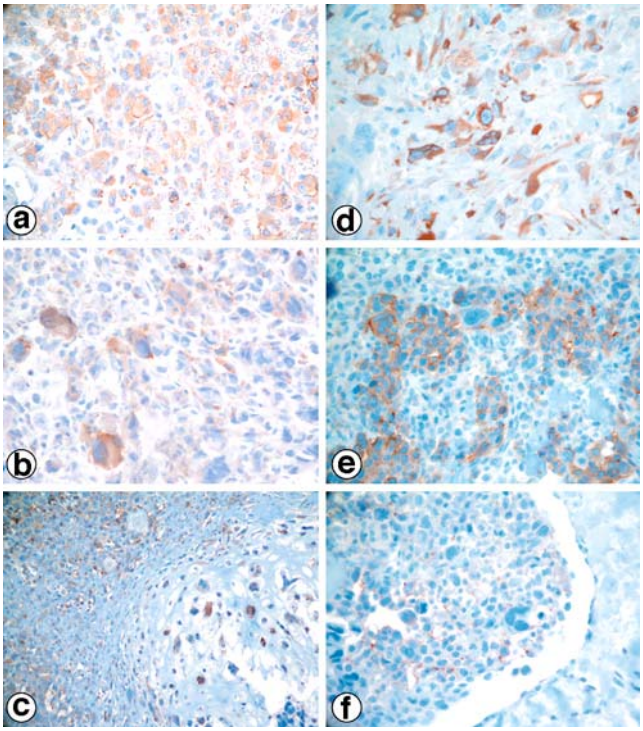

Fig. 1 **a** Ezrin immunostaining in an osteoblastic osteosarcoma: membranous and cytoplasmic staining of 90% of cells, ×40. **b** Ezrin cytoplasmic immunostaining in atypical multinucleated and mononucleated cells of a telangiectatic osteosarcoma, ×40. **c** Ezrin immunostaining in both osteoblastic (*left*) and chondroblastic (*right*) areas, ×40. **d** Ezrin immunostaining in a lung metastasis, ×40. **e** Ezrin immunostaining in a cerebral metastasis, ×40. **f** Membranous ezrin expression in tumour cells in a vessel, ×40

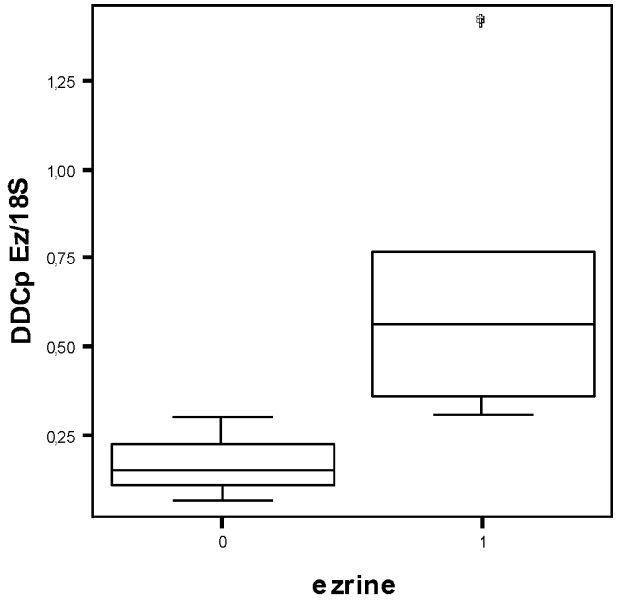
Among patients for whom biopsy and metastasis were available (seven patients), four had ezrin expression in both biopsy and metastasis. In one case, only metastasis was positive. In two cases, biopsy was positive but metastasis was not. CD44H was expressed in both biopsy and metastasis in all cases. For α-smooth muscle actin, only one case showed positivity in biopsy and metastasis.

By QPCR, we found in the four samples of metastases tested a mean level of Ezrin mRNA of 5.95±0.2. All samples were positive by IHC.

Ezrin, CD44H and α-smooth muscle actin expression and patient outcome

The two patients who had metastases at the time of diagnostic showed positivity for both ezrin and CD44H on prechemotherapy incisional biopsies. In one patient, α-



Real-time quantitative RT-PCR (QPCR)

Fig. 2 *Box plot figure* mRNA level of ezrin in negative (*0*) and positive (*1*) biopsies by immunohistochemistry

smooth muscle actin was also positive. Among the 11 patients who presented with metastases during the follow up, nine showed positivity for ezrin in the biopsy and ten for CD44H. For α-smooth muscle actin, the biopsy was positive in 6 of 11 patients. Interestingly, in two biopsies, tumour vascular invasion was present, and positivity for ezrin (Fig. 1f), CD44H and α-smooth muscle actin in tumour cells was seen.

No significant statistical correlation was found between IHC parameters scored as positive/negative or as a continuous variable and the onset of metastasis (for ezrin, p=0.183; for α-smooth muscle actin p=0.851; and for CD44H p=0.658).

No statistical correlation was found between the response to chemotherapy and IHC parameters (for ezrin, p=0.57; for α-smooth muscle actin, p=0.12; for CD44H p=0.79).

In Cox analysis, ezrin (Fig. 3a) was the only prognostic marker for event-free survival (p<0.001, relative risk RR= 1.070; 95 CI [1.033–1.108]), adjusted for the presence of initial metastasis (p=0.06), the preoperative chemotherapy response (p=0.28), the α-smooth muscle actin expression (p=0.77) and the interaction between ezrin and α-smooth muscle actin expressions (p=0.08). Ezrin (Fig. 3b) and α-smooth muscle actin were prognostic markers for overall survival in Cox analysis with p values being, respectively: 0.003 and 0.024 with RR=1.071 (95% CI: 1.024–1.120) and RR=2.547 (95% CI: 1.131–5.735), adjusted for the presence of initial metastasis (p=0.2), the preoperative chemotherapy response (p=0.16) and the interaction between ezrin and α-smooth muscle actin expression (p=0.02).

Discussion

The cytoskeleton linker protein ezrin was initially found in osteosarcoma cell lines and more recently in osteosarcoma specimens [13, 14]. In our series, 62% of paraffin-embedded samples of conventional osteosarcomas were positive for ezrin, which is higher than what Park et al.[27] and Kim et al. [16] recently reported (respectively, 43 and 51,6%). Ezrin staining was mainly cytoplasmic with sometimes a membranous signal as previously reported

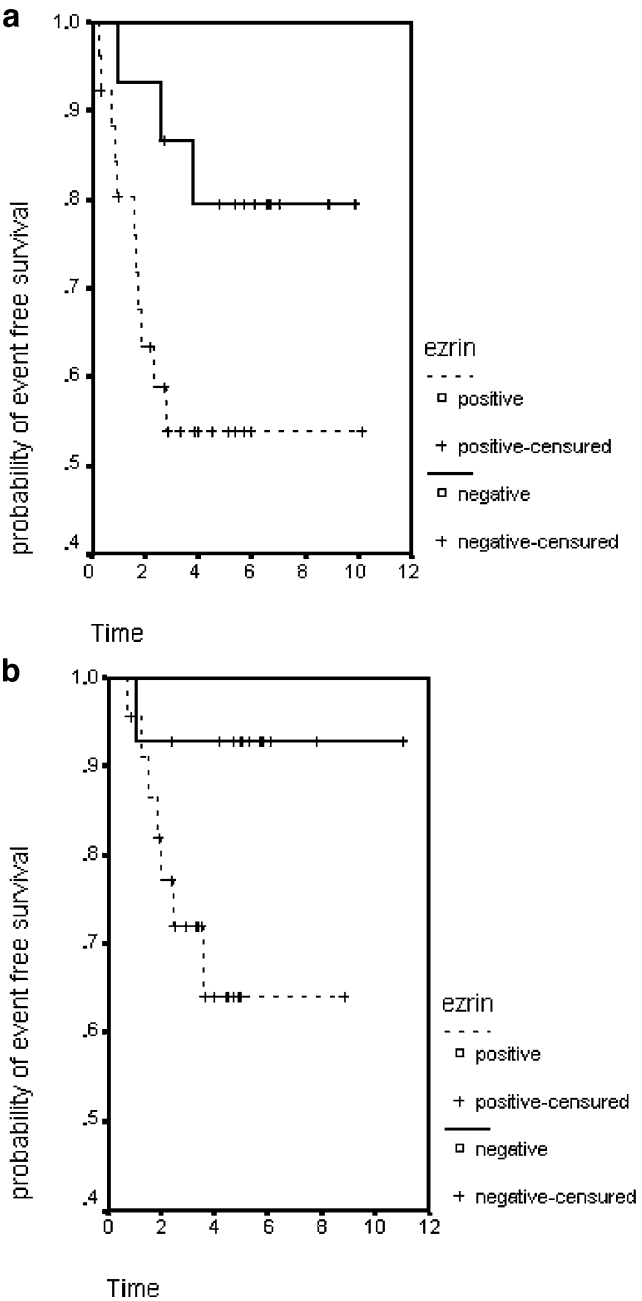


Fig. 3 Survival curves according to ezrin expression by IHC in 37 biopsies of osteosarcoma. **a** Event-free survival, time in years; **b** overall survival, time in years

[41]. Positivity was seen in all histological subtypes: osteoblastic, chondroblastic, fibroblastic and telangiectatic. In contrast to Kim et al., we did not use tissue microarray for IHC. This allowed us to observe ezrin expression in the different histologic components: osteoblastic, chondroblastic or fibroblastic, which often coexist in a same specimen of osteosarcoma.

In the series of Park et al., no ezrin expression was found in central low-grade osteosarcomas, underlining the main difference in prognosis and behaviour between conventional and central low-grade osteosarcomas [27]. In the latter category, metastasis rarely occurs except if multiple recurrence and/or de-differentiation appear. On the other hand, pulmonary metastasis is the most common systemic relapse and the main cause of death in patients with conventional osteosarcomas. Recently, overexpression of ezrin has been correlated with the metastatic potential of several cancers such as melanomas, prostate carcinoma or malignant gastrointestinal stromal tumour (GIST) [12, 17, 26]. Among sarcomas, forced ezrin expression can induce a highly metastatic state in rhabdomyosarcoma cell lines [43]. Ezrin overexpression was also correlated to clinical stage in children with embryonal rhabdomyosarcoma [43]. In adults' high-grade soft tissue sarcomas, ezrin positivity was a predictive factor for metastatic relapse and also an independent prognostic factor for overall survival in multivariate analysis [41]. In a small series of paediatric osteosarcomas (19 cases), the risk of metastatic relapse was 80% greater for patients with high ezrin expression compared to those with low ezrin [14]. In our series, ezrin expression increases during tumour progression, as it was more frequently observed in metastases than in biopsies. However, it was not possible to predict the onset of metastasis on the basis of ezrin expression by IHC on biopsy at the time of diagnosis. This might be explained in part not only because of the size of the cohort and the time of follow up but also because metastasis is a complex progress involving a cascade of linked sequential steps regulated by the activation and/or downregulation of many specific genes. The ezrin gene may be involved in the initiation and/or a transformation of osteosarcoma cells. However, it is unlikely that the ezrin gene alone controls the metastatic behaviour.

In line with a recent study, we found that ezrin expression by IHC was an independent prognostic marker for DFS and overall survival [16]. In particular, no link was found to preoperative chemotherapy, the main prognostic factor in osteosarcoma. This means that molecules and pathways implicated in chemoresistance and metastasis are different. Compared with the histological response to preoperative chemotherapy, ezrin expression is available at the time of diagnostic.

A statistically significant correlation was found between ezrin expression by IHC and mRNA levels assessed by QPCR. Mechanisms of ezrin overexpression are to date unknown. Little or no alteration of the *VIL2* gene copy number detected by comparative genomic hybridisation (CGH) array in malignant high-grade soft tissue sarcomas and by fluorescent in situ hybridization (FISH) in high-grade prostatic intraepithelial neoplasia have been reported [26, 41]. In osteosarcomas, chromosome 6 is not frequently altered, and usually deletion of chromosome 6q is reported [5, 25, 35]. Mechanisms explaining increased ezrin expression may be regulatory effect, epigenetic alteration or activating chromosomal mutation.

For the first time, we report ezrin expression by IHC on resected tumour after chemotherapy in "poor responders". Only two patients had positive cells for ezrin. Although no definite conclusion can be drawn, as prolonged decalcification of the bone can alter antigenicity, a real effect of chemotherapy cannot be excluded. The two patients had a poor prognosis. One patient had a metastasis at the time of diagnosis and died within 10 months. The other patient developed lung metastases 20 months after diagnosis. Positivity for ezrin for both biopsy and residual tumour after chemotherapy seems highly indicative of metastasis.

Concerning CD44H, we found that 62% of the biopsies were positive, which is in line with the literature data (range of positivity between 50 to 85% [18, 41]). However, no correlation was found with metastasis or survival rate in our cohort. Prognostic value of CD44 remains controversial in the literature. Peng et al. [28] found a higher rate of positivity for CD44H in poorly differentiated osteosarcoma variants and those with lung metastasis. Other studies have found a prognostic value only for V5 [15] or V6 variants [18].

Previous studies have shown that nearly 50% of osteosarcomas of various histological subtypes were positive for α-smooth muscle actin [10, 39]. Yamamura et al. [42] have reported the expression by RT-PCR analysis of several smooth muscle differentiation-specific genes, calponin, SM22α, caldesmon and α-actin, in clonal osteosarcoma cell lines and osteosarcomas tissues suggesting a lineage relationship between osteogenic and smooth muscle cells. Moreover, survival rate was found to increase in a group of patients whose tumour cells had basic calponin expression while no prognostic value was found for the other proteins. The mechanism proposed was related to the inhibitory action of calponin on actin-myosin interaction that promotes migration and cytokinesis of tumour cells. In contrast, we have found an unfavourable prognostic value for α-smooth muscle actin for overall survival in multivariate analysis. Maybe osteosarcomas expressing α-smooth muscle actin are a subgroup with a different cell of origin and a different prognostic value. Interestingly, α-smooth muscle actin expression by IHC was not modified by preoperative chemotherapy. Poor prognosis is usually observed in primitive bone sarcomas with more advanced

smooth muscle differentiation such as leiomyosarcomas, which are resistant to chemotherapy [1]. Further studies are required to confirm that expression of smooth muscle proteins could generate different prognostic subgroups of patients with an osteosarcoma.

In conclusion, we have shown that ezrin is expressed in the different histological subtypes of conventional osteosarcomas. Ezrin was an independent prognostic factor for event-free and overall survival rate in multivariate analysis. These data confirm the role of ezrin signalling pathway for tumour dissemination in osteosarcomas in vivo. This also might be of interest for therapeutic strategy to select patient for dose intensification or to use new anticancer agents such as rapamycin, which reduces experimental lung metastases through an ezrin-related pathway [38]. Further prospective studies are required to confirm the prognostic value of ezrin in a large cohort of osteosarcomas to confirm its usefulness in clinical practice. The pattern of ezrin expression in other bone and cartilage forming tumours would also be interesting to investigate searching for a putative diagnostic value for this marker (manuscript in preparation).

Acknowledgments We are grateful to P. Morando and Marie Thérèse Brel for technical assistance.

Abstract Actinomycosis of the jaws is a rare disease, which has been recently described in patients with infected osteoradionecrosis (IORN) and bisphosphonate-associated osteonecrosis (BON). We investigated our archive material for Actinomycosis of the jaws with special regard to underlying disease. Out of a total number of 45 patients with Actinomycosis, 43 (93.5%) suffered from BON (58.7%) or IORN (35.6%), while there were only 3 patients (6.7%) without anti-tumor treatment. In all cases, we found direct association of *Actinomyces* colonies with bone; in the surrounding medullary space, mixed inflammatory infiltrates with variable amounts of osteoclasts were a typical finding. Pseudoepitheliomatous hyperplasia occurred in 60.9% of patients. Cell-rich vessel obliteration was seen in less than 25.9% of BON patients, while hyalinized vessel obliteration was obtained in 37.5% of IORN patients. Additionally performed polymerase chain reaction (PCR) on paraffin-embedded and ethylene diamine tetracetic acid (EDTA)-decalcified tissue specimens confirmed the presence of *Actinomyces israelii* in seven of seven cases analyzed. We conclude that Actinomycosis of the jaws is a particular complication in patients with BON and/or IORN. Patients with Actinomycosis of the jaws during or after these forms of anti-cancer therapy are suggested to represent a distinct patient cohort with a relevant impairment of their general condition.

Introduction

Actinomycosis is a chronic disease caused by non-spore-forming, anaerobic, or microaerophilic bacterial species of the genus *Actinomyces*. *Actinomyces* species were once believed to be fungi due to their branching filaments, but they are now classified as higher prokaryotic bacteria. *Actinomyces* spp. are Gram-positive, pleomorphic, and commonly delicately filamentous microbes [33]. Characteristically, Actinomycosis is a polymicrobial infection, but the most frequent species is *Actinomyces israelii* [32]. By means of histology, *Actinomyces* spp. form typical colonies with Splendore–Hoeppli phenomenon [30, 33]. The latter is described by eosinophilic, pseudomycotic structures composed of necrotic debris and immunoglobulin [28]. The most common form of Actinomycosis is oral-cervicofacial disease. Generally, the disorder presents as a soft tissue induration with frequent abscess formation and multiple fistulae, while genuine actinomycotic osteomyelitis of the

jaws is rarely seen [6, 30]. However, there is increasing evidence from several recent reports that *Actinomyces* osteomyelitis comprises a crucial complication in patients treated for different malignant tumors [3, 15, 17, 20, 23, 25, 36].

The first group with this observation consisted of patients who were treated by radiotherapy due to cancer of the head and neck region. A variable percentage of these patients present with a serious complication of radiotherapy, which is called infected osteoradionecrosis (IORN). Several case reports emphasize a close relationship between Actinomycosis osteomyelitis and IORN [3, 15, 19, 34]. Støre et al. [36] demonstrated DNA of several *Actinomyces* spp., especially *A. israelii* in 10 of 11 tissue probes of patients suffering from IORN. In their investigation, the biopsy material was harvested from the depth of the bone tissue specimens to rule out a superficial contamination effect from the oral microflora. Furthermore, in a recent histological study with 31 IORN patients, we showed that about two thirds of IORN patients (20/31) carried *Actinomyces* in the affected bone tissue, rendering it likely that infection by this microbe was a more frequent problem than previously believed [11].

The second group with a striking occurrence of *Actinomyces* osteomyelitis during anti-cancer therapy comprised the patients suffering from bisphosphonate-associated osteonecrosis (BON). Bisphosphonates are synthetic analogs of the naturally occurring pyrophosphate, and they principally lead to a decrease of bone resorption. Therefore, they are nowadays an important part of the therapy for patients with osseous tumors such as multiple myeloma or bone metastases [7, 16, 27, 29]. Besides these malignant disorders, bisphosphonates are also used in the therapy of osteoporosis and M. Paget. In addition, BON is reported in these patients group. However, following the published data, the frequency of BON is lower as compared with patients suffering from malignant tumors [1, 21]. In contrast to numerous detailed clinical studies, there are only a few histological analyses addressing BON. However, *Actinomyces* was consistently detected in a significant percentage of BON [2, 12, 20–23]. Based on our hitherto examined histological archive material, *Actinomyces* occurs in more than 90% of BON patients (data not published). Besides these two patient groups, there are only a very few reports on patients treated with other forms of anti-cancer treatment (such as chemotherapy) giving an association with *Actinomyces* [2, 17].

In the present study, we investigated the clinicopathological features of patients with Actinomycosis of the jaws with special regard to underlying anti-cancer therapy. Additionally, we complete previous molecular pathological studies [11] performing polymerase chain reaction (PCR) for *A. israelii* on formalin-fixed and paraffin-embedded bone tissues with emphasis on the decalcification procedure.

Materials and methods

Patient data

The records from the archives of the Institute of Pathology (Mainz) from January 2002 to January 2007 were searched for cases encoded as "osteomyelitis of the jaws" and "*Actinomyces*". For definition of Actinomycosis of the jaws, only these cases were accepted, which met the following criteria:

–Actinomyces colonies were confirmed by classical histological morphology, i.e., they exhibited the so-called Drusen with the classical Splendore–Hoeppli phenomenon; alternatively, they were confirmed by at least one of the known special staining techniques for *Actinomyces* (i.e., periodic acid Schiff (PAS), Gram, or Grocott reaction).
–They revealed at least in one focus (means high power field (HPF)=0.306 mm^2) a direct contact with the bone tissue.
–They contained at least one focus with inflammatory tissue.

Using these criteria, we found a total number of 45 cases. They could be divided into three groups: I, bisphosphonate-associated osteonecrosis (BON group); II, infected osteoradionecrosis (IORN group); and III, no specific underlying disease (NOS group). Patient data are summarized in Table 1. The subgroups are briefly described in the following paragraphs. It should be mentioned that several of the patients belonging to group I or II were already described in previous studies [11–14].

The BON group consisted of 26 patients (58.7%; 13 men and 13 women, median age: 67 years). They were treated with bisphosphonates due to bone metastases or osseous involvement of the malignant tumor. The primary neoplasia was multiple myeloma in ten cases, breast carcinoma in nine patients, prostate carcinoma in six cases, and non-Hodgkin lymphoma in one patient. Most patients received zoledronate (Zometa, Novartis, Nürnberg, Germany), followed by treatment with pamidronate (Aredia, Novartis). Patients presented with necrotic bone exposed to the oral cavity. The extent of bone destruction was assessed by standard radiographs or computed tomography. The osteonecrosis occurred in the mandible in 13 patients (50%) and in the maxilla in 7 patients (27%), while 6 patients (23%) presented with osseous lesions in both parts of the jaws.

The IORN group included 16 patients (35.6%, 15 men and 1 woman, median age, 60.7 years). These patients were treated by external radiotherapy due to cancer of the head and neck region. Underlying malignancy was squamous cell carcinoma except of one patient (no. 34), who suffered from an adenoid cystic carcinoma. IORN was defined as

bone necrosis after irradiation of the jaws with clinical signs of infection either as exposure of necrotic bone, inflammatory infiltration, and fistula formation or gross bone sequestration. Bone necrosis was again confirmed by radiography.

NOS group consisted of three patients (6.6%, two men and one woman, median age: 52 years). Underlying systemic disease could not be determined in these cases. Especially, there was no malignant tumor or immunosuppressive therapy. Patients suffered from exposed or sequestrated bone. Osteonecrosis was also demonstrated by radiography.

Histological preparation

In most cases, biopsies or resection specimens were taken both from the mucosal site and the affected bone tissue. Tissue specimens were fixed in 4% phosphate-buffered saline (PBS)-buffered formalin and processed according to standard protocols. In the case of molecular studies, decalcification was performed by ethylenediaminetetraacetic acid (EDTA; 48–96 h). In the other cases, bone tissue was decalcified by trichloric acetic acid for 24–72 h. The specimens were embedded in paraffin, and 4-μm slides were cut. Besides standard histology by hematoxylin and eosin, slides were stained for the Gram, PAS, and Grocott reaction to detect *Actinomyces* colonies. Bone tissue structure was further analyzed by either Goldner or Elastica-van Gieson staining. All histochemical special stains were performed according to previous protocols [8].

Slides were studied and photographed with a Zeiss microscope (type Axiophot, Germany; digital camera type Camedia, Olympus, Hamburg, Germany).

Furthermore, we performed scanning electron microscopy (SEM) of the paraffin-embedded tissue specimens of a total number of five patients (nos. 2, 11, 16, 36, and 45). In brief, dewaxed sections were incubated in 100% ethanol for about 12 h at room temperature (RT). After treatment with hexamethyldisilazane (Polysciences, Warrington, PA, USA), slides were air-dried for about 1 h. Sections were then mounted on metal slide (Plano, Wetzlar, Germany). Slides were sputtered with gold (Sputter Coater S150B; Edwards, Crawley, West Sussex, UK). Finally, slides were microscoped with a scanning electron microscope type DSM 962 (Zeiss).

Molecular testing

For PCR testing, DNA was extracted from formalin-fixed and EDTA-decalcified paraffin-embedded tissues of seven patients according to standard protocols [31]. *Actinomyces*-colonized tonsillar tissue served as positive control, while specimens of acutely inflamed appendicitis were used as negative control. For detection of *A. israelii*, a semi-nested PCR approach was designed targeting the 16S ribosomal RNA gene (GenBank accession no. X82450.1). The procedure was performed as previously described [11].

Results

Bone tissue specimens showed variable amounts of *Actinomyces*. In the case of major resection of the mandibular ramus, large areas of bone marrow spaces and surrounding osseous tissue were colonized by these microbes (Fig. 1). In these regions, bacteria tended to occupy the medullar spaces and showed a close proximity to the bone matrix (Fig. 2). *Actinomyces* was mainly attached to the bone in the absence of inflammatory cells (Fig. 2). In 3 of 45 cases, we additionally found fungi forming non-septated hyphae and spores, which therefore most likely belong to the *Candida* family (Fig. 3). In contrast to *Actinomyces*, mycotic filaments were always broader and showed a double-linear lining (Fig. 3). Furthermore, they were negative in the Gram stain.

Pseudoepitheliomatous hyperplasia was a found in more than the half of the cohort (28/45 patients, 62.2%). It was encountered in a similar percentage in BON patients (59.3%) and in IORN patients (50%). In the NOS group, it was found in two out of three patients. Including the recurrences and excluding the patients without respective data available, pseudoepitheliomatous hyperplasia was found in 12 cases out of a total number of 24 tooth extractions (50%), respectively, while we found the same percentage revealing pseudoepitheliomatous hyperplasia without tooth extraction in the patients' history. In addition,

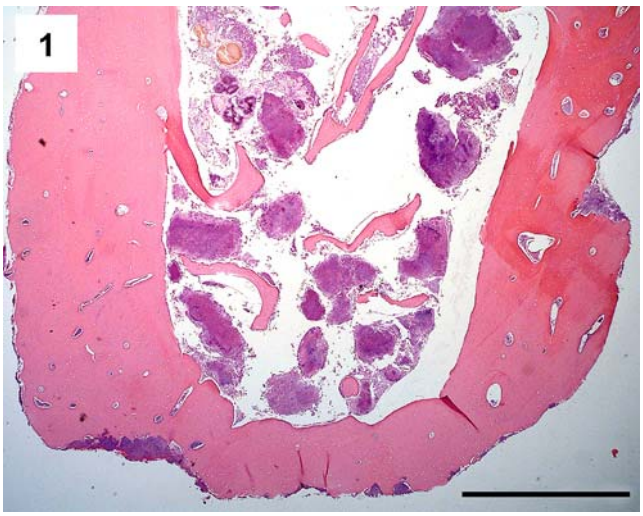

Fig. 1 Histological overview shows the ramus of the mandible occupied with numerous *Actinomyces* colonies (patient 36; HE, *bar*=1 mm)

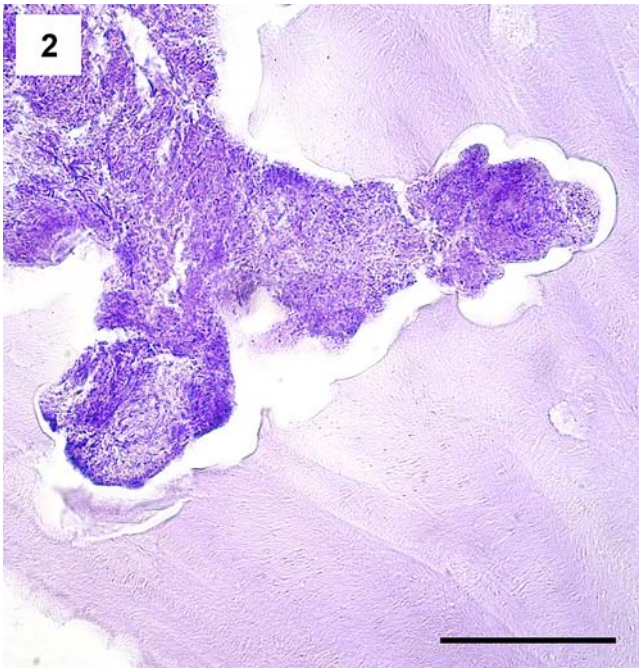

Fig. 2 Gram staining reveals *Actinomyces* colonies that are directly adjacent to the bone tissue (patient 12; Gram, *bar*=50 μm)

we found 17 of 41 cases (41.5%) without tooth extraction in the patients' history, and the large majority of this cohort (12/17; 70.6%) also revealed pseudoepitheliomatous hyperplasia. Sometimes, *Actinomyces* colonies were found between the epithelial lining and the bone tissue (Fig. 4). In one patient (no. 14) we also found a fistula reaching from the epithelial lining of the oral mucosa to the bone. It seems remarkable that, at the bottom of the fistula, *Actinomyces* could be observed in direct contact with bone tissue (Fig. 5), while the fistula itself and the surrounding soft tissues were not directly affected by this microbe. This was consistent with the SEM findings. Using this technique, we found colonies of long and short rods in direct

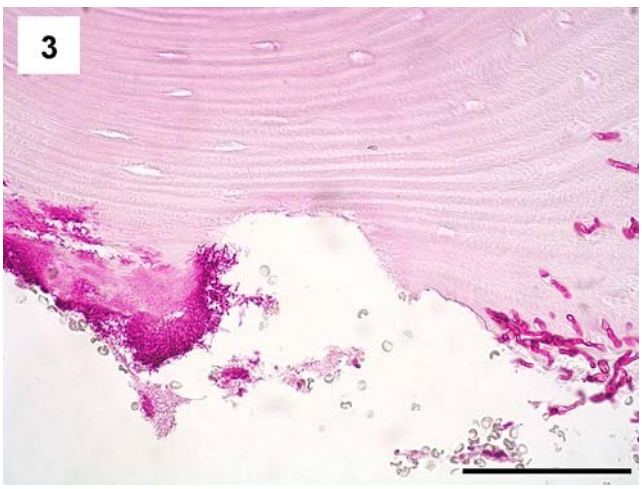

Fig. 3 PAS staining shows *Actinomyces* colonies on the *left side* and fungal spores and hyphae on the *right side* (patient 34; *bar*=50 μm)

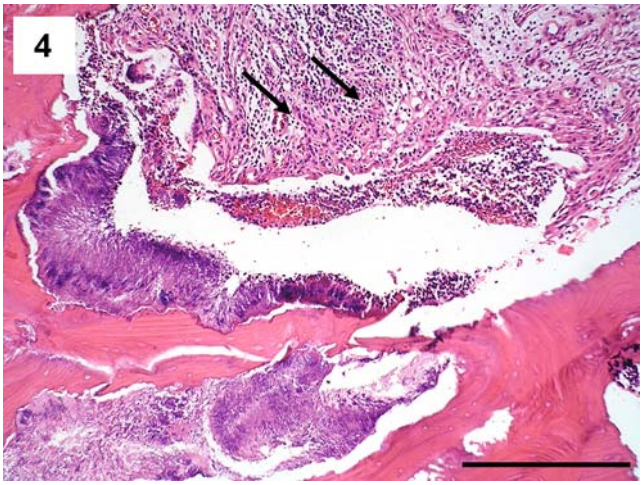

Fig. 4 *Actinomyces* colonies are closely attached to bone. Note that, in this area, there is no inflammatory infiltrate. In the neighborhood, pseudoepitheliomatous hyperplasia is found (*arrows*) surrounded by mixed inflammatory infiltrates (patient 2; HE, *bar*=200 μm)

contact with bone tissue in both BON and IORN cases (Figs. 6 and 7).

Inflammatory infiltrates mainly consisted of variable amounts of predominantly two cell types, namely, neutrophilic granulocytes and plasma cells. The latter revealed sometimes binucleated forms and little variability of the nuclear size; however, signs of atypia were never found. Furthermore, in the case of MM patients, light chain restriction was excluded by additional immunohistochemistry (data not shown). Recurrence of the underlying malignancy was only found in one patient (no. 34) with an adenoid cystic carcinoma. While in BON inflammatory infiltrates were more cellular, there were typically areas of hypocellular fibrosis in the IORN group.

Apart from completely devitalized bone within the genuine sequestration area, BON and IORN showed different patterns of bone necrosis. In BON, necrotic areas characterized by empty osteocyte lacunae were interspersed with bone containing viable osteocytes leading to a non-homogeneous and patchy appearance of bone necrosis. By contrast, uniform osteonecrosis with large areas of empty osteocyte lacunae was typical in the case of IORN. Obliterated vessels were infrequently seen in both BON

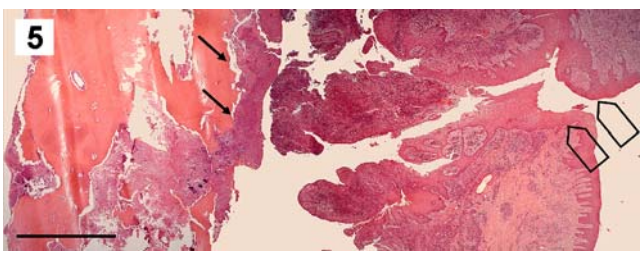

Fig. 5 Histological overview shows a fistula that reaches from the epithelial lining (*arrowheads*) to the bone tissue (*arrows*), here with numerous *Actinomyces* colonies (patient 14; HE, *bar*=1 mm)

and IORN group. They occurred in 7 of 27 BON patients (25.9%) and in 6 of 16 IORN patients (37.5%). While vessel obliteration was predominantly cell-rich in the case of BON (Fig. 8), it was typically cell-poor in the case of IORN. Furthermore, hyalinization of the vessel wall and the surrounding tissue was a typical feature in the latter group (Fig. 9).

Furthermore, tissue probes of seven patients were subjected to PCR method for the presence of *A. israelii* specific DNA sequences as previously described. A single PCR product could be obtained from six of seven cases after first PCR testing resulting in a 237-bp product. In particular, all patients revealed positive results by nested PCR testing exhibiting a 170-bp product (Fig. 10).

Discussion

In the present study, we analyzed patients suffering from Actinomycosis of the jaws. The large majority (93.4%) of these patients was either treated by radiotherapy or by bisphosphonates because of malignant tumors, while only three patients revealed Actinomycosis without primary neoplasia (6.6%). This remarkable relationship could be explained by the fact that tumor patients generally are closely observed during the clinical follow-up control of the anti-tumor therapy, while this might not be the case in the sporadic Actinomycoses. Nevertheless, these findings em-

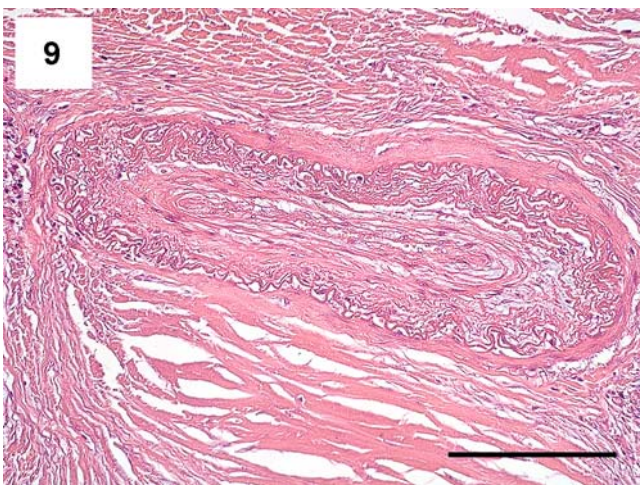

Fig. 9 Obliterated vessel in an IORN patient shows hyalinization and a hypocellular wall. Note that the surrounding stroma shows fibrosis (patient 38; HE, *bar*=100 µm)

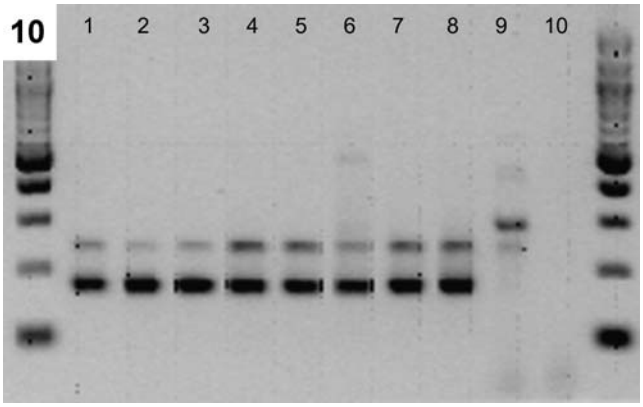

Fig. 10 Results of the semi-nested PCR testing using the first ACM primer and the second ACM primer revealing a 170-bp product. All patients are positive; no cross-amplification is seen. The numbers encode for the following tissues: *1* positive control (tonsillitis); *2–5* BON patients (nos. 10, 16, 3, and 15); *6* IORN case (no. 46); *7* BON case (no. 11); *8* IORN case (no. 38); *9* negative control (appendicitis); *10* water control

phasize the role of Actinomycosis of the jaws as a specific complication in patients with anti-tumor treatment. It is worthy to note that particularly this microbe type, but no other forms of bacteria or fungi (such as *Candida*), is histologically detected in such a large proportion. Concerning the morphological presentation of this lesion, all patients show similar histological features regardless of the primary disorder: First, they show direct association of *Actinomyces* colonies with bone; second, in the surrounding medullary space, mixed inflammatory infiltrates occur with variable amounts of osteoclasts; and third, pseudoepitheliomatous hyperplasia is present in up to 60% of the patient cohort.

Although each of these features has been described in *Actinomyces* of the jaws before, the increased frequency and their combination has not been addressed in such a *large proportion* of patients. Thus, pseudoepitheliomatous hyperplasia of the mandible has been investigated by Warter et al. [38] in three patients suffering from mandibular osteomyelitis, which also was associated with the occurrence of *Actinomyces*. Besides the mandible, we also observed pseudoepitheliomatous hyperplasia in Actinomycosis involving the maxillary bone, which has not been described so far. Furthermore, it should be emphasized that pseudoepitheliomatous hyperplasia is uncommon in the other forms of chronic osteomyelitis [38] and is strongly associated with the occurrence of fistula.

Actinomyces can be commonly found in gingivodental crevices [33]. Moreover, it is well known that the initial step in the pathogenesis of Actinomycosis is disruption of the mucosal barrier, which leads to the implantation into damaged tissue [30, 33]. One cause of this mucosal defect may be tooth extraction, which is frequently seen in both BON and IORN [5, 22, 24, 39] and which was found in about 50% of our patients. We found pseudoepitheliomatous hyperplasia in half of the cases with tooth extractions. On the other hand, in BON and in IORN, osteomyelitis has been shown in several cases without dental extractions [23, 35, 36] suggesting that superficial trauma is not the only portal of entrance for infectious agents. In fact, we found a number of cases without tooth extraction in the patients' history. Interestingly, the large majority of this cohort (70.6%) also revealed pseudoepitheliomatous hyperplasia. Thus, other causes of mucosal defects, like endodontal and periodontal infection [35, 36], have to be considered. Taken together, we suggest that pseudoepitheliomatous hyperplasia is a relatively common feature that reflects the mucosal disruption in Actinomycosis. Regarding the clinical context, we confirm previous data that dental extraction may be an important but not the only cause of mucosal disruption.

The close contact between the bacterial colonies and the bone tissue could be additionally confirmed by SEM. Using this technique, *Actinomyces* colonies show numerous rods, which are in close apposition. In the case of IORN, SEM was previously applied by Støre and Olsen [37]. Microorganisms could be detected in 64% of the patients, again strongly suggesting an association between microorganisms and osteoradionecrosis [37]. In general, tissue probes for SEM are not embedded in paraffin, as presented in our study. However, a few authors have previously performed this modified SEM method as well [18]. The advantage of this method is reflected by the fact that both light microscopical studies with immunohistochemistry and electron microscopical analysis can be performed on the same tissue specimen. In particular, areas of interest can be evaluated by light microscopy first, and afterwards, they can be studied by SEM, even in the case of osseous tissue. The sections are thick enough to perform three-dimensional analysis of the tissue specimens, and thus, information can be obtained concerning the structural relationship between the bacteria and the surrounding tissue.

Actinomycosis is generally considered to present as polymicrobial infection in most cases [30]. For evaluation of the relevant microbes affecting osteomyelitis of the jaws, molecular testing is a suitable method. In a previous study, we evaluated PCR for *A. israelii* in bone tissue specimens, which were decalcified in trichloric acetic acid and therefore revealed a remarkable reduction of sensitivity. Out of a number of 14 probes, which were histologically positive for Actinomyces, we found only three cases that showed positive signals by testing for the housekeeping gene β-actin and for *A. israelii* [11]. In the present study, we confirmed that PCR analysis of relevant infectious agents (*A. israelii* in our case) results in a higher sensitivity if milder decalcification, such as EDTA, is applied. Thus, even bone biopsies primarily used for histology can be used for this molecular approach.

Since the first histological descriptions of BON, the question arose as to whether it is possible to differentiate between BON and IORN by means of histomorphology. Vessel obliteration has been described to occur in both IORN and BON. As this vessel lesion is considered to play a crucial role for the development of avascular bone necrosis, it is suggested that it comprises a major feature of both disorders [4, 10, 22]. Moreover, the association of anti-cancer therapy and osteonecrosis due to vessel obliteration might explain why the overwhelming majority of osteomyelitis of the jaws occurs in BON and IORN but not during other forms of anti-tumor treatment. In a previous histological study, we demonstrated that in IORN, the wall of an obliterated vessel was hyalinized and obtained only few viable cells, while numerous spindle cells narrowing the vessel lumen was a feature encountered in BON [12]. However, on analyzing a larger patient group in the present study, we found obliteration of vessels in less than 30% of BON patients and in less than 40% of IORN patients. Therefore, one has to accept that in the majority of tissue specimens tested, the typical vascular features of BON and/or IORN are absent. Another feature that might help in the differential diagnosis is the pattern of bone necrosis. While in BON osteonecrosis tended to reveal a patchy pattern, bone tissue was rather completely necrotic in the case of IORN. However, the morphological differentiation can be difficult if only small bone biopsies or bone *sequestrae* are studied.

If one bears in mind that the underlying malignancy and the subsequent treatment, particularly in the case of radiotherapy, lead to suppression of the immune response, accordingly to other groups of tumor patients [1], Actinomycosis of the jaws in both BON and IORN patients can be interpreted as an opportunistic infection [26]. Moreover, the general condition of these patients is markedly impaired, as this infectious disease needs an additional long-term antibiotic regime and almost always substantial and even repeated surgical treatment [2, 3, 9, 22]. With regard to the patients' clinical course and outcome, it remains to be investigated whether the histological differentiation between IORN and BON is significant or whether a classification according to the *Actinomyces* status regardless of the origin could be of greater benefit.

Acknowledgement The authors wish to thank Ute Hildebrand, Institute of Pathology, University of Mainz for her excellent technical assistance in molecular testing. Moreover, we are grateful to Marianne Müller, Institute of Pathology, Mainz, for performing the scanning electron microscopy.

Abstract Available ribonucleic acid (RNA) amplification methods are extensively tested for reproducibility, but only a few studies additionally deal with potential amplification bias. On targeted arrays, we evaluated three amplification protocols, which are less time consuming than the commonly used T7-RNA polymerase based in vitro transcription protocols and therefore may be more suitable for clinical use: Template-switching polymerase chain reaction (PCR), Ribo-single primer isothermal amplification and a random primer-based PCR. Additionally, a more sensitive labelling method, Dendrimer labelling, was evaluated. All methods were compared to unamplified RNA labelled at reverse transcription. From our results, we conclude that RNA amplification with template-switching PCR is highly reproducible and results in a reliable representation of the starting RNA population. We then assessed whether RNA amplification of clinical breast and thyroid cancer samples with template-switching PCR showed robust performance when altered cycle numbers or partially degraded RNA were used. Template-switching PCR proved to be a very reliable method for global RNA amplification, even when starting from partially degraded RNA down to a RNA Integrity Number of 4.3. In conclusion, template-switching PCR amplification promises to help micro-array expression profiling of limited amounts of human samples on its way to a clinical routine.

Keywords RNA amplification techniques · RNA stability · Gene expression chips

Introduction

It is not the expression of a single gene but the statistically secure profile of a set of genes that allows ribonucleic acid (RNA) expression to enter clinical practice. Using micro-array expression profiling, genes enabling tumour detection [19], tumour classification [26] and derivation of prognostic information [30] can be identified. Van't Veer et al. showed a 70-marker signature to be a better single prognostic indicator in breast cancer than currently used histological parameters.

A single cell typically contains roughly 10 pg of total RNA. Yet, micro-array experiments require microgram amounts of complementary deoxyribonucleic acid (cDNA) or complementary RNA. Replicate experiments are mandatory for statistical validation, therefore requiring even higher amounts of starting material. One strategy is to enhance the signal intensity by increasing the signal output per molecule using dendrimer technology [27], radioactive labelling, tyramide signal amplification [8] or amino-allyl labelling [14]. However, for minute amounts of samples, those techniques are not sufficient. Therefore, for micro-arrays

analysis of samples obtained by needle biopsies, laser capture microscopy, microdissection and flow-sorted methods, the RNA of the starting material has to be amplified. Several exponential and linear RNA amplification methods are reported: (a) template-switching (TS) polymerase chain reaction (PCR) [15, 17, 18, 22], (b) random-primed amplification methods [7, 9, 10], (c) single primer isothermal amplification (Ribo-SPIA) [1, 2, 23], (d) in vitro transcription (IVT) [29] and its extended form with two rounds of IVT [3] and (e) modifications or combinations of the various amplification techniques [5, 24, 31, 34]. Currently, T7 promoter-based IVT with several slight modifications to the original method, first described by van Gelder and Eberwine [29], are used for most micro-arrays, including Affymetrix GeneChips (Affymetrix, Santa Clara, USA). However, IVT is reported to be time consuming and technically demanding. To introduce micro-array-based gene expression profiling of small samples into clinical practice, the amplification method of choice should be quick and easy to perform, potentially automatable and generally robust.

Two decisive features of a RNA amplification method are its reproducibility and its ability to maintain the relative abundance of the starting RNA population, the so called fidelity of amplification. The fidelity indicates whether a bias towards a RNA sub-population was introduced. Most studies focused mainly on reproducibility, whereas fidelity was scarcely investigated. In general, methods are highly reproducible with correlation coefficients of gene expression ratios above 0.95 between replicate experiments. However, correlation coefficients between methods are usually lower than 0.9. To date, a few studies compared more than one technique to unamplified RNA [5, 7, 18, 20, 28, 33], all of them chiefly involving time-consuming IVT protocols.

In this study, we meet the urgent need to comprehensively revalidate overhastily adopted amplification techniques to ensure quality of micro-array results in the future, especially for the clinical routine. We compare fidelity and reproducibility of amplification techniques, which could potentially be used in a routine clinical setting. The best performing techniques, TS-PCR and Ribo-SPIA, retrospectively, were further tested for their use with clinical breast and thyroid cancer samples.

Materials and methods

Isolation of total RNA from clinical samples and cell lines

Total RNA from MCF7 and Hs578T human breast cancer cell lines was extracted using Trizol (Invitrogen, Paisley, UK) followed by a RNeasy mini column clean up (Qiagen, Hilden, Germany) according to the manufacturer's protocol. Primary breast cancer samples from patients 180/03 and 254/03 with oestrogen receptor (ER)-negative and ER-positive invasive ductal mammacarcinoma were chosen for the study. Primary thyroid cancer samples presenting papillary thyroid cancer entities, as well as additional benign nodular goitre were obtained from the University Hospital Vienna. Clinical samples were collected with approval of the local ethics committee. Primary samples were dissected into smaller pieces if necessary and shock frozen in liquid nitrogen. RNA later ice (Ambion, CA, USA) was applied to the samples at least 1 day before RNA isolation and then kept at −80°C. Samples were disrupted in liquid nitrogen with a mortar and pestle-like device (developed in our laboratory). Samples were homogenized using Qiashredder Columns (Qiagen), and total RNA was isolated by an RNeasy mini-column (Qiagen). Total RNA was concentrated by ethanol precipitation and dissolved in appropriate amount of diethylpyrocarbonate-treated distilled water (dH_2O). All total RNA samples were assessed for integrity using the Agilent 2100 BioAnalyzer and quantified using a NanoDrop 1000 spectrophotometer.

Labelling and amplification procedures

Standard protocol—unamplified RNA

Twenty micrograms of total RNA containing 1:90 diluted Spike-RNA from Lucidea Scorecard (Amersham, Vienna, Austria) was mixed with 4 μl 0.5 μg/μl oligo$(dT)_{12–18}$ primer (Invitrogen). dH_2O was added to 15 μl. The mixture was incubated at 70°C for 10 min and chilled on ice. Five microlitres 5× first strand buffer (Invitrogen), 3 μl 0.1M dithiothreitol (DTT), 0.6 μl of a nucleotide mix composed of 25 mM dA/dT/dGTP and 15 mM dCTP (Invitrogen), 3 μl Cy3 or Cy5 dCTP (Amersham, PA53021, PA55021) and 400 U SuperScript II (Invitrogen) were added. Reaction mixture was incubated at 42°C for 2 h and stopped by addition of 15 μl 0.1 N NaOH followed by incubation at 70°C for 15 min and addition of 15 μl 0.1 N HCl. Labelled first-strand cDNA was purified using a DNA-Clean&Concentrator 5-μg column (Zymo Research) according to the manufacturer's instruction. Purified labelled cDNA was dried down with a vacuum centrifuge.

Dendrimer—labelling

In brief, this method starts with a reverse transcription step where a special RT dT primer is used. Then, the cDNA is hybridized to the micro-array. Last, the fluorescent 3DNA reagent hybridizes to the cDNA because it includes a 'capture sequence' that is complementary to a sequence on the 5′ end of the RT primer. The entire procedure using 2 μg of total RNA with 1:90 diluted Spike-RNA from

Lucidea Scorecard (Amersham) was performed using a 3DNA Array 350-kit (Genisphere, Hatfield, USA) as described in Genisphere's Array 350 protocol: http://www.genisphere.com/pdf/array350_10_19_04.pdf. cDNA was concentrated using Millipore Microcon YM-30 centrifugal filter devices. cDNA hybridization was carried out at 60°C using vial 6 hybridization buffer.

Linear amplification by ovation Ribo-SPIA

Ribo-SPIA amplifications used Ovation Aminoallyl RNA Amplification and Labeling Systems kit (Nugen Technologies, San Carlos, USA). Ribo-SPIA is an alternative isothermal linear amplification method. Excess chimeric RNA/DNA primer is added to reverse-transcribed cDNA. As an anti-sense strand is elongated by a DNA polymerase, its RNA part of the primer is digested by RNase H, which allows a new copy of the primer to anneal. A new DNA polymerase displaces the original strand. Numerous repeats of this procedure allow the same cDNA to be processed by many DNA polymerases, resulting in high amplification. All steps were performed according to the manufactures protocol: http://www.nugentechnologies.com/pdfs/Ovation_RNASys_UserGuide.pdf. Amplified cDNA was purified using a DNA-Clean&Concentrator 25-μg column (Zymo research) washing with 80% EtOH instead of wash buffer. Amionallyl cDNA was labelled with Cy Dyes according to Nugen's recommendations using CyDye Post Labeling Reactive Dye Packs (Amersham). Labelled cDNA was purified using a DNA-Clean&Concentrator 5-μg column (Zymo research) washing with 80% EtOH instead of wash buffer. Purified labelled cDNA was dried down with a vacuum centrifuge.

Exponential amplification by random-primed PCR

Random primed PCR was accomplished by the primer extension pre-amplification (PEP) method, initially applied for whole-genome amplification [35]. Total RNA of 100 ng containing 1:90 diluted Spike-RNA from Lucidea Scorecard (Amersham) were transcribed into first-strand cDNA as described for "Standard protocol—unamplified RNA." Reagents were then added as follows: 2 μl $(N)_{10}$ primer (optical density [OD]=125), 6 μl 2 mM deoxyribonucleoside triphosphate (dNTP; Invitrogen), 6 μl F511 10× buffer, 5 U *Taq* polymerase (Invitrogen) and H_2O in a total volume of 60 μl. The following programme was executed on an ABI GeneAmp 2700 thermocycler: 95°C for 5 min followed by 25 cycles of 95°C for 30 sec, 25°C for 5 min, 45°C for 5 min and 72°C for 3 min and ended by incubation at 72°C for 7 min. PCR product was purified, labelled and precipitated exactly the same way as described for the TS-PCR product in "Exponential amplification by TS-PCR."

Exponential amplification by TS-PCR

TS-PCR amplification was performed as previously described by Petalidis et al. [17] using PowerScript RT kit and Advantage 2 PCR Kit (BD Biosiences, CA, USA). Briefly, 50 ng total RNA with 1:90 diluted Spike-RNA from Lucidea Scorecard (Amersham) was mixed with 10 pMol 3′SMART CDS primer IIA, 10 pMol SMART IIA oligonucleotide and H_2O to a total volume of 5 μl. The mixture was denatured at 70°C for 2 min and chilled on ice. For first strand synthesis 2 μl 5× first strand buffer, 1 μl 20 mM DTT, 1 μl 10 mM dNTP and 1 μl PowerScript RT were added and then incubated at 42°C for 1h and chilled on ice to stop the reaction. The following reagents were added to the total first strand reaction mixture: 72 μl H_2O, 10 μl 10× Advantage 2 PCR buffer, 2 μl 10 mM dNTP, 4 μl PCR Primer IIA and 2 μl 50× Advantage 2 PCR polymerase mix. PCR was performed with a ABI GeneAmp 2700 thermocycler with the following settings: 95°C for 1 min and 17 to 26 cycles of 95°C for 10 s, 65°C for 10 s, 68°C for 6 min. PCR product was purified using Qiaquick PCR Purification Kit (Hilden, Qiagen) according to manufacturer's instructions and labelled with Klenow polymerase. Two micrograms of PCR product were mixed with 2 μl $(N)_{10}$ primer (OD=125), 8 μl 10× Klenow buffer (Epicentre, Madison, USA) and dH_2O. The mixture was incubated at 98°C for 5 min and chilled on ice. Next, the following reagents were added: 6.9 μl of a dNTP mix that contained 0.23 mM dA/dT/dGTP and 0.07 mM dCTP, 1.1 μl Cy3- or Cy5 dCTP (Amersham, PA53021, PA55021) and 20U Exo Minus Klenow DNA polymerase (Epicentre) to a total volume of 80 μl. The labelling reaction mixture was incubated at 37°C for 2 h and heated to 95°C for 3 min to stop the reaction. The labelled product was purified and collected by ethanol precipitation.

Array construction and hybridization

Oligonucleotide probes representing 131 sequences (genes of interest with several isoforms, positive and negative controls) and 116 sequences were designed for breast cancer and thyroid cancer micro-array, respectively. All probes are represented in four replicate spots on the array.

Precipitated or dried-down labelled target was resuspended in 20 μl DIGeasy hybridization solution (Roche, Basel, Switzerland). Dissolved labelled target was heated to 99°C for 2 min, followed by prehybridization at 37°C for 10 min. The entire labelled target was applied to the prewarmed micro-arrays, under M-Series Lifter Slips (Erie Scientific, Portsmouth, USA) and incubated at 42°C for 16 h. Hybridized arrays were washed with 1× sodium chloride–sodium citrate (SSC)/0.2% sodium dodecyl sul-

phate (SDS) for 5 min and 0.1× SSC/0.2% SDS for 5 min and then plunged repeatedly in 0.1× SSC. Slides were dried by centrifugation and scanned using an GenePix 4000A (Axon Instruments, Jersey City, USA).

Data analysis

All data analysis was performed in *R* (www.r-project.org) using bioconductor packages *limma* and *geneplotter* [4, 25]. Every chip was scanned twice at different pmt gains, and images were analysed using either GenePix 5.0 or Spot 3.0. Output files from images analysis were then uploaded into a Microarray database (BASE). Using the BASE-plugin *pmt-merging*, data from the two scans were merged to increase the dynamic range of our assays [13]. Raw data was extracted from BASE using SQL and RODBC at the R-prompt.

First, data was background substracted, and the same offset was added to all arrays to remove negative signal. We fitted the loess curve on the calibration controls (spike controls with a known ratio of 1 [$M=\log2(R/G)=0$]) and applied it to the whole array. Correlation between the methods was assessed in a heatmap based on differentially expressed genes (B value>0 from limma topTable). We also introduced concordance-at-the-top (CAT) plots according to Irizarry et al. [6]. We used the repeated dye-swap direct labelling experiments as the gold standard method to which we compared all other methods on the basis of their most regulated genes (topTable). The lines in the plots show the percent overlap in the topTable of an experiment compared to the topTable of the gold standard. Raw data as well as normalized log2 ratios are available at the Gene Expression Omnibus, series entry GSE5588.

Results

Experimental design

To compare the methods under test, we generated two total RNA pools from breast cancer cell lines MCF7 and Hs578T, respectively, which were used for all techniques under test (Fig. 1). Lucidea Scorecard Spike RNA was diluted 1:90 into those total RNA pools for normalization purposes. RNA quality control using Agilent Bioanalyzer showed a RNA integrity number (RIN) of 9.5 for the MCF7 pool and 8.7 for the Hs578T pool. For each method, a replication including a dye-swap hybridization was performed because of its additional ability to detect dye effects. Overall, non-amplifying methods were replicated two times and amplifying methods four times.

Mean yield for Ribo-SPIA amplification from 5 ng total RNA is 4.4 μg, for 19 cycles of TS-PCR from 50 ng, total RNA is 9.0 μg, and for 25 cycles of PEP-PCR from 100 ng, total RNA is 1.9 μg. One to 2.5 μg of the amplification product was labelled, depending on the various labelling efficiencies. For the standard protocol and dendrimer labelling 20 or 2 μg of total RNA were used, respectively. The labelled target was hybridized onto our breast cancer micro-array, which contains 1,040 spots of 131 unique 65-mer oligonucleotides plus Lucidea Scorecard probes (Amersham). Signal intensity data were preprocessed, normalized, and log2 ratios of intensity values between MCF7 and Hs578T were calculated (M-values).

Reproducibility and fidelity

Pearson correlation coefficients between and within methods are listed in Table 1 and summarized in Table 2.

tsPCR Template-switching PCR

Reproducibility was defined as the mean Pearson correlation coefficient of spot log2 ratios between all replicates of the same method. Fidelity was defined as the mean Pearson correlation coefficient of spot log2 ratios between all replicates of the method under test and all replicates of the standard method.

Dendrimer labelling, a method without RNA amplification, was most comparable to the standard method (r=0.91). TS-PCR proved to be the most reproducible method (r=0.97) and was the RNA amplification method that correlated most to the standard method (direct labelling, r=0.89). Correlation of Ribo-SPIA-amplified RNA with the standard method is somewhat lower (r=0.79). Random-primed PCR amplification by PEP-PCR performed worst in both categories. Correlation within and between methods is shown in more detail by a heatmap (Fig. 2a). Methods generally cluster together because the techniques are more reproducible than comparable to other methods. Differences in expression ratios could not be attributed to either GC content, distance from the 3′ end of the target, longer stretches of GC nor transcript length (Supplementary Fig. 1).

A CAT plot visualizes concordance of differential expression of Ribo-SPIA, TS-PCR and Dendrimer labelling with the standard method [6] (Fig. 2b). Briefly, this CAT plot shows agreement between differential expression calls, defined by ranking genes by their log odds ratio of differential expression. Among the amplifying methods, TS-PCR shows slightly higher concordance in differentially expressed genes with the standard method.

Validation with clinical samples

Next, we investigated whether Ribo-SPIA and TS-PCR are suitable for amplification of rather heterogenous clinical breast cancer samples (e.g., containing connective tissue, invading leukocytes, endothelial cells, fat cells and other cells). The resulting impurities in the RNA may cause problems with subsequent RNA amplification. Total RNA from ER− (patient no. 180/03) and ER+ (patient no. 254/03) breast cancer samples were chosen as targets for hybridization, based on the observation that the expression of roughly a tenth of all genes is associated with ER status [30], therefore resulting in many differentially expressed genes. RNA quality control showed a RIN of 7.8 for 180/03 and 8.5 for 254/03. As tumor material was limited, only one hybridization of unamplified RNA could be performed. For Ribo-SPIA and TS-PCR a replicate including a dye-swap hybridization was carried out. Again, even with heteroge-

Table 2 Summary of the performance of the amplification techniques under test

	Fidelity	Reproducibilty	Starting Material	n	Time required
Direct Labeling		0.930	20 000 ng	2	1.5 days
Dendrimer	0.913	0.940	2 000 ng	2	2 days
Ribo-SPIA	0.788	0.906	5 ng	4	1.5 days

All TS-PCR	0.909	0.924	50 ng	6	1.5 days

Results obtained by breast cancer cell lines are highlighted by blue color. Result obtained from clinical breast cancer samples are highlighted by grey shade. 'Reproducibility' was defined as the mean Pearson correlation coefficient of spot log2 ratios (*M* values) between all replicates of the same method. 'Fidelity' was defined as the mean Pearson correlation coefficient of spot log2 ratios between all replicates of the method under test and all replicates of the standard method. 'Starting material' indicates total RNA used. *n* is number of replicates performed and 'time required' corresponds to the time required, to accomplish a total micro-array experiment including labelling, hybridization and scanning.

nous clinical samples, TS-PCR proved to be highly reproducible and was comparable to the standard method (r=0.91, Table 2).

Robustness of TS-PCR over cycles and varying RNA integrity

For breast cancer samples, TS-PCR was repeated with 17 and 26 cycles instead of the initially tested 19 cycles. Mean yield for 17, 19 and 26 cycles is 4.8, 11.1 and 14.5 μg, respectively. In summary, TS-PCR amplifies total RNA of two distinct cancer types reliably in a range of 17 to 26 PCR cycles (Table 2).

RNA integrity can vary a lot among clinical samples, depending on the handling and time required until cryopreservation. The RNA amplification of choice should therefore be able to equally amplify total RNA of different quality. Total RNA from both breast cancer samples was subjected to artificial degradation by heating to 50°C for 0, 25 and 50 min (Fig. 3), and RNA integrity was assessed on an Agilent Bioanalyzer. Incubation of total RNA for 50 min resulted in a RIN decrease of 1.4 and 1.3 for samples 180/03 and 254/03, respectively. TS-PCR with 19 cycles was performed on total RNA from both samples, and the amplification product was labelled with Cy3. Universal Reference RNA (Stratagene) was used as a common reference and labelled with Cy5. Correlation of *M* values between 25 min incubated RNA and original RNA ranges from 0.93 to 0.99 (Fig. 3). Correlation of *M* values between 50-min-incubated RNA and original RNA ranges from 0.94 to 0.97.

To further pay attention on the clinical setting, we asked whether this was also true for degraded thyroid cancer samples. Thyroid nodules from three different patients (604/05, 607/05 and 618/05) were disrupted into several pieces (suffices Gx in Fig. 4 and Table 3), each of which RNA was extracted from using different tissue lysis approaches (suffice Ex in Fig. 4 and Table 3). This resulted in different RNAs of different quality from the same piece of tumor (Fig. 4). Gene expression profiles are largely maintained with TS-PCR amplification with partially degraded samples. Even after RNA degradation to RIN 4.8, correlation to the original RNA of RIN 7.3 is as high as 0.95 (Table 3).

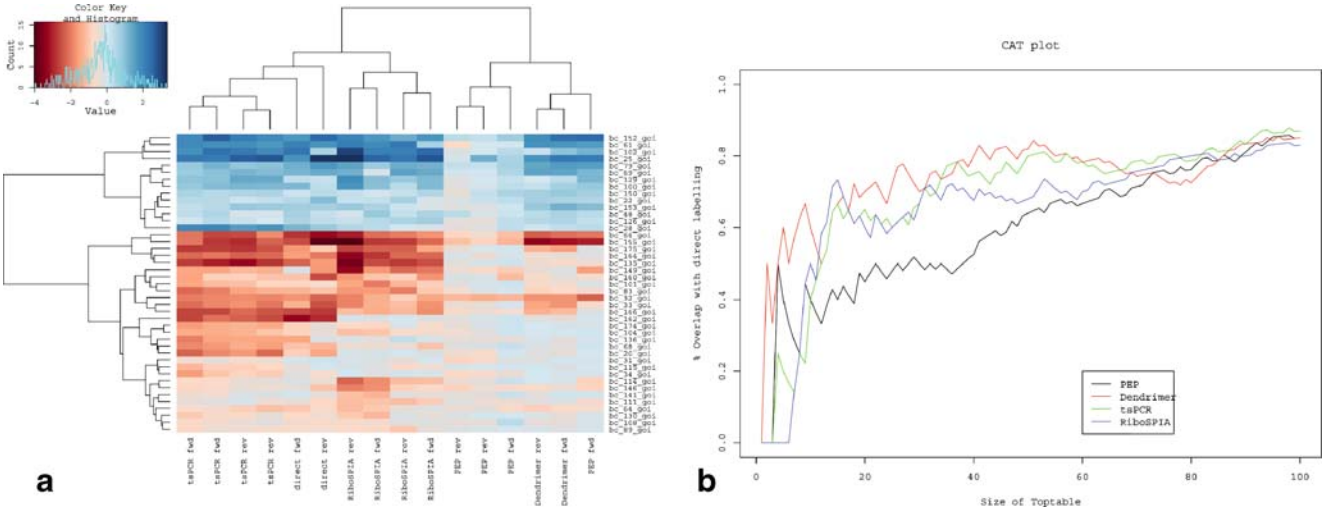

Fig. 2 Heatmap and Concordance-at-the-top (CAT) plot of experiments with total RNA from breast cancer cell lines. **a** Heatmap: Unsupervised hierarchical clustering using manhattan distance measure and complete linkage clustering. Techniques used are clustered horizontally, and probes are clustered vertically. *Color key* indicates the differential expression (*M* values, $M=\log2(R/G)$) between MCF7 and Hs578T breast cancer cell lines. **b** CAT plot: For explanation, see "Materials and methods"/"Data analysis"

In summary, partial degradation of RNA of two breast cancer samples and three thyroid cancer samples cannot corrupt the fidelity of TS-PCR amplification, as correlation to original RNA proves to be high.

Discussion

In the present study, we used a two-colour oligonucleotide micro-array platform to compare one linear and two

exponential RNA amplification methods and a signal amplification method to the standard method of labelling RNA directly at reverse transcription. We chose the micro-array as the tool to detect gene expression profiles because qualitative PCR cannot measure as many targets simultaneously.

We aimed to find a RNA amplification technique suitable for clinical routine, considering only methods that can be accomplished within 1 day including labelling. Therefore, we did not evaluate IVT approaches in this study because IVT is time consuming and requires a great amount of manual work. To date, with one round of IVT, the lowest amount of starting total RNA is 50 ng RNA (MessageAmp II kit, Ambion) suggesting 14 h of IVT to provide sufficient amplification product for micro-array experiments. To obtain detectable signals from less total RNA, a second round of IVT is needed. This usually takes around 3–4 days to be completed and introduces a new source of bias and results in 5′-truncated transcripts. Degradation of RNA progresses with time and additional rounds of IVT, resulting in 5′-truncated transcripts, as reported in several studies [10, 12, 16, 21, 33]. Consequently, GeneChip arrays preferentially contain oligonucleotides derived within 600 bp to the 3′ end of the transcript. Median size distributions of roughly 2 kb for TS-PCR and 1 kb for Ribo-SPIA amplification products are described elsewhere [1, 17, 23]. Not fully in agreement, slightly smaller median sizes of amplification product for both techniques have been observed for the clinical breast cancer samples (Supplementary Fig. 2). Yet, in contrast to the IVT product, TS-PCR amplification product leaves more space in oligo design for carefully considering cross-hybridization conditions. Oligonucleotides designed for splice variants are also more likely to be located further on the 5′ end.

Notably, there are great discrepancies in measured gene expression when either mRNA or total RNA is used [11, 20]. Important for comparability, all methods in this study use total RNA that is first reverse transcribed relying

All RNA was amplified by TS-PCR. Correlation values between extracts derived from the same piece of tumour are highlighted by bold numbers and are above 0.94.

somehow on oligo $d(T)_n$ primers. Dendrimer labelling showed good reproducibility, and results correlated well to the standard method, but with our micro-array, as much as 2 μg of total RNA were necessary to obtain an evaluable signal. Of the RNA amplification methods under test, TS-PCR was most reproducible (r=0.97) and showed the highest correlation of log2 expression ratios to the standard method (r=0.89 for cell culture and r=0.91 for primary mammacarcioma). Results for reproducibility [17, 20, 21, 22] and fidelity [22, 32] of TS-PCR are in good agreement to published data, although they are derived using slightly modified methods or qPCR platforms. In contrast, Puskas et al. observed lower values for reproducibility and fidelity than the other studies.

Recently, Subkhankulova et al. [28] performed a comparison of RNA amplification at the single-cell level. In this study, TS-PCR clearly outperformed two rounds of random-primed PCR and three rounds of IVT in terms of fidelity. In our study, TS-PCR also showed the highest concordance of differentially expressed genes with unamplified RNA among the amplification techniques. Reproducibility of Ribo-SPIA is consistently higher in literature [1, 2, 23]. Surprisingly, inter-method correlation of Ribo-SPIA to unamplified RNA [1, 5] or to one round IVT [23] is lower than fidelity reported by us. Random-primed PCR amplification is reported to be biased [7, 10]. A new approach of random-primed PCR amplification, PEP-PCR, tested in this study even performed slightly worse in terms of fidelity and reproducibility. Taken together, we could confirm results from the literature in an unprecedented comprehensive manner.

Starting amounts of RNA differ between amplification methods because they either amplify linearly or exponentially and additionally vary in amplification efficiency. However, the amount of starting material was not arbitrarily chosen but derived from the manufacturer's recommendation or from the literature.

Clinical samples are usually very heterogenous, which potentially poses a problem for the amplification method of choice. However, TS-PCR (and Ribo-SPIA) showed very similar reproducibility and fidelity when total RNA was amplified from clinical samples. Yields only differ slightly when either breast cancer or thyroid cancer RNA is used. From product yields, we conclude that amplification is still in its exponential phase at 17 cycles and has completely reached its plateau at 26 cycles. However, reproducibility and fidelity remain nearly the same in a range of 17 to 26 cycles. Therefore, laborious optimization of cycle numbers for each tissue under investigation is not necessary. Still, as indicated by Petalidis et al., we also recommend working with the amplified product obtained in an exponential phase of PCR.

RNA integrity is considered decisive for subsequent gene expression analysis, and RNA extracted from clinical samples usually is of varying quality. However, to our knowledge, the influence of RNA integrity on the performance of RNA amplification has not yet been investigated thoroughly. Dependent on the handling after surgery and on

the disruption protocol, clinical samples are often more or less degraded. In our experiments with breast cancer samples, TS-PCR proved to reliably amplify total RNA that diverges in 1.4 and up to 2.6 RIN points. To further prove the good reproducibility of TS-PCR in the light of differing RNA integrity, we compared RNAs from the same thyroid nodule. This serves us as a model for a clinical scenario, where some samples will be more degraded than others. In the presented experiments, we still observed a Pearson correlations of 0.95 when comparing the same RNA with RIN 7.2 and RIN 4.3 and a correlation of 0.98 when comparing RIN 7.9 with RIN 5.3.

In a research environment, RNA amplification methods have long been used for micro-array experimentation. Therefore, much effort has been put into proving the reproducibility and fidelity of the various methods available today. We believe, however, that for use in a routine clinical scenario, a RNA amplification method also needs to be robust against differing RNA integrity and be time effective. We further believe that by these standards, TS-PCR is a promising method on the move of micro-arrays from the research laboratory into clinical practice.

Acknowledgements We thank Rudolf Pichler for full spotting service and Theresa Wohlschlager for extracting total RNA from breast cancer cell lines. We are grateful to Prof. Karl-Heinz Preisseger and Monika Voigt for supplying us with breast cancer cell lines and primary tumours. Furthermore, we thank Prof. Fritz Leisch for critical input on statistical computing. The experiments performed comply with the Austrian laws. This work was supported by FFG, project no. 809596.

Competing Interests Statement The authors declare that no conflicts of interest exist.

Upregulation of cIAP2 in regenerating colonocytes in ulcerative colitis

Jakob B. Seidelin · Ben Vainer · Lars Andresen · Ole H. Nielsen

Received: 23 June 2007 / Revised: 23 September 2007 / Accepted: 27 September 2007 / Published online: 31 October 2007

Abstract It has been reported that colonocytes in ulcerative colitis (UC) upregulate anti-apoptotic cytoprotective pathways. An expression-profiling study of apoptosis-related genes suggested that the cellular inhibitor of apoptosis protein-2 (cIAP2) could be upregulated in epithelial cells in UC. The role of cIAP2 in active UC was therefore investigated. Fourteen patients with active UC and 12 control subjects who underwent routine colonoscopy for control of their disease or as part of their examination program for irritable bowel syndrome were included. cIAP1 and cIAP2 expression was investigated by polymerase chain reaction, Western blotting, and immunohistochemistry. The regulation and role of cIAP2 for apoptosis was further investigated in cell cultures. cIAP2, but not cIAP1, was upregulated during active UC in regenerative epithelial cells. A similar upregulation was found in cell lines stimulated with proinflammatory cytokines and was dependent on nuclear factor κB activation. Inhibition of cIAP2 increases the susceptibility of epithelial cells to Fas ligation. Inflammation during active UC thus causes an upregulation of cIAP2 in regenerating epithelium, which renders the cells less susceptible to Fas ligation. This might play a role in regeneration of the epithelium but might additionally be implicated in carcinogenesis of UC.

Introduction

Ulcerative colitis (UC) is commonly characterized by continuous inflammation or cyclic episodes of relapse and remission [17]. On the histological level, the cycling or ongoing disease activity is accompanied both by increased numbers of apoptotic cells throughout the crypt axis and by corresponding areas of regeneration of the epithelial lining. The inherent ability of the epithelium to regenerate during inflammation indicates that the epithelial cells respond to inflammation by activating cytoprotective programs. Previously, the effect of UC inflammation on cell destiny has focused on the study of apoptosis mechanisms [11, 15, 35]. The interest in apoptosis was caused by the possible pathophysiological role of increased apoptosis and the apoptosis-derived loss of epithelial integrity, which is thought to contribute to the ongoing immunological drive from luminal pathogens allowed to pass the epithelium and diarrhea caused by intestinal leakiness [2, 10, 11, 14, 24]. Accordingly, it has been shown in neoplastic cell lines that exposure to interferon-γ (IFN-γ) and tumor necrosis factor-

α (TNF-α) increases epithelial leakiness through apoptosis and that the cells are more susceptible to cell-death inducers, including Fas ligand [10, 27]. The increased susceptibility to Fas ligand has been shown to be mediated through the IFN-γ-controlled signal transducers and activators of transcription 1 transcription factor [16, 26, 27, 39]. In line with the cell-line studies, it was shown that primary human colonocytes from normal colon undergo apoptosis when stimulated by Fas ligand [35]. The apoptosis response to Fas ligand has, however, never been investigated directly in patients with UC.

We recently performed an mRNA-expression profiling of apoptosis-related genes in an attempt to characterize the pathways of importance for apoptosis in isolated colonocytes, which showed that the primary difference between inflammation and no inflammation in UC was the upregulation of anti-apoptotic cIAP2 (inhibitor of apoptosis protein 2) [33]. This finding is, in particular, interesting, as cIAP2 is well known to be upregulated by cellular stimulation by TNF-α in a nuclear-factor-κB (NF-κB)-dependent manner [5, 38], and as cIAP2 has been implicated as a main regulator of Fas susceptibility in human colonocytes [30].

The current investigation is therefore aimed to investigate regulation of expression and function of cIAP2 and its possible role in UC.

Materials and methods

Patients

Fourteen patients with active UC (patient characteristics, see Table 1) [18], who underwent colonoscopy as part of evaluation of their disease, and 12 control subjects (7 men, median age 57, range 26–86 years), who underwent routine colonoscopy and where the diagnosis of irritable bowel syndrome was later established, were included in the study. Irritable bowel syndrome was defined as abdominal pain or discomfort with altered bowel habits in the absence of organic disease, including a normal endoscopy. No patients with postinfectious colitis were included. No significant differences were found in gender or age between the groups. All UC patients were medicated with mesalazine in the dose range 1.6–3.2 g/day, and 3 of 14 patients were taking glucocorticoids (prednisone in the dose range of 20–40 mg/day). Biopsies in active UC were taken from areas with moderate macroscopic inflammation to avoid biopsies with denuded mucosa due to severe inflammation. Biopsies were taken from inflamed areas in the sigmoideum. Inflammation and diagnosis was confirmed by histology. In three patients, biopsies were obtained from both macroscopically inflamed and uninflamed areas. Biopsies were evaluated by conventional histological criteria, including crypt distorsion, goblet-cell loss, inflammation in the mucosal lamina propria, subcryptal leukocyte infiltration, and absence of changes specific for other diseases such as granulomas. Evaluation of inflammation focused on the presence and degree of activity, which in chronic inflammation bowel diseases is defined as the presence of infiltration of neutrophil granulocytes in the crypts (i.e., cryptitis), formation of crypt abscesses, and ulcerations [9].

Extent of disease	
Left-sided colitis	11
Pancolitis	3

Medians and ranges are shown.

Isolation and culture of human colonic epithelial cells

Colonocytes were isolated as earlier described [32]. In brief, seven colonoscopically obtained biopsies were kept on ice in phosphate-buffered saline (PBS) without Mg^{2+}or Ca^{2+}, containing 50 IU/ml penicillin, 50 μg/ml streptomycin, and 0.5 mg/ml gentamycin and washed three times within 15 min in ice-cold PBS. The biopsies were then incubated in 1 mM ethylene-diamine-tetraacetic acid and 1 mM ethylene glycol-bis(β-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid in PBS without Mg^{2+}or Ca^{2+}at 21°C for 75 min. The chelating buffer was replaced by ice-cold PBS, and crypts and surface epithelium were liberated from the biopsies by shaking. The crypts and surface epithelium were transferred to a new tube and centrifuged in PBS at 20×*g* for 2 min. The loose pellet obtained hereby consists of well-preserved colon crypts without apoptotic features devoid of basal membrane and single cells.

Culture of colonic epithelial cell lines

The human colonic cell lines HT29 and DLD-1 (American Tissue Type Culture Collection; Rockville, MD, USA) were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum (FCS) and passaged twice weekly. For analysis, 10^4 cells were plated in 96-well plates (Nunc, Naperville, IL, USA) in medium containing 10% FCS, 50 IU/ml penicillin, 50 μg/ml streptomycin, and 0.5 mg/ml gentamycine at 37°C in an

atmosphere of 5% CO_2 and relative humidity of 90%. Stimulated cells had either 100 pM TNF-α or the combination of 100 pM TNF-α, 10 pM IFN-γ, and 1 nM interleukin-1β (IL-1β; all cytokines from Sigma-Aldrich) added to the medium and were, in some experiments, co-incubated with the agonistic Fas receptor antibody CH11 (Upstate Technologies, Charlottesville, VA, USA), the mitogen-activated protein kinase inhibitors PD-98059 and SB-203580, the GTPase inhibitor tyrphostin A25, the proteasome inhibitor MG-132, the IAP-inhibitor second mitochondria-derived activator of caspases (Smac)-N7 linked to Antennapedia peptide, or a negative control (SB-202474; all from Calbiochem, San Diego, CA, USA).

Polymerase chain reaction

To investigate the mRNA expression in human primary colonic epithelial cells, mRNA was prepared as previously described [33]. In brief, crypts were transferred directly to Trizol after liberation from the basement membrane. Total RNA was extracted from the colonic epithelium. The integrity and quality of the isolated RNA was determined by evaluation of RNA electrophoresis for each sample.

Reverse transcription (RT) of extracted RNA (100 ng) was performed using RNase H-deficient Superscript II reverse transcriptase and oligo(dT) primers (Life Technologies, Gaithersburg, MD, USA). Aliquots (1 μl) of a diluted RT reaction mixture (20 μl) were used for polymerase chain reaction (PCR). Primers were designed to overlay splice sites in the Hs.127799 gene (BIRC3 gene encoding the cIAP2 protein, UniGene) and in the Hs.123332 gene (BIRC2 gene encoding the cIAP1) using the online Primer3 program. The forward primer for BIRC3 was 5′-CCAAGTGGTTTCCAAGGTGT-3′ and the reverse primer 5′-TGGGCTGTCTGATGT GGATA-3′. The forward primer for BIRC2 was 5′-CCAAGTGGTTTCCAAGGTGT-3′ and the reverse primer 5′-TGGGCTGTCTGATGTGGATA-3′. The forward primer for glutaraldehydephosphate dehydrogenase (GAPDH; Hs.1232332) was 5′-GAGTCAACGGATTTGGTCGT-3′ and the reverse primer 5′-CGGTGCCATGGAATTTGC CAT-3′. Cycling conditions for BIRC3 cDNA amplification was 94°C for 35 s, 59°C for 35 s, and 72°C for 30 s for 28 cycles. The length of the RT-PCR product for BIRC3 was 119 bp. Cycling conditions for BIRC2 cDNA amplification were identical to BIRC3. The length of the RT-PCR product for BIRC3 was 190 bp. The cycling conditions for GAPDH cDNA amplification was 94°C for 35 s, 55°C for 35 s, and 72°C for 30 s for 21 cycles. The length of the RT-PCR product for GAPDH was 175 bp. PCR products were electrophoresed in a 2% agarose gel and subsequently stained with ethidium bromide. Bands were quantified using a laser-equipped fluorescence gel reader (FLA-3000, Fuji-Film, Tokyo, Japan).

The PCR conditions were similar for both cell lines, where 31, 33, and 22 cycles were used for BIRC3, BIRC2, and GAPDH, respectively.

Immunoblotting

Cells were lysed in radioimmunoprecipitation assay buffer [62.5 mM Tris, pH 6.8, 6 M urea, 10% glycerol, 2% sodium dodecyl sulfate (SDS), 0.003% bromophenol blue, and 5% 2-mercaptoethanol], incubated at 95°C for 5 min and then electrophoresed through a 4–12% BisTris SDS/polyacrylamide gel electrophoresis under reducing conditions [36]. Proteins were then blotted to a Hybond enhanced chemiluminescense (ECL) filter (Amersham Biosciences Europe, Freiburg, Germany) using a graphite electrophoresis unit. Filters were incubated at 25°C for 2 h in blocking buffer [5% skim milk and 0.05% Tween 20 in Tris-buffered saline (TBS)] and subsequently incubated overnight at 4°C in diluting buffer (2% skim milk in TBS) containing the primary antibodies. The primary antibodies used were rabbit anti-human cIAP2 polyclonal antibody at dilution 1:2,000, rabbit anti-human cIAP1 1:1,000 (R&D Systems), and rabbit anti-human GAPDH 1:50,000 (Cell Signalling Technology, Beverly, MA, USA). After washing in blocking buffer, filters were incubated for 1 h at 25°C in a diluting buffer containing 1:10,000 dilution of horse radish peroxidase-conjugated secondary antibody (DakoCytomation, Copenhagen, Denmark). Chemiluminescence reaction was performed according to the manufacturer's instructions using ECL Western blotting reagents (Amersham). Filters were digitally photographed by a LSA 1000 (Fuji-Film) cooled charge-coupled device camera and stripped and reincubated with primary antibodies in the following order: cIAP2, cIAP1, and GAPDH. Between reincubations, stripping was tested by applying secondary antibodies.

Protein from colonocytes was extracted from the phenol-methanol-chloroform phase of Trizol after removal of RNA and DNA phases. The protein phase was dialysed against a 0.5% SDS solution overnight in Slide-A-Lyser chambers (Pierce Biotechonolgy, Rockford, IL, USA) and concentrated by ultracentrifugation through a Microcon centrifugal filter (MilliPore, Billerica, MA, USA).

Expression of cIAP1 and cIAP2 in colonic biopsies

For cIAP1 staining, colonic biopsies were snap frozen in liquid nitrogen within 15 s of sampling and then stored at −80°C until analysis. Approximately 4-μm-thick sections were cut and fixed in methanol and acetone (1:1) for 30 min and dried overnight at 4°C. Subsequently, incubation in blocking buffer (PBS with 2% bovine serum albumin and 0.5% Tween) for

10 min was followed by incubation with polyclonal rabbit anti-human cIAP1 antibodies (1:100; R&D Systems) for 30 min at 21°C, and fluorescein-labeled goat anti-rabbit antibodies (1:10; BD Biosciences Pharmingen, San Diego, CA, USA) for 30 min at 4°C. The specimens were then mounted with antifading solution and the fluorescence monitored using a Leica Diaplan fluorescence microscope (Bensheim, Germany) equipped with a fluorescein isothiocyanate filter. Photomicrographs were taken with a Nikon Coolpix 995 digital camera with fixed exposure conditions.

For cIAP2 analysis, colonic biopsies were fixed in 10% buffered formalin, embedded in paraffin in a standard manner, and stored until analysis. Approximately 5 μm-thick sections were cut, deparaffinized, and rehydrated and pretreated with protease, microwaves, and 3% H_2O_2. The slides were incubated with polyclonal rabbit anti-human cIAP2 antibodies (1:800; R&D Systems) for 30 min. This was followed by horseradish peroxidase-conjugated polymers (Envision, DakoCytomation) for 30 min in room temperature. After washing, the specimens were subsequently incubated with diamino benzidine tetrahydrochloride chromogen. Slides were counterstained with Mayer's hematoxylin.

Electrophoretic mobility shift assay

The preparation of nuclear extracts and performance of electrophoretic mobility shift assay (EMSA) was done as previously described [1].

Cell-death assessment

Cell death was quantitated by measurement of lactate dehydrogenase (LDH) release (Cytotoxicity Detection Kit, Roche Diagnostics, Mannheim, Germany). This method is based on the coupled enzyme reaction in which lactate is converted into pyruvate by LDH with the concomitant reduction of NAD to NADH and H^+ which then reduce 2-[4-iodophenyl]-3-[4-nitrophenyl]-5-phenyltetrazolium chloride to the red-colored formazan. LDH-activity was measured in culture supernatants ("released LDH"), and in the remaining cell-monolayer following lysis ("intracellular LDH") with 0.1% Triton X-100. Cytotoxicity was subsequently calculated as: % cytotoxicity = 100% × "released LDH"/("released LDH" + "intracellular LDH").

Statistics

Nonparametric statistics were applied. The Mann–Whitney test was used to compare medians. The chi-square test was used to compare the expression of cIAP2 in histologic samples. A significance level of 0.05 was applied.

Ethics

The Scientific Ethics Committee of Copenhagen County approved the study. All patients gave their informed consent before participation, and the project fulfilled the Helsinki V declaration.

Results

cIAP1 and cIAP2 expression in colonocytes

The level of IAP mRNA in colonocytes was determined by PCR of cDNA based on RNA extracted from freshly isolated colonocytes. Colonocytes from inflamed UC areas had significantly higher mRNA levels of cIAP2 than controls ($p<0.01$). Patients with UC remission had normal cIAP2 values compared to controls.

To determine the cellular localization of cIAP2 at the protein level, immunohistochemistry was made. Colonic epithelium in uninflamed tissue did not express cIAP2. In inflamed colonic tissue, however, cIAP2 was upregulated in regenerative epithelium, whereas colonic epithelial cells in other areas had either low expression levels of cIAP2 or none at all (Fig. 1). Expression was thus found in areas where epithelial cells had delayed differentiation with lack of goblet cells and large hyperchromatic nuclei, indicating that cIAP2 is expressed in regenerating epithelial cells with high cell turnover. cIAP2 expression was not related to the

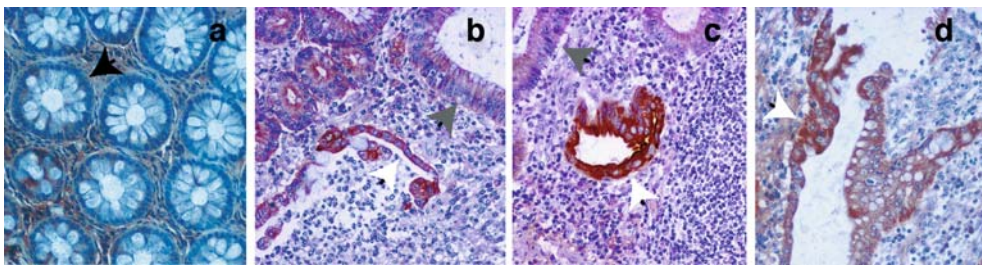

Fig. 1 Microphotographs of control mucosa (**a**) and UC mucosa (**b**–**d**). No staining was seen in control specimen (**a**, *black arrow*). In active UC, cIAP2 expression was limited to regenerative epithelial cells that had high cytoplasmatic expression (**b**–**d**, *white arrows*). Adjacent well-preserved colonic epithelial cells revealed lower or no expression of cIAP2 (**b**–**c**, *grey arrows*). No stromal cells were stained

Table 2 cIAP2 immunohistochemistry results

Samples	Grade of inflammation, median (range)	Epithelial lesions (*n*/*N*)	cIAP2 positive (*n*/*N*)	cIAP2 lesions close to ulceration (*n*/*N*)
Controls	0 (0–0)	0/5	0/5	0/5
Ulcerative colitis	2 (1–3)	5/5	5/5	5/5

Specimens were scored blindly. Grade of inflammation was assessed by conventional histological criteria (see "Materials and methods"). Patients with ulcerative colitis had higher expression of cIAP2 ($p<0.01$).

position along the crypt axis or to surface epithelium. When evaluated blindly, only biopsies from patients with UC showed this pattern of expression ($p<0.01$; see Table 2). cIAP2 protein expression was not detected in biopsies obtained from control subjects.

There was cIAP1 expression in stromal cells, but mRNA and protein cIAP1 levels were identical in UC compared to controls, and no significant epithelial expression was found (data not shown).

cIAP2 regulation upon cytokine stimulation

To further investigate the reason for cIAP2 upregulation in colonic epithelial cells, HT29 and DLD-1 cells were stimulated with either TNF-α or a mixture of TNF-α, IFN-γ, and IL-1β. TNF-α and the cytokine mixture increased cIAP2 mRNA expression in HT29 cells ($p<0.05$), whereas cIAP1 expression remained unchanged (Fig. 2a). Western blot analysis revealed a concomitant upregulation of cIAP2 protein level (Fig. 2c). Contrary to the findings in primary colonocytes, cell lines had a basal expression of cIAP2 on protein level. TNF-α was as effective as the cytokine combination to induce cIAP2 expression (Fig. 2a).

Subsequently, inhibitor assays were performed to determine the possible pathway of cIAP2 induction. Whereas inhibition of MAP-kinase pathways or GTPase inhibition did not alter cIAP expression (Fig. 2d), MG-132, a proteasome inhibitor, dose-dependently downregulated both cIAP1 and 2 expression (Fig. 2b,c). Cytokine-induced cIAP2 induction was additionally downregulated by MG-132 which also inhibited NF-κB activity as shown by EMSA analysis (Fig. 2e).

Effect of proteasome inhibition and inhibition of IAPs on HT29 cell death

To establish whether NF-κB activation and subsequent cIAP2 expression had influence on HT29 cell death, cells were preincubated with MG-132 and stimulated with the agonistic CD95 antibody CH11. MG-132 increased the cell death response to TNF-α alone ($p<0.001$) and to the combination of Fas-agonist and TNF-α ($p<0.0002$ compared to TNF-α and MG-132; see Fig. 3a). This effect was even greater when cells were stimulated by a combination of TNF-α and IFN-γ ($p<0.0002$).

The effect of the cIAP2 upregulation on cell death was subsequently investigated. Cells coincubated with the inhibitor of cIAP2, SmacN7, had increased cell-death response to stimulation with the cytokine mixture and to Fas stimulation ($p<0.008$; see Fig. 3b). The increased cell-death response to

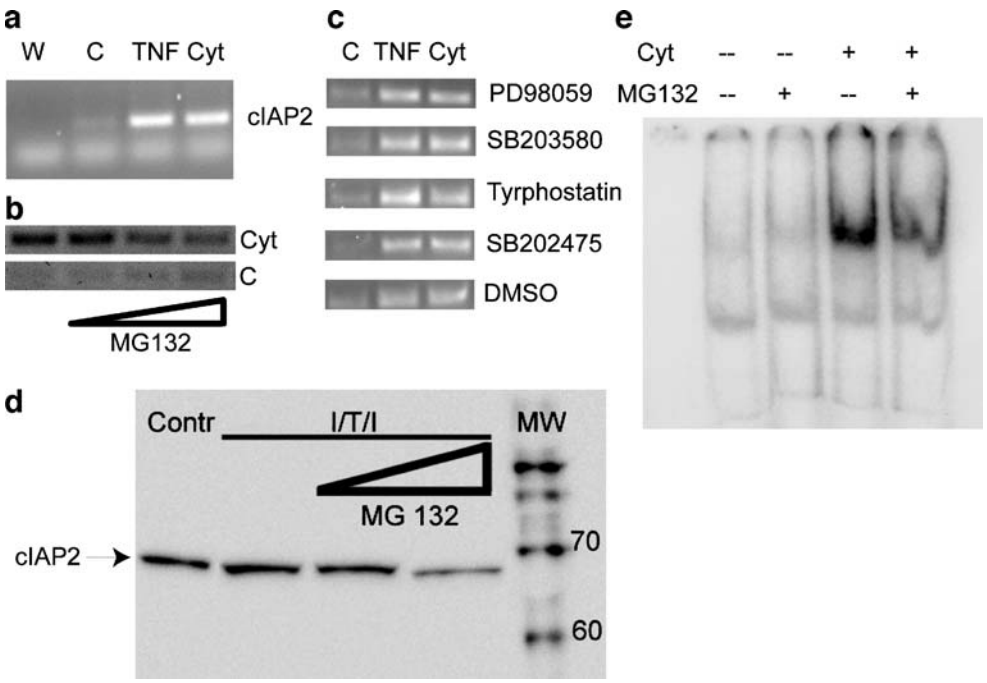

Fig. 2 Analysis of pathways involved in cIAP2 expression in colonic epithelial cell lines. Cytokine stimulation (a combination of IFN-γ, TNF-α, IL-1β; designated Cyt) or TNF-α stimulation (designated TNF) induced cIAP2 expression (**a**, PCR; **d**, Western blot). This upregulation could be inhibited by the proteasome inhibitor MG132 (**b**, PCR; **d**, Western blot). Other MAP-kinase inhibitors and inhibitors of GTPase did not affect cIAP2 expression (**c**, PCR; Western blotting showed similar results, data not shown). A concomitant inhibition of NF-κB was found after MG132 incubation (**e**, EMSA). The notation "*C*" designates control

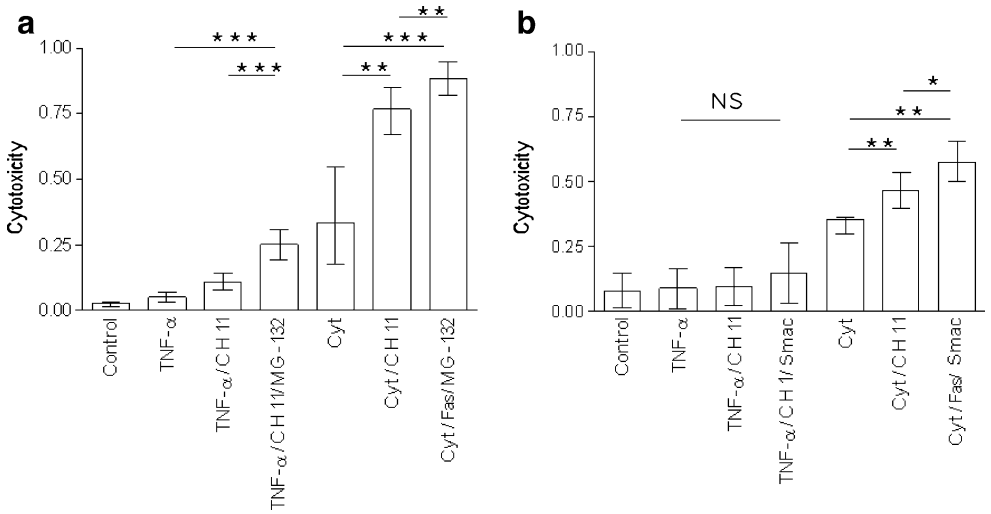

Fig. 3 Histogram showing the cytotoxicity of TNF-α or a combination of TNF-α or IFN-γ, TNF-α, IL1β (designated Cyt) and Fas ligation with the agonistic CH11 Fas receptor antibody. The effect of the proteasome inhibitor MG-132 is depicted in **a**, and the effect of the IAP-inhibitor SmacN7 (designated Smac) is included in **b**. Cytotoxicity is shown as the cytotoxicity rate [dead/(vital cells+dead cells)], and measured by the LDH-release technique. Medians and interquartile are ranges shown. *NS* Nonsignificant; *$p<0.05$; **$p<0.01$; ***$p<0.001$; specific p values are mentioned in "Results"

Fas was seen only after cytokine exposure, suggesting that upregulation of cIAP2 via cytokine stimulation was needed for cIAP2 protection of the cells.

Discussion

We showed that cIAP2, but not cIAP1, is upregulated during mild to moderately active UC, both on mRNA level and on protein level, and that the cells expressing cIAP2 were primarily regenerating epithelial cells. The proinflammatory cytokines IFN-γ, TNF-α, and IL1β, which are of importance in UC, were further shown to upregulate cIAP2 in colonocyte cell lines through activation of NF-κB. Taken together, the current results demonstrate that regenerating colonocytes activate a cytoprotective programme in response to inflammation, which increases the threshold to the cell-death mediator Fas ligand. This response seems to be adequate, as the mucosa during inflammation is invaded by cytotoxic T cells expressing Fas ligand [35]. This can explain why the epithelial lining is often intact in spite of subepithelial accumulation of cytotoxic T cells.

It is well known that the NF-κB pathway is activated in colonocytes in active UC [1]. Activation of the NF-κB pathway is further known to promote survival signaling in a number of cell types, including of course mononuclear immunocompetent cells but also other cell types such as epithelial cells in gastric carcinomas, mesenchymal cells in fibrosarcomas, and mesothelial cells in malignant mesotheliomas [4–6, 12, 38]. In all of these cases, survival appears at least in part due to transcriptional upregulation of IAP proteins as we demonstrated also to be the case during colonic inflammation.

It has been reported that cIAP1 and cIAP2 determines the apoptosis response to Fas ligation in human primary colonocytes [30]. IAPs have recently been assigned another role in colonocytes: Colonic epithelial cells undergo apoptosis when they detach from the basal membrane, a phenomenon called anoïkis. Detachment-induced apoptosis can be inhibited by activating NF-κB in colonic epithelial cells [40]. The resistance to apoptosis has been shown in a number of reports to be due to the activity of IAPs, namely cIAP2 and XIAP [22, 40]. These two IAPs can further be activated by the Ras oncogene, which is not normally activated in epithelial cells but is a known oncogene in colonic carcinomas [20, 21]. When Ras is overexpressed in nonmalignant colonic epithelial cells, these become resistant to detachment-induced cell death as well [21]. Interestingly, bile salts, which previously has been thought to play a role in colon cancer carcinogenesis, also seems to upregulate XIAP through NF-κB activation and thereby render colonic epithelial cells more resistant to apoptosis [37]. Thus, there is ample evidence for a role of IAPs, and especially cIAP2, in the downregulation of apoptotic responses in colonic epithelial cells. Our laboratory is currently investigating the Fas ligand response in primary epithelial cell cultures from patients with active UC.

Activation of cytoprotective pathways goes well along with other modes of regeneration seen during active UC, e.g., that the proliferation is increased [34]. In fact, the mucosa is, during inflammation, not just a hostile milieu but also a milieu that promotes cell survival and generation.

Thus, a wide array of potential proliferation-inducing growth factors are known to be upregulated during inflammation in UC [3, 25]. Many of these growth factors seem to be produced by activated resident cells of the lamina propria, e.g., fibroblasts and myofibroblasts. Although in vitro studies on cell lines have suggested that some of these factors also might decrease cell-death responses, such a mechanism has not been reported in UC [31].

The apoptosis-inhibiting response found in this study could be beneficial by inhibiting apoptotic colonocyte responses during inflammation in UC. It is, however, important to recognize that IAPs are unspecific inhibitors of apoptosis, both by intrinsic and extrinsic pathways [19]. A cytokine-dependent decrease in receptor-mediated apoptosis sensitivity could then be deleterious during chronic inflammatory states by increasing the risk of propagation of DNA-damaged cells where the normal response is either cycle arrest and DNA repair or cell death by apoptosis [8, 28]. The inflammation in UC is accompanied with increased mutagenesis in colonocytes caused by an increased level of reactive oxygen species and dysfunctional DNA repair [13, 23]. These mechanisms might account for part of the increased risk of colorectal cancer found in long-standing and active UC [7]. Interestingly, cIAP2 overexpression has been implicated in tumor initiation in various cancer forms, and p53-mediated apoptosis is, in some cases, known to involve CD95L-CD95 autostimulation [29]. The present results might thus emphasize the importance of inflammation control in prevention of cancer development in UC.

COX-2 localization within plasma membrane caveolae-like structures in human lobular intraepithelial neoplasia of the breast

Abstract Cyclooxygenase-2 (COX-2) is highly expressed in human intraepithelial neoplasia of the breast and takes part in the molecular pathway implicated in progression of breast cancer. Recently, we demonstrated that COX-2 protein is mainly located in plasma membrane of lobular intraepithelial neoplasia (LIN) cells suggesting a localization in caveolae-like structures. The aim of the present study is to establish subcellular locations of COX-2 and its colocalization with caveolin-1 (CAV-1) to caveolae structures in LIN. To establish a relationship between COX-2 and CAV-1, 39 LINs were studied by immunohistochemistry and confocal microscopy analysis. COX-2 and CAV-1 expression was observed respectively in 79.5 and in 94.9% of LIN studied. A positive correlation was found between membrane COX-2 staining pattern and CAV-1 expression, while no correlation was found between cytoplasm COX-2 staining pattern and CAV-1. Confocal analysis showed that COX-2 localized to plasma membrane was strictly associated to CAV-1 suggesting that an amount of COX-2 protein is placed in caveolae-like structures. Our results show that COX-2 is localized within caveolae compartment and colocalized with CAV-1 protein in LIN lesions. Because caveolae are rich in signaling molecules, this COX-2 compartment may play an important role in diverse breast cancer carcinogenesis processes.

Introduction

There is growing evidence that links cyclooxygenase-2 (COX-2) to the development of breast cancer. Liu et al. [16] reported that forced overexpression of COX-2 is sufficient to induce mammary tumorigenesis in transgenic mice. Moreover, a significant reduction in the risk of human breast cancer due to intake of selective COX-2 inhibitors was observed [6].

Recently, we have demonstrated that COX-2 is highly expressed in human ductal intraepithelial neoplasia of the breast and takes part in the molecular pathway implicated in progression of breast cancer [24]. Moreover, our results have demonstrated that COX-2 immunostaining in lobular intraepithelial neoplasia (LIN) shows a prevalent membrane pattern [25] suggesting that COX-2 protein is mainly located in plasma membrane of LIN lesion cells.

It has been reported that COX-2 is localized to endoplasmic reticulum and nuclear envelope [30]. However, recently, Liou et al. [14, 15] have demonstrated in cultured endothelial cells and fibroblasts that a fraction of COX-2 protein is localized to plasma membrane in caveolae-like structures. Caveolins, 21- to 24-kDa proteins, are the major integral membrane component of caveolae [22]. In particular, caveolin-1 (CAV-1) is expressed ubiqui-

tously, and significant levels of CAV-1 protein were demonstrated in normal human mammary epithelial cells [23, 34].

The most active area of research on caveolae/CAV-1 function that is also the most relevant to tumorigenesis focuses on their role as platforms for integrating signal transduction cascades. Caveolae are enriched with membrane receptor-associated signaling molecules and membranous enzymes, anchored to the caveolae via the caveolins [2]. Thus, within the caveolae, a COX-2 interaction with other signaling molecules may be important for the propagation of signal transduction.

The aim of the present study is to recognize subcellular distribution of COX-2 and verify its localization within plasma membrane caveolae-like structures in human LIN of the breast, as the COX-2 compartment in caveolae may participate in specific signaling pathways that are unique to caveolae [22] and thereby contribute to diverse pathophysiological systems such as tumorigenesis [4, 8, 33].

Materials and methods

Clinical material

Immunohistochemical analysis was retrospectively performed on tissue samples that were taken for routine diagnostic purposes. Based on the availability of tissue samples in the archives of the Pathology Service of the Campus Bio-Medico University of Rome, 39 patients with LIN without any invasive component between January 2001 and May 2006 were identified and analyzed. No patient had received chemotherapy, hormonotherapy, or radiation therapy before surgery. Tissue samples were fixed in 10% neutral buffered formaldehyde and embedded in paraffin. Routine hematoxylin and eosin staining was performed on the sections for histopathologic evaluation. LIN histology and LIN grade evaluated at primary diagnosis and extracted from pathology reports were reevaluated by one of the authors (MZ), following Tavassoli criteria published in World Health Organization Classification of Tumours [32]. Based on the quality of the morphologic preservation of all available hematoxylin and eosin-stained slides of the surgical specimen sections, we selected one paraffin block for each case. Consecutive 3-μm sections were recut from each study block. These sections were immunostained for COX-2 and CAV-1 proteins.

Immunohistochemical staining

Immunohistochemistry was performed by the streptoavidin–biotin method. Endogenous peroxidase in the section was blocked by incubating them in 3% hydrogen peroxide. The used antibodies were a mouse monoclonal antibody against COX-2 protein (clone: CX-294, Dakocytomation) and a rabbit polyclonal antibody against CAV-1 protein (clone: N-20, Santa Cruz Biotechnology) at a 1:100 dilution. Sections were incubated with LSAB2 (Dakocytomation). 3–3′-Diaminobenzidine was used for color development, and hematoxylin was used for counterstaining. Negative control slides processed without primary antibody were included for each staining. Macrophages were used as positive internal control for COX-2 staining, while ductal and lobular epithelial cells and blood vessel endothelial cells were used as positive internal control for CAV-1 expression. Slides were examined by two investigators (GP and MZ) without knowledge of the corresponding clinicopathologic data.

Immunostaining was considered positive if appropriate brown staining was seen in membrane or cytoplasm of tumor cell. COX-2 and CAV-1 expression was established calculating the percentage of immunoreactive cells in a total of 1,000 neoplastic cells. LIN lesions with >5% stained cells were recorded as positive [5]. For COX-2 expression, membrane and cytoplasm staining patterns were evaluated separately. Agreement in immunohistochemical evaluation between the two observers was >90%. In cases of disagreement, a final score was determined by consensus after reexamination.

Confocal analysis

Sections were first treated with the antibodies used for immunohistochemical purpose then with tetramethyl rhodamine (TRITC)-conjugated anti-rabbit IgG (Santa Cruz) and fluorescein (FITC)-conjugated anti-mouse IgG (Santa Cruz) both at a 1:200 dilution. After washing with phosphate-buffered saline, coverslips were mounted using an anti-fade solution (AF1, Cityfluor, Cambridge, UK). Negative control slides processed without primary antibodies were included for each staining. Fluorescence images were collected with an E2000U confocal microscope (Nikon, Tokyo, Japan). Acquisition was carried out using the C1 software (Nikon).

Statistical analysis

Spearman's rank correlation test was used to assess relationships between LIN grade, immunohistochemical, and clinicopathological parameters. Values of p of 0.05 were regarded as statistically significant. SPSS software (version 13.00, SPSS, Chicago, IL, USA) was used for statistical analysis.

Results

Patients' characteristics

A total of 39 LIN lesions were studied. The median age of all patients at the time of diagnosis was 57 years (range, 22–83 years), and eight of patients were less than 50 years. Excisional biopsies were performed for calcification in 25, for a mass lesion (5 fibroadenomas, 4 radial scars, and 3 sclerosing adenosis) in 12, and for reduction mammaplasty in 2 cases. Thirteen (33.3%) lesions were LIN1, 20 (51.3%) were LIN2, and 6 (15.4%) LIN3. Data are summarized in Table 1.

Immunohistochemical staining

Among the 39 lesions studied, 31 (79.5%) showed COX-2 expression (Table 2). Macrophages, used as positive internal control, showed only a cytoplasm staining pattern coherently with our recent publications [24, 25]. Membrane COX-2 expression was found in 29 (74.4%) cases, while only 13 (33.3%) lesions showed a cytoplasmic positivity. However, 11 of these latter lesions showed a contemporary membrane immunolabeling; thus, only in two cases cytoplasm staining was present without membrane one (Fig. 1a).

As it concerns CAV-1, 37 lesions (94.9%) showed CAV-1 expression. Immunostaining showed a prevalent membrane pattern associated to a weak cytoplasmic positivity. Stromal tissue around the lesions examined was negative for CAV-1, while ductal and lobular epithelial cells and blood vessel endothelial cells were positive for CAV-1 expression [23], so they were used as positive internal control (Fig. 1b; Table 1).

Correlations between immunohistochemical and patients' characteristics

No statistical significance was found between the age of patients and the expressions of CAV-1 and COX-2. The evaluation of COX-2 expression in different LIN grades showed very similar results to those in our previous analysis performed on another LIN lesion series [25]. A significant correlation was found between COX-2 and LIN grade ($r=-0.394$; $p=0.013$). Furthermore, when membrane and cytoplasm COX-2 staining patterns were separately

Table 1 Patients' characteristics

Characteristics		
Number		39
Age	<50	8 (20.5%)
	≥50	31 (79.5%)
LIN	1	13 (33.3%)
	2	20 (51.3%)
	3	6 (15.4%)
COX-2	Negative	8 (20.5%)
	Positive	31 (79.5%)
CAV-1	Negative	2 (5.1%)
	Positive	37 (94.9%)

Table 2 COX-2 expression in LIN lesion

COX-2 expression	Cases/total	Percentage
Membrane and/or cytoplasm localization	31/39	79.5%
Membrane with or without cytoplasm localization	29/39	74.4%
Membrane without cytoplasm localization	18/39	46.1%
Cytoplasm with or without membrane expression	13/39	33.3%
Cytoplasm without membrane expression	2/39	5.1%

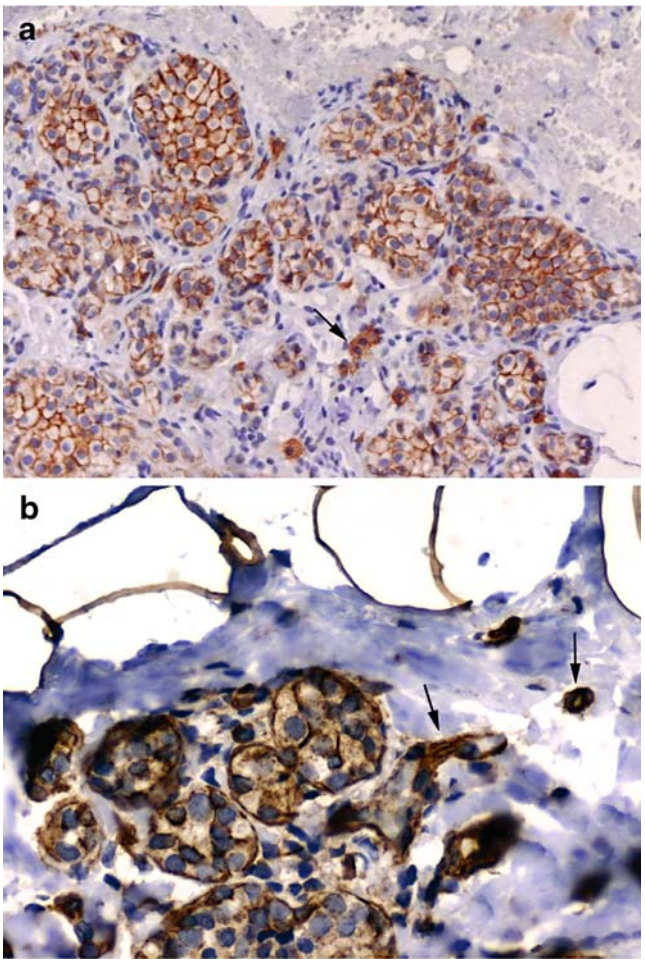

Fig. 1 Immunohistochemical staining. **a** Immunoreactivity with monoclonal antibody anti-COX-2 showed membrane positivity in LIN lesions examined. Tissue macrophages (*arrow*) were used as positive internal control. **b** Immunostaining with polyclonal antibody anti-CAV-1 showed membrane positivity associated to a weak fine granular cytoplasmic staining of LIN cells. Stromal tissue was negative, while blood vessel endothelial cells (*arrows*) were positive for CAV-1 expression; thus, they were used as positive internal control (original magnification: **a** ×200, **b** ×400)

evaluated, a significant correlation was found between membrane COX-2 expression and LIN grade (r=−0.385; p=0.016), while no significant statistical correlation was found between LIN grade and cytoplasm COX-2 expression (r=−0.059; p=0.723; Table 3). Analysis of CAV-1 expression did not provide a significant statistical correlation between this protein and LIN grade (r=−0.04; p=0.81; Table 4).

Relationship between CAV-1 and COX-2 expression

As it concerns the relationship between CAV-1 and COX-2 expression, no significant statistical correlation was found between these two variables (r=0.143; p=0.385). However, when membrane and cytoplasm COX-2 staining patterns were separately evaluated, a positive statistical correlation was found between membrane COX-2 staining pattern and CAV-1 expression (r=0.396; p=0.013), while no significant statistical correlation was found between CAV-1 expression and cytoplasm COX-2 staining pattern (r=−0.306; p=0.058; Table 5).

COX-2 localization in caveolae-like structures

To establish the COX-2 subcellular localization in caveolae-like structures, immunofluorescence double staining experiments between CAV-1 and COX-2 were performed. As previously demonstrated by immunohistochemical experiment, COX-2 and CAV-1 staining showed a prevalent membrane staining pattern. In all LIN lesions examined, the image overlay showed that some portion of the COX-2 localized to plasma membrane was strictly associated to CAV-1 protein, thus suggesting that an amount of COX-2 protein is placed in caveolae-like structures (Fig. 2).

Discussion

COX-2 expression is induced in response to exogenous stimuli such as mitogenic factors and cytokines and occupies a central position in prostanoid biosynthesis: It converts arachidonic acid derived from the upstream enzyme phospholipase A2. By the synthesis of prostaglandin E2, COX-2 affects numerous mechanisms that have been implicated in breast carcinogenesis processes such as angiogenesis [18], immune response [9], and aromatase synthesis induction [35].

Recently, we have demonstrated that COX-2, with a prevalent cytoplasmatic pattern, is highly expressed in human ductal intraepithelial neoplasia of the breast supporting the role of this protein in the early step of breast carcinogenesis and that it takes part in the molecular pathway implicated in progression of breast cancer [24]. Subsequently, we have demonstrated that COX-2 is also expressed in human LIN of the breast. Moreover, when LIN lesions were stratified following Tavassoli classification [32], a significant statistical difference was found between LIN3 vs LIN1–2, thus let hypothesize that this different protein expression pattern could reflect a different biological behavior [25]. Our results have also demonstrated that COX-2 immunostaining in LIN lesions, differently from what was previously established in ductal intraepithelial lesions [24], shows a prevalent membrane pattern, suggesting that COX-2 protein is mainly located in plasma membrane of LIN cells. Furthermore, our results showed a strong correlation between membrane COX-2 staining pattern and LIN grade, while no significant statistical correlation has been found between LIN grade and cytoplasmic COX-2 staining pattern suggesting that membrane COX-2 expression may have a primary role in the evolution of LIN pathology.

The finding that COX-2 expression has a primary role in the first phases of carcinogenesis process is supported by many studies [6, 16, 24, 25]. However, to the best of our knowledge, little is known about the role of a different COX-2 subcellular location in breast carcinogenesis process.

Recent studies have suggested that COX-2 subcellular location is an important determinant for its metabolic

activities and cellular functions [15]. Liou et al. [15] have demonstrated, by subcellular fractionation analysis, that a fraction of COX-2 protein is localized to plasma membrane in caveolae structures in human cultured foreskin fibroblasts.

Caveolins, 21- to 24-kDa proteins, are the major integral membrane component of caveolae [22]. In particular, CAV-1 is expressed ubiquitously, although at different levels in different tissues, with the highest levels in adipocytes, endothelial cells, fibroblasts, smooth-muscle cells, and a variety of epithelial cells [28]. In particular, as it regards mammary tissue, CAV-1 mRNA and protein expression were demonstrated in both epithelial [3, 12, 34] and extra-epithelial components of the human mammary glands (myoepithelial cells) [7, 29]. Furthermore, by immunohistochemical analysis, a clear expression of CAV-1 concentrated at the surface membrane has been confirmed in the human normal epithelial cells of mammary gland [23].

To establish a relationship between COX-2 and caveolae-like structures in LIN pathology, in the current study, a series of LIN lesions were analyzed for COX-2 and CAV-1 expression. A positive statistical correlation was found between membrane COX-2 and CAV-1 expression, while no significant statistical correlation was found between CAV-1 and cytoplasmic COX-2 staining. Furthermore, results obtained by confocal analysis demonstrate for the first time a colocalization of COX-2 and CAV-1 protein on plasma membrane suggesting that some portion of the COX-2 is localized to caveolae of human LIN cells.

COX system is known to be a microsomal enzyme system that is mainly located in endoplasmic reticulum and nuclear envelopment [30]. COX-2 has a stretch of hydrophobic residues that serves as the binding site to the luminal endoplasmic reticulum membrane [10, 26]. It is unclear

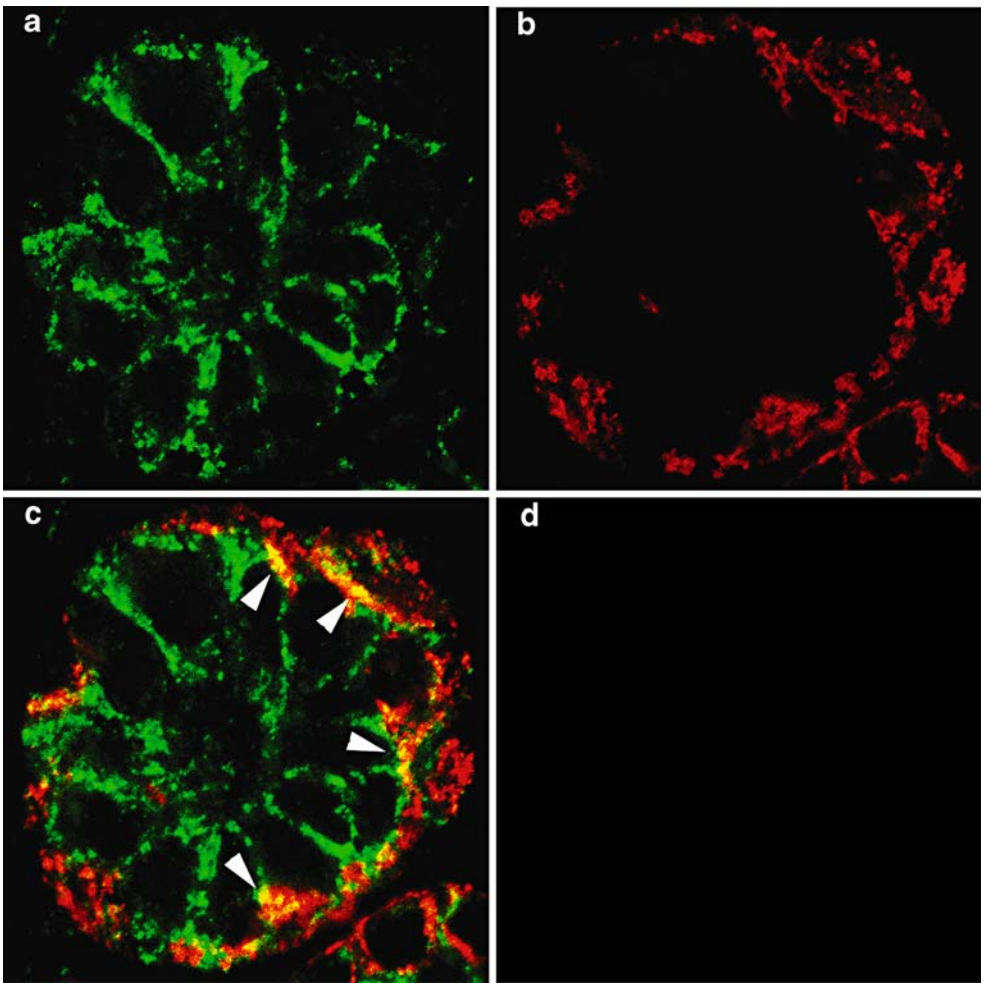

Fig. 2 Confocal analysis. LIN lesions were double-stained with FITC and TRITC and examined by confocal microscope. The figures shown here represent the typical staining pattern for majority of LIN lesions studied. A representative LIN lesion with positive plasma membrane stain for COX-2 (**a**) and CAV-1 (**b**). The image overlay (**c**) of **a** and **b** shows colocalization of CAV-1 and COX-2 on plasma membrane suggesting that plasma membrane COX-2 is located in caveolae-like structures. The image **d** shows the negative control processed without primary antibodies (original magnification ×1,000)

how COX-2 leaves its endoplasmic reticulum residence and migrates to caveolae. One possibility is that COX-2 retention in endoplasmic reticulum is regulated by a posttranslational mechanism, and an alteration of the control mechanism allows COX-2 exit. Once COX-2 comes into the cytosol, it may bind CAV-1 in the cytosolic caveolae-like vesicles, which have been shown to transport proteins to the plasma membrane [19, 21].

The COX-2 compartment in caveolae, which is segregated from the general prostaglandin synthesis factory in endoplasmic reticulum and nuclear envelopment, may participate in specific signaling pathways that are unique to caveolae [22] and thereby contribute to diverse pathophysiological systems such as tumorigenesis [4, 8, 33].

It has been suggested that type IIA and type V secretory phospholipase A2, which are expressed on plasma membrane, are functionally coupled to COX-2 [1, 20]. Functional coupling of secretory phospholipase A2 with COX-2 has been shown to play a major role in the delayed phase of prostaglandin E2 synthesis [11], which affects numerous mechanisms that have been implicated in breast carcinogenesis processes [9, 18, 35].

Furthermore, caveolae are enriched with diverse signaling mediators such as nonreceptor tyrosine kinases [17], components of the Ras-mitogen-activated protein kinase pathway [13, 31], receptor tyrosine kinase (epidermal growth factor receptor, Her2/neu) [3], and plasma membrane estrogen receptor [27]. Because these signaling mediators are specifically involved in the development of breast cancer, COX-2 plasma membrane localization may represent a new frontier for studying its tumorigenic activity.

In conclusion, results of current study represent the first evidence of a colocalization of COX-2 with CAV-1 protein in human LIN lesion suggesting that a portion of COX-2 protein is localized in caveolae-like structures in breast cancer pathology. Further investigations on the regulatory characteristics of COX-2 expression in LIN lesion, such as the sorting mechanism of COX-2 to the caveolae, and on the difference between the microsomal and plasma membranous COX-2 activity may provide us with important clues to the physiology and pathology of COX-2 expression in LIN.

Acknowledgment We express our deep gratitude to Dr. Daniele Santini for critical review and discussion of the manuscript and to Dr. Alessandra Micera for useful collaboration. We have no conflict of interest to declare.

Abstract Limb girdle muscular dystrophy type 2I (LGMD2I) is due to mutations in the fukutin-related protein gene (*FKRP*), encoding a putative glycosyltransferase involved in α-dystroglycan processing. To further characterize the molecular pathogenesis of LGMD2I, we conducted a histological, immunohistochemical, ultrastructural and molecular analysis of ten muscle biopsies from patients with molecularly diagnosed LGMD2I. Hypoglycosylation of α-dystroglycan was observed in all *FKRP*-mutated patients. Muscle histopathology was consistent with either severe muscular dystrophy or myopathy with a mild inflammatory response consisting of up-regulation of class I major histocompatibility complex in skeletal muscle fibers and small foci of mononuclear cells. At the ultrastructural level, muscle fibers showed focal thinning of basal lamina and swollen endoplasmic reticulum cisternae with membrane re-arrangement. The pathways of the unfolded protein response (UPR; glucose-regulated protein 78 and CHOP) were significantly activated in LGMD2I muscle tissue. Our data suggest that the UPR response is activated in LGMD2I muscle biopsies, and the observed histopathological and ultrastructural alterations may be related to sarcoplasmic structures involved in FKRP and α-dystroglycan metabolism and malfunctioning.

Introduction

Limb girdle muscular dystrophy type 2I (LGMD2I) is an autosomal recessive muscular dystrophy caused by mutations in the gene coding for fukutin-related protein (*FKRP*) [6]. LGMD2I is clinically heterogeneous [4, 6, 9, 22, 28], and it is allelic to MDC1C (congenital muscular dystrophy type 1C) with onset in the neonatal period [5].

The function of FKRP in skeletal muscle is largely unknown; however, indirect evidence suggests that FKRP may be a putative glycosyltransferase involved in α-dystroglycan (α-DG) processing [6, 13]. Muscle biopsies of patients affected by either LGMD2I or MDC1C show a variable reduction of α-DG glycosylation [4–6]. α-DG glycosylation is essential for proper interaction of dystroglycan with its extracellular matrix ligands (such as laminin α2) [16] and thus to anchor the muscle fibers to the basement membrane [17].

In the literature, there is a large debate about the subcellular localization of FKRP. Initially, it was hypothesized that FKRP was a Golgi-resident protein required for post-translational modification of dystroglycan and that mislocalization of the mutant protein may underlie MDC1C [13]. Later, it was suggested that FKRP localizes in rough endoplasmic reticulum (ER) [14, 21, 27] and that protein mislocalization is not a common mechanism of disease in LGMD2I/MDC1C [10, 27]. More recently, data indicate that FKRP is present at the muscle cell surface, associates with the dystrophin-glycoprotein complex, and has a unique role in α-DG processing pathway [2].

Here, we have analyzed the histopathological and ultrastructural changes in LGMD2I skeletal muscles in order to further characterize the pathogenesis of LGMD2I.

Material and methods

Patients Muscle biopsies from ten patients affected by LGMD2I were selected from our muscle biopsy database. Both FKRP-mutated alleles were identified in all patients (Table 1). Clinical and genetic findings in all but one patient have been described in detail [4]. All, but patient number 5857, who was asymptomatic, showed proximal muscle weakness. The Gardner-Medwin and Walton functional scale was used to grade muscle function in the patients [15].

At the time of diagnosis, open muscle biopsy was obtained after written informed consent.

Muscle pathology and immunohistochemical studies Thirteen serial sections, 10 μm thick, were obtained from each muscle biopsy. The first section was stained with ATPase at pH 4.3 and the total number of fibers (at least 1,000) counted on photographic enlargement and used to calculate the percentage of fibers immunolabelled with the different antibodies. The fibers area was estimated using the Scion Image Beta 4.03 software.

Twelve different monoclonal antibodies were used as follows: collagen IV (1:50) (Chemicon, Temecula, CA), perlecan (1:100) (MAB1948, Chemicon), laminin α2 directed against the 80-kDa fragment (1:1,000; MAB1922, Chemicon) and against the entire molecule (1:500; NCL-merosin, Novacastra, Newcastle upon Tyne, UK), α-dystroglycan (1:200; IIH6) [12], α-sarcoglycan (1:100; Novocastra), dystrophin (1:100; Novocastra), neonatal myosin heavy chain (1:100; NCL-MHCn; Novocastra), macrophages (CD68; clone EBM11; Dako, Carpinteria, California, USA), CD4 positive helper/inducer T cells (clone MT310; Dako), CD8 positive cytotoxic/suppressor T cells (clone DK25; Dako), and major histocompatibility complex (MHC) class I molecules (W6/32; Dako).

The intensity of reaction was examined by visual inspection by the same observer and graded as follows: absent or normal (−), slight increase or reduction (+), moderate increase or reduction (++), severe increase or reduction (+++).

The severity of the dystrophic process and muscle histopathology was scored as previously described [7].

α-DG immunoblot was done as previously described using the IIH6 antibody [4].

Electron microscopy Small muscle specimens were fixed after surgery in 2.5% glutaraldehyde and postfixed in 1% OsO_4. After dehydration in graded ethanol, the specimens were embedded in Araldite. Thin sections were stained in uranyl acetate and lead citrate and observed in a Philips 410T transmission electron microscope.

Table 1 Clinical and molecular data in LGMD21 patients

Unfolded Protein Response studies RNA was extracted from frozen muscle biopsies from 10 patients and 11 normal controls using SV Total RNA Isolation (Promega, Madison, WI, USA) and reverse transcribed using an ImProm-II Reverse Transcription System (Promega) according to the manufacturer's instructions. Quantitative reverse transcriptase polymerase chain reaction (RT-PCR) was performed using an ABI Prism 7900 (Applied Biosystems, Foster City, CA, USA) and SYBR Green detection (Invitrogen, Carlsbad, CA, USA). The sequence of primers for GRP78 and CHOP were as published [1, 29]. As an internal control, the extent of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) expression in the same tissue was determined. Relative GRP78 and CHOP expressions were given as GRP78/GADPH, and CHOP/GADPH ratios and normalized values were subjected to a 2-ΔΔCt formula to calculate the fold change between controls and patients. All reactions were carried out in triplicate to reduce variation.

Results

Patients Five male and five female patients affected by LGMD2I were studied. Age at onset was on average 22 years (range 2–50 years), and average age at biopsy 30 years (range 2–58 years). Mean disease duration at biopsy ranged from 0 to 35 years. Clinical severity at biopsy ranged from 0 (asymptomatic) to 5 (unable to rise from the floor) according to the Gardner Medwin and Walton scale (Table 1).

α-DG studies Since mutations in the *FKRP* gene result in α-DG hypoglycosylation, we used an antibody directed against a glycosylated epitope of the protein (IIH6) to study muscles biopsies from ten LGMD2I patients and found a depletion in α-DG glycosylation in all biopsies studied (Table 2; Fig. 1). However, comparison between patients showed a complete deficiency in only two of them (numbers 960 and 888) (Fig. 1b), while a variable reduction of α-DG glycosylation ranging from slight to moderate was observed in the remaining patients (Fig. 1c, d). Interestingly, a mosaic-like pattern was also noted in most cases, with some fibers showing clear, strong α-DG labeling at the sarcolemma and others a marked depletion of the protein (Fig. 1c).

α-DG immunoblotting using the IIH6 antibody was done in seven of the ten LGMD2I patients studied and confirmed a depletion in glycosylated α-DG in all. In five patients (patients 960, 1191, 888, 899, 979) only traces of glycosylated α-DG, in patient #5857 about 5%, and in patient #1475 about 20% of controls glycosylated α-DG were detected.

Extracellular matrix and dystrophin-associated protein studies To determine whether modifications of α-DG glycosylation may influence the expression of extracellular matrix proteins, laminin α2, perlecan, and collagen IV were studied in patients' muscle. No significant differences were observed in patient compared with control muscle (Fig. 1). Moreover, to investigate the dystrophin-associated complex, dystrophin and α-sarcoglycan were also studied; their expression in LGMD2I muscle biopsies proved normal compared to controls (Fig. 1).

Muscle pathology According to the severity of the pathological pictures (regeneration, degeneration, and fibrofatty replacement) muscle biopsies were graded as mild, moderate, severe, and active muscular dystrophy (Table 2).

◀ **Fig. 1** α-Dystroglycan immunofluorescence in LGMD2I patients' muscle biopsies. **a** Control, **b** patient number 888, **c** patient number 5342, and **d** patient number 1475 muscle biopsy stained with the IIH6 antibody directed against a glycosylated epitope of α-dystroglycan. α-Dystroglycan was normal in the control and completely negative in patient number 888. Muscle biopsy of patient number 5342 shows a marked reduction of immunostaining but a few scattered fibers are α-dystroglycan-positive in a mosaic-like pattern. α-Dystroglycan of patient number 1475 is mildly reduced. **e**–**j** Muscle biopsy of patient number 888 stained with antibodies directed against various membrane and extracellular matrix proteins. All proteins showed normal reaction in the patient's muscle biopsy

To study muscle regeneration, neonatal myosin was immunostained in patients and controls (Table 2). Neonatal myosin-positive muscle fibers were observed in six patients' biopsies, ranging from <1 to 8% of the total number of fibers. These regenerating fibers were either clustered in small groups of 10–15 elements (in patient numbers 960, 888, 1191, and 5342) or scattered in the muscle biopsies. Degenerating fibers, including hyaline and necrotic fibers and fibers undergoing phagocytosis, were less than 1% in all biopsies studied, and fibrofatty replacement, assessed by visual inspection, ranged from severe to absent (Table 2).

In most patients in our series, muscle histopathology was relatively benign and showed mild (40%) or moderate myopathic features (40%) with fiber size variability, a mild increase in perimysial connective tissue, increased number of central nuclei, and scattered foci of inflammatory cells (Fig. 2b,d). In one patient (number 960; Table 1) muscle pathology was consistent with an active, aggressive muscular dystrophy resembling Duchenne dystrophy (DMD-like; Fig. 2a) and in another (number 5342; Table 1) with a severe, advanced dystrophy. Interestingly, this latter patient was the only one to be biopsied 35 years after onset of symptoms (Fig. 2c).

Muscle infiltrate characterization To characterize the small foci of inflammatory cells observed in the LGMD2I muscle biopsies, a panel of different antibodies specific for T helper/inducer, T cytotoxic/suppressor and phagocyte markers was used (Table 2). A mild or moderate increase in MHC class I was observed in all biopsies. Mononuclear cells, either scattered or organized in small aggregates, were localized in the interstitium and in the perivascular space, and sometimes they surrounded and invaded single muscle fibers. Macrophages formed the most abundant mononuclear cell subset and were seen either surrounding or invading muscle fibers or localized in the perimysium or endomysium. The T cells were predominantly of the CD4+ type (T helper), although a few CD8+ cells were observed.

Electron microscopy Ultrastructural studies were performed on biopsies from three patients (numbers 5342, 3285, and 5857). In all cases, the basal lamina of muscle cells showed abnormalities. In normal muscle, the basal lamina appears as a uniformly fibrillar dense structure overlying the sarcolemma. In LGMD2I, the basal lamina appeared thinner than normal, deranged and often disrupted in non-

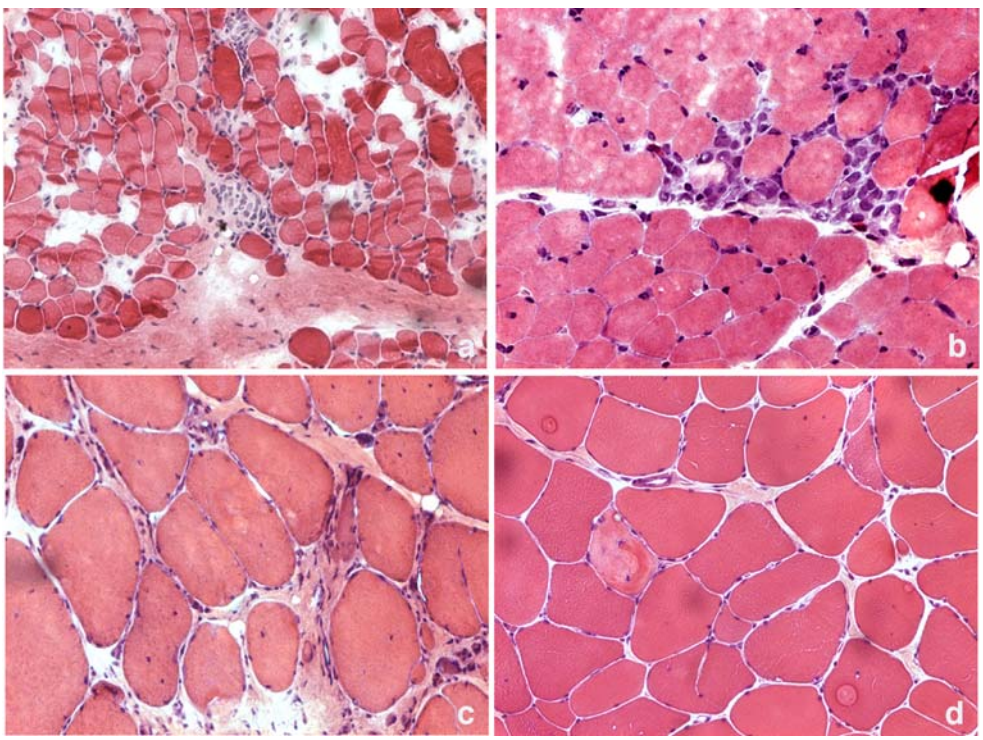

Fig. 2 Muscle histopathology in LGMD2I patients. **a** Patient number 960, **b** patient number 888, **c** patient number 5342, and **d** patient number 1191 muscle biopsy stained with hematoxylin and eosin. **a** Aggressive muscular dystrophy, **b** a small focus of mononuclear cells invading necrotic muscle fibers, **c** an advanced, long-lasting muscular dystrophy, and **d** mild myopathy

necrotic muscle fibers and focally resulting in a skein-like structure (Fig. 3a). In the sarcoplasmic compartment, a severe loss of myofilaments, dilated sarcoplasmic reticulum, and T system profiles were observed. T tubules were often swollen and assembled asymmetrically with supernumerary junctional sarcoplasmic reticulum components (Fig. 3b). The main ultrastructural feature was a marked accumulation of lipid droplets (Fig. 3c) both in the intermyofibrillar region and in the subsarcolemmal area, where it often appeared to be associated with many mitochondria (Fig. 3d).

Unfolded protein response studies In order to verify whether mutant FKRP and/or hypoglycosylated α-DG may elicit an unfolded protein response (UPR), we used quantitative RT-PCR to study the expression of the GRP78 chaperone protein, whose function is to increase the folding capacity of the endoplasmic reticulum, and the expression of CHOP, a proapoptotic transcription factor.

mRNA expression level of GRP78 in LGMD2I patients (GRP78/GADPH ratio±SD, 2.05±1.08) showed a significant increase as compared to controls (GRP78/GADPH ratio±SD, 1.0±0.3), +2-folds ($p<0.007$; Fig. 4).

The expression of CHOP was also up-regulated in LGMD2I patients but to a lesser extent: +1.5-folds compared to controls ($p<0.05$; Fig. 4). The CHOP/GADPH expression ratios were 1.74±0.62 in LGMD2I patients vs 1.18±0.61 in controls.

Moderate variability was observed in the expression level of both GRP78 and CHOP in LGMD2I patients' muscle biopsies (Fig. 4).

Discussion

The molecular mechanisms underlying the wide clinical spectrum due to *FKRP* gene mutations are poorly understood. We studied muscle biopsies from ten patients affected by LGMD2I to further characterize the pathogenesis of the disease and suggest that the activation of an endoplasmic reticulum stress response may partly explain differences in disease severity. Diagnosis in our cohort of patients was based on the identification of both *FKRP*-

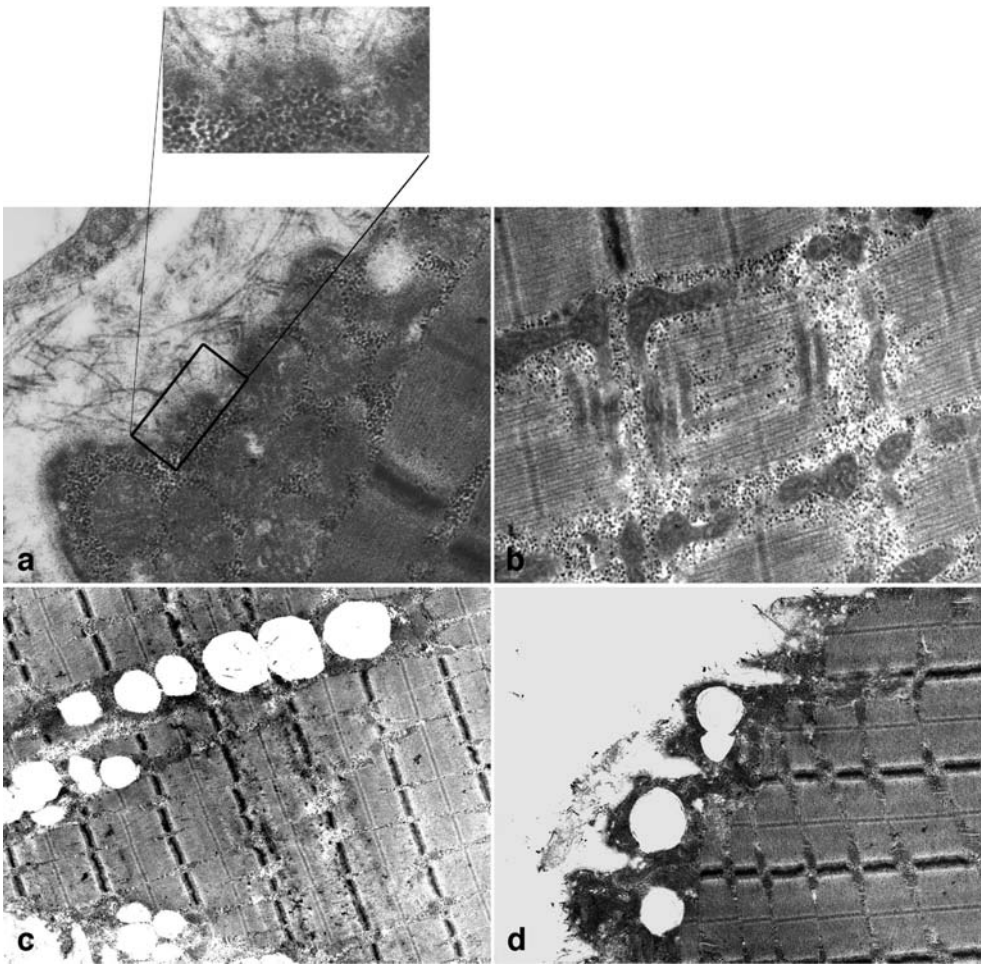

Fig. 3 Transmission electron microscopy in LGMD2I patients. **a** and **c** Patient number 5342, **b** patient number 3285, and **d** patient number 5857. In **a**, the myofiber basal lamina focally features a skein-like structure, and an irregularly-textured appearance (in the *enlargement details* of the deranged basal lamina). Triad reduplication (**b**) is present in the sarcoplasm together with many lipid droplets (**c**) which appear to be mitochondria-associated in the subsarcolemmal region (**d**)

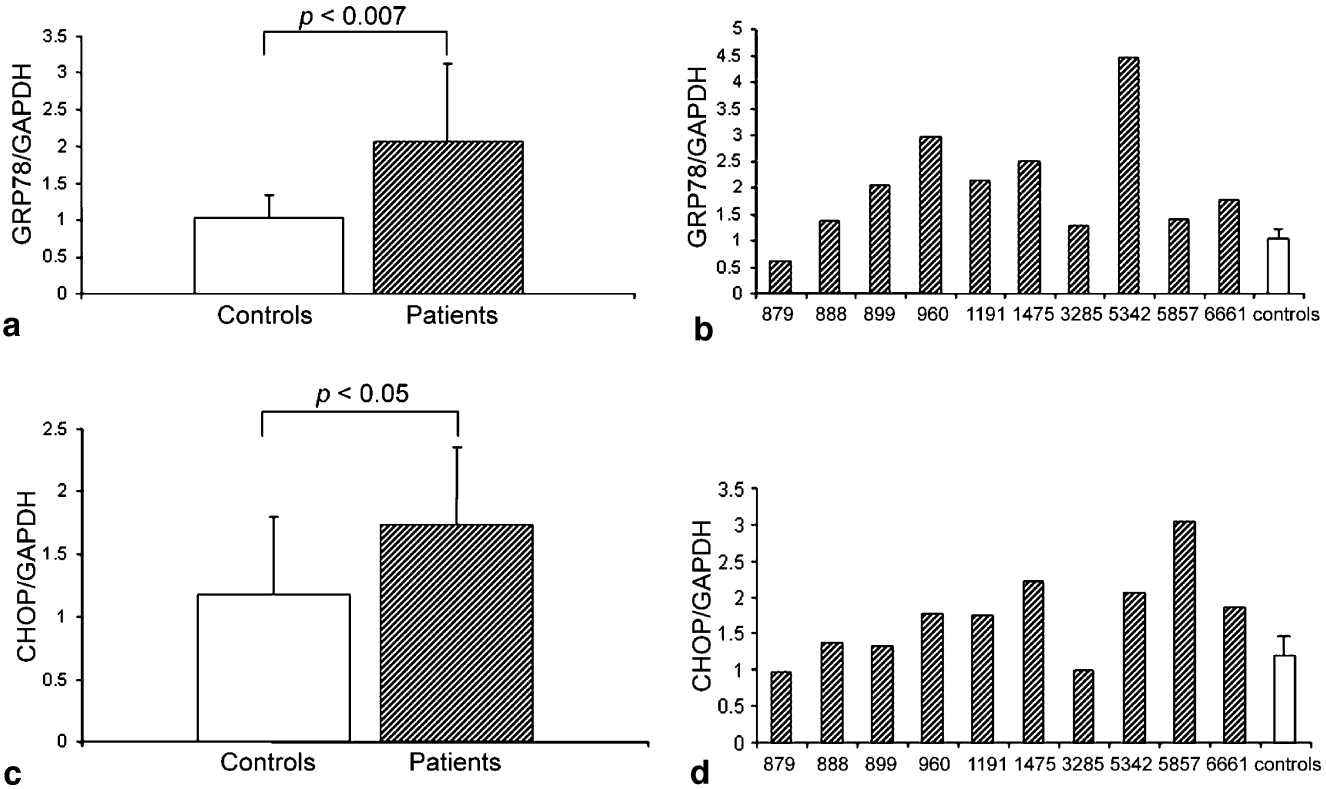

Fig. 4 Up-regulation of GRP78 and CHOP in LGMD2I. Quantitative reverse transcription PCR (RT-PCR) shows significant transcriptional up-regulation of GRP78 and CHOP in LGMD2I patients. The expression of each experimental gene was quantified in relation to GADPH control gene. Quantitation of RT-PCR products is shown with standard deviation and *p* values vs control. **a** and **c** Mean GRP78 and CHOP expression values in patients and controls; **b** and **d** expression values for GRP78 and CHOP for individual patients

mutated alleles in all. The histopathological spectrum in this cohort was not specific, but a variable reduction of α-DG glycosylation was observed in all patients' muscle biopsies, confirming the role of FKRP in α-DG processing in LGMD2I. α-DG is a heavily glycosylated protein that has a pivot role in stabilizing the functional network between the muscle fiber membrane and the extracellular matrix. The interactions between α-DG and its extracellular ligands (laminin, perlecan, neurexin) seem to be mediated by the sugar chains of α-DG itself. Thus it is likely that abnormal glycosylation of this protein may result in derangement of the basal lamina as already observed in other muscular dystrophies due to defective glycosylation of α-DG [19]. Indeed, our ultrastructural studies showed a focally disorganized and thinner basal lamina in LGMD2I.

Various hypotheses have been so far put forward to explain the differences in disease severity in FKRP-related muscular dystrophies (the level of α-DG hypoglycosylation [5, 6, 13], the type and the effect of the *FKRP* gene mutation on the protein function [13], the loss of Golgi localization, and the accumulation of the protein in ER [18]), but none alone fully explain clinical variability.

We hypothesized that mutant FKRP, retained in the ER, may trigger an endoplasmic reticulum stress response and thus modulate clinical phenotype.

Protein glycosylation is an organized and ordered process. Newly synthesized proteins are sequentially modified by glycosyltransferases during transfer from the ER to the Golgi apparatus [11, 23]. Recently, it has been suggested that transportation of mutant FKRP is altered in the cells and leads to ER retention [18]. It is conceivable that mutant FKRP and/or hypoglycosylated dystroglycan may be misfolded in the ER and detrimental to the cell. Misfolded proteins may then trigger an intracellular signalling pathway from the ER to the nucleus, known as the UPR, resulting in transcriptional up-regulation of several ER-resident proteins [11, 23] whose function is to re-establish cell homeostasis. It is interesting to note that by blocking glycosylation, the UPR can be experimentally activated in the yeast *Saccharomyces cervisiae*, the best model system in which UPR has been studied [8].

In order to verify the hypothesis that UPR is activated in LGMD2I, we studied GRP78 and CHOP expression in patients' muscle biopsies. We showed that GRP78, an ER chaperone protein that increases protein folding activity induced by ER stress, is significantly up-regulated in LGMD2I. Moreover, we also showed that CHOP, a pro-apoptotic factor, member of the C/EBP family (C/EBP-homologus protein) also induced by ER stress [20], is up-regulated in LGMD2I, albeit it to a lesser extent. Both

GRP78 and CHOP up-regulation cope with the accumulation of unfolded or misfolded proteins: GRP78 by increasing the folding activity of the ER and CHOP by activating the ER-associated caspases [25].

Moreover, the up-regulation of class I MHC molecules we observed in our cohort of patients may also contribute to the activation of the UPR in LGMD2I. It has recently been shown that overexpression of class I MHC molecules may induce an ER stress response and may mediate muscle-fiber damage and dysfunction in the absence of lymphocytes through a nonimmune pathway involving both Grp78 and CHOP up-regulation [24]. Skeletal muscle fibers do not constitutively express class I MHC molecules, but their up-regulation is an early and consistent feature of human inflammatory myopathies [24]. Interestingly, we observed mild, secondary inflammation in most of our LGMD2I biopsies studied mainly constituted by macrophages, by a few CD4 and CD8 T lymphocytes, and by a variable, but constant, up-regulation of class I MHC molecules.

Lastly, our electron microscopy studies on patients' muscle biopsies provide indirect evidence suggesting that UPR activation occurs in LGMD2I. These revealed rough endoplasmic reticulum proliferation and modifications, as dilated cisternae triad reduplication, and accumulation of lipid droplets.

Expansion of the ER and elevated levels of phospholipid biosynthesis under UPR induction occur in mammalian cells [26] and in yeast [3] and are probably direct to reducing the concentration of unfolded proteins to prevent aggregation.

Unfortunately, we did not find direct correlations between the degree of UPR activation and severity of clinical manifestations suggesting that clinical phenotype in LGMD2I is the result of multiple molecular mechanisms.

The link between the UPR, lipid biosynthesis and biogenesis of the ER in LGMD2I needs further study, but our preliminary data suggest that the histopathological and ultrastructural alterations observed in LGMD2I may be related to the sarcoplasmic structures involved in FKRP and/or α-DG metabolism and malfunctioning.

Abstract In transmissible spongiform encephalopathies (TSEs), the infectious agent, called PrPsc, an abnormal isoform of the cellular prion protein, accumulates and replicates in lymphoid organs before affecting the nervous system. To clarify the cellular requirements for the neuroinvasion of the scrapie agent from the lymphoid organs to the central nervous system, we have studied, by confocal microscopy, the innervations within Peyer's patches, mesenteric lymph nodes and the spleen of mice in physiological conditions and after oral exposure to prion. Contacts between nerve fibres and PrPsc-associated cells, dendritic cells (DCs) and follicular dendritic cells (FDCs), were evaluated in preclinical prion-infected mice. Using a double immunolabelling strategy, we demonstrated the lack of innervation of PrPsc-accumulating cells (FDCs). Contacts between nerve fibers and PrPsc-propagating cells (DCs) were detected in T-cell zones and cell-trafficking areas. This supports, for the first time, the possible implication of dendritic cells in the prion neuroinvasion process.

Introduction

Prion diseases, also called transmissible spongiform encephalopathies (TSEs), are invariably lethal, transmissible neurodegenerative diseases that affect humans and animal species. Prion infections cause characteristic lesions in the central nervous system (CNS). According to the protein-only hypothesis, the causative agent, called prion, is an abnormal conformer of a host membrane glycoprotein. Expression of this normal cell protein (PrPc) is essential to TSE pathogenesis, as the basic pathogenic mechanism involves post-translational conversion of PrPc into the pathogenic conformer, scrapie PrP (PrPsc) [47].

Prions colonize the lymphoid compartment of infected organisms in most TSEs. After intracerebral, oral or intraperitoneal inoculation, prion is detected in many sites of the lympho-reticular system (LRS), including the spleen, lymph nodes, Peyer's patches and tonsils [34]. The accumulation of TSE agents in lymphoid tissues is essential for efficient neuroinvasion [19, 39, 45]. Indeed, it highlights the role of prion-associated cells and the peripheral nervous system, innervating infected lymphoid organs in prions neuroinvasion.

Follicular dendritic cells are stromal-differentiated cells present in the germinal centres of activated lymphoid follicles. Follicular dendritic cells (FDCs) are greatly implicated in prion disease because they accumulate PrPsc

after scrapie infection [30]. Moreover, mice devoid of FDCs and lacking an organized micro-architecture show reduced or impaired prion accumulation in lymphoid organs after peripheral exposure [46]. Immunologic disappearance or de-differentiation of mature and functional FDCs inhibit peripheral prion pathogenesis [35, 40]. However, how TSE agents initially arrive in the FDCs network and spread from the FDCs to the peripheral nervous system remains unclear. TSE agents are unlikely to be transferred directly across an FDC–nerve synapse [34], as such physical contacts between them are rare and each cell type occupies a distinct and separate anatomical site [12, 16]. For example, within the spleen, sympathetic nerves are associated with blood vessels, whereas FDCs are located in the periphery of the white pulp within B-cell follicles. FDCs form immobile networks; thus, a mobile intermediate cell seems necessary to transfer TSE agents to the peripheral nervous system.

The enteric nervous system is an important component of the autonomic nervous system, and it regulates intestinal motility and secretions through stimuli from sympathetic nerves and parasympathetic nerves [15]. Detailed chronological analysis of the distribution of disease-specific PrP within the nervous system of orally inoculated rodents indicates that the scrapie agent subsequently spreads from the gut-associated lymphoid tissue (GALT) to the CNS through the enteric nervous system [6, 7, 27]. Indeed, TSE agents are thought to reach their initial CNS target sites by spreading in a retrograde direction along efferent fibres of both sympathetic and parasympathetic nerves [6, 37]. Parasympathetic nerves, unlike sympathetic nerves, enter the CNS independently of the spinal cord, indicating that TSE agents can enter the CNS through several routes [3]. Once disease-specific PrP enters the spinal cord; it spreads along it in both anterograde and retrograde directions [5]. The neuroinvasion of scrapie in sheep [26, 51], CWD in mule deer [48], sporadic CJD [21] and vCJD in humans [25] from the GALT also seems to occur through the enteric nervous system. Confirmation of the involvement of sympathetic nerves in TSE pathogenesis was provided by experiments demonstrating that neuroinvasion was impaired after depletion of sympathetic nerves [23]. The transmission of TSE agents within the peripheral nervous system and into the CNS is dependent on the expression of PrPc [8, 22]. These findings suggest that innervation of secondary lymphoid organs is a rate-limiting step in the pathway to neuroinvasion [21].

Dendritic cells are migrating cells capable of binding and carrying prion [28]. Interestingly, DCs are sufficient to induce scrapie infection directly via the peripheral nervous system [2]. Anatomical connections between migratory bone-marrow-derived DCs and the peripheral nervous system have been described in Peyer's patches of healthy mice [12, 33]. DCs could function as a bridge between the gut lumen, the TSE replicative machinery and the peripheral nervous system. It is tempting to speculate that DCs could transport prions to the peripheral nerves in lymphoid organs, thereby enabling the process of neuroinvasion.

We examined the topography of the peripheral nervous system in lymphoid tissues, considered to be the likely site of initial neuroinvasion of the infectious prions. We demonstrate contacts between nerve fibres and DCs in preclinical scrapie infected lymphoid organs. These observations support their possible implication in the neuroinvasion process and permit to localise some crucial sites where prions could invade the nervous system.

Materials and methods

Animals

C57Bl/6 mice were maintained with food and drink ad libitum under standard conditions, in compliance with our institution's ethical guidelines. Twelve mice were infected with 139A scrapie strain by oral inoculation of 200 μl of a 10% brain homogenate and were euthanised at the preclinical stage, 105 days post inoculation. Peyer's patches (PP), mesenteric lymph nodes (MLN) and spleens (S) were dissected and available for examination. Twelve age-matched normal brain inoculated control mice were also euthanised at day 105, and lymphoid organs were dissected for examination.

Detection of resistant prion protein

To confirm the presence of scrapie infection in the mice, brains and lymphoid organs were fixed in 4% formalin and embedded in paraplast. Endogenous peroxidase activity was inhibited on sections (7 μm) by a 30-min incubation in 0.3% H_2O_2 in phosphate-buffered saline (PBS). They were pretreated according to the following steps: incubation in 4 M guanidine thiocyanate at 4°C for 2 h, hydrated autoclaving (immersion in citrate buffer pH 6.0) for 10 min at 121°C, immersion in 98% formic acid for 5 min (RT) and in proteinase K at 37°C for 15 min (10 μg/ml). PrPsc detection was performed using the monoclonal antibody SAF 83 (kindly provided by J.Grassi), 1/100 for 2 h at room temperature. The antibody had been pre-incubated with a biotinylated antibody (GAM-biot, Pharmingen, 1/100) at room temperature for 10 min. The enzyme-conjugated streptavidin (AEC, Zymed) and peroxidase-conjugated biotin-avidin complex (ABC, Zymed) were used for light microscopy observations.

Counter-staining was performed by immersion in Papanicolaou solution at room temperature.

Cryosections

The lymphoid organs were immersed in tissue-TEK OCT embedding medium (Sakura, Zouterwoude, The Netherlands) and snap-frozen. Sections (10 μm) were cut at −20°C with a microtome (Microtom HM 500 OM, France), deposited on glass slides coated with poly-L-lysine (Sigma, St. Louis, USA), air-dried, fixed in acetone for 10 min at 4°C and stored at −20°C until use.

Immunofluorescent stainings

After re-hydration, cryosections were incubated with antibodies directed against immune cells and nerve fibers. Incubation with antibodies was performed at room temperature in the dark for 1 h.

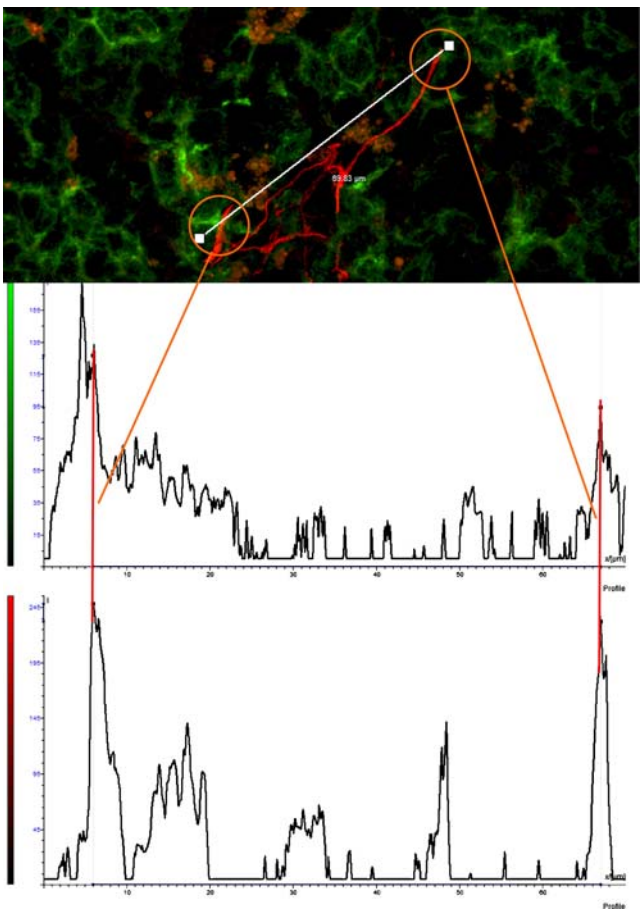

Fig. 1 Confocal analysis of co-localisation of dendritic cells and nerve fibers in scrapie infected mice. Imaging (*left*) and spectral (*right*) analysis of close connections between DCs (*green*) immunolabelled with anti-CD11c antibody and nerve fibres (*red*) detected with anti-NF 150 kDa antibody. The spectral study was realised along the *white bar* on the picture. This picture was one of the confocal images. *Bar* 25 μm

Immune cells were stained with the following antibodies:

1. *Dendritic cells*, anti-CD11c-FITC (1/400) (eBioscience, USA)
2. *Macrophages*, anti-CD11b-PE (1/200) (BD Biosciences, Belgium)
3. *Immature B cells*, anti-IgD-FITC (1/200) (BD Biosciences)

Nerve fibers were labelled with antibodies directed against:

1. *Intermediate neurofilaments*, rabbit anti-mouse *NF H* 1/100 (200 kDa), *NF M* 1/800 (150 kDa) and *NF L* 1/200 (68 kDa; Chemicon, USA).
2. *Schwann cells*, rabbit anti-cow *GFAP* 1/250 (Dako, USA).
3. *Synapses*, rabbit anti-mouse *Synaptophysin* 1/100 (Chemicon)
4. *Catecholaminergic nerve fibers*, rabbit anti-mouse *tyrosin hydroxylase* 1/400 (Chemicon).

A rhodamine-conjugated goat anti-rabbit secondary antibody (Molecular Probe, Leiden, the Netherlands), diluted 1/6,000, was secondary applied on cryosections.

To test the general specificity of the antibodies used, samples were incubated with irrelevant antibodies. Negative controls were obtained by incubating samples with only secondary antibodies.

Confocal analysis

All samples were observed with a Leica (Germany) SP2 confocal microscope. Cryosections of 10 μm were scanned on their best fluorescent zone (5–7 μm), which was divid-

Double immunolabellings of dendritic cells highlighted with antibody directed against CD11c and nerve fibres labelled with antibodies raised against: NF 68 kDa (interfollicular region, **b**); NF 200 kDa (vessel walls, **c**); Synaptophysin (crypts, **d**) and GFAP (villi and SED, **e** and **f**) in transverse sections of scrapie-infected Peyer's patches. The localisation of illustrated neuro-DC interfaces in the organ was summarised in the **a**. The numerous close contacts in yellow are surrounded by a *white ring*. *Bars* 40 μm (**b**); 40 μm (**c**); 80 μm (**d**); 25 μm (**e**); 50 μm (**f**)

ed in 15 sections. Each section was analysed. Virtual colors were attributed for detection channels (green for immune cells and red for nerve fibers) and the merge (yellow). Two analytical methods were used to highlight connections between dendritic cells and nerve fibers: image analysis and spectral analysis of color channel (Fig. 1). These combined approaches allowed us to confirm contacts.

Results

Neuro-dendritic cell interfaces in scrapie infected Peyer's patches

Peyer's patches can be histologically separated in two regions: lymphoid and non-lymphoid compartments. Lymphoid areas include the suprafollicular domes, the inter-

follicular regions (IFR) or T-cell zones, the lymphoid follicles and draining vessels. Non-lymphoid compartments involve lamina propria of villi and crypts.

As described in a previous study on healthy mice using NF antibodies and GFAP [12], the lamina propria is strongly innervated compared with the lymphoid compartments. Our present study on scrapie infected mice, based on additional nerve markers, confirms these observations by highlighting the absence of innervation in the germinal centres (Table 1).

The region IFR is the most innervated lymphoid compartment. In this area, NF 68 kDa, GFAP, TH and NF 150 kDa positive fibres were found in contact with dendritic cells. In the blood vessel walls, DCs established contacts only with NF 200 kDa positive nerve fibres. GFAP, TH, synaptophysin and NF 68 kDa markers were co-localised with DCs within the crypts and in the villi. In the subepithelial domes, above the lymphoid follicles, neuro-DCs interfaces were observed only with the anti-GFAP antibodies (Fig. 2). We obtained the same results in control mice and in mice orally inoculated with scrapie (Table 2).

++ Fairly innervated; + slightly innervated; − no positive nerve fibre. *IFR* Interfollicular regions; *T Zone* T-cell zones; *GC* germinal centres

Neuro-dendritic cell interfaces in scrapie infected mesenteric lymph nodes

Lymph nodes are classically subdivided in three regions: cortex, paracortex and medulla. The cortex includes lymph follicles and the interfollicular areas. Paracortex is a thymus dependent zone (T-cell zone).

Within the IFR, nerve fibres were fairly to slightly positive to NF 68 kDa, GFAP, TH and synaptophysin labellings. In the T-cell zones, some GFAP, TH and NF 150 kDa-positive nerve endings were observed. Once again, along the blood vessels, the innervation was detected only with the anti-NF 200 kDa antibodies. A slight innervation of the medulla was observed with NF 200 kDa, GFAP and TH immunolabellings. Germinal centres did not contain any nerve fibres (Table 3). In comparison to Peyer's patches, the lymph node appeared less innervated, but the innervation of corresponding lymphoid areas was similar.

Proven contacts between dendritic cells and nerve fibres, NF 150 kDa/GFAP and TH positive, were highlighted in the T-cell zone. Along blood vessels, DCs established contacts with NF 200 kDa positive nerve fibres, like in the Peyer's patches, as they did with synaptophysin, GFAP and

Table 4 Neuroimmune contacts between peripheral nervous system and dendritic cells in infected and control mesenteric lymph nodes

+ Proven contact; − absence of contact. *IFR* Interfollicular regions; *T Zones* T-cell zones

TH positive fibres within the IFR. In contrast, nerve endings and DCs were not in contact in the medulla (Fig. 3). Similar results were obtained on both control and orally scrapie-inoculated mice (Table 4).

Neuro-dendritic cell interfaces in scrapie-infected spleen

The T-cell zones that encircle the central arterioles were slightly to fairly innervated, except with the NF 200kDa marker. Vessel walls were labelled by anti-NF 200 kDa and NF 68 kDa antibodies. The marginal zones that surround the lymphoid follicles and the T-cell zones were positive for antibodies against NF 68 kDa, NF 150 kDa and GFAP. No nerve fibre was identified within the germinal centres (Table 5).

Neuroimmune contacts between the peripheral nervous system and the dendritic cells were detected in different areas of the white pulp. In the T-cell zones, established connections between NF 68 kDa, GFAP, synaptophysin positive fibres and DCs were highlighted. In contrast to Peyer's patches and mesenteric lymph nodes, DCs were in contact with NF 68 kDa and NF 150 kDa positive fibres in the vessels of the white pulp. Within the marginal zones,

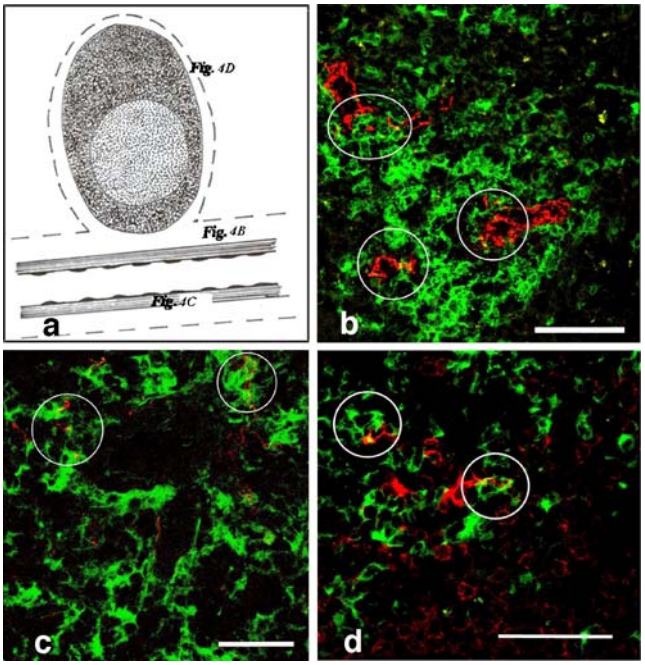

Fig. 4 Neuroimmune connexions within scrapie-infected spleens. Double immunolabellings, replaced in their tissular location in **a**, of dendritic cells highlighted with antibody directed against CD11c (*green*) and nerve fibres (*red*) labelled with antibodies raised against: NF 68 kDa (T-cell zone, **b**), NF 200 kDa (vessel walls, **c**) and GFAP (marginal zone, **d**). dendritic cells established connections with GFAP and NF 150 kDa nerve fibres (Fig. 4). As in the other studied lymphoid tissues, the neuroimmune interfaces were highlighted in the same areas in mice inoculated with scrapie or normal brain (Table 6).

Discussion

The oral route is considered the most likely mode of inoculation in natural TSEs such as scrapie [24], BSE or

vCJD [11]. The sequence of BSE and scrapie agent propagation after oral intake suggests that the agent enters the gut mucosa through Peyer's patches and then invades the mesenteric lymph nodes, followed by the LRS unrelated to the digestive tract (e.g. the spleen) [36]. Two mechanisms of prions dissemination are suspected: the blood spreading [34], which emerged with new cases of vCJD after transfusion and the propagation via nerve fibres, studied here. This last one is initiated during the preclinical period [37, 52]. However, the exact location of prion invasion in the nervous system, inside the lymphoid organs, remains as yet unclear.

Several studies have suggested that neuroinvasion occurs from the FDC network [35], but follicular dendritic cells and the peripheral nervous system seem to be anatomically separated. Except in a recent study on bovines where we described nerve endings in contact with follicular dendritic cells [13] and studies focusing on cats [15], pigs [4] and sheep [27], other studies failed to reveal nerve fibres in germinal centres. In this study, we obtained similar results within murine scrapie-infected lymphoid organs and controls: neuroimmune connections appeared to be localized in the same areas and involved the same cell types. Thus, prion infection did not induce a neuro-FDC interface. Even if abnormal germinal centre reactions were reported [38], it has previously been described that prion do not induced histopathological changes [10, 14] or immunotoxic effects [1].

By morphological analysis in confocal microscopy, we pointed several hypothetical sites of neuroinvasion in lymphoid organs. All of them are associated with the peripheral nervous system and migrating dendritic cells. In scrapie-infected Peyer's patches, DCs and nerve fibres were connected in the lamina propria of villi and crypts, in the IFR and the suprafollicular domes. Villi [29] and the suprafollicular dome [20, 41] are suspected to be the site of prion entry within the gut. Thus, they could also be the first site of prion neuroinvasion. Neuro-DC interfaces in the T cell and the marginal zones of spleen as well as in the T-cell zone and the IFR of mesenteric lymph nodes could be a second site of neuroinvasion.

The mechanism of peripheral neuroinvasion by prions from these sites remains unclear. Three components seem to be implicated: the way by which nerve fibres acquire prions, the effect of infectious prions on peripheral neurons and nerve fibres and the transport of prions along nerve fibres to the CNS.

Prions could infect the nervous system via some mechanisms. Authors have argued that exosomes are the clue for prion dissemination [18, 44, 53]. Cells, especially dendritic cells, may exploit the nature of endosome-derived exosomes to transmit the infectious prion protein, bypassing cell–cell contact. Others have proposed that prions are transported directly via small intercellular projections known as tunnelling nanotubes [9]. These exchange processes could provide a mechanism for the efficient spread of proteins from dendritic cells to new host cells [54]. In addition, recent study suggested that the expression of Muscarinic Acetylcholine receptor M2 on dendritic cells could provide a way of prion neuroinvasion [33]. Neuro-immune synapses were suspected since a long time [49], but little proof was presented. Our study shows connections between dendritic cells and nerve endings or nerve fibres in lymphoid organs. These observations are in favour of a synaptic and a neuritic communication between immune and nerve cells. The mechanism of neuroinvasion, within the described potential sites could involve one or more components.

Contrary to brain's neurons, peripheral neurons seem to be infected [50] but not affected by the presence of prion. It implies that the peripheral nervous system (PNS) accumulates prions [32] without a lack of function or death. Moreover, neuropathology of the PNS did not change prion pathogenesis [31]. These surprising phenomena could be imputed to different accumulation mechanisms involving intracellular trafficking and vesicular compartment [43]. Membrane composition and the type of neurotransmitters released [42] could also induce different levels of neuron sensibility to prions.

Authors estimated that the velocity of transport of infectivity in the PNS does not correspond to either fast or slow axonal transport, indicating that PrPsc transport in the PNS may occur through another mechanism [22]. A domino effect fashion via PrPc-paved chain of Schwann cells was proposed. We demonstrate, in this report, the presence of numerous contacts between dendritic cells and GFAP-positive fibres, thus Schwann cells. This is in favour of the involvement of Schwann cells in prion pathogenesis.

Peripheral nerve fibres seem to be static elements, which are not influenced by scrapie infection. Mobile cells are necessary to bring them in contact with infectious prion. Here, we demonstrate connections between nerve fibres and dendritic cells, in healthy and scrapie-infected mice, at strategic sites in lymphoid organs implicated in prion diseases.

CASE REPORT

Hemorrhagic pulmonary oxalosis secondary to a noninvasive *Aspergillus niger* fungus ball

Abstract We report a case of hemorrhagic pulmonary oxalosis secondary to a noninvasive *Aspergillus niger* fungus ball. A patient with cavitary lung disease and hemoptysis developed progressive lung infiltrates and intractable metabolic acidosis leading to death. At autopsy, aspergillomas were identified in both the right upper and middle lobes surrounded by a large rim of necrotic and hemorrhagic parenchyma. Microscopic examination showed extensive crystal deposition and vascular thrombosis. Fungal growth was limited to the intraluminal mycelia, and no tissue or blood vessel invasion was present. Remote crystal deposits were also localized in the absence of fungal organisms to the contralateral lung and to the tubules of both kidneys. The crystals were birefringent in polarized light and stained with colloidal iron. X-ray powder diffractometry and electron impact ionization mass spectrometry identified the crystals as calcium oxalate monohydrate. Furthermore, non-necrotizing granulomatous lesions were identified in the lungs, liver, and spleen, consistent with sarcoidosis, and may have predisposed this patient to developing pulmonary aspergillomas.

Introduction

Aspergillus is a dichotomously branching septate hyphal mold that causes a variety of diseases in both immunocompetent and immunocompromised hosts [2, 4]. Whereas the term aspergillosis denotes either allergic or tissue-invasive disease as a result of *Aspergillus*, the term aspergilloma describes the mycelial growth of the fungus in a cavitary space [1, 4]. A variety of *Aspergillus* spp. cause disease, including *A. fumigatus* (~85% of cases), *A. flavus* (~10%), *A. niger* (~2%), *A. terreus* (~2%), and *A. nidulans* (~1%) [2].

A. niger and, to a lesser degree, other *Aspergillus* species release oxalic acid ($C_2O_4H_2$), a side product of the tricarboxylic acid cycle, as a mycotoxin. The oxalic acid complexes with free calcium ions in tissue and blood to form calcium oxalate that is deposited primarily as monoclinic calcium oxalate monohydrate ($CaC_2O_4{\cdot}H_2O$, whewellite) crystals when the solubility product is exceeded. Oxalate crystal deposition can be locally toxic, causing hemorrhage and tissue necrosis [3, 4, 9].

In the present study, we present the case of a 61-year-old male who died from complications of both hemorrhagic pulmonary and renal oxalosis caused by a pulmonary *A. niger* fungus ball. We illustrate the diagnostic and therapeutic

challenges of noninvasive *Aspergillus* infection and discuss the patient's possible infectious predisposition because of pre-existing sarcoidosis.

Clinical history

A 61-year-old man was admitted to the hospital with progressive shortness of breath, chest pain, and a 2-week history of multiple daily episodes of hemoptysis, each productive of 5–15 ml of bright red blood. During the preceding several months, he had experienced recurrent fevers and a weight loss of 11 kg. His medical history included type 2 diabetes mellitus, hypercholesterolemia, and diverticulosis. He had never smoked and reported no recent travel.

Three months before admission, he had been hospitalized for a persistent, productive cough with one episode of hemoptysis. Computed tomography (CT) examinations performed during the first hospitalization showed small pulmonary right upper lobe cavitary changes (Fig. 1a), bilateral bronchiectasis, and mild splenomegaly. Bronchoalveolar lavage and sputum specimen cultures obtained during the first admission were positive for rare colonies of *A. niger*. A serum galactomannan immunoassay was negative. He was started empirically on rifampicin, ethambutol, isoniazid, and clarithromycin for mycobacterial coverage, but the treatment was discontinued 2 weeks before the second admission when all cultures returned negative.

A transbronchial right upper lobe lung biopsy performed on day 2 of the second hospitalization showed intraluminal mycelial growth of septate hyphae with pigmented conidia, consistent with an *A. niger* fungus ball, and diffuse oxalate crystal deposition but no evidence of tissue or blood vessel invasion. Empirical treatment was started with intravenous vancomycin, levofloxacin, metronidazole, voriconazole, and liposomal amphotericin B. Chest CT examination showed dense consolidation within the right upper and lower lobes and marked interval increase in the right upper lobe cavitary lesions with adjacent ground glass opacity (Fig. 1b). Unfortunately, the patient's condition deteriorated rapidly, and the patient died on day 5 of the second admission with acute respiratory and renal failure with uncontrolled metabolic acidosis. An autopsy was conducted.

Materials and methods

Fresh tissue samples were fixed in buffered formalin and embedded in paraffin. Routine 5-μm sections were stained with hematoxylin and eosin. Special histological stains were performed according to standard protocols established at the Department of Pathology and Laboratory Medicine, Massachusetts General Hospital, Boston, MA. For immunohistochemical detection of *Aspergillus* spp., rabbit polyclonal IgG at 1:50 dilution was used (CP 106, BIOCARE, Concord, CA) on heat-treated paraffin tissue sections, followed by horseradish peroxidase–diaminobenzidine chemistry and alkaline hematoxylin counterstaining. For crystal extraction, tissue was cleared at 20°C in 7% (m/v) aqueous NaOCl for 24–48 h. The cleared solution was then filtered through a 0.45-μm vacuum-driven filter unit (Millipore, Billerica, MA). The crystalline residual was washed extensively with H_2O, transferred into a 1.5-ml reaction tube, and dried at 37°C. Recovery and purity of the isolated crystals were monitored by microscopic examination of air-dried smears on glass slides in polarized light. X-ray powder

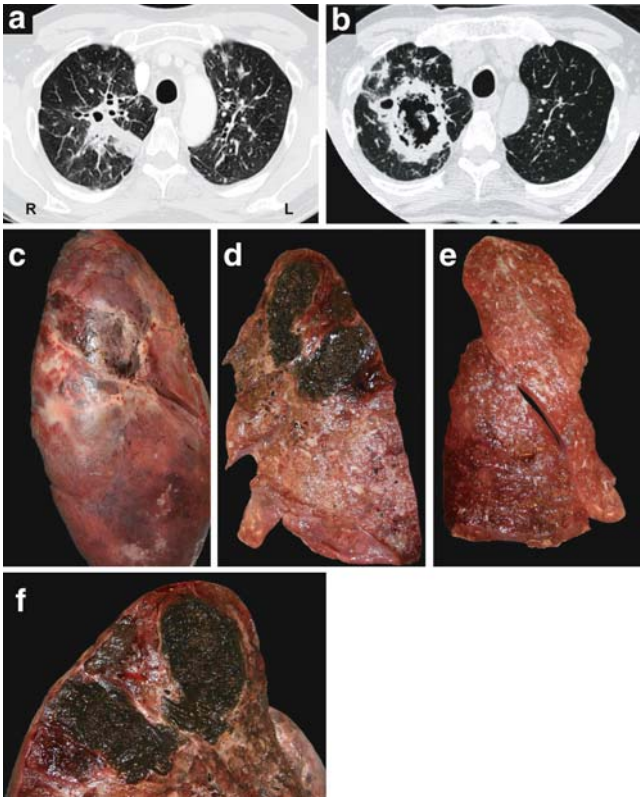

Fig. 1 **a**, **b** Images of transverse chest CT scans through the level of the aortic arch acquired 3 months (**a**) and 5 days (**b**) before the patient's death, respectively, demonstrating the rapid expansile progression of a cavitary lesion in the right upper lobe rimmed by X-ray dense tissue. **c**–**f** Gross autopsy photographs of the intact (**c**) and sectioned (**d**, **f**) right lung showing two communicating cavitary lesions predominantly affecting the upper lobe, each measuring approximately 6 cm in greatest dimension. The lesions are composed of *A. niger* mycelia admixed with dark black, hemorrhagic, and necrotic debris, walled by a thin rim of fibrous tissue, and surrounded by congested, focally infarcted, and hemorrhagic lung parenchyma. The inferior lesion extends partially into the middle lobe. The remaining parenchyma displays moderate consolidation. **e** Representative gross section of the left lung exhibiting moderate consolidation and predominantly inferior lobe congestion. No cavitary lesions were present in the left lung

diffractometry (XRD) was carried out on a Scintag XDS 2000 instrument (Scintag, Cupertino, CA) equipped with a 2.2-kW copper $K_{\alpha 1}$ X-ray source (λ=1.5406 Å) and a vertical theta–theta goniometer. Measured diffraction data were electronically searched against the International Centre for Diffraction Data PDF database (http://www.icdd.com). Electron impact ionization (EI) mass spectra were acquired on a JEOL AX-505H magnetic sector instrument with an electron beam energy of 70 eV (JEOL, Peabody, MA).

Results

Gross pathologic findings At autopsy, the right and left lungs weighed 2,200 and 1,500 g, respectively. Small serosanguineous pleural effusions were present bilaterally. The pleural surface of the right lung showed a circumscribed area of dark red discoloration, surrounded by consolidation of the upper lobe and middle lobes (Fig. 1c). Sectioning of the formalin-inflated lungs revealed two contiguous cavities involving the right upper and middle lobes, each approximately 6 cm in the greatest dimension (Fig. 1d). The lesions contained dark black, friable, hemorrhagic, and necrotic tissue (Fig. 1f). The cavities were surrounded by a rim of tan-gray fibrous tissue and an outer layer of congested, focally hemorrhagic and infarcted lung parenchyma. The remaining right lung parenchyma displayed moderate consolidation and congestion. Gross examination of the left lung revealed moderate parenchymal consolidation and predominantly inferior lobe congestion (Fig. 1e). These findings were suggestive of an evolving acute bilateral bronchopneumonia. No cavitary lesions were present in the left lung.

The remainder of the general autopsy revealed mild biventricular cardiac hypertrophy, serosanguineous ascites, moderate splenomegaly, and mild nephrosclerosis. Neuropathological examination showed mild hypertensive vascular changes in the basal ganglia. All other gross findings were essentially within normal limits.

Microscopic findings Microscopic examination of the right upper and middle lobe cavities revealed abundant intraluminal mycelia with septate hyphae and pigmented conidia. A representative section illustrates the transition from the intraluminal mycelium via a zone of necrotic and hemorrhagic tissue (but free of fungal organisms) to congested and hemorrhagic yet partially viable pulmonary parenchyma (Fig. 2a, left to right). Examination with polarized light revealed abundant deposition of birefringent crystals, predominantly in the necrotic transition zone between the intraluminal mycelium and congested pulmonary parenchyma (Fig. 2b). Crystal deposition was frequently accentuated in the walls of local small- to medium-sized blood vessels containing intraluminal thrombi (Fig. 2b, inset). Extensive histopathological sectioning and examination of the cavitary lesions did not reveal tissue invasion by fungi.

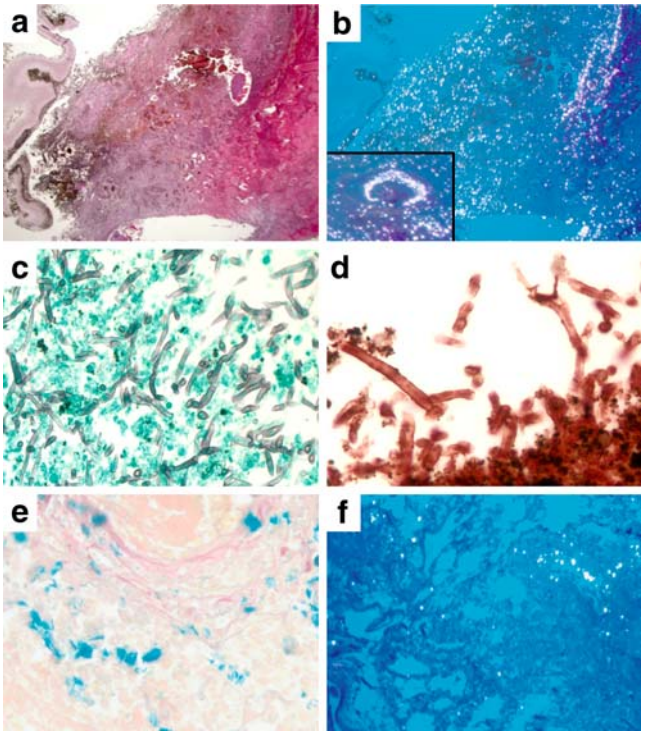

Fig. 2 **a** Hematoxylin–eosin stained representative pulmonary autopsy tissue section taken from a cavitary edge showing (from *left* to *right*) the transition from a well demarcated intraluminal mycelium via a zone of necrotic and hemorrhagic tissue (free of fungal organisms) to congested and hemorrhagic yet mostly viable pulmonary parenchyma. **b** Tissue section identical to **a** but visualized in polarized light revealing abundant deposition of birefringent crystals, predominantly in the necrotic transition zone between intraluminal mycelium and congested pulmonary parenchyma. Note accentuation of crystal deposition in walls of local small- to medium-sized blood vessels (**b**, *inset*). **c** A Gomori methenamine silver stain highlights abundant intracavitary hyphae in the patient's lung lesions. **d** Immunohistochemical identification of the fungal hyphae as *Aspergillus* spp. Note the brown staining reaction of the hyphae, the acute angle branching, and the presence of dark black fungal pigment. **e** The deposited crystals are stained by Hale's colloidal iron reaction (*blue*). **f** Small amounts of birefringent crystals, mostly as intraluminal deposits, are also present in the contralateral (left) lung. However, these deposits were not associated with fungal organisms, hemorrhage, or necrosis. Original magnifications: **a**, **b**, 20× (*inset*, 80×), **c**, **e**, 400×, and **d**, 840×, **f**, 40×

Abundant intracavitary hyphal forms of *A. niger* were seen in the patient's pulmonary cavitary lesions by Gomori methenamine silver staining (Fig. 2c). Immunohistochemically, the fungi reacted with antibodies against *Aspergillus* spp. (Fig. 2d). The morphological appearance (2–5 μm diameter septate hyphae with acute angle branching and pigmented conidia) was consistent with *A. niger*, an impression subsequently confirmed by microbiological culture and speciation of lung tissue samples. The deposited

crystals were stained by Hale's colloidal iron reaction (Fig. 2e). Small numbers of birefringent crystals were also observed in the contralateral (i.e., left) lung, distant from the aspergillomas on the right (Fig. 2f). However, there was no evidence of fungal organisms, hemorrhage, or necrosis.

Both kidneys revealed tubular deposition of crystals (Fig. 3). However, there was no tissue response to the crystals, such as inflammation, hemorrhage, infarction, or necrosis. Furthermore, no crystal deposits along or within blood vessel walls were present in the kidneys.

Numerous scarred non-necrotizing granulomas with occasional multinucleated giant cells were identified in autopsy tissue sections of the lungs, spleen, and liver (Fig. 4). No prominent lymphocytic inflammation was associated with the granulomas. Furthermore, special stains for microorganisms were negative. Taken together, these findings were judged to be consistent with a diagnosis of sarcoidosis.

Analytical chemical findings The chemical composition of the crystalline deposits was analyzed by XRD. We first purified the crystals by clearing lung and renal tissue specimens in aqueous sodium hypochlorite followed by filtration. We then examined air-dried crystal smears on glass slides by XRD. As shown in Fig. 5a, the most intense d-spacing peaks (2θ angles in parentheses) were observed at 5.9116 Å (14.9738°), 3.6377 Å (24.4500°), 2.9626 Å (30.1406°), 2.8335 Å (31.5481°), 2.3520 Å (38.2337°), and 1.9767 Å (45.8688°). The corresponding d-spacing diffraction peaks (2θ angles in parentheses) of a crystalline calcium oxalate monohydrate standard (monoclinic $P2_1/n$ space group), as listed in the International Centre for Diffraction Data PDF database, are expected to appear at 5.93 Å (14.927°), 3.65 Å (24.365°), 2.966 Å (30.104°), 2.840 Å (31.473°), 2.355 Å (38.182°), and 1.978 Å (45.835°). Based on excellent agreement between the experimentally determined d-spacing values and the database entries, the crystals were unambiguously identified as calcium oxalate monohydrate ($CaC_2O_4{\cdot}H_2O$, whewellite).

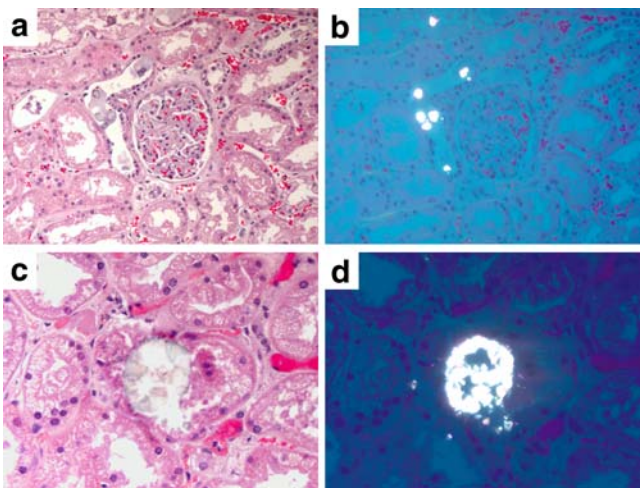

Fig. 3 **a**, **c** Photomicrographs of renal autopsy tissue sections showing intratubular calcium oxalate crystals (hematoxylin–eosin stain). Note the absence of a tissue reaction to the crystals. The tubular epithelium exhibits mild postmortem changes. **b**, **d** Examination in polarized light demonstrates the birefringent property of the crystals. Original magnifications: **a**, **b**, 200×, **c**, **d**, 400×

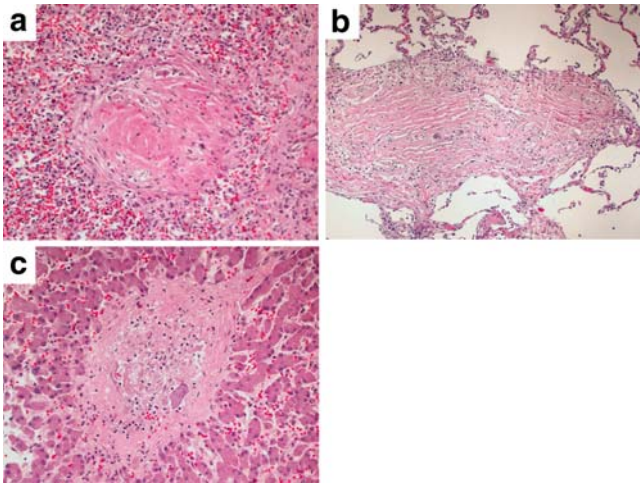

Fig. 4 Photomicrographs of autopsy tissue sections from the patient's spleen (**a**), left lung (**b**), and liver (**c**) showing scarred non-necrotizing granulomas and occasional giant cells without significant lymphocytic inflammation (hematoxylin–eosin stain). These findings are consistent with sarcoidosis. Original magnifications: 100×

The crystalline material was also analyzed by EI mass spectrometry. As shown in Fig. 5b, we readily detected the singly charged molecular cation radical of oxalic acid $\left([C_2O_4H_2{}^{\bullet}]^+\right)$ with a monoisotopic mass of 90 amu. The peak pattern surrounding the major peak at m/z=90 is consistent with reference EI spectra of oxalic acid (Spectral Database of Organic Compounds, http://www.aist.go.jp; NIST Chemistry WebBook, http://webbook.nist.gov) and likely the result of a combination of isotope contributions and gas phase reactions. This finding indicated that free oxalic acid was present among the crystalline material. It should be noted that the components of calcium oxalate salt (free calcium cations and free oxalate anions) are not detectable by EI mass spectrometry.

Discussion

A small number of cases of pulmonary *A. niger* aspergillomas with associated oxalosis have been reported in the predominantly older literature. However, most of these were cases of tissue-invasive aspergillosis [3, 6, 7, 10].

In the present paper, we describe a case of fatal hemorrhagic pulmonary oxalosis secondary to an intracavitary, noninvasive *A. niger* infection. At autopsy, the

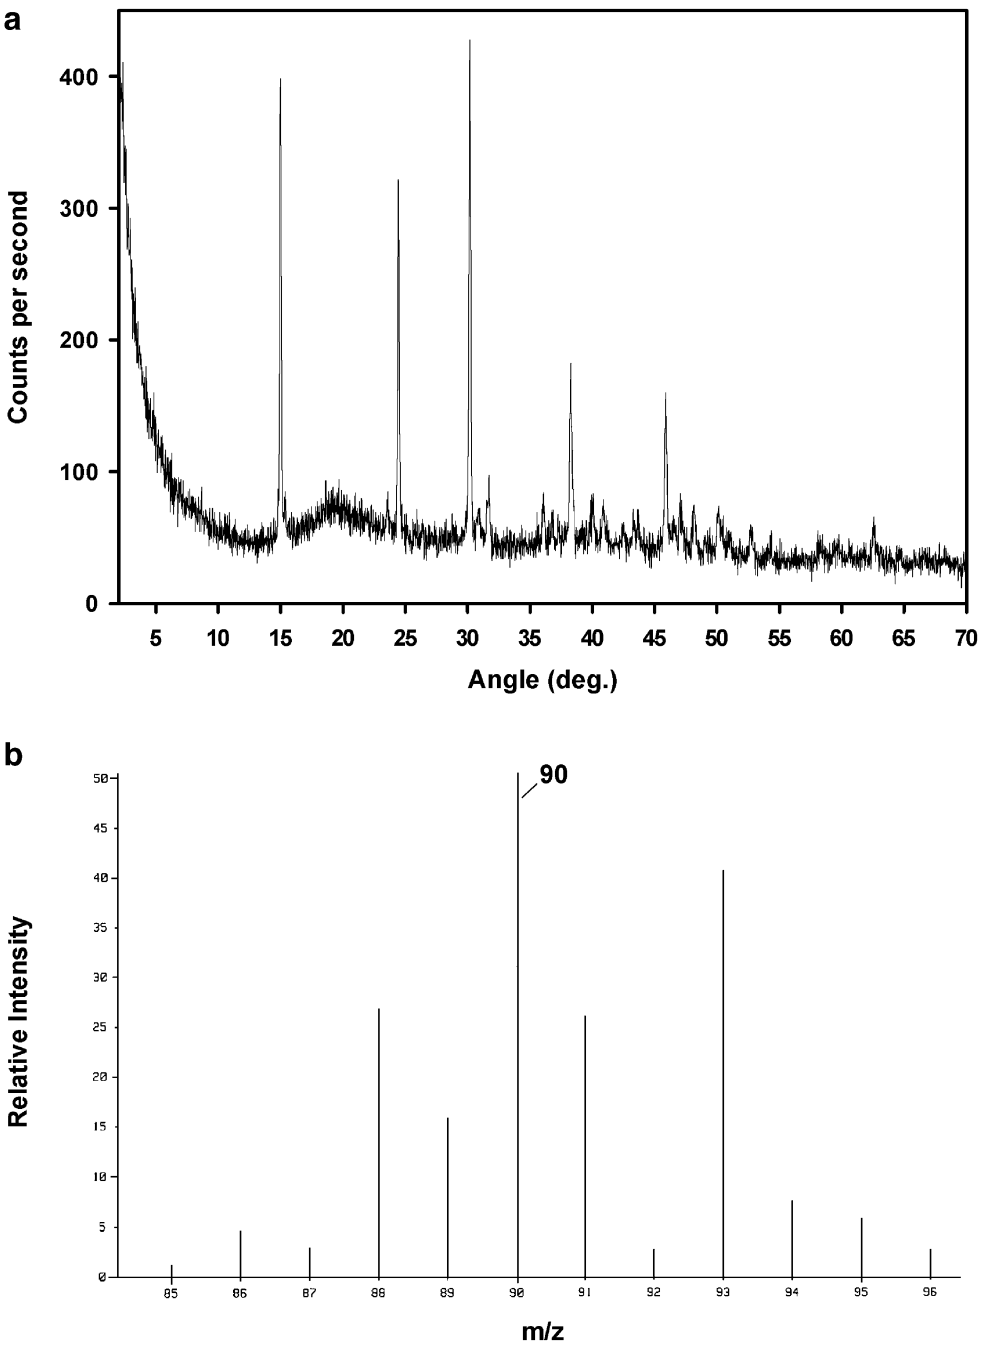

Fig. 5 **a** X-ray powder diffractometry experiment of crystals isolated from the patient's right cavitary lung lesion. The abscissa denotes the 2θ diffraction angle in degrees. The ordinate indicates the measured scattered X-ray intensity in counts per second for a given 2θ angle. Note the sharp diffraction maxima. **b** Electron impact ionization mass spectrum of crystals isolated from the patient's right cavitary lung lesion. The abscissa denotes the measured mass to charge ratio (m/z). The ordinate indicates the relative intensity of ions detected at a given m/z. The largest peak at m/z=90 corresponds to the singly charged molecular cation radical of oxalic acid ($[C_2O_4H_2{}^{\bullet}]^{+}$) with a monoisotopic mass of 90 amu. The peak pattern surrounding the major peak is likely the result of a combination of isotope contributions and gas phase reactions

right upper and middle lobes showed two large communicating cavities containing friable, dark black, partially hemorrhagic material (Fig. 1). Microscopic examination, immunohistochemistry, and microbiological culture identified the lesions as aspergillomas as a result of *A. niger*. There was massive deposition of birefringent crystals in the hemorrhagic and infarcted lung tissue surrounding the fungus balls (Fig. 2). The high concentration of tissue-toxic crystals in and around small pulmonary blood vessels likely caused the extensive hemorrhagic necrosis and rapid expansion of the aspergillomas observed radiographically (Fig. 1a,b) and the rapid clinical deterioration leading to death, all in the absence of fungal invasion of tissues.

Aspergillus hyphae are 2–5 μm wide, frequently septate, and branch at acute angles (Fig. 2) [2]. Often difficult to detect on hematoxylin–eosin stains, hyphae are best visualized by silver stains or by immunohistochemical detection (Fig. 2c,d). Sporulation is rarely observed in tissue, except in air-filled spaces, such as lung cavities or paranasal sinuses. In the absence of sporulating forms, the hyphae cannot be reliably distinguished on morphologic grounds from other pathogenic molds, including *Scedosporium* or *Fusarium*.

The association of *A. niger* infection with tissue crystal deposition is well documented [1–3]. *A. niger*, and to a lesser degree other *Aspergillus* species, release oxalic acid ($C_2O_4H_2$) as a mycotoxin [1, 3, 8]. Oxalic acid is formed as a side product of the tricarboxylic acid cycle by enzymatic hydrolysis of oxaloacetate by oxaloacetate acetylhydrolase (EC 3.7.1.1). The released oxalic acid complexes with calcium ions present in the surrounding tissue and blood to form calcium oxalate molecules that crystallize once the solubility product is exceeded, primarily as monoclinic calcium oxalate monohydrate ($CaC_2O_4{\cdot}H_2O$, whewellite).

Histologic examination of autopsy tissue specimens revealed massive deposition of calcium oxalate crystals in hemorrhagic and infarcted lung tissue surrounding the pulmonary *A.niger* fungus balls (Fig. 2b). It is interesting to note that increased amounts of crystal deposits were seen surrounding and within blood vessel walls in the periphery of the cavitary lesions (Fig. 2b, inset). Oxalate crystal deposition can be locally toxic, causing confined tissue necrosis and hemorrhagic infarction [3, 9]. The deposition of crystals in and around small- and medium-sized arteries may explain the significant degree of hemorrhagic infarction associated with the spatial expansion of the aspergillomas despite the absence fungal tissue invasion.

Examination of both kidneys revealed marked tubular deposition of calcium oxalate crystals (Fig. 3). It is interesting to note that there was no significant inflammatory, hemorrhagic, or necrotizing tissue reaction in the kidneys. Furthermore, there was no clinical evidence of decreased renal function despite substantial crystal burden. It is possible that the renal oxalate deposits developed within a relatively short period before the patient's death, not allowing for the establishment of a histologic response. Alternatively, the local milieu of the kidney may not predispose to or protect against the development of an inflammatory response to oxalate crystals.

We employed analytical chemical methods to establish the molecular identity of the deposited crystals. First, we analyzed crystals isolated from autopsy tissue samples by XRD (Fig. 5a). Crystalline materials have unique and characteristic positions and intensities of X-ray powder diffraction lines (d-spacings). Comparison of our measured data with a comprehensive database of known standard samples (International Centre for Diffraction Data PDF database) unambiguously identified the crystals as calcium oxalate monohydrate ($CaC_2O_4{\cdot}H_2O$, whewellite) in a monoclinic space group. Thus, the presence of significant amounts of other known crystalline forms of calcium oxalate, i.e., di- or trihydrate, was essentially excluded. We next examined the crystalline material by EI mass spectrometry, which can detect molecular cation radicals formed by the impact of electrons possessing low kinetic energy. We readily detected the predicted singly charged molecular cation radical of oxalic acid $\left([C_2O_4H_2{}^{\bullet}]^{+}\right)$ with a monoisotopic mass of 90 amu (Fig. 5b). This finding indicates the presence of free oxalic acid that may be the result of direct release by the fungus before calcium complexation and/or chemical equilibrium conditions between the crystalline salt and the soluble acid.

$CaC_2O_4{\cdot}H_2O$ is poorly soluble at physiologic pH with a solubility product at 37°C of 2.8×10^{-9} mol^2/l^2, corresponding to a saturation concentration of 53 μM. It is interesting to note that the patient's plasma free oxalate concentration determined on hospital day 3 (2 days before death) was normal at 14 μM (normal, <27 μM). This finding suggests that complexation of free oxalate with calcium and subsequent crystallization may primarily occur in confined spaces (e.g., the lungs and the renal tubules) where the local concentration exceeds the solubility product. As a result, the serum free oxalate concentration may be inhibited from rising despite significant fungal burden.

We found that the calcium oxalate crystals stained with Hale's colloidal iron reaction (Fig. 2e). In this reaction, crystals are exposed to aqueous ferric chloride in acetic acid. Under these conditions, ferric ions replace calcium ions as complex partners with the carboxylate groups of oxalate. Subsequent reaction of the bound ferric ions with acidified potassium ferrocyanide results in formation of ferric hexacyanoferrate, a complex of dark blue color (Prussian Blue). The result is of interest because it has been proposed that the adsorption of ferric iron ions available in tissue onto oxalate crystals may contribute to the pathophysiology of crystal deposition in vivo through generation of reactive oxygen species via the Fenton reaction [3].

The patient had experienced several months of progressively productive cough, dyspnea, and weight loss with intermittent hemoptysis. An initial finding of rare colonies of *A. niger* in bronchoalveolar lavage and sputum cultures had been considered to represent saprophytic colonization and had been judged as nondiagnostic for infection in the absence of immunosuppression. Specifically, the patient's differential blood count and the number of circulating $CD4^+$ T cells were within normal limits, and the patient was not taking steroids or other immunosuppressive medications.

Examination of autopsy tissue samples from the lungs, the spleen, and the liver revealed non-necrotizing granulomas with scattered multinucleated giant cells and a paucity of lymphocytic inflammation (Fig. 4). In the absence of microorganisms, these findings were considered most consistent with sarcoidosis. Chronic fibrocystic pulmonary sarcoidosis has been associated with an increased risk of pulmonary aspergilloma [5, 11, 12]. Furthermore, the patient also had type 2 diabetes mellitus, a condition that has been found to predispose to *Aspergillus* infection [4].

Disease manifestations of *Aspergillus* spp. are diverse and depend on the complex interactions between fungus

and host [4]. Within a given tissue or organ, pathology can range from invasive disease to benign, noninvasive saprophytic colonization. Whereas there was no evidence of invasive fungal infection in the present case, the patient ultimately succumbed to massive pulmonary hemorrhage and subsequent multiple organ failure caused by *Aspergillus*-induced calcium oxalate crystal deposition.

In conclusion, we describe an uncommon case of noninvasive chronic cavitary pulmonary aspergillomas as a result of *A. niger*. While clinically not overtly immunocompromised, the patient may have been predisposed to infections by underlying fibrocystic pulmonary sarcoidosis and type 2 diabetes mellitus. In association with the pulmonary aspergillomas, massive deposition of calcium oxalate monohydrate crystals was identified. The chemical identity of the crystals was elucidated by a combination of histological and analytical chemical techniques, including XRD and EI mass spectrometry. The marked hemorrhage and necrosis in the periphery of the rapidly expansile pulmonary lesions were due to the local toxicity of oxalate crystal deposition, rather than direct tissue invasion by fungal hyphae.

This case illustrates the diagnostic challenges posed by noninvasive aspergillomas and sheds new light on the pathophysiology of this disorder. Surgical treatment, which might have been definitive therapy, was precluded in this case by the advanced clinical deterioration at the time of presentation. However, the present case raises questions as to whether the diagnosis of pulmonary aspergilloma as a result of *A. niger* should optimally prompt an early aggressive surgical approach.

CASE REPORT

Adenocarcinoma of the minor duodenal papilla with intraepithelial spread to the pancreatic duct

Masatoshi Kajiwara · Satoshi Fujii · Shinichiro Takahashi · Masaru Konishi · Toshio Nakagohri · Naoto Gotohda · Taira Kinoshita

Received: 23 March 2007 / Revised: 31 July 2007 / Accepted: 1 August 2007 / Published online: 6 September 2007

Abstract It is extremely rare to encounter tumors arising exclusively in the minor duodenal papilla. We report a 60-year-old male patient with a polypoid type of adenocarcinoma of the minor papilla. Preoperative examinations, including computed tomography (CT) and magnetic resonance cholangiopancreatography (MRCP), suggested pancreas divisum and showed a series of stones in the dorsal pancreatic duct. The patient underwent subtotal stomach-preserving pancreaticoduodenectomy (SSpPD). On histology, an adenocarcinoma was located in the minor papilla, which was limited to the mucosa, without invasion of the duodenum, sphincter muscles of the minor papilla, or the underlying pancreas. The carcinoma cells, together with dysplastic and hyperplastic epithelium of the pancreatic duct, extended peripherally within the pancreatic duct. No cystic dilatation of the pancreatic duct was observed. The ventral pancreatic duct was short and narrow; there was evidence of chronic pancreatitis in the dorsal pancreas, whereas the ventral pancreas was almost normal, suggesting the existence of pancreas divisum. Although it is well known that adenocarcinoma of the duodenal papilla is sometimes accompanied by intraepithelial spread in the pancreatic duct, an adenocarcinoma arising in the minor papilla in this case with pancreas divisum was more extended than our thoughts.

Introduction

Tumors of the minor duodenal papilla are rare. Most reported cases have been benign tumors, including carcinoid [12, 15, 19, 22, 23], somatostatinoma [3, 13, 20], adenoma [21], adenomyoma [4], and gangliocytic paraganglioma [11, 14]; only one case of adenocarcinoma has been previously reported [24]. Tumors in the minor papilla may be underestimated because of the difficulty in determining the origin of tumors that involve the papilla because the papilla may be overgrown even by small tumors, and the histological appearance of periampullary tumors is similar [1].

We present a case of primary adenocarcinoma of the minor duodenal papilla that exhibited wide intraepithelial spread in the pancreatic duct. Moreover, the existence of pancreas divisum was also suspected because of the distribution of pancreatitis on microscopic examination.

Clinical history

A 60-year-old male patient complained of transient abdominal pain for 2 months. His general practitioner performed gastroduodenoscopy and found a polypoid tumor of the duodenum. The patient was referred to the Department of Hepatobiliary Pancreatic Surgery at the National Cancer

Center Hospital East for further evaluation and treatment. The patient had no history of alcohol abuse.

Material and methods

The surgical specimen was fixed in 10% buffered formalin and submitted entirely for histology. The paraffin-embedded tissue were sectioned and stained with hematoxylin and eosin (H&E). Subsequently, tissue samples were stained immunohistochemically with the following monoclonal antibodies: cytokeratin (CK) 7 (1:100; Dako), CK20 (1:50; Dako), Muc-2 glycoprotein (1:100; Novocastra laboratories), and Muc-5AC glycoprotein (1:50; Novocastra laboratories).

Results

On physical examination, there were no abnormal abdominal findings. Other than slightly elevated γGTP (57 IU/l: normal 10–47) and blood glucose (107 mg/dl: normal 69–104) levels, all other laboratory tests, including the hematological profile, renal function, pancreatic enzymes, liver enzymes, electrolytes, and tumor markers (carbohydrate antigen (CA) 19-9 and carcinoembryonic antigen (CEA)) were within normal limits.

On gastroduodenoscopy, the stomach appeared normal, but there was a villous polypoid tumor, about 3 cm in diameter, with a stalk in the second portion of the duodenum (Fig. 1). The major duodenal papilla was identified about 2 cm distal to the tumor. Computed tomography (CT) demonstrated a solid 40×35-mm tumor with expansive growth that occupied the lumen of the descending portion of the duodenum and showed slight attenuation with contrast medium. Tumoral extension toward the underlying pancreas was not detected. The CT also showed a series of pancreatic stones within the duct of the head of the pancreas. The distal side of the pancreatic duct was dilated and the parenchyma of the distal pancreas showed mild atrophy. Neither lymph node involvement nor distant metastasis was detected. Magnetic resonance cholangiopancreatography (MRCP) (Fig. 2) and the coronal view of magnetic resonance image (MRI) showed the relationship between the stones and the pancreatic duct more clearly. The series of stones was about 3 cm long; one end of the stones appeared to be positioned near the stalk of the tumor, and the other end was within the main pancreatic duct. The stones were suspected to be located within the dorsal pancreatic duct. MRCP also revealed a short ventral pancreatic duct; a communication between the dorsal and ventral pancreatic duct was not clearly identified. These findings suggested the existence of pancreas divisum.

Pathological examination of the preoperative biopsy specimen revealed a well-differentiated adenocarcinoma. With a presumptive diagnosis of adenocarcinoma of the duodenum or minor duodenal papilla and chronic pancreatitis, the patient had surgery. At laparotomy, because the tumor had a thick and broad stalk on palpation, it was suspected that the tumor might have invaded the duodenum or the underlying pancreas. Consequently, a subtotal stomach-preserving pancreaticoduodenectomy (SSpPD) was performed.

Macroscopic examination showed a villous polypoid tumor, 50×30×25 mm in size; the stalk was 15 mm in diameter. The tumor was located about 2 cm proximal from the major papilla, which was normal in size and shape. The cut surface showed that the dorsal pancreatic duct was

Fig. 1 Gastroduodenoscopy showing a villous polypoid tumor with a stalk in the second portion of the duodenum

Fig. 2 Magnetic resonance cholangiopancreatography (MRCP) showing a short ventral pancreatic duct (*white arrow*); the communication between the dorsal and ventral pancreatic ducts is not clearly identified. A series of stones (*white arrow head*) is seen in the dorsal pancreatic duct

obstructed by a series of stones, as had been demonstrated by the preoperative examinations (Fig. 3).

Microscopic examination showed that the main exophytic tumor was composed of eosinophilic tall columnar cells with oval and pseudostratified nuclei that were arranged in well-formed tubular pattern (Fig. 4a). The tumor was diagnosed as a well-differentiated tubular adenocarcinoma. The main tumor was limited to the mucosa and regarded as in-situ carcinoma without stromal invasion. At the tumor's stalk, muscular bundles similar to the sphincter of Oddi, which encircled the dorsal pancreatic duct, were present. These findings suggested that the tumor had arisen from the minor papilla and not from the duodenum. The adenocarcinoma cells spread through the sphincter bundles and the dorsal pancreatic duct; they replaced the normal pancreatic duct epithelium with intraductal carcinoma peripherally (Fig. 5a). Intraductal adenocarcinoma with micropapillary projection was observed in almost all areas of the dorsal pancreas, predominantly around the dorsal pancreatic duct. At the frontal edge of the intraductal spread, dysplastic epithelium and hyperplastic epithelium were observed (Figs. 5 and 6). At the cut end of the pancreas, the epithelium of the main pancreatic duct and the other branched ducts showed hyperplastic changes, which were considered to be reactive changes caused by tumor spread.

On immunohistochemical staining, both the main polypoid adenocarcinoma and the intraductal lesions showed the mixed positive pattern of CK7 and CK20. Muc-5AC was also multifocally positive both in the main tumor and the intraductal components. Muc-2 was negative except small number of cells in the base of the main tumor. The expression pattern for CK7, CK20, and Muc-5AC in the main tumor was maintained even in the ductal spreading area of the pancreas (Fig. 4).

Chronic pancreatitis was found in the dorsal pancreatic parenchyma, with infiltration of inflammatory cells and fibrocollagenous tissue; the ventral pancreas was almost normal (Fig. 5a). The ventral pancreatic duct was short and narrow, and the epithelium of the ventral pancreatic duct did not include any carcinoma, dysplastic cells, or hyperplastic cells. These findings supported the presence of pancreas divisum. It is surprising to note that intraductal spread of carcinoma cells was observed in the small branches of the uncinate process, which anatomically belongs to the ventral pancreas, which was unaffected by pancreatitis (Figs. 5a and 6). About half of the uncinate process had carcinoma in situ. Neither lymphovascular invasion nor lymph node metastasis was observed.

The postoperative course was uneventful and the patient was discharged on the 13th postoperative day.

Discussion

The minor duodenal papilla is situated in the anterior duodenal wall, about 2 cm proximal to the major papilla [2, 16]. It primarily drains pancreatic fluid from the dorsal pancreas to the duodenum in the embryo [7].

Tumors of the minor duodenal papilla are uncommon, and few cases have been reported. Most reported cases have been submucosal benign tumors, such as carcinoid [12, 15, 19, 22, 23] and somatostatinoma [3, 13, 20]; only a single case of adenocarcinoma of the minor papilla has been previously reported [24]. Yamano et al. [24] reported a 77-year-old male with an ulcerating tumor, in which the dorsal pancreatic duct epithelium was partially replaced by carcinoma cells from the minor papilla; however, details of the pathological findings were not described. In contrast to our case, their case also had an intraductal papillary

adenoma with mucin hypersecretion in the cystically dilated branch duct in the head of the pancreas. Although the two tumors differed in their gross type, both cases had intraductal spread of the cancerous component. In the present case, however, carcinoma in situ had spread close to the cut end margin and also to the tiny peripheral branches without cystic dilatation.

In addition, our case had calcified stones located in the dorsal pancreatic duct. The majority of cases of pancreatic stones are secondary to chronic pancreatitis; however, the

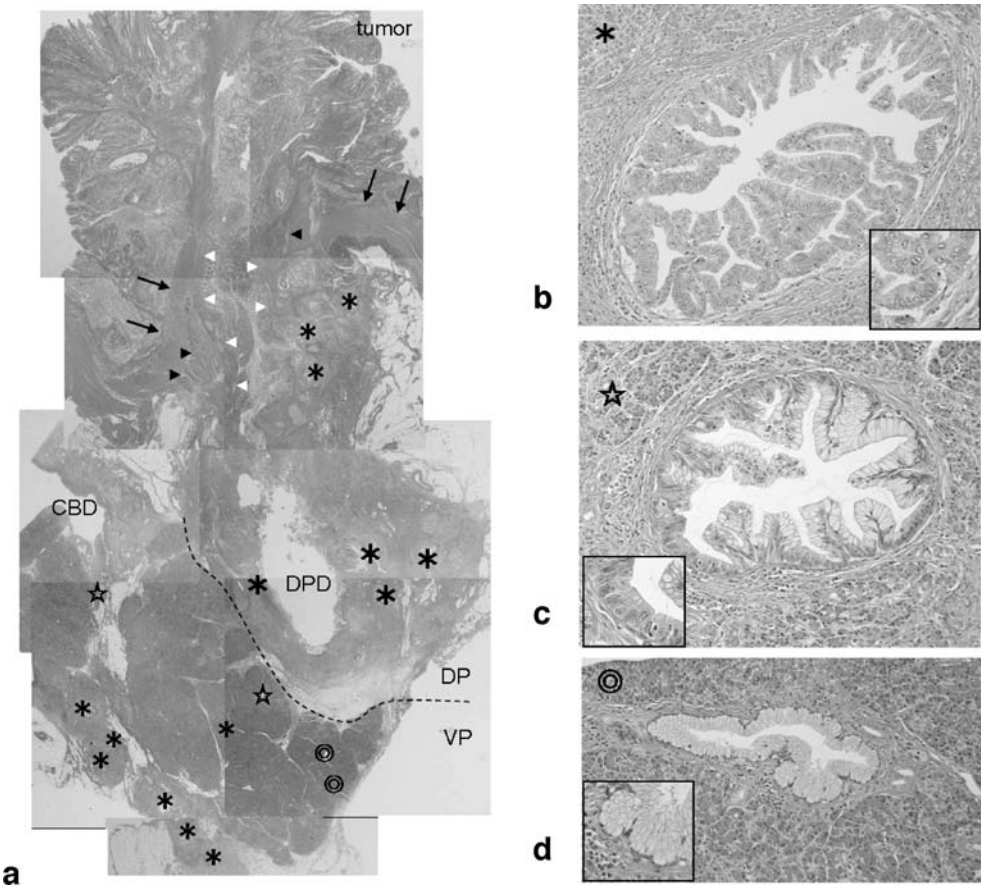

Fig. 5 **a** At the stalk of the tumor, muscular bundles (*black arrow* heads), which encircle the dorsal pancreatic duct (*white arrow heads*), are present. The carcinoma in situ has spread through the sphincter bundles to the branched duct around the dorsal pancreatic duct (DPD); dysplastic and hyperplastic epithelium are present peripherally (*black arrows*, muscular layer of the duodenum; *, carcinoma in situ; ☆, dysplastic epithelium; ◎, hyperplastic epithelium; *CBD*, common bile duct). Chronic pancreatitis is evident in the dorsal pancreas (DP), while the ventral pancreas (VP) appears almost normal. **b** Carcinoma in situ (*) (H–E×100). **c** Dysplastic epithelium (☆) (H–E×100). **d** Hyperplastic epithelium (◎) (H–E×100)

size, number, and distribution of stones vary by the type of pancreatitis [5, 10, 18]. In alcoholic chronic pancreatitis, there are numerous irregular small stones throughout the pancreas. On the other hand, in obstructive pancreatitis, the stone is usually large, solitary, and inside the lumen of the pancreatic duct. The pathogenesis of the stone is considered to be because of the stasis of pancreatic flow [17, 25]. With respect to stones in patients without a history of alcohol abuse, stagnation of pancreatic fluid as a consequence of the duct obstruction by a tumor might lead to development of stones, as in the present case.

The MRCP and MRI findings and the distribution of pancreatitis, which mainly affected the dorsal pancreas, suggested the existence of pancreas divisum. Pancreas divisum is a common congenital anomaly of the pancreas, which results from an abnormal fusion between the ventral and dorsal

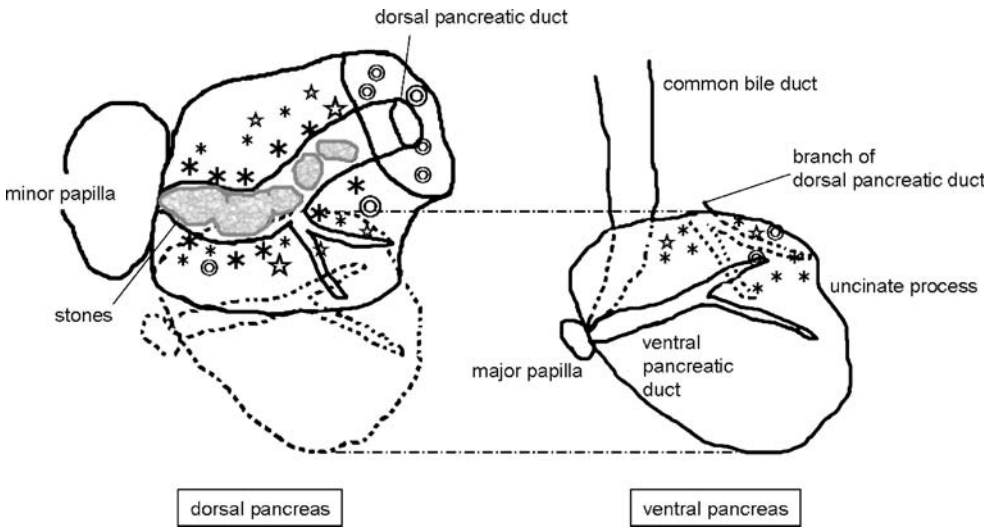

Fig. 6 Schematic distribution of carcinoma in situ (*), dysplastic epithelium (☆), and hyperplastic epithelium (◎). The dorsal and ventral pancreases are depicted separately for convenience. Carcinoma in situ is located predominantly near the dorsal pancreatic duct, and the dysplastic and hyperplastic epithelium is observed surrounding the carcinoma in situ. The branches of the uncinate process, which belongs to the ventral pancreas, are partially involved with cancerous spread

pancreatic ducts during fetal development [8]. It is divided into complete and incomplete types. In the complete type, there is no communication between the two ducts, whereas in the incomplete type, an inadequate communication exists between the two ducts. Pancreas divisum is strongly associated with pancreatitis, especially in alcoholic patients. Irrespective of the type of pancreas divisum, pancreatitis often occurs only in the dorsal pancreas, as was observed in this case. An interaction between a poorly functioning minor duodenal papilla and the increased flow of pancreatic juice caused by alcohol or food intake is thought to cause pancreatitis [8]. The presence of this anomaly in our patient may have promoted stasis of the pancreatic juice and the formation of the pancreatic stones.

In the present case, most of the intraductal carcinoma was limited to the dorsal pancreas, though some carcinoma was observed in the branches of the uncinate process, which is anatomically classified as being part of the ventral pancreas. In complete pancreas divisum, intraductal carcinoma in the dorsal pancreas never spreads to the ventral pancreas. Because intraductal components were observed in the uncinate branches, minor peripheral communications must have existed between the two ducts in our patient.

Pathologically, adenocarcinoma of the major papilla is classified into two types: intestinal and pancreatobiliary type, based on the epithelium of its origin [1, 9]. The former is derived from intestinal (duodenal) mucosa covering the papilla, whereas the latter is associated with pancreatobiliary epithelium lining the common channel and duct systems within the papilla. This classification is also supported by immunohistochemical staining such as cytokeratin and apomucin [26]. CK20 and Muc-2 are associated with the intestinal type, whereas CK7 and Muc-5AC expression is relatively specific for the pancreatobiliary type. Immunohistochemical staining in the present case showed the mixed positive expression for CK7 and CK20. This finding indicated that the tumor might arise from the transitional area between the intestinal mucosa covering the minor papilla and the dorsal pancreatic ductal epithelium. Moreover, the mixed positive pattern for CK7 and CK20 was observed uniformly from the main polypoid adenocarcinoma to the minute intraductal lesions, suggesting that the character of both components was equivalent. This fact supported that the intraductal components were extended from the main lesion.

On microscopic examination, the morphological feature of the intraductal carcinoma component was similar to that seen in intraductal papillary mucinous neoplasm (IPMN) of the pancreas or pancreatic intraepithelial neoplasia (PanIN). IPMN generally demonstrates grossly visible cystic lesions or exophytic masses (usually >1 cm in diameter) along with grossly visible papillae and luminal mucin production [6]. In the present case, the lesion suggesting IPMN was not detected in either radiological or macroscopical examination, and moreover, mucin was not observed on the cut surface of the specimen. In addition, the main polypoid tumor conclusively involved the minor papilla. The intraductal component, which was observed even in the tiny peripheral branches (<5 mm) with lowering the grade of the lesion distally, was in direct continuity with the main tumor. Taken together, it is consistent that the association of IPMN or PanIN was less likely, and the tumor originated from the minor papilla, then extended into the distal pancreatic duct.

The pathogenesis of our case likely involved the following factors: (1) the patient had a congenital, incomplete type of pancreas divisum that had been asymptomatic; (2) the tumor arose in the minor papilla and obstructed the dorsal pancreatic duct; (3) stagnation of the pancreatic fluid from the dorsal pancreas caused pancreatitis and the formation of calcified stones; (4) on the other hand, the intraductal tumor extended widely into the peripheral ducts, and some tumor components traveled through small communications between the dorsal and ventral pancreatic ducts, and eventually reached to the branches of the uncus, which was unaffected by pancreatitis.

It is interesting to note that, in this case, the intraductal component of the adenocarcinoma of the minor papilla extended along the pancreatic duct more than expected; it extended even beyond the minor communication between the dorsal and ventral pancreatic ducts of pancreas divisum, which was detected incidentally.

CASE REPORT

Isolated vasculitis of the female genital tract: a case series and review of literature

Emmanuel Hoppé · Louis-Rémi de Ybarlucéa · Jacky Collet · Jérome Dupont · Bettina Fabiani · Xavier Puéchal

Received: 3 July 2007 / Revised: 5 September 2007 / Accepted: 8 September 2007 / Published online: 3 October 2007

Abstract To provide a clinicopathologic review of vasculitis confined to the female genital tract, we describe three cases, and we searched PubMed from 1965 to 2006 with analysis of all relevant articles. We identified 118 additional cases in the literature of whom 108 had isolated necrotizing vasculitis similar to classical polyarteritis nodosa (PAN-type), and 10 presented isolated giant cell arteritis (GCA-type) of the female genital tract. In most cases, arteritis was discovered surprisingly. The mean age of these patients was 48.6 years for the PAN-type and 64.1 for the GCA-type. Vasculitis affected a single organ in 88 (81.5%) cases of which 71 (65.7%) involved the cervix in the PAN-type, whereas it was limited in the myometrium in five (50%) cases in the GCA-type. There was no progression to a systemic vasculitis in 99.1% of the cases. A comparable favorable outcome was reported after surgery in all cases with a mean follow-up of 40.8 months. We conclude that isolated vasculitis of the female genital tract is a distinct condition, with two different patterns but a similar favorable outcome after resection. Its knowledge is needed to avoid aggressive evaluation and therapy.

Introduction

Vasculitis apparently confined to one organ is well described in the skin, kidney, central nervous system, peripheral nervous system, appendix, pancreas, gallbladder, breast, or epididymis. However, vasculitis confined to the female genital tract is rare, with about a hundred reported cases in the literature. Moreover, the follow-up in these cases was short, with different patterns of histological lesions being reported and systemic involvement sometimes being apparent at the time of operation or at subsequent follow-up.

We report a series of three cases of vasculitis limited to the female genital tract with a prolonged follow-up. We have reviewed their clinical and pathological features and all those reported in the literature to analyze whether vasculitis of the female genital tract may represent a distinct and limited condition and to describe its characteristics.

Materials and methods

Three cases of necrotizing vasculitis of the female genital tract were diagnosed by pathological examination, between 1993 and 1997, at our institution. All pathological specimens were reviewed with an extensive analysis of the entire uterus, fallopian tubes, and ovaries. Paraffin sections were stained by hematoxylin and eosin. The number of vessels

involved and their sizes were determined. The type of parietal infiltrative cells was analyzed. A complete clinical and biological workup was conducted in 2006 for these patients. An extensive literature review was carried out by searching the PubMed Medline database. All relevant publications from 1965 to 2006 in several languages were included. We performed analysis of all relevant articles. We used the 1990 American College of Rheumatology criteria for the classification of polyarteritis nodosa (PAN) [25], giant cell arteritis (GCA) [17], and Wegener granulomatosis [24] and the microscopic polyangiitis definition according to the 1994 Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis [19].

Clinical history

The clinical characteristics and histological features of our three patients with necrotizing vasculitis apparently confined to the female genital tract are reported in Table 1.

Patient 1 A 49-year-old woman complained of pelvic pain and vaginal bleeding. The patient did not present declining general health. No abnormality was found on examination. A full blood count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) were within the normal ranges. Ultrasound investigation showed an enlarged polymyomatous uterus. A total abdominal hysterectomy with bilateral salpingo-oophorectomy was performed.

Histopathology showed necrotizing vasculitis lesions on two artery walls (sizes 360 and 480 μm) only in the uterine cervix. There was severe inflammatory cell infiltration in and around the vascular wall (lymphocytes, neutrophils, and eosinophils) and fibrinoid necrosis of part or the entire vessel (Fig. 1a). Vascular lumina were narrowed, but no thrombus was seen. Examination of the myometrium also found many benign leiomyomas.

The patient had no further treatment and recovered within 2 weeks. Antineutrophil cytoplasmic antibody (ANCA) tests have always remained negative. The patient has remained well with a follow-up of 118 months.

Patient 2 A 54-year-old woman presented with a sudden right pelvic and lumbar pain. There was no sign evoking a systemic vasculitis. Vaginal examination showed a right adnexal mass and a congestive cervix. Laboratory data including a urinalysis, a full blood count, the CRP rate, renal and liver function tests were normal. Ultrasound investigation showed a large pelvic mass with calcifications inside (72×70 mm) spreading from the right fallopian tube to the top of the bladder. A total abdominal hysterectomy with bilateral salpingo-oophorectomy was performed.

Table 1 Clinical characteristics and histological features of our three patients with isolated necrotizing vasculitis of the female genital tract

Number	Age (years)	Symptoms	Type of vasculitis	Site of vasculitis	Number of involved arteries	Size of involved arteries	Pattern	Fibrinoid necrosis	Thrombi	Infarcts	Aneurysms	Infiltrate	Follow-up (months)	Associated lesions
1	49	Menorrhagia, pelvic pain	PAN	Cervix	2	360 to 480 μm	Diffuse	Yes	No	No	No	Lymphocytes, neutrophils, eosinophils	118	Leiomyoma
2	54	Lumbar and pelvic pain	PAN	Myometrium, mesovarium	2	840 μm both	Diffuse	Yes	Yes	No	No	Lymphocytes, neutrophils	170	Right ovarian teratoma
3	72	Fever, ESR=101, CRP=6	PAN	Fallopian tubes, ovaries, myometrium, isthmus, cervix, mesovarium	Numerous	324 to 1,320 μm	Diffuse	Rare	No	No	No	Lymphocytes, rare neutrophils, few giant cells	129	Mucinous cystadenoma

ESR Erythrocyte sedimentation rate (mm/h), *CRP* C-reactive protein (mg/dl), *PAN* polyarteritis nodosa

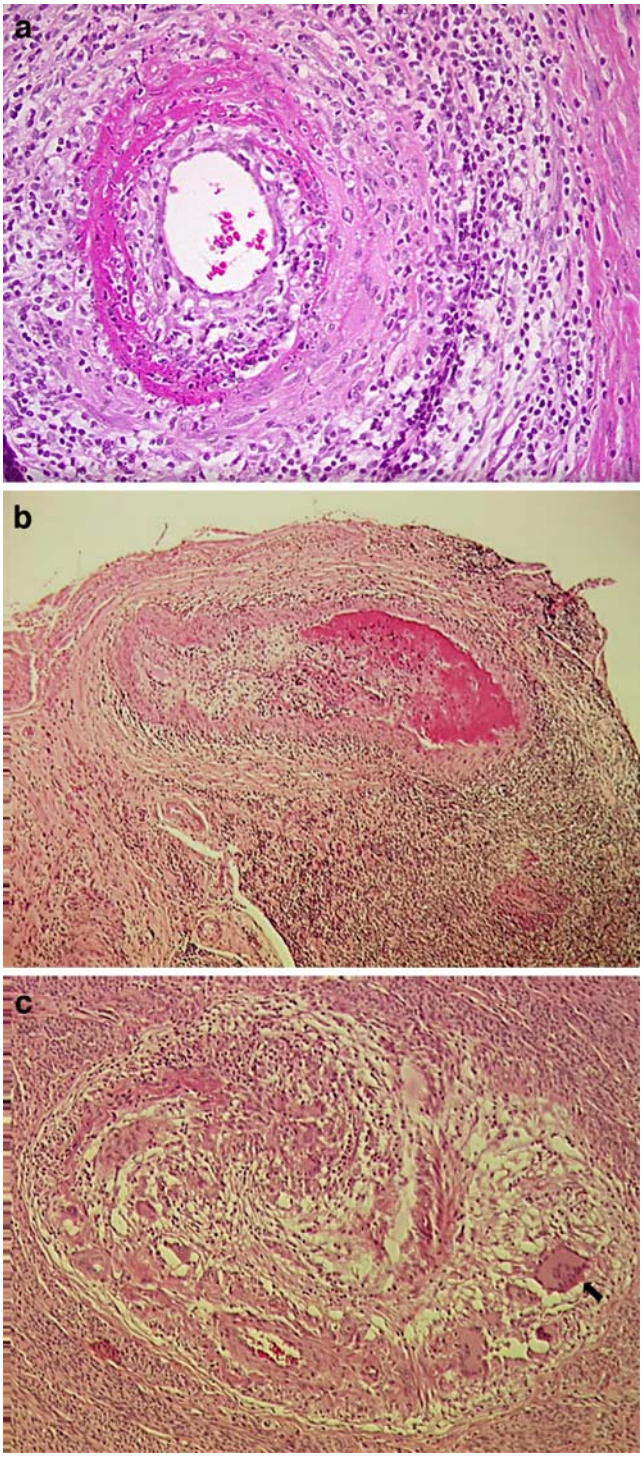

Fig. 1 **a** Inflammatory infiltrate and fibrinoid necrosis of a 480-μm arteriole of the cervix. Patient 1, hematoxylin and eosin ×400. **b** Transmural mixed inflammation and fibrinoid change in an 840-μm artery of the mesovarium, with destruction of the wall and luminal thrombus. Patient 2, hematoxylin and eosin ×200. **c** Mixed inflammation of a 1,320-μm artery wall, in the uterus, including multinucleated giant cells (*arrow*). Patient 3, hematoxylin and eosin ×400

Histopathology showed a mature cystic ovarian teratoma, containing hair and calcifications. Analysis of the myometrium and mesovarium showed necrotizing vasculitic lesions affecting two different 840-μm arteries. Fibrinoid necrosis had spread all through the vessel wall with very severe inflammatory cell infiltration (lymphocytes and neutrophils). One of the arteries was obstructed by a fibrin thrombus (Fig. 1b).

The patient had no further treatment. She recovered within 10 days. With a 170-month follow-up, she has developed no clinical or biological disorder evoking systemic vasculitis. ANCA tests always remained negative.

Patient 3 A 72-year-old woman was admitted because of a 2-month history of isolated fever (37.7 to 38.5°C). The patient was in a good general health. There was no recent infection. Physical examination revealed an isolated enlarged left ovary, whereas she presented neither pelvic pain nor vaginal bleeding. The ESR was 101 mm after the first hour, and CRP was 7.7 mg/dl. Antinuclear antibodies were positive at 1/200 (both Hep-2 and rat liver cells) with no anti-DNA. ANCA test, cryoglobulinemia test, and serologies for hepatitis B and C viruses were negative. Other laboratory data including a full blood count, blood cultures, renal and liver tests were normal or negative. A computed tomography (CT) scan of the pelvis showed a 45-mm cystic mass in the left adnexa. Total abdominal hysterectomy with bilateral salpingo-oophorectomy was performed.

Histopathology showed a mucinous cystadenoma with no evidence of malignancy associated with widespread vasculitis affecting the ovaries and fallopian tubes, the myometrium, the isthmus, the cervix, and the mesovarium. Many arteries (324 to 1,320 μm) showed inflammatory cell infiltration composed mainly of lymphocytes and neutrophils with fibrinoid necrosis of the vessel wall. One giant cell was found (Fig. 1c) but remained isolated despite an extensive pathological examination. The internal elastic lamina was disrupted or totally destroyed. No vascular thrombosis was seen.

No further treatment was performed. Fever disappeared, and ESR and CRP eventually normalized. ANCA tests have always remained negative. With a 129-month follow-up, she has developed no clinical or biological manifestation that would have evoked systemic vasculitis.

Results and discussion

In addition to our three patients, our literature review found a total figure of 118 reported cases of vasculitis confined to the female genital tract [1–7, 9–13, 15, 18, 20–23, 26, 28, 29, 31, 32, 35–41]. Pathological features showed that 108 had isolated necrotizing vasculitis of the female genital tract

Table 2 Clinical characteristics and histological features of 118 patients with isolated vasculitis of the female genital tract

(INVF) and 10 presented isolated giant cell arteritis of the female genital tract (IGCAF; Table 2). The histological patterns in INVF are similar to those described in systemic PAN. These consist of a severe inflammatory cell infiltration in and around the vessel (mainly neutrophils, and eosinophils and lymphocytes) with fibrinoid necrosis of part of or throughout the artery wall. The internal elastic lamina is often disrupted. The vasculitic process is often segmental (only a segment of the artery may be affected along its length) and focal (a normal, unaffected artery may lie side by side with a severely affected one), with coexisting acute and healed vascular lesions. As well as the necrotizing patterns, systemic PAN may also induce luminal thrombi, as seen in case 2 from our series. In IGCAF, arteritis affects the small- to medium-sized vessels, with predominance of giant cells, lymphocytes, macrophages, and less common eosinophils. There is disruption of the internal elastic lamina with luminal narrowing or even thrombus.

The mean age of the patients with INVF was 48.6 years (18–80). In two cases, bleeding related to a vasculitis-induced ulcer [1] or which could have been related to vasculitic lesions of the left ovary [18] was the presenting symptom. However, in most cases of INVF, as in our observations, arteritis was discovered by routine histological examination of specimens obtained for apparently different local gynecological lesions. Indeed, other histological lesions are associated in 82 (75.9%) of 108 reported cases (Table 2), the most frequent being benign leiomyomas (35 cases, 32.4%) [6, 7, 11–13, 32, 35, 41].

One of our patients (case 3) presented with fever and a raised ESR of 101 mm/h that normalized after surgery. She had no systemic symptoms at the time of diagnosis or later with a 10-year follow-up. Patalano and Sommers [33] described vasculitic lesions in the female genital tract in 6 (35%) of 17 necropsied cases of systemic PAN. In the literature, to our knowledge, there are only nine cases of necrotizing vasculitis of the female genital tract revealing a systemic PAN [8, 13, 14, 16, 27, 30, 34, 38]. The mean reported ESR was 96.9 mm/h (range 50–140), and in six cases, the ESR was above 100 mm/h [8, 14, 27, 30, 34, 38]. This contrasts with the low value of ESR found in INVF (mean 16.6, range 2–80, but mentioned in only 24 cases). No ANCA was found in these reported cases. In the literature, there was no progression of INVF to a systemic disease over a mean follow-up of 39.2 months (range 2–276) except a single patient who was reported to have developed a PAN 8 years after hysterectomy [13].

In most cases of INVF, the extent of vasculitic lesions is limited. A single organ being involved was encountered in 88 (81.5%) cases, of which 71 (65.7%) cases involved the cervix [2, 5–7, 10, 12, 13, 20, 23, 32, 35, 38, 39, 41], 10 (9.3%) cases, the ovary [11–13, 18, 21, 39, 40], 10 (9.3%) cases, the myometrium [1, 13, 22, 26, 28, 36, 28], 4 (3.7%) cases, the isthmus [12, 13], 2 (1.9%) cases, the fallopian tubes [13, 39], and 1 (0.9%) case, the parametrium [13] (Table 2). Furthermore, involvement of a single vessel was observed in 29 (26.9%) among the 108 cases of INVF. In contrast, in systemic PAN revealed by gynecological involvement (nine cases), extensive vasculitis lesions of the whole female genital tract were found in five cases (55.6%) [14, 16, 27, 34, 38]. Nevertheless, extension of the vasculitic lesions in the female genital tract cannot predict the outcome in an individual. For example, five cases of INVF with extensive vasculitic patterns never developed a systemic disease [13] and the single patient who developed

a PAN 8 years after INVF had vasculitis initially confined to the small arteries of the cervix [13].

As well as these PAN-type gynecological vasculitides, 48 cases of GCA have been reported with gynecological involvement. In all the cases, GCA of the female genital tract had unexpectedly been discovered upon pathological examination of surgically removed genital organs for different gynecological lesions. More than three out of four patients had signs suggestive of systemic GCA or polymyalgia rheumatica. In contrast, only ten of these patients could be considered as having isolated GCA of the female genital tract (IGCAF) [1, 4, 13, 28, 29, 36]. None presented systemic vasculitis symptoms at the time of diagnosis. Their mean age was 64.1 years (range, 46–79), which is older than for INVF (48.6 years). ESR was raised in four cases [1, 29, 36], with a mean value of 59.5 mm/h (range, 46–67), normal in three cases [13, 28], and not mentioned in three cases [4, 28]. The vasculitic process was confined to the myometrium in five (50%) cases [1, 29, 36], the cervix in two (20%) cases [13, 28], the parametrium in one (10%) case, but was extensive in two (20%) cases [4, 28]. This is different from INVF, which affected only the cervix in two thirds of cases. As in systemic forms, the pathological features may occasionally show some overlap between IGCAF and INVF: fibrinoid necrosis of the media was (infrequently) seen in IGCAF [36], and giant cells were found in a small number of INVF cases [13] as in one of our patients in whom one giant cell was found but remained isolated despite an extensive pathological examination (case 3). In all cases of IGCAF, a favorable outcome was observed after isolated surgery, with a mean follow-up of 59.2 (range, 2–204) months.

In conclusion, vasculitis of the female genital tract rarely occurs in systemic vasculitides. However, isolated vasculitis of the female genital tract is a distinct condition with 121 reported cases, including our series. These cases can be split into 111 PAN-type cases and 10 GCA-type cases. The condition is revealed by gynecological symptoms not due to vasculitis, diagnosed upon pathological findings identical to those of classical PAN or GCA and cured after isolated resection. Its recognition is important for preventing heavy evaluation or medication.

LETTER TO THE EDITOR

Small intestinal CD4+ T-cell lymphoma: a rare distinctive clinicopathological entity associated with prolonged survival

Magali Svrcek · Laurent Garderet · Virginie Sebbagh · Michelle Rosenzwajg · Yann Parc · Monique Lagrange · Malika Bennis · Anne Lavergne-Slove · Jean-François Fléjou · Bettina Fabiani

Received: 14 June 2007 / Revised: 11 July 2007 / Accepted: 11 July 2007 / Published online: 3 August 2007

Dear Editor,

Intestinal T-cell lymphomas are rare and heterogeneous. Most of them are localised high-grade large cell lymphomas and carry a poor prognosis. The WHO classification only recognises one distinct entity of intestinal T-cell lymphoma, called "enteropathy-associated T-cell lymphoma" [5]. This lymphoma arises in pre-existing celiac disease. The neoplastic cells infiltrate the overlying epithelium, mimicking normal intraepithelial lymphocytes (IELS). They are CD3+, CD5−, CD7+, CD8−/+ and also express the homing receptor CD103 antigen, typically seen in normal and malignant intraepithelial T lymphocytes. CD4 is always negative.

In 1999, Carbonnel et al. [1] reported four patients with clinico-pathological features suggesting a new distinct entity defining extensive small intestinal CD4+ T-cell lymphoma.

We had the opportunity to diagnose an additional case of this T-cell low grade lymphoma in a patient without any evidence of celiac disease, associated with prolonged survival.

In January 2004, a 23-year-old man was admitted in our hospital with a 4-month history of diarrhoea, weight loss (−4 kg) and massive abdominal distension.

Laboratory findings revealed marked eosinophilia (absolute eosinophil count, 6,185 per mm^3) and polyclonal hypergammaglobulinemia (16.7 g/l, N<16 g/l) with normal IgM, IgA and IgE levels. An abdominal computed tomography (CT) scan revealed multiple enlarged mesenteric and retroperitoneal lymph nodes.

Histological examination of the ileal biopsies showed an abundant and diffuse pleomorphic infiltrate, predominantly located in the lamina propria. This infiltrate was composed mainly of small- to medium-sized cells, sometimes cleaved, with inconspicuous nucleoli and plasma cells (Fig. 1a). Crypt architecture was preserved. The villi were normal or slightly shortened. There was no increase in IELs. There was no lymphoepithelial lesion. Numerous polymorphonuclear eosinophils and extensive epithelioid granulomatous reaction were associated with the lymphoid infiltrate (Fig. 1b). Gastric and colonic biopsies were normal. A few days later, the patient developed sub-acute small bowel obstruction, and a laparoscopic ileal resection was performed (Fig. 1c). Mesenteric and ileal lymph nodes were

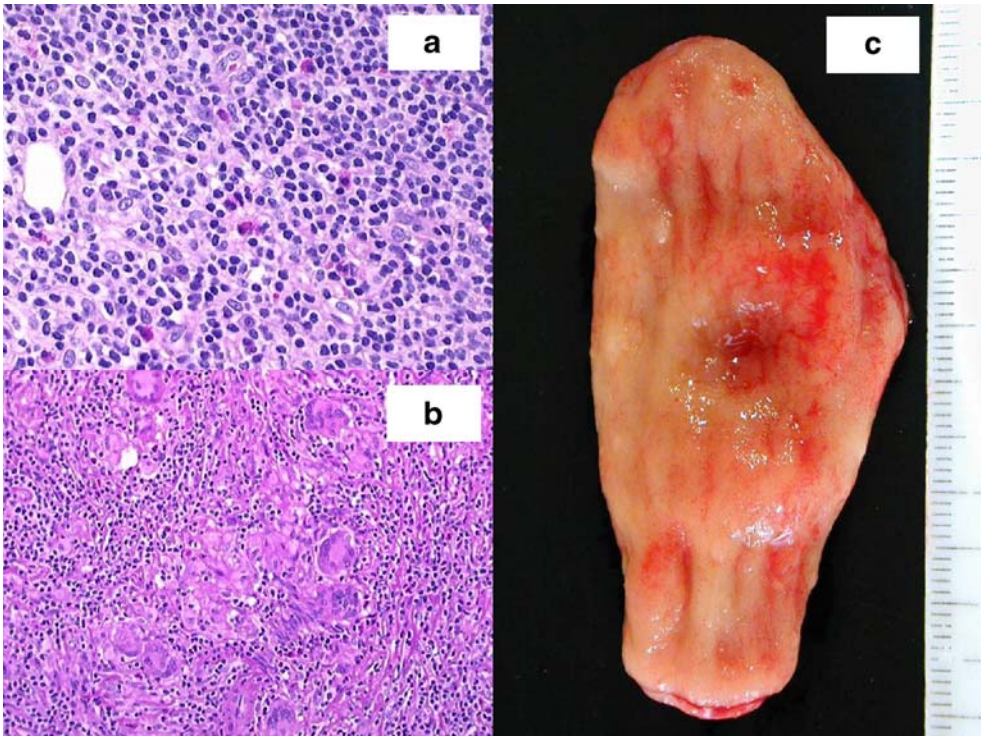

Fig. 1 Neoplastic cells consist of small to medium size cells. Note the presence of eosinophils (hematoxylin and eosin, magnification ×400; **a**). Epithelioid histiocytes with giant cells, forming small clusters and granulomas of different size are intermingled with the neoplastic cells. The granulomas show no central necrosis (hematoxylin and eosin, magnification ×200; **b**). Macroscopic view of surgical ileal resection: the affected bowel segment is oedematous. The tumour presents as a main ulcerating mucosal mass with multiple small nodules all over (**c**)

also resected. In the resected ileal tissue, the infiltrate predominated in the lamina propria, but involved the entire intestinal wall. The mesenteric and ileal lymph nodes architecture was replaced by sheets of small lymphocytes showing the same morphologic features as the neoplastic cells observed in the surgical ileal resection.

The infiltrating lymphoid cells were positive for CD3, CD5, CD2, and CD4 but negative for CD7, CD8, CD15, CD30, granzyme B, TIA-1, CD10, CD23 and CD103 (Fig. 2). The tumor cells have a betaF1-phenotype. A bone marrow biopsy was hypocellular and showed interstitial infiltration by small lymphocytes with a T-cell phenotype

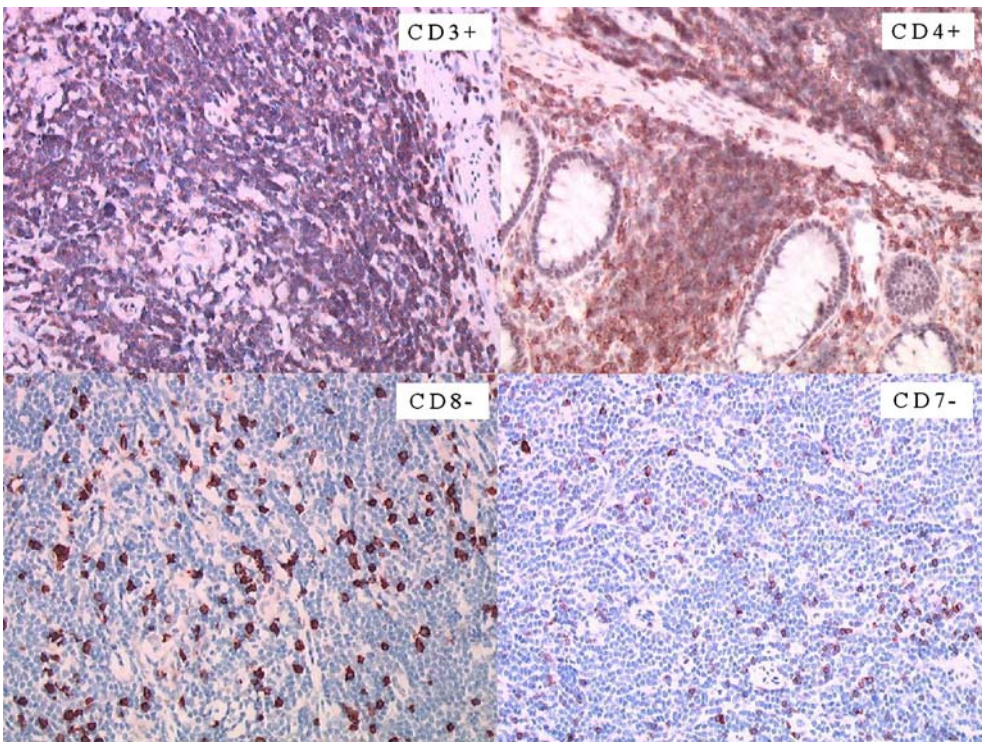

Fig. 2 Immunohistochemical analysis of the surgical ileal resection shows the neoplastic cells are positive for CD3, CD4 and negative for CD8 and CD7 (hematoxylin and dimethylaminoazobenzene, ×200)

similar to that seen in the ileal resection specimen. Molecular study by PCR analysis of TCR γ rearrangement showed a monoclonal pattern, both on the intestinal resection and mesenteric lymph node.

The patient was initially treated with prednisone, which improved his signs and symptoms. He then underwent systemic chemotherapy (ACVB-P regimen and anti-CD52 antibody therapy). Despite incomplete histological remission, the patient is symptom-free on steroid therapy alone, more than 3 years after diagnosis.

The clinical behaviour, the absence of a previous history of gluten-sensitive enteropathy and the immunophenotype of tumour cells distinguish this case from the WHO-defined distinctive enteropathy-type T-cell lymphoma. The current WHO classification of tumours of hematopoietic and lymphoid tissue also recognises two other major categories of extranodal T/NK cell tumours presenting in the intestine, which need to be included in the differential diagnosis: (1) extranodal NK/T cell lymphoma, nasal type and (2) hepatosplenic T-cell lymphoma. Our patient's low-grade T-cell lymphoma clearly differs from these two WHO-recognized distinctive entities.

Five cases with similar clinical and pathological features have been described in the English literature [1, 6]. In these five cases, the age ranged from 28 to 60 years (mean, 49.4 years). There were 4 men and 1 woman. These cases showed morphological homogeneity, with low-grade cytology. Immunophenotypic profiles were similar, with a constant expression of CD4 by tumour cells, whereas CD8 and CD103, which are expressed by normal IELs were negative. All patients had a slow relentless course and a prolonged survival compared to "classic" T-cell lymphomas. We had recently the opportunity to see one of these patients [1] who is still alive, more than 15 years after the diagnosis. Her clinical condition is good, although she presents intermittent skin lesions, mesenteric lymph nodes and non-specific lung opacities. The duodenal infiltrate is still present and unchanged on recent biopsies.

Our patient had hypereosinophilia. The relationship between hypereosinophilia and T-cell lymphoma is well established [2]. Like in three of the five patients reported in the literature, the neoplastic cells were admixed with numerous eosinophils and an extensive epithelioid cell granulomatous reaction. The granulomatous reaction may be due to aberrant cytokine production from T lymphocytes activated by the tumour or from the neoplastic cells themselves [3]. CD4+ lymphocytes are the most important source of granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3), and IL-5, three cytokines active in promoting the development and differentiation of eosinophils in bone marrow.

This new case strengthens the hypothesis of a reproducible clinico-pathological entity, which could be individualized in the WHO classification as a second distinctive intestinal T-cell lymphoma category, as suggested by Isaacson [4]. The phenotype of this lymphoma seems to be in keeping with an origin from normal CD4+ lamina propria T cells.

It is noteworthy that this small intestinal CD4+ T-cell lymphoma shows similarities with the primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma in terms of behaviour, morphology and phenotype: this cutaneous lymphoma is defined by a predominance of small- to medium-sifszed CD4+ pleomorphic T cells and, in most cases, a favourable clinical course. Actually, this neoplasm is classified as "primary cutaneous peripheral T-cell lymphoma, unspecified" (WHO-EORTC classification of cutaneous lymphomas with primary cutaneous manifestations). However, recent studies have suggested that it can be separated out as a provisional entity from this broad group, called "primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma." A real distinctive category will probably be present in the forthcoming WHO classification.

LETTER TO THE EDITOR

Mixed germ cell sex cord-stromal tumours of the testis

Michal Michal · Ondrej Hes · Petr Mukensnabl · Dmitry V. Kazakov

Received: 19 July 2007 / Accepted: 22 August 2007 / Published online: 13 September 2007

Dear Editor,

We have recently published a series of seven cases of mixed germ cell sex cord-stromal tumours (MGSCT) of the testis and ovary comparing their morphological, immunohistochemical and molecular genetic findings [1]. MGSCT of the ovary and testes varied considerably in all these aspects. Germ cells in ovarian MGSCT stained positively with the antibodies to NSE, PLAP, and OCT4 with the exception of one case, which reacted positively for the c-kit protein antibody. The immunoprofile of the germ cells in ovarian MGSCT was identical to that of ovarian dysgerminomas and testicular classical seminomas. In addition, germ cells in one of the ovarian cases showed amplification of 12p, which is a typical feature of ovarian dysgerminomas and testicular classical seminomas [1].

Germ cells in testicular MGSCT were similar in morphology, immunoprofile and molecular genetic findings to those of spermatocytic seminomas. Immunohistochemically, they tested negative with all the above-enumerated antibodies and, in addition, they lacked on molecular biological analysis amplification of 12p [1]. However, there is not a single antibody positively distinguishing germ cells in spermatocytic seminoma from non-neoplastic testicular germ cells in contemporary pathology that we are aware of and that we could have used in our study. It may be one of the reasons why Drs. Ulbright and Young questioned the neoplastic nature of the germ cells in the testicular MGSCT [3, 4]. They reviewed nine testicular sex cord-stromal tumours containing germ cells, which closely mimicked MGSCT but differed from the latter, in that the germ cells were entrapped and non-neoplastic rather than neoplastic [3]. They thought that these tumours closely resembled MGSCT, but represented sex cord stromal tumours with entrapped germ cells, which they considered non-neoplastic. The evidence they presented to support their view was that the germ cells were distributed peripherally, were associated with entrapped seminiferous tubules or occurred in clusters with vaguely tubular shape consistent with preexisting seminiferous tubules [3]. Although some of these cases may have represented sex cord-stromal tumours with entrapped germ cells, in some of them, germ cells seemed not to have any relation to pre-existent seminiferous tubules and were scattered haphazardly forming a true predominant part of the lesion, whilst in other parts of the sex cord, the elements predominated. In one of those cases, inhibin stain showed an association of the germ cells with non-neoplastic Sertoli cells. The germ cells in Drs. Ulbright and Young's cases lacked large, vesicular nuclei with prominent nucleoli, closely resembling type A spermatogonia; the authors thus concluded that true testicular MGSCT most probably does not exist and these neoplasms represent sex cord-stromal tumours with entrapped, non-neoplastic germ cells [3]. A similar view was reiterated by the authors in a letter to the editor in relation to our paper [4].

In our paper, however, we have mentioned a very important morphological finding that proves the neoplastic nature of the germ cells in testicular MGSCT and militates against their reactive nature, namely, the presence of

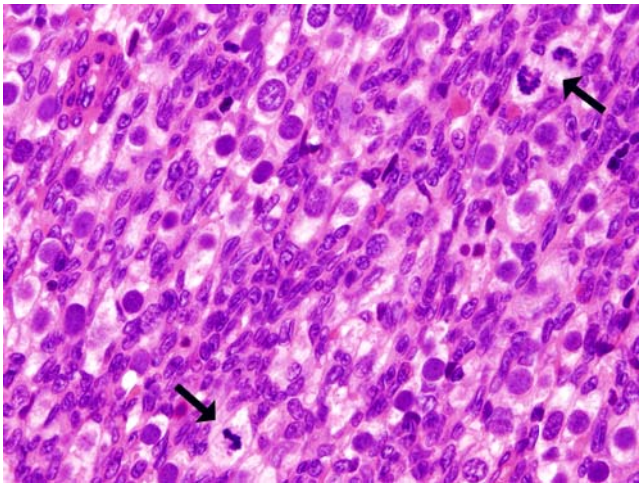

Fig. 1 Testicular MGSCT. Germ cells growing on the background of sex cord-stromal cells. There are three atypical mitoses in the germ cells at low magnification (*arrows*)

atypical, sometimes even bizarre mitotic figures in the germ cell component. We showed one atypical mitosis in Figure 4 of our original paper [1]; however, owing to the photographic reduction of the size, the details are not well apparent. Because this feature was very prominent in case 1 in our series [1] and from this case we were able to process the whole accessed surgical tumour tissues, we decided to cut through all blocks and review the slides again. The newly cut slides demonstrated places where we encountered several atypical mitoses within the germ cells (Fig. 1) (up to five atypical mitoses per one low-power field). When viewed on high magnification, these areas show clearly

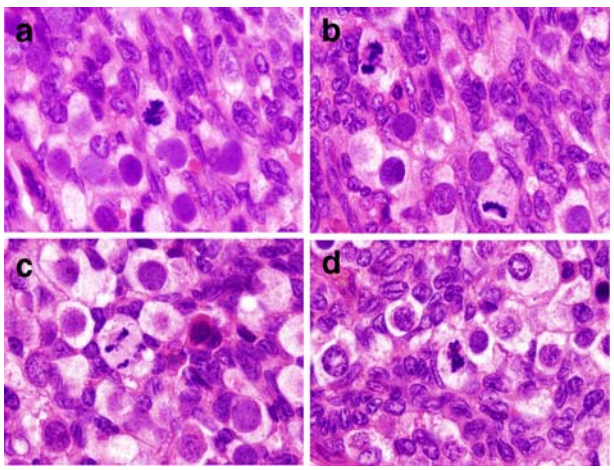

Fig. 2 **a**–**d** Testicular MGSCT. Atypical mitoses in germ cells at high magnification

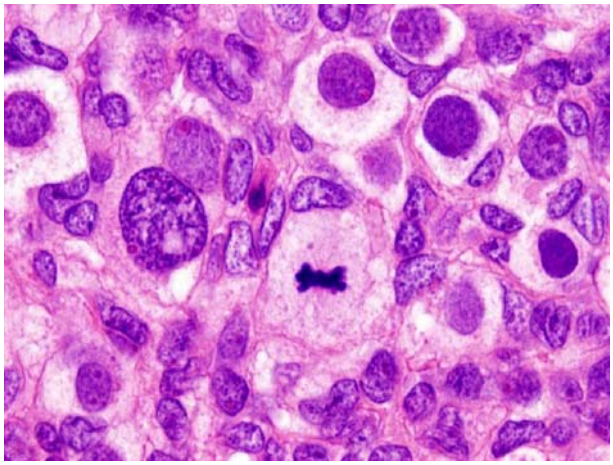

Fig. 3 Testicular MGSCT. Distinct variation in size of the germ cells

the atypical nature of the mitoses in the germ cells that leaves no doubt these germ cells are not only neoplastic, but malignant as well (Fig. 2). In addition, MIB1 antibody in these areas stained up to half of the germ cell component. We also found a distinct variation in size of the germ cells in this case, which would be quite unusual for the non-neoplastic germ cells (Fig. 3.). It is important to note that this morphological variation is quite similar to the germ cells of spermatocytic seminomas. In addition, we have not found a single focus in the entire neoplasm in which the germ cells resembled entrapped cells within testicular tubules or within a sex cord stromal tumour.

In our opinion, all the above-enumerated features point to the neoplastic, rather than reactive, nature of the germ cells in testicular MGSCT and to the existence of testicular MGSCT as an entity. Talerman and Roth recently expressed a similar opinion in their paper dealing with MGSCT [2].

LETTER TO THE EDITOR

Presence of myeloid precursor cells in the endometrium of an AML patient: a diagnostic challenge!

K. Lambein · A. Janssens · S. Weyers · M. Praet · P. De Paepe

Received: 4 June 2007 / Revised: 1 October 2007 / Accepted: 2 October 2007 / Published online: 31 October 2007

Dear Editor, myeloid precursor cells (myeloblasts) in the endometrium are very rare and occur in two conditions: myeloid sarcoma and extramedullary haematopoiesis. Both are very rare and are described in patients with an underlying haematological disorder. Diagnostic difficulties can present when myeloid precursor cells are found in an extramedullary location in an AML patient. We report the case of a female patient with acute myeloid leukaemia (AML) and endometrial extramedullary haematopoiesis.

A 49-year-old woman presents with progressive dyspnoea, leucocytosis, anaemia and thrombopenia. Differential white blood cell count shows 3% myeloblasts in the peripheral blood and 20% myeloblasts in the bone marrow. Examination of bone marrow smear and biopsy lead to the diagnosis of acute myeloid leukaemia, type FAB M4. No cytogenetic aberrations are found.

The patient is treated with chemotherapy and achieves complete remission. Four months later, the patient presents with metrorrhagia resistant to tranexaminic acid and progestins (lynestrenol).

An endometrium biopsy (Fig. 1) reveals arrested secretion due to prolonged intake of progestins, with foci of myeloblasts staining for myeloperoxidase and CD 68 (Fig. 2).

The differential diagnosis between extramedullary haematopoiesis and myeloid sarcoma is considered.

Myeloid sarcoma is an unusual extramedullary manifestation of acute myeloid leukaemia. It can precede or concur with AML, or can be the hallmark of relapse. As myeloid sarcoma can affect almost every organ, the clinical presentation is very diverse. Diagnosis depends on histology and immunohistochemistry. Myeloid sarcoma remains a diagnostic pitfall; up to 75% are initially misdiagnosed [3]. Uterine myeloid sarcoma has been described, although mainly in the cervix [1].

Endometrial extramedullary haematopoiesis is an extremely rare condition. Only a few cases are reported, most of them related to an underlying haematological disorder [4]. Two possible stimuli for endometrial haematopoiesis have been described: GM-CSF (granulocyte-macrophage colony-stimulating factor) and uteroferrin [2]. GM-CSF is secreted by fibroblasts and endothelial cells when appropriately stimulated by interleukin (IL)-1 or tumour necrosis factor (TNF)-α. Uteroferrin is secreted by endometrial cells in certain mammals during pregnancy and after administration of progestins. One case of endometrial extramedullary haematopoiesis associated with retained products of conception after termination of pregnancy is described [4]. This case could also be explained by the uteroferrin hypothesis.

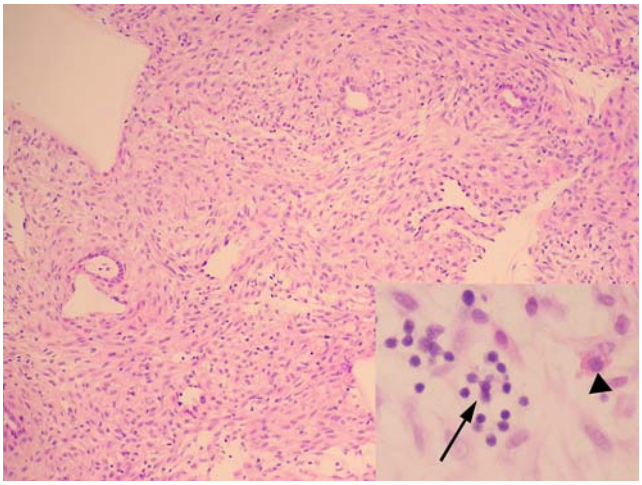

Fig. 1 *Background*: Low-power H&E of the endometrium. *Inset*: High-power H&E of the endometrium containing erythroid precursors (*arrow*) and myeloid precursors (*arrowhead*)

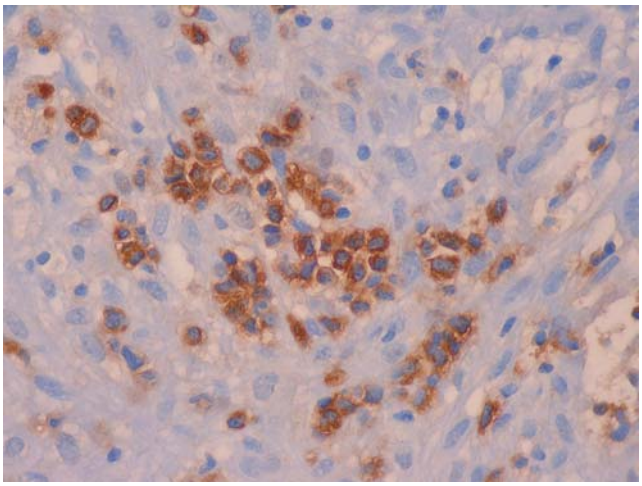

Fig. 2 Myeloperoxidase immunohistochemistry illustrating the myeloid precursors

In our case, the uteroferrin hypothesis seems plausible as our patient received long-time progestin therapy. The diagnostic dilemma in our case was solved with deeper tissue sections revealing the presence of erythroid cells, which were positive for glycophorin.

Female leukemia patients are often treated with progestins to prevent metrorrhagia, as is the case in our hospital. Progestin-induced endometrial extramedullary haematopoiesis could thus occur more often than has yet been proven. Clinicians often relate the uterine bleeding of leukemia patients to thrombopenia. As extramedullary hematopoiesis is not considered and an endometrial biopsy is not performed, little is known on this association.

However, bearing the uteroferrin hypothesis in mind, endometrial extramedullary haematopoiesis should be considered in female leukemia patients with uterine bleeding.

Raising the awareness of both pathologists and clinicians on this association should allow us a better insight into the incidence and the clinical impact of this matter.

MEETING REPORT

The first Sino-German symposium on cancer research, Shanghai May 2007

Yajun Guo · Manfred Dietel

Received: 27 July 2007 / Accepted: 27 July 2007 / Published online: 20 October 2007

Keywords China · Germany · Sino-Germany Science Center

Introduction

This meeting report gives a short overview on the contributions of 17 leading scientists from China and Germany. The symposium was supported by the Sino-Germany Science Center Bejing, the Deutsche Forschungsgemeinschaft and the National Science Foundation, China. It intended to foster communication and collaboration of researchers from both countries.

The "Migrating Cancer Stem Cell"—Concept was discussed by Thomas Brabletz (Dept. of Surgery Univ. of Freiburg). Most colorectal adenocarcinomas (CRC) have mutations in the APC gene leading to overexpression of the Wnt-pathway effector beta-catenin. By acting as a transcriptional activator, nuclear beta-catenin is decisively involved in two fundamental processes in embryonic development: epithelial to mesenchymal transition (EMT) and generation of stem cells (e.g., in intestine development).

We have previously shown that nuclear beta-catenin accumulates in tumor cells at the invasive front undergoing an EMT. The amount of these cells strongly correlates with clinical outcome and metastasis formation. In contrast, tumor cells in central tumor areas are differentiated and often show membranous, E-cadherin-bound beta-catenin. Strikingly, also, metastases show again a differentiated phenotype lacking nuclear beta-catenin, indicating a regulatory role of the tumor environment for malignant progression.

Based on the developmental functions of beta-catenin and our data, we propose that both primary tumors and metastases are derived from the pool of EMT-associated "migrating cancer stem cells" at the tumor host interface, which are defined by strong nuclear beta-catenin accumulation and expression of its target genes. This gives these cells a feature, which drives malignant tumor progression including metastasis: The unusual combination of abilities allowing simultaneously to migrate and behave as a cancer stem cell.

Molecular Targets in Cancer Therapy—New Possibilities and Old Limitations were reported by Reinhard Buettner (Inst. of Pathology, University of Bonn). Increasing knowledge on molecular pathogenesis of malignant tumors and activated signaling pathways has led to the concept of targeted therapies. Small molecularly designed molecules target specifically oncoproteins, and thereby modulate growth, apoptosis, or invasion of cancer cells. Currently, most experiences exit with membrane-coupled growth factor receptors and their intracellularly coupled signaling kinases.

In cancer cells, these tyrosine kinase-triggered signaling pathways are frequently altered and causally involved in malignant transformation. Indeed, some of the tyrosine

kinase-coupled receptors or their respective growth factors were originally cloned as retroviral oncogenes. Therefore, these critical oncogenic effector pathways represent attractive and often highly selective therapeutic targets. However, as experience with patients under long-term therapies with selective tyrosine kinase inhibitors accumulates, it becomes also evident that tumors develop escape strategies leading to resistance to therapy either via specific mutations or switches in intracellular signaling pathways.

We propose to discuss (1) current knowledge of the most frequently employed molecular targets and the strategies to design and develop specific inhibitors, (2) report first experiences with molecular diagnostics of resistance, and to (3) describe putative options for combinational therapies and second- or even third-line molecular therapies to address tumor-escape strategies in response to treatment. (4) Finally, we would also like to discuss implications on the health care system and reflect ethical considerations resulting from a science-based molecular medicine.

Reinhard Dengler (Dept. of Neurology Medical School) gave an overview on Modern Approaches in Functional Neurodiagnosis. A major goal of neurosurgery is to reduce the intervention-associated brain damage and functional deficits to a minimum. This holds especially true if brain tumors are localized in or close to important functional regions such as the eloquential or sensorimotor areas. Structural images may show the extension of the tumor and may allow for differentiation between tumor mass and brain edema, but do not provide precise information on the relation between the tumor and functional areas which may be entirely or partially involved or rather displaced by the space occupying lesion or may be even fully untouched.

In such situations, the neurosurgeon wishes a functionally oriented presurgical diagnosis to make the best strategy for the operation and to avoid as much unnecessary brain damage as possible. Modern functional imaging in conjunction with specific structural imaging is very valuable in solving this task. In addition to classical cranial computer tomography and magnetic resonance imaging (MRI) and its variations including Gadolinium enhancement, functional MRI, and PET studies using tracers such as F-18-Deoxyglucose or C-11-Methonin (or F-18-Tyrosin) can be used successfully. Matching of the images generated by these techniques provides information on tumor extension, metabolically active tumor portions vs inactive or necrotic portions, and anatomical relationship to functional areas. The power of these techniques can be further increased by modern neuronavigation which uses the computerized imaging data. This helps the surgeon to make optimal intraoperative decisions on how much tissue can or must be removed and to minimize postoperative functional deficits.

Manfred Dietel (Inst. of Pathology, Charitè, Berlin) discussed Molecular Pathology and Targeted Therapy. To read a patients' tissue as "deeply" as possible and to get information on morphological, genetic, proteomic, and epigenetic grounds will be the upcoming task of surgical pathologists to provide the clinicians with information relevant for individualized medicine. These data will provide the basis of clinical drug selection as well as development of new drugs.

Molecular diagnostic Following the WHO, malignant tumors are grouped on the basis of histogenesis, histological type, and differentiation. However, tumors of the same group may be heterogeneous. Although histopathology is only partly able to predict clinical behavior, it still plays the dominant role in selecting patients' management. To improve this situation, molecular approach will become part of the diagnostic process, hopefully adding that information which conventional morphology is not able to provide.

Predictive pathology Prediction of the clinical behavior of an individual tumor is a pushing challenge for pathology. Clinicians strongly demand for a reliable prediction regarding prognosis, metastatic potential, and/or response to therapy. Applying DNA arrays, several approaches have been performed successfully to improve predictive accuracy.

Development of new drugs In recent years, the efforts devoted to unraveling potential new therapeutic targets have lead to the development of new drugs. For example, Herceptin and Gleevec are the first designer drugs which are used with considerable success in the clinic. The basis of these developments was provided by tissue-based investigations performed by experimental pathologists.

Bernd Groner (Georg Speyer Haus, Inst. for Biomedical Research, Frankfurt) presented data on "Novel Approaches to Targeted Tumor Therapy". The inappropriate assembly of modular components plays a role in oncogenic transformation and other diseases and can be exploited for therapeutic purposes. These target structures, however, are conventionally considered as "not druggable". As protein–protein interactions are mediated by surface structures of folded proteins, peptides embedded in the context of a scaffold protein can serve as competitive inhibitors of protein recognition modules. Such peptide aptamers can target non-canonical drug binding sites and disrupt intracellular protein functions. Applications of this principle are dependent upon the binding specificities and affinities of the peptide aptamers to their target structures, recombinant expression, and purification of the peptide aptamer-scaffold protein and delivery of the purified protein into cells. We improved upon the scaffold structure and utilized the

human thioredoxin molecule. Removal of five internal cysteines allows the purification of a monomeric protein with high yield. Provision of this molecule with a protein transduction domain, consisting of nine arginines, results in a fusion protein, which is taken up efficiently by cultured cells, inhibits intracellular signaling functions and associated cellular phenotypes. A peptide aptamer which recognizes the intracellular part of the ErbB2 receptor was introduced into breast cancer cells. They reduced the extent of AKT kinase induction upon heregulin treatment of the cells and enhanced resistance towards chemotherapeutic agents in ErbB2 overexpressing cancer cells. A peptide aptamer directed against the dimerization domain of the transcription factor Stat3 prevented Stat3-mediated transactivation and induced growth inhibition and the induction of apoptosis.

Christian Hagemeier (Charité-Berlin, Children's Hospital, Lab for Molecular Biology, Berlin) spoke about Molecular Approaches to Understand and Tackle Acute Lymphoblastic Leukemias in Children. The probability of long-term survival after relapse from acute lymphoblastic leukemia (ALL) is predicted from well-established prognostic, mainly clinical, factors. However, the underlying biological determinants of these prognostic factors are poorly understood. In collaboration with the department of Pediatric Oncology that houses the BFM ALL-REZ study group, we have defined molecular prognostic markers for risk stratification, identified gene expression programs that characterize ALL pathogenesis in patients with poor outcome, and searched for genes that modulate therapeutic approaches. We found that early onset relapse of ALL, which is typically associated with a particularly low event-free survival rate, is distinguished from late disease recurrence by an increased proliferative capacity of leukemic blasts and a distinct expression of genes with functions in cell cycle control, particularly during the process of mitosis. In addition, by employing a genetic shRNA screen, we have identified sets of genes that modulate therapeutic approaches in cell culture-based models. The implications will be discussed.

Per Sonne Holm (Inst. of Experimental Oncology & Research, Technical University Munich) reported on YB-1 as a Target for the Development Oncolytic Adenovirus. It has been shown that YB-1 regulates the expression of a number of genes linked to cell proliferation and growth. In addition, YB-1 is a multifunctional protein involved in regulating translation, mRNA splicing, and DNA repair, indicating that YB-1 is involved in controlling cell survival. In recent years, several laboratories have demonstrated that YB-1 in response to genotoxic stress like chemotherapy translocates from the cytoplasm to the nucleus. Besides transcriptional activation of the human *MDR1* and *MRP1* genes, nuclear localization of the transcription factor YB-1 is associated with base excision and mismatch repair pathways through binding to several DNA repair proteins. YB-1 is found amongst others highly overexpressed in many malignancies, and current results suggest that YB-1 is important in conferring, e.g., drug resistance in many types of tumor cells. Oncolytic adenoviruses have attracted considerable attention for their use as an innovative class of promising cancer therapeutics. We have developed several oncolytic adenoviral vectors which replicate in the presence of YB-1 in tumor cells. The application of YB-1-dependent oncolytic vectors produces a strong antitumor effect in several carcinoma cell lines, and application in vivo in subcutaneous established tumors led to strong tumor growth inhibition, which could further be enhanced by radiation and chemotherapy. In conclusion, YB-1-dependent adenoviruses are highly effective against different malignancies and deserve further clinical testing.

Reinhold Schäfer (Inst. of Pathology Charité Berlin) explained Oncogenic Ras Signaling: Effector Pathways, Targets, Regulation and Interference. Hundreds of transcriptional targets are up-regulated or down-regulated on transition from the normal to the Ras-transformed state. A minority of targets is equally deregulated in different cell types, indicating that there exist a limited number of common Ras pathway targets. The set of up-regulated genes comprises factors involved in growth control, invasion, and metastasis, while many down-regulated genes encode proteins with anti-proliferative, anti-invasive, and anti-angiogenic properties. The involvement of most of the deregulated genes in triggering or executing various aspects of malignant transformation is unknown. Moreover, the global mechanisms controlling their expression are not yet understood. To unravel the regulatory mechanisms perturbing the transcriptional networks downstream of the Ras signaling cascade and to find out which of the targets are primarily involved in tumorigenesis, we are employing several experimental strategies: We have narrowed down the number of critical targets by correlating the effects of blocking individual effector pathways, using pharmacological inhibitors or RNA interference, with the transcriptional patterns and specific phenotypes. We have selected a few targets exhibiting significant differential expression in Ras-transformed vs normal cells for RNA interference experiments. To study the role of DNA methylation in target gene suppression, we subjected Ras-transformed cells to treatment with demethylating agents and determined the fraction of responding targets. As an example, we have shown that clusterin gene suppression is controlled by promoter methylation and by the MAPK-pathway, suggesting a dynamic relationship between Ras signaling and DNA methylation.

Unraveling the relationships between effector pathways and transcriptional networks will provide important clues for understanding the system biology of cancer, help to

identify novel biomarkers, and eventually, more specific nodes for therapeutic intervention.

Xuetao Cao (Inst. of Immunology & National Key Laboratory of Medical Immunology, SMMU, Shanghai) gave a report on Nuclear Entrapment of MEK1/2 by an Oncogenic Ras-Related GTP-Binding Protein Promotes Tumor Progression. Tumorigenesis is widely recognized as an intricate multistep process that involves malfunction in protooncogenes, tumor suppressor genes, and other key cellular genes implicated in cell proliferation, differentiation, survival, and genome integrity. Malfunction of protooncogenes and signaling components has been reported. Among them, the Ras/Raf/MEK [mitogen-activated protein kinase (MAPK)/ERK kinase]/ERK (extracellular signal-regulated kinase) signaling components have been identified to play important roles in tumorigenesis. MEK1/2 are cytoplasmic proteins containing nuclear export signal (NES) and play crucial roles in determining cell growth and differentiation through activation of extracellular signal-regulated kinase (ERK1/2).

RJLs are a family of Ras-related GTP-binding proteins that are characterized by the N-terminal GTP-binding domain (small GTPase domain) and the C-terminal J domain with unknown functions. The full-length human RJL (*hRJL*) cDNA was identified by us via large-scale sequencing of a human peripheral blood monocyte-derived dendritic cell cDNA library. Here, we report that hRJL, a nucleus-localized representative of RJL family, can mediate the accumulation of active MEK1/2 in the nucleus by masking the NES of MEK1/2, which in turn results in constitutive activation of ERK1/2 and malignant transformation. We show that hRJL is overexpressed in most of the tumor cells and tumor tissues and is oncogenic both in vitro and in vivo. Silencing of hRJL expression or disruption of hRJL-MEK1/2 interaction results in regression of tumor growth and metastasis. Our findings suggest that hRJL-mediated nuclear entrapment of MEK1/2 plays important roles in promotion of autonomous tumor progression, and hRJL is a novel oncogenic therapeutic target.

Guo-Qiang CHEN (Dept. of Pathophysiology, Shanghai Jiao Tong University School of Medicine) reported on Hypoxia and Leukemic Cell Differentiation, Evidence From In Vitro and In Vivo. He stated that cobalt chloride and desferrioxamine-mimicked hypoxia and moderate hypoxia can trigger acute myeloid leukemia (AML) cells to undergo differentiation, and intermittent hypoxia significantly prolongs the survival of the transplanted leukemic mice through inducing growth arrest and differentiation with inhibition of leukemic blast infiltration. Based on these in vitro and in vivo observations, we explore the role of hypoxia-inducible factor 1(HIF-1), a protein in leukemic cell differentiation. Our results show that the conditional HIF-1a induction triggers granulocytic differentiation of myeloid leukemic U937T transformants in which HIF-1a is tightly induced by tetracycline withdrawal. The suppression of HIF-1a expression, but not HIF-1b (an essential partner for transcription activity of HIF-1), by specific short hairpin RNAs (shRNAs) effectively inhibits hypoxia-induced differentiation of U937 cells. Further, the inhibition of hematopoietic differentiation-critical CCAAT/enhancer binding protein-alpha (C/EBPa) significantly eliminates HIF-1a-mediated myeloid leukemic cell differentiation. Furthermore, HIF-1a is also shown to interact physically with and to increase the transcriptional activity of C/EBPa and AML1, two critical factors for granulocytic differentiation. Collectively, this work provides several lines of direct evidence for the role of HIF-1a protein through its non-transcriptional activity in myeloid cell differentiation in which C/EBPa elicits a role as an effector downstream to HIF-1a. These discoveries would shed new insights for understanding mechanisms underlying leukemogenesis and designing the new therapeutic strategy for differentiation induction of AML.

Jing Cheng (Medical Systems Biology Research Center, Tsinghua University School of Medicine Haidian District, Beijing) explained Diagnostic Biochips: From Research to Consumer Market. Biochip-based platforms for research have developed rapidly in the past decade, which includes chips that can generate detailed biological information at four different levels—at the gene, protein, cell, and tissue levels. For example, at the gene level, we have SNP and mutation analysis microarrays, comparative genome hybridization microarrays, methylation detection microarray, and mRNA and miRNA expression profiling microarrays; at the protein level, we have established activated transcription factor profiling chips as well as ChIP-GLAS-based promoter chips; at the cellular level, we have chips for single cell ion flux monitoring and multichannel electrophysiology measurement of cell networks; and finally, for pathological examination, we can provide numerous different tissue microarrays, including normal and diseased tissues.

In recent years, demand for general consumption of these new classes of biochips has been keenly anticipated in consumer areas such as disease diagnostics, biosafety testing, etc. Furthermore, in this presentation, different types of consumer biochip products will be introduced, including DNA microarrays for the detection of the presence of SARS Corona virus RNA, for detection of Gram-positive bacteria and the associated drug resistance genes, for detection of mycobacterium and the drug resistance genes for TB, for detection of food-borne pathogen, and protein microarrays for the diagnosis of autoimmune diseases, and for the detection of veterinary drug residues such as antibiotics. This broad range of applications for biochips foreshadows future development of a wider range of sensitive testing products.

Jian-ren Gu (State Key Lab. of Oncogenes and Related Genes, Shanghai Cancer Institute, Jiao Tong University) discussed Conceptual Concerns on Cancer Biology. The major problems in cancer treatment are:

1. Cancer is not a cluster of cancer cells, but a well-organized tissue.
2. Cancer cells are heterogeneous. Among cancer cell population, the cancer stem cells may be crucial targets for treatment.
3. Dissemination may be an early event in most types of cancer, also a different event from metastasis. The mechanism to evoke the growth of disseminated cancer cells into a metastatic lesion is crucial in development of new therapeutic methods to the control of cancer.
4. Cancer could be a systems disease with local manifestation of abnormal cell growth developed on the basis of deregulation of host-cell homeostasis, including neural, humoral, and immune mechanism.

These conceptual considerations may provide some clues to explore the mechanism of carcinogenesis and cancer progression as well as the design of new therapeutic strategy against cancer.

Yajun Guo (International Joint Cancer Institute, SMMU, Shanghai, yjguo@smmu.edu.cn) explained the topic of "Novel Vaccine Development and Cancer Immunotherapy". We developed several novel bispecific antibodies, which consist of two normal binding sites for targeting antigens and a functioning portion of Flt3L. The constructed bispecific antibodies (SM5.1-Flt3L, Anti-her2-Flt3L, and anti-CD20-Flt3L) efficiently target hepatoma, breast, and lymphoma cancer cells both in vitro and in vivo, leading to accumulation of DCs, NK cells, and lymphocytes in local tumor tissues. Administration of these bispecific monoclonal antibodies can protect bone marrow injury caused by chemotherapeutic drugs and stimulates proliferation and maturation of lymphocytes, APCs, and NKs. Systemic administration of these bispecific antibodies (100 μg/each injection×3) significantly inhibited tumor growth and cured established tumors. These bispecific therapeutic proteins are effective in elicitation of long-lasting antitumor immunity. The tumor-specific immunity can be adoptively transferred into naïve animals successfully by transfusion of $CD3^{+}CD8^{+}$ T cells from the treated mice. The results suggest that fusion of Flt3L with therapeutic antibodies can create novel immunotherapeutic proteins, which are more effective in induction of antitumor immunity, and may provide a novel strategy for treatment of cancers.

Yongfeng Shang (Peking University) talked about Gene Regulation by Nuclear Receptors. Steroid receptor coactivators (SRCs) exert profound effects on animal development and physiology. These coactivators are nuclear proteins and transcription co-regulators that function to facilitate the transcription initiation mediated by nuclear receptors as well as by other well-known transcription factors. However, how these co-regulators are functionally regulated is poorly understood. During genome-wide screening for SRC-interacting proteins, we identified a novel ankyrin-repeat-containing protein, *S*RC-*i*nteracting *p*rotein (SIP), which interacts with SRC coactivators in the cytoplasm. We demonstrated that extracellular stimuli, such as the addition of estrogen, induced phosphorylation of SIP in its PEST (proline, glutamate, serine, and threonine-rich) domain by casein kinase II. The phosphorylation of SIP resulted in dissociation of SRC proteins from SIP in the cytoplasm and led to subsequent nuclear translocation of SRC proteins and gene coactivation. Both gain-of-function and loss-of-function experiments indicate that SIP functions to sequester SRC coactivators in the cytoplasm and buffer the availability of these coactivators, thus, providing a mechanism for the regulation of the transcription regulators.

Hongyang Wang (Inst. International Cooperation Laboratory on Signal Transduction Eastern Hepatobiliary Surgery Institute/Hospital, Shanghai SMMU) Negative Regulation of Hepatocellular Carcinoma Cell Growth by Signal Regulatory Protein. 1SIRPα1 is a member of the signal regulatory protein (SIRP) family that undergoes tyrosine phosphorylation and binds SHP-2 tyrosine phosphatase in response to various mitogens. The expression levels of SIRPα1 were decreased in human hepatocellular carcinoma (HCC) tissues, as compared with the matched normal tissues. Exogenous expression of wild-type SIRPα1, but not of a mutant SIRPα1 lacking the tyrosine phosphorylation sites, in SIRPα1 negative Huh7 human HCC cells resulted in suppression of tumor cell growth both in vitro and in vivo. Treatment of Huh7 transfectants with EGF or HGF induced tyrosine phosphorylation of SIRPα1 and its association with SHP-2, which were accompanied by reduced ERK1 activation. Expression of SIRPα1 significantly suppressed activation of NF-κB and also sensitized Huh7 cells to TNFα or cisplatin-induced cell death. In addition, SIRPα1-transfected Huh7 cells dis played reduced cell migration and cell spreading in a fashion that was dependent on SIRPα1/SHP-2 complex formation. In conclusion, these results suggest a negative regulatory effect of SIRPα1 on hepatocarcinogenesis through, at least in part, inhibition of ERK and NF-κB pathway. The heightened sensitivity of cells restoring SIRPα1 function could be exploited in the development of therapeutic regimens which may potentiate the antineoplastic effect of conventional cytokines or chemotherapeutic agents.

Qimin Zhan (Cancer Institute Chinese Academy of Medical Sciences) explained the role of Bacp, a BRCA1-Regulated Centrosomal Protein, in the Control of Genomic

Stability. The essence of successful mitosis in mammalian cells is the generation of two genetically identical daughter cells. The successful mitosis requires the assembly of a strictly bipolar mitotic apparatus that will ensure that chromosomes equally distribute to the daughter cells. This process is controlled by the centrosomes that are required for spindle formation and function. Centrosome stability is required for the successful mitosis in mammalian cells. Amplification of centrosome leads to chromosomal mis-segregation and generation of aneuploidy, which are closely associated with cell transformation and tumorigenesis. The machinery that controls centrosome stability involves multiple important cellular proteins, including p53, BRCA1, Gadd45, p21, and Cdk2/cyclin E. The precise coordination among those regulators maintains centrosome duplication and stability. However, there are currently limited insights into mechanism(s) for this critical biological event.

Breast cancer susceptibility gene BRCA1 is implicated in the control of mitotic machinery, although there is little insight into underlying mechanism(s). Here, we show that BRCA1 physically interacts and co-localizes with Bacp (*B*RCA1 *a*ssociated *c*entrosomal *p*rotein). Interestingly, Bacp centrosomal localization likely depends on normal cellular BRCA1 function, as cells containing BRCA1 mutations or silenced for endogenous BRCA1 reveal disrupted Bacp co-localization to centrosomes. Suppression of endogenous Bacp results in aberrant spindle formation, failure of chromosomal segregation and cytokinesis, and aneuploidy. Bacp is overexpressed in human breast and lung carcinomas, and its deregulation is in part associated with *BACP* amplification. Bacp exhibits strong oncogenic property and induces NIH3T3 fibroblast transformation. Importantly, Bacp transgenic mice mimic the phenotypes of disrupted BRCA1, including centrosome amplification and spontaneous tumorigenesis. Thus, Bacp may cooperatively act together with BRCA1 in mitotic machinery, and abnormalities of Bacp lead to genomic instability and tumorigenesis.

Jingde Zhu (Cancer Epigenetics and Gene Therapy Program, Shanghai Cancer Institute) Cancer Epigenetics (-omics) from DNA Methylation Perspectives in Liver Cancer as a Paradigm Cancer is a complex disease of broad genetic and epigenetic defects. The epigenetic circuit dictates the inheritable transcription profile and therefore the phenotype, better understanding of which would revolutionize the current anti-cancer practice. Epigenetic makeup comprises DNA methylation, histone modification, microRNAs, and chromatin remodeling, which act together to shape the chromatin structure of genome to meet the functional requirements. DNA methylation, an enzymatic process to add a methyl group at the fifth carbon of cytosine within the palindromic dinucleotide 5′ -CpG-3′ sequence is the best-studied pigenetic mechanism. Cancer-associated aberration of DNA methylation goes two opposite directions: global hypomethylation and local hypermethylation, that, in turn, dictate the transcription profile of both repetitive sequences and individual genes, and therefore, the phenotypic profiles unique to cancer states HCC present a major health threat to the people in China, owing to their high incidence and aggressive clinical nature. We are currently carrying out comprehensively profiling the disease-associated CpG methylation pattern at the multiple gene level (1) and at the global level (2) to gain the new mechanistic insights, establish a DNA methylation-based staging and classification system and find effective biomarkers for HCC. To demonstrate the great potential of DNA methylation in cancer detection, I will present the latest results in DNA methylation profiling in urine sediments for sensitive/specific detection of bladder cancer.

Neuroendocrine tumors (2007): Oberndorfer's legacy

Günter Klöppel

Published online: 8 August 2007

Who among us is not familiar with the difficulties that frequently occur in the diagnosis and therapy of neuroendocrine tumors of the gastrointestinal tract, the pancreas, and the lung? The main reason for the problems is that the tumors are quite heterogeneous; despite their relatively uniform histological appearance; their growth is slow but hard to influence, and because of their hormone activity, they often show special clinical features and biology. Moreover, they are so rare that our knowledge of them is relatively limited compared with other neoplasms.

Siegfried Oberndorfer was the first to give a special name to the neuroendocrine tumors. One hundred years ago, he coined the term "carcinoid" [1], and with this contribution, he set the path for the recognition and elucidation of the neuroendocrine tumors. This year's congress of the European Society for Pathology in Istanbul is an excellent occasion to celebrate the 100th anniversary of the term carcinoid and to remember Siegfried Oberndorfer, who worked in Munich, Germany and in his later years in Istanbul, Turkey (see Klöppel et al., this issue).

This supplement to *Virchows Archiv* attempts to provide up-to-date information on the most important neuroendocrine tumors. It contains contributions dealing with the pathology and biology of gastroenteropancreatic neuroendocrine tumors (GEP-NETs), the pathology and genetic background of hereditary GEP-NETs, the receptor status of these tumors, and their molecular profile. There is also a review of the second most frequent group of neuroendocrine tumors, the pulmonary neoplasms of neuroendocrine origin. Then follows a review of goblet cell carcinomas and mixed exocrine–endocrine neoplasms, and finally the rapidly advancing treatment modalities for GEP-NETs are discussed.

The authors of the various reviews published in this issue belong to the NET-WORKs group, which is a working group of the European Neuroendocrine Tumor Society (ENETS). This group recently provided guidelines for the staging and grading of GEP-NETs [2, 3], and these guidelines are also discussed in this issue.

REVIEW AND PERSPECTIVE

Siegfried Oberndorfer: a tribute to his work and life between Munich, Kiel, Geneva, and Istanbul

Günter Klöppel · Katherine Dege · Wolfgang Remmele · Yersu Kapran · Sitki Tuzlali · Irvin M. Modlin

Received: 22 June 2007 / Accepted: 22 June 2007 / Published online: 8 August 2007

Abstract In 1907 Siegfried Oberndorfer published his observations and interpretations on tumorlets ("Geschwulstchen") in the small intestine, which he called carcinoids ("karzinoide Tumoren"). This article pursues the questions why this discovery was so unique and what role it played in the later life of Siegfried Oberndorfer.

Keywords Oberndorfer · Carcinoid · Endocrine tumor

One hundred years ago, Siegfried Oberndorfer (Fig. 1) proposed the term "carcinoid", which he also used to call tumorlets ("Geschwülstchen") in the small intestine (Fig. 2). The name carcinoid was intended to express the distinctions between these tumors and true carcinomas, but also their similarity to carcinomas. Since then the carcinoids have been the topic of numerous studies, which revealed their fascinating nature as endocrine neoplasms. Siegfried Oberndorfer, whose contributions set the path for the recognition of the neuroendocrine tumors and stimulated the elucidation of this novel tumor type, lived in Germany until 1933, when he, being of Jewish origin, was forced by the Nazi regime to emigrate to Turkey. There, he remained as full professor and director of the Department of Pathology of the University of Istanbul until his death in 1944 (Fig. 3). The life of Siegfried Oberndorfer and the evolution of the concept of carcinoid tumors have been the focus of recent publications by one of us [7, 8] and were also extensively reviewed by Dr. Joachim Thomas Katz [2]. In this study, we focus on the questions why Oberndorfer became a pioneer in the field of carcinoid tumor biology, which of his original observations stood the test of time and how he followed the evolving concept of carcinoid tumors in his later years.

What was so special about Oberndorfer's observations?

Oberndorfer's article in which he described seven cases of carcinoid immediately received recognition, although in retrospect it is clear that he was not the first to describe carcinoids. Reports of similar tumors had been published before 1907 (cf. [7, 8]), in some of which the tumors can be clearly identified on the basis of the illustrations [3, 4, 14]. However, the authors of these case reports either did not give any interpretation of the described tumor [3] or regarded it as a primary carcinoma of the ileum [4, 14]. Oberndorfer's conclusion that the described tumors in the ileum form a special group of neoplasms because of their similarity and also dissimilarity to usual carcinomas and their special growth features were therefore novel. Moreover, and most importantly, he coined a term to unmistakably designate the new tumor group.

Fig. 1 Siegfried Oberndorfer and his daughter Helena ("Leni") in Munich in 1911. At this time, when the nature of the carcinoids was heavily debated among the leading pathologists in Germany, Oberndorfer was appointed Professor at the Medical Faculty of the University of Munich at the age of 35

What qualified Siegfried Oberndorfer for his new observations?

The history of his life and particularly his so far unpublished autobiography characterize Siegfried Oberndorfer by four features: He had a general and deep interest in life and nature. He was diligent and highly disciplined. He had an analytical mind and he was an excellent writer.

He satisfied his interest in life and nature through excursions, tours and long journeys, and of course by studying medicine. He was not only a pathologist, but he worked temporarily as a general practitioner, as a ship's doctor, and also as a military doctor. He was interested in all kinds of diseases from both the clinical and the pathological view. The subjects he studied were therefore also manifold. Apart from the carcinoids, he contributed in numerous articles to the study of the pathogenesis of appendicitis, tuberculosis, and many different tumors. But it was not only this wide spanned interest; it was also his will to record what he observed and what he encountered. Thus, he wrote reports, articles, and descriptions of almost everything he experienced and studied during his life. Everything he saw and studied he also analyzed with regard to its nature, causes, and significance. In the last two years of his life, he wrote an autobiography, in which he not only gave a report of his life but also commented and reflected on what he had experienced and what he had done.

What helped him to make his decisive observations?

He started medical school in 1895 in Munich and spent one term in Kiel in northern Germany, which for a Bavarian was a

foreign country. Though only a student, the professor and head of the department of pathology in Kiel, Arnold Ludwig Heller (1840–1913), recognized his great interest in morbid anatomy and taught him his meticulous and "holoptic" autopsy technique which allowed the assessment of the organs in the context of their functional relationship to the surrounding organs. He quickly adopted Heller's technique and also his cleanliness, for which he himself became famous in later years when he was director of a pathology department. It is very likely that he profited very much in his professional and scientific life from his capacity to perform accurate postmortem examinations. At least his first observations of carcinoids, which he made in Geneva [9], are probably because of the fact that he was in the possession of a technique that allowed him to recognize even pea-sized tumorlets in the ileum, which could be easily overlooked.

Since he was never merely a morphologist who focused only on the appearance of lesions, he also considered the clinical history of the patients in whom he detected the carcinoids. As none of his patients had any symptoms related to the tumorlets in the ileum, he regarded these lesions as extremely slowly growing and apparently harmless in nature.

What were Oberndorfer's conclusions in 1907?

Oberndorfer observed the first two cases of carcinoids in Geneva (1900–1901) while working as an assistant to Professor Friedrich Wilhelm Zahn (1845–1904). He reported on these two tumors in the Beiträge zur pathologischen Anatomie und allgemeinen Pathologie in 1901. In Munich, where he started to work as assistant to Professor Otto Bollinger (1843–1909) in 1904, he added four other carcinoid cases and presented his results at the annual meeting of the Deutsche Gesellschaft für Pathologie in Dresden in 1907 [10] (Fig. 4). His lecture was heavily debated and its essence was published in December 1907 in the Frankfurter Zeitschrift für Pathologie. In this report, he summarized his observations and interpretations of the

Karzinoide Tumoren des Dünndarms.

Von

Siegfried Oberndorfer.

(Mit 2 Abbildungen auf Tafel XI.)

Im Laufe der letzten Jahre fand ich verschiedene Male kleine Tumoren im Dünndarm, zum Teil multipel, zum Teil isoliert, von kleiner Stecknadelkopf- bis etwas über Hanfkorngrösse, die grösstenteils mikroskopisch das Bild kleiner Karzinome boten, doch aber so viel Eigenartiges aufweisen, dass es der Mühe wert erscheint, sie einmal im Zusammenhang zu besprechen. Zwei der Fälle habe ich bereits früher veröffentlicht, es handelte sich um multiple Geschwulstbildung in beiden Fällen; in dem einen bei einer 48jährigen, an Knochentuberkulose zu-

(p. 426)

lesions in five statements. The main characteristics of these tumorlets are:

1. They are usually small and often multiple.
2. Their cells form undifferentiated formations, at most with slight indications of glands.
3. They are well defined and show no tendency to penetrate infiltratively into the surroundings.
4. They do not metastasize.
5. They appear to grow extremely slowly, do not reach any great size, and are thus apparently harmless in nature.

The first three statements are still valid, except for the descriptive term "undifferentiated formations", which from today's vantage point does not reflect the differentiation of this particular tumor tissue. The last two statements, however, did not stand the test of time. As more and more carcinoids with lymph node and liver metastases were observed, Oberndorfer already admitted that some carcinoids may also be malignant. In his contribution to Henke and Lubarsch's textbook on special pathological anatomy and histology in 1929 [12], where he discussed his collection of 36 carcinoids of the ileum and appendix, he therefore distinguished carcinoids with benign behavior from "malignant carcinoids".

The carcinoids' endocrine nature was established by Masson [1, 5, 6], who suggested on the basis of his argentaffin staining results that the Kultchitzky cells in the crypts of Lieberkühn and the cells of the carcinoids have an endocrine function. Siegfried Oberndorfer himself abstained from speculating about the histogenesis of the carcinoids. Later, however, he discussed intensively, but also skeptically, the proposed neural-endocrine pathway that Masson proposed for the development of carcinoids in the appendix and their origin from the so-called enterochromaffin cells of the intestinal mucosa [11].

Why did he not return to the carcinoids after 1933?

Siegfried Oberndorfer was appointed full professor and director of the Institute of General and Experimental Pathology at the University of Istanbul shortly after he was forced to retire as director of the Department of Pathology at the München Schwabing Hospital and Associate Professor at the Medical Faculty of the University of Munich. Together with his colleague, Professor Philipp Schwartz (1894–1978) [13], who was also driven out of Germany because of his Jewish background and headed the Institute of Pathological Anatomy in Istanbul, he contributed very much to the development of pathology in Turkey in the fields of diagnostic pathology, cancer research, and training in pathology. Later (1938), he founded and headed the Turkish Institute of Cancer Research (Fig. 5). Conceivably, these

Fig. 5 Siegfried Oberndorfer in Istanbul in 1936

duties and his efforts to live in a foreign country and master its language consumed a great deal of his time. However, with his collaborators from Turkey (Drs. Uveis Maskar, Osman Saka, and Sati Eser) and from Germany (Dr. Peter Ladewig) he again produced approximately 100 contributions to many aspects of the pathology of neoplastic and nonneoplastic diseases and, finally, published textbooks in Turkish on general pathology (1937) and the histological diagnosis of some selected neoplasms (1941). An explanation for the fact that he never returned to the carcinoids may be that in his department he dealt only with surgical specimens, implying that at this time he had very little access to material to increase his experience with these tumors. But his interest in the carcinoids remained. Towards the end of his life he noted in his autobiography:

> "*Meine wesentlichen Arbeiten, so besonders die Wesentlichste, die fortleben wird, die Entdeckung der Bedeutung der "Carcinoide", habe ich nur in ganz kurzen Seiten veroeffentlicht; all das andere, was andere noch hinzugefuegt haben, habe ich zum grossen Teil auch gewusst, aber nicht verwertet. Zum Teil hinderte mich auch eine gewisse Scheu vor der Publizierung, der Verwertung der Arbeit in den grossen wissenschaftlichen Zeitungsschriften, so besonders in Virchows Archiv, eine gewisse Scheu vor dem Urteil der Autoritaeten, das ich retrospektiv nicht zu fuerchten gehabt haette. Aber "tempi passati"; im Ganzen war mein Leben doch nicht ganz sinnlos und ohne Ergebnisse, aber es haette wissenschaftlich noch glaenzender sein koennen*." (from Oberndorfer's unpublished autobiography, 1942–1943).

"My important works, especially the most significant work, which will survive, is the recognition of the significance of the carcinoids. It fills only a few pages. All the rest, which others added to it, I also knew, but made no use of it. In part, a certain hesitancy prevented me from publishing, from utilizing the work in the major scientific journals, particularly in Virchows Archiv, a certain dread of the verdict of the authorities that, retrospectively, I need not have feared. But "tempi passati", on the whole my life was not entirely futile and without results; but scientifically it could have been even more distinguished."

Acknowledgments We would like to thank Dr. Walter L. Castrillón-Oberndorfer, Siegfried Oberndorfer's grandson, for providing us with photographs and allowing us access to personal family records, in particular the unpublished autobiography. We are also grateful to Prof. K. Wurster, Munich, for providing us with information.

Conflict of interest statement We declare that we have no conflict of interest.

REVIEW AND PERSPECTIVE

Site-specific biology and pathology of gastroenteropancreatic neuroendocrine tumors

Günter Klöppel · Guido Rindi · Martin Anlauf · Aurel Perren · Paul Komminoth

Received: 20 June 2007 / Accepted: 20 June 2007 / Published online: 8 August 2007

Abstract The gastroenteropancreatic neuroendocrine tumors (GEP-NETs) are composed of cells with a neuroendocrine phenotype. Well-differentiated tumors, well-differentiated carcinomas, poorly differentiated carcinomas, functioning tumors (with a hormonal syndrome), and nonfunctioning tumors are identified. To predict their clinical behavior, these neuroendocrine tumors are classified on the basis of their clinicopathological features, including size, local invasion, angioinvasion, proliferative activity, histological differentiation, and metastases, into neoplasms with benign, uncertain, low-grade malignant and high-grade malignant behavior. In addition, a tumor/nodes/metastases classification and a grading system are presented. In the light of these criteria, the various GEP-NET entities are reviewed.

Introduction

The neuroendocrine tumors (NETs) of the gastrointestinal tract and the pancreas express antigens that are also common in nerve elements. These antigens have been referred to as neuroendocrine markers, and their demonstration in normal cells and neoplasms has led to the terms neuroendocrine cell system and neuroendocrine neoplasms. Markers of the neuroendocrine phenotype such as synaptophysin, chromogranins A, B, and C [89], HISL-19, neuron-specific enolase (NSE), the proprotein convertases PC2 and PC3, the lymphoreticular epitope Leu-7, and the neural cell adhesion molecule (or CD56) reveal the neuroendocrine differentiation of gastroenteropancreatic NETs (GEP-NETs), independent of hormone production [88].

This review discusses the various GEP-NET entities that are observed in the foregut, midgut, and hindgut regions. The GEP-NETs associated with hereditary diseases and the molecular changes in GEP-NETs are dealt with in separate papers in this issue [5, 117].

Classification

In the gastrointestinal tract and pancreas, 15 neuroendocrine cell types producing different hormones but all expressing the general neuroendocrine marker synaptophysin can be distinguished [150]. They are the source of GEP-NETs. Traditionally, they are separated into benign or malignant neoplasms. In this paper, however, we follow the concept that all GEP-NETs are potentially malignant but differ in their metastasizing capacity (i.e., their biological behavior), depending on a number of features and criteria (see below).

The functional diversity of the neuroendocrine cell types and their nonrandom distribution in the gut and pancreas are probably the reason for the complexity of the tumors derived from them. Classifying these tumors is therefore extremely difficult. In 1963, Williams and Sandler [173] classified the GEP-NETs into foregut (stomach, duodenum, upper jejunum, and pancreas), midgut (lower jejunum, ileum, appendix, and cecum), and hindgut (colon and rectum) tumors, with considerable clinicopathological differences between the three groups. However, in the case of the foregut tumors, the usefulness of such a classification in practical diagnostic work is limited by its failure to characterize individual tumor entities with well-defined histological, hormonal, and/or clinicopathological profiles. The World Health Organization (WHO) 2000 classification, based on earlier work [28], therefore follows a different approach. In a first step, it distinguishes between pure endocrine tumors and mixed endocrine–exocrine tumors (for mixed tumors, see article by Volante et al. (in this issue and [167]). In a second step, a uniform scheme of classification is applied to all pure GEP-NETs, identifying three tumor categories, irrespective of their site of origin:

(1) Well-differentiated endocrine tumors with benign (a) or uncertain behavior (b) at the time of diagnosis
(2) Well-differentiated endocrine tumors with low grade malignant behavior
(3) Poorly differentiated endocrine carcinomas with high-grade malignant behavior

In a third step, the well-differentiated, slowly growing NETs and carcinomas of the gastrointestinal tract and the pancreas, those that are also called carcinoids [110] and islet cell tumors, respectively, and which comprise a number of well defined entities (e.g., insulinomas, gastrinomas, and others), are distinguished on the basis of their localization as well as their morphological and functional features. Poorly differentiated NETs that are composed of cells displaying high mitotic activity and few secretory granules form a separate group, as they are not difficult to recognize as invariably high-grade malignancies.

Undisputable criteria that predict the biological behavior of well-differentiated GEP-NETs are gross tumor infiltration of adjacent organs and/or metastases. Adverse prognostic factors include tumor size, angioinvasion, mitotic activity, and an elevated Ki-67/MiB-1 proliferative index (higher than 2%) [29, 58]. Tables 1 and 2, based on the WHO criteria, provide checklists that allow an appropriate classification of an individual GEP-NET.

As there is an increased demand for a standard in the stratification and treatment of patients with GEP-NETs, the European Neuroendocrine Tumour Society recently developed guidelines that were supplemented by a proposal for tumor/nodes/metastases (TNM) classification [127, 128]. Apart from theTNM staging proposal, a working formulation for the grading of GEP-NETs based on mitotic count and Ki-67 index has been suggested. Both the staging proposal and the grading system still need to be validated.

Epidemiology

Incidence data on GEP-NETs are difficult to obtain because of the rarity of these neoplasms, their long clinical courses, their incomplete recognition, and their classification, which was for a long time rather inaccurate. The Surveillance, Epidemiology, and End Results (SEER) data on carcinoids, which are usually cited when the incidence of GEP-NETs are discussed [99], are probably inexact for gastric and duodenal NETs, as the general availability of endoscopy

Table 1 Criteria for assessing the prognosis of neuroendocrine tumors of the gastrointestinal tract

Biological behavior	Metastases	Invasion of muscularis propria[a]	Histological differentiation	Tumor size (cm)	Angioinvasion	Ki-67 index (%)	Hormonal syndrome
Benign	−	−	Well differentiated	≤1[a]	−	<2	−[a]

[a] Invasion of adjacent organs (e.g., duodenum, stomach)
[b] Insulinomas
[c] Insulinomas and other functioning tumours (e.g., glucagonomas)

has led to a considerable increase in the rates of these NETs that is not yet reflected in the SEER data. For these reasons, the following incidence figures for the NETs of the gut are interpreted with caution. The incidence of all NETs of the gut has been estimated according to a recent Swedish study to be 2.0/100,000 for men and 2.4/100,000 for women [59].

NETs of the esophagus are very rare and represent only 0.05% of all gastrointestinal NETs or approximately 1% of all esophageal cancers [34, 100]. Most patients are men, who are mainly in the sixth to seventh decade [87].

NETs of the stomach were thought to account for 2–4% of all gastrointestinal NETs [99, 100]. However, as the incidence of gastric NETs has not yet really been determined after the increased application of endoscopy, it is quite possible that gastric NETs may lead the list of the most frequent gastrointestinal NETs and account for 11–41% [75]. In Japan, they represent 30% of all gastrointestinal carcinoids.

Duodenal NETs account for approximately 2% of all gastrointestinal NETs in the old series [53, 100]. In more recent series, however, duodenal and jejunal NETs amounted to 22% of all gastrointestinal NETs [33]. The tumors occur slightly more frequently in men (male/female ratio=1.5:1) and are usually seen in the fifth and sixth decade [33].

Ileal NETs account for approximately 25% of all gastrointestinal NETs [33]. Men and women are affected equally. Their age ranges from the third to the tenth decade but has a peak in the sixth decade.

Appendiceal NETs account for approximately 20% of all NETs in the gastrointestinal tract [92, 100]. They are the most frequent tumors in the appendix. In contrast to all other NETs of the gastrointestinal tract, they most commonly present in the second to third decade and affect women more frequently than men [95, 110]. They may also occur in children [9].

While colon NETs are rare, NETs of the rectum account for 20% of the gastrointestinal NETs [32]. Their sex distribution is equal. An increase in incidence in colonic and rectal NETs has been observed in recent years [59, 85, 92, 99, 146]. In western countries, NETs of the colon are primarily diagnosed in male patients during the seventh decade of life and rectal lesions in the sixth decade [59]. A similar trend is observed in women, although at a relatively younger age, in the fifth decade in the colon and the sixth in the rectum [59]. Poorly differentiated neuroendocrine carcinomas develop predominantly in male patients [20].

The prevalence rate of PETs has been estimated at less than 1 in 100,000 [101]. Their incidence is not known, but it is probably substantially lower because of the generally rather favorable prognosis of PETs. For insulinomas alone, an incidence of approximately four tumors per 1 million patient-years has been calculated [141]. PETs appear at any age but occur preferentially between 30 and 60 years. There is no significant gender selection but a slight female preponderance of 55% to 45%.

PETs account for 1–2% of all pancreatic neoplasms [151]. Syndromic or functioning PETs (i.e., PETs that cause hormonal syndromes) make up 60%, with insulinomas being the most frequent type (up to 70%), followed by gastrinomas [22, 73, 76, 79, 135].

Insulinomas have been diagnosed in all age groups. The highest incidence is found between 40 and 60 years. Women seem to be slightly more frequently affected than men (ratio 6:4) [49, 51, 52, 84, 140, 141, 165].

Gastrinomas account for about 20% of endocrine pancreatic tumors [56, 151]. Zollinger–Ellison syndrome (ZES) is more common in men than in women, with a ratio of 3:2, and the mean age at diagnosis is 38 years [13, 27, 69, 126, 154].

Glucagonomas represent about 5% of all clinically relevant pancreatic endocrine tumors and 8% of functioning tumors [151]. The patients most often present between the ages of 40 and 70 years and women are slightly more often affected [136].

VIPomas constitute 3–8% of all pancreatic endocrine tumors, and women are more often (70%) affected than men.

Nonfunctioning PETs may occur at any age; however, they are rare in childhood [143]. Clinically relevant

nonfunctioning PETs are rare, with a prevalence of 0.2–2 per million inhabitants [58]. Small nonfunctioning PETs including microadenomas are much more frequent, with a reported prevalence in autopsy studies from 0.4 to 1.5% (largely depending upon the amount of pancreatic tissue examined) [54, 74]. There is no gender predilection [62].

Esophagus

Most NETs of the esophagus are poorly differentiated neuroendocrine carcinomas and mixed endocrine–exocrine carcinomas, usually of large size (from 4 to 10 cm in diameter) and located in the lower third of the esophagus [34]. They present as fungating or ulcerated masses deeply infiltrating into the esophageal wall and are associated with early spread to the regional lymph nodes or infiltration of adjacent organs. In contrast, most well-differentiated NETs/neuroendocrine carcinomas are less than 4 cm in diameter and present as polypoid lesions. Only few of them were found to be associated with lymph node metastases [61, 115].

Poorly differentiated neuroendocrine carcinomas of the esophagus are often of the large cell type and only positive for synaptophysin (Fig. 1). Well-differentiated NETs/carcinomas show a solid or trabecular–glandular growth pattern and are strongly immunoreactive for synaptophysin and chromogranin A, but mostly negative for the hormones expressed in the gastrointestinal tract. No established grading and staging scheme exists for these NETs.

The majority of well-differentiated esophageal NETs/carcinomas were found in association with Barrett's esophagus and adenocarcinomas. We saw two well-differentiated NETs of the esophagus. Both were incidental findings and associated with heterotopic oxyntic mucosa. They stained strongly positive for the vesicular monoamine transporter 2 (VMAT2) suggesting an origin from the enterochromaffin-like (ECL) cells within heterotopic oxyntic mucosa.

The initial symptoms of these tumors are unspecific because they are functionally silent. Inappropriate antidiuretic hormone syndrome, hypercalcemia, or ectopic production of vasoactive intestinal polypeptide (VIP) have been reported in only single poorly differentiated neuroendocrine carcinomas [34, 66, 169]. Well-differentiated NETs of the esophagus are rarely associated with lymph node metastases and thus have an excellent prognosis. Eleven patients suffering from primary esophageal well-differentiated NETs/neuroendocrine carcinomas for which follow-up was available were all alive and disease-free at 1–23 years after surgical excision (mean 5.5 years). The overall survival of patients with poorly differentiated carcinomas is usually less than 6 months [68, 83]. Mixed endocrine–exocrine carcinomas of the esophagus show a prognosis similar to that of adenocarcinomas, depending on their histological differentiation and tumor stage [36]. Neither associated diseases nor inherited syndromes have been reported for NETs/neuroendocrine carcinomas of the esophagus.

Stomach

There are three distinct types of NETs in the stomach [129], and if the poorly differentiated NET is added, four types of NETs can be distinguished [35, 75]. Type 1 comprises approximately 70–80% of all cases, followed by types 3, 2, and 4 [129]. Recently, a proposal for a TNM staging classification and a grading system for tumors of the stomach was published (Tables 3, 4, and 5).

Type 1 NETs of the stomach present as multiple small tumors (0.3–1 cm; Fig. 2a). Histologically, they are well differentiated (proliferation rate <2%), show a solid pattern, and are composed of intensely synaptophysin and

N1	Regional lymph node metastasis
M—distant metastases	
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1	Distant metastasis

chromogranin A positive ECL cells. These cells, which produce histamin, are specifically recognized by the marker VMAT2 [45, 130] (Fig. 2b). In addition to the tumors, there is always ECL cell hyperplasia in the oxyntic mucosa. The tumors are not associated with any hormonal syndrome but are always found on a background of chronic atrophic gastritis of the oxyntic mucosa of the autoimmune type. This disease occurs mainly in women, aged between 50 and 60 (70–80% of the patients) and leads to the disappearance of the specific glands of the oxyntic mucosa harboring the parietal cells. The consequences of the loss of parietal cells are the insufficient production of intrinsic factor, which triggers pernicious anemia via the decreased resorption of vitamin B12, and deficient production of gastric acid, which stimulates the antral G cells to persistent hypersecretion of gastrin. It is thought that hypergastrinemia promotes the growth of the ECL cells of the oxyntic mucosa so that diffusion to micronodular ECL cell hyperplasia develops and, after a latent period of many years, multiple ECL tumors [14]. The observation that the tumors can also occur in only partially atrophic gastritis and the detection of growth factors such as tumor growth

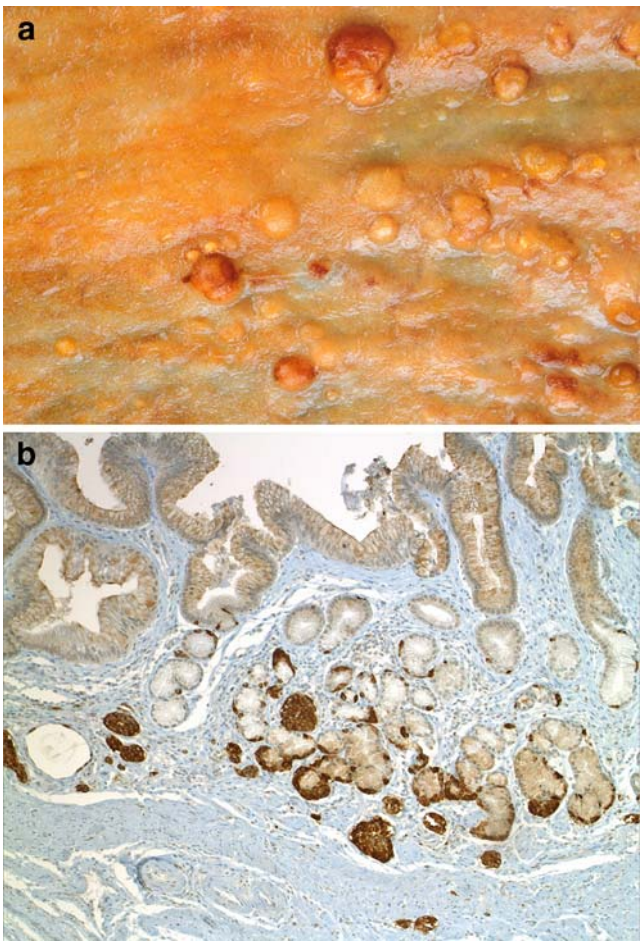

Fig. 2 Well-differentiated neuroendocrine tumors of the stomach associated with chronic atrophic gastritis of the oxyntic mucosa (type 1 gastric NET): **a** multiple small polypoid tumors in the corpus region of the stomach. **b** VMAT2-positive ECL cell hyperplasia in the oxyntic mucosa with microtumors

factor alpha, basic fibroblast growth factor, and B cell leukemia/lymphoma 2 are indications that hypergastrinemia alone probably does not cause these tumors to develop [14, 17]. The prognosis of these tumors is good because they are usually so small that they can be removed endoscopically. Regional lymph node metastases seem to occur only in those very rare cases in which the tumors are larger than 2 cm in size and infiltrate the muscularis propria [124].

Type 2 gastric NETs occur in association with multiple endocrine neoplasia type 1 (MEN1), a hereditary, autosomal dominant disorder, in the course of which a ZES has developed. The genetic changes associated with MEN1 are probably needed for tumor development [42] because so far no such tumors have been found in patients with ZES but without MEN1. As in type 1 NETs, multiple ECL cell NETs are found in the oxyntic mucosa, which, however, is not atrophic but hypertrophic. Men and women with a mean age of 50 years are equally affected [35]. Lymph node metastases may develop in rare cases in which the tumors exceed a size of 1–2 cm [149].

Type 3 gastric NETs are sporadic (unassociated with MEN1) solitary tumors that develop unrelated to chronic atrophic gastritis and occur throughout the stomach (Fig. 3). In one third of the cases, the tumor is already larger than 2 cm at the time of diagnosis. Histologically, they are well differentiated, show a trabecular to solid pattern, and often have a proliferation rate exceeding 2–5%. They consist in most cases of ECL cells. Tumors with EC (serotonin) cells or gastrin cells, by contrast, are extremely rare [75]. They show a predilection for the male sex and occur at a mean age of 55 years [35]. If the tumor is larger than 2 cm, has invaded the muscular layer, and/or shows angioinvasion, metastases are very likely to be present [35]. In 71% of such cases that were surgically removed, lymph node metastases were found [35]. In rare cases, type 3 tumors may be associated with a so-called atypical carcinoid syndrome, characterized by cutaneous flushing in the absence of diarrhea, usually coupled with liver metastases and production of histamine and 5-hydroxytryptophan [35].

Poorly differentiated neuroendocrine carcinomas of the stomach ("type 4 gastric NETs") are rare. Histologically, they often show no special arrangement of the cells, which are medium sized, with a chromatin-rich nucleus and sparse cytoplasm. Immunohistochemically, they are positive for synaptophysin and to some extent also for chromogranin A. Hormones cannot be demonstrated. These tumors are more common in men than in women, aged between 60 to 70 years. They present as a large ulcerated lump with symptoms similar to those of adenocarcinomas, including gastric hemorrhage and obstruction. Hormonal symptoms are absent, and there is no relationship to chronic atrophic gastritis but, in exceptional cases, to MEN1 [16]. At the time of diagnosis, most of the tumors are already in an advanced stage (tumor diameter more than 4 cm) and show extensive metastasis. Their prognosis is poor, with three quarters of the patients dying within 1 year of diagnosis because of extensive metastatic disease [16]. In addition, poorly differentiated large cell neuroendocrine carcinomas or mixed endocrine–exocrine carcinomas (endocrine differentiation in greater than 30% of the tumor) may occur but are extremely rare. Mixed exocrine–endocrine carcinomas should generally be classified as adenocarcinomas [35].

Recently, multiple, up to 1.3 cm large ECL cell tumors were found in a background of ECL cell hyperplasia and parietal cell hyperplasia in patients with hypergastrinemia but without ZES [1, 112]. It was suggested that the development of these NETs is associated with an intrinsic acid secretion abnormality of the parietal cells.

Duodenum and upper jejunum

On the basis of their clinical, morphological, hormonal, and genetic features, several types have to be distinguished: gastrin-producing NETs with ZES (i.e., gastrinomas), gastrin-producing NETs without ZES, somatostatin-producing tumors with or without neurofibromatosis type 1 (NF1), serotonin- or calcitonin-producing NETs, poorly differentiated neuroendocrine carcinomas, and gangliocytic paragangliomas [14, 25, 28, 152]. Their relative frequency is shown in Fig. 4. Tables 6 and 7 show the recently proposed TNM classification for these NETs.

Gastrin-producing and gastrin-secreting NETs causing a ZES are called gastrinomas. Twenty-five to 33% occur in the setting of an MEN1 syndrome. Sporadic and MEN1-associated duodenal gastrinomas usually arise in the first part of the duodenum [43, 109, 156, 163]. They usually form small (<2 cm in diameter) polypoid lesions within the submucosa with an intact or focally ulcerated overlying mucosa (Fig. 5). In a large series of 96 duodenal NETs, the mean size was 0.8 cm for gastrinomas [31, 156]. The gastrinomas in MEN1 are multiple and tiny (sometimes less than 1 mm in diameter) [7]. Both the sporadic and MEN1 gastrinomas are well differentiated, showing a trabecular–pseudoglandular pattern. They all stain for gastrin. Caudal-related homeobox 2 (CDX2) is positive in half of the cases. MEN1-associated gastrinomas are associated with focally accentuated gastrin and somatostatin cell hyperplasia in the mucosa and/or Brunner's glands, while sporadic gastrinomas lack such lesions [6, 7]. Despite their small size, metastases to regional lymph nodes are already found in 60 to 80% of the cases at the time of diagnosis [162, 170]. These metastases may be much larger than the primary tumor and may erroneously be considered pancreatic tumors, especially if they are located at the upper margin of the head of the pancreas [43]. This peculiarity is probably the reason why in early reports primary lymph node gastrinomas were diagnosed and many more pancreatic gastrinomas were recorded than today. Apart from lymph node metastases, duodenal gastrinomas may metas-

tasize to the liver but only in a small percentage of cases (approximately 10%) and only many years after the manifestation of the disease. Thus, 10-year survival rates of 84% have been reported in patients with duodenal gastrinomas [107, 162, 170]. Fast-growing poorly differentiated and metastasizing duodenal gastrinomas are extremely rare.

The ZES is characterized by elevated fasting gastrin serum levels, a positive gastrin secretin stimulation test, and clinical symptoms such as recurrent peptic ulcer disease, gastroesophageal reflux disease, and occasional diarrhea [8, 176]. Between 60 and 75% of patients with sporadic ZES are found to have a duodenal gastrinoma, while the remaining patients are found to have a pancreatic gastrinoma. In MEN1-associated ZES, most, if not all, patients have their gastrinomas in the duodenum [4, 8, 118, 119].

Somatostatin-producing tumors account for approximately 20% of all duodenal NETs (Table 2). Their preferential localization is in the region of the papilla of Vater, and their mean size is 2.3 cm [31, 41, 156]. Histologically, these tumors often have a glandular pattern, frequently with psammoma bodies in the lumina. About 50% of the somatostatin-producing tumors lack chromogranin A immunoreactivity but stain brightly for synaptophysin and somatostatin. If the tumors invade the muscularis propria, metastasis to the paraduodenal lymph nodes has probably occurred [41]. They are not associated with a hormonal syndrome, particularly not with a somatostatinoma syndrome, but may be found in association with NF1 [33, 156]. There are no morphological features to distinguish between NF1- and non-NF1-associated duodenal NETs.

Gangliocytic paragangliomas are rare (Table 2). They are mainly found in the second (periampullary) portion of the duodenum, and their size ranges from 1.5 to 7 cm [31, 125, 156]. The tumors are composed of three different mature cell types: (1) epithelial/endocrine cells, which are arranged in ribbons, solid nests, or pseudoglandular structures, (2) S100-positive neural spindle cells, which usually represent the major component, and (3) scattered or aggregated ganglionic cells. Despite their infiltrative growth, metastasis to the regional lymph nodes is rarely observed [24, 67, 137].

Well-differentiated duodenal NETs producing gastrin but not associated with a ZES have been increasingly recog-

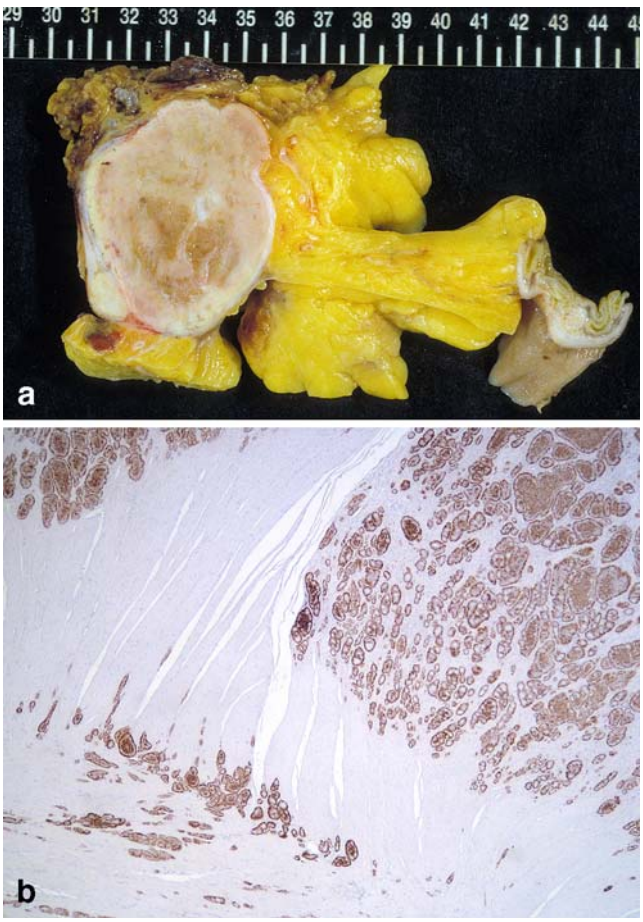

Fig. 6 Small neuroendocrine carcinoma of the ileum with large lymph node metastasis in the mesenterium (**a**). The tumor infiltrates the muscular layer and produces serotonin (**b**)

nized during recent years and are so far not well characterized. They are mostly found in the duodenal bulb as small polypous tumors localized in the mucosa and submucosa. Histologically and immunohistochemically, they are indistinguishable from gastrinomas. Recently, a series of these NETs were reported in patients who were on proton pump blockers and had *Helicobacter pylori* [97]. These tumors were found to be associated with gastrin cell hyperplasia in the adjacent mucosa. Clinically, they are often incidental findings during endoscopy or cause symptoms by virtue of local infiltration such as obstructive jaundice, pancreatitis, hemorrhage, and intestinal obstruction [33]. The prognosis of this group of nonfunctioning tumors is much more favorable than ZES-associated gastrinomas or ampullary somatostatinomas [33]. Metastases are not to be expected until the tumor extends beyond the submucosa.

In rare cases, there are well-differentiated duodenal NETs producing serotonin or calcitonin [31, 156]. Their biology is not well characterized but seems to follow the criteria listed in Tables 6 and 7.

Poorly differentiated neuroendocrine carcinomas of the duodenum occur primarily in the region of the papilla of Vater. They present as ulcerated or protuberant tumors ranging in size between 2 and 3 cm [33]. Histologically, they show a solid arrangement of medium-sized or large cells staining for synaptophysin but only rarely for chromogranin A. A small number of tumor cells may also stain for somatostatin. Clinically, most patients develop jaundice and/or hemorrhage. Hormonally, they are inactive. At the time of diagnosis, advanced metastasis to the regional lymph nodes and the liver has usually occurred [104].

Neuroendocrine tumors of the distal jejunum, ileum, and Meckel's diverticulum

The well-differentiated NETs (carcinoids) of the lower jejunum and the ileum present as small sessile nodules with a diameter ranging between 0.5 and 3 cm but usually between 1 and 2 cm. Most of them occur in the terminal ileum, close to the ileocecal valve, and in 26–30% of the cases, they are multiple [26, 116, 175]. Tumors that are larger than 1 cm almost invariably show infiltration of the muscular layer and the adjacent subserosal fatty tissue. On the cut surface, they are yellow and small (Fig. 6a). Histologically, they are characterized by an insular growth pattern with solid to cribriform tumor structures showing pallisading of the peripheral cell layer. In the glandular cavities, there are sometimes PAS-positive material. The tumor structures are embedded in a sclerotic paucicellular stroma that may lead to kinking of the foregut and subsequently to bowel obstruction. The uniform tumor cells have faintly eosinophilic cytoplasm and a very low mitotic rate, and immunohistochemically, they show the phenotype of serotonin-producing enterochromaffin (EC) cells (Fig. 6b). Between the tumor cells, there may be single S100-positive cells [26]. In addition, carcinoembryonic antigen is found in approximately two thirds of the tumors. The tumor cells may also express neurotransmitters and are positive for CDX2 [81]. There is no endocrine cell hyperplasia in the mucosa adjacent to or distant from the tumors.

If the tumors are smaller than 1 cm in diameter, lymph node metastases are rare, not exceeding 5% of the cases. If the tumors are larger than 2 cm, lymph node metastases are present in 85% of the cases, and very often, there are also liver metastases [158]. The lymph node metastases lie in the mesenterial tissue and are often larger than the primary.

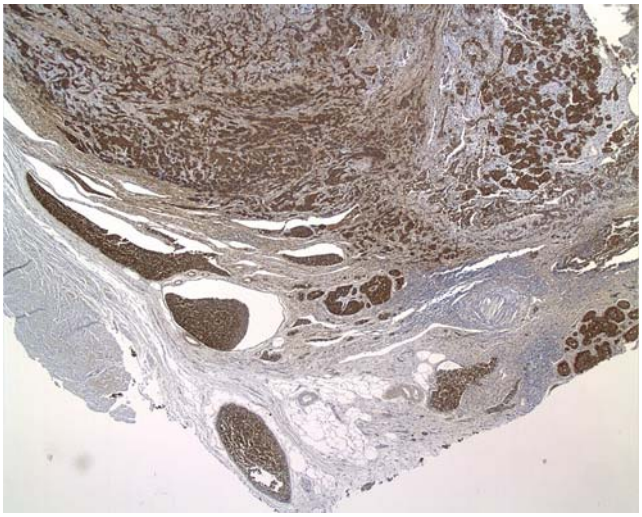

Fig. 7 Well-differentiated serotonin-producing neuroendocrine carcinoma of the appendix with infiltration of the mesoappendixand angioinvasion

Tables 8 and 9 show the newly developed TNM staging system for the tumors [128].

Clinically, the tumors may be discovered during exploration of the gut in search of a primary tumor that gave rise to liver metastases, or the patients have local (bowel obstruction, subileus) and/or systemic symptoms. The systemic symptoms are due to the hormonal effects of serotonin and are called carcinoid syndrome. This is characterized by flush, diarrhea, and carcinoid heart disease mostly causing right-sided heart failure because of tricuspid regurgitation. The carcinoid syndrome is usually seen in patients with liver metastases (95%). However, in some cases, liver metastases can occur without the syndrome. Carcinoid heart disease is a rather late event in the carcinoid syndrome and is responsible for a large number of deaths in these patients. Overall 5-year survival rates range from 50 to 60%, decreasing to 35% if liver metastases are present [158]. There is no association with any known hereditary disease, but approximately one third of the patients have other, mostly intestinal, carcinomas, either synchronous or metachronous [26, 175].

Meckel's diverticulum is a rare site of well-differentiated NETs. These tumors are usually small (<1.7 cm) and when found incidentally have not yet metastasized [26]. However, if symptomatic, metastases are likely to be found [98].

Neuroendocrine tumors of the appendix

The well-differentiated NETs/neuroendocrine carcinomas of the appendix (appendiceal carcinoids) usually occur in the tip of the organ, are 1–2 cm in size, and infiltrate the appendix wall. Histologically, they are characterized by a solid islet-like pattern (i.e., type A pattern according to Soga and Tazawa [147]. Rarely, they show trabeculae and ribbons (Soga's type B). Tumor cells are uniform, with low atypia and rare mitoses, if any. The tumors with a solid pattern are composed of serotonin-producing EC cells. In addition, there are sustentacular cells that are positive for S-100 [150].

A size greater than 1 cm, a location at the base of the appendix, extensive involvement of the mesoappendix, and angioinvasion are important negative prognostic factors (Fig. 7) and are potentially associated with metastases [95]. The risk of lymph node metastases in tumors measuring 1 to 2 cm is 1% and increases to 30% in tumors measuring more than 2 cm [158]. Mesoappendix invasion is a debated variable [91, 134]. Series with sufficiently long follow-up, including children with a median age of 12 years, revealed that no patient treated by appendectomy died of appendiceal NETs with a diameter below 2 cm [114, 158]. A poorly differentiated neuroendocrine carcinoma, as part of a mixed

Table 11 Proposal for disease staging for neuroendocrine tumors of the appendix

exocrine–endocrine carcinoma, has only been reported once so far [133]. Tables 10 and 11 show the newly developed TNM stage system and the grading of the tumors [128].

Most tumors are usually detected because of symptoms of acute appendicitis. A carcinoid syndrome has not been reported in association with a metastasized well-differentiated appendiceal NET. The carcinoid syndrome is exceedingly rare [102].

Neuroendocrine tumors of the colon and rectum

Well-differentiated NETs (carcinoids) are more frequent in the rectum than the colon, whereas poorly differentiated neuroendocrine carcinomas are more common in the colon. The well-differentiated rectal tumors mostly appear during endoscopy as small (<1 cm) movable submucosal tumors. The poorly differentiated neuroendocrine carcinomas of the colon are usually of large size (>2 cm). An average diameter of 4.9 cm was reported [10], and 55 of 129 cases reported by Soga were between 5 and 10 cm in size [145]. The well-differentiated NETs of the colon are mostly small and occur in the cecal region [10, 132, 145] or throughout the colon in cases of ulcerative colitis [94]. Recently, "microcarcinoids" (0.5 to 1.5 mm in size) have been described in polypous colonic adenomas [122].

Histologically, the well-differentiated NETs (carcinoids) of the rectum are characterized by a trabecular pattern (Soga's type B) [150]. The well-differentiated NETs of the colon, in contrast, show the solid pattern that is also found in the tumors of the small intestine (Soga's type A) or a mixed pattern (Soga's type E) [145, 150]. Immunohistochemically, the well-differentiated NETs of the rectum are positive for synaptophysin, glucagon, glicentin, and/or pancreatic polypeptide and are usually negative for chromogranin. In addition to synaptophysin and chromogranin A, the well-differentiated NETs of the cecal region stain for serotonin. In minor tumor cell populations, positivity for motilin, neurotensin, substance P, enkephalins, and other hormones has been described [150]. In addition, prostatic acidic phosphatase was reported positive in the majority of the well-differentiated colorectal NETs, making this a potentially useful marker of lower hindgut origin [46]. Expression of the transcription factor CDX2, although specific for colorectal adenocarcinomas [123], proved to be restricted to the rare colorectal serotonin-positive NETs [81].

Histologically, poorly differentiated neuroendocrine carcinomas are characterized by solid structures, sometimes with "organoid" appearance, extensive "geographical chart" necrosis, small or large cell cytology and high mitotic counts, and Ki67 index [23, 38, 152]. Mucin stain (periodic acid Schiff [PAS] and Alcian/PAS) may be useful to identify occasional, although not uncommon, minor foci of adenocarcinoma or squamous cell carcinoma [20, 21]. Immunocytochemically, there is diffuse immunostaining for synaptophysin and CD56 as well as NSE, while chromogranin A may be absent or only present in individual cells. c-kit expression is found in approximately 20% of the cases and is not associated with an activating mutation in exon 11 of the c-kit gene [3].

Prognostically, well-differentiated NETs of the rectum but also of the colon are likely to have metastasized to the regional lymph nodes and elsewhere if they are larger than 2 cm and have invaded the muscularis propria. Rectal well differentiated NETs less than 1 cm in size have a very low risk of metastasis, while those between 1 and 2 cm may show metastasis to the regional lymph nodes in up to 5% of the cases. If the tumors are poorly differentiated, there is a high rate of metastasis at the time of diagnosis [20, 21]. A recent proposal for a TNM classification and grading system may be of value in the stratification and management of patients with colon and rectal NETs (Tables 12 and 13) [128]. NETs of the colon and rectum rarely cause hormonal symptoms. Some cases of classical carcinoid syndrome were reported in patients with metastatic lesions of cecal origin [144, 145, 150]. An association with inflammatory bowel diseases has been reported in both Crohn's and ulcerative colitis, suggesting that chronic inflammation is a potentially triggering condition for the development of NETs [63, 103, 150]. Synchronous or metachronous colorectal carcinomas are frequently seen [144, 145]. This is particularly the case in poorly differentiated neuroendo-

Table 12 Proposal for a TNM classification for neuroendocrine tumors of the colon and rectum

Abbreviation	Characteristics
T—primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor invades mucosa or submucosa
	T1a size <1 cm
	T1b size 1–2 cm
T2	Tumor invades muscularis propria or size >2 cm
T3	Tumor invades subserosa/pericolic/perirectal fatty tissue
T4	Tumor directly invades other organs/structures and/or perforates visceral peritoneum
	For any T add (m) for multiple tumors
N—regional lymph nodes	
NX	Regional lymph node status cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M—distant metastases (subspecification as in small bowel)	
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1	Distant metastasis

crine carcinomas [21, 23, 47]. Therefore, a common histogenesis for neuroendocrine and nonneuroendocrine aggressive cancers of the colon has been discussed [164, 168].

Neuroendocrine tumors of the presacral region

NETs involving the presacral region between the rectum and the sacrum are rare but well documented [64, 161]. They affect adults of both sexes and are frequently associated with tail gut cysts. Histologically, most of them are well-differentiated NETs resembling rectal carcinoids. Metastases may occur.

Pancreas

Pancreatic NETs (PETs) usually present as solitary well-demarcated neoplasms but lack a well defined capsule (Fig. 8). Their size ranges between 1 and 5 cm. Multiple tumors are rare and should always raise the suspicion of MEN1 or VHL (for details on hereditary NETs, see Anlauf et al. this issue). The majority of the tumors are well differentiated, showing a trabecular or solid pattern [77]. Poorly differentiated carcinomas, which are rare, show a diffuse infiltrative growth pattern.

The biological behavior, i.e., the metastatic potential, may be predicted by a number of criteria and indicators that are summarized in Table 2. Recent studies provided evidence that this multiparameter approach that is applied in the 2004 WHO classification of PETs is a reliable tool for stratifying patients into risk groups and that, in addition, the immunohistochemical marker CK19 may refine the prognostic power of the WHO classification [29, 58, 139]. Furthermore, a proposal for a TNM classification and a grading system has recently been published (Tables 14 and 15) [127].

PETs include several entities that are divided on the basis of their symptomatology into functioning neoplasms (i.e., with hormonal syndromes such as insulinomas, gastrinomas, glucagonomas, or VIPomas) and nonfunctioning neoplasms (i.e., without hormonal syndromes). The majority of the functioning and nonfunctioning PETs fall into the category of well-differentiated carcinomas, with the exception of insulinomas.

Insulinoma These tumors are located in the pancreas or are directly attached to it and present as solitary red brown, mostly soft, well-demarcated tumors with a size between 0.5 and 2 cm. Histologically, they show either solid or trabecular, gland-like tumor growth [56, 79]. The tumor cells are often bland, and cells with large, pleomorphic nuclei are rare. If they occur, they are not predictive of malignancy. A special finding in insulinomas is the deposition of amyloid that can be immunostained for amylin [172]. Immunohistochemically, they stain for insulin and proinsulin. In addition there may be cells

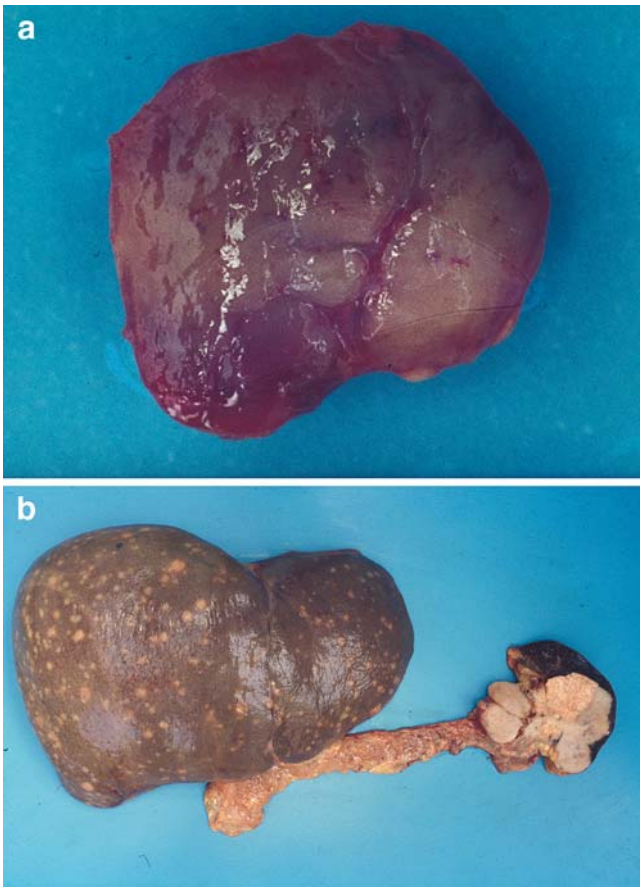

Fig. 8 Pancreatic neuroendocrine tumors: **a** tumor with a diameter less than 2 cm (insulinoma without metastases). **b** Large tumor (>2 cm) in the tail of the pancreas with multiple liver metastases (malignant insulinoma)

Table 14 Proposal for a pTNM classification and disease staging for endocrine tumors of the pancreas

Abbreviation	Characteristics
T—primary tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Limited to the pancreas and size <2 cm
T2	Limited to the pancreas and size 2–4 cm
T3	Limited to the pancreas and size >4 cm or invading duodenum or bile duct
T4	Invading the wall of adjacent large vessels (celiac axis or superior mesenteric artery), stomach, spleen, colon, adrenal gland
	For any T add (m) for multiple tumors
N—regional lymph nodes	
NX	Regional lymph node status not assessed
N0	Absence of lymph node metastasis
N1	Presence of regional lymph node metastasis
M—distant metastases	
MX	Distant metastasis not assessed
M0	Absence of distant metastases
M1	Distant metastasis

expressing glucagon, somatostatin, pancreatic polypeptide or other hormones [72, 79].

The vast majority of insulinomas are benign at the time of diagnosis [151]. This may be due in part to their early detection, as they already become symptomatic at a small size [78, 148] (Fig. 8a). Approximately 8.4% of insulinomas are malignant [49, 51, 52, 84, 140, 148, 157, 165] (Fig. 8b). Malignant insulinomas occur in an older age group and are rare in children [39, 159].

Tumors producing a hypoglycemic syndrome are usually larger than 1 cm; microadenomas (below 0.5 cm in diameter) are functionally silent. Approximately 4–7% of patients with insulinomas suffer from MEN1 [141]. Rare examples of insulinomas have also been described in patients suffering from NF1 [48]. Between 12 and 17% of VHL patients develop endocrine pancreatic tumors, which may show focal insulin immunoreactivity [90], but most of these tumors are clinically nonfunctioning.

Gastrinoma In recent years, it has become obvious that pancreatic gastrinomas are less common than duodenal gastrinomas (see "Duodenum and upper jejenum"). They are associated with the sporadic form of ZES and only very rarely with the MEN1-associated form of ZES [118, 119]. Their preferential localization seems to be in the pancreatic head, where they present as solitary tumors that usually have a diameter of 2 cm or more [43, 153]. The anatomical area comprising the head of the pancreas, the superior and ascending portion of the duodenum, and the relevant lymph nodes has been called the "gastrinoma triangle," as it harbors the vast majority of these tumors [65, 70, 105, 106, 153]. Histologically, they predominantly show a mixed trabecular and solid pattern with some pseudoglandular structures. Immunohistochemically, they are positive for gastrin but may also show some glucagon, somatostatin, or pancreatic polypeptide cells [15, 119]. The risk of liver metastases increases with tumor size, and they occur with a frequency of 30% [151]. Metastases to other organs are rare [155]. In general, the progression of gastrinomas is relatively slow with a combined 5-year survival rate of 65% amd a 10-year survival rate of 51% [70]. Even with metastatic disease, a 10-year survival of 46% (lymph node metastases) and 40% (liver metastases) has been reported [108]. Patients with complete tumor resection have 5- and 10-year survival rates of 90–100%, respectively.

Glucagonoma These are NETs that produce glucagon and are associated a syndrome consisting of skin rash (necrolytic migratory erythema), mild glucose intolerance, anemia, weight loss, depression, diarrhea, and a tendency to develop deep-vein thrombosis [58]. They are usually large, solitary tumors with a diameter between 3 and 7 cm commonly occurring in the tail of the pancreas [136, 151]. Extrapancreatic glucagonomas are extremely rare [131]. On their cut surface, they show a brown red to pink color and a soft consistency. Histologically, they display a mixed trabecular and solid pattern, and immunohistochemically, they stain (often weakly) for glucagon or proglucagon-derived peptides (glicentin, glucagon-like peptides 1 and 2) [18, 55, 136]. In addition, numerous pancreatic polypeptide cells can often be identified.

Approximately 60–70% of glucagonomas are already metastatic at the time of diagnosis [60, 121, 136]. Malignant glucagonomas tend to grow slowly, and patients may survive for many years.

VIPoma This PET is associated with the Verner–Morrison syndrome or WDHA syndrome (watery diarrhea, hypokalemia, hypochlorhydria, alkalosis), characterized by diarrhea (up to 20 l a day), hypokalemia because of potassium loss in the stool, achlorhydria, glucose intolerance, and anemia. These symptoms are caused by inappropriate secretion of VIP and peptide histidine methionine (PHM). The tumors are located in the pancreas, where they are preferentially seen in the tail. They are large and solitary [30]. Histologically, they show a solid or trabecular growth pattern. Immunohistochemically, they stain for VIP and PHM and often in addition for pancreatic polypeptide and other hormones [2, 12, 111].

Most VIPomas have led to metastases in the regional lymph nodes and the liver at the time of diagnosis [93]. The 5-year survival rate is about 59% for patients with metastases and 94% for those without metastases [58].

Somatostatin-producing PETs (so-called somatostatinomas) In 1979, the somatostatinoma syndrome was described in patients presenting with symptoms of diabetes mellitus, cholecystolithiasis, steatorrhea, indigestion, hypochlorhydria, and occasionally anemia in association with a somatostatin-producing and somatostatin-secreting PET [80, 82, 120, 142, 166]. The symptoms were attributed to the inhibitory effects of somatostatin on the function of various cell systems. However, since then, no further convincing reports on the somatostatinoma syndrome have appeared in the literature, although somatostatin-producing NETs (SOM-NETs) have been identified not only in the pancreas but also at other sites, particularly the duodenum [41, 160]. This casts doubt on the existence of a somatostatinoma syndrome and raises the question whether the described symptoms were unspecific manifestations of large malignant PETs [166] that happened to produce somatostatin. The last view is supported by our results in a series of 386 PETs, collected between 1972 and 2006, which contains ten well-differentiated somatostatin-producing PETs, none of which were associated with the so-called somatostatinoma syndrome [50].

SOM-NETs of the pancreas are rare and in approximately 50% of the cases malignant. While most tumors show a trabecular pattern, some display a paraganglioma-like architecture with occasional psammomatous calcifications. The somatostatin-producing PETs in our series were outnumbered by the SOM-NETs found in the duodenum (see "Duodenum and upper jejenum") [31, 156].

Other functioning PETs Apart from insulinomas, gastrinomas, glucagonomas, and VIPomas there may be adrenocorticotropic hormone-producing tumors causing Cushings's syndrome [37, 57, 96], tumors producing growth hormone-releasing hormone (GHRH) causing acromegaly [11, 19, 40, 138], calcitonin-producing tumors causing diarrhea [44, 71], and serotonin-producing tumors causing a carcinoid syndrome [113, 171]. Many of these neoplasms are solitary and large and have metastasized to the liver and lymph nodes when detected. Histologically, they do not differ from the more common functioning tumors. Exceptions are some GHRH-producing tumors, which show a distinct paraganglion-like microglandular pattern and spindle-shaped cells [138]. The hormone causing the syndrome can usually be detected by immunohistochemistry. These tumors tend to be large, and at diagnosis, many patients have already liver metastases. The prognosis is therefore usually poor [58].

Nonfunctioning PETs These PETs are either incidental findings or become clinically apparent because of size, invasion of adjacent organs, or the occurrence of metastases. In rare cases, they present as pancreatitis. They are observed more frequently than previously, although this probably does not reflect an actual increase in frequency but rather improved diagnostic methods [139]. Historically, most of these tumors were large when detected and frequently malignant [73]. More recently, however, smaller nonfunctioning tumors are increasingly detected by modern imaging techniques [139]. Large nonfunctioning PETs are reported to occur most frequently in the head of the pancreas, possibly because they are most likely to produce symptoms such as cholestasis in this location. In general, the presenting symptoms are most often unspecific and may consist of nausea, vomiting, or diarrhea.

Histologically, they may show various types of patterns: a trabecular, solid, pseudoglandular, or gyriform pattern. Immunohistochemically, these tumors stain for synaptophysin and chromogranin A and show a wide range of positivity for hormones including glucagon, somatostatin, and pancreatic polypeptide. Some of these tumors are associated with elevated hormone levels in the blood (e.g., glucagon, somatostatin, or pancreatic polypeptide), reflecting the hormonal immunoreactivity in the tumor. Because the patients lack any hormonal syndrome, they should not be called glucagonomas, somatostatinomas, or Ppomas. A special feature of glucagon-producing but hormonally silent NETs are grossly cystic changes [86, 174].

A minority of nonfunctioning NETs of the pancreas are histologically poorly differentiated, showing a diffuse infiltrative growth pattern and composed of small- to medium-sized cells, occasionally also large cells, that have a high mitotic rate and proliferative activity of more than 20%. Their neuroendocrine differentiation is demonstrated by diffuse staining for synaptophysin and, rarely, for

chromogranin A. Hormones are usually not detected.They may stain for p53.

Prognostically, well-differentiated nonfunctioning NETs of the pancreas have a 5-year survival rate of approximately 65% and a 10-year survival rate of 45%. Follow-up in patients with PETs having a diameter of less than 2 cm revealed that they are often cured by surgery [139].

Tumors smaller than 0.5 cm are designated microadenomas and are usually not visible macroscopically. Most of these tumors are detected incidentally or at autopsy and are present throughout the pancreas. Histologically, they show a trabecular pattern, and immunohistochemically, they stain for glucagon.

Conflicts of interest statement We declare that we have no conflict of interest.

REVIEW AND PERSPECTIVE

Hereditary neuroendocrine tumors of the gastroenteropancreatic system

Received: 11 June 2007 / Accepted: 11 June 2007 / Published online: 8 August 2007

Abstract Approximately 5–10% of neuroendocrine tumors (NETs) of the gastroenteropancreatic system (GEP) have a hereditary background. The known inherited syndromes include multiple endocrine neoplasia type 1, neurofibromatosis type 1, von Hippel–Lindau disease, and the tuberous sclerosis complex. This review discusses for each of these syndromes the: (1) involved genes and specific types of mutations, (2) disease prevalence and penetrance, (3) affected neuroendocrine tissues and related clinical syndromes, (4) special morphological features of NETs and their putative precursor lesions. In addition, GEP-NETs clustering in individual families or associated with other malignancies without known genetic background are discussed.

Introduction

Hereditary cancer susceptibility is more frequent and variable in tumors of endocrine organs than in any other category of human neoplasms. Often, a variety of endocrine and nonendocrine tissues are involved, resulting in complex clinical syndromes.

In the digestive tract, approximately 5–10% of neuroendocrine tumors (NETs) have a hereditary background. Inherited tumor syndromes include multiple endocrine neoplasia type 1 (MEN1), neurofibromatosis type 1 (NF1), von Hippel–Lindau disease (VHL), and the tuberous sclerosis complex (TSC). In this article, we focus for each of these syndromes on: (1) the involved genes and specific types of mutations, (2) the disease prevalence and penetrance, (3) the affected neuroendocrine tissues and the related clinical syndromes, and (4) the morphological features of the respective NETs and their putative precursor lesions. In addition, suspected hereditary backgrounds [e.g., association with other malignancies, familial clustering of gastroenteropancreatic system (GEP)-NETs] are discussed.

Multiple endocrine neoplasia type 1

MEN1 is an autosomal-dominant disorder characterized by multifocal endocrine tumors affecting the anterior pituitary, parathyroids, stomach, duodenum, pancreas, adrenal cortex, thymus, and lungs. In addition, various uncommon tumoral lesions may occur in the skin, central nervous system, and soft tissues [12, 57].

The *MEN1* gene is localized on chromosome 11q13 and consists of 10 exons spanning approximately 9 kb of genomic sequence and encoding a 68-kDa protein of 610 amino acids, named menin [12, 15, 57] (Table 1). Menin is

Table 1 Genetic and clinicopathological features of MEN1 and NF1

	MEN1	NF1
Function	Tumor suppressor gene	Tumor suppressor gene
Chromosomal location	11q13	17q11.2
Gene structure	10 exons (~9 kb)	>50 exons (~300 kb)
Protein	Menin (610 amino acids)	Neurofibromin (2,818 amino acids)
Mode of inheritance	Autosomal-dominant (10% de novo)	Autosomal-dominant
Prevalence	~1:20,000–1:40,000	~1:2,000–1:5,000
Penetrance	>95% (at age 50)	~100% (in childhood)
Diagnosis	According to WHO clinical criteria (genetic testing of family members recommended)	According to WHO clinical criteria (genetic testing not recommended)

Tumors or endocrine hyperfunction outside the GEP	Primary hyperparathyroidism, anterior pituitary adenoma, adrenocortical tumor, thymic and bronchial NET, cutaneous lipoma and angiofibroma	*Cafe au lait* macules, neurofibroma, plexiform neurofibroma, MPNST, pheochromocytoma, optic/brain stem gliomas, bone lesions, renal artery stenosis, congenital glaucoma

NETs Neuroendocrine tumors, *GEP* gastroenteropancreatic system, *MEN1* multiple endocrine neoplasia type 1, *WdNEC* well-differentiated neuroendocrine carcinoma (defined by presence of lymph node metastases or infiltrative growth in the outer smooth muscle layers), *ECL* enterochromaffin-like, *PETs* pancreatic endocrine tumors, *ZES* Zollinger–Ellison syndrome, *NF1* neurofibromatosis type 1, *GIST* gastrointestinal stroma tumor, *MPNST* malignant peripheral nerve sheath tumor

a cell cycle-regulated nuclear protein. Menin is assumed to play an important role in pathways controlling cell growth and differentiation during embryogenesis and postnatal life. To date, menin has been shown to interact with numerous proteins involved in regulation of transcription, DNA replication, mitosis, apoptosis, genome integrity, growth factor signaling pathways, and extracellular matrix organization [12, 57]. However, it remains still unresolved why *MEN1* mutations affect primarily endocrine tissues.

The prevalence of the MEN1 syndrome has been estimated to be between 1:20,000 and 1:40,000. In approximately 10% of patients, MEN1 germline mutations arise de novo without any family history [8, 12, 15] (Table 1). The *MEN1* germline mutations are found spread over the entire exonic and intronic sequences and are not clustered in hotspots. Approximately 60% are truncating mutations, either frameshift (~40%) or nonsense (~20%) mutations; 20% are missense mutations; 10% are in-frame deletions or insertions, and about 10% are intronic and splice-site mutations. Large germline deletions encompassing the whole *MEN1* locus have also been detected [12, 14, 15]. A stringent genotype/phenotype relation correlation could not be demonstrated. Among patients meeting the clinical criteria of a MEN1 syndrome, approximately 10% have no identifiable mutations [43]. Most MEN1-associated tumors show somatic loss of the wild-type allele (loss of heterozygosity; LOH) on chromosome 11q13, consistent with the role of *MEN1* as a tumor suppressor gene [6, 26, 54, 66].

Twenty to 60% of MEN1 patients suffer from a Zollinger–Ellison syndrome (ZES), characterized by elevated fasting gastrin serum levels, a positive secretin stimulation test, and clinical symptoms such as recurrent peptic ulcer disease, gastroesophageal reflux disease, and occasionally, diarrhea [44, 87]. The gastrinomas observed in MEN1 are almost exclusively localized in the duodenum (Table 1). They are multiple and are associated with multifocal gastrin cell hyperplasia and tiny gastrin-producing microtumors. Despite their small size of 0.3 to 5 mm, the gastrinomas tend to metastasize to regional lymph nodes [3, 4, 67]. In addition, the duodenum harbors multiple tiny somatostatin cell neoplasms and multifocal somatostatin cell hyperplasia [6] (Fig. 1). Recently, molecular studies have

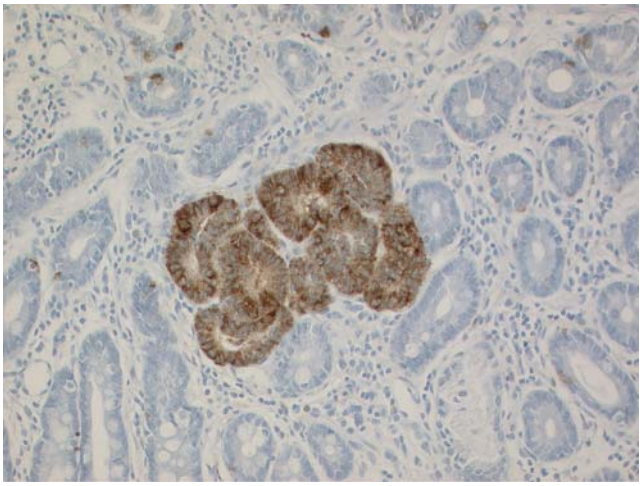

Fig. 1 Linear hyperplasia of somatostatin cells in the duodenal mucosa of a MEN1 patient with ZES

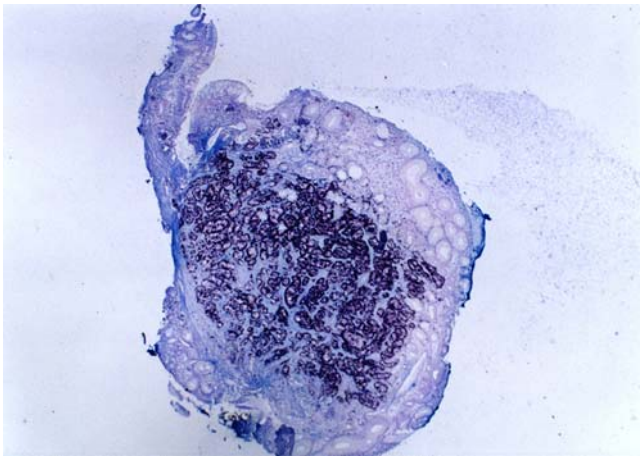

Fig. 3 Polypectomy specimen showing a small benign ECL cell tumor in a MEN1 patient with ZES (immunostaining for the vesicular monoamine transporter 2)

allowed the separation from hyperplastic and neoplastic lesions. LOH of the *MEN1* locus was found in approximately 50% of MEN1-associated duodenal NETs [6]. Allelic loss was detected in tumors as small as 300 μm (gastrin) and 400 μm (somatostatin) in diameter, which therefore represent true neoplasms. In contrast, hyperplastic gastrin and somatostatin cells lacked LOH on chromosome 11q13. These findings suggested that although the hyperplastic cells were hyperproliferative and carried the *MEN1* germline mutation, they had not yet assumed the neoplastic genotype characterized by the loss of the *MEN1* wild-type allele.

In addition to duodenal NETs, MEN1 patients with ZES may show multiple gastric NETs of the enterochromaffin-like (ECL) cells (Fig. 2). These tumors occur in a hypertrophic oxyntic mucosa and are associated with an ECL cell hyperplasia, which can be visualized using antisera against the ECL cell-specific marker vesicular monoamine transporter 2 [25] (Fig. 3). They are probably induced by both the MEN1 germline mutation and the trophic effect of hypergastrinemia. Metastases of these ECL cell tumors are rare, and tumor-related deaths are the exception [9, 10, 12].

Pancreatic NETs lead to symptoms in 30–75% of MEN1 patients [12] and up to 10% of all pancreatic NETs may be associated with a MEN1 syndrome [57]. In a recent study on surgical specimens of the pancreas from MEN1 patients in more than 90% of the cases, numerous microadenomas (i.e., up to 5 mm in diameter) were found [5], a condition that has been called pancreatic microadenomatosis. Although this finding is a hallmark for MEN1, it is not MEN1 specific, as recently, pancreatic microadenomatosis characterized by multiple glucagon-producing or multiple insulin-producing microadenomas was described in several patients who had no evidence of MEN1 or any other known hereditary syndrome [5].

In MEN1 patients, the pancreatic microadenomas are typically multihormonal and are often associated with one or more macrotumors (diameter >5 mm; Fig. 4) [12, 42,

Fig. 2 Cut surface of a gastric specimen from a MEN1 patient with ZES, showing multiple small tumors in the mucosa and submucosa

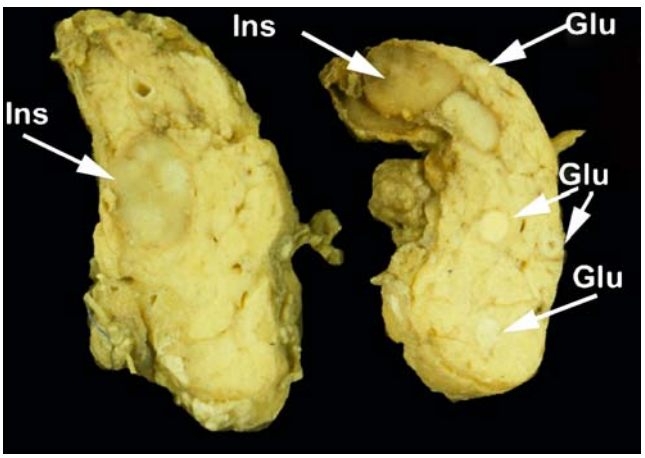

Fig. 4 Pancreatic specimen from a MEN1 patient showing two insulin-positive (*Ins*) macrotumors and four glucagon-positive (*Glu*) microadenomas

77]. The microadenomas in MEN1 are characterized, irrespective of their size (i.e., less than 200 μm), by the following features: (1) frequent expression of glucagon and/or pancreatic polypeptide, (2) trabecular growth pattern, and (3) a distinct stromal component [5, 42, 77]. Their neoplastic nature was demonstrated by LOH of the MEN1 gene [66, 82]. The MEN1-associated macrotumors (≥5 mm) also frequently express glucagon and pancreatic polypeptide or, rarely, somatostatin. In all these cases, the patients do not have a hormonal syndrome. However, if one of the macrotumors produces insulin, the patient presents with a hyperinsulinemic hypoglycemia syndrome. This is seen in approximately 10–25% of the cases. Only exceptionally, there are macrotumors that express hormones such as gastrin, vasoactive intestinal polypeptide, or growth hormone releasing hormone, which then may give rise to the respective hormonal syndromes. Regarding MEN1 patients with ZES, this implies that, with all likelihood, the source of hypergastrinemia is not a pancreatic gastrinoma but multiple duodenal gastrinomas.

Recently, forerunners of microadenomas were identified in the MEN1 pancreas, which have been called monohormononal islet-like endocrine cell clusters [66]. In addition, single irregularly shaped and enlarged islets with an increased number of glucagon cells were found. However, in contrast to the monohormononal islet-like endocrine cell clusters, the cells of the glucagon-cell-rich islets show retention of heterozygosity of the *MEN1* gene and are therefore still nonneoplastic in nature.

In summary, the MEN1 syndrome is characterized by multiple endocrine duodenal and pancreatic NETs expressing several peptide hormones, but preferentially either gastrin or somatostatin (duodenum) or glucagon or pancreatic polypeptide (pancreas). The duodenal NETs are associated with multifocal gastrin and somatostatin cell hyperplasia that can be considered precursor lesions. In the pancreas, the islets with hyperplastic glucagon cells are probably the precursors from which microadenomas evolve. Similar precursor changes have so far not been observed in the usually solitary nonhereditary NETs [6].

Neurofibromatosis type 1

NF1 (i.e., von Recklinghausen disease) shows an autosomal-dominant inheritance and a high penetrance: In almost all patients, there is sufficient evidence of the disorder to allow diagnosis in childhood [27]. The condition is characterized by neurofibromas, *Café au lait* patches of the skin, and bone dysplasia. Neurofibromas occur widely throughout the body, but affect mainly the skin. Other tumors are optic nerve and brain stem gliomas, pheochromocytomas, and malignant nerve sheath tumors [27] (Table 1). Gastroenteropancreatic NETs are rare and occur in 1% of the NF1 patients. They typically arise in the duodenum [23].

The *NF1* gene is localized on chromosome 17q11.2 and consists of more than 50 exons spanning approximately 300 kb of genomic sequence and encoding a 327-kDa protein of 2,818 amino acids, called neurofibromin [81]. Neurofibromin acts as a negative regulator of the ras-related G-proteins by increasing Ras GTPase activity, and thereby, functions at multiple levels: transcription, cell proliferation, cytoskeletal microtubule assembly. Mice that are homozygous for an NF1 mutation fail to develop the normal structure of heart and various neuroectodermal tissues and die in utero [27, 86]. Neurofibromin has been referred to as a tumor suppressor, as malignant peripheral nerve sheath tumors in NF1 patients display LOH of the NF1 gene [27].

Mutation screening is costly and not recommended clinically because of the size of the gene (50 exons) and the fact that the clinical manifestations are so characteristic. Mutations have been identified throughout the *NF1* gene; most mutations are protein-truncating mutations, consisting of nonsense, frameshift, and splice-site mutations. Five to 10% of patients have large deletions, often involving the whole gene, that are easily detectable by fluorescence in situ hybridization [36]. Large deletions of the NF1 gene have been correlated with a greater neurofibroma burden, as well as dysmorphic features, greater mental retardation, and a higher risk of developing malignant peripheral nerve sheath tumors [27]. Except for large deletions, genotype–phenotype correlations have not been described.

Our knowledge about the incidence, histopathology, biology, and functional activity of NF1-associated intestinal NETs is based on reports of single cases or small series of patients and reviews [22, 23, 75, 76]. Most of the GEP-NETs arise in the ampullary region of the duodenum and show glandular structures containing PAS-positive psammoma bodies. Immunohistochemically, they consistently express somatostatin and synaptophysin, but rarely chromogranin A. An association with the so-called somatostatinoma syndrome [i.e., markedly elevated somatostatin levels in the plasma and/or tumor, diabetes mellitus of recent onset, hypochlorhydria, gallbladder disease (cholelithiasis), diarrhea and steatorrhea, anemia, and weight loss] [24] has yet not been described. The clinical symptoms are caused by the site of the tumors, i.e., the ampulla, and lead to obstructive jaundice, intestinal obstruction, and/or bleeding. In our series of 82 duodenal NETs, we identified 15 somatostatin-producing NETs (SOM-NETs), 3 of them associated with the NF1 syndrome (Fig. 5). None of these tumors was associated with a somatostatinoma syndrome. Therefore, the high rate of NF1-associated SOM-NETs reviewed by Soga and Yakuwa [74] could not be confirmed in our series. Precursor lesions of NF1-associated SOM-NETs have not been identified. NF1-associated SOM-NETs

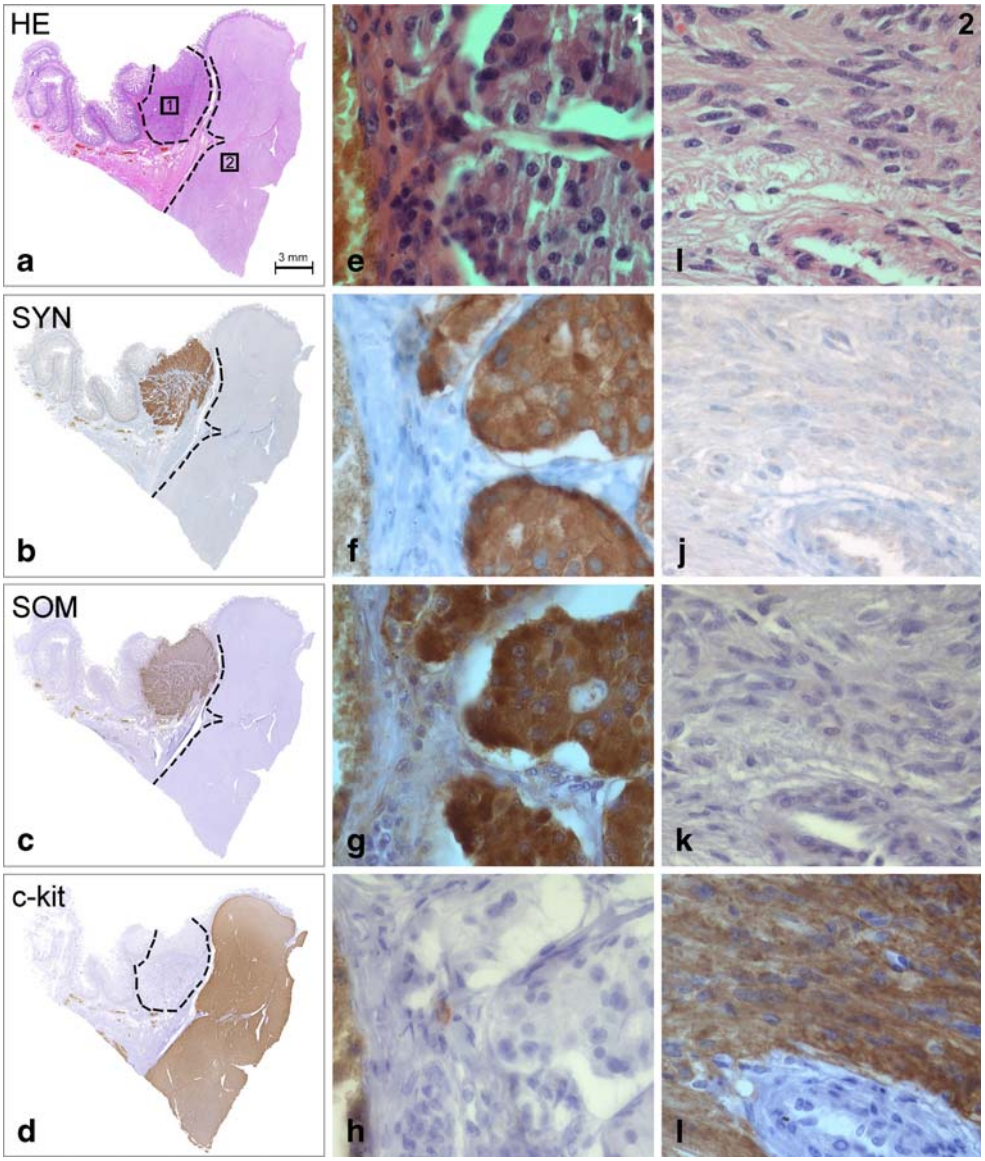

Fig. 5 Simultaneous occurrences of SOM-NET and GIST in a patient with the NF1 syndrome. Whole section scan (**a**–**d**) and high magnification of the SOM-NET (**e**–**h**) showing strong immunoreactivity for synaptophysin (*SYN*, **f**) and somatostatin (*SOM*, **g**) but not for c-kit (**h**). High magnification of the GIST (**i**–**l**) showing absence of synaptophysin (**j**) and somatostatin (**k**) but strong expression of the c-kit antigen (**l**)

may be associated with gastrointestinal stroma tumors (Fig. 5). In addition, gangliocytic paragangliomas and ampullary adenocarcinomas have been reported; however, it remains unclear whether these tumors are coincidental or due to the NF1 germline mutations.

Metastases have been described in 27% of SOM-NETs, mainly to the lymph nodes. They appear to be less aggressive than their sporadically occurring duodenal and pancreatic counterparts [35]. A tumor size of more than 2 cm and infiltration of the outer smooth muscle layers increase the risk of metastases ([76] and personal observations). In addition, a few cases of pancreatic NETs have been described in patients with the NF1 syndrome. These were somatostatin-producing NETs or insulinomas [29, 73, 74]. In our series of 541 non-MEN1-associated pancreatic NETs, we identified 19 somatostatin-producing NETs, none of them associated with NF1, and 162 insulinomas, one of them in a patient with NF1. In this patient, the tumor was proven to lack expression of the wild-type NF1 allele, providing strong evidence that there is indeed a close relationship between NF1 and the development of this insulinoma [65].

von Hippel–Lindau syndrome

VHL is a dominantly inherited familial cancer syndrome caused by germline mutations in the *VHL* tumor suppressor gene. VHL disease shows marked phenotypic variability and age-dependent penetrance [55, 84] (Table 2).

The VHL gene is localized on chromosome 3p25 and consists of three exons encoding two VHL transcripts. The major transcript (isoform I) represents all three exons, whereas exon 2 is absent from isoform II. They encode two

gene products: a full-length 213-amino-acid protein (pVHL30; ~28–30 kDa) and a shorter protein (pVHL19; ~18–19 kDa). The *VHL* gene product has multiple functions, the best characterized of which is the role of pVHL in regulating proteolytic degradation of the subunits of the HIF transcription factors. In addition, there is strong evidence that pVHL targets other proteins for polyubiquination [18, 48, 53, 55]. VHL-associated tumors such as renal clear cell carcinoma, hemangioblastoma, and pheochromocytoma are highly vascular and overexpress a wide range of hypoxia-inducible mRNAs, including vascular endothelial growth factor (VEGF) and VEGF receptor. A variety of VHL mutations have been described. Large genomic deletions account for up to 40% of all mutations, and the rest are divided approximately equally between intragenic missense mutations and protein-truncating mutations (nonsense, frameshift insertions and deletions, splice-site mutations). Germline VHL mutations have been characterized in >500 patients and have provided a wealth of data for genotype–phenotype correlations. VHL mutations may cause (1) VHL diseases, (2) isolated familial pheochromocytoma (VHL disease type 2C), and (3) autosomal recessively inherited polycythemia due to homozygous missense mutations [17, 19, 55, 69, 84].

Although pancreatic involvement in VHL is very common (50–77%), the majority of lesions are cysts. These are rarely of clinical significance, and impairment of pancreatic function is uncommon. Hemangioblastoma occurs rarely in the pancreas of VHL patients [34, 55, 62].

The prevalence of pancreatic NETs in VHL patients has been reported at frequencies of 5–17%. VHL-associated NETs are usually confined to the pancreas and show a solid, trabecular, and/or glandular architecture. In approximately 30–50% of VHL patients, the tumors are multiple. Most of them reveal clear-cell cytology. Immunohistochemically, they are positive for general neuroendocrine

markers (chromogranin A and synaptophysin). A minor subset of tumor cells may be immunoreactive for pancreatic polypeptide, glucagon, somatostatin, or insulin. Clinically, however, almost all of the tumors are functionally inactive and are usually detected by routine radiological assessment of the abdomen in VHL patients [1, 51, 52, 54, 55]. Almost all VHL-related pancreatic NETs reveal LOH of the VHL gene locus on chromosome 3p25, supporting the concept that the VHL gene product acts as a tumor suppressor [54]. Although VHL-related tumors are often multifocal, precursor lesions were not identified in a systematic analysis of 14 patients [54]. VHL-related pancreatic NETs grow slowly. As with other NETs, the risk of malignancy seems to be directly proportional to the diameter of the tumor. In the largest reported series of 30 patients, the median size of the tumor in patients with no metastases was 2 cm (n=25) compared to 5 cm for those with metastases (n=5) [51].

Tuberous sclerosis complex

Tuberous sclerosis is an autosomal-dominant genetic disorder with a prevalence of 1:10,000 and a disease penetrance of approximately 100%. TSC is a multisystem disorder exhibiting a wide range of manifestations characterized by hamartomatous lesions in the brain, skin, eyes, heart, lungs, and kidneys (Table 2). Epilepsy, mental retardation, and autism are often present. A few cases of pancreatic NETs have been described in patients with TSC. TSC is caused by inactivating mutations in either the *TSC1* gene at 9q34 or the *TSC2* gene at 16p13.3 encoding the proteins hamartin (~140 kDa) and tuberin (~200 kDa), which form a complex that affects cell growth, differentiation, and proliferation [70, 71, 78, 85] (Table 2). The diagnosis of TSC is usually based on the clinical and radiological findings. Two thirds of the cases result from new dominant mutations. Clinical manifestations may vary, but there is no well-documented report on nonpenetrance.

The TSC1/TSC2 dimer mediates a key step in the phosphoinositide 3-kinase signaling pathway. Thereby, the TSC1/TSC2 complex is involved in the regulation of the activity of mTOR, a master controller of protein translation, integrating information on growth stimuli, cellular energy levels, nutrient availability, hypoxia, and cell growth [47, 49, 68, 79].

Mutations of the TSC1 and TSC2 genes were detected throughout the genes, with some clustering but no striking hotspots, and include inactivating nonsense, frameshift, and splice-site mutations. For TSC2, additionally in-frame deletions and large deletions involving the adjacent PKD1 gene have been reported. Somatic mosaicism occurs in a minority of patients with TSC and seems to be associated with a milder phenotype. Several studies showed that sporadic TSC2 mutations tend to be associated with a more severe phenotype than sporadic mutations of the TSC1 gene [20, 39, 46, 50]. Among patients meeting the clinical criteria of TSC, 15–20% have no identifiable mutations. These persons generally have milder clinical disease [20, 72]. Somatic mutations often involving large deletions spanning the gene (LOH) account for the majority of tumors occurring in TSC, following Knudsen's two-hit paradigm for tumor suppressor genes [30, 31, 85].

Pancreatic NETs have rarely been described in adults with TSC [21, 28, 33, 38, 41, 80]. In a case report analyzing a 6-year-old child with a de novo mutation of the TSC2 gene, who suffered from an endocrinologically silent malignant pancreatic NET, 16p13 LOH and absence of tuberin protein expression from the tumor were demonstrated [28]. These findings provide evidence for a role of tuberin in the pathogenesis of pancreatic NETs. Based on the small series of reported cases, pancreatic TSC-associated pancreatic NETs are insulinomas or endocrinologically silent. Some of them are malignant. Interestingly, in a postmortem series of nine TSC patients, one 21-year-old woman was found to have an incidental nonfunctioning pancreatic NET in association with multiple endocrine adenomas of the pituitary gland, adrenal, and parathyroid glands [38].

GEP-NETs with suspected hereditary background

Data regarding an association of GEP-NETs with other malignancies are limited. In the older literature, several studies indicated that patients with intestinal NETs are at increased risk for developing another primary malignancy [11, 45, 61]. Chen et al. [16] postulated that intestinal adenocarcinomas and intestinal NETs might have common endogenous or environmental risk factors. Kothari and Mangla [45] found that 36% of patients with ileal NETs (carcinoids) had an associated malignancy. However, these results could not be confirmed by two large population studies that included 1,029 and 245 patients from Denmark and the USA, respectively, and failed to confirm a general excess cancer risk in patients with GEP-NETs [7, 83].

Case reports described ileal and rectal NETs in first-degree relatives without any evidence of a known inherited disease [2, 56, 60, 64]. These observations were also confirmed in a large study including 245 patients with intestinal NETs in which 3.7% of patients had at least one first-degree relative with the same malignancy [7]. This rate was found to be much higher than age-adjusted incidence rates for intestinal endocrine tumors (p<0.00001 small bowel; p=0.008 large intestine). The findings of this study were confirmed by a nationwide epidemiological study from Sweden including 1,933 offspring and 4,713 parents with endocrine tumors at various sites [37]. Similar findings

were reported in four families suffering from lung NETs [63]. None of these studies identified environmental risk factors, which suggests a genetic background for the familial clustering of intestinal NETs that remains to be analyzed in detail.

Further clustering of intestinal NETs was very well established in patients with inflammatory bowel disease [13, 32, 58]. In addition, some case reports described GEP-NETs in patients suffering from familial adenomatous polyposis [40, 59]. However, for both conditions, it remains to be clarified whether and how a hereditary predisposition exists.

REVIEW AND PERSPECTIVE

Molecular profiles of gastroenteropancreatic endocrine tumors

Aurel Perren · Martin Anlauf · Paul Komminoth

Received: 11 June 2007 / Accepted: 11 June 2007 / Published online: 8 August 2007

Abstract Neuroendocrine tumors of the gastroenteropancreatic system are defined by their endocrine phenotype and share many histopathological and clinical features. However, the fact that the hormone production of tumors depends on their site of origin, that the tumors differ in their biology, and that the association with familial syndromes is nonrandom suggests heterogeneity. It is therefore conceivable that the gastroenteropancreatic neuroendocrine tumors also differ in their molecular profile. This review summarizes and discusses the available data in this field.

Keywords Gastrointestinal · Pancreatic · Endocrine tumor · Genetic · Expression array · Comparative genomic hybridization · LOH · Mutation analysis

Introduction

Well-differentiated gastroenteropancreatic neuroendocrine tumors (GEP-NETs) are defined by their capacity to express neuroendocrine markers and to produce and/or secrete peptide hormones, biogenic amines, and tachykinins.

Pancreatic endocrine tumors (PETs) may arise in association with a multiple endocrine neoplasia type 1 (MEN1), von Hippel–Lindau (VHL), or rarely neurofibromatosis type 1 (NF1) or tuberous sclerosis (TSC) syndrome, and the genes responsible for these familial diseases have been described. However, about 90% of PETs and the vast majority of gastrointestinal endocrine tumors are sporadic, and still little is known about the molecular basis of GEP-NETs.

Activation of oncogenes is rare in sporadic PETs [21, 23, 29]. Activating mutations of β-catenin were described in 37% of gastrointestinal NETs [14] but were not detected in exon 3 in a series of 15 PETs (own unpublished data). Mutations of *TP53*, *K-ras*, *p16*, *DPC4*, or *DCC*, which are found frequently in gastrointestinal adenocarcinomas, were not identified in GEP-NETs [22, 28–30, 33, 41]. CGH and loss of heterozygosity (LOH) data point toward the involvement of other chromosomal regions. In this article, we review the genetic alterations that have been identified in GEP-NETs, using ribonucleic acid expression arrays, comparative genomic hybridization (CGH), LOH, and gene mutation analysis.

Pancreatic endocrine tumors

Genome-wide analysis: RNA expression arrays

With the development of high-throughput techniques, analysis of the expression of thousands of genes in a given tumor has become possible. The use of RNA expression arrays can further our understanding of tumor classification. It can also provide signatures (gene lists classifying tumors into distinct groups) that may have prognostic implications. While this technique has led to new (sub)classifications in other tumors (lymphoma, breast cancer), only limited

results have been published for GEP-NETs. For these tumors, class comparison studies rather than class prediction or class discovery studies have been performed. Class comparison studies analyze the gene expression in groups of specimens defined by other methods such as histopathological, immunohistochemical, or clinical features. This analysis identifies genes that are differentially expressed between the different tumor types.

As biological behavior is difficult to predict in PETs, the largest published RNA expression array study on PETs compared metastasized with nonmetastasized PETs [10]. By comparing 12 localized to 12 metastasized PETs, the signature of 51 genes that are downregulated in malignant PETs and 72 that are upregulated in malignant PETs emerged. These genes were involved in pathways related to (1) angiogenesis and remodeling, (2) signal transduction through tyrosine kinases, (3) calcium-dependant cell signaling, and (4) response to therapeutic drugs.

A different approach was taken in the study by Maitra et al. [31]. In this study, transcripts from eight well-differentiated PETs were compared with transcripts of three enriched pancreatic islet cell samples with 80–90% purity. Their aim was to identify potential therapeutic targets and novel tumor markers in PETs. None of the patients had an associated endocrine hypersecretion syndrome; therefore, all eight tumors were nonfunctioning tumors. One of the tumors revealed somatostatin expression. Two tumors had lymph node metastases and measured 2 cm or less in diameter. The authors described 66 transcripts with threefold overexpression in PETs and 119 underexpressed transcripts. The underexpressed genes included cell cycle checkpoint proteins (p21, MICT) and genes involving deoxyribonucleic acid (DNA) damage repair and genomic stability (*O*-methylguanine DNA-methyltransferase and GADD 45). The number of differentially expressed genes was rather low in this study. One reason might be the applied high threshold of "threefold change" and the other, the selection of tumor types. The group of nonfunctioning tumors might be a potpourri of PETs expressing hormones at low levels. Furthermore, the study included many large tumors that may have accumulated extensive genetic changes, at least as expected from CGH studies. While the aim of the study to detect therapeutic markers is not yet accomplished, these gene lists will provide useful candidate genes for further detailed analyses.

In a second study, this group extended their analysis to the differential expression of genes in well-differentiated metastatic and nonmetastatic PETs [18]. The expression profiles of seven metastatic PETs were compared with the profiles of five nonmetastatic PETs. Sixty-five transcripts were overexpressed, and 57 transcripts were underexpressed in metastatic PETs compared to nonmetastatic ones. In this attempt to find a progression model from nonmetastatic to metastatic PETs, the gain of function of genes involved in growth regulation, cholesterol homeostasis, osmotic regulation, and hypoxia-inducible factors were described. Underexpression of genes involved in cell cycle regulation, developmental regulation, and DNA damage repair was described. Theses two studies showed a continuum of upregulation of IGFBP3 from normal islets to nonmetastasizing PETs and to metastasizing PETs. Malignant tumors showed an overall pathway activation of the insulin-like growth factor-signaling cascade, but the underlying mechanisms still have to be elucidated.

The rate of differentially expressed genes described was dramatically higher in the study by Carpuso et al. [7]. Comparing RNA extracts of 13 nonfunctioning PET (NF-PET) samples (eight primaries and five metastases) to extracts of four isolated islet preparations, they found 990 differentially expressed individual genes. Only 20 of the reported 667 upregulated genes were also described in the aforementioned similar studies (fibronectin [31], elongation of very long fatty acid-like 2 [6], coagulation factor V [18], and mitogen activated protein kinase 3 [17]). The authors described a striking similarity between primary malignant PETs and their metastases concerning their genetic profile: Metastases clustered with their corresponding primary tumors in most instances. This is evidence that the metastatic potential is acquired in an early stage of tumor transformation because cells of the primary tumor already carry the metastatic signatures.

Shalev et al. [42] compared isolated islets with and without glucose challenge. Fourteen genes were upregulated by glucose in all three independent experiments, and only six genes were downregulated. The authors were able to show that upregulation of transforming growth factor β (TGFβ) signaling was induced by glucose. As TGFβ is also known to be involved in differentiation, this raises the intriguing possibility that there might be crosstalk between glucose metabolism, development, and the immune system in human pancreatic islets.

The research on PETs using expression array techniques has only recently started, and it is anticipated that significant results will be published in the years to come. Future studies comprising larger numbers of well-characterized tumors are needed, and class prediction studies rather than simple class confirmation studies will allow the identification of subsets of endocrine tumors that are caused by different genetic changes and that might therefore respond to targeted therapies.

Genome-wide analysis: CGH studies

Four conventional CGH studies included a total of 102 PETs. These studies indicate that chromosomal losses occur slightly more frequently than gains, whereas amplifications

are uncommon [45–47, 58]. Genetic alterations seem to accumulate during tumor progression: The total number of genomic changes per tumor appears to be associated with both the tumor volume and the stage of the disease [46] Thus, large and/or malignant tumors and especially metastases harbor a larger number of genetic alterations than small and clinically benign neoplasms [46, 58] These findings point toward a tumor suppressor pathway and chromosomal instability as important mechanisms associated with malignancy in PET. These data have recently been confirmed for insulinomas in a large array CGH analysis studying 30 insulinomas. At least 20 chromosomal alterations and six telomeric losses were the best predictors of malignancy [26]. The alterations described are not randomly distributed on chromosomes but are particularly common in distinct chromosomal regions. Gains are common on 4pq (17% of the tumors), 5q (25%), 7pq (41%), 9q (28%), 12q (23%), 14q (32%), 17pq (31%), and 20q (27%), whereas genomic losses frequently occur on 1p (21%), 3p (19%), 6q (28%), 10pq (14%), 11q (30%), Y (31%), and X (31%) [45–47, 58]. Furthermore, genomic alterations in some chromosomal regions appear to be associated with the stage of the disease and, additionally, with particular tumor types. For example, losses of chromosome 1 and 11q as well as gains of 9q appear to be early events in the development of PETs because they are already present in many small tumors (<2 cm) [46]. Some defects, e.g., losses of 3p, 6pq, and 10pq and gains of 5q, 12q, 18q, and 20q, were shown to be associated with malignant behavior [2, 3, 46], whereas gains of chromosomes 4 and 7 in the presence of losses of 21q prevailed in metastases [58].

Insulinomas exhibit a lower number of genomic alterations than other PETs [45–47, 58]. Insulinomas often have chromosomal aberrations consisting of a gain of 9q32 and loss of 22q13.1, which may occur in the same tumor and appear to be early genetic events in these tumors [25]. Losses of 3p and 6q associated with malignancy are particularly rare in insulinomas [2, 3]. Malignant insulinomas, in contrast, harbor a large number of chromosomal alterations similar to that seen in other types of malignant PET [26].

In pancreatic gastrinomas, only limited chromosomal imbalances are encountered: Losses at 3p and 18q21 occur in approximately 33 and 22% of cases, respectively [46, 47, 58]. It is interesting to know that 18q losses are also common in gastrointestinal NETs, indicating that NETs and pancreatic gastrinomas might be related. NF-PETs in general harbor higher numbers of chromosomal gains and losses than functioning tumors. These genetic aberrations occur in chromosomal loci frequently involved in malignant tumors [58]. Gains of chromosome 4 and losses of 6q appear to be early events because they are already detectable in 40 and 50% of tumors with a diameter of less than 2 cm [46].

Loss of heterozygosity and mutation analysis

Analyses of LOH using polymerase chain reaction microsatellite markers identify the same chromosomal regions as those described by CGH. The rate of alterations detected by microsatellite analysis is, however, approximately twice that of the allelic losses detected by CGH. In the regions 3p23, 6q22, 9p, 11q13, 18q21, and 22q12.1, the differences are even more pronounced, indicating that small deletions that are not detectable by CGH may be involved [2, 3, 16, 19, 20, 32, 33, 37, 41, 59]. These regions displaying losses might harbor tumor suppressor genes involved in the initiation and progression of PETs. However, only a few candidate genes have been thoroughly investigated, and many genes remain to be tested.

The most important candidate gene is the *MEN1* gene. We know that almost all PETs in MEN1 patients, including microadenomas show allelic loss of the wild-type allele [19, 34, 51]. However, somatic mutations of the *MEN1* gene located on 11q13 are detectable in only 21% (33 of 155) of sporadic PETs [11, 16, 32, 43, 53, 59]. When PETs are stratified according to the hormonal syndrome they cause, the rate of *MEN1* mutations varies considerably between the subgroups. Thus, *MEN1* mutations are only detected in 7.7% (5 of 65) of insulinomas and 8% (2 of 26) of NF-PETs. In contrast, gastrinomas, glucagonomas, and VIPomas show a higher mutation rate of 37, 67, and 44%, respectively [11, 15, 16, 32, 43, 53, 56, 59].

In contrast to the low rate of 21% *MEN1* mutations, 68% of all PETs exhibit losses at 11q13 and/or of more distal parts of the long arm of chromosome 11, indicating that there might be a haploinsufficiency of the *MEN1* gene or that the other allele might be inactivated by epigenetic mechanisms. CpG island methylation in the *MEN1* promoter, however, was not identified [8]. Another explanation for this high rate of LOH is that further, yet unknown tumor suppressor genes in this region might be involved [11, 12, 16, 32, 43, 53, 59]. An important role of the *SDHD* gene (one of the candidate genes on 11q23) in the pathogenesis of PETs and other endocrine tumors has recently been excluded [35].

Another familial syndrome associated with PETs is VHL. Intriguingly, somatic *VHL* gene mutations have been detected in only 1 of 22 sporadic PETs, despite the high LOH rate on 3p25, indicating that the gene is less frequently involved than expected [9, 32]. NF1 and TSC patients may also develop PETs. However, the role of the *NF1* and *TSC1/2* genes in sporadic tumors has not been examined so far.

Several other tumor suppressor genes or oncogenes have been examined in PETs. These genes include *p16*, *PTEN*, *k-RAS*, and *p53*, which are only occasionally mutated and therefore seem to be of minor importance [5, 26, 33, 36, 41, 54]. *RET*, *hZAC*, *BRAF*, and *SMAD3* have been excluded as candidate genes [28, 38, 44, 49]. Furthermore, we recently were unable to detect any somatic mutation of the *HRPT2* gene on 1q25 in 25 examined PETs (unpublished observations).

The role of *DPC4/Smad4* in sporadic PETs also seems to be of minor importance. The high mutation rates described by one group [4] could not be confirmed by subsequent studies on a larger number of tumors by several other groups [30, 33, 37]. The classical tumor suppressor genes *PTEN*, *p53*, and *DPC4* are only rarely mutated, mostly in malignant tumors, and alterations of these genes therefore most likely represent late events in PET progression.

Gastrointestinal endocrine tumors

Genome-wide analysis

Knowledge about the genetic background of sporadic gastrointestinal NETs is even sparser than that of PETs. No results of RNA expression array analyses have been reported so far. Only three studies using CGH [50, 57] or 131 microsatellite LOH markers [30] examined genome-wide allelic imbalances in gastrointestinal NETs. The average number (2.9) of genomic changes was lower in gastrointestinal NETs than in PETs, and there was no clear correlation between the number of aberrations and tumor stage [57]. Furthermore, the number of different chromosomes involved was low, genetic alterations apparently being concentrated on chromosome 18. The study by Zhao et al. [57] described losses of the entire chromosome 18 or of its long arm in 38% of gastrointestinal NETs, whereas others reported these losses to occur in 50 [50] or even in 88% of tumors [30]. The high percentage reported by Lollgen et al. [30] is based on microsatellite LOH analysis, in which small deletions are detected with a higher sensitivity than obtained by CGH. The loss of chromosome 18 in gastrointestinal NETs is strong evidence that important candidate tumor suppressor genes are located on this chromosome. Most of these genes are most likely located on the long arm of chromosome 18.

In the three aforementioned studies [30, 50, 57], significant genetic differences between bronchial NETs, gastrointestinal NETs, and PETs were described, suggesting a different genetic background for these tumor groups. For example, losses of chromosome 18 are rare in bronchial tumors and PETs, whereas losses of chromosome 11 are common [57]. Furthermore, losses of 9p, which are detectable in 50% of gastrointestinal NETs, are rare in PETs, which in contrast more frequently exhibit gains of 17q and losses of 11q.37.

LOH and mutation analysis

The candidate genes *DPC4*, *DCC*, and *Smad2* were investigated because of the frequent allelic loss on 18q (88% of gastrointestinal NETs) [30] but were found to be unaltered in a small series of tumors. In the study by Lollgen et al. [30], all eight examined gastrointestinal NETs contained a wild-type C-terminal *DPC4* sequence encoded by exon 8–11 and conserved DPC4 protein expression as demonstrated by immunohistochemistry [30]. In our study on 21 gastrointestinal NETs, *DPC4* and *DCC* mutations were not detected using single-strand conformation polymorphism analysis (unpublished observations). Therefore, other possible tumor suppressor genes located on chromosome 18 remain to be investigated.

Patients suffering from MEN1 often develop NETs; most of which are localized in the duodenum and the stomach. Allelic loss of the corresponding chromosomal arm 11q has been detected in these types of endocrine tumors associated with the MEN1 syndrome. LOH of 11q is also consistently found in a subset of sporadic endocrine tumors of various localizations, although the observed LOH frequency varies. Although it is very low in the ileum (14% of tumors), it amounts to 25% in the ascending colon, to 30% in the pancreas and stomach, to approximately 50% in NETs of the descending colon and rectum, and to 60% in the duodenum [13, 15, 16, 24, 30, 56].

Enterochromaffin-like (ECL)-cell gastric NETs associated with chronic atrophic gastritis (type I gastric NETs) arise in association with ECL-cell hyperplasia and are often multiple [40]. LOH of 11q was present in only one of six such tumors examined. In the setting of the MEN1 syndrome, *MEN1* LOH, however, occurred in 15 of 20 type II gastric NETs arising in patients with a Zollinger–Ellison syndrome because of duodenal gastrinomas [13]. Two examined sporadic gastric NETs (type III gastric NETs) exhibited allelic loss of 11q microsatellite markers [16].

With the exception of sporadic gastrinomas, only few gastrointestinal NETs have been examined for *MEN1* gene mutations. The *MEN1* mutation rate in sporadic gastrinomas was high (31%). This ratio was comparable to that found in PETs [15]. This is not surprising, as duodenal gastrinomas and PETs are both classical MEN1-associated tumors. Somatic *MEN1* mutations have also been detected in a small subset of NETs of the ileum (one of four tumors examined) and colon, indicating that these mutations are not restricted to foregut NETs but may also occur rarely in midgut and hindgut tumors [16].

The tumor suppressor genes *p16* and *TP53* have also been investigated in NETs. Like in PETs, no mutations of the *p16* tumor suppressor gene have been identified. However, a 5′ CpG island of the p16 gene promoter was methylated in 52% of gastrinomas [41] and in other types of gastrointestinal NET [8]. Furthermore, methylation of *p16* was significantly more frequent in NETs than in PETs and thus represents an additional molecular difference between the two tumor groups [8]. It is interesting to know that a recent study also described higher rates of promoter methylation of the *APC*, *MEN1*, *HIC1*, and *RASSF1a* genes in gastrointestinal NETs [1]. This is good evidence that CpG island methylator phenotype (CIMP) is frequent in gastrointestinal NETs. Microsatellite instability does not occur in PETs or gastrointestinal NETs, and the *hMLH1* gene is not methylated [1, 27]. The high rate of *RASSF1a* promoter methylation might explain the frequent expression of extracellular signaling-related kinase (ERK) 1/2, an important downstream point of convergence in the ras-RAF-mitogen-activated protein ERK pathway [49].

Accumulation of the *TP53* protein was detected by immunohistochemistry in only one duodenal gastrinoma with an identified 17p loss and thus seems to be a rare event in NETs [50]. However, in 25% of goblet cell carcinoids of the appendix, *TP53* mutations were reported to occur [39]. The most frequently reported mutated gene in gastrointestinal NETs is β-*catenin*. Mutations in exon 3 of this gene protecting the corresponding protein from phosphorylation and degradation have been reported in 38% (27 of 72) of NETs [14].This leads to cytoplasmic and nuclear accumulation of β-*catenin* (demonstrated by immunohistochemistry) in 79% of these tumors, indicating other, yet unknown, mechanisms of accumulation of this protein. Only one of these 72 tumors (1.4%) displayed a mutation of the APC gene. However, the rate of gastrointestinal NETs with nuclear translocation of β-*catenin* was only 30% in a later study, and exon 3 mutations were absent [48]. The reported overexpression of cyclin D1 and c-*myc* [52] may be a downstream effect of the alterations of the Wnt signaling pathway. Other examined oncogenes appear to be of minor importance. Hardly any tumors show amplifications of the *HER2* gene [50], and in contrast to gastrointestinal adenocarcinomas, no *K-Ras* mutations were detected in gastrointestinal NETs [55] (Table 1).

Conclusion and perspective

The available molecular data indicate that the tumorigenesis of well-differentiated GEP-NETs differs from that of their nonendocrine counterparts. This is supported by results of CGH, LOH, and mutation analyses that point to different genetic pathways leading to the formation of GEP-NETs. In addition, subgroups of GEP-NETs appear to have special genetic pathways. PETs (especially NF-PETs, glucagonomas, and VIPomas) show a higher average number of chromosomal aberrations and allelic losses than gastrointestinal NETs. RNA expression analysis describes deregulation of cell cycle checkpoint proteins as well as genes

Table 1 Genetic changes frequently found in GEP-NETs

GEP-NET Gastroenteropancreatic neuroendocrine tumor, *PET* pancreatic endocrine tumor, *D* duodenal endocrine tumor, *I* ileal endocrine tumor, *gasNET* gastrointestinal neuroendocrine tumor, *CIMP* CpG island methylator phenotype, *MSI* microsatellite instability

involved in DNA damage repair and genomic stability. It will be an important task to find the underlying cause of chromosomal instability (that is particularly observed in malignant PETs and less pronounced in benign insulinomas and duodenal gastrinomas) because this might identify new therapeutic targets. Furthermore, some chromosomal loci are preferentially altered in NETs: Gastrointestinal NETs frequently show 18q losses, while PETs commonly exhibit 11q losses involving the *MEN1* gene. Because PETs, in particular insulinomas and NF-PETs, only rarely harbor somatic *MEN1* mutations and there is no known tumor suppressor gene on 18q, the 11q and 18q losses may suggest that potential new tumor suppressor genes are located in both chromosomal areas. *MEN1* gene deletions are very rare in ileal and appendiceal NET, as are somatic *MEN1* mutations. Additional differences between PETs and gastrointestinal NETs concern the tumor suppressor gene p16 and β-*catenin* as well as the CIMP pathway (Table 1, bottom). p16 is more frequently methylated and β-*catenin* more often mutated in gastrointestinal NETs than in PETs, and gastrointestinal NETs more often exhibit alterations associated with the CIMP pathway, whereas advanced PETs frequently reveal chromosomal instability. Taken together, these data may explain why GEP-NETs, depending on their site of origin and phenotype, differ in their biological behavior and, in addition, stress the importance of classifying endocrine tumors according to their localization and hormone production.

Current results combined with those obtained by new technologies, such as DNA and RNA expression and tissue arrays, will probably result in a more clear-cut picture of the molecular background of the oncogenesis and progression of GEP-NETs. These findings, in turn, might subsequently lead to precisely tailored diagnostic and therapeutic strategies in the near future.

Acknowledgments This work was supported in part by the National Science Research Foundation (31-618845.00; AP and PK). The authors would like to thank Professor Günter Klöppel and Mrs. Kay Dege for critical reading and editing the manuscript and Parvin Saremaslani, Tamara Locher, Claudia Bonvin, and Sonja Schmid for their excellent technical support.

Conflict of interest statement We declare that we have no conflict of interest.

REVIEW AND PERSPECTIVE

Peptide receptor expression in GEP-NET

Jean Claude Reubi

Received: 11 May 2007 / Accepted: 6 June 2007 / Published online: 8 August 2007

Abstract Numerous peptide receptors have recently been reported to be expressed or overexpressed in various human cancers. For instance, somatostatin receptors are particularly frequently expressed in gastroenteropancreatic neuroendocrine tumors (GEP-NET), including both primaries and metastases. The density is often high, and the distribution is usually homogenous. While various somatostatin receptor subtypes can be expressed in these tumors, the sst_2 is clearly predominant. These receptors represent the molecular basis for a number of clinical applications, including symptomatic therapy with octreotide in hormone-secreting GEP-NET, in vivo diagnostic with radiolabeled diethylene triamine pentaacetic acid octreotide (Octreoscan) to evaluate the extend of the disease, and ^{90}Y- or ^{177}Lu-[^{90}Y-DOTA]-D-Phe^{1}-Tyr^{3} octreotide radiotherapy. GEP-NET can, however, express peptide receptors other than somatostatin receptor: Insulinomas have more glucagon-like peptide 1 receptors than somatostatin receptors; gastrinomas express very high levels of secretin receptors. GEP-NET may also express cholecystokinin 2, bombesin, neuropeptide Y, or vasoactive intestinal peptide receptors. Often, several of these peptide receptors are expressed simultaneously in GEP-NET, providing a molecular basis for in vivo multi-receptor targeting of those tumors.

Introduction

In the past decade, there has been increasing evidence for peptide receptor expression on various human cancers [15]. This observation has permitted to develop in vivo peptide receptor targeting of these tumors, for diagnostic and/or therapeutic purposes [12, 13, 15]. The best evidence has been provided for somatostatin receptors expressed in neuroendocrine tumors, which can currently be targeted with ^{111}In diethylene triamine pentaacetic acid octreotide for their in vivo localization or with ^{90}Yttrium- or ^{177}Lutetium-[^{90}Y-DOTA]-D-Phe^{1}-Tyr^{3} (DOTATOC) for targeted radiotherapy [12]. Somatostatin receptor scintigraphy has been shown to be the diagnostic tool of first choice for a subgroup of gut neuroendocrine tumors, as it was superior to all other conventional imaging methods [6], and radiotherapy with ^{90}Y-DOTATOC appears extremely promising in tumors expressing somatostatin receptors, with more than 25% remissions and about 50% disease stabilization [10, 14, 23, 25]. More recently, other peptide receptors have emerged as being overexpressed in selected tumors [15] and appear to have a promising in vivo targeting potential. These are bombesin receptors of the BB_2 subtype, better known as gastrin-releasing peptide (GRP) receptors, which are overexpressed in prostate and breast cancers [15] and can be visualized in vivo in these tumors [22, 24]. Furthermore, cholecystokinin (CCK) 2 receptors expressed in medullary thyroid carcinomas [15] can be selectively targeted in vivo [1, 11], and more recently, neurotensin receptors were visualized in exocrine pancreatic carcinomas [2].

Extensive information on in vitro peptide receptor expression including incidence, density, and subtype characteristics in tumors is required before a novel peptide receptor is chosen as target for in vivo clinical investigations in tumor patients. The aim of the present article is to

review the in vitro evidence for the expression of several regulatory peptide receptors in cancer tissues with morphological methods, including receptor autoradiography and immunohistochemistry. It will focus on human gastroenteropancreatic neuroendocrine tumors (GEP-NET) and somatostatin receptors but will also expand to other peptide receptors such as vasoactive intestinal peptide (VIP), CCK, bombesin, neuropeptide Y (NPY), neurotensin (NT), corticotropin-releasing factor (CRF), and glucagon-like peptide (GLP-1) receptors.

Somatostatin receptors in GEP-NET

GEP-NET are generally known as a group of tumors expressing frequently somatostatin receptors. Table 1 summarizes the main features that are explained in more detail further in the text. There are several possibilities to detect somatostatin receptors morphologically in tissue sections [15]. One possibility is in situ hybridization, which, however, identifies the messenger ribonucleic acid and not the protein. Another possibility is autoradiography that identifies the receptor binding site (protein) that can be pharmacologically characterized and quantitatively assessed. It is a highly sensitive and specific method. Recently, it has been improved to identify the five somatostatin receptor subtypes by using subtype-selective analogs [18]. One drawback is, however, that in vitro autoradiography does not have a very high resolution. A method analyzing the protein with a higher resolution is receptor immunohistochemistry, which, while dependent on a high quality antibody, can precisely identify membrane-bound receptors in formalin-fixed tissues [16].

It is not sufficient to know whether a tumor is somatostatin receptor positive or negative; it is also necessary to assess its density, its distribution, and its somatostatin receptor subtype profile. GEP-NET can have a wide variability of somatostatin receptor density among individuals, ranging from low density, as found in lymphomas, to high density, as seen in meningiomas, medulloblastomas, or growth hormone adenomas. In the majority of the cases, GEP-NET belong preferably to the group of tumors with a high density range of receptors. Both pancreatic NET (including gastrinomas, glucagomas, vipomas) and gut NET (foregut, midgut, and hind gut tumors) can express somatostatin receptors in 80–100% of the cases. Insulinomas have a lower incidence (50–70%). In general, the somatostatin receptors are expressed homogeneously in these tumors, a characteristic that represents an advantage in view of an optimal in vivo targeting of as much tumor cells as possible during peptide receptor radiotherapy. Worth mentioning is also the differentiation-dependent expression of somatostatin receptors. Well-differentiated tumors express usually somatostatin receptors, while undifferentiated GEP-NET may not [17]. Such observations are relevant in regard to therapeutic options [9]. The existence of five sst subtypes has made the evaluation of somatostatin receptors in tumors quite complex. There is consensus, based on various methodologies, that GEP-NET can often express more than one sst subtype; moreover, sst_2 is usually the most prominent, followed by sst_1 and sst_5, while sst_3 is less frequent and sst_4 almost absent [15, 18]. Because excellent sst_2-selective antibodies are now available, the sst_2 receptors can conveniently be assessed by immunohistochemistry on formalin-fixed tissues [7, 16, 21]; if frozen tissue is available, receptor autoradiography using subtype-selective analogs is the method of choice to identify the five sst subtypes.

In clinical practice, in vivo Octreoscan scintigraphy has become the method of choice to evaluate the somatostatin receptor status in the great majority of GEP-NET patients. It is a sensitive, specific, and noninvasive method giving receptor information for the patient's whole body. However, next to in vivo scintigraphy, the in vitro somatostatin receptor evaluation of tumors remains in specific cases an important additional current diagnostic option. It may simply be used as a complementary and confirmatory method to Octreoscan, providing information on sst subtypes, tissue localization, and on receptor homogeneity. It may replace Octreoscan if Octreoscan is not available or uneasy to interpret. The somatostatin receptor status can be established in vitro, either immunohistochemically in the formalin-fixed resected tumor using appropriate antibodies [7, 16, 21] or, if frozen tumor tissue samples have been secured, by somatostatin receptor autoradiography [17].

Table 1 Somatostatin receptor expression in GEP-NET

Main features	Characteristics
Receptor incidence	80–100% (Most pancreatic and gut NET) 50–70% (Insulinomas)
Receptor density	predominantly high
Receptor distribution	predominantly homogeneous
Receptor expression	differentiated tumor>undifferentiated tumor
Receptor subtype	$sst_2 >> sst_1 = sst_5 > sst_3 >> sst_4$
Receptor localization	usually membrane bound (sst_2)

Other peptide receptors in GEP-NET

Although somatostatin receptors have been found to be extremely useful targets for the diagnosis and therapy for a majority of GEP-NET, it is worth summarizing the data available for other regulatory peptide receptors in this type of tumors, as they may potentially play an equally important role. Indeed, several peptide receptors are

Table 2 Selection of peptide receptors expressed in GEP-NET (see text for detail)

Somatostatin receptors
GLP-1 receptors
Secretin receptors
Cholecystokinin receptors
VIP receptors
Bombesin receptors
CRF receptors
NPY receptors

expressed in selected GEP-NET in much higher incidence and/or density than somatostatin receptors [18].

GLP-1 receptors

This is the case for GLP-1 receptors in insulinomas, which are expressed in virtually all cases in extremely high concentrations. We have identified several examples of insulinomas with a high density of GLP-1 receptors but no sst_2 receptors [18]. Furthermore, gastrinomas express GLP-1 receptors with a very high incidence but a lower density than insulinomas. One third of carcinoids have a low to moderate GLP-1 receptor density, as well as half of the four tested glucagonomas [18].

CCK receptors

CCK receptors are also widely expressed in GEP-NET. Virtually all insulinomas express CCK_2 receptors, often in high amounts, but no CCK_1 receptors [18]. More than half of the ileal carcinomas express CCK_2 receptors, and one third expresses CCK_1 receptors [18]. In several cases, both receptor subtypes are expressed concomitantly. Half of the gastrinomas express CCK_1 but not CCK_2 receptors.

VIP receptors

Virtually all ileal carcinomas and insulinomas and a large proportion gastrinomas and glucagonomas express $VPAC_1$, while $VPAC_2$ is absent [18].

Bombesin receptors

While bombesin receptors are rarely detected in insulinomas, gastrinomas express frequently the GRP receptor subtypes (BB_2), while ileal carcinoids preferentially express the neuromedin B receptor subtype (BB_1) [18].

NPY receptors

NPY receptors have been identified in two thirds of ileal carcinoids and one fourth of pancreatic carcinoids, in a relatively low density however (Körner and Reubi, unpublished data).

Secretin receptors

Secretin receptors are expressed in extremely high amounts in the great majority of gastrinomas cases [8]. These wild-type secretin receptors are likely to be responsible for the positive secretin provocation test in Zollinger–Ellison syndrome [5]. However, these receptors can be silenced if, exceptionally, they are expressed concomitantly with a misspliced variant with exon 3 deletion [4].

CRF receptors

Only one study has investigated CRF receptors in GEP tumors, where only endocrine pancreatic tumors were analyzed: 6 of 15 insulinomas express CRF_2 receptors, while glucagomas and gastrinomas rarely express CRF_1 or CRF_2 receptors [20].

NT receptors

GEP-NET have not been found to express significant amounts of NT receptors [19].

Multiple receptors

It is now well documented that a large proportion of GEP-NET can express concomitantly several peptide receptors that could be used as targets simultaneously. Insulinomas often express CCK_2, GLP-1, sst_2, and $VPAC_1$ receptors simultaneously. Gastrinomas are characterized not only by a very high incidence and density of sst_2 and secretin receptors but also a high incidence of GLP-1 receptors and a marked expression of GRP receptors [18]. The coexpression of multiple receptors in human GEP-NET may be biologically relevant [18]. Indeed, many of the involved peptides, e.g., GRP, CCK, VIP, SS, somatostatin secretin, are known to have growth stimulatory or inhibitory properties [15]. Many of these peptides will affect tumor growth, depending on the individual receptor profile of the tumor. Peptide receptor coexpression may also have clinical implications. The concomitant application of multiple radioligands may be extremely attractive to improve the efficacy of peptide targeting in tumors; it will selectively increase the accumulation of radioactivity in the tumors, an advantage not only for diagnostic but especially for radiotherapeutic purposes. Specifically, GLP-1 and CCK_2 receptors may be highly efficient targets in all insulinomas, and the use of a mixture of sst_2, secretin, GLP-1, and GRP radioligands could offer optimal targeting of gastrinomas. As some of the receptors are nonhomoge-

neously expressed by tumors, such as CCK_1 and CCK_2 in ileal carcinoids [18], a combination of the corresponding receptor-selective radiopeptides may further improve the targeting efficacy during radiotherapy by destroying more than one receptor-expressing tumor area. Furthermore, a cocktail of different peptides may possibly reduce the risk of a loss of efficacy during peptide radiotherapy that may be due to tumor dedifferentiation with a resulting loss of some but not all peptide receptors. Finally, an advantage of using a cocktail of radioligands is the possibility to label each of them with different isotopes namely, with β-emitters of different ranges to obtain an optimal radiotherapy for large and small tumoral lesions [3]. Whenever possible, before the concomitant use of several radiopeptide ligands in vivo, it would be worth determining the individual peptide receptor affinity profile of the tumor under consideration, by in vitro receptor determination using the previously described methodology in a surgically resected biopsy sample.

Conflict of interest statement We declare that we have no conflict of interest.

REVIEW AND PERSPECTIVE

Neuro-endocrine tumours of the lung. A review of relevant pathological and molecular data

Luisella Righi · Marco Volante · Ida Rapa · Giorgio V. Scagliotti · Mauro Papotti

Received: 28 May 2007 / Accepted: 6 June 2007 / Published online: 8 August 2007

Abstract Neuroendocrine (NE) tumours of the lung include pure and mixed forms. In the former group, a continuum of lesions is recognised ranging from benign typical carcinoids to atypical carcinoids (having a low-grade behaviour, although often associated with regional and distant metastases), to the highly aggressive poorly differentiated carcinomas of the small and large cell types. In the mixed tumour group, the NE component is extensively represented in association with any of the non-small cell carcinoma subtypes (so-called combined carcinomas), or the NE component is restricted to a cell population scattered among adenocarcinoma cells (or more rarely within squamous or large cell carcinomas). The molecular profile of NE tumours has been widely investigated to identify features helpful for the diagnosis, prognosis and even therapy for this special lung tumour category. Specific chromosomal alterations, oncogene mutations and cell cycle molecule disregulation has been documented in NE tumours of the lung, as well as the expression of specific receptors or enzymes implicated in the response to biotherapies or to chemotherapeutic agents. The "molecular classification" of NE tumours should be integrated to morphology, for a better definition of the different histological types and a more appropriate selection of the therapeutic strategy.

Keywords Lung · Neuroendocrine · Carcinoid · Small cell carcinoma · Classification

Introduction

Neuroendocrine tumours (NET) of the lung share most morphological and clinical features observed in neuroendocrine (NE; carcinoid) tumours of other organs, e.g. pancreas and intestine. Similarly, pulmonary NETs do not constitute a single, uniform entity but build up a spectrum of NE differentiated lesions associated to specific pathological features on the one side and to a variable clinical behaviour on the other. Typical carcinoids (TC) and atypical carcinoids (AC), as well as poorly differentiated NE carcinomas of the large and small cell types were identified.

Appropriate diagnostic and classification criteria, of high clinical and prognostic value, have been established for NETs of the lung, although a precise "functional" classification of these tumours, in terms of hormonal production, is still lacking. As a consequence, only "common" NE markers are of diagnostic significance in the definition and identification of pulmonary NETs. Among such markers, chromogranins/secretogranins are of major interest. Their detection by specific anti-bodies or by molecular procedures (to reveal the specific mRNA) is not only of diagnostic importance, but it allows drawing of information on cell metabolism and on the storage or release of neurosecretory granules as well. Chromogranin A (CgA), the most widely and intensely expressed member of the family, is stored in high amounts in carcinoids and to a variable extent in poorly differentiated NE carcinomas.

This review will briefly summarise the current diagnostic criteria of each single type of pulmonary NET (both pure and combined forms) with special reference to difficult issues for the differential diagnosis, and will finally

consider the phenotypic and molecular data having a pathological and/or clinical relevance.

NE cells in normal lung and in non-neoplastic conditions

Normal NE cells (also called Kulchitsky cells) of the bronchial tree occur solitarily or in small aggregates, so-called neuroepithelial bodies, within the ciliated epithelium [17]. Lung NE cells produce a variety of peptides such as serotonin, bombesin/gastric releasing peptide, calcitonin and the recently identified ghrelin [60], while in hyperplastic or neoplastic conditions, adrenocorticotropic hormone (ACTH), vasoactive intestinal peptide or somatostatin productions have been reported [9].

A role of NE cells in lung development, growth and repair has been suggested based on their increased expression levels in infants with pulmonary dysplasia, cystic fibrosis or prolonged assisted ventilation [52].

NE cell hyperplasia is a microscopic finding only that displays three different patterns including: (1) increased number of scattered NE cells, (2) linear proliferations along the bronchial mucosa and (3) nodular hyperplasia in the mucosa. Most cases are idiopathic ("diffuse idiopathic pulmonary NE cell hyperplasia," associated with obliterative bronchiolar fibrosis in the absence of known causes of interstitial or airway fibrosis or inflammation) [28], while others may be incidentally found in chronic bronchial inflammation [42], Langerhans cell hystiocytosis [2] or bronchopulmonary dysplasia [16].

At the extreme of this spectrum, the term "tumourlet" defines NE cell proliferations that extend beyond the basal membrane of bronchi and bronchioles, having a size less than 5 mm and a dense fibrous stroma surrounding cell clusters.

NE tumours

The WHO classification of NETs of the lung has combined architectural patterns (e.g. organoid growth vs small cell diffuse growth) with other parameters, with the mitotic index and the presence of necrosis as the two most relevant, for the purpose of recognising the four different categories proposed in the spectrum of pure NETs of the lung (Table 1).

Typical carcinoid

TC represents less than 1% of lung tumours. As opposed to other NE lung tumours, it is not related to smoking and develops in adults (mean age of 55 years) with an equal male/female distribution. The most common location is in the large airways, presenting as a polypoid mass, which protrudes in the bronchial lumen. Several histo-morphologic patterns can be recognised, most often in combination. Tumour cells are polygonal, with abundant, finely granular and eosinophilic cytoplasm. Nuclei show clumped open chromatin and small dark nucleoli. The growth pattern is most often trabecular with cords or ribbons of tumour cells dispersed in a delicate fibrovascular stroma. More rarely, spindle cell, acinar or glandular patterns, with occasional oncocytic and clear cell changes, can be recognised.

Necrosis is always absent and mitosis are less than 2×10 high power fields (HPF): both features are essential to differentiate TCs from other NE lung tumours of higher grade (see also Table 1).

Spindle cell variety of TC should be distinguished from nerve sheath proliferations and haemangiopericytomas, defined by S-100 protein and vascular markers immunoreactivity, respectively, in contrast to the presence of NE markers in TCs. Carcinoids having glandular formation may be hardly distinguished from well-differentiated adenocarcinomas, especially when mucin secretion is observed. Clear cell changes may resemble clear cell (sugar) tumours, which are invariably positive for CD34 and HMB45 and lack NE markers.

Atypical carcinoid

AC represents nearly 10% of NE lung tumours, even if different series are difficult to compare because, in some of them, large cell NE carcinomas (LCNEC) are included in

Table 1 Differential pathological findings in NE lung tumors

	Typical carcinoid	Atypical carcinoid	Large cell NE carcinoma	Small cell carcinoma
Organoid pattern	Characteristic	Characteristic	Present, less extensive	Absent
Cell size	Large	Large	Large	Small
Cytoplasm	Abundant	Abundant	Abundant	Scanty
Nuclear pleomorphism	Usually absent	Occasionally present	Present	Present
Prominent nucleoli	No	No	Yes	No
Mitoses (x10 HPF)	<2	2–10	>10 (mean 70)	Mean 70
Necrosis	Absent	Usually focal	Extensive	Extensive
Approximate 5-year survival	100%	70%	25%	<10%

this same group. ACs are more often associated with cigarette smoking, they have a male pre-dominance and are more frequently peripherally located, compared to TCs. Conversely, they share the same morphologic, cytologic and architectural features as TCs (Fig. 1), and the correct diagnosis of the two forms may be difficult, especially in small biopsies. As already mentioned, the main differential criteria are the presence of necrosis and a higher mitotic count (2–10 × 10 HPF) in ACs. Necrosis has a peculiar focal, punctate, sharply demarcated appearance. Focal nuclear pleomorphism may also occur. It has to be considered that up to 20% of ACs may lack NE markers. Peripherally located tumours more frequently show spindle cell appearance and smaller cell size. These cases have to be separated from small cell carcinomas, which usually have a higher mitotic count, a dense and uniform nuclear chromatin, and extensive necrosis. The distinction between ACs and LCNECs is even more difficult and will be discussed in the next paragraph.

Large cell NE carcinoma

LCNEC was recognised in 1991 as a separate entity [54] based on the observation that a group of highly aggressive NE lung carcinomas exists, apart from the well-known small cell (oat cell) carcinoma. Because these tumours maintain at least in part the organoid and trabecular growth patterns (typical of carcinoid tumours) and are made of large cells, the term LCNEC was proposed. NE differentiated carcinomas with extensive necrosis, high mitotic index and marked propensity to invasion and distant spread were grouped in this novel category and found to have a clinical behaviour not different from that of small cell carcinoma [5, 54, 55] (Fig. 2). Unfortunately, in the last WHO classification of lung tumours [56], this tumour entity was included in the large cell carcinoma group, generally encompassing non-NE carcinoma subtypes and having nothing to do with LCNEC, with the possible exception of cell size. The main differential diagnostic problem is represented by ACs. LCNECs share the classical solid

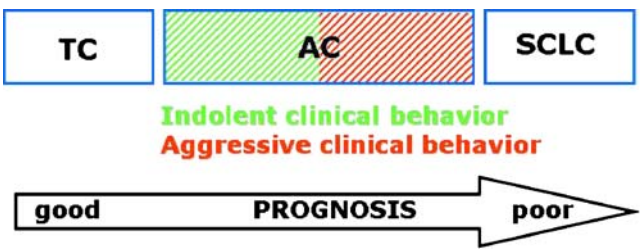

Fig. 1 Spectrum of NETs of the lung: AC was separated from TC, based on high-grade morphological features [4]. AC had a more aggressive behaviour than benign carcinoid, but in this group, cases with indolent clinical course co-existed with highly aggressive neuroendocrine carcinomas

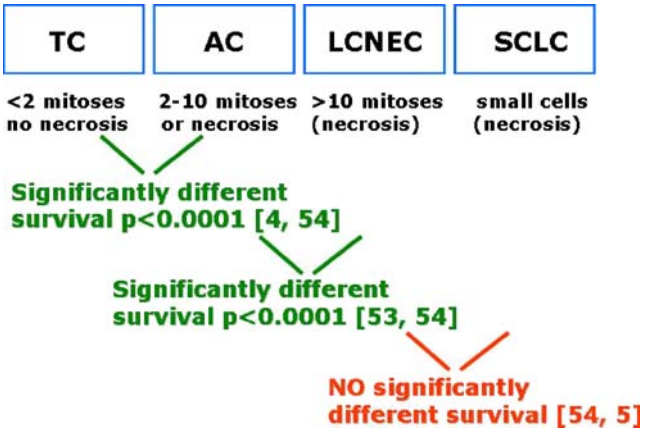

Fig. 2 Spectrum of NETs of the lung: the intermediate group of NETs, i.e. the ACs, was further split into two entities, having a LCNEC subtype recognised [54]. The latter had a significantly different clinical behaviour from carcinoid tumors [55, 54], but no differences in outcome were seen between LCNEC and small cell carcinoma [5, 55]

organoid and lobulated NE morphology but have an extensive, geographic-type necrosis, with a prominent infarct-like appearance and a mitotic count exceeding 10 mitoses per 10 HPF. Large tumour size, marked pleomorphism, lower nuclear to cytoplamic ratio and large nuclei with prominent nucleoli are additional features. The cell size distinguishes large cell NE from small cell carcinoma, but cases of co-existing small and large cell components are well documented. In such instances, an uncommittal report of poorly differentiated NE carcinoma with combined small land large cell features may be sufficient for the purpose of selecting the appropriate therapeutic strategy (chemotherapy; Figs. 3, 4). Two other highly malignant tumours enter into the differential diagnosis with LCNEC: basaloid carcinoma and large cell carcinomas. Minor morphological features (solid growth in large cell type, peripheral palisading in basaloid carcinoma) and, more importantly,

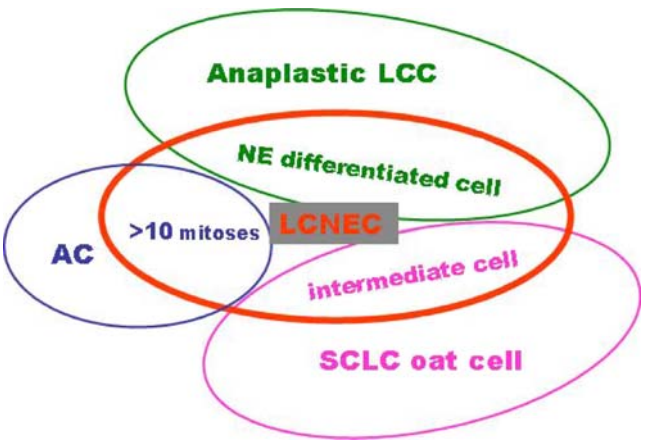

Fig. 3 The LCNEC subtype [54] (*red circle*) includes former anaplastic large cell carcinomas (*LCC*) with NE differentiation, former small cell cancers (*SCLC*) of the intermediate cell type and those former *AC* having >10 mitoses/10HPF

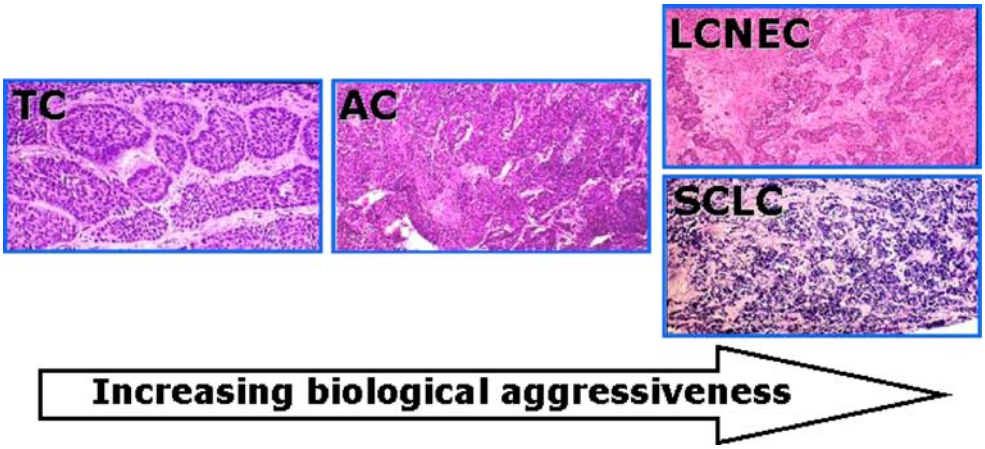

Fig. 4 Proposed spectrum of NE lung tumors based on biological behaviour

expression of NE markers help to discriminate between these entities. The diagnostic immuno-histochemical profile of LCNEC includes more or less extensive (depending also on the use of antigen retrieval procedures) expression of cytoplasmic CgA and synaptophysin as well as neural cell adhesion molecule at the cell membrane level [25]. The simultaneous absence of high molecular weight cytokeratin (types 1, 5, 10, 14 of the Moll's catalog) reactivity is an additional finding supporting a diagnosis of NET. These cytokeratins are in fact restricted to non-NE carcinomas of the lung [50, 59] and of other organs [36].

Small cell lung carcinoma

Small cell lung carcinoma (SCLC) usually arises as a rapidly growing tumour of the major airways. It is made up of small cells with scanty cytoplasm and condensed small nuclei, approximately three lymphocytes in size. Neoplastic cells grow in diffuse sheets loosely connected in a thin stroma. The distinction in three groups, according to the cell size, as oat cell, intermediate and combined cell type, has poor correspondence to clinical features and seems, at least for the first two forms, to be related more to tissue preservation, especially in biopsy specimens, than to true cell characteristics. In addition, several cases of intermediate cell variant are now reclassified as LCNEC. High mitotic rate and large infarct-like necrosis are additional main features.

Small cell carcinoma should be differentiated from several small cell proliferations, both of epithelial and mesenchymal origin. With regard to the latter, pulmonary lymphomas may resemble small cell carcinoma, and several nuclear and cytologic features may overlap, making immuno-histochemistry mandatory for a correct diagnosis. Other small cell tumours, which may be confused with small cell carcinoma include basaloid carcinoma, poorly differentiated squamous cell carcinoma and peripheral neuroectodermal tumours of the thoracic wall (so-called Askin tumours). The differential diagnosis with the former three is based on immuno-histochemical findings and on few morphologic features, such as loose connective tissue, nuclear condensation and scanty cytoplasm, which are more prominent in small cell carcinoma. The distinction from Askin tumour may be more difficult because of several shared features. In Askin tumour, however, the nuclei have a more dispersed chromatin, one or more small nucleoli, and specific immuno-histochemical markers, such as CD99, are constitutively expressed.

Although absent in TC and AC [50], TTF-1 is positive in the majority of both large and small cell NE carcinomas and is therefore useful to differentiate these lesions from poorly differentiated NE carcinomas of other sites. High molecular weight cytokeratins are not expressed in small cell lung cancer, in contrast with non-NE carcinomas [59].

Combined NE carcinomas

A small proportion of NE carcinomas are histologically heterogeneous. This occurs mostly with poorly differentiated carcinomas, both small and large cell types, which may grow in association with squamous cell carcinomas and adenocarcinomas, or, less frequently, with sarcomatous tumours. Combined carcinomas share many clinical, epidemiologic and prognostic features of the NE counterpart, so that, in the WHO classification of lung tumours, they are generally considered as variants of small and LCNECs (codes 8045/3 and 8013/3, respectively). The morphology of such tumours recapitulates the specific features of the individual components. The type of mixture of the two cell populations may either be represented by an intimate intermingling of cell types, with divergent differentiation along NE and "exocrine" lineages, or may represent a sort of "collision" tumour with a small/large cell carcinoma growing adjacent to a non-small cell lung carcinomas (NSCLC), with minimal interplay between the two components. Immuno-histochemistry is helpful for the correct identification of combined tumours and in our opinion a panel of markers, including CgA and CD56 (for NE cells) and high molecular weight cytokeratins (for NSCLC types),

is sufficient to detect the differential reactivity of the two cell populations.

NE differentiation in NSCLC

More or less extensive areas of NE differentiation can be easily detected by CgA immuno-histochemistry in otherwise conventional NSCLC, as also observed in carcinomas of several other organs. This finding does not address to a diagnosis of mixed or combined NE-exocrine carcinoma, unless the extent of NE cells exceeds 30% of the whole tumour (according to the definition of mixed exocrine–endocrine carcinomas) and is generally restricted to a minor cell population. In fact, the recognition of a NE phenotype is possible with immuno-histochemistry only, in the absence of light microscopical features of the NE origin. NE features may be recognised in all lung carcinoma types, most frequently in adenocarcinomas but also in squamous and large cell carcinomas or in sarcomatoid carcinomas/blastomas [1, 6, 10, 47]. The percentage of NE cells may range from 3 to 25%, either as single cells scattered among non-NE glandular or squamous neoplastic cells, or more rarely as small clusters of neoplastic cells admixed within the non-NE component. Little is known about the significance of NE differentiation in NSCLC, and controversial data exist in the literature about the different behaviour and response to chemiotherapy for NE differentiated vs conventional NSCLCs. A recent study [19] indicates that NE differentiation has no impact on survival of a series of NSCLC, at variance with other studies [38], which found a worse prognosis in stage I NSCLC with NE differentiation. This is not surprising because NE differentiation is a well-known indicator of poor prognosis in prostate cancer [7] and in gastric adenocarcinoma [22].

Molecular profiling of lung NETs

The molecular profile of NE lung cancer has been extensively investigated with the goal of identifying features helpful for diagnosis, prognosis and even therapy for this special lung tumour category. The endpoint of genome, gene transcript, cell product, receptor and regulatory peptide expression analysis is ultimately to create a “molecular classification” of lung NETs that can serve as a complement or alternative to morphology to better define the different histological types and address the appropriate therapeutic strategy.

In the search for molecular markers of lung NETs, gene expression profile studies are increasing. Apart from common NE markers (such as chromogranins), insulinoma-associated (IA-1) gene and human achaete-scute homolog-1 (hASH1) gene overexpression were observed [8, 15, 51]. Among them, hASH1 is a recently described marker for NE differentiation in lung tumours [21] and was also suggested as a therapeutic target because of its cell growth modulation effect in lung cancer cell lines [33]. Other reports [3] found that carcinoids (typical and atypical) had genes that clustered with gliomas, while SCLC clustered with bronchial epithelium, suggesting a different histogenesis of these two tumour subtypes. Subsequent studies confirmed such distinct molecular subgroups [8, 23]. Moreover, by immuno-histochemistry, an expression profile of positive carboxipepditase E (CPE) and negative gamma-glutamil hydrolase (γGH) was preferentially detected in TC and AC thus significantly predicting good prognosis, whereas the opposite phenotype (negative CPE and positive γGH) was a feature of LCNEC and SCLC [18].

Comparative genomic hybridisation identifies genome alterations of chromosome copy number, gains and losses, as well as gene amplifications, although the precise localisation of the altered loci cannot be obtained with this methodology. The most common genetic feature in both TCs and ACs is the allelic deletion of the long arm of chromosome 11. Different loci in 11q are altered in these tumours, being 11q13 (linked to the MEN1 gene locus) lost in nearly one third of sporadic carcinoids, both typical and atypical. It was recently demonstrated that the main genetic defect of MEN1 consist in loss of heterozygosity (LOH) or micro-satellite instability (MSI), which lead to the consequent absence of the gene product menin in TC and AC [58]. However, the development of lung carcinoids in MEN1 syndrome is a rare occurrence. MEN1 gene alterations are also virtually absent in poorly differentiated NE carcinomas, and MEN1 kindreds do not present these types of tumours as inherited carcinomas. Interestingly, familial lung carcinoid syndromes different from MEN1 have been described, and still need to be better defined [31].

With regard to SCLC, the vast majority shows deletions of the short arm of chromosome 3, being the putative tumours suppressor genes still to be completely identified. The von Hippel Lindau (3p25) and FHIT (3p14.2) genes seem to be the most likely candidates, and LOH of both has been detected in a high percentage of SCLC. However, although the frequency of LOH at 3p was higher in the group of poorly differentiated NE carcinomas, large and small cell types had different LOH patterns at 3p and also at 22q), and a significantly different genetic background was observed in these two forms [53]. Finally, DNA gain in 17q24–25 was demonstrated as markers of brain metastases in SCLC [41].

Among alternative mechanisms of gene inactivation, hypermethylation contributes to the silencing of genes acting as tumour suppressors (DNA repair, cell cycle regulation, angiogenesis and invasion modulators, etc). As compared to other lung cancer types, this mechanism is

rarely acting in lung NETs. In fact, DNA methylation rarely involves TC, whereas RASSF1A and Caspase 8 are more frequently altered in AC and SCLC [48].

Among genetic alterations involving cell cycle regulators, *p53* gene point mutations are frequently present in LCNEC and SCLC, while absent in all TCs and most ACs [32]. In this context, immuno-histochemical detection of *p53* protein has been proposed in the differential diagnosis of NE lung tumours. Mutations in *RB1* gene with loss of function of the retinoblastoma gene product have also been detected in most SCLC [13, 24]. Similarly, mutations of the *PTEN* gene were also mainly restricted to SCLC [61].

Concerning key pathways that regulate the cell cycle, altered expression patterns of proteins acting in several steps have been described, with diagnostic or prognostic implications. Rb/*p16*/cyclin D1 pathway aberration is one of the most common in NETs, with a variety of molecules and different mechanisms involved, probably reflecting variable genetic divergency among individual tumours [20]. Signalling pathway of the E2F family of transcriptional factors (E2F1, E2F3) was studied in lung NETs [11]. Recently, Salon et al. [46] provided evidence of a direct and functional interconnection between the E2F-1, Skp2 and cyclin E oncoproteins in poorly differentiated lung NE carcinomas, but not in TC and AC, suggesting their co-operation in the development of these tumours.

Telomerase activity was widely studied in NE lung tumours. Telomerases are the enzymes that synthesise telomeric DNA strands, thereby compensating the DNA losses during each cell division. A high intra-cellular telomerase activity can be considered the compensation to telomere length shortening resulting from uncontrolled proliferation. SCLCs have high telomerase activity in nearly 90–100% of the cases, confirming the model of a high proliferation with extensive genetic instability, as demonstrated by their numerous allelic losses [26]. Moreover, a significantly higher telomerase activity in LCNEC than in TC was recently described [30, 62]. In lung cancer, a significant correlation between telomere length and diagnostic/prognostic factors has only occasionally been documented. Telomerase inhibitors are being investigated in the clinical setting, in combination with cytotoxic chemotherapy for advanced lung cancers, although anti-telomerase therapies need a better comprehension of the telomere elongation machinery and of the response to telomere shortening induced-DNA damage [27].

Finally, limited data have been generated on molecules regulating invasive growth in pulmonary NETs. Salon et al. [45] described a correlation between progression and levels of E-cadherin and β-catenin. In particular impaired expression of E-cadherin and β-catenin correlate with lymph node metastasis and advanced stage disease in carcinoids and LCNEC [39].

Tumour profiling for therapeutic purposes

Novel therapeutic strategies are arising from a better understanding of cancer biology. Innovative therapies targeted to peptide receptors, signalling molecules or catalytic enzymes proved to be helpful in patients with several tumour types, including NETs. An accurate expression profile of the various peptide receptors in lung NETs can be helpful for therapeutic purposes, including the choice of radioligands or non-radioactive peptide analogues [40, 44]. Among them, somatostatin receptors (SSTRs) have been demonstated in NE and non-NE lung tumour [37]. The tissue localisation of SSTRs in lung tumours was widely analised by means of auto-radiography [43], in situ hybridisation, immuno-histochemistry and RT-PCR [35, 37]. Recently, the SSTR type 2 immuno-histochemical expression was investigated in 58 NETs of the lung (12 TC, 20 AC, 19 LCNEC and 7 SCLC) and correlated with follow-up [40]. A strong membrane reactivity was detected in 91% of TC, 65% of AC, 57% of LCNEC and 43% of SCLC.

Thymidylate synthetase (TS) is an enzyme playing an important role in cellular proliferation and growth [29], catalysing the methylation of fluorodeoxyuridine monophosphate to deoxythimidine monophosphate, an essential precursor for DNA synthesis [14]. Five-fluorouracil (5-FU) is an anti-cancer agent largely used in various human neoplasms, that inhibits TS and blocks DNA synthesis [49]. The predictive role of TS quantification in tumours treated with anti-folate drugs such as 5-FU has been extensively described in a variety of human tumours. NETs represent potential targets of anti-folate agents, and we have recently conducted a study on the quantification of TS mRNA and protein levels in these tumours, showing a differential expression of TS in the spectrum of pulmonary NETs, being higher in poorly differentiated NE carcinomas, and indicated TS as a predictive marker of clinical response in a group of patients treated with 5-FU (Ceppi et al., submitted).

The signalling pathway involving mTOR (the mammalian target of rapamycin) is one of the main regulators of cell growth and proliferation and is located at the crossroad of several major signal transduction molecules (including, PTEN/Pi3-kinase, AMKP, Ras/Raf). Its functions in mammalian cells include the control of mRNA translation and metabolism. All mTOR functions are blocked by rapamycin as well as by other mTOR inhibitors under development, such as everolimus and temsirolimus [12, 63]. The only available literature data on mTOR in NE lung tumours are represented by experimental models in SCLC cells. In fact, it has been shown that blocking PI3k/Akt/mTOR pathway with rapamycin is sufficient to overcome chemoresistance and promote apoptosis in SCLC cells [57]. A recent preliminary report on phase II clinical trial, in which the

rapamycin derivative temsirolimus was evaluated in SCLC patients after chemotherapy, failed to show any beneficial effect for the patients [34]. No data exist on the distribution of mTor protein (with special reference to its Serin 2448-phosphorylated active form) and its downstream targets (S6K and 4EBP1) in the spectrum of pulmonary NETs. The immuno-histochemical expression of these molecules was analysed in the same series of 58 lung NETs. The preliminary data indicate that well-differentiated tumours had a higher expression level of mTor (75% of TC vs 43% of SCLC), but no correlation with the expression of the target proteins S6K and 4EBP1 (implicated in protein synthesis and cell proliferation) was observed. With regard to the expression of hypoxia-related factors, HIF1alpha (which is targeted by mTor via the initiation factor eIF4E), but not HIF2, was strongly expressed in the nuclei of mTor positive tumours only, although no differential reactivity was observed between well-differentiated tumours and high-grade NETs (unpublished data).

Conclusive remarks

A spectrum of NETs of the lung exists including pure forms and mixed forms. In the former group, a continuum of lesions is recognised ranging from benign TCs to ACs (having a low-grade behaviour, although often associated with regional and distant metastases), to the highly aggressive poorly differentiated carcinomas of the small and large cell types, which share the same poor prognosis. In the mixed tumour group, again several tumour types are recognised, being the NE component extensively represented in association with any of the NSCLC subtypes (so-called combined carcinomas), or being the NE component restricted to a cell population scattered among conventional adenocarcinoma cells (or more rarely within squamous or large cell carcinomas).

The correct morphological identification of all these tumour types together with the definition of a molecular profile may allow to better characterise individual NETs, with the ultimate goal of providing a combined morphological and molecular classification of lung NETs, useful for the choice of the most appropriate therapeutic strategy.

REVIEW AND PERSPECTIVE

Goblet cell carcinoids and other mixed neuroendocrine/nonneuroendocrine neoplasms

Marco Volante · Luisella Righi · Sofia Asioli · Gianni Bussolati · Mauro Papotti

Received: 31 May 2007 / Accepted: 6 June 2007 / Published online: 8 August 2007

Abstract Within the spectrum of neuroendocrine tumors arising in different organs, intermediate and controversial entities exist displaying a coexistence of neuroendocrine and nonneuroendocrine cell populations, and that are grouped under terms such as "goblet cell carcinoid", "mixed endocrine-exocrine carcinoma", "combined carcinomas", or "adenocarcinoma with neuroendocrine differentiation". These tumors may display variable amounts of the two components, potentially ranging from 1 to 99%, and variable structural patterns, ranging from single scattered neuroendocrine cells to a well-defined neuroendocrine tumor cell component organized in typical organoid, trabecular, or solid growth patterns. Although variably included in the site-specific World Health Organization classification schemes, clear definitions and diagnostic features are still missing, as well as a definite knowledge of their biological properties and histogenesis. In the present report, the main characteristics of tumors showing mixed neuroendocrine and nonneuroendocrine features will be described, using morphological patterns and site of origin as schematic guidelines. Moreover, molecular and clinical aspects, which might help to understand their possible histogenesis and biological behavior, will be reviewed.

Background

Cells belonging to the neuroendocrine system may be divided into those which give raise to neuroendocrine glands, such as pituitary, parathyroids, paraganglia, and adrenal medulla, and those which are disseminated in different organs and systems, such as the respiratory, gastrointestinal, biliary and urogenital tracts, the pancreas, the thyroid, the skin, and others. The neoplastic counterpart of the former group is represented by the characteristic pure neuroendocrine tumors, specific for each gland (pituitary and parathyroid adenomas/carcinomas, paraganglioma, and pheochromocytoma), whereas the latter may give origin to either pure neuroendocrine tumors (both well and poorly differentiated) or neoplasm showing combined aspects of both neuroendocrine differentiation and nonneuroendocrine features specific to the site of origin.

Neuroendocrine tumors originating from diffuse neuroendocrine cells are only partially classified under the same scheme [63], while in part follows the classification of the tumors of the specific site of origin (i.e., in the respiratory and urogenital tract); such almost contradictory state of affairs concerns also the group of mixed neuroendocrine and nonneuroendocrine neoplasms. Major points are represented by the morphological background which should be recognized in these lesions, the extent of the two components to be recovered, and even their clinical implications (Table 1). The role of immunohistochemical markers in the identification of mixed neuroendocrine nonneuroendocrine neoplasms is not different from the diagnostic approach of

Table 1 Clinical relevance of the recognition of mixed neuroendocrine and nonneuroendocrine neoplasms

Variant of mixed NE/non-NE tumor	Clinical behavior
Goblet cell carcinoid	More aggressive than typical carcinoid
Goblet cell carcinoid + adenocarcinoma	Dictated by the adenocarcinoma component
MEEC with well-differentiated neuroendocrine component	Dictated by the exocrine (usually adenocarcinoma) component
MEEC with poorly differentiated (small or large cell) neuroendocrine component	Dictated by the neuroendocrine component
(Adeno)carcinomas with focal neuroendocrine differentiation	Same as ordinary adenocarcinomas (except in the prostate, having worst prognosis)
Mixed medullary/follicular carcinoma	Usually dictated by the medullary component (radioiodine therapy however indicated)

NE Neuroendocrine, *MEEC* mixed exocrine-endocrine carcinoma

pure neuroendocrine tumors and we will focus only on peculiar aspects related to specific entities or histopathogenetic studies.

Pathological features

In general terms, two major morphological patterns in mixed neuroendocrine and nonneuroendocrine neoplasms are encountered: as a first possibility, the two components grow strictly intermingled, to the point that individual cells co-express both exocrine products and endocrine granules (Fig. 1); this pattern is typical of the so-called goblet cell carcinoid. As an alternative, the two components are clearly distinguishable by morphology, although growing within the same nodule, and this type of tumors is generally grouped under the term mixed exocrine-endocrine carcinoma (MEEC). A third possibility is represented by the occurrence of focal neuroendocrine differentiation in otherwise nonneuroendocrine tumors (mainly adenocarcinomas from various sites). Although this latter aspect is of pathogenetic and possibly clinical relevance, it represents in our opinion a separate part of the spectrum although it enters in the possible differential diagnosis of MEEC [74]. It is worth noticing that focal neuroendocrine differentiation in non-neuroendocrine tumors has been described in a variety of different locations (breast, prostate, lung, colon, stomach, and so on) with a frequency which is greatly related to the method (and corresponding sensitivity) employed to detect the neuroendocrine counterpart. In nonsmall cell lung carcinoma, neuroendocrine differentiation has been reported in up to 36% of cases, depending on the method used to identify neuroendocrine cells [1, 28]. Focal neuroendocrine differentiation, although not mentioned in the WHO classification of tumors of the digestive system [23], has been reported in esophageal [24], gastric [51], colorectal [3, 5, 13, 21, 22, 30, 53], and extrahepatic duct carcinomas [27]. In the breast, more or less extensive neuroendocrine differentiation foci were described in conventional lobular or ductal carcinomas [62, 68, 73], and are kept separate from the exceptional "carcinoid tumors" of the breast and the neuroendocrine carcinoma subtype, both of which display neuroendocrine features in more than 50% of tumor cells [68]. In the prostate and bladder, neuroendocrine differentiation has been described in a fraction of prostatic and bladder carcinomas [6, 25]. The interest for neuroendocrine differentiation in nonneuroendocrine tumors embraces histogenetic, diagnostic, and clinical issues, mostly related to the correct morpho/functional (hormonal) typing of different neoplastic components in both primary and metastatic tumors. Additionally, significant clinical and prognostic correlates were proven in prostatic adenocarcinoma only, while remaining mostly controversial for cancers at other sites.

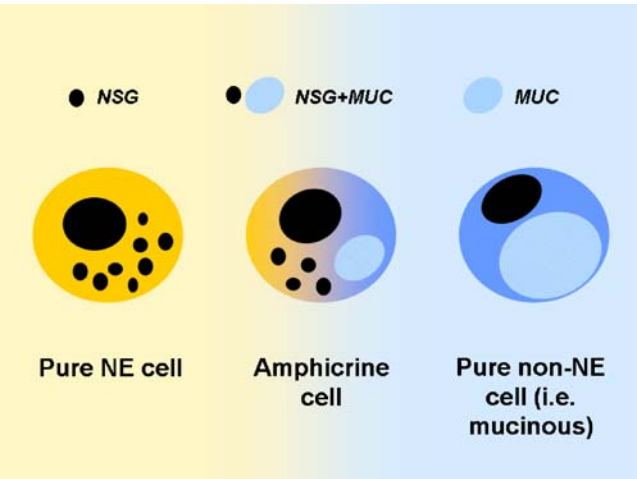

Fig. 1 Schematic illustration of amphicrine cells containing both neuroendocrine granules (NSG) and exocrine products (i.e., mucinous material-MUC)

Goblet cell carcinoids

The term goblet-cell carcinoid was introduced in 1974 for tumors of the appendix exhibiting histological features different from both ordinary carcinoid and adenocarcinoma [66]. Since the original description, they were considered low-grade malignant tumors, although aggressive cases

with extensive local spread and metastases were observed. In 1978 the term "adenocarcinoid" was coined, and despite abundant mucin production and goblet-cell arrangement, a closer relationship to carcinoid than to adenocarcinoma was postulated [76]. Morphologically, goblet cell carcinoids represent an intimate mixture of mucin-laden signet ring cells and highly granulated neuroendocrine cells in a tumor with classical organoid pattern. In addition, both aspects may be recognizable in some individual cells of the tumor. At least in the appendix, goblet cell carcinoids were the first reported examples of mixed nonneuroendocrine and neuroendocrine tumors, and are classified as their pure neuroendocrine counterparts, according to the 2000 World Health Organization (WHO) classification [63]. Indeed, the relative proportions of the two components are variable and the majority of cases present a predominance of one of the two main aspects, either limited mucinous cell population or more scant neuroendocrine cell among signet ring cells, whereas only in some cases both neuroendocrine and exocrine aspects are well represented. The distinction between goblet cell carcinoid and other types of tumor is of great importance because of the implications for treatment and prognosis. Frank adenocarcinoma can arise from goblet cell carcinoids, and tumors with both components are classified as mixed goblet cell carcinoid–adenocarcinoma (Fig. 2). The adenocarcinoma component of the latter determines their prognosis, which is generally worse than that of pure goblet cell carcinoid. Recommendation for an aggressive approach is adopted by a greater part of the surgical community, since lymph-node involvement may be observed in more than 12% of the patients [65]. Exceptional cases of combined goblet cell carcinoid and mucinous cystoadenoma of the appendix have been also reported [2].

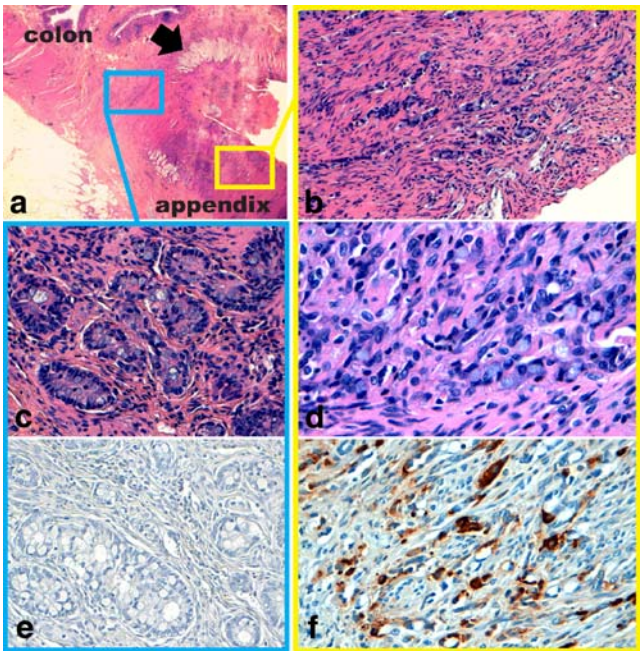

Fig. 2 Invasive goblet cell carcinoid of the appendix (**a**, bottom right); extending to the subsierosa (**b**) with typical signet ring neoplastic cells (**d**) and positive for chromogranin A (**f**), admixed with a frank adenocarcinomatous component infiltrating the wall of the cecum (**a**, top; **c**), with mucin production (**a**, arrow), negative for chromogranin A immunohistochemistry (**e**) (original magnifications: **a** 20×; **b** and **e** 200×; **c**, **d**, and **f** 400×)

Goblet cell carcinoids are mostly affecting the appendix, although reported in other sites of the gastrointestinal and biliary tract. Cases showing composite appearance of signet ring carcinoma, goblet cell carcinoid, and glandular adenocarcinoma have been described in the stomach [15]. A case of multiple microscopic signet ring cell carcinoids was reported in the gallbladder, in which many small organoid-patterned carcinoid tumors infiltrated the gallbladder wall and had focal exocrine cell differentiation, in the form of scattered mucin-laden signet ring cells in the neoplastic nests [54]. Only scant amphicrine cells were found by double stainings and the proportion of signet ring cells did not exceed 20% of the whole tumor.

Immunohistochemical studies determined similar patterns of E-cadherin and beta-catenin in goblet cell carcinoids and conventional carcinoids of the appendix, as compared to colon adenocarcinoma [42], although higher proliferation rate and dysregulation of several cell cycle modulators (cyclin D1, p21, and p16) were observed in goblet cell carcinoids [33], a finding which could explain their more aggressive behavior as compared to usual carcinoid tumors. It is interesting to note that a differential pattern of S-100 protein expression was observed in classical and goblet cell carcinoids of the appendix, being the former invariably positive, and the latter negative. These features suggest a possible origin from different progenitor cells, namely subepithelial neuroendocrine cells and epithelial crypt stem cells for classic and goblet cell carcinoids, respectively [19].

Mixed exocrine–endocrine carcinomas

In the literature, the definition of MEEC and the distinguishing criteria from carcinomas with neuroendocrine differentiation are not uniform: some take into account the extension of the neuroendocrine component only, while others consider type and extent of the observed morphological patterns [7, 9, 14, 41, 62, 73]. This lack of standardization created several controversies in both fields of tumor recognition and treatment of these lesions. In addition, especially in pulmonary and gastroenteropancreatic locations, a relatively wide spectrum (and possibly a continuum) of neuroendocrine differentiated tumors exist including tumors with well-represented (>30% of tumor area) neuroendocrine cell component and tumors with scattered neuroendocrine cells only [1, 31, 49, 51, 53, 62].

With regard to the criterion of neuroendocrine component extension within the tumor, the "rule" of at least 30%

of neuroendocrine differentiated areas, mentioned in the 2000 WHO classification of endocrine tumors [63], allows to consider as true MEECs those tumors with a well-represented or significant neuroendocrine cell population only. On the other hand, however, no reasonable explanation is provided for this limit from both a pathogenetic and histogenetic point of view. By morphology, MEECs are the result of intermingling of frankly glandular areas with typical organoid neuroendocrine areas (in the case of a well-differentiated tumor) or classical small cell carcinoma areas. The criterion of the structural pattern in the definition of MEEC is relevant to allow separation of conventional adenocarcinoma with a less represented neuroendocrine cell population randomly spread in the exocrine tumor, in the absence of carcinoid-like or small cell areas (see above).

MEEC can be encountered virtually at all sites, with either common or peculiar aspects according to the site of origin. Some of the main pathological features of MEECs according to their localization are summarized below.

MEEC in the pancreas, gastrointestinal, and biliary tract The WHO classification of endocrine tumors has incorporated MEEC in the section on endocrine tumors of the pancreas and briefly commented these forms in the paragraphs on stomach and appendiceal endocrine tumors [63]. In the pancreas and stomach, these were defined as epithelial malignant tumors characterized by a combination of a predominant exocrine component and a neuroendocrine cell subpopulation represented by at least one third of the tumor area [10, 23, 63]. This same definition has been applied in the 2004 classification of tumors of endocrine organs, concerning pancreatic endocrine tumors [10]. In the pancreas, MEEC include mixed ductal–endocrine carcinoma and mixed acinar–endocrine carcinoma. Exocrine tumors, in which the neuroendocrine component, is represented by scattered individual cells constituting mostly a tumor-associated but non-neoplastic cell population, were not defined as truly mixed exocrine–endocrine tumors [37]. As for most other locations, mixed ductal–endocrine and mixed acinar-endocrine carcinomas are exceptionally rare [37]. Mixed ductal-endocrine carcinomas account for approximately 0.5% of all ductal adenocarcinomas [49] and 15% of all acinar carcinomas of the pancreas [36]. As for conventional pancreatic carcinomas, the majority of mixed ductal–endocrine carcinomas occur in the head of the pancreas [37, 49], while acinar–endocrine carcinomas are equally divided between the head and tail [36, 50]. Endocrine-related symptoms may be present, and a case with hypergastrinemia has been reported [69].

In the case of ductal–endocrine carcinoma, the exocrine component of these tumors is represented by moderately to poorly differentiated ductal or glandular structures or mucinous (colloid) carcinomatous structures, whereas the neuroendocrine component can be well or poorly differentiated. The well-differentiated neuroendocrine component is represented by solid, trabecular, or acinar structures formed by small- to medium-sized cells, positive for neuroendocrine markers and negative for mucin stains. The cell population and growth pattern of the poorly differentiated neuroendocrine component are similar to those of small cell carcinoma of the lung [49].

In many mixed acinar–endocrine carcinomas, the two different tumor components can be convincingly identified only with immunohistochemical stainings. In some cases, the acinar component can be recognized at morphological level because of the organization of neoplastic cells in small glandular units and tintorial properties different from the surrounding neoplastic component. The neuroendocrine component, on the contrary, consists most frequently of solid nests or trabeculae of cells with randomly oriented nuclei and amphophilic cytoplasm.

Metastases affect the liver and regional lymph nodes, although distant spread to other organs is reported in some cases [36, 69]. The behavior of mixed exocrine–endocrine carcinomas is dictated by the exocrine component; so duct–endocrine carcinomas have the same poor prognosis as ductal adenocarcinomas and the same is true for mixed acinar–endocrine carcinomas [36, 37].

Among the variety of MEEC in the gastrointestinal tract (Fig. 3), variable combination of morphological aspects have been reported, and an attempt to list all reported cases would fail to be comprehensive. In the stomach peculiar aspects include cases showing at immunohistochemical and ultrasctructural levels the presence of amphicrine features [77], also in liver metastases [57], and pancreatic-like acinar differentiation in the exocrine component [16, 31]. As well, in the small and large intestine MEEC cases have been documented, showing both well-differentiated [32] and poorly differentiated features [61, 71] of the neuroendocrine component. Gallbladder carcinomas with combined adenosquamous and large-cell neuroendocrine features have also been reported [48]. MEEC may also occur in the ampullary region, and we recently observed a case located in the periampullary region predominantly in the submucosa and extending to the main pancreatic duct, showing two distinct architectural patterns intermingled within the same lesion, composed of a predominant large cell neuroendocrine carcinoma component admixed with moderately differentiated neoplastic glandular structures. The presence of both neoplastic counterparts was evident at preoperative brushing cytology, which displayed the coexistence of mucin-laden cells and synaptophysin positive cells (Fig. 4). The patient is currently alive with disease 11 months after surgery.

Lung A small proportion of neuroendocrine lung tumors, in most instances poorly differentiated carcinomas of the small and large cell types, may grow in association with

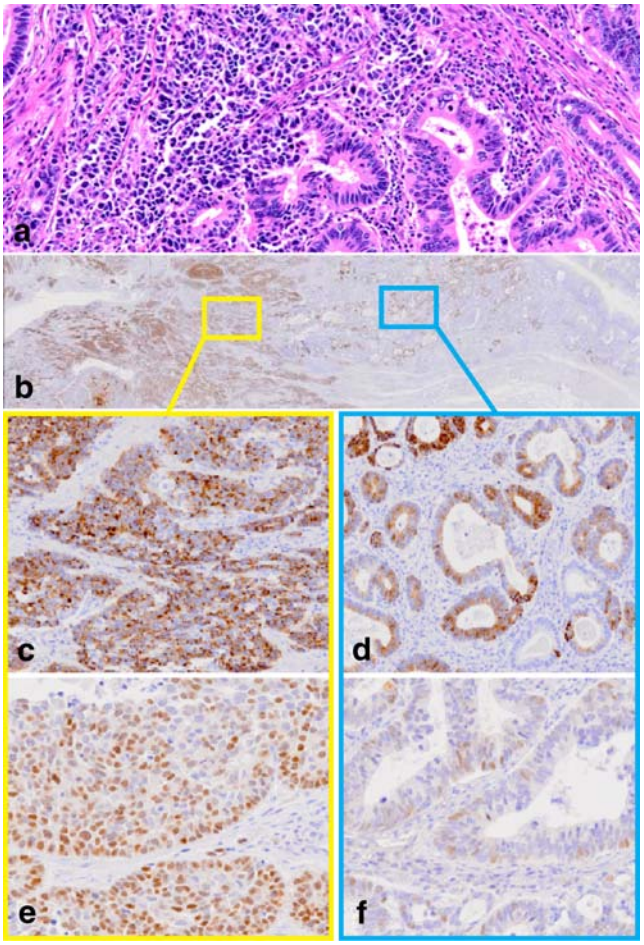

Fig. 3 MEEC of the stomach, with poorly differentiated-large cell-neuroendocrine component (**a**, left) and adenocarcinoma (**a**, right) features. Chromogranin A (**b**) was positive in the neuroendocrine component (**c**) but also in adenocarcinoma glands close to the neuroendocrine areas (**d**). Human ASH-1, a transcription factor involved in neuroendocrine differentiation, paralleled chromogranin A immunohistochemical pattern (**e** and **f**, neuroendocrine and adenocarcinoma components, respectively) (original magnifications: **a**, **e**, and **f** 400×; **b** 20×; **c** and **d** 200×)

squamous cell carcinomas and adenocarcinomas, or, less frequently, with sarcomatous tumors. According to the WHO classification of lung tumors [70] they are classified under the term "combined carcinomas". The morphology of such tumors, as well as their clinical behavior, recapitulate the specific features of the individual components, and this tumor group is described in detail elsewhere in the current issue [60].

Thymus A variety of tumors including neoplasms showing neuroendocrine and thymic epithelial features, representing less than 1% of all thymic tumors, has been introduced in the WHO classification of thymic tumors [70]. The neuroendocrine component may be represented by either thymic carcinoid (usually atypical) or small cell carcinoma and the thymic epithelial component by variable thymoma/

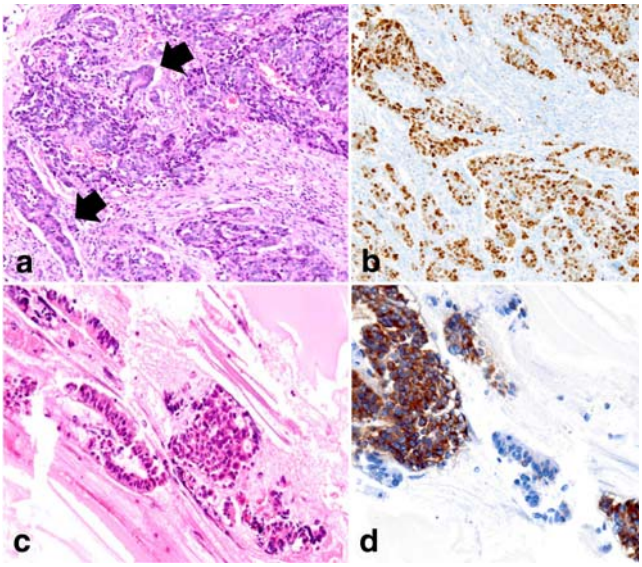

Fig. 4 MEEC of the periampullary region, with poorly differentiated-large cell-neuroendocrine component (**a**), highly proliferating by ki-67 immunohistochemistry (**b**), admixed with adenocarcinoma features (**a**, arrows). The lesion was preoperatively diagnosed by endoscopic brushing sampling and displayed in the cytological specimen the presence of a double component, made of glandular structures and aggregates of medium to large-sized cells (**c**). The latter is positive for synaptophysin (**d**) (original magnifications: **a** and **b** 200×; **c** and **d** 400×)

thymic carcinoma types [44, 46, 58]. Ectopic hormone (i.e., ACTH) secretion in thymic neuroendocrine tumors is quite common, and, although not reported in the literature, it should be expected also in thymic mixed neuroendocrine nonneuroendocrine neoplasms. Mixed neuroendocrine carcinoma-thymoma should not be confused with conventional thymic carcinoma which may display focal areas of neuroendocrine differentiation in a large proportion of cases [26, 39, 40].

Thyroid Peculiar endocrine–neuroendocrine differentiation in thyroid carcinoma occurs in the so-called mixed medullary–follicular carcinomas (MMFC), which are defined as tumors showing both the morphological features of medullary carcinoma together with immunoreactive calcitonin, and the morphological features of follicular (or papillary) carcinomas together with immunoreactive thyroglobulin [10]. MMFC are very rare tumors, accounting for less than 0.2% of all thyroid tumors [34, 56]. As for conventional medullary carcinoma, MMFC may arise as sporadic tumors, in the vast majority of reported cases, or associated with MEN2 syndrome [38, 43, 47, 55], both type 2A and type 2B. MMFC is an extremely heterogeneous group of tumors in terms of morphological features. The vast majority of cases present as a predominant medullary carcinoma admixed with follicular-derived structures, in a variable degree of extension, atypia, and differentiation. The medullary component generally comprises 70–80% of the tumor, and the follicular derived cell

population is predominant in very few cases. No specific morphological features have been reported on the medullary carcinoma side, whereas the follicular population may be represented by any follicular cell-derived carcinoma entity. The spectrum of morphological pictures of the follicular counterpart, in fact, comprise single follicles admixed in an otherwise classical medullary carcinoma, which should be present deep into the tumor and display cytological atypia (to differentiate them from entrapped follicles at the periphery of a conventional medullary carcinoma), or cluster of cells arranged both in follicular or papillary structures presenting the diagnostic nuclear features of papillary carcinoma. Other morphological patterns of growth in the follicular component include oxyphilic carcinoma, poorly differentiated solid/trabecular carcinoma, and anaplastic carcinoma [56], as well as amphicrine tumors with calcitonin and mucin coproduction [20]. Immunohistochemistry (mainly thyroglobulin and calcitonin) is helpful to highlight the two different components, although the diagnosis relies mostly on morphology.

Their clinical behavior is not different from classic medullary carcinoma, although it has to be remembered that metastatic cases may present both components in the secondary localizations, thus supporting the evidence that a combination of therapeutic strategies (including radioiodine) has to be considered in such cases.

Urogenital tract In the prostate, apart from the prognostically relevant neuroendocrine differentiation in conventional adenocarcinoma (described above), pure neuroendocrine neoplasms may be present, both well differentiated (carcinoids) and poorly differentiated (small and large cell carcinomas). The former are almost invariably pure neuroendocrine neoplasms, whereas in up to 50% of small cell carcinomas an adenocarcinoma component may be present [11], thus representing mixed neuroendocrine and nonneuroendocrine tumor entities. The frequency of such finding strongly suggests a common origin of the two different tumor components.

The same holds true for the urothelial tract, which may very rarely develop pure well differentiated neuroendocrine tumors, and more frequently poorly differentiated small cell carcinomas (usually in the urinary bladder) [11]. Again, in about 50% of cases, areas of nonneuroendocrine urothelial carcinoma are mixed within the lesion, thus representing mixed neuroendocrine and nonneuroendocrine tumors. A contradictory issue, however, is based on the agreement that the diagnosis of small cell carcinoma of the bladder could be addressed even in the absence of immunohistochemical evidence of neuroendocrine differentiation (therefore just based on morphological ground).

Skin Primary Merkel cell-neuroendocrine carcinoma of the skin, may present biphasic differentiation with squamoid, eccrine, or even melanocytic components. The association with squamous cells carcinoma has been frequently described as synchronous closely intermixed tumors or metachronous lesions [4]. Furthermore, cases of Merkel cell carcinoma have been described to contain glandular, melanocytic, striated muscle, and lymphoepithelioma-like features [8, 12, 14, 55]. These latter findings further support the hypothesis of tumors showing divergent differentiation. As also stated for other sites, these entities should be separated from nonneuroendocrine tumors showing neuroendocrine differentiation, as frequently observed in basal cell carcinoma [18] or sweat gland apocrine and eccrine carcinomas [67].

Molecular findings

Few reports in the literature have appeared addressing the histopathogenetic issue of mixed neuroendocrine/nonneuroendocrine tumors, and mostly reported heterogeneous and controversial data, thus making the different histopathogenetic hypothesis still open.

The genetic background of goblet cell carcinoids has been explored in few studies. By gene expression analysis, differential expression of genes involved in adhesion, metastasis and apoptosis were found in goblet cell carcinoids and malignant carcinoids, as compared to classic carcinoids discovered as incidental findings [45].

A rather higher frequency of 11q (25%), 16q (38%), and 18q (56%) losses was found in goblet cell carcinoids of the appendix as compared to other gastrointestinal carcinoids; by contrast, no mutations of K-ras, beta-catenin, or DPC4 genes were detected in any case [64]. In another study, p53 mutations were found in 25% of cases, as compared to 44% of classic carcinoids [59].

In gastrointestinal MEEC, genetic studies applying alternative techniques (loss of heterozygosity, mutational analysis, clonality analysis, and others) have been reported. A common genetic origin of the two tumor components have been proved by most of them [17, 29, 35, 61, 75] especially in those cases in which the neuroendocrine component is represented by poorly differentiated small or large cell carcinoma, whereas rebutted by others [71].

Detailed genetic studies on mixed exocrine–endocrine carcinomas of the pancreas have never been reported so far. No somatic or germline point mutations in the MEN1 gene were detected in the neuroendocrine component of four cases we analyzed (Volante M and Bussolati G, unpublished observation).

Concerning MMFC, very few cases reported in the literature were analyzed for the presence of specific genetic alterations. Excluding the patients affected by known MEN2 syndromes, somatic point mutations in the *RET* protoonco-

gene have been detected in some sporadic tumors [52, 72]. The majority harbored the M918T mutation in exon 16, but an A883F point mutation in exon 15 was also detected in a single case. In the larger reported series [72], the percentage of somatic *RET* point mutations was similar to that of conventional medullary carcinoma (25%, 3/12 cases). In this same study, the genetic analysis on the two different components, isolated by means of laser-based microdissection, revealed that somatic *RET* mutations were restricted to the medullary counterpart. Moreover, the analysis of three female patients by means of the HUMARA method showed differential clonal patterns in the medullary and follicular-derived tumor components, thus disproving the hypothesis of a common progenitor stem cell.

Concluding remarks

The group of mixed neuroendocrine and nonneuroendocrine neoplasms includes rare tumors, located in an intermediate position between pure neuroendocrine and nonneuroendocrine tumors, virtually present in any location, and which display highly heterogeneous morphological patterns. In general terms, to achieve their diagnosis, the two components—neuroendocrine and nonneuroendocrine—should be recognized at morphological level and both components should be present in a tumor cell population representing at least one third of the whole lesion. Such definition separates these forms from exocrine tumors, which present focal areas of neuroendocrine differentiation, recognizable exclusively by immunohistochemical stainings for neuroendocrine markers and in less than one third of the tumor.

The histogenesis of mixed neuroendocrine/nonneuroendocrine tumors is not completely understood, being molecular data either proving or disproving a unique origin of the two components from a common progenitor cell. Still controversial is also the clinical meaning of their recognition, although their clinical behavior is generally related to the more aggressive component.

Acknowledgments Supported by grants from the Italian Ministry of University (ex 60% to MP and MV).

Conflicts of interest statement We declare that we have no conflict of interest.

REVIEW AND PERSPECTIVE

Treatment of gastroenteropancreatic neuroendocrine tumors

U. Plöckinger · B. Wiedenmann

Received: 16 May 2007 / Accepted: 6 June 2007 / Published online: 8 August 2007

Abstract Neuroendocrine tumors are rare; thus, individual experience with the diagnosis and treatment of these tumors is mostly low, except in specialized centers. For histological diagnosis, standards have been described recently. Pathological classification and clinical staging influence diagnostic and therapeutic decisions. This chapter aims at demonstrating the importance of pathological and clinical classification of neuroendocrine tumors on therapeutic decisions, indicating the appropriate therapy for different stages of the disease. Surgical therapy will be discussed shortly, including palliative surgical strategies. However, the focus of the manuscript is medical therapy. Biotherapy, its effects, and remaining uncertainties are presented as well as different chemotherapeutic schemes. Finally, new options of palliative medical therapies like kinase inhibitors and anti-angiogenetic drugs will be discussed.

Keywords Gastroenteropancreatic neuroendocrine tumors · Biotherapy · Somatostatin analogue · Interferon · Chemotherapy · Streptozotocin · Tyrosine kinase inhibitor · Anti-angiogenic therapy

Introduction

Neuroendocrine tumors are classified according to their differentiation, localization, and functionality. The pathological classification and the stage of the tumor disease have important prognostic implications and, thus, influence therapeutic decisions. This chapter starts with a brief discussion of surgical options, then focuses on the established indications of bio- and chemotherapy in gastroenteropancreatic neuroendocrine tumors of the foregut and midgut. Finally, the evolving new therapeutic options are discussed.

Surgery

Surgery is the only curative therapy available in gastroenteropancreatic neuroendocrine tumors. Unfortunately at diagnosis, most tumors have already metastasized, and thus, surgery is rarely curative. Surgery is rarely indicated in patients with small (<1 cm) gastric neuroendocrine tumors type 1 or type 2, due to the mostly benign course of the disease. In contrast, oncological resection of the tumor is imperative in malignant type 3 gastric neuroendocrine tumors [53, 54, 58]. Duodenal and pancreatic primaries are both indications for surgical therapy. However, palliative surgery of the primary, in patients with inoperable hepatic metastasis, has no positive effect on survival. It has been suggested, that palliative surgery of hepatic metastases, either in combination with surgical therapy for the primary or following R0-resection of the primary tumor, does prolong survival in patients with pancreatic or midgut neuroendocrine tumors. All series so far are, however, retrospective analysis of monocentric experiences, and selection bias has to be taken into account. Surgical intervention for hepatic metastasis, without removal of the primary, is not recommended. In general, surgical therapy adheres to oncological principles [12, 22, 30, 31, 49, 53]. However, for appendiceal neuroendocrine tumors due to the excellent prognosis of small (<2 cm) tumors, appendectomy is now considered curative, and right hemicolectomy is indicated only in tumors larger than 2 cm with deep mesoappendiceal invasion [53].

Further, more palliative treatment options such as radiofrequency ablation, chemo-embolization of liver metastases, and peptide radio-receptor therapy have been reviewed recently and will not be discussed here [53].

Medical therapy

Biotherapy can be used as a symptomatic treatment in patients with functioning neuroendocrine tumors, i.e., in patients with the carcinoid syndrome, watery diarrhea-, or glucagonoma syndrome. Symptomatic therapy for insulinomas is rarely necessary, as most of these tumors are benign, and thus, surgery is curative. The objective of symptomatic biotherapy is to reduce signs, symptoms, and complications of hormone hypersecretion syndromes and, thus, to increase the quality of life and overall survival. In addition, biotherapy has been used as an antiproliferative treatment in slow-growing malignant, well-differentiated (World Health Organization classification), metastasized neuroendocrine carcinomas. While tumor regression is rare, stabilization of tumor growth has been demonstrated.

Most gastroenteropancreatic neuroendocrine tumors present with malignant, metastatic disease. Chemotherapy is a palliative option in both slow-growing, well-differentiated, or rapidly proliferating, poorly differentiated, neuroendocrine tumors. In slow-growing, well-differentiated tumors, tumor growth is unpredictable, and slow tumor progression may alternate with long intervals of stable disease. As the quality of life is good in most patients with metastasized well-differentiated neuroendocrine tumors, antiproliferative therapy should only be initiated whenever progressive disease has been demonstrated according to standard criteria. While different treatment regimens have been shown to be effective in well-differentiated pancreatic neuroendocrine carcinomas, chemotherapeutic options for tumors of the small bowel are poor. Localization of the primary is not as important for poorly differentiated carcinomas, as these rapidly growing tumors respond to different chemotherapeutic agents, irrespective of the localization of the primary. These tumors may grow rapidly, and medical treatment should not be withheld to demonstrate progressive disease.

Biotherapy

Biotherapy is defined as the therapy for hormonal hypersecretion syndromes and/or tumor growth with substances or pharmacological derivatives thereof occurring naturally in the body. Despite the widespread therapeutic use of biotherapy in neuroendocrine tumors, data fulfilling the criteria of evidence-based medicine are rare. The interpretation of study results has to be done with some caveats. Data referring to the therapeutic efficacy of biotherapy only rarely give primary endpoints like mortality or the time to progression. Most studies include a variety of neuroendocrine tumors, the number of patients is low, and most studies represent single center experience. The results of different studies are difficult to compare, as dosage, treatment duration, and a variety of different pretreatments were employed. There are only few prospective, randomized multicenter studies in therapy-naïve patients with documented progress before initiation of biotherapy. No placebo group was ever included in these studies. However, despite these drawbacks, there are indications of the benefit of biotherapy on symptoms of hormone hypersecretion, while on the other hand, definite data on the antiproliferative effectiveness and its positive effect on survival are still lacking.

Somatostatin analogues (SSA)

Endogenous somatostatin (SS) circulates in two biological active forms, i.e., SS-14 and SS-28. SS binds with high affinity to five G protein-coupled membrane receptors (sst1-5). Ligand binding inhibits adenylate cyclase activity, reduces calcium influx, and negatively influences hormone synthesis and secretion. An inhibitory influence on proliferation may be due to the activation of phosphotyrosine phosphatases, the mitogen-activated protein kinase activity [38], and to the inhibition of the transcription factor complex activator protein 1. In vitro, high doses of SSA induce apoptosis in tumor cells, and this could translate into inhibition of tumor growth. Additional antiproliferative effects may be related to the anti-angiogenic activity of SS either directly or via inhibition of growth factors [11]. Most neuroendocrine tumors express a higher density of sst in tumor tissue compared to the normal tissue. This allows for specific, tumor tissue-targeted, therapeutic effects and should reduce the number of side effects, i.e., suppression of physiologically secreted hormones. However, sst-subtype expression varies considerably between different tumor types and among tumors of the same type. Even within a given tumor, sst expression is not homogenously distributed [27].

The clinically used SSA, octreotide and lanreotide, preferentially bind to sst2 and sst5 (Table 1). For these analogues, serum half-life is increased considerably compared to native somatostatin. The subcutaneous injectable octreotide has to be given three times daily, while long-acting preparations, (lanreotide long-lasting and octreotide long-acting repeatable [LAR]), allow for one intramuscular injection every two (lanreotide) to four (octreotide LAR) weeks. In the case of lanreotide autogel, an interval up to 6 weeks between injections and the possibility to be injected by the patients themselves, may increase patients' comfort and compliance. Recently, pasireotide has been introduced, a

Table 1 Binding affinities of somatostatin analogues to somatostatin receptor (sst) subtypes

sst	SS-14	Octreotide	Lanreotide	Pasireotide
sst1	0.93±0.12	280±80	180±20	9.3±0.1
sst2	0.15±0.02	0.38±0.08	0.54±0.08	1.0±0.1
sst3	0.56±0.17	7.10±1.40	14±9	1.5±0.3
sst4	1.40±0.40	>1,000	230±40	>100
sst5	0.29±0.04	6.3±1.0	17±5	0.16±0.1

Binding affinities are given as mean±SEM IC-50 (nmol/l)

SSA with high affinity for sst1-3 and sst5. It has been shown to be effective in patients who do not respond to the currently available SSA octreotide and lanreotide. However, its use is still restricted to clinical studies.

Octreotide and lanreotide both effectively inhibit autonomous hormone or neurotransmitter secretion by neuroendocrine gastrointestinal tumors. Unfortunately, tachyphylaxis develops after months or even years of treatment in virtually all patients. Tachyphylaxis may be due to desensitization, homologous agonist-induced down-regulation in sst numbers on the cell surface, heterologous regulation of SS receptor expression, or even SS receptor gene mutations [27].

Indications for SSA therapy

SSA are indicated in patients with symptoms due to excessive, autonomous hormone release by a neuroendocrine tumor or its metastases. In patients with the carcinoid syndrome, octreotide LAR is equally potent in the control of flushing and diarrhea. SSA are indicated in the therapy of the watery diarrhea syndrome, reducing the secretion of vasoactive intestinal peptide, and thus, diarrhea, dehydration, and electrolyte imbalance. In patients with insulin hypersecretion, SSA may reduce the insulin concentration in tumors expressing sufficient sst2 or sst5, i.e., mostly malignant insulinomas. However, as SSA inhibit glucagon secretion as well, patients have to be observed closely at the beginning of therapy to prevent severe hypoglycemia due to the reduced glucagon-dependent counter-regulation. SSA effectively inhibit glucagon secretion in patients with a glucagonoma syndrome; skin lesions improve, and catabolism is reduced (Table 2).

SSA induce remission and/or stabilization of tumor markers in approximately 70% of the patients [46] (Table 3). The decline of tumor markers, like chromogranin A, is due to the anti-secretory effect of SSA and should not be interpreted as evidence for tumor volume reduction. Tumor shrinkage is demonstrated in less than 10% of the patients. However, stabilization of tumor growth, after computer tomographic-documented progression before treatment, occurs in up to 50% of the patients with neuroendocrine tumors of various locations. (Table 4). The median duration of stabilization was 18–26.5 months [3]. In a highly selected group of patients with progressive disease, forty-seven percent of the patients demonstrated at least stable disease when treated with a high dose of lanreotide (3×5 g/day). This was confirmed recently in 75% of the patients with advanced midgut carcinoids, with stabilization for 6 to 24 months. There are no good predictors of the clinical outcome of SSA therapy. Patients achieving a positive response (stabilization) after 6 months of treatment maintain it throughout long-term follow-up and live longer than patients unresponsive to therapy [50]. Frequently occurring side effects like abdominal discomfort, bloating, and steatorrhea due to the inhibition of pancreatic enzymes are mostly mild and subside spontaneously within the first weeks of therapy. Persistent steatorrhea can be treated with supplementation of pancreatic enzymes. Cholestasis with subsequent cholecystolithiasis does occur in up to 60% of the patients due to inhibition of cholecystokinin and production of lithogenic bile. Prophylactic therapy with chenodeoxy–cholic acid and ursodeoxy–cholic acid may be able to prevent the occurrence of gallstone disease in patients on long-term SSA therapy. Serum vitamin B12 concentration may decline, possibly due to a direct inhibition of the intrinsic factor secretion at the parietal cell [52].

In summary, SSA effectively control symptoms of hypersecretion in patients with neuroendocrine tumors of the gastrointestinal tract. Despite the minor effects on tumor volume reduction observed so far, an antiproliferative effect does occur, with stabilization of the disease for up to

Table 2 Effects of somatostatin analogues on hypersecretion syndromes

Syndrome	Symptom	Hormone/ neurotransmitter	Tumor marker
Carcinoid syndrome	Flush≥diarrhea	Serotonin	5-HIAA, CgA
Watery diarrhea syndrome	Diarrhea, dehydration, acidosis	VIP	VIP
Glucagonoma syndrome	Migratory necrolytic erythema	Glucagon	Glucagon
Insulin hypersecretion[a]	Fasting hypoglycemia	Insulin	Insulin
Zollinger–Ellison syndrome	Peptic ulceration, GERD	Gastrin	Gastrin

5-HIAA 5-Hydroxyindol-acetic acid; *GERD* gastro-esophageal reflux disease

[a] Benign insulinomas rarely express sufficient sst2 and 5 for SSA to be effective. Thus, SSA are only indicated as second-line therapy in malignant insulinomas (see text)

25 months. Survival may be prolonged in those patients responding positively to SSA therapy. In addition, SSA significantly increase the quality of life in patients with symptoms related to hormone secretion, while side effects of SSA therapy are limited.

Interferon

Interferon-α 2a, or 2b (IFN) production is a physiological response to substances as microbes, tumor cells, and antigens. IFN react with specific cell surface receptors to activate a cytoplasmatic signal transduction cascade, inducing the transcription of multiple IFN inducible genes, which act as tumor suppressor genes. IFN-α acts on 2′ 5′-A-synthetase and p-68 kinase. Both enzymes induce the degradation of peptide hormone and growth factor messenger RNA, inhibiting protein synthesis. The induction of 2′ 5′-A-synthetase correlates with clinical efficacy. The antiproliferative effect of IFN is probably due to a blockade of the cell cycle in the transition of $G_0 \rightarrow G_1$ [45]. This is due to the inhibition of cyclin B expression, resulting in reduced CDC 2 kinase activity and, thus, inhibition of the cell cycle [13]. Furthermore, induction of apoptosis, as well as increased expression of class I antigens on the tumor cell surface (which marks the cell as a target for cytotoxic T lymphocytes) may add to the antiproliferative effects. In addition, an anti-angiogenic effect has been suggested.

IFN-α has been widely used for the treatment of solid tumors. In neuroendocrine tumors, the indications for IFN are comparable to those of SSA, with carcinoid crisis being the exception. However, there are only few data on the effect of IFN therapy in patients with pancreatic neuroendocrine tumors. Most investigations used recombinant IFN-α 2a or 2b.

Indications for IFN-α therapy

Symptomatic remission is seen in 30–70% of the patients with carcinoid syndrome, with a better effect of IFN therapy on flushing compared to diarrhea. While the control of symptoms of hypersecretion by IFN is comparable to SSA, its onset of response is delayed. A biochemical response is observed in 50% of the patients. Tumor marker remission or stable 5-HIAA concentration occurred in 36 and 35% of the patients, respectively. Analyzing results of ten clinical studies with mixed tumor populations (N=255), a partial remission or stabilization of tumor markers occurs in 44 and 30% of the patients, respectively. These data are comparable to a recent meta-analysis, with median response rates of biochemical markers in up to 44% of the patients

[60]. Tumor shrinkage occurs in 10% of the patients, whereas stable disease is observed in up to 70%. Progressive disease was seen in 23% of the patients. Table 5 gives data on a large cohort of patients with evaluable results on tumor mass (N=274) treated with IFN in ten studies. The median survival was >80 months. Again, the data should be interpreted with caution. Information on spontaneous tumor growth is lacking in most of these studies. Patients with different pretreatment modalities consisting of surgical interventions, embolization therapy, and/or chemotherapy have been included. In addition, the dose regimen, the type of IFN-α (rIFN-α2a, rIFN-α2b, human leukocyte IFN), and treatment time differed considerably between the studies. In these slow-growing tumors, changes might only be obvious after long treatment periods (up to 30 months). No randomized, prospective multicenter studies have been performed. Endpoint analysis, i.e., overall survival or time to progression, is given in about one third of the trials. Overall, results of these investigations delineate a consistent pattern of efficacy for IFN on symptom control.

In almost all patients (97%) a "flu-like" syndrome occurs in the first 5 days. Anorexia, weight loss (59%), and fatigue (51%) may adversely affect well-being. Bone marrow toxicity like anemia, leukocytopenia, and thrombocytopenia have been observed in 31, 7, and 18% of the patients, respectively, as well as hepatotoxicity (31%). These effects are dose dependent. Autoimmune reactions occur in 20% of the patients [46]. Rare side effects are depression, mental disturbances, and visual impairment.

In summary, IFN therapy is primarily given in patients with metastasized neuroendocrine tumors of the gut. The effect on symptoms of hormone hypersecretion is comparable to SSA, while the onset of response is delayed compared to SSA. IFN treatment will not cure the disease; however, it may be able to control tumor growth over extended periods, the smaller the tumor burden, the more so. Thus, IFN should be given rather early in the course of the disease. Side effects of IFN therapy are more pronounced than with SSA. Individualized doses allow a reasonable quality of life.

Combination therapy: SSA plus IFN-α

The combination of SSA and IFN-α was used in an effort to enhance the antiproliferative effect of IFN therapy, to add the positive effect of SSA on hypersecretion syndromes, and to reduce the dose of IFN-α and, thus, the number of IFN-related side effects.

Earlier studies gave contradictory results showing either no additional or an increased antiproliferative effect with combination therapy. However, a recent, well-designed prospective multicenter study showed no advantage of combination therapy, neither on biochemical nor antiproliferative results, while the number of side effects increased [23]. Thus, combination therapy is not recommended as a standard treatment regimen.

In summary, biotherapy is preferentially indicated for the treatment of hormone hypersecretion syndromes in patients with neuroendocrine tumors. Antiproliferative effects are not convincing, but stabilization of the disease does occur in up to 50% of the patients with either SSA or IFN therapy. Combination treatment does not provide any additional effect and is not recommended.

Systemic chemotherapy

Chemotherapy is a palliative option in metastasizing neuroendocrine carcinomas. Streptozotocin (STZ), fluorouracil (5-FU), doxorubicin, dacarbazin (DTIC), etoposide, and cisplatin have been used. As the response rate to monotherapy has been low, most chemotherapeutic regimens for neuroendocrine tumors rely on combination therapy.

STZ is an alkylating nitrosurea compound. STZ enters the pancreatic β cell via the GLUT2 glucose transporter. However, the molecular mechanism of cytotoxicity is still unknown. STZ is effective in the treatment of neuroendocrine tumors of the pancreas. It is used in combination with either 5-FU or doxorubicin. STZ induces nausea and vomiting in up to 90% of patients, and glomerular and tubular dysfunctions occur in 20–75%. Bone marrow toxicity is low; thus, combinations with 5-FU or doxorubicin are possible.

5-FU is a pro-drug and needs to be metabolized for antineoplastic action. Its metabolites inhibit thymidilate synthetase, thus blocking DNA synthesis. In addition, RNA

synthesis is reduced. 5-FU preferentially inhibits proliferating cells, resulting in bone marrow toxicity and gastrointestinal side effects. Patients with coronary heart disease or cardiomyopathy are at risk for cardiotoxic side effects.

Doxorubicin is supposed to interact with DNA base pairs, and this may result in steric inhibition of DNA synthesis. Additional antineoplastic actions are possibly due to the formation of free radicals, an effect on tumor cell membranes and the inhibition of topoisomerase II activity. Myelosuppression is a dose-limiting side effect. Immediate, reversible, or irreversible cardiotoxicity has been observed. Nausea and vomiting are seen in up to 80% of the patients.

DTIC has cytostatic effects and inhibits the cell cycle. Additional effects are reduction of the DNA synthesis and alkylating effects. Therapy with dacarbazin can induce a rare veno-occlusive syndrome. However in most patients, toxicity is low, and the side effects experienced are mostly nausea and vomiting.

Cisplatin is an alkylating agent and, thus, interferes with DNA replication. Nausea and vomiting occur in up to 75% of the patients, myelosuppression is usually mild to moderate, with high-dose therapy. Nephrotoxicity is possible, peripheral neuropathy is common and is dose and duration dependent.

Etoposide, a podophyllotoxin derivative, is used in combination with cisplatin for poorly differentiated NET. Cytotoxicity is due to breaks of DNA strands. Etoposide interacts with topoisomerase II. The inhibition of the cell cycle during S and G2 phase is cytostatic. Side effects like nausea, vomiting and diarrhea, myelosuppression, and alopecia are common.

In neuroendocrine tumors of the pancreas, overall response rates of 17, 18–26, and 21% were obtained with monotherapy using STZ, 5-FU, and doxorubicin, respectively. Combination therapy for well-differentiated, neuroendocrine tumors of the pancreas, on the other hand, resulted in a median response of 36%. Median remission lasted 17 months, while median overall survival was almost 2 years (Table 6). The combination of STZ and 5-FU (N= 147) resulted in an objective response in 21% of the patients, with a median survival time from the start of therapy of less than 8 months. A recent randomized prospective trial (N=163) failed to confirm the suggested superiority of STZ and doxorubicin over STZ and 5-FU [62]. Objective remission was 16% for both arms, progression-free survival was 4.5 and 5.3 months, respectively. Overall survival was higher with STZ/5FU (24.3 vs 15.7 months, p<0.03), arguing for the less toxic approach with STZ/5-FU. Other combination schemes like dacarbazin, 5-FU and leucoverin (response rate 27%), dacarbazin, 5-FU and epirubicin (response rate 30%), lomustine and 5-FU (response rate 21%) were comparable. In a recent trial, 84 patients with pancreatic neuroendocrine tumors were treated with STZ, 5-FU, and doxorubicin [33]. This triple combination achieved a response rate of 39% and a median progression-free survival of 9.3 months, confirming earlier data in small investigations [57, 67].

In contrast, chemotherapy is less effective in neuroendocrine tumors of the small intestine. An overview over ten trials (1979–2005) indicates a median response rate of 25% and a median survival of 11 months (Table 7). Thus, in well-differentiated neuroendocrine tumors of the gut, chemotherapy is not a preferred option.

In contrast, in 18 patients with undifferentiated, anaplastic, neuroendocrine tumors (five tumors were of midgut/hindgut origin), 67% objective responses were obtained [43] with a median duration of remission of less than 8 months.

In interpreting these data, it has to be kept in mind that most studies comprise only a small number of patients; the patients usually are heterogeneous groups with respect to the localization of the tumor, total tumor burden, and pretreatment schemes.

In summary, combination therapy with STZ, 5-FU, with the possible addition of doxorubicin, are now standard treatment schedules in patients with well-differentiated neuroendocrine tumors of the pancreas. For neuroendocrine tumors of the small bowel, there is still no convincing evidence for improved survival with chemotherapy, and thus, other palliative options should be discussed. However, in patients with anaplastic neuroendocrine carcinomas, the

combination of etoposide and cisplatin yielded a response rate of 67%, making this regimen a rewarding tool in undifferentiated neuroendocrine tumors of the intestine.

Novel agents

In tumor cells, the regulation and modulation of growth pathways is disturbed or mutated. This, in turn, leads to dysregulation of signalling pathways, accelerated cell proliferation, and growth. Targeted interaction with key components of these dysregulated signalling pathways may present a new option of tumor therapy. Possible targets are growth factors, growth factor receptors, angiogenetic molecules, and kinases involved in proliferation pathways [26]. Targeted therapy aims at different levels of these proliferation pathways like antibody-induced neutralization of vascular endothelial growth factor (VEGF) ligands or the epithelial growth factor receptor to prevent ligand–receptor interaction or direct inhibition of the receptor tyrosine kinase by small molecules. The best known examples of multi-kinase inhibitors are imatinib or sunitinib, with activity against kinases of platelet-derived growth factor receptor (PDGF-R), bcr-abl, c-kit and PDGF-R, VEGF-R, RET, and c-kit, respectively. RAD001 (everolimus) a rapamycin analogue, is an inhibitor of the mammalian target of rapamycin (mTOR). Inhibition of the protein kinase mTOR may reduce cell growth, increase apoptosis, and reduce metastatic spread. It may have synergistic effects with SSA, as the mTOR pathway is stimulated by IGF-1, which is inhibited by SSA.

These novel targeted therapies are now used in clinical trials for neuroendocrine tumors of foregut and midgut origin. Theoretical background is the known expression of PDGF-R and VEGF-R in neuroendocrine tumors. Results of in vitro investigations in neuroendocrine tumors cell models demonstrated effective inhibition of cell proliferation. Most of the following data are not yet published, but have been presented in abstract form.

Tyrosine kinase inhibitors

First clinical trials in neuroendocrine tumors with tyrosine kinase inhibitors demonstrated partial remission in 5–18%,

[a] Plus 3 pheochromocytomas
[b] Overall survival
P Pancreas; *SB* small bowel; *PR* partial remission; *SD* stable disease; *PD* progressive disease; *med* median

stable disease in 14–93% and progressive disease in 6–15% of the patients. Progression-free survival ranged from a median of 24 to 42 weeks or up to 60% at months 6. These first data indicate a slightly better result for patients with neuroendocrine tumors of the small bowel. Unfortunately, progressive disease was not a prerequisite for inclusions in all trials, and different tumor groups were included in the studies (Table 8). Side effects were tolerable in most of these studies, and the incidence of grade 4 toxicities was low.

In summary, the antiproliferative or stabilization effect of tyrosine kinase inhibitors is probable comparable to biotherapy. These molecules may have synergistic effects in combination with established treatment regimen. Thus, they may well widen the spectrum of effective therapeutic strategies in neuroendocrine tumor diseases.

Anti-angiogenic therapy

Anti-angiogenic therapy is directed vs the formation of new blood vessels. Tumor angiogenesis is regarded as a critical point in the development of growth and metastases. Thus, VEGF, an endothelial growth factor, VEGF-R, or the VEGF-R kinase are potential targets for anti-angiogenic therapy. Neuroendocrine tumors are highly vascularized, and VEGF expression is high. A correlation of the VEGF plasma concentration with tumor growth has been suggested. Therefore, anti-angiogenic therapy targets either the VEGF-R ligand, the VEGF-R, or VEGF-R kinase activity.

Endostatin or angiostatin act as inhibitors of the VEGF-R, antibodies like bevacizumab interfere with VEGF, and multikinase inhibitors like vatalanib (PTK/ZK) [63] inhibit angiogenesis. Thalidomide inhibits angiogenesis by interference with VEGF and basic fibroblast growth factor (bFGF) pathways and the extracellular matrix. These drugs reduce the formation of new vessels and act cytostatic. In contrast, substances directed vs existing tumor vasculature-like combrestatin induce cell necrosis and act cytotoxic. Due to their serious side effects, none of these vascular targeting therapies are clinically available at the time being.

With all the different anti-angiogenic strategies used so far, partial remission was seen in 0–25%, stabilization occurred in 68–92% and progressive disease in 2–20% (Table 8). Again, results are still preliminary, as most of these data are only published in abstract form. As progressive disease was no prerequisite for inclusion in some studies, the rate of stabilization as well as the intervals for progression-free survival or overall survival may be overestimated. Most therapy regimen were well tolerated. The combination of thalidomide and temozolamide, however, resulted in high bone marrow toxicity (~70%) with opportunistic infections in 10% of the patients with infectious complications [36].

In summary, molecular targeted therapies and angiogenesis inhibitors offer a promising approach to antiproliferation in neuroendocrine tumors. Results of ongoing trials will provide more stringent data due to more homogenous tumor groups, inclusion of patients with similar pre-therapeutic regimen, and demonstrated progressive disease. It is to be expected that these new drugs will preferentially be used in combination with standard treatment regimen to improve stabilization rates in well-differentiated neuroendocrine tumors. Long-term effectiveness of targeted therapy may well be overcome by the development of alternative intracellular signalling pathways, thus reducing therapeutic efficacy of the new regimen. On the other hand, depending on the expression pattern of targeted molecules in the tumor, pre-therapeutic patient selection may improve success rates in selected patients. Thus, classifying neuroendocrine tumors according to the expression of possible targeted molecules may be the future standard for effective therapeutic strategies.

Conflict of interest statement We declare that we have no conflict of interest.
