REVIEW AND PERSPECTIVE

Stem cells and solid cancers

Abstract Recently, there have been significant advances in our knowledge of stem cells found in tissues that can develop solid tumours. In particular, novel stem cell markers have been identified for the first time identifying multipotential cells: a required characteristic of a stem cell. The scarcity of cancer stem cells has been questioned. Current dogma states that they are rare, but novel research has suggested that this may not be the case. Here, we review the latest literature on stem cells, particularly cancer stem cells within solid tumours. We discuss current thinking on how stem cells develop into cancer stem cells and how they protect themselves from doing so and do they express unique markers that can be used to detect stem cells. We attempt to put into perspective these latest advances in stem cell biology and their potential for cancer therapy.

Introduction

Cancer is most likely a disease of stem cells. This appears to be a rather didactic statement and can be argued for and against; however, the hypothesis that stem cells are at the root of a hierarchical cellular organization of the majority of cancers seems intuitive. The fact that stem cells appear to be the only cell type that can self-renew heavily implicates them in cancer development that can also be seen as a disease with dysregulated self-renewal [1]. They are also one of the limited number of cell types that survive long enough to accrue sufficient numbers of mutations needed to develop into a tumour: the mutation and selection theory of cancer development [2]. Furthermore, there can be multiple differentiated cell types within tumours, which can be readily explained if there is a multipotent stem cell at its source [3].

The cancer stem cell theory was first proposed by Hamburger and Salmon [4] who demonstrated that only a small percentage of tumour cells were able to form colonies in soft agar. This raises the possibility that only a minority of self-renewing cells within a tumour are capable of sustaining it, and therefore, therapies need only target the cancer stem cell (CSC). The identification of this population of CSCs has been at the forefront of tumour biology.

Here, we review the current literature describing how a normal tissue stem cell develops into a cancer stem cell, potential markers of such cells, the mechanisms behind the

mutation and selection theory and finally how such mutations spread through rapidly renewing tissues such as the gastrointestinal tract. We discuss recent developments, which have questioned the role of stem cells in cancer development, their numbers in individual tumours and molecular signatures.

Cells with stem cell-like characteristics were first described in the bone marrow in 1961 by Till and McCulloch [5] as cells that gave rise to multilineage haematopoietic colonies in the spleen. Stem cells can be defined by two essential features: first they have the ability of indefinite self-renewal, so-called longevity. Second, they are multipotent, meaning they can differentiate into various cell lineages within their tissue of origin. Adult stem cells are immature, undifferentiated cells, which are thought to exist in small numbers in nearly all post-embryonic tissue [6]. These key properties of adult stem cells enable them to replenish terminally differentiated cell populations and facilitate tissue repair within their tissue of origin [7–10]. The differences in developmental potential between stem cells and progenitor cells form a hierarchical structure with stem cells residing at the base and their progeny above, becoming more differentiated with each division [11].

Tissues such as blood, skin or the gut perpetually renew their cell populations; however, a large number of tissues in adult mammalians exhibit very low cellular turnover under normal circumstances. Some of these even respond poorly to tissue damage such as the heart, whilst others, like the liver, respond well. Although adult stem cells have been widely studied in the haematopoietic system, candidates for tissue stem cells have been described in the nervous system [12], the myocardium[13], skeletal muscle [14], epidermis [15], intestinal track [16–20], liver [21] and pancreas [22].

The stem cell niche

Adult stem cells are thought to reside in a *stem cell niche* [23]. The niche is a specialised microenvironment that contains the signalling molecules required to maintain stem cell identity. Within the niche, a cell that has intrinsic stem cell potential will have a stem cell phenotype. Upon leaving the niche, such a cell will lose its stemness. A number of stem cell niches have been characterised. In the intestinal crypt for example, stem cells are thought to reside towards the crypt base (see Fig. 1a). Surrounding stromal cells, the *pericryptal myofibroblasts* secrete messenger proteins, including members of the Wnt and BMP families, which contribute to cell fate determination and regulate proliferation in the stem cell compartment (reviewed in [24]). The colonic crypt illustrates the

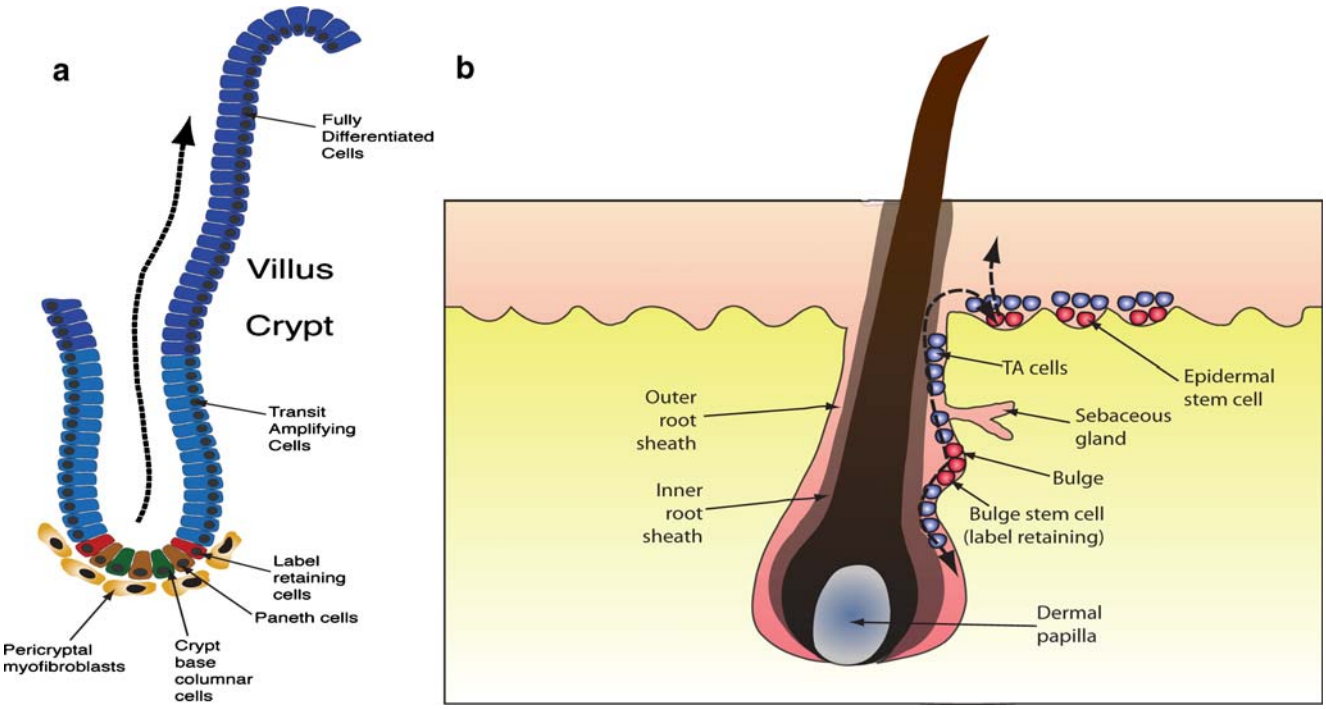

Fig. 1 The stem cell niche. **a** The small intestinal crypt. The stem cell zone is believed to be superior to the Paneth cell zone, but recent evidence suggests that Lgr5-expressing cells are located within the Paneth cell zone. These are entirely distinct from Paneth cells and have been called crypt base columnar cells (CBCs). The crypt is surrounded by a pericryptal myofibroblast sheath and this defines the crypt niche. Cross-talk between the stem cell and the myofibroblast is thought to maintain 'stemness'. **b** Epidermis. Here there are two populations of stem cells, one in the basal layer of the epidermis and one in the bulge region below the sebaceous gland. The progeny of the latter are thought differentiate into the follicle itself

reciprocal relationship in maintaining stemness that is shared between cells and their niche. In the crypt, epithelial cells themselves also express signalling molecules: for example, expression of the Hedgehog (Hh) ligands *Indian* and *Sonic Hedgehog* is restricted to the epithelial cells away from the crypt base [25, 26]. Hedgehog signalling antagonises proliferative Wnt signals, inhibiting proliferation in Hh^{+} cells and so restricting cell division to the stem cell compartment. In the fly testis, germline stem cells are clustered around a hub of non-dividing cells, which express the niche-ligand *Unpaired* (*Upd*). Upd stimulates the JAK–STAT pathway, which maintains stem cell identity [27, 28]. Spradling et al. have argued that a stem cell niche should persist on the removal of the stem cells [29]. Indeed, transplantation of germline stem cells from donor mice into the testes of sterile mice restored spermatogenesis [30]. Correspondingly, in the murine intestinal crypt, the stem cell compliment is readily restored following depletion by radiation or mutagen.

Given the remarkable proliferative potential of stem cells, tight regulation of stem cell division is required to prevent aberrant growth. Proliferation of stem cells must balance the need for self-renewal of the stem cell population with the constant requirement for new short-lived tissue-specific differentiated cells. One mechanism to balance this trade-off between renewal and proliferation is *asymmetric* stem cell division. Asymmetric division results in a stem cell producing one differentiated daughter cell and one daughter stem cell. In this manner, the normal stem cell compliment is maintained. The immediate differentiating cell progeny of the stem cells are thought to be *transit amplifying cells* (TA cells). TA cells have limited replicative potential and divide only a relatively small number of times to produce the bulk of the specialised, terminally differentiated (TD) cells in the tissue. Ohlstein and Spradling show clear evidence of this hierarchical tissue structure in the fly mid-gut [31]. Crypt-like structures in the fly are maintained by a single proliferative stem cell, which divides asymmetrically to produce differentiated enterocyte and enteroendocrine progeny. Hierarchical tissue structure has also been demonstrated in the mammalian intestine [32, 33]. Hierarchical tissue structures may have evolved to restrict the accumulation of mutations and so could be an anti-cancer mechanism. This idea is discussed in the next section.

Are all stem cell divisions asymmetric? The answer to this question is almost certainly no. Mutant stem cells can repopulate an entire niche [34–36], and further, analysis of the diversity of heritable methylation patterns in colon crypts is incompatible with a model where all stem cell lineages are immortal [37]. Thus, some stem cell divisions must be *symmetric*, producing either two stem cell progeny or two differentiated cell progeny. In order maintain a constant number of stem cells in the niche, the symmetric divisions resulting in two daughter stem cells (growth of a stem cell clone) must occur at the same frequency as symmetric divisions resulting in two differentiating daughter cells (death of a stem cell clone). Disruption to this balance can lead to aberrant growth and the formation of a tumour.

In the small intestinal crypt, cells migrate from the base of the crypt, along the vertical crypt axis and onto the villus (Fig. 1a). Thus, the crypt stem cells, the source of the differentiated cells, are very likely to be located at the base. Indeed, localisation of the putative stem cell marker Lgr5 (described later) to the cells at positions 1–3, suggests the intestinal stem cells reside between the Paneth cells at the crypt base [38]. Contrastingly, label retaining cells are located at positions 4–5 [39], where the putative stem cell marker Bmi1 [40] is also localised (described later). Proliferation in the crypt tends to be restricted to the bottom two-thirds [41]. Stem cells produce transit amplifying cells whose progeny constitute the bulk of the crypt cell population [33]. Regulation of cell division and differentiation of stem cell progeny into either Goblet or enteroendocrine cells or enterocytes are provided by a range of signalling pathways including Wnt, Notch and BMP pathways (reviewed in [42]).

Stem cell niches are thought to be present in all proliferative tissues. The structure of the epidermal stem cell niche has also been extensively investigated. Figure 1b schematically describes the structure of the follicle and surrounding epidermis. Briefly, there are two putative stem cell zones within the epidermis: the basal layer of the epidermal proliferative unit (EPU) of epidermis and the bulge region of the hair follicle. Each stem cell zone has its own independent niche. It should be noted that only thin, relatively unexposed skin exhibits EPUs: thicker, more exposed skin does not and is heavily keratinised. However, within an EPU, the basal layer is the most proliferative and high expression of adhesion markers such as β1 intergrins have been proposed as a stem cell marker in the basal layer [23] particularly in conjunction with a physical connection to the basement membrane. Stem cells in the bulge region primarily appear to be responsible for hair growth and maintenance of the sebaceous gland. Bulge cells have been characterised by their ability to retain DNA label and express the α4 integrin, transplanting these cells led to patches of hair-producing epidermis [43].

Self-defence in stem cell populations

Since DNA replication is not perfect, mutations occur each time a cell divides. In renewing tissues, such as the gastrointestinal epithelium, many millions of cell divisions

occur each day. When viewed in this light, the eventual acquisition of a tumorigenic mutation by a stem cell clone seems inevitable. Yet, cancers are relatively rare. Why is this? One persuasive answer is that the mechanisms that regulate stem cell divisions have evolved to limit somatic evolution in the stem cell population. Mathematical modelling shows that *hierarchical tissue structures*, whereby a few infrequently dividing stem cells produce short-lived transit amplifying cells that generate the bulk of the tissue mass, restrict the likelihood of oncogenic transformation of stem cells in a niche [44].

In 1975, John Cairns introduced his 'immortal strand hypothesis' (Fig. 2a) as a mechanisms by which adult stem cells protect themselves from accumulation mutations and hence minimising the risk of developing cancer [45]. The basic assumption is that the template DNA is selectively retained in asymmetrical division whilst the newly synthesised strand is passed on to the daughter cell, the transit-amplifying cell. Thus, any errors in replication will be transferred to progenitor cells and lost from the population [45]. Experimentally proving the hypothesis has been challenging; however, the presence of cells that apparently are able to segregate their template DNA strand has been observed in a limited number of tissues including small intestinal [46] and breast [47] epithelial cells and muscle satellite cells [48].

The hypothesis has been challenged, however, and no molecular mechanism for the selective retention of template DNA has been proposed. Furthermore, the immortal strand hypothesis requires that such label-retaining cells undergo

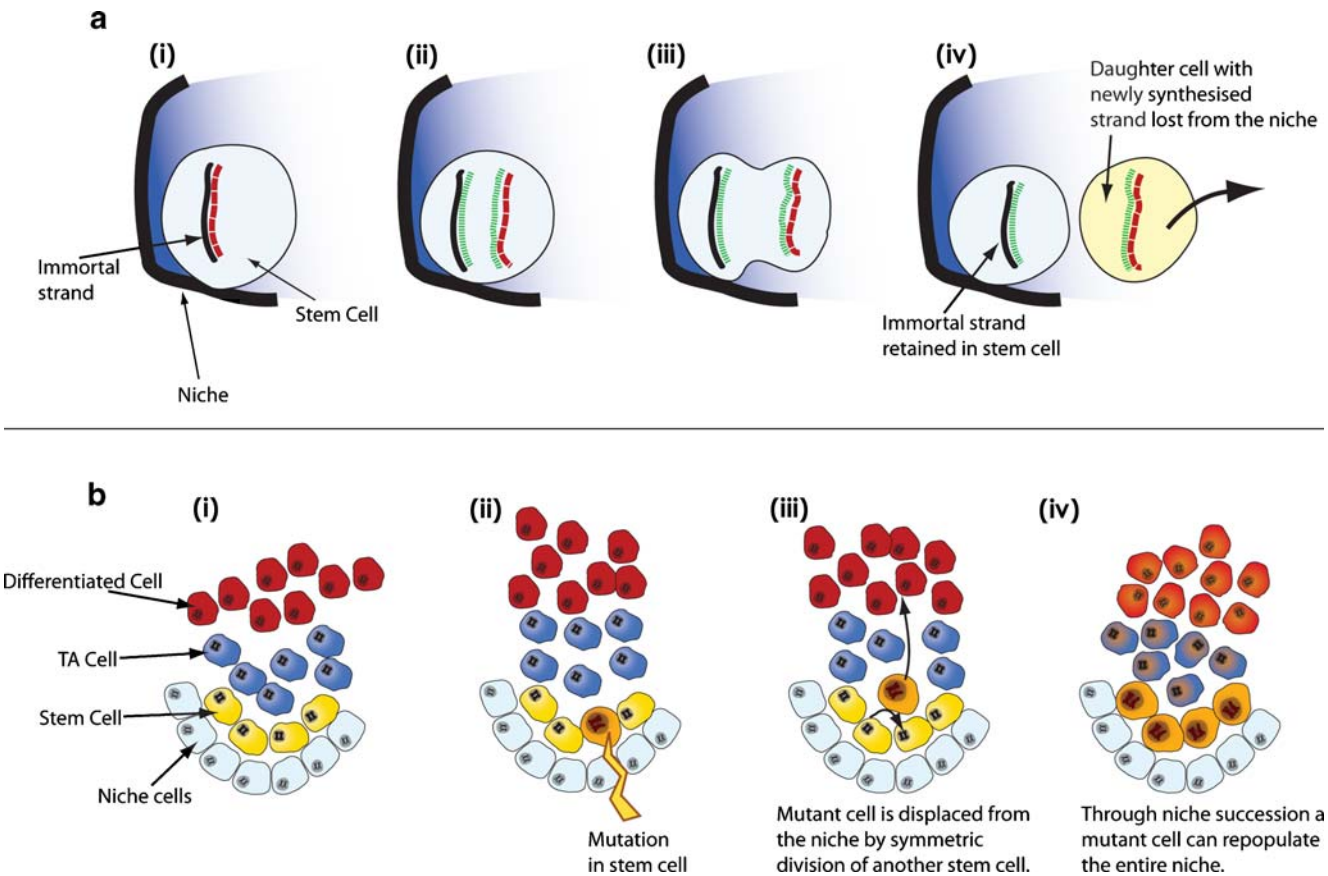

Fig. 2 Niche defence mechanisms. **a** The immortal strand hypothesis. Stem cells may selectively segregate newly formed, and hence error-prone, DNA strands to their short-lived progeny, and retain the original, error-free, template strand. *i* A stem cell in its niche with an immortal DNA strand (*black*), and the complementary new strand (*red*). *ii* DNA replication, with newly synthesised strands (*dashed green*). *iii* Mitosis. Chromatids are aligned in preparation for selective chromatid segregation. *iv* The stem cell retains the immortal strand, whilst the daughter cell inherits the newly synthesised DNA. **b** Hierarchical tissue structures restrict the accumulation of mutations. *i* The stem cell niche is maintained by a small number of stem cells (*yellow*), which produce transit amplifying progeny (*blue*) that divide frequently to produce the bulk of the differentiated cell population (*red*). *ii* A stem cell in the niche acquires a mutation (*orange*). Mutations could result from exposure to a mutagen or simply through random DNA replication errors. *iii* A symmetric division of an adjacent stem cell displaces the mutant cell from the niche. The mutant cell will be subsequently lost from the niche, and the niche reverts to being entirely wild-type. *iv* Alternatively, through niche succession, the mutant cell can repopulate the entire niche. The niche is now described as mono-clonally converted. Some stem cell mutations will provide a selective advantage for the mutant cell compared to the other stem cells in the niche, increasingly the likelihood the mutation is retained in the niche

further division but retain the template strand: this has yet to be shown experimentally. Lansdorp [49] recently proposed the 'silent sister' hypothesis, suggesting that cell fate in asymmetric division is co-directed by epigenetic differences between sister chromatids, inducing a non-random segregation of sister chromatids during mitosis. The daughter cell remaining as a stem cell selectively retains chromatids with active stem cell genes, with the loss of stem cell properties in the cell that inherits the opposite 'silent' sister chromatids [49]. Not all studies agree with the hypothesis. Haematopoietic stem cells (HSCs) with long-term repopulating activity have been shown not to segregate their template DNA strand nor do they retain label [50].

Occasional *symmetric divisions* of stem cells, which result in a stem cell producing two daughter stem cells, or two daughter differentiated cells, also restrict the rate at which mutations can accumulate in the stem cells in a niche [51]. This is because symmetric divisions eventually result in the loss of a stem cell clone: in order to keep the number of stem cells in a niche roughly constant, symmetric division of stem cells, producing two daughter stem cells, must be balanced by a second symmetric stem cell division which results in two differentiated cells and the eventual loss of the stem cell clone. Correspondingly, if a niche contains N stem cells, these random losses and expansions of stem cell lineages mean that the probability that a neutral mutation will become *fixed* in the niche is $1/N$, so that most neutral mutations are shed from the niche. This could therefore act as a defence mechanism whereby a neutral mutation, if it was allowed to continue to survive within the niche, may propagate a field of genetic instability encouraging further, possibly tumorigenic, mutations. This is illustrated in Fig. 2b.

Stem cells are also thought to have developed strategies in order to protect them from toxic environment agents. This seems to confer them with a resistance to xenobiotics, including many drugs used to treat cancer. A well-described defence mechanism involves the expression of members of the ATP-binding cassette (ABC) superfamily of membrane transporters. These proteins have the ability to hydrolyse ATP to support substrate efflux against steep concentrations, usually from the intra- to the extracellular space. Goodell et al. first reported the isolation of HSCs on the basis of their ability to efflux a fluorescent dye, Hoechst 33342 [52]. Cells that actively efflux the Hoechst dye appear as a distinct population of cells called the 'side population' (SP). Many studies suggest that the ABCG2 transporter, a member of the ABC superfamily [52], also known as the breast cancer resistance protein, determines the SP phenotype. The SP fraction often equates to the stem cell population in normal tissues as well as tumours [53, 54]; however, not all SP cells are stem cells [55]. The expression of such ABC transporters in cancer stem cells could enable them to efflux drugs and hence contribute to relapses and drug resistance in cancer.

There are other mechanisms known to protect stem cells in healthy tissue and possibly lead to resistance in cancer stem cells. HSCs for example have high levels of aldehyde dehydrogenase (ALDH), a detoxifying enzyme that confers resistance to alkylating reagents such as cyclophosphamide [56]. Indeed, a subpopulation of cells with high levels of ALDH has been found to define a poor prognosis group in acute myeloid leukemia (AML) [57]. In the bronchiolar epithelium, stem cells appear to be rare pollutant-resistant cells linked to a deficiency in phase 1 drug metabolising enzyme CYP450 [58]. In the liver, progenitor cells have been shown to expand despite exposure to pyrrolizidine alkaloids due to a similar deficiency in cytochrome P450 [59].

Markers of adult stem cells

It is not possible to morphologically distinguish a tissue stem cell from its 'non-stem' cell neighbour. As such, there has been a rush to find a stem cell marker that not only is specific for a stem cell area but can also demonstrate the multipotential properties of such cells. Recently, there have been significant advances in the identification of adult stem cell markers; no longer do we rely on markers that tag the supposed stem cell zone but instead use techniques that actually demonstrate multipotentiality, a crucial property of stem cells.

There is no doubt that the Wnt (reviewed elsewhere [60]) signalling pathway is inextricably linked to stem cell renewal and maintenance of the niche. Nuclear β-catenin has been shown to be present in normal basal intestinal crypt cells [61], and these could be stem cells; however, Paneth cells can also express nuclear β-catenin during their maturation [62], so this is probably not a reliable marker of stem cells. Barker et al. [38] have demonstrated a Wnt target gene, leucine-rich-repeat-containing-G protein-coupled receptor 5 (*Lgr5*) as a potential stem cell marker within the gastrointestinal tract of mice. After crossing *Lgr5-Cre-lox* transgenic mice with ROSA26-*LacZ* mice [38], this group was able to trace the development of Lgr5+ve cells within crypts via the expression of LacZ. Initially, cells appeared in crypt base columnar (CBC) cells in the small intestine and at the base of the colon. Over time, LacZ expression spread throughout the crypt telling us that Lgr5 expression was induced in a stem cell and the progeny eventually formed all the differentiated epithelial phenotypes within the crypt, therefore demonstrating multipotentiality. Furthermore, a recent paper by the same group has elegantly shown that isolation and culture of *lgr5*+ve cells results in the in vitro

formation of rudimentary crypts and villi in an organoid fashion [63]. What is so interesting about this paper is that crypts and villi appear to form in the absence of an obvious niche. If this can be repeated in other systems, we may have to rethink the dogma that a stem cell only remains a stem cell whilst is in a niche.

Subsequent to this, another marker of murine intestinal stem cells was proposed using a similar approach. Bmi1, a member of the Polycomb group gene family, was first described as an oncogene that induces leukaemias [64] and appears to play a role in stem cell self-renewal [65]. Bmi1 has been shown to be over-expressed in intestinal cancers [66, 67]. By using a transgenic mouse model that expressed *Cre* under the *Bmi1* locus crossed with a *Cre*-inducing *LacZ* (Rosa26) mouse, Sangiorgi and Capecchi [40] demonstrated that 20 h post-tamoxifen injection, Bmi1+ve cells (by β-gal expression) appeared at cell position 4, the originally proposed stem cell position [68]. Over time, these cells expanded eventually taking over the entire crypt, in a similar fashion to that shown by Barker et al., with Lgr5. Interestingly, the Lgr5 transgenic mice showed little in the way of intestinal epithelial abnormalities; however, when the Bmi1 transgenic mice were crossed with a mouse expressing the diphtheria toxin, tamoxifen injections resulted in a loss of crypt number over time, indicating that there has been a loss of the stem cell compartment and that Bmi1 has an important function in the maintenance of tissue stem cells. Thus, maybe a two-tier system operates in the small intestine, with rapidly cycling CBC stem cells supported by slowly cycling, so-called label retaining stem cells at cell positions 4–5.

There have been a number of other markers that have been suggested, the most notable being Musashi-1 (Msi1). Msi1 is an RNA-binding protein that blocks the translation of *m-Numb* RNA and so has a positive regulating effect on Notch signalling [69]. Msi1 is expressed at the base of the colonic crypt and at cell positions 3–4 in the small intestinal crypt [70]. It is also expressed in the so-called CBC cells (small, slender cells that sit in amongst the Paneth cells) within the small intestine, which are also positive for Lgr5 [67]. It has been shown to suppress the differentiation of Paneth cells and may have a role in maintaining 'stemness' [71]. Before Msi1 can be considered a true marker of intestinal stem cells, it must be shown to be expressed on cells that demonstrate multipotentiality. Other markers of intestinal stem cells have been proposed including DCAMKL-1 [72], EphB receptors [73] and label-retaining cells [46], all of which have been shown to be expressed in the stem cell zone but have not yet been shown to have any robust stem cell properties.

Unlike the intestine, the liver does not have a well-defined niche; indeed, the liver is normally proliferatively quiescent. This has led to the belief that there may not be a stem cell population within the liver, but rather a slow but continuous turnover of cells such as hepatocytes. However, upon partial hepatectomy, a fast regenerative response occurs which involves all hepatic cell types, restoring the liver to its original state [74], suggesting that there may be progenitor/stem cell-like populations in the liver. Recently, our group has shown that mitochondrial DNA mutations can be used as a marker of clonal expansion of a stem cell clone from the portal area in vivo [34]. Markers of hepatic stem cells have been proposed (label-retaining cells [75], STAT3 and Oct4 [76]), and indeed these cells are located proximal to the portal area, but none have adequately been demonstrated as stem cells.

Cancer stem cells

For many years, it has been apparent that stem cells feature in processes as diverse as wound healing, metaplasia and cancer. Two-stage models of skin cancer in rodents carried out in the 1950s strongly suggested that cancers had their origins in long-lived epidermal stem cells, but the idea that cancers themselves might have malignant CSCs is only just gaining widespread acceptance, despite the fact that Hamburger and Salmon in 1977 [4] using colony formation in soft agar as a surrogate stem cell assay found that for many human tumours, only one in 1,000 to one in 5,000 cells was able to form a macroscopic colony.

Cancer could arise from the dedifferentiation of mature cells that have retained the ability to divide, or it could result from the 'maturation arrest' of immature stem cells [77]. The idea of 'blocked ontogeny' has gained wide acceptance, and we now believe that the arrested differentiation of tissue-based stem cells or their immediate progenitors is closely linked to the development of not only tetratocarcinomas and haematological malignancies, but also carcinomas. Some of the most frequent cancers occur in tissues with a high cell turnover such as the skin and the epithelial lining of the gastrointestinal tract. It is argued, not unreasonably in our view, that in these tissues the stem cells are the only cells with sufficient life span to acquire the requisite number of genetic abnormalities for malignant transformation. Additionally, with a self-renewal mechanism already in place, seemingly fewer alterations are required to change normal stem cells into CSCs. In the now classical two-stage model of mouse skin carcinogenesis, severely delaying the interval between 7,12-dimethylbenz(*a*)anthracene initiation and the application of the phorbol ester promoter had no bearing on subsequent tumour yield—strongly suggestive of an origin in a long-lived cell, an epidermal stem cell [78].

Direct genetic labelling of adult stem cells in the mouse small intestine has revealed that tumours, in this case, adenomas, arise directly from adult stem cells [79,

80]. Notwithstanding the current debate about whether cancer stem cells, or more correctly tumour-initiating cells (TICs), are rare or quite common, it is quite clear that more than one marker has been used to enrich for TICs from a given tumour type. For example, both CD133 and CD44 have been employed for enrichment of TICs in both colorectal [81, 82] and pancreatic cancer [83, 84]. Indeed, there may well be phenotypic diversity amongst the CSC population within a single tumour population as suggested for gliobastoma multiforme [85]. In fact, the CSC population may be a moving target as cells lose or acquire properties of 'stemness', as seen when Twist or Snail is up-regulated in breast cancer epithelial cells resulting in epithelial–mesenchymal transition (EMT)—remarkably these mesenchymal-like cells also acquired the widely perceived breast CSC phenotype, $CD44^{+}CD24^{low}$ [86]. The development of metastasis might well involve the dissemination of CSCs, particularly involving those cells at the tumour margins that have undergone EMT—the so-called migrating cancer stem cells [43]. This process may be aided by the expression of chemokine receptors on CSCs as observed in pancreatic cancer [83]. These concepts are depicted in Fig. 3.

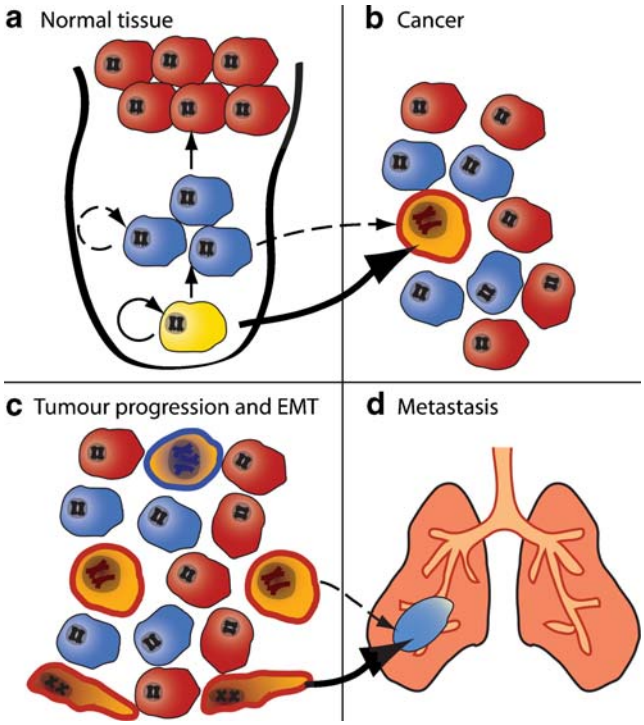

Fig. 3 Current concepts regarding stem cells and tumour evolution in tissues with ordered structure such as epithelia. **a** In normal tissues, adult stem cells (ASC, *yellow*) self-renew and give rise to transit amplifying cells (TAC, *blue*) that divide several times before undergoing terminal differentiation (TD, *red*). Many lines of evidence, including direct lineage tracing from genetically marked ASC indicate that tumours arise from ASCs, though an origin from TACs is also possible. **b** Tumours also have a hierarchical structure, albeit a relatively disorganised one, the cancer stem cells (CSC, *yellow*, altered chromosomes) may have a single phenotype (X surface colour denotes a specific surface phenotype, e.g., $CD44^{+}CD24^{low/-}$ in breast cancer) and be rare or relatively common. **c** Genetic or epigenetic events may result in new clones driven by phenotypically diverse populations of CSCs (*yellow cells* with Y surface colour). Further genetic or epigenetic changes may result in some cells undergoing epithelial–mesenchymal transition (EMT, *yellow* fibroblast-like cell) equipping them with CSC properties, and **d** metastasis may be caused by migrating CSCs detaching from the tumour mass, in particular these may be the CSCs formed through EMT that may respond to chemotactic gradients by virtue of expression of chemokine receptors such as CXCR4

Markers of CSCs

Considerable effort is being expended in the search for 'markers' of stem cells, with every expectation that many of the molecules expressed by normal stem cells will also be found in their malignant counterparts. Collectively, these molecules appear to be involved in maintaining 'stemness' (transcription factors such as Oct-4 and Nanog), ensuring adhesion to the niche and be involved in cytoprotection [87]. Many putative stem cells have acquired the ability to withstand cytotoxic insults through either efficient enzyme-based detoxification systems or by the ability to rapidly export potentially harmful xenobiotics. This would include high expression of ABC transporters, responsible for the SP and ALDH gene superfamily encoding detoxifying enzymes for many pharmaceuticals and environmental pollutants [88]. As expected, high expression of ALDH can be detrimental to tumour eradication; cyclophosphamide treatment of human colonic xenografts enriches for CD44+ALDH+ cells, and these double positive cells were more tumorigenic than cells selected by solely CD44 positivity [89].

As discussed earlier, another proposed stem cell marker is Bmi1, required, for example, for the self-renewal of HSCs. Loss of Bmi1 leads to a depletion of neural stem cells, associated with upregulation of $p16^{Ink4a}$ [90]. The premature senescence of murine neural stem cells is prevented by Bmi1, suppressing transcription at the *Ink4a/Arf* locus that encodes $p16^{Ink4a}$ and $p19^{Arf}$ [90].

Perhaps, the most 'popular' marker of putative stem cells is Prominin-1 (CD133), the first identified member of the rapidly growing prominin family of pentaspan membrane proteins [91, 92]. The specific functions and ligands of the prominins are still relatively unclear, but they are distinct in their restricted expression within plasma membrane protrusions, such as epithelial microvilli [93]. Two antibodies, CD133/1 (aka AC133) and CD133/2 (aka AC141) recognise different glycosylated epitopes, and most studies use CD133/1. In combination with other markers, CD133 has been used to isolate HSCs and endothelial progenitor cells (EPCs), but its greatest utility has been in the enrichment of cells with tumour-initiating ability (so-called cancer stem

cells) in immune-deficient mice from a variety of human solid tumours, including brain, prostate, liver and colon [94]. However, a recent study has found that most normal and malignant colonic epithelial cells express CD133, and moreover, CD133-negative cells isolated from colorectal liver metastases were at least as tumorigenic as their CD133-positive counterparts [95].

Cancer stem cells in solid tumours

Colorectal cancer is one of the most common forms of solid tumour in the western world and accounts for approximately 10% of cancer-related deaths in Europe [96]. There is therefore a distinct need to develop markers to develop our understanding of the origins of colorectal cancer at a cellular level and evaluate the contribution of stem cells in this disease.

CD133 (Prominin-1) has received the most attention as such a colorectal cancer stem cell marker. Initial publications by O'Brien et al. and Ricci-Vitiani et al. demonstrated that when CD133-positive cells were purified from clinical colorectal tumours they were capable of initiating tumours in immunodeficient mice. Indeed, tumours were established by transplanting as few as 3,000 CD133-positive cells and grew faster than when 10^6 whole tumour cell populations were injected; when CD133-negative cells were injected, no tumours arose. This was potentially a very significant observation, showing for the first time a specific population of cancer cells that expressed a marker that was easily identified and was able to initiate tumour growth although the true function of CD133 in such cells has not been identified. As with nearly every other potential marker of cancer stem cells, it was not long before CD133 as a cancer stem cell marker in the intestine was called into question. Shmelkov et al. created a knock-in *LacZ* reporter mouse whose LacZ expression was driven by the CD133 promoter. They showed that CD133 expression was not restricted to the stem cell zone of the crypt, but expressed all over the intestinal epithelium. When they crossed $CD133^{LacZ/+}$ mice with IL-$10^{-/-}$ mice (who develop spontaneous colonic inflammation progressing to adenocarcinoma [95]), the entire tumour expressed CD133. Furthermore, they also demonstrated that both CD133-positive and CD133-negative metastatic colon cancer cells, derived from clinical material, were able to initiate tumours. This does not hold true for all cancer stem cell systems. In cells isolated from brain cancer, clonogenicity and self-renewal seem to be exclusive to a subpopulation of cells expressing CD133 and nestin, regardless of the tumour phenotype [97].

The observation that SP cells, characterised by their ability to efflux Hoechst 33342 dye, represents a stem cell or even cancer stem cell population has been proposed [98], but does not apply to all tissues. In the mouse hair follicle for example, the SP cells are found beneath the label-retaining bulge and thus correspond to TACs [99]. Likewise, in human epidermis and the murine haematopoietic system, the SP phenotype does not appear to be specific for stem cells [99]. Haraguchi et al. [100] demonstrated that human colorectal cancers do contain a SP and that these cells expressed ABCG2. However, recent evidence from our group has suggested that SP cells are not enriched for cancer stem cells [101] and SP-enriched or SP-negative cells are both equally able to induce tumours in immunodeficient mice.

Despite the vast amount of research into putative cancer stem cell markers in colorectal tumours, only Lgr5 has been shown to be a marker of normal crypt stem cells, and it also has been used to demonstrate that crypt stem cells can be the TIC population that gives rise to colorectal cancer. Barker et al. [102] elegantly demonstrated that deletion of *Apc* in a *Lgr5* knock-in transgenic mouse quickly lead to transformation (dysplastic cells expressing β-catenin) within a few days. Over time, this spreads in a bottom-up fashion [103] leading to the development of monocryptal adenoma-like crypts and eventually to large adenomas (Fig. 4). Along with evidence that the expression of Lgr5 is greatly increased in advanced colorectal cancers [104], this has the potential to be an extremely promising marker for targeted therapy.

Evidence for the existence of CSCs in the lung was first described more than 25 years ago in a study by Carney et al. [105]. In this study, a small population of cells (<1.5%) isolated from the tumours of both adenocarcinoma of the lung and small cell lung cancer (SCLC) patients were able to form colonies in a soft agar cloning assay. As with other solid tumours, CD133 expression features predominantly in the search for CSCs in the lung. In non-small cell lung cancer (NSCLC), 1,000 $CD133^+$ cells could form tumours in SCID mice, but 10^4 CD133-negative cells never did [106]. The CD133-positive cells showed enhanced expression of Oct-4 and ABCG2; siRNA knockdown of Oct-4 blocked clonogenicity and enhanced chemosensitivity. In both SCLC and NSCLC a small (<1%) population of CD133-posiive cells has been found, with 10^4 of these cells capable of forming tumours in SCID mice with features of the parent tumours [107]. These in vitro sphere-forming cells often expressed Oct-4 and Nanog along with CCSP and SP-C. Exploiting the perceived chemoresistance of CSCs, CSCs have been enriched in a NSCLC cell line by treating with the likes of cisplatin and doxorubicin [108]; 5×10^3 drug selected cells regularly formed tumours in SCID mice. These cells expressed CD133 and CD117 and the embryonic stem cell markers SSEA-3, TRA1-81 and Oct-4 and had nuclear β-catenin. In the cell line, the SP fraction was 5.2%, but

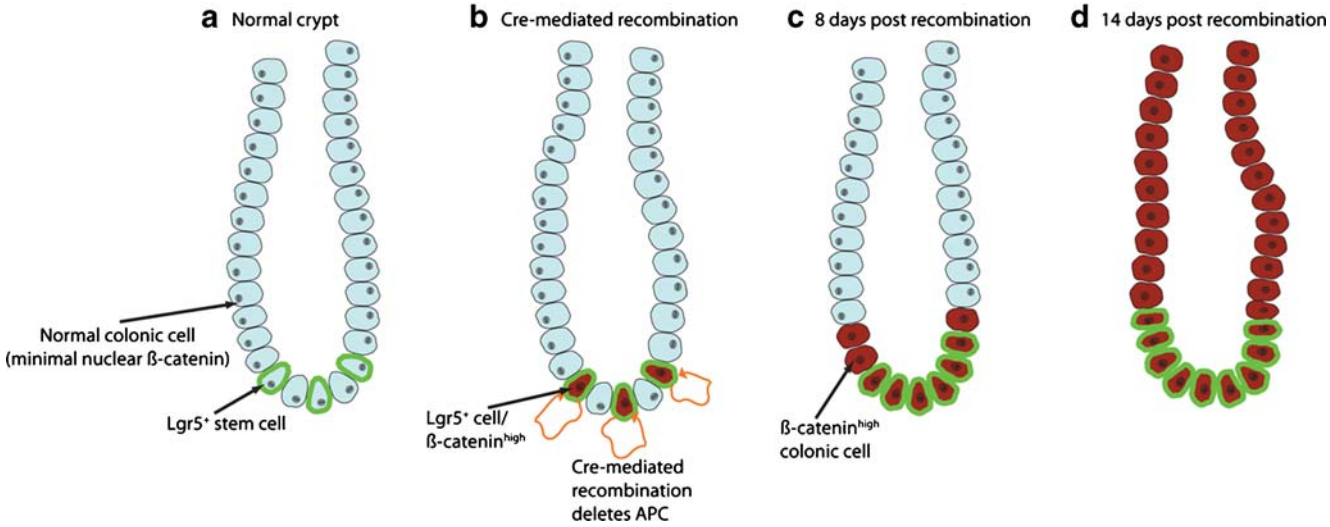

Fig. 4 To demonstrate the process by which a stem cell at the base of a crypt can transform the crypt to an adenoma, we illustrate the work done by Barker et al. [102]. **a** A normal colon crypt contains between 4 and 6 Lgr5+ stem cells (*green border*) located at the crypt base, between the Paneth cells. In Lgr5-EGFP-IRES-creER mice, Lgr5-expressing cells are transiently labelled with GFP and also express creER. **b** Following tamoxifen injection, the creER, which is expressed only in Lgr5+ cells, is activated and the resulting cre-mediated recombination removes the floxed APC gene in these cells. The transformed cells rapidly become strongly positive for β-catenin (*brown cells*), a marker of adenomatous growth. **c** At 8 days post-recombination, the β-catenin high cells were still restricted to the base of the crypts. **d** At 2 weeks post-recombination, crypts entirely composed of β-catenin high cells were observed—therefore niche succession and monoclonal conversion has occurred. In these adenomatous crypts, Lgr5 expression was still localised to the putative stem cell zone at the crypt base (*brown cells*, *green border*). At 36 days post-recombination, multiple β-catenin high adenomas were observed throughout the intestine

after drug treatment this was increased to 35%. Clearly, drug resistance and lung CSCs are heavily entwined. In the A549 NSCLC cell line, a large (24%) SP has been found, with enhanced resistance to doxorubicin and methotrexate related to ABCG2 activity [109].

Using the CD133/1 antibody, a number of studies have suggested that the CD133-positive fraction enriches for hepatocellular carcinoma (HCC) CSCs [110, 111]. As might be expected of CSCs, they appear as a minority (<2%) population in primary tumours, though continued passaging has resulted in considerable enrichment of $CD133^+$ cells in some HCC cell lines, up to 90% [110]. HCCs with higher than the median number (1.32%) of CD133-positive cells are correlated with shorter survival, higher recurrence rates and higher tumour grade [112], and $CD133^+$ cells appear highly resistant to conventional therapeutic drugs such as 5-FU and doxorubicin [113].

Are cancer stem cells rare?

CSCs are believed to have stem cell characteristics, particularly the ability to self-renew and to give rise to a hierarchy of progenitor and differentiated cells, albeit in a disorganised manner that gives rise to more CSCs. Operationally at present, CSCs are regarded as prospectively purified cells that are more tumorigenic than the bulk or the marker-negative tumour population in a suitable tumour development assay, e.g., after transplantation to NOD/SCID mice. More stringently, a CSC should be a cell that can reconstitute, in a recipient animal, a tumour identical to the original tumour in the patient, which can then be serially xenotransplanted indefinitely. At present, most putative CSCs are identified by their tumour-initiating ability and are thus referred to as TICs. The conventional wisdom is that CSCs are rare based upon having to xenotransplant large numbers of human tumour cells into immunodeficient mice to further propagate the tumours; however, this might have more to do with a hostile murine microenvironment. For example, a few as ten mouse lymphoma or AML cells can regularly propagate the tumours when transplanted into histocompatible mice, so are all cells in these tumours possible TICs? [114]. Using standard immunodeficient mice, the frequency of TICs in human melanoma has been reported to be in the order of one in 10^6 [115], but even single human melanoma cells can form tumours in more highly immunocompromised NOD/SCID/IL2Rγ null mice [116]. The rarity of cancer stem cells has also been questioned in lung cancer; using up to a dozen murine lung cancer cell lines, cell colonies could be regularly generated from randomly selected cells, and when 2×10^5 cells from these clonally derived colonies were allografted into histocompatible mice, tumours were consistently produced, suggesting that perhaps that the

TICs do not have a unique surface marker signature [117]. Thus, perhaps we need to modify the CSC hypothesis accordingly:

1. CSCs are cells that can be prospectively isolated and initiate malignant growth in vivo.
2. CSCs are not necessarily rare, but they must be effectively targeted for definitive cures since they can often be especially radioresistant and chemoresistant.

Implications for treatment

For tomorrow's oncologist, a variety of druggable targets and strategies related to CSCs present themselves and include:

- Wnt signalling
- Hedgehog signalling
- Notch/Delta signalling
- mTOR
- ABC transporters
- Targeting the stem cell niche
- Small molecule cancer therapeutics (miRNAs, tyrosine kinase inhibitors)
- Gene therapy

Proliferation of CSCs is likely to involve dysregulation of the pathways present in normal stem cell self-renewal such as the Wnt-/β-catenin, PTEN, Notch and Hedgehog pathways, as well as the products of the *Bmi1* and other polycomb genes. In many tissues, key regulators of stem cell renewal appear to be members of the Polycomb group protein family of transcriptional repressors (Bmi1, Rae28, Mel-18). Bmi1 targets genes such as $p16^{INK4A}$ and $p14^{ARF}$ preventing stem cell senescence by respectively maintaining cyclinD/Cdk4 signalling and Mdm2 destruction of p53. Bmi1 is in fact a downstream target of the morphogen Sonic hedgehog (Shh) through the latter's activation of the Gli family of latent transcription factors. Shh acts on the receptor complex of Patched (PTCH) and Smoothened (SMO), blocking the restraining influence of PTCH on SMO, resulting in SMO signalling activating the Gli family of transcription factors and so activating target genes like *Bmi1*. Inhibiting the action of SMO with the antagonist cyclopamine is a highly effective strategy against some cancers. It has been claimed that almost all SCLCs ubiquitously express Bmi1 [117], and antisense *Bmi1* RNA therapy reduces proliferation of A549 cells [118]. The Notch family of receptors is also critical for stem cell self-renewal. Engagement of ligands of the Delta and Jagged families causes cleavage, mediated by the γ-secretase protease complex, of the intracellular portion of Notch and its translocation to the nucleus where it binds to the transcription factor CSL, changing it from a transcriptional repressor to an activator. The use of γ-secretase inhibitors may have utility in cancers where Notch signalling is inappropriately activated [119].

Apart from the renewal and proliferation pathways, there are many other potential molecular targets relating to CSCs. As many tumours have SP fractions, almost certainly enriched for CSCs, targeting ABC transporter activity will be an obvious strategy for overcoming chemoresistance as well as directly eradicating stem cells, drug resistance being particularly problematic in SCLCs [120].

Antibody-based targeting of CSCs exploiting the over-expression of the likes of CD133 is another possible approach, while CSCs may reside in areas rich in blood vessels, so-called vascular niches. So while anti-angiogenic therapy is not new, used to debulk tumours through disruption of their blood supply, the destruction of the CSC niche adds a new twist to the story. Small molecule therapeutics that target growth factors, growth factor receptors and their kinases, and more specifically tyrosine kinase inhibitors such as imatinib that target c-Kit-positive cells are also gaining widespread usage.

Conclusions

Novel markers of tissue stem cells have recently been proposed that are able to identify cells that are multipotential in nature. These include Lgr5 and Bmi1. Although further research is required to demonstrate these molecules as definitive stem cell markers within human tissues, work done in transgenic mice has opened up their potential. Whether or not such markers identify tumour-initiating cells in cancer patients is unclear. It is likely that tumour-initiating cells are indeed stem cells and that tumours themselves are maintained by a population of cancer stem cells—these may not be the same cell. Cancer stem cells are thought to be rare; however, recent studies have shown that these may be far more common within the tumour than was initially thought.

Art and the teaching of pathological anatomy at the University of Florence since the nineteenth century

Gabriella Nesi · Raffaella Santi · Gian Luigi Taddei

Received: 14 January 2009 / Revised: 12 May 2009 / Accepted: 17 May 2009 / Published online: 9 June 2009

Abstract In 1840, the University of Florence was the first university in Italy to confer a Professorship in Pathological Anatomy. The origin of this teaching post is linked to the history of the Pathology Museum founded in 1824 by the Florentine *Accademia Medico-Fisica*. The Museum houses anatomical specimens and waxworks depicting pathological conditions in the nineteenth century. Both the need to instruct medical students in pathology without resorting to corpse dissection and the difficulty of the lengthy preservation of anatomical preparations made it necessary to produce life-sized wax duplicates of diseased parts of the body. Through the history of the Pathology Museum of Florence, we describe how pathology developed and, in particular, how pathologists from a literary circle laid the foundations of modern surgical pathology in Italy. Museum visits for the medical students guided by lecturers are still today a component of the course of Pathological Anatomy.

Keywords Historical materials · Didactic materials · Museum specimens · Anatomy · Wax models · Pathology

The foundation of the Pathology Museum of the University of Florence

The Pathology Museum of the University of Florence houses a vast collection of anatomical casts and more than a hundred waxworks that document the most common diseases in the nineteenth century, when the collection was set up [1].

It was created by the Florentine *Accademia Medico-Fisica*, which stemmed from the prestigious association of "men of letters", which was the *Gabinetto Vieusseux*, founded in 1819 by Giovan Pietro Vieusseux (1779–1863) [2]. Originally a reading room that provided leading European periodicals for Florentines and visitors from abroad, the *Gabinetto* soon became a reference point in the panorama of Italian nineteenth century culture. In 1820, Vieusseux inaugurated the *Antologia*, a periodical of intellectual and political commitment. Substantially dedicated to the natural sciences, geography, and travel, it also published medical articles and the minutes of the meetings of the Florentine *Accademia Medico-Fisica* [3].

Among the better-known members were Pietro Betti (1784–1863) and Filippo Pacini (1812–1883). In 1835, the latter delivered a report illustrating sensorial corpuscles, which were subsequently given the denomination "Pacini's corpuscles". Of particular interest was the lively discussion on the nature of cholera, which led to the rules of hygiene and potability of water [2].

It was during the first assembly of the *Accademia* on 4 February 1824 that the proposal by Pietro Betti to allow each member to contribute anatomical specimens was accepted, and after a few months, it was decided to institute a pathology museum, following the wishes of Angiolo Nespoli (1786–1839), then President of the *Accademia* [4].

Pietro Betti, rightfully considered the mastermind of the Museum, was appointed custodian of pathological casts and dedicated himself to looking after the Museum and increasing its value both in quantity and quality [5]. On 5 May 1824, he suggested ways for recording pathological casts, thus preluding the Catalogue, which, as well as chemical analyses, provided case histories and illustrations [1].

In a short time, the museum treasures had outgrown the assembly hall of the *Gabinetto Vieusseux* and non-medical members aspired to more pleasurable surroundings for their meetings. Such a situation drove Museum supporters in January 1825 to seek temporary accommodation in private premises at No. 3 *Via delle Belle Donne* [4]. The *Accademia Medico-Fisica* was then moved to the *Imperiale e Reale Arcispedale di Santa Maria Nuova* in March 1838, and the Pathology Museum was incorporated into the one already existing in that hospital.

In 1959, the Institute of Pathological Anatomy and the Museum were transferred to Careggi General Hospital, the foremost medical institution in Florence. The Museum is currently housed in the Department of Human Pathology and Oncology of the University of Florence (Fig. 1).

Visits to the Pathology Museum guided by the lecturers are nowadays a standard component of the course of Pathological Anatomy at the Faculty of Medicine, while students of the Fine Arts periodically visit the collection to sketch the wax models and anatomical casts.

The rise of pathological anatomy in Italy

In 1839, the *Ordinamento delle Autopsie nell'Arcispedale* was approved, where it was specified that every autopsy was to be presided over by the director of the Pathology Museum and that the medical history of every deceased patient was to be archived. Clinical diagnoses were to be compared with the autopsy findings, and the diseased parts of the body which had been surgically removed handed over to the Museum. Finally, if the patient was instead cured, the doctor was required to send the Museum a report on the therapy employed [6]. This handling of matters suggested an approach to modern clinico-pathological correlation in Italy, and a network was created among clinicians, surgeons, and pathologists.

Fig. 1 Overall view of the pathology museum at the Department of Human Pathology and Oncology of the University of Florence

A *Registro delle Autopsie* was set up in 1839; the practice of recording autopsies having never been suspended since. Included in the volumes are the 1,469 clinical histories of autopsy cases performed between 1839 and 1881 [1]. In actual fact, the protocol for carrying out and registering the autopsies was considered so effective that it constituted a model for the first legislation on the subject after the establishment of the Kingdom of Italy.

These were fertile years for pathology. As Superintendent of the *Imperiale e Reale Arcispedale di Santa Maria Nuova*, Betti proposed to institute a Professorship of Pathological Anatomy in Florence in his *Progetto di coordinamento degli Studi medico-chirurgici in S. M. Nuova coll'insegnamento già sanzionato per l'Università di Pisa* [5]. In this document, he also stated that the main responsibility of the Assistant to the Professor of Pathological Anatomy was the management of the Museum. In 1840, the first Chair of Pathological Anatomy in Italy was set up and entrusted to the surgeon Carlo Burci (1815–1875), previously curator of the Museum and translator of the treatise *De abditis nonnullis ac mirandis morborum et sanationum causis* by Antonio Benivieni (1443–1502).

The foundation of the Pathology Museum went hand in hand with the Pathological Anatomy Professorship, as did the nominations of the Professor and the curator of the pathological casts. Giuseppe Ricci was appointed Assistant to the Professor of Pathological Anatomy. Formerly Anatomy Dissector, he moulded most of the waxworks (about 60) seen today in the Museum [1].

Succeeding Burci as Professor of Pathological Anatomy was the Director of the Museum, Ferdinando Zannetti (1801–1881), well known for having removed a bullet from the hip of General Garibaldi at the battle of Aspromonte in 1862, thus avoiding amputation of the leg [7].

Ceroplastics and waxes as didactic tools in medicine

The decision to set up wax duplicates of diseased parts of the body was prompted by difficulties in conserving pathological material and by the need to instruct young doctors without resorting to corpse dissection. All the same, the artistic value of these works should not be underestimated (Fig. 2). They are an admirable example of symbiosis between Art and Science, in the wake of the Bolognese school of wax modelling acclaimed in the eighteenth century, with the works of Ercole Lelli (1702–1766), Giovanni Manzolini (1700–1755) and his wife, Anna Morandi (1716–1774) [8, 9].

Building on the anatomical discoveries made in the age of scientific enlightenment, wax models gave medical

students hands-on experience of both normal and aberrant processes not provided by fixed organs and tissues, considering that, in addition to tri-dimensionality, they offered the "dimension" of colour, an essential element for a correct gross diagnosis [10].

Since antiquity, wax votive figures had been offered to the divinities in propitiation, in requesting divine intervention in an ailment or as token of gratitude for grace received. Often, such works were made in the form of the body part, which needed the healing favour. For a long time after 1400, the Florentine church of the Annunziata housed the most splendid series of this type of figure (*boti* in the Florentine dialect). There were carpenter and wax workshops in the precincts of the church. One of these belonged to the Benintendi family, of whom the artist Orsino was a member, mentioned by Vasari as a pupil of Verrocchio [8, 11].

The use of wax was well known to artists and particularly to sculptors, both because they moulded wax models (whether the finished or the preparatory versions) and because of the increasing application of the so-called *cire perdue* or "lost wax" technique, in use since 2000 BC [12, 13].

It was from the fifteenth to the eighteenth centuries that the art of ceroplastics enjoyed its climax. With the contributions of Leonardo da Vinci and the impulse imparted by Paolo Mascagni (1755–1815), these specimens, especially dedicated to the study of lymph vessels, came closer to technical perfection [11].

In 1775, the *Imperiale e Regio Museo di Fisica e Storia Naturale* was established under the patronage of the first Hapsburg duke of Tuscany, Pietro Leopoldo, a remarkably enlightened and progressive leader. Attached was a wax studio, called *La Specola* after an astronomical and meteorological observation tower housed in the same building (Fig. 3). This laboratory produced a truly conspicuous number of waxworks of normal anatomy under the supervision first of Felice Fontana (1730–1805), a professor of Logic from Pisa, followed by a string of skilful dissectors and modellers, among whom were Clemente Susini (1754–1814), Luigi Calamai (1796–1851), Francesco Calenzuoli (1796–1829), Filippo Uccelli (1770–1832) and Egisto Tortori (1829–1893) [8, 13–15].

Produced on commission of Emperor Joseph II were the anatomical casts from the *Josephinum* collection at the Viennese Institute of the History of Medicine. These waxes, totalling 1,190 pieces, were at that time paid 30,000 gold coins. Other waxworks were sent to Perugia, Genoa and Cagliari and attracted a cultured, elitist class of tourists not often acquainted with medicine [16].

Moulage production in Berlin began immediately after the International Congress in Paris in 1889, thanks to Oskar Lassar (1849–1907), founder of the Dermatological Society in Berlin [17]. Lassar was of the opinion that the diagnostic ability of specialists in dermatology would be improved if they themselves were able to create moulages. One of the courses was held by Lassar himself and his mouleur Heinrich Kasten. For a specialist in dermatology, this 1-month course would have been enough to expand basic knowledge in moulaging. However, if there were no knowledge of skin diseases, the learning process would have taken much longer. These courses were, therefore, restricted to doctors trained in dermatology, who, apart from the technique of moulaging, could then instruct their

own mouleurs in the morphology of normal and diseased skin. Lassar and Kasten kept an approachable stance towards education in the art of moulaging, in contrast to other places in Europe where the few respected mouleurs were reluctant to give any details about the preparation of the plaster and wax mixtures, colouring methods, refinement and mounting [17].

At the beginning of the nineteenth century, a second revolution in biological investigations was started, with the physiological and histological sciences taking root. Although major anatomical institutes remain important components of medical education, they became largely inactive regarding research. The poor techniques of cadaver fixation limited the study of anatomical specimens. For this reason, dissections were best carried out in winter within 4 days. The introduction of more advanced fixation techniques allowed dissections to continue over the course of many days or weeks. Dissected specimens could also be preserved for long periods, which allowed for a more detailed study.

Fig. 5 Wax model by E. Tortori of a monoventricular heart in a newborn infant

Fig. 6 One of the four volumes of the Museum Catalogue detailing case histories and pathological specimens

Although the Florentine production of anatomical waxes ceased on Tortori's death in 1893, modelling in a more modest form has been carried on to the present day. Such models, produced by firms like Auzoux and Somso, represent valid tools in modern medical education [13].

The Pathology Museum of Florence: collection of anatomical casts and wax models

The Pathology Museum of the University of Florence, lodged on the top floor of the Department of Human Pathology and Oncology at Careggi Hospital, covers an area of 200 m^2. The collection includes wax reproductions and pathological specimens, both dried and fixed in formalin, displayed in elegant wooden cabinets. All in all,

Fig. 7 Detail of the so-called "Leper", a full-scale reproduction by L. Calamai of a man affected by Norwegian scabies

there are 116 waxes, mostly the work of Giuseppe Ricci, with the contribution of two talented artists from *La Specola* workshop, Luigi Calamai and his pupil Egisto Tortori (Figs. 4 and 5).

The general condition of the waxworks is variable with occasional fissures, crevices, small wax defects and yellowish discolouration. The wax models are often mounted on white canvas and fixed to black wooden boards, with the diagnosis written on card labels. Details of the patients and their case histories are described in the original four-volume Catalogue (Fig. 6).

The waxwork considered to be the jewel in the crown of the Museum is the so-called "Leper" by Luigi Calamai (Fig. 7). This is a life-sized model, realistically reproducing the body of a man affected with an acute form of Norwegian scabies. Cast in 1851, it may have caused the celebrated wax master's death from his prolonged exposure to the mercury solution used for the preservation of the corpse during the moulding of the statue [15].

The Museum also houses a large collection of anatomical specimens, perfectly preserved and amenable to investigation by means of modern biomolecular techniques, for the study of the aetiology and pathomorphosis of diseases in relation to the profound modifications in the composition and socio-economic conditions of the resident Florentine population over the nineteenth and twentieth centuries. These specimens are a macroscopic demonstration of rare disease entities. In the realm of teratology, the collection comprises general malformations, including veritable monstruosities (e.g., the "two-sided Janus", the "Siren" and the "Cyclops"). Most of the anatomical casts are kept in antique glass jars, filled with buffered formalin solution, hermetically sealed with wax between the lid and the lip of the jar. The specimens are labelled in obsolete terms, often at odds with present-day medical terminology, thus making histology mandatory in order to establish the correct diagnosis. As an example, one cast labelled *mollusco con morbo follicolare di Rayer*, on histological examination, proved to be neurofibromatosis type I.

Conclusions

Since the beginning, the Pathology Museum of the University of Florence has contributed to the teaching of Pathological Anatomy to medical students, for whom it constitutes a unique, three-dimensional teaching tool. At the same time, it is a culturally formative experience bringing to their attention the history of Florence, particularly that of public hygiene and of figurative art. Radiological and molecular biology investigation of the pathological specimens could provide an aetiological background relevant to present-day knowledge. An additional project which could be undertaken is the digitalization of specimens (ideally in 3-D) in order to make them informatically available to pathologists, anatomists, artists and historians all over the world.

Acknowledgements Thanks are due to the Ente Cassa di Risparmio di Firenze for their support of the Pathology Museum of the University of Florence. The authors wish to express their gratitude to Dr. Marta Poggesi and the staff of *La Specola* for the invaluable cooperation.

Conflict of interest statement We declare that we have no conflict of interest.

Thyroid tumours of uncertain malignant potential: frequency and diagnostic reproducibility

Véronique Hofman · Sandra Lassalle · Christelle Bonnetaud · Catherine Butori · Céline Loubatier · Marius Ilie · Olivier Bordone · Patrick Brest · Nicolas Guevara · José Santini · Brigitte Franc · Paul Hofman

Received: 14 April 2009 / Revised: 19 May 2009 / Accepted: 3 June 2009 / Published online: 20 June 2009

Abstract The term thyroid tumours of uncertain malignant potential (TT-UMP) has been proposed for a subgroup of follicular-patterned thyroid tumours for which benignancy or malignancy cannot be assessed with certainty. The frequency, diagnostic reproducibility, immunohistochemistry and molecular genetic profiling of such tumours have been poorly explored. We, therefore, investigated (1) the frequency of TT-UMP diagnosed in a single institution (Nice, France: 2004–2008), (2) the observer variation among four pathologists, (3) whether immunohistochemical and molecular genetic profiling of TT-UMP provide additional information concerning such lesions. A series of 31 diagnosed TT-UMP (2.9%) out of 1,078 consecutive thyroidectomies were analysed. It comprised 15 follicular thyroid tumours of UMP (FT-UMP) and 16 well-differentiated tumours of UMP (WDT-UMP). Observer concordance was 70% for all TT-UMP. More than 50% of FT-UMP expressed galectin-3 and CK19, whereas more than 50% of WDT-UMP expressed HBME-1. Five cases of TT-UMP showed N-RAS mutations, while one showed H-RAS mutation and another PAX8/PPARγ rearrangement. In conclusion, the frequency of TT-UMP is low in our institution. Diagnostic reproducibility is within the same range as other published data on follicular-patterned thyroid tumours. The ancillary methods have a low impact on aiding diagnosis of such lesions.

Keywords Thyroid · Follicular lesion · Uncertain malignant potential tumour · Observer variation · Molecular biology · Immunochemistry

Introduction

For decades, conventional histology has failed to classify some encapsulated follicular thyroid tumours as benign or malignant because these lesions share overlapping histological features [1–9]. This difficulty is underscored by recently reported substantial inter-observer variability, either in the pathological assessment of thyroid nodules or in the identification of underlying diagnostic criteria, such as papillary nuclear features, vascular and/or capsular invasion [10–12]. These difficulties are especially relevant in some encapsulated follicular-patterned thyroid tumours in determining whether they belong to strict adenomas or to differentiated thyroid carcinomas. To point out to the physicians such difficulties, several terminologies have been given to avoid performing either unnecessary aggressive surgery or missing out on using necessary aggressive surgical therapy and the general term of "thyroid tumours of uncertain malignant potential" (TT-UMP) has been recently proposed [5, 13, 14]. For tumours showing questionable capsular and/or vascular invasion, it is recommended to call them "follicular tumour of uncertain malignant potential" (FT-UMP) if papillary carcinoma-type nuclear changes are absent and "well-differentiated tumour of uncertain malignant potential" (WDT-UMP) if these nuclear changes are imprecise [13].

In these lesions, immunohistochemistry and the detection of somatic mutations via genotyping have not been extensively adopted in the routine practice of surgical pathology [15–19]. The use of this terminology has been actively discussed by pathologists since it is controversial, particularly for surgeons when considering the therapeutic strategy point of view and because observer variation among pathologists may be high [4, 20].

The frequency of TT-UMP is difficult to determine since this condition has only been defined recently and since it is not an international classification and not adopted by all pathologists. Thus, as formulated in the last edition of the WHO publication concerning the term TT-UMP, "the use of this nomenclature has not been generally accepted" [13].The observer variation among pathologists of different institutions for the diagnosis of FT-UMP and WDT-UMP has not yet been evaluated. Finally, the usefulness of a combined morphological, immunohistochemical and molecular biological approach in optimising the diagnosis and the prognosis of such borderline follicular lesions has been poorly studied to date.

The purpose of this work was to evaluate the incidence of TT-UMP diagnosed in a single institution (Pasteur Hospital, Nice, France) by using the criteria defined in the last edition of the WHO publication [13] in a prospective study performed between 2004 and 2008. We analysed the observer variation among four surgical pathologists from two different institutions. In parallel, we examined the clinicopathological characteristics of such diagnosed cases. In addition, the impact on diagnosis of ancillary methods, such as immunohistochemistry and molecular genetic profiling of a series of diagnosed TT-UMP was determined.

Materials and methods

Cases

The cases were selected from the records of the Laboratory of Clinical and Experimental Pathology (Pasteur Hospital, Nice France) from January 2004 to January 2008. Thirty-one TT-UMP were initially diagnosed by one or more of the three pathologists of the same institution (pathologists B, C or D). However, the diagnosis of TT-UMP was finally made in 31 tumours after a second evaluation. These 31 TT-UMP (15 FT-UMP and 16 WDT-UMP) were diagnosed according to the WHO 2004 diagnostic criteria [13]. The clinical (age, sex, previous medical history and ultrasound analysis) and pathological (fine-needle aspiration (FNA), frozen section, tumour size and location and diagnosis) data were recorded. Each case was processed as follows: complete analysis of the interface of the tumour capsule was performed. For this purpose, specimens of 3-mm thickness of the interface were obtained, fixed in 10% formaldehyde and 10 serial sections of each embedded specimen were stained with haematoxylin–eosin safran (HES). Different features were noted in the initial report that was made by one of the pathologists (pathologist A). The capsule was described as thick, thin or incomplete or poorly formed. Absence of capsular invasion or incomplete protrusion of the capsule (only the inner half of the capsule) with single or multiple foci was noted. The cellularity was divided into three groups: low, with abundant colloid simulating an adenomatoid nodule, moderate and high with compact cell growth. Nuclear-papillary thyroid carcinoma (PTC) changes were classified as questionable and corresponded to diffuse or focal not well-developed nuclear features or focal obvious nuclear changes. Absence or questionable vascular invasion was noted. Finally, the presence of associated lesions in the adjacent thyroid parenchyma was noted: nodular hyperplasia, lymphocytic thyroiditis, PTC, papillary microcarcinoma and C cell hyperplasia.

Observer variation analysis

A set of 10% formaldehyde fixed, paraffin-embedded tissue sections, stained with HES comprising 10 slides per case

was sent to the four panellists. Each case among the 31 diagnosed TT-UMP was previously randomly anonymised without knowledge of the initial diagnosis. Each panellist reviewed the cases independently. A file per case and per panellist was filled. Three pathologists belonged to the same institution (CB: B, VH: C, SL: D) and one to a different institution (BF: A).

Immunohistochemistry

Immunostaining for HBME-1, galectine-3 and CK19 were performed on paraffin-embedded sections using the Ventana Benchmark automated system (entire procedure, from pretreatment to counterstaining; Ventana Benchmark, Ventana, Tucson AZ). Deparaffinized sections were incubated with the following monoclonal antibodies for 30 min: HBME-1 (Dako, Coppenhagen, Denmark; dilution 1/200), galectin-3 (Novocastra, Newcastle, UK; dilution, 1/100) and CK19 (Dako, dilution 1/30). Paraffin sections from a PTC positive for these antibodies were used as a positive control. The immunoreactivity was scored as negative (−), focally positive (±: less than 10% positive cells), positive (+: 10% to 50% positive cells) and strongly positive (++: more than 50% positive cells). Signals showed a membranous and apical staining for HBME-1, a cytoplasmic and/or membranous staining for galectin-3 (predominantly cytoplasmic) and CK19. Combined expression of two or three proteins was analysed.

Molecular biology

B-RAF, N-RAS, K-RAS and H-RAS mutations Genomic DNA from frozen tissue samples was extracted using the MagNA Pure Compact Nucleic Acid Isolation Kit Large Volume (Roche) according to the manufacturer′s instructions. After initial denaturation at 95 C for 5 min, gDNA (50 ng) for B-RAF, K-RAS and N-RAS analysis was subjected to 35 cycles of polymerase chain reaction (PCR; 95 C for 30 s, 57 C for 30 s and 72 C for 30 s) using Taq platinum (Invitrogen, San Diego, CA) followed by final extension at 72 C for 7 min. The primer pairs used for amplification are given in Table 1. Negative controls were included in each set of amplification. After amplification, post-PCR purification was performed using the Qiaquick Purification PCR kit (Qiagen, Basle, Switzerland) in accordance with the manufacturer′s recommendations. All samples were bidirectionally sequenced on an ABI 310 sequencer using the Big Dye Terminator kit (Applied Biosystems, Inc., Foster City, CA). B-RAF (Exon 15: Codon 600/T1799A and 601/A1801G) and RAS (Exon 1: Codons 12 and 13 for K-RAS and H-RAS, Exon 2: Codon 61 for N-RAS and H-RAS) genes found mutated in patients were reanalyzed by a second amplification and sequencing. Genomic DNA extracted from A375 cells (harbouring a B-RAF mutation), T84 and A549 cells (K-RAS mutations), THP1 and HL60 cells (N-RAS mutations) were used as positive controls.

RET/PTC1, RET/PTC3 and PAX8/PPARγ rearrangements Total RNA was extracted from frozen samples with Trizol solution (Invitrogen, San Diego, CA), and the integrity of the RNA was assessed using an Agilent BioAnalyser 2100 (Palo Alto, CA). Synthesis of cDNA was performed with 2 μg of total RNA at 37 C for 90 min, using random hexamer primers and reverse transcriptase Superscript III in

accordance with the manufacturer′s recommendations (Invitrogen). The thermoprofile for cDNA generation was 25 C for 10 min, 42 C for 50 min, 70 C for 15 min and 4 C for 5 min. RT-PCR with primers specific for the human GAPDH gene was performed for the mRNA control. After initial denaturation at 95 C for 5 min, cDNA was subjected to 40 cycles of PCR (95 C for 30 s, 55 C for 2 min and 72 C for 2 min) for RET/PTC1 and 3 and 40 cycles of PCR (95 C for 1 min, 61 C for 1 min and 72 C for 1 min) for PAX8/PPARγ, using Taq platinium (Invitrogen), followed by final extension at 72 C for 10 min. The primer pairs used for amplification are given in Table 1. Negative controls were included in each set of amplification. Total RNA extracted from TPC1 cells (kind gift of Pr Santoro, Napoli, Italy) was used as a positive control for RET/PTC1 PCR. For the PAX8/PPARγ PCR, cDNA (kind gift of Dr. V Leite, Lisbon, Portugal) isolated from RNA extracted from previously characterised thyroid samples was used as a positive control. After positive amplification, post-PCR purification was performed using the Qiaquick Purification PCR kit (Qiagen) in accordance with the manufacturer′s recommendations. Patients′ samples positive for a rearrangement were bidirectionally sequenced on an ABI 310 sequencer using the Big Dye Terminator kit (Applied Biosystems, Inc., Foster City, CA).

Statistical analysis

The cumulative agreement (and percent) between the pathologists for WDT-UMP, FT-UMP and TT-UMP diagnosis was calculated for the 31 TT-UMP diagnosed cases by one or more of the four pathologists. The concordant rate was examined for the three pathologists of the same institution and for the four pathologists. A study of sample parameters allowing differentiation of FT-UMP and WDT-UMP was done. The statistical significant of the studied parameters was examined using the χ^2. A p value of 0.05 or less was considered to be significant.

Results

The TT-UMP frequency in a prospective series of thyroidectomy from a single institution (Nice Hospital, France)

A total of 1,078 thyroidectomies were performed from January 2004 to January 2008 in our hospital (Department of ORL, Pasteur Hospital, Nice, France). Among these specimens, 166 were malignant tumours and 31 TT-UMP. Among the TT-UMP, there were 15 FT-UMP and 16 WDT-UMP, representing 2.9% of total thyroidectomy specimens.

Observer variation

Observer variation was studied taking into consideration the initial diagnosis of 31 TT-UMP made by at least one of the four pathologists. The diagnostic concordance was 70% (22/31) for the four pathologists. Diagnostic concordances were 87% (14/16) and 53% (8/15), for the diagnosis of WDT-UMP and FT-UMP, respectively (Table 2). The diagnosis made by each pathologist is shown in Table 3.

Clinicopathological characteristics

Among the 31 TT-UMP, the patient age ranged from 16 to 78 years (mean, 54.1 years) for FT-UMP and from 26 to 78 years (mean, 52.1 years) for WDT-UMP. Females predominated with a female to male ratio of 2/1 (10 females and five males) for FT-UMP and 3/1 (12 females

and four males) for WDT-UMP. No statistical difference for age or sex was noted for WDT-UMP and FT-UMP. FNA performed on 10 patients with FT-UMP was interpreted as non-diagnostic (one case) and an uncertain malignancy (nine cases: follicular neoplasm (seven cases) and Hurthle cell neoplasm (two cases)). FNA performed on 10 patients with WDT-UMP was interpreted as nondiagnostic (two cases), benign lesion (two cases) and uncertain malignancy (two cases: follicular neoplasm (three cases) and cellular, suspicious for malignancy (three cases)). It was noteworthy that nuclear abnormalities typical of papillary carcinoma were not observed in this latter group of tumours. The mean size of tumours was 3 cm (range from 0.8 to 7.0 cm) for FT-UMP and 3.2 cm (range from 1.0 to 8.0 cm) for WDT-UMP. No preferential localization on the thyroid gland was noted for these two groups of tumours. The diagnosis made from frozen sections was "epithelial tumours without uncertain signs of malignancy" in 26/31 TT-UMP. Diagnosis of a strict benign tumour was not immediately made from frozen sections since the capsule was thick, not well-defined and with possible invasion by follicles. Diagnosis of "follicular adenoma" was made in 5/31 TT-UMP (all WDT-UMP). Data concerning these different cases are shown in Table 4. The majority of TT-UMP were moderately or highly cellular, with a vesicular or, less frequently, with a trabecular architecture. Two cases of WDT-UMP were poorly cellular, with macrovesicular architecture. All FT-UMP showed a capsule, generally thick, or thin, in a few cases. This capsule was thin, not well-defined, not complete or complete in WDT-UMP. Capsular invasion (not complete, isolated or multiple) was present in all FT-UMP (Fig. 1a, b) and in two WDT-UMP. Questionable vascular invasion was noted in one FT-UMP and in one WDT-UMP. Nuclear abnormalities looking like those observed in PTC were observed in WDT-UMP (Fig. 1c–f). These abnormalities were not complete, isolated or diffuse (Fig. 1c, d) or characteristics of PTC (Fig. 1e, f) and isolated. Thyroid tissue adjacent to tumours was normal in 31% of WDT-UMP and 40% of FT-UMP. Other TT-UMP showed at their periphery, nodular hyperplasia and thyroiditis, and interestingly, four WDT-UMP were associated with PTC. Table 5 summarises the main histological criteria observed in our series. For 22/31 (71%) patients, a thyroid nodule that was surgically removed was clinically present between 24 and 37 months (mean=30 months) before surgery. For all cases, no additional therapy was given and non-recommended by the clinician. However, medical supervision was enhanced and consisted in a medical examination with ultrasound examination of the thyroid every 6 months. Finally, for all cases, no tumour recurrence has been noted to date after surgery (follow-up range from 12 to 48 months, mean=31 months).

Immunohistochemical results

The tumours of the WDT-UMP group showed HBME-1, galectin-3 and CK19 expression (more than 10% positive cells) in 9/16 (56%), 9/16 (56%) and 10/16 (62%) tumours, respectively. HBME-1 was expressed in more than 50% of the cells in 7/16 (44%) cases (Fig. 2a) and sometimes showed a more intense signal in regions where nuclear anomalies were obvious (Fig. 2b), whereas galectin-3 and CK19 were expressed in 4/16 (25%) and 3/16 (19%) cases, respectively (Fig. 2c, d). Immunostaining with two or three of these antibodies was found in 56% of the cases. The

WDT-UMP well-differentiated tumour of uncertain malignant potential; *FT-UMP* follicular tumour of uncertain malignant potential; *FNA* fine needle aspiration; *F* female; *M* male

tumours of the FT-UMP group showed galectin-3 and CK19 immunoreactivity (more than 10% positive cells) in 6/15 (40%) and 8/15 (53%) cases, respectively, and most often in more than 50% of the cells (Fig. 2e, f). HBME-1 was expressed in 3/15 (20%) cases and on more than 50% of cells; 6/15 (40%) cases showed co-expression of two or three antigens. Finally, none of these three proteins were significantly expressed in either of the two subgroups of TT-UMP. The details of the immunohistochemical results are summarised in Table 6.

Molecular biology

The results of the molecular biological analyses are summarised in Table 7. None of the 31 TT-UMP showed B-RAF mutations and RET-PTC1 or RET-PTC3 rearrangements. Two FT-UMP and three WDT-UMP showed a N-RAS mutation and one FT-UMP showed H-RAS mutation. One FT-UMP showed a PAX8-PPARγ rearrangement. The cases of mutated N-RAS WDT-UMP corresponded to highly cellular tumours with microvesicular and trabecular patterns and diffuse questionable nuclear abnormalities (one associated with capsular invasion). Two of these latter cases were associated with a micropapillary carcinoma. No statistical differences were noted for the group of TT-UMP showing N-RAS mutation for the following criteria: age, sex, tumour size, cellularity, capsular invasion, HBME-1, galectin-3 and CK19 staining. Finally, FT-UMP with H-RAS mutation and PAX8-PPARγ rearrangement were histologically similar to other FT-UMP studied in this series.

Discussion

Our study should be considered as a complement to the previous studies published, in the last decade, into observer variation in the diagnosis of encapsulated follicular lesions of the thyroid [10–12]. Moreover, none of these studies specifically focused on the generally not accepted nomenclature of TT-UMP. It remains to be determined whether or

Table 5 Histological features of FT-UMP and WDT-UMP

not this category of disease, initially defined by Williams et al. [14] and then classified in the last edition of the WHO publication [13] should or should not still be defined separately. Our inter-observer variation lies within the value already reported in other studies but with a higher level of agreement in the WDT-UMP group [10–12]. Even if we consider a "centre effect" (three of the observers belonging to the same institution) the level of agreement between the four pathologists was 87% for the WDT-UMP cases and 53% for the FT-UMP cases. In addition, we note that most of the discord concerned diagnosis of a follicular adenoma instead of a TT-UMP either in 1/16 (6%) WDT-UMP and in 6/15 (40%) FT-UMP. A pending diagnosis of malignancy was made in 1/16 (6%) WDT-UMP and in 1/15 (7%) FT-UMP. Therefore, the reticence expressed in the most recent publication of the WHO [13] is fully justified, and our study highlights the fact that the TT-UMP diagnosis tips more toward diagnosis of a follicular adenoma diagnosis than of a malignancy.

Numerous previous studies have demonstrated that the use of ancillary techniques such as immunohistochemistry can significantly improve diagnosis in thyroid pathologies [21–28]. However, a single marker is usually suboptimal in terms of sensitivity and specificity. Panels of two or more antibodies are usually more effective and can improve diagnostic accuracy when based on paraffin-embedded tissue. Our immunohistochemical data (HBME-1, galectin-3, CK19) still demonstrate that the "TT-UMP lesions" had an immunohistological profile that was not typical of a follicular adenoma, which has already been suggested by others for WDT-UMP [29–34]. The immunohistochemical profile has been less studied in the FT-UMP group, a pathology that is not as well-known in North America as in Europe, where it is a matter of concern [31, 32]. Moreover, most of the published studies used only HBME-1 [33] or galectin-3 [29, 30], HBME-1 and galectin-3 [32] or HBME-1, galectin-3 and CK19 [31, 34]. Previous reports showed that WDT-UMP, also called "encapsulated

lesions with questionable features of PTC" by Sconamiglio et al. [34], expressed HBME-1 in around 60% to 70% cases, and galectin-3 in around 60% to 80% cases [32, 34]. In one series, WDT-UMP expressed CK19 in 63% tumours [34]. In our series, the results were quite similar since WDT-UMP expressed HBME-1, galectin-3 and CK19 in respectively, 56%, 56% and 62% cases. In the study of Papotti et al., FT-UMP expressed HBME-1 and galectin-3 in 62% and 37% of tumours [32], whereas in our series, HBME-1 and galectin-3 were expressed in 25% and 50% of tumours, respectively. Previous studies using the terminology of atypical adenoma or follicular neoplasm of

undefined malignant behaviour showed HBME-1 expression in 45–60% tumours, galectin-3 expression in 70–85% tumours and CK19 expression in 20% tumours [29, 31, 33]. Interestingly, in the present study, HBME-1 was more often expressed in WDT-UMP, whereas galectin-3 and CK19 were similarly expressed in FT-UMP and WDT-UMP. As in our series, previous reports showed that around half of the WDT-UMP expressed both HBME-1 and galectin-3 [22, 32]. Coli et al. have suggested that tumours demonstrating "cytological atypia suggestive but not diagnostic of PTC" may have started to change phenotype towards a PTC [22]. Interestingly, in the present study, HBME-1 was more often expressed in WDT-UMP, whereas galectin-3 and CK19 were similarly expressed in FT-UMP and WDT-UMP. However, when associated, the three antibodies did not discriminate between FT-UMP and WDT-UMP. In addition, we demonstrate that the immunohistological profiles of TT-UMP are not tumour-size-dependant.

TT-UMP represent a true "grey zone" of lesions that need to be further characterised in order to determine whether or not they represent a borderline category requiring specific curative procedures and postoperative follow-up. The "exponential increase in papers" on this topic [4, 13, 14, 20, 35, 36] has permitted more precise definition of the underlying criteria necessary, as highlighted by our good inter-observer agreement in WDT-UMP. However, it is less obvious in FT-UMP which is less frequent, and for which "questionable invasive criteria" are still poor and less convincing. As the nomenclature for TT-UMP is recent and since not all pathologists recognise the controversial entity, the current incidence of TT-UMP is difficult to appreciate. In our institution, TT-UMP represented 2.9% of thyroid surgical pathologies. However, it is necessary to point out that such problematic histological cases in the field of thyroid pathology make up only a very small fraction of thyroid cases but when seen by experienced surgical pathologists in thyroid pathology. Moreover, in a routine diagnostic setting, the current histological criteria for classification tumours, especially follicular-patterned thyroid tumours, is hampered by considerable variability depending on experience. In this regard, the terms TT-UMP, FT-UMP and WDT-UMP have not been introduced as an easy option for the surgical pathologists when dealing with the evaluation of difficult cases or as a way of avoiding the commitment required in making a clear diagnosis of malignancy or benignity.

Recently, major advances in the molecular characterisation of the well-differentiated carcinoma of the thyroid have been made [37–48]. We report here one of the first analyses of mutations and chromosomic rearrangements in a large series of TT-UMP. None of the WDT-UMP had mutations for B-RAF V600. RAS mutations were noted in a few tumours belonging to the two subgroups of TT-UMP. Among the latter tumours, a poorly differentiated carcinoma was ruled out in particular in the three cases of WDT-UMP corresponding to highly cellular tumours with microvesicular and trabecular patterns. Interestingly, one FT-UMP showed a PAX8/PPAR γ rearrangement. Secondary histological analysis in this latter case did not modify the diagnosis of minimally invasive FC. No RET mutation was observed in cases of TT-UMP, which contrasts with results obtained by Fontaine et al. who found three RET/PTC1 rearrangements and did not detect any N-RAS mutations in exon 2 [31]. However, other larger studies are lacking in this field. Moreover, it may be useful to increase the sensitivity of these molecular biology methods by using laser capture microdissection followed by RT-PCR amplification in archival samples [49, 50]. This approach will procure pure-

Table 7 Mutations and rearrangements in WDT-UMP and FT-UMP

WDT-UMP well-differentiated tumour of uncertain malignant potential; *FT-UMP* follicular tumour of uncertain malignant potential

cell populations showing questionable PTC-nuclear changes when looking for rearrangements and mutations of interest.

Taken together, these data confirm that the ancillary methods are not prognostic in TT-UMP. This is not surprising, since these methods are of low significance in evaluating the potential aggressiveness of most epithelial thyroid tumours. The discovery of new biomarkers, particularly to evaluate the potential onset of metastasis or recurrence of TT-UMP will be useful. In this regard, some studies have shown the potential interest of using microarray technology in thyroid pathology [51–54]. Based on a recent study, it is promising to note that a DNA microarray gene expression approach was able to define a gene expression signature which can clearly distinguish the different TT-UMP from other epithelial thyroid tumours [31].

In conclusion, the clinical course of TT-UMP is currently unknown since their incidence is certainly underestimated, and because, if any, their recurrence and metastatic onset can occur several years after the initial surgical resection. After making the diagnosis, treatment of TT-UMP is most of the time the same as for benign epithelial thyroid tumours. We strongly believe that the terminology of TT-UMP should be quickly tested in different referent centres. Moreover, some ancillary methods, particularly for the PAX8/PPARγ rearrangement in FT-UMP should be examined in a larger series. In the present study, immunohistochemistry and molecular genetic profiling were not useful in detecting a low- and high-risk population of patients among the different TT-UMP subgroups. Standardisation of the different procedures, particularly for sampling thyroid

tumours is critical in improving our knowledge of these controversial issues. In this regard, we are still waiting for a biomarker to appreciate the real aggressiveness of such lesions. Only long-term survival data of the follow-up of patients over at least 20 years will prove whether TT-UMP are able to metastasize or whether surgical pathologists are just over-cautious in front of such features suggesting they are actually dealing with benign tumours mimicking features of WDT carcinoma.

Abstract *RET* rearrangements (*RET*/PTC) is a major genetic alteration in papillary thyroid carcinomas. However, the prevalence of *RET*/PTC differs considerably among investigators, and its impact on cancer progression has been controversial. In the current study, we applied interphase fluorescence in situ hybridization (FISH) to touch imprint cytology of 14 papillary thyroid carcinomas along with reverse-transcription polymerase chain reaction (RT-PCR) analysis. FISH DNA probes included *RET* locus, and PCR primers were designed targeting *RET*/PTC1 or *RET*/PTC3. Split FISH signals of *RET* was observed in 78.6% (11/14) of tumors. Proportions of tumor cells having split *RET* signals ranged from 1.8% to 19.6% (mean 9.7%) in those 11 tumors. In RT-PCR analysis, *RET*/PTC was found in 28.6% (4/14) of tumors. Among tumors with split *RET* signals, 36.4% (4/11) of tumors exhibited detectable messenger RNA of *RET*/PTC1 or *RET*/PTC3. The remaining seven tumors with split *RET* signals had no *RET*/PTCs amplicon. In conclusion, the current study disclosed that *RET*/PTCs occur in a small population of tumor cells in papillary thyroid carcinomas. Even though *RET*/PTC is a specific genetic event in the carcinomas, our results suggested the possibility of *RET*/PTC as "passenger" abnormalities rather than "driver" oncogenic mutation during thyroid cancer progression, warranting further studies on mechanisms and implication of *RET* gene instability.

Introduction

Papillary carcinoma is the most common thyroid malignancy and shows a favor prognosis even when the patient has metastasis in the regional lymph nodes. Molecular studies in papillary thyroid carcinomas have provided several genetic alterations, such as point mutations in the *BRAF* and *RAS* genes and rearrangements of *RET* gene (*RET*/PTC) [1–3]. The *RET* proto-oncogene, which is located in the long arm of chromosome 10 at band q11.2, encodes a receptor tyrosine kinase for the glial cell-line-derived neurotrophic factor [4]. The somatic rearrangements of *RET* proto-oncogene always involve intron 11 of *RET* and lead to the juxtaposition of its intracellular tyrosine kinase domain to the 5′ portion of different donor genes [5, 6]. *RET*/PTC generates a novel amino-terminal portion and consecutively ligand-independent *RET* tyrosine kinase activation [7, 8]. The fusion protein of *RET*/PTC permits the binding of SHC and activation of RAS-RAF-MAPK cascade [9]. Although a number of *RET*/PTC subtypes have been reported so far, the main forms of *RET*/PTC are *RET*/PTC1 and *RET*/PTC3, resulting from paracentric inversion on chromosome 10q. The tyrosine kinase domains of *RET* fuses with *H4* (*RET*/PTC1) and *RFG/ELE1* (*RET*/PTC3) [6, 10, 11].

na not available

Interpretation of *RET* rearrangements in thyroid cancers is still controversial. The high frequency of *RET* rearrangements in subclinical papillary microcarcinomas is consistent with these changes representing early events in the neoplastic process [12]. Meanwhile, heterogeneity of *RET* rearrangements in a single large tumor has been interpreted as indicating a relatively late event [13]. The low prevalence of expression of *RET*/PTCs in poorly differentiated and undifferentiated thyroid carcinoma might indicate a minor role in tumor progression [14, 15]. Furthermore, the prevalence rates of *RET* rearrangements in papillary thyroid carcinomas are considerably wide among investigators, raising a possibility of methodological differences [16].

In the current study, we applied interphase fluorescence in situ hybridization (FISH) analysis on touch cytology specimens to investigate the distribution of *RET* rearrangements in papillary carcinoma cells and also performed conventional reverse-transcription polymerase chain reaction (RT-PCR) analysis for both *RET*/PCT1 and *RET*/PTC3 using same tissue samples. We compared the different methodologies for detecting *RET* rearrangements and discussed heterogeneity in the prevalence of *RET*/PTCs in papillary thyroid carcinomas.

Materials and methods

Patients

We studied 14 surgical specimens from thyroid papillary carcinomas collected from the Yamanashi University Hospital. A thorough review of clinical data revealed nothing to suggest radiation exposure of the neck in any patients. Informed consent was obtained before resection in all patients. The pathological diagnoses were made on the basis of the second edition of *Histological Typing of Thyroid Tumours* (World Health Organization) [17]. Histologically, all thyroid papillary carcinomas studied for this report were the classical type of papillary carcinoma without foci of poorly differentiated and/or anaplastic components and more than 9 mm in size. Summary of clinicopathological features was shown in Table 1. Numbers of case listed in Table 1 are in accordance with those in Table 2.

Cell and tissue preparation

For FISH analysis and immunofluorescence, touch imprint cytology specimens were prepared from fresh tissue taken from the pure tumorous lesions and the normal tissues. Normal thyroid tissue samples are obtained from six patients who underwent subtotal or total thyroidectomy for papillary carcinomas (case nos. 1, 3, 4, 10, 11, and 13). They were fixed for 30 min with 95% ethanol and stored at −80°C. The formalin-fixed paraffin-embedded tissue was routinely processed for pathological diagnosis and RT-PCR analysis.

Microdissection and RNA extraction from paraffin-embedded tissue

Four serial sections, 10 μm thick, were cut from routinely processed, formalin-fixed, and paraffin-embedded tissue blocks. These sections were stained with hematoxylin after deparaffinization. Microscopically comparing the sections for orientation, each tumor tissue was microdissected with a

disposable syringe needle under a stereomicroscope, as previously described [1]. Total RNA was extracted using the acid guanidinium–phenol–chloroform system (ISOGEN PB Kit, NipponGene, Toyama, Japan) according to the manufacturer's instructions.

Reverse-transcription polymerase chain reaction analysis

One microgram of total RNA was reverse-transcribed (RT) using Moloney murine leukemia virus reverse transcriptase (Wako, Osaka, Japan) primed with random hexamers (Roche, Tokyo, Japan). All RT reactions were performed at 25°C for 10 min, 42°C for 45 min, and 95°C for 5 min. After RT reactions, amplification of complementary DNA corresponding to *RET*/PTC1 and *RET*/PTC3 was performed by PCR using a thermal cycler. The primary and nested amplifications were performed as previously described [1].

The human thyroid cancer cell line, TPC-1, kindly provided by Dr. Noboru Takamura, Nagasaki University, served as positive control for *RET*/PTC1 [18]. Amplification of glyceraldehyde-3-phosphate dehydrogenase was used as quality control for RNA integrity.

Immunofluorescence

Monoclonal mouse antithyroid transcription factor (TTF) 1 antibody (ZYMED Laboratories, CA, USA) was used as a primary antibody. After a 60-min incubation with the primary antibody, the sections were incubated with a 1:100 dilution of rhodamine-labeled goat antimouse F $(ab)'_2$ fragment (DAKO, Hamburg, Germany) in 1% phosphate saline buffer containing bovine serum albumin. After a 30-min incubation, images were obtained with a fluorescence microscope IX71 (Olympus, Tokyo, Japan) and a scientific-grade, cooled, charge-coupled device camera, Sensys (Photometric, Tucson, AZ, USA), connected to a personal computer.

Multicolor fluorescence in situ hybridization

Figure 1 shows the color scheme for the multicolor FISH strategy using *RET*-, *H4*-, and chromosome-10-specific DNA probes to detect *RET* rearrangements. After microscopic observation for fluorescence of TTF-1, the preparations were refixed with 95% ethanol overnight. FISH was performed on the same preparations using bacterial artificial chromosome clones: RP11-351D16 (Advanced Geno Tech Co.), spanning the entire region of *RET* proto-oncogene, and RP11-368L1 (Advanced Geno Tech Co. Japan) containing the telomeric region of *H4*. DNA was extracted and labeled with digoxigenin-11-dUTP (RP11-351D16) and biotin-16-dUTP (RP11-368L1) by nick translation (Vysis Inc; Downers Grove, IL, USA). Whole chromosome 10 probe labeled with Cy3 (Cambio Ltd., Cambridge, UK) was used to confirm the locations of these genes. The preparations were then pretreated and subjected to hybridization with the DNA probes and detected with antibodies labeled with fluorescein isothiocyanate (FITC; RP11-351D16) and Alexa 647 (RP11-368L1). Nuclei were counterstained with 4′,6-diamiono-2-phenylindole (DAPI). We used normal (46, XY) Metaphase CGH Target Slides (Vysis Inc.; Downers Grove, IL, USA) as control to verify the specificity of above-mentioned DNA probes. Two and four FISH signals were observed in the nuclei in interphase and metaphase cells, respectively.

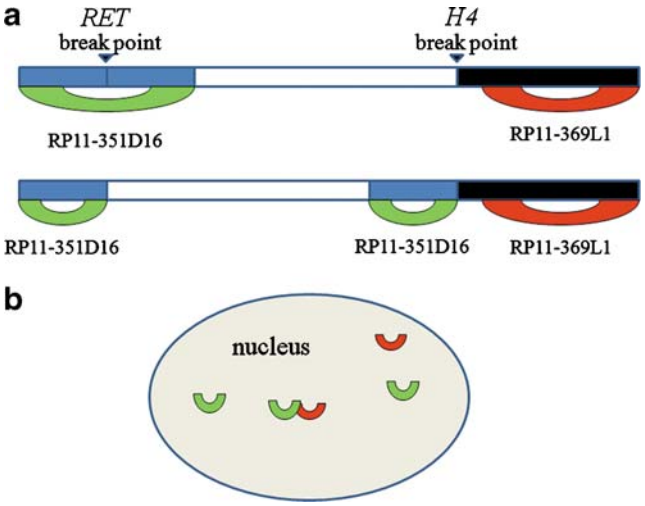

Fig. 1 Scheme of the multicolor FISH strategy to detect *RET*/PTC1. **a** Paracentric inversion on chromosome 10q (inv(10)(q11.2 q21)) suggests *RET*/PTC1 (break point, *arrow head*). *RET* (*blue*)—specific DNA probe covers the entire region of *RET* (RP11-351D16, *green*). *H4* (*black*)—specific DNA probe covers the telomeric region of H4 (RP11-369L1, *red*). **b** The nucleus having *RET* rearrangements is designed to demonstrate attachment of one split signal suggesting *RET* (*green*) and one signal suggesting H4 (*red*)

After staining by the immunofluorescence method for TTF-1 and prior to interphase FISH, we took pictures at low and high magnifications. During fluorescence microscopy of FISH, we searched the same areas at low magnification and identified the same nuclei comparing the immunofluorescence images. We estimated FISH signals only in isolated tumor cells because of the difficulty in estimating these signals in clustered or overlapping tumor cells. We counted 217–267 cells (average 225.6) per tumor and 211–253 cells (average 227.3) per normal thyroid tissue.

Statistic analysis

Statistic analysis was carried out using Fisher's exact test, comparing prevalence rates of the *RET* rearrangements as determined by FISH and RT-PCR. To compare the pairs of means of tumor cells with *RET* rearrangements, Student *t* test was used with a significance level of 5%.

Results

Prevalence rate of *RET* rearrangements

It is difficult to discriminate tumor cell nuclei from nontumor cells such as stromal fibroblasts, vascular endothelium, and inflammatory cells on interphase FISH examination using touch imprint cytology. Therefore, we performed immunofluorescent staining for TTF-1, a marker of thyroid follicular cells, on the same preparation prior to interphase FISH analysis to evaluate the cancer cell population with *RET* rearrangements. TTF-1 was diffusely positive in the large and irregular-shaped nuclei, suggesting papillary thyroid carcinoma cells (Fig. 2b, d).

Interphase FISH analyses with the *RET*-specific DNA probe were performed in 12 papillary carcinomas. By using this method, *RET* gene rearrangements were seen as three signals (Figs. 2a and 3a) and lack of *RET* gene rearrangements as two signals (Figs. 2b and 3a) in the nuclei of tumor cells.

On interphase FISH analysis, the tumor cells with split signals, suggesting *RET* rearrangements, were demonstrated in 11 of 14 papillary thyroid carcinomas (78.6%). We observed split signals in none of the nuclei of the non-tumorous follicular cells from the six normal thyroid tissues.

In contrast, RT-PCR analyses with specific primers for *RET*/PTC1 and *RET*/PTC3 revealed that *RET*/PTC1 was detected in four (28.6%) tumors and *RET*/PTC3 in no tumors (Table 2, Fig. 4). The prevalence rate of *RET* rearrangements (78.6%) as determined by interphase FISH was significantly higher than that (28.6%) by RT-PCR ($p < 0.05$). All four papillary thyroid carcinomas that were positive for *RET*/PTC1 by RT-PCR were also positive by interphase FISH. However, RT-PCR analysis did not detect *RET*/PTCs in seven papillary carcinomas which were positive by interphase FISH (Table 2).

Tumor cell population having *RET* rearrangements

Interphase FISH analysis suggested that tumor cells with and without *RET* rearrangements coexisted in the same tumor (Fig. 3a). Therefore, we assessed the percentage of rearranged cells in 11 papillary thyroid carcinomas having *RET* rearrangements. The percentage of rearranged tumor cells were ranged from 1.8% to 19.6% (average 9.7%), indicating that majority of tumor cell were nonrearranged cells in all 11 tumors (Table 2).

In four papillary carcinomas with *RET* rearrangements detected by both RT-PCR and interphase FISH, the population of rearranged tumor cells ranged from 6.0% to 19.6% (average 14.1%). In contrast, in the seven papillary thyroid carcinomas with *RET* rearrangements demonstrated by interphase FISH alone, the population of rearranged

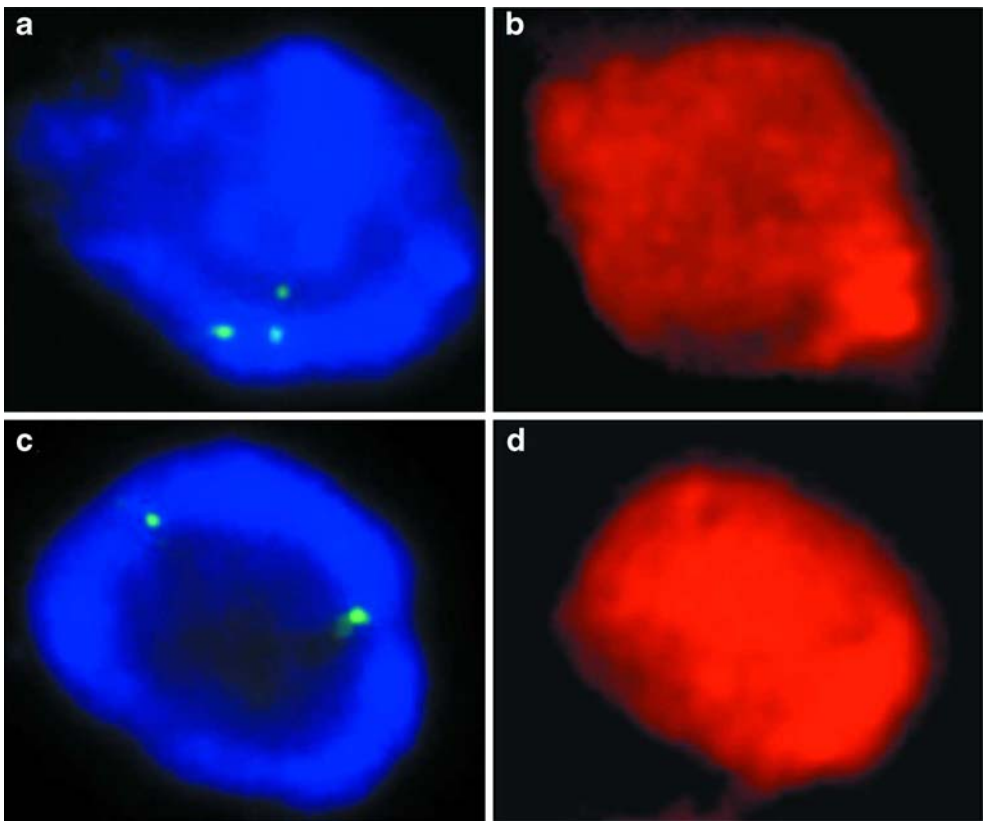

Fig. 2 Immunofluorescence microscopic findings of interphase FISH analysis with the *RET*-specific DNA probe and immunofluorescence for TTF-1 performed in the same nuclei of the papillary thyroid carcinoma cells. **a** A nucleus stained with DAPI (*blue*) having three FISH signals (FITC, *green*) suggests *RET* rearrangement. **b** Same nuclei showing immunopositivity for TTF-1 (rhodamine, *red*). **c** A nucleus stained with DAPI (*blue*) having two FISH signals (FITC, *green*) suggests lack of *RET* rearrangement. **d** Same nuclei showing immunopositivity for TTF-1 (rhodamine, *red*) TTF-1, thyroid transcription factor-1; *DAPI*, 4′,6-diamiono-2-phenylindole; *FITC*, fluorescein isothiocyanate

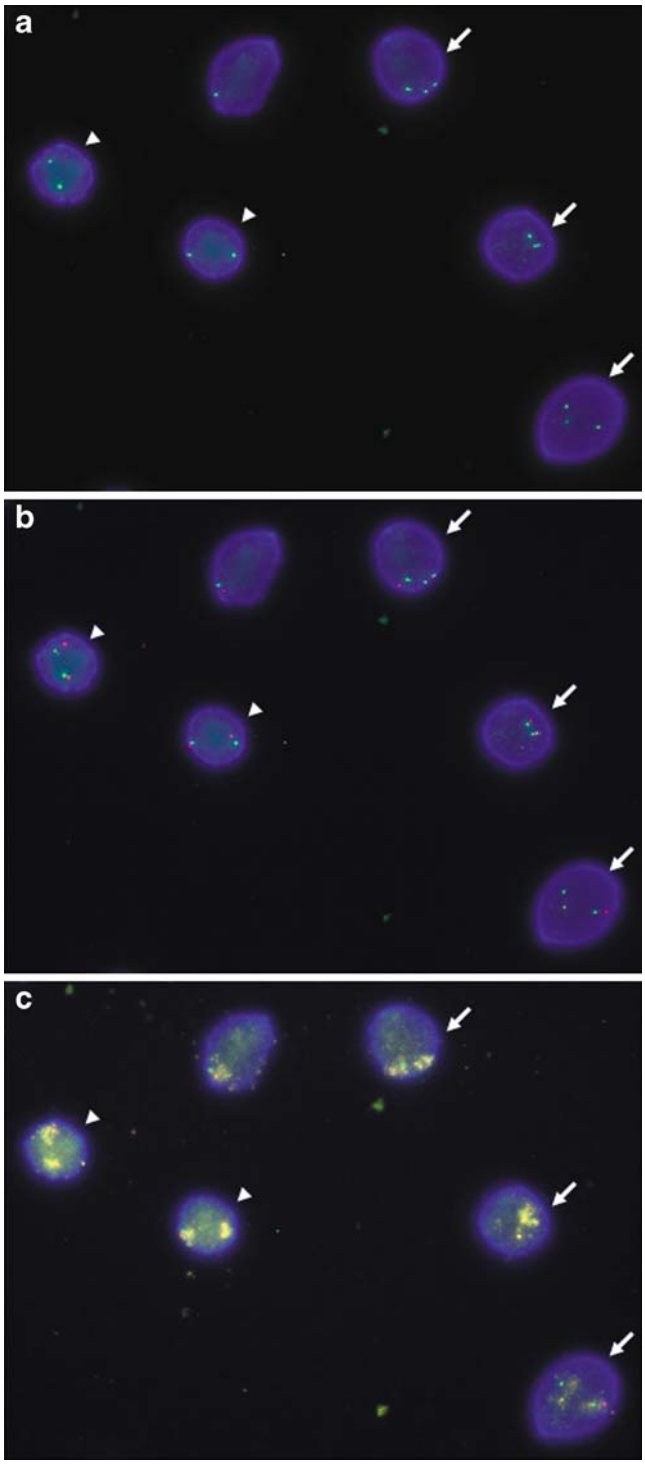

Fig. 3 Multicolor FISH analysis using *RET*- and *H4*-specific DNA probes and whole chromosome-10-specific probe in the same nuclei of a papillary thyroid carcinoma. **a** Tumor cell nuclei with three RET gene signals suggesting *RET* rearrangement (*arrows*) and with two *RET* gene signals suggesting lack of *RET* rearrangement (*arrow head*) are intermingled. **b** One *H4* gene signal (*red*) is attached to a *RET* gene signal (*green*), suggesting *RET*/PTC1 in the rearranged tumor cell nuclei (*arrow*). **c** All signals of *RET* and *H4* genes are located in chromosome 10. *RET* gene signal: FITC, *green*; *H4* gene signal: Alexa 647, *red*; chromosome 10 signal: Cy3, *yellow*

tumor cells ranged from 1.8% to 12.2% (average 7.2%). Although the population of tumor cells with *RET* rearrangements was greater in the former group (detected by both RT-PCR and interphase FISH) than in the latter group (detected by interphase FISH alone), it was not a statistically significant difference in the rearranged tumor cell population between these two groups.

Interphase FISH analysis for *RET*, *H4*, and chromosome 10

We also performed multicolor FISH analyses using *RET*-, *H4*-, and chromosome-10-specfic DNA probes in the cases positive for *RET*/PTC1 by RT-PCR. Multicolor imaging for FISH signals in rearranged tumor cells revealed that one of three *RET* signals attached to one signal of *H4*, and all these signals were located in chromosome 10, suggesting *RET*/PTC1 (Fig. 3b, c).

Discussion

RET rearrangements (*RET*/PTC) in papillary thyroid carcinomas have been studied by RT-PCR using formalin-fixed and paraffin-embedded tissues [1, 16]. The reported prevalence rates of *RET*/PTC in papillary thyroid carcinomas extensively varied from 0% to 85% between studies [19, 20]. It is conceivable that this wide range of prevalence in RT-PCR analysis is due, in part, to technical or methodological factors. For example, degradation of RNA during processing tissues through formalin fixation and paraffin embedment or the difficulties in discriminating tumor cells and interstitial cells largely affect the results.

Touch imprint cytology specimens fixed with ethanol have some advantages for evaluating exact prevalence rates of *RET* rearrangement. On FISH analysis, cytology specimens allow us to observe the exact number of FISH signals in the whole cell nucleus. In addition, it is important that nucleic acids are well preserved in cells with ethanol fixation. Therefore, we employed interphase FISH analysis on touch cytology specimens from 14 papillary thyroid carcinomas to detect *RET* rearrangements.

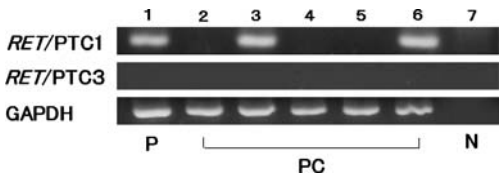

Fig. 4 Representative results of *RET*/PTC1 and *RET*/PTC3 detected by RT-PCR analysis in papillary thyroid carcinomas (PC; *lanes 2–6*). Positive bands for *RET*/PTC1 are shown in *lanes 3* and *6*. No bands for *RET*/PTC3 were demonstrated. *Lane 1* (*P*) is positive control for *RET*/PTC1 (TPC-1 cell line) and *lane 7* (*N*) is negative control (no template)

In the current study, interphase FISH analysis revealed a high prevalence rate (78.6%, 11/14) of *RET* rearrangements. To date, as shown in Table 3, there has been five papers on *RET* rearrangements in papillary thyroid carcinomas using interphase FISH analysis [13, 21–24]. The prevalence rates of *RET* rearrangements in these studies varied from 33.3% to 92.3%. Therefore, our data were not too high compared to other previous reports. We also performed RT-PCR analyses with the specific primers for *RET*/PTC1 and *RET*/PTC3 and found that *RET*/PTC1 was detected in 28.6% of papillary thyroid carcinomas. The prevalence rate of *RET*/PTC as determined by RT-PCR was apparently lower than that by interphase FISH.

Several explanations are raised to explain the discrepant prevalence between FISH and RT-PCR in papillary thyroid carcinomas. In this study, RT-PCR analysis was performed with primers targeting *RET*/PTC1 and *RET*/PTC3, while interphase FISH, with the probe covering the whole region of *RET*, might pick up the other types of *RET*/PTC rearrangements. The other possible reason is that interphase FISH can detect small number of cells with DNA rearrangement, while the messenger RNA transcript of the gene rearrangements would be undetectable by RT-PCR when the population of rearranged cell is small. Therefore, it is not surprising that interphase FISH is more sensitive than RT-PCR in detecting *RET* rearrangements.

In the previous studies using the FISH procedures, they used the cutoff levels (less than 10%) in the estimation of *RET*/PTC for tumor tissues because *RET*/PTC was observed in a small number of the nuclei of the nontumorous thyroid tissues. In this FISH study, we did not recognize *RET*/PTC in the nuclei of the nontumorous follicular cells despite of careful microscopic observations and, therefore, no cutoff level was set to elucidate *RET*/PTC in tumor tissues. It has been reported that variable stimuli, such as Hashimoto's thyroiditis and irradiation, induce genetic instability (*RET*/PTC) in nonneoplastic follicular cells [22, 25]. We have reassessed the histological and clinical findings of normal control and found Hashimoto's thyroiditis in none of the patients for normal control. We have also verified that none of the patients had neck irradiation.

The mean tumor cell populations containing *RET*/PTC has been reported to range from 9.8% to 54%. In the current study, the percentage of tumor cells with *RET*/PTC was rather low in papillary thyroid carcinomas, ranging from 1.8% to 19.6% (mean 9.7%). These data suggested that most papillary thyroid carcinomas with *RET* rearrangements are comprised of nonrearranged tumor cell. Unger et al. [13] described that this genetic heterogeneity of *RET*/PTC can be interpreted in two different ways: *RET*/PTC is the first event with new clones emerging later or *RET*/PTC is, at least in some carcinomas, a late event in thyroid carcinogenesis. Of these two hypotheses, the latter hypothesis could be more likely because the population of *RET* rearranged cells is small in all papillary thyroid carcinomas examined.

Recently, "driver and passenger" theory is discussed in cancer genomics [26, 27]. Cancer cells carry the DNA abnormalities that initiate malignant proliferation and induce additional genetic events. Some of these secondary mutations will be accelerating pathogenic factors during the cancer progression (driver mutation), while others may be incidental abnormalities as nononcogenic or less oncogenic (passenger mutation), resulting from mutational exposures, genome instability, or simply the large number of cell doublings. Flavin et al. found the presence of *RET* rearrangements in a small population of primary peritoneal carcinomas by FISH analysis. They presumed that *RET* rearrangements in peritoneal carcinomas represent as "passenger mutation" reflecting *RET* instability in subclone rather than oncogenic mutation [28]. These observations lead us to conjecture that some of *RET* rearrangements reflect passenger mutation in thyroid cancers, congruent with low prevalence of *RET* rearrangements in poorly and undifferentiated thyroid carcinomas. However, our previous study confirmed restrictive detection of *RET*/PTCs in papillary carcinoma among thyroid neoplasms. Furthermore, thyroid-targeted expression of *RET*/PTC1or *RET*/PTC3 induces thyroid neoplasms in transgenic mice. These

findings implies oncogenic roles *RET* rearrangements in thyroid carcinomas, conflicting with the idea of passenger mutation.

In conclusion, we disclosed that *RET* rearrangements occur in a small population of tumor cells in papillary thyroid carcinomas using interphase FISH analysis on touch imprint cytology. Even though *RET*/PTCs is a specific genetic event in papillary thyroid carcinomas, heterogeneity of *RET* rearrangements, shown in the present study, implies *RET* rearrangements is subclonal event. Our results raised the possibility of *RET* rearrangements as "passenger" abnormalities rather than "driver" oncogenic mutation on thyroid carcinogenesis, warranting further studies on mechanisms and implication of *RET* gene instability.

Abstract Tenascin C (Tn-C) is an extracellular matrix glycoprotein that is expressed early in carcinogenesis including intraepithelial neoplastic lesions of different organs. In this study, we analyze whether stroma reaction seen by Tn-C expression is detected early in tumorigenesis of medullary thyroid carcinoma (MTC) including medullary microcarcinoma and C-cell hyperplasia (CCH), which is accepted to be a precursor lesion of MTC in the setting of RET oncogene germ-line mutation. Tn-C was expressed in the stroma of all medullary microcarcinoma and in the stroma next to CCH. Stromal Tn-C expression was significantly more often seen in CCH with concomitant MTC than in isolated CCH of hereditary as well as nonhereditary cases (p=0.001 and p=0.016, respectively). We conclude that Tn-C expression and thus early stroma remodeling is seen in medullary microcarcinoma and CCH. Stromal Tn-C expression seems to be an indicator of a further step in carcinogenesis of MTC irrespective of a RET oncogene germ-line mutation.

Keywords Medullary thyroid carcinoma · C-cell hyperplasia · Tenascin C

Introduction

Molecular genetic studies, calcitonin screening, and the resulting prophylactic thyroidectomies allowed studying early C-cell lesions including medullary thyroid microcarcinoma and C-cell hyperplasia (CCH) in familial but also sporadic cases [1–5].

In the setting of RET oncogene germ-line mutation, CCH is accepted to be a precancerous lesion. Results of several studies indicate an age-related progression of C-cell lesions from CCH towards medullary thyroid carcinoma (MTC) in patients with germ-line mutations of the RET oncogene [6–8]. In nonhereditary (sporadic) cases, the role of CCH in carcinogenesis is discussed controversially [5, 9–11]. Perry et al. suggested that only CCH of hereditary cases show morphologic atypia, and nonhereditary, so-called reactive CCH do not [9]. However, other authors did not find morphologic differences between CCH of hereditary and nonhereditary cases, indicating that CCH might be a precursor of MTC in a sporadic setting as well [5, 12, 13].

In MTC, we could show that only tumors with a desmoplastic stroma reaction may show lymph node metastasis and hence concluded that stroma remodeling might play an important role in the progression of MTC [14–16]. However, its role in the early tumorigenesis in MTC is not analyzed.

An extracellular matrix glycoprotein expressed in the stroma of malignant tumors including MTC is tenascin C (Tn-C) [15, 17, 18]. It promotes cell migration, inhibits cell adhesion to fibronectin, and induces tumor proliferation and metastasis in model systems [19–22]. Tenascin C is expressed early in carcinogenesis including intraepithelial neoplastic lesions of various organs such as breast (DCIS), prostate (PIN), vulva (VIN), and cervix (CIN) [23–26]. Hence, it is considered an indicator of early stroma remodeling in carcinogenesis.

The aim of this study was to investigate Tn-C expression systematically in medullary thyroid microcarcinoma as well as in concomitant and isolated CCH in sporadic and hereditary cases.

Materials and methods

Case selection

Seventy-seven cases of isolated C-cell hyperplasia and 70 cases of medullary thyroid microcarcinoma were obtained from the Department of Clinical Pathology of the Medical University of Vienna. Clinicopathologic data including gender, age, and lymph node status were available. Additionally, all cases were examined for germ-line mutations in exons 8, 10, 11, 13, 14, 15, and 16 of the RET proto-oncogene as described by Fink et al. [27].

One hundred thirty-three of 147 cases were retrieved from a consecutive series where basal calcitonin levels were routinely measured in patients with thyroid and parathyroid disorders who were referred to the Department of Surgery at the University of Vienna. An elevated basal calcitonin level and an abnormal pentagastrin-stimulated calcitonin level indicated surgical removal. For calcitonin measurements, either a modified two-site radioimmunometric assay (CIS-Biointernational, Gif-sur-Yvette, France) or a chemiluminescence immunoassay (Nichols Institute Diagnostics, San Clemente, CA, USA) was used as described [4, 28, 29]. In three nonfamilial cases (one case of MTC and two cases of CCH), normal basal calcitonin level was detected, but suspect nodular lesion of the thyroid led to the surgical procedure. In 11 cases (seven cases of MTC and four cases of CCH), prophylactic total thyroidectomy was performed based on the known germ-line mutation of the RET proto-oncogene. In the other hereditary cases including six cases with isolated CCH, elevated basal calcitonin level and an abnormal pentagastrin-stimulated calcitonin level indicated surgical removal.

Total thyroidectomy was done in each case. The thyroid gland was cut in 2–3 mm sections, fixed in 4% formaldehyde, and embedded in paraffin. Serial 3 μm sections were cut and used for histopathological and immunohistochemical evaluation. One section of each block was stained with hematoxylin–eosin. In addition, we performed immunohistochemical staining with antibodies against calcitonin (monoclonal mc, Chemicon, Temecula, California, USA, 1:600) for all blocks and additionally Tn-C (TN2, mc, DAKO, Golstrup, Denmark, 1:200) in representative blocks of the medullary microcarcinoma and of the CCH. In four cases, Tn-C expression could not be investigated in MTCs as the small tumors were not seen on the consecutive sections. The lymph node metastasis were not investigated by Tn-C immunohistochemistry.

Antigen retrieval for Tn-C was performed by incubating 10 min in protease X. Slides were incubated at room temperature for 1 h with the primary antibodies followed by incubation with biotinylated secondary antibodies and the avidin–biotin peroxidase complex (ABC) using the Vectastin ABC kit (Vector Laboratories, Burlingame, CA, USA). The final reaction was visualized with 3,3′ diaminobenzidine. Sections were counterstained with Harris' hematoxylin. Negative controls included omission or substitution of primary antibodies by nonspecific, isotype-matched antibodies.

Histomorphology

C-cell hyperplasia is defined by more than 50 C cells in a low-power field (magnification, ×100) in both thyroid lobes [5]. For the C-cell count, the calcitonin immunostained sections were scanned at low magnification (×40), and the area with the highest density (hot spot) of C cells was selected. The C-cell count was determined by counting all C cells per low-power field (×100 magnifications, area of 3.33 mm^2).

Medullary thyroid microcarcinoma was defined as an MTC according to the WHO criteria [30] and a tumor diameter of 1 cm or less.

Statistical evaluation

For statistical analysis, the SPSS program (SPSS, Chicago, IL, USA) was used. Tn-C expression was correlated with gender, age, calcitonin level, and number of C cells in isolated and concomitant CCH. Tenascin C expression was considered as positive whenever an expression is seen in the extracellular matrix surrounding C cells in at least one focus of C cells (stromal Tn-C expression) or when it was seen within C cells (intracellular Tn-C expression). Both expression patterns were calculated separately. Familial (hereditary) and nonfamilial (sporadic) cases were analyzed separately. For statistical analysis, qui-quadrate calculations and Student's t test were applied whenever appropriate. A two-tailed p value of <0.05 was considered as significant.

Results

Patients data

Hereditary cases

Ten of 77 cases of isolated CCH and 30/70 cases of MTC showed germ-line mutations in the RET proto-oncogene. Different mutations in the exons 10, 11, 13, 14, and 15 were detected (see Table 1).

The ten cases of isolated CCH consisted of seven male and three female patients with a mean age of 39±22 years, ranging from 6 to 69 years. The 30 cases of medullary thyroid microcarcinoma consisted of 14 male and 16 female patients with a mean age of 45±22 years, ranging from 5 to 80 years.

Sporadic cases

The 67 cases of isolated CCH consisted of 55 male and 12 female patients with a mean age of 55±11 years, ranging from 23 to 75 years. The 40 cases of medullary thyroid microcarcinoma consisted of 25 male and 15 female patients with a mean age of 61±12 years, ranging from 26 to 82 years.

Histomorphology

Hereditary cases

In the 30 cases of micro-MTC, the mean tumor diameter was 4.4±2.7 mm, ranging from 1 to 10 mm. Six of 30 (20%) MTCs had metastasized to the regional lymph nodes. Concomitant CCH was seen in 27/30 (90%) cases. In all cases, the concomitant CCH was seen in close proximity to an MTC. The mean number of C cells was 337±169 ranging from 97 to 751. Tenascin C expression was seen in the stroma of all investigated MTCs and in the stroma of the concomitant CCH in 89% (24/27). In MTC, the stromal tenascin expression was often accentuated at the peritumoral invasion front. Tenascin expression in CCH was seen in the stroma surrounding non-invasive C-cell clusters.

In the ten patients with isolated CCH, the mean number of C cells was 497±271 ranging from 195 to 1,025. Stromal Tn-C expression next to isolated CCH was observed in 30% (3/10) of the cases (Table 1). The expression pattern of stromal tenascin C did not differ from the pattern seen in concomitant CCH.

The difference in the frequency of stromal Tn-C expression comparing isolated and concomitant CCH was significant (p= 0.001). Stromal Tn-C expression was not correlated with gender, age, calcitonin level, and number of C cells.

Intracellular Tn-C immunoreactivity of C cells was detected in 2/27 (5%) concomitant and in 1/10 (10%) isolated CCH and additionally in invasive C cells of 2/28 (7%) MTC. No correlation was seen between intracellular Tn-C expression with any of the investigated clinicopathologic parameters and stromal tenascin expression.

Seventeen of forty specimens showed nodular goiter. Inflammatory thyroid disease was seen in 5/40 cases, and nonmedullary neoplastic diseases was observed in three cases (one follicular adenoma, two papillary thyroid carcinomas—both microcarcinomas).

Sporadic cases

Concerning the 40 cases of medullary thyroid microcarcinoma, the mean tumor diameter was 4±2.9 mm, ranging from 0.5 to 10 mm. Five of the 40 (13%) MTCs had metastasized to the regional lymph nodes. Concomitant CCH was seen in 32/40 (80%) cases. In all cases, concomitant CCH was seen in the vicinity of the MTC. The mean number of C cells was 445±299 ranging from 61 to 1,259.

Tn-C expression was seen in the stroma of all investigated MTCs and in the stroma next to concomitant CCH in 78% (25/32) of the cases. The staining pattern of stromal tenascin C in MTC and CCH was similar to the pattern seen in the hereditary cases. In the 67 cases with isolated CCH, the mean number of C cells was 490±278 ranging from 111 to 1,231. Half of the cases (52%, n=35) with isolated CCH showed Tn-C expression (see Fig. 1). The difference in the frequency of stromal Tn-C expression comparing isolated and concomitant CCH was significant (p=0.016). Stromal Tn-C expression was not correlated with gender, age, calcitonin level, and number of C cells.

Intracellular immunoreactivity of C cells was detected in 6/32 (19%) concomitant and in 16/67 (24%) isolated CCH and additionally in invasive C cells of 10/38 (26%) MTC (see Fig. 1). Six cases of CCH without stromal Tn-C deposition showed intracellular Tn-C expression. No correlation was seen between intracellular Tn-C expression with any of the investigated clinicopathologic parameters and stromal tenascin expression.

Concerning the MTC cases, nodular thyroid disease was observed in 25/40 specimens, inflammatory thyroid disease in 9/40 cases, and nonmedullary neoplastic diseases in 15/

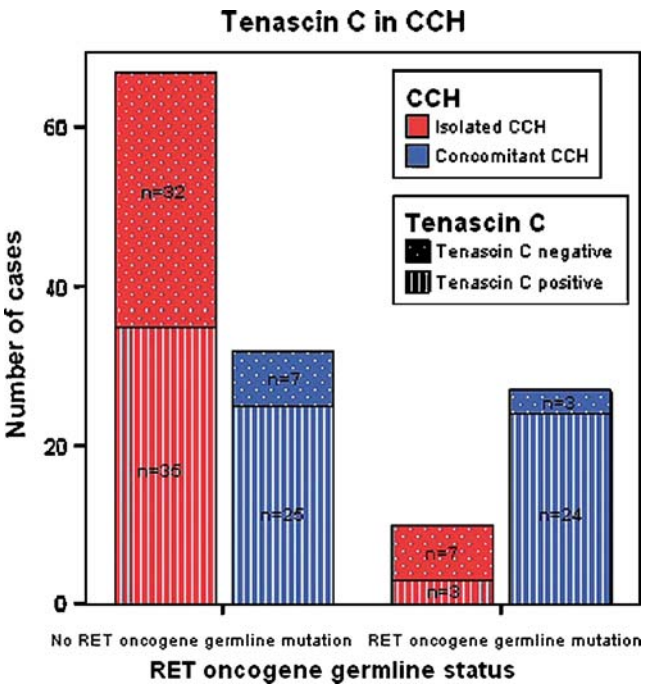

Fig. 2 Tenascin C in isolated and concomitant CCH of familial and sporadic cases. In patients with and without RET oncogene germ-line mutation, stromal tenascin C expression is more often seen in concomitant CCH (24/27 and 32/40, respectively) than in isolated CCH (3/10 and 35/67, respectively)

40 cases (11 papillary thyroid carcinomas—all microcarcinomas—and four follicular thyroid adenomas).

Fifty-one of 67 patients with isolated CCH showed nodular thyroid disease. Inflammatory disease was seen in 11/67 cases. Concomitant neoplastic diseases include 18 cases of papillary thyroid carcinomas—including 17 microcarcinomas—and four cases of follicular adenomas.

Discussion

Tenascin C is an extracellular matrix glycoprotein that contributes to pattern formation during development. Connective tissue of adult organs such as thyroid shows no tenascin expression under physiologic conditions [31] but under various pathologic conditions, e.g., wound healing, inflammation, and tumorigenesis [32]. It is expressed early in carcinogenesis including intraepithelial neoplastic lesions of different organs like breast, prostate, vulva, and cervix [23–26].

C-cell hyperplasia in the setting of germ-line RET oncogene mutation is accepted as precancerous lesion [6, 33], however, its role in nonhereditary cases is discussed controversially [5, 9–11]. Hence, our aim was to analyze whether Tn-C expression is seen in the context of carcinogenesis of MTC.

We observed stromal Tn-C expression in all medullary thyroid microcarcinomas and additionally in most concomitant as well as in a fraction of isolated CCHs irrespective of the RET oncogene germ-line status (Fig. 2). Thus, Tn-C expression in CCH parallels early stromal remodeling described next to intraepithelial neoplasia of diverse organs [23–26].

A recent study indicated a distinct age-related progression of hereditary medullary thyroid carcinoma in carriers of the different RET oncogene germ-line mutations. Depending on the RET oncogene mutation CCH, MTC and its lymph node metastasis developed on different consecutive time points [33].

Regarding the hereditary cases, we found stromal Tn-C expression in 24 of 27 CCHs concomitant to MTC, whereas only three of ten isolated CCHs expressed stromal Tn-C. Hence, the Tn-C expression could indicate a step in the progression from CCH to MTC. However, due to the low number of hereditary cases and the high variability of RET germ-line mutations, no reliable genotype/phenotype/age correlation can be made.

In our study, the nonhereditary cases parallel the findings of the hereditary cases. Tenascin-C expression was more frequent in concomitant CCH (25/32) than in isolated CCH (35/67). These observations together with the findings that the stromal deposition of Tn-C is seen in the development of other preneoplastic conditions such as CIN, PIN, etc. strongly suggest that many CCHs of sporadic cases might represent a preneoplastic lesion with the same stepwise progression to MTC as seen in the hereditary cases.

Additionally to the stromal expression, Tn-C was also seen in the cytoplasm of the tumor cells. Expression of tenascin in tumor cells was seen in other carcinomas and correlated with prognosis in breast carcinoma [34, 35]. We found intracytoplasmatic Tn-C immunoreactivity not only in C cells of MTC but also in some isolated and concomitant CCH. No correlation was seen between intracellular Tn-C expression with any of the investigated clinicopathologic parameters and stromal Tn-C expression. Due to the expression of tenascin in neural crest cells, the expression in C cells may be an incidental phenomenon due to its neurocrest origin [36–39].

We conclude that the Tn-C expression and consequently the stromal remodeling seem to indicate a further step in the carcinogenesis of MTC. We cannot exclude that the Tn-C expression is only a side effect rather than it plays a pivotal role in tumorigenesis. For this question, further experimental studies are necessary. As the stromal activation in sporadic cases was similar to that seen in hereditary forms, a progression of CCH to MTC as seen in hereditary cases seems likely.

Conflict of interest statement We declare that we have no conflict of interest.

Abstract This study was designed to analyse the potential diagnostic value of miR-181b and miR-21 for discriminating hyperplastic polyps (HP) from sessile serrated adenomas (SSA) without cytologic dysplasia. Using real-time polymerase chain reaction expression levels of miR-181b and miR-21 in 18 HPs, 19 SSAs without cytologic dysplasia and 20 normal colonic mucosal specimens were examined. In addition, 20 colorectal cancers specimen were analysed for miR-181b expression. Data were normalised to RNU48 as an internal control. A differential expression of miR-181b and miR-21 was found in HPs, SSAs, and normal colonic mucosa with highest expression levels in SSAs. Levels of miR-181b but not miR-21 differed in HPs and normal mucosa. SSAs exhibited both significantly higher miR-181b levels (up to 2.01-fold; $P<0.001$) and miR-21 levels (up to 1.82-fold; $P=0.011$) than HPs. In contrast to HPs, SSAs are characterised by high levels of miR-181b and miR-21 expression. However, due to the overlap of values, miR-181b and miR-21 evaluation did not allow discrimination of the two lesions in every case.

Introduction

Hyperplastic polyps (HP) are common lesions in the large bowel, especially in the distant bowel [1]. Typical HPs are small, usually <5 mm in diameter, symmetrical, and uniform. While adenomatous polyps have been documented to progress into colorectal carcinoma [2], such evidence has not been documented for HPs. Thus, the non-neoplastic nature of HPs has developed into an unchallenged dogma for several decades. Most HPs are typically located in the recto-sigmoid and are still considered as lesions lacking a malignant potential [3, 4]. The recognition of a morphologically different variant of HP, which is mainly located in the proximal colon, has led to the identification of a lesion we now call sessile serrated adenoma (SSA). The SSA is part of a novel pathway called the serrated pathway [5]. Various lesions may show serrated epithelial infolding and are united into the term "serrated polyp". This has led to a currently proposed classification [6] that includes four morphological categories (HPs, SSA, admixed polyps, and traditional serrated adenomas). Although HPs and SSAs share some morphological features, several distinct characteristics have been recognised [5, 7] that help to differentiate between these two type of lesions. Nevertheless, histopathological diagnosis of SSA still remains difficult.

MicroRNAs (miRNAs) are a class of recently discovered small RNA molecules that regulate the expression of genes at the translational level [8, 9]. Our understanding of these recently discovered tiny RNA molecules is still in its infancy, but studies indicate that microRNA-mediated gene regulation is likely to play key roles in human development, cellular differentiation, and oncogenesis. MicroRNA are endogenously expressed short noncoding RNAs, which are 18–25 nucleotides in length and that are capable of

repressing protein translation through binding to target messenger RNA (mRNA). The single-stranded miRNAs, derived from miRNA duplex complexes, can associate with the RNA-induced silencing complex (RISC) [10]. The miRNA-RISC has been shown to bind to specific mRNA targets and cause the translational repression or cleavage of these mRNA sequences.

For pathologists, the measurement of microRNA levels might offer a new set of diagnostic tools that may also be used to improve our understanding of cancer. This study focuses on potential diagnostic value of several microRNAs (miR-181b, miR-21, miR-133, and miR-let 7c) that have been found to be differentially expressed in colorectal tumour tissue [11].

Materials and methods

Patient material

The study comprised SSAs, HPs, colorectal cancers, and specimens with normal colonic mucosa. Table 1 depicts the exact numbers of specimens used for microRNA analysis. Diagnosis of SSA was performed according to diagnostic criteria published by Torlakovic et al. [6]. Figure 1 represents a typical SSA with its peculiar morphological features. Patients with SSAs and HPs had a mean age of 60.1 and 62.5 years, respectively. Tissue was retrieved from paraffin-embedded material using a punching tool of 0.6 mm diameter. At least three cores were taken from each specimen and the whole cores were used for RNA extraction. Standard H&E staining was performed on each cored specimen in order to ensure that removed tissue samples were representative for the lesion (Fig. 2). The normal colon mucosa was retrieved from resections margins of diverticulosis specimens lacking any inflammatory activity. Colorectal cancer specimens were collected from diagnostic tumour biopsies. Patients were not subject to any neoadjuvant or adjuvant therapies.

RNA isolation and reverse transcription

Total RNA isolation was performed using the Rneasy FFPE isolation kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. miR-181b, miR-21, miR-133, and miR-let 7c were analysed by the real-time reverse transcription (RT)-polymerase chain reaction (PCR) scheme for miRNA quantification according to the protocol of Applied Biosystems (P/N: 4364031). The RNA concentration and purity (A260:A280>2.0; A260:A230>1.8) were measured using NanoDrop™ 1000 spectrophotometer (Thermo Scientific, Wilmington, DE, USA). The reverse transcriptase reaction was carried out in a 15-µl reaction mixture containing gene-specific stem-loop primers according to the TaqMan MicroRNA Assay protocol (Applied Biosystems, Darmstadt, Germany), 5× RT buffer, 10 mM deoxynucleotide triphosphate (dNTPs) (ROTH, Ultrapure dNTP-Set), 200 U/µl RT (Fermentas, RevertAid M-MuLV Reverse Transcriptase, Vilnius, Lithuania), 40 U/µl Ribo-Lock RNase Inhibitor (Fermentas), and 20 ng/µl RNA. The reaction was performed in a peqlab cycler (primus 25 advanced, MWG Biotech, Ebersberg, Germany) for 30 min at 16°C, 30 min at 42°C, and 5 min at 85°C, and the reaction mixture containing the resulting complementary DNA (cDNA) was stored at 4°C.

Real- time PCR

The 12-µl real-time PCR mixture contained 5.25 µl cDNA (diluted 1:25), TaqMan Universal PCR master mix (No AmpErase UNG), and 1 µl of TaqMan MicroRNA assay hsa-181b/hsa-21/hsa-133/hsa-let7c and RNU48 (Applied Biosystems). The reaction was initiated at 95°C for 10 min, followed by 40 cycles of 95°C for 15 s, and 60°C for 1 min. The reaction was carried out using an Applied Biosystems 7500 fast real-time PCR system (Applied Biosystems Inc., Foster City, CA, USA).

Statistical analysis

Default threshold settings were used to determine the threshold cycle data. The relative amount of each miRNA was calculated using the comparative threshold (Ct) method with $\Delta Ct = Ct\,(miRNA) - Ct\,(RNU48)$. Relative quantification of miRNA expression was calculated with the $2^{-\Delta\Delta Ct}$ method (Applied Biosystems User Bulletin No. 2 [P/N: 4303859]). This method is called the comparative C_T method, which is widely used to present relative gene

Table 1 Cases analysed for miR-181b, miR-21, miR-133, and miR-let 7c expression

	miR-181b	miR-21	miR-133	miR-let 7c
Normal mucosa	20	20	8	4
Hyperplastic polyp	19	19	4	4
Sessile serrated adenoma	18	18	5	5
Colorectal cancer	20	0	24	4

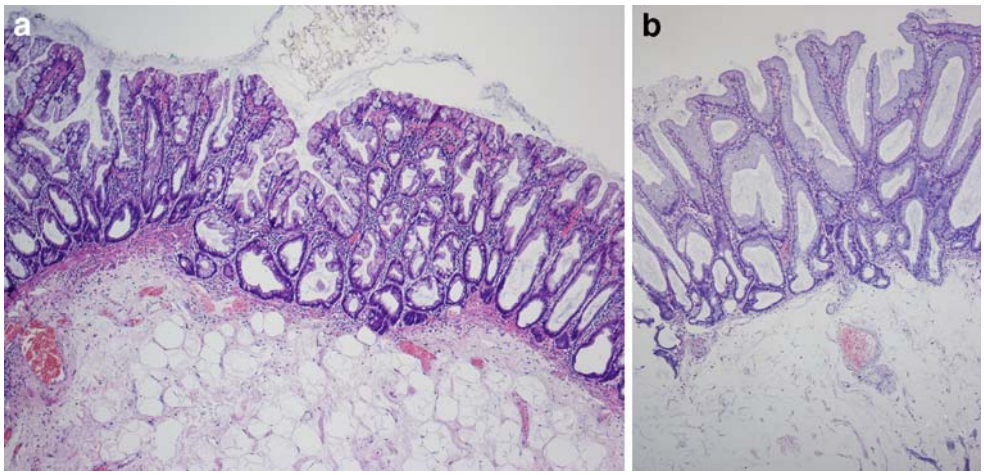

Fig. 1 Sessile serrated adenoma without cytological dysplasia. The lesion shows characteristic architectural features such as branching of crypts, dilatation of the base of the crypts, and a specific growth pattern in which crypts seem to grow parallel to the muscularis mucosae (**a**). Note the peculiar feature of so-called microherniation with herniation of crypts through the muscularis mucosae (**b**)

expression [12]. Normalisation is an essential step for the accurate quantification levels. In our study, three different approaches were used for data normalisation. MicroRNA expression data were normalised to levels of RNU48, RNU6b, and let-7a-1. Out of these three internal standards, RNU48 was proven to have the lowest variability, and the values were therefore calculated by normalisation with RNU48.

Statistical differences between localization and lesion type were performed using chi-square analysis. Differences between microRNA expression levels among the two groups were evaluated using nonparametric Mann–Whitney *U* test and the Kruskal–Wallis test for three or more groups. *P* values <0.05 were considered significant. Statistics were performed with Statistical Package for the Social Sciences version 17 (SPSS Inc., Chicago, IL, USA).

Results

Anatomical localization of HPs and SSAs

Out of 18 HPs, three (16.7%) were located in the proximal colon, four (22.2%) in the transversal or distal colon, and

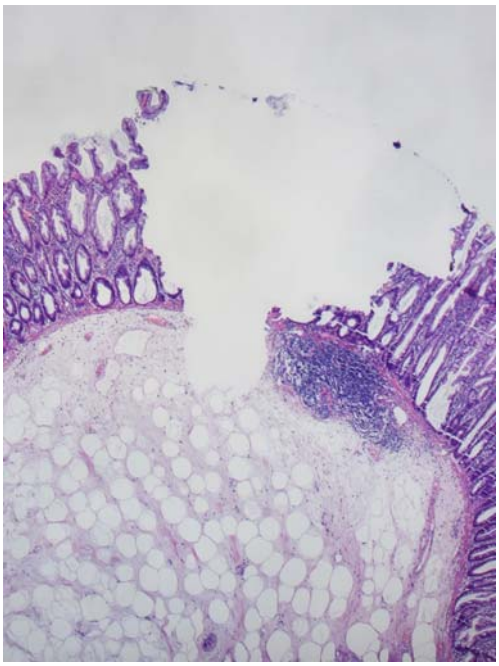

Fig. 2 Micrograph showing a control staining demonstrating the area of which the cores were taken for microRNA analysis. At least three cores of 0.6 mm diameter were taken from each specimen

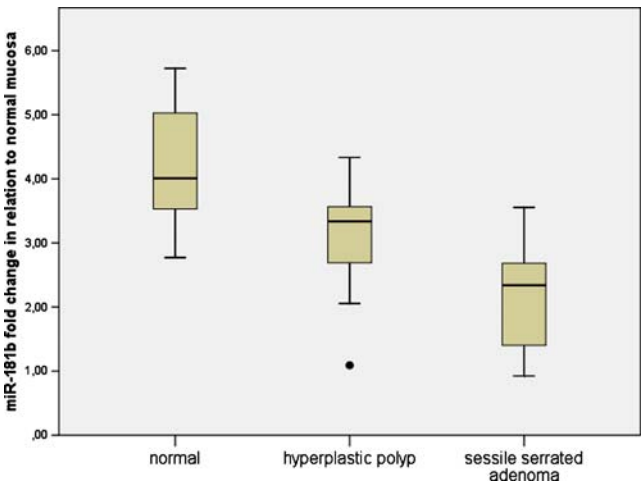

Fig. 3 Boxplot showing the different levels of miR-181b expression (data presented in ΔCT of relative threshold cycles indicating fold changes over normal mucosa; low values indicate high levels of miRNA). miR-181b is expressed at higher levels in sessile serrated adenomas compared to normal colonic mucosa and hyperplastic polyps ($P<0.001$; Kruskal–Wallis test). *Circles* indicate outliers. *Inside the boxes* lies a *central line* demonstrating the median value

Table 2 MicroRNA expression in sessile serrated adenomas in relation to hyperplastic polyps

	Sessile serrated adenoma	
	Fold change	*P* value
miR-181b	2.01 ↑	<0.001
miR-21	1.82 ↑	0.011

Fold change normalised to hyperplastic polyp

11 (61.1%) in the rectum. In contrast, out of 19 SSAs, 11 (57.9%) were located in the proximal colon, six (31.6%) in the transversal or distal colon; whereas, only two (5.4%) were located in the rectum. Thus, there was a specific distribution pattern with SSAs being located more frequently in the proximal colon and HP in the rectum (chi-square analysis, $P=0.006$).

Expression levels of microRNA

High values of relative threshold cycles indicate low microRNA quantity, and data were normalised to RNU48 expression.

Expression levels of miR-181b

The highest level of miR-181b was found in the group of SSAs (2.14, SD 0.78), followed by colorectal cancer (2.21, SD 1.36), HPs (3.14, SD 0.82), and normal colonic mucosa (4.19, SD 0.92). When comparing all groups, miR-181b expression levels showed a differential expression among normal mucosa, HPs, SSAs, and colorectal cancers ($P=0.001$; Fig. 3).

In the subgroup of HPs and SSAs, miR-181b expression of HPs was distinctly different from that of SSAs with an upregulation of miR-181b in SSAs of up to 2.01-fold. Compared to normal colon mucosa, we found elevated miR-181b expression levels in SSAs up to 4.16-fold. In addition, normal colon mucosa and HPs exhibited significant differences with miR-181b being upregulated in HPs up to 2.06-fold. Tables 2 and 3 depict data on miR-181b expression levels.

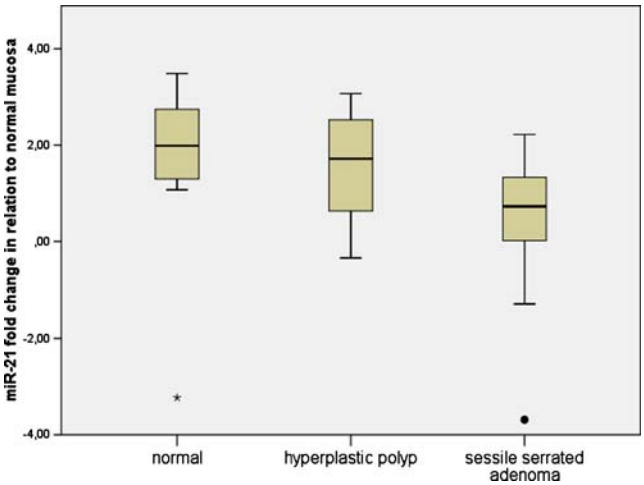

Fig. 4 Boxplot showing the different levels of miR-21 expression (data presented in ΔCT of relative threshold cycles indicating fold changes over normal mucosa; low values indicate high levels of miRNA). miR-21 is expressed at higher levels in sessile serrated adenomas compared to normal colonic mucosa and hyperplastic polyps ($P=0.003$; Kruskal–Wallis test). *Circles* indicate outliers. *Stars* indicate extreme values. *Inside the boxes* lies a *central line* demonstrating the median value

Expression levels of miR-21

Data from miR-21 expression in colorectal cancer was not available. The highest level of miR-21 was found in the group of SSAs (0.48, SD 1.33), followed by HPs (1.69, SD 1.09), and normal colonic mucosa (1.82, SD 1.39). When comparing all groups, MiR-21 expression levels showed a differential expression among normal mucosa, HPs, and SSAs ($P=0.003$; Fig. 4).

In the subgroup of HP and SSA, miR-21 expression of HPs was distinctly different from that of SSA with an upregulation of miR-21 in SSA of up to 1.82-fold. Compared to normal colon mucosa, we found elevated miR-21 expression levels in SSA; whereas, normal colon mucosa and HPs exhibited no differences. Tables 2 and 3 depict data on miR-21 expression levels.

Expression levels of miR-133

The highest level of miR-133 was found in the group of normal colonic mucosa (5.43, SD 2.44). Levels decreased

Table 3 MicroRNA expression in hyperplastic polyps, sessile serrated adenomas, and colorectal cancers in relation to normal mucosa

[a] Fold change normalised to normal colonic mucosa

Variants	Hyperplastic polyp		Sessile serrated adenoma		Colorectal cancer	
	Fold change[a]	*P* value	Fold change	*P* value	Fold change	*P* value
miR-181b	2.06	0.004	4.16	<0.001	3.94	<0.001
miR-21	1.17	NS	2.13	<0.001	–	–

to 5.77 (SD 0.98) in SSAs and 6.86 (SD 1.01) in HPs. Lowest expression values were found in colorectal cancers (7.91, SD 1.99). When comparing all groups, MiR-133 expression levels showed no differential expression among normal mucosa, HPs, and SSAs; whereas, colorectal cancers exhibited significant lower expression levels of miR-133 compared to normal colonic mucosa (P=0.025). In the subgroup of HPs and SSAs, miR-133 expression did not differ significantly.

Expression levels of miR-let 7c

The highest level of miR-let 7c was found in colorectal cancer (4.09, SD 1.05), followed by SSAs (4.78, SD 0.75), normal colonic mucosa (5.28, SD 0.28), and HPs (5.82, SD 0.95). When comparing all groups, due to overlapping values, miR-let 7c expression levels showed no differential expression among normal mucosa, HPs, SSAs, and colorectal carcinomas. In the subgroup of HPs and SSAs, miR-let 7c expression did not differ significantly.

Discussion

Altered microRNA expression has been identified in many human cancers. Comparison between human cancers and their normal counterparts has revealed that microRNA exhibit differential expression profiles in normal versus cancer tissues [13, 14]. Thus, unique microRNA expression signatures or even expression levels of certain microRNAs might be used to differentiate tumours or precursor lesions. This study focused on miR-181b and miR-21, since both these microRNA were shown to be upregulated in colorectal cancer tissue [11]. The study is based on paraffin-embedded tissue, which recently has been shown to be suitable for microRNA expression studies [15]. Initially, we started with two additional microRNAs (miR-133a and miR-let7c) that have been described to be upregulated in colorectal cancer [11]. However, our investigation of a small primary series revealed no differential expression of these microRNAs in HPs versus SSAs. Thus, we proceeded with miR-181b and miR-21 in serrated lesions.

Our data shows that these two lesions with close morphological resemblance, namely, HP and SSA, without cytologic dysplasia, exhibit significantly different miR-181b and miR-21 expression levels. miR-21 is one of the most prominent microRNAs implicated in the genesis and progression of human cancer. Recently, it was shown for the first time that a tumour suppressor (Pdcd4) was negatively regulated by miR-21 in colorectal cancer [16]. This study demonstrated miR-21 association with invasion, intravasation, and metastasis in colorectal cancer cells. Little is known about the target genes of miR-181b. It is possible to utilise TargetScan (http://www.targetscan.org) to identify putative target genes regulated by this microRNA. However, such data remains speculative only, thus, we have refrained from discussing possible target mRNAs. Future investigations are necessary to link the miR-181b and miR-21 expression levels with genetic and epigenetic alterations of SSA.

The presented study has focused on the differential expression of miRNA in serrated lesions. Moreover, we have compared miR-181b expression levels in SSA and colorectal cancer specimens. We are aware that the present series of 20 colorectal cancers is likely to represent mostly sporadic colorectal cancers and not adenocarcinomas evolved through the so-called serrated pathway. Reproducible histopathological criteria for serrated adenocarcinoma have recently been established and have been qualified by DNA expression analysis for 7,928 genes. Tuppurainen et al. were able to identify serrated adenocarcinomas as a molecular entity distinct from conventional adenocarcinoma [17]. We did not perform additional methods to characterise the genetic background of the present series of colorectal cancers. It would be desirable in the future to examine miRNA profiles in an established series of colorectal cancer with a “serrated” morphology and distinct genetic profile.

In conclusion, assessment of miR-181b and miR-21 expression in serrated polyps might help separating SSAs without cytologic dysplasia from ordinary HPs. Unfortunately, due to overlap of values of miR-181b and miR-21 expression observed in the groups of SSAs and HPs studied, measurement of these parameters is not likely to allow a clear separation of these lesions at individual patient level. Nevertheless, our results point towards a potential biological relevance of these microRNAs in the serrated polyp development.

Conflict of interest We declare that we have no conflict of interest.

Abstract An acute enteritis is commonly followed by intestinal neuromuscular dysfunction, including prolonged hyperexcitability of enteric neurons. Such motility disorders are associated with maintained increases in immune cells adjacent to enteric ganglia and in the mucosa. However, whether the commonly used animal model, trinitrobenzene sulphonate (TNBS)-induced enteritis, causes histological and immune cell changes similar to human enteric neuropathies is not clear. We have made a detailed study of the mucosal damage and repair and immune cell invasion following intralumenal administration of TNBS. Intestines from untreated, sham-operated and TNBS-treated animals were examined at 3 h to 56 days. At 3 h, the mucosal surface was completely ablated, by 6 h an epithelial covering was substantially restored and by 1 day there was full re-epithelialisation. The lumenal epithelium developed from a squamous cell covering to a fully differentiated columnar epithelium with mature villi at about 7 days. Prominent phagocytic activity of enterocytes occurred at 1–7 days. A surge of eosinophils and T lymphocytes associated with the enteric nerve ganglia occurred at 3 h to 3 days. However, elevated immune cell numbers occurred in the lamina propria of the mucosa until 56 days, when eosinophils were still three times normal. We conclude that the disruption of the mucosal surface that causes TNBS-induced ileitis is brief, a little more than 6 h, and causes a transient immune cell surge adjacent to enteric ganglia. This is much briefer than the enteric neuropathy that ensues. Ongoing mucosal inflammatory reaction may contribute to the persistence of enteric neuropathy.

Introduction

A considerable body of evidence links intestinal inflammation and intestinal neuromuscular disorders, both in the clinical literature and in animal models [1–6]. Even though the period of inflammation may be brief, and the region of overt inflammatory damage is circumscribed, the effects on enteric neurons are long-lasting [7, 8] and significant changes in organ function are observed in regions that are remote from the inflammation [9–12].

In experimental animals, inflammation causes substantial increases in the excitability of enteric neurons [13–16]. These studies investigated the enteric nervous system 3–

10 days after the induction of inflammation, a time when the inflammatory response, in terms of tissue damage and immune cell activation, is still apparent. Two animal studies have extended the investigation of neuronal changes to 8 weeks [8, 17]. In both cases, the structural effects of inflammation were resolved before 8 weeks, as judged by histological examination and assay of myeloperoxidase activity in tissue extracts, but the changes in the physiological properties of myenteric neurons [17] and submucosal neurons [8] persisted. This implies that the inflammation may cause a prolonged change in the intrinsic properties of the neurons. On the other hand, histopathological studies in human indicate that an on-going inflammation of enteric ganglia (ganglionitis), including infiltration of the ganglionated plexuses by lymphocytes, can occur in intestinal neuromuscular disorders [3, 18]. Inflammatory changes in the mucosa have also been associated with persistent changes in motility and pain perception, for example in irritable bowel syndrome patients [19] and changes in the mucosa persist for 6 months or more following an acute episode of clinical enteritis [20]. However, there is not a detailed study of the time course of immune cell infiltration of enteric ganglia and inflammatory cell presence in the mucosa in the animal models which have been used for functional studies of enteric neurons. Thus, we have investigated the process of mucosal repair and inflammatory cell attraction to enteric ganglia in an animal model previously used to investigate the changes in enteric neuron function that follow inflammation.

Materials and methods

Experiments were performed on guinea pigs (150–275 g) of either sex from the inbred Hartley strain colony of the Department of Anatomy and Cell Biology at the University of Melbourne. All procedures were conducted according to the Code of Practice of the National Health and Medical Research Council of Australia and were approved by the University of Melbourne Animal Experimentation Ethics Committee.

Inflammation was induced in the guinea pig ileum as previously described [16]. 2,4,6-Trinitrobenzene sulphonic acid (TNBS, Wako Industries, Nagoya, Japan) was given in an amount of 30 mg/kg in 1 mL of 30% ethanol into the distal ileum. Animals were taken at intervals from 3 h to 56 days after TNBS injection. Sham animals were treated identically, except that phosphate buffered saline (PBS, 0.15 M NaCl in 0.01 M sodium phosphate buffer, pH 7.2) was injected into the lumen. At the time of taking tissue, animals were stunned by a blow to the head and killed by cutting the carotid arteries and severing the spinal cord.

Histology

Samples for histology were taken from the site of application of TNBS or sham and placed into PBS containing 1 μm nicardipine, pinned on balsa board mucosa up and fixed in fixative (2% formaldehyde plus 0.2% picric acid in 0.1 M sodium phosphate buffer, pH 7.2) at 4°C overnight. Tissue was also taken from untreated guinea pigs and from 10 and 20 cm proximal to the region of inflammation. Tissue was placed into histology cassettes and dehydrated through graded ethanol to histolene and embedded in paraffin. Sections were cut transversely at 5 μm thickness and processed for standard haematoxylin and eosin (H&E) and the periodic acid-Schiff reaction (PAS). Following staining, the tissue was mounted using permanent mounting medium.

Immunohistochemistry

T cells were localised in whole mounts of the myenteric and submucosal plexuses that were double stained with anti-calbindin to reveal the ganglia. Preparations were incubated in 10% normal horse serum to block non-specific binding of labelled immunoglobulins. They were then incubated in a mixture of mouse anti-guinea pig T-cell antibody (Fitzgerald Laboratories, Niagara Falls, NY, USA; 1:1,000) and rabbit anti-calbindin (Swant, Bellinzona, Switzerland; 1:2,500), overnight at 4°C. After washing in PBS, the preparations were incubated for 1 h in a mixture of horse anti-mouse gamma globulin coupled to biotin (1:100, Vector Laboratories, Burlingame, CA, USA) and donkey anti-rabbit gamma globulin coupled to Alexa488 1:1,000 (Molecular Probes, Eugene, OR, USA), followed by streptavidin coupled to Texas Red 1:400 (Amersham, Melbourne, Australia), also for 1 h.

Results

Macroscopic and histological observations

Macroscopically, at 3 h after TNBS injection into the lumen of the ileum, there was obvious bleeding within the wall of the ileum, over a distance of about 5–8 cm oral to the site of injection. The extent of haemorrhage was variable in this region. Histological examination at 3 h showed an almost complete loss of the mucosal epithelium facing the lumen, and parts of the mucosal surface that had separated were found in the lumen (Fig. 1). The villi were completely ablated, but the bases of the glands remained and the crypts had normal appearance (Fig. 1b). At 6 h, the macroscopic appearance was similar, but the histology showed a substantial restoration of the mucosal epithelium (Fig. 1c),

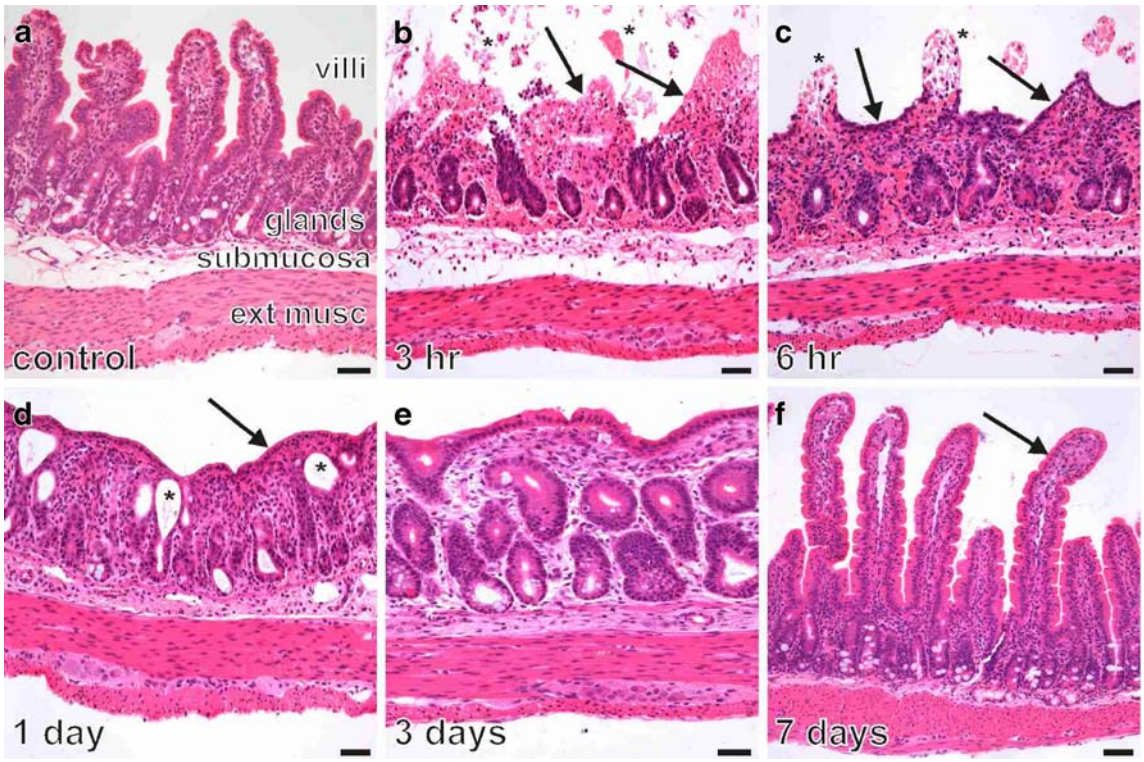

Fig. 1 Time course of histological change in the ileum after intralumenal application of TNBS. Sections are stained with haematoxylin and eosin. **a** Control ileum, with principal components of the organ labelled: external muscle layers (*ext musc*), submucosa, mucosal glands and villi. **b** The appearance 3 h after TNBS. The surface epithelium has been completely stripped from the villi (*arrows*), and the villi have broken up and formed debris in the lumen (*asterisks*). However, crypts and crypt epithelium are normal. **c** At 6 h, a partial covering of squamous epithelium (*arrows*) has formed over a flattened mucosal surface. Numerous haemorrhagic foci (*asterisks*) were seen at this stage. **d** At 1 day, a complete covering of squamous or low cuboidal epithelium has formed (*arrow*), which separates the lamina propria from the lumen. Some cysts have been included beneath the reformed epithelium (*asterisks*). **e** At 3 days, the mucosa has thickened and the surface epithelium has matured, but villi have not yet formed. **f** At 7 days, the structure of the mucosa appears similar to that of control ileum. Villi (*arrow*) have normal height and morphology. *Scale bars* 50 μm

which at this stage had a squamous or low cuboidal profile (Fig. 2a). The restored epithelium was breached at intervals, which provided microscopic haemorrhagic foci, from which there was bleeding into the lumen (Fig. 1c).

At 12 h and 1 day, the mucosal epithelium facing the lumen was continuous and haemorrhages into the lumen were not found (Fig. 1d). The epithelium was now composed of cuboidal cells (Fig. 2b). At 3 and 7 days

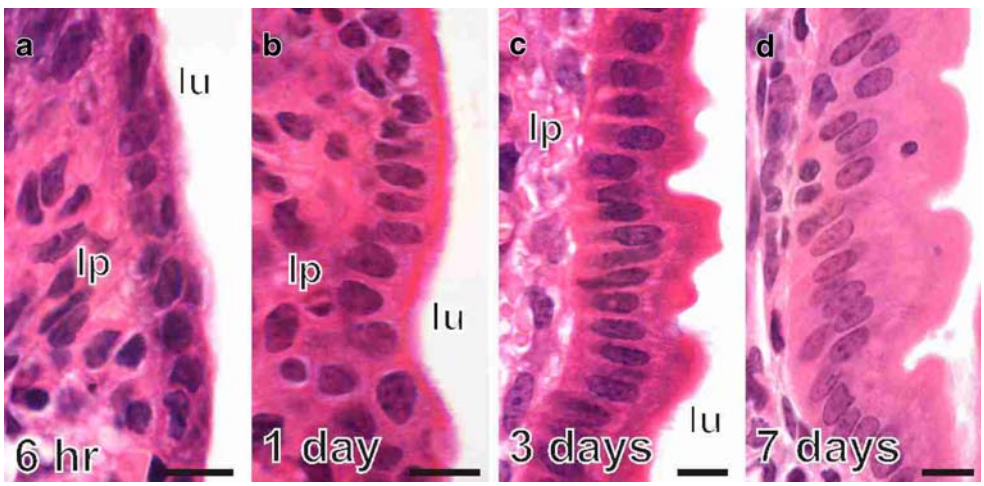

Fig. 2 Re-differentiation of enterocytes following TNBS-mediated disruption of the mucosal surface. **a** At 6 h after TNBS, the epithelium has formed as a continuous layer of squamous epithelial cells over most of the surface. *lp* lamina propria, *lu* lumen. **b** At 1 day, the epithelium is formed by a regular layer of cuboidal cells. **c** At 3 days, the epithelial cells have elongated and are similar to those in the normal ileum. **d** By 7 days, the epithelium has its normal appearance. *Scale bars* 10 μm

(Fig. 1e, f), the epithelium was intact. Villi began to be recognisable at 3 days, although there were still flattened regions. They were normal at 7 days. From 1 to 7 days, numerous small enclosed haemorrhages (petechiae) were observed in the wall, and the muscle layers were usually thickened. Sub-epithelial cysts were observed at 1 and 3 days (Fig. 1d), but these had resolved by 7 days. There was slight crypt dilatation at 1 and 3 days (Fig. 1d, e). At 7, 28 and 56 days, the intestine appeared macroscopically and histologically normal, except for increased numbers of eosinophils in the lamina propria, which is described below. The change in epithelial cell morphology from squamous to columnar between 6 h and 7 days (Fig. 2) was accompanied by the re-appearance of goblet cells (Fig. 3). In the first stages of re-epithelialisation, at 6 h, the proportion of goblet cells in the epithelium was lower than normal and there was no continuous brush border revealed by PAS staining (Fig. 3b). At 1 day, although goblet cell numbers had barely increased, the brush border and glycocalyx had returned. Goblet cell numbers continued to increase and had returned to normal proportions between 7 and 28 days (Fig. 3).

At 1, 3 and 7 days, numerous surface epithelial cells contained lysosome-like inclusions (Fig. 4). Many of the inclusions were strongly basophilic. Occasional intra-epithelial lymphocytes and eosinophils were found. Basophilic inclusions that were observed at 7 days were almost exclusive in epithelial cells at the tips of villi (Fig. 4d). In some cases, the engulfed material had the appearance of eosinophil or neutrophil cell residues (Fig. 4c), similar to the phagocytosed plasma cells that have been described in

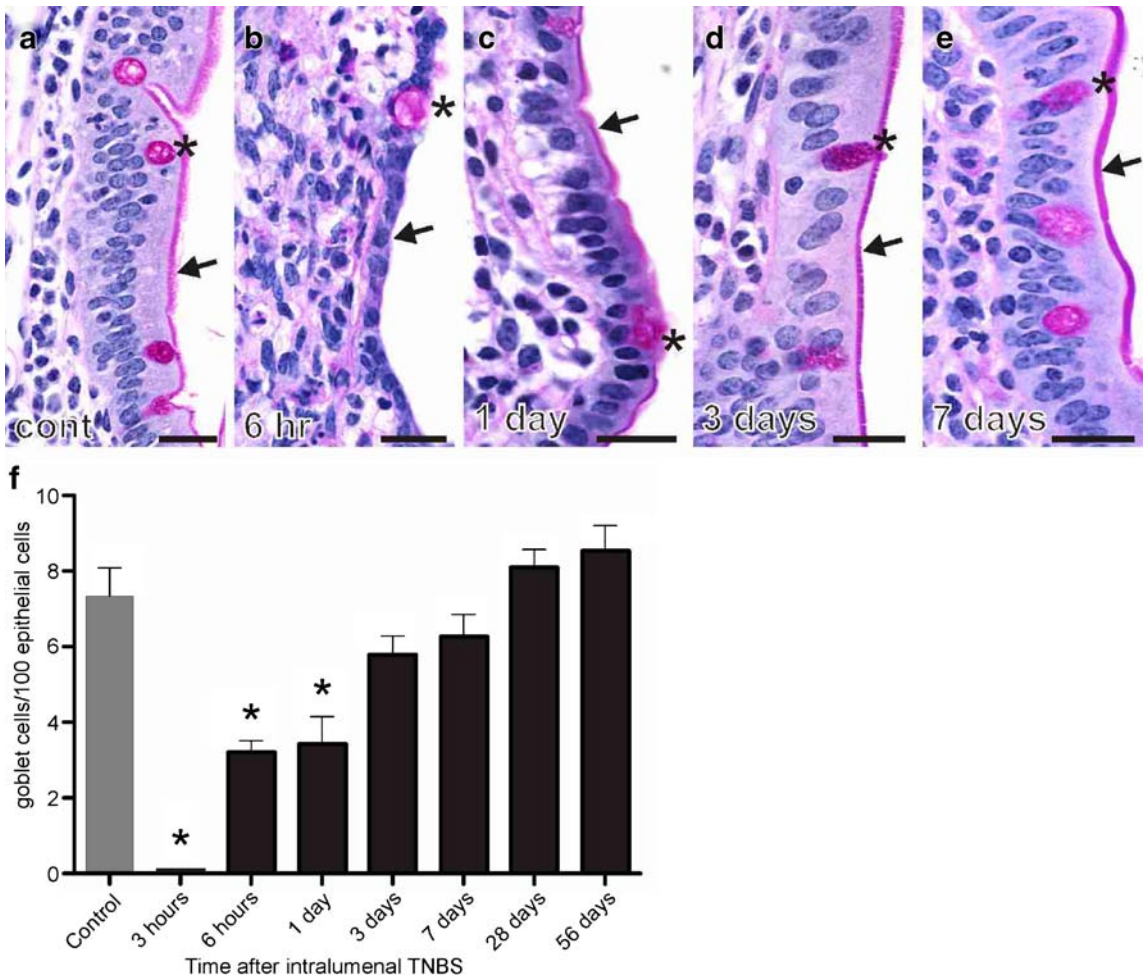

Fig. 3 Changes in goblet cells and surface mucus following inflammation with TNBS. **a** In the control, the goblet cells (*asterisk*) appear regularly in the epithelium, and a coating of mucus covers the lumenal surface (*arrow*). **b** At 6 h, goblet cells (*asterisk*) are rare at the surface, and a brush border and glycocalyx has not formed (*arrow*). **c** At 1 day, although goblet cells in the epithelium are still rare, the surface mucus layer is present (*arrow*). **d** At 3 days, the goblet cells (*asterisk*) appear mature, and there is a well-formed brush border. **e** The goblet cells and brush border appear to be normal at 7 days. **f** Goblet cell numbers at different times after infusion of TNBS into the lumen (mean ± SEM, $n=3$ animals for each time). TNBS treatment has a significant effect on goblet cell numbers (one-way ANOVA, $P<0.0001$). Numbers of goblet cells at 3 and 6 h and 1 day are significantly different to control (Dunnett's multiple comparison test, $P<0.05$, *asterisks*). *Scale bars* 20 μm

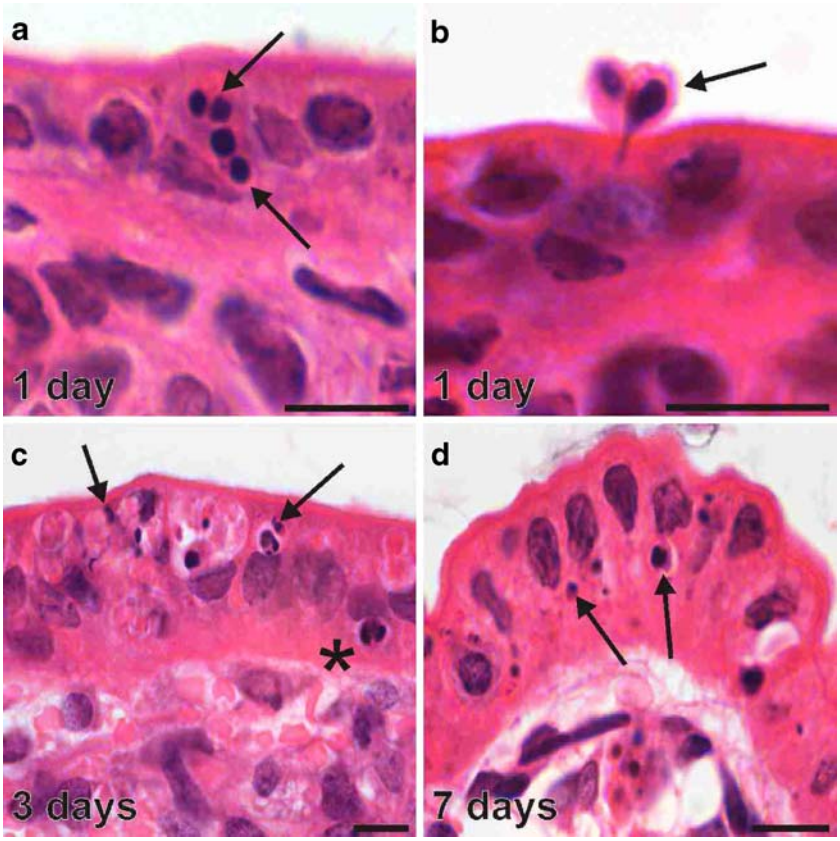

Fig. 4 Intra-epithelial inclusions, many probably being apoptotic bodies, indicative of the assumption of a phagocytic role by enterocytes. No inclusions were found in the normal intestine or in intestine from sham operations. **a** One day after TNBS, dark inclusion bodies are seen in healthy-looking enterocytes (*arrows*). **b** Small cytoplasmic extrusions into the lumen (*arrow*) that contain dense inclusions. These may indicate that debris is removed from the lamina propria and expelled into the lumen by phagocytic enterocytes. **c** Intra-epithelial inclusions 3 days after TNBS (*arrows*). An inclusion with the appearance of a neutrophil is indicated by the *asterisk*. **d** Inclusions at 7 days. Most of the enterocytes that have inclusions are at the tips of villi at this time. *Scale bars* 10 μm

the lung [21]. Some of the basophilic inclusions, surrounded by small amounts of cytoplasm, could be seen in the apparent process of extrusion at the luminal surface (Fig. 4b). No histological changes were observed in the intestine from sham-operated animals.

Immune cells

Eosinophils

Eosinophils were readily recognised in the haematoxylin and eosin-stained sections (Fig. 5). In the external layers, they were found close to myenteric ganglia, but they were not seen within the ganglia (Fig. 5a, d). The close eosinophils often appeared to be adhering to the surfaces of the ganglia (Fig. 5a, d). No eosinophils were found adjacent to myenteric ganglia in tissue from untreated guinea pigs, or from sham-operated guinea pigs, or in intestinal samples taken 10–20 cm proximal to the region affected by TNBS. In contrast to the infiltration of the spaces around the myenteric ganglia, eosinophils did not invade the circular or longitudinal muscle layers (Figs. 5a and 6). Eosinophil numbers also increased in the lamina propria and submucosa (Fig. 5b, c). The increase in eosinophil numbers peaked at about 6 h in each of the lamina propria, submucosa and myenteric plexus (Fig. 6). An increase was already apparent at 3 h in the lamina propria and submucosa, but not adjacent to myenteric ganglia. Eosinophil numbers declined and were no different to those of untreated guinea pigs by 3 days after TNBS in the submucosa and myenteric plexus (Fig. 6). However, the numbers remained elevated until 56 days in the lamina propria of the mucosa. In the tissue from sham animals, there was a slight increase in cell numbers at 6 h in the lamina propria and submucosa, but there was no increase in the region adjacent to the myenteric ganglia. There were no significant differences of shams from untreated animals at other time points.

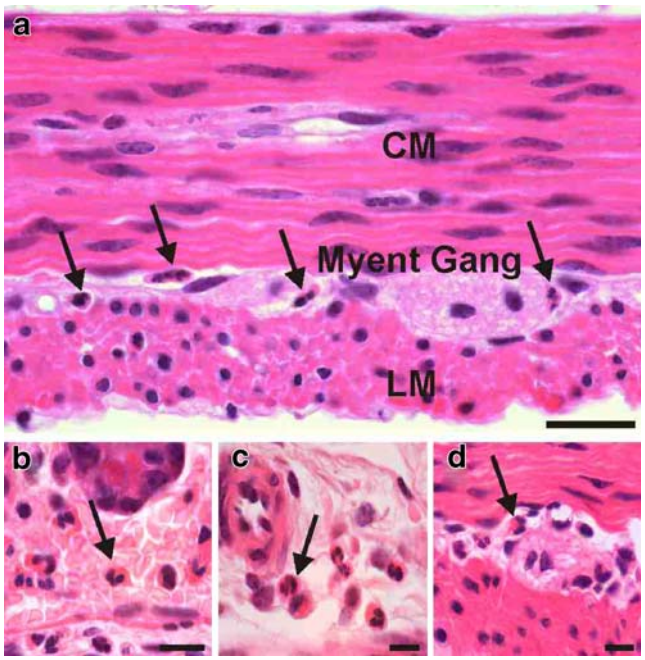

Fig. 5 The localisation of eosinophils in the wall of the ileum following inflammation. **a** Eosinophils located close to myenteric ganglia in the inflamed region, 1 day after the injection of TNBS into the lumen. Eosinophils are commonly found close to the ganglia (*arrows*), but were rare in the circular muscle (*CM*) and longitudinal muscle (*LM*). **b** Eosinophils in the lamina propria, 6 h after TNBS. At this stage, eosinophil numbers were already significantly elevated; six cells can be seen in this small field, one of which is indicated by the *arrow*. **c** Eosinophils in the submucosa, 1 day after TNBS (example at *arrow*). **d** An eosinophil close to a myenteric ganglion at 6 h. *Scale bars* 20 μm (**a**), 10 μm (**b**–**d**)

T lymphocytes

Very few T lymphocytes occurred adjacent to the myenteric ganglia of the control ileum, greater numbers were found in the submucosa and lymphocytes in the mucosa were numerous. TNBS injection into the lumen caused a substantial increase in submucosal lymphocyte numbers, 8-fold over the control at 6 h and 1 day (Fig. 7). Lymphocyte numbers declined to about half of the 1 day peak at 3 days, but were still above control at 7 and 28 days. They had returned to control at 56 days. In non-inflamed regions oral to the inflammation, there was a transient increase at 6 h, but the numbers were not different to control at 3, 7, 28 and 56 days.

TNBS injection into the lumen caused a greater than 50-fold increase in T-lymphocyte numbers in the myenteric plexus at 1 day at the site of mucosal exposure to TNBS (Fig. 8). The numbers of lymphocytes had dropped to a tenth of the 1-day value by 7 days and were back to control numbers at 28 and 56 days. In non-inflamed regions, there was a much smaller increase in T-cell number, less than 10% of the response in the area of TNBS injection.

Discussion

This study has defined the sequence of histological changes that occur following acute damage to the small intestinal lining by the hapten, TNBS, which is one of the agents commonly used to induce inflammation in animal models of acute human inflammatory bowel conditions, primarily because the immune reaction to TNBS resembles that observed in human mucosal inflammation [22].

Time course of mucosal repair

We observed that the mucosal surface is almost completely ablated at 3 h after TNBS, and that re-epithelialisation is extremely rapid, with the surface being almost fully covered, except for small foci of haemorrhage, by 6 h. It is notable that the crypts and crypt epithelium remained intact. By 12 and 24 h, surface re-epithelialisation is complete, but the epithelium has not differentiated. At this time, there are very few goblet cells; these did not return to normal numbers until after 7 days. Prior to 1 day, the lack of goblet cells was associated with a lack of brush border and associated glycocalyx at the epithelial surface, suggesting that the mucosa would be susceptible to further damage at this stage. A transient loss of goblet cells has also been reported following dextran sodium sulphate-induced colitis in the rat [23]. Inclusion cysts occurred in the early period after the restitution of the epithelium, as is also apparent in the paper of Gaudio [23]. A rapid return of epithelium is also observed after other destructive treatments [24, 25]. Experiments similar to ours, but on mouse colon, have shown re-epithelialisation at 1 day after dinitrobenzene sulphonate (DNBS; 300 mg/kg in 0.1 mL) and a similar early loss of mucin [26]. Epithelial repair was still incomplete in the rat colon 7 days after TNBS (150 mg/kg in 0.25 mL) in another study [27]. This compares with our use of 30 mg/kg in 1 mL. Slower repair is associated with deep erosion of the intestinal wall [25].

In the present study, the primary trigger for the inflammatory events, the disruption of the mucosal surface, allowing the entry of TNBS and gut flora, was largely over by 6 h, and there was an apparently complete sealing of the mucosal epithelium by 12 h. Experimentally, this provides a well-defined time of initiation of the events which follow, including the changes in enteric neuron properties, that are observed from 7 days to at least 56 days after TNBS [8, 14, 16, 17].

Mucosal phagocytic activity

A prominent feature of the epithelial changes was the appearance of dense lysosome-like intracellular inclusions at 1, 3 and 7 days. Thus, the epithelial cells assume a

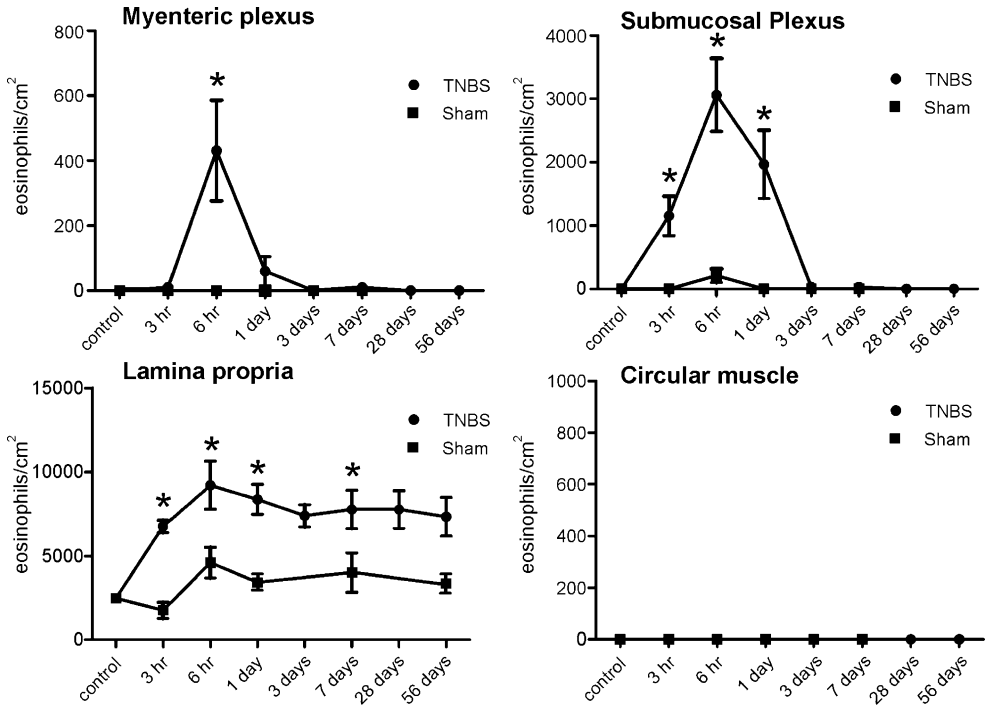

Fig. 6 The time course of changes in eosinophil numbers adjacent to ganglia of the myenteric plexus, submucosal plexus, lamina propria and circular muscle following the injection of TNBS into the lumen of the distal ileum. *Filled squares*, data from sham operations; *filled circles*, data from TNBS-treated guinea pigs. Myenteric plexus: eosinophils are normally absent from the myenteric plexus; numbers peaked at 6 h after TNBS and then subsided quickly; sham operation had no effect. Submucosal plexus: numbers rose very quickly, even at 3 h, peaked at 6 h and declined quickly; only a slight transient elevation in numbers occurred in the shams. Lamina propria: Cell numbers rose quickly and remained at an elevated level for at least 56 days; numbers after sham operation rose slightly. Circular muscle: Eosinophils did not occur in the circular muscle after TNBS or in the shams. Numbers of eosinophils are significantly changed by TNBS treatment in the myenteric plexus, submucosal plexus and lamina propria (two-way ANOVA, $P<0.001$). Differences are significant at 6 (myenteric plexus), 3 and 6 h and 1 day (submucosal plexus) and at all time points in the lamina propria (Bonferroni's test, post hoc, $P<0.05$, *asterisks*). Data are mean ± SEM, $n=3$ animals for each time

phagocytic phenotype, similar to that observed in other damaged surface epithelia [21, 28, 29]. This phagocytic activity of epithelia is thought to be important in clearing tissues of apoptotic cells, especially dying immune cells and cell debris [28]. We have observed the apparent extrusion of phagocytosed material into the lumen, suggesting that this process is important to remove debris from the lamina propria of the intestinal mucosa. Phagocytic activity continued for at least a week in our study, that is, it continues for 6 days after the epithelium has sealed and points to a very active role of the epithelium in dealing with the early stages of mucosal damage. Phagocytic inclusions in gastrointestinal epithelial cells have also been reported after aspirin damage to the gastric lining [30] and acid damage to the duodenal mucosa [31], but not previously after hapten-induced enteritis, as far as we have been able to determine.

Immune cells in the lamina propria

Increased numbers of immune cells in the lamina propria after inflammation have been seen in animal models [32] and in human post-infectious irritable bowel syndrome [19, 20, 33]. In humans, increased immune cell numbers in the rectal mucosa have been documented for at least a year after an acute *Campylobacter* enteritis [20]. Increased mucosal immune cell numbers are also seen in patients with long-standing intestinal neuromuscular dysfunction [6, 19]. In a previous investigation of the mucosa after intralumenal TNBS, increased mucosal lymphocyte numbers were observed at 10–14 days, but compared to the present study, this was a much more severe challenge that caused transmucosal necrosis [32]. In the present work, after TNBS causing only superficial mucosal damage, we found that eosinophil numbers peaked at 6 h and then remained elevated to about the same extent up to 56 days, in the mucosa of the guinea pig ileum. Our data suggest that in both experimental animals and in human, an acute injurious insult to the mucosa causes a long-term inflammatory reaction.

Immune cells and enteric ganglia

In a previous study, neutrophils were detected close to the myenteric ganglia 6 h following injection of DNBS into the colon lumen of rats, their numbers peaking at about 2 days

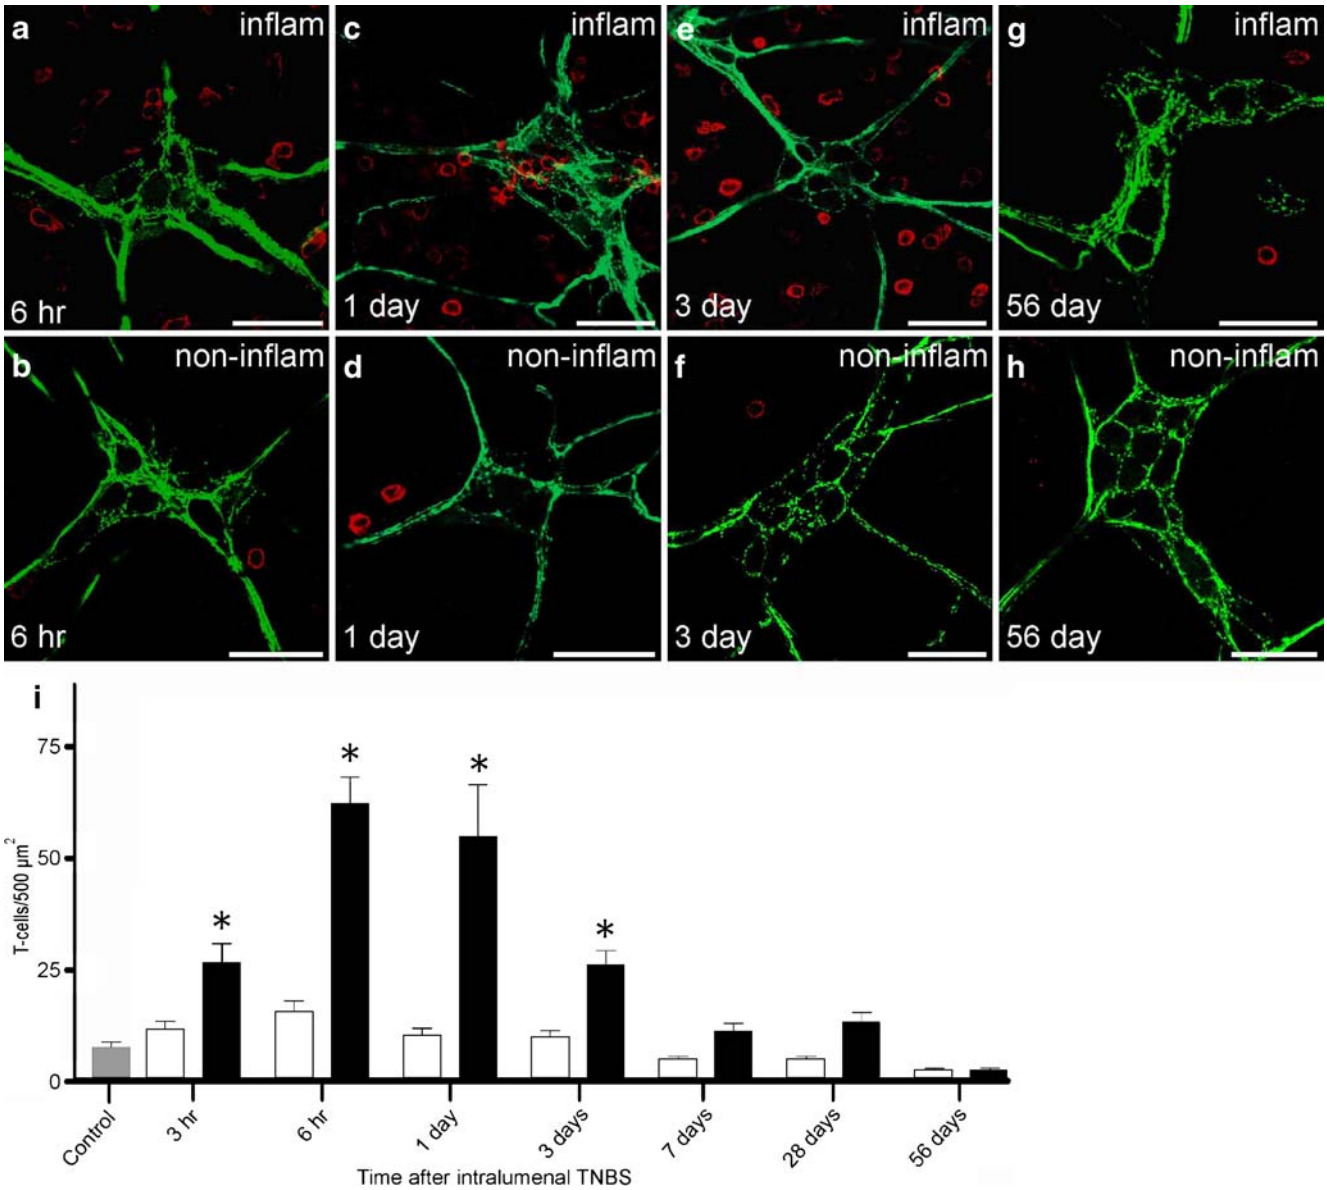

Fig. 7 T lymphocytes adjacent to submucosal ganglia of inflamed and non-inflamed regions of guinea pig small intestine at 3 h to 56 days after the injection of TNBS into the lumen. Tissue was taken from the region of inflammation and from intestine that was 10–20 cm proximal to the inflammation. T cells are *red* and the myenteric ganglia are revealed by immunoreactivity for calbindin (*green*). **a**, **b** At 6 h after injection of TNBS, T cells were observed adjacent to the ganglia from the inflamed region in increased numbers. **c**, **d** At 1 day, there were substantial numbers of T cells adjacent to the ganglia. Cell numbers were still elevated at 3 days (**e**, **f**), but had subsided by 56 days, when very few cells were observed close to ganglia (**g**, **h**). **i** Quantitation of T-cell numbers at different times after the inflammatory stimulus (mean ± SEM, n=3 animals for each time). Data are from inflamed (*black bars*) and non-inflamed (*open bars*) regions of the small intestine of the same guinea pigs at 3 h to 56 days after the application of TNBS. Numbers of T cells are significantly changed by TNBS treatment in the submucosal plexus (two-way ANOVA, $P<0.001$). Differences are significant at 3 and 6 h and 1 and 3 days (Bonferroni's test, post hoc, $P<0.05$, *asterisks*). Control: *grey bar*. *Scale bars* 50 µm

[34]. Similar observations were made in the guinea pig colon; neutrophils, eosinophils and lymphocytes, identified by their morphology, increased in numbers close to myenteric ganglia at 2 to 24 h after TNBS [35]. The next time point examined was 6 days, at which time the numbers of immune cells had declined to be close to control. Our data are consistent with these observations: we observed a rapid and transient appearance of eosinophils and T cells immediately adjacent to myenteric ganglia, whereas no eosinophils and few T cells were close to the ganglia in normal intestine. In addition, we investigated the submucosa where there was also a rapid early increase in immune cell numbers. TNBS increased the immune cell numbers in the submucosa at 3 h to 3 days. The increase in eosinophil

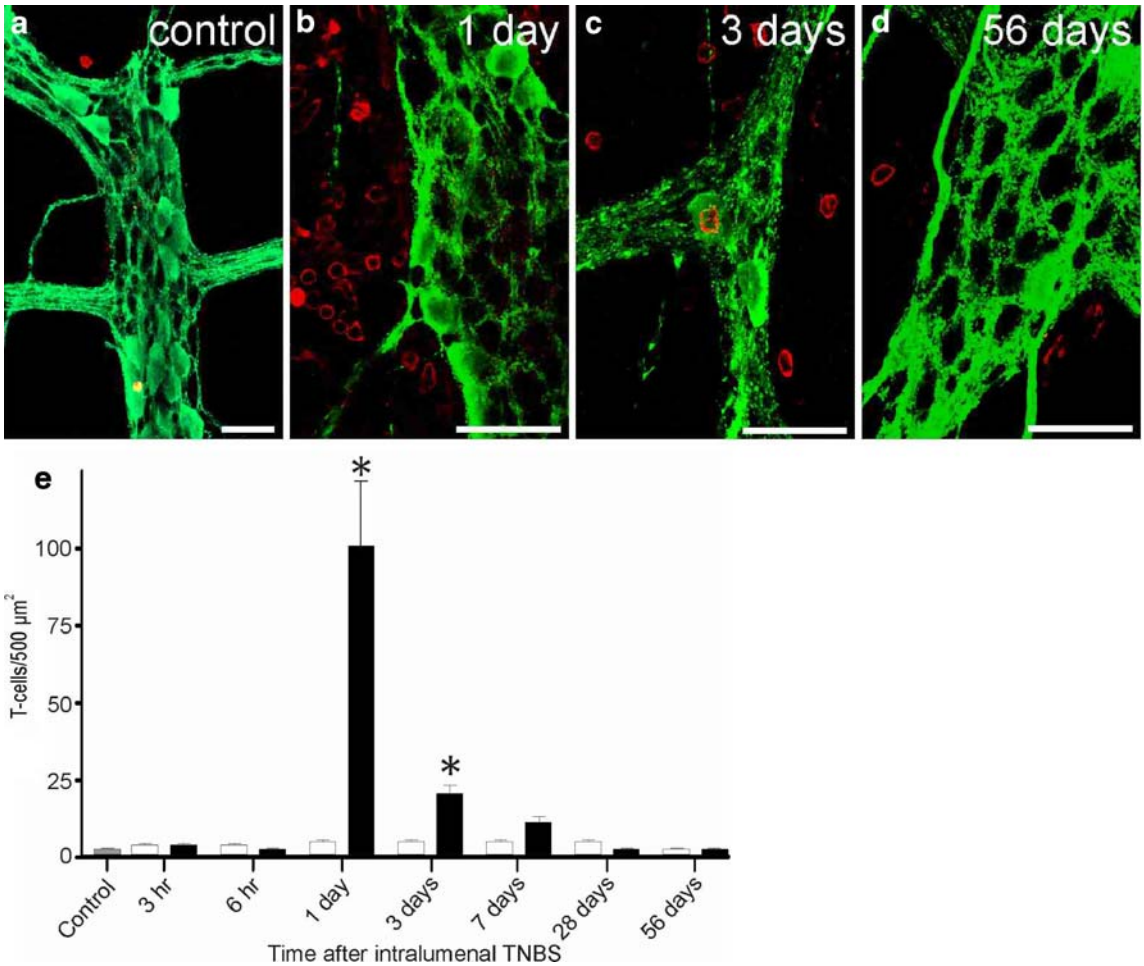

Fig. 8 The time course of changes in T-cell numbers at the level of the myenteric plexus. **a** Control preparation, in which T cells are *red* and the myenteric ganglia are revealed by immunoreactivity for calbindin (*green*). Few lymphocytes were found. **b** Numerous lymphocytes were adjacent to myenteric ganglia 1 day after TNBS treatment. **c** At 3 days after TNBS, numbers of lymphocytes were elevated, but were many fewer than at 1 day. **d** T-lymphocyte numbers were similar to control at 28 and 56 days. **e** Quantitation of T-cell numbers at different times after the inflammatory stimulus (mean ± SEM, $n=3$ animals for each time). Data are from inflamed (*black bars*) and non-inflamed (*open bars*) regions of guinea pig small intestine at 3 h to 56 days after the application of TNBS. Control: *grey bar*. Numbers of T cells are significantly changed by TNBS treatment in the myenteric plexus (two-way ANOVA, $P<0.001$). Differences are significant at 1 and 3 days (Bonferroni's test, post hoc, $P<0.05$, *asterisks*). *Scale bars* 50 µm

and T-cell numbers in the vicinity of submucosal ganglia was apparent at 3 h, whereas the rise in the myenteric plexus occurred slightly later. Eosinophils were first observed adjacent to myenteric ganglia at 6 h, and T cells were observed at 1 day. The time differences may reflect the fact that resident immune cells are common in the submucosa and can increase by local proliferation, whereas cells probably need to extravasate to colonise the myenteric ganglia. Following TNBS, eosinophils and T cells were common adjacent to myenteric ganglia but were rare in the muscle layers, indicating a specific targeting to enteric ganglia. Such selective targeting of immune cells to the ganglia, rather than the muscle, is also observed in human myenteric ganglia following inflammation [18, 36].

Implications

In normal intestine, there are no eosinophils associated with myenteric ganglia, and T cells are found in their vicinity only rarely. Thus, their presence in elevated numbers is an indication of ganglionitis and suggestive of neuropathology [6]. In this experimental model, the presence of immune cells adjacent to myenteric ganglia and the increased numbers close to submucosal ganglia were transient (peaks at about 6 h to 1 day which subsided by about 7 days), whereas the hyperexcitability of myenteric and submucosal neurons remains prominent for at least 56 days [8, 17]. This suggests that there is an enteric neuronal memory of previous insult. However, persistent mucosal inflammation

(indicated by increased eosinophil numbers) is still observed at 56 days, when the numbers of these cells are only slightly fewer than the peak at 6 h and about three times the numbers found in control. Thus, the immune state of the mucosa is re-set by a severe insult that ablates the mucosal surface. The major neuron type in myenteric ganglia whose properties are changed by a brief severe inflammation are the intrinsic primary afferent neurons (IPANs) [14, 16]. These neurons have processes in the mucosa that are stimulated by local mediators, for example short-chain fatty acids, adenosine triphosphate, 5-hydroxytryptamine and dietary amino acids [37–39]. Thus, the exposure of their nerve terminal in the mucosa to the products of immune cells may contribute to the maintenance of increased excitability of IPANs.

Conclusions

The immediate damage to the mucosa caused by TNBS is rapidly reversed (<1 day), and the increases in immune cell numbers close to enteric ganglia peak at 6 h to 1 day and have subsided by 3 days. However, the re-constituted epithelium is actively involved in clearing debris from the sub-epithelial connective tissue for at least a week and increased immune cell numbers in the mucosa and elevated enteric neuron excitability persist for at least 8 weeks. Thus, the ongoing hyperexcitability of enteric neurons is not due to a persistent ganglionitis, but ongoing mucosal inflammation may be a contributing factor.

Abstract Genes of the Wnt and Frizzled class, expressed in HNSCC tissue and cell lines, have an established role in cell morphogenesis and differentiation, and also they have oncogenic properties. We studied Wnt and Fz genes as potential tumor-associated markers in HNSCC by qPCR. Expression levels of Wnt and Fz genes in 22 unique frozen samples from HNSCC were measured. We also assessed possible correlation between the expression levels obtained in cancer samples in relation to clinicopathologic outcome. Wnt-1 was not expressed in the majority of the HNSCC studied, whereas Wnt-5A was the most strongly expressed by the malignant tumors. Wnt-10B expression levels were related with higher grade of undifferentiation. Related to Fz genes, Fz-5 showed more expression levels in no-affectation of regional lymph nodes. Kaplan–Meier survival analyses suggest a reduced time of survival for low and high expression of Wnt-7A and Fz-5 mRNA, respectively. qPCR demonstrated that HNSCC express Wnt and Fz members, and suggested that Wnt and Fz signaling is activated in HNSCC cells.

Introduction

Squamous cell carcinoma (SCC) is the most frequent malignant tumor of the head and neck area. In the last years, there has been great progress in identifying molecular changes that occur during the malignant transformation of cells.

Although many molecular markers have been evaluated, the role of Wnt and Fz in carcinogenesis of HNSCC remains poorly understood. The diverse receptor–ligand pairs of the Wnt and Frizzled families play essential roles in the regulation of the cell growth, motility, and differentiation during embryonic development [1, 2]. Genes of the wingless (Wnt) and frizzled (Fz) class have an established role in cell morphogenesis and cellular differentiation [3–5].

Wnt genes encode a large family of secreted glycoproteins expressed in species ranging from *Drosophila* to human. The Wnt family constitutes 19 members in the human genome. The Wnt glycoproteins are ligands for the Fz receptors, which exert their effects through activation of distinct intracellular signaling pathways. The intracellular Wnt signaling have been recognized in four

distinct branches: the canonical β-catenin pathway, which activates the target genes in the nucleus; the planar cell polarity pathway, which involves JNK (Jun N-terminal kinase) and cytoskeletal rearrangements; the Wnt/Ca^{2+} pathway, which involves activation of PLC (phospholipase C) and PKC (protein kinase); and a pathway that regulates spindle orientation and asymmetric cell division [6–10].

Aberrant activation of the Wnt signaling pathway has been reported during neoplastic progression, and became evident in cancer with the discovery that a number of Wnt genes have now been associated with the development of various human cancers [11–17].

To date, different roles for Wnt have been recognized in squamous cell carcinomas of the oral cavity [18, 19]. Also, it is known that Wnt and Fz proteins are expressed in HNSCC cell lines, suggesting that they play a role in cell growth and survival. However, no examination has been made on Wnt and Fz expression in human oral carcinomas specimens by qPCR.

In the present study, we have studied expression levels of Wnt and Fz family members. The hypothesis that prompted this study was that human HNSCC might show different Wnt and Fz expression patterns than to those shown in tumor cell lines. We examined frozen human samples of HNSCC for the expression of five Wnt and two Fz genes.

Materials and methods

Processing of clinical tissue specimens

Fresh primary tumor samples of head and neck squamous cell carcinomas (HNSCC) from 22 patients, who underwent surgical removal of their tumors, were obtained from the Maxillofacial Surgery Service, A Coruña University Hospital. Among the total specimens, 22 samples comprised central tumor tissue and 16 comprised peritumoral tissue; both tissues were obtained from the same HNSCC patient (Table 1). As control, a pool of healthy human oral mucosa (n=19) was used. The study was approved by the Institutional Review Board of the Ethic Committee of Clinical Investigation of Galicia (Spain). All tumor samples were confirmed by histopathological analysis. Tissue samples were dissected under stringent sterile conditions to prevent RNA contamination and immediately were frozen in liquid nitrogen and stored at −80°C until RNA extraction.

RNA extraction

Isolation of total RNA from frozen healthy and malignant specimens was performed, following manufacturer's protocols, using Tripure Isolation Reagent (Roche, Mannheim, Germany).

Characteristics of the head and neck tumors analyzed

SCC squamous cell carcinoma, *TNM* TNM status, *F* female, *M* male

For the isolation of each tissue sample, 50 to 100 mg was processed. Total RNA were treated with DNase I.

RNA integrity was confirmed by 2% agarose gel electrophoresis stained with ethidium bromide. RNA was also assessed for quantity at 260 nm using a GENIOUS UV spectrophotometer. A260/A280 relation was calculated for quality, quantity, and purity.

cDNA synthesis

Reverse-transcription PCR (RT-PCR) was performed using Super-Script™ First-Strand Synthesis System for RT-PCR (Invitrogen, Spain) up to a total volume of 20 µl. One microgram of total RNA, 2.5 nM random hexamers, 0.5 mM dNTP mix, and 3 µl of DEPC-treated water were denatured at 65°C for 5 min and chilled on ice for at least 1 min. On the other hand, 2 µl of 10× RT buffer, 5 mM $MgCl_2$, 0.01 M DTT, and 40 U of RNase-OUT™ Recombinant Ribonuclease Inhibitor were mixed, collected by centrifugation, and incubated at 25°C for 2 min. After incubation, 50 U of Super-Script™ II RT was added and incubated at 25°C for 10 min, 42°C for 50 min, and 70°C for 15 min in a Thermocycler (Gene AMP PCR System 9700, Applied Biosystems, Spain). Finally, samples were chilled on ice and incubated with 2 U of RNAse H for 20 min at 37°C before proceeding to the amplification of the target cDNA. Positive and negative controls were included in each experiment.

RNA extraction, reverse-transcription PCR assay setup, and post reverse-transcription PCR product analysis were carried out in separate designated rooms to prevent cross-contamination. cDNA was quantified and assessed for purity using a Genious UV spectrophotometer. cDNA concentration was measured at 260 nm. Also, A_{260}/A_{280} relation was calculated in order to know cDNA quality, quantity, and purity.

Quantitative real-time PCR (qPCR)

Quantitative real-time PCR analysis was performed, using LightCycler® 480 SYBR Green I Master Kit (Roche), on a LightCycler® 480 Real Time PCR System (Roche). PCR reaction consisted of 10 µl of Master Mix 2× conc., 0.35 µM of each forward and reverse primer, template cDNA, and PCR-grade water up to a final volume of 20 µl in the LightCycler 480 Multiwell Plate 96. Multiwell plate was centrifuged at 3,000 rpm for 2 min and was loaded in the LightCycler 480 Instrument until the PCR program started. An initial activation at 95°C for 5 min followed by an amplification target sequence 50 cycles of 95°C for 10 s, 59–60°C (depending on the primers pair used) for 10 s, and 72°C 9–20 s (depending on the amplicon size amplified) was used. For melting curve analysis, one cycle of 95°C for 5 s, 70°C for 15 s, and 95°C for 1 s was used. Finally, a cooling step was used at 40°C for 10 s. PCR primers for the amplification of the different Wnt and Fz genes were carefully designated using the web-based ProbeFinder software (Universal ProbeLibrary Design Center) accessible at [43] or via Roche Applied Science home page [44]. PCR primers were positioned to span exon–intron boundaries in order to reduce the risk of detecting genomic DNA. Primers were purchased from Roche Mannheim (Germany). The following list summarizes the primer pairs used: Wnt-1: 5′ TCT TCG GCA AGA TCG TCA A 3′ (forward); 5′ ACA CGT GCA GGA TTC GAT G 3′ (reverse). Wnt-5A: 5′ TGG TGC CTG ATA TCT CAA AGT C 3′ (forward); 5′ GAG AAA TAA CCC CAG AGT AAA CTG TAA 3′ (reverse). Wnt-7A: 5′ GGG AAG GAG CTC AAA GTG G 3′ (forward); 5′ CTG GCC TTG CYY CYC TTT GT 3′ (reverse). Wnt-10B: 5′ AAT GCG AAT CCA CAA CAA CA 3′ (forward); 5′ TCC AGC ATG TCT TGA ACT GG 3′ (reverse). Wnt-13: 5′ AAG ATG GTG CCA ACT TCA CCG 3′ (forward); 5′ CTG CCT TCT TGG GGG CTT TGC 3′ (reverse). Fz-2: 5′ CAT CGA GGC CAA CTC TCA GT 3′ (forward); 5′ AGG CCT ACG AAG CAC ACG 3′ (reverse). Fz-5: 5′ TAC CCA GCC TGT CGC TAA AC 3′ (forward); 5′ GGA TTC CAG GGA AAG GAC TCT 3′ (reverse). HPRT: 5′ TGA CCT TGA TTT ATT TTG CAT ACC (forward); 5′ CGA GCA AGA CGT TCA GTC CT 3′ (reverse). Suitable selection of housekeeping gene was performed using Human Endogenous Control Gene Panel (TATAA Biocenter, Sweden). The Excel macro named GeNorm VBA applet for Microsoft Excel was used to determine the gene with the most correlated expression in the set of samples. HPRT (hypoxanthine-guanine phosphoribosyltransferase) was used as internal control. Also, housekeeping gene was used to verify integrity of RNA and efficacy of reverse transcription. Any specimen with inadequate housekeeping mRNA level was excluded from the study.

We verified that amplifications and the expected size of each qPCR product were specific. Agarose gel electrophoresis (1.8%) of all PCR products revealed a single band that corresponded to the single-amplified products as predicted by the melting curve analysis of the PCR. The amplification efficiency was determined for both target and housekeeping genes and was equal (99–100%).

Data analysis was performed with LightCycler® 480 Relative Quantification software (Roche). Relative expression levels (R.E.L) were calculated by the $2^{-\Delta\Delta Ct}$ method [20]. Each assay was done at least in triplicate and it included marker-positive and marker-negative controls and reagent with no template controls.

DNA sequencing

Al least one qPCR product coming from each quantitative real-time PCR experiment was used as template

DNA in order to verify the specificity of the amplified amplicon. Products were purified by enzymatic method (ExoSAP-IT, Amersham USB). DNA sequencing was performed on an ABI 3700 system (Applied Biosystems) using Big Dye terminators. Forward and reverse primers used in sequencing reactions were the same as for the real-time PCR.

Statistical analysis

Statistical analysis of the results was performed with SPSS program (version 12.0 for Windows). The relationship between Wnt and Fz expression values and clinicopathological data was studied by non-parametric statistic, Kruskal–Wallis, and Mann–Whitney *U* tests. The relationship among the different markers tested with patient's survival was performed by Cox regression and Kaplan–Meier curves analyses. Statistical significance of differences was evaluated at the 95% confidence level; p values <0.05 were considered to be significant.

Other procedures

Standard procedures for manipulation of nucleic acids were essentially those previously reported [21].

Results

Expression of Wnt genes in head and neck squamous cell carcinoma and healthy human oral mucosa of head and neck

To assay Wnt gene expression as potential tumor-associated markers in HNSCC, we analyzed various tumors by qPCR. With the exception of Wnt-1, all the genes tested showed expression in peritumoral and central tumor tissues of oral mucosa. Of the Wnt genes, Wnt-1 was not expressed in the majority of the HNSCC studied; only three cases showed expression. Wnt-5A was the most strongly expressed by the central zones of the malignant tumors, followed by Wnt-13, Wnt-10B, and Wnt-7A. Regarding peritumoral tissues, Wnt-5A was also the most strongly expressed, followed by Wnt-10B, Wnt-13, and Wnt-7A. Wnt-5A, Wnt-7A, and Wnt-13 showed higher mRNA expression levels in central tumor tissues than in the peritumoral zones (Fig. 1a). When we compared Wnt mRNA expression levels in human central tumor tissues against healthy human oral mucosa, we observed that the higher levels were obtained in central tumor zones (Fig. 1b). When we compared Wnt mRNA expression levels in human peritumoral tissues against healthy human oral mucosa, we observed that the higher levels were obtained in peritumoral zones (Fig. 1c).

Expression of Fz genes in head and neck squamous cell carcinoma and healthy human oral mucosa of head and neck

To assay Fz gene expression as potential tumor-associated markers in HNSCC, we analyzed various tumors by qPCR. Both genes tested showed expression in peritumoral and central tumor tissues of oral mucosa. Of the Fz genes, Fz-2 was the most strongly expressed by the central tumor zones of the malignant tumors, followed by Fz-5. Regarding peritumoral tissues, Fz-2 was the most strongly expressed, followed by Fz-5 (Fig. 1a). When we compared Fz mRNA expression levels in human central tumor tissues against healthy human oral mucosa, we observed that the higher levels were obtained in central tumor zones (Fig. 1b). When we compared Fz mRNA expression levels in human peritumoral tissues against healthy human oral mucosa, we observed that the higher levels were obtained in peritumoral zones (Fig. 1c).

Correlation of Wnt and Fz gene expression with clinicopathological parameters and patient's survival

mRNA expression levels of the different Wnt genes tested in central tumor zones were correlated, by means of non-parametric statistics, with different clinicopathological parameters that included TNM status, stage, tumor localization, degree of differentiation, sex, and age (Table 2). Among all Wnt genes, WNT10B expression levels were correlated with higher grade of undifferentiation (Mann–Whitney *U* test, $p=0.013$). Related to Fz genes, Fz-5 showed higher expression in no-affectation of regional lymph nodes (Mann–Whitney *U* test, $p=0.009$). Fz-5 was not correlated with TNM status (Kruskal–Wallis test, $p>0.05$), although it could seem to exist a direct relation between them. More tumor specimens of HNSCC should be screened to validate these findings.

In order to know if there is any relationship among the different markers tested and patient's survival, we performed Cox regression and Kaplan–Meier curves analyses. Cox regression analyses showed that there is no statistically significant relationship among the different markers studied with patient's survival. However, when we performed Kaplan–Meier curves analyses, using the median of the R.E.L for each marker tested as cut-off value, we could appreciate that for Wnt-7A and Fz-5 we obtained values with statistical significance. Regarding Wnt-7A marker, we suggest that patients with R.E.L above the median (median=1.056) have higher survival than those with R.E.L. below the median ($p=0.024$). Also, for Fz-5 marker, we suggest that patients with R.E.L. above the median (median=5.859) have lower survival than those with R.E.L. below the median ($p=0.011$). In this way, Kaplan–Meier survival analyses

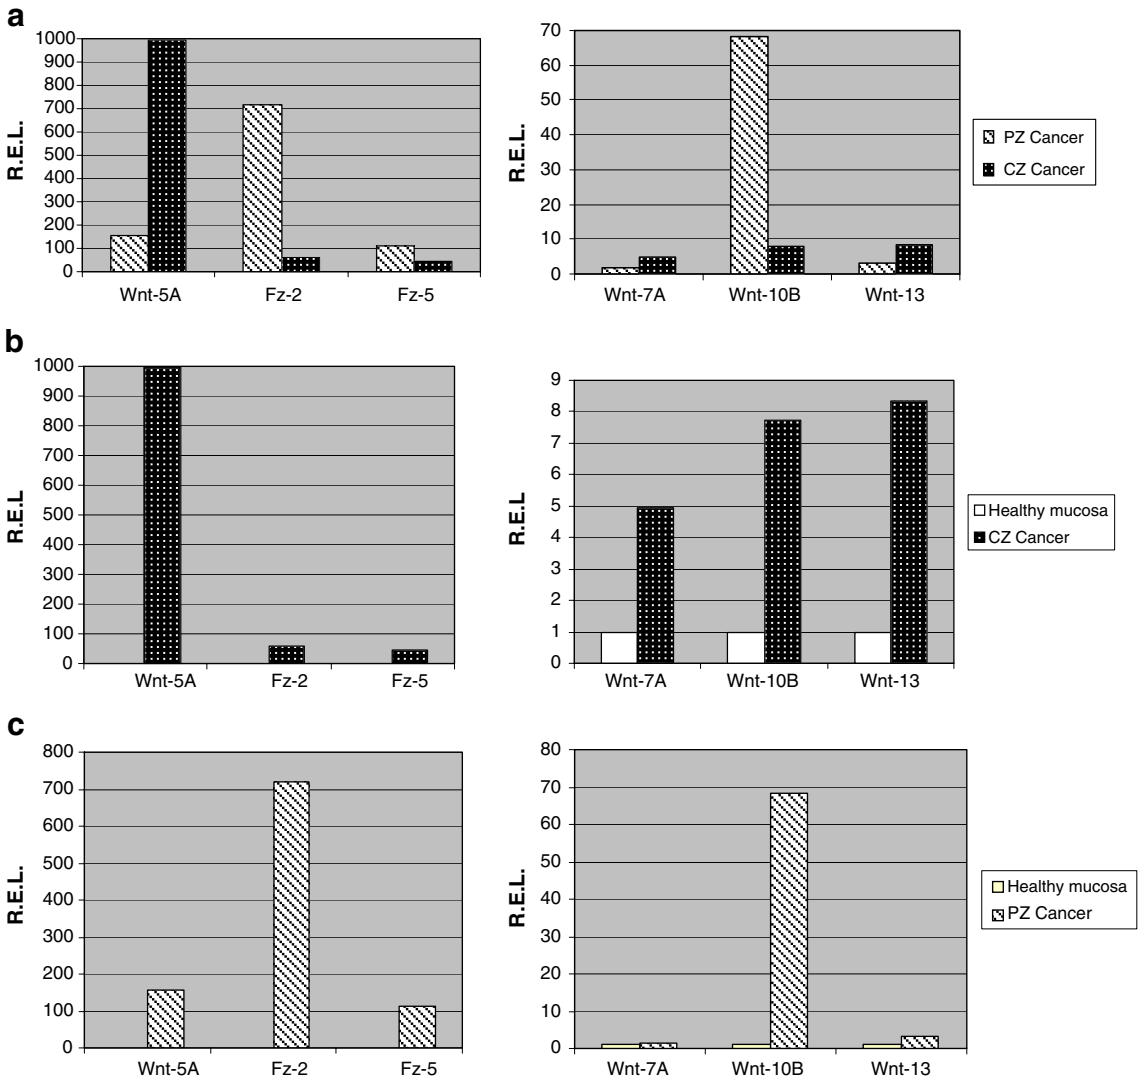

Fig. 1 Wnt and Fz mRNA expression levels in different human HNSCC, peritumoral zone (*PZ Cancer*, $n=16$) versus central tumor zone of the tumor (*CZ Cancer*, $n=22$) (**a**). Wnt and Fz mRNA expression levels in a pool of healthy human oral mucosa ($n=19$) versus central tumor tissue (*CZ Cancer*, $n=22$) (**b**). Wnt and Fz mRNA expression levels in a pool of healthy human oral mucosa ($n=19$) versus peritumoral tissue (*PZ Cancer*, $n=16$) (**c**). *Y* axis represents Wnt and Fz mRNA relative expression levels (*R.E.L.*) and *X* axis represents the different human Wnt and Fz genes tested. mRNA levels were measured by quantitative real-time PCR as described in Materials and methods. Quantitative real-time PCR results are the mean of at least three independent measurements. Data were normalized versus the values obtained in healthy human oral mucosa which were considered equal to 1

suggest a reduced time of survival for low R.E.L. of Wnt-7A mRNA and for high R.E.L. of Fz-5 mRNA (Fig. 2).

Discussion

To evaluate Wnt and Fz gene expression as potential tumor-associated markers in HNSCC, we screened various tumors by qPCR. The results revealed that Wnt-5A was the most strongly expressed by the central tumor tissues, but Wnt-1 was not expressed in the majority of the HNSCC studied (only three cases expressed Wnt-1). On the contrary, Rhee et al. [14] observed that Wnt-1 was one of the most expressed in HNSCC cell lines besides Wnt-10B and Wnt-5A. Also, they observed no differences in Fz-5 expression in HNSCC cell lines against normal human broncho-epithelial and oral squamous epithelial cell lines, whereas in HNSCC tissues we obtained an increased expression of Fz-5 with regard to healthy human oral mucosa. Among all Wnt genes, expression levels of Wnt-10B in central tumor zone were related with higher grade of undifferentiation. The present study demonstrates that HNSCC express Wnt and Fz members and that all Wnt and Fz genes tested were overexpressed not only in peritumoral zone but also in central tumor tissues of human HNSCC specimens.

Correlation between Wnt and Fz expression status and various clinicopathologic variables

a Mann–Whitney *U* test, *b* Kruskal–Wallis test

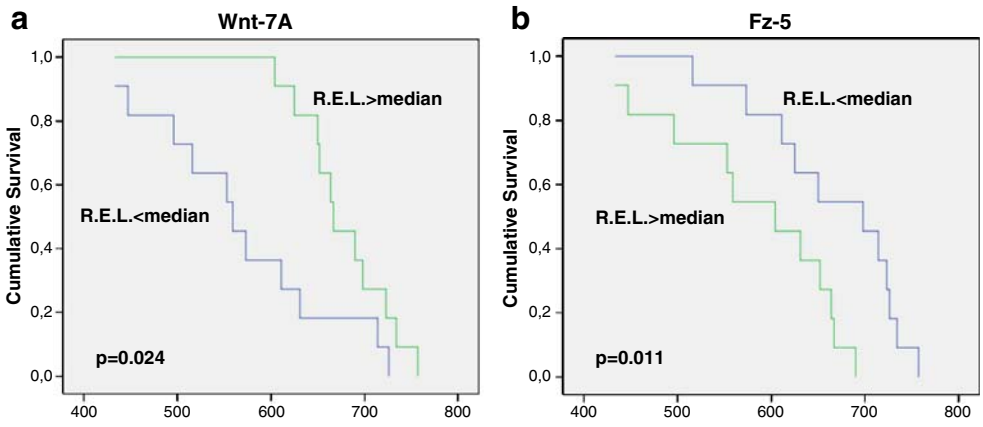

Fig. 2 Kaplan–Meier graphs for time of survival according to R. E.L. of Wnt-7A (**a**) and Fz-5 (**b**) mRNA in central tumor tissue of HNSCC; *p* values are given for log rank tests

Aberrant activation of the Wnt and Fz signaling pathway has been reported in HNSCC lines [14]. These investigators found that Wnt-1, Wnt-10B, Wnt-13, and Fz-2 were overexpressed in ten HNSCC lines in comparison to normal human bronchial epithelium, suggesting that the growth and survival of a subset of this tumor may depend on the Wnt/Fz pathway. Other studies focusing on the involvement of Wnt family expression in oral squamous cell carcinomas (OSCC) tissue samples and cell lines showed that carcinoma cells express many Wnt family members [18, 19].

Our finding of a weak expression of Wnt-1 and a high Wnt-10B expression not only in central tumor zone but also in peritumoral tissue is compatible with the idea that Wnt-1 and Wnt-10B have a redundant function [22]. If this is true, it may be speculated that, in differentiated HNSCC, Wnt-1 plays a role in the control of differentiation, proliferation, and invasiveness of cells. This cellular defense mechanism may subsequently be lost in undifferentiated steps and while the Wnt-1 expression is silenced the expression of Wnt-10B is emerging in undifferentiated carcinomas. Wnt-1 is part of a Wnt cluster conserved in all vertebrates comprising Wnt-1 and Wnt-10B. The function of Wnt-10B during oncogenesis has not been explored yet. In zebrafish, Wnt-10B is expressed in a pattern overlapping extensively with that of Wnt-1; Wnt-1 and Wnt-10B provide partially redundant functions [22].

Interestingly, in human genome, Wnt-1 maps to linkage group (LG) 23 in close proximity to another Wnt paralog, Wnt-10B [23, 24]. The linkage of Wnt-1 and Wnt-10B paralogs has been conserved in the vertebrate linkage, and this relationship may reflect the existence of three ancient Wnt paralogs present before the divergence of protostomes and deuterostomes, Wnt-1, Wnt-6, and Wnt-10 [25]. The conservation of the spatial arrangement of Wnt-1 and Wnt-10B raises the possibility that their expression may be regulated in a coordinated and sequential fashion [26, 27]. In support of this assertion, a fragment of Wnt-10B gene showed an expression pattern that may be similar to that shown by Wnt-1 [28].

Our study demonstrates an increased expression of Wnt-10B mRNA in HNSCC, whereas Wnt-1 expression was low or undetectable. This pattern does not fit to observations in oral squamous cell carcinoma lines where Wnt-1 mRNA was overexpressed [14]. This Wnt-1 strong expression in carcinoma cell lines but a complete loss in human head and neck squamous cell carcinomas could indicate a post-translational deregulation. Discrepancy between transcriptional and translational control fits to observations in other tumor types as aggressive invasive breast ductal cancers where, in the undifferentiated state, a selective loss of protein expression was found in parallel to an aggressive state of the tumor [29].

Although many Wnt genes have been evaluated in HNSCC, the role of Wnt-5A remains poorly understood. In the study of Rhee et al. [14] and in the study of Uraguchi et al. [18], Wnt-5A was expressed in 4/10 and 5/14 carcinoma HNSCC cells lines, respectively. In contrast, we found a strong expression of WNT-5A not only in peritumoral zone but also in central tumor tissue of HNSCC specimens. The importance of Wnt-5A signaling and their function in HNSCC are currently incompletely understood. It is known that in other human tumorsWnt-5A serves as an antagonist to the canonical Wnt signaling pathway with tumor suppressor activity in differentiated carcinomas. Also, Wnt-5A expression is compatible with the idea that Wnt-5A has a tumor activity; Wnt-5A plays a role in the control of tumor differentiation, proliferation, and invasiveness of cells [30–33].

While some Wnt genes, expressed in normal tissues during embryonic or post-natal period, induce cell morphological changes and cellular differentiation, the same Wnt genes can be expressed in both normal adult and tumoral tissues. These disappointing behaviors suggest that members of the Wnt family implicated in normal physiologic tissue development or repair are not expressed when the tissue has ceased proliferating and exhibit overexpression in hyperplastic or oncogenic transformation. Wnt proteins have a different function in carcinogenesis, and based on their ability to transform mouse mammary epithelial cells, they can be divided into three different classes: Wnt-1, Wnt-3A, and Wnt-7A have the greatest transforming capacity; Wnt-2, Wnt-5B, and Wnt-7B have an intermediate transforming capacity; and Wnt-4, Wnt-5A, and Wnt-6 are non-transforming [34]. Although detailed mechanisms are not well understood why Wnts are overexpressed in one tumor and downregulated in another, the pleiotropism of Wnt signaling is evident [35]. Previous results confirmed that some components of the Wnt family have aberrant expression that affects the tumor proliferation in non-small cell lung carcinomas (NSCLCs) [36–38].

The present study demonstrated that HNSCC of the oral cavity express a set of Wnt and Fz genes, and suggests as in other published works that this signaling pathway is activated in carcinoma cells. The implication of both Wnt and Fz signaling pathways in the pathogenesis of human cancer is becoming more clearly understood [39–41]. A recent work demonstrated a relationship among Wnt signaling pathway and expression values of COX-2 and Ku [42]. If more Wnt gene expression in HNSCC are studied in the future, the role of the Wnt pathway during oral squamous cell carcinoma induction and its significance in HNSCC will be well understood. Development of targeted therapies and novel drugs, perhaps based on Wnt-7A, Wnt-10B, and Fz-5, could represent an attractive field for suppression of tumor progression.

ORIGINAL ARTICLE

Topographical distribution of bronchial eosinophilia: significance for biopsy diagnosis

Russell P. Sherwin · Valda Richters

Received: 29 January 2009 / Revised: 8 April 2009 / Accepted: 8 May 2009 / Published online: 3 June 2009

Abstract Field-by-field (0.324 × 0.09 μM) counts of eosinophils were applied to the lamina propria of cartilaginous bronchi from 47 Los Angeles and 22 Miami residents 11 to 30 years of age who died suddenly from violence. A highly variable topographical distribution was found that appeared to be due mainly to variations in confluent eosinophil-positive fields and "hot spots" (≥3 eosinophils per field). Since biopsy is the gold standard for the diagnosis of bronchial eosinophilia, there is a need to resolve the problem of non-uniformity. New measurements applicable to biopsy diagnosis are presented having potential usefulness for providing insight into the severity and topographical distribution of eosinophilia within bronchi that are the sites of biopsy. The additional finding of a 30.4% incidence of moderate to marked eosinophilia (>1.5 eosinophils/mm reticular basement membrane) suggests a high level of asthma or asthmatic-like disease in the young subjects of this study.

Keywords Eosinophilia · Main stem bronchus · Topographic quantitation

Introduction

Recent reports [1–4] have challenged a long-standing belief that bronchial eosinophilia in the asthmatic is uniformly distributed when measurements are adequately controlled [5–9]. Should bronchial eosinophilia not be uniform, it could substantially undermine the reliability of biopsy in view of the exceedingly small amount of the bronchial tree that is sampled. What is needed to help answer the question of uniformity is information on the topographical distribution of eosinophils within cartilaginous bronchi, but to date, there are no reports affording that information. An opportunity to obtain quantitative data on topographical distributions of bronchial eosinophilia was provided by an independent and ongoing medical examiner autopsy study of young Los Angeles (LAC) and Dade-Miami County (DMC) residents who died suddenly from violence [10]. Feasibility was supported by an earlier subjective study [11] of a similar group of individuals where a 10% incidence of bronchial eosinophilia was found in association with an apparent highly variable topographical distribution of eosinophils. The specific aim was to establish topographical distributions through field-by-field counts of eosinophils within the lamina propria of cartilaginous bronchi and to derive quantitative measurements for biopsy use that could provide insight into the level and extent of eosinophilia within the bronchial tree. An additional goal was to determine the prevalence of eosinophilic airway inflammation (EAI) in young victims of sudden and violent death, with special attention given to the question of what is an abnormal level of eosinophilia for an individual bronchus since there are no uniformly defined or uniformly applied criteria.

Materials and methods

As described previously [10], main stem bronchi were obtained from autopsies of LAC and MDC residents who died suddenly from homicide, vehicular accident, or

other violence. Criteria for acceptance into the study were sudden death from violence, five or more years of LAC or MDC residency, ages 11 to 30, no history of drug use, no history or gross autopsy evidence of disease, and a postmortem time no more than 3 days. A left or right lung was perfusion-fixed with 10% buffered formalin at 25 cm water pressure for at least 24 h using an apparatus of identical construction at each site. A transverse section of main stem bronchus was excised at a level ~2 mm proximal to the carina. Gross and microscopic examinations were carried out by the principal investigator (RPS).

Quantitative measurements

Paraffin sections (4 μM) of main stem bronchi were stained with hematoxylin and eosin (H&E). Eosinophil counts were limited to the lamina propria, defined as the connective tissue layer between the reticular basement membrane (RBM) of the mucosal lining and the adluminal margins of smooth muscle, cartilaginous plates, submucosal fibrocollagenous tissue, and submucosal glands. Autolyzed or otherwise technically unsatisfactory segments of bronchi were excluded from counting. Areas of suboptimal preservation of one or more continuous fields within the lamina propria were included in the counting when there was good preservation of at least a part of the overlying epithelial lining, leucocytes in general, and/or submucosal glands. Each 500× high power field (HPF), measuring 0.324 μM in length and 0.09 μM in depth, of lamina propria was examined using a 10× Zeiss ocular, 1.25× Zeiss Optovar, 40× objective, and a calibrating eyepiece reticule having a 1.0-mm scale divided into 0.10-mm increments. Eosinophils were identified as monolobed or bilobed cells containing coarse eosinophilic granules. Eosinophils were counted with the assistance of a Veeder-Root hand counter, with overlap of contiguous fields controlled by tissue landmarks. Intraepithelial eosinophils were excluded from the counting. Measurements included eosinophils/HPF, HPFs/bronchus, eosinophil-positive HPFs/bronchus, and eosinophils/mm RBM. Additional measurements were derived from an observation identified as a confluent eosinophil-positive field (CEF) and defined as aggregates or clusters of two or more abutting eosinophil-positive HPFs. Two quantitative derivatives relating to CEFs were obtained, CEF density (eosinophils/CEF) and CEF length (HPFs/CEF). The integrity of the epithelial lining was graded on a scale of 0–10, with 10 being fully intact. A micrometer was used to obtain from one to several measurements of RBM thickness, excluding poorly preserved tissue and tangentially sectioned areas. Data were analyzed by *t* tests, with significance based on critical two-tail values ($p<0.05$).

Demographic study

For all MDC cases, autopsy permission was obtained and interviews with next-of-kin successfully carried out prior to lung accessioning. The LAC autopsies were authorized under a legislative mandate. Contact of next-of-kin for interview followed lung accessioning over varying periods of time, with about half of the interviews successful. Medical examiner investigational reports (LAC) provided additional data. Accessioned lungs that were not suitable for processing or histopathological examination were excluded from the study. The respective transplantation services carried out all next-of-kin interviews in accord with a protocol modified from the independent investigation noted earlier [10]. Demographic data were not made available to the principal investigator until the pathological studies had been completed.

Results

Main stem bronchi from 69 subjects were suitable for study, 47 LAC (26 with and 21without next-of-kin interviews) and 22 MDC. Approximately half of the bronchi had been obtained from subjects of the prior independent study [10]. Mean ages were 21.0 [11–29] and 21.5 [13–30], LAC and MDC, respectively (NS). Levels of EAI were defined as follows: marked (≥5 eosinophils/mm), moderate EAI (>1.5–<5 eosinophils/mm), slight (0.15–<1.5 eosinophils/mm), and totally absent, with frequencies of 15.9%, 14.5%, 44.9%, and 8.7%, respectively. The frequency of marked eosinophilia was not significantly different between the LAC and DMC groups, 14.9% vs. 18.2%, respectively. The highest mean EAI level for a single bronchus was 17.8 eosinophils/mm per RBM. Comparisons between LAC and MDC groups showed a consistent but not significant trend towards higher mean EAI levels (eosinophils/mm) for the DMC group (Table 1). There was a trend toward longer CEHs for the DMC group in that mean HPFs/CEF (CEF lengths in mm/RBM) were higher for the MDC group (4.0 ± 5.2 and 5.7 ± 6.9, respectively), but with significance only for individual bronchi ($p=0.02$) and not by group analysis. No differences in measurements were found between the interviewed and non-interviewed LAC groups.

Four main topographical distributions of eosinophilia were observed in the transverse bronchial sections: widespread, multifocal, skewed or polarized, and scattered isolates or clusters. A *widespread* distribution (Fig. 1a), defined as ≥75% eosinophil-positive HPFs, was observed in 8.7% (6/69), and all had mean EAI levels greater than 5 eosinophils/mm in association with numerous CEFs. The predominant presentation of EAI (62.3% of bronchi) was multifocal eosinophilia with 9.9% to 68.1% of the lamina

[b] One reading

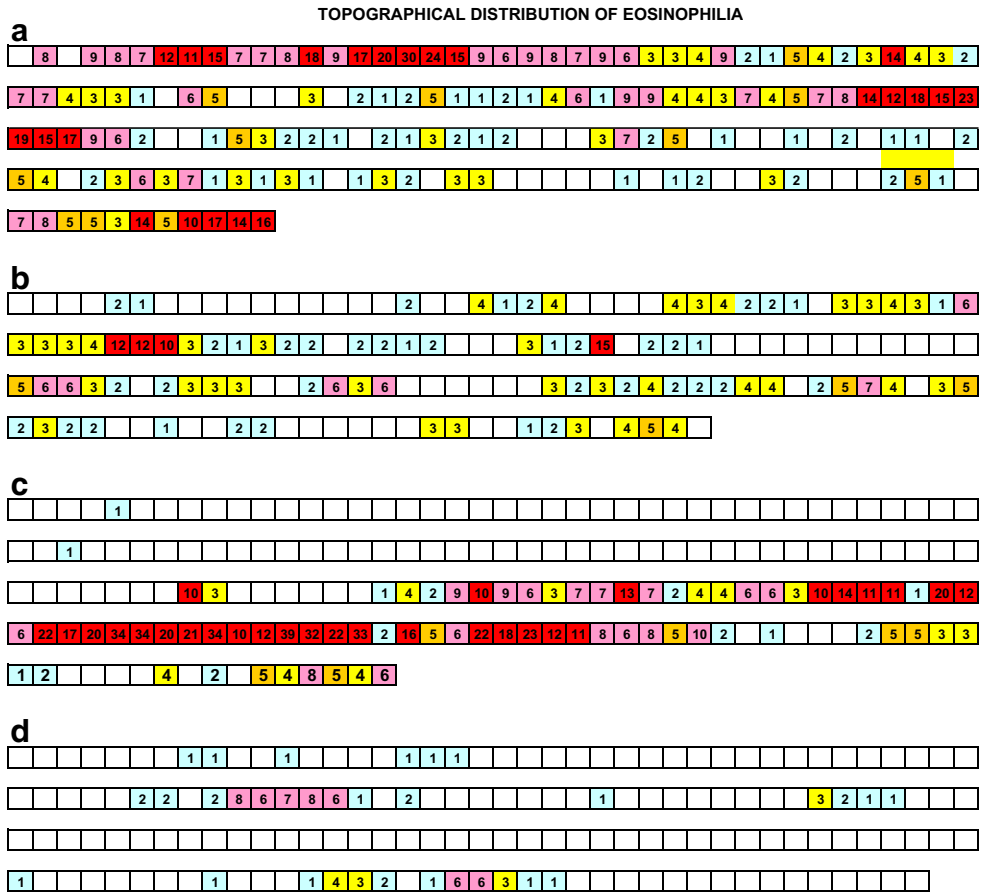

Fig. 1 **a** Widespread EAI (26 B/M). Of 171 HPFs, 80.1% contain one or more eosinophils. "Hot spots" ≥10 eosinophils/HPF appear as apparent epicenters within abutting eosinophil-positive HPFs (CEHs). **b** Marked multifocal EAI (11 H/M with "slight asthma"). Of 149 HPFs, 58.4% are eosinophil-positive. The presence of 17 CEHs contrasts with only two isolated eosinophil-positive HPFs. A hypothetical biopsy sampling a CEH of three HPFs (each with 12, 12, and 10 eosinophils) would yield a mean of 35 eosinophils/mm vs. 6.0 eosinophils/mm for the bronchus. **c** Polarized or skewed EAI (24 H/M). Half of the lamina comprised mostly eosinophil-positive HPFs, with a 17.8-mm-long CEH (55 HPFs) occupying 31% of the bronchial circumference. The other half is largely eosinophil-negative. The entire lamina exhibits a moderate to marked round cell infiltrate that is mainly lymphocytic, with eosinophils most prominent in densely packed nodular aggregates of lymphocytes. Chains of eosinophil-positive HPFs (CEHs) separated by a few eosinophil-negative HPFs may be part of a longer chain separated by artifact or postmortem loss of eosinophils. **d** Moderate multifocal EAI (19 B/M). Only 21% of 158 HPFs are eosinophil-positive, but a single hypothetical biopsy 0.972 mm in diameter could yield a level as high as 22 eosinophils/mm and three biopsies might result in a mean EAI as high as 15.1 eosinophils/mm vs. the bronchial mean of 1.7 eosinophils/mm

propria occupied by eosinophil-positive HPFs and ranging from slight (Fig. 2b) to marked (Fig. 2d). *Skewed* or *polarized* localizations were observed in 5.8% (4/69), with from 9.9% (Fig. 2a) to 46.6% (Fig. 1c) eosinophil-positive HPFs and with mean EAI levels ranging from 1.7 to 13.5 eosinophils/mm, respectively. Eosinophils most frequently presented as scattered isolates or clusters of eosinophil-positive HPFs. In the latter respect, bronchial involvement ranged from 0.09% to 4.3%, with mean EAI levels <0.15 eosinophils/mm and with CEFs usually absent or, when present, being very short (aggregates of two or three eosinophil-positive HPFs). Long CEFs tended to have frequent "hot spots" (≥3 eosinophils/HPF) and were usually associated with high mean bronchial EAI levels, e.g., a CEF 17.8 mm in length (Fig. 1c) in a bronchus having a mean EAI of 13.5 eosinophils/mm. A caveat is that just a few "hot spots" in an otherwise eosinophil-negative bronchus can result in an abnormal EIA level, e.g., two CEFs occupying only 9.9% of the lamina (Fig. 2a) but with a bronchial mean EAI of 1.7 eosinophils/mm. "Hot spots" ≥10 eosinophils/HPF were almost invariably associated with marked (≥5 eosinophils/mm) bronchial mean EAI levels (Figs. 1a–c and 2d), with one exception of a bronchus with moderate EAI (3.8 eosinophils/mm) despite a content of four HPFs, each containing ≥10 eosinophils (Fig. 2c).

An abnormal level of EAI (>1.5 eosinophils/mm) was found in 30.4% (21/69), with no significant differences between groups, i.e., 33%, 27%, and 32% for LAC non-interviewed, LAC interviewed, and MDC groups, respectively (Table 1). Of four subjects with a history of asthma, EAI was identified in

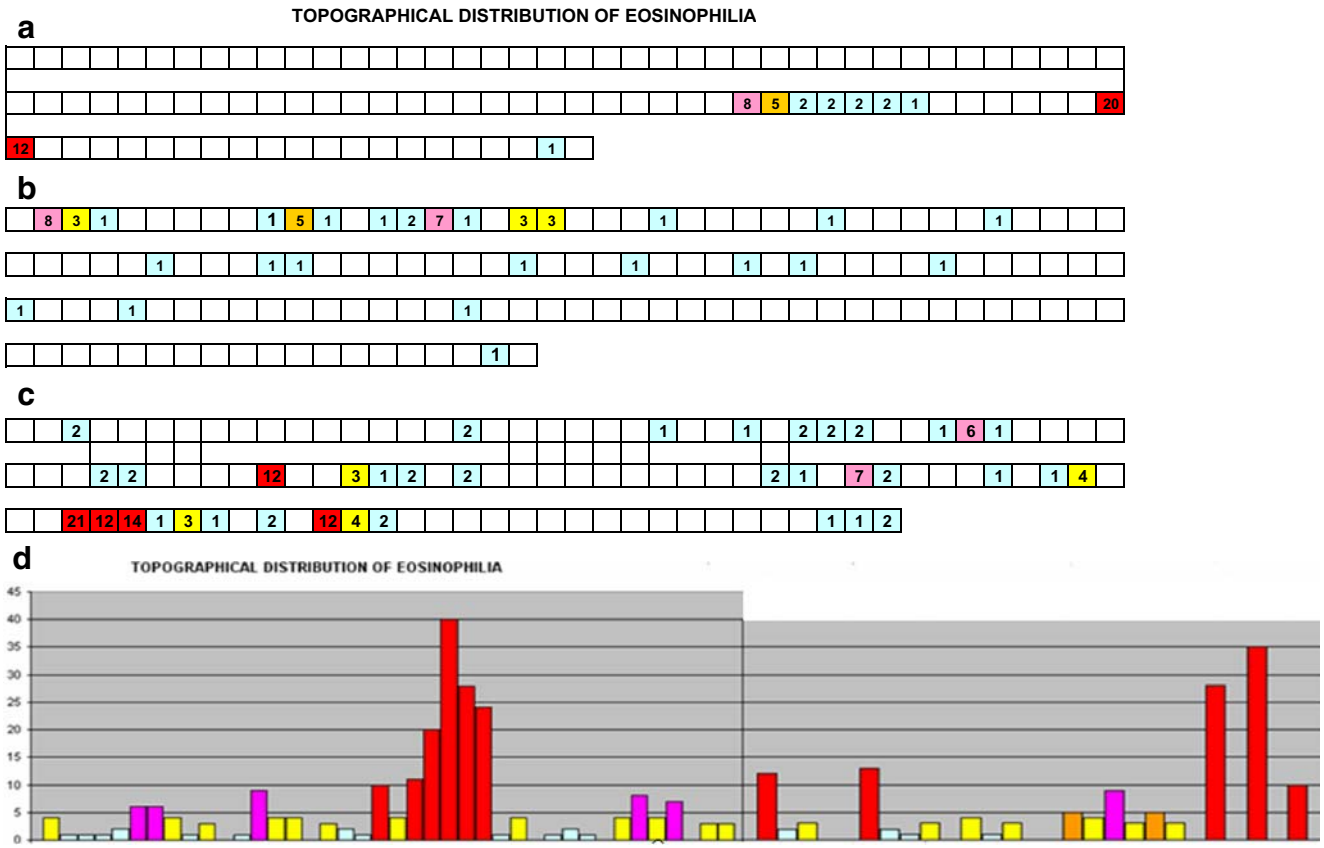

Fig. 2 **a** Polarized or skewed distribution of eosinophil-positive HPFs (20 H/M). A hypothetical 0.972-mm biopsy that sampled the 0.972 mm CEH comprising 20, 12, and 0 eosinophils would yield an EAI as high as 32.9 eosinophils/mm vs. as high as 15 eosinophils/mm for the second CEH (eight, five, and two eosinophils) vs. the bronchial mean of 1.7 eosinophils/mm. Of course, biopsy sampling that is entirely negative is more likely. **b** Multifocal slight and polarized EAI (19 C/M). At one pole of the lamina, there are four closely associated CEHs containing "hot spots" ranging from three to eight eosinophils/HPF. HPFs containing a single eosinophil are scattered elsewhere. A hypothetical 0.972-mm biopsy might result in an EAI level as high as 12.4 eosinophils/mm vs. the bronchial mean of 1.1 eosinophils/mm vs. a most likely very low or totally negative result. **c** Multifocal moderate EAI (18 H/M). Hypothetically, a 0.972-mm biopsy might yield a level as high as 47 eosinophils/mm for a single CEH vs. the bronchial mean of 3.8 eosinophils/mm. One CEH containing exceptionally dense "hot spots," beginning with 21, 12, and 14 eosinophils/HPF, would probably have encompassed at least 12 eosinophil-positive HPFs, but fell short by two interspersed eosinophil-negative HPPs that are probably falsely negative due to degranulation or poor postmortem preservation. **d** Profile of topographical distribution of eosinophilia (17 H/M who worked with metals and wood dust). The "hot spots" appear as multiple epicenters in a widespread eosinophilia that involves 83.1% of the bronchial circumference. A hypothetical single 0.972-mm biopsy might vary from a high of 94.7 eosinophils/mm to a low of 3.0 eosinophils/mm vs. the bronchial mean of 17.8 eosinophils/mm

two (Table 2), one with marked and one with moderate EAI, 6 eosinophils/mm (Fig. 1b) and 2.1 eosinophils/mm, respectively. A pathologic diagnosis of asthma was not sustainable in any of the 69 subjects. With respect to seven subjects where mention was made of environmental exposure, marked eosinophilia was observed in three (42.9%; Table 2).

Discussion

Historical background

Earlier reports considered the distribution of eosinophilia to be uniform throughout the bronchial tree, as for example statements that a tissue sample 1.0 × 0.1 mm along the basement membrane is sufficient to obtain constant cell numbers [8]; cell counts can be restricted to "one airway level only" [5], and small samples of either large or small airways are "likely to be representative when comparing cases," the latter with the reservation that an "up to fivefold variation" was occasionally seen between proximal and distal airways in fatal cases of asthma [7]. However, recent studies have found substantial intrasubject variation with respect to upper vs. lower lobes [1], proximal vs. distal airway generations [2, 4], between as well as within biopsy sections [3, 12], and between sections of a single biopsy [13]. Moreover, a "mapping" of eosinophilia from nasal mucosa to lung parenchyma found "great variability of

Table 2 Demographic data

eosinophil content within different regions in the same patient" [14]. The uncertainty raised is a serious challenge to the reliability of biopsy measurements of bronchial eosinophilia, bearing in mind that biopsy "still remains the gold standard" for assessing airway inflammation in asthma [15] and "will continue to have a major role in asthma research" [1]. Further, recent validation of bronchial biopsy as a safe procedure [16] is likely to increase utilization, and this adds to a well-recognized need to "optimize quantification of the cellular infiltrate" [3]. In the latter respect, Richmond et al. [1] recommended "power calculations" applied to data from groups of ~15 subjects to control wide intrasubject variability between anatomic site, which compares to other reports recommending groups of five to 15 [7] and eight to 25 [3] subjects. With respect to bronchial biopsy of an individual, little information is available on measures to control quantitation other than the recommendation by Sont et al. [3] for "counting the largest possible area within a biopsy and/or averaging data obtained from multiple sections and/or biopsies." The special need is for insight on biopsy examination into the severity and extent of eosinophilia within the bronchial tree. A first step towards gaining that insight is the acquisition of data on topographical distributions of eosinophilia within large bronchi.

Baselines of eosinophilia

There is no prior report on the topographical distribution of bronchial eosinophilia. Two studies providing measurements of eosinophilia within transverse sections of bronchi have been found which shared basic materials and methods in common, i.e., medical examiner cases of sudden death, cell counts based on H&E-stained transverse tissue sections of cartilaginous bronchi, and measurements according to numbers of eosinophils/mm per RBM [17, 18]. The two reports primarily presented data on EAI levels for groups of subjects, with measurements for individual bronchi limited for the most part to graphic displays, e.g., maxima of 3.8 eosinophils/mm [17] and ~10 eosinophils/mm [18]. In the absence of baselines on eosinophilia for individual bronchi, we defined a normal EAI level as ≤1.5 eosinophils/mm by arbitrarily selecting the higher of the two reported group control means, namely, 1.5 eosinophils/mm [17] vs. 1.0 eosinophils/mm [18], and also with guidance from a ranking of our data (Table 1). We assumed that EAI levels >1.5 eosinophils/mm reported in both control groups [17, 18] represented cases of either clinically covert asthma or non-asthmatic eosinophilic bronchitis. An EAI level >0.15 and ≤1.5 eosinophils/mm was defined as a *slight* but clinically normal eosinophilia, and isolated eosinophil-positive HPFs were considered to be incidental infiltrates. With the foregoing reported results in mind and with reference to a ranking of our data, we defined an abnormal level of EAI for an individual bronchus as greater than 1.5 eosinophils/mm. We noted that the reported group means for non-fatal asthmatics [17] and subjects with cystic fibrosis cases [18] were very low and virtually identical (1.8 eosinophils/mm) vs. the 11.0 [17] and 62.7 [18] eosinophils/mm reported for fatal asthmatics. We defined marked EAI as ≥5 eosinophils/mm based largely on observations by Carroll et al. [17] showing that 100% of fatal cases of asthma had group means of ≥5 eosinophils/mm vs. 20% for non-fatal cases of asthma.

Interpretation of biopsy data

With respect to insight on biopsy into the probable level of eosinophilia within the bronchial tree, we believe that measurements of numbers and magnitude of "hotspots" (≥3 eosinophils/HPF) offer the most potential for reliability.

Even a single HPF containing three eosinophils within biopsy tissue will in itself more likely than not reflect an abnormal level of eosinophilia for a hypothetical transverse bronchial section, i.e., 51.2% (20/41) of main stem bronchi having three eosinophils in at least one HPF had a mean EAI level >1.5 eosinophils/mm. As might be expected, a "hot spot" of ≥5 eosinophils/HPF tended to be associated with more frequent and higher levels of eosinophilia. Of 26 bronchi with one or more HPFs containing ≥5 eosinophils/HPF, a marked mean EAI level (≥5.0 eosinophils/mm) was found in 44% and some level of abnormality (>1.5 eosinophils/mm) in 84%. The finding that mean EAI was normal for the remaining 16% despite the presence of ≥5 eosinophils in one or more HPFs raises the question of underdiagnosis from inadequate sampling or poor tissue preservation. Figure 2a is an example of a bronchus with 91% of the lamina propria comprising eosinophil-negative HPFs and a slightly elevated mean EAI (1.7 eosinophils/mm), but "hot spots" present raise the question of underdiagnosis. Specifically, biopsy sampling of two ~1 mm in length sites (three HPFs each 0.324 mm long) would yield mean EAI levels of 33 and 15.4 eosinophils/mm if the two "hot spots" present are selected, i.e., 20,12, and 0 eosinophils per 0.972 mm and 8, 5, and 2 eosinophils per 0.972 mm, respectively. Moreover, a highly elevated mean bronchial EAI may understate localized EAI, e.g., the mean EAI of 17.2 eosinophils/mm of the bronchus shown in Fig. 2d is the highest we recorded, but sampling limited to "hot spots" could hypothetically result in a single EAI level as high as 94.7 eosinophils/mm or a mean EAI of 65.5 eosinophils/mm. Conversely, mean EAI of that same bronchus (Fig. 2d) could be greatly understated since one fifth (19.4%) of the HPFs is entirely eosinophil-negative and nearly half of the eosinophil-positive HPFs (43.6%) contains less than three eosinophils.

Localized aggregation of eosinophils in the assessment of eosinophilic airway inflammation

Clustering has been reported to have special meaning in eosinophilic airway inflammation. Sont et al. [3] stated that "clustering might provide specific information about the inflammatory process," and Sullivan et al. [13] suggested that clustering of eosinophils within airway tissue is a "likely explanation" for the variability of eosinophilia. Of related pertinence, a report on tumor-infiltrating eosinophils [19] pointed out that eosinophils "invariably" presented as clusters, making counts of the highest density of eosinophils within tumor tissue more in accord with functional status than classical counts of eosinophils. Our introduction of the term CEF expands the concept of clustering to allow for new quantitative measurements on frequency, density, and extent of clustering, specifically: numbers of CEFs/biopsy tissue (frequency), eosinophils/CEF (density), and eosinophil-positive HPFs/CEF (extent). Measurements of numbers and severity of "hot spots" (≥3 eosinophils/HPF) within CEFs have been given special attention since they commonly present as apparent epicenters of CEFs (Figs. 1c, b and 2d), which suggests that they play a central role in the development and progression of eosinophilia. With the latter in mind, we attempted to relate "hot spots" to focal epithelial sloughing, but the results were inconclusive due mainly to unsatisfactory postmortem tissue preservation. While sloughing has been dismissed as artifact [9, 20], a strong rebuttal argument has been made [21] and a number of studies report a relationship of eosinophilia to increased epithelial cell loss [22–24]. Additional encouragement for exploring a relationship of "hot spots" to injury are reports of localized eosinophil infiltrates adversely affecting tissues other than the epithelial lining, notably neural injury [25–27] and the "clustering of eosinophils around airway nerves" [28]. Long CEFs (Fig. 1c) seem especially likely to be a reflection of injury, in particular patchy infiltrates which are by definition ≥10 mm in diameter. The latter were seemingly anticipated by Sont et al. [3] who called attention to "a patchy focal phenomenon sometimes in clusters of indefinable numbers." Patchy CEFs will ordinarily not be demonstrable in biopsy tissue, but four or more tissue samples at 2 mm [29] or 2.6 mm [30] in diameter may afford observations of ~24 HPFs, i.e., 8 mm of total tissue with three HPFs/0.972 mm. Thus, patchy or widespread eosinophilia may be suspected when long CEFs predominate in multiple tissue specimens. Assessment of eosinophilia in general may benefit from a scoring methodology that gives weight to frequency, density, and extent of CEFs and "hot spots."

Eosinophilia in asthma and asthma-like diseases

Our recording of a 30.4% frequency of moderate to marked EAI (>1.5 eosinophils/mm) appears to be reasonably acceptable as a reflection of asthma and asthma-like diseases, the latter including possible environmental exposures. Pertinently, four LAC subjects had historical information suggestive of environmental exposures at work or in the classroom, and two of the four had eosinophilia, a frequency 7.7% for the group (2/26; Table 2). Of related pertinence, a Minnesota report found 37.3% of children having one or more recorded diagnoses of asthma and asthma-like diseases, the latter without a diagnosis of asthma and represented by reactive airway disease, exercise-induced bronchospasm, or recurrent wheezing or bronchospasm [31]. Further, a cross-sectional survey of 5- to 18-year-old New Orleans schoolchildren found lifetime prevalences of wheezing and asthma to be 39.4% and 24.4%, respectively [32]. The demographic data of the

present study are too limited for conclusions, but it is of interest that 15.4% (4/26) of the LAC youths with next-of-kin interviews had a history of asthma and two of the four had abnormal EAI levels (>1.5 eosinophils/mm). In comparison, California data show a 23% frequency of asthma and asthma-like breathing problems, with asthma alone having an incidence of 13% [33]. It should be noted that none of the 69 subjects had pathological findings in support of a diagnosis of asthma. Mention should also be made that neither the presence of eosinophilia or thickening of the RBM necessarily supports a diagnosis of asthma. While eosinophilia is well recognized as a characteristic of both childhood and adult asthma [24], the finding has been said to be "untenable" as a "hallmark feature of asthma," and that is also the case with RBM thickening [34]. Moreover, there are studies showing that EAI may not be accompanied by airway hyperresponsiveness and RBM thickening can be found in non-eosinophilic asthma [35–37].

Covert chronic lung inflammation and eosinophilia

A final consideration is the significance of bronchial eosinophilia in the absence of known clinical manifestations. Our earlier subjective measurements of chronic inflammation of airways [11, 38] and airspaces [10] of comparable groups found eosinophilia in 10% and chronic lung inflammation in approximately one of four. In some of those subjects, lung remodeling was observed that included peribronchiolar fibrosis, alveolar airspace derangement, and/or parenchymal scarring [10]. Moreover, we noted that four LAC subjects included in the present study had earlier been shown to have chronic lung inflammation, eosinophilia, and remodeling [10], the latter including one individual with peribronchiolar fibrosis and, as shown in the present study, an EAI level of 2.0 eosinophils/mm. Two other subjects had airspace derangement but normal EAI levels (≤1.5 eosinophils/mm). The foregoing findings suggest that bronchial eosinophilia in some young residents of metropolitan cities with or without clinically manifested asthmatic disease is likely to be associated with chronic lung inflammation and remodeling, which tends to support the suggestion by Pohunek et al. [39] that early remodeling in children may occur with developing asthma "before a reliable diagnosis of asthma could be made based on clinical features." Of potentially equal if not greater significance is that those living cohorts of the present study who share in common marked EAI and chronic lung inflammation may be experiencing an inordinate rate of depletion of functional and structural lung reserves sufficient to place them at risk as an especially susceptible subpopulation. Of special interest in the latter respect is a report on sudden unexpected deaths in soldiers which attributed death of 10 of the 151 soldiers (6.7%) to asthma. Further, three of the ten soldiers who died from asthma had no prior history of asthma, with the reservation that historical information may have been withheld due to an eagerness to serve [40].

Acknowledgments This study was supported by a Cooperative Agreement (CR 8215756) between the National Health and Environmental Effects Research Laboratory (NHEERL), US Environmental Protection Agency, and the University of Southern California. The authors wish to acknowledge the assistance of R. B. Everson, PhD, formerly of the Human Studies Division (MD-58C) of the National Health and Environmental Effects Research Laboratory, US Environmental Protection Agency, Research Triangle Park, Raleigh, NC 27711. The autopsy cases were provided by the Los Angeles County Department of Coroner and the Dade County Medical Examiner's Office. We are indebted to Dr. Lakshmanan Sathyavagiswaran, Chief Medical Examiner of the Los Angeles County Department of Coroner, and to Drs. Joseph H. Davis and Roger E. Mittleman of the Dade County Medical Examiner's Office. Assistance has also been provided by Scott Hanks, Ann C. Hughes, Jeffrey A. Thomas, and Margaret Acosta. We thank Dr. Arnis Richters for technical assistance. The project was approved by the Institutional Review Board of the Los Angeles County-University of Southern California Medical Center and the Research Committee of the Department of Coroner of Los Angeles County.

Disclaimer Although the research described in this article has been supported by the United States Environmental Protection Agency through Cooperative Agreement CR 821576-01-0 with the University of Southern California, it has not been subjected to Agency review and therefore does not necessarily reflect the views of the Agency, and no official endorsement should be inferred. ORIGINAL ARTICLE

Immune cell subsets in necrotizing fasciitis: an immunohistochemical analysis

A. J. Saenz · A. F. Koreishi · A. E. Rosenberg · R. L. Kradin

Received: 16 December 2008 / Revised: 9 April 2009 / Accepted: 17 April 2009 / Published online: 16 June 2009

Abstract Current concepts of the pathophysiology of necrotizing fasciitis (NF), a life-threatening infection of soft tissues associated with a toxic shock syndrome, emphasizes the role of bacterial superantigens as mediators of cytokine release by immune lymphocytes. In order to assess the cellular basis of immune activation, immunohistochemistry was applied to the analysis of inflammatory cell subsets in situ in 13 patients with NF. The percentage of inflammatory cells in skin and soft tissue was scored from 0 to 3+ (>50%). Substantial numbers of CD15+ polymorphonuclear leukocytes were present in 12 of 13 patients. CD3+ T-lymphocytes accounted for >10%, CD68+ macrophages for >50%, and Factor XIIIa+ mononuclear cells for >10% of the mononuclear cell infiltrates, respectively, in 10 of 13 patients, whereas CD1a+ cells were present in only 3 of 13 cases and accounted for <10% of mononuclear inflammatory cells. We conclude that immune lymphocytes and accessory immune cells are represented in substantial numbers in the early lesions of NF, and their presence supports current concepts with respect to the pathophysiology of this disorder.

Introduction

Necrotizing fasciitis (NF) is an uncommon life-threatening infection of subcutaneous tissues. The disease is attributable to bacterial infection that spreads along fascial planes, producing extensive liquefactive necrosis that largely spares the superficial skin and skeletal muscle associated with a syndrome of toxic shock. The treatment of NF generally requires a combination of antibiotics, surgical debridement, and hemodynamic support. Clinically, NF has been subclassified into three types [1]. Type I occurs most commonly following surgery in diabetic patients and in those with peripheral vascular disease and is caused by a mixed aerobic and anaerobic infection [1]; type II is caused predominantly by group A beta hemolytic streptococci, but community-acquired methicillin resistant *Staphylococcus aureus* (MRSA) infection has also been reported [2]; type II infection occurs in all age groups; predisposing factors include drug injection, local trauma, and burns. Type III is caused by *Vibrio vulnificus* introduced into tissues via puncture wounds or the ingestion of shellfish in patients with hepatic compromise [1, 3].

The diagnosis of NF by the surgical pathologist often requires intraoperative examination of frozen sections. Stamenkovic and Lew [4] have suggested that the key criterion for the diagnosis of NF is the presence of neutrophils in fascial tissues, associated with liquefactive necrosis of fascia, fat necrosis, thrombosis of blood vessels, vasculitis, and abundant microorganisms [4, 5].

Although tissue neutrophils have been regarded as the sine qua non of the inflammatory response in NF

[4], current concepts of pathogenesis favor a primary role for bacterial toxin mediated cytokine release by T-lymphocytes rather than the pyogenic response that often accompanies bacterial infection. But diagnostic pathologists have paid little attention to the presence of T-lymphocytes and accessory cells, including dendritic cells, monocytes, and Langerhans cells, in NF. In the present study, we investigated the representation of immune cell subsets in NF by in situ immunohistochemical staining.

Materials and methods

Cases

The computerized electronic medical records of the Department of Pathology at the Massachusetts General Hospital from 2004 to 2007 were searched for the diagnosis "necrotizing fasciitis". Thirteen patients were identified with both clinical and histological evidence of necrotizing fasciitis. Rapid frozen sections were examined in five cases (38%). In these cases, the diagnosis was suggested by rapid frozen section examination and subsequently confirmed on examination of the permanent sections. A diagnosis compatible with necrotizing fasciitis on the rapid frozen section resulted in a larger surgical procedure in all cases, including either debridement and/or amputation.

Histopathology

The specimens were derived from the definitive surgical procedures. Full thickness specimens of skin that included the deep fascia and microscopic fragments of skeletal muscle were examined in all cases. Sections were fixed in 10% buffered formalin, routinely processed, sectioned at 5 μM, and stained with hematoxylin and eosin.

Immunohistochemistry

Serial 5-μm tissue sections were mounted on Superfrost slides. Immunohistochemical staining was performed with monoclonal antibodies (all Ventana Medical Systems) directed at CD3 (predilute), CD15 (predilute), CD1a (predilute), CD68 (predilute), and Factor XIIIa (1:1,400). All staining was performed on an automated Ventana Benchmark Autostainer (Ventana Medical Systems, Tucson, AZ, USA) with the Ultra View Detection Kit incubated for 32 min. Sections were deparaffinized, and antigen retrieval was performed by heating sections in CC1 (Ventana Medical Systems) EDTA at a pH of 8 for 30 min.

Data analysis

The hematoxylin-and-eosin-stained slides and immunohistochemical results were reviewed and scored by consensus of two pathologists (AS, RLK). Inflammatory cells were enumerated in five randomly selected high-power fields, including the dermis and fascia. Immunostaining was scored as a percentage of the total mononuclear cell infiltrate in each field and an average score ranging from negative, 1+ (<10%), 2+ (10–50%), to 3+ (>50%) was calculated.

Results

The pertinent clinical information is summarized in Table 1. There were six men and seven women, with ages ranging from 48 to 90 (mean=63) years. All patients were treated with antibiotics, surgical debridement, and/or amputation. The underlying disorders in these patients are listed in Table 1. Diabetes mellitus was the most common associated medical disorder (6 of 13). A history of either major or minor trauma was elicited in 2 of 13. Chronic obstructive pulmonary disease (3 of 13), cancer (2 of 13), cirrhosis (1 of 13), ethanolism (1 of 13), and peripheral vascular disease were other concomitant disorders. All of the patients survived their acute infection to leave the hospital; however, three died subsequently from complications of their underlying disease.

Gram-positive bacteria were identified in situ by tissue gram or GMS stains (gram-positive cocci) in 11 of 13. Gram-negative bacteria were not identified by tissue gram stain and were isolated in the microbiology laboratory. Bacteria were isolated from tissues in all cases. Three patients showed laboratory evidence of polymicrobial infection. These included group A beta hemolytic *Streptococcus* (3 of 13), *Enterococcus* (2 of 13), alpha hemolytic *Streptococcus* (1 of 13), non-hemolytic *Streptococcus* (1 of 13), *Staphylococcus* spp. (4 of 13), *Escherichia coli* (2 of 13), and *Proteus mirabilis* (1 of 13).

The key histopathologic findings of NF in the present series are listed in Table 2. All cases were diagnosed within 48 h of developing clinical symptoms and were judged to be in the acute phase of the disease. Dermal and fascial inflammation with neutrophils and mononuclear inflammatory cells was present in all cases (13 of 13; Fig. 1), necrosis of dermis and fascia (13 of 13; Fig. 2), vascular thrombi (7 of 13; Fig. 3), and microorganisms within necrotic dermis and fascia (11 of 13; Fig. 4).

The immunohistochemical findings are summarized in Table 3. CD15+ polymorphonuclear leukocytes were present in all cases and accounted for >10% of all inflammatory cells in 12 of 13 patients. CD3+ T-

Table 1 Pertinent clinical information

Patient	Age	Sex	Clinical status	Anatomic site (frozen section)	Microbiology	Clinical outcome
1	69	F	Peripheral vascular disease, hypertension	Left forearm (NF)	Beta hemolytic *Streptococcus* group A (very rare)	Surgical debridement; healed skin graft; alive at 2 years

Lobular panniculitis
Relative sparing of deep striated muscle
Neutrophils
Macrophages and lymphocytes
Vascular thrombi

lymphocytes were also present in all cases, as were CD68+ macrophages and Factor XIIIa+ mononuclear cells. CD1a+ dendritic cells were identified in 3 of 13 cases. Representative immunohistochemical staining results are shown in Fig. 4.

Discussion

Previous studies have addressed the histopathology of NF [4, 5]. Stamenkovic and Lew identified necrosis, neutrophilic infiltration, microorganisms, vasculitis, and thrombosis in the superficial fascia, deep dermis, and proximal adipose tissue in NF [4]. In this disorder, low-power screening invariably reveals a sparsely inflamed and edematous superficial dermis, whereas the deep dermis has a "dirty" appearance due to liquefactive necrosis of fascia and fat of the subcutis.

In the present study, mononuclear cell inflammation was demonstrated to be a common feature of NF, and CD68+ macrophages and Factor XIIIa+ mononuclear cells accounted for the majority of macrophages leukocytes.

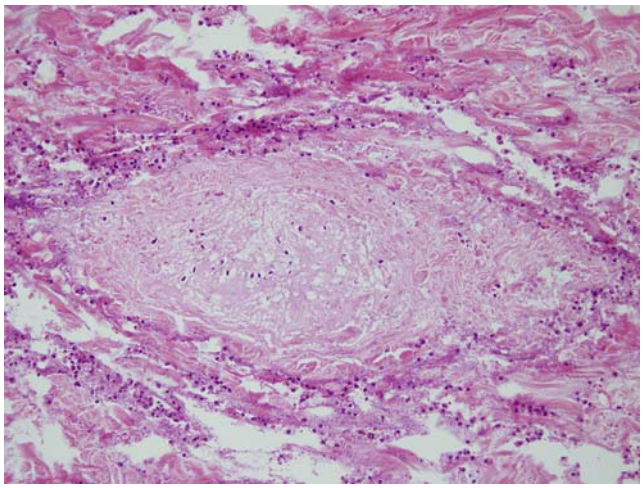

Fig. 2 Skin biopsy demonstrates subtle liquefactive necrosis of the fascia with microorganisms and acute inflammation. H&E, magnification ×200

Factor XIIIa+ dendritic macrophages and Langerhans' cells are effective class II MHC-restricted antigen presenting cells, and together with activated subsets of CD68+ macrophages, they provide accessory activities for the local proliferation of immune T-lymphocytes and for cytokine release. The presence of substantial numbers of CD3+ lymphocytes and putative accessory cells in the early lesions of NF support current concepts with respect to its pathogenesis.

Necrotizing fasciitis is a potentially fatal deep infection of skin with risk factors that include immunosuppressed states, minor cuts, burns, surgical procedures, chronic skin disease, insect bites, and blunt trauma [6]. The early clinical findings include edema of the involved area followed by bulla formation and erythema. The latter typically extends rapidly and progress to gangrene, with

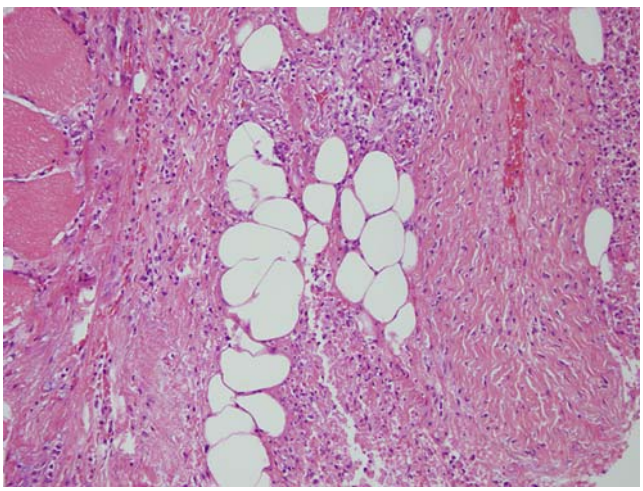

Fig. 1 Subcutaneous adipose tissue and fascia showing acute inflammation and mononuclear cell infiltrate with sparing of contiguous skeletal muscle. H&E, magnification ×200

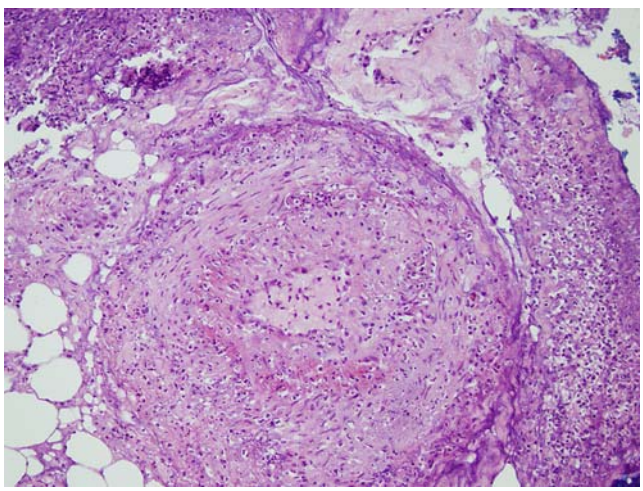

Fig. 3 Skin biopsy demonstrates vasculitis with surrounding necrosis, acute inflammation, and mononuclear cell infiltrate. H&E, magnification ×200

systemic symptoms, shock, and multiorgan failure [7, 8]. The clinical findings mimic those of the toxic shock syndrome caused by staphylococcal and streptococcal infections [7–9].

Associations exist between group A streptococcal (GAS) strains, especially those of M-protein types of 1, 3, 12, and 28, and the toxic shock syndrome [7, 10]. Like the streptococcal disease scarlet fever, pyrogenic exotoxins

Table 3 Immunohistochemical staining results in necrotizing fasciitis

Patient no.	CD3+	CD68+	CD1a+	CD15+	Factor XIIIa+
1	1+	3+	Negative	3+	1+
2	1+	2+	1+	3+	3+
3	1+	2+	Negative	3+	1+
4	1+	3+	Negative	3+	3+
5	1+	2+	Negative	2+	1+
6	2+	3+	Negative	3+	3+
7	1+	3+	Negative	3+	2+
8	2+	3+	1+	3+	3+
9	2+	3+	Negative	3+	3+
10	1+	3+	1+	3+	2+
11	2+	3+	1+	3+	3+
12	3+	3+	Negative	3+	2+
13	1+	3+	Negative	3+	2+

produced by GAS appear to be responsible for the systemic effects that accompany localized infections [7, 10–12]. Streptococcal exotoxins A and B can mediate both local tissue damage and systemic toxicities [13]. Furthermore, GAS M-proteins can serve as superantigens that bind to major histocompatibility complex class II antigens on professional antigen presenting cells, linking them to specific variable beta regions of the T-cell receptor [6, 14] and leading to the release of potent cytokines, including tumor necrosis factor alpha and beta, interleukin-1 beta, interleukin-6, interleukin-2, and interferon gamma [15, 16]. Other streptococcal toxins that can function as superantigens include streptolysin O, streptococcal superantigen, and mitogenic factor [17, 18]. *Streptococcus* spp. are often a component of polymicrobial infections [4, 19].

Mononuclear cell inflammation is a constant and likely significant feature of the histopathology of NF. With respect to the three clinical subtypes of NF, only patients with type I (diabetes with polymicrobial disease) and II (group A streptococci) were examined in this study. There was no discernible difference in the histopathology or representation of mononuclear subsets between these groups. Immune lymphocytes and mononuclear accessory cells appear to play a critical role in mediating the local and systemic effects of this disease. Whereas the presence of fascial and dermal neutrophils is consistent with the histopathological diagnosis of NF, it is not specific and can be seen, e.g., in cellulitis. For this reason, the surgical pathologist should query the surgeon as to the presence of the characteristic "dish water" exudate, particularly at the time of frozen section, and the concomitant presence of mononuclear cell inflammation should be sought, as it may lend further support to the correct diagnosis.

LETTER TO THE EDITOR

Cytokeratin RNA amplification as a molecular method for the detection of lymph node metastases in breast cancer patients

Hans Kreipe

Received: 25 February 2009 / Accepted: 4 March 2009 / Published online: 24 March 2009

Keywords Sentinel lymph node · Breast cancer · Cytokeratin · RNA expression

Dear Sir:
In their recently published study, Schem and coworkers state that analysis of sentinel lymph node specimens in breast cancer patients by polymerase chain reaction (PCR) for expression of cytokeratin genes yields a reliable and standardized instrument with benefit for patients equalling histological analysis [1].

The data presented, however, could be read in a different way resulting in an opposing interpretation. A major shortcoming of the study is that no sensitivity tests have been performed: how many single cytokeratin-positive cells can be detected among how many lymphocytes? This could have been evaluated by simple mixing experiments with cell lines and lymphocytes isolated from the blood or from tissue samples. No quantitative analysis at all appears to be possible from what has been described in the paper because no calibration experiments have been performed.

Furthermore, the study suffers from a lack of gold standard to evaluate the sensitivity and specificity of the new technique to detect tumor cells in extracts of lymph node tissues. Histological proof of tumor cells could have been the gold standard as it provides the method currently used in practice. If this gold standard had been accepted, then an intolerable rate of discordance would have been the result. Rate of falsely positive samples would have amounted to 25 out of 343 equalling 7.3% and falsely negative samples to four out of 343 equalling 1.2%. A total discordance rate of 8.5% would have been the consequence.

Results become even worse when macrometastases, which might have been noticed by macroscopic evaluation alone and not requiring elaborate PCR methodology, are omitted: out of nine micrometastatic cases, two were falsely negative in the PCR assay (22.2%) and out of three samples with isolated tumor cells, two were negative in PCR. Hence, in samples with macroscopically nonvisible metastasis, four out of 12 samples were discordant (25%). The authors decided to compromise histology as a gold standard because of potential sampling bias. A second principle of verification was introduced consisting of additional evidence of the presence of epithelial cells by Western blot and three additional PCR reactions for putatively cancer-specific transcripts (CK19, SPDEF, and FOXA1). This principle, however, was not applied to every sample in the study, which could have meant a gold standard, but only to a selected subgroup of discordant cases. Sampling bias was assumed when at least one of the additional tests for epithelial gene expression was positive. Again, no experiments with controlled conditions, e.g., by mixing experiments, have been performed to evaluate how frequently only one of the additional markers turned positive and what, for example, the significance might be if CK19 PCR and Western blot are negative, whereas FOXA1 is the only further marker in support of the one-step nucleic acid amplification (OSNA) result (e.g., sample 11). What is the justification for assuming that one additional positive marker is sufficient to prove sampling bias, whereas three

H. Kreipe (✉)
Institute of Pathology, Medizinische Hochschule Hannover,
Carl Neuberg Strasse 1,
30625 Hannover, Germany
e-mail: Kreipe.Hans@mh-hannover.de

negative markers do not argue in favor of a discordant result?

The approach of the study to prove sampling bias as a major source of discordant results could be further questioned if those four cases are considered from which different samples with discordant results between positive OSNA and negative histology were derived. Three of these four cases yielded mixed results, with one sample being in favor of sampling bias and the others demonstrating discordance. The only case out of the four with a uniform result in all samples (7 and 13) homogeneously showed discordance. The other cases were constantly negative in histology (except one ITC) but yielded varying results with regard to RNA or protein detection of tumor cells in lymph node lysates, shedding light on the limited reproducibility of these evaluation methods (1 and 15; 22, 23, and 24; 18 and 20).

No information about the reproducibility of OSNA can be extracted from the description of the experiments. Were they done in duplicate or triplicate and what was the concordance between repeated tests?

Besides the methodological concerns, the conclusion of the authors that the adoption of the method as a clinical approach could lead to a benefit for the patients appears hard to follow when further consequences of the technique are considered. Material which has been used for PCR analysis is lost for histological evaluation. Consequently, a prognostically relevant discrimination between micrometastasis and isolated tumor cell involvement is no longer possible if the sample was the only part of the lymph node involved. As stated by the authors, the PCR reaction in terms of copy number did not correlate with the amount of tumor cells in the sample.

The most effective way to study the value of the new OSNA technique would have been to perform a randomized study comparing the ability of histology versus PCR-based techniques to predict from the analysis of the sentinel node further axillary lymph node involvement by breast cancer. Until that has been done, histology of the sentinel lymph node will remain the ultimate gold standard.

The intention of Schem and coworkers to test potential alternatives to intraoperative frozen section investigation of sentinel lymph nodes, which is not available everywhere in the world, is appreciated and there is no doubt that alternative techniques have to be evaluated. However, being confronted, as many of my colleagues in Germany have been in recent months, with an aggressive marketing strategy of companies trying to force the corresponding devices onto the market, I felt inclined to give a critical reappraisal of the currently available evidence for improved sentinel lymph node diagnostics by molecular means.

Conflicts of interest I declare that I do not have any conflicts of interest in this matter.

LETTER TO THE EDITOR

One-step nucleic acid amplification—a molecular method for the detection of lymph node metastases in breast cancer patients; results of the German study group

Christian Schem

Received: 27 May 2009 / Accepted: 30 May 2009 / Published online: 23 June 2009

Abstract On behalf of all co-authors, I appreciate Prof. Kreipe's thoughts concerning our presented study results very much. In order to sustain this fruitful discussion about new developments and techniques in pathological diagnostics, we would like to comment on the questions raised in the Letter to the editor.

Keywords Breast · Metastasis · Lymph nodes

This published study describes the use of a commercially available molecular system, designed for the detection of lymph node metastases in breast cancer patients, in comparison with intensive histology.

Any experiments related to basic research of the IVD-CE marked product, such as the establishment of sensitivity and reproducibility of the one-step nucleic acid amplification (OSNA) assay, were not part of this study but reported elsewhere [1] and declared in the product information provided by the manufacturer (Sysmex, Kobe, Japan). Amplification of CK19 mRNA as part of OSNA is not based on PCR, as mentioned by H. Kreipe, but on reverse-transcription loop-mediated isothermal amplification (RT-LAMP) which includes six primers and is carried out at an isothermal temperature. The use of six primers ensures a high degree of specificity.

The OSNA system can detect macrometastases and micrometastases but not isolated tumor cells [1, 2] which are, according to the TNM classification of the UICC 6th edition [3], designated as pN0(i+) and therefore were recorded as histology negative in this study. In contrast to what Prof. Kreipe stated in his letter, OSNA detected all macrometastases (97/97) and seven out of nine micrometastases indicated by histological analysis in this study. Homogenates of the two discordant samples showed negative results upon further investigation with quantitative reverse-transcription PCR (QRT-PCR) and Western blotting.

In a recent publication, Daniele et al. [4] pointed out that, for studies in which alternating sections of the same sentinel lymph node are used for a comparison of molecular and histological methods, tissue allocation bias is the main source of discordant results. We therefore performed further analysis with molecular methods of the homogenates (discordant case investigation=DCI) in order to confirm this concept for our study.

DCI was established with a cohort of lymph nodes from histologically negative and positive lymph nodes (LN) from breast cancer patients according to the criteria described in Tsujimoto et al. [1] and Visser et al. [2]. A panel of three markers was used for QRT-PCR in order to supplement for potential downregulation of any of those markers in the tumor deposits. All markers can distinguish well between histologically positive and negative cases [1]; however, FOXA1 mRNA and SPDEF mRNA are less strongly expressed in histologically positive lymph nodes [1] than CK19 mRNA. On the other hand, rare cases with low CK19 expression can occur. Because of this, different results among the three markers for one sample can be observed. Since CK19 protein expression is partially regulated on a post-transcriptional level [5], even a positive result in QRT-PCR and a negative result in Western blotting for CK19 can be obtained.

In another study using a different molecular system for SLN analysis, DCI with a multi-marker panel was

e-mail: Christian.Schem@uk-sh.de

performed in a similar fashion, and likewise a subgroup of assay positive/histology negative as well as assay positive/histology positive cases could not be confirmed by additional molecular testing [6].

As for the importance of OSNA as an intra-operative diagnostic tool for the detection of SLN metastasis, large multi-centric studies were recently performed in the UK and France with manuscripts in preparation. Up-to-date several institutes in five European countries are using OSNA as an intra-operative diagnostic tool for the assessment of the SLN status, with some users analyzing the whole SLN with OSNA and others leaving a 1 mm middle slice of the SLN for histological analysis. Ultimately, more published data and randomized studies will have to shed more light on the value of this innovative technique in the future.

Conflict of interest statement We declare that we have no conflict of interest.

LETTER TO THE EDITOR

Primary thyroid-like renal tumor or renal metastasis from the thyroid?

William Sterlacci · Gregor Mikuz

Received: 4 May 2009 / Accepted: 17 May 2009 / Published online: 18 June 2009

Dear Editor,

With great interest, we read the comment by Insabato et al. [1] and the original report by Amin et al. [2], underlining the importance of distinguishing metastatic thyroid carcinoma to the kidney from a primary thyroid-like renal neoplasm. The authors accurately describe six cases of this extremely rare renal epithelial tumor, providing a comprehensive and noteworthy discussion. Our comment is as follows.

The renal tumor we described, resembling a follicular thyroid carcinoma and lacking immunohistochemical expression of thyreoglobulin as well as thyroid transcription factor-1 (TTF-1) [3], was not accepted as such by Amin et al. [2], due to a subsequent pulmonary nodule demonstrating immunoreactivity with TTF-1. The antibody panel, consisting of CK-7, CK-20, CAM5.2, vimentin, CD-10, CD-117, TTF-1, and thyreoglobulin, was examined in both tumors. We reported all staining results concerning the renal neoplasm and the differing results for the lung focus. Accordingly, the pulmonary tumor did not express thyreoglobulin. As previously discussed [4], TTF-1 positivity alone does not prove this pulmonary neoplasm originating from the thyroid. Possible explanations include non-neoplastic lung tissue entrapped within metastatic renal thyroid-like follicular cancer, TTF-1 immunoreactive tumor cells reflecting microenvironmental influences by lung tissue, or a separate primary lung carcinoma showing thyroid-like follicular carcinoma morphology. Amin et al. point out that metastatic carcinoma from the thyroid is usually widespread by the time of renal involvement, which is associated with poor survival, especially for follicular thyroid carcinoma. The patient we reported on is disease-free to date, amounting to a follow-up period of 7 years.

An extremely small thyroid carcinoma remaining undetected is possible though unlikely. At our institute, all thyroids excised due to malignancy are completely embedded in paraffin in maximally 3-mm-thick sections. Therefore a tumor must be smaller than 3 mm to escape histological diagnosis. The described renal tumor predominantly demonstrated typical follicular architecture, which would most likely be associated with a large primary and an advanced tumor stage in the case of a primary thyroid carcinoma. Follicular carcinoma of the thyroid disseminates hematogenously and predominantly metastasizes to bone, lungs, brain, and liver, whereas renal metastasis is a very rare occurrence. The vast majority of incidental carcinomas present with papillary histology. In addition, it is known that the normalization of iodine supply in an endemic goiter region, which is our situation, results in an increase of papillary carcinomas and a reduction of follicular carcinomas, as well as a shift towards earlier tumor stages at diagnosis. Also arguing against an overlooked occult primary of the thyroid is the fact that, after a thorough workup, all clinical examinations including ultrasound, laboratory parameters, 99-technetium scintigraphy, 18-fluordeoxyglucose positron emission tomography, and 131-iodine whole-body scans were without pathological findings.

Tumors resembling thyroid carcinoma have also been reported in other organs [5]. In conclusion, a crucial aspect when differentiating between a primary thyroid-like tumor and a metastasis from the thyroid is exact clinicopathologic correlation. Especially in cases that are not straight forward, this gains immense importance.

LETTER TO THE EDITOR

Anti-MTOC-MT antibody is commonly detected by AIT test in colorectal cancer patients

Jung-UK Sir · Think-You Kim

Received: 25 May 2009 / Accepted: 27 May 2009 / Published online: 10 June 2009

To the Editor:

After reading the article, "β_{III}-tubulin at the invasive margin of colorectal cancer: possible link to invasion", by Portyanko et al. [1], we would like to express our experiences and opinions on host immune reaction in cancer patients.

In the article, the expression of β_{III}-tubulin, which is an isotype of tubulin, a major component of microtubule (MT) found in the budding margin of colorectal cancer tissue, was confirmed by immunohistochemical staining using anti-β_{III}-tubulin, and this phenomenon was considered to have deep relations with invading activity of cancer cell.

Up until current times, there had been several reports that confirmed the existence of various autoantibodies in cancer patients, and that these antibodies do affect the process of cancer growth [2].

We had discovered the existence of autoantibody against microtubule organizing center with microtubule (MTOC-MT) in the serum of cancer patients for a long time, and many extensive studies in various cancers are currently in progress [3]. The anti-MTOC-MT positive rates were 15.2% in our colorectal cancer cases and 10.8% (20/186) in gastrointestinal cancer cases (Table 1). Anti-MTOC-MT was measured by AIT (autoimmune target) test that uses indirect immunofluorescence method. Instead of using HEp-2 cell as in the conventional test, AIT test uses the human macrophage cell (IT-1) as a substrate that plays a pivotal role in the autoimmune and tumor immune pathways, and this test can detect various spectrums of autoantibody that were not possible to be seen by conventional antinuclear antibody test. Due to the unique nature of high intracellular and intercellular activity of macrophage, the size of MTOC-MT is especially large and is easy to observe [4, 5].

In terms of host immunity, our results provide evidence that can support and reinterpret the results of the above article. In other words, MT is playing an important role in the metastatic invasion of cancer cell, and can create anti-MTOC-MT by 'spitting out' a MT-related soluble form of autoantigen into host immune network. Looking at the fluorescence pattern of anti-MTOC-MT by AIT test, involved autoantigen can be related to various types of MT-associated components including β_{III}-tubulin. Also, anti-MTOC-MT formed by such process could be understood as playing a role of host defense mechanism against cancer cell invasion. As a conclusion, we think that, when

Table 1 Prevalence of anti-MTOC-MT pattern of AIT test in gastrointestinal cancer patients (n=186)

Type of malignancy	Anti-MTOC-MT positive cases	Total cases	Percent
Esophagus	2	22	9.1
Stomach	11	118	9.3
Colorectal	7	46	15.2
Total cases	20	186	10.8

MTOC-MT microtubule organizing center with microtubule, *AIT* autoimmune target

β_{III}-tubulin could be a marker in estimating the invading activity of cancer cell, anti-MTOC-MT could be considered as a new cancer marker that can represent the host immune reaction against cancer cell.

Conflict of interest statement T.Y. Kim holds patent relating to the IT-1 cell line.

Multiple sporadic gastrointestinal stromal tumours arising at different gastrointestinal sites: pattern of involvement of the muscularis propria as a clue to independent primary GISTs

Abstract Multifocal sporadic gastrointestinal stromal tumours (GISTs) may be misinterpreted as recurrent or metastatic disease, leading to inappropriate treatment. As molecular analysis is generally not available in routine practise, histological criteria that would facilitate diagnosis of multiple primary GISTs in routine slides are needed. We studied 14 GISTs (mean size, 2.7 cm) from six men and one woman (mean age, 70 years) applying morphological features and direct sequencing of *KIT*, *PDGFRA*, *BRAF*, and *KRAS*. Diagnosis was synchronous in five and metachronous in two patients. Paired tumours originated in stomach/small bowel (n=5), duodenum/jejunum (n=1), and stomach/oesophagus (n=1) and revealed spindle (n=10) and mixed spindle and epithelioid (n=4) phenotype. Tumours were well circumscribed and have involved the muscularis propria in a pattern typical of primary GISTs. Different somatic *KIT* mutations were found in tumours from four patients. One patient had a *KIT*-mutated and a *BRAF*-mutated (V600E) tumour. Two patients had wild-type tumours. No *PDGFRA* or *KRAS* mutations were detected. Our results underscore the molecular heterogeneity of sporadic multifocal GISTs. The characteristic involvement of the muscularis propria and the site-typical morphology and immunophenotype facilitated the diagnosis of primary GISTs in all cases and correlated with molecular findings, emphasising the value of conventional histology in recognising independent primary GISTs.

Introduction

A majority of gastrointestinal stromal tumours (GISTs) occur as sporadic solitary neoplasms in adults with a mean age of 65 years [1]. Somatic *KIT* (80%) and *PDGFRA* (10%) mutations represent mutually exclusive gatekeeper molecular events in GISTs [2, 3]. A subset of GISTs (approximately 10%), in particular, paediatric GISTs [4] and GISTs in patients with neurofibromatosis 1 (NF1) [5], and the Carney triad [6] lack mutations in *KIT* and *PDGFRA* (wild-type GISTs). Of the latter, approximately 4% were found to harbour the *V600E BRAF* mutation as alternative molecular oncogenic events in two recent studies [7, 8]. Paediatric and Carney triad-associated GISTs

arise commonly as multifocal or multinodular gastric tumours [4, 9]. On the other hand, patients with NF1 [5] and those with germline mutations in *KIT* [10] and *PDGFRA* [11] are characterised by the development of numerous GISTs in one or different parts of the GI tract, usually in a background of diffuse interstitial cell of Cajal (ICC) hyperplasia. The small intestine (duodenum, jejunum, and ileum) represents predilection sites for NF1-associated GISTs, but other sites may be involved as well [5]. On the other hand, patients with *KIT* or *PDGFRA* germline mutations develop GISTs at different sites including stomach, small bowel, and other rare locations [10, 11].

Recent studies revealed a predilection for multiple sporadic GISTs to develop in the proximal gastric body as a result of distinct *KIT* and *PDGFRA* mutations, suggesting a possible "field effect" [12, 13]. However, GISTs originating multifocally in different GI sites in patients lacking familial GIST syndromes and NF1 are probably under-recognised; many such GISTs might have been interpreted as recurrent or metastatic disease. Accordingly, their molecular pathogenesis is not sufficiently studied. To date, less than ten such cases have been analysed in three previous studies [14–16], but molecular findings have been inconsistent in some of the cases analysed.

Although the growth pattern and relationship of a neoplasm to surrounding tissue/mucosa has been long applied to resolve the dilemma of *primary* versus *metastatic tumour* in surgical pathology practise, to our knowledge, this aspect has not been addressed in GISTs to date. Accordingly, there exist no criteria that permit a diagnosis of primary versus recurrent tumour in patients with a history of GIST and those presenting initially with multifocal disease. Previous reports have focused mainly on the mutational status as the only hint to their multifocal primary nature, but no detailed description of gross and microscopic features was given. Thus, it is not surprising that tumours completely localised in the peritoneum, a common site for metastatic spread in GIST, were included in previous studies and turned out to be metastatic disease [16]. Furthermore, a proportion of previously studied cases revealed identical mutations [14], findings that in conjunction with peritoneal location and high-risk histology would favour metastatic spread.

In this study, we analysed 14 GISTs from seven patients for their gross and histopathological features, with emphasis on the pattern of involvement of the muscularis propria as a clue for distinct primaries. In addition to *KIT* and *PDGFRA*, we investigated for the first time the presence of *BRAF* and *KRAS* mutations in multiple sporadic GISTs. The results indicate the value of histological features in initial recognition of primary GISTs, supplemented by molecular analysis in equivocal cases.

Materials and methods

Cases were retrieved from the surgical pathology files of our institutions. Only cases in which GISTs were diagnosed at distinct GI sites (e.g., stomach and any other part of the GI tract) or originated in different parts of the small bowel (duodenum, jejunum, or ileum) were considered. Tumours that were closely associated in the proximal stomach have been published previously and are not included here [13]. The BRAF-mutated tumour from one patient has been included in a recent study [8]. No patient had a known history of NF1, familial GIST syndrome, or features of the Carney triad, and none had received imatinib therapy prior to surgery. All gross descriptions and available gross photographs as well as conventional slides from all tumours have been evaluated by an experienced pathologist (A. A.) without knowledge of the molecular findings. No cases with apparently advanced metastatic tumours involving the peritoneum have been included. A minimum of five blocks were submitted from tumours ≥5 cm. Tumours were carefully analysed, both grossly and microscopically, for any association with the muscularis propria as was described previously in so-called extra-gastrointestinal GIST [17]. In particular, the following was noted as suggestive of primary GIST: (1) at least partial intramural localization with or without dissection of the muscularis propria along the plane of the Auerbach plexus, (2) attachment of a predominantly extramural lesion to the outermost gut wall by a narrow pedicle partially obliterating the external muscle layer, and (3) evidence of remnant muscle fibres at the tumour periphery/capsule. If applicable, tumours have been classified into one of the eight histological subtypes described by Miettinen et al. for gastric GISTs [18] in order to correlate their morphologies with anatomic sites. Risk assessment was based on the National Institutes of Health consensus criteria [19]. Immunohistochemistry was performed using the methods and primary antibodies described previously [20].

Molecular analysis for *KIT*, *PDGFRA*, *BRAF*, and *KRAS* mutations

Extraction of tumour DNA from formalin-fixed paraffin embedded material, polymerase chain reaction (PCR) amplification, direct sequencing of *KIT* exons 2, 9, 11, 13, and 17 and *PDGFRA* exons 12, 14, and 18, and verification PCR were performed using the methods previously described [20]. For *BRAF* and *KRAS* mutation

analysis, the sequences of primers used for the PCR were as follows:

BRAF exon 15 forward	5′ CTTCATGAAGACCTCACAGTAAAAATAGG 3′
BRAF exon 15 reverse	5′ TAGCCTCAATTCTTACCATCCACAAA 3′
KRAS exon2 forward	5′ TTTTTATTATAAGGCCTGCTGAAAATG 3′
KRAS exon2 forward nested	5′ TATTATAAGGCCTGCTGAAAATGACTG 3′
KRAS exon2 reverse	5′ AATGGTCCTGCACCAGTAATATGCATAT 3′
KRAS exon2 reverse nested	5′ GTCCACAAAATGATTCTGAATTAGCTGTA 3′

BRAF and *KRAS* amplification required one step and two steps of amplification, respectively. For the first and the nested PCR, a 50-cycles amplification step was performed using an AmpliTaq Gold (Applied Biosystem) under the following conditions: 20 s at 95°C for the denaturation, 10 s at 55°C for the annealing, and 40 s at 72°C for the elongation.

Results

General incidence and localization of multiple primary GISTs

Initially, a total of ten patients (with two distinct GISTs each) fulfilled the above criteria for independent primary GISTs. Two patients with small bowel GISTs had a known NF1 and were excluded from further analysis. A third patient had two simultaneous duodenal and jejunal GISTs expressing S100 protein. NF1 was suspected, but our initial enquiries were inconclusive for NF1. However, upon a thorough review of old pathology request forms, it turned out that this patient had clinical signs of NF1. Thus, this patient was also excluded from further analysis. The remaining seven patients represented 1.6% of 419 consecutive GISTs at our departments and are the subject of this study. Paired tumours originated from the stomach body/fundus and small bowel (n=5), stomach body and oesophagus (n=1), and duodenum and jejunum (n=1).

Clinical features and patients characteristics

The clinicopathological features of all patients are summarised in Table 1. There were six men and one woman. Patient ages at diagnosis of the first tumour ranged from 39 to 84 years (mean age, 70 years). Presenting symptoms were upper GI bleeding (n=2), extensive peritoneal sarcomatosis from ileal GIST (n=1), intermittent abdominal pain with palpitation (n=1), and non-specific abdominal symptoms (n=2). Four small tumours were incidental findings during abdominal surgery for malignant (n=2) and benign (n=2) diseases. Two tumours were incidental to surgery for symptomatic GIST. The duodenal GIST in patient 5 was thought to represent a pancreatic head tumour on computed tomography scan. A second jejunal GIST was detected in this patient intra-operatively. In one patient, both tumours were incidental finding at autopsy. Diagnosis of both tumours was synchronous in five patients and metachronous in two. The interval between first and second tumour in the patients with metachronous presentation was 5 and 6 years, respectively.

Pathological findings

Gross features

Tumours ranged from 0.1 to 7.5 cm in size (mean, 2.7 cm). Gross features were similar to those previously reported for GIST in general, the majority being tan to grey-whitish with variable areas of cystic degeneration and haemorrhage. All tumours were well circumscribed grossly (Fig. 1a, b). Larger symptomatic tumours were commonly transmural with both peritoneal and luminal growths (Fig. 1c). Almost all incidentally detected second tumours (n=8) were predominantly extramural or partially subserosal nodules attached to the outer layer of the gut wall by a narrow pedicle. The tumour pedicle obliterated the muscularis propria, indicating intramural origin of the tumour with subsequent extramural growth (Fig. 1d).

Microscopic and immunohistochemical features

All tumours revealed a variable degree of involvement of the muscularis propria in a pattern typical of primary GISTs, and none was completely intra-peritoneal/extra-gastrointestinal or confined to the subserosa, contrasting with metastatic deposits (Table 1). Dissecting growth along the plane of the myenteric plexus was a common feature, at least focally (Fig. 2a, b). Of interest, it was remarkable that tumour tissue in the vicinity of the muscularis propria was generally hypocellular and spindled with bland histology, even in tumours with otherwise high cellularity and epithelioid morphology (Fig. 2c). Residual muscle fibres were consistently seen at tumour periphery (Fig. 2d). Intimate association with the myenteric plexus and the Cajal cells was well recognisable in most cases (Fig. 2e, f). Gastric tumours revealed sclerosing spindle (n=4), cellular spindle (n=1), and mixed spindle and epithelioid (n=1) morphology according to Miettinen et al. [18]. The duodenal tumour from patient 4 and the gastric tumour from patient 5 displayed distinct lobules of cellular

Note tumour pedicle obliterating the external muscle coat (CD117)

epithelioid and sclerosing/cellular spindle morphology separated by residual muscle fibres with focally recognisable transitional areas (Fig. 2g, h). Small bowel tumours revealed high to moderate cellularity with numerous skeinoid fibres seen in most of them (Fig 2i). No precursor lesions (ICC hyperplasia) were seen in the surrounding muscularis propria in any of the cases.

Immunohistochemically, all tumours were strongly KIT positive (Fig. 1f). However, expression of CD34 and smooth muscle actin (SMA) was site-dependant. In particular, gastric tumours were uniformly CD34 positive and SMA negative. On the other hand, small bowel tumours were more commonly CD34 negative or only focally positive, and diffusely SMA positive. None of the tumours expressed S100 protein or desmin.

Molecular findings

In nine of 14 tumours (64%) corresponding to five of seven patients (71%), a mutation was detected in *KIT* (n=8) and *BRAF* (n=1; Table 1). No mutations were detected in *PDGFRA* or *KRAS*. *KIT* mutations involved exon 11 in seven tumours (five-point mutations and four deletions) and exon 9 in one tumour. Two tumours had both deletions and point mutations. The mutational status for paired tumours was as follows: *KIT* exon 11/*KIT* exon 11 (three patients), *KIT* exon 11/*KIT* exon 9 (one patient), *KIT* exon 11/*BRAF* (one patient), and wild-type/wild-type (two patients). Patient 3 had a gastric GIST with V559D and a small bowel GIST harbouring the V600E *BRAF* mutation (Fig. 3). Different mutations were detected in four of the five mutation-positive cases. Patient 5 had the same *KIT* exon 11 deletion in both tumours, in addition to a point mutation and a silent mutation detected only in his small bowel GIST. However, tumours from this patient showed a strikingly distinct morphology (Fig. 2g–i). Of note, no multiple mutations involving more than one gene or different exons of the same gene were detected in the same tumour in any of the cases. Analysis of normal tissue revealed wild-type sequences in all cases, thus ruling out germline mutations.

Discussion

This is the first study to analyse the gross and histological pattern of involvement of the muscularis propria as a potentially reliable clue to the primary nature of GISTs. We applied the same method we used previously to critically assess the origin of so-called extra-gastrointestinal GISTs (EGIST) [17]. Typical patterns of involvement of the muscularis propria seen in the current cases included (1) splitting of the muscularis propria at a level corresponding to the intermuscular plane of the Auerbach plexus; (2) non-destructive dissecting infiltration of the muscle coat by bland-looking less cellular spindled tumour tissue with occasional sclerosis, even in otherwise hypercellular and epithelioid neoplasms; (3) presence of compressed capsule-like smooth muscle fibres at the tumour periphery in extramural tumours; (4) small myenteric nerves or residual ganglionic elements within the tumour; (5) presence of a

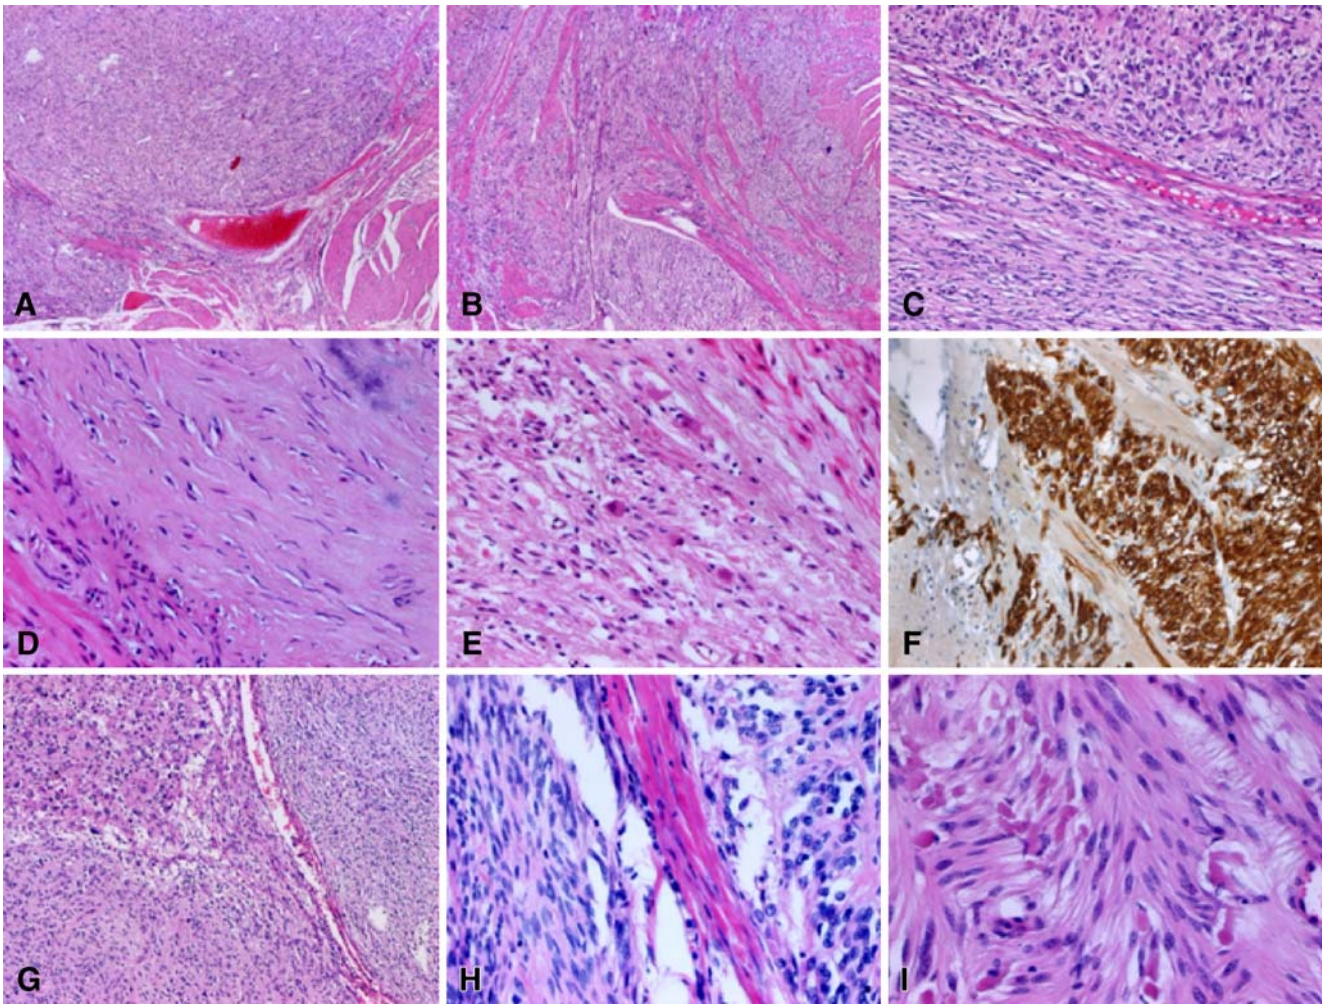

Fig. 2 **a** Typical splitting of the muscularis propria along the plane of the myenteric plexus. **b** Sheets of tumour cells diffusely dissecting the muscle coat. **c** Cellular epithelioid gastric GIST (*upper field*) with a bland-looking spindle cell focus at the border to the muscularis propria. **d** Sclerosing spindle cell gastric GIST showing residual muscle tissue at the tumour periphery. **e** Residual myenteric nerve and ganglion cells at the border to the muscle coat in a small bowel GIST. **f** CD117 highlighting close association of GIST (*upper right*) with ICCs (*lower left*). **g** Typical multinodular spindle and epithelioid pattern in gastric GIST (patient 5) with intervening fibromuscular septum deriving from the muscularis propria in **h**. **i** Second tumour from the same patient found intra-operatively showing small bowel-typical histology with skeinoid fibres

tumour pedicle obliterating the external muscle coat and abutting the myenteric plexus; and (6) presence of thin fibromuscular septa arising from the muscularis propria and traversing tumour nodules, particularly in epithelioid and mixed neoplasms. These observations were consistent with the notion that GISTs, as tumours of ICCs, do arise invariably within the muscularis propria but may adopt varied growth patterns in the later course of the disease [17]. Although infiltration of the muscularis propria may occur in metastatic GIST, in our experience, this is uncommon and if occurred, such metastatic tumours generally have high-grade features, are less well circumscribed, and have irregular infiltrative borders with entrapment of fat and other tissue derivatives besides the muscularis propria. Furthermore, the above-listed features typical of primary GISTs are unusual in metastatic GISTs infiltrating the GI musculature.

The site-typical morphology and immunophenotype represent further criteria that may be of great value in identifying primary GISTs. Gastric GISTs reveal a strikingly varied but characteristic morphology with eight reproducible histological types [18] that generally differ from small bowel GISTs [21]. In our study, paired tumours originating in the stomach and small bowel in the same patient displayed discordant, site-typical morphology, respectively. In particular, gastric tumours showed sclerosing spindle, cellular spindle, or mixed morphology with a common expression of CD34, but not SMA in most of the cases. On the other hand, small bowel tumours were typically moderately cellular with numerous skeinoid fibres and commonly

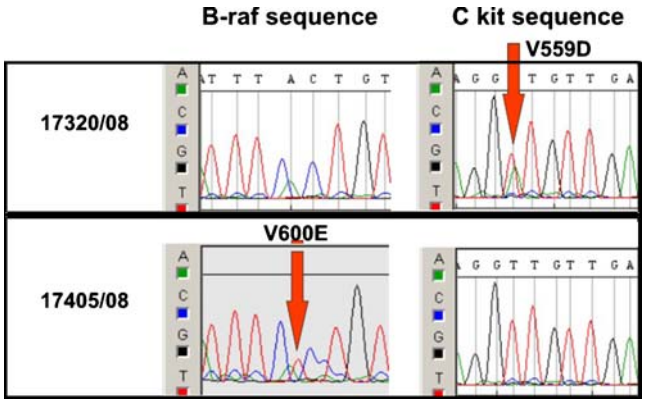

Fig. 3 Chromatograms of the complementary reverse sequence of *BRAF* exon 15 and the forward sequence of *KIT* exon 11 from the gastric GIST (*above*) and small bowel GIST (*below*) in patient 3. The two mutually exclusive mutations detected in his two tumours are indicated by the *red arrow*

CD34+/SMA−. Furthermore, the generally bland histology seen in many tumours and the low mitotic activity should also suggest independent neoplasms. A careful analysis of these distinct morphological features in different tumours from the same patient allowed appropriate interpretation and were also in line with their distinct molecular pathogenesis demonstrated by mutational analysis.

Recognising multiple primary GISTs developing synchronously in a patient with a history of GIST is mandatory to avoid misinterpretation as metastasis with the hazard of unnecessary over-treatment. Our two cases with metachronous presentation of primary GISTs in patients without a syndrome represent a hitherto unreported observation and should be distinguished from tumour recurrence. Mutational analysis plays an important role in equivocal cases. While detection of distinct mutations in imatinib-naïve multiple GISTs clearly indicates independent primary tumours, the occurrence of the same mutation in two tumours fulfilling histological criteria for independent GISTs should warrant analysis of the normal tissue to confirm or rule out a germline mutation. Rarely, independent GISTs may arise from ICCs harbouring the same somatic mutation [13]. On the other hand, patients with a germline *KIT* mutation may present with metachronous-isolated disease mimicking recurrent solitary sporadic GIST [22]. The latter case points to the potential pitfalls related to dependence on molecular analysis alone in confirming recurrent GISTs. While the presence of numerous variably sized and confluent nodules localised mainly to the peritoneum and showing high-grade histological features are typical of metastatic disease, rare extramural gastric GISTs may present as multiple omental EGIST, thus mimicking metastatic disease [23, 24]. Combined careful analysis of morphological and molecular features will facilitate correct diagnosis in equivocal cases (Fig. 4).

A novel finding in this study is the detection of the V600E *BRAF* mutation in the small bowel GIST of one patient who had a *KIT*-mutated gastric tumour. Both mutations were mutually exclusive. *BRAF V600E* mutation has been detected in 4% and 7% of *KIT/PDGFRA* wild-type GISTs in two recent studies [7, 8]. This case demonstrates that multiple GISTs in the same patient can be initiated by mutations involving different genes, as reported by Haller et al. and Miselli et al. [12, 15]. The wild-type in the tumours from case 7 could be the result of poor DNA preservation and contamination by abundant hyaline fibrous tissue. However, the pathogenesis of the wild-type intestinal GISTs in patient 6, who displayed no clinical features of NF1, remains unclear. This patient might have either an undiagnosed NF1 or have tumours initiated by other rare types of mutations.

In summary, we described further seven patients with sporadic GISTs arising multifocally at different GI sites, demonstrating a great heterogeneity in their molecular profiles and emphasising the value of histological features in their appropriate initial interpretation as independent

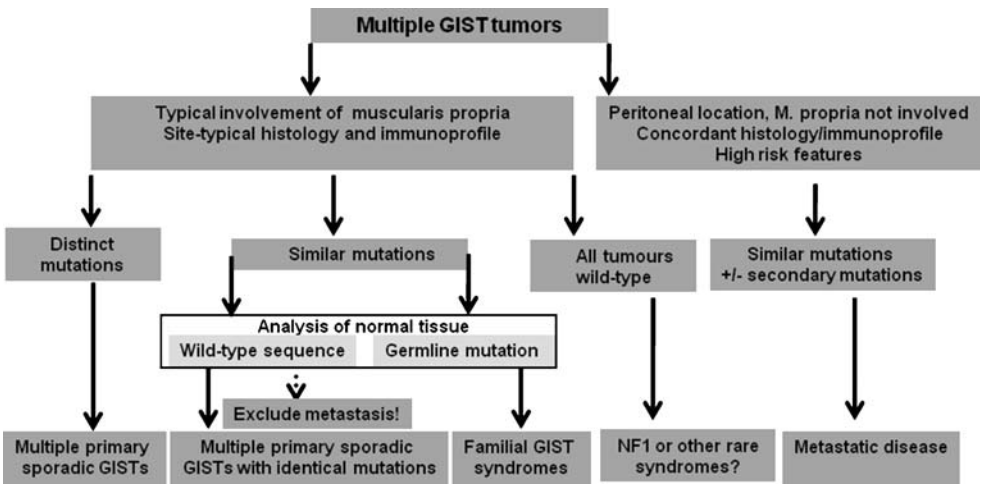

Fig. 4 An algorithm for evaluating multiple GIST nodules of unknown pathogenesis

primary neoplasms. It is mandatory to exclude multiple independent tumours, particularly in patients with an apparent recurrence or metastasis from a previously treated low risk GISTs.

Conflict of interest statement We declare that we have no conflict of interest.

The distribution of lesions in 1–14-mm invasive breast carcinomas and its relation to metastatic potential

Tibor Tot · Gyula Pekár · Syster Hofmeyer · Thomas Sollie · Mária Gere · Miklós Tarján

Received: 9 April 2009 / Revised: 19 June 2009 / Accepted: 24 June 2009 / Published online: 21 July 2009

Abstract We analyzed 301 consecutive cases of 1–14-mm invasive breast carcinomas documented in large-format histological sections to determine the distribution of invasive and in situ foci. We also aimed to determine whether this distribution was related to the frequency of demonstrable vascular invasion and lymph node metastases. One third of the carcinomas (31.9%, 96 cases) had a multifocal invasive component and a more than doubled relative risk of vascular invasion (RR=2.3642, 95% confidence interval (CI)= 1.5077–3.7073) and lymph node metastasis (RR=2.7760, 95% CI=1.6337–4.7171) compared to unifocal invasive carcinomas. Invasive carcinomas with diffuse in situ component had an elevated relative risk for vascular invasion (RR=2.2201, 95% CI=1.4049–3.5083) and lymph node metastasis (RR=1.9201, 95% CI=1.1278–3.2691) compared to those with unifocal or multifocal in situ lesions. However, multifocality of the invasive component was associated with a substantially elevated risk of vascular invasion and lymph node metastasis, even in cases with diffuse in situ component. Similar observations were made in the 1–9- and 10–14-mm invasive carcinoma subgroups. These findings indicate that lesion distribution has prognostic relevance for 1–14-mm invasive breast carcinomas and underline the importance of using special techniques in breast pathology for proper assessment of this parameter.

Introduction

Breast carcinoma is the most common malignancy among women in the Western world and is the leading cause of premature death in younger women [1]. The prognosis depends largely on tumor stage at the time of detection. While advanced carcinomas, which are larger and may have metastasized, often have an unfavorable outcome, the vast majority of patients with small tumors without metastatic spread have excellent disease-free survival and overall survival prognosis [2]. Population-based mammography screening has substantially increased detection of small, early-stage, nonmetastatic carcinomas with favorable prognosis; this has contributed to lower mortality from breast cancer during the last few decades [3, 4]. However, some patients with early-stage breast cancer still have an unfavorable outcome indicating that additional prognostic parameters are needed in order to identify and properly treat higher-risk patients even in this category of the tumors.

Many studies have addressed the value of various prognostic parameters in predicting the outcome of early breast carcinomas, sometimes generating conflicting results [5]. Regarding lymph node metastasis (LNM) in T1 tumors, increasing tumor size, poor histological grade, the presence of lymph vessel invasion (LVI), and younger age are the most important predictive variables [6–11]. We recently reported that multifocality of the invasive component of breast carcinomas is associated with increased frequency of vascular invasion and lymph node metastasis and that this seems to be unrelated to tumor size [12, 13]. In the present study, we focused on 1–14-mm carcinomas with invasive

foci, assessed the distribution of the tumor foci using large-format histological sections, and tested whether this distribution was related to the metastatic capacity of the tumors.

Materials and methods

A consecutive series of breast carcinoma cases with 1–14-mm invasive tumors was selected from the files of the Department of Pathology and Clinical Cytology at the Central Hospital in Falun, Sweden, from January 2005 to December 2008. All cases were documented in large-format standard histological sections (maximum size, 10×8 cm). The technical protocol has been described previously in detail [14–16]. The large sections represented coronal cross sections of entire sector resection specimens and sagittal cross sections from mastectomies. Cross sections that were larger than the maximal dimension of the standard object glass were bisected and embedded in two or three adjoining blocks. One to eight blocks were prepared for each case and were sectioned at two to 14 levels. Large thick sections, also called three-dimensional histology slides [16], were prepared for selected cases.

A dedicated team of experts analyzed all cases in diagnostic routine. Detailed preoperative and postoperative radiological/pathological correlation of the mammogram, ultrasonogram, and magnetic resonance image findings to the large-format histological sections findings were used by the pathologist to assess the distribution of the lesions and the extent of the disease. The clinical, radiological, and pathological data were registered in a database. One of the authors (TT) reviewed all the large sections in this series for the purposes of the present study.

We analyzed the distribution of the in situ and the invasive components of the tumors separately using our previously published criteria [12, 13]. In brief, we defined multifocality of the invasive component as the presence of two or more well-defined invasive tumor foci separated from each other by tissue that did not contain invasive tumor structures. A unifocal tumor was characterized by a solitary invasive focus. A diffuse invasive component was defined as a tumor growing without forming a well-defined tumor body, much like a spider's web. The in situ component was also assessed and categorized as unifocal, multifocal, or diffuse. Unifocal in situ tumors were defined as a well-delineated cluster of tumor-filled dilated acini corresponding to a distended lobule or to several neighboring distended lobules without uninvolved breast tissue in between them. Multifocal in situ component was characterized by distended lobules containing in situ carcinomas separated from each other by uninvolved breast tissue; larger ducts were generally tumor free in these cases. Diffuse in situ carcinomas involved mainly the larger ducts and were difficult to delineate. Tumor size was measured at the largest diameter of the largest invasive focus. Figures 1 and 2 show typical examples of tumors with unifocal and multifocal invasive components; Fig. 3 shows a typical example of an invasive tumor with a diffuse in situ component.

To assess the metastatic capacity of the tumors, we correlated the distribution of the in situ and the invasive components with the presence or absence of vascular invasion and lymph node metastasis. Vascular invasion was defined as tumor cells or tumor cell groups surrounded by endothelial cell-lined spaces and was assessed in routinely stained large histological sections and in peritumoral regions. D2-40 antibody staining (Dako Glostrup, Denmark) helped identify LVI in tumors diagnosed in 2007–2008. Lymph node metastases data, comprising the summarized results of the sentinel lymph node procedure and/or axillary clearance, were obtained from our database. Only macrometastases with a diameter greater than 2 mm were included in the statistical analysis. Relative risk was calculated using a commercially available statistical program (MedCalc Statistics for Biomedical Research; MedCalc Software, Belgium).

Results

During the study period, 815 breast carcinomas were diagnosed in our department. Of these, 119 (14.6%) were purely in situ and 696 had an invasive component. Of the invasive tumors, 301 (43.2%) were 1–14 mm in size. All

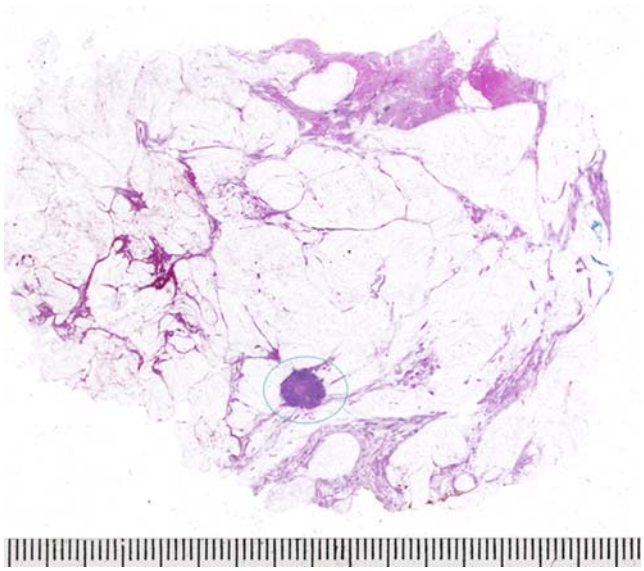

Fig. 1 Large-format histology image of a 6-mm unifocal invasive breast carcinoma (*encircled*) with no multifocal or diffuse in situ components

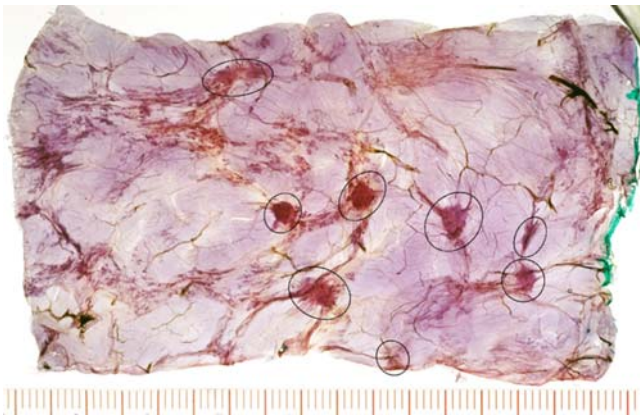

Fig. 2 Large-format thick-section histology image of a multifocal invasive breast carcinoma with eight individual tumor foci (*encircled*) that are less than 10 mm

but 26 of the 301 invasive tumors contained an in situ component. The distribution data for the lesions in relation to LVI and LNM in 1–14-mm carcinomas are summarized in Table 1.

In this series of 301 1–14-mm invasive carcinomas, 205 (68.1%) had unifocal and 96 (31.9%) had multifocal invasive components. None had a diffuse invasive growth pattern. LVI was observed in 19.6% (59/301) of the tumors: in 32.3% (31/96) of the multifocal tumors and in 13.7% (28/205) of the unifocal tumors. The relative risk of having LVI in multifocal versus unifocal carcinomas was 2.3642 (95% CI=1.5077–3.7073). Macrometastasis in the axillary lymph node(s) was present in 15.3% (46/301) of the cases: in 27.1% (26/96) of the multifocal cases and in 9.8% (20/205) of the unifocal cases, giving a relative risk of 2.7760 (95% CI=1.6337–4.7171).

An in situ component was found in large sections from 275 of the 301 invasive carcinomas. The in situ component was unifocal in 108 (39.3%), multifocal in 91 (33.1%), and diffuse in 76 (27.6%) cases. Invasive carcinomas with a diffuse in situ component had an elevated risk of LVI (RR=2.2201, 95% CI=1.4049–3.5083) and LNM (RR=1.9201, 95% CI=1.1278–3.2691) compared to those with unifocal or multifocal in situ components.

The carcinomas were divided into two subcategories by size. There were 137 (45.5%) 1–9-mm and 164 (54.5%) 10–14-mm invasive carcinomas. The invasive component was unifocal in 97 (70.8%) of the 1–9-mm carcinomas and multifocal in 40 (29.2%) cases. The multifocal tumors exhibited an elevated relative risk for LVI (RR=3.8144, 95%CI=1.7960–8.0870) and for LNM (RR=2.4250, 95% CI=0.7424–7.9266) compared to their unifocal counterparts. The presence of a diffuse in situ component carried a substantially elevated risk for LNM (RR=4.667, 95% CI=1.2724–17.1154). For 10–14-mm invasive carcinomas, multifocality of the invasive component also conferred an elevated risk for LVI (RR=1.7256, 95% CI=0.9766–3.0488) and for LNM (RR=2.7000, 95% CI=1.5127–4.8159), as did the presence of a diffuse in situ component. These results are summarized in Tables 2 and 3.

We also asked whether the distribution of the invasive component influenced the frequency of LVI and LNM in the group of invasive 1–14-mm carcinomas having a diffuse in situ component. Multifocality of the invasive component was associated with a substantially elevated risk of LVI (7.4286, 95% CI=1.8196–30.3273) and LNM (3.4286, 95% CI=0.7174–16.3847) in 1–9-mm tumors having a diffuse in situ component. Risk of LNM was elevated in 10–14-mm such tumors (2.000, 95% CI=0.6360–6.2891). Regarding multifocal 1–14-mm invasive carcinomas having diffuse in situ component versus unifocal tumors, the relative risk of LVI was 2.1438 (95% CI=1.0878–4.2249) and the relative risk of LNM 2.8941 (95% CI1.1316–7.4017).

Discussion

The definition of “early breast carcinoma” is still ambiguous. Historically, tumors up to 5 cm in diameter and involving up to three metastatic axillary lymph nodes have been called “early” in some studies, as reviewed by Tot [5]. Other studies use the term “minimal breast carcinoma” and define it as in situ carcinoma and/or invasive carcinoma up to 5 mm [17] or 10 mm [18]. The common characteristic of these tumors is ≥90% long-term survival of the patient. As we demonstrated previously, mammography screening and improved therapy modalities have resulted in excellent long-term survival prognosis for patients with invasive carcinomas up to 14 mm [19]. This motivated us to focus

[a] Relative risk of LVI and LNM in tumors with diffuse in situ component compared to that in tumors with unifocal or multifocal in situ components

on this category of invasive carcinomas in the present study.

Defining and measuring the diameter of an invasive breast carcinoma is not always easy. The most widely accepted way to define the size of a unifocal tumor is to measure the largest dimension of the largest invasive focus. In multifocal tumors, however, using the combined diameter of the invasive foci has been proposed as being more accurate than using the largest dimension of the largest invasive focus [20, 21]. Recent studies have not confirmed the value of using a combined diameter to define these tumors [22, 23]; thus, in the present study, we used the standard definition, i.e., the largest dimension of the largest invasive focus, to define tumor size.

Similarly, the definition of tumor multifocality is still being debated. On one hand, the current TNM classification states "…tumors are defined as arising independently only if they occur in different quadrants of the breast…" [24]. On the other hand, some studies count and measure every individual tumor focus [25], while others call the tumor multifocal if there is 1, 2, or 4 cm between individual foci [26, 27]. In this study, we considered well-defined invasive foci to be individual foci when they were delineated from each other by tissue that did not contain invasive structures, irrespective of the distance between the foci or the quadrant localization of the foci. Our criteria for defining the distribution of in situ structures have been published previously (i.e., unifocal localized in one lobule or in neighboring lobules, multifocal localized in lobules distant to each other, diffuse involving larger ducts) [28, 29]. In this study, we did not use the combined distribution of in situ and invasive components as this may give a large number of combinations and complicate the analysis [12]. Instead, we assessed the distribution of the in situ and the invasive components of the same tumor separately and also tested their individual influence on metastatic potential separately.

A limitation of our study is that follow-up results were not included. This is primarily because the follow-up period is still very short. However, testing the metastatic capacity of tumors by assessing LVI and LNM is reliable: LVI is a strong prognostic factor for operable patients with breast carcinoma as a predictor of poor prognosis in both lymph-node-negative and lymph-node-positive cases [30, 31]. LVI

Table 2 Distribution of lesions in 137 invasive 1–9-mm breast carcinomas in relation to lymphovascular invasion (LVI) and axillary lymph node metastasis (LNM)

		Unifocal	Multifocal	Diffuse	Sum	Relative risk
In situ component	LVI	15.6% (7/45)	16.2% (6/37)	24.4% (10/41)	18.7% (23/123)	1.5385[a]
						95% CI=0.7383–3.2060
	LNM	0.0% (0/45)	8.1% (3/37)	17.1% (7/41)	8.1% (10/123)	4.6667[a]
						95% CI=1.2724–17.1154
Invasive component	LVI	9.3% (9/97)	35.0% (14/40)	–	16.8% (23/137)	3.8144
						95% CI=1.7960–8.0870
	LNM	5.2% (5/97)	12.5% (5/40)	–	7.3% (10/137)	2.4250
						95% CI=0.7424–7.9266

[a] Relative risk of LVI and LNM in tumors with diffuse in situ component compared to that in tumors with unifocal or multifocal in situ components

Table 3 Distribution of lesions in 164 invasive 10–14-mm breast carcinomas in relation to lymphovascular invasion (LVI) and axillary lymph node metastasis (LNM)

		Unifocal	Multifocal	Diffuse	Sum	Relative risk
In situ component	LVI	15.9% (10/63)	18.5% (10/54)	40.0% (14/35)	22.4% (34/152)	2.3400[a]
						95% CI=1.3245–4.1341
	LNM	17.5% (11/63)	25.9% (14/54)	31.4% (11/35)	23.7% (36/152)	1.4709[a]
						95% CI=0.8075–2.6808
Invasive component	LVI	17.6% (19/108)	30.4% (17/56)	–	22.0% (36/164)	1.7256
						95% CI=0.9766–3.0488
	LNM	13.9% (15/108)	37.5% (21/56)	–	22.0% (36/164)	2.7000
						95% CI=1.5127–4.8159

[a] Relative risk of LVI and LNM in tumors with diffuse in situ component compared to that in tumors with unifocal or multifocal in situ components

correlates significantly with LNM [30], and LNM is a well-established morphological prognostic parameter. We included only cases with macrometastasis because the prognostic significance of micrometastases and isolated cancer cells in lymph nodes is still unclear [32].

The proportion of "multifocal" invasive cases varies in different series of breast carcinomas and depends on the histological method, the diagnostic criteria, and the case selection. Values as low as 11% [33] and as high as 75% have been reported [34]. Use of the large-section technique clearly facilitates identification of multiple foci in breast tissue [35]. Gallager and Martin [34], using a technique that was very similar to that used in the present study, reported "extensive neoplastic transformation of the ductal epithelium and multiplicity of the invasive sites" in three quarters of the 38 mastectomy specimens studied; most of these cases were large advanced tumors. Holland et al. [36] reported that 63% of the Tis and T1-2 breast carcinomas had tumor foci around the "referent mass," 20% within 2 cm, and 43% that were even more distant (27% being in situ foci). Using whole-organ sectioning, Luttges [37] reported 46% (76/166) multifocal and 22% (36/166) multicentric cases. Large-section technique has been used routinely in our laboratory for every operated breast cancer specimen for more than 20 years. Our dedicated and experienced technicians produce large-format histological slides of the same high quality as those obtained with conventional small-block technique. In our experience, large-format histology together with detailed preoperative and postoperative radiological–pathological correlation represent the best currently available tool for assessing tumor size and extent and distribution of the lesions. Using this approach in the present study, we found that 31.9% of carcinomas had multifocal invasive components; 31.1% had multifocal in situ and 27.6% had diffuse in situ components. These results are comparable to the results of the cited studies and are in agreement with our previous series [13]. This also indicates that the distribution of in situ and invasive tumor foci of 1–14-mm invasive carcinomas is similar to the distribution of lesions in larger tumors.

The prognostic parameters cited most often for 1–14-mm invasive carcinomas are tumor grade [38], tumor size [5], extent of the in situ component [39], casting-type microcalcifications associated with invasive carcinoma as detected by mammography [19], and lymph node status. The most important predictors of LNM in 1–14-mm invasive breast carcinomas are increasing tumor size, poor histological grade, presence of LVI, and younger patient age [6–11]. Based on the results of the present study, multifocality of the invasive component and diffuse pattern of the in situ component are additional predictors of increased risk for LNM in this tumor category.

The prognostic significance of multifocality is seldom addressed in the literature, and typically only the invasive component is considered. Methodological differences and differing definitions of multifocality make it difficult to compare study results. Worse overall survival rates were reported for patients with multifocal carcinomas versus single-site tumors by Egan [40], but more recent studies have not confirmed these results [41, 42]. Regarding disease-free survival, some studies have found higher local recurrence rates for multifocal tumors compared to unifocal tumors [41, 42]. In a recent study, multifocality was the only parameter significantly associated with residual disease in reexcision specimens for close margins for patients with invasive carcinoma [43].

Tumor size correlates with lymph node positivity [7, 12, 13] as well as with LVI [8, 13, 31]. Thus, the percentage of cases with LVI and LNM in the present series of 1–14-mm carcinomas was expected to be relatively low. In the study by Maibenco et al., LNM was found in 9.6% of T1a tumors and in 14.2% of T1b cases [7]. Yip et al. found LNM in 7.7% of T1a, 12.3% of T1b, 29.2% of T1c, and 48.2% of T2 tumors [11]. Chadha et al. reported LNM in 27% of T1

cases [6]. Gajdos et al. found LVI in 35% of tumors larger than 1 cm and in 13% of smaller carcinomas [8]; Gurleyik et al. reported LVI in 29% of T1, in 54% of T2, and in 100% of T3 tumors [31]. Thus, our results, i.e., 15.3% LNM and 19.6% LVI for the entire study group of 1–14-mm invasive breast carcinomas, were comparable to the results reported in these studies. In addition, we found LNM in 7.3% and LVI in 16.3% of 1–9-mm tumors and in 22% (both parameters) of 10–14-mm tumors. Our results in this series thus confirmed the positive correlation between tumor size and metastatic potential.

The elevated risk of LVI and LNM in multifocal carcinomas compared to their unifocal counterparts has been previously reported regarding breast carcinomas not categorized by size [20, 33, 41] and also in the 1–14-mm size category [13]; those studies reported results similar to the findings in the present study. Others found no significant difference in the risk of LNM between unifocal and multifocal tumors [22]. Comparing the results of the present study with our previous findings [12, 13], a doubled risk of LVI and LNM in multifocal versus unifocal invasive breast carcinomas seems to be the general rule, regardless of tumor size. Theoretically, two types of invasive tumor multifocality are observed in breast cancers: separate foci that develop independently from each other from in situ carcinomas and foci that are the result of intramammary tumor spread. In the first type, the multifocal tumor is really an early carcinoma, and, in the second type, this is less clear. Intramammary spread of the tumor may be the initial step in generating LNM and is probably associated with involvement of the prelymphatic system [44] and/or with LVI [45]. Involvement of the prelymphatic system was previously demonstrated in invasive lobular carcinomas using large-format histology sections [46].

The elevated risk of LVI and LNM in cases with a diffuse in situ component versus those with unifocal and multifocal in situ components in this series may be interpreted as an unexpected finding. However, diffuse distribution of the in situ lesions (involvement of the larger ducts) is associated with high nuclear grade, comedo necrosis, and casting-type microcalcifications in the majority of cases [29]. LNM has been reported not only in invasive breast carcinoma but also in rare cases of ductal carcinoma in situ without demonstrable invasive component; these cases were mostly high-grade comedo lesions [47, 48]. Casting-type calcifications on the mammogram are also associated with higher rate of LNM than the cases without such calcifications [49]. These findings indicate a possible association between diffuse distribution of the in situ component, its grade, and the risk of LNM and may explain the findings of the present study. Our findings are concordant with the experience of some leading experts who, although advocating restrictive approach in offering sentinel lymph node biopsy in cases of in situ carcinomas, recommend such procedure in cases with "diffuse or pluricentric microcalcifications" [48].

In the present study, we also demonstrated that multifocal distribution of the invasive component had prognostic significance in cases with a diffuse in situ component. According to the sick lobe theory [28, 50], malignant transformation in the breast is initially restricted to a single lobe that had abnormal embryonic development. This transformation may involve the lobules and/or the larger ducts within the sick lobe. In contrast to lobular localization, involvement of the larger ducts of the sick lobe seems to confer an unfavorable prognosis associated with an elevated risk of LVI and LNM as demonstrated in the present study and is also associated with higher mortality [19] observed in patients with 1–14-mm invasive breast carcinomas.

In conclusion, multifocality of the invasive component and diffuse distribution of the in situ component are associated with elevated risk of LVI and LNM in 1–14-mm invasive breast carcinomas. Thorough histological assessment of these parameters is essential in modern breast pathology.

Conflict of interest statement We declare that we have no conflict of interest.

Overexpression of PTK6 (breast tumor kinase) protein—a prognostic factor for long-term breast cancer survival—is not due to gene amplification

Abstract In a previous retrospective study, we demonstrated the prognostic value of protein tyrosine kinase 6 (PTK6) protein expression in breast carcinomas. Here, we analyzed PTK6 gene amplification using fluorescence in situ hybridization technique in a cohort of 426 invasive breast carcinomas and compared it with PTK6 expression level as well as with the clinical outcome of patients. Forty-five percent of tumors show increased PTK6 gene copy numbers when compared to normal tissue. Most of these, however, were related to chromosome 20 polysomy (30%), while gene amplification accounted for only 15%. Only "low level" amplification of the PTK6 gene, with up to eight signals per nucleus, was found. The PTK6 cytogenetic status (normal, gene amplification, polysomy 20) was not associated with histopathological parameters or with the protein expression of HER receptors. No statistical association was identified between PTK6 gene status and expression level. Further, the PTK6 gene status does not influence the disease-free survival of patients at ≥240 months. Based on these results, we state that the PTK6 overexpression is not essentially attributed to gene amplification, and the PTK6 protein expression—but not gene status—is of prognostic value in breast carcinomas. PTK6 protein overexpression may result from polysomy 20 in a minority of the tumors. In a marked proportion of tumors, however, the overexpression is likely to be caused by posttranscriptional regulation mechanisms.

Introduction

Gene amplification represents a key mechanism leading to gene activation and overexpression [1]. Amplification is widely observed in human tumors where it represents an oncogene-activating genetic mechanism [2] that may indicate an aggressive behavior of the tumor and a poor prognosis [3]. Among the various proto-oncogenes amplified in primary breast cancer, HER2/neu, located on chromosome 17q11–12, is the best studied [4]. Approximately 20–25% of primary breast cancers show amplification of the Her2/neu proto-oncogene with amplification values in many cases up to 20 gene copies [4]. Her2/neu overexpression/amplification is associated with worse prognosis [5, 6]. Anti-HER2/neu receptor antibody therapy with Trastuzumab induces tumor regression in approximately 30–35% of patients with HER2-amplified metastatic breast cancer [7]. This response rate indicates that additional signaling molecules may influence the biological response to Trastuzumab.

Signal transduction of the HER receptor family (EGFR/HER1, HER2/neu, HER3, and HER4) is thought to be transmitted through the action of nonreceptor protein tyrosine kinases (TK) in the cytoplasm. These TK proteins frequently show alterations in their activities in human tumorigenesis [8], and selective inhibitors of TKs are being investigated for the treatment of cancers [9]. One of these TKs is protein tyrosine kinase 6 (PTK6, BRK), a cytoplasmic tyrosine kinase, which is not only overexpressed in two thirds of breast carcinomas [10–15] but is also overexpressed in colon and prostate tumors and several cancer cell lines [11, 12, 16–18]. In vitro studies to define the physiological role and to identify the PTK6 interaction partners confirmed that PTK6 functions downstream of the HER receptors [18, 19]. This makes PTK6 an interesting tumor marker and a potential new therapy target.

Knowledge of PTK6 expression in tumor tissues is limited, although PTK6 overexpression is established in breast carcinogenesis [15, 19, 20]. High levels of PTK6 are also observed in differentiating noncancerous epithelial tissues such as the gastrointestinal tract, skin [12, 21], and prostate [17]. The extent of PTK6 expression may be influenced by the level of differentiation of breast tissue with evidence for an association with estrogen receptor expression [22] and with the expression of HER receptors [13, 15]. More significantly, the expression of PTK6 has been shown to be a prognostic indicator of outcome in invasive breast carcinomas [15].

The mechanisms behind increases in PTK6 protein overexpression as well as its role in tumorigenesis and prognosis are not understood. We are not aware of studies of PTK6 protein expression or gene status in relation to clinical outcome in invasive breast carcinomas. We conducted a study to compare the prognostic impact of PTK6 gene copy number and protein expression. We performed fluorescence in situ hybridization (FISH) for PTK6 and for the chromosome 20 alpha satellite and studied associations between the FISH signal counts and histopathological and immunohistochemical parameters as well as with the clinical course of disease. We demonstrate that increased PTK6 gene copy number is mainly attributed to polysomy of chromosome 20, not to gene amplification, and that there is no statistical association between PTK6 gene status and PTK6 protein levels. Furthermore, unlike PTK6 protein levels, gene status is not a significant predictor of disease-free survival.

Material and methods

Tumor samples and patient data

Formalin-fixed and paraffin-embedded archival material was obtained from 426 patients with invasive breast carcinomas, as recently described [23]. This cohort contains 244 lymph node negative and 182 node positive tumors, and a total of 234 tumors were less than 2 cm in size. The median follow-up of patients was 80 months (mean 94, maximum 264 months) with 121 (28%) of the patients showing disease recurrence by distant metastases and/or local recurrence. In addition to the standard histopathological parameters (lymph node status, tumor size, and histological grade and type), immunohistochemical data were available for HER2, HER3, HER4, PTK6, estrogen receptor (ER), and progesterone receptor (PrR).

Tissue microarrays (TMAs) were produced as described [15] using a tissue-arraying instrument (Beecher Instruments Inc., Silver Spring, MD, USA). Five-micrometer sections were cut and transferred to adhesive slides using the "paraffin-tape-transfer system" (Instrumedics, Hackensack, NJ, USA). Hematoxylin- and eosin-stained sections from the TMAs, as well as from the original paraffin block, were reexamined to validate representative sampling.

FISH

FISH was performed on 5-μm thick TMA sections. Pretreatment of the sections was done by heating the slides for 12 min in a microwave oven (750 W), digestion with Pronase E (0.05%) for 6 min, and denaturation at 75°C for 15 min, as described elsewhere [24].

The DNA hybridization probes were obtained from Chrombios (Molecular Cytogenetics Chrombios, Raubling, Germany). The PTK6 probe was labeled with Cy3 (red fluorescence), and the centromere 20 probe (20q11.21, CEP20) was labeled with FITC (green fluorescence).

Counterstaining of the sections was done using 4',6-diamidino-2-phenylindole (DAPI). The probes were applied sequentially; after the first hybridization using the PTK6 probe, slides were washed as described [24] and the hybridization procedure repeated using the centromeric probe.

Image acquisition and evaluation of FISH signals

The hybridized slides were viewed under a confocal laser scanning microscope (LSM 510, Zeiss, Jena, Germany) equipped with the Apotome Extension (Zeiss Vision) and appropriate filters [24]. Images were captured using a C-Apochromat ×63/1.2 W objective, and 3-dimensional image projections (AxioVision software) were used for PTK6 signal counting. Multiple tumor areas were scored from each case, and FISH signals were evaluated by counting at least 50 non-overlapping tumor nuclei. Signals were also counted in normal tissues involved in the TMAs, with a mean signal count of 1.54 (± 0.15 SD). Consequently, the presence of ≤2 PTK6 signals per nucleus (corresponding to mean + 3 times SD) were considered normal.

The signals for centromere 20 were counted directly under the microscope and registered as normal (≤2 signals per nucleus) or as increased (>2 signals per nucleus).

The ratio PTK6/CEP20 was interpreted as normal (PTK6 and CEP20≤2 signals), as polysomy of chromosome 20 (>2 signals for PTK6 and for CEP20) or as gene amplification (>2 PTK6 signals and ≤2 CEP20 signals).

Quantitative mRNA analysis

From 90 randomly selected cases, total RNA was isolated and purified from paraffin sections as described elsewhere [13], and RNA was reverse-transcribed using Superscript II Reverse Transcriptase (Invitrogen) according to manufacturer's directions. Intron-spanning primers and probes (FAM™ dye-labeled) were obtained from Applied Biosystems (Assay-on-Demand™, PE Applied Biosystems, PTK6: HS00178742). For the TBP reference gene (*T*ATA-*B*ox binding protein), intron-spanning primers and oligonucleotide probes with 5' fluorescent reporter dye (FAM) and a 3' quencher dye (TAMRA) were designed (Primer-Express software, PE Applied Biosystems, Weiterstadt, Germany) [13]. Polymerase chain reaction (PCR) amplifications were performed as described elsewhere [13], following established criteria. Relative expression levels for the target gene were determined by the standard curve method using a reference RNA (MCF7 breast cancer cell line) [13], and the target amount was divided by the endogenous reference amount to obtain a normalized target value. Final results are expressed as *N*-fold differences in expression relative to the TBP gene. In normal tissues, the mean PTK6 mRNA expression was 0.55 (± 0.8). Therefore, values ≥10-fold (corresponding to mean +2-fold logarithmic SD) were considered as increased mRNA expression.

Statistics

The Spearman rank correlation test was used to examine the relationship between two markers and between markers and clinical parameters. Statistical significance was considered at the $p \leq 0.05$ level.

Survival analysis was performed using disease-free survival, which was defined as the interval from the date of surgery to the first loco-regional recurrence and/or distant metastases.

For univariate survival analysis, Kaplan–Meier curves were calculated, and differences between strata were tested with the log-rank Chi-Square value. Multivariate analyses were performed using Cox proportional hazards regression and a combined stepwise selection algorithm (SAS Inst., Cary, NC, USA). All parameters reaching a significance level of $p \leq 0.15$ in univariate analysis were offered to multivariate analysis. In all other tests, statistical significance was considered proven if $p \leq 0.05$.

Results

PTK6 gene amplification and polysomy 20 in invasive breast cancer

PTK6 FISH signals were detectable in 389 of the tumors examined. A normal PTK6 gene copy number (signal frequency ≤2 signals/nucleus) was found in 55% (n=213) of the invasive breast carcinomas (Table 1). An increased PTK6 gene copy number (>2 signals, as defined in normal tissue) was present in 45% (n=171) of the tumors. In most of these cases, overrepresentation of the gene copy number was caused by polysomy of chromosome 20 (30%); gene amplification was seen in only 15% (Table 1). In Fig. 1, examples for polysomy 20 (a) and for PTK6 amplification (b) are shown. The highest PTK6 gene copy number in our tumors was eight signals/nucleus (corresponding to a 4-fold

Table 1 Frequency of PTK6 gene copy number in comparison with the cytogenetic status

PTK6 signal frequency	Percent of cases	Cytogenetic status*	Percent of cases
≤2.0	55% (n=213)	n	55%
>2.0	45% (n=171)	Polysomy	30% (n=115)
		Amplification	15% (n=56)

Cytogenetic status = ratio of PTK6/CEP20 signals

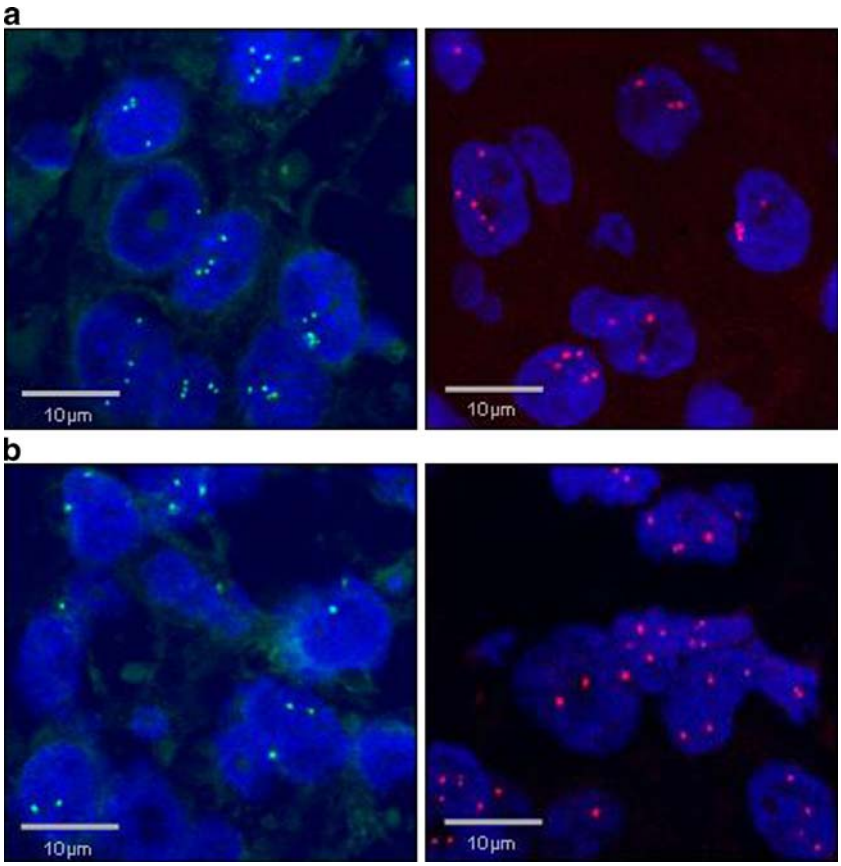

Fig. 1 Examples for an increased PTK6 signal count in breast cancer, caused by polysomy 20 (**a**) or by PTK6 gene amplification (**b**). PTK6 signals = red fluorescence; CEP20 signals = green fluorescence; counterstaining: DAPI

gene dosis); no higher levels of amplification were found. The majority of tumors with an increased signal count showed between two and four signals (n=150); only a minority of cases showed >4 signals (n=18). Therefore, in comparison to other gene amplifications like the HER2 receptor in breast cancer, the PTK6 gene is amplified only on low level.

Correlations between FISH signal counts and other parameters

As shown in Table 2, the PTK6 signal count was significantly associated ($p \leq 0.05$) with ER status, histological grade, and tumor size. The number of tumors with normal and increased signal counts in the three different histological grades is given in Table 3. Most of the cases with normal PTK6 signal counts are classified as grade 1 or 2 (n=152 vs. n=37), whereas the majority of cases with increased signals are grade 2 or 3 (n=142 vs. n=35). The number of centromeric CEP20 signals correlated with tumor size and histological grade. The cytogenetic status (ratio PTK6/CEP20) does not show association with any of the histopathological parameters (Table 2).

The number of PTK6 gene copies was significantly correlated with the immunohistochemical staining intensities of HER3 and HER4 (Table 4), and CEP20 signals revealed significant correlation with HER2, HER3, and HER4 receptor staining. The ratio of PTK6/CEP20 signals does not show any significant correlation with the immunohistochemical parameters (Table 4). Remarkably, there was neither any statistical association between PTK6 IHC and PTK6 FISH gene copy numbers (p=0.5).

To compare gene copy number with mRNA expression and with protein expression, we performed quantitative RT-

Table 2 Associations between FISH signals (PTK6, CEP20, ratio PTK6/CEP20), the PTK6 mRNA, and the histopathological parameters

	Lymph node status	Histological grade	Tumor size	ER	PrR
PTK6 FISH	0.2	**0.0015** 0.17	**0.02** 0.12	**0.003** 0.15	0.15
FISH CEP20	0.6	**0.023** 0.13	**0.036** 0.12	0.06	0.8
ratio PTK6/CEP20	0.2	0.6	0.9	0.4	0.4

Table 3 Number of tumors with normal and increased PTK6 signal counts in the three different histological grades

Grade	≤2 signals/nucleus (n=189)	>2 signals/nucleus (n=177)
1	50 (26.4%)	35 (19.8%)
2	102 (54.0%)	82 (46.3%)
3	37 (19.6%)	60 (33.9%)

Spearman rank correlation test p=0.02

PCR for PTK6 in 90 of our tumors. An increased expression (≥10-fold) was found in 71% of cases. PTK6 mRNA expression showed significant association with the expression of ER and PrR ($p \leq 0.01$; Table 2), and at least a trend (p=0.08) was indicated between PTK6 mRNA and PTK6 IHC (Table 4). No significant association was found between mRNA expression and the FISH results (PTK6 signals, p=0.95; CEP20 signals, p=0.6; ratio PTK6/CEP20, p=0.85).

Correlations with the disease-free survival of patients

As recently published by us, the PTK6 protein expression showed significant correlation with the disease-free survival of patients in multivariate analysis, together with the lymph node status and the tumor size [23]. In the study presented here, which was performed on the same tumor cohort, no statistical significant association was present for normal (≤2) or increased (>2) PTK6 signal counts and the clinical course (p=0.36). Further, neither CEP20 signals nor the ratio PTK6/CEP20 shows association with the clinical course of patients in univariate analysis. Parameters, positively correlated with a disease-free survival of patients in univariate analysis, were lymph node status and tumor size ($p \leq 0.0001$) and histological grade (p=0.002), and an inverse association was found for PTK6 IHC ($p \leq 0.0001$), progesterone receptor status (p=0.02), and HER4 staining intensity (p=0.03), as published else [23].

In multivariate analysis for a disease-free survival of patients, all parameters reaching a significance level of ≤0.15 in univariate analysis were offered. We found an independent prognostic value for lymph node status (p=0.0003, relative risk 2.13), protein expression of PTK6 (p=0.0007, 0.62), and tumor size (p=0.003, 1.55) [23]. The FISH values (PTK6, CEP20, PTK6/CEP20) as well as the mRNA expression values do not influence this result due to insufficient significance.

Discussion

PTK6 is overexpressed in about two thirds of breast carcinomas [10–15], but the mechanisms behind this overexpression are still unknown, and the physiological role of PTK6 in overexpressing cells is not defined. In this study, we show that most tumors with increased PTK6 gene copies are attributed to polysomy of chromosome 20, not to gene amplification, and that there is no statistical association between PTK6 gene status and protein or mRNA expression. Hence, besides an increased dose caused by polysomy 20, there may be additional mechanisms contributing to overexpression as, for example, posttranscriptional regulation mechanisms.

Gene amplification is one major mechanism to increase gene dosage and has importance for both prognosis and targeted therapy. For example, amplification of HER2, MYC, and CCND1 have been reported to be significantly associated with high grade in breast cancer, and a decrease of survival was observed with increasing number of co-amplifications [25]. Amplification is also one of the underlying causes of resistance to therapy [4] as, for example, BCR-ABL gene amplification in patients with chronic myeloid leukemia [26] or clinical resistance to 5-fluorouracil in liver metastases [26].

Although enhanced expression is often the consequence of gene amplification, there are alternative pathways to increase protein expression such as activating regulatory mutations or posttranscriptional and posttranslational mechanisms [4] and, especially in the case of PTK6, via activation by other kinases. Protein overexpression without gene amplification was also described for HER2 protein in some urothelial carcinomas [27] and for hypoxia inducible factor-1alpha in human breast cancer [28].

About half of the tumors analyzed in our study showed increased PTK6 signals; however, most of them had 2–4 signals and only a minority had >4 PTK6 signals. This and, in particular, that most tumors with increased PTK6 signals are caused by polysomy let as state that PTK6 amplification in breast cancers is present only on low level and that it cannot account for the protein overexpression found in two thirds of the tumors. There are also indications that

Table 4 Associations between FISH signals (PTK6, CEP20, ratio PTK6/CEP20), the PTK6 mRNA expression, and the immunohistochemically determined expression of HER2, HER3, HER4, PTK6, and the hormone receptors

	HER2	HER3	HER4	PTK6 IHC

PTK6 mRNA	0.8	0.1	0.4	0.08

Significant correlations are highlighted in bold, and in addition, the Spearman correlation coefficients are given

chromosomal polysomy may, to a certain degree, cause protein overexpression, as has been reported for chromosome 17 polysomy and HER2 in breast carcinomas [29, 30] and in esophageal and gastric carcinomas [31]. In the current study, the majority of tumors with increased PTK6 signals exhibited polysomy 20.

We found no association between the signal ratio PTK6/CEP20 and tumor size or histological grade, whereas both PTK6 and CEP20 signals showed a significant correlation with these histopathological parameters. This indicates that increased signal counts are predominantly found in high histological grades and in tumors larger in size. The cytogenetic status, as described by the ratio PTK6/CEP20, is indicative for gene amplification and does not show significant correlation. Consequently, these associations with histopathological parameters are based upon polysomy of chromosome 20, not on gene amplification. Likewise, the PTK6/CEP20 ratio was not associated with the HER2, HER3, or HER4 protein expression, whereas PTK6 signals as well as CEP20 signals showed significant inverse correlations with HER receptor expressions, indicating that polysomy 20 is associated with normal or low HER receptor expression. There is growing evidence in the literature that HER3 overexpression is associated with worse, HER4 with good prognosis [32, 33]. Some other studies, however, have indicated that HER3 overexpression may be a good prognostic factor [34]. In our tumor cohort, both markers showed a similar (inverse) tendency in univariate survival analysis, although HER3 did not reach significance. This explains the inverse correlation of CEP20 and PTK6 signals with HER3 and HER4. It is remarkable that there was no statistical association between PTK6 IHC or mRNA and the PTK6 gene status. This further emphasizes that overrepresentation of PTK6 appears at the messenger RNA or protein level. Consequently, the altered synthesis and degradation rates of the gene products seem to play a crucial role.

We further show that PTK6 protein expression—but not PTK6 gene status or mRNA expression—is significantly associated with the clinical course of patients. So far, no other study described PTK6 FISH analysis on breast carcinomas with correlation with the clinical outcome. Only one study [9] reported that six of seven high-grade ovarian carcinomas showed PTK6 amplification with an up to 3-fold increase of the PTK6 gene. The authors concluded that gene amplification may be responsible for the observed protein overexpression in ovarian tumors. However, such a small cohort may not allow to draw the conclusion that increased gene dosage may be the reason for protein overexpression. Further, in comparison to our results here with a maximum of eight PTK6 gene signals (corresponding to a 4-fold gene dosage), the level of gene dosage in ovarian carcinomas was up to 3-fold [9]. Compared to other oncogene amplifications in breast cancer, e.g., HER2/neu with >20 gene copies, we would classify those PTK6 gene increases from both studies only as "low level" amplifications. After all, such low-level amplifications in only part of our tumors (15%) cannot account for PTK6 protein overexpression in two thirds of breast carcinomas.

PTK6 has been linked to proliferation of carcinoma cells [35] and represents a potential target for the development of novel cancer therapies based on interfering with its functions [35]. Therefore, it is important to understand how it contributes to the phenotypic effect. Here, we showed that gene amplification cannot account for the protein overexpression in two thirds of breast cancers. Further studies, however, are necessary to define protein–protein interactions and to further uncover therapeutic opportunities.

Clinical relevance of neuroendocrine differentiation in non-small cell lung cancer assessed by immunohistochemistry: a retrospective study on 405 surgically resected cases

Received: 27 May 2009 / Revised: 16 July 2009 / Accepted: 17 July 2009 / Published online: 4 August 2009

Abstract Neuroendocrine differentiation in non-small cell lung cancer is a common feature, which has caused contradictory conclusions concerning survival estimates and responsiveness to therapy. Aiming to clarify this conflict, we analyzed neuroendocrine differentiation by immunohistochemistry in 405 surgically resected non-small cell lung carcinomas using standardized tissue microarray platform and the currently recommended antibody panel consisting of chromogranin-A, synaptophysin, and neural-cell adhesion molecule. Diagnostic criteria provided by the World Health Organization were applied. Histological subtypes were primarily reclassified according to current guidelines, assisted by auxiliary immunohistochemistry. Extensive clinical data was acquired, enabling detailed clinicopathological correlation. Importantly, neuroendocrine differentiation assessed by immunohistochemistry showed no significant relation to overall survival estimates, which remained unaffected by histological subtype, neuroendocrine marker type, adjuvant therapy, and recurring disease. The only exception was a small group consisting of three large cell carcinomas, each expressing all three neuroendocrine markers and demonstrating decreased survival. In conclusion, additional immunohistochemical detection of neuroendocrine differentiation in non-small cell lung cancer is presently not of prognostic importance and does not justify a distinct consideration.

Introduction

Lung cancer is the most common cancer in the world and the leading cause of cancer-related mortality [1]. Nearly all lung cancers are carcinomas and about 80% thereof are non-small cell carcinomas (NSCLC) [2]. Exact histological classification is required for proper therapy and prognostic estimates. Neuroendocrine differentiation may occur in any entity, although the relevance of this feature has not yet been entirely clarified. The four major categories of morphologically distinguishable neuroendocrine lung tumors recognized at present are small cell carcinoma, typical carcinoid, atypical carcinoid, and large cell neuroendocrine carcinoma (LCC-NE), which all show varying degrees of neuroendocrine features by light microscopy [3]. LCC-NE requires additional confirmation of neuroendocrine differentiation by immunohistochemistry [3]. Some pulmonary carcinomas without neuroendocrine morphology by light microscopy demonstrate immunohistochemical expression of neuroendocrine markers and are termed non-small cell carcinoma with neuroendocrine differentiation (NSCLC-ND) [3]. This entity has generated controversial conclusions concerning survival time and responsiveness to chemotherapy resulting in the current

recommendation to note neuroendocrine differentiation in NSCLC without an according separate category. This implies immunohistochemistry or electron microscopy of all NSCLC to determine neuroendocrine expression. Studies report improved [4], decreased [5], and unaffected survival [6] as well as better [4] and worse [7] responses to chemotherapy in NSCLC-ND. Reports also show discrepancies concerning the definition of neuroendocrine differentiation [8], the panel of antibodies used [9], and the interpretation of immunohistochemical results [10], providing possible explanations for such conflicting data. Thus, it still remains to be determined what prognostic significance, if any, is associated with immunohistochemical neuroendocrine differentiation in NSCLC. Furthermore, uniform standards should be followed in order to compare results.

This study analyzes the prognostic significance of neuroendocrine differentiation in 405 surgically resected NSCLC using a standardized tissue microarray (TMA) platform and the currently recommended antibody panel [3, 11]. Diagnostic criteria comply with the current guidelines by the World Health Organization (WHO) [3]. Extensive clinical data for each case enabled detailed evaluation.

Patients, materials, and methods

Cases

NSCLC cases diagnosed at the Institute for Pathology, Medical University of Innsbruck, between 1992 and 2004 were selected from the pathology archives. Cases were selected only based on tissue preservation. Hematoxylin and eosin (H&E) stains from all available slides (whole tumor sample) of all cases were reclassified by two pathologists (W.S. and A.T.) without knowledge of patient information, according to the current WHO classification of tumors of the lung [3]. Categories included squamous cell carcinoma (SCC), adenocarcinoma (ACA), large cell carcinoma (LCC), adenosquamous carcinoma (ASC), pleomorphic carcinoma (PLM), and mucoepidermoid carcinoma (MEC). ACA included growth type (bronchioloalveolar, papillary, acinar, solid, and mixed) as well as mucin status as assessed on alcyan–PAS-stained slides. In morphologically equivocal cases, expression of thyroid transcription factor-1 (TTF-1) and cytokeratin 7 (CK 7) in favor of ACA as well as p63, cytokeratin 34βE12 (CK 34βE12), and cytokeratin 5/6 (CK 5/6) in favor of SCC were also considered for proper tumor classification. LCCs were diagnosed on light microscopy by lack of cytological and architectural features described for small cell, glandular, or squamous differentiation [3] and categorized as LCC "classical" type (LCC-CL) or LCC with neuroendocrine features (LCC-ND). Features suggestive of neuroendocrine differentiation by light microscopy (LCC-ND) consisted of trabecular growth, rosettes, or perilobular palisading patterns [3]. Organoid nesting in LCC-ND was not taken into account because nesting is also a feature described for LCC-CL, and the distinction between organoid nesting and nesting is not clearly defined. LCC-ND with additional immunohistochemical expression of at least one neuroendocrine marker is currently defined as large cell neuroendocrine carcinoma (LCC-NE) [3]. Accordingly, a group of LCC-CL with neuroendocrine differentiation arises (LCC-CLNE). Around 50% of LCC-NE is known to express TTF-1, whereas expression of CK 34βE12 is uncommon [3]. Currently, no specific immunohistochemical profile for LCC-CL is recognized. Extensive necrosis was noted independently of tumor category. Tumors were also regraded according to well, moderate, or poor differentiation. Typical and atypical carcinoids were not included. The clinical information was documented within the TYROL survey (Twelve Years Retrospective of Lung Cancer), a project aiming at analyzing various features of a large number of lung cancer patients. These patients mainly originated from the Austrian county of Tyrol and were all diagnosed and treated at the Medical University Hospital of Innsbruck and associated hospitals (Table 1). Approval for data acquisition and analysis was obtained from the Medical University of Innsbruck Ethics Committee (the local Institutional Review Board). In this project, the basic patients' characteristics including symptoms at presentation, smoking habits, comorbidities, and laboratory parameters, as well as the complete course of treatment modalities, including surgery, all lines of chemo-, and radiotherapy, were documented. Regarding therapy modalities, the patients were routinely discussed at the Medical University of Innsbruck Tumor Board, and a state of the art recommendation of therapy adapted to the condition of the patient was given. Accordingly, there was a continuous shift of therapy modalities routinely applied in this comparably large interval of patients recruited into the survey. Efficacy of the different therapy lines in routine patients can therefore be evaluated in detail [12, 13].

Tissue microarray construction

Tumor material consisted of paraffin embedded tissue after fixation in 10% neutral buffered formalin. Representative tumor areas were marked on H&E stained slides, and four cylindrical 0.6-mm tissue cores each were arrayed from the corresponding paraffin blocks into a recipient block using an arraying machine from Breecher Instruments. The core coordinates were recorded for exact location using Microsoft Excel, and printouts assisted the subsequent immunohistochemical evaluation. Four micrometer-thick paraffin sections were cut from a total of three resulting

array blocks. The first sections were stained with H&E to confirm validity, the following used for alcyan staining and immunohistochemistry (Fig. 1). Adhesive transfer tape was not used.

Immunohistochemistry

Immunohistochemistry was performed using the automated staining system Ventana Benchmark XT by Ventana Medical Systems Inc. The primary antibodies used and their dilutions are listed in Table 2.

Evaluation

Only spots containing at least twenty vital tumor cells were evaluated. If all four spots of a case did not meet this criterion for any marker diagnostic of neuroendocrine differentiation, it was excluded from further analysis. Tumor cells were counted independently by two pathologists (W.S. and A.T.), and the percentage of positive cells were noted for each spot, followed by the calculation of the arithmetic mean value. Staining was considered positive for chromogranin-A (CHA), synaptophysin (SYN), protein gene product 9.5 (PGP9.5), and neuron-specific enolase (NSE) when located within the cytoplasm, usually demonstrating a finely granular pattern. Neural-cell adhesion molecule (N-CAM, CD56) was regarded positive when a membranous pattern was observed. Neuroendocrine differentiation was diagnosed when one marker was positive, excluding PGP9.5 and NSE. Staining for cytokeratins (CK 7, CK 5/6, and CK 34βE12) was considered positive when located within the cytoplasm; positive staining for TTF-1 and p63 was diagnosed when a nuclear pattern was observed. These five auxiliary markers were classified as negative or positive, as with the daily routine practice in Innsbruck and Basel. Actually, there were no cases expressing the respective markers in less than one third of the tumor cells. Staining intensity for neuroendocrine markers was noted as weak, moderate, or strong but not taken into account. Intensity for all other markers was not assessed.

The prognostic relevance of respective markers was assessed by means of receiver operating characteristic-analysis, selecting death as the state variable. Optimal cutoff values were calculated using the Youden index (*J*) [14].

Statistical analysis

Association between variables was analyzed using the Spearman test. Kaplan–Meier curves were calculated for survival estimates and a log-rank statistic used to determine differences between groups. P values <0.05 were considered significant. Statistical calculations were performed using SPSS 15.0 software (SPSS, Chicago, IL).

Results

Reclassification of histology on surgical tumor samples

After revision of all 405 cases using all available tumor material, 207 were diagnosed ACA, 126 SCC, 58 LCC (44 LCC-CL and 14 LCC-ND), 9 ASC, 4 PLM, and 1 MEC. Histological subtypes were altered in 108 cases; the largest group consisting of 31 LCC reverted to ACA, followed by 17 ACA reclassified as LCC. For equivocal cases, auxiliary immunohistochemistry was taken into account (Table 3). The alteration of histological subtype in part of the cases, resulting in modified overall survival estimates, was mainly due to the revised diagnostic guidelines published by the WHO in 2004 as well as extensive immunophenotypic workup of equivocal cases [3].

When comparing cumulative overall survival estimates between original and reclassified histology, a significant

difference of overall survival between the reclassified histologies was noted due to the group of PLM showing extraordinary dismal outcome (Fig. 2a, b). When solely comparing ACA, SCC, and LCC (excluding ASC and PLM), these types did not show any difference in overall survival for the reclassified cases ($p=0.17$). Distribution of pathological tumor stage by Union Internationale Contre le Cancer (UICC) revealed 196 (57%) stage I, 61 (18%) stage II, 54 (16%) stage IIIA, 19 (5%) stage IIIB, and 14 (4%) stage IV. The patient population comprised 290 men and 115 women with an average age of 62 years (range 23 to 83 years).

Tissue microarray evaluation: immunohistochemistry

Three hundred eighty-five cases were valid for evaluation of immunohistochemical expression of CHA, SYN, and N-CAM, revealing 62 (16.1%) NSCLC-ND (Table 4). Calculated potentially prognostically relevant cutoff values were 2% for CHA and 5% each for SYN, N-CAM, PGP9.5, and NSE. Staining was usually focal and weak, except for N-CAM, which mostly demonstrated a moderate intensity. Strong staining was only noted for CHA in one ACA, for N-CAM in one LCC, and for SYN in three LCC. LCC and ACA demonstrated neuroendocrine expression more

frequently than SCC ($p<0.001$ and $p=0.001$). Six tumors were positive for two neuroendocrine markers. Coexpression of SYN and CHA was found in two ACA as well as in two LCC. Coexpression of SYN and N-CAM was detected in one case each of LCC and ASC. A positive combination of CHA and N-CAM was not present. Only three cases were positive for all three markers, and restricted to LCC-CL. Altogether, LCC-CL revealed 11/42 (26%) and LCC-ND 5/14 (36%) cases with neuroendocrine marker expression.

Tissue microarray evaluation: survival analysis

There was no significant difference in overall survival time when comparing NSCLC without neuroendocrine differentiation to NSCLC-ND (Fig. 2c). This remained unaffected by histological subtype, neuroendocrine marker type, adjuvant therapy, and recurring disease. A further clinical substratification for overall survival analysis was not feasible due to the many various settings of therapies (e.g., neoadjuvant, adjuvant, palliative; chemotherapy, radiotherapy, combination of both). Concerning the amount of positive markers, a significantly reduced survival time ($p=0.044$) was determined only for triple positive NSCLC-ND when compared with all other NSCLC. The former group consisted of only three cases, exclusively LCC-CLNE, two in pathological UICC (pUICC) stage IIIA and one in stage II. Analyzed only within the LCC group, this statistical significance was not apparent.

Discussion

The present study demonstrated that neuroendrocine differentiation is a common phenomenon in NSCLC, being present in 16% of cases overall, which is consistent with the commonly reported 10–20% [3]. This confirms the applied antibody panel as well as staining interpretation, calculated cutoff values, and the representativeness of the study material.

In accordance with previous reports, neuroendocrine differentiation was not associated with a significant difference in overall survival [10, 15]. Others, however, have reported contradictory results demonstrating decreased [16] as well as increased [17] survival times, particularly when smaller cohorts were analyzed, or the chosen antibodies did not meet current recommendations for diagnosis of neuroendocrine differentiation. To strengthen validity, the present study evaluated a large number of patients as recommended by Howe et al. and applied a standardized TMA platform [10]. TMA technique offers an ideal method to evaluate a large number of cases. Compared with standard viewing of slides, this approach reduces staining variations and minimizes observer differences since (1) all samples are processed and evaluated in one day, which minimizes biases due to staining variability and daily variations in the gaging of the observer, and (2) interpretation of immunostains is based on the findings within a well-defined small area of well-preserved tissue (and not immunohistochemical "hot spots") in which absolute cell counts can be easily assessed to determine the percentage of positively stained cells [18]. Quadruplicate cores, as analyzed here, improve accuracy compared with the usual duplicate core method and reduce microheterogeneity biases to a neglectable minimum [19].

Concerning prognostic relevance, the present data showed no correlation between histological subtype, neuroendocrine marker expression, and overall survival. Others, however, have linked ACA to a worse prognosis when neuroendocrine expression was present [16, 20]. LCC showed the highest rate of neuroendocrine differentiation, with three cases positive for all three neuroendocrine markers diagnostic of NSCLC-ND. All three patients had a short survival, which, primarily, may be attributed to their locally advanced stages at initial diagnosis. When examining neuro-

endocrine differentiation within the histological subtypes, LCC and ACA were those with the largest proportion of neuroendocrine differentiation which is in accordance with previous reports focusing on ACA [15, 21]. Other groups failed to define a correlation between neuroendocrine differentiation and histological NSCLC subtype [5, 10].

In our study, we had four groups of LCC, which resulted from a simple algorithm: either LCC-CL or LCC-ND by light microscopy, followed by the possible presence of neuroendocrine differentiation by immunohistochemistry, resulting in the additional groups LCC-CLNE and LCC-NE, respectively. Only LCC with immunohistochemical confirmation of neuroendocrine differentiation (LCC-CLNE and LCC-NE) were included in the group of NSCLC-ND. It has been stated that LCC-ND consistently demonstrates immunoreactivity for neuroendocrine markers [16], which was not the case here. Indeed, 5/14 (36%) of LCC with definite neuroendocrine features by light microscopy showed expression of neuroendocrine markers, thus representing the group with the highest proportion of cases with neuroendocrine phenotype, but, importantly, 9/14 (64%) of those tumors with definite neuroendocrine features by light microscopy (trabecular growth, rosettes, perilobular palisading patterns) were negative for all markers. This emphasizes the necessity of additional confirmation of neuroendocrine differentiation by immunohistochemistry using the immunhistochemical markers CHA, SYN, and N-CAM for the diagnosis LCC-NE, independent of neuroendocrine morphology by light microscopy, as required by the WHO [3]. We applied this approach to NSCLC subtypes other than LCC-ND for defining neuroendocrine differentiation since no separate guidelines are provided. LCCs with neuroendocrine differentiation are known to have a worse overall survival rate than stage-comparable NSCLCs without neuroendocrine differentiation and should benefit from a systemic adjuvant standard small cell lung cancer (SCLC)-based chemotherapy [22, 23]. Marchevsky et al. even claimed that LCC-NE and SCLC should be merged as a single group of high-grade neuroendocrine carcinomas [24]. A resulting debate, which occurred, was whether to exclude LCC with neuroendocrine differentiation from survival analysis. This is not a straightforward matter since two morphologically different groups were present within LCC demonstrating neuroendocrine differentiation (LCC-CLNE and LCC-NE). Complicating matters further is the group of LCC with light microscopical features of neuroendocrine differentiation though lacking immunohistochemical confirmation (LCC-ND). Which entity or entities deserve exclusion? Does a logical or validated approach exist? The present study aims at analyzing neuroendocrine differentiation in NSCLC since this entity is still controversial. Unfeasible comparison between studies is often due to differences regarding inclusion criteria, interpretation of results, and lack of generally accepted definitions. With this in mind, we used the current diagnostic criteria by the WHO to design our study [3]. We acknowledge that this is not optimal, considering the behavior of LCC with neuroendocrine differentiation. On the other hand, accurately following current recommendations has the advantage of reproducibility, comparability, and less bias, which is what we opted for here. From the clinical point of view, it would be worth studying a large collective of LCC-CLNE and LCC-NE, whether the response rates to chemotherapy and survival rates are similar. In our small series of 5 LCC-NE and 11 LCC-CLNE cases, we found no survival differences (data not shown).

Some of the previously mentioned differences between studies concerning prognostic value of phenotypic neuroendocrine differentiation in NSCLC may be due to inconsistencies of the panels of antibodies used. Another source of discrepancy is the determination of cutoff values for positive staining results and incorporation of staining intensity into “scores” [10]. Evidence suggests that staining intensity is particularly prone to variation between cases, runs, and batches due to different tissue preservation, applied batches, detection/amplification systems, and even to minimal changes in chromogen incubation duration [25]. Interestingly, by incorporating staining intensity to determine neuroendocrine differentiation, only two more cases would have been positive, raising the incidence by a mere 0.5%. This suggests that staining intensity may be disregarded when assessing neuroendocrine differentiation. Studies using the same antibodies have reported relative proportions of N-CAM> SYN>CHA [10]. In our series, however, SYN was the most frequently positive marker, followed by N-CAM and CHA. NSE revealed positive staining results comparable to SYN, which does not entirely reflect its reported low specificity [10]. PGP9.5, on the other hand, was positive in 58% of the specimens and should not be considered as part of a diagnostic panel when examining neuroendocrine expression due to obviously lacking specificity.

Why at all is it a matter of interest to discriminate NSCLC into two subentities characterized by neuroendocrine differentiation? Indeed, the entity NSCLC-ND has generated many controversial conclusions concerning survival time and responsiveness to therapy. We conclude that, in addition to classical light microscopy analysis, neuroendocrine immunohistochemical subdifferentiation of NSCLC is not of high importance in terms of clinical consequences at present, except for LCC-NE, in which cases with phenotypic expression of multiple neuroendocrine markers might be accompanied by a worse outcome. With the development of new targeted therapies, this insignificance may change, and more differentiated, tailored treatment modalities may aim at phenotypic profiles studied here.

Conflict of interest statement The authors declare that they have no conflict of interest.

Abstract Histamine is involved in the pathogenesis of several tumors; however, there are no data on its possible involvement in human adrenocortical tumorigenesis. The expression of genes and proteins involved in the biosynthesis (histidine decarboxylase, HDC), action (histamine receptors: HRH1–HRH4), and metabolism of histamine is largely unknown both in the normal human adrenal cortex and in adrenocortical tumors. In this study, we examined the expression of histamine-related genes and proteins and histamine content in normal adrenal cortex, benign adrenocortical adenomas, and malignant adrenocortical cancer (ACC). Fifteen normal adrenals and 43 tumors were studied. mRNA expression was examined by real time RT-PCR. Western-blotting and immunohistochemistry were used for the study of proteins. Tissue histamine content was determined by enzyme-linked immunosorbent assay. We found that all proteins involved in histamine biosynthesis and action are present both in the normal adrenal cortex and in the tumors studied. HDC expression and histamine content was highest in the normal tissues and lower in benign tumors, whereas it was significantly less in ACCs. HRH3 expression was significantly higher in ACC samples than in the other groups. Adrenocortical tumorigenesis might, thus, be characterized by reduced histamine biosyn-

Introduction

The biogenic amine histamine is involved in the regulation of numerous physiological and pathological processes. Histamine has been implicated in the pathogenesis of several human tumors, e.g., malignant melanoma [1], breast [2], colon cancer [3–5], and pancreatic endocrine tumors [6]. In malignant melanoma and breast cancer tissues, histamine may act as an autocrine growth factor being secreted by the tumor cells themselves [1, 2]. Although there are some reports on the action of histamine on adrenal functioning, the relevance of histamine in normal adrenal gland physiology is not clear, and there are no data on its possible involvement in adrenal tumorigenesis.

Adrenal tumors are common; their prevalence reaches up to 5–9% in pathological series [7]. More than 80% of adrenal tumors are of adrenocortical origin. The majority of these tumors are hormonally inactive benign adenomas, but cortisol- or aldosterone-producing adenomas are also found. If left untreated, hormonally active benign tumors are associated with significant morbidity and mortality [8]. Adrenocortical carcinoma (ACC) is rare, and its prognosis is poor with an overall 5-year survival below 30% [9–11]. The pathogenesis of sporadic adrenocortical tumors is poorly elucidated. In this study, we attempted to characterize the expression of histamine-related genes and proteins both in normal and neoplastic adrenocortical tissues.

Histamine is synthesized from the amino acid L-histidine by the single enzyme histidine decarboxylase (HDC). Its action is realized via four receptors: histamine receptor 1 (HRH1) is a major regulator of allergic responses, histamine receptor 2 (HRH2) is involved in the regulation of gastric acid secretion, and both of them are involved in many immune processes and tumorigenesis, as well. Histamine receptor 3 (HRH3) is primarily localized on the presynaptic membranes of central nervous system neurons. The recently discovered histamine receptor 4 (HRH4) is mostly involved in immune cell migration and inflammatory mediator release [12]. Two enzymes, the diamino-oxydase (DAO) and histamine-*N*-methyltransferase (HNMT), are involved in histamine degradation [13, 14].

Most available data on the relevance of adrenal histamine involve adrenomedullary actions. The first described action of histamine on adrenal functioning was the stimulation of catecholamine secretion that did not depend on splanchnic nerve innervation [15]. Histamine was found to be present in the adrenal gland: immunhistochemical studies of adult rat adrenal glands localized histamine to clusters of noradrenergic chromaffin cells in the medulla but failed to detect it in nerve fibers, adrenaline-containing chromaffin, and cortical cells [16]. HDC immunoreactivity has been documented both in normal human adrenomedullary chromaffin cells, as well as in human adrenomedullary tumors (phaeochromocytomas) [17]. Histamine evoked catecholamine secretion from bovine chromaffin cells via HRH1 [18]. HRH2 mRNA expression was detected in guinea pig adrenal medulla [19], but there is no evidence for expression of functional HRH3 and HRH4 receptors in chromaffin cells [20].

The expression pattern of histamine-related genes and proteins in the normal human adrenal cortex and adrenocortical tumors is unknown.

Materials and methods

Tissue samples

The study, approved by the Ethical Committee of the Hungarian Health Council, involved 58 tissue samples: 18 hormonally inactive adenomas (all from females, mean

age=49.4, range=30.8–61.8 years), eight cortisol-producing adenomas (CPA; seven females and one male, mean age=38.3, range=24–46.8 years), nine aldosterone-producing adenomas (APA; six females and three males, mean age=45.9, range=20.7–69.1 years), eight ACC (six females and two males, mean age=55.9, range=26.1–70.4 years), and 15 normal adrenal tissues (11 females and four males, mean age=49.7, range=19.3–67.9 years). All patients were of Caucasian descent. All malignant adrenocortical tumors were cortisol-secreting. Only tumor samples where clinical, laboratory, and histological data were all available and clear-cut were included in our study. Normal adrenocortical tissues were obtained from adrenal glands removed during operations for kidney tumors.

Immunohistochemistry

Formalin-fixed and paraffin-embedded tissues were cut and mounted onto SuperFrost slides. Specimens were deparaffinized, then two slides were stained with hematoxylin–eosin and toluidine blue [21]. Immunohistochemistry was carried out on a Ventana ES automated staining system (Ventana Medical Systems, INC, Tucson, AZ, USA) according to the instructions of the manufacturer. Rabbit polyclonal anti-human HRH1 (H1R12-A), HRH2 (H2R21-A), HRH3 (H3R32-A), HRH4 (H4R41-A; Alpha Diagnostic International, San Antonio, TX), HDC (ab37291), HNMT (ab63147; Abcam plc, Cambridge, UK), and DAO (WH0001610M1; Sigma–Aldrich Corp., MO, USA) antibodies at a dilution of 1:100 and iWIEW DAB Detection Kit (Ventana Medical Systems, INC, Tucson, AZ, USA) for automatization were used. Cleaned coverslips were mounted on the slides using Tissue Tek GLC Class Coversiper with GLC Mounting Medium (Sakura Finetek Europe B.V., Zoeterwoude, The Netherlands). Immunostainings were examined by a Nikon Eclipse i80 microscope (Nikon Spot Advanced Program, Nikon, Tokyo, Japan). Normal human colon and antral stomach tissues were used as positive controls. All negative controls, performed by omitting the primary antibodies, demonstrated negligible background.

RNA isolation, reverse transcription, and QRT-PCR

Samples were snap frozen in liquid nitrogen immediately after adrenalectomy. Total RNA was isolated using RNeasy Lipid tissue Mini Kit (Qiagen GmbH, Hilden, Germany). RNA quality was verified by an Agilent 2100 bioanalyzer (Agilent Tech. Inc., Santa Clara, CA, USA). Samples with RNA integrity number above 7.0 were used. One microgram RNA was transcribed to cDNA using high capacity cDNA Reverse Transcription Kit (Applied Biosystems, Foster City, CA, USA). QRT-PCR was performed by TaqMan Fast Universal Master Mix on a 7500 Fast Real-Time PCR system according to the manufacturer's instructions. TaqMan assays were used as follows: HDC (Hs00157914_m1), human HRH1 (Hs00911670_s1), HRH2 (Hs00254569_s1), HRH3 (Hs00200610_m1), HRH4 (Hs0222094_m1), histamine-*N*-methytransferase (HNMT, Hs00199373_m1), DAO (Hs00266481_m1), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH, Hs02758991_g1) as internal housekeeping gene (all materials from Applied Biosystems, Foster City, CA, USA). All samples were run in triplicate. Normalized signal levels were calculated using the comparative CT ($\Delta\Delta$CT) [22] method relative to GAPDH according to the manufacturer's instructions (SDS program, Applied Biosystems, Foster City, CA, USA).

Western-blotting

Tissue samples were lysed in lysis buffer (10 nM Tris-HCL (pH 8.0), 10 mg/ml leupeptin, 0.5 mM EGTA, 25 mM PMSF, 2% NaF, 1% Triton X-100, 2% Na-orthovanadate). Fifteen-microgram heat-denaturized and β-mercaptoethanol-treated protein samples were loaded on 10% Ready Gel Tris-HCl gels (Bio-rad Lab., Hercules, CA, USA) and blotted to PVDF-membranes (Bio-rad Lab., Hercules, CA, USA). Membranes were probed with rabbit anti-human polyclonal HRH1 (H1R12-A), HRH2 (H2R21-A), HRH3 (H3R32-A), HRH4 (H4R41-A; all from Alpha Diagnostics Int., San Antonio, TX, USA), HDC (ab37291), and HNMT (ab63147; Abcam plc, Cambridge, UK) antibodies at concentrations of 1 μg/ml. Secondary peroxidase-conjugated goat polyclonal anti-rabbit IgG (Sigma–Aldrich Corp., MO, USA) antibodies were used at a concentration of 0.1 μg/ml. As loading control, rabbit anti-β-actin antibody (A5060; Sigma–Aldrich Corp., MO, USA) was applied (concentration=1 μg/ml). Specificity of primary antibodies has been previously checked with blocking peptides [3]. Relative protein expression levels were calculated from X-ray film densitometry data normalized to the respective β-actin bands. Image analysis was done using Fluorchem 8000 image analysis platform and the Chemilmager 5500 image analysis software package (Alpha Innotech Corp., San Leandro, CA, USA).

ELISA

Histamine was extracted from 100 mg of homogenized sample by 0.2 M perchloric acid and 1 M potassium borate. All measurements of histamine concentration were performed using EIA Histamine Kit (Beckman Coulter, Inc., Fullerton, CA, USA) according to the manufacturers' instructions. Absorbance was measured at 405 nm on a microplate reader (Multiskan MS, Labsystems, Finland).

Detection of mast cells

The presence of mast cells was examined by toluidine blue staining [21] and CD117 (c-kit receptor) immunohistochemistry [23, 24] in normal adrenal tissue samples. Immunohistochemistry was performed as above.

Statistical analysis

Results were analyzed by one-way ANOVA with Scheffé post hoc test using the STATISTICA 7 and Microsoft EXCEL softwares (Microsoft Inc., Redmond, WA, USA).

Results

Immunohistochemistry of histamine-related proteins in normal adrenocortical tissues

HDC was detected in all three layers of the adrenal cortex (zona glomerulosa, fasculata, and reticularis; Fig. 1a).

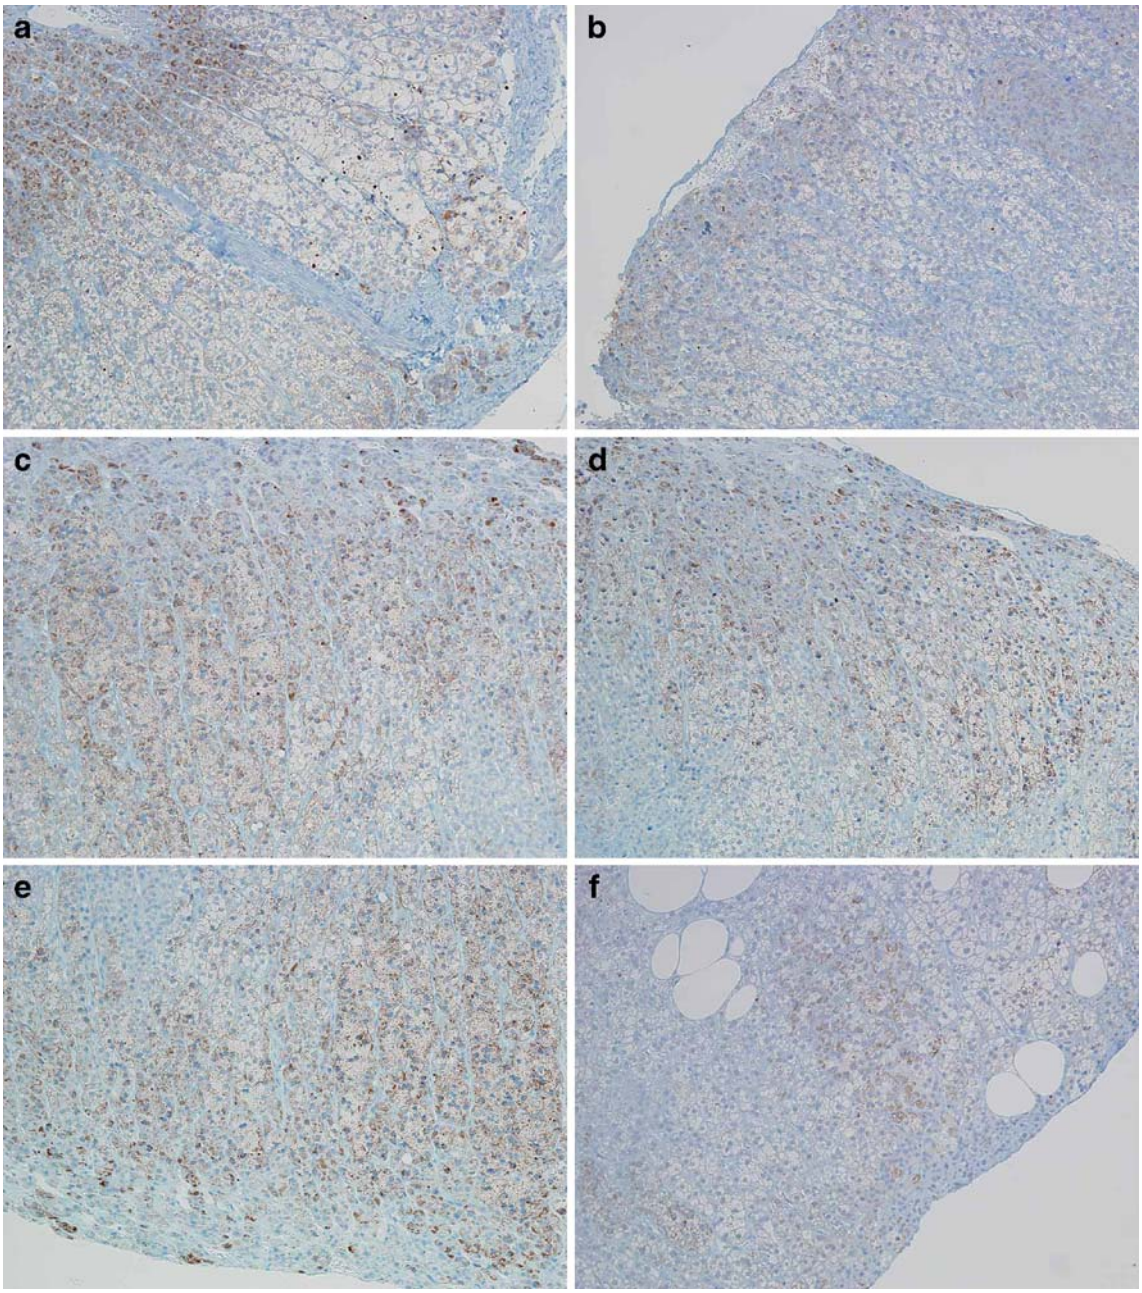

Fig. 1 Immunohistochemistry of histamine-related proteins in the normal adrenal cortex (representative images). **a** HDC, **b** HRH1, **c** HRH2, **d** HRH3, **e** HRH4, **f** HNMT (magnification ×20)

HRH1 immunohistochemistry showed focal staining in all adrenocortical layers (Fig. 1b). HRH2 and HRH3 were positive in the fasciculata and reticularis layers, but they were absent from the zona glomerulosa (Fig. 1c, d). HRH4 showed focal staining in the zona fasciculata (Fig. 1e). HNMT was colocalized with HDC in all three layers (Fig. 1f). DAO was undetectable (data not shown).

The pattern of HDC and HNMT immunohistochemistry was dot-like cytoplasmic. HRH1 and HRH2 immunohistochemistry revealed diffuse cytoplasmic staining, whereas HRH3 and HRH4 expression was dot-like. Available literature data on HRH1 and HRH2 expression in epithelial and mesenchymal cells show similar staining patterns (e.g., basolateral cytoplasmic in gastric epithelial cells and dot-like cytoplasmic in chondrocytes) [25, 26].

Having confirmed the presence of all proteins involved in histamine physiology in the normal adrenal cortex at the protein level, we next examined their mRNA and protein expression in adrenocortical tumors.

Expression of HDC and histamine content in adrenocortical tumors

HDC expression was detected in all examined tumors both at the mRNA and protein levels. Both quantitative real-time PCR and Western-blotting showed that the expression of HDC mRNA and protein was the highest in the normal adrenal cortex and benign hormonally inactive adenomas, somewhat lower in hormone-producing adenomas, whereas significantly lower expression was found in the ACC group (Fig. 2a–c). Immunohistochemical analysis revealed the presence of HDC in both benign and malignant tumor cells (Fig. 2e, f). Having proven the presence and different expression of the histamine biosynthetic enzyme HDC in adrenocortical samples, we next examined whether histamine content (by ELISA) of normal and neoplastic adrenocortical tissues was different. Parallel to the results of HDC mRNA and protein expression, histamine content was significantly lower in all tumor samples compared to normal adrenocortical tissues (Fig. 2d).

Histamine receptors in adrenocortical tumors

Quantitative RT-PCR and Western-blotting studies failed to demonstrate any significant differences in the expression of HRH1 (Fig. 3a, b). Expression of HRH2 was significantly lower in CPA and APA (Fig. 3c, d) and HRH4 showed significantly lower expression in CPA compared to normal adrenocortical tissues and other tumors (Fig. 3g, h). HRH3 expression was significantly higher both at the mRNA and protein levels in malignant tumors than in both normal tissues and benign tumors (Fig. 3e, f and 4). All types of histamine receptors were detected in adrenocortical tumor cells by immunohistochemistry (data not shown).

Histamine metabolizing enzymes

HNMT was detected both by Western-blotting and immunohistochemistry; however, no differences in expression were found either at the mRNA or protein levels (Fig. 3i, j). DAO was undetectable both at the mRNA level and by immunohistochemistry (data not shown).

Detection of mast cells

We have not detected metachromatic cells characteristic for mast cells by toluidine blue staining and only very few c-kit-positive cells were found by immunohistochemistry (data not shown).

Discussion

The present study provides novel data on the expression of histamine-related genes and proteins, and histamine content in the normal human adrenal cortex and adrenocortical tumors. We demonstrated the expression of HDC, HNMT, and all histamine receptors both at the mRNA and protein levels in the normal adrenal cortex and compared these data to those observed in various benign and malignant adrenocortical tumor subtypes. We found significant differences in HDC expression, histamine content, and receptor expression profiles.

Only few studies on the adrenocortical actions of histamine have been reported to date, and these presented contradictory results [27–30] that may be in part due to species differences. Yoshida et al. failed to detect any effect of histamine on basal cortisol secretion of isolated bovine adrenocortical cells; however, if co-cultured with bovine adrenomedullary cells, histamine dose-dependently induced cortisol secretion acting indirectly via the stimulation of adrenomedullary catecholamine secretion [27]. In another study, however, performed on isolated human adrenocortical cell cultures without adrenomedullary cells, histamine decreased aldosterone and cortisol and increased dehydroepiandrosterone sulfate (DHEAS) production [28]. When histamine was administered together with adrenocorticotropin (ACTH), it increased ACTH-stimulated DHEA production, decreased ACTH-stimulated cortisol and aldosterone production, and did not affect ACTH-stimulated DHEA levels [29]. The molecular mechanism of these actions was unclear, but a direct action of histamine on adrenocortical cells may be supposed. There have been no available data on the expression of histamine receptors in the normal human adrenal cortex.

Mean±SE. *$p<0.05$,+*control* positive control (mRNA from antral stomach mucosa)

Our study may present a possible basis for these phenomena, as all histamine receptors were detected in adrenocortical cells. It seems, therefore, likely that histamine may directly influence the functioning of the human adrenal cortex without the intervention of adrenomedullary cells. Previous reports indicated that HRH1 may be implicated in the regulation of steroid hormone production in normal adrenocortical cells [28, 29]. We identified HRH1 on both normal and neoplastic adrenocortical cells; however, no difference was noted in HRH1 expression in the tissues studied.

HDC immunoreactivity has been described both in rat and human adrenomedullary chromaffin cells [16, 17]. Our results show that all three layers of the adrenal cortex harbor HDC-positive adrenocortical cells, as well. In addition, the quantity of HDC-positive cells in our samples was invariably much higher in the cortex than in the medulla (data not shown).

Mast cells are considered to be the major cellular source of histamine in most tissues [31]. In the rat adrenal gland, mast cells have been detected in the adrenal capsule. ACTH appears to increase adrenal blood flow via the induction of

mast cell degranulation. Both mast cell-derived histamine and serotonin may be implicated in this phenomenon [32]. Lefebvre et al. detected isolated, perivascular mast-like cells in the human adrenal cortex [33]. Serotonin secreted by these cells stimulated adrenocortical cortisol secretion and may, thus, be implicated in the paracrine regulation of cortisol release [33].

In the study by Aiba et al., abundant mast cells were found in a rare 11-deoxycorticosterone-producing adrenocortical tumor but were absent from CPAs. Few mast cells were identified in some normal adrenocortical tissues and several in APA samples [34]. Serotonin released by mast-like cells in APAs may exert a tonic stimulatory effect on aldosterone secretion and may, thus, be implicated in the pathophysiology of these tumors [35].

In contrast with serotonin that seems to be exclusively produced by intraadrenal mast-like cells in the normal adrenal cortex [33], our studies show that the histamine biosynthetic enzyme HDC is mostly expressed by the adrenocortical cells. The regulation of secretion of these two major biogenic amines, thus, seems to be different in the adrenal cortex.

We revisited the question of mast cell presence in the normal adrenal cortex both by toluidine blue staining [21] as well as c-kit (CD117) immunohistochemistry that is regarded as a specific detection method for mast cells [23, 24]. Only few c-kit-positive cells were found in our samples. Zhang et al. failed to detect c-kit-positive cells in the normal adrenal cortex [36]. Moreover, histamine content in APA samples (that were previously shown to harbor several mast cells [34]) has been significantly inferior to that in normal adrenocortical samples. This may support our hypothesis that mast cells do not represent a major source of histamine either in the normal cortex or in adrenocortical tumors. It can, therefore, be concluded that adrenocortical cells may be an important source of adrenal histamine in humans.

Histamine is involved in the pathogenesis of several tumors. These effects are realized via both direct histamine–tumor interactions and indirect tumor–stroma interactions [2]. In human melanoma cell lines, histamine may act as an autocrine growth factor inducing tumor progression via HRH1 and HRH2 [37]. In transgenic BF16-F10 melanoma cells, higher HDC expression induced tumor progression in vivo [38]. Furthermore, histamine may also influence tumor progression via modulation of antitumor immunity. Histamine may dysregulate the local balance between Th1, Th2, and Treg lymphocytes in neoplastic tissues [39]. Systematic histamine treatment decreased Th1-promoting IL-12 and IFN-γ expression and increased Th2-facilitating IL-10 expression in murine colorectal tumor implants [40].

HDC immunoreactivity was detected in all adrenocortical tumors studied, and malignant adrenocortical cancer tissues were characterized by significantly decreased HDC expression. Histamine content was significantly lower in both benign and malignant tumors. Reduced expression of some other genes and proteins has already been described in ACC (e.g., aldo-keto reductase family 1, member B1 (*AKR1B1*) and *novH*) that, together with the loss of HDC expression, may be interpreted as signs of loss of differentiation [41].

Remarkable differences in histamine receptor expression were also noted. Benign hormone-secreting adenomas (CPA and APA) displayed significantly lower HRH2 expression, and HRH4 was significantly lower in CPA than in hormonally inactive benign tumors or ACC. The marked overexpression of HRH3 (10-fold relative to normal) in ACC that is a non-neuronal tumor is noteworthy.

Signaling of histamine receptors involves mainly G-protein-mediated pathways. HRH2 is primarily associated with cyclic AMP (cAMP) accumulation, whereas HRH3 and HRH4 activation mostly inhibits adenylate cyclase activity [42, 43]. Alterations of the ACTH-cAMP-PKA pathway may be involved in adrenocortical tumorigenesis, but several contradictory findings have been reported to

date [44]. Germline mutations of the *PRKAR1A* gene were identified in Carney complex involving primary pigmented nodular adrenocortical disease [45].

If the relative underexpression of HRH2 in CPA and APA, together with the overexpression of HRH3 in cortisol-secreting ACCs, were considered, one might have the impression that histamine might be associated with reduced cAMP signaling in hormone-secreting tumors. It should also be taken into consideration, however, that the histamine content in all tumors was significantly lower than in normal tissues, and no studies on histamine receptor signaling in adrenocortical tissues have been performed to date.

In contrast with other neoplasms, where histamine seems to act in a tumor-promoting manner (malignant melanoma, gastric, and colorectal cancer), we found decreased histamine content and HDC expression in malignant tumors. It is, therefore, likely that the action of histamine is different in tumors of various organs. The significant differences among histamine receptor expression patterns may also have pathogenetic relevance; however, it is very difficult to interpret these findings without the mastery of histamine effects on adrenal functioning and gene expression in normal and neoplastic adrenocortical cells. Further, in vitro studies on adrenocortical cell cultures and cell lines are necessary to elucidate the physiological and pathophysiological relevance of histamine.

In conclusion, these findings raise the possibility that histamine might be involved in the pathogenesis of adrenocortical tumors. Expression of histamine-related genes and proteins was detected in both normal and neoplastic adrenocortical tissues; thus, the whole histaminergic machinery including biosynthetic and degrading enzymes as well as histamine receptors were found to be present. Since histamine mainly acts in a paracrine fashion, its secretion by adrenocortical cells might influence steroid biosynthesis, adrenocortical blood flow [30, 32], immune response, etc. Further, experimental studies (e.g., actions of histamine receptor agonists and antagonists on adrenocortical cancer cell lines) are needed to clarify the relevance of histamine in the normal adrenal cortex and to examine the consequences of decreased histamine biosynthesis and altered receptor repertoire in adrenocortical tumor development.

Lymphangiomatoid pattern in diffuse malignant mesothelioma of the pleura: a report of six cases

Ruchira Ruangchira-urai · Eugene J. Mark

Received: 30 March 2009 / Revised: 3 June 2009 / Accepted: 17 June 2009 / Published online: 18 July 2009

Abstract The multiplicity of epithelioid and mesenchymal forms of diffuse malignant mesothelioma includes patterns that may mimic another process. Identification of the multiplicity of patterns may help in the diagnosis of diffuse malignant mesothelioma. One pattern that has not been described is lymphangiomatoid. We observed six cases with ovoid or elongated or irregular anastomosing vascular-like spaces lined by flattened cells simulating lymphangioma. The luminal spaces could contain proteinaceous material simulating lymph but not erythrocytes. The cells lining the spaces were mesothelial by immunohistochemical staining. The lymphangiomatoid areas never constituted more than 40% of the area of the tumor on the slides. When seen in more solid areas of tumor, the lymphangiomatoid structures generally did not produce diagnostic difficulty. However, when seen at the edge of solid tumor or forming an irregular nodule or invading into adjacent adipose tissue, these lymphangiomatoid structures could be confusing. All six patients had been exposed to asbestos either by occupation or by spousal exposure. Three patients received chemotherapy. One patient died of diffuse malignant mesothelioma of the pleura.

Introduction

Diffuse malignant mesothelioma (DMM) can have epithelioid or mesenchymal attributes, and a combination of the two together is useful in the diagnosis. The epithelioid and mesenchymal aspects reflect the histogenesis of the mesothelial cell as it arises from the schizocoelom, whereby mesenchymal tissue separates to form a cavity and the resulting surface cells acquire both mesenchymal and epithelioid attributes.

The epithelioid forms include solid epithelioid areas, squamoid solid areas, stranding, complex lace-like network, papillae, cotyledonous structures, deciduoid cells, glomeruloid features, insular features, macrocysts, microcysts, jelly roll-like structures, lymphohistiocytoid forms, tubuloglandular structures, small cells, clear cells, foam cells, and rhabdoid cells [1-16]. Transitions between these epithelioid forms generally occur.

In the course of reviewing several hundred cases of malignant mesothelioma, we observed seven cases where a large portion of the tumor resembled lymphangioma to a degree that the pattern could lead to an erroneous consideration of a lymphatic proliferation including either lymphatic dilatation due to obstruction or lymphangiomatosis or lymphangioma.

A pattern resembling lymphangioma in DMM has not been described to our knowledge and constitutes this report.

Materials and methods

Four hundred and seventy-two cases of DMM reviewed in consultation form the basis for the data in this report. These cases were tabulated with an emphasis on distinctive

Table 1 Clinical features of six DMMs with lymphangiomatoid pattern

Case	Age/sex	Signs and symptoms	Radiological findings	Operative findings	Treatment	Exposure to asbestos
1	69/M	SOB	Rt pleural effusion and a pleural mass	Rt lung encased with thick and dense fibrous peel	Partial decortication; chemotherapy	Laborer and maintenance helper
2	55/M	SOB and nonproductive cough	Lt pleural effusion, pleural thickening and calcification	NA	Talc pleurodesis; radical extrapleural pneumonectomy; intraoperative heated chemotherapy	Household exposure through his father, who worked as a laborer Father's uncle with DMM Great uncle and aunt with asbestosis
3	74/M	SOB	Rt pleural effusion, circumferential nodular pleural thickening and bilat pleural plaques	Extensive pleural based nodules	NA	Laborer, seaman, carpenter, drywaller and tile installer
4	67/M	Dyspnea, weight loss, and recurrent pleural effusion	Pleural effusion	White deposits in pleura	Talc pleurodesis; chemotherapy	Laborer and paper machine worker
5	82/F	SOB	Rt pleural effusion and loss of volume at the lung base	Marked thickening pleura	NA (Died 4 months after Dx)	Exposed through her husband, who worked as a millwright and mechanic
6	72/M	SOB	Lt pleural effusion with pleural based masses and bilat plaques	NA	NA	Worked around boilers

Bilat bilateral, *DMMs* diffuse malignant mesotheliomas; *Dx* diagnosis; *F* female; *Lt* left; *M* male; *NA* not available; *Rt* right; *SOB* shortness of breath

patterns of growth of both epithelioid and mesenchymal forms of DMM. Six cases of DMM of the pleura showed lymphangioma-like areas and constitute the body of this report. A seventh case of a malignant mesothelioma of the peritoneum with such a pattern was also encountered. All seven cases were medical-legal in origin. As the slides could not be retained, we recorded detailed histologic description and digital photomicrographic images in addition to clinical history and treatment record and exposure to asbestos.

Immunohistochemical staining had been done at the original laboratory in all cases. Because of the multiple laboratories involved, a variety of markers were performed,

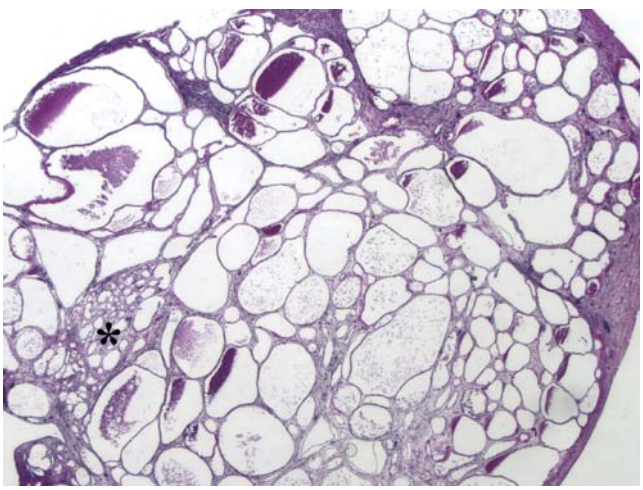

Fig. 1 Ovoid spaces lined by flattened cells and containing pink proteinaceous material mimicking lymphatic spaces. A small adenomatoid component (*asterisk*) is present

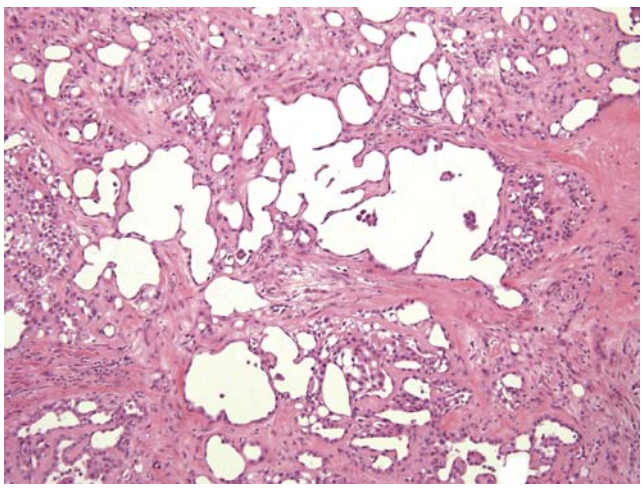

Fig. 2 Irregularly contoured and branching and serpentine structures lined by flattened cells

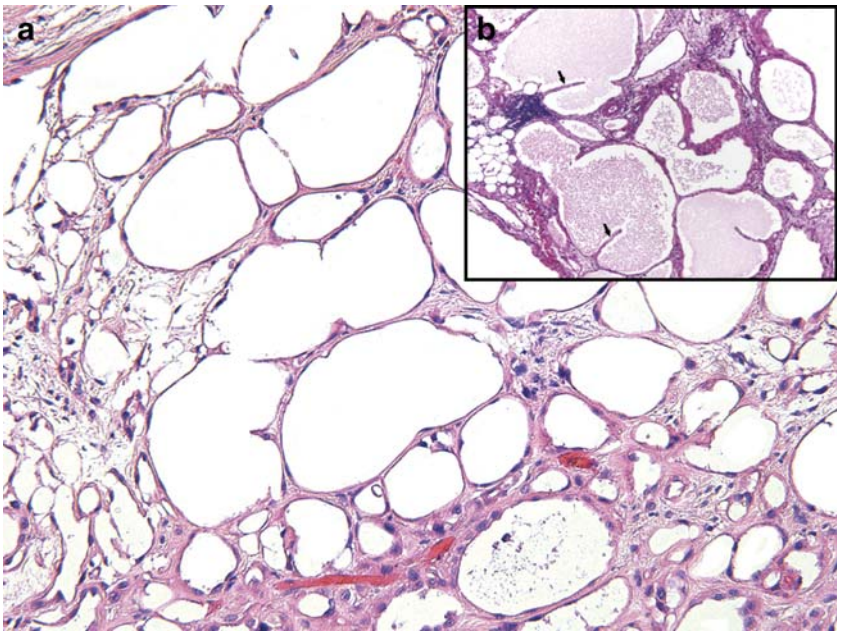

Fig. 3 Thin membranous structures forming vascular-like spaces, and filled with proteinaceous material (*inset*) and with valve-like structures (*arrows*)

including AE1/AE3, calretinin, CK5/6, CK7, CK20, WT-1, vimentin, MOC-31, D2-40, CEA, HBME-1, TTF-1, B72-3, BerEp4, CDX2, CD15, desmin, prostate-specific antigen, and prostate-specific acid phosphatase. Stains for keratins and calretinin were performed in all cases. Among other markers, staining for D2-40 was performed in two cases. The immunohistochemical stains were performed at multiple laboratories. Because these were cases referred for medical legal reasons, blocks were not available to perform additional staining, and this would include endothelial markers other than WT-1 and D2-40.

Results

Patient demographics and clinical findings

The summary of the patients' clinical features including occupational exposure to asbestos are given in Table 1. Five of the patients were males, and one was female. The age range was 55 to 82 years with a mean of 69.8 years. All patients presented with shortness of breath. Three patients were treated with chemotherapy, one with pleural decortication, and one with radical extrapleural pneumonectomy.

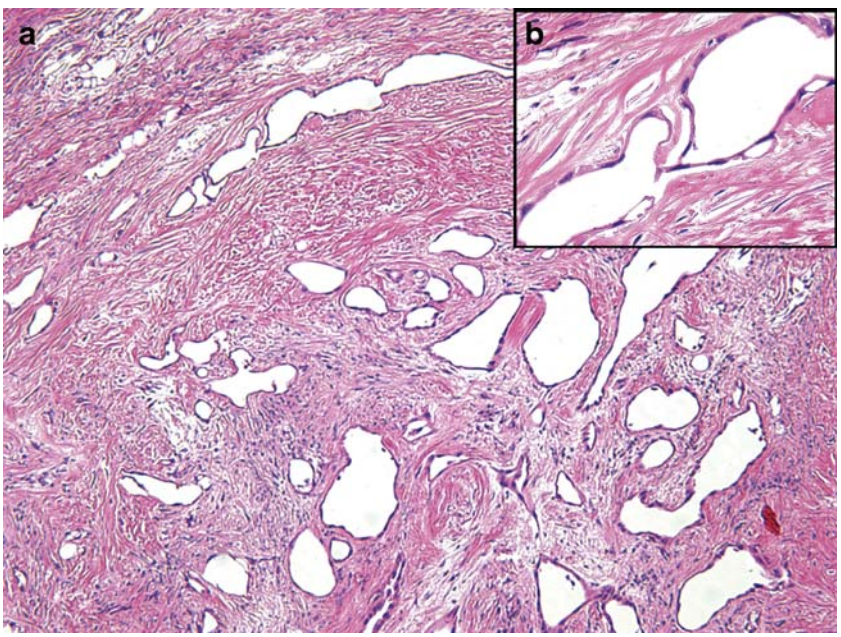

Fig. 4 Lymphangiomatoid structures within dense collagen and aligned along the axis of bundles of the collagen (*inset*), and lined by thin attenuated mesothelial cells

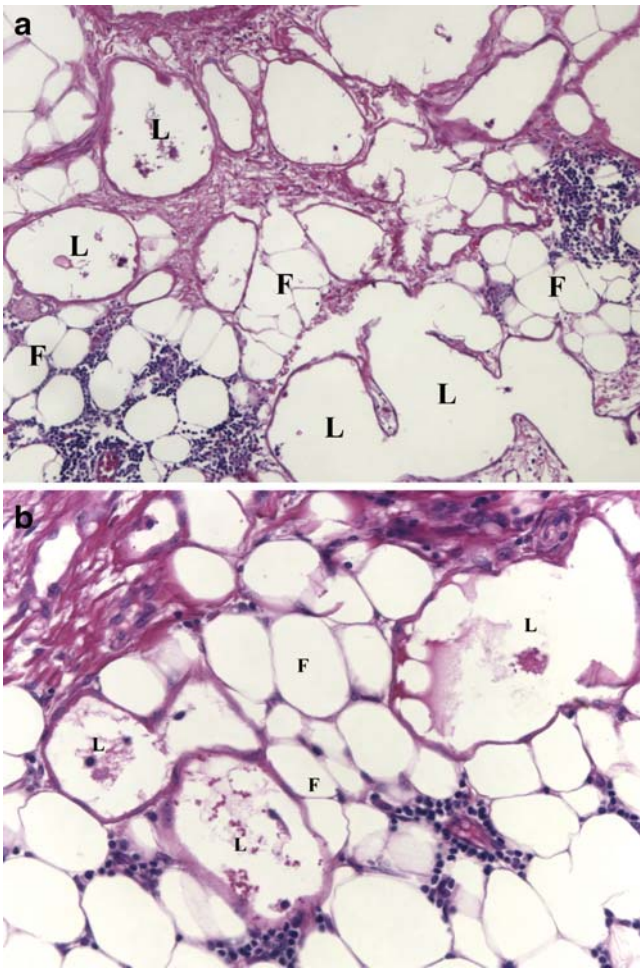

Fig. 5 Irregular but smoothly contoured structures resembling lymphangioma (**a**) invading into fat and causing fat necrosis with focal lymphocytic inflammation (**b**). *L* lymphangioma-like structures; *F* fat

All patients had pleural effusions on initial radiographic studies of the chest. Four of the patients had either a pleural mass or pleural thickening. Initial pathological diagnosis was made on specimens obtained by thoracoscopic biopsy in three patients, wedge biopsy of pleura and lung in one, pleural decortication in one, and radical extrapleural pneumonectomy in one. Follow-up is short. Six patients were alive 6 months or less after the diagnosis of DMM. One patient has died of DMM.

Two of the cases had pleural hyaline plaques noted on X-ray bilaterally, and three other cases had pleural hyaline plaques found pathologically in the operative specimen. All patients were exposed to asbestos.

Histopathological findings

Four of the cases were entirely epithelioid, and two were biphasic.

Ovoid (Fig. 1) or serpentine (Fig. 2) structures bounded by flattened cells comprise the commonality in all cases. The lymphangiomatoid structures constituted from 10% to 40% of the overall area examined histologically in the slides available for review. The lymphangiomatoid areas were found in more solid epithelioid areas in all cases. Leaflet- or valve-like membranous structures extended into the vascular-like spaces (Fig. 3 inset) in two cases. The lymphangiomatoid structures could be found in dense pleural fibrous tissue (Fig. 4 inset). The lymphangiomatoid structures could extend beyond the main tumor and into adipose tissue and cause fat necrosis (Fig. 5a, b).

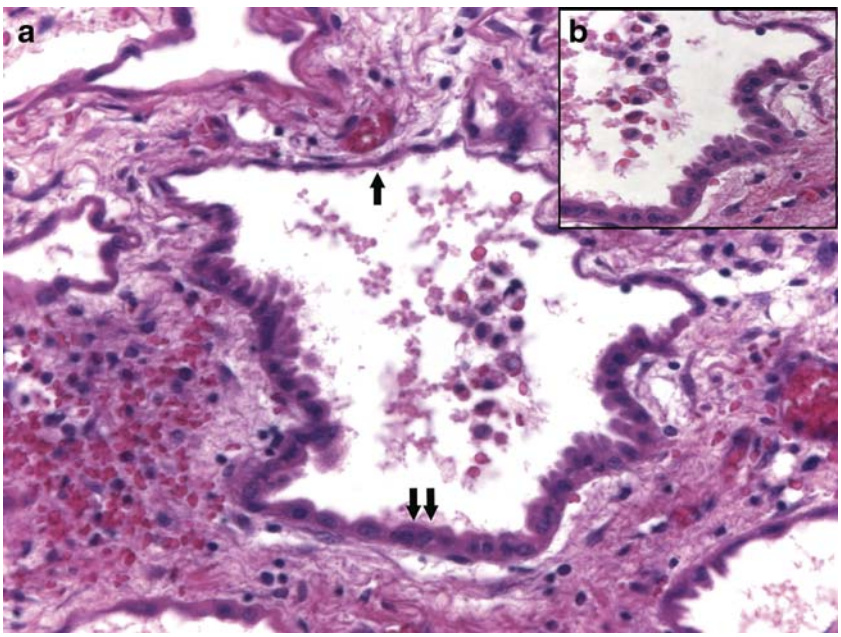

Fig. 6 Irregular space lined by flattened mesothelial cells (*single arrow*) to cuboidal cell (*double arrow*) and a gradual transition between the two. Cuboidal cells have more epithelioid aspects and a hobnail appearance (*inset*)

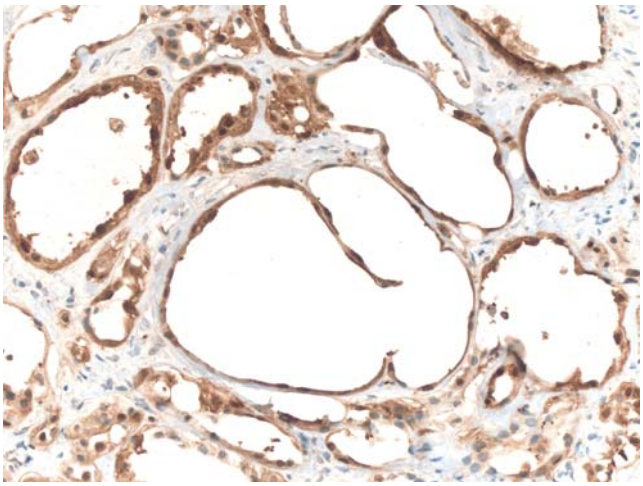

Fig. 7 Immunostain for calretinin highlighted the cells lining lymphangiomatoid spaces

The attenuated cells generally could be traced to cells with more copious cytoplasm and bland regular nuclei typical of DMM in early phase (Fig. 6 inset).

Lymphangiomatoid pattern was particularly evident in those cases which also had coexistent adenomatoid patterns. The lymphangiomatoid pattern was not seen in mesenchymal components of DMM in the two cases with a mesenchymal component.

Immunohistochemically, cells lining the lymphangiomatoid spaces stained for calretinin in all cases (Fig. 7), for cytokeratin 5/6 in five cases, for cytokeratin 7 in two cases, and for Wilms tumor-1 in five cases. In none of the cases did the cells not stain for these three agents. Staining for D2-40, a marker for both mesothelial cells and for endothelial cells, was positive in the two cases in which it was performed. Expected negative expression in DMM are documented in all cases. Five cases were negative for TTF-1 and CEA, three cases for CK20 and MOC-31, two cases for B72.3 and prostate specific antigen, and one case for prostate-specific acid phosphatase and CD15. One case weakly positive for MOC-31. Results of immunohistochemical staining are included in Table 2.

Discussion

Historically, DMM was not identified as a distinct entity until the late 1940s. In a 30-volume encyclopedia of pathology edited by Henke and Lubarsch in the interval of 1928–1931, the statement was made that if malignant mesothelioma existed, it was so rare that pathologists were not sure of its existence [13-15]. Of note for our paper is that among the various descriptions and terminology used for controversial cases of pleural tumors at that time was endothelioma of the pleura. One author of a treatise on pathology of tumors in 1960 stated that all tumors called pleural mesotheliomas were, in fact, metastases from an undiscovered primary carcinoma [16].

The differential diagnosis of pleural-based tumors includes epithelioid hemangioendothelioma. This malignant tumor of endothelial origin generally has epithelioid features, moderate to marked nuclear pleomorphism, and intracytoplasmic lacunes thought to represent incipient vascular lumina. Such cases are not similar to what we are describing.

Lymphangiomatoid pattern could be an accentuation of the more frequent adenomatoid pattern. However, the distinctive distended lymphatic-like spaces in lymphangiomatoid pattern differ from slit-like or pseudotubular spaces in adenomatoid pattern.

Lymphangiomatosis can involve the mediastinum or lung, particularly in children [17]. The lymphangiomatosis may permeate through the lung following lymphatic pathway and, thus, proliferate in the pleura. Pleural lymphangiomatosis typically causes a chylous pleural effusion. A differential diagnosis between lymphangiomatosis and the lymphangiomatoid pattern in DMM is unlikely to arise because no solid mass is present in lymphangiomatosis, the condition is seen mainly in younger patients, and the entire lesion consists of vascular spaces lined by the attenuated endothelial cells. In our cases, the lymphangiomatoid pattern could be traced into more solid areas of epithelioid DMM, and in these areas, the true nature of the tumor was apparent.

However, a diagnostic difficulty may arise when the lymphangiomatoid pattern is seen apart from the more solid

Table 2 Immunohistochemical results

6	+	NA	+	+	NA	NA	NA	NA

[a] Weakly positive

areas of tumor. Particularly when the lymphangiomatoid pattern is seen in adipose tissue of chest wall apart from solid tumor, the impression may be that these are dilated lymphatics rather than invasive tumor. If there is a doubt as to whether these spaces are lymphatic or DMM, immunohistochemical staining for mesothelial markers and lymphatic endothelial markers, respectively, should provide the solution. However, we call attention to lymphangiomatoid DMM because there may be cases where the biopsy specimen samples principally lymphangiomatoid histology and leads to a problem in correct interpretation.

Conclusion

Lymphangiomatoid pattern occurs rarely in DMM. When invasive into fibroadipose tissue, it should be recognized as such rather than as lymphatic dilatation due to obstruction or lymphangioma. Recognition of a lymphangiomatoid pattern facilitates the diagnosis of DMM based on slides stained with hematoxylin and eosin alone because it adds to one of the distinctive patterns of DMM, but immunohistochemical studies can be performed in confusing cases to make the distinction of endothelial cells from mesothelial cells.

Conflict of interest statement Dr. Mark has served as an expert in legal cases where the patient believed his or her disease was related to asbestos.

Abstract Nuclear irregularities including nuclear pseudoinclusions and nuclear grooves are characteristic of papillary thyroid carcinoma cells and are regarded as important diagnostic clues in histopathology. We observed nuclear features of thyroid carcinoma cell lines (KTC-1 and TPC-1) in various culture conditions and performed immunocytochemical examinations for cytoskeleton molecules to clarify the morphogenesis of thyroid carcinoma nuclei. We found that nuclear irregularities presenting as bean-like nuclei (BLNs) and donut-like nuclei (DLNs) appeared in cells from confluent cultures, but not in cells from sparse cultures. On immunocytofluorescence analyses, clusters of γ-tubulin, representing a centrosome, frequently localized at the indentation of BLNs or in the hole of DLNs of thyroid carcinoma cells. In conclusion, we suggest that cell-to-cell contact may affect nuclear changes such as BLNs and DLNs in cancer cell lines and that centrosomes may be involved in the morphogenetic process of these nuclear changes.

Introduction

Normal cells have round or oval nuclei with a smooth nuclear contour. In contrast, carcinoma cells generally display nuclear atypia, being irregular in size and shape [1, 2]. In particular, papillary thyroid carcinoma (PTC), the most common subtype of thyroid malignancies, has characteristic nuclear figures, including nuclear grooves and nuclear pseudoinclusions. Nuclear grooves are notches in the nuclear contours usually evident parallel to the long axis of the nucleus, and nuclear pseudoinclusions are invaginations of nuclear contours with cytoplasm appearing as circumscribed punched-out holes [3, 4]. These nuclear shapes are important clues for the diagnosis of PTC in fine-needle aspirates as well as histological sections [5, 6]; however, little is known about the morphogenetic mechanism of these nuclear features of PTC cells.

Past reports suggest that these nuclear features form cooperatively between the nuclear envelope and cytoskeletons [7-12]. The cytoskeleton is a dynamic network which plays an important structural role in such things as orientation of organelles, cell division, cellular organization, and maintenance of cell shape [9, 10]. Cytoskeletons are classified into three groups which include microtubules, intermediate filaments, and microfilaments, and all three groups have a connection with nuclear membrane proteins [8, 11]. Microtubules are composed of α- and β-tubulin heterodimers, along with γ-tubulin, the functional unit of the centrosome which stabilizes and anchors the minus end of the microtubule [13, 14]. The intermediate filament group includes many kinds of proteins such as cytokeratin, vimentin, and desmin.

Nuclear irregularities are common in PTCs. These features may be associated with vimentin and desmin [15]; however, it was reported that distribution and

expression of the major structural proteins of the nuclear envelope, including lamin A, lamin B1, and lamin C, were not altered relative to the nuclear irregularities of PTCs [16]. Thus, we hypothesize that aberrant cytoskeleton molecules may contribute to the abnormal nuclear shapes in PTCs.

In the current study, we cultured papillary thyroid carcinoma-derived cell lines which contained donut-like nuclei (DLNs) and bean-like nuclei (BLNs) within a confluent cell density to clarify the morphogenesis of nuclear irregularities. We studied the relationship between nuclear morphology and various cytoskeleton molecules using immunocytofluorescence.

Materials and methods

Cell lines and cell culture

We selected KTC-1 cells (papillary carcinoma) [17], TPC-1 cells (papillary carcinoma) [18], WRO cells (follicular carcinoma), and 8505C (undifferentiated carcinomas) to represent various histological types of human thyroid carcinomas [19]. Cells were maintained in RPMI 1640 (Gibco, Grand Island, NY, USA) supplemented with 10% fetal bovine serum, streptomycin sulfate (100 mg/L), and penicillin G sodium (100 mg/L). Cells were cultured in a standard humidified incubator at 37°C in a 5% CO_2 atmosphere.

Thyroid carcinoma cells were plated in 3.5-cm glass-bottom dishes with different numbers of cells (1×10^4, 1×10^5, or 1×10^6 cells) and then microscopically examined for nuclear morphology on the first, third, and seventh days of incubation.

Preparation for imprint cytology

Touch imprint cytology was prepared from fresh PTC tissues taken from patients undergoing lobectomy or total thyroidectomy at the University of Yamanashi Hospital. Touch imprint specimens were washed three times with phosphate-buffered saline (PBS) and then fixed with 3.7% formaldehyde in PBS at room temperature for 30 min. Hematoxylin–eosin stain at room temperature and nuclear DNA stain by 0.8 mM Hoechst 33258 (Molecular Probes, OR, USA) or propidium iodide (PI) were performed at 4°C for 30 min. PI staining required pretreatment for RNA digestion using 0.01% Raze at 37°C for 30 min. The institutional ethics board of the University of Yamanashi approved all protocols.

Immunocytofluorescence

We stained culture cells and touch imprint specimens for indirect immunofluorescence using primary antibodies: anti-α-tubulin, anti-β-tubulin, anti-γ-tubulin, anti-cytokeratin-19, anti-vimentin, anti-lamin B, and anti-emerin. Detailed information of the primary antibodies, their resources, dilutions, and pretreatment are presented in Table 1. For antigen retrieval, slides were treated by autoclave at 120°C for 5 min in the 0.01 M citrate buffer, pH 6.0. Then, the samples were incubated first with primary antibody at room temperature for 1 h, then with fluorescent dye-conjugated second antibody at room temperature for 1 h. Biotin-conjugated secondary antibody was visualized using streptavidin Alexa Fluor 647 (1:50; Molecular Probes) at room temperature for 1 h. For double immunofluorescence stains, appropriate secondary antibodies were selected based on the primary antibody host. After the nuclear counter stain, the samples were mounted by ProLong Gold antifade reagent (Molecular Probes).

Phalloidin (Alexa Fluor 546, Molecular Probes) was used to visualize actin filament in the cytoplasm. After pretreatment with acetone at −20°C, the cells were treated with phalloidin for 20 min at room temperature.

The fluorescence images were acquired through an epi-illuminant fluorescence microscope, BX50, equipped with a scientific grade, cooled CCD camera (DP30BW, Olympus, Tokyo, Japan) connected to a personal computer. Confocal images were obtained using laser scanning confocal microscopy (FV1000, Olympus).

Table 1 Lists of primary antibodies used for immunofluorescence staining

Antibody	Host	Dilution	Antigen retrieval	Resource
α-Tubulin	Mouse	1:100	Citrate buffer, pH 6.0, autoclave, 5 min	Molecular Probes (Eugene, OR, USA)
β-Tubulin	Rabbit	1:100	Citrate buffer, pH 6.0, autoclave, 5 min	Lab Vision (CA, USA)
γ-Tubulin	Rabbit	1:100	Citrate buffer, pH 6.0, autoclave, 5 min	Sigma-Aldrich (St. Louis, MO, USA)
Cytokeratin 19	Mouse	1:100	Citrate buffer, pH 6.0, autoclave, 5 min	Dako (Glostrup, Denmark)
Vimentin	Mouse	1:100	Citrate buffer, pH 6.0, autoclave, 5 min	Dako (Glostrup, Denmark)

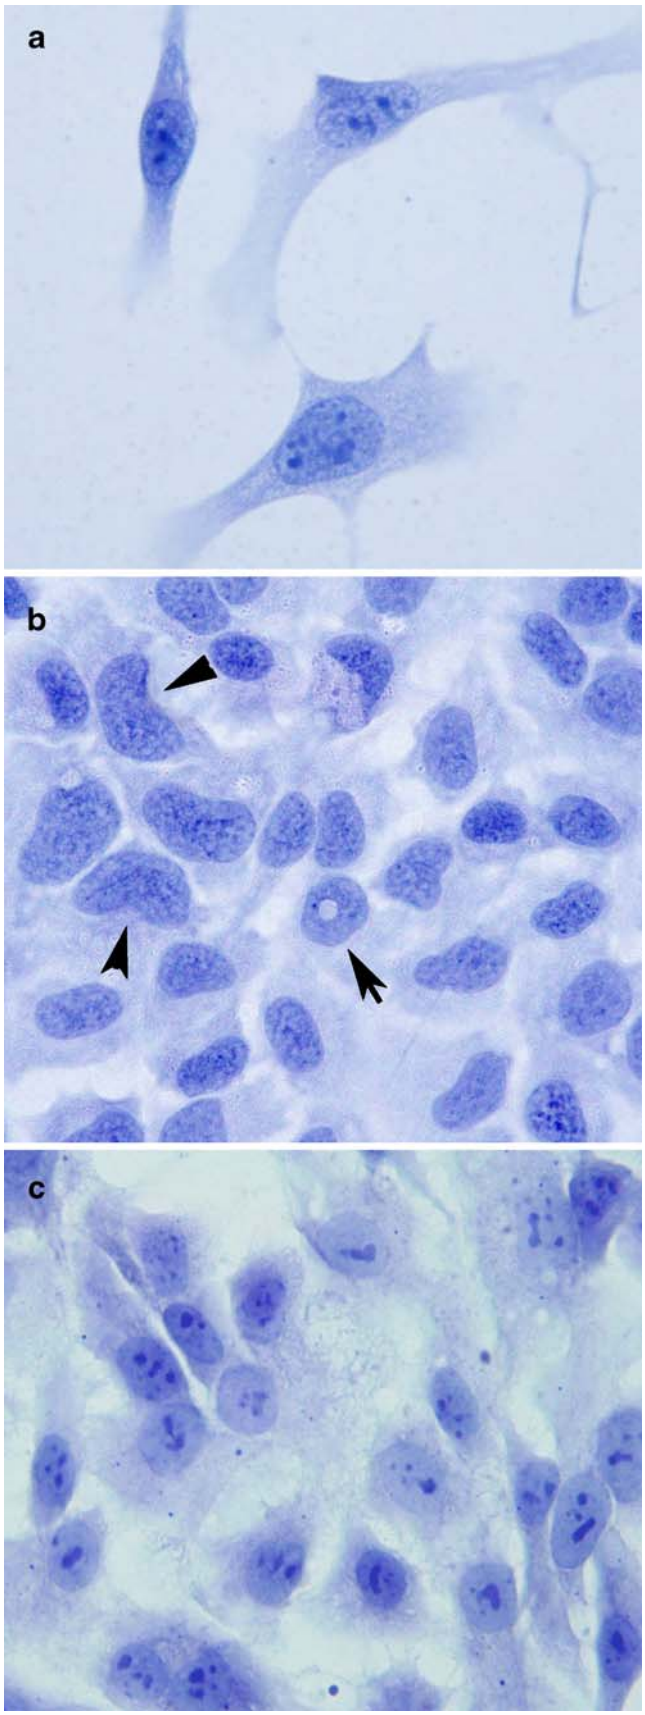
Emerin	Mouse	1:20	Citrate buffer, pH 6.0, autoclave, 5 min	Novocastra Lab (Newcastle, UK)



◀ **Fig. 1** The morphology of KTC-1 cells relative to cell density in the dishes. **a** Early during culturing, the nuclei of cells were round with smooth a contour. **b** Cells from a confluent cell density had nuclei with irregular nuclear contours; BLN (*arrowhead*) and sporadically DLN (*arrow*). **c** The nuclei of 8505C cells show neither BLNs nor DLNs within the confluent cultures

Results

Nuclear morphology of thyroid carcinoma cell lines

The nuclei of the KTC-1 and TPC-1 cells from the sparsely populated cultures had round, smooth contours during early culturing (Fig. 1a). However, we found the characteristic nuclear features such as BLNs and DLNs within the confluent cultures. BLNs had a dent in their nuclear contour, creating a bean or horseshoe shape, and DLNs looked as though they had a punched-out hole (Fig. 1b). We did not observe these unique nuclear figures in non-papillary thyroid carcinoma cell lines (WRO and 8505C cells) from the sparsely populated or confluent cultures (Fig. 1c).

Frequencies of BLNs and DLNs

The frequencies of BLNs and DLNs in KTC-1 cells and TPC-1 cells are shown in Table 2. BLNs were seen on the third and seventh days in the dishes containing 1×10^5 and 1×10^6 plated cells from both cell lines. Frequency of BLNs tended to be higher in the TPC-1 cell line (3.6% to 6.4%) than in the KTC-1 cell line (1.2% to 3.9%). DLNs were identified only on day 7 in dishes containing 1×10^5 and 1×10^6 plated cells in the KTC-1 cell line and on days 3 and 7 in the dishes containing 1×10^6 plated cells from the TPC-1 cell line. Neither BLNs nor DLNs were identified at any time in the dishes of the 1×10^4 plated cells.

Table 2 Frequency of bean-like nuclei and donut-like nuclei in thyroid carcinoma cells

Cell lines	No. of plated cell/dish	Frequency of BLNs (%)			Frequency of DLNs (%)		
		Day 1	Day 3	Day 7	Day 1	Day 3	Day 7
KTC-1	1×10^4	0	0	0	0	0	0
	1×10^5	0	1.2	2.4	0	0	3.1
	1×10^6	0	2.6	3.9	0	0	2.6
TPC-1	1×10^4	0	0	0	0	0	0
	1×10^5	0	3.9	5.1	0	0	2.6

DLNs donut-like nuclei

Immunocytochemistry

We carried out our immunofluorescence study for microtubules using antibodies against α-tubulin, β-tubulin, γ-tubulin, cytokeratin-19, vimentin, lamin B, and emerin. Double immunofluorescence techniques for α- and γ-tubulins on papillary thyroid carcinoma-derived cells (KTC-1 and TPC-1 cells) from sparsely plated cultures revealed γ-tubulin in a cluster and localized near the nuclei representing a centrosome, while α-tubulin was immunoreactive in fibers, or microtubules, growing from the centrosome to the cell membrane (Fig. 2a). Within the confluent culture, we found that a γ-tubulin centrosome was occasionally localized at the dent of a BLN and in the hole of a DLN, while microtubules positive for α-tubulin were most consistently found within the sparsely cultured cells (Fig. 2b–d). After carefully examining all DLNs, we estimated the frequency of those having a cluster of γ-tubulin in their hole to be 64.6% (31 of 48 DLNs) from the KTC-1 cell line and 55.6% (35 of 63 DLNs) from the TPC-1 cell line (Table 3). In non-papillary thyroid carcinoma cell lines (WRO and 8505C cells), cluster of γ-tubulin localized near the nuclei representing a centrosome with the same pattern as papillary thyroid carcinoma-derived cells from sparsely plated cultures (Fig. 2e)

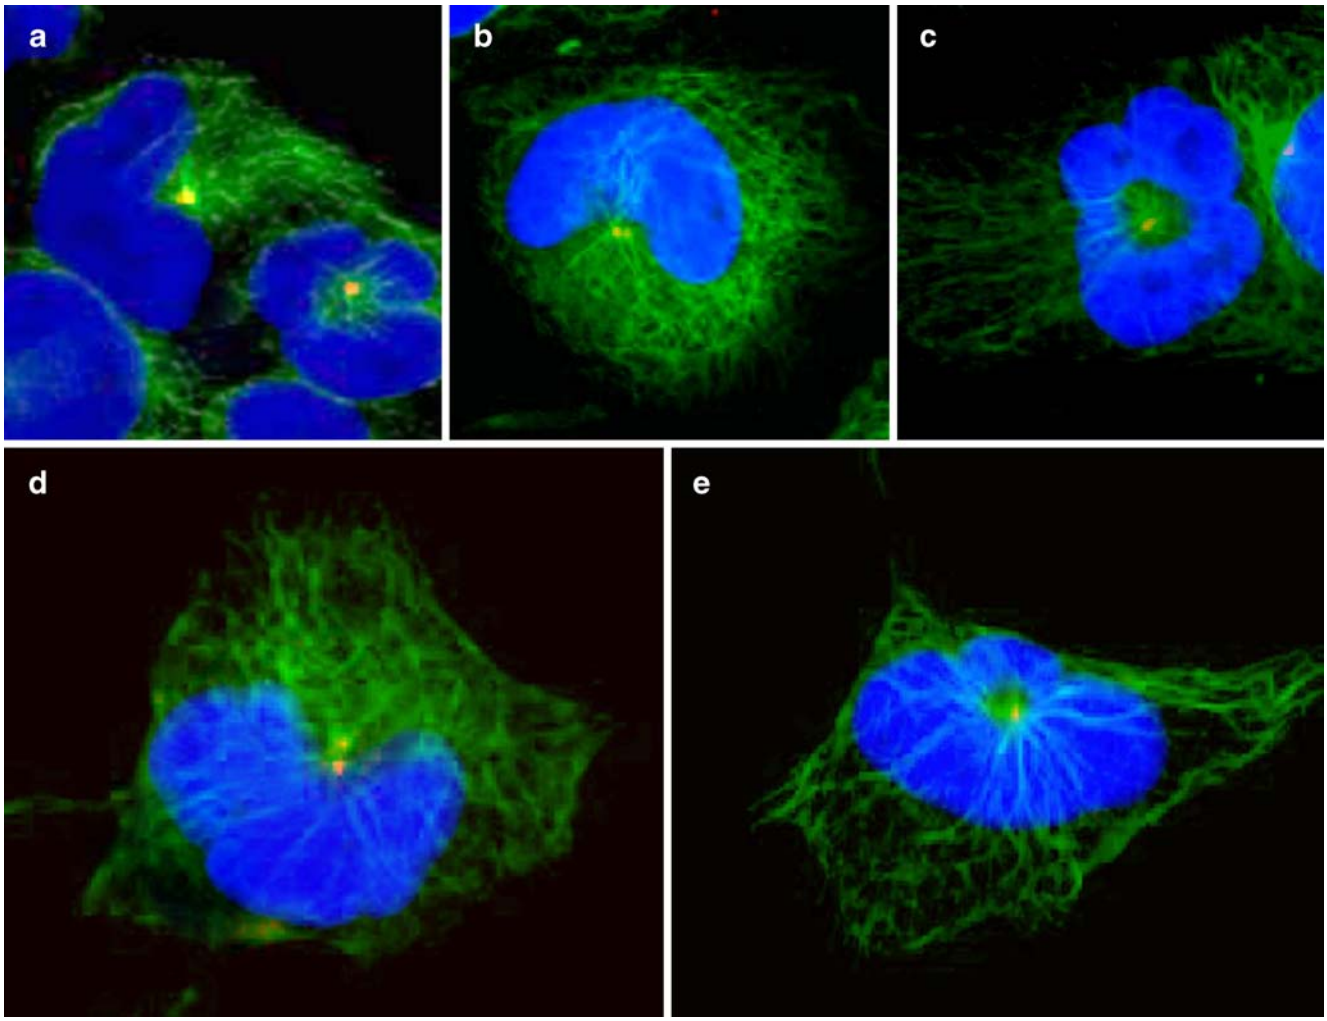

Fig. 3 Confocal images of double immunofluorescence staining of tubulins in culture cells. Alpha-tubulin and gamma-tubulin are visualized by FITC (*green*) and TRCR (*red*), respectively. Red color is seen as yellow due to an overlap with green color. Nuclei are stained by Ho (*blue*). Confocal images of alpha-tubulin and gamma-tubulin of KTC-1 (**a**–**c**) and TPC–1 (**d**–**e**) cell lines, respectively. Alpha-tubulin filaments are radiating from a gamma-tubulin centrosome. **a** Confocal image of the same cells shown in Fig. 2b. **b**, **d** The gamma-tubulin is positioned close to the BLN. **c**, **e** The positioning of gamma-tubulin centralized within the DLN is confirmed by confocal laser scanning microscopy

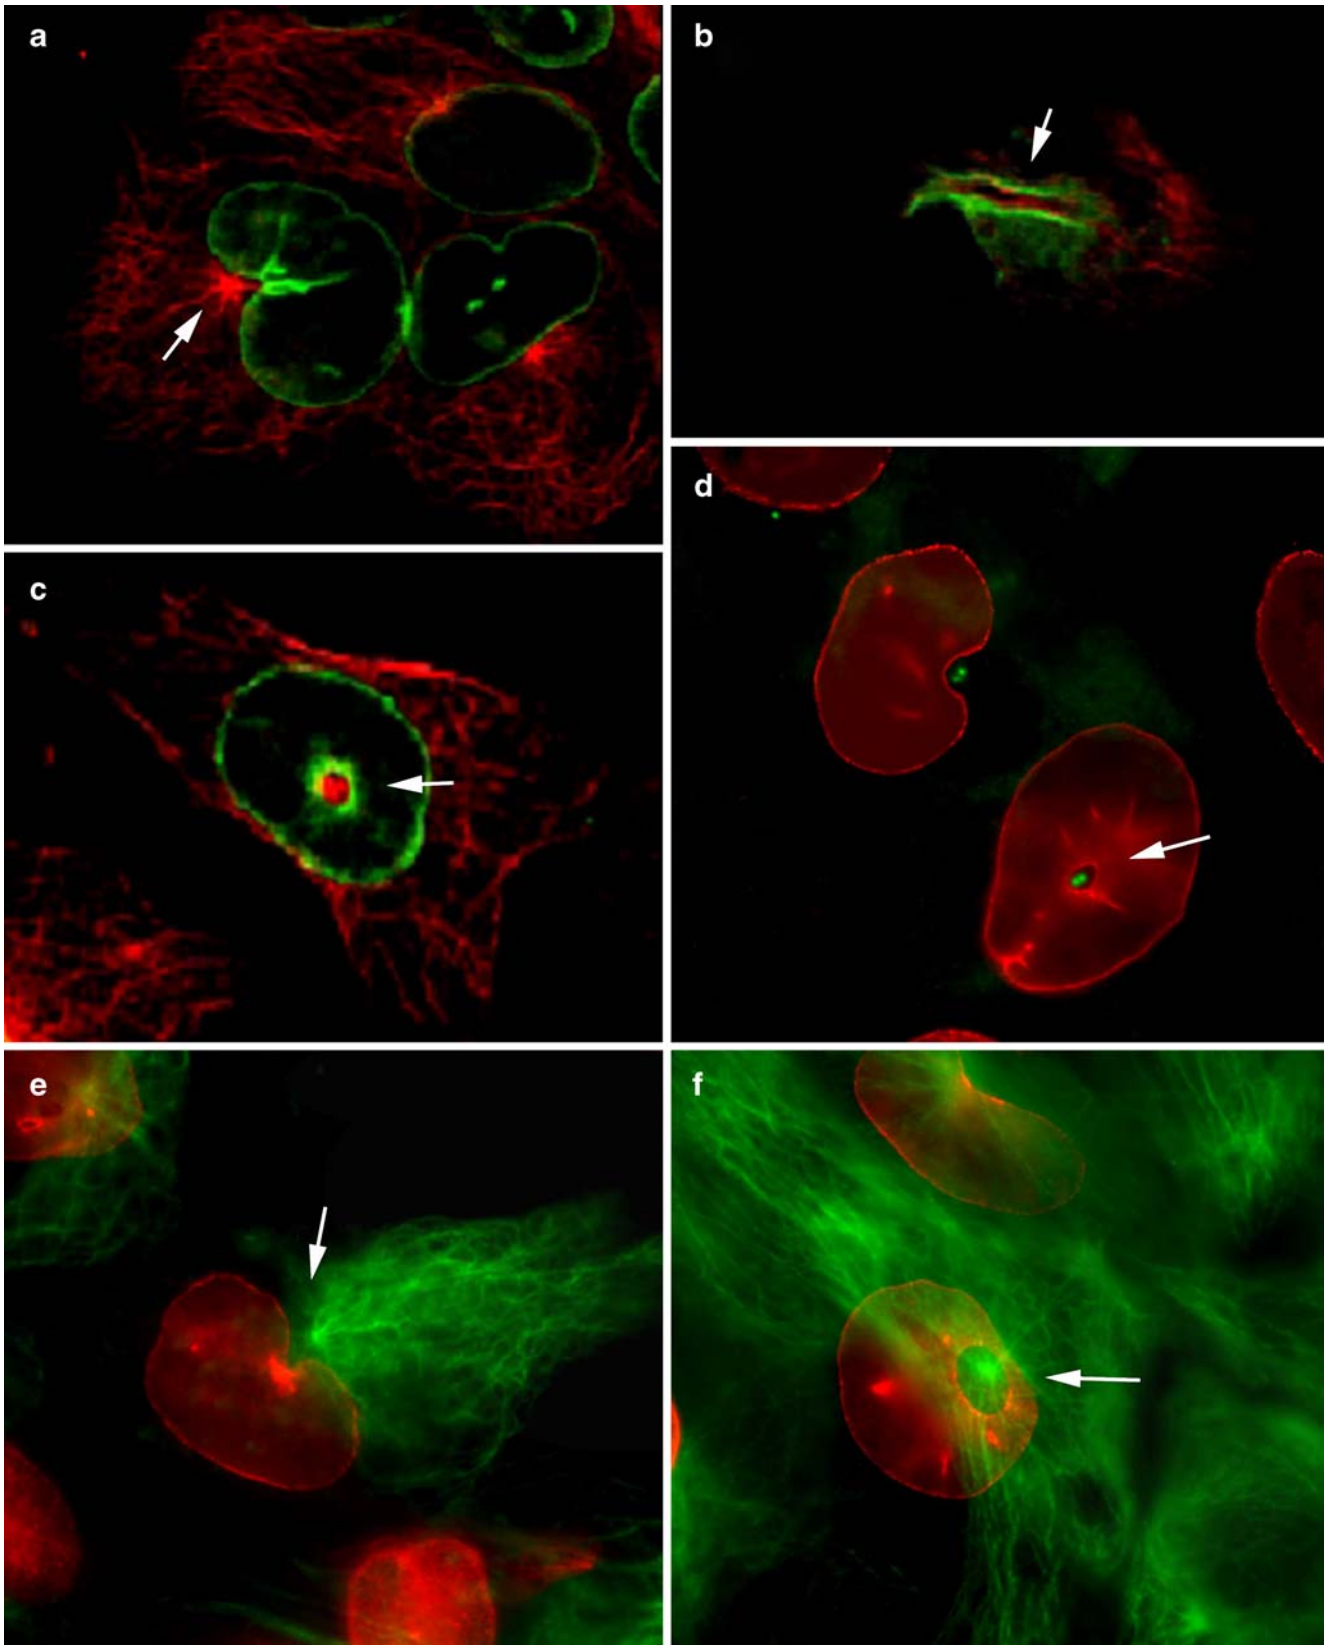

a
b
c
d
e
f

Immunohistochemistry using confocal laser scanning microscopy confirmed that γ-tubulin centrosomes localized at dents of BLNs and in the holes of DLNs (Fig. 3). In addition, our double immunofluorescence study for nuclear membrane proteins (lamin B and emerin) and γ- or β-tubulin also supported the close relationship between DLNs/BLNs, centrosomes, and microtubules (Fig. 4). Although we also stained for F-actin and intermediate filaments including cytokeratin-19 and vimentin, we did not find any distributional association with the nuclear figs of BLNs and DLNs (Fig. 5).

Human papillary thyroid carcinoma

We examined touch-imprinted cells from human papillary thyroid carcinoma tissues in the same manner as our plated cells. Immunofluorescent examination revealed γ-tubulin centrosomes in nuclear pseudoinclusions or near nuclear grooves in the human papillary carcinoma cells (Fig. 6).

Discussion

In our current study, we examined nuclear irregularities of thyroid carcinoma cells, focusing on cytoskeletal molecules using light and confocal microscopy. We found unique morphological figures such as BLNs and DLNs in papillary thyroid carcinoma cell lines (KTC-1 and TPC-1). The BLNs and DLNs appearing in these cell lines were morphologically similar to nuclear grooves and nuclear pseudoinclusions in papillary thyroid carcinoma cells. Similar nuclear findings in a papillary carcinoma cell line (NPA cell line) have been described by Papotti et al. [4] in 2004. Using confocal microscopic analysis and tridimensional reconstruction, they demonstrated that the nuclear holes and grooves seen during light microscopy correspond to invaginations and tunnels. From a morphological point of view, the BLNs and DLNs in KTC-1 and TPC-1 cell lines can be related to invaginations and tunnels of cancer cell nuclei.

Overlapping nuclei representing high cell density is a characteristic of papillary thyroid carcinomas [5, 20, 21]. Interestingly, the frequency of BLNs and DLNs corre-

◀ **Fig. 4** Images of both KTC-1 cells with double immunofluorescence staining of beta-tubulin and lamin B (**a**–**c**) and TPC-1 cells with double immunofluorescence staining of beta-tubulin and emerin and gamma-tubulin and emerin (**d**–**f**). Beta- and gamma-tubulins are visualized with FITC (*green*); lamin B and emerin are visualized with TRCR (*red*). **a**, **e** Beta-tubulin filaments accumulated in the cytoplasm near and extending to the nuclear envelope (lamin B, emerin) at the side of the BLN (*arrow*). **b** Confocal image of the top plane of cells is shown. sponded with the number of plated cells and days of incubation: BLNs and DLNs were found more frequently in cultures that were initially plated with a higher number of cells and/or at later days of incubation. These findings suggest that cell-to-cell contact and/or cell density may be related to the morphogenesis of nuclear irregularities.

The nuclear envelope is firmly fastened to the cytoskeleton [22], and the cellular scaffold that comprises the nuclear matrix and cytoskeleton provides mechanical support for the cell and may play some role in nuclear structure. Therefore, we performed an immunofluorescence study for several cytoskeleton molecules and nuclear membrane proteins such as α-tubulin, β-tubulin, γ-tubulin, cytokeratin-19, vimentin, lamin B, and emerin in the cultured cells with and without BLNs and DLNs. We found that a cluster of γ-tubulin, a centrosome, was positioned in the hole of a DLN or near a BLN, whereas α- and β-tubulin heterodimers accumulated more within the BLNs and DLNs. In addition, we had similar findings in the touch imprint specimens of PTCs. Therefore, it is conceivable that centrosomes and microtubules may be involved with the nuclear irregularities of PTC cells.

It has been reported that a significant fraction of emerin is located at the outer nuclear membrane and linked directly with the centrosome [23]. Also, we know that numerical and structural aberrations of centrosomes play an initial role in the carcinogenic process [24, 25]. These data support our hypothesis that centrosomes may be related to the nuclear morphogenesis of PTCs.

In conclusion, we suggest that cell-to-cell contact may affect nuclear changes such as BLNs and DLNs in cancer cell lines and that centrosomes may be involved in the morphogenetic process of these nuclear changes. Our findings contribute to the understanding of characteristic nuclear features in papillary thyroid carcinomas.

Abstract Human herpesvirus 8 (HHV8) is necessary for Kaposi sarcoma (KS) to develop, but whether the tissue viral load is a marker of KS progression is still unclear. Little is known about the level of expression of apoptosis-regulating proteins and of hypoxia-inducible factors (HIFs) in KS tumour cells relative to HHV8 expression. We therefore investigated the expression of the latency-associated nuclear antigen (LANA-1) of HHV8, Bcl-2, Mcl-1, Bax, Bcl-xL, caspase 3 and HIF-1αin KS tissue specimens at different stages of the disease. The expression of these proteins was evaluated immunohistochemically using tissue microarrays (TMAs) in tissue specimens from 245 HIV-positive patients at different stages of the disease. Both LANA-1 and HIF-1α were expressed in KS biopsies taken at different stages, but their level increased throughout tumour progression. Additionally, the levels of Bcl-2 and Mcl-1 were higher in visceral KS lesions compared to levels observed in cutaneous and mucosal KS. This study demonstrates that late tumour stages of KS in tissues from HIV-positive patients are associated with high levels of LANA-1, HIF-1α and of the anti-apoptotic proteins, Bcl-2 and Mcl-1. Finally, the expression of these proteins can be potentially used as a tissue biomarker in defining patients with a higher risk of disease progression.

Introduction

By 1989, 15% of all reported acquired immunodeficiency syndrome (AIDS) cases in the USA had Kaposi sarcoma (KS) as the primary AIDS-defining illness [1]. KS is still the most common tumour in HIV-infected individuals, but in different parts of the world the epidemiological trend is changing. In the era of highly active anti-retroviral therapy (HAART), the incidence of AIDS-KS has declined considerably [2, 3]. In contrast, the prevalence of KS remains high in untreated HIV patients, in particular amongst Africans [4]. Finally, the increase in KS after initiation of HAART may be a manifestation of the immune reconstitution inflammatory syndrome [5, 6].

A better understanding of the pathogenesis of KS came with the identification of the human herpesvirus 8 (HHV8) in all forms of KS [7–9]. Viral oncogenesis and cytokine-induced growth, as well as some immunocompromised

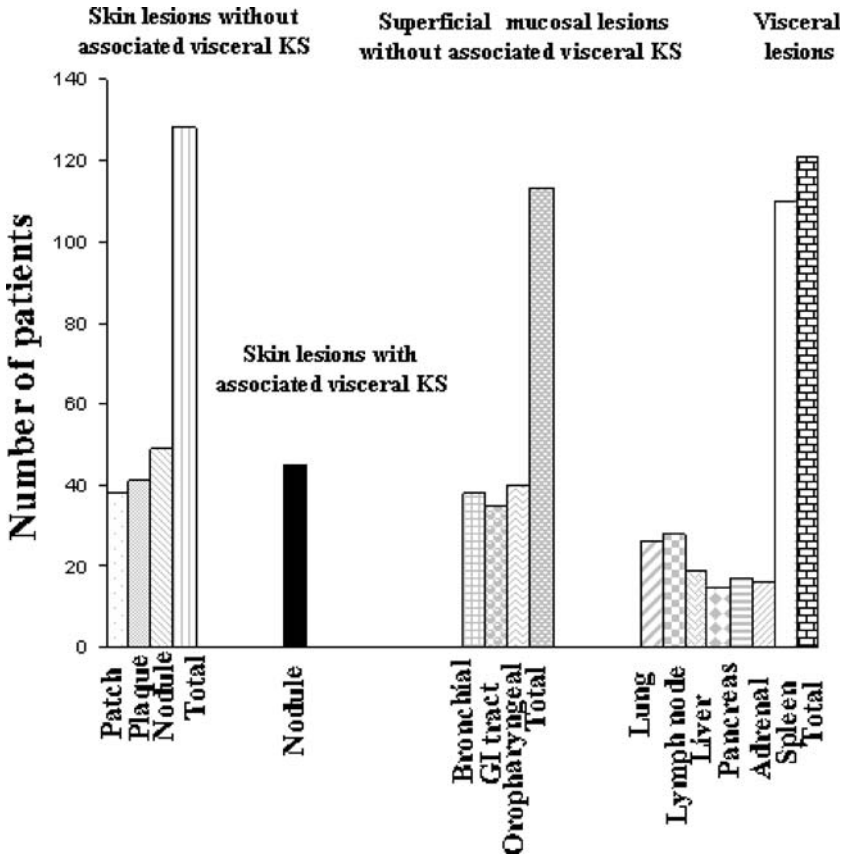

Fig. 1 Summary of the tissue lesions included for tissue microarray construction

states, contribute to its development. Clinically, AIDS-KS commonly presents with cutaneous lesions beginning as macules and papules, which frequently evolves into plaque-like and then into nodular tumours [10]. Histologically, patch-stage KS is the earliest pattern, followed by the plaque stage and nodular stage [11]. Similar lesions are observed at mucosal surfaces, mostly in the conjunctiva and in the oropharyngeal, gastrointestinal (GI) and bronchial tracts. These lesions can be unique or multiple, with or without associated visceral involvement [10, 11]. Finally, progression of AIDS-KS causes significant mortality with different organ manifestations and post-mortem studies suggest that more than 25% of patients with cutaneous AIDS-KS also have visceral lesions [12–14]. KS most commonly involves the lung, spleen, liver, lymph nodes, stomach, rectum/anus and liver, but any organ can be involved [13, 14].

Several HHV8 genes that are expressed during latency or during the lytic life cycle can affect binding, cell growth, proliferation, inflammation and angiogenesis [15]. HHV8 has developed alternative means of expressing proteins that overcome the usual responses to viral infection by helping to oppose cell cycle arrest, apoptosis and activation of cellular immunity. Amongst the different molecules acting during KS development and progression, the latency-associated nuclear antigen (LANA) of HHV8 (encoded by ORF 73) may act as a transcriptional regulator and modify gene expression of viral and cellular genes [16]. HHV8 seems to have pirated some relevant cellular genes linked to apoptosis and angiogenesis that leads to dysregulation of these processes [17]. In this regard, it has been suggested that the pathogenesis of KS in the HIV-infected population may be related to escape from apoptosis rather than to an increase in proliferation [18, 19]. However, it is still not clear whether the development and progression of KS in HIV-positive individuals infected by HHV8 are related to increased cell growth and/or to decreased cell death. Recent research has demonstrated that the hypoxia-inducible factor-1α (HIF-1α), a key player in angiogenesis, is highly expressed in KS lesions [20, 21]. Finally, it is not clear if the level of viral antigens, such as LANA-1, is linked to stages of the disease and whether it is correlated with the level of apoptosis-related and/or the HIF-1α protein.

The aim of this study was to investigate and to quantify the expression of LANA-1, anti-apoptotic (Bcl-2, Mcl-1)

pro-apoptotic (caspase 3, Bcl-xl, Bax) and HIF-1α proteins, at different stages of KS disease progression. These proteins were identified immunohistochemically using TMA technology, from tissue specimens of 245 HIV-infected individuals and their level compared to KS clinico-pathological features. LANA-1 protein expression was compared to Bcl-2, Mcl-1 and HIF-1α protein expression.

Materials and methods

Patients and samples

The medical records of the Department of Pathology of Pasteur Hospital (Nice, France) were searched from 1983 to 2004 for cases of KS in HIV-positive patients not treated with HAART. Tissue specimens of 245 patients were included in this study. These patients ranged in age from 28 to 74 years, with a mean of 37 years. All except 18 were men and all were Caucasian living in the Nice area. Risk factor(s) for HIV infection were noted in all patients; 28 men were intravenous drug users; 199 men were homosexuals or bisexuals. Women were heterosexuals without known risk. CD4+ T cell counts ranged from 8 to 122 per cubic millimetre, with a mean of 49 per cubic millimetre. For patients with cutaneous KS, clinical data were obtained from the Department of Dermatology of the Archet Hospital (Nice, France). Seventy-nine patients presented with KS lesions of different stages (patch 25 cases, plaque 27 cases, nodule 27 cases) isolated from the skin (Figs. 1 and 2a). Sixty-three patients presented with KS mucosal lesions of different sites (bronchial tract 18 cases, GI tract 24 cases, oropharynx 21 cases). Finally, 118 patients presented with a visceral KS lesion of different organs (liver 19 cases, lymph node 21 cases, pancreas 13 cases, lung 23 cases, adrenal 21 cases, spleen 21 cases; Fig. 1**).**

Tissue microarray and immunohistochemistry

Representative KS lesions obtained for each patient for building TMAs were selected from haematoxylin and eosin (HE)-stained sections. TMA construction and high-throughput analysis of tissue samples were performed in accordance with institutional guidelines. HE sections of KS lesions were reviewed by five pathologists (EL, IL, VH, CB and PH), and areas of tumours were marked on the slides. Areas of necrosis, large haemorrhage and normal tissue were avoided. TMAs were set up as previously described [22, 23]. Briefly, three tissue cores (600 μm in diameter) corresponding to three representative central areas of the lesion were selected. The tissue cores were arrayed into a recipient paraffin block as previously described [24]. TMAs with KS specimens contained normal skin tissue (6 tissue cores), which served both as a control and as a regulating mark spacing of 1 mm between core centres. A 4-μm HE-stained section was reviewed to confirm the presence of morphologically representative areas of the original lesions.

Immunohistochemical methods were performed using the automated immunostainer Bond-X system (Medite, Nunningen, Switzerland) on serial 2-μm deparaffinized TMA sections. Briefly, these sections were incubated with 0.1% trypsin (Sigma Chemical Co, St. Louis, MO, USA) in phosphate-buffered saline (PBS, pH7.5) for 10 min at 37°C. After washing with distilled water, sections were incubated with 0.03% hydrogen peroxide containing 0.2% sodium azide for 20 min (for blocking intrinsic peroxydase), then washed with PBS. In studies into Bcl-2, Bcl-X and caspase 3, antigen retrieval was carried out as reported previously in ethylenediaminetetraacetic acid (EDTA) buffer pH8.6 by heating in a microwave oven for 5 min and repeated three times. Citrate buffer (0.01 mol/l, pH6.0) microwave antigen retrieval was used in place of the EDTA buffer in studies into Mcl-1. The monoclonal mouse anti-LANA-1 (Novocastra, Newcastle, UK; clone 13B10) antibody was added at a dilution of 1:25 in Tris buffer for 1 h. Immunostaining was performed following heat-induced epitope retrieval with retrieval ER 2 solution (Novocastra) at 95°C for 20 min. The anti-human Bcl-2 mouse antibody (monoclonal immunoglobulin G (IgG), DAKO, Carpinteria, CA, USA, clone 124; diluted 1: 50), mouse anti-human Bcl-xL antibody (monoclonal IgG, Santa Cruz, San Diego, CA, USA; clone H-5, diluted 1:400), rabbit anti-human antibody Mcl-1 (polyclonal IgG, Lot 057; diluted 1:30), mouse anti-human Bax (A3533; diluted 1:100) and anti-caspase 3 (A3537; diluted 1:50) antibodies were all from DAKO, and the mouse anti-HIF-1α monoclonal antibody (BD Biosciences Pharmingen; San Diego, CA, USA; clone 54; diluted 1:500) was incubated on sections at room temperature for 1 h. After rinsing with PBS, sections were incubated with peroxidase-labelled anti-mouse Igs or peroxidase-labelled anti-rabbit Igs (DAKO) for 45 min. Negative controls were performed by omission of the primary antibody and by using normal mouse IgG_1 (DAKO) in each experiment. Sections were then washed with PBS, coloured with 3-amino-9-ethylcarbazole in acetate buffer containing hydrogen peroxide, counterstained with haematoxylin and mounted with aqueous mounting medium. After staining, slides were analysed with an image analysis workstation (Spot Browser version 7, Alphelys,

Paris, France) as previously described [24, 25]. Briefly, the signal intensity and number of positive nuclei of digitised images were determined using Spot Browser software. For each patient, the mean of the score of a minimum of two core biopsies was calculated. Discrepancies were resolved by five pathologists (EL, MI, VH, CB and PH) under a multiheaded microscope. Correlation of staining for LANA-1 and HIF-1α, Bcl-2 or Mcl-1 was done by comparing the percentage of positive cells obtained for HIF-1α, Bcl-2, Mcl-1 and the number of LANA-1-positive cell nuclei in different KS lesions. They were classified into different groups (from 1 to 9, according to the number of LANA-1-positive detected cells): group 1 five to ten positive nuclei cells, group 2 ten to 50 positive nuclei; group 3 50–100 positive nuclei; group 4 100–150 positive nuclei cells; group 5 150–200 positive nuclei cells; group 6 200–250 positive nuclei cells; group 7 250–300 positive nuclei cells; group 8 300–350 positive nuclei cells; group 9 350–400 positive nuclei cells. Moreover, whole-tissue sections from tumour blocks of a subset of 20 cutaneous nodular KS were stained and compared by visual inspection with the corresponding TMA discs. For figures, polychromatic high-resolution spot images (1,392×1,040 pixels) were obtained using a Leica DMR optic microscope (Leica Microsystems, Rueil-Malmaison, France).

Statistical analysis

Histospots containing less than 10% of a lesion were excluded from additional analyses. Nonparametric correlation (Spearman's *P* coefficient; SPSS release 12.01) was used to compare data from whole-tissue sections and discs as previously described [24]. The number of positive nuclei was compared between the groups of studied lesions using the Mann–Whitney test. Correlation between the number of positive nuclei for LANA-1 staining, the number of positive nuclei for cells protected against apoptosis and/or the positive nuclei for HIF-1α staining was evaluated with the Spearman's rank correlation test. Values were expressed as a mean (±SEM). A $p<0.05$ was considered statistically significant.

Results

LANA-1 expression in nodular, patch and plaque cutaneous KS lesions and in mucosal KS lesions

Immunohistochemistry with an anti-LANA-1 antibody was performed on biopsies taken from cutaneous patch, plaque and nodule lesions and from mucosal lesions without associated visceral or disseminated disease (Fig. 2a, a1–d1). Evaluation of the density of nuclei expressing LANA-1 was performed only on representative spots (Fig. 2a, a2–d2). Positive nuclei were observed mainly in endothelial cells lining vessels and in a few other spindle cells (Fig. 2a). In patients with cutaneous patch (Fig. 2a, a3–a4) and plaque lesions (Fig. 2a, b3–b4), positive nuclei were 77±22 and 104±21 cells per square millimetre, respectively (Fig. 2b). The density of nuclei expressing LANA-1 increased strongly in patients with cutaneous nodules (178±45 per square millimetre; $p<0.05$; Figs. 2a, c3–c4, and 2b). Nuclei positive for LANA-1 staining were similarly found in patients with isolated mucosal lesions from the GI, bronchial and oropharyngeal tract (Fig. 2a, d3–d4, and 2b). Positive nuclei were observed both in endothelial lining vessels and in other spindle cells.

LANA-1 expression in visceral KS lesions and in nodular KS lesions with or without associated visceral KS lesions

The number of positive nuclei detected by immunostaining with an anti-LANA-1 antibody was strongly increased in

visceral KS lesions in comparison with nodular cutaneous KS lesions with or without associated visceral and disseminated KS disease (Fig. 3a, b). Nuclei positive for LANA-1 staining in visceral KS lesions were observed in endothelial cells lining vessels and in other spindle cells (Fig. 3a).

LANA-1 expression in female and male KS lesions

The number of positive nuclei for LANA-1 staining was evaluated by immunohistochemistry in the cutaneous (patch, plaque, nodule), mucosal and visceral KS lesions according to gender (Fig. 4). No significant differences were found in the number of positive cell nuclei expressing LANA-1 in the different tissue specimens obtained from women and men (Fig. 4).

Expression of apoptosis-related proteins in KS lesions and correlation with LANA-1 staining

Cell apoptosis in different KS lesions was evaluated by immunohistochemical staining for Bcl-2, Mcl-1, Bax, Bcl-xL and caspase 3. Interestingly, the number of cells expressing the anti-apoptotic (Bcl-2, Mcl-1) proteins was increased in nodular cutaneous KS lesions when compared to patch and plaque cutaneous and mucosal KS lesions (Fig. 5a, a1). Moreover, the number of cells expressing Bcl-2 and Mcl-1 correlated with the density of cell nuclei positive for LANA-1 staining (Fig. 5a, a2 and a3). The number of cells expressing Bax, Bcl-xL and caspase 3 was similar in patch, plaque and nodular cutaneous and mucosal KS lesions (not shown). The nine different groups were classified arbitrarily according to the number of LANA-1-positive cell nuclei. Groups 1–3 corresponded to patch KS specimens, groups 4 and 5 to plaque and mucosal KS specimens and groups 6–9 to nodular and visceral KS specimens. Additionally, the number of apoptotic cells was lower in visceral KS lesions in comparison with those observed in cutaneous KS lesions associated with visceral KS dissemination (Fig. 5b, b1). In all these lesions, the number of Bcl-2- and Mcl-1-expressing cells correlated with the density of positive cell nuclei for LANA-1 staining (Fig. 5b, b2 and b3).

HIF-1α expression in KS lesions and correlation with LANA-1 expression

Immunohistochemistry with an anti-HIF-1α antibody was performed on biopsies taken from cutaneous patch, plaque and nodule lesions and mucosal KS lesions without associated visceral or disseminated disease and from different visceral KS lesions (Fig. 6a, b, b1). In patients with cutaneous patch and plaque lesions, positive nuclei were 50±18 and 54±22 cells per square millimetre, respectively (Fig. 6b, b1). Positive nuclei were observed mainly in endothelial cells lining vessels. The density of nuclei expressing HIF-1α was strongly increased in patients with cutaneous nodules (250±15 cells per square millimetre, $p<0.05$; Fig. 6a, b, b1). Most positive nuclei were noted in spindle cells. Nuclei positive for HIF-1α staining were also found in patients with isolated mucosal lesions from GI, bronchial and oropharyngeal tracts (Fig. 6b, b1). Positive nuclei were observed both in endothelial lining vessels and in other spindle cells. The number of positive nuclei after immunostaining with HIF-1α antibody was strongly increased in all visceral KS lesions in comparison to nodular cutaneous KS lesions associated with visceral and disseminated KS disease (Fig. 6a, b, b1). Nuclei positive for HIF-1α staining were mostly observed in all spindle cells. Interestingly, the number of cells expressing LANA-1 staining correlated with the density of positive cells for HIF-1α (Fig. 6b, b2). The nine different groups classified arbitrarily according to the number of LANA-1-positive cell nuclei revealed that groups 1–3 corresponded to patch, plaque skin KS and GI tract, bronchial and oropharyngeal mucosal KS specimens, groups 4–6 to nodular cutaneous KS and groups 7–9 to visceral KS lesions.

Discussion

The natural history and pathogenesis of HHV8 infections in immunosuppressed patients has been extensively studied by different groups [21, 26–30]. The identification of KS patients with poor survival is essential in determining the treatment strategy. However, discrepant results have been reported with reference to the HHV8 viral load in patients' sera in early and late stages of HIV-associated KS. Some studies reported an increase in the KSH/HHV8 DNA load of patients with clinical KS [21, 28, 29]. In contrast, other studies showed a decrease in the HHV8 viral load in sera from patients with late stages of KS, indicating the probability of suppression of HHV8 release and/or immunosegregation of virus during these later stages [26, 30–32]. Another study showed that measurement of the HHV8 load

LANA-1 expression

in peripheral blood mononuclear cells provided a limited correlation with the clinical stage of KS [33]. A recent study performed in AIDS-related KS from Uganda demonstrated that the HHV8 load in peripheral blood was positively and significantly associated with the rate of KS progression but not with the KS burden [34]. Finally, a clinical scoring system to predict survival in HIV-associated KS, which includes the CD4 count, age, association with another AIDS-associated illness, has been established previously in cases with KS as the AIDS-defining illness [35]. Although HIV infection is neither necessary nor sufficient for KS development, it is associated with an increased incidence and a more aggressive course of KS. Moreover, decreased CD4 and/or CD8 lymphocyte counts have been associated with KS progression in HIV-positive patients.

Discrepancies exist between tissue biomarkers and their potential usefulness in various clinico-pathological stages of KS. In this regard, our study was conducted so as to determine the level of expression of LANA-1 in tissues taken from cutaneous, mucosal and visceral HIV-associated KS. LANA encoded by ORF73 is one of the few HHV8-encoded proteins that is highly expressed in all latently infected tumour cells, which strongly suggests that LANA-1 plays a critical role in the maintenance of a latent HHV8 infection. A previous study showed that the highly concentrated expression of LANA-1, anchored to the host genome in the nuclear foci of latently infected cells and replicated through each cell generation, may function as an epigenetic modifier [36]. In our study, we demonstrate that LANA-1 expression is increased in later stages of KS in HIV-positive patients. In cutaneous KS, immunostaining showed a significantly ($p<0.005$) higher rate of positive nuclear nodules than in patch and plaque lesions. Moreover, the level of LANA-1-positive nuclei was dramatically increased in all visceral KS compared to superficial mucosal KS ($p<0.001$) and to nodular cutaneous KS ($p<0.005$). Thus, our observations indicate a strong correlation between the presence of HHV8 in tissue specimens and the KS clinico-pathological features. These results indicate that the viral infection is not aborted during KS progression and that the higher clinical aggressiveness of visceral KS could be linked to a higher HHV8 load in tissues. This is in accordance with a previous study that showed by polymerase chain reaction an increase in the HHV8/KSHV load in cutaneous lesions of AIDS-KS during progression from early (patch/plaque) to late (nodular) stages [37].

In Western countries, AIDS-KS has a clear male predominance [1]. The paucity of KS in women was initially attributed to lower androgenic hormones. However, KS occurs infrequently in women in the Western world since they are only rarely infected with HHV8. In our study, we demonstrate that the level of LANA-1 positive nuclei was similar in tissue specimens from HIV-positive men and women and correlated similarly to the clinico-pathological stages of the disease.

Most people infected with HHV8 do not develop KS, suggesting that HHV8 is a necessary but not sufficient factor for the development and probably the progression of the disease. Thus, in addition to the expression of LANA-1, different molecules involved in cell growth and cell death have been studied in KS biopsy specimens, but data on the development and progression of KS related expression of these molecules are controversial [38–45]. Studies have implicated some genes of HHV8 in the reduction of apoptosis in KS lesions. HHV8 encodes homologues of proteins that are involved in the control of apoptosis (i.e., v-Bcl-2, v-IL6, v-FLIP) or in the control of cellular proliferation and/or differentiation (i.e., v-cyclins, v-G protein-coupled receptors)[17, 18]. Stürzl et al. have shown in a small series of biopsies that sequences encoding the anti-apoptotic protein viral-FLIP are expressed at very low levels in early KS lesions, but expression increases dramatically in late-stage lesions [44]. Other studies suggested several mechanisms to explain the high apoptotic rate in early stage KS. For example, high concentrations of inflammatory cytokines, such as TNF-α and interferon-γ may induce endothelial cell apoptosis [45]. Alternatively, apoptosis in early lesions could be due to activated T cells expressing the pro-apoptotic Fas ligand [19]. However, it is still not clear whether the development and progression of KS are related to increased cell growth or to decreased cell death or both mechanisms. The rather low number of mitoses seen in most KS lesions, together with the absence of a correlation between the histological progression of KS and its proliferation fraction, suggests that the pathogenesis of KS may be related to escape from apoptosis rather than to increased proliferation. In our study, Bcl-2 and Mcl-1 were found to be highly expressed in tumour cells of late-stage KS lesions. Moreover, the level of both these anti-apoptotic proteins strongly correlated with the level of LANA-1 during the different pathological KS stages These findings obtained in a large series of patients strongly support the premise that anti-apoptotic mechanisms have to be operative to allow growth of KS lesions.

In this study, we were interested in looking at the potential role of HIFs in KS progression. It is well known that tumour hypoxia and the critical molecular mediators of hypoxia, HIFs, regulate multiple steps of tumourigenesis including tumour formation, progression and response to therapy [46–48]. HIF-1α is commonly increased in a variety of human tumours [49]. A study demonstrated that hypoxia has a protective effect on apoptotic cell death [50]. Moreover, angiogenesis is critical for tumour progression and HIF can directly activate the expression of a number of pro-angiogenic factors, including VEGF and VEGF recep-

tors [46]. In this regard, recent work has demonstrated that LANA-1 can function as an inhibitor of HIF-1α suppressor proteins, but can also induce nuclear accumulation of HIF-1α during latent infection [20]. Moreover, it has been shown in vitro, that HHV8 infection of primary cultures leads to increased expression of HIF-1α and the activation of HIF may play a role in KS formation, localization and tumour progression [51]. Our present work clearly demonstrates that the levels of HIF-1α and LANA-1 are significantly correlated.

Although the mechanism(s) by which HHV8 is involved in the progression of KS lesions cannot be elucidated from the mostly descriptive data presented here, we can put forward different hypotheses. Our finding that LANA-1 expression increases from early patch to late nodular cutaneous and visceral KS lesions are consistent with several previous reports of increased cell survival caused by the inhibition of apoptosis by viral gene [31, 42, 44]. In this regard, a bimodal model of KS tumour development from an early (cutaneous patch) reactive lesion to late (cutaneous nodule and visceral involvement) progressively clonal tumour cell proliferation can be proposed. In addition, a significant difference in proliferation between LANA-1 positive and negative spindle cells was found previously and suggests that LANA-1 positive spindle cells may have a proliferative advantage [37]. However, the reason why the HHV8 load increases during tumour progression is still unclear and further studies are needed to determine if viral permissiveness is increased in the different subpopulations of cells present in KS lesions during tumour progression. A potential mechanism to explain how HHV8 stimulates tumour progression could implicate the action of virally encoded G-protein-coupled receptor (vGPCR), an HHV8 lytic gene product that has been functionally linked to HHV8-mediated tumourigenesis [52]. By activating the Ras, Raf and Rac intracellular signalling pathways, vGPCR could induce the expression and secretion of vascular endothelial growth factor in an autocrine and paracrine manner [53]. Moreover, this process might also involve the direct phosphorylation of HIF-1α [54].

Finally, we demonstrated, in a large series of AIDS patients with KS, a stage-related increase in LANA-1, Bcl-2, Mcl-1 and HIF-1 α protein levels that is strongly associated with a strong correlation of these molecules in KS progression. In future, the data may be useful in distinguishing between patients with a low- and high-risk of disease progression and in predicting their survival.

Abstract To investigate the involvement of transdifferentiation and dedifferentiation phenomena inside atherosclerotic plaques, we analyzed the differentiation status of vascular smooth muscle cells (VSMC) in vitro and in vivo. Forty normal autoptic and 20 atherosclerotic carotid endarterectomy specimens as well as 20 specimens of infrarenal and suprarenal aortae were analyzed for the expression of cytokeratins 7 and 18 and β-catenin as markers (epithelial transdifferentiation) as well as CD31 and CD34 (embryonic dedifferentiation) by conventional and double fluorescence immunohistochemistry and reverse transcription polymerase chain reaction. Looking at these markers, additional cell culture experiments with human aortic (HA)-VSMC were done under stimulation with IL-1β, IL-6, and TNF-α. Cytokeratins and β-catenin were expressed significantly higher in atherosclerotic than in normal carotids primarily localized in VSMC of the shoulder/cap region of atherosclerotic lesions. Additionally, heterogeneous cellular coexpression of CD31 and/or CD34 was observed in subregions of progressive atherosclerotic lesions by VSMC. The expression of those differentiation markers by stimulated HA-VSMC showed a time and cytokine dependency in vitro. Our findings show that (1) VSMC of progressive atheromas have the ability of differentiation, (2) that transdifferentiation and dedifferentiation phenomena are topographically diverse localized in the subregions of advanced atherosclerotic lesions, and (3) are influenced by inflammatory cytokines like IL-1β, IL-6, and TNF-α.

Introduction

The process of atherosclerosis is described as a chronic and complex immune-mediated inflammatory disease [1]. This model is supported by the detection of an enlarged inflammatory cell infiltrate in atherosclerotic plaques, possibly caused by infectious agents (like viruses [cytomegalovirus or herpes virus] or bacteria [*Chlamydia pneumoniae* or *Helicobacter pylori*]) [2]. Additionally, the response-to-injury hypothesis of atherosclerosis focuses on the central role of activated and proliferating vascular

smooth muscle cells (VSMC) that are histologically observed in the early and late stages of atherosclerosis, thus being a key event in atherosclerosis [3–5].

It is now accepted that VSMC can display at least two different phenotypes in the pathogenesis of atherosclerotic lesions: (1) highly differentiated, contractile cells of the media and (2) synthetically active and proliferating cells invading the intima [6]. Inside normal arteries, VSMC are highly differentiated cells being responsible for the regulation of blood pressure and vascular tension. In atherosclerotic plaques, VSMC can display a more active cell type, i.e., proliferating, migrating, and secreting different proteins leading to intimal thickening and fibrosis of the vascular wall [7]. Intimal thickening seems to be the first sign of atherosclerosis, but until today, it is not known what kind of injury leads to the response of initiating atherosclerosis.

The gene expression pattern of end-differentiated VSMC is well characterized (e.g., α- and β-smooth muscle actin, smooth muscle 22α, calponin, smoothelin, and smooth muscle myosin heavy chain) [6]. Many studies dealing with proliferating VSMC show evidence that VSMC of artery walls have a multilineage potential [8] and express many different cell line antigens. Until now, a specific marker of the synthetic state of VSMC has not been established [6, 9]. The phenomena of transdifferentiation and dedifferentiation are highly conserved processes of organism development as well as of organ regeneration and reparation [10]. Recent hypotheses raised the question whether unregulated processes of the transition state could essentially be involved in chronic degenerative and inflammatory diseases like atherosclerosis as has been shown for tumorigenesis [11–13]. Therefore, understanding these processes could help to develop new therapeutic targets. Relevant and systematically evaluated data of transdifferentiation and dedifferentiation phenomena analyzing the phenotypic states of typical cellular components of normal arterial walls and of progressive atherosclerotic lesions in vitro and in vivo are still sparse or missing [14].

Therefore, in our studies, we aimed to investigate the capacity of VSMC to transdifferentiate and dedifferentiate by investigating the expression of (1) cytokeratin 7 (CK7)/cytokeratin 18 (CK18) and β-catenin (transdifferentiation) and of (2) CD31/CD34 (dedifferentiation) in vivo (normal vessels vs. early and advanced atherosclerotic lesions) as well as in vitro.

Materials and methods

Tissue preparation

In our study, 20 carotid arteries of patients (mean age 69± 11.4 years [median, 67 years; range, 55–81 years]; 58% male) who underwent carotid endarterectomy at the Department of Vascular Surgery, University Hospital Bochum and University of Bremen after ischemic stroke were analyzed by histology and immunohistochemistry. All of them showed at least type VI atherosclerotic lesions according to the American Heart Association (AHA) classification of human atherosclerotic lesions [15]. Stroke was diagnosed according to the World Health Organization criteria [16]. Patients with evidence of any cerebral disease proven by brain autopsy were excluded from the control group. Forty unaltered carotids from autopsy cases which were morphologically free of atherosclerosis and showed at most early lesions corresponding to type I/II of the AHA classification at light microscopy served as controls.

To evaluate atherosclerotic lesions in other localizations and of different plaque category, 20 aorta specimens from routine autopsy cases were acquired and classified histologically into three groups: normal arteries, early lesions, and advanced atherosclerotic lesions (mean age 63± 12.4 years [median, 62 years; range, 51–82 years]; 54.2% male) representing types I to VII grade atherosclerotic lesions according to the AHA classification.

All specimens were divided in halves. One part was frozen immediately and stored at −80°C; the other half was routinely fixed with buffered formalin (5% [*v*/*v*]), decalcified in 0.4 M ethylenediaminetetraacetic acid, dehydrated, and embedded in paraffin. Five-micrometer-thick paraffin sections were cut and stored at room temperature until use.

Histochemical methods

Routine hematoxylin and eosin staining was used to classify the extent of atherosclerosis according to the AHA classification [15].

Immunohistochemical analysis

For the purpose of detecting CK7 and CK18, β-catenin (monoclonal and polyclonal), CD31, and CD34 immunohistochemical (IHC) staining was performed. In short, mouse antibodies (IgG1) against CK7, CK18, β-catenin, as well as CD31/34 were applied (Table 1), followed by a biotinylated rabbit antimouse (goat antirabbit in the case of the CD154 and the polyclonal β-catenin antibody; both from Dako, Denmark) secondary antibody. Immunoreactivity was detected by peroxidase staining using the streptavidin–biotin–peroxidase method (Dako, Denmark), based on alkaline phosphatase and 3-hydroxy-2-naphtylacid 2,4-dimethylanilid (Fast Red, Sigma-Aldrich, Germany) as chromogen following Dako's recommendations. Nuclei were counterstained with hematoxylin.

To compare the expression levels of CK7, CK18, β-catenin, as well as of CD31 and CD34, all cells (stained

P pronase (2 mg/mL, PBS, pH7.4, 10 min at 37°C; Sigma, Germany), *Pt* protease XXIV (0.05 mg/mL, PBS, pH7.2, 10 min at 37°C; Sigma, Germany), *MW* microwave (10 mmol/L citrate buffer, pH6.0; 10 min at 800 W and 10 min at 560 W), *TRS* target retrieval solution (pH6.0; DakoCytomation, Denmark) used instead of citrate buffer, *na* not applicable

positive and negative) were counted in ten randomly selected high-power fields by two independent observers, and the number of immunohistochemically positive cells are given as the percentage of all cells in the investigated areas. Furthermore, immunohistochemistry for CD68, smooth muscle actin, and CD40/CD40L (CD154) was performed on consecutive slides in order to characterize the cells expressing these markers. CD40/CD40L staining was done as described above but with 3,3′-diaminobenzidine instead of Fast Red as peroxidase substrate.

Double immunofluorescence staining was done as follows. In formalin-fixed, paraffin-embedded tissue sections, antigen retrieval was done using Dako TRS® (target retrieval solution, Dako Denmark code S1700). In short, after rehydration and washing with 10% Tris-buffered saline (TBS), every slide was coated with Dako TRS® for 30 min at room temperature. In chamber slide probes, the fixation was done with ice-cold methanol (−20°C); so after rehydration, no antigen retrieval had to be done. Primary antibodies were applied after washing with 10% TBS in the same dilutions as done with conventional immunohistochemistry (see Table 1), but secondary antibodies were replaced by goat antimouse antibodies labeled with Alexa Fluor® (Molecular Probes, Invitrogen, Germany; dilution 1:250) dye with a maximum excitation at 488 nm (green) or 568 nm (red). Using the polyclonal rabbit anti-β-catenin primary antibody, a goat antirabbit antibody labeled with Alexa Flour® 488 (Molecular Probes, Invitrogen, Germany) was applied as secondary antibody. In all stainings, Alexa Fluor® 568 (red) was applied to mark smooth muscle cell actin whereas green (Alexa Fluor® 488) labeled the second epitope. Nuclear staining was done using 4′,6-diamidino-2-phenylindole (DAPI, dihydrochloride; FluoroPure®, Invitrogen, Germany). For the use of two different secondary antibodies from the same species, the technique of Negeoscu et al. [17] was used. In short, the first secondary antibody was used at five times higher concentration (dilution 1:50) than in normal immunohistochemistry (1:250) and incubated for 4 h at room temperature. After washing, the sections were incubated overnight with goat antimouse IgG, F(ab)2-fragment (1:10, Danova, Germany) in order to saturate all antimouse binding sites. Then the second primary antibody was applied and further staining was done as in conventional immunohistochemistry. The staining was evaluated using a Leica microscope (Leica DM6000B, Germany) with ImagicAccess Enterprise 5® software (Imagic AG, Switzerland) to

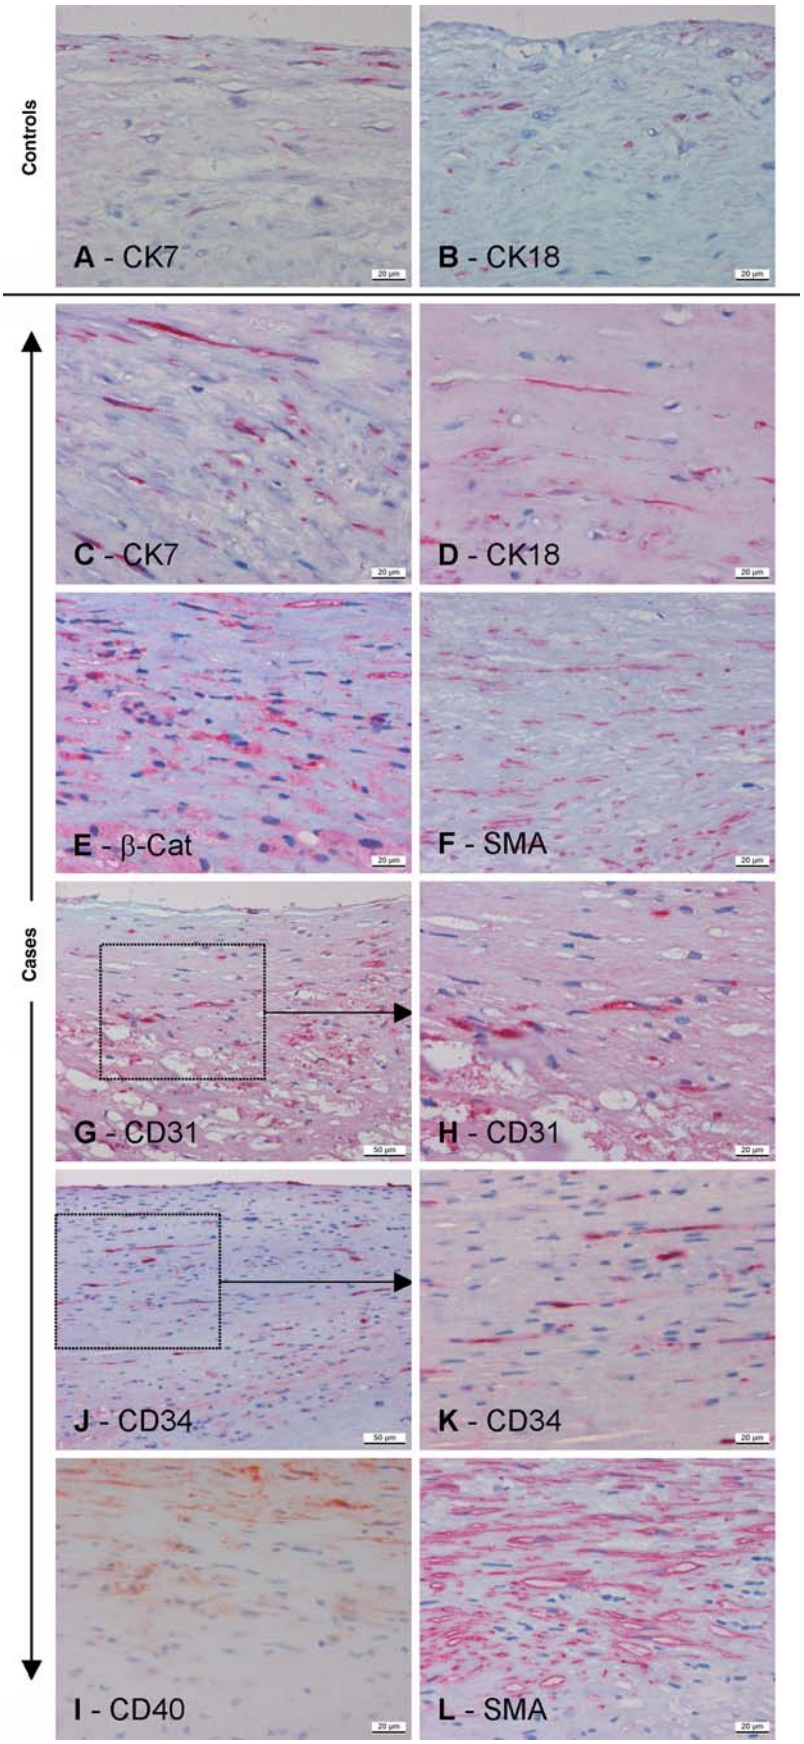

Fig. 1 Typical IHC distribution of CK7, CK18, β-catenin, CD31, and CD34 in normal controls (**a**, **b**) and in atherosclerotic lesions (**c**–**l**). In short, expression of CK7 (**a**; control PASN04) and CK18 (**b**; control PASN12) was very focally in controls, whereas higher frequency of CK7-positive (**c**; case GCH_B12) and CK18-positive (**d**; case GCH_B12) cells could be observed in cases. In comparison to CK7 and CK18, β-catenin (**e**; case GCH_B12), CD31 (**g** and, in detail, **h**; case GCH_B28), and CD34 (**j** and, in detail, **k**; case GCH_B28) as well as CD40 (**i**; case GCHB_28) were expressed sparse to low in cells of atherosclerotic plaques in cases in comparison with the expression of smooth muscle actin on consecutives slides (**f**; case GCH_B12 and **l**; case GCH_B28). Magnifications ×400 (**a**–**f**, **h**, **l**, **k**, and **i**) and ×200 (**g** and **j**)

processed as described above. All control samples were negative (not shown).

To estimate the extent of CD31-positive and CD34-positive signals derived from macrophages, all immunofluorescence stainings were repeated with an anti-CD68 antibody (to mark macrophages) replacing the anti-SMA antibody.

To investigate the reliability of the categories for evaluating the expression of CK7, CK18, β-catenin, as well as CD31 and CD34, the analyses were repeated in all specimens by an independent observer. The agreement of the classification was good ($\kappa \geq 0.70$).

RNA isolation and reverse transcription

For RNA analysis, approximately 10 mg of frozen tissue or the content of one cell culture well of a six-well plate was homogenized for 30 s in 1 mL (700 µL for cell culture) RNAPure™ (PeqLab Biotechnology, Erlangen, Germany). Further RNA isolation was done by peqGOLD RNAPure™ according to the manufacturer's recommendations. Total RNA concentration was evaluated photometrically and RNA integrity was confirmed on an agarose gel. RNAs were frozen instantly and stored at −80°C until further processing. For reverse transcription, we used 1 µg of the isolated RNA, 100 pmol oligo-dT, 50 pmol random primer, and 100 U Superscript II (Invitrogen) following the recommendations of the supplier. The cDNA was stored at −20°C until use.

Quantitative real-time PCR

Real-time reverse transcription polymerase chain reaction (RT-PCR) was performed as recently described [19]. In short, the LightCycler FastStart DNA Master SYBR Green I Kit (Roche, Mannheim, Germany) was used according to the manufacturer's instructions. The 20-µL probe contained 5 mM $MgCl_2$, 0.4 µM of each primer, 2 µL of the DNA template, and 2 µL of the Master Mix (including polymerase, dNTP). The PCR was performed as follows: (1) initial denaturation at 95°C for 10 min; (2) 40 cycles of denaturation at 95°C for 10 s, annealing at 60°C for 5 s, and elongation at 72°C for 10 s; and (3) a melting curve was arranged at 95°C, 60°C, and 95°C following the manufacturer's recommendations. Measurements were done in triplicate and standardized to GAPDH. To exclude variations in the expression of GAPDH [20, 21], 18S rRNA of the human specimen was measured as a second reference to substantiate our results. The expression of 18S rRNA and GAPDH showed a positive significant correlation ($p<0.001$, Pearson's $r=0.964$). The quantitative real-time PCR analyses were performed on a LightCycler real-time PCR machine (Roche).

The sequences of primers are listed in Table 2 and were synthesized at MWG Biotech AG (Ebersberg, Germany).

Fig. 2 Double immunofluorescence staining for CK7, CK18, β-catenin, as well as for CD31 and CD34 using Alexa Fluor® 488 (*green*) in combination with staining for smooth muscle cells with Alexa Fluor® 568 (*red*). Nuclear staining was done with DAPI. Overall, colocalization of fluorescence signals in the cytoplasm (in descending order of intensity) of CK7, CK18, β-catenin, CD31, and CD34 with SMA could be observed, whereas the expression of CD31 and CD34 (see *arrows*) was very low by SMA-positive VSMC showing no lumen. Magnifications ×630 (CK7, CK18, and β-catenin) and ×1,000 (CD31 and CD34)

Each PCR assay was repeated three times for each cDNA sample. To monitor the amplification of possible contaminating DNA, distilled water served as a negative control.

Cell culture experiments

In order to reflect inflammatory conditions in atherosclerosis, we carried out stimulation experiments of VSMC with the major proinflammatory and proatherosclerotic cytokines IL-1β, IL-6, and TNF-α [22, 23].

Human aorta VSMC (T/G HA-VSMC, Promochem, London, UK) were cultivated on six-well tissue plates (Becton Dickinson, Mannheim, Germany) in Dulbecco's modified Eagle's medium high-glucose medium with L-glutamine (PAA Laboratories, Pasching, Austria) containing 10% fetal bovine serum (Biochrom) at 37°C and 5% CO_2. According to the manufacturer (ATCC), the HA-VSMC smooth muscle cell line was derived from the normal aorta of an 11-month-old female, blood type O rhesus positive. The cell line has been reported to undergo a total of 30 to 35 passages before the onset of senescence. Cells were grown to 75% confluence before stimulation with TNF-α (25 ng/mL), IL-1β (10 ng/mL), and IL-6 (10 ng/mL; Strathmann Biotech, Hannover, Germany). Cells were harvested after 6, 12, and 24 h of stimulation. RNA isolation with RNAPure was carried out immediately as described. For statistical reasons, all stimulation experiments were repeated thrice. Data shown on Fig. 5 are based on three independent experiments. For immunohistochemistry, cells were grown in chamber slides (NUNC®, Germany) and fixed after stimulation in ice-cold methanol (−20°C) for 20 min before immunohistochemistry was carried out as described above.

Ethics

The study was approved by the local ethics committee (# 1041/1998) and the Data Protection Committee of the University of Erlangen–Nuremberg. Informed consent was obtained from all case and control subjects. The participants who were not able to consent for themselves had given consent through their next of kin or guardian.

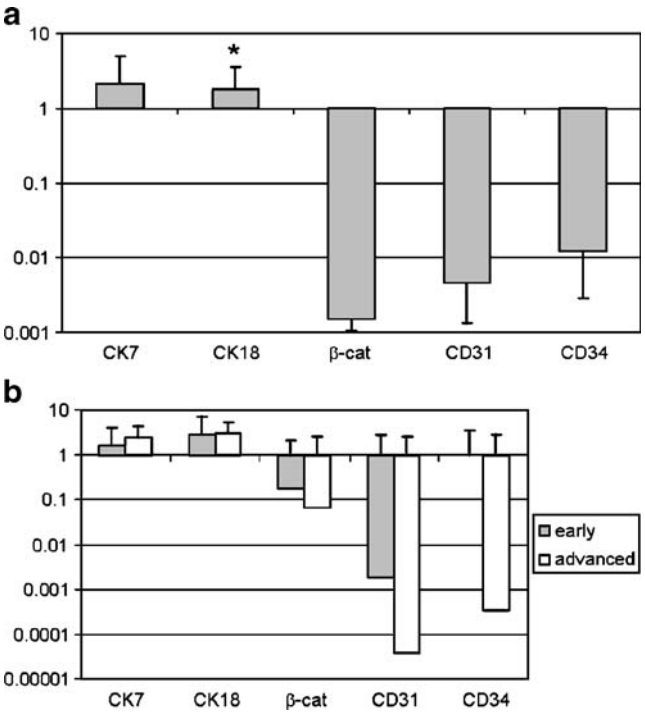

Fig. 3 Quantitative RT-PCR. Relative mRNA content of atherosclerotic lesions of arteries of elastic type [carotid artery (**a**) and abdominal aorta (**b**)]. mRNA content was normalized to GAPDH and is expressed in relation to normal vessels (set at 1.0) for each gene of interest. Mean values (with standard deviation) of three independent PCR analyses are shown. *$p<0.05$, significant changes (Student's *t* test)

Statistics

Statistical analysis was done using the SPSS 15 software package (SPSS, USA). The Student's *t* test and Mann–Whitney *U* test were used to proof differences in interval and ordinal variables. For testing the reliability of the quantification of CK7, CK18, β-catenin, as well as CD31 and CD34 expression between the investigators, kappa statistic was used. All tests were two-tailed, and statistical significance was determined at an alpha level of 0.05.

Results

Immunohistochemistry of carotids

Expression of CK7 and CK18 as well as β-catenin as markers for epithelial transdifferentiation was significantly ($p<0.05$) higher in symptomatic than in normal carotids. The percentage of positively stained cells decreased from β-catenin, CK7, and CK18 in cases and from β-catenin, CK18, and CK7 in controls (see Table 3). Although it is assumed that IHC staining with polyclonal antibodies against β-catenin is better for detecting nuclear β-catenin expression, we did not find a difference in the cellular distribution but in the amount of β-catenin between monoclonal or polyclonal antibodies (see Table 3).

Looking closer at the subregions of the plaques, the expression of cytokeratins and β-catenin was, besides the core region, maximal in the shoulder and/or cap region of atherosclerotic lesions (see Table 3). Additionally, expression levels of monoclonal β-catenin were similar in the cap and basis plaque subregions. On the cellular level (VSMC, fibroblasts, macrophages, and endothelial cells), positive staining of CK7 and CK18 as well as β-catenin was higher in VSMC and macrophages, whereas in endothelial cells, their expression was only a rare event interpreting immunohistochemistry of consecutive slides with smooth muscle actin and CD68 (Fig. 1). β-Catenin staining showed increased cytoplasmatic positivity of VSMC inside atherosclerotic lesions while staining of the nuclei could rarely be observed. Coexpression of β-catenin and CD40 could be observed on serial sections (Fig. 1).

Although the rate of CD31-positive and CD34-positive cells with VSMC morphology indicating embryonic dedifferentiation was low in controls and cases, the amount of CD31-positive or CD34-positive cells was significantly higher in atherosclerotic plaques of cases than in normal arteries of controls ($p<0.05$; see Table 3). Overall, the expression of CD34 was significantly higher than of CD31 ($p<0.05$). Inside the plaques, CD31 and CD34 were, besides the endothelium, mainly expressed in the shoulder region of the plaques (see Table 3 and Fig. 1), whereas the expression levels inside the cap and basis regions were comparable in contrast to CK7 and CK18.

No association between expression of cytokeratins, β-catenin, CD31, and CD34 was found looking at the whole plaque or plaque subregions expression using correlation analysis.

Double immunofluorescence of carotid specimen

Double immunofluorescence stainings of selected carotid samples confirmed the results of the conventional immunohistochemistry: inside the shoulder and core regions, SMA-positive VSMC had a strong coexpression of CK7 and CK18 with a sizeable overlapping of fluorescence

Fig. 4 **a** Typical IHC expression of CK7, CK18, β-catenin, CD31, and CD34 of smooth muscle cell lines after treatment with IL-1β (10 ng/mL), IL-6 (10 ng/mL), or TNF-α (25 ng/mL) compared to untreated controls (magnification ×400). **b** Double immunofluorescence staining for β-catenin using Alexa Fluor® 488 (*green*) in combination with staining for smooth muscle cells with Alexa Fluor® 568 (*red*) after treatment with TNF-α (25 ng/mL) compared to untreated controls. signals in the cytoplasm (Fig. 2). A nuclear expression of CK7 or CK18 was not detected. The level of expression of β-catenin was lower than with CK7 and CK18 but with a similar cytoplasmatic overlap as seen in CK7 and CK18. Partially, β-catenin could be localized predominantly cytoplasmatic near the nucleus using DAPI nucleus staining (Fig. 2). Finally, CD31 and CD34 were focally coexpressed by SMA-positive VSMC showing no lumen (see arrows Fig. 2).

The double immunofluorescence staining of CD68 (for macrophages) and CK7, CK18, β-catenin, as well as CD31 and CD34 showed that coexpression of these markers (especially CK7 and CK18) is a very sparse event, indicating that, inside atherosclerotic lesions, the process of transdifferentiation and dedifferentiation is mainly associated with VSMCs (data not shown).

RNA analysis of carotids and infrarenal aorta specimen

The normalized expression levels of CK7, CK18, β-catenin, CD31, and CD34 were comparable in carotid and aortal specimens. Corroborating the IHC results, mRNA levels of CK7 and CK18 were significantly higher inside the plaques (Fig. 3a, b) and especially the CK7 levels increased with progression of the atherosclerotic lesion (Fig. 3b). Unlike the IHC results, β-catenin, CD31, and CD34 expressions were lower with a trend towards significance in atherosclerotic plaques. The levels declined in dependence of the atherosclerotic lesion (see Fig. 3b).

Cell culture experiments of human aorta vascular smooth muscle cells

Immunohistochemical results of stimulated HA-VSMC

The modification of markers for transdifferentiation and dedifferentiation during stimulation inside chamber slides with IL-1β, IL-6, and TNF-α is shown in Fig. 4a: In summary, the basal expression levels of all investigated markers were low (CD31 and CD34) to moderate (CK7, CK18, and β-catenin) within the time range investigated. IL-1β-stimulated HA-VSMC showed a lower intensity of all investigated markers in comparison to untreated controls independent of time. HA-VSMC treated with TNF-α or IL-6 also express lower levels of all markers analyzed for the first 12 h. After 24 h of stimulation with TNF-α or IL-6, staining for CK7, CK18, and β-catenin was more intense in comparison to the untreated controls, whereas CD31 and CD34 displayed negative or low positive pattern during the entire experiment. Noteworthy, β-catenin stained cytoplasm of controls but was located in a perinuclear pattern during stimulation with IL-1β, IL-6, and TNF-α being exemplarily highlighted using double immunofluorescence stainings after treatment with TNF-α (see Fig. 4b).

mRNA analysis of stimulated HA-VSMC

The results of RT-PCR analysis of HA-VSMC stimulated in six-well plates with the same cytokines as described above are shown in Fig. 5 and are corroborative with the immunohistological findings. In short, IL-1β reduced the expression of all investigated markers over the whole observation period. Particularly, CD31, CD34, CK7, and CK18 expressions were suppressed, whereas β-catenin remained unaffected. The reduction of the mRNA expression of CK7 and CK18 was time-dependent.

Stimulation with IL-6 lowered the expression levels of CD31 and CD34 throughout the period of surveillance. In contrast to that, the expression of CK7, CK18, and β-catenin was diminished during the first 12 h. After 24 h of stimulation with IL-6, the expression of CK7, CK18, and β-catenin was higher than in the controls.

Under the influence of TNF-α, all investigated cytokeratins showed a decreased expression for the first 12 h. After that, parallel to the effect seen under IL-6 stimulation, CK7, CK18, and β-catenin exceeded the levels seen in the controls. CD31 and CD34 expression after 24 h of stimulation with TNF-α was higher than in the controls.

Discussion

The process of atherosclerosis is in the beginning characterized by intimal thickening caused by hyperplasia of VSMC. Different models of how migrating, secreting, and proliferating VSMC appear inside the arterial wall are currently discussed: One possibility is that circulating smooth muscle precursor cells of myeloid or hematopoietic lineage relocate from the blood into atherosclerotic lesions [24] and start to proliferate. Another possibility is that local VSMC of the contractile phenotype reobtain the embryonic potential of proliferation and migration [25–32] via transdifferentiation and dedifferentiation processes as a response to injury. Additionally, the reactivation of localized predisposed smooth muscle cells are regarded as being essentially involved in these of process intimal thickening using embryonic pathways, too [33].

In our study, we were able to show that, inside atherosclerotic specimens, (1) VSMC of progressive atheromas have the ability of differentiation, (2) transdifferentiation and dedifferentiation phenomena are topographically dependent on subregions of advanced atherosclerotic lesions, and (3) this phenotype plasticity is influenced by inflammatory stimuli and associated with plaque progression and possibly also plaque rupture. These findings corroborate that VSMC could exhibit high plasticity which is associated with and is possibly involved in advanced atherosclerosis.

Whereas the gene expression pattern of differentiated VSMC is well characterized [6], many in vivo and in vitro studies dealing with proliferating VSMC showed heterogeneous cell marker expressions of multilineage differentiation [8, 9]. Very well known is the capacity of VSMC for phenotypic changes in cell culture stimulation experiments emphasizing the differentiation potency of VSMC [34]. One possible way to characterize the multilineage potential of VSMC is to analyze gene expression indicating differential gene regulation being associated with extracellular matrix remodeling as well as with cell motility in general [35]. Another way to approach understanding the morphological and molecular phenotype switching of VSMC is to look at vascular development. Interestingly, similar to atherosclerosis, processes of multilineage differentiation with transition states could be observed during vascular development [9, 34, 36, 37]. Embryonic VSMC derive from different cells of origin via transdifferentiation, e.g., coronary VSMC from epicardial lining, aortic VSMC from local mesenchyme (for details, see [38]).

Interestingly, VSMC can express cytokeratins during development and in atherosclerotic lesions, indicating a highly conserved phenomenon of transdifferentiation, too [11, 25–32]. Overall, the expression of cytokeratin by VSMC is linked to a proliferative state of VSMC (see also review [39]). We were able to confirm these findings of high expression of cytokeratins inside progressive atherosclerotic lesions on mRNA and protein level. Our results are, therefore, in line with previous reports of a distinct CK18 expression in either proliferating fetal smooth muscle cells, in dedifferentiated cultured smooth muscle cells, or in atherosclerotic lesions [29, 32, 39]. Additionally, using immunohistochemistry, we were able to localize cytokeratins and β-catenin in subregions of progressive plaques, emphasizing the importance to discriminate different plaque regions. In detail, markers of transdifferentiation such as CK7 and CK18 were predominantly found in areas being relevant for plaque instability, whereas markers of activation such as β-catenin were detected all over the plaque indicating an enhanced level of whole plaque remodeling. Another marker of activation, CD40, which plays a key role in the inflammatory scenario of atherosclerosis [40], is coexpressed in β-catenin-positive cells. Interestingly, different expression levels of cytokeratins were found in atherosclerotic arteries of muscular type (data not shown). Our cell culture experiments confirmed these findings and highlight the importance of VSMC in the progression of atherosclerosis. Obviously, cytokeratin expression of smooth muscle cells is influenced by inflammatory cytokines such as IL-1β, IL-6, and TNF-α. These findings are in line with cDNA array data showing that reduced expression of cytoskeleton proteins (such as cytokeratins) is linked with an invasive phenotype [35].

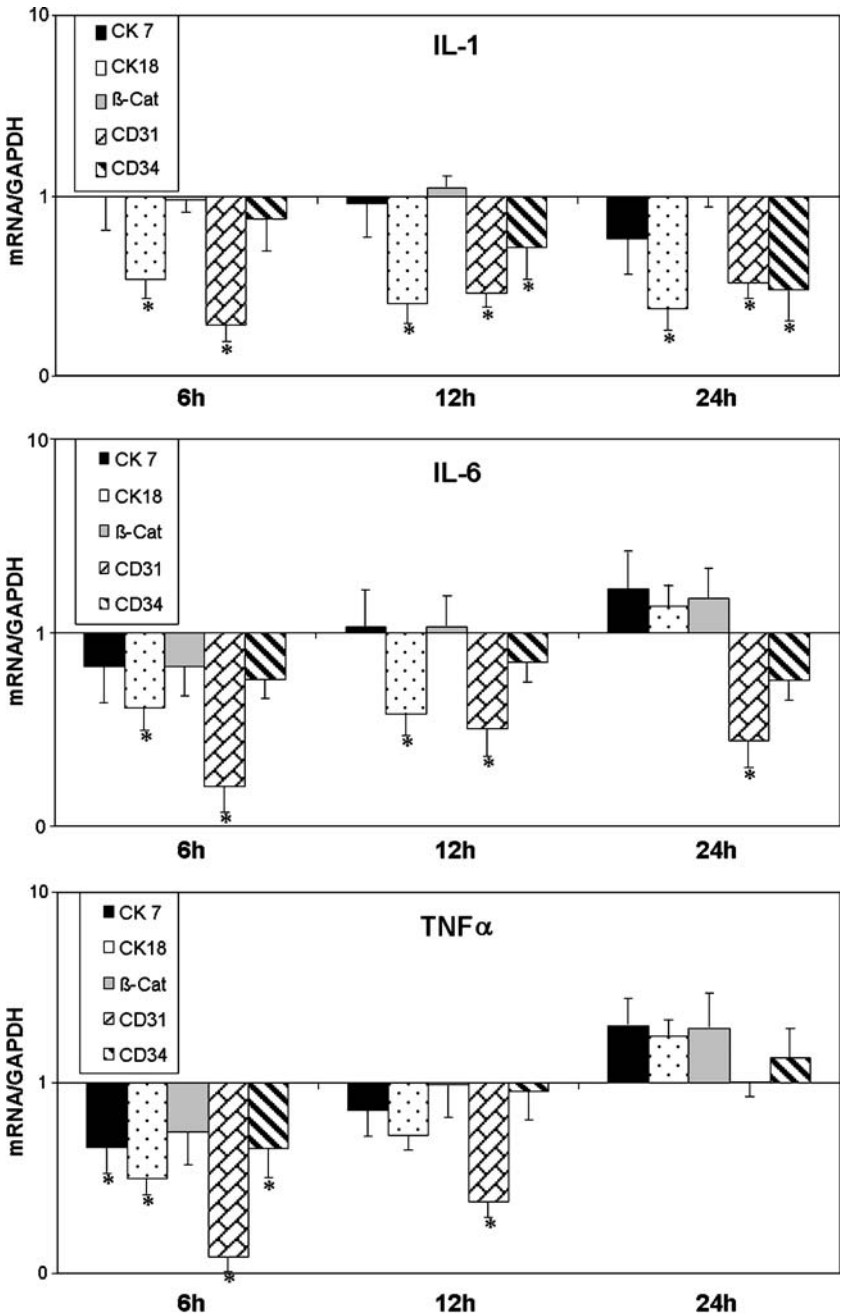

Fig. 5 Quantitative RT-PCR. Relative mRNA content of smooth muscle cell lines after treatment with IL-1β (concentration 10 ng/mL), IL-6 (10 ng/mL), or TNF-α (25 ng/mL); mRNA content was normalized to GAPDH and is expressed in relation to untreated controls (set at 1.0) for each gene of interest. Mean values (with standard deviation) of three independent PCR analyses are shown. *$p<0.05$, significant changes (Student's *t* test)

Another possible link to the process of embryonic dedifferentiation of VSMC is the finding that multipotent CD34-positive stem cells could display a VSMC-like phenotype [14, 34, 41–46]. The term of dedifferentiation describes an embryonic-like status with temporary multilineage potency [10]. Looking at atherosclerosis and VSMC, there is a lot of evidence that VSMC progenitor cells are essentially involved in the progression of atherosclerosis [47]. The origin of such VSMC progenitor cells is under debate, i.e., whether these cells derive from bone marrow or dedifferentiated intimal cells. This indicates, however, that there may be many possible origins of VSMC [47–49]. It has been recently shown that vascular progenitor cells exist inside normal vessel walls and the number is increased in atherosclerotic lesions [50]. Serial sections of carotid specimens showed a heterogeneous expression of CD31 and CD34 of cells displaying typical smooth muscle cell morphology, being in line with the hypothesis that, not only bone marrow, but also local vascular-derived stem cells could be detected in atherosclerotic lesions [50]. Overall, the analysis of expression levels of these markers of dedifferentiation indicates that processes of dedifferentiation are low but increase in progressive atherosclerotic lesions in all areas. Our cell culture experiments illustrated

a heterogeneous response to stimulation with proinflammatory cytokines, indicating an influence of those cytokines on the differentiation status of VSMC. Overall, the prolonged suppression of the CD34 and CD31 expression over the observation period suggested that dedifferentiation is not an early event under inflammatory influence in vitro.

Additionally, the β-catenin/Wnt signaling pathway could modulate the proliferation, activation, and differentiation state of VSMC [14, 51–55] similar to what is known and well established for different cancer types. In our cell culture experiments, after a downregulation over the first 12 h, we could observe a β-catenin upregulation after 24 h of stimulation being in line with the observations of an upregulation of β-catenin after experimental balloon injury of rat vessels [53]. It is noteworthy that we found a discrepancy between β-catenin mRNA levels as determined by RT-PCR and IHC staining results which indicate a phenotypic stabilization of the protein with transcriptional suppression of the cognate mRNA. Interestingly, low-density lipoprotein receptor protein is associated with VSMC proliferation and survival via β-catenin linking the β-catenin signaling cascade not only with mechanic (such as balloon injury) but also with lipid status and biochemical pathways [56]. Furthermore, differentiation phenomena in epithelial cell types, e.g., colorectal or pancreatic cancer, have also been shown to involve Notch or β-catenin signaling as has also been demonstrated for VSMC during atherosclerosis [13, 39]. Other growth factors like platelet-derived growth factor (PDGF) have been linked to vascular homeostasis and atherogenesis, predominantly after mechanical or rheological stress and release from macrophages in vivo [57, 58]. The role of PDGF in vitro, in contrast, is still controversial with studies reporting proatherogenic and proproliferative effects on smooth muscle cells [59] or induction of apoptosis in fibroblasts [60]. We, therefore, investigated the effect of classical inflammatory cytokines in our setting, although we acknowledge that PDGF, fibroblast growth factor, or vascular endothelial growth factor may also play a role in the complex pathogenesis of atherosclerosis in vivo.

Taken together, our in vitro experiments show that markers of transdifferentiation are re-expressed sooner than those of dedifferentiation in vitro. Possibly, the earliest main effect of the VSMC is cell cycle arrest and, after that, starting differentiation pathways. Although early molecular events should be observed, our in vitro time period of 24 h after stimulation could not exclude that differentiation markers raised dramatically. Another possible explanation is that, in our in vitro experiments, only a selection of inflammatory cytokines was used. In vivo, there are not only additional influences by extracellular matrix molecules, but there is also a combination of different cytokines affecting VSMC differentiation.

Unregulated processes of a transition state could essentially be involved in tumor genesis as well as in chronic degenerative and inflammatory diseases like atherosclerosis [11–13]. Our study shows that the observed activation of differentiation pathways is essentially associated with progressive atherosclerosis-like inflammation and matrix remodeling (see review [4, 12]).

In summary, our experiments give evidence that transdifferentiation and dedifferentiation processes of VSMC are present in atherosclerosis and that expression of several differentiation markers can be influenced by proinflammatory cytokines known to be relevant in atherosclerosis.

CASE REPORT

Pulmonary histiocytic sarcoma mimicking pulmonary Langerhans cell histiocytosis in a young adult presenting with spontaneous pneumothorax: a potential diagnostic pitfall

Elvira Stacher · Christine Beham-Schmid · Hans-Joachim Terpe · Nektaria Simiantonaki · Helmut Hans Popper

Received: 23 February 2009 / Revised: 1 June 2009 / Accepted: 6 June 2009 / Published online: 27 June 2009

Abstract We present a case of a histiocytic sarcoma incidentally detected in peripheral lung tissue resected for a spontaneous pneumothorax. Furthermore, we discuss the practical approach to pulmonary Langerhans cell histiocytosis, the main differential diagnosis of this lesion in the lung, based on morphological and immunohistochemical features. A 23-year-old male patient presented with recurrent pneumothoraces. The pulmonary tissue showed a single round granuloma-like lesion measuring 4 mm in diameter in close neighbourhood to a bronchial wall. The granuloma consisted of histiocytic cells with enlarged pale nuclei, plasma cells, lymphocytes and scanty eosinophilic granulocytes giving the impression of a granuloma of pulmonary Langerhans cell histiocytosis on haematoxylin and eosin (H&E) stains. Immunohistochemically, the histiocytic cells were negative for CD1a and S-100. They were positive for CD68, HLA-DR, CD14, CD4, CD11c, CD45LCA and lysozyme. MIB1 (Ki67) showed a nuclear staining of approximately 10% of the histiocytic cells. In summary, these findings were in keeping with a histiocytic sarcoma, a rare haematopoetic neoplasm. By demonstrating this particular case, we emphasise the importance of proving the diagnosis of pulmonary Langerhans cell histiocytosis by means of immunohistochemistry. In case of a negative CD1a reaction in a histiocytic lesion, further immunohistochemical studies have to be performed in order not to misdiagnose a malignant haematopoetic lesion.

Introduction

A variety of underlying or concomitant conditions and diseases in the occurrence of spontaneous pneumothoraces is known. Apart from the frequently seen different emphysematous changes including juvenile, bullous or scarring emphysema, smoking-related diseases like respiratory bronchiolitis (RB) and respiratory bronchiolitis–interstitial lung disease (RB-ILD) as well as pulmonary Langerhans cell histiocytosis (PLCH) have recently been reported more often in the context with spontaneous pneumothoraces [1, 2]. In contrast, malignant lesions in this setting are encountered to a far lesser extent.

In this article, we present a case of a histiocytic sarcoma incidentally detected in a peripheral lung specimen resected for a spontaneous pneumothorax. Furthermore, we discuss the practical approach to the differential diagnosis of PLCH based on morphological and immunohistochemical features.

Clinical history

In February 2008, a 23-year-old male patient, a never-smoker without any relevant past medical history, presented with his second spontaneous pneumothorax of his right lung. On conventional X-ray and on computed tomography (CT) scans,

the lung parenchyma was unremarkable except for focal emphysematous changes and the pneumothorax itself.

Video-assisted thoracoscopic surgery for a bullae resection and pleurodesis was performed. On macroscopic examination, a firm greyish nodule with a diameter of 4 mm was found and embedded completely. The surrounding peripheral lung tissue was unremarkable except for minor emphysematous changes.

Materials and methods

The lung tissue was fixed in 4% buffered formalin and processed routinely according to standard protocols. H&E-stained sections of 4-µm thickness were obtained. Immunohistochemistry using commercially available antibodies was performed according to the manufacturers' recommendations. The list of antibodies used and the results are displayed in Table 1.

Results

Histologically, the bronchi and bronchioles were essentially unremarkable. The peripheral lung tissue showed mild emphysematous changes according to the macroscopic impression. In close neighbourhood of a bronchial wall, the tissue displayed a single, round tumour-like or granulomatous lesion measuring 4 mm in diameter. It was sharply demarcated, but not encapsulated and showed no foci of necrosis. The lesion consisted of cells with a histiocytic appearance with moderately polymorphic enlarged pale nuclei and fine but unevenly distributed chromatin. Nuclear folding was frequently observed. In most histiocytic-like cells, one or two nucleoli were visible, some of them quite prominent. Mitotic figures were not encountered. Within the lesion, inflammatory infiltrates consisting of plasma cells and lymphocytes were present and scanty eosinophilic granulocytes were scattered within the granulomatous lesion. Based on H&E sections, the tentative diagnosis of PLCH was rendered.

Table 1 Panel of antibodies used

Antibody	Clone	Company	Dilution	Results
CD1a	O10	Immunotech	r.t.u.	0
CD1a	O10	Dako	1:50	0
S-100		Dako	1:2,000	0
CD68	KP1	Dako	1:300	3+
HLA-DR	CR3/43	Dako	1:200	3+
CD45LCA	2811+DD7/26	Dako	1:50	3+
Lysozyme	EC3.2.1.17	Dako	1:300	2+
CD4	BC/1F6	Biocare	1:50	2+
CD11c	B-6	Santa Cruz	1:25	3+
CD14	7	Novocastra	1:50	3+
MIB-1	Ki-67	Ventana	r.t.u.	10–15%
CD3	T3	Dako	1:200	0
CD10	56C6	Novocastra	1:10	0
CD21	1F8	Dako	1:200	0
CD35	BerNACDRC	Dako	1:10	0
PLAP	SP15	NeoMarkers	1:50	0

Immunohistochemical staining refers to tumour cells

0: negativity; 2+: moderate positive; 3+: strong positivity

r.t.u. ready to use

Using immunohistochemistry, the histiocytic-like cells were negative for CD1a. This staining was repeated with a different antibody to CD1a provided by another company giving a negative result again. Also, the staining with an antibody to S-100-protein revealed a negative result. In contrast, the cells strongly expressed CD68. In additionally performed stains with antibodies to HLA-DR, CD45LCA and lysozyme positive results in the vast majority of tumour cells were observed. Most tumour cells expressed CD4 and all tumour cells expressed CD11c and CD14, proving the histiocytic origin. With an antibody to CD3, the intermingled T lymphocytes cells were stained positively. A few interspersed follicular dendritic cells were stained positively using antibodies to CD21 and CD35, whereas the tumour cells themselves did not express these markers. Furthermore, the tumour cells did express neither CD10 nor PLAP. MIB1 (Ki67) demonstrated a nuclear staining of approximately 10–15% of the histiocytic tumour cells. In summary, these findings were in keeping with a histiocytic sarcoma.

Photographs of the lesion (H&E stains, immunohistochemical stains) are displayed in Fig. 1a–h.

Discussion

Histiocytic sarcoma (HS), previously named "true histiocytic lymphoma", is a rare haematological neoplasm usually affecting the lymph nodes, the skin and the gastrointestinal tract. In case of a multiple involvement of different sites, this systemic presentation is referred to as "malignant histiocytosis" [3]. HS arising in the lung has rarely been reported; indeed, only few well-documented reports of cases in humans exist [4, 5]. According to the WHO, HS should be regarded as an aggressive haematopoetic neoplasm with a poor response to therapy being reflected by the study of Vos et al. [6] who reported five cases of HS. Four patients died within 2 to 15 months of their disease. In another patient group, two patients out of 14 died 4 and 5 months, respectively, following initial diagnosis [5].

In our case, the very small tumour was discovered incidentally and completely excised. The patient has been

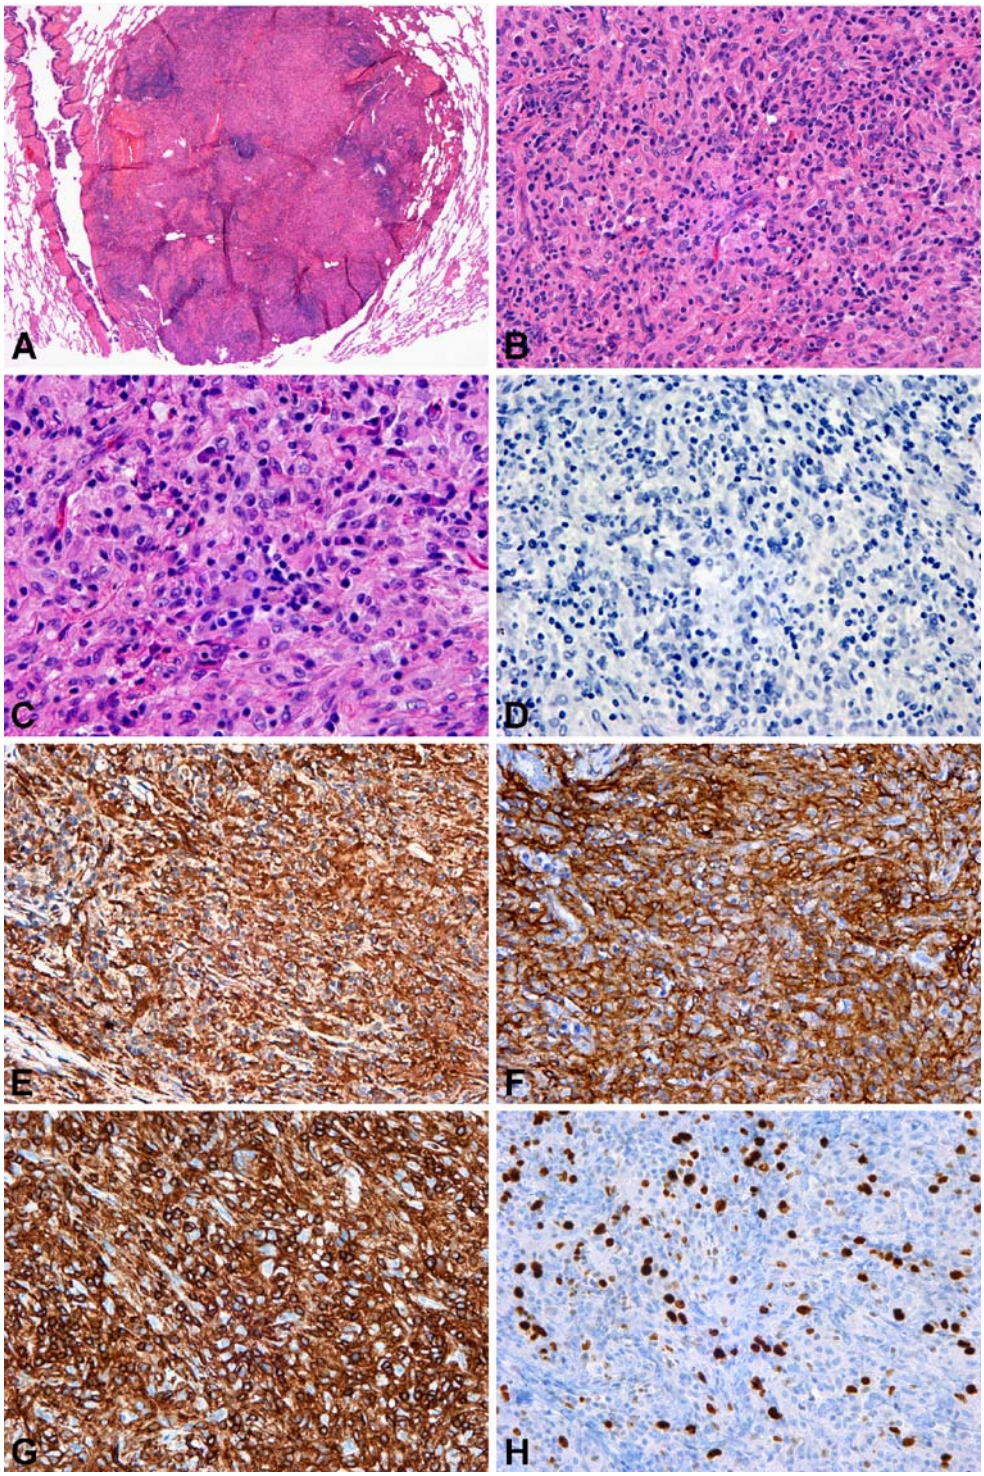

Fig. 1 **a** Well-circumscribed unencapsulated lesion closely attached to a bronchiolar wall. **b**, **c** Cells with a histiocytic appearance with moderately polymorphic enlarged pale nuclei and fine chromatin surrounded by inflammatory infiltrates consisting of plasma cells and lymphocytes. Few eosinophilic granulocytes. **d** CD1a. **e** CD68. **f** CD11c. **g** CD45LCA. **h** MIB-1

followed up on a three-monthly basis including clinical examinations, CT scans and a bone marrow biopsy. Neither a recurrence nor an involvement of other organs has been found. Until today, he has not received any chemotherapy. Meanwhile, the unfortunate patient suffered a third spontaneous pneumothorax 3 months after the initial diagnosis of the HS which was treated by a resection of the right upper lobe. On histological examination of the lung tissue, no residual tumour was found.

It is very unlikely that the tumour itself led to the spontaneous pneumothorax, as we think that it just happened to be an incidental finding. Interestingly, it has been questioned whether the routine histological examination of lung tissue excised in case of a pneumothorax is justified at all,

as it hardly ever changes the treatment of the patient [7]. We think that this particular case once more demonstrates that the histological examination can indeed be pivotal in order not to miss an underlying malignancy.

Focusing on pulmonary diseases, a differential diagnosis of this entity one has to consider is PLCH. In its active phase, it shows airway-centred interstitial infiltrates consisting of a special type of histiocytes, the so-called Langerhans cell histiocyte. This cell is regularly CD-1a as well as S-100-positive, but does not express CD68. Eosinophilic granulocytes in variable amount most often accompany these histiocytes, which reflects the historical term "eosinophilic granuloma". The surrounding peripheral lung parenchyma usually is either unremarkable or may display foci of RB [8, 9]. As PLCH progresses, its diagnostic hallmark is the airway-centred stellate scar. The cellular infiltrates decrease in number with the age of the granulomas; finally, the Langerhans cell histiocytes as well as the eosinophilic granulocytes may even be absent.

By demonstrating this case, we emphasise the importance of proving the diagnosis of PLCH by means of immunohistochemistry. We recommend the use of an antibody to CD1a preferably to antibodies to S-100-protein since an S-100 positivity has been reported in a certain percentage of cases of HS [5, 10, 11], which, taken by itself, may in fact not help to distinguish between these two entities. Recently, the use of antibodies to Langerin, a lectin associated with the formation of Birbeck granules, was reported to be a highly sensitive marker for Langerhans cells. However, it has to be borne in mind that also in a minority of cases tumour cells of a HS might be Langerin-positive [12].

The newly characterised CD163, a haemoglobin scavenger receptor, is a promising marker in the diagnosis of true histiocytic malignancies [6, 13, 14]. Its expression in cells of Langerhans cell histiocytosis has not been extensively studied; however, in one report dealing with this objective, a positive expression in three of five cases has been observed [15].

Given the fact that PLCH is a well-known cause for spontaneous pneumothoraces, we feel that it might be a diagnostic pitfall to rely on H&E sections alone when a histiocytic lesion in this setting is encountered. We strongly recommend immunohistochemical stainings, and in the case of a presumed PLCH with a negative CD1a reaction, further immunohistochemical studies have to be performed in order not to misdiagnose a malignant haematopoetic lesion.

Acknowledgement We are grateful to the expert haematopathologist Prof. Annette Schmitt-Gräff (Medical University of Freiburg, Germany) who reviewed this case and confirmed the diagnosis of a histiocytic sarcoma.

Conflict of interest We declare that we have no conflict of interest.

MEETING REPORT

Protein analysis of tissues—current views and clinical perspectives

Karl-Friedrich Becker · Axel Walch · Marius Ueffing

Received: 2 June 2009 / Accepted: 3 June 2009 / Published online: 26 June 2009

Abstract Proteomics raises high expectations in finding novel and reliable biomarkers for diagnosis, prognosis and therapy prediction. The goal of the 2-day workshop "Protein analysis of tissues—current views and clinical perspectives" was to bring together scientists from multiple areas of protein research interested in tissue analysis.

Keywords Proteomics · Molecular pathology · Meeting report

Much progress in tissue proteomics has been made for applications in basic sciences; translation of these methods for treatment of patients, however, is slow because the realities in the clinic are rarely taken into account and proteomic changes in cultured cell lines might not fully reflect human diseases due to the lack of the tissue (micro) environment. The goal of the 2-day workshop "Protein analysis of tissues" was to bring together scientists from multiple areas of protein research. The workshop was conceived by molecular and cell biologists, pathologists and protein scientists, supported by industry, the German Society of Protein Research and a Coordination Action funded by the European Union. A key strength of the meeting was that it combined lectures and practical aspects (wet lab courses).

Researchers from 12 European countries participated in the meeting. The fact that about 80% of the participants described themselves as primarily involved in protein analysis and only 20% were involved in histology indicated that pathologists may not be aware that there has been recent progress in protein studies—other than immunohistochemistry—in human tissues, including the use of samples stored for decades in huge archives in pathology departments.

Proteomics raises high expectations in finding novel and reliable biomarkers for diagnosis, prognosis and therapy prediction. H. Meyer (Bochum, Germany) presented data for the identification of biomarkers for liver cirrhosis using tissue microdissection, differential gel electrophoresis (DIGE) technology and mass spectrometry. Applications of laser microdissection, 2D-DIGE and matrix-assisted laser desorption/ionisation (MALDI) time-of-flight from heterogenous prostate carcinoma tissues in biomarker discovery were presented by S. Skvortsov (Innsbruck, Austria). F. Lottspeich (Martinried, Germany) presented results for the comparison of 2D-DIGE, Sypro-2D, and isotope-coded protein labelling for quantitative proteome analysis of brain tissues. H. Langen (Basel, Switzerland) explained in his talk why biomarker tests should be developed as "companion diagnostics" and escort the drug development at all stages (pharmacodiagnostic tests). This is crucial for the effective development and successful commercialisation of medicines and innovative drugs.

G. Schmidt (München, Germany) introduced an image analysis software platform for robust and fully automated means to extract quantitative information from tissues slide scans.

A joint workshop between Helmholtzzentrum München and Technische Universität München, München, 6–7 March 2009.

Clinical tissues are typically formalin-fixed and paraffin-embedded (FFPE) for histopathological diagnosis. In order to shift diagnosis to prediction, novel tools are needed for precise protein measurements of FFPE tissues. The alternatives include the use of frozen tissues and the development of novel tissue fixatives. It is estimated that more than one billion FFPE tissue blocks exist worldwide. Many of those samples are connected to clinical data. Some lively debate at the conference focused on the use of FFPE tissues for protein analysis. KF Becker (Munich, Germany) and T. Geoui (Hilden, Germany) gave overviews about recently established methodologies for the suitability of FFPE tissue samples for protein studies. They focused on the extraction of full-length proteins from FFPE samples and the quantitative analysis of the extracted proteins using protein microarray technology. Other applications for FFPE tissues include mass spectrometry and 2D polyacrylamide gel electrophoresis.

T. Joos (Reutlingen, Germany) described applications and future challenges for protein microarrays. This technology is likely to evolve into a key technology for the characterisation of complex samples.

The almost complete absence of protein synthesis of platelets makes them ideal systems for protein studies. A. Sickmann (Dortmund, Germany) presented data on the identification of more than 2,500 proteins, more than 1,000 phosphorylation sites and more than 350 glycosylation sites. Using these data, the knowledge about platelet function will certainly benefit.

MALDI mass spectrometry has become a powerful tool in biological research, especially in proteomics. Recently, MALDI techniques were developed for direct tissue analysis and molecular imaging, allowing the detection and localisation of a large number of compounds directly from tissue sections in one acquisition. Unlike other visualisation techniques such as immunohistochemistry or fluorescence microscopy, so-called MALDI-IMAGING does not require a target-specific reagent (e.g. antibody) and, therefore, is a valuable discovery tool, since it can survey a broad range of proteins simultaneously. The advantage of maintaining the spatial location of proteins is critical in achieving a comprehensive analysis of heterogeneous tissue samples, such as cancers. S.O. Deininger (Bremen, Germany) and A. Walch (München, Germany) presented exciting novel data about the use of MALDI-IMAGING for tumour proteomics.

M. Ueffing presented data for the interactome of lebercilin, which is genetically linked to a severe form of blindness, Leber congenital amaulrosis. The interactome links this protein to the transport of vesicular cargo to the outer segment along ciliar structures.

One of the major health challenges of the twenty-first century is type 2 diabetes. H. Sarioglu (München, Germany) used liquid chromatography tandem mass spectrometry to identify 4,000 quantitative profiles of protein markers in a type 2 diabetes mouse model.

The second day of the workshop focussed on practical aspects of protein analysis from tissues. Protocols were provided and explained in detail for protein extraction from FFPE tissue samples and subsequent protein microarray analysis, MALDI-IMAGING, quantitative immunohistochemistry and quantitative approaches for mass spectrometry-based and gel-based proteomics. After a short theoretical introduction to each of the topics, participants were allowed to try some of the assays by themselves.

Because of the great success of the workshop, the organisers plan to repeat the meeting in 2011, hoping to attract more histology-oriented researchers.

MEETING REPORT

From virtual microscopy to systems pathology

A meting report of the 1st European workshop on tissue imaging and analysis, Heidelberg, Germany, 13–14 February 2009

Niels Grabe · Peter Schirmacher

Received: 9 July 2009 / Accepted: 10 July 2009 / Published online: 4 August 2009

Introduction

Virtual microscopy encompasses the high-resolution scanning of tissue slides and cell preparation and derived technologies including automatic digitalization and computational processing of whole microscopic slides, cytological preparations and tissue arrays, and web-based easy accessibility and analyses. For the first time, it enables high-throughput imaging and quantitative measurements of tissue structures. By integrating mass tissue data and derived analyses, virtual microscopy creates novel synergies between technological disciplines such as pathology/histology, bioinformatics, medical informatics, image analysis, as well as cell and molecular biology. These technical synergies may pave the way for new structures in research, clinical diagnostics, education, and training and fundamentally support newly arising disciplines like medical systems biology. The 1st European Workshop on Tissue Imaging and Analysis, held in Heidelberg on 13th and 14th February 2009 intended to provide a discussion forum for multiple disciplines related to virtual microscopy, like pathology, systems biology and pathology, computer-assisted high-throughput diagnostics, cell-based cancer diagnostics, bioinformatics and image processing, and the scientific exchange of key players in the field. Over 140 participants from 10 European countries as well as USA and Japan took part in the meeting.

Sessions

Research applications

Several speakers covered topics from tissue banking over the systematic evaluation of tissue morphology using image processing up to systems biological modeling of tissues. *Niels Grabe* (*University Heidelberg*, *Germany*) introduced virtual microscopy as a tool and its increasing role in Medical Systems Biology as it generates the necessary data of tissue morphology in which molecular computational models of diseases will be embedded. This has motivated the foundation of the first interdisciplinary institutions linking Pathology, Systems Biology, and Medical Informatics, such as the Tissue Imaging and Analyses Center at the University of Heidelberg [1]. *Ulf-Dietrich Braumann* (*University Leipzig*, *Germany*) presented how microscopy is presently undergoing a transformation due to the increasing availability of digital image acquisition devices. He demonstrated how growth of carcinoma of the cervix, prostate, and skin as well as regeneration processes and tissue formation, for example of nerves and joint cartilage, can be quantified using image data obtained by virtual microscopy [2]. *Nobert Wey* (*University Zurich*, *Switzerland*) showed what is needed to quantify Alzheimer plaque on virtual slides. His work provided an excellent example for the necessity of having an efficient work flow allowing

the automated analysis of high volume imaging data. *Pascal Tomakidi* (*University Freiburg*, *Germany*) provided data on the use of virtual microscopy in epithelial tissue cultures, especially how quantitative spatial profiles of markers of epithelial homeostasis were generated. These analyses may form the basis for prospective simulation attempts of epithelia formation and regeneration [3]. *Andreas Heffel* (*University Leipzig*, *Germany*) reported how automated image segmentation and classification provide an indispensable requirement for a large-scale analysis of in situ hybridization gene expression patterns (GEP). He presented an automated process flow for segmentation, classification, and clustering in large-scale sets of Drosophila melanogaster GEP that is capable of dealing with most of the technical problems implicated in these images. *Peter Schirmacher* (*University Heidelberg*, *Germany*) described tissue banks as essential platforms for modern biomedical and translational research. Besides tissue storage, distribution, project management, and support in morphology-based techniques, tissue banks offer an optimal platform for decentralized tissue-based research projects, including centralized scanning of decentrally obtained stains, especially multi-tissue arrays, data storage, and data analysis as well as decentralized access to data, their analyses as well as reference slides. These tools can be extended through further integration of additional tissue technologies (e.g., fluorescence techniques) and bioinformatics.

Industrial applications

Technical capabilities and the application potential of currently available virtual microscopy technologies as a key technology in industrial research were discussed by several speakers. *Maria Athelogou* (*Definiens*, *Germany*) described how "Intelligent Image Analysis" plays an important role and moves into the heart of R&DS and Diagnostics. She stressed that accurate information from image processing is critical for pathologists and oncologists as it determines the predictive and prognostic outcome of morphological studies. *Niels Foged* (*Visiopharm*, *Denmark*) demonstrated that the quantitative analysis of the HER-2 immunostaining in breast cancer tissue sections represents an important challenge for digital pathology. He introduced a novel, highly discriminative algorithm for scoring HER-2 and thereby also presented the widely applicable principles of image sampling, data management, and quantification in whole slide images. *Heinrich Bürgers* (*TissueGnostics*, *Austria*) sketched a novel approach to imaging, analysis, diagnosis, and documentation of histological slides by the use of FACS equivalents for cells in tissue slides and smears. *Catherine Conway* and *Lynn Dobson* (*Slidepath*, *Ireland*) showed quantitative data resulting from a study using the application of image analysis as adjunct to manual evaluation of HER-2 status. They described the development of a HER-2 image analysis algorithm that classified cases based on both the intensity and continuity of membrane staining. The performance of the algorithm was validated across a large cohort of clinical cases and achieved a 91% concordance with manual review by a pathologist. Agreement with gene amplification status as the gold standard was also found to be higher for the automated review, suggesting a potential of this technology as a support to increase the diagnostic standardization of HER-2 evaluation [4]. *Lars Schmidt* (*Agfa*, *Germany*) described the technical requirements for the embedding of virtual microscopy in a hospital setting as an example for an administrative–medical workflow in the field of digital pathology. *Masafumi Oshiro* (*Hamamatsu Photonics*, *Japan*) elaborated on the basic concepts of virtual microscopy already introduced in 1997, since then becoming rapidly an indispensable tool to support digital pathology applications. Thereby, the technical implications of slide scanning determine the potential of virtual microscopy. Furthermore, new features, such as virtual fluorescence slides and Z-stack for focusing, were presented, which may enable the introduction of novel clinical applications.

Education and training

Research and training represent the areas where virtual microscopy has first entered practical application, and in this field, the most advanced experiences exist. *Jim Diamond and Peter Hamilton* (*Queens University Belfast*, *Ireland*) noted that we currently experience a tipping point in tissue-based research and education [5]. The importance of pathology diagnostics as a central discipline for translational research and biomarker discovery was stressed, and the technical challenges including storage, remote slide viewing, and high-performance image processing were sketched. From this, novel opportunities for application in education, quality management, tissue archiving, and research were elaborated. *Peter Riegman* (*Erasmus Medical Center*, *Rotterdam*, *The Netherlands*) showed how virtual microscopy is increasingly replacing conventional microscopy in students training at Rotterdam Medical School. He reported VM to enable teachers to spend more time on teaching and collaboratively discussing histology and pathology topics. He also showed that students appreciated virtual microscopy far more than conventional microscopy. *Alberto Pérez-Bouza* (*RWTH Aachen*, *Germany*) demonstrated his innovative approaches and experiences when implementing virtual microscopy in histology courses since June 2006. He analyzed the acceptance of the web-based digital microscopy by questionnaires filled out by students and also by an analysis of

the number of visits on the web server. He found that students not only appreciated the possibility of learning microscopy through the Web but also used the system intensively for training purposes and self-assessment prior to examinations. Moreover, the integration of the virtual histology into a video podcast containing macroscopic images, drawings, etc. has improved the acceptance of clinical pathology as an attractive and modern subject. *Katharina Glatz* (*University of Basel*, *Switzerland*) presented Pathorama as a publicly accessible modular e-learning platform used at all levels of pathology education, including a searchable atlas containing more than 600 virtual slides. Various contributors have fed categorized metadata including the slide URL into the central slide database while the slides are stored on servers at the contributing institutes [6]. *Marco Novelli* (*University College London*, *Great Britain*) reported positives experiences of applying the virtual microscopy technology, including fast remote virtual slide access; reported improvements were benefits in the quantitative measurements of virtual slides (Breslow's thickness measurement, proliferation index), remote reporting, and greatly improved e-learning. He also elaborated on difficulties like hospital firewalls, the need of technical education, as well as relatively high costs for image processing, storage, and scanning.

Clinical applications

Peter Hufnagl, *Karsten Schlüns*, and *Norman Zerbe* (*University Berlin-Charité*) discussed the basic requirements for the use of virtual microscopy in routine pathology. Despite being widely accepted in Pathology for educational purposes and teleconsultation, they stated that the broad routine use of VM in surgical pathology is currently not in sight due to the technical requirements and some further limitations. Instead, they identified application potential in the fields of education, second opinion, and interdisciplinary tumor centers, routine marker quantification for small departments as well as large university institutes [7]. Furthermore, the rise of tumor centers is expected to promote the routine use of VM. In conclusion, similarities to digital radiology were identified although the introduction was estimated to take some years. *Peter Sinn* (*University Heidelberg*, *Germany*) reported recent experiences in the application of virtual microscopy in reference pathology and external clinical services. Telepathology and teleconsultation were presented as important application fields. He showed results from a diagnostic trial in cryosection evaluation. He concluded that telepathology is almost equivalent to conventional microscopy in the evaluation of frozen sections if no evaluation of the macroscopic aspects of the specimen is required, e.g., in the frozen section diagnoses of sentinel lymph node biopsies [8]. *Thomas Fuchs* (*ETH-Zürich*, *Switzerland*) presented a framework for biomarker quantification using tissue microarrays based on experiences with clear cell renal cancer by computational pathology including correlation with survival analysis [9]. Quantified histological assessment of human tissues was identified as the key point for the automation and objective assessment in predictive pathology. *Manfred Schmitt and Lina Seiz* (*Technical University München*, *Germany*) reported on the assessment of Urokinase plasminogen activator (uPA) and its inhibitor (PAI-1) which are accepted predictive markers in breast cancer by virtual microscopy. Automated scanning, followed by computer-assisted quantitative scoring of uPA and PAI-1 immunohistochemistry, may represent a potential alternative to the established ELISA measurements, recently recommended for clinical application in the ASCO guidelines 2007. *Niels Halama* (*National Center for Tumor Diseases*, *University Heidelberg*, *Germany*) presented a quantitative analysis of immune infiltrates in primary colorectal cancers and their liver metastases. Quantitative cell counts based on immune cell surface molecules (CD3, CD8, Granzyme B, and CD45RO) were independent predictors of patient outcome. Using virtual microscopy, the intratumoral heterogeneity of the investigated immune cells was assessed. Computational simulation of tissue microarrays from the virtual slides showed that intratumoral heterogeneity of all measured surface molecules was so high that a reliable measurement of the surface molecules for an individual patient was only achieved by analysis of full-size tissue sections. He suggested studies for the definition of potential biomarker cutoffs. Potential diagnostic tests should include quantitative assessments of intratumoral heterogeneity. This could be reliably achieved by measurements in full-size tissue slides using virtual microscopy [10]. *Thomas Schrader* (*University of Applied Sciences*, *Brandenburg*, *Germany*) elaborated on the need for standardization when embedding virtual microscopy in the Integrated Healthcare Enterprise [11]. A communication concept was presented connecting virtual slide scanners and pathology laboratory information systems. *Nicolas Wentzensen* (*National Cancer Institute*, *Bethesda*, *MD*, *USA*) presented the innovative application scenario of virtual microscopy in cervical cancer screening cytology. Virtual microscopy has the potential to improve this process at several levels. Novel biomarkers allow the automated detection of abnormal cells with increasing sensitivity and a reduced evaluation time. Web-based evaluation allows cytologists to analyze specimens without the need for circulating glass slides. Archiving of digital microscopy images preserves slides under optimal conditions and saves storage space.

Conclusions

The workshop provided a comprehensive overview over novel technologies and applications of virtual microscopy and a forum for stimulating interdisciplinary discussions, representing diverse fields such as pathology, computer sciences, systems biology, biomedical informatics, biotechnology, epidemiology as well as basic biomedical research. It is intended to be pursued in a regular, most likely annual format.

ORIGINAL ARTICLE

A combined histologic and molecular approach identifies three groups of gastric cancer with different prognosis

Received: 27 May 2009 / Revised: 6 July 2009 / Accepted: 15 July 2009 / Published online: 12 August 2009

Abstract The limited prognostic value of currently used histologic classifications of gastric cancer and their failure to account for the complexity of the disease as revealed by more recent investigations prompted a combined reinvestigation of histologic, molecular, and clinicopathologic patterns in 294 extensively sampled, invasive gastric cancers representing all main histotypes and stages of the disease and followed for a median of 150 months. Among histologic parameters tested, only cellular atypia, angio-lympho- or neuroinvasion, Ki67 proliferation index, expansile/infiltrative type growth, and T8 cell-rich high lymphoid intra-/peritumor response (HLR) proved to be stage-independent predictors of patient survival. Among molecular tests, p53 gene exon 7 (loop 3) and 8 (loop-sheet-helix motif and S-10 band), but not p53 protein overexpression, TP53 LOH or 18qLOH, were found to worsen prognosis. Microsatellite DNA instability was a favorable prognostic factor when coupled with HLR. Patient survival analysis of the main histotypes and their subtypes confirmed the favorable prognosis of HLR, well-differentiated tubular, muconodular, and low grade diffuse desmoplastic cancers, and highlighted the worse prognosis of anaplastic and infiltrative-lymphoinvasive mucinous cancers compared to ordinary cohesive and diffuse cancers. Distinct roles of individual morphologic and molecular factors in tumor progression of the different histotypes have been recognized. The combination of survival-predictive histotypes and individual histologic or molecular parameters allowed us to develop a classification of all gastric cancers into three grades of increasing malignancy which proved to be of high prognostic value.

Introduction

Currently used histologic classifications are of limited value in the prognostic evaluation of gastric cancer [1–3]. Separation of gland-forming 'intestinal' from scattered-cell 'diffuse' tumors according to Lauren [4] is known to predict the natural history of gastric cancer, including its association with intestinal metaplasia and blood-borne liver metastases or with direct serosal invasion and peritoneal carcinosis, respectively [5]. Different molecular changes

have also been detected in the two tumor types: p53 gene mutation, p53 protein accumulation, microsatellite DNA instability, 18qLOH, or c-erbB-2 expression are preferentially associated with the intestinal type and cadherin E mutation or loss of membrane expression with the diffuse type [6–12]. However, despite early suggestions that diffuse tumors had a poorer prognosis [13], Lauren's classification failed to predict patient survival independently from tumor stage [1, 3]. Attempts to improve prediction power by considering the type of local tumor growth (expansile vs. infiltrative) [14], by introducing different degrees of glandular differentiation (well vs. moderate vs. poor) [15, 16], by combining glandular differentiation with mucin production [17–19], or by separating solid and mixed from glandular and diffuse cancers [2, 3] had limited success and failed to impact significantly on clinical practice.

However, a few histologic features have consistently been found to predict tumor behavior such as vascular invasion [2, 3, 20] and intratumor lymphoid cell infiltration [21–24]. In addition, some molecular findings have also been reported to be prognostically informative, i.e., high level instability of microsatellite DNA (MSI-H) [10, 11], Epstein–Barr virus (EBV) infection [25], p53 gene mutation [8, 26], 18qLOH [27], SMAD4 or 7 gene expression [28, 29], c-erbB2 expression [30], E cadherin gene mutation [7], and gene loss or gain by comparative genomic hybridization [31]. Unfortunately, so far, none of these molecular findings have proven to be contributive and cost effective enough to enter routine diagnostic practice.

Nevertheless, some of the histologic, phenotypic, or molecular patterns were helpful in identifying tumor subsets predictive of patient survival. Those showing better survival included very well-differentiated tubular cancers with intestinal phenotype [32, 33], the muconodular-expansile subtype of mucinous cancer [33], and the low grade, tumor cell-embedding variant of diffuse desmoplastic cancer [34], in addition to MSI-H [10, 11] and lymphocyte-rich cancers [21–24]. On the contrary, various kinds of anaplastic cancers with poor outcome have been identified, with or without neuroendocrine features, from small to intermediate or large cell [35–37], diffuse to solid in structure, sometimes with signs of hepatoid, choriocarcinomatous, or squamoid differentiation [3, 34, 38, 39].

Thus, in order to develop a more informative and practical classification system, a systematic reinvestigation of potentially predictive histological and molecular parameters seems to be required on a sufficiently large series of invasive gastric cancers covering all the main stages and histotypes and with long-term follow-up (fundamental in identifying long survivors with low grade tumors). The aim of this study was to: (a) further check the prognostic power of individual parameters; comparatively and simultaneously in the same patient series; (b) search for possible histotype restriction of their distribution and diagnostic or prognostic power; (c) test the prognostic value of resulting tumor types and subtypes; (d) develop a simple grading system based on predictive histologic factors or histotypes, into which contributive molecular findings could be easily incorporated.

Materials and methods

Tumor selection Invasive (T1b to T4) gastric cancers were selected from cases undergoing surgery with curative intent at the San Matteo General Hospital in Pavia from 1984 to 2000 or at San Martino General Hospital in Genova in 1998–1999. The study considered only cases with extensive sampling of the tumor (two to 12 blocks, depending on size) and surrounding non-tumor tissue and carefully assessed perioperative TNM stage [40]. Special attention was paid to tumors whose invasion was limited to the deep submucosa (penetrating T1b, 44 cases) or muscularis propria (T2a, 55 cases) or whose histologic patterns suggested low or high malignancy or showed a structure differing from that of ordinary glandular and diffuse cancers. In all, 294 cases were collected. Corresponding patients by the end of January 2009 had either died of the disease or other causes or were still alive and had been followed for at least 7 years, with a median follow-up of 150 months (25th–75th=90–186).

Histologic and histochemical stains Paraffin sections were stained with hematoxylin–eosin, Alcian blue–PAS, Giemsa, or immunoperoxidase using specific antibodies for MUC1, MUC2, MUC5AC, and MUC6 mucins [33, 34]; cytokeratins 7, 19, 20, and AE1/AE3 (Dako, Denmark); CD8 antigen (C8/144B clone, Dako); Ki67 protein (MIB1 clone, Dako); p53 protein (D07 clone, Dako); and h-MLH1 (G-168.15 clone, Pharmingen, San Diego, CA, USA) or h-MSH2 (Fe11 clone, Oncogene, Cambridge, MA, USA) mismatch repair proteins. In situ hybridization for the EBER-1 gene [3] or for EBER-1 and EBER-2 genes (probe Y5200, Dako) was used to detect Epstein–Barr virus (EBV) infection.

For molecular investigation, tumor tissue was carefully dissected under microscopic control to enrich the tumor cell component to more than 60%. A PCR-based denaturing gradient gel electrophoresis (DGGE) method, followed by DNA sequencing with a 3100 Applied Biosystems equipment, was used to detect p53 gene mutations at exons 5 to 8 [8]. For microsatellite instability analysis, Bat 25 and Bat 26 loci were first investigated; tumors showing concordant stability or instability at both loci were classified as either stable (MSS) or highly unstable (MSI-H), respectively. Those showing discordant findings were further tested at Bat 40, D5S346, and D2S123 loci. Only tumors with

instability involving at least two of the five loci were classified as MSI-H; the others were classified as low instability (MSI-L) and included in the MSI-negative tumor group together with MSS cases [10, 11, 41]. In most MSI-H cases, loss of MLH1 nuclear stain was observed immunohistochemically while only two cases lacked MSH2 reactivity.

Loss of heterozygosity (LOH) at chromosome 18 was examined as previously described [12] in paired tumor and non-tumor DNAs using 12 highly polymorphic microsatellite markers (D18S56, D18S67, D18S34, D18S460, D18D450, D18S474, D18S484, DCC-vNTR, D18S69, D18S55, D18S58, and D18S70) spanning most of the long arm of the chromosome, from band 18q11.2 up to q23 near the q-ter. For TP53 LOH at 17p13.1, a CCA117-732 probe was used in accordance with Vogelstein et al. [42].

Histologic evaluation Glandular differentiation was scored 0 (predominantly diffuse or solid structure), 1 (mixed diffuse/solid and glandular structure, at least 40% each of the two components), 2 (>60% glandular structure), or 3 (well-differentiated, purely glandular structure). Assessment of tumor cell anaplasia was mainly, but not exclusively, based on nuclear features [43]. Score 1 tumors were characterized by monomorphous, small- to medium-sized nuclei of regular shape, fairly uniform chromatin distribution, and small to inapparent nucleoli inside cells with fairly abundant cytoplasm. They often presented signs of functional differentiation (including mucin secretion), with or without cell polarization and well-developed intercellular junctions or glandular structure. In contrast, score 3 tumors showed larger, polymorphic nuclei, ranging from vesicular with prominent nucleoli to dense, hyperchromatic with relatively small nucleoli, inside poorly cohesive, non-polarized cells with scarce (small cells) to abundant (large cells) cytoplasm, usually mucin free, albeit sometimes with signs of abortive endocrine (poorly differentiated neuroendocrine cancers), hepatoid, chorionepitheliomatous, or squamoid differentiation, often with multifocal necrosis [3, 34, 36, 37, 39]. Tumors showing moderate to considerable nuclear pleomorphism in cells of various size, shape, and aggregation status, with intermediate patterns between those of score 1 and 3, were classified as score 2.

Mitotic figures were counted in ten high power fields (HPF, ×400) while the percent of Ki67 positive nuclei was assessed at ×250 magnification by counting at least 1,000 cells in areas showing the highest proliferation [34]. Routine hematoxylin–eosin preparations were adequate in most cases to assess lymphatic and blood vessel invasion. When tumor cells were found in vessel-like spaces of doubtful interpretation, the CD31 endothelial cell marker (M823 antibody, Dako) was applied. Lymphoinvasion and neuroinvasion were graded 0 (absent), 1 (sporadic, i.e., no more than one invaded vessel or nerve in a tumor section), or 2 (multifocal); only score 2 invasion proved to be unquestionably predictive of survival in this study. A single finding of unequivocal blood vessel invasion was sufficient to classify the tumor as angioinvasive, while the presence of either score 2 lymphoinvasion and/or angioinvasion indicated vascular invasion. Both endoneural and closely adherent perineural invasion were considered [34]. Only those cases which showed a well-demarcated regular boundary between a "pushing" tumor growth and surrounding non-tumor tissues were classified as expansile; all the remaining cases were considered as infiltrative.

Tumor types Of the 294 tumors, careful investigation of hematoxylin–eosin, Alcian blue–PAS, and Giemsa-stained sections identified 74 cases with diffusely infiltrating, poorly cohesive cells dispersed in the stroma as single elements or in small aggregates with little or no gland formation (diffuse cancers) [34], 42 cases with prominent extracellular mucin (mucinous cancers) [33], and 21 cases formed predominantly or exclusively by anaplastic, highly proliferative (≥20 mitoses/10 high power fields) small to large cells with scarce stroma and frequent necrosis, regardless of their diffuse or cohesive structure and usually poor expression of endocrine or exocrine markers (anaplastic cancers) [3, 34, 36].

Among the remaining 157 tumors, 56 cases showed increased intra-peritumor lymphoid cell infiltration (lymphocyte-rich or LR cancers) [21, 24], of which 47 "high lymphoid response" (HLR) cancers showed either (a) lymphoepithelioid (LEP; 17 cases, 12 of which are EBV positive) pattern with intimate admixture of abundant lymphoid cells and epithelial tumor cells, often dissociated from each other by the infiltrate, or (b) ≥300 CD8+ cells/10 HPF inside the tumor growth, coupled with a prominent band of lymphoid cells, rich in CD8+ cells, surrounding the expansile edge of the tumor or its nodules. The remaining 110 non-HLR tumors formed the cohesive cancers group, with more or less prominent glandular (tubular, papillary, or cystopapillary) differentiation or even with solid histology.

In addition, three low grade subtypes were identified according to previously published criteria, i.e., muconodular cancer, characterized by prominent mucin lakes with expansile growth and moderately numerous tumor cells freely floating in them [33], separated from the remaining mucinous cancers showing an infiltrative pattern, low grade diffuse desmoplastic cancer with prominent desmoplasia entrapping tumor cells with a limited or no invasive pattern, to be separated from ordinary diffuse cancer [34], and very well-differentiated tubular cancer with monostratified, low grade epithelium and a limited or no invasive pattern [32, 33], somewhat reminiscent of tubular breast cancer [44], to be separated from ordinary cohesive cancers.

Statistical analysis Data distribution was expressed as counts and percents for categorical variables and was compared by means of the Fisher exact test. The Spearman R correlation coefficient was used to measure the association of variables on a continuous scale.

The follow-up extended from the date of surgery to the date of death from gastric cancer or to the last available assessment. Patients dying from other causes were censored at the date of their death. Median follow-up and its interquartile range (25th–75th) was computed by means of the inverse Kaplan–Meier method. Cox regression was used to assess the prognostic role of cytologic atypia and of a series of other potential risk factors. Uni- and multivariable models were fitted. Clinically relevant variables were included in the multivariable model in addition to stage, provided they were not collinear. Hazard ratios (HR) and their 95% confidence intervals (95% CI) were computed. The proportional hazard assumption was tested based on Schoenfeld residuals. Death rates per 100 persons per year (95% CI) were also computed as summary measures. To assess model performance, we also calculated the Royston explained variation, Harrell's *C* statistic for discrimination, and the Le Cessie–van Houwellingen shrinkage coefficient (and noise in model=1—shrinkage) for calibration. A two-sided p value <0.05 was considered statistically significant. Stata 10.1 (StataCorp, College Station, TX, USA) was used for computation.

Results

In the 294 tumors under investigation, a series of potentially prognostic, histologic, or molecular parameters were analyzed for patient survival (Table 1). Several histologic features (Figs. 1, 2, and 3) proved to be predictive at univariable as well as at stage-inclusive bivariable analysis, among which grade 2 and 3 anaplasia, expansile vs. infiltrative growth, vascular (either score 2 lymph or any blood vessel) invasion, and high lymphoid intra-/peritumor response. The outcome predictive value of lymphoinvasion and angioinvasion was also supported by their strong association with local T invasion level, lymph node metastases, and distant metastases (Fisher exact test, $p<0.001$ for all associations).

Glandular differentiation showed significant prognostic influence at univariable analysis, which, however, largely vanished at stage-inclusive analysis; a trend toward improved survival was retained only by high tubular differentiation. Neuroinvasion (score 2), though significantly predictive of worse survival regardless of stage, was often difficult to ascertain, especially in T1b or T2a tumors sparing deep muscularis propria, where larger nerves and ganglia are likely to be found. It was assessed only in 244 of the 294 cases investigated. Both mitotic and Ki67 proliferative indices predicted worse survival independently of stage when cases above/below the median were compared. When comparing tertiles of their distribution, Ki67 proved to be superior (log rank test for Ki67 $p=0.002$, for mitoses $p=0.023$), especially in discriminating the lower (death rate=6.21, 4.50–8.56) from the intermediate tertile (death rate=12.45, 9.84–15.77); however, both Ki67 ($p=0.071$) and mitoses ($p=0.297$) failed to survive stage-inclusive Cox bivariable analysis. Mucin production, either intracellular or extracellular, failed *per se* to predict survival, while showing an inverse relationship with intra- and peritumor lymphoid cell response and a trend towards lower tumor cell proliferation.

Among molecular tests (Figs. 4 and 5), only exon 7 and 8 p53 gene mutations (of which 33/37, 89%, were in the L3 loop, 12 cases, S-10 strand, two cases, or the loop-sheet-helix motif, 19 cases, three regions crucial for target DNA interaction) proved to be stage-independent predictors of worse survival; p53 exon 5 to 8 mutations, p53 gene locus LOH, or p53 protein nuclear accumulation, though significantly predictive on univariable analysis, showed only borderline trends when stage was included. Exon 5 and 6 mutations lacked any prognostic value. High level microsatellite instability and 18qLOH revealed non-significant trends for improved or worse survival, respectively.

Of the 56 lymphoid cell-rich (LR) tumors, lymphoid infiltrates were distributed unequally in nine cases leaving significant lymphocyte poor tumor areas or lacked a T_8 cell-rich peritumor band, thus failing to fulfill all criteria for HLR cases. The remaining 47 tumors formed the HLR group, which showed highly improved survival (HR 0.26, 0.15–0.47, $p<0.001$) compared to the 247 non-HLR cases. The interplay between HLR, EBV, MSI-H, and p53 status in terms of prognosis is analyzed in Table 2, where it appears that the HLR pattern *per se* represents the most powerful prognostic factor and that the favorable effect of MSI-H may act mostly through HLR, as suggested by its inefficacy among HLR-negative cases. In addition, Table 2 shows that, besides EBV and MSI-H positive tumors, a third group of 12 tumors developed HLR, possibly through expression of increased, highly antigenic, and mutated proteins like p53. Indeed, eight such tumors (67%) showed either p53 gene mutation (seven cases, six of which in exons 5 or 6) and/or p53 protein overexpression (seven cases), in contrast to the reduced trend for both changes among EBV+ or MSI-H tumors.

Among the 80 tumors (including all 56 LR and 47 HLR cases) tested for EBV infection by in situ hybridization, 16 cases, all from the HLR group, proved to be EBV positive and showed worse survival compared to the remaining 31 HLR tumors at univariable analysis. This, however, was not confirmed by stage-inclusive bivariable analysis (Table 2).

[a] Bivariable Cox analysis inclusive of stage; stage I vs. II vs. III+IV, TNM system

[b] Model: wild type vs. mutated exon 5, 6 vs. mutated exon 7, 8

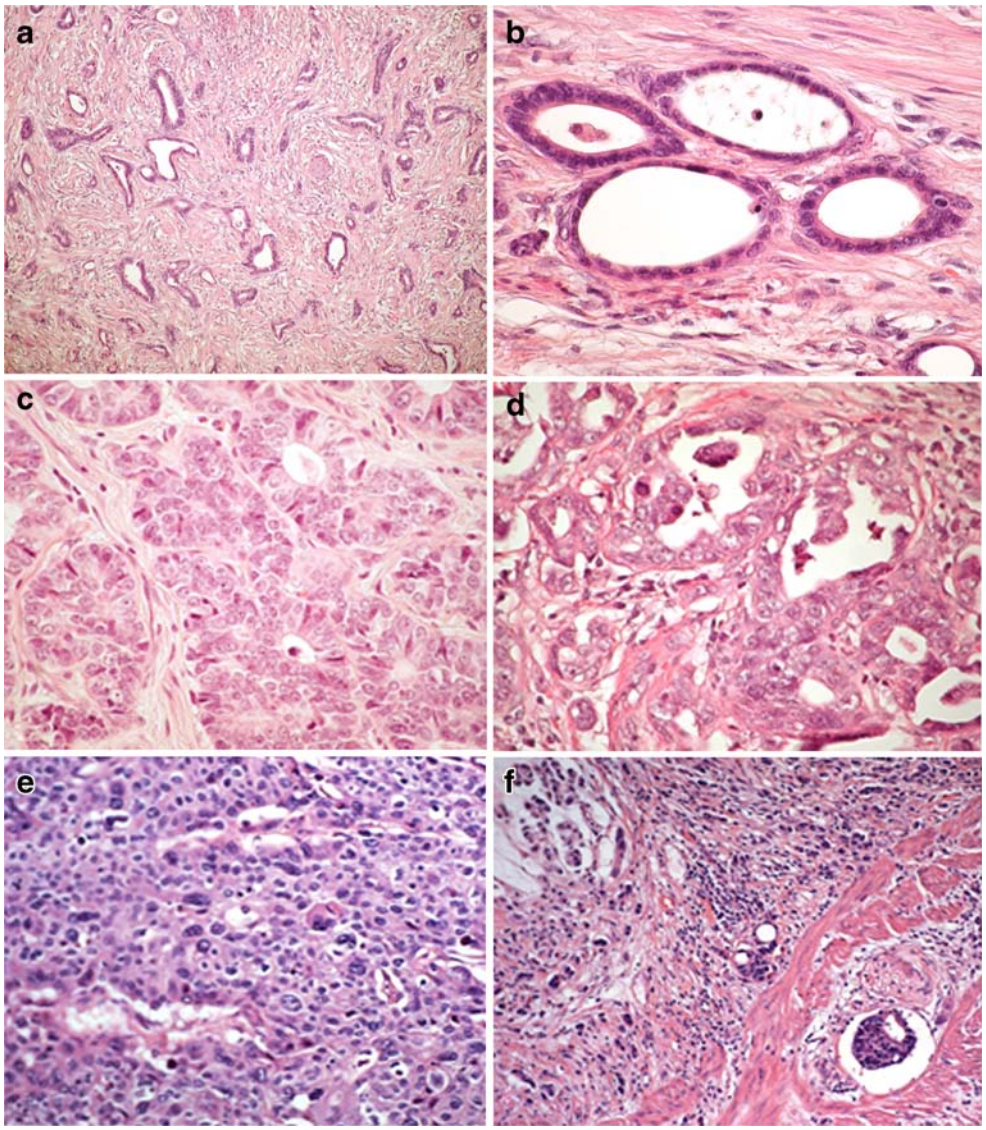

Fig. 1 **a**, **b** Well-differentiated (glandular score 3), low grade tubular cancer with moderately atypical (score 1 anaplasia), polarized cells arranged in a monostratified epithelium. **c** Ordinary cohesive (tubulo-trabecular), intermediate grade cancer formed by moderately atypical (score 1 anaplasia) cells with relatively regular nuclei. **d** Ordinary cohesive (tubulopapillary) cancer with frankly atypical (score 2 anaplasia) cells of pleomorphic nuclei and an exon 8 p53 gene mutation. Intermediate (Table 6A) to high (Table 6B) grade. **e** Anaplastic, high grade cancer formed by highly atypical, disorganized cells (score 3 anaplasia). **f** Diffusely infiltrative component of an high grade mucinous cancer with lymphoinvasion (*bottom right*)

Compared with the 247 non-HLR tumors, EBV+ cases showed only a slight, non-significant trend toward improved survival.

In Table 3, a Cox multivariable analysis confirms that, in addition to tumor diameter and stage, anaplasia, vascular invasion, expansile growth, Ki67 index, and p53 exons 7 or 8 mutations are independent survival predictors. HLR, which showed high collinearity (0.64) with expansile growth, also proved to be predictive (HR 0.36, 0.20–0.68, p=0.002) when substituted for expansile growth in the same model. Mitoses, when substituted for Ki67 index, failed to show significant predictive power.

We then analyzed the histotype distribution of parameters proven (see Tables 1, 2, and 3) to be of prognostic value in our gastric cancer population taken as a whole. We first considered five histotypes: cohesive (i.e., glandular+solid), diffuse, mucinous, anaplastic, and HLR cancers. Table 4 illustrates that the 21 anaplastic cases showed an obvious concentration of worsening factors like higher T (T_3–T_4), N (N_2–N_3), stage (III–IV), distant metastases, larger diameter, blood and/or lymph vessel invasion, neuroinvasion, proliferative indices (including a median of 45 mitoses/10 HPFs for the 21 cases, well above the median of 18 to 19 in the whole series), and p53 exon 7 or

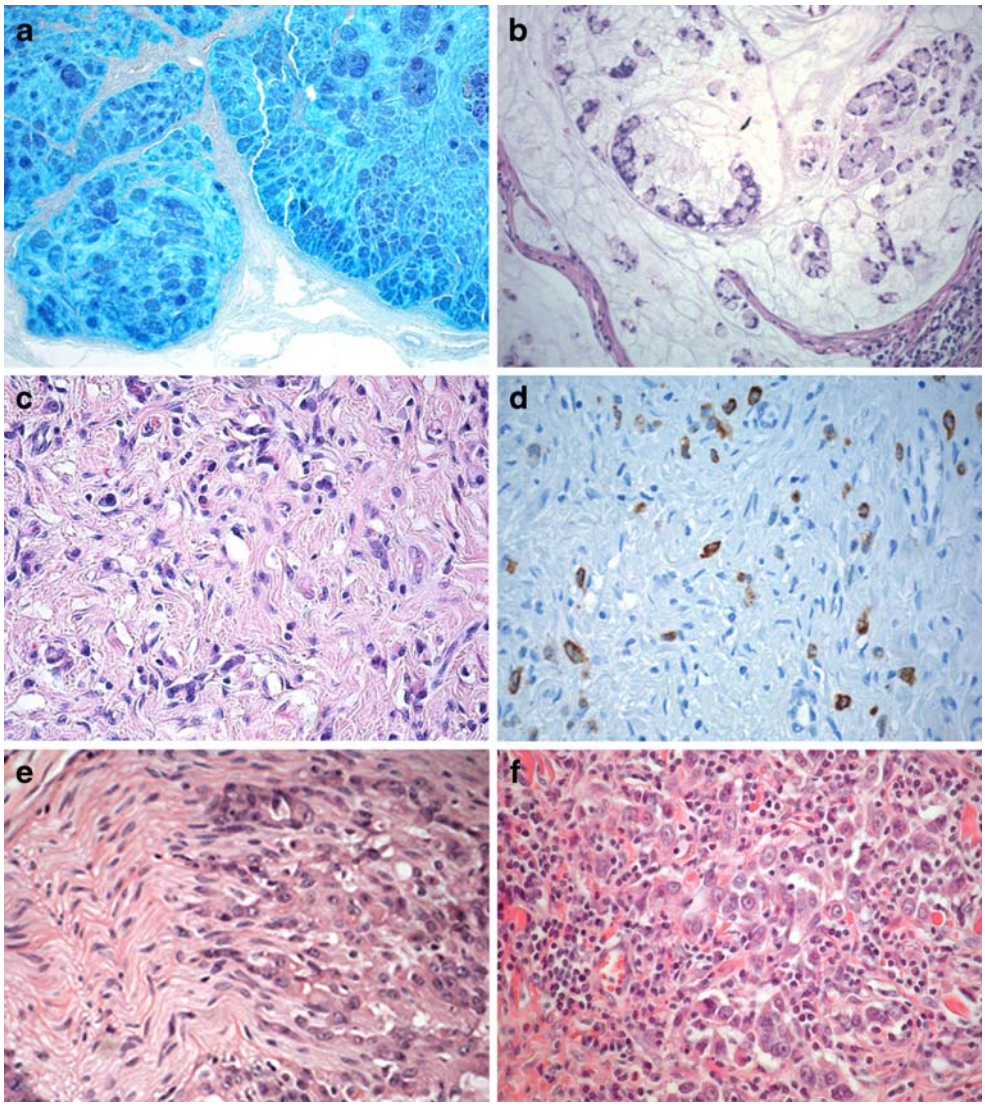

Fig. 2 **a** Alcian blue/PAS reactive mucin lakes with expansile borders in a low grade muconodular cancer. **b** Predominance of unstained extracellular mucin over tumor cells, either signet ring or forming small cords, inside a muconodule of a low grade case. **c** Epithelial tumor cells , cytokeratin reactive in (**d**) are scattered inside an overwhelming, fibroblast-rich stroma of a low grade desmoplastic cancer. **e** Gastric wall nerve invaded by neoplastic cells from an intermediate grade, ordinary diffuse cancer. **f** Low grade HLR cancer showing a lymphoepithelioid pattern resulting from heavy intratumor lymphoid cell infiltration dissociating cancerous cells of apparently prominent nuclear atypia (score 2 anaplasia)

8 mutations, in addition to score 3 anaplasia, their main diagnostic feature. Among cohesive, diffuse, and mucinous tumors, no major T, N, or M stage difference was found; however, we found a trend towards higher blood vessel invasion, proliferative rates, p53 protein expression, and exon 7+8 mutations in cohesive compared to diffuse and mucinous as well as towards neuroinvasion in diffuse compared to cohesive cancers. Unexpectedly, a significantly higher rate of 18qLOH, mainly involving from q21.1 up to q-ter loci, was found among mucinous compared to all other cancers as a whole (Fisher test, $p<0.001$) or taken individually ($p<0.001$ vs. diffuse and HLR; $p=0.007$ vs. cohesive; $p=0.021$ vs. anaplastic).

Given their frequently borderline structure between cohesive (solid-medullary or glandular) and diffuse (lymphoepithelioid) histology as well as their distinctive, mostly favorable prognosis, we considered the 47 HLR tumors separately. They turned out to show lower T, N, M stage, lymph or blood vessel invasion, neuroinvasion, p53 protein expression, and 18qLOH, in addition to more expansile growth and higher MSI-H rate, all features predicting favorable survival. The only exceptions were mitotic and Ki67 proliferative rates, which were increased ($p<0.001$ for both) compared to the remaining tumors, excepting anaplastic cancers.

We also tested parameter distribution among three histologic subtypes recently proposed to imply a favorable

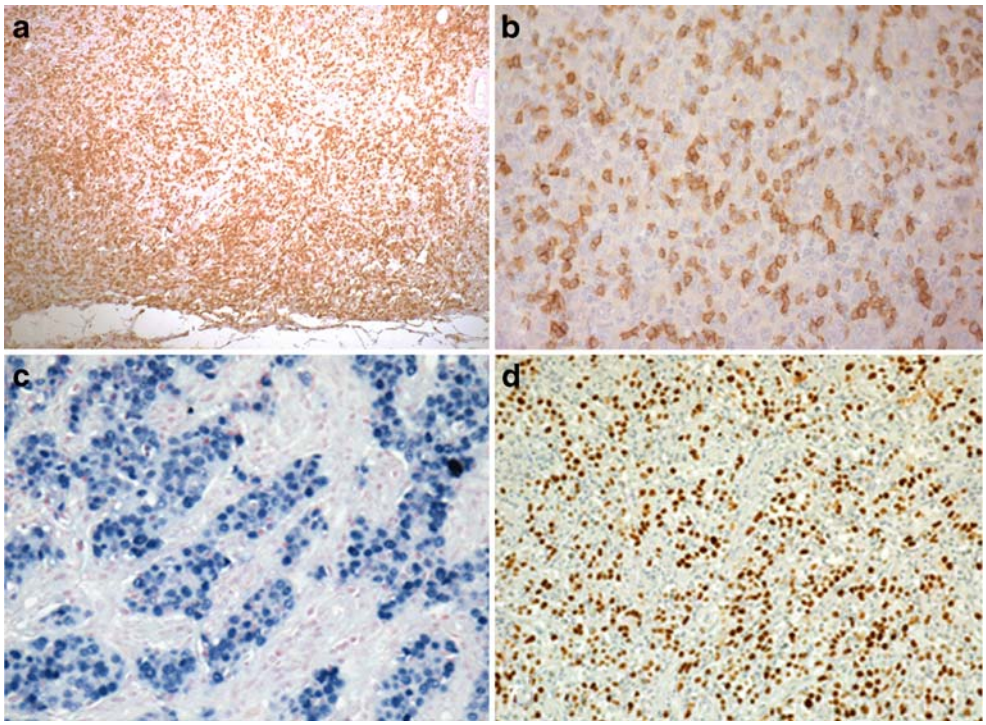

Fig. 3 **a** Low grade HLR cancer with heavy intratumor infiltration of CD8 positive T cells enveloping unreactive epithelial cells; note a regular, expansile border (*bottom*) mostly formed by CD8 reactive lymphocytes. **b** MLH1 unreactive neoplastic epithelial cells inside a low grade, MSI-H and HLR cancer with medullary structure; note MLH1 reactivity of intratumor lymphoid cells. **c** Positive EBV in situ hybridization of cancer cells forming islets and trabeculae separated by unreactive, abundant lymphoid cells (low grade HLR case). **d** Nuclear p53 protein immunoreactivity in a low grade, lymphoepithelioid type HLR tumor negative for both EBV and microsatellite DNA instability, while showing an exon 5 p53 gene mutation

prognosis, i.e., low grade mucinous (muconodular) cancer [33], low grade desmoplastic cancer [34], and very well-differentiated tubular cancer [32]. In all three subtypes, a clear-cut concentration of prognostically favorable parameters was observed, compared to remaining non-low grade cohesive (100 cases), diffuse (59), and mucinous (23) cancers (Table 4). It should be added that the 99 tumors showing invasion confined within the muscularis propria included 22 (47%) HLR, six (60%) well-differentiated tubular, nine (60%) low grade diffuse desmoplastic, and 15 (75%) muconodular cases. Collectively, the four low grade histotypes accounted for 52/99 (53%) T1b+T2a

[b] On continuous scale

[c] When replaced with HLR: HR 0.36 (0.20–0.68), $p=0.001$

Table 5 analyzes patient survival of the five main histologic types as well as of the three additional low grade subtypes and corresponding non-low grade cohesive, diffuse, or mucinous cancers. The results outline a favorable prognosis in HLR and low grade tubular, desmoplastic diffuse, or muconodular tumors and a worse prognosis in both anaplastic and infiltrative mucinous cancers, compared to ordinary cohesive and diffuse cases. No significant survival difference was observed between cohesive and diffuse or between anaplastic and infiltrative mucinous tumors or even among the three low grade subtypes and HLR cases. Therefore, all histologic types/subtypes were grouped into three categories of increasing malignant potential: (1) low grade histotypes (91 cases) encompassing 47 HLR, 10 well-differentiated tubular, 15 diffuse with embedding desmoplasia, and 19 muconodular tumors; (2) intermediate grade histotypes (159 cases) with ordinary cohesive and diffuse cancers; and (3) high grade histotypes (44 cases) corresponding to infiltrative mucinous and anaplastic cancers (Table 6A). The three groups showed clear-cut survival differences.

Based on the histologic parameters proven to predict survival in Tables 1, 2, and 3, another, more refined and flexible, though more complex, approach to a three-level grading system of gastric cancers was also developed. Thus, 47 tumors with HLR and score 1 or 2 anaplasia

(regardless of their angio-, lympho-, or neuroinvasive pattern) and 62 non-HLR tumors with score 1 anaplasia in the absence of angiolymphoinvasion or neuroinvasion formed the 109 cases in the grade 1 group. Grade 3 tumors included, in addition to 21, score 3 anaplasia cases and 19 infiltrative mucinous cancers also showing lymphoinvasion, a further 16 cases showing exon 7 or 8 p53 gene mutations coupled with score 2 anaplasia and angio-lympho or neuroinvasion. The remaining 129 cohesive (78 cases), diffuse (47), or mucinous (four) tumors formed the grade 2 group. Table 6B shows clear-cut survival differences among the three groups at both univariable and stage-inclusive bivariable analysis. Kaplan–Meier curves of patient groups in Table 6A and B are reported in Fig. 6.

Discussion

A number of histologic features have been found to be prognostically informative by univariable survival analysis in a large series of invasive (T1b to T4) gastric cancers. On stage-inclusive bivariable and multivariable analysis, only high intra- and peritumor lymphoid cell response (HLR) and expansile type local growth, largely correlated to each other, were confirmed to predict improved prognosis, while tumor lymph or blood vessel invasion, cellular anaplasia, and a high (≥40%) Ki67 index proved to worsen prognosis. Another stage-independent predictor of worse survival, neuroinvasion, proved difficult to assess in a substantial proportion (26%) of tumors, while mitotic counts above the median (>18/10 HPF) failed to survive multivariable analysis.

Out of several molecular changes tested, including p53 gene mutation or protein expression, TP53 LOH, microsatellite DNA instability, and 18q11.2–23 LOH, only exon 7 and 8 p53 gene mutations had a clear-cut negative influence on patient survival. This finding on gastric cancer p53 gene mutations fits in with previous results on lung [45, 46], head and neck [47], and colorectal cancers [48]; it is likely to be related to the high concentration of DNA contact and gain of function mutations in exons 7 and 8, with special reference to L3 loop, S-10 band, and loop-sheet-helix (LSH) mutations [49]. Indeed, 89% of exon 7 or 8 mutations that we found in our gastric cancers were of this type, with hot spots at codons 248 (exon 7, L3) and 273 (exon 8, LSH). It should be added that the lack of prognostic influence of exon 5 and 6 mutations is likely to account for the reduced predictive power of p53 mutations as a whole and, possibly, also of related parameters like p53 protein expression and TP53 LOH.

In our series, high level microsatellite DNA instability failed *per se* to predict a favorable outcome unless coupled with a high intra- and peritumor, T_8-rich lymphoid cell response. The higher proportion of mucinous, high grade,

and advanced stage cases we found among MSI-H tumors lacking HLR, compared to their HLR positive counterpart, is likely to account for the present failure to confirm the prognostic value of MSI-H *per se* reported in other series [10, 11]. Our results confirm previous findings on colon and gastric cancer [23, 50] in showing the prognostic dominance of HLR. In addition, we have seen that HLR, invariably present in all our EBV positive tumors, was also found in a third small subset of tumors negative for both microsatellite instability and EBV infection.

Expression of a wide range of mutated proteins coded by unstable microsatellite DNA genes [51], as yet undefined EBV virus proteins [52, 53] and other highly antigenic and/or mutated proteins like p53 [54, 55], may explain the high lymphoid cell response. Interestingly, both MSI-H/HLR positive and the third group of HLR tumors showed a preference for the distal stomach (antrum) with an obviously favorable prognosis. On the contrary, tumors in the EBV+ group, as already observed [25], were concentrated significantly in the proximal stomach and showed a trend towards an intermediate prognosis between that of the above two groups and of the HLR-negative tumors as a whole. The oncogenic potential of the EBV virus itself might work as a progression factor in EBV tumors, thus partly counteracting their strong T cell antitumor response, as well as favoring immune escape phenomena [52, 56].

In addition to individual histologic or molecular parameters, some tumor histologic types have also been suggested to predict patient survival, among which lymphoid cell-rich [21–24], very well-differentiated tubular [32], muconodular

[33], and a low grade subset of diffuse desmoplastic cancers [34] were all associated with a more favorable outcome, whereas various kinds of anaplastic cancers, with or without poor neuroendocrine, gut exocrine, hepatoid, choriocarcinomatous, or epidermoid differentiation, were associated with worse outcome. Therefore, the predictive power for the outcome of individual histologic types and subtypes was extensively reinvestigated in the whole series. The results, besides confirming previous suggestions [21–24, 32–34], allowed us to recognize infiltrative mucinous cancer, especially when associated with lymphoinvasion, as a highly malignant cancer with a significantly worse prognosis than ordinary cohesive or diffuse cancers and no substantial difference from anaplastic cancer. It should be recalled that mucinous cancers as a whole have been repeatedly shown to have a higher incidence of lymph node metastases, lymph vessel invasion, deep gastric wall invasion, large size and advanced stage, as well as worse overall survival which, however, was essentially accounted for by their more advanced stage [57, 58]. We confirm that no significant survival difference was found when the whole population of mucinous, cohesive, and diffuse cancers were compared to each other; however, when their respective low grade subtypes were taken out, infiltrative mucinous cancers showed a poorer stage-independent survival rate than that of ordinary cohesive and diffuse cancers comparable to that of anaplastic cancers.

These findings suggest that infiltrative mucinous cancers should be added to anaplastic cancers in a high grade tumor group having a significantly worse prognosis than ordinary cohesive or diffuse cancers. Thus, gastric cancer has been categorized into three malignancy grades, where HLR, very well-differentiated tubular, embedding desmoplasia diffuse and muconodular tumors make up the low grade, anaplastic and infiltrative mucinous cancers the high grade, and the remaining cohesive or diffuse cancers the intermediate grade group.

A systematic investigation of the distribution of survival-predictive histologic, molecular, or stage-linked parameters among main histologic types and subtypes disclosed a considerable histotype dependence of many such factors. For instance, expansile growth, long known to predict more favorable outcome [14], was a prominent and informative finding only among HLR and muconodular tumors, both showing better survival. In addition, 18qLOH was highly concentrated among mucinous tumors and, albeit less evidently, among cohesive tumors, with no significant prognostic value despite its known association with advanced stage [12, 27]. Of interest were also the increased proliferative rates found among favorable outcome HLR tumors as well as the lower rates found among worse outcome diffuse cancers. These findings, contrasting with the otherwise general parallelism between proliferative rates and survival, may weaken the prognostic value of both mitotic counts and the Ki67 index. They might also explain in part the failure of the predictive power of mitotic counts (which may be affected by the amount of stroma, abundant in many diffuse cancers) to survive multivariable analysis. Apparently, only vascular invasion and cellular anaplasia were distributed fairly equally among histotypes, essentially according to their malignancy grade.

Clarification of the selective role played by some of the histologic or molecular factors in the behavior of individual histotypes may open the possibility of a more fruitful reconstruction of their distinctive natural history, including pathogenetic and therapeutic aspects. It should be outlined that most parameters predicting worse survival were highly represented among anaplastic cancers and that many of them, especially histologic lymphoinvasion, lymph node metastases, T level invasion, and high maximum diameter, were also prominent among infiltrative mucinous cancers. In general, the differential distribution of many parameters among histotypes supported their characterization as individual neoplastic growths with distinctive morphology, molecular background, and, to some extent, natural history. For instance, the high 18qLOH shown by mucinous cancers compared with its low prevalence among diffuse cancers, with special reference to its signet-ring cell subtype, outlines the substantial difference between the two neoplastic diseases, despite their common excessive production of mucins, either extracellular (mucinous cancer) or intracellular (signet-ring cancer). The precise molecular link between 18qLOH and mucin dislocation, whose impact on tumor natural history has already been outlined [17–19, 59], remains to be investigated, with special reference to a possible relationship between DCC and SMAD genes (at 18q21 band) activity and tumor cell functional polarization and stroma interaction [12, 33].

The unequal distribution of predictive parameters among different histotypes and their complex reciprocal interplay has discouraged any attempt to develop a global scoring system for gastric cancer similar to that used, for instance, for ductal breast cancer [43]. However, the spectrum of survival-predictive histologic and molecular patterns obtained was taken as a base to further develop a three-grade classification of high prognostic value. Thus HLR tumors and, in addition, non-HLR tumors with score 1 cellular anaplasia and without angio-lympho- or neuro-invasion made up the grade 1 group (109 cases, 37%); tumors with score 3 anaplasia, invasive mucinous cancers as well as score 2 anaplasia tumors showing an exon 7 or 8 p53 gene mutation coupled with angio-, lympho-, or neuroinvasion formed the grade 3 group (56 cases, 19%); while the remaining 129 cases (44%) formed the grade 2 group. Further investigations on continuous, non-selected series are warranted in order to assess reliable figures of

tumor distribution among the three different grades. Despite this limit, the classification system appears to contribute substantially to the prognostic evaluation of gastric cancer as a whole.

It should be outlined that the two grading systems developed gave largely similar and partly overlapping findings. The histotype-based system has the advantage of allowing an easier identification and clinicopathologic characterization of distinctive tumor entities from well-recognizable structural patterns. On the other hand, the more complex system, integrating histotypes with individual parameters, provides a more balanced tumor distribution among the three grades while retaining stage-independent predictive power.

In conclusion, extensive investigation of histologic and molecular parameters, as well as histotypes of potential prognostic value in a large series of invasive gastric cancers, identified a limited number of independent, survival-predictive factors which were used to classify each tumor according to a three-grade highly discriminative scale of increasing malignancy. While the present investigation adds feasibility and scientific background to our approach, its effectiveness in routine diagnostic practice should be checked further on independent, continuous tumor series extensively sampled so as to ensure an appropriate grading, especially when identifying low grade histotypes.

Abstract DNA copy-number gains of chromosomes 8q, 13q, and 20q are frequently observed in gastric cancers. Moreover gain of chromosome 20q has been associated with lymph node metastasis. The aim of this study was to correlate DNA copy-number changes of individual genes on chromosomes 8q, 13q, and 20q in gastric adenocarcinomas to clinicopathological data. DNA isolated from 63 formalin-fixed and paraffin-embedded gastric adenocarcinoma tissue samples was analyzed by whole-genome microarray comparative genomic hybridization and by multiplex ligation-dependent probe amplification (MLPA), targeting 58 individual genes on chromosomes 8, 13, and 20. Using array comparative genomic hybridization, gains on 8q, 13q, and 20q were observed in 49 (77.8%), 25 (39.7%), and 49 (77.8%) gastric adenocarcinomas, respectively. Gain of chromosome 20q was significantly correlated with lymph node metastases (p=0.05) and histological type (p=0.02). MLPA revealed several genes to be frequently gained in DNA copy number. The oncogene c-*myc* on 8q was gained in 73% of the cancers, while *FOXO1A* and *ATP7B* on 13q were both gained in 28.6% of the cases. Multiple genes on chromosome 20q showed gains in more than 60% of the cancers. DNA copy-number gains of *TNFRSF6B* (20q13.3) and *ZNF217* (20q13.2) were significantly associated with lymph node metastasis (p=0.02) and histological type (p=0.02), respectively. In summary, gains of chromosomes 8q, 13q, and 20q in gastric adenocarcinomas harbor DNA copy-number gains of known and putative oncogenes. *ZNF217* and *TNFRSF6B* are associated with important clinicopathological variables, including lymph node status.

Introduction

Gastric cancer is a major health problem and ranks second as a cause of cancer death worldwide [1]. The only possible curative treatment is complete surgical resection. One of the hallmarks of solid cancers, including gastric cancer, is chromosomal instability leading to gains and losses of parts of, or even whole chromosomes [2]. The mechanisms underlying this instability phenotype in gastric cancers are still poorly understood. Patterns of DNA copy-number aberrations can be analyzed at high resolution by array comparative genomic hybridization (CGH). Gains of chromosomes 3q, 7p, 7q, 8q, 13q, 17q, and 20q and losses of chromosomes 4q, 5q, 6q, 9p, 17p, and 18q have been consistently described in gastric cancer studies using CGH or array CGH analysis [3–11]. In addition, gains of chromosomes 7q, 8q, 9q, 11q, 13q, and 20q and losses of chromosomes 4p, 5q, 6, 9p, 17p, and 18q can already be

detected in gastric cancer precursor lesions with direct malignant potential, indicating these as early events in the pathogenesis of gastric cancer [12–16]. Results from array CGH studies have shown that patterns of chromosomal aberrations can be correlated with clinicopathological variables. In previous studies, we have shown different patterns of chromosomal instability to correlate with lymph node status and with age of onset of the disease [17, 18].

DNA copy-number gains of chromosomes 8, 13, and 20 have been described to play an important role in colorectal adenoma to carcinoma progression [19, 20]. Also in gastric adenomas and adenocarcinomas, gains of these chromosomes have frequently been detected, indicating the importance of genetic events on these chromosomes for gastric cancer pathogenesis. Moreover, gain of chromosome 20q has been described to correlate with lymph node metastasis in gastric cancer and poor clinical outcome in colorectal cancer [3, 21, 22]. The most widely used array CGH platforms, so far, use spotted bacterial artificial chromosomes (BACs), which means that the probe sequences on the arrays cover up to 1 kb of DNA. This approach is very suitable for detecting patterns of DNA copy-number changes but has limitations in pinpointing individual genes whose normal function is disrupted due to these chromosomal aberrations. Multiplex ligation-dependent probe amplification (MLPA) [23] allows to determine in a single experiment DNA copy-number ratios of up to 40 individual genes and can be used to zoom in on chromosomal areas that show aberrations with array CGH [24, 25]. The aim of the present study is a detailed analysis of DNA copy-number changes of individual genes within gained areas on chromosomes 8, 13, and 20 in gastric adenocarcinomas and to correlate gene specific alterations to clinicopathological data.

Materials and methods

Materials and DNA isolation

DNA of 63 formalin-fixed and paraffin-embedded (FFPE) gastric adenocarcinomas of which 53 were obtained from Leeds (Leeds University Hospital, UK) and 10 were obtained from the Dutch D1/D2 trial [26], was isolated as previously described [17] using a commercial available DNA isolation kit (QIAmp DNA microkit, Qiagen, Hilden, Germany). Briefly, areas of at least 70% tumor cells were demarcated on a 4-μm haematoxylin- and eosin-stained tissue section. Adjacent serial sections of 10 μm were cut, and after deparaffination, the tumor tissue was macrodissected using a needle. After an overnight incubation with sodium thiocyanate (1 M) at 37°C, followed by proteinase K treatment, DNA was extracted. DNA concentrations were measured on a Nanodrop ND-1000 spectrophotometer (Isogen, IJsselstein, The Netherlands), and DNA quality was assessed by isothermal amplification as previously described [27]. Only DNA of excellent, good, and intermediate quality was used for further analysis.

Table 1 An overview of DNA copy number gains of chromosomes 8q, 13q and 20q detected by array CGH in 63 gastric adenocarcinomas, and the correlation to lymph node status and histological type of the tumor

Gain of 20q is significantly correlated to lymph node status and histological tumor type (in *bold*)

LN0 lymph node-negative, *LN1* lymph node-positive

DNA labeling and array CGH)

DNA labeling and array CGH were essentially performed as previously described [17, 28]. In short, tumor and normal DNA were differentially labeled using random priming (Bioprime DNA Labeling System; Invitrogen, Breda, The Netherlands) and hybridized on a BAC array containing approximately 5,000 clones printed in triplicate, consisting of the Sanger BAC clone set with an average resolution along the whole genome of 1.0 Mb (http://www.ensembl.org/Homo_sapiens/cytoview), the OncoBac set (http://informa.bio.caltech.edu/Bac_onc.html), containing approximately 600 clones corresponding to 200 cancer-related genes, and selected clones of interest obtained from the Children's Hospital Oakland Research Institute (CHORI) to fill any gaps larger than 1 Mb on chromosome 6 and to have full-coverage contigs of regions on chromosomes 8, 11, 13, and 20. All clones were printed on Codelink™ slides (Amersham BioSciences, Roosendaal, The Netherlands) at a concentration of 1 μg/μl in 150-mM sodium phosphate, pH 8.5, using an OmniGrid 100 microarrayer (Genomic Solutions, Ann Arbor, MI, USA) equipped with SMP3 pins (TeleChem International, Sunnyvale, CA, USA), and processed according to the manufacturer's protocol.

After hybridization, images of the arrays were acquired by scanning (Microarray scanner G2505B; Agilent technologies, Palo Alto, USA), and spot analysis and quality control were automatically performed using BlueFuse 3.4 software (BlueGnome, Cambridge, UK). When the Blue-

Table 2 Overview of patient and tumor characteristics of the 63 gastric adenocarcinomas analyzed in the study

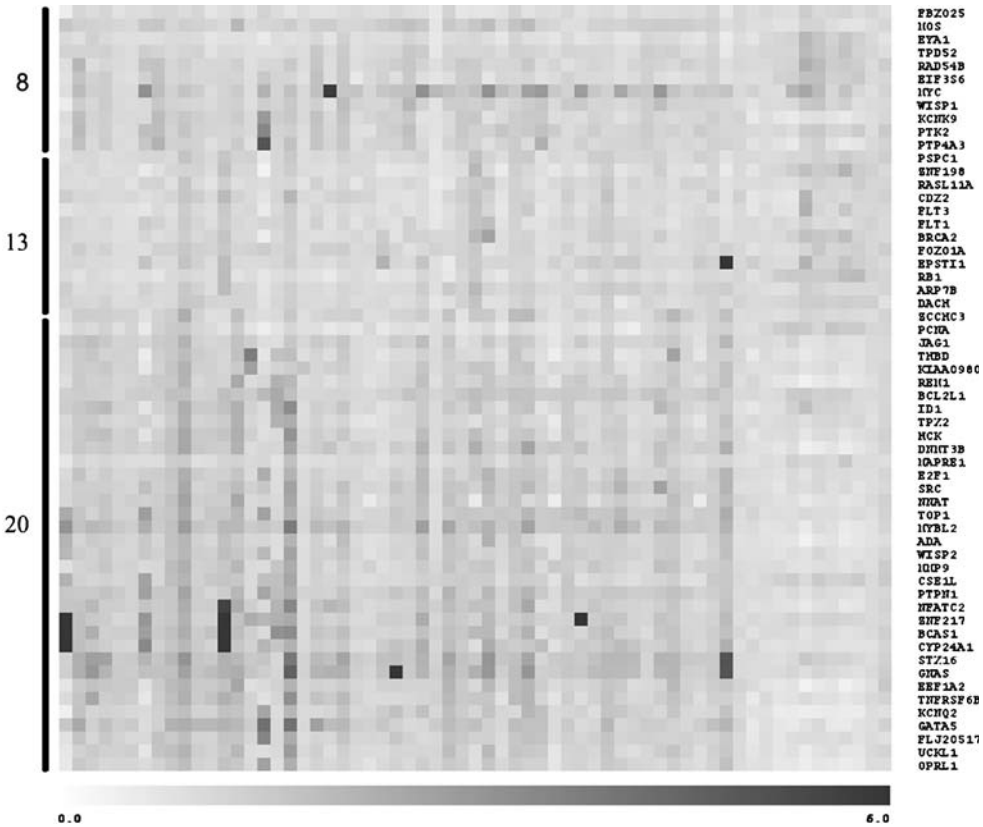

Fig. 1 Heatmap of DNA copy number ratios of 11 genes on chromosome 8, 12 genes on chromosome 13, and 35 genes on chromosome 20. The *columns* represent different gastric adenocarcinomas, and the *rows* represent the different genes. *Darker squares* indicate higher DNA copy number ratios

Fuse quality flag was below one or the confidence value was below 0.1, spots were excluded from further analysis. The $\log_2$ tumor to normal fluorescence ratio was calculated for each spot and normalized against the mode of the ratios of all autosomes. The package CGH call was used for data segmentation and defining copy-number gains and losses of each clone in the array CGH profile [29].

Multiplex ligation-dependent probe amplification

MLPA was performed, as previously described, [24] using two different probe mixes. One probemix contained 38 probes representing 31 different genes on chromosome 20 and 10 control probes located on chromosomes 2, 3, 4, 5, 12, and 16. The second probemix contained 11 probes on chromosome 8, 12 probes on chromosome 13, 16 probes on chromosome 20 representing 14 different genes, and 8 control probes located on chromosomes 2, 4, 12, and 16. Some genes on chromosome 20 are present in both probe mixes, leaving 35 different genes on chromosome 20 by combining these two probe mixes. DNA of the cell line HT29, showing a gain on chromosomes 8, 13, and 20, was used as positive control. A human pool of DNA isolated from blood of 36 healthy individuals and a pool of DNA isolated of 30 normal gastric and colon mucosa, spleen, liver, and kidney tissue samples (FFPE), were used as normal controls.

Of each sample, approximately 100 ng of DNA in a volume of 5 µl was denaturated at 98°C for 5 min. A mixture of 1.5-µl salsa probes (1–4 fmol of each short synthetic probe oligonucleotide and each phage M13-derived long probe oligonucleotide in TE (10 mM Tris-HCl, pH 8.2, 1 mM ethylenediamine tetraacetic acid (EDTA))) and 1.5 µl of MLPA buffer (1.5 M KCl, 300 mM Tris-HCl, pH 8.5, 1 mM EDTA) was added. The mixture was heated for 1 min at 95°C followed by 16 h of incubation at 60°C to allow the MLPA hemipobes to hybridize. Next, 32 µl of ligase-65 mixture (dilution buffer containing 2.6 mM $MgCl_2$, 5 mM Tris-HCl, pH 8.5, 0.013% non-ionic detergents, 0.2 mM of nicotinamide adenine dinucleotide (NAD), and 1 U of ligase-65 enzyme) was added to each sample for ligation of hybridized hemiprobes during a 10–15 min of incubation at 54°C, followed by a 5 min of incubation at 98°C to inactivate the ligase.

Polymerase chain reaction (PCR) was performed with 10 µl of polymerase mixture containing the PCR primers (10 pmol), dNTPs (2.5 nmol), and 2.5 U *Taq* polymerase (promega), 4 µl of PCR buffer (2.6 mM $MgCl_2$, 5 mM Tris-HCl, pH 8.5, 0.013% non-ionic detergents, 0.2 mM NAD), 26 µl of water and 10 µl of MLPA ligation reaction.

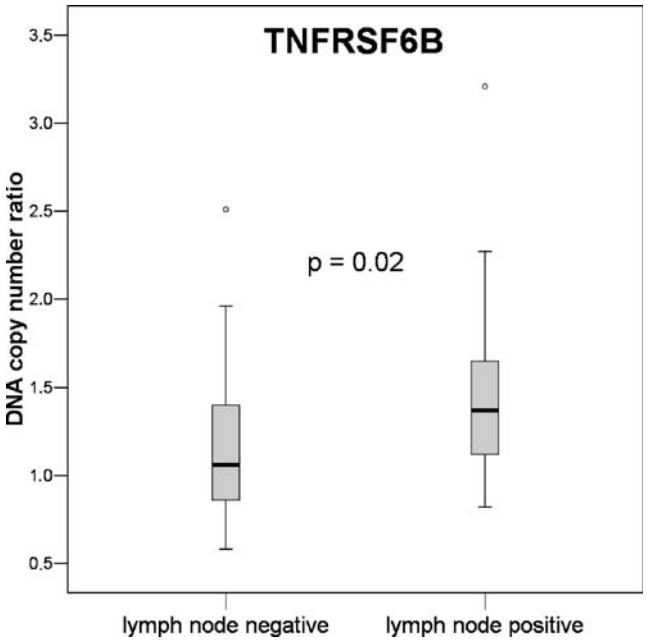

Fig. 2 Box plot of DNA copy number ratios of the gene *TNFRFS6B* between lymph node-negative and lymph node-positive gastric adenocarcinomas. Lymph node-positive gastric adenocarcinomas have significantly higher DNA copy number ratios of *TNFRFS6B* compared with lymph node-negative gastric adenocarcinomas (p=0.02). The *central box* covers the middle 50% of the data values between the upper and lower quartiles. The *line* across the box indicates the median. The *whiskers* extend from the box to the minimum and maximum values with the exception of outliers, which are marked by *circles*

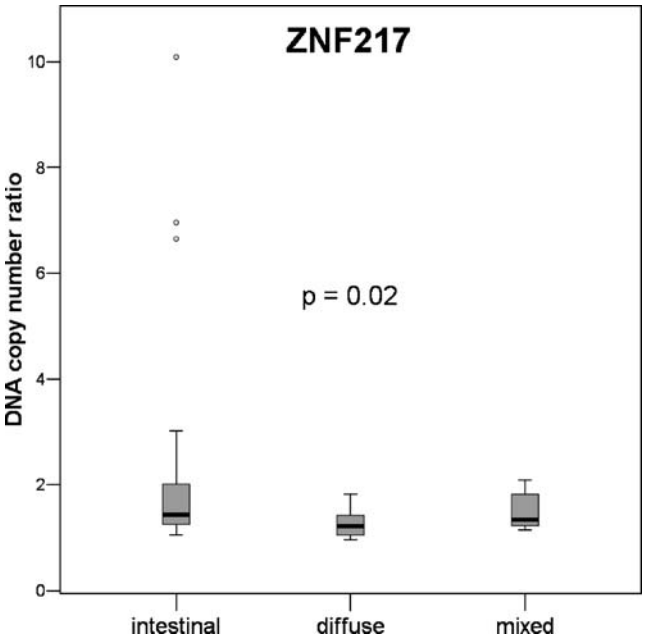

Fig. 3 Box plot of DNA copy number ratios of the gene *ZNF217* between intestinal-, diffuse-, and mixed-type gastric adenocarcinomas. DNA copy number ratios of *ZNF217* are significantly different between gastric adenocarcinomas of different histological types (p=0.02)

Multiplex ligation-dependent probe amplification data analysis

Analysis of the MLPA PCR products for each gene was performed on an ABI 3100 capillary sequencer (Applied Biosystems, Warrington, UK) in a mixture of 8.5 µl of deionized formamide (Applied Biosystems, Warrington, UK), 1 µl of PCR product and 0.5 µl marker including a ROX-labeled internal size standard (ROX-500 Genescan; Applied Biosystems, Warrington, UK). Data analysis was performed using the MLPAnalyzer version 8.0 (http://www.mlpa.com/coffalyser/) [30]. For each tumor, peak heights for every probe were derived from the ABI output and median peak heights of at least two different ligation reactions and three different PCR reactions were calculated. For each sample, tumor to normal DNA copy-number ratios was calculated per probe by dividing the median peak heights in the tumor tissue by the median peak heights in the reference DNA. All ratios were normalized by setting the median of the tumor to reference DNA copy-number ratios of the control genes in the probe mixture to 1.0. When multiple probes were present for one gene, the mean value of the probes was calculated and used for further analysis. Tumor to normal ratios below 0.7 and above 1.3 was considered as a loss or gain, respectively. TMEV software 3.1 (http://www.tigr.org/) was used to present descriptive data.

Statistical analysis

Box and scatter plots were used to present descriptive statistics. Chi-square test was used to evaluate associations of DNA copy-number gain of chromosomes 8q, 13q, and 20q with clinicopathological variables. t Test was used to evaluate differences in DNA copy-number aberrations and age of the patients. Mann-Whitney U test and Kruskal-Wallis H test were used to evaluate differences in DNA copy-number changes of each gene between lymph node status and histological tumor type according to the Laurén classification [31], respectively. Correlation coefficients between the $\log_2$ ratios for the array CGH and MLPA analysis were obtained by Spearman correlation (SPSS 12.0.1 for Windows; SPSS Inc. Chicago, IL, USA). A threshold of 0.05 for significance was used.

Results

Array CGH analysis and correlation with lymph node status and histological type

Of the 63 gastric adenocarcinomas analyzed by array CGH, 49 (77.8%) showed gains on chromosome 8, 25 (39.7%)

Table 3 A detailed overview of the frequencies of DNA copy number gains per gene, determined by MLPA analysis and mean DNA copy number ratio and range, per tumor group, i.e., lymph node-positive versus lymph node-negative gastric adenocarcinomas and intestinal- versus diffuse- versus mixed-type gastric carcinomas

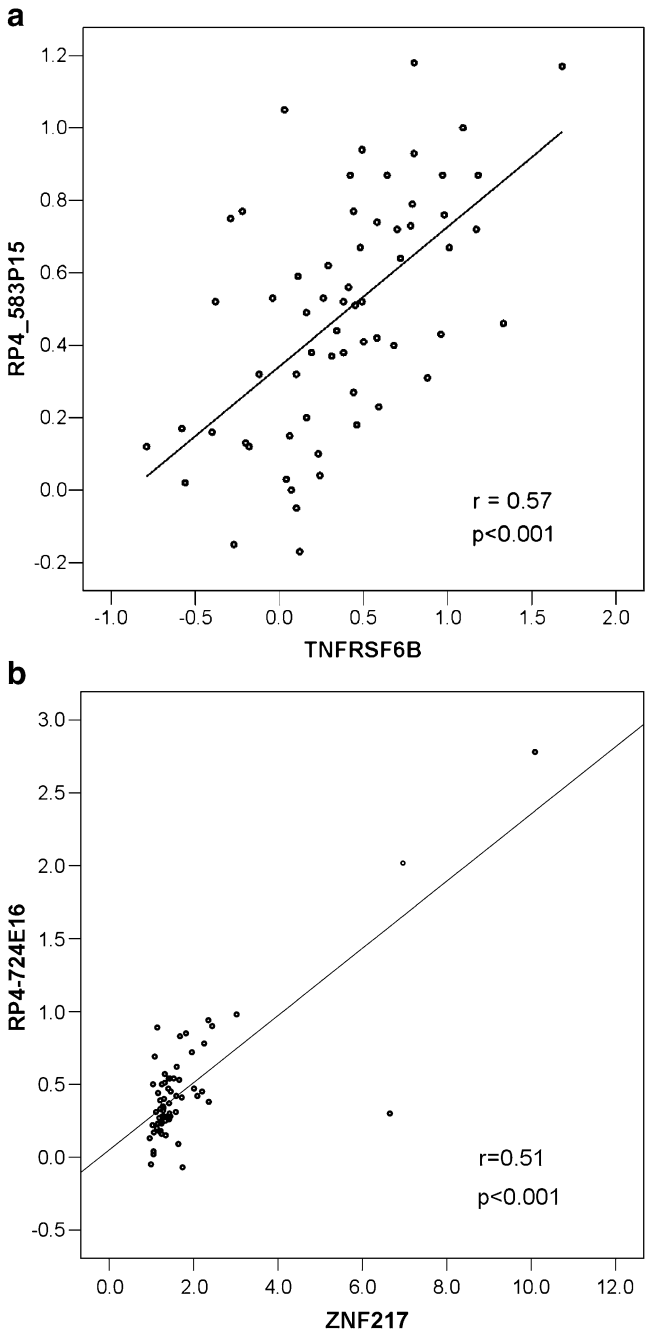

Fig. 4 Scatter plots of the $\log_2$ ratios of the BAC clone and MLPA probe of the *TNFRFS6B* (**a**) and *ZNF217* (**b**) genes. A significant correlation was detected for both genes ($p<0.001$, $r=0.57$ and $r=0.51$, respectively)

showed gains on chromosome 13, and 49 (77.8%) showed gains on chromosome 20. Concurrent gains of chromosomes 8 and 13, 8 and 20, and 13 and 20 were observed in four (6.3%), 24 (38.1%), and three (4.8%) of the gastric adenocarinomas, respectively. Concurrent gains of chromosomes 8, 13, and 20 were observed in 17 (27%) gastric adenocarcinomas. Gain of chromosome 20q was significantly correlated with lymph node status ($p=0.05$) and histological type of the tumor ($p=0.02$), being more common in lymph node-positive gastric cancers (85%) than in lymph node-negative gastric cancers (64%) and more common in intestinal-type (87%) and mixed-type (88%) gastric cancers than in diffuse-type (53%) gastric cancers. No significant (NS) correlation was found between 20q gain and age and gender of the patients and tumor size. No correlation of 8q gain or 13q gain with clinicopathological variables was found. An overview of the frequencies of copy-number gains on chromosomes 8q, 13q, and 20q detected by array CGH analysis is given in Table 1. An overview of patient and tumor characteristics is given in Table 2.

Multiplex ligation-dependent probe amplification analysis of DNA copy-number aberrations and correlation with lymph node status and histological type

All 63 gastric adenocarcinomas analyzed by array CGH were analyzed by MLPA. An overview of the DNA copy-number ratios of all individual genes on chromosomes 8, 13, and 20 in all tumor samples is presented as a heatmap in Fig. 1.

Gains of genes on chromosome 8q were observed in 9.5%–73.0% of the gastric adenocarcinomas, with the highest frequencies of gains observed in c-*myc* (73.0%). Gains of genes on chromosome 13q were detected in 11.1%–28.6%, with the highest frequencies of gains observed in *FOXO1A* and *ATP7B* (both 28.6%). Frequent DNA copy-number gains of multiple genes on chromosome 20q were observed. Gain of *TOP1*, *PTPN1*, *CYP24A1*, and *GATA5* was observed in more than 60% of the gastric adenocarcinomas, and gain of *BCL2L1*, *MYBL2*, *STX16*, and *GNAS* was observed in more than 70% of the gastric adenocarcinomas. When correlating gene-specific copy-number status to lymph node status, *EIF3S6* ($p=0.04$), located on chromosome 8q22 and *TNFRSF6B* ($p=0.02$), located on chromosome 20q13.3, were significantly different between lymph node-positive and lymph node-negative gastric adenocarcinomas. Although Mann-Whitney *U* test yielded a significant difference in copy-number of the gene *EIF3S6* between lymph node-positive and lymph node-negative gastric adenocarcinomas, mean copy-number ratio of both carcinoma groups were within the normal copy-number range (DNA copy-number ratio between 0.7 and 1.3). Lymph node-positive gastric adenocarcinomas showed gain (DNA copy-number ratio >1.3) of *TNFRSF6B* while lymph node negative gastric adenocarcinomas showed normal copy-number ratios of this gene (Fig. 2). When correlating gene-specific copy-number ratio to histological tumor type, Kruskall-Wallis *H* test yielded five significant genes. Mean copy-number ratios of *FBXO25* ($p=0.01$), located on 8p23.3, *RASL11A* ($p=0.03$), located on 13q12.2 and *CDX2* ($p=0.03$), located on 13q12, were within the normal copy-number range for all three tumor types. Mean

copy-number ratio of *ZNF217* (p=0.02), located on 20q13.2, showed gain in intestinal and mixed histological gastric cancer types versus normal in the diffuse histological types (Fig. 3). *STX16* (p=0.03), located on 20q13.32, showed mean copy-number gain in all three tumor types, but higher mean copy-number ratios in the intestinal and mixed types of gastric carcinomas compared with diffuse-type gastric carcinomas (1.90, 2.03, and 1.47, respectively). A detailed overview of the frequencies of gains per gene and mean copy-number ratio per tumor group, i.e., lymph node-positive versus lymph node-negative gastric adenocarcinomas and intestinal- versus diffuse- versus mixed-type gastric carcinomas are given in Table 3.

Correlation of copy-number status of MLPA and array CGH

The BAC clones RP4-583P15 and RP4-724E16 comprised the location of the *TNFRSF6B* and *ZNF217* genes, respectively. To evaluate the correlation between the array CGH and MLPA data, the MLPA DNA copy-number ratios were transformed to a $\log_2$ scale. Spearman correlation yielded a significant correlation between array CGH and MLPA data for both *TNFRSF6B* (r=0.57, p<0.001; Fig. 4a) and *ZNF217* (r=0.51, p<0.001; Fig. 4b).

Discussion

Gastric cancer is a common disease with a poor prognosis [1]. Chromosomal instability is a major mechanism of genetic instability in gastric cancers which has been widely studied by array CGH analysis [2, 32]. Frequent copy-number gains of chromosomes 8q, 13q, and 20q have been detected in gastric adenocarcinomas by this technique [3–10]. In this study, we report a detailed analysis of DNA copy-number changes of genes located on chromosomes 8, 13, and 20 in gastric adenocarcinomas aiming to correlate gene-specific alterations to clinicopathological data.

In the present study of 63 gastric adenocarcinomas studied by array CGH, nearly 80% of the cancers showed gain of chromosomes 8q and 20q. These frequencies of gains are consistent with previous studies where gains of chromosomes 8q and 20q were reported in 40–80% and 50–80% of gastric cancers, respectively [4, 10, 13, 14, 17, 33]. Both gains and losses of chromosome 13q have been detected in gastric cancers. Losses of chromosome 13q have been described in up to 30% of gastric cancers and gains of 13q have been described in up to 40% of gastric cancers [4, 10, 13–15, 17, 33], which is consistent with the findings of the present study.

When analyzing DNA copy-number gain at the gene level, mean copy-number ratio of two genes, *EIF3S6*E (8q22) and *TNFRSF6B* (20q12.3), correlated significantly with lymph node status. Mean copy-number ratios of *EIF3S6E* were within the normal range for both lymph node-positive and lymph node-negative gastric cancers, corresponding to the array CGH results in this study. Mean copy-number ratio of *TNFRSF6B* was significantly higher in lymph node-positive compared with lymph node-negative gastric cancers and was within the range of DNA copy-number gain and normal, respectively. Although 20q gain CGH data correlated with lymph node metastasis, of the 20q genes tested, only DNA copy-number gain of *TNFRSF6B* was significantly correlated with lymph node metastasis. *TNFRSF6B* is a member of the tumor necrosis factor receptor superfamily and is also known as decoy receptor 3 (DrR3). *TNFRSF6B* binds to FasL and inhibits FasL-induced apoptosis [34]. Overexpression of this gene has been observed in multiple cancer types, including cancers of the gastrointestinal tract. Interestingly, gastric cancers with pN2 and pN3 diseases have been shown to have significantly higher *TNFRSF6B* expression compared with gastric cancers with pN0 and pN1 diseases. Serum levels of *TNFRSF6B* were correlated with TNM stage in gastric cancers [35, 36]. We found *TNFRSF6B* DNA copy-number ratios on average to be gained in gastric cancers metastasized to the lymph nodes (pN1–3) compared with on average normal DNA copy-number ratios of *TNFRSF6B* in non-metastasized gastric cancers (pN0). Although previous studies have reported overexpression of *TNFRSF6B* without gene amplification [37], results of the present study indicate that DNA copy-number status of *TNFRSF6B* could be a valuable marker for identifying lymph node-positive gastric cancers.

DNA copy-number status of five genes, *FBXO25* (8p23.3), *RASL11A* (13q12.2), *CDX2* (13q12), *ZNF217* (20q13.2), and *STX16* (20q13.32), correlated significantly with histological tumor type, i.e., intestinal-, diffuse-, or mixed-type gastric cancer. Mean DNA copy-number ratios of *FBXO25*, *RASL11A*, and *CDX2*, however, were within the normal copy-number range for all three histological types, in consistence with the array CGH data of this study. The biological meaning of this difference, therefore, is not immediately clear, but could, e.g., relate to only a subpopulation of tumor cells being affected.

STX16 showed significantly higher mean copy-number ratios in intestinal- and mixed-type compared with diffuse-type gastric cancers; however, DNA copy-number gain was observed in all three tumor groups. *STX16* encodes a syntaxin protein which plays a role in intracellular trafficking [38], but its role in cancer still has to be elucidated.

ZNF217 encodes a transcription factor which was shown to be involved in immortalization of breast cancer cells when overexpressed [39]. High-level amplifications of *ZNF217* have been previously described in approximately 10% of gastric cancers [9, 10, 40]. In the study of Weiss et

al. on three tumors, all of the intestinal-type, out of 27 gastric adenocarcinomas, showed an amplification on 20q13. Fluorescence in situ hybridization (FISH) analysis was performed on these three tumors, confirming the copy-number increase at this locus [9]. Results from the present study suggest that DNA copy-number gain of *ZNF217* plays a more important role in intestinal- and mixed-type compared with diffuse-type gastric cancers, since gains of mean copy-number ratios are observed in intestinal- and mixed-type gastric cancers and normal mean copy-number ratio in diffuse-type gastric cancers.

In summary, we present a detailed DNA copy-number analysis of a panel of genes located on chromosomes 8, 13, and 20 in gastric adenocarcinomas. We found that DNA copy-number gain of *ZNF217* plays a role mainly in intestinal- and mixed-type but not in diffuse-type gastric adenocarcinomas. In addition, we showed that DNA copy-number gain of *TNFRSF6B* is significantly correlated to gastric cancers with lymph node metastasis, indicating a potential role for this gene as a biomarker for identifying patients at high risk of lymph node metastasis, who might, therefore, benefit from extended lymph node resection or neoadjuvant chemotherapy to improve gastric cancer outcome.

Abstract *Helicobacter pylori* infection is one of the most significant risk factors for gastric cancer. The infection is established early in life and persists lifelong leading to a sustained chronic inflammation. Iron is essential for most living organisms. Bacteria use several mechanisms to acquire iron from their hosts, including the synthesis of the potent iron chelators known as siderophores. Hosts cells may express the siderophore-binding protein neutrophil gelatinase-associated lipocalin (NGAL/lipocalin-2 (Lcn2)) in response to infection, thus preventing bacterial iron uptake. We have characterized here the pattern of expression of NGAL/Lcn2 in gastric mucosa (45 non-neoplastic and 38 neoplastic tissue samples) and explored the connection between NGAL/Lcn2 expression and *H. pylori* infection. Immunohistochemical analysis showed high NGAL/Lcn2 expression in normal and gastritis-affected mucosa compared to low expression in intestinal metaplasia, dysplasia, and gastric cancer. In normal and gastritis-affected mucosa (n=36 tissue samples), NGAL/Lcn2 was more frequently seen in epithelial cells located at the neck and base of the glands in *H. pylori*-positive cases than in similar epithelial cells of noninfected cases (Fisher's exact test, p=0.04). In conclusion, the high expression of NGAL/Lcn2 in normal and gastritis-affected mucosa infected with *H. pylori* suggests that NGAL/Lcn2 is upregulated locally in response to this bacterial infection. It is discussed whether this may have a causal relation to the development of gastric cancer.

Introduction

Gastric cancer is the second most common cause of cancer deaths worldwide [1]. It is the final result of a multistep process initiated by environmental factors, including diet and *Helicobacter pylori* infection [2, 3]. *H. pylori* infection is one of the most important risk factors for this malignancy [4, 5]. The infection is usually established early in life and persists lifelong in the absence of treatment [6]. The infection leads to a sustained chronic inflammation characterized by infiltration of a number of inflammatory cells in the gastric mucosa and expression of inflammatory mediators by immune and epithelial cells [7]. It is the combination of bacterial factors, host immune response, and environmental insults that drives the stepwise transformation starting with mucosal atrophy through metaplasia and dysplasia to overt gastric cancer [8, 9].

Iron is an essential element for a number of metabolic processes in almost all living organisms. During infection, bacteria utilize several mechanisms to obtain iron from their hosts, including synthesis of so-called siderophores, which chelate Fe^{3+} with high affinity and facilitate its transport into the pathogen [10–12]. An important host defense mechanism, which interferes with bacterial uptake of iron has been unraveled by the discovery of neutrophil gelatinase-associated lipocalin (NGAL or lipocalin-2 (Lcn2)) [13, 14] or NGAL-homologous proteins (24p3 in mouse and NRL in rats) [15] as siderophore-binding proteins [16]. NGAL/Lcn2 binds some bacterial siderophores and prevents their uptake into bacteria [17]. NGAL/Lcn2 expression has been shown to be upregulated in response to inflammation in epithelial cells of several mucosal surfaces including the gastrointestinal tract and the lower respiratory tract [18–20]. Elevated expression of the NGAL-homologous proteins has also been found in animal models (mice and rats) in response to bacterial infections [21, 22]. The significance of this was demonstrated in a mouse model, where NGAL-deficient mice challenged with a clinical strain of *Escherichia coli* (H9049 strain) had a substantial increase in bacteremia and bacterial burden in some organs, including liver and spleen and a strikingly decreased survival compared to the wild-type mice [23], and also in response to pulmonary *Klebsiella pneumoniae* infection [22].

Iron is fundamental for the pathogenesis of *H. pylori.* The ability of *H. pylori* to acquire iron is considered important for colonization, persistence, and virulence of this microorganism in the gastric mucosa [24–27]. Expression of NGAL/Lcn2 in the stomach has been reported both at the protein and mRNA level [14, 28]. In a mouse model, immunoreactivity for the NGAL-homologous protein, 24p3, was observed in epithelial, endothelial, and infiltrating inflammatory cells in the stomach in response to various forms of gastrointestinal injury [29]. Recently, increased expression of NGAL/Lcn2 was reported in rhesus macaques challenged with *H. pylori* [30]. These observations suggest that NGAL/Lcn2 is expressed in gastric mucosa in response to inflammation/infection. Here, we study the expression of NGAL/Lcn2 in human gastric mucosa and show for the first time that NGAL/Lcn2 is upregulated in response to *H. pylori* infection and inflammation.

Material and methods

Tissue samples

Formalin-fixed and paraffin-embedded tissue samples were obtained from patients undergoing surgery for gastric cancer in two hospitals in Costa Rica (Max Peralta Hospital and Rafael Angel Calderón Guardia Hospital) and one in Bergen, Norway (Haukeland University Hospital). The samples encompassed non-neoplastic mucosa adjacent to the malignant tissue (n=45; 37 from Costa Rica and eight from Norway) and neoplastic lesions (n=38; 32 from Costa Rica and six from Norway). Three to four micrometer thick paraffin-embedded tissue sections were cut from the non-neoplastic material, stained with H&E, and evaluated by a pathologist (ODL). Among the 45 non-neoplastic sections, there were foci characterized as normal mucosa (with some degree of inflammation; n=6), gastritis (n=30), intestinal metaplasia (IM; n=17), and dysplasia (n=11). Information regarding the histopathological subtype of gastric cancer was collected for all 38 neoplastic lesions. The histopathological classification was according to Laurén's classification system (Norwegian cases) and Japanese classification system (Costa Rican cases). For the purposes of this study, Costa Rican cases were reclassified according to Laurén's classification system following established criteria given by the Japanese Gastric Cancer Association [31]. Of the 38 cases, 20 were classified as intestinal subtype and 18 as diffuse subtype, and they were all non-cardia cancers (from corpus and antrum regions of the stomach). The study was

approved by the ethics committees and institutional review boards of each institution (Costa Rica: VI 742-94-571, VI 742-99-340; Norway: REK 053228) and performed in accordance with the World Medical Association Declaration of Helsinki, 1996.

Antibodies

Affinity purified mouse monoclonal antibody (mAb) against human NGAL/Lcn2 (clone 211.1) has been described previously [32]. Rat mAb against human NGAL/Lcn2 was purchased from R&D systems (Minneapolis, USA). mAbs against cytokeratins (CKs, clones AE1/AE3), neutrophil elastase (clone NP57), and rabbit polyclonal antibodies (pAbs) against *H. pylori* (code no. B0471), fluorescein isothiocyanate (FITC)-conjugated goat anti-mouse IgG and nonimmune rabbit IgG were purchased from Dako (Glostrup, Denmark). Cy3-conjugated goat anti-rabbit was obtained from Jackson Immunoresearch (West Grove, PA, USA). Monoclonal antibody directed against trinitrophenyl hapten (TNP, IgG1) was previously described [33].

Immunoperoxidase staining

Three micrometer thick paraffin-embedded tissue sections were deparaffinized with xylene and hydrated in gradual series of ethanol–water dilutions. For NGAL immunohistochemistry with mouse and rat mAbs, sections were heat-treated in a T/T micromed microwave processor (Milestone, Sorisol, Italy) at 98°C for 30 min in target retrieval solution pH 6,0 (code no. S1699, Dako). For immunohistochemistry with antibodies against neutrophil elastase, CKs, *H. pylori*, and TNP, sections were pretreated with proteinase K (10 μg/mL) for 20–25 min at 37°C. Endogenous peroxidase activity was blocked by incubation in 1% hydrogen peroxide solution for 15 min and washed briefly in Tris Buffered Saline (TBS; 50 mM Tris, 150 mM NaCl, pH 7.6) containing 0.5% triton X-100. The primary antibodies were diluted in antibody diluent (Dako) and incubated for 2 h in Shandon racks (Thermo Shandon, Pittsburg, PA, USA) at the following dilutions: NGAL mouse mAb 1:200 (5.0 μg/mL), NGAL rat mAb 1:350 (1.4 μg/mL), Neutrophil Elastase 1:200, CKs 1:300, and anti-*H. pylori* 1:150. Subsequently, the primary antibodies were detected with EnVision reagent using either anti-mouse IgG or anti-rabbit IgG horseradish peroxidase-conjugated polymers (Dako) and polyclonal rabbit anti-rat immunoglobulins/HRP (code no. P0450, Dako). The reactions were visualized by incubating the sections with NovaRED (Vector Laboratories, Burlingame CA, USA) or DAB chromogen (Dako; for *H. pylori* pAbs) according to manufacturer's instructions and counterstained with Mayer´s haematoxylin.

Negative controls

The sections were pretreated in the same way as described above for the NGAL antibody. The mouse NGAL monoclonal antibody was substituted with anti-TNP mAb incubated at the same concentrations as that for NGAL.

Double immunofluorescence staining

The sections were processed as described above for the NGAL mouse mAb using heat-induced retrieval in target retrieval solution pH 6.0 (code no. S1699, Dako). The anti-NGAL mouse mAb (1:150, 6.7 μg/mL) was diluted in antibody diluent (Dako) together with anti-*H. Pylori* pAbs (1:150) and incubated in the tissue sections for 2 h at room temperature. The antibodies were subsequently detected with FITC-conjugated goat-anti-mouse IgG, 1:200, and Cy3-conjugated goat anti-rabbit IgG, 1:200, respectively. After brief rinses with TBS, the sections were mounted with ProLong Gold antifade (Molecular Probes, Eugene, Oregon).

Confocal microscopy

The double stained sections were analyzed using a confocal laser-scanning microscope, LSM 510 META (Carl Zeiss, Jena, Germany), equipped with a 488 nm argon laser and a 543 nm HeNe1 laser, as previously described [34].

Scoring for the immunoperoxidase stainings

The tissue sections stained with NGAL mouse mAb from both non-neoplastic gastric mucosa adjacent to cancer tissue and from gastric cancer lesions were evaluated by two independent investigators (WAA and ODL). Neutrophils present in the microvasculature and within the tissue served as internal positive control for NGAL/Lcn2 expression. NGAL/Lcn2 immunoreactivity was scored, according to the estimated percentage of crypts showing NGAL/Lcn2-positive epithelial cells, in the following four types of non-neoplastic gastric mucosa: normal mucosa, gastritis, IM, and dysplasia. The scoring was as follows: 0, less than 10% positive crypts; 1+, between 10% and 30% positive crypts; 2+, between 30% and 60% positive crypts; and 3+, more than 60% positive crypts. In gastric cancer lesions, NGAL/Lcn2 immunoreactivity was scored based on the estimated percentage of positive cancer cells seen in the whole section. Thus, the percentages of positive cancer cells were grouped into the following categories: 0, less than 5% NGAL/Lcn2-positive cancer cells detected; 1, between 5% and 30% positively stained cells; 2, between 30% and 60% positive tumor cells; and 3, when more than 60% of cancer cells were positive.

H. pylori positivity was scored based on the density of bacteria and the number of crypts containing bacteria into the following categories: −, no evidence of *H. pylori* on the section; +, less than three crypts with small clusters of bacteria; ++, either less than three crypts with dense clusters of bacteria or more than three crypts with small clusters; and +++, three or more crypts with dense clusters of bacteria.

Statistical analysis

χ^2 analysis was performed to evaluate the differences regarding the frequency of cases having NGAL/Lcn2-positive cancer cells in intestinal versus diffuse subtypes of gastric cancer. χ^2 analysis and Fisher's exact test were used to assess the correlation between NGAL/Lcn2 expression in gastric epithelial cells and *H. pylori* infection in normal-like and gastritis-affected mucosa. $p \leq 0.05$ was considered statistically significant in all cases.

Results

NGAL/Lcn2 expression in non-neoplastic and neoplastic gastric mucosa

Immunoperoxidase staining for NGAL/Lcn2 in non-neoplastic and neoplastic tissue sections demonstrated NGAL/Lcn2 staining in all the specimens studied. We separately characterized the pattern of expression of NGAL/Lcn2 for each of the different states of the gastric mucosa: normal mucosa, gastritis, IM, dysplasia, and cancer. In general, the NGAL/Lcn2-positive cells observed in the non-neoplastic and neoplastic tissue samples included neutrophils, epithelial cells, and cancer cells. The NGAL/Lcn2 immunoreactivity of the normal mucosa (with some degree of inflammation) and gastritis-affected mucosa was intense (high frequency of sections scored as 3+), while that of IM, dysplasia, and cancer was low (high frequency of the sections scored as 0–1+; Table 1). This suggests that the expression of NGAL/Lcn2 is upregulated locally in the early steps of the gastric carcinogenesis that are characterized by chronic inflammation of the gastric mucosa.

The pattern of expression of NGAL/Lcn2 varied substantially according to the level of affection of the gastric mucosa. In normal and gastritis affected mucosa, NGAL/Lcn2 immunoreactivity was mainly seen in epithelial cells (Fig. 1a–d). NGAL/Lcn2 was, however, differentially expressed depending on the location of the epithelial cells in the crypts, with the most intense signal being observed in epithelial cells located at the neck and base of the crypts and weak or negative immunoreactivity at the surface epithelial cells (Fig. 1d). The expression of NGAL/Lcn2 was absent at foci with IM, where scattered NGAL/Lcn2-positive neutrophils were seen in the lamina propria (Fig. 1c–e). In dysplastic mucosa, NGAL/Lcn2 immunoreactivity was seen in epithelial cells of the glands located deeper into the gastric mucosa (Fig. 1f). In gastric cancer lesions, NGAL/Lcn2 staining was seen in 53% (20 out of 38) of the cases in cancer cells widespread within the malignant growth, with similar frequency in intestinal (Fig. 1g) and diffuse (Fig. 1h) histological subtypes (Table 1; $p=0.84$; $\chi^2=0.04$). NGAL/Lcn2 immunoreactivity in neoplasia was heterogeneous, being intense in some areas of the tumor growth and weak and/or negative in other areas (not shown).

Table 1 NGAL/Lcn2 immunoreactivity in non-neoplastic and neoplastic tissue sections according to the different states of the gastric mucosa and histological subtypes of gastric cancer

Lesion	*n*	NGAL/Lcn2 scoring[a]

NGAL neutrophil gelatinase-associated lipocalin, *Lcn2* lipocalin-2, *IM* intestinal metaplasia

[a] Scoring method is described in Material and methods section

[b] Scoring according to *Helicobacter pylori* status is shown in Table 2

[c] χ^2 analysis for normal and gastritis vs intestinal metaplasia and dysplasia, $p<0.0001$

[d] χ^2 analysis for intestinal versus diffuse, $p=0.84$

The specificity of NGAL/Lcn2 immunoreactivity was verified by analysis of a series of positive and negative controls. Similar NGAL/Lcn2 staining was obtained with mouse and rat mAbs against NGAL/Lcn2 in both non-neoplastic (Fig. 1i, j) and neoplastic tissue (not shown) in all of 15 cases tested. As negative control, we substituted the NGAL mouse mAb with a mAb against TNP. No specific staining was obtained with this antibody when incubated at similar immunoglobulin concentration as the respective anti-NGAL antibody preparation (Fig. 1k, l).

H. pylori infection associates with the induction of NGAL/Lcn2 in gastric mucosa

We observed, as described above, a clear and consistent NGAL/Lcn2 immunoreactivity in epithelial cells of normal mucosa and from gastritis (Table 1, Fig. 2b). Since it is known that *H. pylori* infection induces a chronic inflammatory

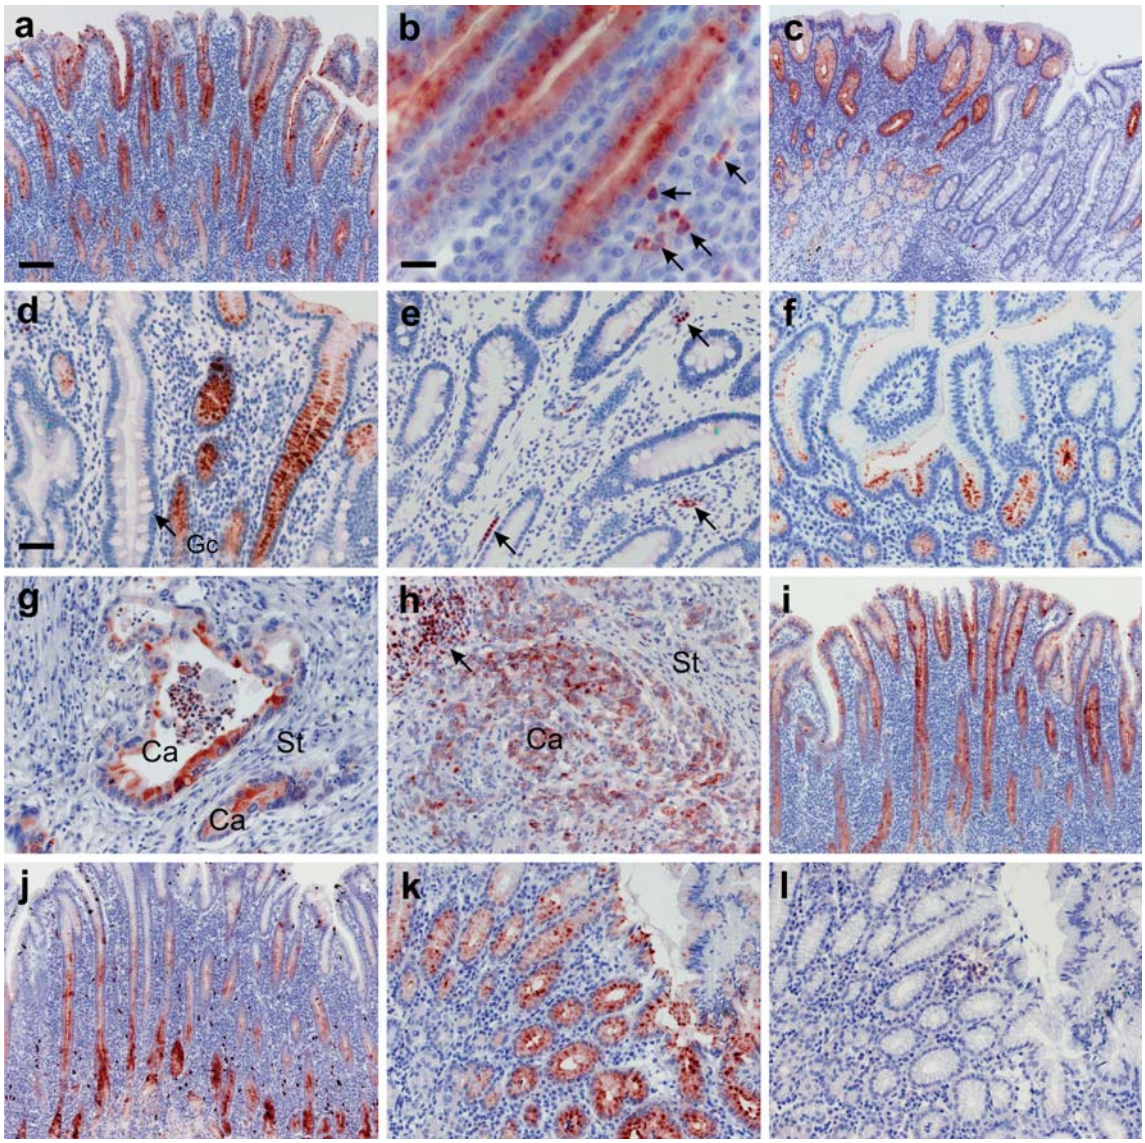

Fig. 1 Immunoperoxidase staining for NGAL/Lcn2 in non-neoplastic and neoplastic gastric tissue. Paraffin sections from non-neoplastic (**a**–**f**, **i**–**l**) and neoplastic (**g**–**h**) gastric mucosa were incubated with mouse mAb against NGAL/Lcn2 (**a**–**i**, **k**), rat mAb against NGAL/Lcn2 (**j**), and a mAb against TNP (**l**). Panels **i**–**j** and **k**–**l** represent adjacent sections. In gastritis-affected mucosa (**a**–**d**), NGAL/lcn2 is expressed by epithelial cells of gastric mucosa and scattered neutrophils in the lamina propia (**b**; neutrophils (*arrows*)). NGAL/Lcn2 is seen in epithelial cells located at the neck and base of the crypts more evidently than in surface epithelial cells (**d**). NGAL/Lcn2 expression is absent in intestinal metaplasia (**c**–**e**), next to gastritis foci showing intense immunoreactivity (**c** and **d**; goblet cells (*Gc*)), where only scattered NGAL/Lcn2-positive neutrophils are observed in the lamina propia (**e**; *arrows*). In dysplasia (**f**), NGAL/Lcn2 is observed in epithelial cells of glands located deep into the mucosa. In the gastric cancer lesions, NGAL/Lcn2 immunoreactivity is observed in cancer cells that are widespread within the tumor growth in both intestinal (**g**; stroma (*St*), cancer (*Ca*)) and diffuse subtype (**h**). A similar staining pattern is seen with mouse mAb (**i**) and rat mAb (**j**). As negative control, the mAb against NGAL/Lcn2 (**k**) was substituted with a mAb against TNP (**i**), and no specific staining is seen. Sections were counterstained with hematoxylin. *Scale bars*: ~100 μm (**a**, **c**, **i**, **j**), ~50 μm (**d**–**h**, **k**, **l**), ~25 μm (**b**)

response in gastric mucosa [35] and that NGAL/Lcn2 expression is upregulated in response to bacterial infection and inflammation [36], we explored the possibility that the expression of NGAL/Lcn2 in epithelial cells of the gastric mucosa is associated with *H. pylori* infection. Tissue samples from non-neoplastic mucosa, with foci of normal and gastritis affected mucosa, were selected and stained for *H. pylori*. Immunoperoxidase staining showed *H. pylori* in 72% (26 out of 36) of the cases. *H. pylori* clusters were observed at the luminal edge of the crypts, in deeper areas of the crypts, and inside some of the mucosal glands, with the highest density of bacteria in gastritis-affected mucosa (Fig. 2c). We next scored the NGAL/Lcn2 immunoreactivity in epithelial cells of the normal and gastritis-affected mucosa from adjacent

tissue sections, as described in Material and methods, and noticed that the majority of the *H. pylori*-positive cases had an elevated expression of NGAL/Lcn2 (scores 2–3+) as compared to *H. pylori*-negative cases (Table 2). It has been shown that NGAL/Lcn2 is expressed at a basal low level in a number of human epithelial tissues such as the respiratory tract, the gastrointestinal and urinary tracts that are exposed to the external environment and thereby prone to infections [14, 18, 28], indicating that a low expression level is to be expected in mucosal surfaces. We, therefore, dichotomized the expression of NGAL/Lcn2 into NGAL/Lcn2 low immunoreactivity (scores 0, 1+) and NGAL/Lcn2 high immunoreactivity (scores 2+, 3+; Table 2) for a statistical analysis. Using this classification, we found a significant association between the expression of NGAL/Lcn2 in epithelial cells and *H. pylori* infection ($p=0.02$; $\chi^2=5.43$; df=1; Fisher exact test $p=0.04$). Double immunofluorescence analysis for NGAL/Lcn2 combined with *H. pylori* in non-neoplastic normal and gastritis-affected mucosa from 24 of the gastric cancer patients (18 *H. pylori*-positive and 6 *H. pylori*-negative), indeed showed intense and consistent NGAL/Lcn2 immunoreactivity in crypts where epithelial cells were in direct contact with *H. pylori* bacteria in the *H. pylori*-positive cases (Fig. 2d, f). In contrast, in *H. pylori*-negative cases, the NGAL/Lcn2 signal was weak in epithelial cells at similar locations (not shown).

Discussion

We have investigated the expression of NGAL/Lcn2 in each of the pre-neoplastic stages leading to gastric cancer, focusing on the potential induction of this protein in response to *H. pylori* infection. By performing immunohistochemistry and immunofluorescence analysis, we show that NGAL/Lcn2 is upregulated in epithelial cells of normal and gastritis-affected mucosa infected with *H. pylori.* These are typical sites of robust inflammatory activity [7]. Interestingly, we also observed that the expression of NGAL/Lcn2 is absent at foci with IM adjacent to areas of gastritis. At IM, *H. pylori* infection is spontaneously eradicated and inflammation is partially resolved [2, 37]. Our results, therefore, support the role of NGAL/Lcn2 as a component of the innate immunity and suggest that *H. pylori* infection is causatively associated with upregulation of this molecule in gastric mucosa.

In the present study, we found a significant higher NGAL/Lcn2 immunoreactivity in gastric epithelial cells of *H. pylori*-infected individuals than in those non-infected, which was substantiated by observing *H. pylori* clusters in close proximity to NGAL/Lcn2-positive epithelial cells in our double immunofluorescence analysis. NGAL/Lcn2 has been shown to be constitutively expressed in epithelial cells of a number of tissues that are often challenged by microorganisms such as the respiratory tract and the urinary and gastrointestinal tracts [14, 28]. NGAL/Lcn2 mRNA and protein levels are greatly increased in response to pneumococcal and mycobacterial infections in the respiratory tract and urinary tract infections, in both animal models and humans [22, 36, 38, 39]. Taking together these observations and our results, we suggest that the constitutive basal expression of NGAL/Lcn2 that is observed in the gastric epithelium ([14, 28] and this paper) is substantially upregulated upon *H. pylori* infection. A recent study in rhesus macaques, showing that NGAL/Lcn2 is induced in gastric mucosa of monkeys challenged with certain *H. pylori* strains [30], is in agreement with our observations and suggests that the upregulation of NGAL/Lcn2 by *H. pylori* may be related to specific bacterial virulence factors.

A particularly interesting finding of this study was the abrupt down-regulation of NGAL/Lcn2 expression observed at IM foci located next to normal and gastritis *H. pylori*-infected mucosa showing intense NGAL/Lcn2 immunoreactivity. A number of histological and physiological changes occur in the gastric epithelium during the pre-neoplastic stages leading to gastric cancer, including a focal loss of glands and specialized cells (atrophic gastritis), followed by the transformation of the stomach mucosa into an intestinal-like epithelium (IM) [8, 40]. These changes are not well tolerated by *H. pylori* and results in its spontaneous disappearance from the transformed epithelium [37, 41]. Accordingly, we did not observe *H. pylori* bacteria at intestinal metaplastic glands. It is, therefore, tempting to suggest that the abolition of NGAL/Lcn2 expression on IM is a consequence of the natural eradication of *H. pylori* occurring at these foci. Thus, our findings in IM argue in favor of the potential link between *H. pylori* infection and the upregulation of NGAL/Lcn2 in the gastric epithelium.

Iron is an essential element for the growth and virulence of *H. pylori*, and the general consensus is that *H. pylori* obtains this element from human molecules, mainly lactoferrin and heme [27, 42–44]. Despite one study suggesting the production of siderophores by *H. pylori* [45], most investigations have been unable to reproduce that finding or to demonstrate the use of exogenous siderophores as a source of iron by this bacterium [44, 46]. Nevertheless, the induction of NGAL/Lcn2 is not restricted to microorganisms that produce or uptake siderophores.

The induction of NGAL/Lcn2 has been consistently linked to inflammation. High NGAL/Lcn2 mRNA and protein levels have been found in epithelial cells in inflammatory colorectal diseases such as inflammatory bowel disease, appendicitis [18], as well as in other processes associated with intense inflammatory activity [20, 47]. As part of the inflammatory response against *H. pylori* infection, a complex set of inflammatory mediators are released by

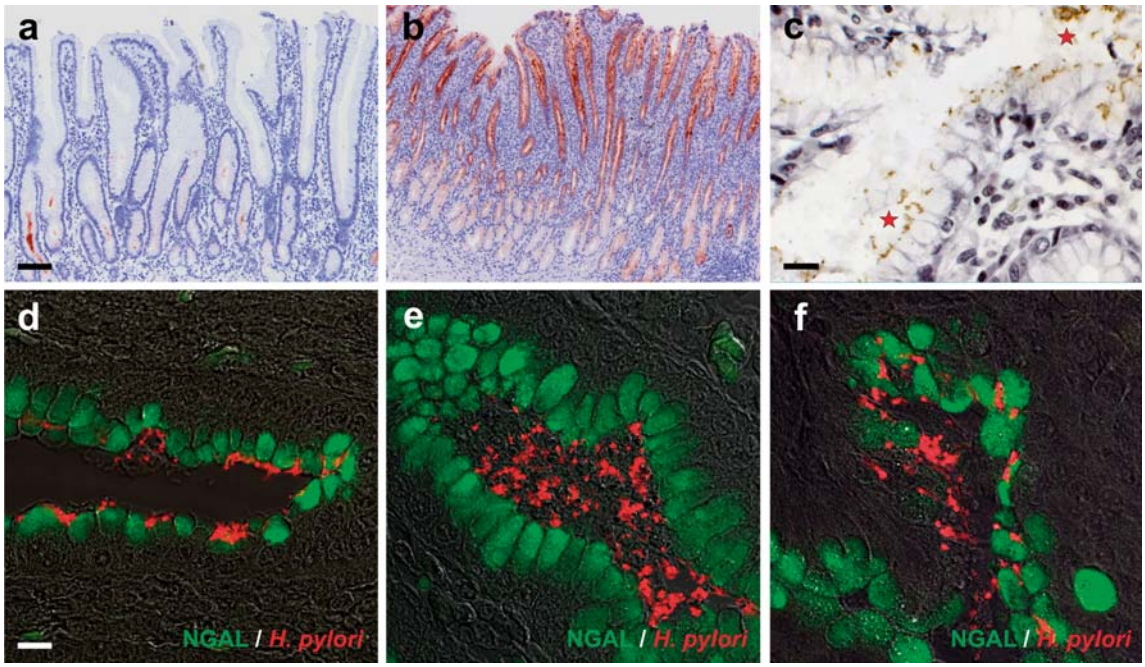

Fig. 2 Immunohistochemical analyses of NGAL/Lcn2 and *H. pylori* in non-neoplastic gastric mucosa. Sections from samples with gastric mucosa adjacent to the neoplastic lesion were processed for immunoperoxidase staining for NGAL/Lcn2 (**a**, **b**), *H. pylori* (**c**), or for immunofluorescence analysis (**d–f**) using mAb against NGAL/Lcn2, pAbs against *H. pylori*, and NGAL mAb together with *H. pylori* pAbs, respectively. NGAL/Lcn2 immunoreactivity is weak, if observed, in *H. pylori*-negative mucosa (**a**). In *H. pylori*-infected mucosa, NGAL/Lcn2 is strongly expressed on epithelial cells (**b**). *H. pylori* clusters (*red stars*) can be observed at the luminal side in some of the crypts along the gastric epithelium with the highest density in gastritis-affected mucosa (**c**). In the double immunofluorescence analysis, mAb against NGAL/Lcn2 together with pAbs against *H. pylori* (double staining in **d–f**) were detected with FITC-conjugated goat antimouse (green fluorescence) and Cy3-conjugated goat antirabbit (red fluorescence), respectively. Intense NGAL/Lcn2 immunoreactivity is seen in epithelial cells that are in direct contact with *H. pylori* bacteria (**d-f**). Nomarsky DIC imaging technique was used in **d–f**. *Scale bars*: ~100 μm (**a**, **b**), ~12 μm (**c**), ~20 μm (**d–f**)

epithelial and infiltrating inflammatory cells into the gastric mucosa, including IL-1β and NF-κβ [48]. Certain *H. pylori* virulence factors have been shown to potentiate this inflammatory response [49]. It has been demonstrated that IL-1β and NF-κβ (stabilized by its cofactor IκB-ζ) play a central role in the induction of NGAL/Lcn2 in epithelial cells [19, 50]. Thus, it is likely that the upregulation of NGAL/Lcn2 by *H. pylori* in gastric epithelial cells is driven by mediators of inflammation being released into the gastric epithelium in response to the bacterial infection.

Table 2 NGAL/Lcn2 immunoreactivity in epithelial cells in relation to the *Helicobacter pylori* status in non-neoplastic tissue sections diagnosed as normal-appearing and gastritis-affected mucosa

	n	NGAL/Lcn2 scoring			
		0	1+	2+	3+
H. pylori negative[a]	10	3	1	1	5
H. pylori positive[a]	26	2	0	0	24

NGAL neutrophil gelatinase-associated lipocalin, *Lcn2* lipocalin-2

[a] Fisher's exact test for *H. pylori*-positive versus *H. pylori*-negative, $p=0.04$

It was recently demonstrated in animal models (rhesus macaques and mice) that pathogenic strains of *Salmonella enterica* induce NGAL/Lcn2 in colonic mucosa, which confers a competitive advantage to the bacterium for colonizing and growing in the inflamed intestine [51]. In agreement to this view, Hornsby et al. [30] hypothesized that the induction of a set of antimicrobial molecules, including NGAL/Lcn2, in rhesus monkeys infected with *H. pylori* may indeed serve to increase the competitive advantage of this bacterium. We, therefore, do not exclude the possibility that high expression of NGAL/Lcn2 in gastric mucosa may facilitate *H. pylori* infection.

Other functions have been suggested for NGAL/Lcn2 in addition to its antimicrobial role [52]. NGAL/Lcn2 has been shown to be expressed on neoplastic cells in several types of adenocarcinomas including breast, pancreas, colon, and ovarian cancer [28, 53–56], and elevated protein levels have been correlated with poor prognosis in some of these malignancies [56, 57]. In the current study, we observed

NGAL/Lcn2 immunoreactivity in gastric cancer cells in one half of the studied cases, with similar frequency in both intestinal and diffuse gastric cancer histological subtypes. A recent study found that NGAL/Lcn2 levels in tissue and urine from breast cancer patients are associated with invasion and metastasis and demonstrated, in cell lines transfected with NGAL/Lcn2, that this molecule promotes breast cancer progression by inducing epithelial to mesenchymal transition [58]. The molecular mechanisms explaining the role of NGAL/Lcn2 in carcinogenesis remain entirely unknown, but it has been speculated that expression of NGAL/Lcn2 provides the carcinoma cells the ability to acquire iron and thus, supporting their growth [52, 59]. Therefore, the expression of NGAL/Lcn2 in gastric cancer in connection to progression and prognosis of the disease should be further investigated.

Received: 23 February 2009 / Revised: 7 July 2009 / Accepted: 27 July 2009 / Published online: 14 August 2009

Abstract Ubiquitin and telomerase immunohistochemical expression patterns in cervical cancer were compared with normal cervical tissue samples. Eighty-one cervical cancer cases and 22 normal exo–endocervical tissue were examined with polyclonal antibody for ubiquitin and 44G12 clone for telomerase using tissue microarrays. The results were interpreted using a semiquantitative scale The average age of patients was 50.67 years. The most frequent histological types were moderately differentiated epidermoid carcinoma (43.5%), according to the degree of differentiation, and endocervical adenocarcinoma (42.1%). Immunohistochemical findings were as follows: 98.7% of cervical cancers showed immunoexpression for ubiquitin and 52.6% for telomerase. Statistically significant differences were found in tumor immunoreactivity when compared with control tissue ($p<0.0007$) for both biomarkers. There was no significant difference in biomarker expression at different histological types of tumors, although telomerase was less expressed in endocervical adenocarcinoma. Our findings confirm that abnormal immunoexpression pattern of ubiquitin and telomerase is common in HPV-positive cervical cancer, indicating the existence of an intense degradation of proteins, subsequent cellular immortalization and maintenance of the malignant phenotype.

Keywords Cervical cancer · Immunohistochemical expression · Telomerase · Ubiquitin

Introduction

Cervical cancer and precursor lesions are induced by persistent infection with certain types of high-risk human papillomavirus (HR-HPV) [1, 2]. These viruses are able to activate different molecular mechanisms by inducing the development of a cellular clone with malignant phenotype [3, 4]. Such mechanisms are mediated by proteins used as molecular markers and alteration indicators in cellular control mechanisms. Thus, the study of these complex molecular pathways using different diagnostic techniques such as immunohistochemistry can be conducted. The continual expression of the E6 and E7 HR-HPV oncogenes in high-grade squamous intraepithelial lesions (HSIL) as well as in invasive cancer alter the functionality of a great variety of regulating cellular proteins [5–8]. HPV infection alone is thought to be insufficient for the development of invasive carcinoma.

Telomere length stability is required for the survival of germline human cells and differentiating cells and also for the immortalization of the cellular phenotype derived from

cancer. This characteristic is achieved through telomerase, a ribonucleoprotein enzyme capable of extending chromosome ends with specific telomeric DNA sequences. This enzyme compensates for the end replication problem and allows cells to proliferate indefinitely [9, 10].

Multiple studies have been carried out to evaluate telomerase as a possible HSIL and invasive cervical cancer marker, considering that detection of telomerase activity is useful for cytological screening of cervical lesions using cellular and tissue samples of uterine cervix [6, 11–14]. The HR-HPV E6 oncoprotein activates the oncogenic hTERT enzyme, mainly by stimulating the transcription of *hTERT* gene [15–17], and by immortalizing transformed cervical cells [6, 17]. Studies have shown that the activity of this enzyme is increased in comparison to normal cervical tissue in cervical cancer and in HSIL HPV 16- and 18-positive samples [17–21].

The rapid removal of enzymes and proteins is essential for the control of cellular growth and metabolism. A rapid intracellular protein degradation pathway is created with the addition of multiple ubiquitin monomers, followed by the recognition and degradation of specific substrate-protein by the 26S proteasome [22]. The ubiquitin-proteasome degrades a variety of cellular proteins, which generally have a short half life and include cyclines (D1 and E), cycline-dependent kinase inhibitors (specifically the p27KIP1), tumor-suppressor gene products (p53 and Retinoblastoma protein), transcription factors (E2F), and membrane receptors, among others. Furthermore, those mutated proteins that might also affect cellular homeostasis may be degraded by this pathway [5, 23].

Apart from protein degradation, ubiquitin is involved in physiological and pathological cell signaling processes such as gene transcription, DNA repair, and intracellular traffic. This signaling mechanism functions similarly to protein phosphorylation [24]. Substrate proteins that should be degraded are polyubiquitinized during an adenosine triphosphate (ATP)-dependent reaction. Several ubiquitin molecules are added in chains to these proteins. This polyubiquitinized substrate is recognized by the 26S proteasome and catalyzes the rupture of the substrate protein until it obtains small peptides of six to 12 amino-acids [25, 26].

In many human tumors, the ubiquitin-proteasome protein degradation pathway remains active, with the subsequent rapid degradation of many proteins conveying the lack of control known in cellular proliferation of neoplasias [22]. In the process of cervical carcinogenesis, the integration of HR-HPV in the cellular genome accepts the continuous uncontrolled expression of the HPV E6 and E7 oncogens; both E6/E7 are required for efficient immortalization of their natural host cells. Covalent union of HPV oncoproteins with ubiquitin and other related proteins modifies and induces cellular protein degradation. The E6/E7 oncoproteins are a target of the ubiquitin-proteasome system, and the resultant complex attracts target cellular proteins for their degradation. The ability of E6 and E7 to deactivate the normal function of the main tumor suppressors contributes to their oncogenic potential [3, 7].

The HR-HPV 16 and 18 use the cellular proteolytic ubiquitin-proteasome system to target p53 and pRb by eliciting rapid degradation of these regulating proteins through the continuous expression of E6 and E7 oncogenes. To facilitate HR-HPV replication and persistence, the infected cells must be irreversibly directed towards the synthesis phase of the cell cycle; as a result, the HR-HPV E7/pRb complex releases the E2F transcription factor. This interaction leads toward the ubiquitin-proteosome-mediated degradation of pRb [27, 28]. The HR-HPV E7 recruits the E3 ubiquitin-ligase enzyme to target the pRb and cause later degradation. It is also possible that the HR-HPV E7 serves as a direct link between pRb and the 26S proteasome, so that the pRb may degrade rapidly without previous ubiquitinization [7, 29]. Thus, the pRb may be deactivated and rapidly degraded in those cervical epithelial cells infected by HR-HPV.

The specific action of the HR-HPV E6 on p53 is functionally equivalent to p53 inactivation through mutation, which indicates that the HR-HPV E6/p53 complex represents one of the most important events in cervical carcinogenesis, given the interruption of the control points and apoptosis inhibition. The HR-HPV E6 protein binds to E6-AP, a cellular E3 ubiquitin-ligase, to form a dimer that binds p53. The complex results in E6AP-mediated ubiquitine and degradation p53 degradation. As a consequence, the immunohistochemical expression of p53 in neoplastic cervical cells could be negative. This effect could also be affected by the MDM2 protein that induces the ubiquitination and proteasomal degradation of p53 [7]. Degradation of p53 induced by E6-AP is a significant achievement of the HR-HPV, and results in malignant transformation of cervical epithelial cells together with the inactivation and degradation of pRb [5].

In this study, ubiquitin and telomerase immunohistochemical expression patterns were evaluated in cervical cancer in comparison with normal cervical tissue samples.

Materials and methods

Materials

Normal tissue samples (22 cases) and cancer from the uterine cervix were collected from archives of the Pathology Department of the University Hospital of Valencia, Spain. Two groups of cervical cancer samples were

included; the first with 66 cases diagnosed from 2000 to 2005 and the second with 15 cases of cervical cancer diagnosed between 1969 and 1998. The original hematoxylins of well-preserved cervical cancer cases were reevaluated [21]. Also, 22 cases of normal exocervical and endocervical tissues were included as a control group.

Immunohistochemical study

The tissue microarrays were constructed with distinct tumor areas of squamous cell cervical carcinoma and cervical adenocarcinoma. Tissue microarrays of normal exocervical (n=22) and normal endocervical (n=22) were also prepared taking the exocervical and endocervical sections from each block. Immunohistochemical staining was then carried out. In summary, deparaffinization in xylene and hydration in decreasing alcohol series was performed. Antigen retrieval with citrate buffer pH 6.0 was cooled in the same buffer; subsequently, endogenous peroxidase with 3% hydrogen peroxide at room temperature for 30 min was blocked. Similarly, tissue collagen was blocked to avoid nonspecific unions with a 20% horse serum solution at room temperature for 20 min.

The tissue microarrays were then incubated with primary antibodies for ubiquitin: a polyclonal antibody (DAKO Cytomation, Denmark) diluted at 1:500 and telomerase: 44F12 clone (Novocastra, UK) for 1 h at room temperature. The tissue microarrays were then incubated with biotin-labeled secondary antibody contained in the LSAB+ System-horseradish peroxidase (HRP) kit (DAKO Cytomation, Denmark), and liquid diaminobenzidin (DAB)+ Substrate Chromogen System (DAKO Cytomation, Denmark) was used to develop the reaction. All rinses were carried out with phosphate buffered saline (PBS; pH 6) and finally, the tissue microarrays were counterstained with Harris's hematoxylin before mounting. In the specific case of telomerase, the EnVision™ detection kit, the HRP (DAKO Cytomation, Denmark), and later the chromogene (EnVision™) substrate-DAB solution were used. Immunostaining against the telomerase antigen (diluted at 1:50) was carried out following conventional procedures and contrasting it with Harris's hematoxylin. However, since no satisfactory results were obtained in the case of cervical neoplasia, despite the positive control (lymphoma) showing intense reactivity (+++) for telomerase, a second immunostaining was carried out with diluted antibody 1:20, again using (EnVision™) and counterstaining with hematoxylin again. Finally, a third immunostaining was carried out, but contrasting with 0.5% methylium green. Thus, cases with no reactivity (true negatives) were confirmed while those with doubtful reactivity (false negatives) were reclassified.

All rinses were carried out with PBS (pH 6). Negative control included the substitution of a subclass-matched monoclonal antibody that was generated against an irrelevant antigen. Positive controls were made up of neoplastic tissue with known reactivity against the biomarkers under study, from a vesicular tumor, a breast tumor and a lymphoma. These controls were included in each one of the tissue microarrays. Cell counting was carried out including the entire diameter of the tumor disc as the total (100%). The positive reaction was represented by the presence of brown precipitation at the membrane, cytoplasm or in both cellular compartments. The percentage of neoplastic or normal cells with reactivity was estimated considering a minimum of 100 cells per tissue. The distribution of the immunoreactive cells was classified according to the following scale: negative=<5%; positive= >5% to <25%; ++=between 25% and 50%; +++=>50%. In the case of telomerase, any nuclear staining was interpreted as positive and considered overexpression or abnormal expression. In the case of ubiquitin, cytoplasmic and nuclear immunostaining were considered overexpression or abnormal expression. Moreover, we estimated staining intensity and scored as follows: low, moderate, or high. All tissue microarrays were evaluated first by an observer and later by an experienced pathologist without knowledge of clinical data.

Detection and genotypification of HPV DNA

Only tumor samples were submitted to HPV evaluation. A paraffin block with no embedded tissue (empty block) was prepared previously. The following recommendations were followed: gloves were used and changed regularly; the microtome was cleaned first with disinfectant, then with xylene, and finally with ethanol; a new knife was used to cut each block and its corresponding empty paraffin block. Five 5 μm thick cuts were made and placed in 1.5 ml Eppendorf tubes. We removed the block, cleaned as indicated previously, changed the knife, and cut the corresponding empty paraffin block. The same procedure was used for the subsequent tumor blocks. For isolation of cell DNA, five cuts were submitted for deparaffinization with xylene and washed with absolute ethanol. The pellet was resuspended in 500 μl of lysis solution (SDS, 0.5%; Tris-HCl, 10 mM; pH 8; NaCl, 0.15 M; EDTA, 5 mM). 25 μl of proteinase K (0.5 mg/ml) were added to each tube and incubated overnight at 55°C. DNA was extracted using phenol-chloroform-isoamilic alcohol, and then precipitated by adding one tenth volume of sodium acetate and 2.5 volumes of ethanol. A polymerase chain reaction (PCR) test was carried out before estimating the quality of DNA extracted through amplification of the interferon gene INF primers INF150DR: CTGGGATGCTCTTCGACCTC and INT150DF: TCTTTTCTTTCCCGATAGGT. Samples with a clear band of electrophoresis for INF150 were submitted

Table 1 Ubiquitin and telomerase expression in case controls and cervical cancer cases

	Controls (*n* (%))		Cases (*n* (%))		*p* value
	Positive	Negative	Positive	Negative	
Ubiquitin	34 (76.8)	10 (23.2)	79 (98.7)	1 (1.3)	0.0007
Telomerase	10 (22.7)	34 (77.3)	41 (52.6)	37 (47.4)	0.0007

for amplification of the 65 pb segment of the L1 region of HPV DNA using the set of SPF10 primers (INNO-LiPA; Innogenetics Inc., Belgium). The reaction was carried out at a final volume of 50 μl containing 2 mM of $MgCl_2$, Triton X-100 at 0.1%, 200 μM for each dNTPs, 10 μl of the mixture of SPF10-biotinylated primers, 1.5 UI of AmpliTaq Gold DNA polymerase (Perkin-Elmer), and 10 μl of isolated DNA. The PCR conditions were as follows: initial denaturalization and activation of the polymerase for 9 min at 94°C was followed by 40 cycles of 30 s at 94°C, 45 s at 52°C, and 45 s at 72°C, and a final extension for 5 min at 72°C. Positive and negative HPV 6 (Innogenetics, Belgium) controls containing only master mix reaction were included. PCR products were analyzed by electrophoresis in 2% agarose gel stained with ethidium bromide. The samples resulting from positive HPV DNA for SPF10 PCR were submitted for genotypification of HPV using the reverse hybridization band probe assay method (INNO-LiPA; Innogenetics Inc., Belgium). The SPF10 PCR products were mixed with a denaturing and hybridized solution with specific probes to identify 24 different HPV types (namely, HPV 6, 11, 16, 18, 31, 33, 35, 39, 40, 42, 43, 44, 45, 51, 52, 53, 54, 56, 58, 59, 66, 68, 70 and 74).

Statistical analysis

Association between different variables was determined using the Chi-square (X^2) test with the Yates and the Fisher's Exact Probability Test. The SPSS® statistical package was used for the statistical analysis and statistical significance was set at $p<0.05$.

Results

For this study, the age for each cervical cancer case was obtained from the clinical information originally found at the hospital service (range, 28–79 years; mean, 50.67 years). For the control group the age range was 36–75 years, with a mean age of 51.82 years. A total of 81 cases of cervical cancer were studied: 62 (76.5%) squamous cell cervical carcinomas (SCC) and 19 (23.5%) cervical adenocarcinomas. In SCC, the moderately differentiated (MD) group tumors (43.5%) predominated, followed by well-differentiated (WD) tumors (21%). The group of carcinomas with less differentiation was made up of 22.6% poorly-differentiated (PD) and 12.9% undifferentiated (UD). The greater portion of adenocarcinomas belonged to the endocervical type (42.1%), followed by the endometrioid type (26.3%); the villoglandular and papillary types reached 15.8% and 10.5%, respectively; the remaining 5.3% represented a mucinous type. Forty-four normal cervical tissues (control group: 22 exocervical/22 endocervical) were also included.

Of the 81 cervical tumors, three (3.7%) were excluded due to inadequate DNA; the remaining 78 cases (96.3%) were all HPV positive, of these, 67 (85.9%) cases showed a single HPV infection and 11 (14.1%) multiple HPV type infections. The most frequent specific viral type was HPV 16 in 46 (58.97%) cases, followed by HPV 18 in 12 (15.38%), HPV 45 in three (3.84%), HPV 58 in two (2.56%), and viral types HPV 31, HPV 66, HPV 68, and HPV X in equal numbers, one of each (1.28%). The squamous cell carcinomas as well as the adenocarcinomas showed predominantly one type of viral sequence 83.1% and 94.7%, although they did not reach statistical significance ($p=0.208$). HPV 16 was the most frequent viral type in SCC 35 (71.4%) as well as in cervical adenocarcinomas ten (55.6%), with equal *p* value 0.248; the HPV 18 was detected in 44.4% of the cervical adenocarcinomas and in 10.2% of SCC, which were statistically significant ($p<0.001$). These results are not shown.

Immunoexpression of biomarkers in tumors and controls

Ubiquitin A 98.7% of cervical cancers showed ubiquitin overexpression; only one case was negative (1.3%). With respect to case controls, 23.2% were negative for ubiquitin. We found highly significant differences ($p<0.0007$) when comparing ubiquitin expression in tumors and case controls; protein degradation was more intense in tumors than in case controls (See Table 1 and Fig. 1).

Fig. 1 Telomerase immunoexpression showing as tiny dots (**a** and **b** normal cervical tissue; **c** and **d** cervical cancer) within the nuclei and nucleoli (**c** poorly differentiated carcinoma). The normal exocervical tissue shows telomerase staining at the level of isolated nuclei in the deep strata, while being negative in the endocervix. Ubiquitin (**e** and **f** normal cervical tissue; **g** and **h** cervical cancer) showed marked expression, both nuclear and cytoplasmic. The normal endocervical epithelium also expresses a low positivity at nuclear and cytoplasmic level. Table 2 Ubiquitin and telomerase expression in histological types of cervical cancer

	Squamous cells carcinoma (*n* (%))		Adenocarcinoma (*n* (%))		*p* value
	Positive	Negative	Positive	Negative	
Ubiquitin	60(98.4)	1(1.6)	19(100)	–	0.620
Telomerase	32(52.5)	29(47.5)	9(52.9)	8(47.1)	0.595

Telomerase Nuclear staining in the lymphocytes was used as a positive internal control in addition to the external positive control that corresponded to a lymphoma. The counterstaining with cytoplasmic 0.5% methylium green confirmed the negative cases and permitted reclassification with doubtful reactivity. Both internal and external, positive and negative controls showed the expected reactivity. From the cervical cancers, 41 (52.6%) were positive for telomerase, while 37 (47.4%) did not show reactivity. Case controls were evaluated completely: ten (22.7%) positive and 34 (77.3%) negative. No cytoplasmic staining was observed in any case or in case controls. Telomerase immunoexpression from both tumors and case controls also showed highly significant differences ($p<0.0007$) given that this enzyme expression was greater in tumors (Table 1).

Immunoexpression of the biomarkers in histological types of cervical tumors

Ubiquitin A 98.4% of SCCs and 100% of the adenocarcinomas were positive for ubiquitin, without showing significant differences ($p=0.620$) (Table 2). Cervical carcinomas showed immunoreactivity for ubiquitin in the nucleus as well as in the cytoplasm. In many cases, nuclear staining was more evident than cytoplasmic, which indicates that protein degradation is constant and occurs in both cellular compartments. Staining intensity was moderate and/or marked. In the stroma, reactivity was also positive (Fig. 1b, d). Ubiquitin was expressed in 100% of the WD, MD, and UD carcinomas, and 92.9% of PD ($p=0.879$). It was also expressed in 100% of the histological subtypes of the cervical adenocarcinoma without significant differences ($p=0.329$). The greatest case proportion 14/19 (73.7%) was expressed in more than 50% of malignant cells. These results are summarized in Table 3.

Telomerase Regarding the distribution of cervical carcinomas with or without telomerase expression, we observed that both types of tumors were positive, showing similar percentages (52.5% for SCCs and 52.9% for adenocarcinomas) and with no statistically significant differences ($p=0.595$) (Table 2). The immunoreactivity was only nuclear and nucleolar. The staining pattern was characterized by a very fine granular homogenous appearance and a pale sharp-edge aspect. The nucleus of both malignant cells and stromal lymphocytes showed reactivity, this being more intense. The nucleoli turned greyish-brown and became highly noticeable within the nucleus. In general, staining was less intense. In Table 3, telomerase immunoexpression in the histological types of cervical cancer is shown in detail. Reactivity resulted in similar percentages between the various degrees of SCCs differentiation, being higher at UD (62.5%), followed by the MD (55%), and the same proportion in the WD and PD (46.2%), with no significant differences ($p=0.667$). Cervical adenocarcinoma showed telomerase expression with statistically significant differences between the different histological types ($p<0.028$): in 100% of the villoglandular type and in the unique mucinous case, followed by the endometrioid and papillary histological subtypes in equal proportions (50%). The endocervical adenocarcinoma showed a small proportion of reactive cells (28.6%). No correlation between HPV presence, and ubiquitin ($p=0.305$) and telomerase ($p=0.656$) immunoexpression was observed.

Immunoexpression of biomarkers in normal cervical tissues

Ubiquitin The nucleus at the deep layer of exocervical tissue together with some intermediate cells were stained moderately-to-slightly. Pale cytoplasmic staining was also observed. Stroma staining was more evident in the vascular endothelium (Fig. 1a). In normal endocervical epithelium, staining was nuclear, intense, and focally cytoplasmic. Stroma cells nuclei and cytoplasms were stained (Fig. 1c). We included a special positive case control to compare ubiquitin immunostaining which corresponded to a non-gestational endometrial tissue. This resulted in mainly cytoplasmic staining and some highly intense nuclei.

Telomerase Occasional staining in cellular nuclei was observed (less than 10% of cells) in deep layer exocervical tissue. There was no nuclear staining in intermediate and superficial layers. Stroma staining was sporadic. Some endocervical cells and stromal nuclei were stained.

Discussion

In this study, highly significant differences in ubiquitin detection between study cases and case controls have been observed. In cervical lesions associated with HR-HPV,

Table 3 Immunoreactivity of malignant cells in the squamous cell carcinomas according to degree of differentiation and in the histological subtypes of cervical adenocarcinoma

Cervical cancer		Scale	Ubiquitin	*p* value	Scale	Telomerase	*p* value

WD well differentiated, *MD* moderately differentiated, *PD* poorly differentiated, *UD* undifferentiated

these viruses are considered a vital mechanism for the degradation of the main regulating cell proteins, through the elimination of the check points that protect the cell from alterations of its internal homeostasis, such as the tumor suppressing protein p53 [7, 30, 31] and the Retinoblastoma protein [7, 28]. Similarly, HR-HPV oncoproteins use the ubiquitin-proteosome system to target many other cell regulatory proteins for degradation [8]. In consequence, not only cell proteins are functionally inactive, but their expression levels tend to be lower due to intense degradation [7]. In this study, we have found a high expression of ubiquitin in cervical carcinoma, which indicates an intense protein degradation, regardless of the degree of differentiation in squamous cell carcinoma, although more intense in the poorly differentiated cases, and quite similar in the various subtypes of adenocarcinomas.

Immortalization of telomerase enzyme activation has been detected in malignant neoplasias, considering its expression as an essential step towards malignant transformation of human tissue [6, 32, 33]. This capacity allows unlimited multiplication of malignant cells. Multiple studies have been carried out to evaluate telomerase as a possible marker of HSIL and cancer and have found it useful as a complement to cytological diagnosis, especially in patients with cytological abnormalities associated with HR-HPV [6, 11–14]. These studies used the Telomeric Repeat Amplification Protocol TRAP method, which permitted the determination of enzymatic activity by amplifying PCR, in which up to 100% of this enzyme expression has been reported [19, 21, 33, 34]. In the present study, 52.6% of cervical cancer cases showed telomerase immune expression. These differences are possibly due to a higher sensitivity of the method used for capturing and amplifying the reduced quantity of telomerase synthesized in malignant and premalignant cervical cells and to the criteria used for evaluating enzymatic expression. Despite the advantages offered by molecular techniques, it is also possible to estimate telomerase expression in human cervical samples through immunohistochemistry. This technique has the advantage of allowing accurate observation of localized protein expression in premalignant and malignant cells in cervical tissue samples [35].

Efficiency of telomerase immunodetection depends on the conditions related to an adequate dilution of primary antibodies and on the use of highly sensitive antigen-antibody reaction detection systems. In addition, for doubtful cases, due to the observation of a fine and homogeneous sharp-edged immunoreactive pattern, it is necessary to use a cytoplasmic counterstaining that permits better nuclear observation and differentiation staining. It is possible that, the percentage of this enzyme expression may be higher in our tumor series because it may influence a dilution of inappropriate anti-hTERT antibodies. This could be proved in future research studies, where other forms of antigenic recovery [35, 36] might be considered.

In this study, 53.8% of the WD carcinomas were negative for telomerase, while UD showed positively in 62.5% of the cases. It is possible that tumor heterogeneity may influence the enzymatic analysis. As Jorboe et al. [6] explained, the telomerase activity could be related to the degree of tumor differentiation. In fact, well-differentiated tumors have less enzymatic expression, as shown in our results.

With respect to the endocervical adenocarcinomas, 71.4% were negative telomerase (<5% of reactive cells). These tumor cells may be found in apoptosis [35], telomerase inhibiting factors may exist when blocking their activation, and the enzyme may present qualitative modifications (hypophosphorylation) [36, 37]. In addition, hTERT variants not transported to the cytoplasm nucleus could be detected for their activation [35]. Finally, perhaps the cell may synthesize at minimum or nondetectable enzymatic levels, together with the development of other mechanisms that may keep the malignant phenotype, among other causes [38]. Future research could give answers to these hypotheses.

Normal cervical epithelium showed less immunoreactivity against the studied biomarkers when compared with the neoplastic tissue, which revealed abnormal expression in tumors with statistically significant differences. The biomarker immunoexpression in neoplastic tissue compared with the normal cervical tissue confirmed that in malignant cervical neoplasia, a diversity of interactions and altered molecular mechanisms induce cycle deregulation and uncontrolled cell proliferation. These alterations are apparently produced by HR-HPV E6/E7 oncoproteins associated with telomerase activation in cells with genomic instability and activated *myc* gene. The formation of E6-*myc* complex stimulates the expression of the *hTERT* gene by activating the promoter of this gene [39, 40]. HR-HPV E6 expression is relevant for the process of cell immortalization and suggests that other cell genes (*myc*) could be regulated by this viral protein in favor of cellular progression and immortalization [41].

The present findings confirm that an abnormal immunoexpression pattern of ubiquitin and telomerase, determined by immunodetection, is common in HPV-positive cervical cancer in comparison with normal cervix. This may be related to the existence of an intense protein degradation, with a consequent cellular immortalization which leads to the maintenance of a malignant phenotype.

Acknowledgments The authors thank Alejo Sempere and Laura Martínez from the Department of Pathology, School of Medicine, University of Valencia, for their invaluable support and training immunohistochemical technicians.

Conflict of interest statement We declare that we have no conflict of interest.

Abstract An immunohistochemical (IHC) study has been conducted on 34 cases of untreated endocervical adenocarcinomas collected among three institutions (Ospedale S. Andrea, Rome; Istituto Nazionale Tumori "Fondazione G. Pascale", Naples; and Clinica Malzoni, Avellino). The E-cadherin and α- and β-catenin complex status has been investigated along with p16INK4a in all studied cases with the aim to study whether the pattern of expression of the cadherin–catenin complex could be causally related to the expression of P16INK4a protein. Results were evaluated for statistical significance by a non-parametric test (Kruskal–Wallis). Endocervical adenocarcinomas as a group were uniformly expressing p16INK4a except for two cases, and all lesions displayed downregulation of the cadherin–catenin complex, without demonstrating statistically significant differences among the different histotypes. The lack of nuclear accumulation of β-catenin found in this group of lesions probably implies that no alteration of the β-catenin/Wnt metabolic pathway is present in endocervical adenocarcinoma, as opposed to what is found in the literature for squamous carcinoma of the cervix. The diffuse expression of p16INK4a protein in this group of neoplasms stresses the important role of high-risk human papillomavirus infection in neoplastic causation possibly via the viral E7-mediated inactivation of pRB tumor-suppressor protein and also underlines the useful role of p16INK4a immunostaining in the diagnostic algorithm of endocervical adenocarcinomas. In consideration of these findings, investigation of downstream β-catenin genes c-myc and cyclin D1 is sought as possibly contributive in the molecular pathogenesis of endocervical adenocarcinoma.

Introduction

The rising incidence of endocervical adenocarcinoma in relation to squamous cell carcinoma of the uterine cervix, as well as the increasing rate of adenocarcinoma per population at risk, have raised the attention of researchers to primary glandular neoplasms of the uterine cervix [1]. Endocervical adenocarcinoma is a heterogeneous group of neoplasms with a wide variability of histological patterns but generally showing an aggressive biological behavior. Furthermore, its early detection in a screened population is often negatively affected by sampling and/or diagnostic pitfalls [2].

E-Cadherin and its cytoplasmic-associated cell adhesion molecules such as catenins have been recognized to be important biomarkers of tumor differentiation [3, 4]. E-Cadherin, which is an epithelial cell adhesion molecule, is a transmembrane protein with a cytoplasmic domain that connects to the actin cytoskeleton through a complex with its associated cytoplasmic proteins, α-, β-, and γ-catenins [5, 6]. Calcium is required for E-cadherin to mediate its adhesive function, and the extracellular portion of E-cadherin contains several calcium-binding sites. E-Cadherin molecules form homodimers on the cell surface and carry out their adhesive function by binding to E-cadherin molecules on adjacent cells (homotypic adhesion), being also able to form extensive multidimers of E-cadherin [7]. Loss of E-cadherin expression has been correlated with the in vitro invasive phenotype of cancer cell lines [8, 9]. Furthermore, previous studies reported the reduced or aberrant expression of E-cadherin and/or catenins in different human cancers: in neoplastic thyroid tissue [10], in esophageal cancer [11], in breast cancer [12, 13], in gastric [14] and pancreatic carcinoma [15], in bladder [16] and prostatic cancer [17], and in melanoma [18] and meningioma [19]. Defects in the E-cadherin/catenin adhesion complex have also been described in several gynecologic cancers, mainly in cervical [20, 21], endometrial [22–24], and ovarian tumors [25].

Fewer studies have recently focused also on the E-cadherin–catenin complex expression in endocervical adenocarcinomas [26–28], and all have showed decreased expression of the E-cadherin–catenin complex with atypical patterns of α- and β-catenin expression.

P16INK4a is known to play a critical role as a negative regulator of cell cycle progression and differentiation by controlling the activity of the tumor-suppressor protein pRb. Increased levels of p16 appear to be indirectly related to high-risk human papillomavirus (HR-HPV), possibly via the production of the viral oncoprotein E7, which binds and inactivates the host cellular tumor-suppressor proteins pRB [29]. In this respect, the cyto-histological study of p16 expression has overcome many of the conceptual and practical problems associated with the detection of HR-HPV types as an adjunctive test and, as a matter of fact, it is now widely used as a surrogate test to diagnose HR-HPV infection, often with superior sensitivity to DNA-hybridization [30].

Notwithstanding the important role of HR-HPV infection in the initiation and progression of cervical cancer, it has also been demonstrated that HPV is a necessary but not sufficient cause to develop invasive carcinoma and, at least in the pathogenesis of squamous cell carcinoma, a "second hit" or metabolical disturbance is required to develop cervical cancer. Pérez-Plasencia et al. [31, 32] used wide genome analysis to identify altered metabolic pathways in cervical squamous cell carcinomas carrying HPV 16 infection; in their study, they found an alteration of the β-catenin/Wnt pathway. In particular, the so-called canonical activation pathway of Wnt gene transcripts impedes phosphorylation of β-catenin, causing its stabilization with nuclear accumulation and abnormal cytoplasmic expression. This, in turn, leads to the activation of target genes involved in cell proliferation and cell cycle progression, like c-myc and cyclin D1.

In this paper, we evaluated the tissue distribution of adhesion molecules such as E-cadherin and α- and β-catenin in endocervical adenocarcinoma by IHC techniques with the aim to investigate whether differences in the expression of these molecules exist in the different histotypes of endocervical adenocarcinoma and their possible biological significance. In this study, parallel staining for p16INK4a was also performed to investigate the role of HR-HPV infection as indirectly shown by p16INK4a expression in endocervical carcinogenesis.

Materials and methods

Thirty-four tissue specimens (14 biopsies from curettings and 20 surgical samples) previously diagnosed as endocervical adenocarcinoma were collected among three institutions (Ospedale S. Andrea, Rome; Istituto Nazionale Tumori "Fondazione G. Pascale", Naples; and Clinica Malzoni, Avellino). The original diagnoses concerned patients who had not received preoperative therapy at the time of diagnosis and were reviewed by three of us (E.C., F.F., and N.S.L.) by using newly cut 5 μm histopathological sections stained with hematoxylin and eosin, alcian, and alcian-periodic acid Schiff; tumor grading and histological reclassification of the neoplasms were performed according to current criteria by World Health Organization System. The age of the patients varied between 36 and 74 years, with a median age of 52. Pathological staging information was available only in 20 cases: among these, there were two cases (10%) of in situ adenocarcinoma, five cases (25%) were classified as pT1a, 11 cases (55%) as pT2, two cases (10%) were classified as pT4.

To be enrolled in this study, all cases had already undergone preliminary IHC staining for vimentin, monoclonal carcinoembryonic antigen (mCEA), and estrogen and progesterone receptors (ER and PR) using commercially available antibodies and performed in the participating institutions. This material had been made available to us and, when unavailable, preliminary immunocytochemical staining for the above stated markers had been repeated by us on new sections taken from the available tissue blocks. Only cases showing cytoplasmic positivity for mCEA and negativity for ER, PR, and vimentin were considered for

further study. All tissue samples had been fixed in 10% buffered formalin. Table 1 synthetically shows the histological diagnoses, tumor grade, and data from IHC score of all the studied specimens. To assess reactivity for adhesion molecules, immunohistochemistry was performed according to a standard streptavidin-biotin peroxidase complex method (Zymed, San Francisco, CA, USA). E-Cadherin, α-catenin, and β-catenin expression were assessed by using commercial specific mouse monoclonal antibodies (Zymed, San Francisco, CA, USA): HECD-1 specific for human E-cadherin, α-CAT-7A4 raised against a synthetic peptide corresponding to the C-terminus of mouse α-catenin (dilution 1:100), and CAT-5H10 raised against a recombinant protein corresponding to the C-terminus of chicken β-catenin (dilution 1:100). Four-micrometer sections were deparaffinized in xylene, rehydrated in graded ethanols, and washed with phosphate-buffered saline, then treated in a microwave oven for 15 min in 0.01 M citrate buffer (pH 6.0) and cooled down at room temperature for 20 min. Endogenous peroxidases were quenched by incubation in 0.3% hydrogen peroxide, and sections were then incubated in serum-blocking solution to reduce non-specific labeling. No further inhibition of endogenous biotin was performed as this was already contained in the developing kit. Anti-E-cadherin primary antibody, anti-α-catenin, and anti-β-catenin primary antisera were added, and sections were then incubated for 1 h at room temperature. Positive controls were known E-cadherin and α- and β-catenin expressing epithelial tissues; negative controls were carried out by using unrelated isotype matching antibody. The secondary biotinylated antibody was incubated as previously described. The reaction was developed by adding diaminobenzidine-tetrahydrochloride (DAB) chromogen mixture (Zymed, San Francisco, CA, USA). After hematoxylin counterstaining, slides were permanently mounted and analyzed for the presence and distribution of the immunostaining. Staining was scored by two of us (E.C. and F.F.) based on semiquantitative assessment of the distribution pattern of staining (nucleus, plasma membrane, and/or cytoplasm) and number of immunoreactive epithelial cells. In order to obtain data in the proper format for statistical evaluation, the following scoring system was employed: the number of immunoreactive nuclei/cytoplasms/cell membranes and total of immunoreactive cells (independently of the subcellular distribution of IHC signal) were expressed on a percent basis and were added sequentially, so as to generate an absolute numerical value (range 0–400), where numbers between 0 and 100 indicated low levels of IHC reactivity, numbers between 101 and 200 indicated moderate immunoreactivity, and numbers >200 indicated strong immunoreactivity for a given IHC marker.

For p16INK4a IHC analysis, a commercially available monoclonal antibody (clone E6H4, CINtec $p16^{INK4a}$, MTM Laboratories, Heidelberg) was used. Briefly, after antigen unmasking in epitope retrieval solution in heated water bath for 10 min at 95–99°C and endogenous peroxidase block, slides were stained with the primary antibody for 30′ at room temperature and subsequently with visualization

reagent solution. After developing with substrate-chromogen solution (DAB), slides were counterstained with hematoxylin and evaluated for both nuclear and cytoplasmic staining. A reaction in <1% of cells was considered negative, according to a previous study [26].

Statistical analysis

Statistical differences with relation to histological grading and to the expression of p16INK4a, E-cadherin, and α- and β-catenin in the different diagnostic categories were analyzed by using the non-parametric Kruskal–Wallis test. A p value <0.05 was considered statistically significant.

Statistical correlation with pathological tumor stage was not performed, as this data was not complete and limited only to 20 cases with surgical samples.

Results

The histopathological reclassification of 34 endocervical adenocarcinomas and their histological grading are shown in Table 1 along with their immune reactivity scores for P16INK4a, E-cadherin, and α- and β-Catenin.

Table 2 illustrates the IHC score distribution for each antiserum tested.

p16INK4a reactivity

Two of 34 (5.9%) of the tested cases, both mucinous adenocarcinomas, showed no reactivity for p16INK4a, even after repetition of the IHC staining and tissue pre-treatment with trypsin. Twelve cases (35.3%) showed low-level reactivity, ten cases (29.4%) moderate, and ten cases (29.4%) high level of immunoreactivity.

Nuclei of the neoplastic cells were most commonly stained (Fig. 1); cytoplasms and cell membranes were progressively decorated with increasing IHC scores. The diagnostic categories with the higher median IHC scores for p16 were represented by adenosquamous (with more marked expression in the squamoid areas) and endometrioid adenocarcinomas (Fig. 2; respectively, 130 and 240); serous and mucinous adenocarcinomas showed decreasing median IHC scores (Tables 1 and 2).

Table 2 Immunocytochemical score distribution for each tested antiserum in 34 cases of endocervical adenocarcinoma

IC score	0	≤100	101–200	201–300	301–400
P16INK4a	2	9	12	10	0
E-Cad	17	12	1	4	0
α-Cat	1	24	9	0	0
β-Cat	13	19	2	0	0

E-cad E-cadherin, *α-cat* α-catenin, *β-cat* β-catenin (see also text for explanation)

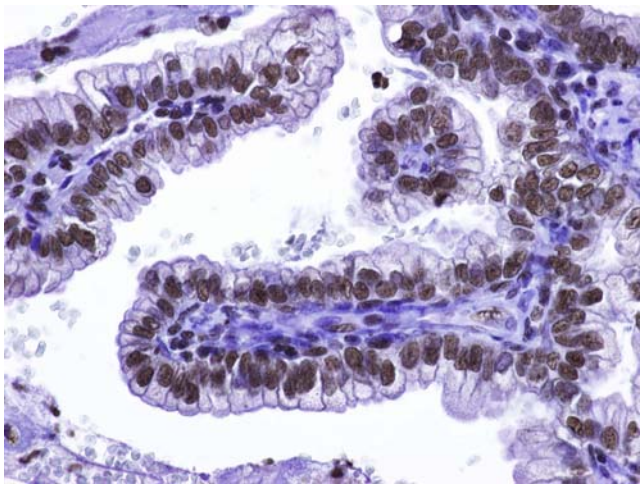

Fig. 1 Exclusive nuclear expression of p16INK4a protein in moderately differentiated mucinous-type endocervical adenocarcinoma (immunoperoxidase, ×400). E-Cadherin and α- and β-catenin staining were completely negative in this case

E-cadherin staining

A typical membranous expression of E-cadherin with strong decoration of the lateral (and often also apical) cytoplasmic cell borders was found in 6/34 cases only (17.6%; Fig. 3). In the other three cases (8.8%), a combined membranous and cytoplasmic expression was found, while in eight cases (23.5%), pure cytoplasmic staining without lateral membranous staining was obtained. Seventeen of 34 cases (50%) resulted negative. The highest IHC score for E-cadherin were found in the mucinous adenocarcinoma

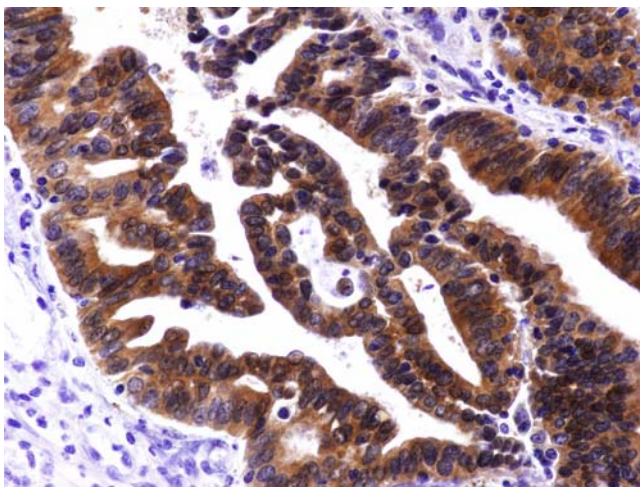

Fig. 2 Nucleocytoplasmic expression of p16INK4a protein in endometrioid adenocarcinoma (immunoperoxidase, ×400, original magnification)

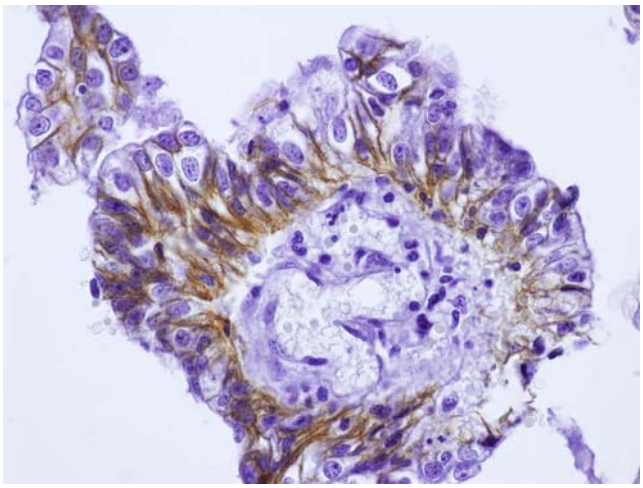

Fig. 3 E-Cadherin staining in mucinous adenocarcinoma of the cervix. Besides the lateral cell borders, there seems to be a tendency for circumferential cytoplasmic staining (immunoperoxidase, ×400, original magnification)

category (max score: 160; Tables 1 and 2). In our series, we could verify the findings by Heathley [26] on the circumferential rather than lateral membranous expression of E-cadherin in endocervical adenocarcinoma in cases with strong expression of the molecule. No statistical correlation was found, however, between histological grading of the neoplasms and E-cadherin IHC staining score.

α- and β-catenin expression

α-Catenin expression was slightly more conserved than that of E-cadherin, with median scores in the low range of expression (between 30 and 90; Table 1).

In particular, 1/34 (2.9%) cases scored 0, 24/34 cases (70%) showed low-range expression, and 9/34 (26.4%) showed moderate expression. No cases were found in the strong to very strong range of expression (Table 2).

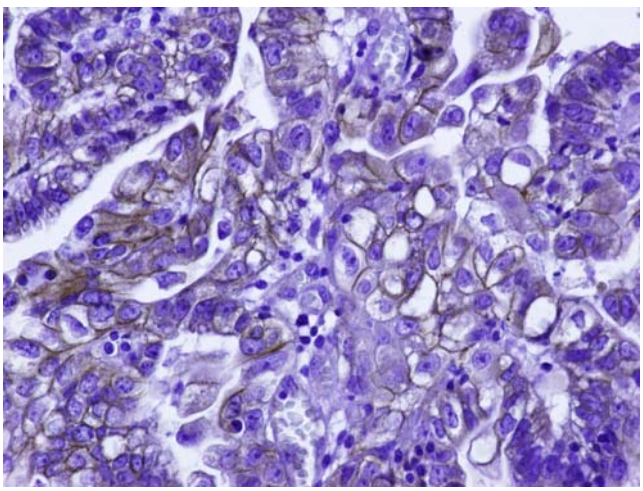

Fig. 4 α-Catenin staining in clear adenocarcinoma of endocervix. Pure membranous pattern of slight to moderate intensity can be observed (immunoperoxidase, ×600, original magnification)

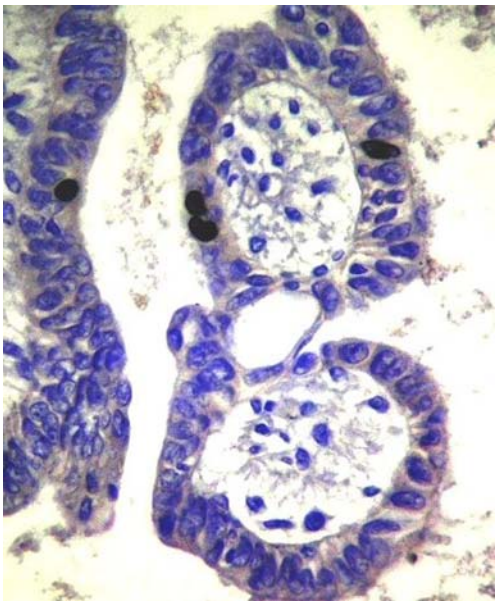

Fig. 5 α-Catenin staining in adenocarcinoma of the cervix. Notice focal nuclear staining in rare neoplastic cells (immunoperoxidase, ×400, original magnification)

The IHC distribution of the staining was membranous in 20/34 cases (59%; Fig. 4), membranous and cytoplasmic in 11/34 cases (32.3%), and cytoplasmic in two cases (5.8%). One case was totally negative. In one case of endometrioid adenocarcinoma, pure nuclear staining was found in rare nuclei only, coupled to focal cytoplasmic staining (Fig. 5).

β-Catenin was the least expressed adhesion molecule (median scores between 0 and 30), and its expression was

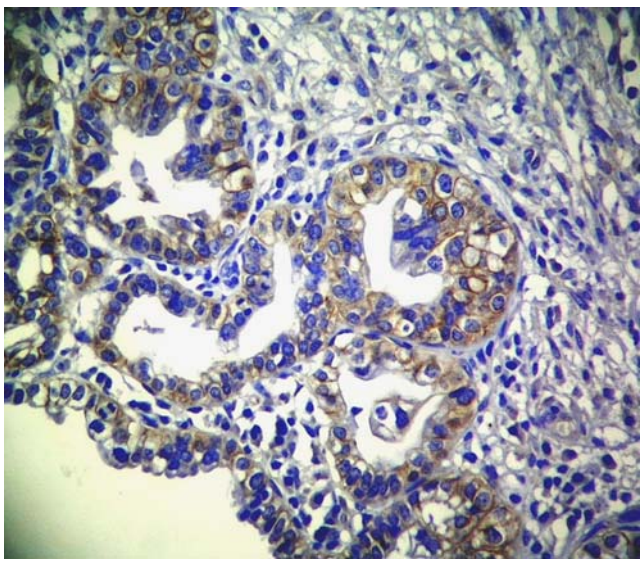

Fig. 6 β-Catenin staining in mucinous adenocarcinoma with clear cell differentiation. Notice moderate membranous positivity (immunoperoxidase, ×400, original magnification)

totally lost in the adenosquamous adenocarcinoma category (Table 1). In particular, 13/34 (38.2%) cases scored 0, 19/34 (55.8%) were in the low reactivity range, and only 2/34 cases (5.8%) were in the moderate reactivity range (Fig. 6; Table 2).

Statistical evaluation

Statistical evaluation of IHC scores by using a non-parametric (Kruskal–Wallis) test did not show significant differences among the various histopathological categories, while showing significant variation in the homogeneity of the histological grading scores, with $p=0.005$.

Discussion

In this paper, the authors have examined a relatively large series of endocervical adenocarcinomas collected among four different institutions.

The histopathological reclassification of the neoplasms has lead to the identification of four main histotypes (mucinous, adenosquamous, endometrioid, and serous adenocarcinomas, with one case of clear cell carcinoma and one case of signet ring mucinous carcinoma). The numerical consistence of the histological categories reflects their relative frequencies in the literature [1, 2].

IHC study of this group of lesions has shown that p16INK4a is consistently expressed at a variable intensity in cervical adenocarcinomas, with the only exception, in this series of 2/34 cases (5.9%). The diffuse expression of p16INK4a in this group of lesions most probably links endocervical adenocarcinoma to HR-HPV infection, possibly through inactivation of the pRB protein by E7 HPV protein [26, 27].

The study of E-cadherin and α- and β-catenin expression in our series has fully confirmed previously published reports dealing with reduced expression of the E-cadherin–catenin complex in many human epithelial neoplasms [9–18, 20–25].

With reference to β-catenin pattern of expression, our results, while confirming its diffuse downregulation in endocervical adenocarcinomas, do not fully support in this group of lesions the findings of Pérez-Plasencia et al. [28, 29] in squamous carcinoma. These authors found, besides to diffuse downregulation of the cadherin–catenin complex, also frequent nuclear accumulation of β-catenin. This led to the pathogenetical hypothesis of a possible "second hit" mutation causing a disturbance of the β-catenin-Wnt metabolic pathway in squamous carcinoma of the cervix. In our series, as a matter of fact, we were not able to demonstrate any nuclear accumulation of β-catenin, notwithstanding the frequent finding of its pure cytoplasmic expression, that is suggestive of an altered functional activity of this protein.

In this, endocervical adenocarcinoma, though sharing with squamous carcinoma of the cervix, the strong association with p16INK4a expression (and hence HR-HPV infection) may show a different pathogenetic mechanism implying a more direct interaction between the accumulation of p16INK4a protein and derangement of pRB protein.

Anyhow, further studies are needed in our opinion to definitively exclude alterations of the β-catenin/Wnt pathway in order to determine the status of downstream oncogenes, like C-myc and cyclin D1.

The high frequency of p16INK4a expression in our series of endocervical adenocarcinomas (32/34 cases; 94.11%) confirms what was already found by Negri et al. [29] on the usefulness of this immunocytochemical staining in the diagnostic algorithm of endocervical adenocarcinoma.

Acknowledgments The authors gratefully thank Dr. Emiliano Palmieri, M.D., for performing statistical evaluation of data, and the Lega Ialiana per la Lotta ai Tumori (LILT, Sezione di Napoli) for the generous contribution to this study. The authors would like to thank Dr. Alessandra Trocino for her excellent bibliographic services.

Conflict of interest statement We declare that we have no conflict of interest.

ORIGINAL ARTICLE

Prevalence, viral load, and physical status of HPV 16 and 18 in cervical adenosquamous carcinoma

Tomomi Yoshida · Takaaki Sano · Tetsunari Oyama · Tatsuya Kanuma · Toshio Fukuda

Received: 3 June 2009 / Revised: 24 July 2009 / Accepted: 12 August 2009 / Published online: 29 August 2009

Abstract Adenosquamous carcinoma of the uterine cervix is a rare mixture of malignant squamous and glandular epithelial elements and accounts for approximately 10% of cervical carcinomas. The aims of the present study were to evaluate the prevalence, physical status, and viral load of HPV 16 and 18 in adenosquamous carcinoma. Formalin-fixed paraffin-embedded tissue samples from 20 cases of histologically diagnosed adenosquamous carcinoma were examined. The squamous and glandular components were separately microdissected and analyzed for their HPV DNA subtype, viral load, and physical status using real-time polymerase chain reaction (PCR). The percentages of HPV 16- and 18-positive cases among all the HPV-positive cases were 36.8% (7/19) and 57.9% (11/19) in the squamous epithelial elements and 33.3% (6/18) and 61.1% (11/18) in the glandular elements, respectively. PCR analysis with E2 primers revealed that seven of eleven (63.6%) HPV 18-positive cases had the pure integrated form in both elements. The mean HPV 16 DNA copy numbers/cell was 7.22 in the squamous elements and 1.33 in the glandular elements ($p=0.04$) while the corresponding mean HPV 18 DNA copy numbers/cell was 1.50 and 0.89, respectively. The prevalence of HPV 18 in adenosquamous carcinoma was high and many HPV 18-positive cases were the pure integrated form resulting in very low copy numbers/cell. It is possible that more aggressive transformation with early integration of HPV 18 results in cases with greater chromosomal instabilities, higher growth rates, and rapid progression.

Introduction

Up to 80% of uterine cervical carcinomas are squamous cell carcinoma while the majority of the remainder is adenocarcinoma and adenosquamous carcinoma. Adenosquamous carcinoma of the uterine cervix is a rare mixture of malignant squamous and glandular epithelial elements. Adenosquamous carcinoma of the cervix is less common than adenocarcinoma. Recent studies have reported that the incidence of adenosquamous carcinoma is increasing especially among young women even though the overall incidence of cervical carcinoma has declined [1, 2].

It has been clearly established that the strong association of human papillomavirus (HPV) infection with the development of cervical squamous lesions and the risk of cervical squamous cell carcinoma is related to high-risk HPV subtypes, viral physical status, and viral load. However, the relationship between HPV and adenosquamous carcinoma remains unclear owing to the limited data

available. Previous studies reported that the prevalence of HPV DNA in adenocarcinoma varies significantly (32–100%) and that the high-risk HPV type 18 is more frequently detected in adenocarcinoma and adenosquamous carcinoma than HPV 16 [3–9]. A few studies have reported differing rates of HPV DNA detection in adenosquamous carcinoma (30–100%) [10–13], and the pathogenic role of HPV in the development of adenosquamous carcinoma remains uncertain.

Several pathways for the histogenesis of adenosquamous carcinoma have been proposed, namely that (1) neoplastic columnar cells may turn into squamous metaplasia in a subset of adenocarcinomas, (2) reserve cells may become neoplastic and differentiate into both glandular and squamous lineages, or (3) pure adenocarcinoma and pure squamous cell carcinoma may collide with each other [14, 15]. However, the detailed mechanism remains unclear. Although a few studies on HPV 18 DNA integration in squamous cell carcinoma have been reported, the importance and necessity of viral DNA integration in the pathogenesis of adenosquamous carcinoma are not well established [16]. The aims of the present study were to evaluate the prevalence, physical status, and viral load of HPV 16 and 18 in adenosquamous carcinoma.

Materials and methods

Case selection and subclassification

Formalin-fixed paraffin-embedded tissue samples from 20 cases of histologically diagnosed adenosquamous carcinoma were chosen from the pathology files of routine surgical specimens of the Gunma University Hospitals. The specimens were removed by cone biopsies or hysterectomies between 1998 and 2008. The subjects ranged in age from 27–62 years (mean, 39 years). Three cervical cancer cell lines (SiHa, CaSki, and HeLa) and HPV 18 in a plasmid vector were used as controls.

All cases were reconfirmed by pathologists according to the World Health Organization (WHO) criteria [17] and subclassified into histological subtypes A–C according to the features of the malignant glandular and squamous components. Each case was subclassified as follows: type A, both the squamous and glandular elements are well-differentiated and well-bordered with foci of clear keratinizing and glandular components; type B, ill-defined mixture of poorly differentiated carcinoma components, with partial squamous and glandular differentiation; type C, predominance of solid or sheet-like cancer cells consisting of squamous differentiation within foci of goblet cells, but glandular formation is not seen. Type C may correspond to mucoepidermoid carcinoma in previous criteria [17].

Microdissection and HPV DNA detection and typing

The squamous and glandular components were separately microdissected from paraffin sections using a microtome blade. DNA was isolated from each microdissected sample by digestion with proteinase K in 10 mM Tris-HCl buffer (pH 8.0) containing 1 mM EDTA and 1% Tween-20. HPV DNA was amplified by polymerase chain reaction (PCR) using consensus primers (L1C1/L1C2) for the L1 open reading frame (ORF). The primers for the L1 region allowed the identification of at least seven types of genital HPV DNA (16, 18, 31, 33, 35, 52, and 58) on the basis of restriction fragment length polymorphisms with three restriction enzymes and direct sequencing. The PCR conditions were described previously [18]. HPV 16- and 18-positive cases were further analyzed by quantitative real-time PCR with HPV 16- and 18-specific primers for the E2 and E6 regions [19].

Quantitative real-time PCR for HPV 16 and 18 DNA

All HPV 16- and 18-positive cases were further examined for quantification of the viral load and analysis of the physical status of their HPV DNA. Two sets of primers for the E6 and E2 segments were used for HPV 16 or 18 genome amplification [19, 20]. For HPV DNA quantification by real-time PCR, primers for the HMBS gene were used as internal controls to quantify the cell DNA [21]. This gene was chosen as a control because no differences were detected between its levels of expression in normal and cancerous cervical tissues.

An aliquot (1 μl) of template DNA was added to a final reaction volume of 50 μl containing 25 μl of Platinum SYBR Green qPCR SuperMix-UDG (Invitrogen Corporation, Carlsbad, CA), 0.2 μM of each primer (forward and reverse) in 5 μl and 14 μl of H_2O. PCR amplification was performed using an Mx3000P™ Multiplex Quantitative PCR System (Stratagene Japan, Tokyo, Japan). The PCR amplification was initiated at 95°C for 10 min and completed by 45 amplification cycles (denaturation at 95°C for 10 s and annealing and extension at 60°C for 25 s). During the thermal cycling, the emission from each sample was recorded, and the fluorescence data were processed by the Mx3000 software (Stratagene Japan) to produce a threshold cycle (Ct) value for each sample. SiHa and CaSki cell DNA (HPV 16-positive) as well as HeLa DNA and HPV 18 in a plasmid vector (HPV 18-positive) samples were used as positive controls. The viral load was expressed as the HPV copy number/cell in each sample according to a previously reported formula [22]. The copy number/cell of each sample was measured in a relative manner by setting the SiHa cell line at 1 copy/cell.

Physical status of the HPV 16 and 18 genomes by real-time PCR

The primer sequences were located in the E2 and E6 segments of HPV types 16 and 18. The E2 region is usually deleted upon viral DNA integration into the host genome, and preferential disruption of E2 causes absence of the E2 product in PCR amplification. We defined an HPV as the pure integrated form if the E2 product was not detected but the E6 product was amplified.

Statistical analysis

The data were analyzed statistically using Student's *t* test. Values of $p<0.05$ were considered to indicate statistical significance.

Results

Subclassification of histological patterns

The 20 cases were histologically subdivided into type A (9/20, 45%), type B (6/20, 30%), and type C (5/20, 25%; Fig. 1a–c). The mean ages of the patients with the three subtypes were 41, 35, and 41 years, respectively. No relationships were detected between the histological subtypes and the patient ages.

Detection and typing of HPV DNA by consensus primer PCR

Using consensus primer PCR, HPV DNA infection was detected in 95% (19/20) of the squamous epithelial elements and 90% (18/20) of the glandular or goblet cell elements in adenosquamous carcinoma. The percentages of HPV 16- and 18-positive cases among all the HPV-positive cases was 36.8% (7/19) and 57.9% (11/19) in the squamous epithelial elements and 33.3% (6/18) and 61.1% (11/18) in the glandular elements, respectively (Table 1). These data revealed that >50% of the cases was HPV 18-positive in both elements of the adenosquamous carcinomas. The remaining one case was HPV 31-positive in both elements. The mean ages of the HPV 16- and 18-positive cases was 38.6 and 37.2 years, respectively. The relationships between HPV 16- and 18-positivities and the histological patterns were 3/7 (42.9%) and 4/7 (57.1%) for type A, 1/6 (16.7%) and 5/6 (83.3%) for type B, and 2/4 (50%) and 2/4 (50%) for type C, respectively. These data showed that HPV 18 was detected more frequently in type B cases, but the differences were not significant. Interestingly, the detected HPV subtypes were identical in the glandular

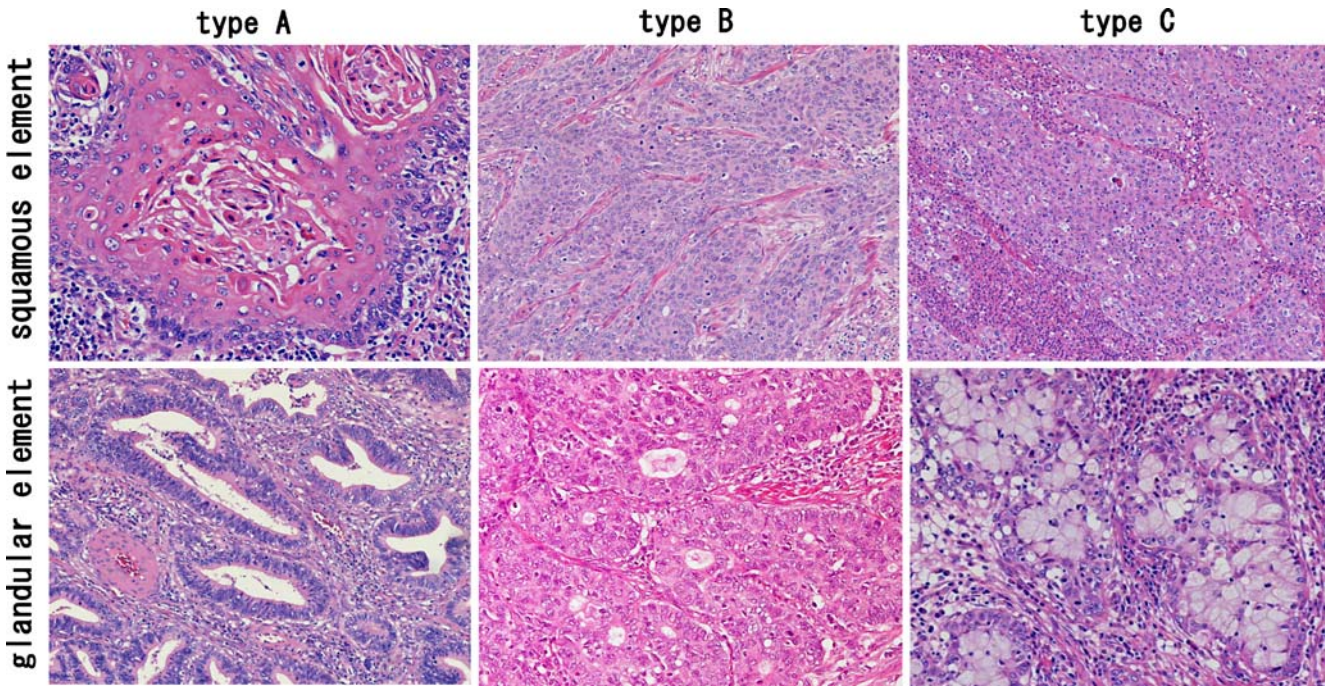

Fig. 1 Histological subtypes of adenosquamous carcinoma. *Type A*: Both squamous and glandular elements are well differentiated and well bordered, with foci of clear keratinizing and clear glandular components. Type B: Ill-defined mixture of poorly differentiated components, with partial squamous and glandular differentiation. Type C: Predominance of solid or sheet-like cancer cells showing squamous differentiation with foci of goblet cells, but glandular formation is absent

Table 1 Rates of HPV infection and integration in each element of adenosquamous carcinoma

	Squamous element	Glandular element
All HPV-positive	19/20[a] (95%)	18/20[b] (90%)
HPV 16	7/19 (36.8%)	6/18 (33.3%)
Integrated	1/7 (14.3%)	1/6 (16.7%)
HPV 18	11/19 (57.9%)	11/18 (61.1%)
Integrated	7/11 (63.3%)	7/11 (63.6%)

[a] One case was HPV 31-positive

[b] One case was HPV 31-positive and one case was HPV-negative

and squamous elements in all cases with the exception of one case in which the squamous element was HPV 16-positive, but the adenocarcinoma component was HPV-negative.

Physical statuses

PCR analysis with the E2 primers revealed that seven of 11 (63.6%) HPV 18-positive cases had the pure integrated form in both the squamous and glandular elements. Meanwhile, one of seven (14.3%) and one of six (16.7%) HPV 16-positive cases had the pure integrated form in the squamous and glandular elements, respectively, and each integrated form in the squamous and glandular elements was identical. It is very interesting that most of the HPV 18-positive cases contained the integrated form while only a few HPV 16-positive cases contained the integrated form among adenosquamous carcinomas as one histological subtype of cervical cancer (Table 1).

Assessment of the HPV 16 and 18 DNA copy numbers by real-time PCR

The mean HPV DNA copy numbers/cell in the three histological categories of adenosquamous carcinoma was 4.36 for type A, 1.04 for type B, and 0.48 for type C. The mean HPV DNA copy number/cell for type A cases with a well-differentiated squamous cell carcinoma component was higher, and significant differences were observed between type A and types B and C (Fig. 2).

The mean HPV DNA copy numbers/cell was 3.52 for the squamous epithelial elements and 1.05 for the glandular elements (p=0.04; Fig. 3). Among the HPV subtypes, the mean HPV DNA copy numbers/cell was 4.27 for the HPV 16-positive cases and 1.20 for the HPV 18-positive cases (Fig. 4). The mean copy number/cell was higher for cases infected with HPV 16 and significantly lower for cases infected with HPV 18 (p=0.02). Furthermore, the mean HPV 16 DNA copy numbers/cell was 7.22 in the squamous epithelial elements and 1.33 in the glandular elements (p=0.04) while the corresponding mean HPV 18 DNA copy numbers/cell was 1.50 and 0.89, respectively. The mean copy numbers/cell in both the HPV 16- and 18-infected cases tended to be higher in the squamous epithelial elements without any significant difference for the HPV 18-positive cases.

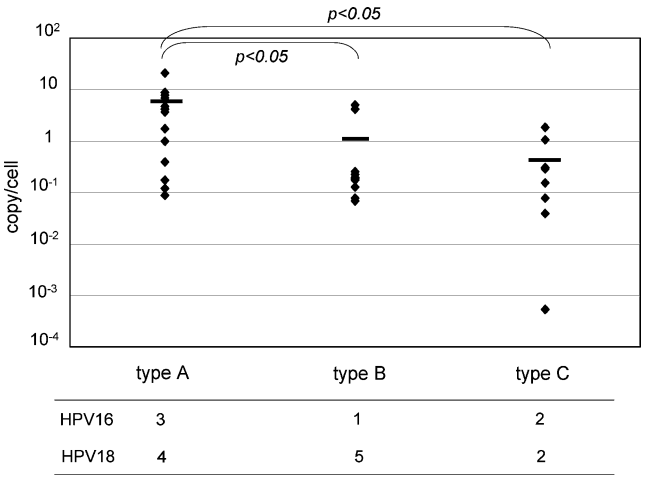

Fig. 2 HPV subtypes and viral loads in the histological subtypes. Significant differences are observed between type A and types B and C

The mean HPV DNA copy number/cell was significantly lower in the pure integrated cases, in which PCR products for the E2 region were absent, than in the nonintegrated cases (0.43 vs. 6.13, p=0.02; Fig. 5). The mean copy number/cell of the pure integrated cases, especially the HPV 18-positive cases, was much lower than that in the nonintegrated cases (0.28 vs. 2.81, p=0.009). Furthermore, the mean copy number/cell in the HPV 18-positive pure integrated cases was significantly lower than that in the HPV 16-positive pure integrated cases (0.28 vs. 1.51, p=0.001). The physical statuses were not related to the histological types or patient ages.

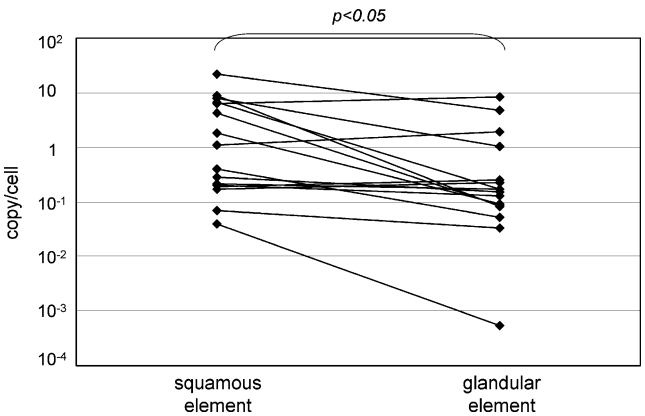

Fig. 3 Viral loads in the histological elements. The HPV copy numbers/cell are higher in the squamous component and lower in the glandular component in all cases

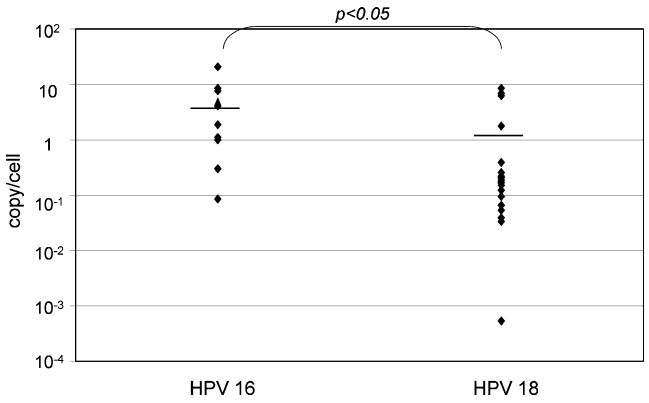

Fig. 4 Viral loads in the HPV subtypes. The mean copy numbers/cell are higher in cases infected with HPV 16 and significantly lower in cases infected with HPV 18

Discussion

Many reports have suggested that the incidence of cervical cancer in young women is continuing to increase steadily [23–25]. The majority of invasive cancers are squamous cell carcinomas, although greater prevalence of adenocarcinoma and adenosquamous carcinoma in young women have been reported [25–28]. In the present study, the mean age of the subjects was 39 years (range, 27–62 years), which is younger than the squamous cell carcinoma cases examined in our previous study in Japan [29]. Liu et al. [30] also showed that obvious increases in the overall incidence rates of adenocarcinoma and adenosquamous carcinoma were mainly observed in women aged 20–49 years.

The age-related high-risk HPV prevalence rates among women with normal cytology in Japan are 23.1% in women aged 20–29 years and 7.9% in women aged 30–49 years [31]. In Japan, a study on the prevalence of HPV 18 reported rates of 0% for women with normal cytology and low-grade squamous intraepithelial lesions, 4.7% for high-grade squamous intraepithelial lesions, and 11.1% for

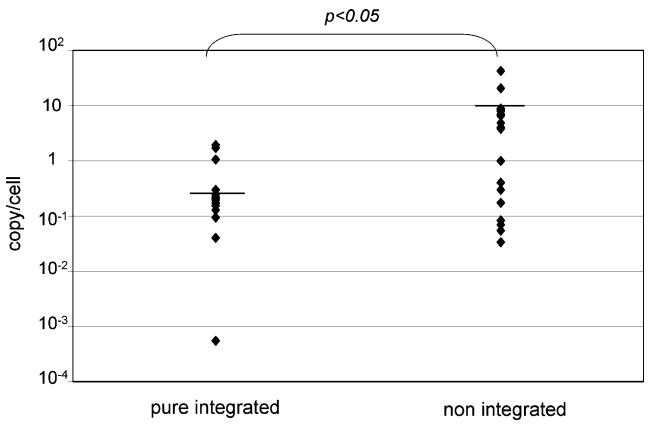

Fig. 5 Viral loads in different physical statuses. The mean copy numbers/cell is significantly lower in the pure integrated cases

cervical cancer [32]. In the present study, HPV DNA was detected in 95% of squamous lesions and 90% of glandular lesions. HPV 16 DNA was detected in 36.8% of squamous lesions and 33.3% of glandular lesions while HPV 18 DNA was detected in 57.9% of squamous lesions and 61.1% of glandular lesions. The reported HPV DNA detection rates in adenosquamous carcinoma vary among previous studies ranging from 30–100% [10–13]. Our present data revealed a high prevalence of HPV 18 DNA in adenosquamous carcinoma compared with HPV 16 DNA, but no difference was observed between the components. The frequencies of HPV 18 in adenocarcinoma and adenosquamous carcinoma are known to be much higher than those of HPV 16, although HPV 16 is the most common viral type identified in cervical cancers.

In the present study, we subclassified all the adenosquamous carcinoma cases into three subtypes, type A, B, and C. Examination of the relationships between the HPV subtypes and the histological types showed that HPV 18 was most frequently observed in type B cases (5/6, 83.3%). This finding is probably caused by the fact that most of the type B cases were poorly differentiated carcinomas, suggesting that type B cases may be classified as poorly differentiated adenocarcinomas. No relationships between the three histological types and the patient ages were observed.

Integration of high-risk HPV types into the host genome is considered to be an important step in malignant transformation. It is well established that HPV integration indicates an advanced stage of cervical lesions [33, 34]. The integration usually occurs within the E1 or E2 ORF in a manner that results in loss of its expression. The E1 or E2 ORF is an important viral regulator encoding transcriptional modulators, and disruption of E2-dependent negative feedback controlling E6 and E7 transcription is considered to be a selective event in tumor development and progression [35–37]. In the present study, the rates of integration were 63.6% in HPV 18-positive cases for both the squamous and glandular components compared with only 14.3% and 16.7% in the HPV 16-positive cases, respectively. Badaracco et al. [38] showed that HPV 18 integration occurred with significantly higher frequency than HPV 16 integration and was even detected in preneoplastic lesions. These findings are consistent with our data showing the predominant presence of HPV 18 pure integrated cases. Similar findings were reported by Cullen et al. [39], who detected a significant difference in viral integration between HPV 16 and 18, and indicated that many cases of HPV 16-positive cervical cancers only contain episomal forms of the virus. Our results showed that adenosquamous carcinoma tends to occur in a younger age group (mean age, 39 years) than squamous cell carcinoma, and this may be associated with early integration of HPV 18 [40] and its clinically higher aggressiveness

than HPV 16 [39, 41], although no significant difference in clinical tumor stages between HPV16 and HPV 18 positive cases was observed in this study. This difference may be derived from the different biological behaviors of the individual viral subtypes.

During integration, disruption of the E2 gene has been proposed as a mechanism of tumor progression, since it allows expression of the E6/E7 viral oncogenes. Meanwhile, Casas et al. [42] reported that Asian-American E2 variants of HPV 16 with retention of E1/E2 were present in some clinical samples and showed high levels of viral amplification with episomal multimeric or tandem integration. These findings suggest that disruption of the E2 gene, especially that of HPV 16, is not necessary for deregulation of the expression of the E6/E7 viral oncogenes and that the E2 variants may be an alternative mechanism for deregulating the expression of viral oncogenes. If this mechanism is operative, these data suggest that the Asian-American E2 variants of HPV 16 with retention of E1/E2 may also be present in the nonintegrated form in the categories defined in the present study.

Berumen et al. [43] suggested that integration and inactivation of E2 are not always essential for the development of HPV 16-positive carcinomas, which differ from HPV 18-positive cancers in this respect, and reported that the mean copy number/cell for HPV 18-positive tumors was significantly lower than that for HPV 16-positive tumors. Our data provide evidence that E2 integrity is essential for viral replication in invasive carcinoma and that its disruption impairs the ability of the viral genome to replicate. Badaracco [38] suggested that viral genome deletions may affect the production of infection particles, thereby limiting diffusion of the virus. Therefore, it is conceivable that the variable integration levels between HPV 16 and 18 are responsible for different viral diffusions and consequently different viral prevalence.

Our data revealed significant relationships between the viral copy numbers and the squamous and glandular components. The copy numbers/cell was 3.52 for squamous epithelial elements and 1.05 for glandular elements ($p<0.05$) and 4.36 for type A, 1.04 for type B, and 0.48 for type C ($p<0.05$). A previous study showed that high viral copy numbers/cell were always associated with E1/E2 amplification in keratinizing invasive tumors compared with nonkeratinizing tumors [43] and obtained similar data to our data showing that the copy number/cell was highest in type A tumors, which include a squamous keratinizing component. However, few reports have independently detected HPV DNAs in squamous and glandular lesions. A previous study using in situ hybridization showed that the HPV DNA localization in each component in adenosquamous carcinoma gradually increased from the pure adenocarcinoma component (28.6%) through the mixed component (54.5%) to the pure squamous cell carcinoma component (83.3%) [44]. These results can be explained by the sensitivity of the in situ hybridization method judging from our finding that the HPV copy number was higher in the squamous component and lower in the glandular component.

Various pathways for the histogenesis of adenosquamous carcinoma have been proposed in the past; however, the detailed mechanism remains unclear. Ueda et al. [45] suggested that adenosquamous carcinoma is derived from single stem cells, which have pluripotency to differentiate into both squamous and glandular cells. Interestingly, we observed that the same subtype of HPV was detected, and the physical status was the same in both the glandular and squamous elements in all of the HPV-positive cases. Therefore, our results agree with the above proposal that the main pathway for the histogenesis of adenosquamous carcinoma is from primitive reserve cells that become neoplastic and differentiate into two different cell types while collision of pure adenocarcinoma and pure squamous cell carcinoma with each other is a rare pathway for the histogenesis of adenosquamous carcinoma.

In the present study, we investigated 20 adenosquamous carcinomas for HPV infection, physical status, and viral load. In particular, the prevalence rate of HPV 18 was high, and many cases of HPV 18-positive cancer were the pure integrated form resulting in very low copy numbers/cell. It is possible that more aggressive transformation with early integration of HPV 18 results in cases with greater chromosomal instabilities, higher growth rates, and rapid progression.

Conflict of interest statement The authors declare that there are no conflicts of interest.

An allelotype analysis indicating the presence of two distinct ovarian clear-cell carcinogenic pathways: endometriosis-associated pathway vs. clear-cell adenofibroma-associated pathway

Sohei Yamamoto · Hitoshi Tsuda · Kozue Suzuki · Masashi Takano · Seiichi Tamai · Osamu Matsubara

Received: 4 June 2009 / Revised: 21 July 2009 / Accepted: 21 July 2009 / Published online: 5 August 2009

Abstract Patterns of allele loss (loss of heterozygosity (LOH)) were studied to identify the genetic backgrounds underlying the two putative carcinogenic pathways of ovarian clear-cell adenocarcinoma: carcinomas thought to arise in endometriosis (endometriosis-associated carcinomas, 20 cases) and carcinomas thought to be derived from clear-cell adenofibroma ((CCAF)-associated carcinomas, 14 cases). Each tumor was assessed for LOH at 24 polymorphic loci located on 12 chromosomal arms: 1p, 3p, 5q, 8p, 9p, 10q, 11q, 13q, 17p, 17q, 19p, and 22q. For all informative loci, the frequency of LOH was not statistically different between the two carcinoma groups: 38% (66/172 loci) in the endometriosis-associated carcinomas and 35% (40/113 loci) in the CCAF-associated carcinomas. In the endometriosis-associated carcinomas, LOH was detected at high frequencies (>50%) at 3p, 5q, and 11q and at low frequencies (<20%) at 8p, 13q, and 17p. In the CCAF-associated carcinomas, LOH was detected at high frequencies at 1p, 10q, and 13q and at low frequencies at 3p, 9p, 11q, and 17q. The frequencies of LOH at chromosomes 3p, 5q, and 11q were significantly higher in the endometriosis-associated carcinomas than in the CCAF-associated carcinomas (P=0.026, 0.007, and 0.011, respectively). Immunohistochemical analysis demonstrated a close association between the allelic status of the 3p25–26 locus and levels of von Hippel–Lindau (VHL) protein expression (P=0.0026). These data further support the presence of two distinct carcinogenic pathways to ovarian clear-cell adenocarcinoma; the allelic status of the 3p, 5q, and 11q loci may provide a means to identify the precursor lesions of these carcinomas.

Introduction

Clear-cell adenocarcinomas comprise 5% to 10% of epithelial ovarian cancer in Western countries and, for unknown reasons, 15% to 20% of such tumors in Japan [1–6]. Ovarian clear-cell adenocarcinoma is characterized by its distinctive histology and highly chemoresistant nature, resulting in an extremely poor prognosis when surgical cytoreduction is insufficient [1–4]. Although the etiology of ovarian clear-cell adenocarcinoma has not been fully elucidated, two distinct precursor lesions have been suggested, namely, endometriosis and clear-cell adenofibroma (CCAF).

Histological and epidemiological observations have consistently demonstrated a close association between endometriosis and ovarian clear-cell adenocarcinoma [7–13], and the molecular basis of the transformative pathway from endometriosis to clear-cell adenocarcinoma has been described, i.e., genetic instability or DNA aneuploidy in the endometriotic lesions, with loss of heterozygosity (LOH) or mutation of the tumor-suppressor gene *PTEN* detected in both endometriosis and co-existing clear-cell adenocarcinomas [14–17].

On the other hand, CCAF, a major form of benign or borderline ovarian clear-cell tumor, may also be a precursor of clear-cell adenocarcinoma [1, 4, 18–22]. Benign or borderline CCAF is a rare form of neoplasm, accounting for less than 5% of all ovarian clear-cell tumors [1, 4, 18, 19]. However, a study from our institution demonstrated that CCAF components co-existed in 21% of surgically resected clear-cell adenocarcinomas [20]. The CCAF components co-existing with clear-cell adenocarcinoma often contain both benign CCAF and borderline CCAF [18–20]. Recently, we analyzed LOH using 17 polymorphic markers to examine the genetic linkage between CCAF and co-existing clear-cell adenocarcinoma of the ovary and suggested that CCAF can be a clonal precursor for clear-cell adenocarcinoma in certain cases [21]. In that study, allelic losses were observed to accumulate from benign CCAF through borderline CCAF to co-existing clear-cell adenocarcinoma, and several specific chromosomal regions appeared to undergo genetic changes earlier (i.e., 5q, 10q, and 22q) or later (i.e., 1p and 13q) in the CCAF-associated clear-cell carcinogenic pathway [21].

These observations suggest, but do not yet establish, that clear-cell adenocarcinoma associated with CCAF components is a distinct clinicopathological entity in ovarian clear-cell adenocarcinoma [20, 23]. A study from our institution showed that, in comparison with clear-cell adenocarcinoma without CCAF components, clear-cell adenocarcinoma with CCAF components shows several distinct clinicopathological characteristics, such as a lower frequency of co-existing endometriosis, a higher frequency of histologically low-grade tumor with tubulocystic proliferative architecture, a lower cancer cell proliferative activity, and better patient prognosis [20]. In that study, carcinomas without CCAF components frequently harbored endometriosis in the ipsilateral adnexa to the carcinoma, and therefore, these two distinct carcinogenic pathways might contribute to the distinct clinicopathological features of the tumors [20]. However, the molecular genetic evidence underlying the differences between these putative pathways has not been elucidated.

Because the development of many cancers is believed to be the result of a multistep process involving a series of genetic events and the subsequent clonal evolution of cells with accumulated genetic errors, the chromosomal loci most frequently showing LOH would be expected to differ between tumors arising via distinct developmental pathways. Therefore, to clarify whether differences in genetic background underline the two possible carcinogenic pathways to ovarian clear-cell adenocarcinoma (endometriosis-associated pathway vs. CCAF-associated pathway), we performed polymerase chain reaction (PCR)-based LOH analyses using 24 polymorphic markers located on 12 chromosomal arms where relatively frequent LOH has been reported in ovarian epithelial tumors, including clear-cell adenocarcinoma or endometriosis [15–17, 24–31]. We then compared the allelic patterns of carcinomas with putative distinct precursors, since demonstrating the presence or absence of divergent carcinogenic pathways in ovarian clear-cell adenocarcinoma will provide insight into the genetic origin of this tumor.

Materials and methods

Cases analyzed

According to the histopathological criteria described previously [20–22], a total of 20 clear-cell adenocarcinomas with synchronous endometriosis (endometriosis-associated carcinomas) and a total of 14 clear-cell adenocarcinomas with adjacent CCAF component (CCAF-associated carcinomas) were identified from the files of the Department of Laboratory Medicine, National Defense Medical College Hospital, Japan (Fig. 1). All of the 34 patients underwent surgical resection between 1988 and 2006, and none had undergone chemotherapy or radiation therapy prior to surgery. All specimens were formalin-fixed and paraffin-embedded. The presence of cytological or structural atypia in the putative precursor lesions was not considered in this study. Although histologic examination revealed endometriotic lesions in two of the 14 cases with CCAF-associated carcinomas, these endometriotic lesions were present in the adnexa contralateral to the carcinomas and none of these 20 cases with endometriosis-associated carcinoma and 14 cases with CCAF-associated carcinoma overlapped. Clinical staging of disease was done according to the International Federation of Gynecology and Obstetrics system. Of the 20 cases with endometriosis-associated carcinoma, 14 (70%) were stage I, one (5%) was stage II, four (20%) were stage III, and one (5%) was stage IV. Of the 14 cases with CCAF-associated carcinoma, ten (71%) were stage I, one (7%) was stage II, two (14%) were stage III, and one (7%) was stage IV. The research protocol was approved by the ethics committee of the National Defense Medical College, Tokorozawa, Japan.

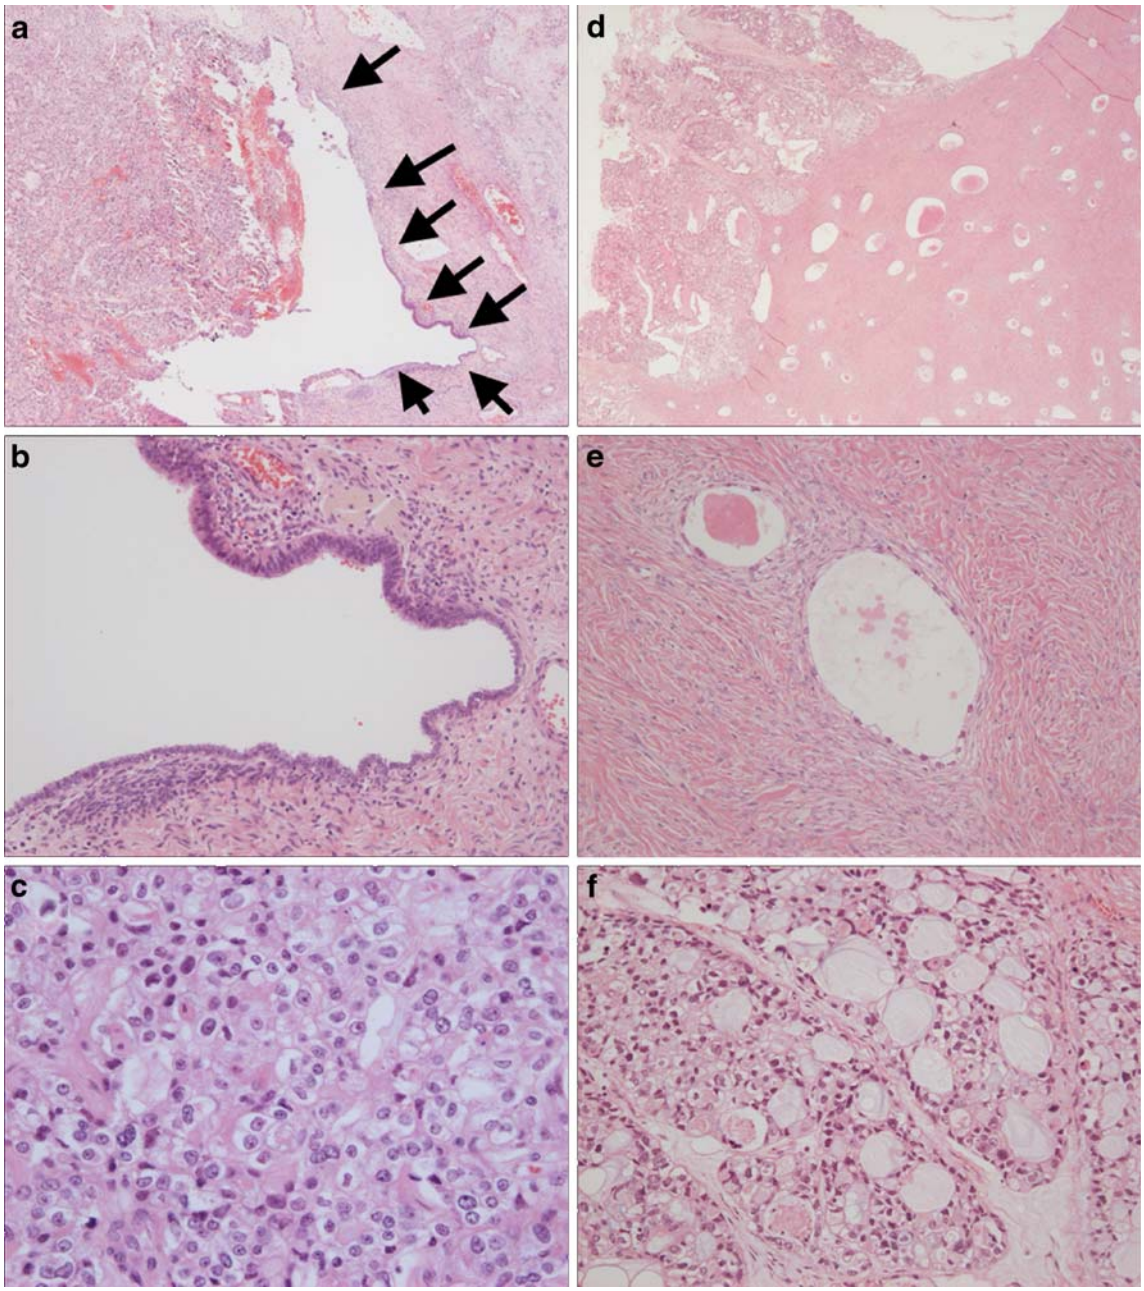

Fig. 1 Representative histological features of ovarian clear-cell adenocarcinoma with synchronous endometriosis (**a**, **b**, and **c**) and ovarian clear-cell adenocarcinoma with adjacent CCAF component (**d**, **e**, and **f**). **a** Clear-cell adenocarcinoma (middle to left side) arising within endometriotic cyst. *Arrows* indicate endometriotic epithelium. **b** High magnification of the endometriosis shown in (**a**). **c** High magnification of the clear-cell adenocarcinoma component shown in (**a**). **d** Clear-cell adenocarcinoma (left side) with adjacent CCAF component (middle to right side). **e** High magnification of the CCAF shown in (**d**). Glands are delineated with monolayers of cuboidal glandular cells with clear cytoplasm. Cytological atypia is not evident in this case. **f** High magnification of the clear-cell adenocarcinoma component shown in (**d**). HE stain, original magnification ×20 for (**d**); ×40 for (**a**); ×200 for (**b**), (**e**), and (**f**); ×400 for (**c**)

Tissue microdissection and DNA extraction

DNA was extracted from selected regions of carcinomas in which tumor histology was highly representative for a diagnosis for clear-cell adenocarcinoma and apart from tissue degeneration or inflammation, and normal areas by laser microdissection using a Leica LMD 6000 (Leica; Narishige Micromanipulator, Wetzlar, Germany) as described previously [21]. We performed constitutional microdissection from at least five serial 8-μm-thick tissue sections of the 10×10 mm or larger representative cancer tissues. DNA extraction was performed using the same

methods as described previously [21], and the concentration of DNA from each sample was adjusted to 0.05 μg/μl. Extracted DNA samples were stored at 4°C until use.

Selection of polymorphic markers

Twenty-four polymorphic markers, located on 12 chromosomal arms, were selected on the basis of the following criteria: (1) the markers were localized on regions in which frequent LOH events have been reported in primary ovarian carcinomas and/or endometriosis [15–17, 24–31], (2) the sizes of the amplified fragments were expected to be smaller than 200 bp for reliable amplification of template DNA from formalin-fixed tissue.

Two paired polymorphic markers were used for each chromosomal locus examined, and pairs of forward and reverse primers of 24 oligonucleotide polymorphic markers corresponding to the sequences retrieved from the Genome Database (http://gdbwww.gdb.org/gdb/) were synthesized commercially and purchased from Perkin Elmer (Applied Biosystems, Foster City, CA). Chromosomal regions and paired markers used were as follows: 1p36.12–36.32 (*D1S199, D1S2663*), 3p25–26 (*D3S1110, D3S1038*), 5q13.3–23 (*D5S424, D5S346*), 8p21.3–22 (*D8S261, D8S254*), 9p21 (*D9S161, D9S1748*); 10q23.2–23.3 (*D10S608, D10S574*), 11q23–24 (*D11S1336, D11S1356*), 13q12.3–13 (*D13S263, D13S267*), 17p13.1 (*D17S786, D17S1289*), 17q21 (*D17S579, D17S1322*), 19p13.3 (*D19S413, D19S894*), 22q13 (*D22S284, D22S304*). The 5' ends of the forward primers were labeled with 6-carboxyfluorescein.

Polymerase chain reaction and analysis of allelic pattern

PCR amplification of genomic DNA was performed in a total volume of 25 μl of reaction mixture containing 2 μl of DNA solution corresponding to 100 ng of genomic DNA, 0.4 pmol/μl of each primer, and 1× TaqMan Universal PCR Master Mix (Applied Biosystems) using a GeneAmp® PCR system 9600 (Applied Biosystems). Details of PCR-cycling conditions have been described previously [21].

Aliquots of the PCR products were then mixed with size standards and formamide, denatured, and run on an ABI 3130 automated capillary electrophoresis DNA sequencer (Applied Biosystems). The allelic products were assessed for peak height and peak area with GeneMapper software version 3.7 (Applied Biosystems).

Non-cancerous DNA samples with two different amplified bands were defined as informative cases for LOH analysis. LOH was considered to exist if the relative ratio of peak heights calculated by the following formula was lower than 0.5 or greater than 1.5: [Peak height of the affected allele (allele A) of the tumor × peak height of the unaffected allele (allele B) of normal cells] / [peak height of allele A of normal cells × peak height of allele B of tumor cells]. When tumor DNA samples showed a significant reduction in the relative ratio of peak height in the initial PCR, the cases were reexamined at least twice to confirm that the LOH data were reproducible. Results were considered non-informative when the normal tissue was homozygous, when the tissue lysate failed to be amplified, or when the results could not be interpreted unambiguously. A case was considered to be positive for LOH when at least one of the two paired markers on each chromosomal region showed a pattern of allelic loss.

Immunohistochemistry

Sections of 4-μm-thick tissue were deparaffinized in xylene and rehydrated through a series of alcohols. Antigen retrieval was achieved by microwave heating (97°C for 30 min) in 0.01 mol/l citrate buffer (pH 6.0), followed by cooling at room temperature. Endogenous peroxidase was blocked using 5% hydrogen peroxide, and non-specific binding of secondary antibody was blocked by incubation with normal swine serum. Individual sections were incubated at 4°C overnight with primary antibodies against VHL (ab11191, mouse monoclonal, dilution 1/100; Abcam, Cambridge, UK). The slides were then reacted with a dextran polymer reagent combined with secondary antibodies and peroxidase (DAKO, Glostrup, Denmark) for 1 h at room temperature. Specific antigen–antibody reactions were visualized with 0.2% diaminobenzidine tetrahydrochloride and hydrogen peroxide, and counterstaining was performed using Mayer's hematoxylin. Non-neoplastic kidney tissue was used as a positive control, and sections without the primary antibody were used as negative controls.

We evaluated cell membranous and cytoplasmic immunoreaction and did not separate these because distinction between cytoplasmic and membranous expression was often difficult in the tumor cells with scant cytoplasm or rich in cytoplasmic glycogen. Cases were considered as positive for VHL protein expression if more than 10% of the tumor cells examined showed membranous/cytoplasmic immunoreactivity with intensity equal to or more than that in the positive control; otherwise, cases were considered as representing downregulation of VHL protein expression.

Statistical analyses

Statistical analyses were performed using StatMate III software (ATMS, Tokyo, Japan). To compare the frequencies of LOH occurrence or the immunohistochemical results, the chi-squared test or Fisher's exact test was used as appropriate. Differences at $P<0.05$ were considered to be statistically significant.

Results

Allelotype analysis

A representative case showing LOH at the *D3S1038* locus is presented in Fig. 2. LOH data derived from the allelotype analysis are summarized in Tables 1 and 2. When all the chromosomal regions studied and all the informative cases were combined, the total frequency of LOH events was 37% (106 of 285 informative loci), and there was no statistically significant difference in the frequency of LOH between the endometriosis-associated carcinomas (38%, 66 of 172 informative loci) and the CCAF-associated carcinomas (35%, 40 of 113 informative loci). In all the 34 cases examined, LOH events were detected at high frequencies (>50%) at chromosomes 5q (72%, 18 of 25 informative cases), 1p (54%, 14 of 26), and 10q (50%, 7 of 14), followed by 11q (42%, 13 of 31), 3p (39%, 13 of 33), 19p (35%, 9 of 26), 22q (33%, 10 of 30), 13q (33%, 3 of 9), 8p (27%, 9 of 33), 17q (20%, 4 of 20), and detected at low frequencies (<20%) at chromosomes 9p (19%, 5 of 27) and 17p (8%, 1 of 12). In the 20 endometriosis-associated carcinomas, LOH events were detected at high frequencies (>50%) at chromosomes 5q (93%, 14 of 15 informative

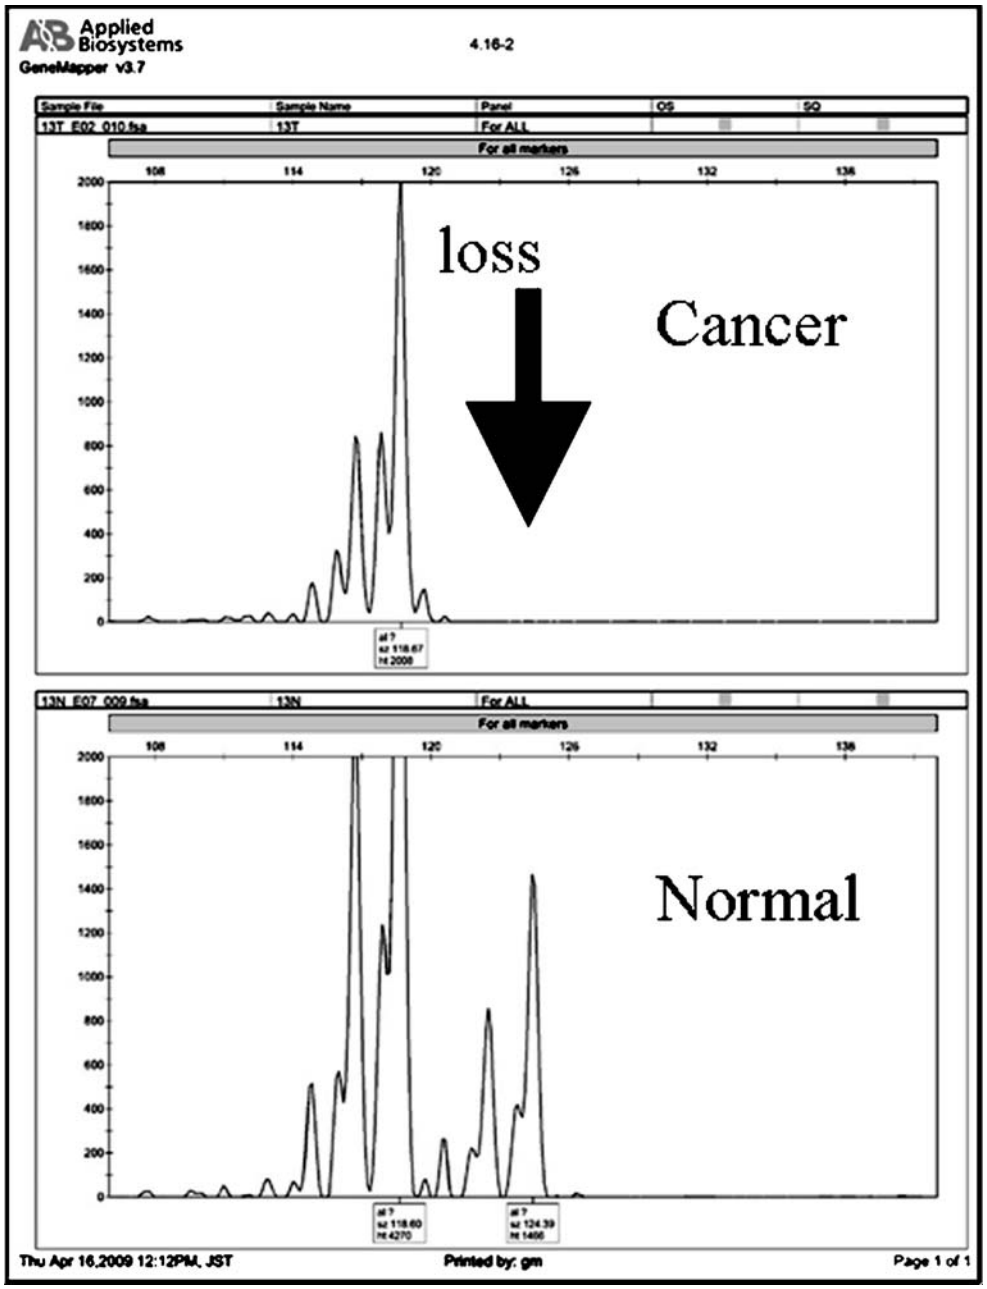

Fig. 2 An electrophoretogram showing allelic loss at the *D3S1038* locus on chromosome 3p25–26 in a case of ovarian clear-cell adenocarcinoma. Loss of heterozygosity is identified as a reduction of the relative intensity of one of the two alleles in the cancer DNA to less than 50% of that in the corresponding normal DNA. The longer allele is deleted (*arrow*). According to the definition given in the text, the case was judged to carry LOH

CCAF clear-cell adenofibroma, *LOH* loss of heterozygosity

(67%, 2 of 3), and 10q (57%, 4 of 7), followed by 22q (45%, 5 of 11), 19p (44%, 4 of 9), 8p (43%, 6 of 14), 5q (40%, 4 of 10), and 17p (20%, 1 of 5), and detected at low frequencies (<20%) at chromosomes 3p (15%, 2 of 13), 11q (15%, 2 of 13), 17q (14%, 1 of 7), and 9p (9%, 1 of 11; (Table 2). In comparison with the CCAF-associated carcinomas, the incidences of LOH on chromosomes 3p, 5q, and 11q were statistically significantly higher in the endometriosis-associated carcinomas (P=0.026, 0.0068, and 0.011, respectively; Table 2). On chromosomes 1p, 8p, and 13q, the incidences of LOH were substantially higher in the CCAF-associated carcinomas than in the endometriosis-associated carcinomas (1p, 73% in the former and 40% in the latter; 8p, 43% in the former and 16% in the latter; and 13q, 67% in the former and 17% in the latter), but these differences were not statistically significant (P=0.104, 0.092, and 0.226, respectively; Table 2).

Immunohistochemical analysis for VHL protein expression

The results of immunohistochemical detection of VHL protein are summarized in Table 3. A case showing positive immunoreactivity for VHL protein and another case showing downregulated expression of VHL protein are presented in Fig. 3. Of the 34 clear-cell adenocarcinomas, 26 (76%) and eight (24%) were considered as positive and downregulated for VHL protein, respectively. There was no statistically significant difference in the score of VHL immunoreactivity between endometriosis-associated carcinomas and CCAF-associated carcinomas (Table 3). However, of the 33 cases in which information on LOH on chromosome 3p25–26 was available, the score of VHL immunoreactivity was strongly and significantly associated with allelic status on chromosome region 3p25–26: seven (54%) of 13 LOH-positive tumors and only one (5%) of 20 tumors with constitutional heterozygosity were scored as downregulated expression of VHL protein, respectively (P=0.0026).

Discussion

It is generally accepted that genetic instability and alterations play an important role in human carcinogenesis, and the development of many cancers is believed to be the

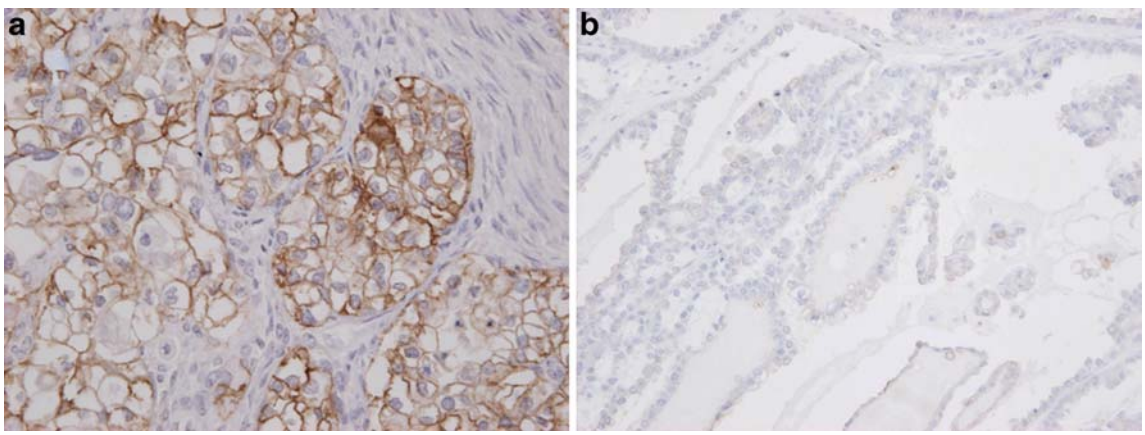

Fig. 3 Immunohistochemistry for VHL protein in ovarian clear-cell adenocarcinoma. **a** A case of clear-cell adenocarcinoma showing diffuse membranous/cytoplasmic immunoreactivity for VHL protein. **b** A case of clear-cell adenocarcinoma assessed as showing reduced expression of VHL protein. Immunoperoxidase stain, original magnification ×400 for (**a**) and ×200 for (**b**)

result of a multistep process involving a series of genetic events and the subsequent clonal evolution of cells with accumulated genetic errors. Consequently, if different chromosomal alterations play particular roles in tumors with distinct clinicopathological features, the chromosomal loci most frequently showing LOH would differ among these tumors, and divergent genetic backgrounds would underlie the development of each tumor type.

In the present study, we have demonstrated that the total frequency of LOH on all informative chromosomal loci in the endometriosis-associated carcinomas and the CCAF-associated carcinomas was 38% and 35%, respectively, suggesting that the overall extent of genetic alterations was not different between the two carcinoma groups. However, analysis with respect to specific chromosomal loci did reveal differences between the two carcinoma groups. These loci were chromosomes 3p25–26, 5q13.3–23, and 11q23–24, where the endometriosis-associated carcinomas exhibited LOH with frequencies of 55%, 93%, and 61%, respectively, compared with 15%, 40%, and 15% in the CCAF-associated carcinomas. These data suggest that these less frequently altered regions in CCAF-associated carcinomas may harbor genes responsible for the clinicopathological characteristics of the type, namely, a higher frequency of histologically low-grade tumors with tubulocystic proliferative architecture as well as lower cancer cell proliferative activity [20].

As our previous study suggested a relatively better prognosis for patients with CCAF-associated carcinomas [20], a point of interest is whether allelic losses on chromosomes 3p25–26, 5q13.3–23, or 11q23–24 are associated with tumor aggressiveness, i.e., ability to metastasize or resistance to chemotherapy. Therefore, tumor suppressor genes (TSGs) mapping to these chromosomal regions, such as *VHL* on 3p, *adenomatous polyposis coli* (*APC*) on 5q, and *ataxia telangiectasia mutated* (*ATM*) on 11q, or products of these genes, are of interest [32–34]. Although there have been conflicting reports on the association of LOH at 3p with histological grade or clinical stage of ovarian cancers [25, 35, 36], Zheng et al. [35] have shown that 3p deletions are associated with high-grade ovarian carcinomas. Allan et al. [37] demonstrated LOH on 5q in 50% of sporadic ovarian carcinomas, but the *APC* TSG was not mutated in these tumors, suggesting that this gene is not responsible for ovarian tumorigenesis. A study by Gabra et al. [38] reported that LOH on chromosome 11q23–24 was significantly associated with advanced stage and poor prognosis in patients with ovarian or breast cancer, and suggested that a late-acting progression-suppressor may be located within this region.

We have demonstrated that immunohistochemical expression of VHL protein was significantly correlated with the allelic status of the clear-cell adenocarcinomas studied. The *VHL* gene is located at 3p25–26, and alterations on chromosome 3q or the *VHL* locus have been described to occur in a variable proportion of ovarian carcinomas [25, 28, 35, 36, 39]. However, in some series, a significant number of tumors, including those with allelic deletion at the *VHL* locus, showed a normal VHL protein-staining pattern [39]. However, our observation that seven (54%) of 13 LOH-positive tumors and only one (5%) of 20 LOH-negative tumor showed reduced expression of VHL protein indicates that, at least in our series, LOH at the *VHL* locus is associated with decreased *VHL* gene function, suggesting a tumor suppressor role of VHL in a proportion of ovarian clear-cell adenocarcinomas.

The best understood function of VHL relates to its ability to target hypoxia-inducible factor (HIF) for poly-ubiquitination, and hence destruction [40]. HIF is a heterodimer composed of DNA-binding alpha/beta complexes and directs various transcriptional responses involving the induction of genes responsible for tumor growth and angiogenesis [41]. The HIF-1alpha subunit interacts with VHL protein and is degraded by ubiquitin-mediated proteolysis in the presence of oxygen. An increased level of HIF-1alpha has been reported in various human malignancies, including ovarian clear-cell adenocarcinoma [39, 41–43]. Osada et al. [39] reported that patients with ovarian carcinomas showing nuclear HIF-1alpha expression had poor prognosis, and that the topological distributions of HIF-1alpha and VHL protein were inversely correlated in the ovarian clear-cell adenocarcinoma specimens. Therefore, it is possible that the decreased levels of VHL protein have an accelerating role in ovarian clear-cell carcinogenesis via upregulation of HIF1-alpha, and this merits future study.

Overall, however, there appears to be some overlap of the patterns of allelic loss between the two groups of ovarian clear-cell carcinomas, for example, involvement of 1p36 and 10q23.3, and these points of overlap may represent common areas where genetic alterations play fundamental roles in the carcinogenesis of this tumor. Mutational analysis of the remaining alleles may yield additional information concerning the significance of LOH at these loci in ovarian clear-cell carcinogenesis.

In summary, we have assessed patterns of allelic loss in two groups of ovarian clear-cell adenocarcinomas with possible distinct precursor lesions. We found significant differences in the frequencies of LOH at chromosomal regions 3p25–26, 5q13.3–23, and 11q23–24. These data further support the presence of two distinct carcinogenic pathways to ovarian clear-cell adenocarcinoma; the allelic status of the 3p, 5q, and 11q loci may be useful in differentiating the distinct precursor lesions of these carcinomas.

Acknowledgments This work was supported in part by a grant-in-aid for promotion of defense medicine from the Ministry of Defense, Japan (S.Y., H.T., and O.M.), and by a grant-in-aid for cancer research from the Ministry of Health, Labour, and Welfare, Japan (H.T.).

Conflict of interest statement The authors declare no actual or potential conflicts of interest in this study.

CASE REPORT

Fibroadenoma and intraduct papilloma—a common pathogenesis?

Margaret C. Cummings · Leonard da Silva · David J. Papadimos · Sunil R. Lakhani

Received: 5 July 2009 / Accepted: 27 July 2009 / Published online: 11 August 2009

Abstract This report describes two cases, each showing fibroepithelial proliferation, admixed with intraduct papillomas. Case 1 was from a 13-year-old female who presented with a breast mass, while case 2 was from a 60-year-old female who also had a breast lump. Case 1 showed proliferative breast disease with multiple small papillomas, some with leaf-like contours. Broad-based parenchymal proliferations protruding into ducts were also seen, and there were overlap features between the two ends of this spectrum. Case 2, similarly, demonstrated a mixed intraductal proliferation, with papillomas on narrow stalks together with low-grade phyllode areas extending into ducts from a wider base. That fibroadenoma and intraduct papilloma may have a common pathogenesis is discussed.

Introduction

Fibroadenomas are benign tumours of the breast with both epithelial and fibrous connective tissue elements. They are round or ovoid, and, while not encapsulated, are well demarcated and are easily separated from the surrounding breast tissue. Phyllode lesions also have stromal and epithelial elements but have a more leaf-like architecture and a relatively greater stromal component. Intraduct papillomas have a branching connective tissue core invested by a layer of epithelial and myoepithelial cells and are connected to the wall of their surrounding duct by a narrow stalk.

We present two cases, each showing a predominantly intraductal architecture, with varying proportions of fibroepithelial and papilloma components together with elements showing overlap features.

Clinical history

Case 1

The patient was a 13-year-old female, who presented with a large right-sided breast mass, which, clinically, was thought to be a papilloma. A wide local excision was performed, with two pieces of tissue removed.

Case 2

The patient was a 60-year-old female who presented with a lesion superior and lateral to the right nipple. A wide local excision was undertaken.

Materials and methods

The surgical specimens were fixed in 10% buffered neutral formalin and embedded in paraffin. All sections were stained with haematoxylin and eosin. On selected paraffin sections for case 1, immunohistochemical examination was performed for oestrogen receptor protein (ER; Clone 6F11/2, 1:100, Leica Microsystems), progesterone receptor protein (PR; Clone 16, 1:500, Leica Microsystems), Ki67 (Clone MIB-1, 1:50, Dako) and HER2 (Dako Herceptest Kit, K5207). Staining for ER, PR and Ki67 was performed automatically using the Leica Bond Max immunostainer with Bond Polymer Refine Detection Kits (Leica, DS9800) and heat-induced epitope retrieval pH 9.0 (Leica, ER2, AR9640) for 40 min, 30 min and 20 min, respectively. Staining for HER2 was performed using the Dako Herceptest Kit (K207) according to the kit insert.

ER, PR and Ki67 were considered positive when there was nuclear staining, and HER2 was assessed using the HERCEPT test guidelines.

Results

Pathology

Macroscopic findings

Case 1 The specimen comprised two irregular pieces of breast tissue, the smaller measuring 30 x 15 x 10 mm and the larger measuring 50 x 40 x 35 mm. On more than one surface, papillary tissue was seen, and, on sectioning, there were large and small spaces filled with papillary material seen throughout the specimen. A small amount of adjacent white breast tissue was also present.

Case 2 The specimen was a piece of breast parenchyma measuring 55 x 40 x 20 mm, within which was a firm nodule measuring 23 x 20 x 14 mm.

Microscopic findings

Case 1 Histological examination of the breast tissue showed a range of appearances with widespread proliferative breast disease (Fig. 1a). There were many greatly dilated ducts in which multiple, crowded, small papillomas were seen, many with rounded contours and prominent sclerosis (Fig. 1b). Some of the papillomas had more convoluted, somewhat leaf-like contours, reminiscent of a phyllode pattern. Compared with these intraduct papillomas, with their characteristically narrow stalks, other areas showed breast parenchyma protruding into ducts from a far broader base. This varied from only slightly encroaching on the involved duct to projecting into and filling the lumen and even apparently compressing and distending the opposite wall of the duct, giving an appearance of early, small fibroadenomas (Fig. 1c). In some ducts, there was a mixture of broad-based papillary protrusions extending into them together with some connected to the duct walls by only very narrow stalks (Fig. 1d). Much of the covering surface epithelium showed a relatively flattened layer of cuboidal epithelial cells; although, in areas, there were more pronounced hyperplastic features. Overall, the main features were of small fibroadenomas, admixed with intraduct papillomas and areas resembling phyllode tumour.

Immunostaining for the proliferation marker Ki67 showed 1–2% of cell staining, and these were mostly epithelial cells rather than stromal. There were relatively more positively staining glandular epithelial cells in the broad-based projections compared with the epithelium seen in the opposite indented side of the ducts (Fig. 2a, b).

There was strong staining for both ER and PR in approximately 95% of the epithelial cells (Fig. 2c, d). Staining for HER2 was negative (0).

Case 2 Histological examination showed breast parenchyma with a fibroepithelial proliferation extending into and distorting and surrounding some ducts. Distension of the ducts with compression of the overlying ductal epithelium was seen. In areas, there was a relatively prominent stroma. A leaf-like contour was focally present. Some of the intraduct proliferations were more broadly based while in others there was a narrow stalk with the characteristic appearance of benign intraduct papillomas. The overall diagnosis was of a composite lesion with fibroadenoma, intraduct papilloma and low-grade phyllode features (Fig. 1e).

Discussion

There have been many studies concerning the pathogenesis of fibroadenomas, but there is little information available concerning the pathogenesis of intraduct papillomas. We show two cases here whose features suggest that these two entities may share a common pathogenesis. Both cases include foci comprising typical intraduct papillomas; both also show fibroepithelial type proliferation, in the first, giving fibroadenoma areas and, in the second, giving a low-grade phyllode appearance. Both also show features which are intermediate or transitional between the two entities, suggesting that both entities develop along similar pathways, sharing a common evolution.

Several old and very elegant studies have been performed concerning the origin and nature of fibroadenomas. Delbet, in 1898, held that epithelial proliferation and the formation of cysts was the initial step in their development and that subsequent connective tissue overgrowth and the invagination of cysts later produced the characteristic architecture [1]. Cheatle, on the other hand, felt that fibroadenomas arose predominantly because of stromal proliferation, both around terminal ducts and within lobules [2]. In a particularly thorough study, Demetrakopoulos made a three-dimensional reconstruction of a small fibroadenoma using composite drawings of serial histological sections [3]. He also felt that the key component of a fibroadenoma was the connective tissue proliferation and that that accounted for its architectural features. He observed that the connective tissue often invaginated the

walls of ducts, and, similar to what the current cases show, the intraluminal connective tissue was sometimes so prominent that it pushed one wall of the involved duct against the opposite wall, partly occluding the lumen. He also noticed that in other instances, the connective tissue projected in a tongue-like fashion in either direction within the lumen of the duct, similar to the intraduct papilloma components of the current cases.

In their comprehensive study on the origins of fibroadenomas, Koerner and O'Connell concluded that the stromal cells of fibroadenomas arose from the loose, specialised connective tissue seen around ducts and lobules and that the glandular epithelial component was merely caught up within the growing stroma [4]. They felt that, while the epithelial elements of a fibroadenoma are thought to derive largely from a single ductal system, as the process evolves, more ducts and lobules may gradually become included within the growing mass.

That fibroadenomas are hyperplastic rather than neoplastic was supported by the work of Noguchi et al. who showed that both the epithelial and stromal components were polyclonal [5]. The diffuse and strong staining for both oestrogen and progesterone receptor proteins seen in case 1 is consistent with a hyperplastic process; this is compared with the usual staining pattern for the hormone receptor proteins where only occasional cells are stained. While mitoses were not seen and Ki67 showed infrequent positivity, there did appear to be relatively more proliferative activity in the glandular epithelium of the parenchymal component that was protruding into the duct lumen, indicating that it may be the glandular proliferation in particular that promotes the development of fibroadenomas rather than that of the accompanying dependent stroma.

Compared with fibroadenomas, there appears to have been relatively little interest in how intraduct papillomas develop and evolve. An intraduct papilloma has a fibrovascular stromal core, sometimes with branching fronds and it is covered by a layer of epithelial and myoepithelial cells. The stromal connective tissue core, generally, has only a narrow stalk linking it to the duct wall. The so-called solid intraduct papilloma is thought to arise when there are multiple papillary projections within a duct that somehow merge together. Showing some aspects that are similar to the present cases, Chung et al. described a case of intraductal fibroadenomatosis with overlap features of papillomas, intraductal adenomas, fibroadenomas and benign phyllode tumours [6].

When fibroadenomas or intraduct papillomas are seen by one histologically, these have usually been there for quite some time and, so, are well advanced in terms of their own natural history. Earlier on, they would generally not cause symptoms. Case 1 described here is very unusual in that it shows features of both fibroade-

noma and intraduct papilloma, both in their initial developing stages. Case 2 shows an admixed fibroepithelial proliferation with intraduct papillomas. The early evolution of both components occurring together in case 1, sometimes within the one duct, suggests that the two entities, fibroadenoma and intraduct papilloma, could share a common pathogenesis. If breast parenchyma projects into a cavity on a narrow stalk or base, an intraduct papilloma occurs. Conversely, if there is a wider or a more broad base to the projection, then the opposite duct wall becomes compressed over it, eventually attenuates, and a fibroadenoma occurs. Why one develops and not the other, and generally not both together, is unclear.

ORIGINAL ARTICLE

Loss of RKIP expression is associated with poor survival in GISTs

Olga Martinho · António Gouveia · Paula Silva · Amadeu Pimenta · Rui Manuel Reis · José Manuel Lopes

Received: 8 June 2009 / Revised: 17 July 2009 / Accepted: 30 July 2009 / Published online: 25 August 2009

Abstract Gastrointestinal stromal tumours (GISTs) are rare mesenchymal tumours of the digestive tract and are commonly driven by oncogenic mutations in *KIT* and *PDGFRA* genes. Tumour size, location, mitotic index and *KIT/PDGFRA* mutations are the most important prognostic parameters in GISTs. However, additional studies screening for new molecular prognostic markers in GISTs are missing. Raf kinase inhibitor protein (RKIP) has been considered as a suppressor of metastasis and a prognostic marker in several neoplasms. In the present study we aimed to examine whether RKIP expression is associated with GIST clinical–pathological features. Using immunohistochemistry, we determined RKIP expression levels in a well-characterised series of 70 GISTs. We found that RKIP is expressed in the great majority of cases, and absent in approximately 9% of GISTs. Additionally, we found that loss of RKIP expression was not due to the promoter methylation as assessed by methylation-specific PCR. Loss of RKIP expression was associated with poor disease-specific survival and with tumour necrosis in GISTs. Furthermore, a statistical tendency was observed between the positive RKIP expression and absence of metastasis. So far, this is the first study assessing RKIP expression levels in GISTs. We conclude that loss of RKIP expression could have an important role as prognostic marker in GISTs.

Introduction

Gastrointestinal stromal tumours (GISTs) are rare mesenchymal tumours of the digestive tract [1, 2]. Gain-of-function mutations in *KIT* and *PDGFRA* oncogenes have been identified in a great majority of GISTs and are considered to be one of the first molecular events in their pathogenesis [3, 4]. The tyrosine kinase inhibitor imatinib mesylate is the gold standard in the treatment of metastatic GISTs, leading up to 75% response rates [5]. Several studies have shown the importance of *KIT* and *PDGFRA* molecular status in imatinib response [6, 7].

Tumour size, location and mitotic index are the most important prognostic parameters of GISTs [8, 9]. Several authors have proven the usefulness of these and other classification parameters in GISTs clinical follow-up [10, 11]. Moreover, other studies have shown that molecular

genetic markers, such as the type of *KIT* and *PDGFRA* mutations, might also have prognostic value [12, 13]. However, a part of GISTs behave unpredictably leading to the need of screening new molecular prognostic markers.

The MAP kinase (RAS/RAF/MEK/ERK) pathway, one of the KIT downstream cascades, is highly preserved and implicated in cell growth, differentiation, migration and survival [14]. Activated RTK phosphorylates RAS, which binds RAF-1 kinase that phosphorylates MEK1/2, leading to ERK1/2 activation. Phosphorylated ERKs translocates into nucleus and regulates gene expression through several transcription factors like c-Myc, CREB and AP-1, ultimately leading to changes in gene expression [14]. Recently, we and others observed activation of this pathway in GISTs by presence of *BRAF* activating mutations [15, 16]. In addition, we described the absence of *RAS* mutations, and suggest that MAP kinase could also be activated through SCF/KIT autocrine/paracrine mechanisms in a subset of *KIT/PDGFRA* wild-type GISTs [16].

Raf kinase inhibitory protein (RKIP; also known as PEBP, for phosphatidylethanolamine-binding protein) was originally identified as an endogenous inhibitor of the RAS/RAF/MEK/ERK pathway by interfering with the phosphorylation and activation of MEK by Raf-1 [17, 18]. Subsequently, RKIP was shown also to suppress the activation of the nuclear factor Kappa B (NFkB) cell survival pathway by blocking the inactivation of the inhibitor of NFkB, namely IkB [19]. In mammals, RKIP is also a negative regulator of G-protein coupled receptors [GPCRs] by inhibiting GRK-2 [20], and may be involved in regulating the partitioning of chromosomes and mitosis progression through RKIP binding to centrosomal and kinetochore regions of metaphase chromosomes [21]. The collective evidence indicates that RKIP regulates the activity and mediates the crosstalk between several important cellular signalling pathways including cell differentiation, cell cycle, apoptosis and cell migration. Attenuation of RKIP function is implicated in several human diseases, such as neurologic diseases and metastases in cancer [22, 23].

RKIP is a widely expressed and highly conserved protein [24–26], which is downregulated in several tumours, including highly metastatic prostate carcinoma, breast, colon and gastric carcinoma, hepatocellular carcinoma, melanoma, insulinoma and ovarian carcinoma [27–36]. Furthermore, RKIP is also a prognostic marker in prostate, colorectal and gastric carcinomas [34, 36–38]. The molecular mechanisms underlying RKIP downregulation in cancer is not yet fully understood. Some authors suggested *RKIP* promoter methylation as a potential RKIP silencing event [21, 39].

In the present study we aimed to clarify the role of RKIP in the prognosis of GISTs.

Materials and methods

Tissue samples

Seventy formalin-fixed paraffin-embedded primary sporadic GISTs, classified according to WHO criteria and risk group [40], previously characterised immunohistochemically for CD117, actin, S100, desmin and CD34, and molecularly for *KIT* and *PDGFRA* mutations, were retrieved from the Pathology Department of S. João Hospital files (1989–2005), Porto, Portugal [10, 41]. All patients were Caucasian and of Portuguese origin, with a mean age of 62.1 years (range 20–88). Thirty-six (51.4%) patients were female and 34 (48.6%) were male. Most frequent tumour location was gastric (n=40) and small intestine (n=23); other location were: colon (n=2), rectum (n=1), oesophagus (n=1) and omentum/mesentery (n=3). Three GIST patients with surgically resected tumours were treated with imatinib (400 mg daily, with escalation to 600 mg daily whenever indicated), because of tumour recurrence. Of these patients, two are alive with stable disease and one died due to the disease. Follow-up data was available in all patients, as at December 2007, and collected through direct interview with patients or their relatives, and by review of in-hospital patient files. The median follow-up time of patients was 54.1 months (range, 1–206). The diagnosis of metastases, including the two cases with very limited biopsy material, was based on definitive imagiological evidence obtained during the follow-up of the patients.

Immunohistochemistry analysis for RKIP

Representative 3-μm thick sections were subjected to immunohistochemical analysis according to the streptavidin–biotin peroxidase complex system (UltraVision Large Volume Detection System Anti-Polyvalent, HRP; Lab Vision Corporation). Briefly, deparaffinised and rehydrated slides were submitted to heat-induced antigen retrieval for 20 min at 98°C with 10 mM citrate buffer (pH6.0). After incubation with the primary antibodies raised against RKIP (dilution 1:600; incubation 2 h at RT; Upstate Biotechnology, Lake Placid, NY), the secondary biotinylated goat anti-polyvalent antibody was applied for 10 min followed by incubation with the streptavidin–peroxidase complex. The immune reaction was visualised by 3,3′-diamonobenzidine as a chromogen. All sections were counterstained with Gill-2 haematoxylin. For negative controls, primary antibody was replaced by a universal negative control antibody (CEA, rabbit anti-human, DAKO Corporation, Carpinteria, CA). A prostate carcinoma was used as positive control.

Tumour samples were evaluated for both extension and intensity of the immunoreactions. The score used was the

sum of the percentage of positive cells (0, negative; 1, less than 25% positive cells; 2, 26% to 50% positive cells and 3, more than 50% positive cells) and the staining intensity (0, negative; 1, weak; 2, moderate and 3, strong). Scores between 0 and 2 were classified as negative, 3 and 4 as moderate positive and 5 and 6 as strongly positive.

DNA isolation

Selected areas contained at least 85% of tumour tissue were macrodissected into a microfuge tube using a sterile needle (Neolus, 25G-0.5 mm) and DNA isolation was performed using Qiagen's QIAamp® DNA Micro Kit, as previously described [42].

Methylation analysis of *RKIP* promoter

DNA methylation pattern in the promoter region of the *RKIP* gene was determined by methylation-specific PCR (MSP), as previously described [39] with some modifications. Briefly, bisulphite treatment of 200 ng DNA was done using EZ DNA Methylation Golf Kit (Zymo Research Corporation, USA) according to the manufactures instructions. The PCR was carried out in a total volume of 15 µl, consisting of 1 µl of bisulphite modified DNA, 0.2 µM of both sense and anti-sense primers (MWG-Biotech, Ebersberg, Germany), 200 µM of dNTPs (Fermentas, USA), 1,5 mM of MgCl2 (Bioron, Germany), 1× Taq Buffer incomplete (Bioron, Germany) and 1 U of Taq Superhot DNA Polymerase (Bioron, Germany). The reaction consisted of an initial denaturation at 95°C for 10 min, followed by 40 cycles with denaturation at 95°C for 30 s, annealing at 52–58°C for 30 s and extension at 72°C for 30 s, followed by a final extension for 10 min at 72°C, in a Thermocycler (BioRad). To MSP reaction, were used specific primers to distinguish methylated DNA (204 bp PCR product) from unmethylated DNA (205 bp PCR product), as described [39]. CpGenome Universal Methylated DNA (Chemicon International, USA) was used as methylated control. Blood DNA of a young healthy individual was used as unmethylated control.

Statistical analysis

The available clinical–pathological and immunohistochemistry data were analysed with SPSS software for Windows,

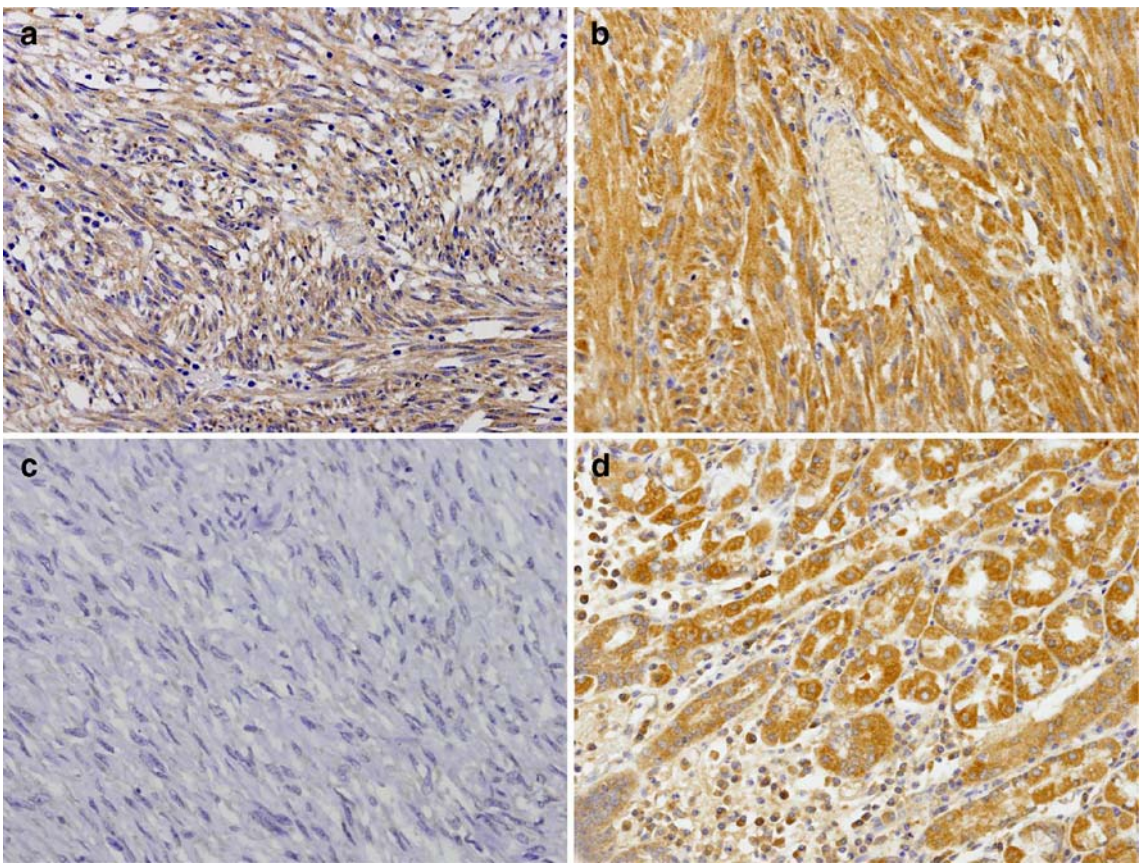

Fig. 1 Immunohistochemistry analysis of RKIP in GISTs. **a** Weak expression (×200), **b** strong expression (×200), **c** negative expression (×200), **d** positive expression of RKIP in normal adjacent tissue (×200)

version 15.0. Correlations between categorical variables were performed using Fischer's exact test. Disease-specific survival (DSS) was calculated from the time of diagnosis until death related with the disease, or censored at the time of latest follow-up, as described [10]. Cumulative survival probabilities were calculated using the Kaplan–Meier method. Differences between survival rates were tested with the log-rank test. p value inferior to 0.05 was considered significant.

Table 1 Association between RKIP expression and clinical–pathological parameters in GISTs (n=70)

Parameter	RKIP expression			
	N	Negative (%)	Positive (%)	p[a]
CD117 expression				
Negative	6	2 (33.3)	4 (66.7)	0.079
Positive	64	4 (6.3)	60 (93.7)

Results

RKIP expression

In the present study, we used a series of 70 GISTs which comprises 91.4% of CD117 positive cases and 63% of *KIT/PDGFRA* mutated GISTs, as previously characterised [41]. Immunohistochemical approach was done to detect RKIP protein expression and distribution in GIST cases. We observed cytoplasmatic expression of RKIP in 64 (91.5%) of the 70 GISTs studied: 30 cases showed moderate and 34 strong positivity (Fig. 1a and b). The remaining 8.5% (6/70) of cases were considered as negative for RKIP expression (Fig. 1c). In a subset of cases, it was possible to analyse the normal adjacent tissue that showed to be strongly positive for RKIP expression (Fig. 1d).

RKIP methylation

To determine whether absence of RKIP expression was due to gene promoter hypermethylation, we performed methylation-specifc PCR in all six cases without RKIP expression. None of the cases exhibited *RKIP* promoter hypermethylation (Fig. 2).

Clinical–pathological features and statistical analysis

After univariate statistical analysis we observed that there is no correlation between RKIP expression and CD117 staining and *KIT/PDGFRA* mutations status (Table 1). Concerning clinical–pathological data, no significant correlations ($p>0.05$) were found between RKIP expression and age, gender, risk grade, cellular morphology, tumour size and mitotic index (Table 1). RKIP negativity was correlated with presence of necrosis ($p=0.038$). There was a tendency ($p=0.051$) for absence of RKIP expression in gastric GISTs and a tendency ($p=0.058$) for the development of metastasis in RKIP negative cases (Table 1).

Regarding clinical–pathological parameters and disease-specific survival (univariate analysis), we found that a shorter DSS was significantly associated with male gender ($p=0.014$), high-risk GISTs ($p<0.001$), tumour size >10 cm ($p=0.001$), mitotic index >5 ($p=0.009$) and development of metastasis ($p<0.001$). Loss of RKIP expression was significantly ($p=0.023$) associated with poor DSS (Table 1 and Fig. 3). Only three cases were treated with imatinib-based therapy, hampering any statistical analysis. The low number of cases precluded multivariate analysis of the studied parameters.

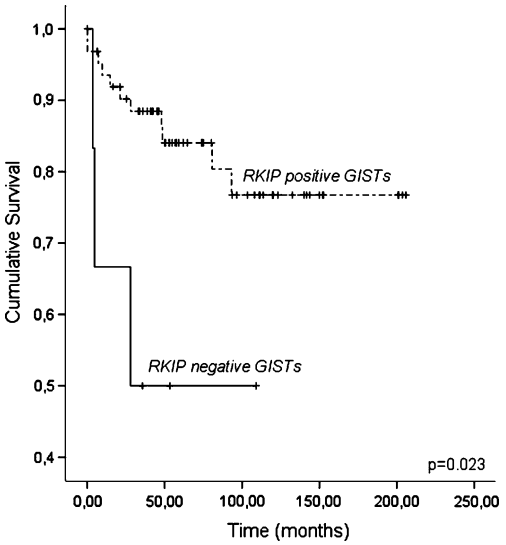

Fig. 3 Disease-specific survival (DSS) according to RKIP expression in GISTs ($n=70$). Cumulative survival is significantly lower in cases with RKIP loss of expression ($p=0.023$)

Discussion

Unresectable or metastatic GIST is a fatal disease resistant to conventional cytotoxic chemo and radiotherapy. The median survival time for patients with metastatic GIST is approximately 20 months, and 9–12 months for patients with local recurrences [43]. Treatment with imatinib mesylate is the first option for metastatic disease [44]. However, further molecular characterization is warranted for the treatment of primary and secondary imatinib-resistant GISTs. Furthermore, excepting *KIT* and *PDGFRA* mutations, no other molecular alterations have been consistently associated with prognosis of GISTs [12, 13].

RKIP is considered to be a signal transduction modulator and a metastasis suppressor [45]. The first evidence came from cell lines derived from metastatic prostate carcinomas, which display decreased levels of RKIP as compared with primary tumour cell lines [27]. In human breast carcinoma [32] and metastatic colorectal carcinoma [34, 46], RKIP expression is consistently lost in lymph node metastases but not in primary tumours, supporting the suggestion that RKIP is downregulated in metastatic development. Moreover, overexpression of RKIP in vitro and in vivo prostate and melanoma tumour models suggest that RKIP represent an important suppressor of metastasis by decreasing vascular invasion [27, 29]. Consistent with the role of RKIP as a potent suppressor of metastatic development, several studies described that highly metastatic prostate carcinoma [27], malignant melanoma [29], breast cancer lymph node metastases [32], insulinoma [31], colorectal carcinoma [46], hepatocarcinoma [33], ovarian carcinoma [35], Merckel cell carcinoma [47] and thyroid carcinoma [48] display frequently a marked decrease in RKIP expression.

Work by Eves et al. [49] also indicates that the absence of RKIP may increase the genetic instability of the cell

while work with hepatoma cells suggests that the absence of RKIP may increase the rate of cell division [33].

Furthermore, loss of cytoplasmatic RKIP has also been associated with colorectal carcinoma recurrence [34] and with poor prognosis in prostate, colorectal and gastric adenocarcinomas [34, 36–38]. Recently, it was proposed that the level of RKIP in the blood can be used as a prognostic marker for prostate cancer patients [38]. Thus, loss of RKIP expression may be considered as a marker of tumour progression.

In our series, well-established prognostic markers (male gender, high risk, tumour size >10 cm, mitotic index >5 and development of metastasis) were significantly associated with DSS [10]. Regarding RKIP expression, our results in GISTs has shown that a negative cytoplasmatic expression, found in approximately 9% of the cases, is significantly correlated with the presence of necrosis and with DSS of GIST patients. Furthermore, a tendency was observed between the presence of RKIP expression and absence of metastasis. So far, there are no reported studies of RKIP expression in GISTs. We recently demonstrated that MAPK pathway alterations occur at low frequency in *KIT* and *PDGFRA* wild-type GISTs, corroborating the low percentage of RKIP absence of expression in the present study [16]. Further studies with a largest series are needed to validate RKIP expression as a prognostic marker in GISTs. Furthermore, it will be also interesting in the future to assess the expression levels of RKIP in the metastatic biopsies of GISTs.

Despite the increasing evidence that RKIP is lost during tumour progression, especially in metastasis, the mechanisms of RKIP down-regulation remains to be unraveled [21]. To further elucidate the genetic event that underlies RKIP down-regulation in GISTs, we analysed the methylation status of the CpG islands of RKIP promoter in RKIP negative GISTs. All six GISTs without RKIP expression were found unmethylated for RKIP promoter. Former studies concerning RKIP methylation are discrepant. RKIP methylation was described in a cohort of 12 patients with hyperplastic polyposis coli [39]. Noteworthy, the same authors, using 28 colorectal carcinomas, reported that methylation of the RKIP promoter was not responsible for loss of RKIP expression [46]. Recently, Al-Mulla et al. [21] reported that 72.5% of 40 RKIP negative colorectal carcinomas were methylated at the RKIP promoter, and suggested it as the major mechanism by which RKIP is silenced [21].

The role of RKIP in tumour progression and in metastases development raises hope for tailored therapeutic approaches, using drug-induced modulation of RKIP expression, to control tumour aggressiveness. Locostatin has already been shown to abrogate the ability of RKIP to inhibit Raf-1 [50]. In some prostate and breast carcinoma cell lines, increasing levels of RKIP expression re-sensitise cells to drug-induced apoptosis. In drug-sensitive cell lines, down-regulation of RKIP led to the resistance to DNA-damaging drugs [9-nitrocamptothecin, taxol and cisplatin] [28]. Rituximab up-regulates RKIP, which has been shown to sensitise non-Hodgkin's lymphoma cell lines to chemotherapeutic-induced apoptosis [51]. Both inhibition of the MEK–ERK pathway and inhibition of the NFkB pathway were suggested as possible mechanisms for these drug-sensitising effects [51]. Recently, RKIP expression levels in pituitary adenomas were found to correlate with both acute and long-term clinical response to octreotide [52]. Furthermore, Bonavida et al. demonstrated that nitric oxide mediated chemo/immunosensitization via inhibition of NFkB may also involve the induction of RKIP. Induction of RKIP inhibits anti-apoptotic pathways that regulate tumour cell sensitivity to apoptotic stimuli [53].

In the present study we describe for the first time that GIST RKIP expression levels correlate with clinical–pathological parameters in univariate analysis. We found that the loss of RKIP expression was independent of promoter methylation in a subset of GISTs. Most important, loss of RKIP was associated with tumour necrosis and with a poor survival, i.e., a potential prognostic marker for GIST patients. Further studies with larger series and with in vivo/in vitro tumour models are warranted to evaluate the role of RKIP in metastatic development and survival of GIST patients.

Abstract The aim of this study was to clarify whether diffuse large B-cell lymphoma (DLBCL) with a high number of epithelioid histiocytes (DLBCL-EH) could have distinctive clinicopathological characteristics. Clinicopathological findings in 22 cases with DLBCL-EH and, as a control, 96 cases with ordinary type of DLBCL were analyzed. There were ten men and 12 women with ages ranging from 38 to 91 (median, 64) years. The primary site was lymph node in 16 cases, extranodal organs in three, and unknown in three. Stage of disease was I in five cases, II in three, III in nine, and IV in five. Histologically, there was a diffuse proliferation of large lymphoid cells admixed with numerous clusters of epithelioid histiocytes sprinkling throughout the lesions. Immunohistochemically, the large lymphoid cells were $CD20^{+}$, $CD15^{-}$, and $CD3^{-}$ and positive for CD10, bcl-6, and MUM1 in nine (41%), eight (36%), and 12 (55%) of 22 cases, respectively. Epstein–Barr virus positive rate was higher in DLBCL-EH (23.8%) than that in ordinary DLBCL (4.5%; $P<0.05$). Clonality analysis revealed monoclonal bands in all of the examined 20 cases with DLBCL-EH. Multivariate analysis revealed the prominent epithelioid reaction to be an independent factor for favorable prognosis. These findings suggest that DLBCL-EH could be a specific morphological variant of DLBCL associated with a better prognosis.

Introduction

In the World Health Organization (WHO) classification for lymphoid neoplasias, malignant lymphomas are largely divided into B-cell neoplasia, T/NK-cell neoplasia, and Hodgkin's lymphoma (HL). Diffuse large B-cell lymphoma (DLBCL), the most common category constituting about 30% of all lymphomas in the world, is defined as a diffuse proliferation of large neoplastic lymphoid B cells [1, 2]. Based on this criteria, it is

postulated that DLBCL comprises morphologically, immunohistochemically, and clinically heterogeneous tumors with each unique clinical and pathologic features. Therefore, attempts have been undertaken to classify the DLBCL into biologically and clinically relevant subgroups. On the basis of the gene expression profile, DLBCL could be categorized into the germinal center B-cell type (GCB) and activated B-cell type (ABC) [3, 4]. Approximately 50% of adult DLBCLs are reported to be GCB subgroup [3].

DLBCL is categorized as one of the aggressive non-Hodgkin's lymphomas (NHL). At present, the International Prognostic Index (IPI) is widely adopted for the prediction of outcome in patients with aggressive NHL [5]. It incorporates patient age, performance status, serum lactate dehydrogenase (LDH), clinical stage, and number of extranodal lesions.

Through a review of cases registered with Osaka Lymphoma Study Group (OLSG), we found 22 cases of DLBCL with a high number of epithelioid histiocytes (DLBCL-EH). Follow-up study revealed that patients with DLBCL-EH showed a much more favorable course than ordinary DLBCL.

Patients and methods

Patients

From November 1999 to December 2007, a total of 3,468 cases were registered with OLSG, Japan. Histologic specimens obtained by biopsy were fixed in 10% formalin and routinely processed for paraffin embedding. Histologic sections, cut at 4 μm, were stained with hematoxylin and eosin and immunoperoxidase procedure (ABC method). All of the histologic sections were reviewed by one of the authors (KA) and classified according to the WHO classification. A diagnosis of malignant lymphoma was confirmed in 2,808 of 3,468 cases (81.0%). Of these 2,808 cases, 2,541 (90.5%) were NHL and 267 (9.5%) HL. The number of DLBCL cases was 1,220, which constituted 48.0% of all NHL. In 22 cases (1.8%) of DLBCL, there was a diffuse proliferation of large B-lymphoid cells admixed with numerous clusters of epithelioid histiocytes sprinkling throughout the lesions mimicking "Lennert lymphoma": They were selected for the present study. Ninety-six cases of DLBCL registered during August 2000–May 2005 were used as the control group (DLBCL-CG) because adequate clinical data and unstained sections for additional immunohistochemical analyses and in situ hybridization were available. Clinicopathological findings of DLBCL-EH and DLBCL-CG are summarized in Table 1.

Adequate clinical information was available in all patients. There were ten men and 12 women with ages ranging from 38 to 91 (median, 64) years. Primary site was lymph node in 16 cases and extranodal organs (spleen, orbit, and spinal epidural region) in three. Primary site could not be defined in three cases due to advanced disease involving both lymph nodes and extranodal organs. On the basis of the records of physical examinations, surgical notes, and pathologic examinations of the specimens, the Ann Arbor staging system was applied. Stage of disease was I in five cases, II in three, III in nine, and IV in five. The IPI score was calculated with five adverse factors (age>60 years, Ann Arbor stages III and IV, Eastern

Cooperative Oncology Group performance scores 2–4, elevation of serum LDH, and two or more extranodal lesions) present at the time of diagnosis [5]. For cases under 60 years, an age-adjusted IPI score was applied, in which advanced stage, low performance score, and elevation of LDH were considered as adverse factors [5]. In one patient (67-year-old man) with stage II disease at presentation, lymphadenopathy disappeared without any adjuvant therapy and the complete remission continued for more than 4 years. Chromosomal analysis in this case revealed t(8;14)(q24.1;q32). All of the remaining patients with DLBCL-EH received the combination chemotherapy, cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP) in 15 cases, pirarubicin, cyclophosphamide, vincristine, and prednisolone (THP-COP) in three, and etoposide, mitoxantrone, cyclophosphamide, vincristine, prednisolone, and bleomycin (VNCOP-B) in two. One patient underwent combined chemotherapy and radiotherapy. In the latter half of 2003, rituximab was included in the regimen for most patients. Rituximab (R) was used in 14 (63.6%) of 22 DLBCL-EH patients: ten received R-CHOP, two R-THP-COP, one R-VNCOP-B, and one R only. Rituximab was used in 51 (53.1%) of 96 DLBCL-CG patients. There was not a statistically significant difference in frequency of patients receiving rituximab between DLBCL-EH and DLBCL-CG. Clinical outcome was evaluated according to the guidelines of the International Workshop to standardize response criteria for NHL [6]. Recurrence of disease after the chemotherapy was found in three patients with DLBCL-EH: All these patients underwent biopsy.

Immunohistochemistry

Monoclonal antibodies used for immunophenotyping were CD20, CD3, CD8, Bcl-6, MUM1, CD68, MIB-1, CD15, CD30 (Dakocytomation, Glostrup, Denmark, dilution at 1:400, 1:50, 1:100, 1:50, 1:100, 1:100, 1:1, 1:25, 1:50, respectively), CD4 (Novocastra Laboratories, Newcastle, UK, 1:40), CD10, CD23 (Nichirei Biosciences, Tokyo, Japan, used as prediluted antibodies), and programmed cell death 1 (PD-1; abcam, Tokyo, Japan, 1:50). Tonsils with reactive lymphoid hyperplasia served as external control tissues. In MIB-1 staining, the number of positive cells among 300–1,000 large lymphoid cells was counted: MIB-1 index was calculated as positive cells/100 cells.

In situ hybridization

RNA in situ hybridization using the Epstein–Barr encoded RNAs (EBER-1) probe was performed to examine the presence of Epstein–Barr virus (EBV) genome on the formalin-fixed paraffin-embedded sections according to the method previously described with some modifications [7]. Briefly, a 30-base oligonucleotide probe, 5′-AGACACCGTCCTCACCACC CGGGACTTGTA-3′, which was the sense and antisense for a portion of the EBER-1 gene, a region of the EBV genome that is actively transcribed in latently infected cells, was synthesized using a DNA synthesizer. As a positive control, the Raji cell line was used. As negative controls, the hybridizing mixture containing sense or antisense probe after RNase treatment was used. The presence of EBV genomes was evaluated in 21 cases of DLBCL-EH and 44 cases of DLBCL-CG. When the in situ hybridization yielded positive signals in the nuclei of more than 1% of the proliferating cells, such cases were defined as EBV positive.

Clonality analysis with the use of Ig and BCL2-IgH gene rearrangement

One to five sections with 4–10 μm thickness were cut from the paraffin-embedded samples, deparaffinized with xylene, washed with absolute and 70% ethanol, and subsequently digested in lysis buffer (50 mM Tris–HCl, 10 mM EDTA, 150 mM NaCl, 0.5% sodium dodecyl sulfate, and 0.4 mg/l proteinase K) at 55°C for overnight. DNA was extracted with phenol-chloroform extraction-based protocol, followed by ethanol precipitation and re-dissolved in TE buffer. Immunoglobulin (Ig) gene rearrangement was assessed by eight PCRs with 41 primers according to BIOMED-2 protocols [four multiplex PCRs and one single PCR with 28 primers for Ig heavy chain (IgH) gene; two multiplex PCRs with ten primers for Ig kappa light chain (Igκ) gene; one multiplex PCR with three primers for Ig lambda light chain (Igλ) gene] [8]. When the PCR amplification was not sufficient because of small amount of extracted DNA or fragmentation of DNA, we modified PCR condition of BIOMED-2 protocols as described in Table 2. The amplified PCR products were electrophoresed in 5.0% or 6.6% polyacrylamide gel based on fragment

Table 2 Summary of the PCR protocols for the original and modified BIOMED-2 PCR reactions

	Original BIOMED-2	Modified BIOMED-2
PCR reaction mix		
Template DNA	40 ng/50 μL	20 ng/50 μL
dNTP	200 μM	No change
Buffer ($MgCl_2$)	1.5 mM	No change
Primer	0.2 μM	0.5 μM
AmpliTaq Gold	1 U/50 μL	2.5 U/50 μL
PCR run parameters		
Denature	30 s	No change
Annealing	30 s	No change
Extention	30 s	No change
Cycles	35	40

sizes. For detection of BCL2-IgH chimera gene generated by t(14;18)(q32;q21), BIOMED-2 PCR protocol for MBR, 3′MBR, and mcr was applied as described previously [8]. Genotypic study could not be performed in two DLBCL-EH cases because enough amounts of paraffin-embedded materials for DNA extraction were not available.

Follow-up

The DLBCL-EH patients were followed until June 2008; the follow-up periods for survivors ranged from 2.8 to 98.8 (average, 35.1) months. Nineteen of 22 patients were alive at the end of the observation period. The Kaplan–Meier estimated survival rate for the DLBCL-EH at 5 years was 85.9%. As for the control group, the follow-up periods for survivors ranged from 11 to 99 (average, 45) months. Forty-nine of 96 patients were alive at the end of the observation period: 5-year survival rate was 50%.

Statistical analysis

Differences in frequencies of various clinical and pathologic factors between cases with DLBCL-EH and DLBCL-CG were compared with the chi-square test or the Fisher's exact probability test. Differences of means were compared with the *t* test or the Mann–Whitney test. Survival curves and overall survival rates were calculated with the Kaplan–Meyer method and were compared by the log-rank test. Multivariate analysis was performed with the Cox proportional hazard regression model.

Results

Histologic and immunohistochemical findings

Outstanding feature of DLBCL-EH is the presence of numerous clusters of epithelioid histiocytes sprinkled throughout the lesion with appearance of Langhans type or foreign body-type giant cells in two cases; among them, large lymphoid cells were discernible with occasional formation of large areas of the proliferating cells. This histologic appearance could be called lymphoepithelioid lymphoma (Fig. 1). Varying amount of small lymphocytes were present in the lesions but never predominated over the epithelioid histiocytes even when they were numerous. They were predominantly CD8 positive in 13 of 21 cases examined and rather equal in number of CD4- and CD8-positive lymphocytes in the remaining eight cases. Immunohistochemistry of CD4 and CD8 was not available in one DLBCL-EH case. More than 10% of small T lymphocytes were PD-1 positive in three of 21 DLBCL-EH cases. Staining with CD23 revealed the absence of follicular dendritic cells in 18 cases and faintly stained meshwork in two. Plasma cells and eosinophils were frequent in two cases. As a result, all of DLBCL-EH showed a polymorphous pattern of proliferation. Necrotic foci were occasional in three cases. Appearance of fine fibrous tissues in the background of the lesions was more frequent in the DLBCL-EH (17 of 22 cases) compared to that in DLBCL-CG (47 of 96 cases; $P<0.05$; Table 1).

Morphologic appearances of the large lymphoid cells were identical to centroblasts in 13 cases, centroblasts and immunoblasts in five, and unclassifiable because of tissue artifacts in four. Immunohistochemically, the large lymphoid cells were $CD20^+$ (Fig. 1), $CD3^-$, and positive for CD10, bcl-6, and MUM1 in nine (41%), 8 (36%) and 12 (55%) of 22 cases, respectively. DLBCL-EH could be categorized into GCB with $CD10^+$ or $CD10^-$/$bcl\text{-}6^+$/$MUM1^-$ and non-GCB with $CD10^-$/$bcl\text{-}6^-$ or $CD10^-$/$bcl\text{-}6^+$/$MUM1^+$ [9]. Ratio of GCB to non-GCB between DLBCL-EH and DLBCL-CG was similar in the present series. Large lymphoid cells were CD15 negative in all cases (0/21) and CD30 positive in three of 20 cases. Mean mitotic count per high-power field and MIB-1 labeling index among large lymphoid cells were 2.7 and 57.1, respectively.

Recurrence of disease was found in three patients: They were biopsied. The histology of two cases was also DLBCL-EH with appearance of Reed–Sternberg (R–S)-like cells and increased number of eosinophils in one. R–S-like cells were never found in the initial biopsy of any cases. In one case, precise evaluation was not possible because of tissue artifacts.

In situ hybridization

In situ hybridization with EBER-1 probe yielded positive signals in the nucleus of large lymphoid cells in five (23.8%) of 21 cases with DLBCL-EH (Fig. 1). Percentage of EBV-positive cells among large lymphoid cells was 3% in one case, 20% in two, 30% in one, and 70% in one. The EBV positive rate in DLBCL-EH was higher than that in two (4.5%) of 44 cases with DLBCL-CG ($P<0.05$). DLBCL-EH in one patient, who showed the spontaneous regression of lymphadenopathy without adjuvant therapy, was EBV positive.

Molecular genetic study

Genotypic study was performed in 20 cases with DLBCL-EH. All cases showed the monoclonal rearrangement of Ig genes with at least one primer. Monoclonal bands for both IgH and Ig light chain (IgL) genes were found in 17 cases, only for IgH gene in one, and only for IgL gene in two (Fig. 2). The BCL2-IgH gene rearrangement was detected in two (10%) of 20 cases examined. Tumor cells in these two cases showed the positive immunoreactivity for CD10.

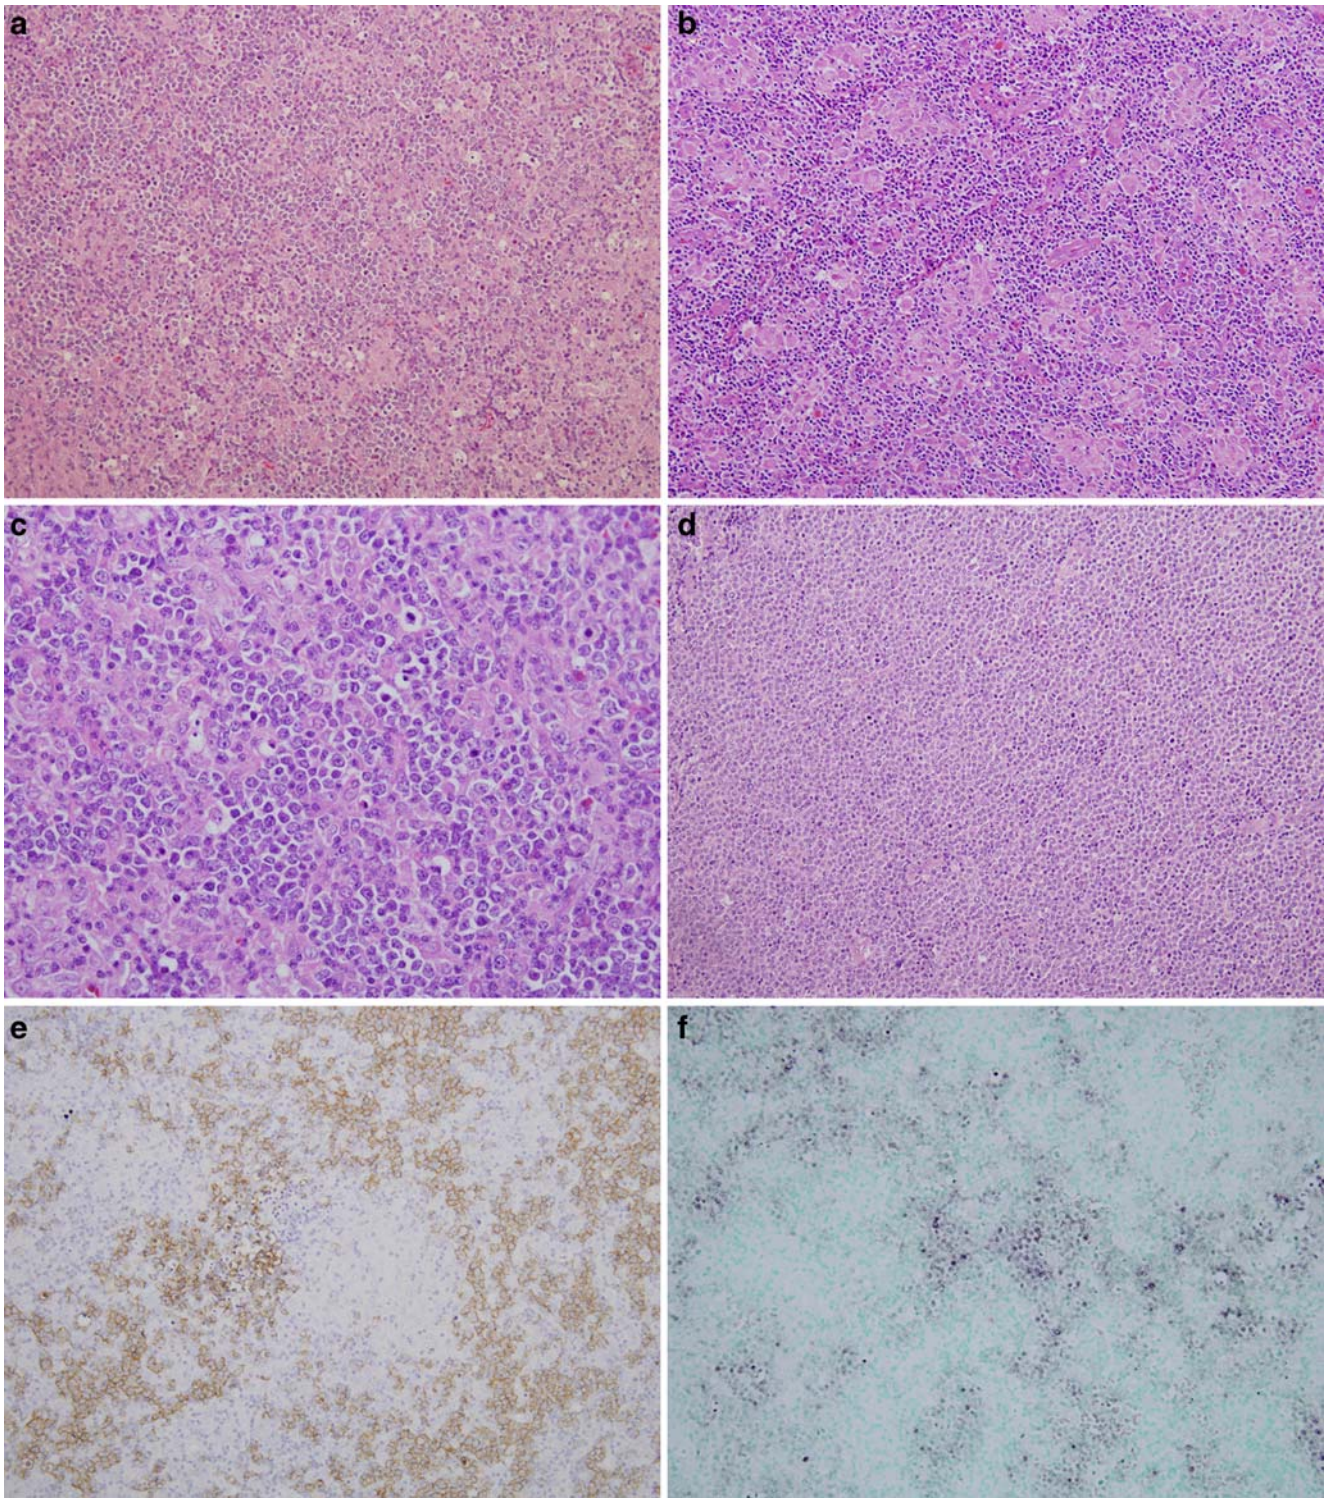

Fig. 1 **a** Diffuse large B-cell lymphoma (DLBCL) with a high number of epithelioid histiocytes (DLBCL-EH). There was a diffuse proliferation of large lymphoid cells admixed with numerous clusters of epithelioid histiocytes sprinkling throughout the lesions. A few small lymphoid cells were found, H&E ×200. **b** Many reactive lymphoid cells were found among clusters of epithelioid histiocytes together with diffuse proliferation of large lymphoid cells in some cases with DLBCL-EH, H&E ×200. **c** Higher magnification illustrating the immunoblast- and centroblast-like proliferating cells in DLBCL-EH, H&E ×400. **d** DLBCL with the ordinary histology showing almost monomorphous proliferation of large lymphoid cells, H&E ×200. **e** Immunohistochemically, the large lymphoid cells in DLBCL-EH were $CD20^{+}$, ×200. **f** In situ hybridization with EBER-1 probe revealed positive signals in the nucleus of large lymphoid cells in DLBCL-EH, x200

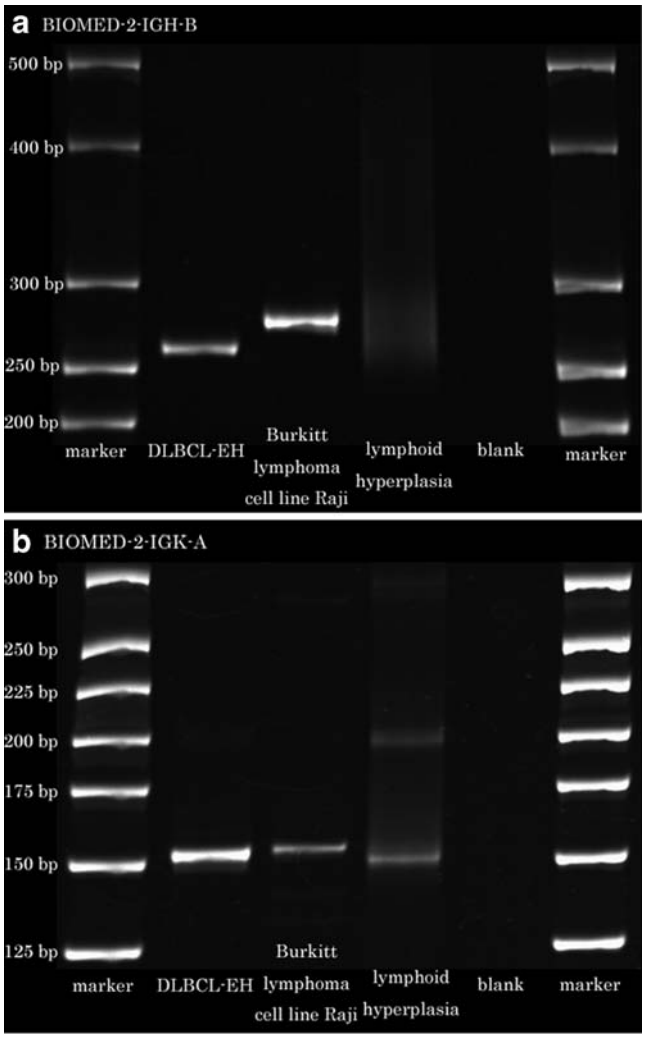

Fig. 2 Clonality analysis with use of immunoglobulin (Ig) heavy chain (IgH) gene (**a**) and Ig kappa light chain (Igκ) gene (**b**). Monoclonal bands were found in lanes of diffuse large B-cell lymphoma with a high number of epithelioid histiocytes (DLBCL-EH) and Burkitt lymphoma cell line Raji

Clinical findings

Brief clinical and pathological findings are summarized in Table 1. There were no findings suggestive of the presence of immunodeficient conditions. Two patients had a past history of autoimmune diseases, one each of idiopathic thrombocytopenic purpura and rheumatoid arthritis. One patient had a past history of chronic hepatitis caused by hepatitis B virus. One patient suffered from chronic hepatitis caused by hepatitis C virus and prostatic cancer. Agents supposed to cause immunosuppression such as methotrexate, steroid, or chemotherapeutic drugs for cancer were never used in these patients. No significant differences were found in age, serum LDH level, performance status, number of involved extranodal organ, IPI, response for chemotherapy, and the ratio of GCB to non-GCB subgroup between cases with DLBCL-EH and DLBCL-CG. Female preponderance and the higher frequency of advanced disease (stage III+IV) were found in DLBCL-EH, but the differences of these factors between DLBCL-EH and DLBCL-CG were not significant. Significant difference was found in the primary site (nodal vs extranodal) between DLBCL-EH (16:3) and DLBCL-CG (39:35; $P<0.05$).

Prognostic factors

The estimated survival rate at 5 years for the DLBCL-EH (85.9%) was significantly higher than that for DLBCL-CG (50%; log-rank, $P<0.05$) (Fig. 3). Results of the univariate analysis are shown in Table 3. Elevated serum LDH level, low PS, advanced stage, involved extranodal organ>1, and high IPI score were unfavorable factors for prognosis. The presence of prominent epithelioid cell response and GCB subgroup were favorable factors for prognosis. Multivariate analysis revealed that low PS was an independent factor for poor prognosis, and prominent epithelioid cell response was a favorable prognostic factor (Table 4). GCB subgroup showed a marginal significance for favorable prognosis ($P=0.062$).

Discussion

In the WHO classification (2008), several variants of DLBCL, not otherwise specified, are listed such as T cell/histiocyte-rich large B-cell lymphoma (THRLBCL), primary DLBCL of the central nervous system, primary cutaneous DLBCL, leg type, and EBV-positive DLBCL of the elderly [1]. At first, a difference of DLBCL-EH from THRLBCL should be commented. The new classification provides a description that "THRLBCL is characterized by a limited number of scattered, large, atypical B-cells embedded in a background of abundant T cells and frequent histiocytes" [10]. In the DLBCL-EH, large B cells are numerous and form sheets of

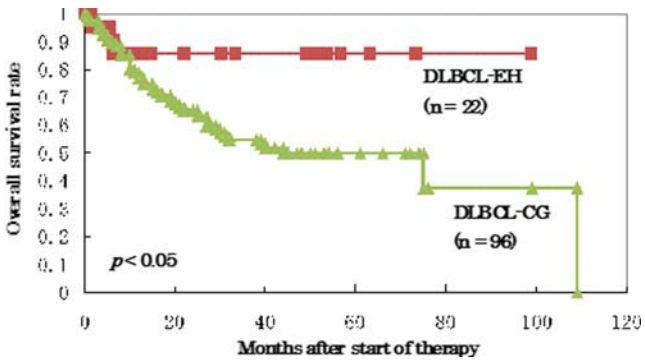

Fig. 3 Overall survival curve for patients with diffuse large B-cell lymphoma (DLBCL) with a high number of epithelioid histiocytes (DLBCL-EH) and DLBCL-control group (DLBCL-CG; Kaplan–Meier method). The estimated survival rate in patients with DLBCL-EH at 5 years (85.9%) was significantly favorable than that in DLBCL-CG (50.0%) (log-rank, $P=0.045$)

DLBCL-EH diffuse large B-cell lymphoma (DLBCL) with a high number of epithelioid histiocytes; *DLBCL-CG* DLBCL-control group, *OS* overall survival, *L/LI* low/low-intermediate, *HI/H*, high-intermediate/high, *GCB* germinal center B-cell type, *NS* not significant

cells as shown in Fig. 1a and e. Marked appearance of cluster of epithelioid histiocytes, as shown in this study (Fig. 1), is not described and illustrated. Lymphoepithelioid B-cell lymphoma was differentiated from THRLBCL by predominance of histiocytes to small lymphocytes and their epithelioid morphologies, not by percentages of histiocytes and lymphocytes in the present study as also in the study by Achten et al. [11]. Achten et al. described that histiocytes in their cases with histiocyte-rich, T-cell-rich B-cell lymphoma, which corresponds to the THRLBCL, were not epithelioid in appearances. Chetaille et al. [12] reported that the T cells in all of THRLBCL cases expressed PD-1 antigen. This showed a clear contrast to the present cases, in which only three of 21 cases were PD-1 positive.

Table 4 Multivariate analysis of clinicopathological factors for overall survival of patients with DLBCL-EH and DLBCL–CG

Characteristic	Relative risk	95% CI	*P* value

DLBCL-EH diffuse large B-cell lymphoma (DLBCL) with a high number of epithelioid histiocytes, *DLBCL-CG* DLBCL control group, *CI* confidence interval, *IPI* International prognostic index, *HI/H* high-intermediate/high, *NS* not significant

Some of the similar cases to the present series were included in the previous reports under the headings of TCR-, T/HR- or TC/HR-(L)BCL [13–15], but prognosis of this special type of THRLBCL was not commented in comparison with representative cases of THRLBCL without prominent epithelioid reaction. Large B-cell lymphomas generally fail to provoke a substantial immune reaction; therefore, prominent epithelioid cell reaction is exceptional: Frequency of DLBCL-EH among all DLBCL cases registered with the OLSG is only 1.8%.

Patients with DLBCL-EH showed the significantly favorable prognosis than those with DLBCL-CG, i.e., ordinary type of DLBCL. This finding contrasts to the disease diagnosed as THRLBCL by the WHO criteria, which shows similar prognosis to stage- and IPI-matched ordinary DLBCL [15–18]. The present multivariate analysis revealed that the prominent epithelioid cell response was an independent factor for favorable prognosis. The present clonality analysis based on the Ig gene rearrangement confirmed the clonal nature of B-cell proliferation in the DLBCL-EH. Proliferative activity, as revealed by MIB-1 labeling index, was rather similar between DLBCL-EH and DLBCL-CG. It has been reported that DLBCL of non-GCB subgroup showed a more unfavorable prognosis than that of GCB subgroup [4, 9, 19]. Frequency of GCB and non-GCB cases in the present series was rather similar, which is identical to the previous reports on DLBCL [3].

DLBCL is divided into the two types based on the gene expression profiles of the proliferating cells, i.e., GCB type and ABC with more favorable prognosis of the former than the latter type [3, 4]. Recently, Lenz et al. [20] reported that DLBCL could be categorized based on the gene expression signatures of stromal cells surrounding the neoplastic large B-lymphoid cells. The stromal cell gene signature found in cases showing histiocyte-rich host reaction to the lymphoma cells was correlated with favorable prognosis of the patients. This finding is concordant with the present finding that DLBCL-EH shows a favorable prognosis.

DLBCL-EH is characterized by a predominantly nodal presentation and higher EBV positive rate compared to DLBCL-CG. EBV positive rate in the ordinary type of DLBCL is reported to be less than 10% worldwide. Therefore, the higher EBV-positive rate in the DLBCL-EH is unique. One of the present patients with EBV-positive DLBCL-EH showed the spontaneous regression without adjuvant therapy. Spontaneous regressions of EBV-positive DLBCL were reported previously [21, 22], but their histologies were not epithelioid rich.

Present findings suggest that DLBCL-EH could be a morphological variant of DLBCL that has an apparent better clinical outcome than conventional DLBCL. The peculiar morphological aspect of the tumor raises several important differential diagnoses. Then, differential points of this lymphoma from other types of diseases are discussed below. Firstly, distinction of DLBCL-EH from the lymphoepithelioid cell variant of peripheral T-cell lymphoma, not otherwise specified (PTCL-NOS) is necessary. Indeed, the authors, as the pathology board members of the OLSG, initially interpreted the histologic pictures of DLBCL-EH as the lymphoepithelioid cell variant of PTCL-NOS on the purely morphological grounds. However, the immunohistochemistry revealed the B-cell nature of the proliferating large lymphoid cells. In addition, genotypic study confirmed the clonal proliferation of B cells. The presence of fine fibrous tissues and necrotic foci might be frequent to occasional in DLBCL-EH but uncommon in the lymphoepithelioid cell variant of PTCL-NOS.

Classical HL of mixed cellularity type (CHL-MC) occasionally show the histology containing a high content of epithelioid histiocytes, with rather favorable clinical course than ordinary CHL-MC [23]. Thus, distinction of DLBCL-EH from CHL-MC may be needed in some cases. Indeed, Reed–Sternberg cell-like cells appeared in the recurrent lesion of one of the present cases. However, diagnostic Reed–Sternberg cells were absent even in this lesion. Such kind of cells was never found in the initial biopsy of any cases. Complete absence of CD15-positive cells and presence of CD30-positive cells in a quite limited number of the present DLBCL-EH cases indicated that a diagnosis of CHL-MC was unlikely. CD30 immunoreactivity seems not to be a distinguishing feature of CHL, as it may be observed in the THRLBCL as well [11]. In addition, clonal B-cell proliferation was confirmed in all of the DLBCL-EH cases examined. Although mononuclear Hodgkin and multinucleated Reed–Sternberg (HRS) cells contain monoclonal Ig gene in greater than 98% of cases and monoclonal T-cell receptor gene in rare cases in the DNA isolated from the single HRS cells, the monoclonal rearrangements are usually not detectable in the whole tissue DNA [24]. With combination of histologic, immunohistologic findings and genotypic study, distinction of DLBCL-EH from CHL-MC with a high content of epithelioid histiocytes is possible.

In conclusion, the DLBCL-EH is distinct from ordinary DLBCL in its higher EBV-positive rate, predominant nodal presentation, and favorable prognosis. Because the follow-up period in the present series was rather short, further study on the DLBCL-EH with more high number of cases and adequately long follow-up period would provide a robust conclusion.

ORIGINAL ARTICLE

DLK is a novel immunohistochemical marker for adrenal gland tumors

Eszter Turányi · Katalin Dezső · Sándor Paku · Peter Nagy

Received: 13 March 2009 / Revised: 19 June 2009 / Accepted: 30 July 2009 / Published online: 14 August 2009

Abstract Delta-like protein (DLK) is expressed in fetal and adult adrenal glands. We have investigated if this expression is maintained in adrenal gland-derived tumors. All the studied 37 cortical tumors, including five carcinomas, stained positively as well as the 13 examined pheochromocytomas. Thus, DLK is a very sensitive marker for adrenal tumors of cortical and medullary origin. Renal cell carcinomas, presenting the major differential diagnostic problem for cortical tumors, were all negative, as well as melanomas, which are similar to high portion of adrenocortical tumors that react with melan-A. However, all paragangliomas, some carcinoids, and thyroid medullary carcinomas were also positive for DLK. Therefore, this novel immunohistochemical marker seems useful for the identification of adrenocortical tumors while it has limited value for the distinction of pheochromocytomas from diagnostically related neuroendocrine tumors.

Introduction

Delta-like protein (DLK), an epidermal growth factor like multidomain glycoprotein, is expressed in several fetal tissues, e.g., in immature liver and in adult adrenal glands [1]. We have recently described [2] that DLK expression is maintained in the hepatoblasts upon malignant transformation, and it can be applied as a diagnostic immunohistochemical marker for hepatoblastomas. DLK expression has been reported in normal adrenal cortex [3], in ganglioneuroblastomas, in pheochromocytomas, and in other endocrine tumors [4–6], but no comprehensive immunohistochemical analysis has been performed on adrenocortical tumors. In this present work, we have collected adrenal gland-derived and differential diagnostically related tumors from our archives and investigated their DLK expression by standard immunohistochemistry. All the investigated adrenal gland-derived tumors are positive for DLK, and this immunophenotype, especially in cortical tumors, can be useful to resolve certain aspects of diagnostic challenges.

Materials and methods

Formalin-fixed, paraffin-embedded tissue was used for immunohistochemical staining. The most important parameters of the investigated tumors are listed in Tables 1 and 2. No peculiar variants of cortical adenomas (black, oncocytic, etc.) occurred among the investigated tumors.

Traditional, avidin biotin-based immunohistochemistry was performed. In brief, after blocking the endogenous peroxidase activity in methanol and hydrogen peroxide, the antigens were retrieved by heating in 10 mmol citrate buffer (pH 7.0) in a microwave oven for 10 min. The sections were then blocked with normal horse serum (blocking

serum from the kit) diluted in phosphate-buffered saline before overnight incubation with the primary antibodies (DLK: R&D Systems, Minneapolis, MN, USA, Catalog number: AF1144; goat polyclonal antibody, dilution 1:100) at 4°C. The VECTASTAIN Elite ABC Kit (goat; Vector Laboratories, Burlingame, CA, USA, Catalog number: PK-6105) was used for developing the reactions with diaminobenzidine as chromogen. The negative control slides were covered by normal goat serum (Vector Laboratories, Catalog number: S-1000) instead of the primary antibody. No staining was observed on the negative controls (data not shown). Hepatoblastomas were used as positive controls.

Results

DLK expression in normal adrenal gland

In our immunohistochemical staining in the peritumoral, normal adrenal gland confirms earlier observations [1, 3]. DLK is present in both substances of the glands, contrary to their different embryological origin. The staining pattern is usually not even; the reaction is stronger in the cells of the zona glomerulosa and decreases in central direction (data not shown).

Carcinoid	1	0	2	19	22
Thyroid medullary carcinoma	3	2	0	6	11

+ positive reaction in less than 5%, ++ positive reaction between 5% and 50%,+++ positive reaction over 50% of the tumor area

DLK expression in adrenal gland tumors

Each of the examined 37 adrenocortical tumors stained positively for DLK (Fig. 1a, b). The reaction was usually diffuse; it always covered at least 20% of the tumorous areas. The staining pattern on cellular level was variable. In most cases, in addition to the diffuse cytoplasmic staining, strong paranuclear dots were observed, and membranous reaction was present occasionally (Fig. 1b). The different staining patterns were mixed sometimes in the same tumor, but usually, there was a dominant type of distribution. We could not observe any correlation among the reaction patterns and/or the clinical, morphological characteristics, and the endocrine activity of the tumors (data not shown). The situation was similar to hepatoblastomas [2], when no connection was recognized between the distribution of the DLK immunostaining and other features of the tumors.

Metastasis formation proved the malignant nature of five of the investigated cortical tumors. Neither the intensity nor the distribution of the reaction was different in the carcinomas and adenomas. The pulmonary metastasis of one carcinoma was available, and it was positive for DLK.

Similar to the cortical tumors, each investigated pheochromocytomas proved to be DLK positive (Fig. 1c). The dominant but not exclusive reaction was the dot formation in paranuclear position. The immunostaining was confined to the tumor cells, and no reliable reaction was present on the endothelial cells.

DLK expression in differential diagnostically related tumors

We stained several kidney tumors consisting of clear cells: 31 renal cell carcinomas (29 clear cell, 1 papillary, and 1 chromophobe carcinomas) and 9 angiomyolipomas for DLK, but no positive reaction was observed (Fig. 2a).

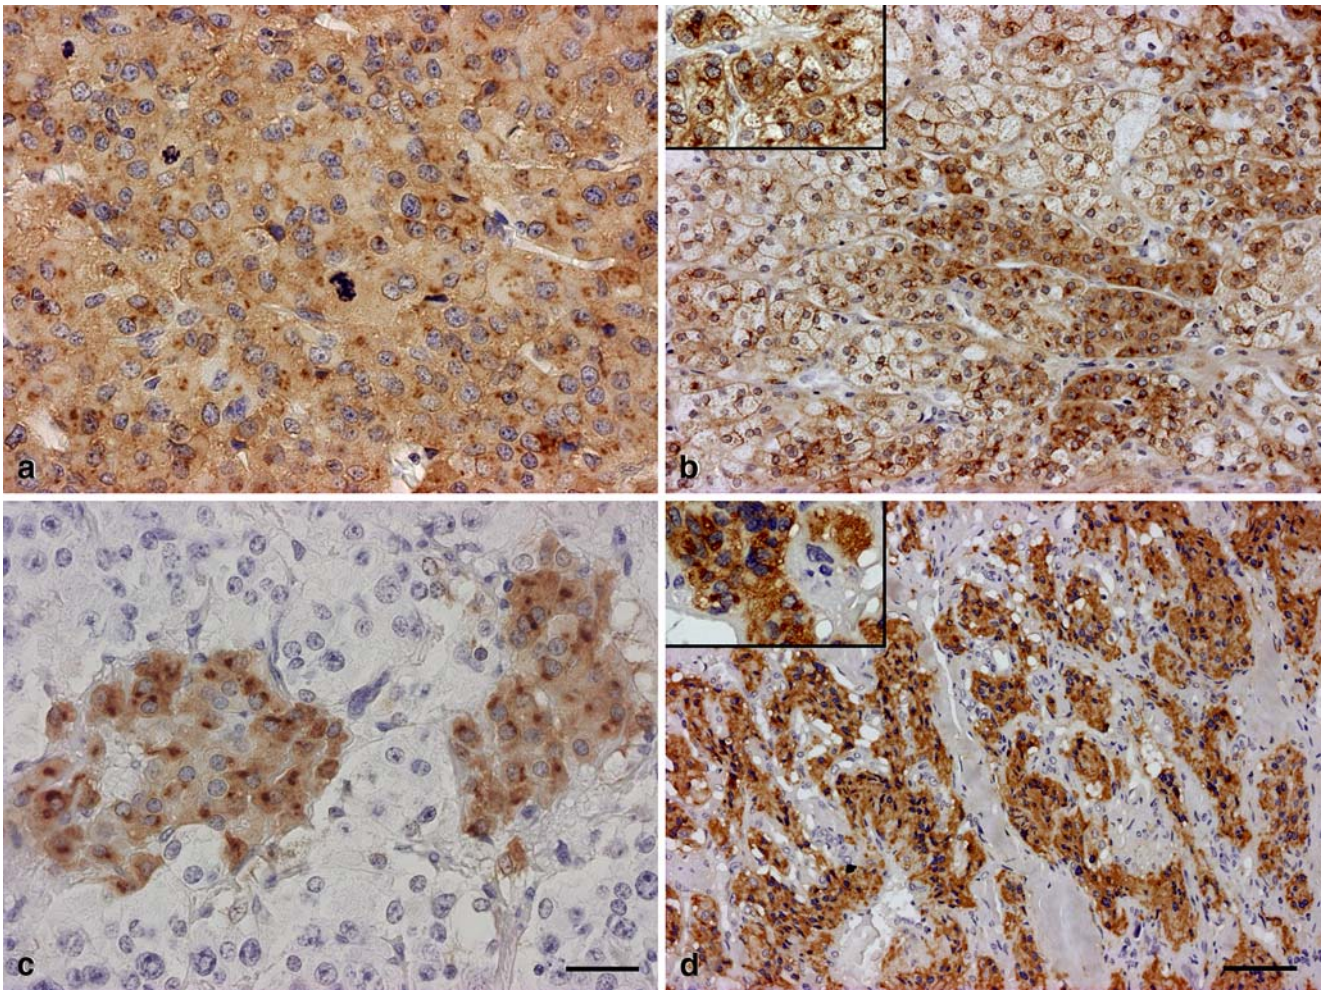

Fig. 1 DLK immunostaining in adrenocortical carcinoma (**a**), adrenocortical adenoma (**b**), pheochromocytoma (**c**), and paraganglioma (**d**). Note the membranous staining and paranuclear dots on the high magnification *inserts*. *Scale bars* for **a**, **c**: 50 μm; **b**, **d**: 100 μm

In the histogenesis of extra-adrenal pheochromocytomas, paragangliomas is basically identical with those of the adrenal tumors. So, it was not surprising that these tumors could not be distinguished from adrenal pheochromocytomas by DLK stainings (Fig. 1d). The majority of the other investigated neuroendocrine tumors: carcinoids (14 stomachs, 4 appendices, 1 ileum, 1 colon, 1 pancreas, and 1 lung) and thyroid medullary carcinomas were DLK negative, but positively stained tumors also occurred (Fig. 2b, c). There was diffuse reaction in one lung and one stomach tumors. Furthermore, in one additional stomach carcinoid, the DLK positivity was focal. Five of the 11 studied medullary carcinomas also reacted with the DLK antibody. The staining pattern was focal in three and intermediate in two samples. Neither of the melanomas were decorated by DLK (Fig. 2d). Finally, the negative control sections of all the investigated specimens remained unstained. The results of DLK immunostainings are summarized in Table 2.

Discussion

We have investigated the expression of DLK by immunohistochemistry in adrenal gland neoplasms and differential diagnostically related tumors. Each of the studied adrenocortical tumors and pheochromocytomas proved to be positive, but occasional reaction occurred in the other tumors as well. Thus, the sensitivity of DLK for adult adrenal tumors was 100% while the specificity on our samples was 87%. No neuroblastomas were included in this work, because DLK expression in this group of tumors has been thoroughly analyzed [4]. Neuroblastomas were reported negative while the differentiating cells of ganglioneuromas became positive. We observed similar staining on a few investigated tumors [2]. The presence of DLK messenger RNA (mRNA) in a human neuroblastoma cell line [5] also has been described.

The occurrence of DLK mRNA and protein has been documented in the normal adrenal gland several times [1,

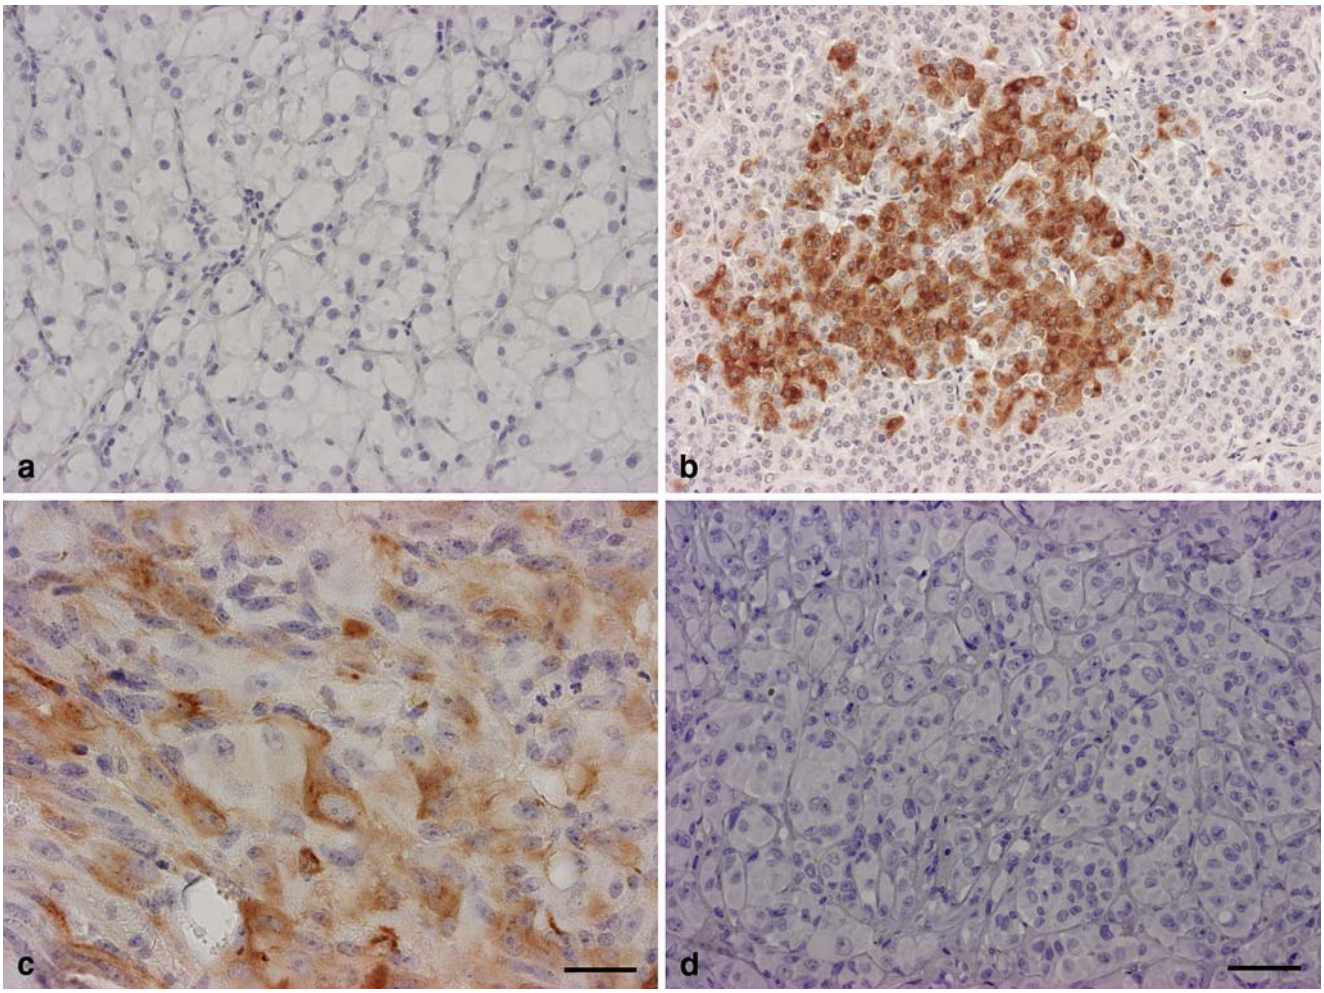

Fig. 2 DLK immunostaining in renal cell carcinoma (**a**), stomach carcinoid (**b**), thyroid medullary carcinoma (**c**), and melanoma (**d**). *Scale bars* for **a**, **b**, and **d** 100 μm; **c** 50 μm

7–9]. In fact, one of the alternative names for DLK is human adrenal-specific complementary DNA [8]. The presence of this antigen is well-documented in different neuroendocrine tumors. DLK is an established marker of small cell lung carcinoma and pulmonary carcinoids [5, 9]. It is present in certain endocrine tumors of the pancreas [6]. The tumor cells of pheochromocytomas were reported negative for DLK while it could be detected in the tumor vasculature [4]. Others reported the presence of DLK mRNA in a pheochromocytoma cell line [5].

As far as we know, nobody analyzed the DLK expression in adrenocortical tumors so far. All the studied adrenal cortex-derived tumors were positive in our present experiment. Although DLK is a new player among the routinely used immunohistochemical markers, its expression in adrenocortical tumors is not a unique feature. However, in certain context, our observation could be utilized in diagnostic algorithms. If we are challenged by a clear cell tumor from the adrenal region, the three major differential diagnostic problems are: (1) distinction between adrenal tumors and renal cell carcinomas, (2) distinction between adrenal cortical and medullar tumors, and (3) distinction between cortical adenomas and carcinomas. DLK, based on our results, cannot contribute to answer the latter two questions, but may be the key issue regarding the first problem. There are several overlaps between the immunophenotypes of renal cell carcinomas and adrenocortical tumors (vimentin positivity and uncertain keratin staining) [10, 11], and the clear cells of perivascular epithelioid cell component in angiomyolipomas may be also similar to adrenal tumors. Each investigated renal cell carcinomas and kidney angiomyolipomas were clearly negative, so the DLK staining would strongly support the diagnosis of adrenal tumors in such cases.

The value of the exact histopathological diagnosis from metastatic tumors will increase in the upcoming age of molecular targeted therapy. So far, no specific immunohistochemical marker for adrenocortical tumors has been established. There are a few new candidates (Ad4BP/SF-1, DAX-1) with very little available data [12]. Zhang et al.

[13] recommended the combination of melan-A, calretinin, and inhibin alpha for the differential diagnosis of adrenocortical tumors from other clear cell neoplasms. All of these antibodies recognize other tumors as well. Depending on the special differential diagnostic problem (e.g., distinction from melanomas), DLK may be an equally useful member of this battery.

DLK seems equally sensitive to recognize pheochromocytomas and paragangliomas. However, since other diagnostically related neuroendocrine tumors may be also positive, the diagnostic value of DLK among neuroendocrine tumors is not clear yet.

The function of DLK is largely unknown [14], but considering that it is a transmembrane protein with a quite restricted distribution in healthy adults [5], it may be a readily accessible target for antibody imaging or therapy.

Conflict of interest statement We declare that we have no conflict of interest.

EDITORIAL

Hermann Lebert (1813–1878): a pioneer of diagnostic pathology

Hellmuth Pickel · Olaf Reich · Raimund Winter · Robert H. Young

Received: 17 July 2009 / Accepted: 31 July 2009 / Published online: 18 August 2009

Abstract Hermann Lebert (1813–1879) was a pioneer of diagnostic pathology and medical iconography. He was born in Breslau, then Prussia, and died in Nice (France). He lived in Switzerland as a general physician, in France as a pathologist, and eventually became the chairman for internal medicine in Zurich and Breslau, respectively. The significance of Hermann Lebert for medical posterity has three aspects: firstly, scientific linking of the French (Parisian) school and its distinctive clinical/practical orientation to the later clinical/pathological German school of Johann Lukas Schönlein, Johannes Müller, and Rudolf Virchow; secondly, his pioneering of the diagnostic use of the microscope in pathological anatomy; and finally, his remarkable book, *Traité d'anatomie pathologique générale et spéciale*, which has almost fallen into oblivion, being unknown to most contemporary workers.

Keywords Pathologist · Microscopy · Cytology · Pathologic atlas

Most who read these words use a microscope as part of their routine work as a diagnostic pathologist without giving any thought, quite reasonably, to when this modality first became used in medical care. If they do, they may think it has been since not long after the time of Van Leeuwenhoek. However, at least one authority on the history of pathology has noted the rather surprising delay in the utilization of the microscope in the practice of pathology [1], and indeed, if one views our discipline from the broad perspective of human history, light microscopic analysis of tumors and other lesions is still relatively "new." In this essay, we consider one of the pioneers of microscopy in pathology, Hermann Lebert, and discuss his books, one of which is surely one of the most magnificent in the rich tradition of diagnostic pathology.

It is a sad reality that, with the passage of time, remarkable contributions of prior investigators and even the investigators themselves often become progressively overlooked and, in some cases, end up completely unknown by current workers. This includes some whose innovation can be considered fundamental to the development of our field. We recently came across the stunning book *Traité d'anatomie pathologique générale et spéciale* [2] by the French/German physician–pathologist Hermann Lebert. It stimulated us to investigate his life and other contributions [3, 4], which, although noted in standard books on the history of pathology [1, 5, 6], we suspect, are either not known or are little known by most readers. Our researches clearly indicated a person of great substance whose contributions merited exposition for the current generation.

Paris was the center of the medical world in the early years of the nineteenth century when a transition from speculative medicine to medicine based on rational observation was taking place. The new "philosophy of observation" had its breakthrough due to the Enlightenment and the French Revolution of 1789. In 1794, the teaching of medicine and the organization of the hospitals in France underwent a radical reform. It was mostly clinicians, and primarily surgeons, who benefited from this. Thanks to the

vast number of patients in the large Parisian hospitals; they had ample opportunity to practice bedside observation. Aside from focusing on observation and care of patients, they also emphasized pathological anatomy, largely autopsy based. In France and Great Britain, clinicians were regularly in charge of postmortem examination at the large hospitals up to the twentieth century. The first half of the nineteenth century saw the creation of textbooks and manuals of pathological anatomy, mainly in France, which remained standard works for a long time. They were profusely illustrated masterpieces of macroscopic iconography, with little to no consideration of the microscopic dimension, which was yet to be fully developed [7].

Hermann Lebert was born in Breslau (then in the kingdom of Prussia, now Wroclaw in Silesia/Poland) on June 9, 1813, the son of a Prussian merchant Isidore Jakob Lebert and his wife Johanna, nee Fanty [8]. His parents lived primarily in Berlin (then the capital of the Kingdom of Prussia) but fled to Breslau for a brief period of time to escape the conditions caused by one of the Napoleonic wars (1813–1814).

Lebert studied medicine and the natural sciences in Berlin and then in Zurich under Johann Lukas Schönlein (1793–1864). Before and after receiving his medical doctorate at the University of Zurich in 1834, Lebert traveled with his close friend Jean de Charpentier (1786–1855) throughout Switzerland and studied botany. After receiving a doctorate with a thesis on botany, he focused on theoretical and practical medicine for the next 1 1/2 years. In Paris, he attended postgraduate courses, particularly under two famous figures in the history of medicine, the surgeon Guillaume Dupuytren (1777–1835) and the physician–pathologist Pierre Charles Alexandre Louis (1787–1872), the father of medical statistics. In 1838, Lebert began to work as a country doctor in Bex, a mountainous village in the Rhone Valley in the Swiss Canton of Vaud. During the summer months, he practiced medicine in Bex, but he spent the winter months of 1842–1845 in Paris, occupied with both clinical and microscopic studies in the great Paris hospitals. He attended the microscopic courses of the prominent French clinician and microscopist Alfred Francois Donné (1801–1878) (chef de clinique at the Hopital de la Charite in Paris, the discoverer of thrombocytes, trichomonades, and *Candida albicans* and the inventor of microphotography) [9]. In Paris, he became friends with his later pupils, the pathologist/clinician Charles Robin (1821–1885) and Paul Broca (1824–1880). In 1844, he witnessed the short but bloody civil war in the Swiss canton of Valais, where he served as an army doctor. During a stay in Berlin in the winter of 1845–1846, he made the acquaintance of two promising German pathologists (later to become legendary figures), Johannes Müller (1801–1858) and Rudolf Virchow (1821–1902), who both became his friends.

In *figure 5* (*middle bottom*) native cancer tissue with blood vessels

In 1846, Lebert finally moved to Paris, devoting his efforts to his extensive private practice in the morning and to his scientific work in the afternoon and evening. These years saw the beginning of his work on his monumental iconography of pathological anatomy (see later). The previous year, 1845, saw the publication of his first book, considered by us later. In 1848, he experienced the February revolution in Paris, and in 1849, he witnessed the outbreak of cholera, in the same city, which resulted in 10,000 deaths. For his work combating that epidemic, he received the cross of the Legion d'honneur from the French president Louis Napoleon Bonaparte (later Emperor Napoleon III, 1808–1873). He left Paris and went to Zurich in 1852; there, he was appointed professor of clinical medicine at the university. He resigned from this position in 1859 when he was offered a similar position at the University of Breslau. In the same year, 1853, he married Isaline Fayod with whom he had five children. He witnessed the Austro-Prussian war in Breslau in 1866 and served again as a high-ranking military officer in the Prussian army. In 1869, he took part in the fight in Silesia against another epidemic, typhoid fever, as the medical adviser for the city of Breslau. He resigned from his position in Breslau in 1874 and divided his time in the last 4 years of his life between Nice, France and Vevey and Bex in Switzerland. He died in Bex on August 1, 1878, from rupture of an aortic aneurysm. He is buried in Nice [8].

Hermann Lebert was a very prolific author and added greatly to the knowledge of biology, pathology, and clinical medicine of his time [10, 11]. In his autobiography, published in 1869, he listed 101 major contributions [12]. However, Reichert, in a subsequent biography, listed 124 publications [8]. The most prominent among them is the colossal *Traité d'anatomie pathologique générale et spéciale* published in four volumes (two volumes text and two volumes atlas) edited by Baillière in Paris in 1857 and 1861 [2]. Lebert subtitled his work *Description et iconographie pathologique*. This is one of the most comprehensive and important work of the pre-photographic era of medical

illustration (Fig. 1). Contributors to the enormous pathological and clinical material contained within it were physicians from Paris, most notably the surgeons Alfred-Armand Velpeau (1795–1867) and Charles Marie Edouard Chassaignac (1805–1879) as well as the syphilidologist Philippe Ricord (1799–1889).

The quality of Lebert's work has only been equaled in our times by means of color photography. Apparently, the illustrations were steel-faced copper engravings using multiple plates printing ("Planches dessinées d'aprés nature, gravées et coloriées"), and their technical quality is superb [7]. This was aided by having it printed by the most renowned publishing house of that time, J.-B. Baillière et fils in Paris, which had also published and printed Cruveilhier's magnum opus. The composition of Lebert's atlas resembles the work of his great predecessor Cruveilhier, but it is much larger and has a richer layout. In contrast to Cruveilhier's work, Lebert combines his text in two complete and well-arranged volumes and provides detailed and clear explanations in the two atlases [1] Lebert surpasses the work of Cruveilhier by not only describing microscopic findings but also by documenting them in detail in his illustrations as well.

The work consists of four volumes in large folio size (12 1/4 in. wide×18 3/4 in. tall): two text volumes (766 and 733 pages) as well as two atlas volumes (the first volume featuring 94 tables ("planches") including several illustrations and 46 pages of explanations, and the second volume 106 tables with several pictures and 44 pages of explanations). This work was sold to more than 300 subscribers throughout the world. Most of the subscribers were large university libraries both in Europe and the Americas, primarily the USA. However, bookstores and individuals also appear as subscribers. In 1863, Lebert's work received an award from the Imperial French Medical Academy. These words do not do justice to Lebert's work, which proverbially "needs to be seen to be believed."

The first volume contains a historical overview of pathological–anatomical iconography followed by a comprehensive essay on general pathology with relevant clinical case histories. The second volume is entirely dedicated to special pathology and also includes case histories and, among them, cases of tumor pathology. The scope of the two atlases is remarkable with the 200 large and mainly colored plates of the highest quality designed by outstanding artists such as the draftsman Lackerbauer and the engravers Oudet and Visto. The complete work was produced by the fine-art printers L. Martinet in Paris. To further emphasize the magnificence of the work, we note that each plate contains a minimum of ten and usually many more individual illustrations.

Lebert's most historically significant other publication was his two-volume *Physiologie pathologique* published in 1845 [3]. In it, he combines clinical observation, animal experiments, and microscopic observations as well as biochemistry. The first volume deals with inflammatory disorders. The second volume deals exclusively with tumors. Lebert expresses his theory of the characteristics of malignant cells for the first time in this work; this would become very controversial later. By means of uncolored cytological preparations, he described the morphological features of neoplastic cells, which are still valid today, such as those pertaining to the nucleolus.

The importance of the aforementioned work was brought home to us while we were preparing this essay, devised initially mainly to draw attention to the remarkable two volume text and atlas already considered. As part of the associated reading of various texts, we consulted the small but wonderfully detailed and strongly recommended book on the history of pathology by Dr. E. B. Krumbhaar published in 1937 [1]. In his chapter on "cellular pathology," which considers primarily Virchow, Krumbhaar reflects on the relatively late application of the microscope in the study of morbid anatomy we noted earlier. The first work Krumbhaar credits for applying microscopy to pathologic anatomy is the 1843 book of Julius Vogel *Icones Histologicae Pathologicae*. He then notes the 1845 work of Lebert, making it, obviously, one of the earliest works in which microscopy was used in the pathology literature. Similar significance is given to Lebert's 1845 book in Long's consideration of the *History of Pathology* [5], and these observations are reinforced by Dr. Steven Hajdu [13], in a much more recent contribution, and in the outstanding recent book on the *History of Histopathology* by Professor Georg Dhom [9].

Lebert figures in a significant way in the second chapter of the latter work when Dhom discusses the Paris school. Indeed, Lebert gets more coverage in that chapter than any other individual, and Dhom illustrates the frontispiece of two of his books as well as a number of other illustrations from his texts. The mention Lebert has received in these contributions only heightened our feeling that his role in the development of diagnostic pathology merited further highlighting. However, despite the attention he received in the works just noted, we feel that, overall, he is not as well-known as he should be to most current workers. Lebert wrote a third book published in 1851 [4]. Like all his works, the work is an impressive one, albeit not as monumental as the Atlas we have focused on. The 1851 book runs to 885 pages and is divided into two parts. The first has four chapters concerning the microscopic characteristics of neoplasia and the second part ten chapters considering separate organs and systems of the body in turn. Among those he dedicates the work, three are giants, such as Cruveilhier, Louis, and Müller.

Very early in his career, Lebert advocated the diagnostic use of the microscope in the assessment of biopsy material [14] following the pioneering work of Alfred Donné. There

was no practical technique for dying tissue at the time, and observers had to rely on the assessment of individual cells or, at best cell clusters, from cytological preparations [9]. Thus, Lebert propagated the "Stückchen-diagnose" (small piece diagnosis of malignant tumors) decades before Ruge [15] and Veit [16] did. In his role as director of the Medical Clinic in Breslau/Wroclaw, Lebert emphasized: "Uterine cancer must be diagnosed directly in life by means of a microscope in that one can examine larger pieces of tissue" [17].

Lebert's other important publications (for a complete list, see references) focused on botany and zoology (entomology) as well as medical/historical topics. Publications from his early years were in French, but the majority of those dating from the beginning of his academic career and his call to Zurich in 1853 was written in German.

The significance of Hermann Lebert for medical posterity has three aspects: firstly, scientific linking of the French (Parisian) school and its distinctive clinical/practical orientation to the later clinical/pathological German school of Johann Lukas Schönlein, Johannes Müller and Rudolf Virchow; secondly, his pioneering of the diagnostic use of the microscope in pathological anatomy; and finally, his remarkable book, *Traité d'anatomie pathologique générale et spéciale*, which has almost fallen into oblivion, being unknown to most contemporary workers.

Acknowledgements Mr. Jack Eckert, Senior Librarian at the Center for the History of Medicine at the Francis A. Countway Library of Medicine at Harvard Medical School, was most helpful in enabling review by one of the authors (RHY) of the three books of Lebert noted herein. His assistance is much appreciated. Dr. Gregory Y. Lauwers, Director of Surgical Pathology at the Massachusetts General Hospital kindly translated selected portions of Lebert's atlas for RHY.

ORIGINAL ARTICLE

The importance of precise pT diagnosis for prognostic prediction of uterine cervical cancer—a single institutional report at a Japanese comprehensive cancer hospital

Norihiro Teramoto · Rieko Nishimura · Koichi Mandai · Takashi Matsumoto · Takamitsu Nogawa · Masamichi Hiura

Received: 23 April 2009 / Revised: 9 August 2009 / Accepted: 7 September 2009 / Published online: 24 September 2009

Abstract We previously reported that the majority of Japanese pathologists misunderstand the International Union against Cancer-pT2 criteria for uterine cervical cancer (UCC). We compared the prognosis of originally diagnosed pT2 (ori-pT) UCC cases at our hospital with reclassified pT2 (re-pT) cases to assess the importance of making a correct pT diagnosis. There were 43 International Federation of Gynecology and Obstetrics (FIGO) II (i.e., cT2) and/or ori-pT2 UCC cases who received surgery without neoadjuvant chemotherapy at Shikoku Cancer Center from 1991 to 2003. The cases (seven ori-pT1 and 36 ori-pT2; 43 cN0 with six pN1) were reclassified as 22 re-pT1 and 21 re-pT2. Fifteen of the 23 ori-pT2a cases (65%) were re-pT1 because their vaginal extension had only been intraepithelial. The difference in the 5-year survival rate (5Y-SR) was not significant between the ori-pT1 and ori-pT2 cases using Fisher's exact test (F test): $P=0.236>0.05$, whereas 5Y-SR of re-pT1 cases was significantly higher than re-pT2, including pN1 cases and excluding them (F test: $P=0.00164<0.01$ and $P=0.0108<0.05$, respectively). The 5Y-SR of ori-pT2-re-pT1 (overdiagnosed pT2) was significantly higher that of ori-pT2-re-pT2 (true pT2) including pN1 cases and excluding them (F test: $P=0.00694<0.01$ and $P=0.0305<0.05$, respectively). These results indicated that pT2 of UCC could be frequently misdiagnosed at an institutional level, and that misdiagnosed pT2 might impair the evidence-based medicine of UCC. Multi-institutional assessment of the accuracy of pTNM is recommended, because it is not likely that this is an endemic problem to our hospital.

Introduction

To establish evidence-based cancer therapy, cancer stages must be evaluated uniformly among institutions with as little error as possible. For cancers at most sites, the cancer stage provides corroborating evidence for estimating the risk to the patient's life [1, 2]. Therefore, the cancer stage is an extremely important indicator for the selection of the treatment method and for grouping patients for various kinds of investigations.

This work was partly supported by a grant-in-aid for cancer research from the Ministry of Education, Science, Sports, Culture and Technology of Japan.

In most cancers, the cancer stage is defined by the combination of TNM, which stands for the local extent of primary tumor (T), regional lymph node metastasis (N), and distant metastasis (M) [1, 2]. Grouping of the combinations of TNM according to the risk to life indicates the stage. International Union against Cancer (UICC)-TNM classification consists of the clinical TNM classification before treatment (cTNM) and the pathological TNM after tumor resection (pTNM). In uterine cervical cancers, the International Federation of Gynecology and Obstetrics (FIGO) stage is widely accepted among gynecologists [3]. The FIGO stage classification is similar to the UICC stage, except for the stipulations that the FIGO stage of uterine cervical cancer (UCC) be determined only by clinical data collected before therapy, not by postsurgical information, and that lymph node metastasis is not included in the FIGO stage. Therefore, FIGO II UCC is cT2N0M0 or cT2N1M0, while FIGO II UCC is not always pT2N0M0 or pT2N1M0.

Despite its importance, little attention has been paid to the accuracy of pTNM classifications for UCC as well as cancers of other sites. Recently, we reported the result of a questionnaire survey of pathologists working in the *Gan-shinryo-renkei-kyoten Byoin* (Local Core Cancer Hospitals) on pTNM classification [4]. The results suggested that Japanese pathologists have insufficient knowledge about the UICC-TNM, which might lead to inaccurate TNM classification. The percentage of correct answers to questions concerning the following important criteria was only about 60%, despite the fact that the questions were yes–no ones: "When it is difficult to judge TNM, the lesion is classified into the lower category", and "Direct invasion of the lymph node is a N component" [4]. In the survey, more than half of Japanese pathologists regarded a UCC as T2a if the carcinoma in situ accompanying UCC extended to the vagina, [4] although an intraepithelial component does not raise the UICC-T stage [5]. The results clearly indicated that pT2 of UCC was misdiagnosed in many institutions. Recently, we also reported that the pTNM staging of lung cancer was frequently done incorrectly when a clear description of the UICC-TNM was not provided to pathologists, including a clear description of the distinction between intrapulmonary metastasis vs synchronous tumor. Thus, the inaccurate use of pTNM might lead to the misperception of its prognostic significance [6].

The Shikoku Cancer Center is a comprehensive cancer hospital in the Chugoku and Shikoku districts of Japan. It handles the largest number of patients with gynecological tumors in these districts. The Gynecology Department of our hospital is a member of the Gynecology Oncology Group and the Japanese Gynecology Oncology Group. Our hospital's former chief pathologist was a pathology committee member of the group that produced the *General Rules for the Clinical and Pathological Study of Uterine Cervical Cancer in Japan* (GR-UCC) [7] and was responsible for the diagnosis of a small proportion of the cases assessed in the present study.

In this study, we assessed the accuracy of pT diagnosis of UCCs, with a focus on T2 lesions that were diagnosed as locally advanced and were surgically treated at our hospital, the Shikoku Cancer Center. We compared the prognosis of patients with correctly diagnosed T2 lesions to that of patients whose T2 lesions were misdiagnosed to assess the importance of making an accurate pT diagnosis.

Materials and methods

Case selection and rules for reclassification

The list of UCC cases treated between 1991 and 2003 that belonged to either FIGO II or pT2 was obtained from the files of the pathology department of the Shikoku Cancer Center. The cases were reexamined microscopically with reference to pathological reports and macroscopic photos of the excised specimens by N.T. and R.N. to reclassify the pT according to the UICC-TNM, 6th edition [2]. The definitions of T1 and T2 did not change from 1991 to 2003 [2]. The reasons why pathologists deviated from making an accurate diagnosis of pT are shown in Tables 1 and 2. The original pT recorded in the pathological report is hereinafter referred to as ori-pT, and the reclassified pT as re-pT. ori-pTX reclassified as re-pTX is referred to as ori-pTX-re-pTX, ex ori-pT2-re-pT1. In this study, we considered the re-pT to be the true pT. As in the UICC supplement book, only the extension of an invasive component of a carcinoma raises T [5], and a cancer component in the lymphovascular space of the parametrial tissue does not assure pT2b [8]. The subdivision of pT1a1 vs. pT1a2 and pT1b1 vs. pT1b2 was not conducted because this study was focused on T2 lesions. Information about the prognosis was obtained from the hospital-based cancer registry. Prognosis was analyzed by overall survival. Follow-up data longer than 5 years were available for 40 patients. Eight patients died within 5 years, and two others died within 5 to 10 years.

Table 1 Pitfalls of the TNM classification of uterine cervical cancer (only vaginal involvement by the invasive component deserves classification into T2a)

T2a	ori-pT2a	ori-pT2a-re-pT2a	Concordance rate
No. of cases	23	8	35%

Vaginal extension of the intraepithelial component is not considered to be T2a

ori-pT original-pT, *re-pT* reclassified-pT, *ori-pT2a-re-pT2a* ori-pT2a cases reclassified as re-pT2a

Table 2 Pitfalls of the TNM classification of uterine cervical cancer (only grossly or histologically evident continuous invasion beyond the myometrium is classified as T2b)

T2b	ori-pT2b	ori-pT2b-re-pT2b	Concordance rate
No. of cases	13	12	93%

Questionable invasion is not T2b. Intravascular or lymphaticular extension to the parametrium is not considered to be T2b

ori-pT original-pT, *re-pT* reclassified-pT, *ori-pT2b* cases reclassified as re-pT2b.

Statistical analysis

Using Fisher's exact test (F test), we examined the 5-year survival rate after surgery with StatMate (ATMS, Tokyo, Japan). The survival function of ori-pT1-re-pT2 and that of ori-pT2-re-pT2 were compared using the Kaplan–Meier estimator. Differences were considered significant at $P<0.05$.

Results

Results of reclassification

At Shikoku Cancer Center, there were 537 hysterectomy cases between 1991 and 2003. Of 537 cases, 126 cases were diagnosed as either FIGO II (i.e., cT2) or ori-pT2. Forty-three of the cases had not received preoperative chemotherapy or radiotherapy. The 43 cases consisted of 17 FIGO I (FIGO IA: three, FIGO IB: 14) and 26 FIGO II (FIGO IIA: 20, FIGO IIB: six). The ori-pT of the 43 cases were seven ori-pT1 (ori-pT1a: one, ori-pT1b: six) and 36 ori-pT2 (ori-pT2a: 23, ori-pT2b: 13). These 43 cases comprised all the cT2 and/or ori-pT2 cases at the Shikoku Cancer Center during this period. All 43 cases were cN0M0, and six of them were proven to be pN1 at the pathology examination. They were reexamined with regard to their pTNM. According to the UICC-TNM, 6th edition, the 43 cases were reclassified into re-pT1 in 22 cases (re-pT1a: three, re-pT1b: 19) and re-pT2 in 21 patients (re-pT2a: eight, re-pT2b: 13). None of the pN and M had to be revised. These results are summarized in Tables 3 and 4.

None of the cases with re-pT2 lesions were ori-pT1, suggesting that in our hospital, there was a tendency to overdiagnose the stage in the ori-pT evaluation (Table 3). Fourteen of the 23 ori-pT2a cases (61%) were re-pT1 and one was ori-pT2b (Table 3). The overestimation of stage was due to the intravaginal extension of intraepithelial neoplasia (Fig. 1). An ori-pT2b case was downgraded to re-pT1 because cancer tissue in the parametrial lymphovascular space had been regarded as evidence of pT2b. Seventeen of the 43 cases were FIGO I-ori-pT2, and ten were re-pT2 (Table 4). The number of FIGO I cases without preoperative chemotherapy between 1991 and 2003 was 248. Therefore, the rate of underdiagnosis of FIGO I to re-pT2 was about 4% (10/248). Conversely, 15 of the 26 FIGO II cases were re-pT1 lesions. The rate of misdiagnosis of FIGO II to re-pT1 was 58% (15/26). Details of the patients are shown in Table 5.

Table 3 The correlation between reclassified pT versus original pT

		ori-pT				
		T1a	T1b	T2a	T2b	Total
re-pT	T1a	0	0	3	0	3
	T1b	1	6	11	1	19
	T2a	0	0	8	0	8
	T2b	0	0	1	12	13
	Total	1	6	23	13	43

Note that no case was in the squares consisting of re-pT2a-2b and ori-T1a-1b, but that 15 cases belonged to the squares consisting of re-pT1a-1b and ori-T2a-2b

Relationship between the reclassified pT lesions and the prognoses

The prognosis could be followed up for more than 5 years after the surgery in 40 of the 43 patients. Eight of them died within 5 years after the operation, and two others died in the next 5 years. None of the patients with ori-pT1 or re-pT1 lesions died within 5 years.

The 5-year survival rates were compared by the F test between the patients with FIGO I and FIGO II lesions ($P>0.05$), between ori-pT1 and ori-pT2 lesions ($P>0.05$), and between re-pT1 and re-pT2 lesions ($P<0.01$). Only re-pT was correlated with the 5-year survival rate (Table 6). Even if pN1 cases were excluded, the difference of the 5-year survival rate was still significant between the re-pT1 and re-

Table 4 The correlation between reclassified pT versus FIGO stage

		FIGO				
		IA	IB	IIA	IIB	Total
re-pT	T1a	3	0	0	0	3
	T1b	0	4	13	2	19
	T2a	0	3	4	1	8
	T2b	0	7	3	3	13
	Total	3	14	20	6	43

Note that only 11 of 26 FIGO II cases were in the squares consisting of re-pT2a-2b

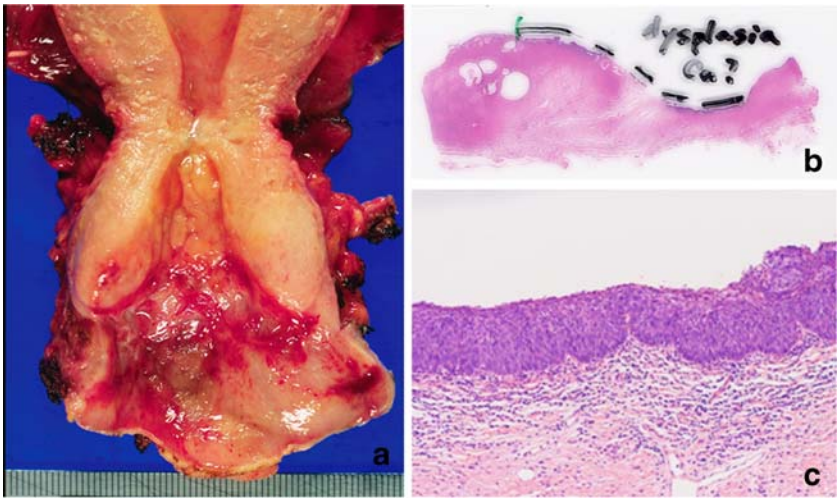

Fig. 1 Intravaginal growth of UCC. **a**–**c** Uterine cervical cancer diagnosed as FIGO IIA, ori-pT2a but re-pT1b. **a** A macroscopic image. **b** A panoramic image. Note that the person making the original diagnosis wrote "dysplasia-Ca(ncer)?" on the glass. **c** Only CIN3 was observed in the vagina

pT2 lesions ($P<0.05$) but not between the ori-pT1 and ori-pT2 lesions ($P>0.05$; Table 6).

Eight of the 20 patients with ori-pT2-re-pT2 lesions/true pT2 (40%) died within 5 years after surgery, while none of the ori-pT2-re-pT1 patients/overdiagnosed pT2 (0/14) died within 5 years of the operation. The 5-year survival rate was significantly lower in true pT2 than in overdiagnosed pT2 (F test: $P<0.01$). Since two patients, including one ori-pT2-re-pT1 case, died between the sixth and tenth year, the survival risk for 10 years of ori-pT2-re-pT2 and that of ori-pT1-re-pT2 were compared using the Kaplan–Meier estimator. The prognosis of the former was significantly worse than that of the latter, either including pN1 cases (Logrank, $P<0.01$) or excluding them (Logrank, $P<0.05$; Fig. 2).

Among the nine FIGO I-re-pT2 patients (pT2 cases underdiagnosed as FIGO I), four (44%) died within 5 years after surgery, while none of the 13 patients with FIGO II-re-pT1 lesions (pT1 cases overdiagnosed as FIGO II) died within 5 years of the operation. The prognosis was significantly worse in the former than in the latter cases ($P<0.05$). This showed again that the pathologic stage correlates better with prognosis than the clinical stage correlates with prognosis [1, 2]. These findings are summarized in Table 6.

Discussion

As shown in our past report, the majority of Japanese pathologists do not seem to know the precise TNM rules of UCC [4]. Therefore, it is not likely that stage classification of UCC at our hospital is particularly less accurate among Japanese hospitals. Brierley et al. reported that the accuracy of pTNM classification for all gynecological cancers in Princess Margaret Hospital in Canada was 81% [9]. We have not found any reports on interinstitutional or international pTNM accuracy. Thus far, not much attention has been paid to the pitfalls of pTNM classification in certain conditions.

GR-UCC is the textbook for cervical cancer diagnosis in Japan, published collectively by the Japan Society of Obstetrics and Gynecology, the Japanese Society of Pathology, and the Japan Radiation Society [7]. The statements of the rules of the UICC-TNM as well as the GR-UCC are not detailed enough to allow users to make a precise TNM classification [2, 7]. The UICC-TNM rules state that a carcinomatous component in the parametrial lymphovascular space is not a T2b component, but the GR-UCC rules do not have this stipulation in the text [2, 7]. It is not clearly stated in either the GR-UCC or the UICC-TNM, 6th edition, that vaginal involvement by a noninvasive component of UCC is not a T2a component [2, 7]. With regard to pT2 lesions of UCC, the rules established by the UICC provide the following broad descriptions: "pT2: beyond uterus but not pelvic wall or lower third vagina. T2a: no parametrium, T2b: parametrium" [2, 8]. Obviously, more detailed descriptions are needed. Another reason for inaccurate pTNM staging in Japan is that the pTNM staging is not considered the main responsibility of pathologists and is thus mainly conducted by clinical physicians at many institutions who do not actually check the pathology specimens.

There was a significant difference in prognosis between re-pT1 and re-pT2, but not between ori-pT1 and ori-pT2 (Table 6). The difference in the mortality between the ori-pT2-re-pT2 cases and ori-pT2-re-pT1 cases accentuates the importance of an accurate pT diagnosis on the prediction of prognosis of locally advanced UCC patients.

Table 5 Patients' data of the cases examined

Original pT		Revised pT	FIGO	pN	Outcome	Follow-up (months)	5-year survival
2b	>	1b	IIA		Alive	42	Lost
2b	=	2b	IIB		Died	10	No
2b	=	2b	IIB	pN1	Alive	60	Yes
2b	=	2b	IIB	pN1	Died	19	No
2b	=	2b	IIA		Died	17	No
2b	=	2b	IIA	pN1	Died	16	No
2b	=	2b	IB		Died	40	No

Follow up longer than 10 years was indicated as 121 months. 5-year survival; "Yes", "No" and "Lost" mean "alive more than 59 months after surgery", "dead within 59 months of surgery", and "lost in follow-up within 59 months", respectively.

pN only pN1 cases are indicated, *pN0* cases are left blank

We analyzed only FIGO II and/or ori-pT2 cases in this study. Before conducting this study, however, we already had data showing that these cases are a frequently misdiagnosed group in UCC-TNM diagnosis (data not shown). Ori-pT1 and ori-pT2 did not show a significant difference of vital risk in this study (Table 6), because ori-pT2 was contaminated with ori-pT2-re-pT1. However, because the number of ori-pT1-FIGO I cases at our hospital, which were not analyzed in this study, is several-fold greater than the number of ori-pT1-FIGO II cases

Table 6 5-year survival of FIGO, original pT and re-classified pT

	Total cases	Died	Alive	Fisher's exact test
FIGO I	16	4	12	P=0.853>0.05

re-pT2 w/o N1	15	5	10	
ori-pT2-re-pT2	20	8	12	P=0.00694<0.01
ori-pT2-re-pT1	14	0	14	
ori-pT2-re-pT2 w/o N1	15	5	10	P=0.0305<0.05
ori-pT2-re-pT1 w/o N1	13	0	13	
FIGO I-re-pT2	9	4	5	P=0.0172<0.05
FIGO II-re-pT1	13	0	13	

ori-pT original-pT, *re-pT* reclassified-pT, *w/o N1* without pN1 cases, *ori-pT2-re-pT2* ori-pT2 cases reclassified as pT2 (i.e., true pT2), *ori-pT1-re-pT2* ori-pT2 cases reclassified as pT1 (i.e., overdiagnosed pT2), *FIOGI-re-pT2* FIGO I cases classified as re-pT2 (underdiagnosed FIGO I/cT1), *FIOGII-re-pT1* FIGO II cases classified as re-pT1 (overdiagnosed FIGO II/cT2).

analyzed in this study, there would be a significant difference in the prognosis between ori-pT1 and ori-pT2 cases if ori-pT1-FIGO I cases were included. However, this might have hitherto concealed the problem of UCC-pT2 diagnosis.

In operated cases, the prognosis can be predicted more reliably by the pTNM classification than by the FIGO stage, which is a pure clinical staging without lymph node evaluation. An accurate pT diagnosis in operated cases is important for the accurate FIGO stage classification system itself, because a misdiagnosed pT could lead clinicians to incorrectly judge the FIGO stage for the next UCC case at the institution.

It is important to assess the accuracy of the pTNM classification of UCC [1, 2]. For example, the evaluation of pT in stage I and II UCC cases is extremely important for researching the efficacy of postoperative chemotherapy as well as for assessing the risk of recurrence in specific histological subtypes and gene types. Without appropriate pT evaluation, it is virtually impossible to compare patients whose prognostic risks are homogeneous. The desired level of accuracy of TNM is not defined in the UICC-TNM. In clinical cancer research studies, the pathology exclusion rate should not be higher than 10% of the cases [10, 11], and for the therapeutic purpose of a patient, it should be far less than 10%.

Our past report suggested that the pTNM may be misdiagnosed in many institutes due to insufficient knowledge about TNM [4]. We also showed that pTNM diagnoses were not actually accurate, especially in certain situations where the description of TNM was unclear [6]. Although the present study was a single-institutional study, it suggested the possibility that misdiagnosed pT might threaten the evidence-based medicine of locally advanced cancer. Misdiagnoses of UCC-pT2 were frequent, and would impair both the prognostic predictability of pTNM

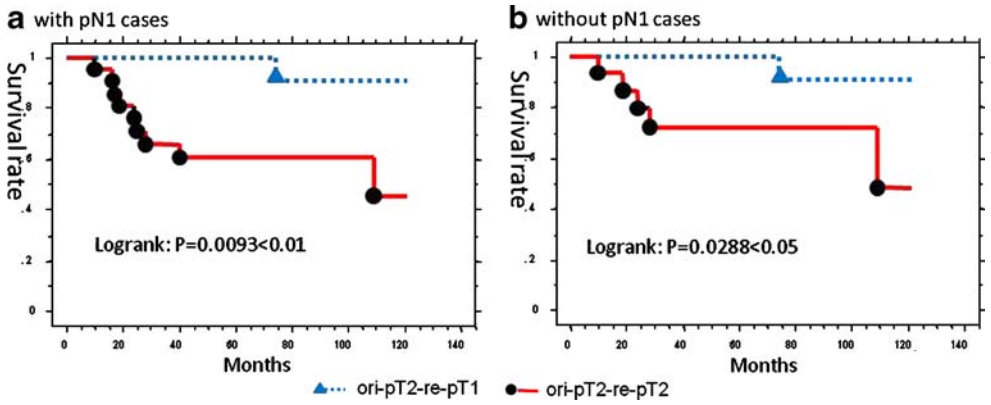

Fig. 2 Survival function of pT2 uterine cervical cancers. Prognosis of ori-pT2-re-pT1 (cases originally diagnosed as pT2 and reclassified as pT1, i.e., overdiagnosed uterine cervical cancers) is significantly better than that of ori-pT2-re-pT2 (cases originally diagnosed as pT2 and reclassified as pT2, i.e., true pT2 uterine cervical cancer). **a** Logrank: P=0.0093<0.01, including pN1 cases. **b** Logrank: P=0.0288<0.05, excluding pN1 cases

on a patient basis and the quality of the clinical research of locally advanced UCC. Here, we have only described the results of assessment at a single institution. Multi-institutional assessment of the accuracy of pT in Japan is needed because we believe that this problem is not endemic to our hospital. The misdiagnosis of pT2 may also occur in other countries. In addition, we are certain that this problem is not specific to UCC, but occurs with other cancers[6].

Acknowledgments We would like to thank Dr. Shosuke Moriwaki, the former director of the Shikoku Cancer Center, for collecting and storing detailed data. Thanks also go to the past and present laboratory technicians of the pathology department of our hospital for their enthusiastic preparation and management of the specimens, and to the staff of the intrahospital cancer registration of our hospital.

Conflict of interest statement We declare that we have no conflict of interest. All the authors are employees of the National Hospital Organization of Japan. This work was partly supported by a grant-in-aid for cancer research from the Ministry of Education, Science, Sports, Culture and Technology of Japan.

ORIGINAL ARTICLE

Acute and chronic placental membrane hypoxic lesions

Jerzy Stanek

Received: 17 April 2009 / Revised: 8 September 2009 / Accepted: 18 September 2009 / Published online: 15 October 2009

Abstract Laminar necrosis (LN) and microscopic chorionic pseudocysts (MCP) are the two histological placental membrane lesions. This study retrospectively compares the clinical and placental associations of LN and MCP on a large placental material. Four hundred seventy-nine placentae featuring membrane LN (group 1), 220 placentae with MCP (group 2), and 50 placentae with both LN and MCP were identified in the database of consecutively signed by the author 4,853 placentae from 18 to 42 weeks pregnancies in years 1994–2007. Frequencies or averages of several clinical conditions and gross and microscopic placental features were compared among the groups (Yates chi-square or analysis of variance, where appropriate). Statistically significant differences were observed for preeclampsia, diabetes mellitus, stillbirths, cesarean section deliveries, placental weight, gross chorionic cysts, maternal chorioamnionitis, fetal chorioamnionitis, marginate placentae, and excessive amount of extravillous trophoblasts, respectively. Based on the above results, LN, a membrane infarction, appears to be an acute membrane hypoxic lesion, while MCP is a chronic lesion related to a more widespread extravillous trophoblasts accumulation in the placental disk. There was a substantial overlap of other clinical and placental conditions among the groups, paralleling not uncommon coexistence of acute and chronic placental hypoxia, therefore, LN and MCP, in same placentae.

Presented at the Paediatric Pathology Society 54th Annual Meeting, 4–6 September, 2008, Helsinki, Finland.

Introduction

Several hypoxic–ischemic placental lesions can be identified by pathology consultation [1–5]. The real diagnostic significance of many of them has not been firmly established. The time honored villous placental lesions are placental infarction (a focal lesion) and global (diffuse) hypoxic pattern of placental injury. Both are evaluated in the chorionic disk. Recently, two placental membrane lesions have been added to the pathologist's armamentarium and separately correlated with pregnancy outcome, fetal condition, and other placental features. These are laminar necrosis (LN), a band of coagulative necrosis (infarction) present at the choriodecidual interface of the placental membranes [6, 7] (Fig. 1), and microscopic chorionic pseudocysts (MCP), which are lakes of fibrinoid material, surrounded by migratory extravillous trophoblast of the chorionic layer of placental membranes [8] (Fig. 2a, b). LN was observed in 27% placentas from mothers with hypertensive disorders (preeclampsia or chronic hypertension) and was linked to other maternal, fetal, neonatal, and placental conditions known to be associated with perinatal hypoxia, with hypoxia-inducible factor, apoptosis, and oxidative stress playing role in the pathomechanisms [7, 9, 10]. Recently, a leukocytoclastic necrosis of the decidua basalis, a lesion histologically very similar to LN and similarly to LN associated with preeclampsia, preterm birth, and decreased fetal growth, but involving the maternal floor, was described [11]. MCP are even more strongly

associated with preeclampsia and diabetes mellitus, with their incidence almost mirroring the incidence of preeclampsia throughout gestation, peaking in early third trimester [8]. MCP are also statistically associated with placental hypoxic lesions, such as placental infarction, global hypoxic pattern of placental injury, and LN [8].

As LN and MCP have never been mutually compared, this analysis is intended to retrospectively compare the frequency of selected clinical and placental factors associated with LN and MCP on a large placental material.

Material and methods

All consecutive placentas from ≥20-week pregnancies with histological diagnosis of LN and MCP were extracted from the database of 4,853 placentas signed by the author at three institutions (University of Cincinnati Hospital Medical Center, Cincinnati, Ohio, U.S.A; Sheffield Children's NHS Trust, Sheffield, United Kingdom; and Canterbury Health Laboratories, Christchurch, New Zealand) in years 1994–2007. Four hundred seventy-nine placentas featuring membrane LN constituted group 1, 220 placentas with MCP constituted group 2, and 50 placentas with both LN and MCP constituted group 3. Frequencies or averages of several clinical conditions and gross and microscopic placental features were compared among the three groups (Yates chi-square at two degrees of freedom, or analysis of variance (ANOVA), where appropriate).

The placentas were submitted for examination at discretion of obstetricians because of high risk nature of the pregnancies, fetal distress, poor condition of the neonate, operative delivery, or grossly abnormal placenta. Placental examination was performed according to generally accepted criteria; specifically, two sections of placental membrane rolls and at least two paracentral full thickness

chorionic disk sections were routinely taken as a part of the placental examination if no gross lesions were identified. All grossly seen lesions were additionally sampled. The samples were fixed in buffered formalin, followed by routine paraffin embedding, cutting, and staining with hematoxylin and eosin [1–3, 12]. Only cases with at least three microscopic chorionic lakes in membranes were reported as MCP in the placental diagnosis and as LN only

Succenturiate lobe	8	1.7%	9	1.9%	1	4%	

[a] Only central/paracentral placental infarctions involving at least 5% of placental parenchyma were included

[b] Global (diffuse) placental hypoxia (preuterine, uterine, or postuterine) was histologically diagnosed based on the type of placental maturation (heterogenous or homogenous), excessive syncytial knotting (granular or smudgy chromatin), amount of extracellular matrix of chorionic villi (increased or decreased), density of villous cytotrophoblastic cells (increased or decreased), density of Hofbauer cells (increased or decreased), and villous vascularity (increased or decreased branching of capillaries) [17–19]

[c] More than five cell islands/placental septa per slide

cases in which this lesion involved at least 10% of membrane rolls [7, 8].

Results

LN was found in 9.9% of placentas and MCP in 4.5% placentas, thus LN was twice more common than MCP in this high-risk pregnancy population. There were no statistically significant differences in gestational age between the groups studied. One ninth of LN placentas showed also MCP, and one fourth of MCP placentas also showed LN. Of pregnancy risk factors (Table 1), MCP were statistically significantly associated more frequently than LN with preeclampsia (25.9% vs 17.7%) and diabetes mellitus (10.4% vs 3.5%) but not pregnancy-induced hypertension (0.9% vs 0.4%) or chronic hypertension (4.5% vs 2.3%, respectively). Cesarean deliveries were also more common in groups 2 and 3 than group 1 (47% vs 32%, respectively). Of fetal factors (Table 2), total perinatal mortality was four times more prevalent in group 1 than in groups 2 and 3, this being true both for macerated and nonmacerated stillbirths but not neonatal deaths. Congenital malformations were also more common in group 1. Of placental factors (Table 3), higher placental weight, fetal chorioamnionitis, marginate or vallate placentas, excessive amount of extravillous trophoblasts, and macroscopic chorionic cysts were seen more frequently with MCP than LN. Only maternal chorioamnionitis was seen more commonly with LN than MCP. Fetal–placental weight ratio was lower with MCP (5.4) than with LN (5.7). Although proportions of such clinical conditions as abnormal fetal heart tracings (Table 1), intrauterine growth restriction (Table 2), or other placental hypoxic lesions such as global placental hypoxia or infarction (Table 3) were higher in each group than in this high-risk placental population (not shown), they did not differ statistically significantly between groups 1, 2 and 3 (p>0.05).

Discussion

In this analysis, we intentionally did not analyze separately a specific clinical diagnosis (e.g., preeclampsia) but rather a pair of placental membrane morphologic features (LN and MCP) in a population of high-risk pregnancy. The two discussed membrane lesions are easy to appreciate during placental examination. The LN is easily recognizable despite concerns expressed by some authors [9] who doubt whether this lesion can be reliably distinguished from membrane fibrin deposition. Paying attention to the presence of trophoblastic and/or decidual ghost cells, one can easily distinguish between the two (Fig. 1d). Also, inflammatory necrosis is usually of the liquefactive type, with obliteration of cellular details and stratification of membranes. Leukocytoclastic LN must be distinguished from acute chorioamnionitis. In the former, leukocytes and leukocyte-derived nuclear fragments are adjacent to the decidual aspect of a band of LN (Fig. 1c) and are absent elsewhere in the membranes where necrosis is absent. The mechanism of the leukocyte accumulation is most likely same as in other infarction-associated inflammation, as for example in myocardial infarction. By contrast, chorioamnionitis-associated leukocytes are usually observed at the maternofetal interface of the membranes, frequently without necrosis (except in the most severe acute chorioamnionitis where diagnosis of LN cannot be rendered). MCP are also easily recognizable as they clearly stand out on microscopic

examination even on low power magnification. The only differential diagnosis is fibrosed/hyalinized/atrophic chorionic villi [8], which do not pose a significant diagnostic differential problem (Fig. 2a).

Based on analysis of the presented clinical material, LN, a membrane infarction, appears to be an acute membrane hypoxic lesion, statistically associated with intrauterine fetal death, while MCP are related to a more widespread extravillous trophoblasts accumulation, both in membranes [13] and in chorionic disk (Table 3). This excessive accumulation of extravillous trophoblasts in the chorionic disk may be associated with an increased number of chorionic plate (Fig. 2c), cell island (Fig. 2d), placental septa (Fig. 2d, e), and maternal floor (Fig. 2f) microscopic chorionic pseudocysts as well as macroscopically seen gross chorionic cysts (Table 3). The increased accumulation of extravillous trophoblast (EVT) cells may predispose to secondary pseudocyst formation as the aggregates are avascular [2, 3]. It is reasonable to conclude that such accumulation needs time to develop; MCP is, therefore, a chronic placental lesion. This observation corresponds to the findings of Redline et al. that showed an increased amount of proliferating (by proliferating cell nuclear antigen) and immature (by decreased amount human placental lactogen) trophoblasts in the maternal floor in preeclamptic placentas [14]. It is interesting that the frequency of massive perivillous fibrin deposition which is even larger EVT and fibrinoid deposition was not different among the studied groups, meaning that it is a qualitatively distinct lesion and not a part of the spectrum of increased number of placental septa/placental cell islands. Association of MCP with chronic complications of pregnancy such as preeclampsia and maternal diabetes mellitus and frequent deliveries by cesarean section but less with perinatal mortality could indicate that more generous cesarean section deliveries might have prevented fetal deaths in many cases of groups 2 and 3. Likewise, the greater amount of congenital malformations in group 1 might have accounted for the differences. While the differences in frequency of chorioamnionitis were not statistically significant, maternal chorioamnionitis (acute inflammation of the membranous chorion and amnion and/or acute subchorial intervillositis) was significantly more common in LN, while fetal chorioamnionitis (umbilical cord vasculitis, chorionic vasculitis) in MCP. The cause of this remains unclear. The substantial overlap of high-risk clinical conditions and complications and placental features between groups 1 and 2 may be explained by the tendency of the acute in utero hypoxia to occur more frequently in conditions complicated by chronic uteroplacental insufficiency (the "acute-on-chronic hypoxia"). That is probably why LN occurs more frequently in smaller placentas and why both lesions may be seen together (group 3).

While the pathomechanism of LN is clearly the placental hypoxia and oxidative stress [8] with contribution of the hypoxia-inducible factor2α [10], two pathomechanisms may be operative in formation of MCP [8]: (1) The MCP formation may be a result of increased secretory activity of extravillous trophoblasts. The microscopic appearance of most MCP indicates their secretory nature since the cysts have smooth walls with their content usually uninterrupted, intensely eosinophilic and granular, with occasional scalloping at the cell/matrix border, similar to that seen in thyrotoxic goiter (Fig. 1a, d, f) [4]; (2) The pseudocysts may also form secondary to degeneration of exuberant extravillous trophoblasts and its subsequent liquefaction. In that case, MCP feature their ragged walls with frequent absence of content (Fig. 1e); (3) Both mechanisms may be operative and be hypoxia driven, as some MCP morphologically show mixed features (Fig. 1c).

In summary, because of insufficient sensitivity and specificity of the known and time-honored placental hypoxic lesions, any additional one that can improve the accuracy of placental consultation should be considered for implementation. Placental lesion multiplicity rather than a single lesion poses a risk for fetal growth restriction and neurological impairment [15, 16]. The current analysis proved the relevance and usefulness in retrospective analysis of pregnancy outcome of MPC and LN, the yet relatively unknown placental membrane lesions to general pathologists.

Conflict of interest statement I declare that I have no conflict of interest.

Nodular pattern of bone marrow infiltration: frequent finding in immunosuppression-related EBV-associated large B-cell lymphomas

Deborah W. Sevilla · Erin M. Weeden · Suzy Alexander · Vundavalli V. Murty · Bachir Alobeid · Govind Bhagat

Received: 30 June 2009 / Revised: 29 August 2009 / Accepted: 14 September 2009 / Published online: 6 October 2009

Abstract Different patterns of bone marrow (BM) infiltration by diffuse large B cell lymphomas (DLBCL) have been described. A pure nodular pattern is uncommon, and the pathologic features, as well as the clinical correlates of DLBCL manifesting this pattern in the BM have not been well characterized. We evaluated BM biopsies involved by large B cell lymphomas diagnosed at our institute over an 11-year period to assess the morphology, phenotype, cytogenetic abnormalities, and clinical features of cases associated with a nodular pattern. A distinct nodular pattern of BM involvement was noted in 14 out of 55 (25%) cases. Although both EBV+ and EBV− DLBCL with this pattern were identified, a pure nodular pattern was significantly more common in EBV+ DLBCL compared to EBV− DLBCL (8/9, 89% versus 6/46, 13%; P=0.00002). The majority of EBV+ DLBCL associated with a nodular pattern had distinctive morphologic features (polymorphic cellular infiltrate and pleomorphic cytology), and CD30 expression was more commonly observed in this group (P=0.0163). All EBV+ DLBCL and two out of six (33%) EBV− DLBCL had nongerminal center phenotypes. No recurrent cytogenetic abnormalities were detected in either group. Importantly, all EBV+ DLBCL occurred in individuals with immune dysfunction (organ transplant recipients, HIV infection) or in those >50 years of age. Our study indicates a much higher predilection for EBV+ DLBCL to involve the marrow in a nodular pattern compared to EBV− cases and highlights similarities in the morphologic pattern of BM involvement by previously recognized subsets of immunodeficiency-related EBV+lymphomas and the newer entity of "EBV+ DLBCL of the elderly."

Introduction

Bone marrow (BM) examination is an integral part of the Ann Arbor staging system for B cell non-Hodgkin lymphomas (B-NHL). Bone marrow involvement indicates stage IV disease, which is an adverse prognostic factor in the International Prognostic Index (IPI), but it is also independently associated with a worse prognosis [1]. The frequency of BM involvement by B-NHL varies according to disease subtype. Marrow infiltration is more commonly observed in patients with low grade B-NHL, ranging from 30% for marginal zone lymphomas to virtually 100% for chronic lymphocytic leukemias [2–7], compared to diffuse large B cell lymphomas (DLBCL; 8–35%) [2, 3, 8–13]. Differences in the frequency of BM involvement by DLBCL, with regard to their phenotype or association with Epstein–Barr virus (EBV) infection, are currently unclear. Characteristic patterns of BM infiltration by different subtypes of B-NHL have also been reported, with the paratrabecular pattern more commonly seen in follicular lymphoma, the interstitial

diffuse and/or nodular pattern frequently observed in chronic lymphocytic leukemia/small lymphocytic lymphoma and lymphoplasmacytic lymphoma, and the sinusoidal pattern most often associated with splenic marginal zone lymphoma [2, 14, 15]. Only a few studies have described different patterns of BM involvement by DLBCL [2, 6, 16]. These include diffuse, interstitial, paratrabecular, nodular, and mixed patterns. A pure nodular pattern appears to be one of the least common, observed in 0–23% of cases [2, 4–6, 16], and DLBCL manifesting this pattern of BM infiltration have not been well-characterized. Thus, we undertook this study to assess the morphology, phenotype, associated cytogenetic abnormalities, and clinical features of DLBCL with a distinct nodular pattern of BM involvement. We observed nodular BM infiltrates in both EBV− and EBV+ DLBCL; however, this pattern was significantly more common in EBV+ DLBCL. All of the EBV+ DLBCL in our series occurred in immunosuppressed patients and included cases representing the recently described entity of EBV+ DLBCL of the elderly.

Methods

Case selection and clinical characteristics

A search of our departmental database was performed to identify BM biopsies, which had infiltrates of DLBCL over a period of 11 years (January 1997–December 2007). Morphologic features were assessed using H&E stained sections of Bouin's fixed paraffin-embedded BM biopsies. The pattern of BM involvement was analyzed to identify cases with pure nodular infiltrates of DLBCL. A distinct or pure nodular pattern was defined as the presence of well-delineated or circumscribed aggregates of large neoplastic lymphocytes with <10% of the neoplastic cells demonstrating a different pattern of infiltration (i.e., single scattered cells) [2]. The corresponding formalin-fixed paraffin-embedded lymph node (LN) or soft tissue biopsies of the DLBCL, where available, were also evaluated to characterize architectural and cytologic features.

Data regarding patient demographics, EBV viral load and/or serology, immune status, immunosuppressive regimen, chemotherapy and/or radiation therapy, and clinical outcomes were obtained from our laboratory information system. Epstein–Barr virus reactivation was defined as detection of >100 copies per milliliter of EBV antigen by polymerase chain reaction (PCR) analysis.

Immunohistochemistry and in situ hybridization

Immunohistochemical stains were performed on the BM biopsies and LN or soft tissue biopsies, using the primary antibodies listed in Table 1, after heat-induced antigen retrieval, and were visualized with Envision plus (DAKO, Carpinteria, California, USA) and DAB. Cases were scored as positive for the antigen of interest if >30% of the neoplastic cells expressed it. Based on the expression of CD10, BCL6, and IRF4, the DLBCL were classified as either germinal center (GC) type (CD10+ or CD10−/BCL6+/IRF4−) or non-GC type (CD10−/BCL6+/ IRF4+ or CD10−/BCL6−/IRF4+) [17]. Semiquantitative assessment of the reactive T cells within the nodules of DLBCL was performed on CD3-stained sections (<10%=mild, >10–50%=moderate, >50%=marked).

In situ hybridization for EBV-encoded small RNAs (EBER) was performed using the supplied protocol (INFORM EBER, Ventana, Tuscon, Arizona, USA). Cases were considered EBV+ when the vast majority (>90%) of neoplastic cells expressing one or more of the B cell antigens (CD20/PAX5/OCT2) demonstrated a positive signal by EBER.

Cytogenetic analysis

Giemsa banding was performed on metaphase preparations obtained after short term (12 h) unstimulated cultures of the BM aspirate, LN, or soft tissue biopsies using standard methods. Karyotypes were described according to the International System for Human Cytogenetic Nomenclature [18]. Fluorescence in situ hybridization (FISH) was performed on methanol/acetic acid fixed cells using immunoglobulin heavy chain gene (*IGH*), *BCL6*(3q27), and *c-MYC*(8q24) dual color break-apart probes (VYSIS, Downers Grove, Illinois, USA) or locus specific probes for *TP53/ATM* (VYSIS) and *BLIMP1*(*PRDM1*)(6q21) [19], as indicated, according to standard protocols. Fluorescence signals were captured after analyzing 200–300 cells and counterstaining with DAPI using the Cytovision Imaging system attached to a Nikon Eclipse 600 microscope (Applied Imaging, Santa Clara, California, USA).

Immunoglobulin heavy chain gene rearrangement

Polymerase chain reaction analysis to detect *IGH* variable region gene rearrangement was performed on bone marrow aspirates and LN or soft tissue biopsies, using the Biomed-2 primers (IVS Gene Clonality Assay Kit, InVivo Scribe Technologies, San Diego, CA, USA).

Statistical analysis

The observed data were tested for normalcy using a Kolmogorov–Smirnov test. Statistical significance of differences between groups was calculated using the one-tailed Student's *t* test with a significance threshold of $P<0.001$ or

Fisher's exact probability test, and a P value of <0.05 was considered significant.

Results

Case and patient characteristics

Fifty-five cases of DLBCL involving the BM were diagnosed at our institute during the study period, and the most common primary pattern of BM involvement was diffuse (23/55, 42%), followed by nodular (18/55, 32%), interstitial single-cell (12/55, 22%), and paratrabecular (2/55, 4%). Of the 18 cases with a nodular component, four were eliminated since they exhibited a mixed pattern and did not fulfill our definitional criteria (three had a component of diffuse infiltrate and one had numerous single scattered cells). Thus, 14 of 55 (25%) BM biopsies exhibited a pure nodular pattern. In all, except one case, besides the nodular aggregates, the minor component of single scattered or small clusters of neoplastic cells, represented <5% of the DLBCL infiltrate; one case had an additional component of scattered neoplastic cells approaching 10% of the total DLBCL infiltrate. EBV− DLBCL with a nodular pattern accounted for six of 46 of all EBV− cases (13%), whereas EBV+ DLBCL with a nodular pattern represented eight of nine (89%) of all EBV+ cases involving the BM (P=0.00001967868), only one EBV+ DLBCL with a non-nodular pattern (single cell interstitial infiltrate) was seen in our series.

Clinical characteristics of the patients are described in Table 2. All patients presented with de novo DLBCL, except one patient with an EBV+ DLBCL who had a history of B-NHL, not otherwise specified, 14 years prior to the current BM biopsy. The morphology was identical in the previous BM biopsy; however, no material was available to perform in situ hybridization for EBER in the prior biopsy. A male predominance was observed for EBV+ DLBCL (M:F=5:3), while patients with EBV− DLBCL had an equal gender distribution (M:F=3:3). There was no significant difference in the median age of patients that had EBV+ or EBV− DLBCL (66 years versus 59 years, range 3–83 years and 34–84 years, respectively; P=0.4192). Additionally, no difference in the mean age of patients with EBV− nodular DLBCL, and those that had EBV− DLBCL with other patterns of BM involvement was noted. No significant difference in lactate dehydrogenase (LDH) levels, IPI, Eastern Cooperative Oncology Group (ECOG) performance status, or response rates was seen between the two groups. EBV+ DLBCL with a nodular pattern were seen exclusively in immunocompromised patients: HIV+ (n=2), solid organ transplant (n=3), and old age (>50 years, n=3); two of the recipients of solid organ transplants were >50 years of age, while five of six (83%) individuals with EBV− nodular DLBCL were >50 years of age, but none of the latter had any apparent immune dysfunction. None of the patients had a concurrent (or prior) T cell lymphoma or an autoimmune or collagen vascular disease, and with the exception of PTLD patients, none received immunosuppressive medication (e.g. methotrexate).

At diagnosis, PCR-based EBV viral load assessment was performed in five of eight patients with EBV+ DLBCL and in two of six patients with EBV− DLBCL. An elevated serum EBV viral load was noted at the time of diagnosis in all five EBV+ DLBCL (range 411,000–1,352,000 copies per milliliter; mean 852,000). Epstein–Barr virus was undetectable on follow-up evaluation in two of the five cases, both PTLD patients (1 month and 1 year after diagnosis). None of the tested EBV− cases had measurable viral loads at the time of diagnosis.

Morphology and phenotype

The nodules in all eight EBV+ DLBCL were discrete and had rounded contours, with numerous admixed histiocytes, small lymphocytes, occasional plasma cells, and variable numbers of neoplastic cells (Fig. 1). Histiocyte-rich nodules (highlighted with a stain for PGM-1), with histiocytes comprising >50% of the nodule cellularity, were seen in five of eight (62%) cases. The nodules varied in size, both within the same biopsy and between different biopsies, ranging from small (nodules occupying ≤1/2 of a high power field, 400×) to large and expansile (nodules occupying at least one high power field; Table 3). BM biopsies in three of eight cases (38%) showed only interstitial nodules, and only paratrabecular nodules were seen in three cases (38%); two (25%) had both paratrabecular and interstitial nodules (Table 3). A single case showed one nodule in which the neoplastic cells displayed an angiocentric pattern with accompanying coagulative necrosis (Fig. 2f); while in three cases, the nodules had single-scattered apoptotic cells. Neoplastic cells were quantified based on CD20, PAX5 and/or OCT2 staining as assessment of H&E stained slides always underestimated the number of neoplastic cells. In the majority of biopsies (5/8, 62%), large neoplastic cells comprised a minority of the cellular elements (20–30%) that were either seen as scattered cells at the periphery (targetoid pattern) or randomly distributed throughout the nodules (Fig. 3). In the remaining cases (3/8, 38%), neoplastic cells comprised >30% of the nodular cellular infiltrate (Fig. 2h). The neoplastic cells had centroblastic morphology (large lymphocytes with scant to moderate amphophilic cytoplasm, round to ovoid nuclear contours, fine chromatin, and multiple small nucleoli) in only two of eight (25%) cases (Fig. 2h), with the majority (6/8, 75%) displaying pleomorphic cytologic features (large lymphocytes with angulated or irregular nuclear contours) and bizarre or Reed–Sternberg (RS)-like cells were identified in four (66%) of the latter biopsies (Fig. 2d).

Table 2 Clinical characteristics of patients with nodular infiltration of bone marrow by DLBCL

[a] Number of cases (%)

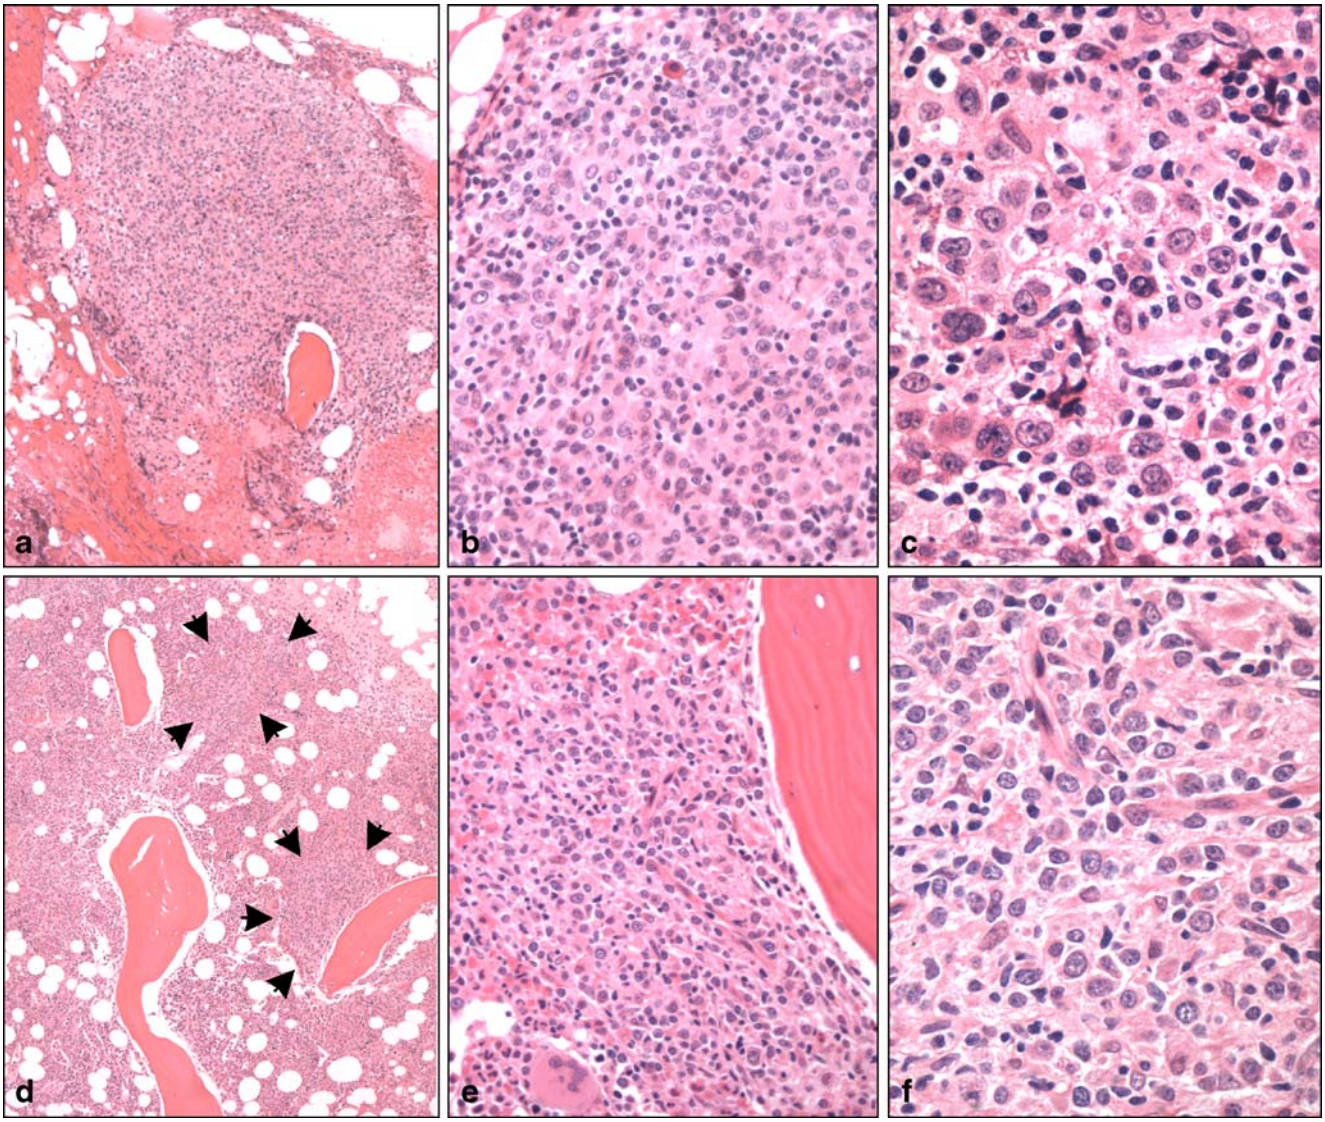

Fig. 1 EBV+ DLBCL of the elderly involving the BM in a nodular pattern (case number 7). **a** BM shows a well-defined paratrabecular nodular infiltrate, clearly visible at low magnification (H&E, 40×). **b** The polymorphic cell population including histiocytes, small lymphocytes, and intermixed neoplastic cells is demonstrated at intermediate magnification (H&E, 200×), while **c** high magnification highlights pleomorphic cytology and occasional RS-like cells (H&E, 400×). EBV− DLBCL with a nodular pattern (case number 12). **d** BM biopsy shows less conspicuous nodules delineated by *arrowheads* (H&E, 40×). **e** Intermediate (H&E, 200×) and **f** high magnification (H&E, 400×) images show a high proportion of centroblast-like cells within the nodules

In contrast, nodules of the six EBV− DLBCL had irregular contours in the majority of cases (4/6, 66%; Fig. 1). Only a few admixed histiocytes were noted (10–30% of all cellular elements within the nodules) that were present in similar numbers as the adjacent uninvolved marrow, and two cases had fewer histiocytes within the nodules compared to the uninvolved marrow, imparting a "negative image" (Fig. 4f). The nodules also had a higher number and density of neoplastic cells compared to most of the EBV+ cases (Fig. 1; Table 3). In all EBV− DLBCL, the neoplastic cells comprised at least 50% of the cellular elements, and in the majority (4/6, 66%), large cells comprised >80% of the nodular cellular infiltrate (Fig. 4e). Half of the biopsies (n= 3) showed only interstitial nodules, while the remaining half showed both interstitial and paratrabecular nodules. The neoplastic cells in the majority of cases (5/6, 83%) demonstrated centroblastic morphology; only one (17%) DLBCL had pleomorphic cytology. The numbers of admixed T cells were variable in EBV+, as well as EBV– DLBCL, and most cases showed a predominance of CD8+ T cells. The inverted CD4:CD8 ratio was especially marked in the 2 EBV+ HIV-associated DLBCL (Table 1). None of the nodules showed evidence of follicular dendritic cell meshworks as assessed by immunohistochemical stains for CD21 and CD23.

In 11 of 14 (79%) cases, corresponding LN or tissue biopsies were available. Of the seven cases of EBV+ DLBCL available for review, four occurred at extranodal sites (two gastrointestinal tract, one liver, and one kidney), while three were LN-based (one axillary, one mediastinal, and one cervical). Four cases showed variable areas of a polymorphic infiltrate, comprising histiocytes, plasma cells, and small-sized reactive lymphocytes with scattered neoplastic cells being the minority component (Fig. 2a). The two PTLD cases were of the monomorphic type, and the LNs showed near total effacement by sheets of large neoplastic lymphocytes, one had pleomorphic neoplastic cells (Fig. 2i), while the other displayed plasmacytoid features. Overall, pleomorphic neoplastic cells were seen in five cases, and numerous anaplastic or RS-like cells were seen in the majority (4/7, 57%) of cases, similar to findings in the BM biopsies (Fig. 2c). Four of the six EBV− DLBCL, with tissue biopsies available for review, were equally distributed between those occurring at extranodal sites (one testes and one retroperitoneal mass) and LNs (one axillary and one cervical). All these cases displayed centroblastic morphology. As in the corresponding BM biopsies, only a minimal infiltrate of admixed histiocytes was observed. One of the two EBV− nodular BM DLBCL, without available tissue biopsies, demonstrated pleomorphic morphology.

All DLBCL expressed one or more B lineage antigens (CD20, PAX5, OCT2) (Table 1). All EBV+ DLBCL (n=8) were EBER+ by in situ hybridization and had non-GC phenotypes, while two of six (33%) and four of six (66%) EBV– DLBCL had non-GC and GC phenotypes, respectively (Table 3). The neoplastic cells of EBV+ DLBCL more commonly expressed CD30 compared to EBV– DLBCL (7/8, 88% versus 1/6, 17%; P=0.016317; Fig. 4d). All EBV– DLBCL were fascin-negative, while only one of eight (12%) EBV+ DLBCL showed weak fascin staining. Six of eight (75%) EBV+ DLBCL had a type II viral latency pattern (LMP1+ and EBNA2−), and two cases (25%) displayed type III latency (LMP1+ and EBNA2+), both of the latter were PTLDs. In the latter, the number of EBER+ cells was greater than the EBNA2+ and LMP1+ cells combined, and nonoverlapping EBNA2+, and LMP1+ subsets were also seen, consistent with the presence of cell populations with different, as well as transitional, EBV latency types. None of the cases showed any staining for LANA.

Cytogenetic analysis

In 12 of 14 (86%) cases, either BM aspirates or LN/soft tissue biopsies were submitted for cytogenetic analysis. Of these, seven cases had abnormal karyotypes, and all but one exhibited a complex karyotype (Table 3). The most

common cytogenetic aberrations were rearrangements of *IGH* (14q32) detected in five cases (71%). Two cases (one EBV+ and one EBV−), both with non-GC phenotypes, showed t(8;14)(q24;q32) indicative of balanced reciprocal translocations involving *IGH* and *c-MYC*. One EBV+ DLBCL showed t(14;19)(q32;q13) involving *IGH*, and the region encoding *BCL3* and one EBV− DLBCL demonstrated t(3;14)(q27;q32) confirmed to represent a translocation involving *IGH* and *BCL6*. An EBV− DLBCL showed rearrangement of *IGH* only detected by FISH; however, due to the complexity of the karyotype, the partner could not be determined (FISH excluded *BCL6* and *c-MYC*).

Immunoglobulin heavy chain gene rearrangement

In seven of 14 (50%) cases, PCR analysis for *IGH* variable region gene rearrangement was performed, and clonal products were detected in six of seven (86%) cases (Table 3).

Discussion

Bone marrow involvement by DLBCL is less common than low grade B-NHL and occurs in 8–35% of cases [2, 3, 8–13]. However, EBV-associated DLBCL, which represent a small subset of DLBCL (8–12%) [10, 20–24] were shown to have a slightly greater proclivity for the BM (39%) in a recent study [10], compared to EBV − DLBCL. Similar to low grade B-NHLs, different morphologic patterns of BM involvement by DLBCL have been described, which include a predominant or near exclusive presence of diffuse (15–50%), paratrabecular (0–53%), nodular (0–23%), or single cell (17–24%) infiltrates of neoplastic cells [2, 4–6, 13, 16]. Similar patterns and frequencies of marrow involvement by DLBCL were also observed in our series. We decided to focus on DLBCL with a pure nodular pattern in this study since little is known about the phenotypic and clinical spectrum of such cases. A nodular pattern of BM infiltration was noted in 25% of all our cases with BM involvement by DLBCL, and although both EBV− and EBV+ cases were observed, the latter predominated. Of interest, among all cases of EBV+ DLBCL with BM involvement, the vast majority (89%) exhibited a nodular pattern, and EBV+ nodular DLBCL were exclusively seen in patients with documented (organ transplantion, HIV infection) or presumed (old age) immune dysfunction. Differences in the morphologic, phenotypic, and clinical characteristics of EBV+ and EBV– DLBCL with a nodular pattern of BM infiltration were also noted.

EBV+ nodular DLBCL had distinctive morphologic features. The nodules were well circumscribed, and the neoplastic cells usually represented a minor component scattered within a heterogenous population of nonneoplastic inflammatory cells, including histiocytes in most cases. Pleomorphic cytology was quite common, and RS-like cells were observed in 50% of cases. In contrast, the nodules of EBV− DLBCL had more irregular contours, and centroblast-like neoplastic cells comprised the major cellular component in the majority of cases. Lymph node and soft tissue biopsies of the EBV+ DLBCL displayed features similar to those observed in the BM with at least some areas demonstrating neoplastic cells scattered within a polymorphic nonneoplastic background, while all LN biopsies of EBV− DLBCL evaluated showed diffuse infiltrates of centroblast-like cells, similar to what is seen in routine cases of DLBCL.

All EBV+ and one third of the EBV− DLBCL had non-GC phenotypes, and a significant number of EBV+ DLBCL showed CD30 expression by at least a proportion of neoplastic cells compared to EBV − DLBCL, in agreement with prior studies [22, 25]. Staining for fascin, a protein involved in the formation of dendritic processes that is expressed by RS cells in virtually all cases of classical Hodgkin lymphoma (CHL) [26], and approximately 50% of anaplastic large cell lymphomas [27], was seen in the BM and corresponding LN biopsy in only one (13%) of our EBV+ DLBCL, similar to the frequency reported previously [27]. Previous studies of EBV+ DLBCL in PTLD patients have shown high frequencies (36–64%) of type III latency profiles [28, 29]. Lower frequencies of this latency type have been reported in HIV patients (41–50%) [30, 31]. All, except two of the EBV+ cases in our series, displayed type II latency. Both PTLDs, which were of the monomorphic subtype (DLBCL), exhibited type III latency profiles, but populations of cells with different latency types were seen in these cases, similar to previous observations [28, 29]. Our three cases of EBV+ DLBCL of the elderly (see below) showed type II latency, which is the more common latency profile described in these lymphomas [23, 25]. Type III

latency has, however, been described in a small proportion of such cases (14–36%) [12, 20, 22, 23, 25, 32].

An interesting finding in our study relates to the presence of EBV+ DLBCL that fulfill the criteria of the recently recognized entity termed EBV+ DLBCL of the elderly [15, 23, 32, 33]. The current World Health Organization classification defines these lymphomas as those occurring in patients >50 years old without any known predisposing

immunodeficiency [15, 23, 32, 33]. A recent survey of EBV-associated lymphomas by Cho et al. described 29 patients with EBV+ DLBCL, 24 of whom were elderly or had a prior history of hepatitis B or C virus infection, tuberculosis, or CHL, suggesting decreased immunity associated with old age and/or environmental cofactors as contributors to lymphomagenesis [20]. It is thought that age associated immune dysfunction, a phenomenon described as "immune senescence," predisposes older individuals to EBV+ lymphomas [34]. Similarities of EBV+ DLBCL of the elderly to B-NHL arising in immunodeficient or immunocompromised patients have been previously described, including a propensity for extranodal disease and the morphologic spectrum of lymphoproliferations, ranging from polymorphic lymphomas resembling polymorphic PTLDs to large cell monomorphic lymphomas indistinguishable from conventional DLBCL [12, 15, 20, 23, 25, 32, 33, 35, 36]. Although, BM involvement has been documented in EBV+ DLBCL of the elderly, to the best of our knowledge, the patterns of BM involvement have not been described. It remains to be seen whether a nodular pattern is the most prevalent pattern of BM involvement in this entity, as seen in our study. Virtually, all prior studies of EBV+ DLBCL have been reported from Asia, whereas, all our three patients were Caucasian and of European descent. Moreover, in contrast to the Asian experience, our cases did not show extranodal involvement.

The morphologic and phenotypic features of our nodular DLBCL also showed an overlap with other types of B cell malignancies, which include T cell/histiocyte-rich large B cell lymphoma (THRLBCL), especially the micronodular variant [37], lymphomatoid granulomatosis (LG), and CHL. Bone marrow involvement, although rare in some of these entities, has been described [38, 39]. The paucity of neoplastic cells and the presence of a polymorphic background, often rich in histiocytes and small reactive T cells, in all these entities, can pose a diagnostic challenge, especially, when reviewing BM biopsies. T cell/histiocyte-rich large B cell lymphomas are usually EBV−; however, rare cases of EBV+ THRLBCL with CD30+ neoplastic cells showing RS-like morphology have been described [40]. However, by definition, the diagnosis of THRLBCL requires the presence of at least a 90% component of nonneoplastic cells, without any aggregates or sheets of large neoplastic cells [15]. All our DLBCL, though rich in nonneoplastic cells, had clusters and/or sheets of neoplastic cells that comprised at least 20% of all cellular elements of the nodules of EBV+ DLBCL and >50% of the EBV− DLBCL. Lymphomatoid granulomatosis also has a polymorphic infiltrate with variable numbers of large EBV+ lymphocytes that may also express CD30. However, these lymphoproliferations show angiocentricity and/or angiodestruction and although occasional bizarre lymphocytes may be seen, classic RS-like cells are infrequent [15]. Angiocentricity and angiodestruction with associated coagulative necrosis was observed focally in only one BM biopsy of our EBV+ DLBCL, within a nodular aggregate that had a large proportion of neoplastic cells. Nodal involvement, which is rare in LG, is usually characterized by a predominance of small-sized T cells in the background, while the LN biopsy of the aforementioned case showed a diffuse infiltrate of predominantly large neoplastic cells, and there was no evidence of extranodal disease arguing against the possibility of LG [41]. Classical Hodgkin lymphoma often presents as nodular polymorphic lymphohistiocytic infiltrates with infrequent CD30+ RS-like cells in the BM [42]. RS cells in CHL coexpress CD30 and CD15 in the majority of cases (80%), are uniformly positive for fascin, and although a minority can express bright CD20 (30%), they usually do not express OCT2 or PU-1 [15, 26]. The CD30+ RS-like cells in our EBV+ DLBCL were uniformly negative for CD15, expressed CD20 in the majority of cases (88%), expressed PU-1 in 50%, and fascin was only expressed in one case. Moreover, all except one case tested, showed clonal immunoglobulin gene rearrangements, which are less commonly detected in CHL by the current assays. The morphologic and phenotypic features of one of our EBV+ cases was similar to the so-called mediastinal gray zone lymphomas, although there was no evidence of mediastinal disease and the latter tend to be EBV− [43]. Methotrexate-related lymphoproliferative disorders can also display similar features, but none of our patients received methotrexate therapy [44]. Although, even nonneoplastic disorders (especially infectious mononucleosis) could morphologically mimic the findings we describe, involvement of the bone marrow is exceptionally rare in these situations. Our study highlights the utility of an extensive immunophenotypic panel, examination of tissue from other sites, and correlation with the clinical features in order to distinguish between these different diagnostic considerations when a nodular pattern of DLBCL is encountered in BM biopsies.

Cytogenetic analysis demonstrated complex cytogenetic aberrations in approximately 50% of our EBV+ and EBV− DLBCL evaluated, but recurrent cytogenetic abnormalities were not observed. Translocations involving *IGH* (14q32) were the most frequently encountered abnormality, detected in almost half of the cases with cytogenetic abnormalities; however, the partners varied. Translocations of *IGH* and *c-MYC* were detected in one case each of EBV+ and EBV− DLBCL. Both had complex karyotypes and non-GC phenotypes, effectively ruling out a diagnosis of Burkitt lymphoma. Intriguingly, an EBV+ DLBCL showed a t(14;19)(q32;q13) on karyotypic analysis, potentially involving the *BCL3* locus, which has been previously reported in a variety of B-NHLs [45]; however, FISH was not performed to confirm involvement of *BCL3* in this case.

Cytogenetic findings have not been previously described in surveys of EBV+ DLBCL of the elderly. Our results suggest that the spectrum of cytogenetic aberrations in these cases might be similar to conventional DLBCL [46]. All, but one of our cases, showed clonal IgH gene rearrangement products by PCR analysis. Addition of PCR assays for Ig light chains might have increased the yield of our clonal cases, since cases have been described that show clonality only on using light chain (IgK) primers [47].

Lastly, but importantly, our study suggests investigation of the patient's immune status and evaluation for EBV infection if one observes a nodular pattern of BM involvement by DLBCL with the described features. Determination of EBV status is clinically relevant as multiple studies have demonstrated that EBV+ DLBCL patients have significantly lower overall survival rates, compared to individuals with EBV– DLBCL [10, 22, 24, 33]. We did not see any significant difference in ECOG status, LDH levels, IPI, or clinical outcomes between EBV+ and EBV– DLBCL patients, which might be attributable to our small sample size and/or selection of patients with advanced stage disease (BM involvement). High mortality was seen in both groups, and the small number of patients precludes any assessment of the type of therapy. Since immunosuppressed patients with T cell dysfunction are at risk for "reactivation" of EBV and subsequent development of EBV-associated lymphoproliferative disorders, viral load monitoring in patients with EBV+ PTLDs is performed to detect early disease recurrence and response to treatment [48, 49]. EBV viral load assessment performed in five of our patients at diagnosis of EBV+ B-NHL, which included individuals with PTLD, HIV associated DLBCL, and EBV– DLBCL of the elderly, showed evidence of viral reactivation. Future studies need to investigate the utility of serial serologic or EBV viral load monitoring, as performed in PTLD patients, in detecting early disease recurrence in EBV+ DLBCL of the elderly. Clinical trials using targeted therapies that induce the lytic form of infection in EBV+ lymphoid malignancies in conjunction with gancyclovir treatment have shown promising results [50]. This strategy might also be useful in treating EBV+ DLBCL of the elderly. Since altered lymphocyte development and function contribute to immunosenescence in the elderly, recently proposed treatment approaches aimed at rejuvenating the immune system and augmenting innate immunity in the elderly might be alternative therapeutic options [51].

◀ **Fig. 4** Immunohistochemical studies of the bone marrow (100×). Case number 7 (EBV+ DLBCL), **a** Scattered CD20+ neoplastic B cells representing less than 50% of all cells within the nodule. **b** The nodule is rich in histiocytes (PGM1); **c** neoplastic cells express EBER; and **d** many are CD30+. In contrast, case number 12 (EBV− DLBCL), **e** has numerous CD20+ neoplastic cells within the nodules and **f** fewer histiocytes (PGM1); **g** EBER is negative; and **h** the neoplastic cells do not express CD30

Conflict of interest statement We declare that we have no conflict of interest.

Splenic micronodular T-cell/histiocyte-rich large B-cell lymphoma: effect of prior corticosteroid therapy

Elena Kan · Itai Levy · Daniel Benharroch

Received: 20 April 2009 / Revised: 16 August 2009 / Accepted: 24 August 2009 / Published online: 9 September 2009

Abstract We report on three patients who were treated with corticosteroids only prior to the diagnosis of splenic lymphoma. Corticosteroids were administered for different conditions, at different doses, and for various periods of time. The primary diagnosis was splenic micronodular T-cell/histiocyte-rich large B-cell lymphoma in the three cases, and it was reached with variable difficulty. We suggest that the corticosteroid treatment was one of the causes for the complications in reaching a diagnosis. The morphologic appearance of the microscopic splenic nodules was the most variable feature and may possibly reflect the dose and duration of the corticosteroid therapy. However, the histopathologic changes are probably not related with Epstein-Barr virus-induced immunosuppression.

Keywords Splenic micronodular lymphoma · T-cell/histiocyte-rich large B-cell lymphoma · Corticosteroids

Introduction

Splenic micronodular T-cell/histiocyte-rich large B-cell lymphoma (SMTHLBCL) is a rare lymphoma variant related to T-cell/histiocyte-rich large B-cell lymphoma (THLBCL), which occurs at other body sites as well as in the spleen. First described as SMTHLBCL by Dogan et al. in 2003, it presents with systemic symptoms, anemia, and splenomegaly, with minimal to usually absent lymphadenopathy [1]. In this condition, the spleen shows multiple micronodules and a mixed population of small T cells and plasma cells. The tumoral cells dispersed among the previously mentioned population are large lymphoid cells that are $CD20^+$, $Bcl\text{-}6^+$, and to a variable extent EMA^+, $CD30^+$, and $Bcl\text{-}2^+$. The features of this variant lymphoma are similar to those of THLBCL [2]. Most of the 17 patients described by Dogan et al. died within 2 years of diagnosis [1].

A search into the older literature disclosed three cases of lymphoma described by Braylan et al. These patients presented with splenomegaly but no lymphadenopathy. In these spleens, multiple epithelioid granulomas masked the neoplasm and delayed diagnosis. It is possible that these authors had described prematurely the same lymphoma variant [3].

Sarcoid-like granulomas, as seen in Hodgkin as well as in non-Hodgkin lymphomas, often obscure the neoplasm. Moreover, sarcoidosis by itself may be related to non-Hodgkin lymphoma. These two conditions may be extremely difficult to distinguish, especially when no clinical evidence of sarcoidosis is present [4, 5].

Patients with suspected malignant hematolymphoid disease have at times been subjected to exclusive corticosteroid therapy prior to a primary biopsy [6]. Indications for the steroid therapy have varied from hemolytic anemia, dermatologic disorders, asthma, and auto-immune diseases, to life-threatening conditions such as superior vena cava syndrome and respiratory insufficiency [7–9]. Except for the rare tumor lysis syndrome, complications of corticosteroid administration prior to a biopsy have rarely been reported [9]. In an ongoing study on this subject (manuscript in preparation), we found that a complication in the primary diagnosis was the most frequent consequence of this preliminary corticosteroid therapy. Among the patients

with lymphomas examined in the previously mentioned study, there were three who received corticosteroids before bone marrow biopsy, liver biopsy, and splenectomy were performed. These three patients, diagnosed with variable difficulty as suffering from SMTHLBCL, are the subject of this report. No additional SMTHLBCL case was found in our Registry that was not related with prior corticosteroid treatment.

Case histories

Case 1. C.R., a 70-year-old woman with asthma, presented because of weight loss. She was found to have splenomegaly and hemolytic anemia for which she was given 60 mg prednisone a day for 6 months. As lymphoma was suspected, in the absence of lymphadenopathy, splenectomy was carried out. The patient was given six courses of rituximab, cytoxan, adriamycin, vincristine, and Prednisone (R-CHOP), and 1 year after the first marrow biopsy, she showed evidence of complete remission. At that time, a bone marrow biopsy showed no evidence of malignancy.

Case 2. B.E., a 59-year-old man, was admitted because of fever of 3 months' duration, weight loss of 15 kg, night sweats, splenomegaly, and anemia of 12.8 g%. He was obese, a heavy smoker, and suffered from diabetes. He was given 60 mg prednisone because of fever of unknown origin in the absence of peripheral lymphadenopathy or a clear-cut malignant tumor. A diagnostic splenectomy was performed. The patient was treated with six courses of R-CHOP and was in remission 15 months after diagnosis.

Seven years after presentation, the patient was admitted because of a right orbital tumor. It was located in the lacrimal gland and its histology was that of a low-grade marginal zone B-cell lymphoma. The patient refused treatment and is well, 26 months following complete resection of the lacrimal gland.

Case 3. S.M., a 63-year-old woman, complained of fever, weight loss, fatigue, and pruritus, and was found to have splenomegaly. Anemia and hypogammaglobulinemia were evident. The patient received prednisone 40 mg a day for 3 months for dermatitis followed by tapering off the dose. A laparoscopic splenectomy was performed. No additional abdominal organ seemed to be involved in the process. The patient was treated with six cycles of R-CHOP. She suffered neutropenic fever on several occasions. The patient is now in complete remission, 36 months after presentation.

Materials and methods

The three patients reported herein are part of a larger cohort retrospectively investigated as they were treated with corticosteroids only prior to a primary lymphoma biopsy. They presented with isolated involvement with what seemed to be a splenic lymphoma.

The history of the patients and splenic, marrow, and liver biopsies, when available, were reviewed. The possible effect of prior corticosteroid therapy was studied. Notably, we scrutinized the size and composition of the microscopic nodules. We evaluated the degree to which the diagnoses of Hodgkin lymphoma, peripheral T-cell lymphoma, and benign granulomatous lesions were tenable.

These patients are reported since we reached a diagnosis of SMTHLBCL in the three cases. Clinical features were retrieved from the patients' files (Table 1). To evaluate a possible link between this outstanding occurrence and EBV-induced immune suppression, we carried out Epstein-Barr virus small RNA (EBER) in situ hybridization (ISH), using the kit from Biogenex, (San Ramon, CA, USA).

Results

The bone marrow biopsies showed predominant groups of epithelioid histiocytes, numerous $CD3^+$ or $CD5^+$ T cells, and a small number of large $CD20^+$ B cells. In two of the three cases, the infiltrates were paratrabecular (Fig. 1a).

In case 2, a first liver biopsy showed several epithelioid aggregates (Fig. 1b), numerous small T cells, and a few large lymphoid cells that were $CD20^+$, $CD30^+$, $CD15^-$. In a second liver biopsy, the microscopic nodules were fibrotic (Fig. 1c), at least in part, and lacked epithelioid histiocytes and most of the small T lymphocytes.

The spleens weighed 744, 850, and 540 g. The cut section was uniformly dark red. On histology, multiple microscopic nodules included epithelioid cell aggregates at their centers (Fig. 1d). They also included isolated large B cells (Fig. 1e) and some $CD30^+$ (Fig. 1f), focally positive for EMA, Bcl-6, and BCl-2. Immunostains for CD10, CD15, CD23, and LMP-1 were all negative. EBER ISH was negative in all three cases. A few small B cells were also found. A reticulin stain highlighted the fine nodularity of the spleens. The red pulp was often spared. The microscopic nodules varied in size and composition from case to case. In some of these, as in case 1, all the components were well represented. In the other cases, epithelioid and small T cells were few. In case 2, some micronodules were fibrotic.

The following diseases were initially considered as a probable diagnosis: granulomatous inflammation (cases 1

and 2), Hodgkin lymphoma, peripheral T-cell lymphoma (case 3), granulomas reactive to and masking a malignant lymphoma (case 1), and nodular lymphocyte-predominant Hodgkin lymphoma (case 2). However, in establishing the diagnosis of splenic micronodular T-cell/histiocyte-rich large B-cell lymphoma, we were influenced by the similarity of the microscopic nodules to T-cell/histiocyte-rich large B-cell lymphoma as it presents in lymph nodes. We may have been biased by the SMTHLBCL case that we reported several months ago.

Patient 2 developed marginal B-cell lymphoma of the right lacrimal gland 7 years after the splenic lymphoma. The three patients are in complete remission from 12 to 36 months following last evidence of lymphoma.

Discussion

Splenic micronodular T-cell/histiocyte rich large B-cell lymphoma has rarely been described. In fact, the diagnosis is a very difficult one to make and several conditions have to be excluded first. Follicular lymphoma has rarely involved the spleen in the absence of nodal disease. Moreover, bone marrow involvement by SMTHLBCL has been diagnosed before as follicular lymphoma [10].

Granulomatous inflammation of the spleen should also be considered and is difficult to rule out. The microscopic nodules, in contrast to granulomas, show a morphologic and immunophenotypic composition similar to that of T-cell/histiocyte-rich large B-cell lymphomas. The presence of large CD30-positive lymphoid cells, small T cells, and eosinophils should suggest the diagnosis of Hodgkin lymphoma, but a micronodular pattern with uniformly large CD20-positive B cells, even though few in number, should exclude this lymphoma. Involvement of the spleen by a T-cell lymphoma is usually marked by extensive necrosis and an admixture of lymphoid cells of all sizes. Nodular lymphocyte predominant Hodgkin lymphoma rarely presents with isolated involvement of the spleen [1, 10].

Difficult as it may be to diagnose, it seems that prior treatment with corticosteroids renders the diagnosis of SMTHLBCL even more remote. Such preliminary therapy is given to patients with conditions such as hemolytic anemia, idiopathic thrombocytopenic purpura, dermatoses, and autoimmune diseases [6, 7].

It is of note that although few patients with SMTHLBCL have been described to date, none are reported to have received pretreatment with corticosteroids. Variation in the appearance of the microscopic nodules is marked in our patients, from well-developed microgranuloma-like nodules to more cellular nodules with predominant small T cells and at times fibrosed nodules. These changes may reflect the dose and duration of the prior corticosteroid therapy.

It is possible that in several of the 40 or so cases of SMTHLBCL that have been identified to date, prior corticosteroid treatment was administered but unreported [10]. This may have contributed to the complexity of the diagnostic approach. Is it possible that the SMTHLBCL variant itself is the consequence of corticosteroid treatment in patients with an unrelated lymphoma entity or a benign lesion?

Glucocorticoids are known for their marked effect on a variety of mammalian cells. These hormones modify both cellular metabolism and gene expression and show a cytotoxic effect on some cell types, most markedly on lymphocytes [11]. Corticosteroids have been shown to cause apoptosis in most nucleated cells of the hemolymphatic system: thymocytes [12], T lymphocytes [13], B lymphocytes [14], monocytes, and macrophages [15].

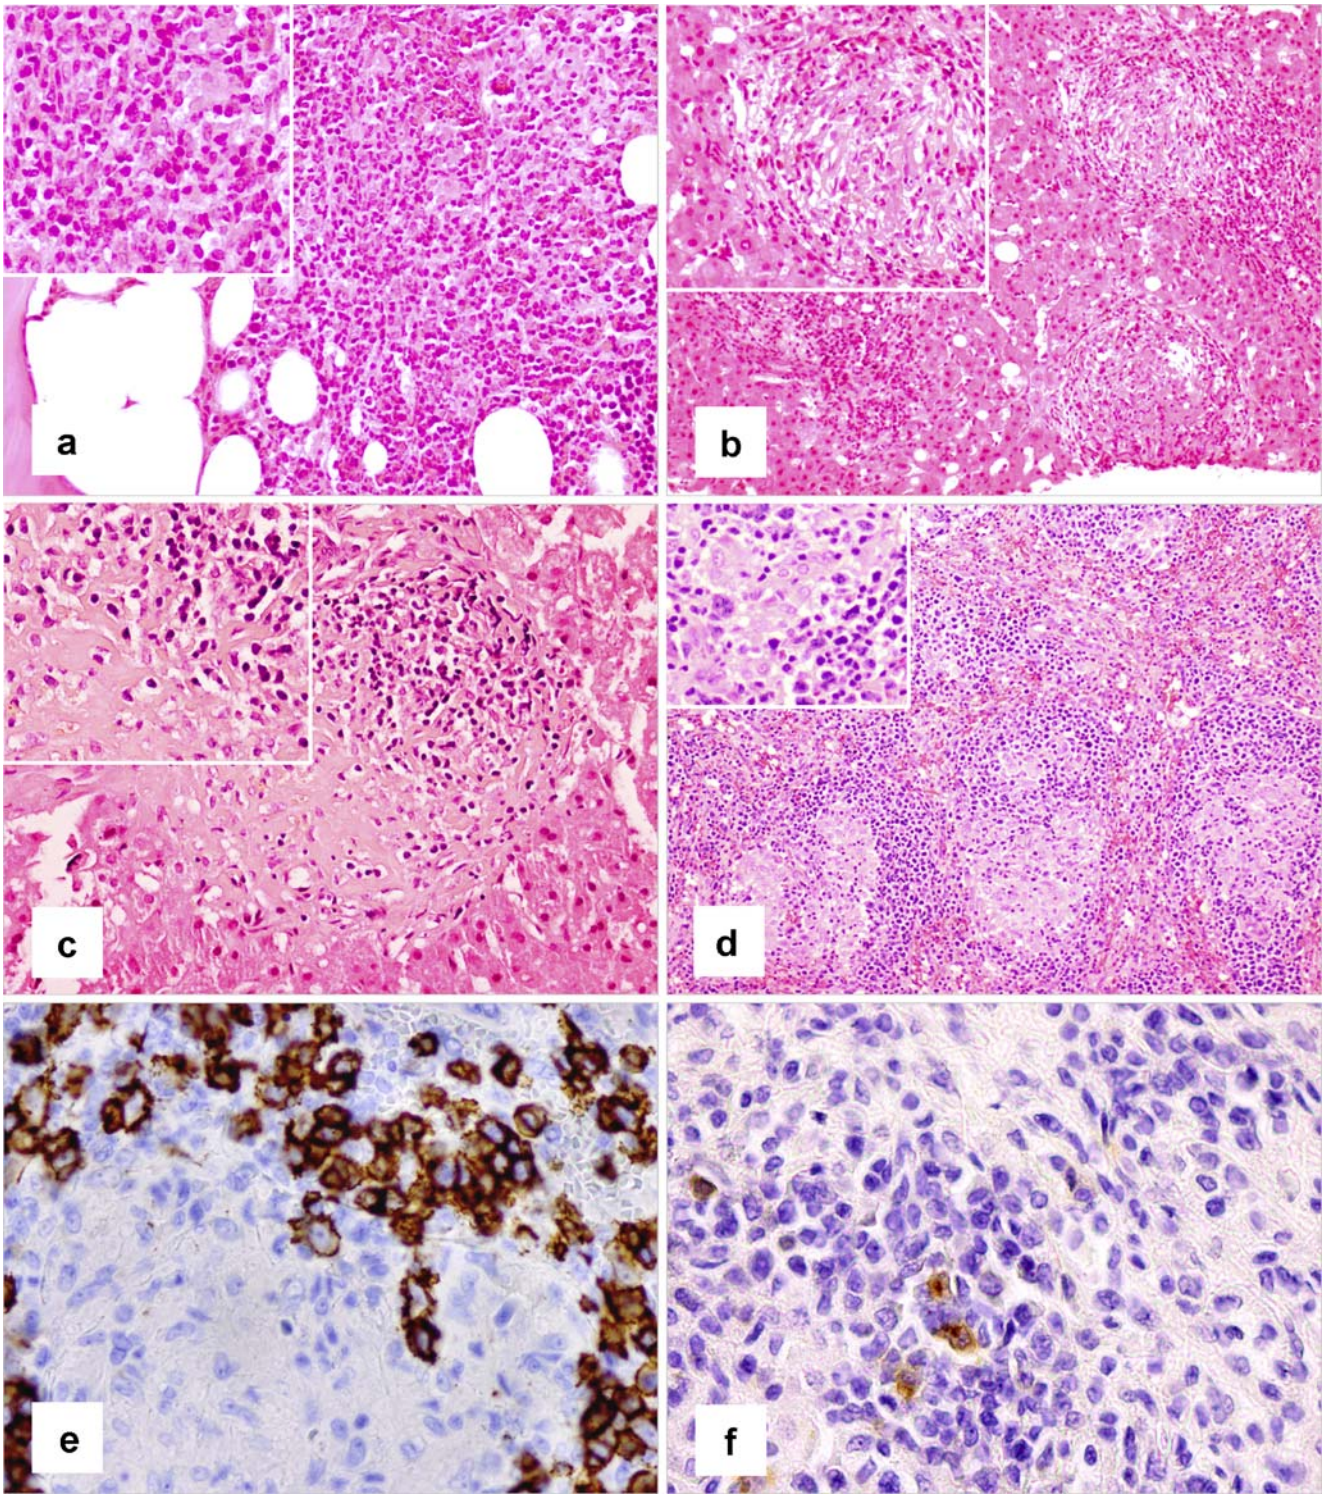

Fig. 1 **a** Micronodular involvement of bone marrow by tumor (H & E, ×240). The presence of a mixed population, including small and larger lymphoid cells is seen (*inset*). **b** Three microscopic tumor nodules in liver biopsy of case2 (H & E, ×240). The *inset* shows the margin of a tumor nodule. **c** Predominantly fibrosed nodule in second liver biopsy of case2 (H & E, ×310). The fibrosis is emphasized (*inset*). **d** Case1, section of spleen—several micronodules with predominant epithelioid cells (H & E, ×240). In addition, large lymphoid cells (see *inset*). **e** Large CD20-positive cells in splenic nodule (Immunoperoxidase with Diaminobezidine substrate, ×360). **f** Large CD30-positive cells in splenic microscopic nodule (Immunoperoxidase with Diaminobenzidine substrate, ×360)

When, however, T lymphocytes over-expressed the Bcl-2 oncogene, the glucocorticoids inhibit apoptosis [16]. As a consequence of this therapy, the lesions are expected to present reduced numbers of these cells.

In this context, one should note the association between immune suppression and the subsequent development of lymphomas. Corticosteroids are notable for their immune suppressive effect. The negative results both with LMP1 immunostains and with EBER RNA ISH do not support such an occurrence in our cases, as such lymphomas are most often EBV-associated. Knowledge of the effect of corticosteroids on the lymphoreticular system, as a most important component of the immune system, and its neoplasms, is at best incomplete [17]. Corticosteroids are an integral part of the CHOP regimen; however, remission may be obtained with corticosteroids alone, and may even be sustained.

It seems that malignant lymphomas of the central nervous system are more prone than other lymphomas to the masking effect of prior corticosteroids [18, 19]. An extensive search of the effect of prior corticosteroid therapy in lymphomas in general did not disclose further data.

The present cases were selected from a larger cohort of lymphomas that were diagnosed following steroid therapy. This expanded study is pending and is the subject of a future publication.

The splenic pathology that may precede the corticosteroid effect would therefore be richer in T and B cells and in histiocytes, and may well be of the common brand of THRLBCL. The unknown component, though critical, is the micronodular pattern and should not be a priori consequence of corticosteroids. Thus, although it is tempting to relate the occurrence of SMTHLBCL to this iatrogenic effect, this is not probable.

We eventually reached the diagnosis of SMTHLBCL because we had been made aware of this lymphoma variant following our publication of a single case report of patient 3 (S.M.). In this report, we had missed the significance of the prebiopsy corticosteroid treatment [10].

Although the primary diagnosis of SMTHLBCL is extremely difficult by itself, the use of corticosteroids in the reported cases may have postponed establishment of the diagnosis by supporting alternative diagnoses. Moreover, it would have complicated the diagnosis by modifying the size and composition of the microscopic nodules.

In conclusion, we have described three patients who received a preliminary treatment with corticosteroids for different conditions and who eventually, with differing difficulties, were diagnosed as having splenic micronodular T-cell/histiocyte-rich large B-cell lymphoma. We have been unable to identify a case of SMTHLBCL in our registry that was not related with corticosteroid treatment.

Conflict of interest statement We declare that we have no conflict of interest.

CpG island hypermethylation and repetitive DNA hypomethylation in premalignant lesion of extrahepatic cholangiocarcinoma

Baek-hui Kim · Nam-Yun Cho · So Hyun Shin · Hyeong-Ju Kwon · Ja June Jang · Gyeong Hoon Kang

Received: 16 April 2009 / Revised: 5 August 2009 / Accepted: 24 August 2009 / Published online: 10 September 2009

Abstract Biliary intraepithelial neoplasia (BilIN) is the premalignant lesion of extrahepatic cholangiocarcinoma (EHC), and there are no published data regarding epigenetic changes throughout disease progression from normal biliary epithelia to BilIN to EHC. The objective of this study was to identify the occurrence of CpG island hypermethylation and repetitive DNA hypomethylation in BilIN. A total of 50 EHCs, 31 BilINs, and 31 normal cystic duct samples were analyzed for their methylation status in seven genes and two repetitive DNA elements. The number of methylated genes increased with disease progression (normal bile duct, 0.6; BilIN, 2.0; EHC, 3.6; $P<0.001$). The methylation level of examined genes was significantly higher in BilIN than in normal samples (*TMEFF2*, *HOXA1*, *NEUROG1*, and *RUNX3*, $P<0.05$) and in EHC than in BilIN samples (*TMEFF2*, *HOXA1*, *NEUROG1*, *RUNX3*, *RASSF1A*, and *APC*, $P<0.05$). Long interspersed nucleotide element-1 (*LINE-1*) and juxtacentromeric satellite 2 (*SAT2*) methylation levels were markedly lower in EHC than in normal duct and BilIN samples, and BilIN samples showed a decrease of *SAT2* methylation levels but no decrease of *LINE-1* methylation levels compared to normal samples. These findings suggest that most of cancer-specific CpG island hypermethylation occur in the stage of BilIN and that CpG island hypermethylation seems to occur earlier than repetitive DNA element hypomethylation.

Introduction

Extrahepatic cholangiocarcinoma (EHC) is an uncommon malignant neoplasm that arises from the extrahepatic bile ducts. The pathogenesis of EHC is not fully understood, but it has been proposed that EHC develops through a multistep carcinogenesis process and that EHC is preceded by a precursor lesion, biliary intraepithelial neoplasia (BilIN) [1]. BilINs are found adjacent to carcinoma lesions in 20–80% of EHCs, supporting the hypothesis that BilIN is a premalignant lesion of invasive carcinoma [2–4]. The lack of standard classification, relatively low incidence, difficulty in approach to the anatomic location, and the small tissue sample size of BilIN make it hard to investigate the BilIN–EHC sequence [5]. For this reason, few studies concerning BilIN have been reported, even though certain molecular alterations, including *KRAS* and *p53* mutations, have been revealed in EHC [6, 7]. However, there have been some studies regarding morphologic and molecular features of premalignant lesions arising from intrahepatic bile ducts [8–11]. Results of these studies support that BilIN of large intrahepatic bile duct is also a precursor lesion of intrahepatic cholangiocarcinoma.

In the traditional concept of molecular carcinogenesis, genetic alterations play a pivotal role in cancer progression. Recent advancements in epigenetic studies have changed this concept, however, and much data support the contribution of epigenetics to tumorigenesis [12]. Aberrant DNA hypermethylation and hypomethylation are the most consistently observed and widely studied epigenetic events in human cancers. Hypermethylation of promoter CpG islands is closely related to silencing of tumor suppressor genes, which is a common finding in human cancers regardless of tissue types [13]. However, various tissue types of human cancers show distinct methylation profiles that differ from those of normal tissues [13]. On the other hand, genome-wide DNA hypomethylation causes chromosomal instability and is believed to play an important role in cancer progression [14, 15]. Measurements of methylation of repetitive DNA sequences, including long interspersed nucleotide element-1 (*LINE-1*) and juxtacentromeric satellite 2 (*SAT2*), are reproducible and correlate well with genome-wide methylation levels [16]. In the multistep carcinogenesis model, genetic changes as well as epigenetic changes accumulate with tumor progression [12, 17–20]. In this regard, a stepwise increase in promoter CpG island methylation and a stepwise decrease in genome-wide methylation levels are expected in the normal bile duct–BilIN–EHC sequence. Little is known, however, about DNA methylation changes in BilIN of the extrahepatic bile duct.

We previously determined methylation profiles for 24 CpG island loci in EHCs using methylation-specific polymerase chain reaction (PCR; MSP) and found that methylation frequencies of seven individual CpG island loci (*HOXA1*, *TMEFF2*, *NEUROG1*, *CDH1*, *RUNX3*, *RASSF1A*, and *APC*) were >23% in EHC [21]. Their methylation frequencies were significantly higher in EHCs than in normal bile ducts, indicative of cancer-related hypermethylation. In the present study, we analyzed BilIN and EHC samples for their methylation status in the seven CpG island loci using real-time PCR-based quantitative methylation analysis (MethyLight technology) to determine whether promoter CpG island hypermethylation is an early event in multistep carcinogenesis of EHC. In addition, we examined whether repetitive DNA hypomethylation occurs in EHC and BilIN.

Materials and methods

Patients and tissue samples

A total of 112 formalin-fixed, paraffin-embedded archival tissue samples (50 EHC, 31 BilIN, and 31 cholecystitis) were previously obtained from 84 patients (53 EHC and 31 cholecystitis) who underwent surgical resection for EHC or chronic cholecystitis at the Seoul National University Hospital, Seoul, South Korea between January 2001 and December 2004. From the surgical specimens of EHC patients (n=53), we obtained 31 BilIN samples, 28 of which were matched samples of EHC and BilIN. The remaining three BilIN samples were obtained from three EHC cases in which archival tissue blocks of invasive cancers were not available for the present study. All samples of EHC and BilIN were obtained from extrahepatic biliary tree (distal and proximal common bile ducts, common hepatic duct, confluence of hepatic duct, and cystic duct), and gallbladder lesions were not included in this study (Table 1 and Supplemental Table 1). We classified BilIN into two grades (low and high) instead of three grades (BilIN-1, BilIN-2, and BilIN-3), and low-grade BilIN corresponds to BilIN-1, and high-grade BilIN corresponds to BilIN-2 and BilIN-3 of the consensus proposal [5]. We selected high-grade BilIN more than 1 cm away from invasive carcinoma to eliminate potential contamination of carcinoma cells. Loss of cellular polarity, nuclear pseudostratification reaching upper third of cytoplasm, and nuclear changes including enlargement, hyperchromasia, and irregular nuclear membrane were used as diagnostic criteria for high-grade BilIN. Dysplastic lesions showing abrupt severe nuclear atypia or nuclear atypia equivalent to invasive carcinoma were excluded to eliminate the possibility of sampling cells from intraepithelial or lateral spreading of adenocarcinoma. We also excluded low-grade BilIN from the study because of the ambiguity of diagnostic criteria for hyperplastic or reactive epithelial lesions and low-grade BilINs. We considered dysplastic lesions with basally located nuclei, mild nuclear atypia, and relatively uniform nuclei as low-grade BilIN [5]. EHC samples were obtained from invasive tumor portions of surgical specimens. Cystic duct portions from cholecystectomy specimens were used as surrogates for normal bile duct samples, which are usually denuded of their epithelium in the surgical specimens submitted for histologic examination. Two pathologists reviewed all slides of surgical specimens and pathologic stages, and tumor grade was determined using the latest criteria of the cancer staging manual of the American Joint Committee on Cancer and World Health Organization classification system [22, 23]. This study was approved by the Institutional Review Board of Seoul National University Hospital.

DNA extraction and bisulfite modification

Five serial sections (8 μm thick) from each paraffin block sample were stained with hematoxylin and eosin and were examined microscopically. Regions consisting of more than 70% neoplastic cells were marked and manually dissected

Table 1 Locations and histologic features of extrahepatic cholangiocarcinoma and biliary intraepithelial neoplasia

EHC extrahepatic cholangiocarcinoma, *BilIN* biliary intraepithelial neoplasia, *CBD* common bile duct, *CHD* common hepatic duct

[a] These patients are both included in extrahepatic cholangiocarcinoma and biliary intraepithelial neoplasia groups

and placed in microtubes. The collected tissue samples were digested in lysis buffer containing proteinase K. Bisulfite modification of the digested tissue samples (18 μl) was performed using the EZ DNA methylation kit (Zymo Research Co., Orange, CA, USA) according to the manufacturer's protocol.

DNA hypermethylation assay

We quantified hypermethylation using MethyLight technology. Based on a previous study, we selected seven promoter CpG island loci that were methylated in EHC at frequencies significantly higher than those in normal bile ducts [21]. Primer and probe sequences are listed in Table 2. PCR was performed in 30 μl containing 0.2 mM deoxyribonucleotide triphosphates, 0.3 μM forward and reverse primers, 0.05 μM probe, 3.5 mM $MgCl_2$, 0.05% gelatin, 0.01% Tween-20, 1× PCR buffer, and 0.5 U of AmpliTaq Gold polymerase. The amplification conditions for all primers consisted of 95°C for 10 min, followed by 50 cycles of 95°C for 20 s and 59°C for 40 s. *ALU* repeats were used as an internal reference to normalize input DNA and to generate a standard curve. Bisulfite-modified placental genomic DNA treated with M.*Sss*I was used as a control reaction for the *ALU* repeat and selected promoter CpG loci. The percentage of methylated reference (PMR) of each genetic locus was calculated as 100 times the *GENE*/*ALU* methylation ratio of each sample divided by the *GENE*/*ALU* methylation ratio of reference DNA treated with M.*Sss*I. The methylation status of each sample was determined as positive when PMR >4, which cutoff value was based on validated data [24].

DNA hypomethylation assay

Methylation levels of repetitive DNA elements, including *LINE-1* and *SAT2*, correlate with global DNA methylation levels [25, 26]. *LINE-1* methylation level was measured using the combined bisulfite restriction analysis (COBRA) technique as described [20]. *LINE-1* sequences in bisulfite-modified DNA were amplified, and the PCR products were digested with *Tas*I and *Taq*I to digest unmethylated and methylated *LINE-1* alleles, respectively. Then, the digested DNA fragments were separated using polyacrylamide gel electrophoresis. The methylation level of *LINE-1* was calculated as the intensity of *Taq*I-digested band divided by the sum of intensities of *Taq*I- and *Tas*I-digested bands. Measurement of band intensity was performed with ImageJ software (http://rsb.info.nih.gov/ij). We measured methylation of *SAT2* using MethyLight technology as described [16]. Primers and probe for *SAT2* are shown in Table 2.

Statistical analysis

The two-tailed Student's *t* test and one-way analysis of variance (ANOVA) test were used to evaluate the significance of the differences observed between two means and among three or more means, respectively. All statistical analyses were performed using SPSS software (SPSS version 12.0, Chicago, IL, USA). *P* values less than 0.05 were considered statistically significant.

Results

Histologic features of EHCs and BilINs

We analyzed histologic features of EHCs and BilINs. Gross morphology and histologic differentiation of invasive adenocarcinoma were determined according to World Health Organization classification system. Among 53 EHC patients, background biliary disease was noted in three patients (two gallbladder stone and one choledochal cyst), and *Clonorchis sinensis* infection was not identified in serologic, histologic, and cytopathologic examination. Data are shown in Table 1 and Supplemental Table 1.

Histologic patterns of BilINs are divided into three groups (adenoma like with glandular extension, tufting, and micropapillary pattern; Fig. 1). Multiple patterns were noted when remaining epithelium of BilINs was sufficiently large. When multiple patterns are present in BilIN, most prominent pattern was recorded (Table 1 and Supplemental Table 1).

Methylation profiles of seven CpG island loci in normal, BilIN, and EHC tissue samples

We performed MethyLight analysis of seven CpG island loci on 112 DNA samples from normal cystic duct (n=31), BilIN (n=31), and EHC (n=50) tissue samples. PMR values for each sample and each locus were calculated using MethyLight reaction data (Fig. 2). The DNA methylation frequencies (PMR≥4) for each gene were calculated in normal cystic duct, BilIN, and EHC tissue samples. The number of methylated CpG island loci was 0.6, 2.0, and 3.6 in normal cystic duct, BilIN, and EHC tissue samples, respectively (P<0.001, ANOVA test; Fig. 3a). When methylation levels of individual CpG island loci were compared among normal cystic duct, BilIN, and EHC samples (Fig. 4a), *TMEFF2*, *HOXA1*, *NEUROG1*, and *RUNX3* were methylated in BilIN samples at levels significantly higher than those in normal cystic duct samples (P<0.05, Student's t test). The methylation levels of six CpG island loci (*CDH1* was the exception) were significantly higher in EHC samples than in BilIN samples (P<0.05, Student's t test).

The above-mentioned six CpG island loci showed methylation frequencies >20% in EHC tissue samples with *HOXA1* and *TMEFF2* methylation frequencies >90%. Five genes were not methylated or rarely methylated (methylation frequency <4%) in normal bile duct samples except for *TMEFF2*, for which the methylation frequency was >50% in normal bile duct samples. Four genes exhibited >14% methylation frequencies in BilIN samples. Based on methylation frequencies of these six genes in three tissue types, three different groups of genes were recognizable according to their methylation behaviors during multistep carcinogenesis (Fig. 4b): (1) genes methylated in a non-neoplastic stage, including *TMEFF2*; (2) genes methylated in an early neoplastic stage, including *HOXA1*, *NEUROG1*, and *RUNX3*; and (3) genes methylated in a late neoplastic stage, including *RASSF1A* and *APC*.

Hypomethylation of repetitive DNA elements in biliary intraepithelial neoplasia and EHC tissue samples

We performed the COBRA assay to determine *LINE-1* methylation levels and the MethyLight assay to determine *SAT2* methylation levels using 112 DNA samples from normal cystic duct (n=31), BilIN (n=31), and EHC (n=50) tissue samples. When compared with methylation levels of *LINE-1* and *SAT2* in normal cystic duct samples (Fig. 3b, c), the methylation levels of *LINE-1* did not change in BilIN but sharply declined in EHC samples, whereas methylation levels of *SAT2* decreased in BilIN and further decreased in EHC samples.

Discussion

Aberrant DNA methylation in human cancer cells is characterized by both focal hypermethylation of gene-associated CpG islands and generalized genome-wide reduction in 5-methylcytosine, which are found in virtually all tissue types of human cancers [27–29]. Subsets of CpG island loci which are hypermethylated in a cancer-specific manner have been demonstrated to be hypermethylated in premalignant or in situ neoplastic lesions, including colon adenomas [30], gastric adenomas [31], pancreatic intraepithelial neoplasia [32], and prostatic intraepithelial neoplasia [33], although the methylation frequencies or methylation levels at each locus are generally lower in premalignant lesions than in their malignant counterparts. Of the six CpG island loci showing cancer-specific methylation in EHC samples, four loci, *TMEFF2*, *HOXA1*, *NEUROG1*, and *RUNX3*, were found to be methylated in BilIN samples at levels significantly higher than those of normal bile duct samples. These findings suggest that promoter CpG island hypermethylation occurs at an early stage of multistep choledochal carcinogenesis and likely contributes to the development of BilIN or the progression of BilIN to EHC.

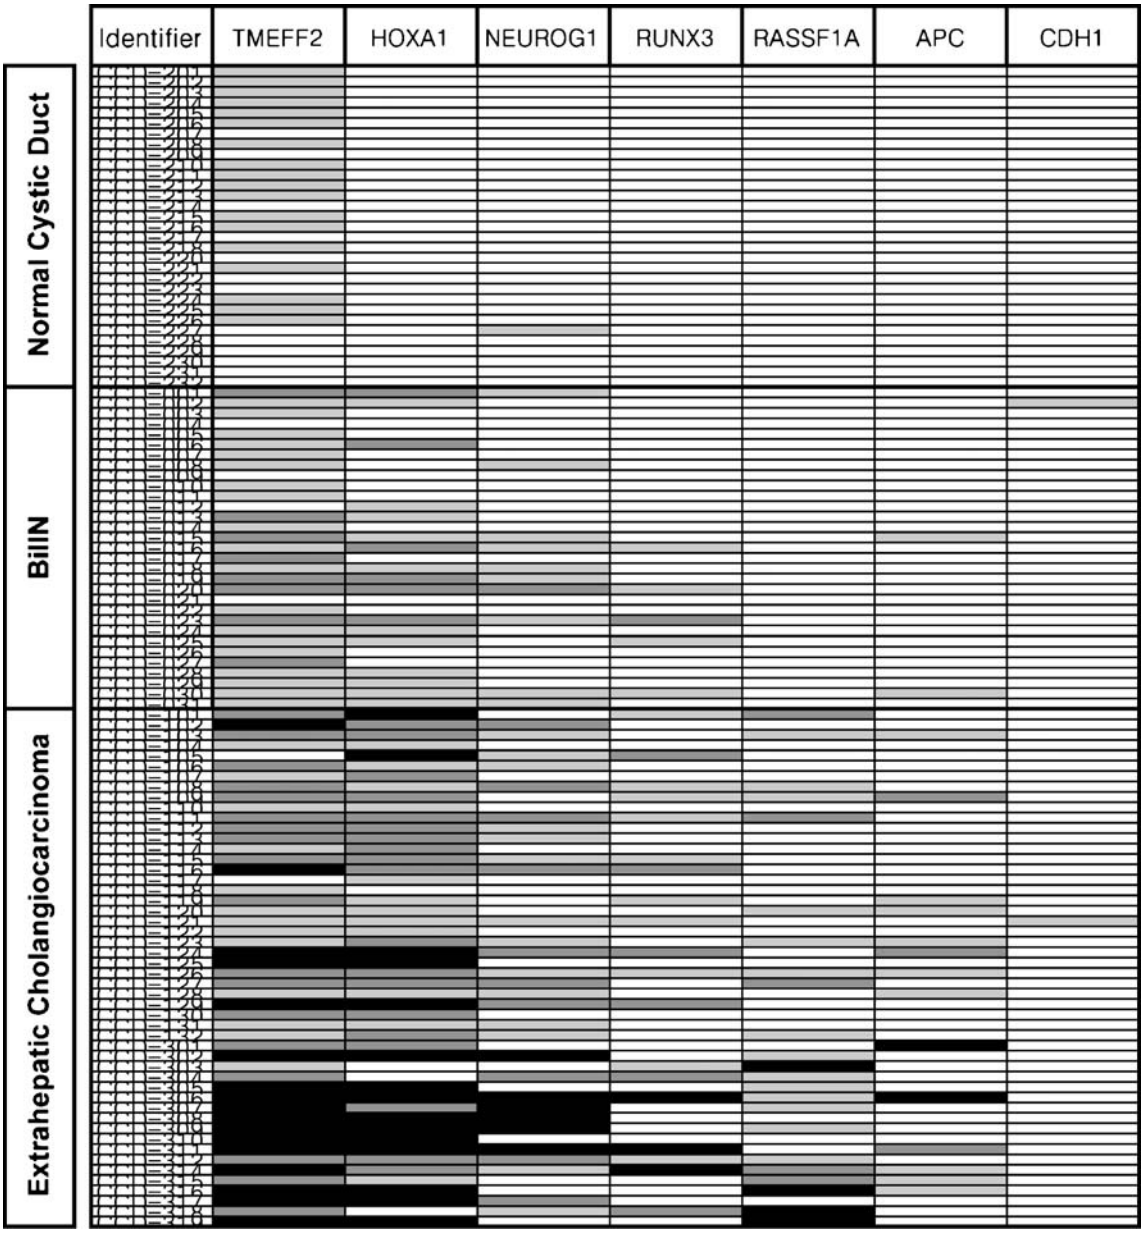

Fig. 2 Map of gene methylation in extrahepatic cholangiocarcinoma, biliary intraepithelial neoplasia, and normal cystic duct tissue samples. *Box color* represents the degree of allele methylation [PMR≥50 (*black*), 20≤PMR<50 (*dark gray*), 4≤PMR<20 (*light gray*)], and *open boxes* represent PMR<4

Repetitive DNA elements, comprising 45% of the genomic DNA, consist of tandem repeats, such as *SAT2*, and interspersed repeats, such as *LINE-1*. The methylation levels of the repetitive DNA elements are closely correlated with 5-methylcytosine content of the genome [16]. In the present study, EHC samples demonstrated hypomethylation of *LINE-1* and *SAT2* compared with normal cystic duct samples, whereas BilIN samples showed decreased methylation levels of *SAT2* but similar methylation levels of *LINE-1* compared with the respective ones of normal cystic duct samples. From our findings, it can be speculated that genomic hypomethylation begins with pericentromeric satellite DNA in the early stages and then involves *LINE-1* on chromosomal arms in a later stage along the multistep process of carcinogenesis. Differential hypomethylation of repetitive DNA elements also has been found in cancers of other tissue types, including stomach and liver, during disease progression [34].

When comparing the methylation frequencies of the seven CpG island loci between our previous study [34] and the present study, the methylation frequencies of six loci (*TMEFF2*, *HOXA1*, *NEUROG1*, *RUNX3*, *RASSF1A*, and

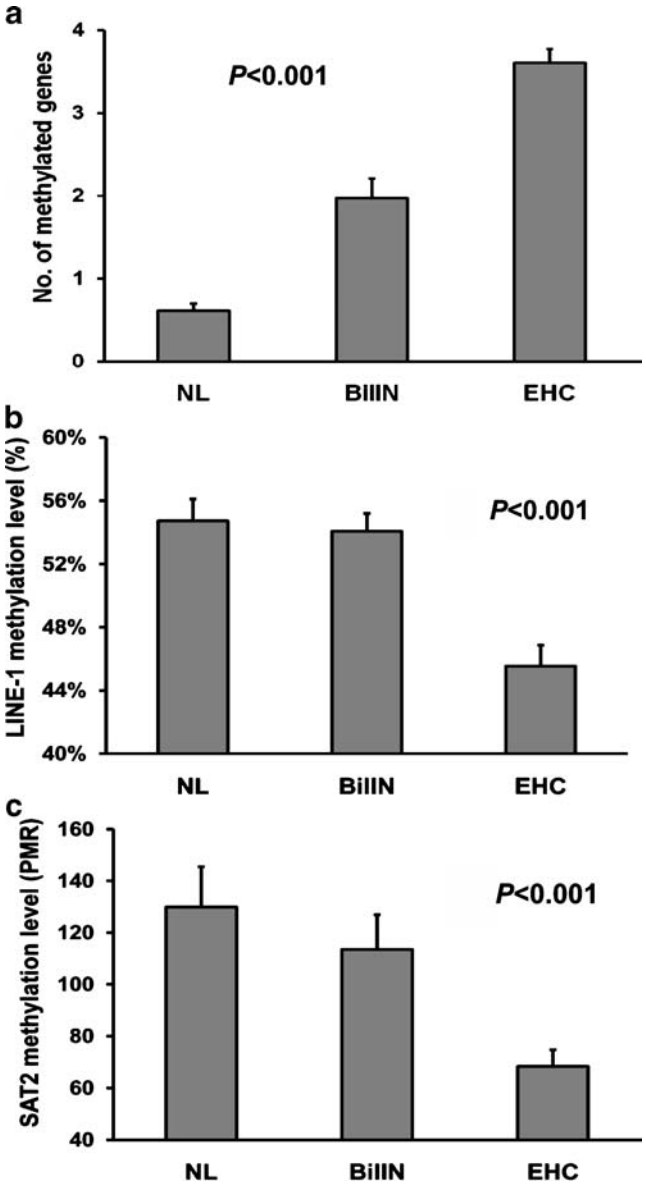

Fig. 3 Number of methylated genes of the seven loci tested (**a**) and *LINE-1* (**b**) and *SAT2* (**c**) methylation levels in extrahepatic cholangiocarcinoma (*EHC*), biliary intraepithelial neoplasia (*BilIN*), and normal cystic duct (*NL*) tissue samples. Data represent means± standard error of the mean (*error bars*). The significance (*P*) after ANOVA analysis is shown

APC) were similar, but the methylation frequency of *CDH1* was markedly lower in the present study. This discrepancy of *CDH1* methylation frequency might be attributable to the inadequacy of the oligonucleotide primers used in our previous *CDH1* MSP assay. The oligonucleotide primers contain three CpG sites (two forward primers and one reverse primer) that do not fulfill the minimal requirements for designing MSP primers recommended by the Herman group [35, 36]. Thus, *CDH1* MSP might give rise to false positives. Alternatively, the heterogeneity of methylated DNA alleles with respect to the methylation status of each CpG site within a given segment may differ. Notably, bisulfite genomic sequencing has shown that different alleles of *CDH1* are differentially methylated at individual CpG sites [37]. Thus, *CDH1* MSP may detect DNA alleles having differentially methylated CpG sites within the segment between the forward and reverse primer sequences. In contrast, *CDH1* MethyLight detected near-perfect methylated DNA alleles because the primers and probe for *CDH1* MethyLight targeted seven CpG sites within a 96-bp DNA sequence. Thus, traditional MSP can detect both partially methylated alleles as well as the highly methylated alleles detected by MethyLight technology, which might explain the discrepancy in *CDH1* methylation frequencies produced by MSP and the MethyLight assay.

EHCs generally have a low rate of preoperative histologic or cytologic diagnosis [38], and the poor prognosis of EHC patients is related to the delayed diagnosis of the disease. Because of technical difficulties in EHC tissue biopsy via choledochoscopy, several inves-

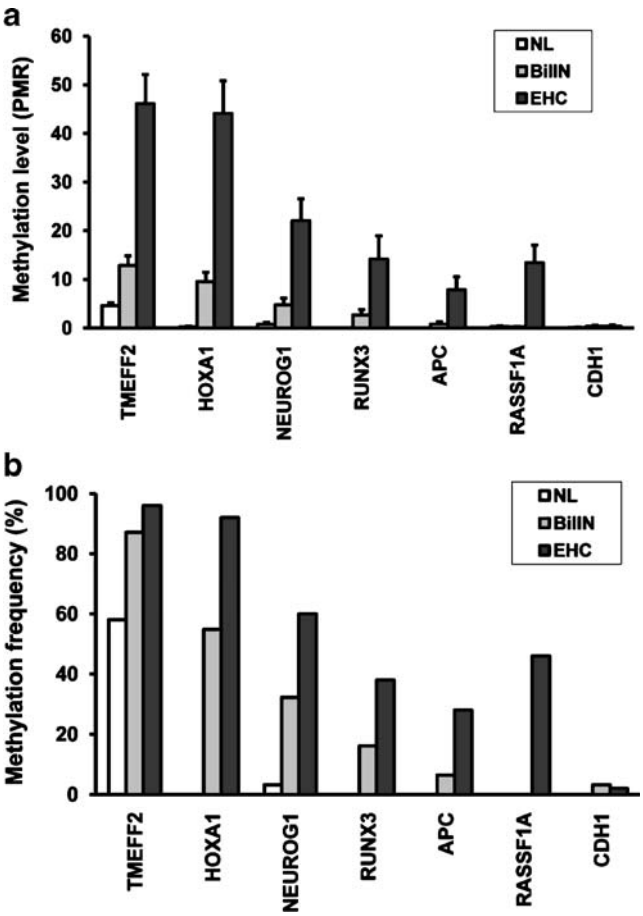

Fig. 4 Comparison of the methylation levels of seven CpG island loci among extrahepatic cholangiocarcinoma (*EHC*), biliary intraepithelial neoplasia (*BilIN*), and normal cystic duct (*NL*) tissue samples (**a**). The means and the standard errors (*error bars*) are shown. **b** Comparison of the methylation frequency of the individual CpG island loci among EHC, BilIN, and NL tissue samples

tigators have attempted to develop molecular markers to detect EHC in bile juice. To date, however, no sensitive/specific molecular markers for EHC have been identified [39]. Still, promising markers include DNA methylation marks, which are chemically stable and relatively easy to detect. In our present and previous studies, *HOXA1* was hypermethylated in more than 95% of EHC tissue samples but never hypermethylated in normal bile duct samples. Thus, *HOXA1* methylation looks promising as a tumor biomarker in bile juice for the detection of biliary epithelial tumors.

In conclusion, using quantitative methylation analysis technologies, we have demonstrated that promoter CpG island hypermethylation occurs not only in malignant tumors of biliary epithelia but also in premalignant lesions. Promoter CpG island hypermethylation appears to precede repetitive DNA hypomethylation. Lastly, *HOXA1* hypermethylation may constitute a highly sensitive and specific marker for biliary epithelial neoplasms.

Abstract The accurate distinction between primary endocervical adenocarcinomas (ECA) and endometrial adenocarcinomas (EMA) may require the use of multiple ancillary monoclonal antibodies in panels of immunohistochemistry stains. In addition to reappraising the expressions of four commonly used individual monoclonal antibodies [estrogen receptor (ER), Vimentin (Vim), carcinoembryonic antigen (CEA), and $p16^{INK4}$], this study was designed to investigate whether CEA and $p16^{INK4}$ can be effectively exchanged between two relevant three-marker panels (ER/

Vim/CEA vs. ER/Vim/p16^{INK4}) in distinguishing ECA from EMA. A tissue microarray was constructed using paraffin-embedded, formalin-fixed tissues from 35 hysterectomy specimens, including 14 ECA and 21 EMA. Utilizing the avidin–biotin technique, tissue array sections were immunostained with the four aforementioned individual markers (ER, Vim, CEA, and p16^{INK4}). In addition to the four individual monoclonal antibodies, both their respective three-marker panels, proposed here, showed statistically significant ($p<0.05$) frequency differences between these two gynecologic tumors (ECA vs. EMA). The panel performance and test effectiveness revealed that both three-marker panels are promising and very helpful. According to our data, when histomorphological and clinical doubt exists as to the primary site of origin, we recommend using either of these two conventional three-marker panels, which consist of ER/Vim/CEA and ER/Vim/p16^{INK4}. CEA and p16^{INK4} can be interchanged with confidence without significantly influencing the panel presentations and efficiencies in distinguishing between adenocarcinomas of endocervical and endometrial origin.

Keywords Endocervical adenocarcinomas (ECA) · Endometrial adenocarcinomas (EMA) · Endocervical (EC) · Endometrial (EM) · Tissue microarray (TMA) · Immunohistochemistry (IHC) · Estrogen receptor (ER) · Vimentin (Vim) · Carcinoembryonic antigen (CEA) · p16^{INK4} (p16)

Background

Although careful morphological examination usually allows a confident diagnosis, the distinction between a primary endometrial (EMA) and endocervical adenocarcinoma (ECA) may be difficult with small biopsies or curetted tissue specimens. In some cases, tumors may be present in both endometrial and endocervical sites, and preoperative imaging does not help to establish the site of origin. Difficulties may also occur in the pathologic examination of large surgically resected specimens when the tumor involves both the lower uterine segment and upper endocervix. Since the initial choice of therapy may differ substantially, it is important to ascertain the cancer site of origin. For EMA, staging is surgical; while for ECA, staging is clinical. Treatment plans and adjuvant therapies are totally different between these two gynecologic malignancies (ECA vs. EMA) [1, 2].

McCluggage et al. [3] have already proposed that a conventional three-marker [estrogen receptor (ER)/Vimentin (Vim)/carcinoembryonic antigen (CEA)] panel generally allows a confident preoperative distinction between primary ECA and EMA. Recent studies have also demonstrated that p16^{INK4} immunohistochemistry (IHC) is of diagnostic value in distinguishing primary ECA from EMA [4–7]. In this study, we plan to reappraise the expression status of four individual monoclonal antibodies (ER, Vim, CEA, and p16^{INK4}) and investigate whether CEA and p16^{INK4} can be effectively interchanged between their relevant traditional three-marker panels (ER/Vim/CEA vs. ER/Vim/p16^{INK4}) without influencing the panel performance in distinguishing ECA from EMA.

Methods

Study materials

The study materials consisted of slides and selected formalin-fixed, paraffin-embedded tissue blocks from 35 hysterectomy specimens retrieved from the archives of the Tissue Bank of the Clinical Trial Center at Chung-Shan Medical University Hospital. These endocervical (endocervical-type ECA, $n=14$) and endometrial (endometroid-type EMA, $n=21$) specimens were acquired between 2004 and 2008. Two board-certified pathologists (CP Han and LF Kok) reviewed all the hematoxylin–eosin (H&E)-stained slides for these cases. A slide with representative tumor tissue was selected from each case, and the tumor area of interest was circled. The area corresponding to the selected area on the slide was also circled on the block with an oil marker. All donor tissue blocks were sent to the Bio-Chiefdom International Co. Ltd, Taiwan for tissue microarray (TMA) slide construction. They were cored with a 1.5-mm diameter needle and transferred to a recipient paraffin block. The recipient block was sectioned at 5 μm and transferred to silanized glass slides.

Immunohistochemical staining

Using the avidin–biotin complex technique, slides were stained with monoclonal antibodies whose main characteristics are summarized in Table 1. Formalin-fixed, paraffin-embedded tissue array specimens with 1.5-mm, 5-μm individual cores were deparaffinized in xylene, rehydrated through serial dilutions of alcohol, and washed in phosphate-buffered saline (PBS; pH 7.2). The pH 7.2 PBS buffer was used for all subsequent washes. Slides were stained with the following monoclonal antibodies: ER (NCL-L-ER-6F11, Leica Microsystems), 1:100 dilution; Vim (NCL-L-VIM-V9, Leica Microsystems), 1:400 dilution; CEA (NCL-L-CEA-2, Leica Microsystems), 1:100 dilution; and p16^{INK4a} (F12, sc-1661, Santa Cruz), 1:200 dilution (Table 1). Negative controls were obtained by excluding the primary antibody. Appropriate positive controls were applied. The slides were mounted for examination, and images were captured

Table 1 Antibodies used in this study

Antigen	Clone	Product code	Antibody class	Supplier	Dilution	Antigen retrieval
ER	Mouse Monoclonal, 6F11	NCL-L-ER-6F11	IgG1	Leica Microsystems	1:100	Citrate
Vim	Mouse monoclonal, V9	NCL-L-VIM-V9	IgG1	Leica Microsystems	1:400	Citrate
CEA	Mouse monoclonal, 12-140-10	NCL-L-CEA-2	IgG1	Leica Microsystems	1:100	Trypsin
$p16^{INK4a}$	Mouse monoclonal, F12	sc-1661	IgG2a	Santa Cruz	1:200	Citrate

Scoring of immunostaining

In this study, the TMA slides were simultaneously reviewed and scored by the two aforementioned pathologists, using a two-headed microscope. Since both nucleic and cytoplasmic IHC scoring algorithms have not been optimized and standardized, all CEA, ER, Vim, and $p16^{INK4a}$ expressions were interpreted using the German semi-quantitative scoring system in considering the intensity and extent of staining. The intensity of marker expression was quantified using the following scores: 0=negative, 1=weakly positive, 2=moderately positive, and 3=strongly positive. The extent of marker expression was quantified by evaluating the percentage of the positive staining areas in relation to the whole cancer area in the core. A score of 0 points was given for 0% reactivity, 1 point was assigned for 1–10% reactivity, 2 points were assigned for 11–50% reactivity, 3 points were assigned for 51–80% reactivity, and 4 points were assigned for 81–100% reactivity.

Although the term "semiquantitative" lacks clear definition, it implies having both features of "quantitative" and "qualitative." In fact, the "semiquantitative" scoring mechanism has generally been defined as the calculation of the expression index, which associates the "quantitative" area fraction of labeled tumor cells with their "qualitative" immunostaining intensity. The final immunoreactive score was determined by multiplying the positive intensity and the extent of positive area scores, yielding a range from 0 to 12 [8–12]. The threshold for differentiating between final positive and negative immunostaining was set at 4 for interpretation. This optimal cutoff value for this study was determined using receiver operating characteristic curve analysis [13–15]. The results are expressed by dividing cases into scores of 0–3 (essentially negative) and 4–12 (at least moderately positive in at least 11–50% of cells). This method of assessment has been widely accepted and used in previous studies [15–23].

Statistical analysis

A chi-square test or Fisher's exact test was performed to test the frequency difference of immunostaining (positive vs. negative) between each IHC biomarker and the two adenocarcinomas. The results are expressed by dividing cases into scores of 0–3 (negative) and 4–12 (positive; at least moderately positive in at least 11–50% of cells). The Mann–Whitney *U* test was used to analyze the immunostaining raw scores between the two adenocarcinomas, given the lack of normally distributed IHC scores. To distinguish between primary ECA and EMA, the sensitivity and specificity of EC- and EM-type immunoprofiles were compared. Sensitivity was defined as a ratio of accurate expression of a typical immunoprofile type among the primary adenocarcinoma of origin. Specificity was defined as the number of tissues that lacked a typical immunoprofile type of expression over the number of tissues that were not actually the primary adenocarcinoma of origin [24]. Analyses were performed using SPSS statistical software (SPSS, Inc., Chicago, IL). All tests were two-sided, and a $p<0.05$ was considered significant.

Results

In this study, we reappraised the expressional status of four individual monoclonal antibodies (ER, Vim, CEA, and $p16^{INK4}$). H&E and immunoreactivities for ER, Vim, CEA, and $p16^{INK4a}$ can be seen in two cases representative of primary ECA (tissue code 18) and EMA (tissue code 40; Fig. 1). The IHC findings of all four immunomarkers are summarized in Table 2. Using a score of ≧4 points as a cutoff, the immunomarkers (ER, Vim, CEA, and $p16^{INK4a}$) showed significant frequency differences in ECA and EMA tissue immunostainings. The ER marker stained positive in two of 14 (14.3%) ECA tumors with a median staining score of 0.50 and a range of 0–6. The ER marker stained positive in 15 of 21 (71.4%) EMA tumors ($p<0.001$), with a median staining score of 6.00 and a range of 0–12 ($p<0.001$). The Vim marker stained positive in one of 14 (7.1%) ECA tumors with a median staining score of 0.00 and a range of 0–6. The Vim marker stained positive in 15 of 21 (71.4%) EMA tumors ($p<0.001$) with a median staining score of 6.00 and a range of 0–12 ($p<0.001$). The CEA marker stained positive in ten of 14 (71.4%) ECA tumors with a median staining score of 5.00 and a range of 1–12. The CEA marker stained positive in

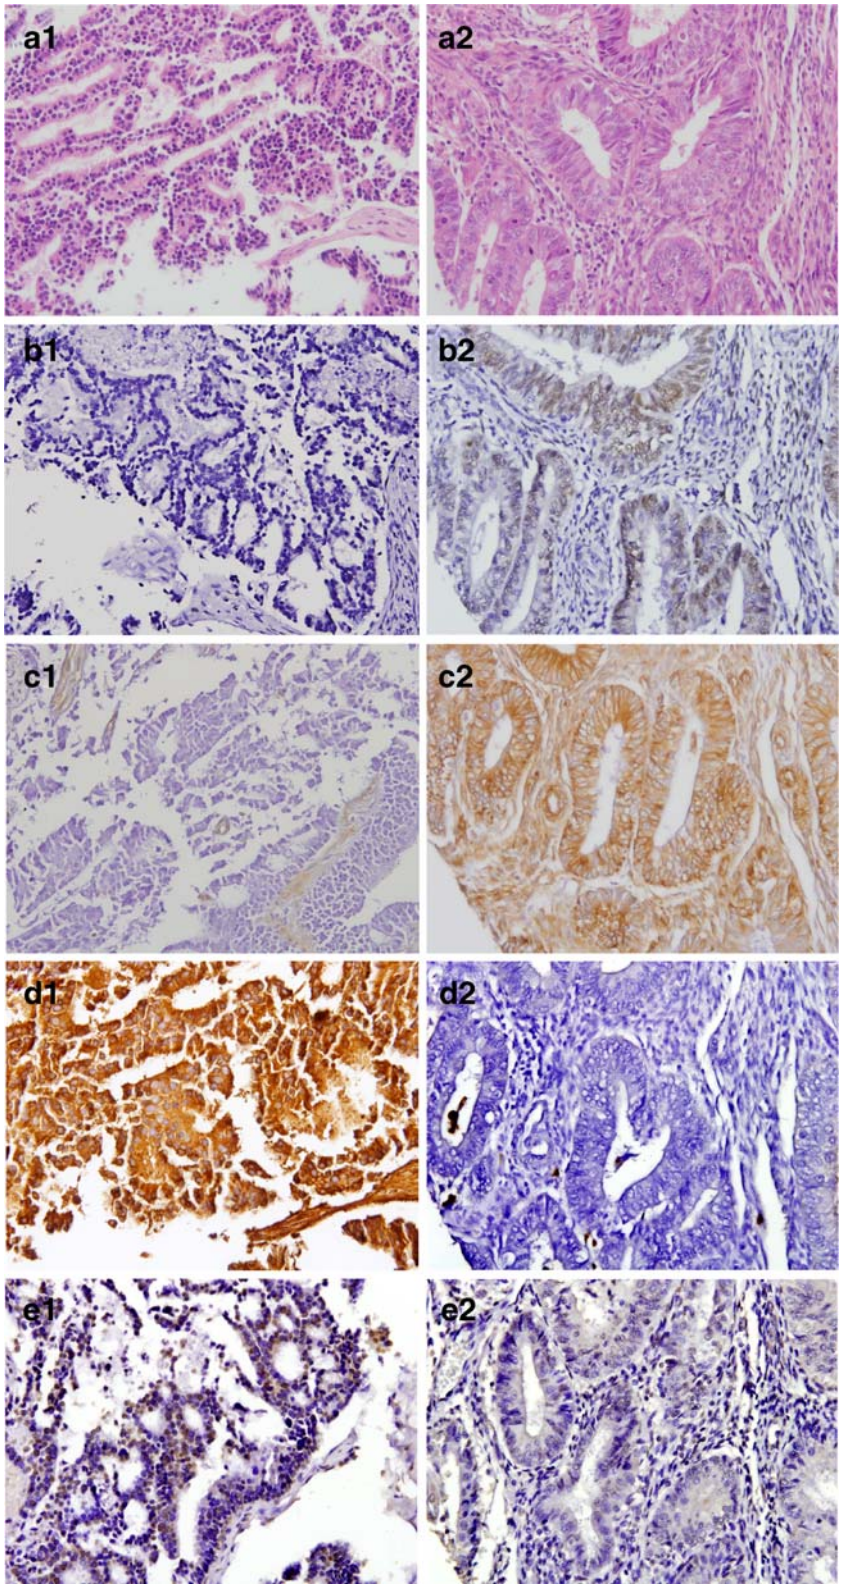

Fig. 1 H&E and immunohistochemical stains for ER, Vim, CEA, and p16^{INK4a} identified in endocervical adenocarcinomas (ECA) versus endometrial adenocarcinomas (EMA). Photographs *a1*, *b1*, *c1*, *d1*, and *e1* are from an ECA case (code no. 18), while photographs *a2*, *b2*, *c2*, *d2*, and *e2* are from an EMA case (code no. 40). *a1* H&E stain of endocervical type endocervical adenocarcinoma. *a2* H&E stain of endometroid type endometrial adenocarcinoma. *b1* Negative estrogen receptor (ER) IHC stain of ECA tumor cells, score: 0 points. *b2* Positive estrogen receptor (ER) IHC stain of EMA tumor cells, score: 9 points. *c1* Negative Vimentin IHC stain of ECA tumor cells, score: 0 points (**c2**) positive Vimentin IHC stain of EMA tumor cells, score: 9 points. Internal controls of stromal tissues were also positive in both *c1* and *c2*. *d1* Positive carcinoembryonic antigen (CEA) IHC stain of ECA tumor cells, score: 12 points. *d2* Negative carcinoembryonic antigen (CEA) IHC stain of EMA tumor cells, score: 0 points. *e1* Positive p16^{INK4a} (p16) IHC stain of ECA tumor cells, score: 6 points. Only nucleic p16^{INK4a} (p16) labeling in tumor cells was considered positive, regardless of the unexpected cytoplasmic reactivity. *e2* Negative p16^{INK4a} (p16) IHC stain of EMA tumor cells, score: 2 points (all images are ×400 magnification)

four of 21 (19.0%) EMA tumors (p=0.004) with a median staining score of 2.00 and a range of 0–9 (p=0.001). The p16^{INK4a} marker stained positive in 11 of 14 (78.6%) ECA tumors with a median staining score of 5.00 and a range of 2–12. The p16^{INK4a} marker stained positive in seven of 21 (33.3%) EMA tumors (p=0.009) with a median staining score of 2.00 and a range of 0–9 (p=0.001). correspond with previous reports on Caucasian women [9–11, 14].

In addition, we also compared the performances between two three-marker panels (ER/Vim/CEA vs. ER/Vim/$p16^{INK4}$). A typical EC-type immunoprofile is defined as ER-/Vim-/CEA+ or ER-/Vim-/$p16^{INK4a}$+, whereas a typical EM-type immunoprofile is defined as ER+/Vim+/CEA or ER+/Vim+/$p16^{INK4a}$. A non-typical immunoprofile is defined as the three-marker expressions other than typical EC- and typical EM-type expression patterns [3, 5–7, 15–23] (Tables 3, 4, and 5).

Despite the typical expression patterns of the ECA and EMA immunoprofiles, there were several other non-typical expression patterns for both three-marker panels. Table 3 represents the panel expression patterns in primary ECA. Of the 14 ECA cases, there were (1) eight cases with a typical EC-type immunoprofile and six cases with a non-typical immunoprofile in the three-marker (ER/Vim/CEA) panel containing CEA, as well as (2) eight cases with a typical EC-type immunoprofile and six cases with a non-typical immunoprofile in the three-marker panel (ER/Vim/$p16^{INK4}$) containing $p16^{INK4a}$. Table 4 exhibits the panel expression patterns in primary EMA. Of the 21 EMA cases, there were (1) ten cases with a typical EM-type immunoprofile and 11 cases with a non-typical immunoprofile in the three-marker (ER/Vim/CEA) panel containing CEA, as well as (2) seven cases with a typical EM-type immunoprofile and 14 cases with a non-typical type immunoprofile in the three-marker (ER/Vim/$p16^{INK4}$) panel containing $p16^{INK4a}$.

As seen in Table 5, in the three-marker (ER/Vim/CEA) panel containing CEA, the typical EC-type immunoprofile was present in eight of 14 (57.1%) ECA tumors as well as in one of 21 (4.76%) EMA tumors (p=0.001). The typical EM-type immunoprofile was present in none of 14 (0%) ECA tumors as well as in ten of 21 (47.62%) EMA tumors (p=0.002). The non-typical immunoprofile was present in six of 14 (42.86%) ECA tumors, as well as in ten out of 21 (47.62%) EMA tumors. In the three-marker (ER/Vim/$p16^{INK4a}$) panel containing $p16^{INK4a}$, the typical EC-type immunoprofile was present in eight of 14 (57.14%) ECA tumors as well as none of 21 (0.0%) EMA tumors (p<0.001). The typical EM-type immunoprofile panel was present in none out of 14 (0%) ECA tumors as well as in seven of 21

(33.33%) EMA tumors (p=0.027). The non-typical type immunoprofile panel was present in six of 14 (42.86%) ECA tumors as well as in 14 of 21 (66.67%) EMA tumors.

Table 6 presents the comparisons of the test effectiveness and performance between the two three-marker panels with typical EC-type or typical EM-type in diagnostically distinguishing between 14 ECA and 21 EMA. Of the expressions of typical immunoprofiles in the first conventional three-marker (ER/Vim/CEA) panel, the sensitivity and negative predictive value (NPV) were 57.1% and 76.9% in ECA as well as 47.6% and 56.0% in EMA. On the other hand, the specificity and positive predictive value (PPV) were 95.2% and 88.9% in ECA as well as 100% and 100% in EMA. The accuracy rate was 80.0% in ECA and 68.6% in EMA. Of the expressions of typical immunoprofiles in the second three-marker (ER/Vim/p16^{INK4a}) panel, the sensitivity and NPV were 57.1% and 87.8% in ECA as well as 33.3% and 50.0% in EMA. On the other hand, the specificity and PPV were 100% and 100% in ECA as well as 100% and 100% in EMA. The accuracy rate was 82.9% in ECA and 60.0% in EMA.

Discussion

Distinguishing between primary ECA and EMA before planning the patient treatment is clinically important. The primary EMAs of the endometroid type usually have distinctly different histological appearances from ECAs of the endocervical type; therefore, careful gross and histomorphological examinations often allow a confident distinction. Generally speaking, the former is usually composed of tubular glands with a complex tubulopapillary and cribriform architecture that are mostly dilated and lined by stratified or pseudostratified columnar cells that may have cilia. However, the glands of the latter are frequently smaller and obscurely mucinous. Their lining cells tend to have more intense amphophilic to eosinophilic cytoplasm,

Three-marker panel (ER/Vim/p16^{INK4a}) with typical EC-type immunoprofile: ER-/Vim-/p16^{INK4a}+. Three-marker panel (ER/Vim/p16^{INK4a}) with typical EM-type immunoprofile: ER+/Vim+/p16^{INK4a}−. Non-typical types: immunoprofile other than the typical types in all the above mentioned

are more mitotically active, and show more apoptosis, etc. Despite these morphological differences in the majority of cases, there are other cases in which morphological overlap is such that other findings may aid in this distinction [25, 26]. When there is still doubt and indistinguishable primaries, IHC may assist. McCluggage et al. [3] has reported that the conventional three-marker (ER/Vim/CEA) panel generally allows distinction between a primary endometrial and ECA. We also know that the p16^{INK4a} marker is currently the most important focus of attention and carries more diagnostic weight than the others. However, no single antibody is totally specific or any one neoplasm [4–7, 15–22]. Herein, we have re-evaluated these two commonly used three-marker (ER/Vim/CEA and ER/Vim/p16^{INK4a}) panels to see whether they both show similar promising performance and effectiveness in distinguishing between primary ECA and EMA.

ECA tends to be ER-/Vim-/CEA+ and EMA tends to be ER+/Vim+/CEA− in the first traditional three-marker (ER/Vim/CEA) panel, whereas ECA tends to be ER-/Vim-/p16^{INK4a}+ and EMA tends to be ER+/Vim+/p16^{INK4a}− in the second three-marker (ER/Vim/p16^{INK4a}) panel [3–7, 15–23]. In this study, we reappraised the expressional status of four individual markers (ER, Vim, CEA, and p16^{INK4a}) and investigated whether p16^{INK4a} and CEA are mutually interchangeable between both their relevant three-marker (ER/Vim/CEA and ER/Vim/p16^{INK4a}) panels in distinguishing ECA from EMA. We demonstrated that all these four individual monoclonal antibodies and their two commonly applied three-marker panels revealed significant frequency differences (p<0.05) between these two gynecologic tumors (ECA vs. EMA). Our data will help in the referral and management of ECA and EMA cases worldwide. On the other hand, immunohistochemical overlap may exist, and the immunoprofiles are not always definitive in some cases. Unexpected "aberrant" expressions can occur with any of the markers from the two panels discussed. This diagnostic dilemma still remains unresolved, as there are many kinds of non-typical immunoprofiles.

Regarding the typical EC- or EM-type immunoprofile, the sensitivity and NPV were 57.1% and 76.9% in ECA as well as 47.6% and 56.0% in EMA in the first three-marker (ER/Vim/CEA) panel and 57.1% and 77.8% in ECA as well as 33.3% and 50.0% in EMA in the second three-marker (ER/Vim/p16^{INK4}) panel. All of these results indicate a high false-negative rate. If the staining results are not in agreement with the typical EC- or EM-type immunoprofile, despite the panel used, there is a high probability that the corresponding ECA or EMA tumor diagnosis would be doubtful and inconclusive. The low sensitivity and NPV are the limiting factors for applying either three-marker panel as the screening tool for ECA and EMA. On the other hand, the specificity and PPV were 95.8% and 88.9% in ECA as well as 100% and 100% in EMA in the first conventional three-marker (ER/Vim/CEA) panel and 100% and 100% in ECA as well as 100% and 100% in EMA in the second three-marker (ER/Vim/p16^{INK4}) panel. Both indicated a low false-positive rate. If the staining result matches up with the typical EC- or EM-type immunoprofile, despite the panel used, there is a high probability that the corresponding ECA or EMA tumor diagnosis will be accurate and conclusive. The high specificity and PPV of both panels are the favorable factors for applying either three-marker panel as a confirmatory tool for ECA and EMA.

Above all, accuracy means the degree of veracity. When using both three-marker panels with typical EC-type (ER-/Vim-/CEA+ and ER-/Vim-/p16^{INK4}+) immunoprofiles in definitively diagnosing primary ECA, the ER/Vim/p16^{INK4} panel has a more favorable accuracy rate than the ER/Vim/CEA panel (82.9% vs. 80.0%). When using both three-marker panels with typical EM-type (ER+/Vim+/CEA− and ER+/Vim+/p16^{INK4}−) immunoprofiles in definitively diagnosing primary EMA, the ER/Vim/CEA panel has a more favorable accuracy rate than the ER/Vim/p16^{INK4} panel

(68.6% vs. 60.0%). All these similar promising values and possible trade-offs in statistical characteristics provide evidence-based information that $p16^{INK4}$ and CEA can be mutually interchanged with confidence between both relevant three-marker panels (ER/Vim/CEA and ER/Vim/$p16^{INK4}$) in distinguishing primary EMAs from ECAs in this tissue microarray study.

In summary, no single antibody is totally specific for any one neoplasm. It should be stressed that IHC results should always be interpreted in the context of morphology, and, in general, panels of antibodies should be used rather than relying on a single antibody. It is known that each of the four monoclonal antibodies directed against ER, Vim, CEA, and $p16^{INK4a}$, as well as their two respective panels comprised of three-markers each (ER/Vim/CEA and ER/Vim/$p16^{INK4a}$), could help in distinguishing between adenocarcinomas of endocervical and endometrial origin. After assessing the parameters of panel performance and test effectiveness, such as sensitivity, specificity, NPV, PPV, and accuracy rate of the two three-marker panels, this study has demonstrated that both three-marker panels are similarly promising and helpful. CEA and $p16^{INK4}$ can be interchanged with confidence. Despite the limited number of cases, these data provide significant and valuable references for further investigations of other useful markers or panels, which will definitively distinguish between primary ECA and EMA.

Conclusions

Distinguishing between primary ECA and EMA can often be accomplished by routine gross and histological examination, but some cases reveal tumors with undetermined origins or overlapping histomorphological features. Accurate diagnosis may require the use of ancillary IHC stains. The results from this TMA study provide valuable references of consistency between Taiwanese and Caucasian women. We found that both three-marker panels (ER/Vim/CEA and ER/Vim/$p16^{INK4a}$) can sufficiently provide an advantageous, cost-effective, and easier means of appropriately distinguishing between ECA and EMA. Based on our data, we scientifically demonstrated that CEA and $p16^{INK4a}$ are of similar importance and are mutually interchangeable between both of their relevant panels (ER/Vim/CEA and ER/Vim/$p16^{INK4a}$) in distinguishing primary ECA from EMA.

ORIGINAL ARTICLE

Tissue transglutaminase expression in celiac mucosa: an immunohistochemical study

Abstract Tissue transglutaminase (tTG) constitutes the main autoantigen in celiac disease (CD). The aim of the study was to clarify weather celiac disease is associated with changes in tTG expression in duodenal mucosa. Tissue transglutaminase was assessed immunohistochemically (clone CUB 7402) in duodenal biopsy specimens from 22 untreated CD patients, ten normal controls (NC) with unremarkable duodenal mucosa, and nine disease nonceliac controls (DC). In 15 CD patients duodenal biopsy specimens were repeatedly assessed after these patients had been prescribed gluten-free diet. Positive pixel count algorithm of ImageScope was used for quantitative evaluation of immunohistochemistry. Tissue transglutaminase expression in superficial epithelium differed significantly between the three groups ($p<0.001$). It was increased in DC in relation to NC ($p<0.001$) and in CD—in relation to NC ($p<0.001$) and DC ($p=0.003$). In CD and DC, cryptal epithelium was stained more intensively than in NC ($p<0.001$), but there was no difference between CD and DC ($p=0.507$). The same pattern was seen in lamina propria. A significant decrease in tTG expression in all the compartments was seen in repeatedly assessed samples. Untreated CD is associated with tTG overexpression, which is reversible. Tissue transglutaminase up-regulation does not seem to be specific for CD and can appear in other pathological conditions.

Introduction

Transglutaminase (TG) family includes enzymes which cross-link proteins through an acyl transfer reaction between the γ-carboxamide group of glutamine in glutamine-donor proteins and the ε-amino group of lysine in glutamine acceptor proteins, which results in the formation of the irreversible ε-(γ-glutamyl)-lysine (isopeptidyl) bond [1]. One of the members of this family, type II TG or tissue TG (tTG), is an ubiquitous multifunctional protein, which is involved in cell death and differentiation, matrix stabilization, and cell adhesion [2]. Today, type II TG rate is a key player in a number of human pathological states [1]. Celiac disease (CD) is a gluten-triggered autoimmune enteropathy in which tTG constitutes a main autoantigen [3]. The exact pathogenesis of CD is not yet fully understood, but there is convincing evidence of the important role of tTG in the disease development. According to present-day knowledge, tTG deamidates glutamine residues of the glutamine-rich gliadins, which results in the increased affinity for HLA-DQ2/DQ8 molecules on antigen presenting cells and consequent T cell stimulation [4–7].

Apart from this, tTG could be implicated in CD pathogenesis by some other mechanisms:

– tTG catalyzed cross-linking of gliadin peptides with extracellular matrix molecules; it creates long-term reservoirs of antigenically potentiated gluten components and forms immunogenic neoepitopes, which may play a role in secondary autoimmune diseases associated with CD [8];

- tTG itself cross-links with gliadin and might act as a hapten for the formation of antibodies; the presentation of gliadin-tTG complexes results in the formation of antibodies against gliadin, tTG, and the cross-linked proteins [9];
- tTG autoantibodies may be involved in the activation of the epithelial cell proliferation by interacting with the extracellular membrane-bound tTG [10];
- expression of tTG in celiac mucosa seems to be subjected to up-regulation effect of gliadin peptides as opposed to nonceliac mucosa [11].

Considering a special role of tTG in CD, it seems logical to suppose that celiac mucosa might have some specific characteristics of tTG expression or activity. If it is really so, it could be useful in CD diagnostic and helpful in understanding of CD pathogenesis more exactly. At present, there is evidence of tTG overexpression in jejunal mucosa of CD patients [12–14], but the mechanism causing increased tTG activity is not yet understood. The data about tTG distribution pattern in celiac mucosa are controversial, and the source of its increased activity remains unclear [15]. It remains also unclear whether tTG up-regulation in intestinal mucosa is specific for CD or constitutes a universal reaction to tissue damage. Thus, our aim was to assess tTG expression and its distribution pattern in intestinal mucosa of CD patients.

Materials and methods

Patients

Four groups of patients have been studied (Table 1).

The first group (normal duodenal controls—NC) included ten controls with unremarkable duodenal mucosa who were negative for anti-tTG-IgA and did not have Ig-A deficiency.

The second group (untreated CD patients—CD) consisted of 22 untreated patients with celiac disease (Table 2). Celiac disease was diagnosed on the basis of commonly accepted histological and serological criteria. All CD patients were positive for at least one of the following serological markers: anti-tTG-IgA, antigliadin-IgA (AGA-IgA), antigliadin-IgG (AGA-IgG). All of them, but two, had HLA DQ2 or DQ8. DQ2/DQ8-negative cases, malabsorbtion, showed typical celiac serology and histology, and dramatically improved on gluten-free diet (GFD), so there was not any doubt in diagnosis.

The third group (treated CD patients) included 15 patients from group CD who were repeatedly assessed after the prescription of GFD.

The fourth group (disease controls—DC) consisted of nine anti-tTG-IgA and AGA-negative patients with the following duodenal changes: 5—acid-related duodenitis with atrophy in duodenal bulb, 1—Waldenstrom macroglobulinemia with prominent lymphangiectasia, 1—focal atrophic active duodenitis in Crohn's disease, 1—abetalipoproteinemia, 1—diffuse atrophic enteritis associated with *Campylobacter jejuni* infection.

The study was approved by the local ethics committee, and each patient gave an informed consent before the endoscopy.

Biopsy/histology

In all the patients, the upper endoscopy was performed and multiple biopsy samples were obtained in the patients with acid-related duodenitis from duodenal bulb and in the other patients from the distal duodenum. All biopsy samples were placed on filter paper luminal side upward just after they had been obtained and then fixated in 40 g/L formaldehyde. After dehydration, the biopsy specimens were embedded in paraffin, cut in 4 μm thick sections, and stained with hematoxylin/eosin. A routine histology assessment was performed, and the changes in CD samples were classified according to Marsh criteria.

Immunohistochemistry

The immunohistochemical staining was performed on formalin-fixed, paraffin-embedded 4 μm sections. The slides were deparaffinized, rehydrated, and the endogenous peroxidase activity was blocked for 20 min by 30 g/L hydrogen peroxide. After that, the slides were subjected to antigen retrieval by boiling (16 min) in 10 mM citrate buffer, pH 6 and then incubated with 10 g/L bovine serum albumin in tris-buffered saline (TBS) for 30 min to block nonspecific binding. Next, the slides were incubated overnight (4°C) with anti-tTG antibody (clone CUB 7402, LabVision, UK), diluted 1:100 in blocking solution. Subsequently, they were extensively washed with TBS and incubated with a secondary reagent (Envision kit) according to the manufacturer's (Dako, Denmark) instructions. Following additional washes, color

was developed with DAB (Dako, Denmark), the sections were counterstained with hematoxylin and mounted. For a negative control, the primary antibody was replaced with an isotype control antibody (Zymed, Invitrogen Corp.).

Evaluation of immunohistochemical staining

All the specimens were evaluated using a Leica DM5000B microscope with HC PL FLUOTAR objectives. For each patient, the best oriented section was chosen, and images were obtained at ×100 using a DFC420C Leica digital camera (1798×1438 pixels). The images were analyzed by the image analysis software, ImageScope version 9.0.19.1516 (Aperio Technologies, Inc.). Bamboo pen tablet (Wacom Co. Ltd.) was used for drawing out different image compartments. Villus or superficial epithelium, cryptal epithelium, and lamina propria compartments were outlined using pen tool of ImageScope and thus, selected for subsequent analysis. Artifacts were excluded from analyses with negative pen tool. Each compartment was divided into separate regions according to the opportunity to draw a non-breaking curve.

Positive pixel count algorithm version 9 was used for quantitative evaluation of immunohistochemical staining. From the automatically calculated parameters the following were selected for our study:

- Total number of pixels: TN = number positive + number negative,
- Positivity = number positive/TN, and
- Average intensity of all pixels: Iavg = (Iweak positive+ Ipositive + Istrong positive) / (Nweak positive + Npositive+Nstrong positive). According to the manufacturer instructions, intensity is the measure of brightness of the pixel, which ranges from zero (black) to 255 (bright white), so that a large intensity value means that

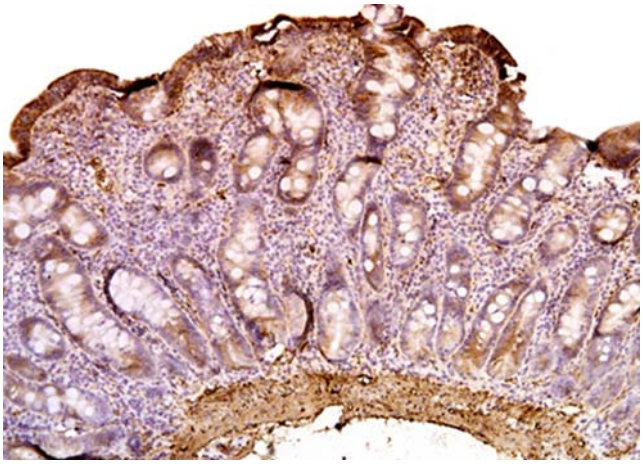

Fig. 2 Duodenal mucosa from a newly diagnosed CD patient (Marsh IIIC) × 100. There is strong staining of superficial epithelium, tTG expression in cryptal epithelium, and lamina propria is also seen

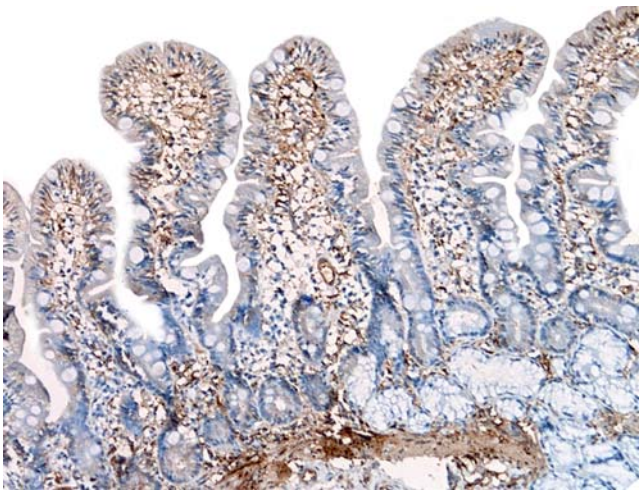

Fig. 1 Normal duodenal mucosa stained with anti-tTG antibodies × 100. Only weak epithelial TTG expression on the top of villi is seen, but it is strong in muscularis mucosae and lamina propria

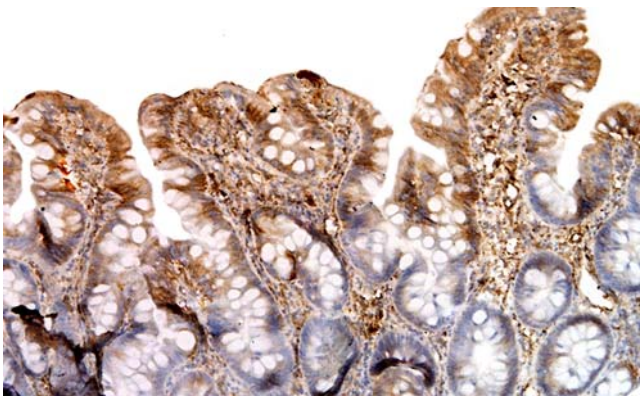

Fig. 3 Duodenal mucosa from patient with atrophic enteritis associated with *Campylobacter jejuni* infection × 200. Strong staining of villus epithelium and lamina propria

the pixel is brighter. To avoid confusion due to change of parameters in opposite directions, we have introduced one more parameter, which is index of intensity= 255−Iavg, and used it as a measure of staining intensity.

All the parameters were separately calculated for every epithelial region and were used for group comparison. For pair comparison of the same patient's data during follow up, the mean parameters, calculated together automatically for all the regions of each patient, were used.

Statistics

Mann–Whitney's U test, Wilcoxon matched pairs test, and Kruskal–Wallis' test were used to analyze the data. For multiple (three) pair comparisons, we used Bonferroni correction and considered p value <0.017 to indicate statistical significance. In the rest of cases, the differences were considered to be significant at $p<0.05$.

Results

Comparison of normal controls, celiac disease patients, and disease controls

In negative control slides, no staining was observed. In control group, tTG expression in epithelium was mostly absent or quite weak (Fig. 1). The ascending gradient along the crypt-villus axis was noticeable, and some foci of strong staining were seen on the top of villus in two controls. Tissue transglutaminase expression was also found in both villus and intercryptal lamina propria. All CD patients were remarkable by significant staining of superficial epithelium

Table 3 Quantitative evaluation of tTG expression in normal controls, celiac disease patients, and disease controls

	Normal controls (NC)	Celiac disease (CD)	Disease controls (DC)	p for multiple comparison[b]	p for pair comparison[c]: CD vs NC DC vs NC CD vs DC

[a] Median (lower and upper quartiles)

[b] Kruskal–Wallis ANOVA

[c] Mann–Whitney's U test

[d] Difference considered to be significant

(Fig. 2). Cryptal tTG distribution was absent in some cases, but in most patients, weak or focal staining was evident. Tissue transglutaminase was also present in lamina propria and seemed to be more concentrated in its upper part beneath superficial epithelium or around crypts. In disease controls, the staining of epithelium varied from full absence (one case of acid-associated duodenitis) to being rather strong (Crohn's duodenitis and atrophic enteritis associated with *C. jejuni* infection; Fig. 3). The last case also showed increased tTG expression in lamina propria while the other pathological controls did not demonstrate any evident peculiarities of the staining in lamina propria.

The results of quantitative evaluation of tTG expression are shown in Table 3. The positivity of superficial/villus epithelium differed significantly between the three groups. It was increased in both CD and DC, and CD patients showed more conspicuous increase. In relation to NC, both these groups also demonstrated stronger tTG expression, which was proved by higher index of intensity, although, the difference between CD and DC was not significant. Cryptal epithelium in CD group had a higher level of positivity than NC, but low index of intensity showed that this extensive positive area was stained rather weak. The same pattern was seen in DC which showed even a lower intensity level than CD patients. In lamina propria, we also found an increase in positivity in CD and DC while the intensity was similar in all the three groups.

Comparing the average index of intensity in different compartments of each group, we also revealed a difference in tTG distribution in duodenal mucosa. In NC, the index of intensity was similar in villus epithelium, cryptal epithelium, and lamina propria ($p=0.407$, Kruskal–Wallis ANOVA). In contrast, the index of intensity was different among these three compartments in CD ($p<0.0001$) and DC ($p<0.0001$). In both groups, the level of intensity in superficial epithelium was higher than in cryptal epithelium ($p<0.0001$), and in CD, it was even higher than in lamina propria ($p<0.0001$).

Table 4 Individual histological and serological data before and after a follow-up period

Number of case	Marsh grade, initial assessment	Increased serological markers, initial assessment	Follow-up period (month)	Marsh grade, repeated assessment	Increased serological markers, repeated assessment	Comments

The *downward arrow* indicates a marker showing a significant decrease in relation to the initial level, but is still above the normal limit

GF gluten-free diet, *HGD* hypogluten diet

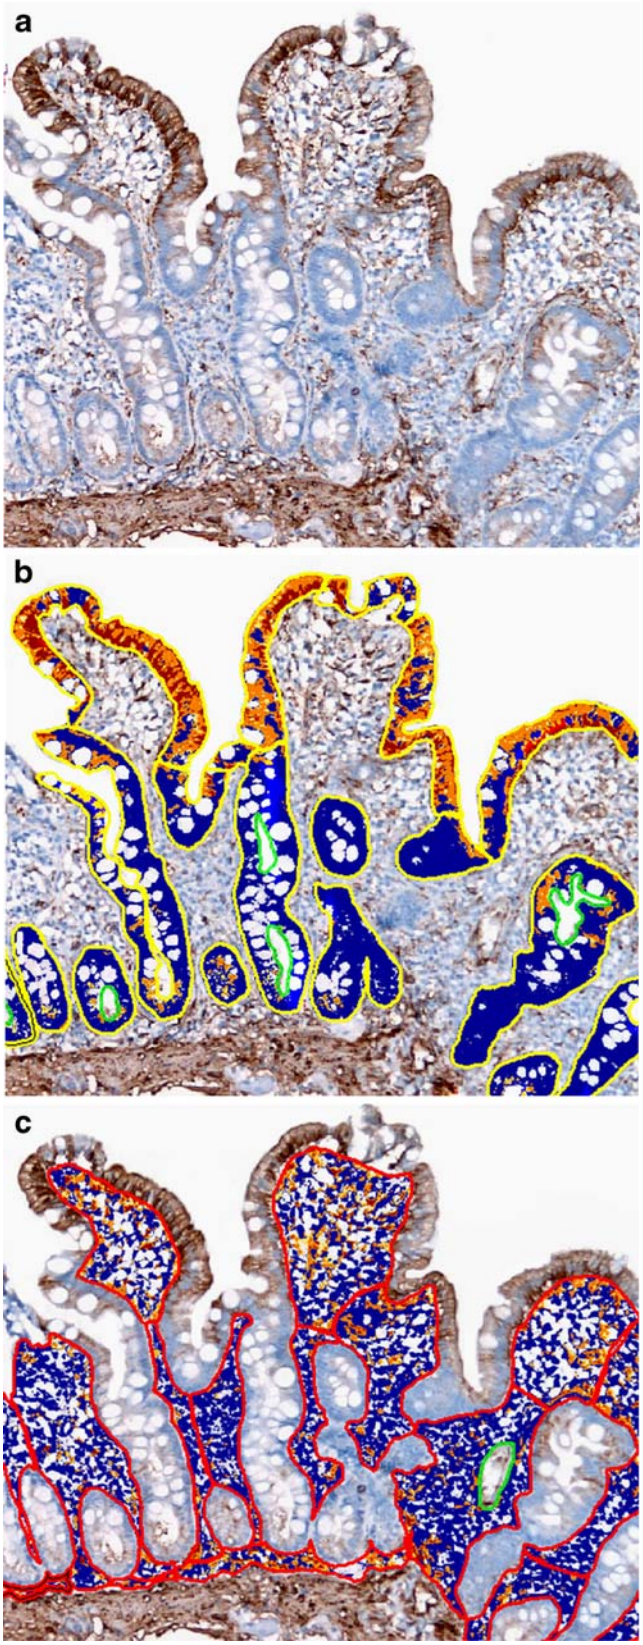

Fig. 4 Duodenal mucosa from a patient with untreated CD (Marsh IIIB) × 100. **a** Native immunohistochemical image. **b** Markup image after evaluation of the epithelial staining by positive pixel count algorithm. **c** Markup image after evaluation of the lamina propria. Color meanings on the markup images are as follows: *blue*—negative pixels, *yellow*—weak positive pixels, *orange*—positive pixels, and *red*—strong positive pixels

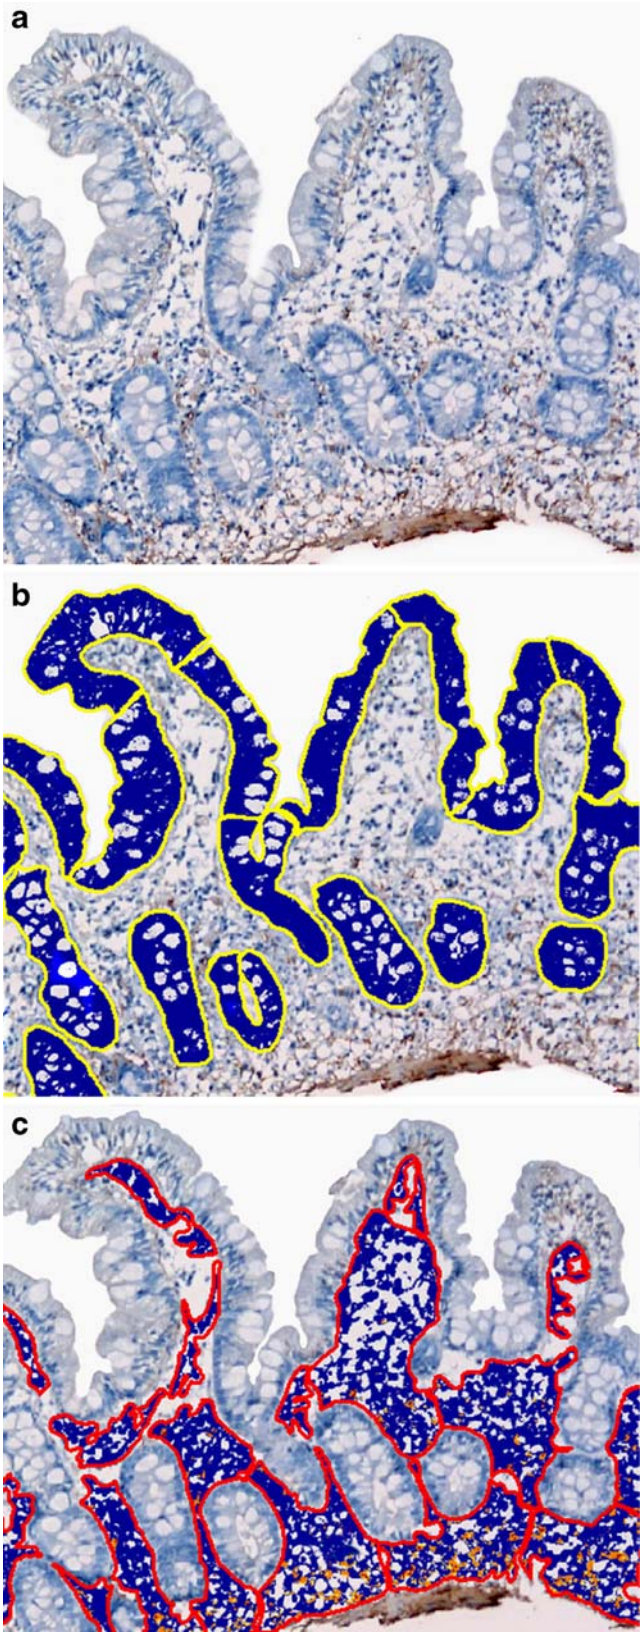
Follow-up of celiac disease patients

After CD diagnosis, all the patients were recommended to keep on GFD, and in 15 of them, tTG expression was assessed repeatedly (Table 4). All these patients reported a decrease in gluten intake and had clinical improvement. Eight out of 15 complied with the GFD and significantly decreased or normalized their serological markers during the follow-up period (strict GFD); the others did not fully comply as reported by the patients themselves and supported by a persistently elevated level of serological markers (hypogluten diet). There was one case of CD complicated with collagenous sprue in this group. This patient followed strict GFD and normalized her serological markers, but mucosal atrophy and significant clinical symptoms persisted that is why GFD was supplemented with permanent taking of prednisolone or azathioprine. In two more cases, prednisolone was given initially due to severe condition and then stopped.

Pair analyses of the each patient's results showed a significant decrease in positivity and/or index of intensity in superficial epithelium for 12 patients (Fig. 4, 5, 6a). In most cases, a decrease in positivity of cryptal epithelium and lamina propria was also seen, but the intensity in these compartments seemed to be quite variable (Fig. 6b-c). Three of 15 patients had opposite changes in all the compartments and were remarkable by the following peculiarities: patient 2—persistently taking nonsteroidal anti-inflammatory drugs (NSAID) due to rheumatoid arthritis; patient 10—not fully compliant with GFD; patient 15—suffering from collagenous sprue with persisting atrophy despite GFD. Excluding this last case, we also performed a pair group comparison (14 pairs) using Wilcoxon matched pair test and found that the positivity of superficial epithelium, cryptal epithelium, and lamina propria significantly decreased in the follow-up group (Fig. 7), while there were no significant changes in intensity.

Fig. 5 Duodenal mucosa from the same patient as in Fig. 4 after GFD (Marsh IIIA) × 100. **a** Native immunohistochemical image. **b** Markup image after evaluation of the epithelial staining by positive pixel count algorithm. **c** Markup image after evaluation of the lamina propria. In comparison with Fig. 4, decrease in tTG expression is evident. Color meanings on the markup images are as follows: *blue*—negative pixels, *yellow*—weak positive pixels, *orange*—positive pixels, and *red*—strong positive pixels



Discussion

The previous studies have shown that tTG appears in normal intestinal mucosa. It does not raise doubts that it can be found just beneath the epithelium, in lamina propria, and in the muscularis mucosae [16–19], but the data about its epithelial localization is conflicting. Some investigators have revealed epithelial tTG expression in normal duodenal mucosa [20], but the others have not [16, 17, 21]. We also have not found any significant epithelial tTG expression in most patients with normal duodenal mucosa except two cases with small focal areas of staining and believe that epithelial tTG expression is not usual for the normal duodenum. There is evidence from many studies conducted in the last 20 years that tTG is up-regulated in celiac mucosa [12–14], but till now, there exists some controversy concerning tTG distribution pattern in celiac mucosa and the source of its increased activity [11, 17, 19, 20, 22].

Our study has shown that celiac duodenal mucosa differs from normal controls by a significant increase in tTG expression in lamina propria, which agrees with the data of the other authors [17]. This tTG overexpression can be explained by externalization of tTG by lamina propria cells [23], namely, macrophages, which are present in increased numbers in celiac mucosa [20] or production of tTG by endothelial cells [22].

Our study has also demonstrated that the epithelial tTG expression is a characteristic for CD. We have revealed the significant increase in tTG expression in cryptal and, especially, in superficial epithelium in patients with untreated CD. Earlier, the presence of tTG in intestinal epithelium in CD was found by some investigators [17, 21, 24], but the number of examined patients with untreated CD in those studies was rather small (5–10). So, we have confirmed these results on a larger group of CD patients. Apart from that, following up the patients who were recommended to stop gluten intake, we have demonstrated a decrease in tTG expression in epithelium and lamina propria in a repeatedly taken mucosa samples. It testifies that a high tTG expression in CD patients is not constitutive and might be affected by some factors. Due to a relatively small number of pairs, we did not further stratify these patients, although, the analysis of individual cases showed that the data of some individuals were inconsistent with the group data. It can be supposed that such factors as mucosal atrophy, inflammation, gluten intake, and medication like prednisolone, azathioprine, or NSAID could influence the tTG expression. Biagi F. et al., being based on their own study, concluded that epithelial distribution of tTG was gluten dependent [21]. Our results, based on the follow-up of the same patients before and after GFD, do not fully allow in agreeing with that statement as we did not find any decrease in tTG expression in some patients keeping to

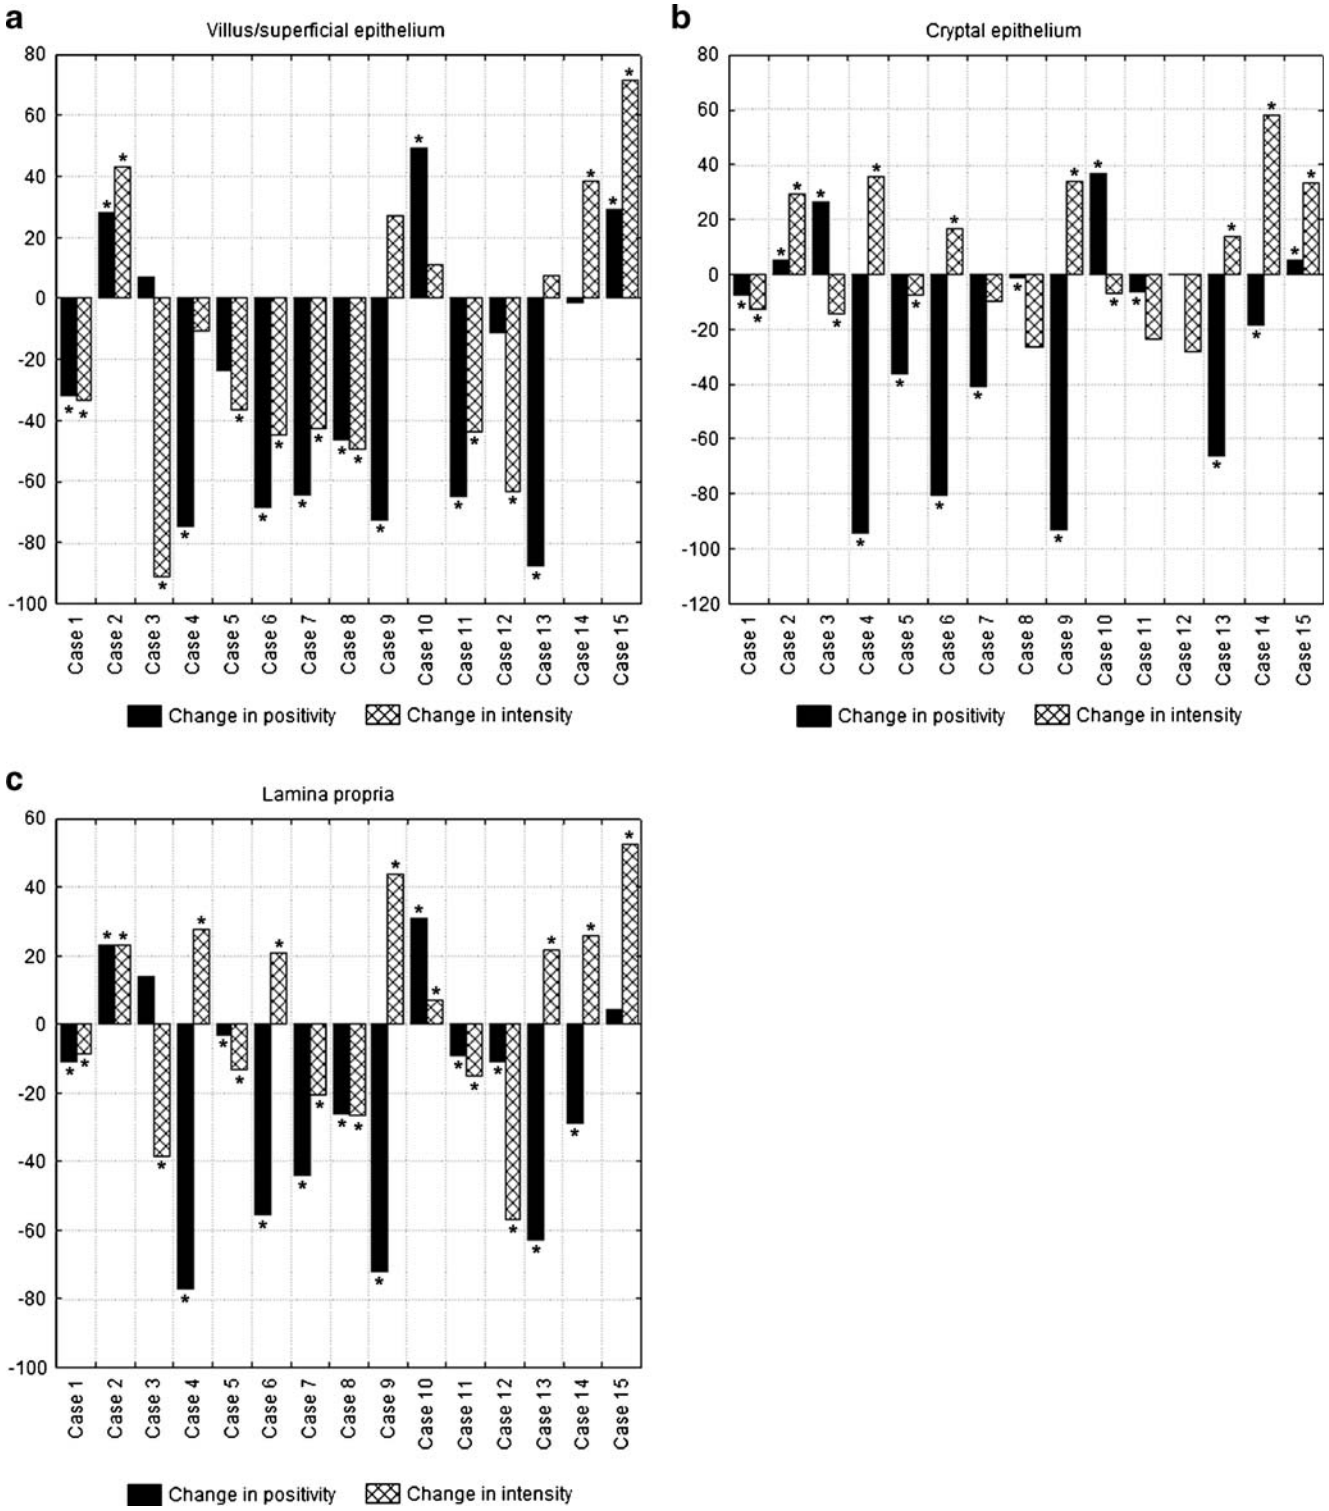


Fig. 6 Individual changes in positivity and index of intensity after prescription of GFD. **a** Superficial/villus epithelium. **b** Cryptal epithelium. **c** Lamina propria. Positive values mean an increase in parameters while negative ones—a decrease. The *asterisk* indicates that the difference is significant; $p<0.05$; Mann–Whitney's U test

strict GFD. On the other hand, as the sensitivity of AGA and anti-tTG in assessment of adherence to gluten-free diet is not the same, the possibility of misinterpretation of compliance to GFD cannot be fully excluded.

Contrary to the above-mentioned studies, W. Sakly et al. found that in CD group there were significantly less patients displaying tTG expressing enterocytes than in the control group [20]. Maiuri L. et al. did not manage to discover epithelial tTG expression in both treated and untreated celiac mucosa using anti-tTG CUB 7402 [11]. There are also some studies which failed to reveal any difference in tTG expression pattern between CD patients and normal controls [5, 6, 17]. Such controversy regarding tTG expression in celiac mucosa could be possibly explained by heterogeneity of CD, but can also be due to methodological differences. In contrast with other authors who assessed immunohistochemical or immunofluorescent staining qualitatively or semi-quantitatively, we used special image analysis software to analyze our samples. Although such approach needs much more time for all samples to be analyzed, it allows subjectivity to minimize and to prove significant differences even in relatively small group of samples. Thus, based on our own data and similar results of other investigators, we believe that CD, at least in part of patients, is associated with changes in tTG distribution in intestinal mucosa.

At present, there is no one opinion concerning the specificity of epithelial tTG expression in CD [17, 21]. That is why our study has been also designed to assess if the tTG distribution pattern found in CD is disease specific. Investigating our pathological controls, we revealed that the changes in tTG distribution are similar to those ones in CD group, namely, increase in tTG expression in epithelium and lamina propria. So, we believe that these changes of

the tTG expression are not specific for CD and could represent a universal mucosa reaction to inflammation or atrophy. Contrary to us, Biagi F. et al. had found epithelial tTG expression to be specific for CD, but only one non-CD condition, such as autoimmune enteropathy, served as pathological control in that study [21]. Thus, it could be also supposed that absence of tTG expression in enterocytes might be specific for autoimmune enteropathy. Our conclusion concerning nonspecificity of tTG overexpression is supported by the results of other authors. The increase in tTG expression in small bowel Crohn's disease has already been shown in the study of D'Argenio G. et al. [25] and was also noticeable in our pathological control with duodenal Crohn's disease. Just recently, Villanacci V. et al. have found that mucosal tTG distribution in duodenitis is the same as in CD, and the positivity in this study was similar in frozen and fixed material [22]. It is also known that tTG overexpression can be found in inflammatory conditions affecting other organs, e. g., idiopathic inflammatory myopathies [26] or anterior polar cataracts [27]. The inflammatory cytokines (IFN-gamma and TGF-beta) seem to be responsible for the tTG up-regulation, at least partly [28, 29]. In its turn, the increased tTG activity triggers NF-kappaB activation inducing the polymerization of NF-kappaB inhibitory protein I-kappaB-alpha and participating in that way in the regulation of inflammation [30, 31].

In conclusion, finding tTG overexpression in lamina propria and intestinal epithelium is a characteristic but not specific for celiac mucosa, which seems to agree with the recent data about involving tTG in the inflammation process. Further investigations are needed to clear up how far an altered expression and distribution of tTG contributes to CD pathogenesis.

Acknowledgments We express our gratitude to Dr. O. Karatysh, Dr. I. Dergacheva, Dr. H. Usau, and Dr. S. Kondrashov for their collaboration and help with the clinical part of the study. The excellent technical assistance of Mrs. S. Klimovich and Mrs. M. Pavlova is also gratefully acknowledged.

Conflict of interest statement We declare that we have no conflict of interest.

Abstract The evaluation of immunohistochemistry (IHC) is usually semiquantitative, and thus subject to observer variability. We analyzed the reproducibility of different IHC measures. Fifty TMA cores of prostate cancer were stained for PDX-1, a transcription factor overexpressed in the cytoplasm of prostate cancer cells. The strongest intensity was scored 0–3 and 1–3 was used for extent (1–33%, 34–66%, and 67–100%). The stains were evaluated twice by four observers: two genitourinary pathologists, and two medical doctors with no formal pathology training. Staining intensity was also measured with automated image analysis. The pathologists read the slides faster than nonpathologists (total time 88 and 178 min, respectively, $p=0.03$). Mean weighted kappa for intraobserver agreement was 0.85 (range 0.81–0.89) for intensity and 0.43 (range 0.38–0.51) for extent with similar results among pathologists and nonpathologists. Mean weighted kappa for interobserver agreement was 0.80 (range 0.77–0.84) for intensity and 0.21 (range 0.11–0.26) for extent. The subjective estimations of intensity correlated with results of image analysis ($r=0.61$–0.66, $p<0.001$), but the correlation between observers was stronger ($r=0.75$–0.81) and correlated better with Gleason grade. Thus, subjective assessment of intensity can be done with a high level of reproducibility while estimation of staining extent is less reliable. Although educated pathologists were faster, the level of pathology training is not crucial for obtaining reproducible results in the analysis of TMA-based studies.

Introduction

Immunohistochemistry (IHC) has been widely used for protein detection in tissue sections for more than 30 years. Although many other methods have appeared recently, IHC is still extensively used in both diagnostic pathology and research. It is therefore essential that the procedures of immunostaining and evaluation are uniform and that human errors are minimized, thus providing reliable results.

Methodological issues of IHC laboratory techniques have been extensively addressed [1–4] but the assessment of staining is also of great importance [5, 6]. The evaluation of IHC is often semiquantitative, and thus subject to observer variability. The reproducibility of this evaluation is seldom considered. There is no consensus on the preferred evaluation method. The intensity and extent of staining are often assessed [7–14]; but the scales and calculation methods vary. In our group, the strongest

intensity and the extent of this intensity are graded and multiplied to obtain a product from 0–9 [7, 11, 13, 14]. Some groups multiply several intensity levels in the same specimen by their extents and then add them [8, 15]. Depending on the scales for intensity and extent, this scoring system is sometimes referred to as the Histon score [16, 17]. In the Allred score, the proportion of positive cells is added to the average intensity [18]. The quickScore has a similar scoring system but with other scales [19, 20]. Volante et al. used a system where subcellular localization and extent of staining is scored simultaneously on a four-tier scale that includes both intensity and subcellular location [21]. Other scoring systems such as percentage of positive stained cells, without regard to the intensity, exist as well [22].

Often, more than one observer is used for validation [9, 18]. The slides may be read by several observers in an open discussion at a multiheaded microscope [17] or the observers may do individual and independent observations, followed either by calculation of an average score [7, 11, 13, 14] or by an open discussion about the cases that obtain conflicting results [21, 23].

Tissue microarrays (TMA) were first described in 1998 [24] and have since then become a common method for evaluation of large series of tissue samples, both using IHC and other methods such as fluorescent in situ hybridization. Compared to full mount tissue samples, TMA is a high-throughput method. Thus, less antibody is needed, staining time is shorter, evaluation is quicker and simpler, and less space is needed for storage. It may be argued that only small parts of samples are studied, but this is the case also in full mounts since only thin sections are stained.

Rubin et al. showed that three cores per tumor were required for correct assessment of prostate cancer IHC [25]. Singh et al. reported that a minimum of five cores per tumor was necessary in order to take tissue heterogeneity into account [26]. Number of cores that are required most likely depends on the investigated marker. In studies of prostate cancer, one [12, 27], two [23, 28] or three cores [7, 11, 13, 14, 29, 30] of tumor tissue per case are commonly used but sometimes even more than that [15]. TMA requires a careful selection of material for core harvesting. This is particularly true for prostate cancer since this is a very heterogeneous tumor type.

Our aim was to analyze inter- and intraobserver reproducibility of scoring of a cytoplasmic staining. Pancreatic duodenal homeobox-1 (PDX-1) was used as test staining. PDX-1 is a Hox-type transcription factor expressed during early embryonic stages of pancreatic development. The main function involves regulation of glucose-dependent insulin gene transcription. PDX-1 expression and overexpression has been seen in several forms of human carcinomas [31–33]. Our group has recently demonstrated a cytoplasmic overexpression of PDX-1 in prostate cancer [11]. In the current study, we also attempted to evaluate subjective scoring against results of image analysis, i.e., presumably objective methods.

Materials and methods

Tissue collection and preparation

The cores selected for this study were part of a larger tissue microarray series consisting of 289 formalin-fixed, paraffin-embedded radical prostatectomy specimens collected from 1998 to 2002 at Karolinska Hospital, Solna, Sweden. None of the patients had received hormonal therapy or radiotherapy prior to surgery. TMAs were constructed using a Beecher Manual Arrayer I (Beecher Instruments Inc, Sun Prairie, WI, USA). Three tumor cores with a diameter of 1 mm were collected from each specimen.

Immunohistochemistry

After rehydration, endogenous peroxidase was inactivated for 30 min in 0.3% H_2O_2 in methanol. Slides were boiled in a microwave oven for 15 min in Vector H 3300 antigen unmasking solution (Vector Laboratories, Burlingame, CA, USA). Nonspecific binding sites were blocked with 5% skimmed milk in PBS with 0.1% BSA. The slides were incubated with a primary rabbit polyclonal antibody against PDX-1 (Abcam, Cambridge, MA, USA) at 1:4,000 dilutions at 4°C overnight. The secondary antibody (Elite kit Vector 5 ml/ml in PBS with 0.1% BSA) was applied for 30 min at room temperature. The signal was increased with the ABC kit (20 ml A+20 ml B/ml PBS-0.1% BSA) at 37°C for 45 min and detected with DAB (Vector kit SK 4100). The slides were counterstained with hematoxylin. Human breast cancer was used as positive and negative control according to the manufacturer's instructions.

Core selection

After immunostaining, 50 cores from the first three blocks were selected. The selection was done in consecutive order, with one core from each case. Only cores containing a large amount of cancer were selected. This was done to simplify the evaluation and minimize error due to difficulty in distinguishing prostate cancer from benign or premalignant changes. Therefore, cores containing prostatic intraepithelial neoplasia (PIN) or a large percentage of benign glands were not chosen. As we included observers with little pathological training this selection was considered necessary to ensure that the correct glands were graded. Reference cores for standardization of intensity levels were selected from the same three blocks and were not included in the reproducibility study dataset.

Evaluation of TMA

Subjective

Intensity and extent of immunoreactivity (IR) and their product (IRP) were evaluated in each core by four independent observers (HB, LE, SJ, FP), including two senior pathologists specialized in urogenital pathology (LE, FP), and two medical doctors with no formal training in pathology (an oncology resident with no training in evaluation of IHC and a PhD student with experience of reading IHC slides). The material was evaluated at two occasions with a two-week interval. The intensity was scored from 0 (no staining) to 3 (most intense staining) based on the strongest staining of the core. The extent of positive intracytoplasmic staining was evaluated in a semiquantitative manner. Scoring was based on percentage of stained epithelial cells and graded from 1 to 3, signifying 1–33%, 34–66%, and >66%, respectively.

Digital image analysis

Color intensity (brown) was measured by digital image analysis (Noesis, Paris, France). No selection was made of areas involved by color intensity measurement, i.e., false positive areas in stroma were not excluded. Regression analysis was calculated between the results of the automated measurement and against the subjective assessments. A second measurement with digital image analysis was performed on the same TMA spots 6 months later and compared with the first measurement by regression analysis.

Statistical analysis

Weighted kappa statistics were used for assessment of inter- and intraobserver variability of immunoreactivity scores. Kappa statistics measures the agreement between observers. A kappa value of 1 indicates perfect concordance, 0 means agreement at the level of chance, and negative values agreement worse than chance agreement. A weighted kappa also takes the magnitude of the disagreement into account so that for example 1 vs. 3 on a three-tier scale is worse than 2 vs. 3. A kappa value of 0 to 0.2, 0.21 to 0.4, 0.41 to 0.6, 0.61 to 0.8, and 0.81 to 1 was considered as slight, fair, moderate, substantial, and almost perfect agreement, respectively. Spearman rank regression analysis was used for comparison of the results of image analysis and subjective assessments. Paired and unpaired Student's t test was used when appropriate for comparisons of time spent on the analyses. A p value of <0.05 was considered significant.

Ethics committee decision

The study was approved by the ethics committees at the Karolinska University Hospital, Stockholm (2006/4:10) and at IARC, Lyon (06–08).

Results

The pathologists needed less than half the time of that required by the nonpathologists to perform the first evaluation ($p=0.001$; Table 1). In the second evaluation, the nonpathologists improved their speed considerably and there was no longer a significant difference in time needed for evaluation compared to the pathologists ($p=0.32$). The total time taken to read the slide twice was less for the pathologists ($p=0.025$).

Mean weighted kappa for intraobserver agreement of intensity, extent, and IRP were 0.85 (range 0.81=0.89), 0.43 (range 0.38–0.51), and 0.83 (range 0.73–0.89), respectively (Table 2). Pathologists and nonpathologists had similar intraobserver agreement evaluation 2 for intensity (mean 0.84 and 0.86), extent (mean 0.41 and 0.45), and IRP (mean 0.81 and 0.85). Mean weighted kappa for interobserver agreement of intensity, extent and IRP were 0.80 (range 0.77–0.84), 0.21 (range 0.11–0.26), and 0.79 (range 0.67–0.88), respectively (Table 3). Pathologists and nonpathologists had similar interobserver

Average		0.851	0.431	0.830

P pathologists, *NP* nonpathologists, *IRP* immunoreactivity product (the product of intensity and extent)

Table 4 Correlation coefficient between the four observers (evaluation 1)

Observer	Intensity	Extent	IRP
1 vs. 2	0.805	0.169	0.734
1 vs. 3	0.802	0.169	0.783
1 vs. 4	0.799	0.332	0.815
2 vs. 3	0.754	0.415	0.721
2 vs. 4	0.804	0.453	0.758
3 vs. 4	0.750	0.475	0.787

IRP immunoreactivity product (the product of intensity and extent)

agreement for intensity (0.81 and 0.79), extent (0.24 and 0.25), and IRP (0.79 and 0.82).

The correlation coefficients between observers for intensity, extent and IRP were 0.75–0.81, 0.17–0.48, and 0.72–0.82, respectively, in evaluation 1 (Table 4), and 0.77–0.86, 0.30–0.43, and 0.72–0.86, respectively, in evaluation 2 (Table 5). The subjective estimation of intensity by each observer correlated with results of automated image analysis (r=0.61–0.66, p<0.001). The results of the two automated measurements were not identical, but correlated strongly with each other (r=1.0, p<0.001). The mean difference in measured intensity was only 0.012% (0–0.24%).

The subjective estimation of the staining intensity correlated with the Gleason pattern of the core in three observers (r=0.31–0.39, p=0.015–0.028), but not in one of the nonpathologists (r=0.19, p=0.19). The automated analysis showed no correlation with Gleason pattern (r=−0.001, p=0.99).

Discussion

IHC is a standard method for protein detection and quantitation in research and clinical work, but has many potential sources of error. Technical and methodological aspects of the staining have been thoroughly investigated, while the evaluation of slides has received less attention. Microscopic evaluation of IHC is subjective and based on different scoring systems and scales with poor standardization. In research, this leads to a lack of reproducibility, while in clinical applications it is even more problematic, since IHC results may alter treatment with great effect for the individual patients. There is no gold standard for IHC annotation, and perhaps there never will be, as each antibody must be considered individually. Some proteins are easily classified as cytoplasmic, membranous or nuclear, while others are expressed in several cell compartments, e.g., both in the cytoplasm and nucleus. Blotchy, heterogeneous staining is also common and may benefit from a different evaluation scale. It is conceivable that the clinical implication of staining varies between different proteins and tissues. Whereas, the mere existence of hormone receptors may be an indication for hormone therapy in breast cancer, the varying levels of other proteins in cancer tissue may be important.

In this study, evaluation of staining intensity reached a surprisingly strong intraobserver agreement that was almost perfect as measured by kappa statistics. Interobserver agreement was likewise high, ranging from substantial to almost perfect. This indicates that subjective estimation of the staining intensity may be sufficient for reliable and

Table 3 Interobserver agreement (weighted kappa) between the four observers

IRP immunoreactivity product (the product of intensity and extent)

robust measurement of IHC in TMA. The use of internal reference cores representing each intensity grade may have contributed to the high intra- and interobserver agreement (Fig. 1). It has been suggested that an internal control should be used to overcome batch variations [6].

By contrast, extent of staining showed a poor intra- and interobserver agreement. In previous studies, we have found that extent generally correlate less well with outcome measures than intensity [11]. We have also routinely calculated the product of intensity and extent, although this measure has provided no or marginal improvement over intensity alone for e.g., prediction of prognosis. These earlier results indicate that extent of staining may be of less importance than previously assumed. The present study raises serious concern about extent as a reproducible measure in TMA assessment. Standard cores for extent were not used, but whether this would be useful is questionable. Interestingly, the weighted kappa values of IRP were almost as good as those of intensity. This indicates that the poor reproducibility of extent may be balanced by the intensity. If an observer hesitates between an intensity of 2 with extent 3 and an intensity of 3 with extent 1, the relative discrepancy of extent exceeds that of the product of intensity and extent.

There was no difference in the reproducibility achieved by trained pathologists and nonpathologists, which indicates that IHC assessments can be performed with a high accuracy early in pathology training. In the current study, cores were selected to contain sufficient amount of invasive carcinoma because our aim was to measure the ability to evaluate IHC itself and not the ability to accurately diagnose prostate cancer. If the series would have been unselected and included pitfalls such as PIN, benign proliferations or unusual cancer types, the results may have been different. However, we nevertheless believe that it is possible to train devoted junior colleagues to do IHC assessment in research.

The evaluation of the slides was more time-consuming for nonpathologists than for pathologists in the first evaluation, while the difference decreased in the second evaluation. Thus, junior observers seem to have compensated lack of experience with more careful observation. Both groups of participants increased their speed in the second evaluation, probably because the observers had already seen the slides once and established their internal references.

To obtain a more objective and reproducible evaluation of IHC, it has been suggested that subjective assessment should be replaced by automated image analysis [34, 35]. The correlation between Noesis, the automatic image analysis system used in this study, and subjective analyses was significant but weaker than the correlation between the human observers. For image analysis, a representative area was chosen manually. To obtain adequate results, it is critical that the appropriate tissue compartment is measured, in this case cancerous epithelium, while benign epithelium, premalignant lesions, and stroma need to be avoided. The lower correlation between Noesis and manual analyses compared to the correlation between human observers may be explained by the difficulty involved in segmentation of microscopic images. As shown in this study, objective assessment by image analysis is not necessarily better than subjective estimation and a standardization of this system is necessary to stabilize the analysis in the future. Interestingly, the subjective assessments correlated better with tumor grade than automated analysis. There are two possible explanations of this finding. Subjective assessment may better reflect the biology of the tumor as the observer can make sure artifacts is excluded and that the appropriate invasive cancer

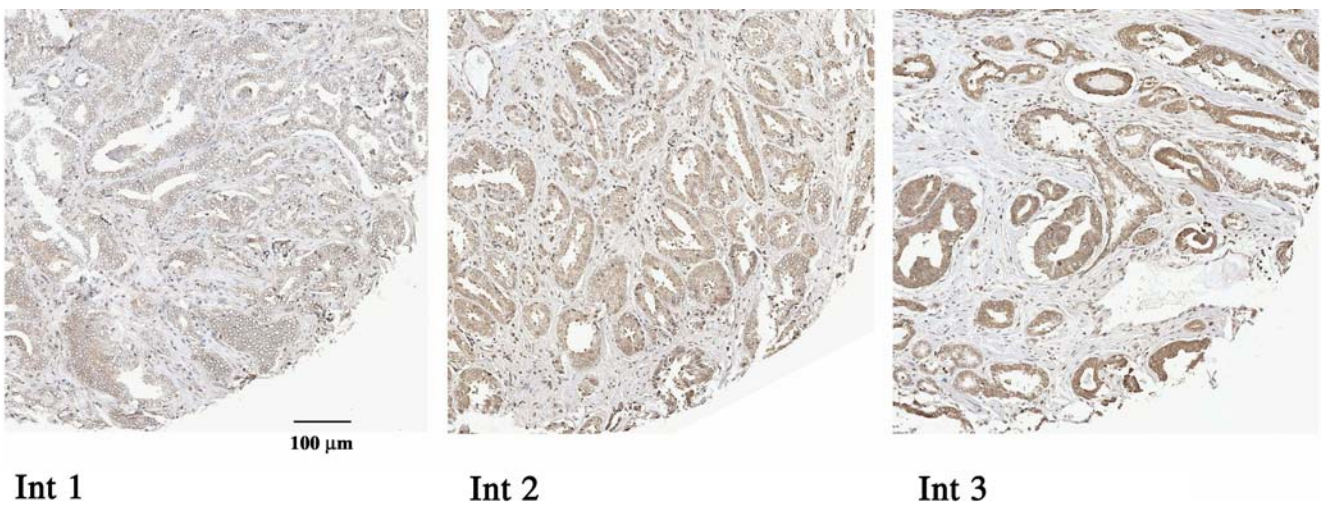

Fig. 1 TMA cores used for standardization of staining intensity grading. Reference cores for intensities 1, 2, and 3. Immunohistochemical staining against PDX-1

component is measured. On the other hand, subjective observers may be biased by their knowledge of tumor grade (as it is not possible to be entirely blinded for when reading slides) and staining intensity. It may be no coincidence that the only subjective observer that did not reach a significant correlation with tumor grade was a nonpathologist who had not received any systematic training in prostate cancer grading. Whether subjective or automated measurements are the best predictors of patient outcome is not possible to evaluate based on the current series of 50 patients. It should also be emphasized that the current study for practical reasons was performed on one single antibody and results may theoretically differ between different biomarkers.

We have compared intra- and inter reproducibility of IHC evaluation in prostatic TMA both using subjective and digital analysis. We have shown that subjective assessment of IHC staining intensity is highly reproducible, regardless of previous training of the observer. Although one single scale of evaluation may not be desirable, we want to emphasize the importance of standardized scoring systems, in order to improve reproducibility within and between research groups.

Conflict of interest statement We declare that we have no conflict of interest. The Noesis company has let us use the Noesis digital analysis system free of charge, however, it has not been possible for the company to influence the results of this study

Received: 27 July 2009 / Revised: 1 September 2009 / Accepted: 3 September 2009 / Published online: 9 October 2009

Abstract The occurrence of liposarcoma in the tongue is rare with only 34 cases published so far. We report six new cases of atypical lipomatous tumor (ALT) of the tongue, and detection of mdm-2 and CDK4 expression by immunohistochemistry and fluorescence in situ hybridization (FISH), respectively, was performed. The series comprised three males and three females, aged 11–78 years. The tumors arose at the lateral side of the tongue, and in one case, multiple tumor nodules were noted. Follow-up information in five cases (range from 4 to 159 months) revealed one local recurrence at 6 months. Microscopically, four cases had features of lipoma-like ALT, whereas two cases displayed patterns of sclerosing ALT. Immunohistochemically, tumor cells revealed expression of vimentin (five of five), S100 (five of five), mdm-2 (three of five), and CDK4 (four of five). Two cases were also examined by FISH; amplification of mdm-2 gene was found in both cases, whereas amplification of CDK4 gene was present in one case only. To the best of our knowledge, this is the third largest series reporting occurrence of ALT in the tongue and the first one where analysis of mdm-2 and CDK4 proteins/genes expression/amplification was performed. Both these markers may be of help in the differential diagnosis of ALT versus lipoma. Although most ALTs of the tongue behave in the nonaggressive fashion, they may recur locally. Based on current data, the term ALT is strongly recommended for tumors occurring in the tongue to prevent inadequate treatment.

Keywords Atypical lipomatous tumor · Well differentiated liposarcoma · Tongue · Oral cavity · Head and neck

Introduction

Liposarcoma (LS) is the most common soft tissue sarcoma in adulthood. According to current WHO classification of soft tissue tumors [1], LSs are categorized into five subtypes: atypical lipomatous tumor (ALT)/well-differentiated LS (WDLS), dedifferentiated LS, myxoid/round cell LS, pleomorphic LS, and mixed-type LS. Since it has become apparent that WDLS and ALT are identical tumors which show no metastatic potential unless they undergo dedifferentiation, the term ALT has been proposed for surgically amenable WDLSs, which are curatively treated by wide excision with free margins [1].

ALT accounts for about 40–45% of all LSs occurring as extremity or retroperitoneal tumor in late adult life, mainly between the fifth and the seventh decades. ALT is further subclassified into the lipoma-like, sclerosing, inflammatory, and spindle cell subtypes [1].

The occurrence of LS in the tongue is extremely rare, with only 34 cases reported in the English-written literature so far, as reviewed by Allon et al. [2] in 2005 with two subsequent cases reported by DeWitt et al. [3] in 2008. Among the histological subtypes, ALT is by far the most common in this particular location [2]. It has very good prognosis with a tendency for local recurrences, namely if incompletely excised, but with virtually no metastatic potential.

We report herein six new cases of ALT of the tongue, where detection of mdm-2 (murine double minutes) and CDK4 (cyclin-dependent kinase 4) by both immunohistochemistry and fluorescence in situ hybridization (FISH) was used in the diagnostics. The clinical course, diagnostic criteria as well as differential diagnosis are discussed.

Materials and methods

Six cases of ALT of the tongue examined during the years 1996–2009 were retrieved from the archive and consultation files of the authors. The paraffin blocks for additional immunohistochemical and FISH analysis were available all but one case (no. 4). The specimens were immediately fixed in formalin, embedded in paraffin, and routinely processed.

Indirect immunohistochemistry using monoclonal/polyclonal antibodies against vimentin (clone V9, dilution 1:50, Dako (Glostrup, Denmark)), S100 protein (S100; polyclonal, 1:6,000, Dako), mdm-2 (IF2, 1:200, Invitrogen (Carlsbad, CA, USA)), CDK4 (DC9-31, 1:400, Biosource (Nivelles, Belgium)), and Ki-67 (MIB-1, 1:50, Dako) was performed. For antigen retrieval of vimentin, the tissue was processed in the microwave vacuum histoprocessor RHS 1 (Milestone) at pH 6.0 at 120°C for 4 min. For detection of other antigens, the retrieval was performed in a water bath for 40 min at 97°C in the target retrieval buffers at different pH values—at pH 6.0 for S100 and at pH 9.0 for Ki-67—and in a water bath for 30 min at 95°C at pH 9.0 for mdm-2 and CDK4, respectively.

Endogenous peroxidase activity was inhibited by immersing the sections in 3% hydrogene peroxide. Finally, for vimentin, S100, and Ki-67, the sections were incubated with EnVision+ Dual Link System-HRP (Dako) and for mdm-2 and CDK4 with LSAB™ Kit (Dako), respectively. The reactions were visualized using diaminobenzidine.

The FISH was performed on 3-μm sections of formalin fixed, paraffin-embedded tissue after baking at 65°C for 16 h, deparaffinization with xylene, and dehydration with ethanol. All tissue sections were pretreated with a 30% solution of pretreatment solution and digested with proteinase K following the instructions of the suppliers (Q-Biogene, Heidelberg, Germany). Digestion times were optimized on a case-by-case basis. Amplification of the mdm-2 and CDK4 genes was detected by hybridization of digoxigenin-labeled bacterial artificial chromosomes followed by binding to fluorescein isothiocyanate antidigoxigenin. After a second hydration step, the probes were applied to the sections, and the cover slides were sealed with a rubber cement, heat-denaturated, and hybridized at 37°C for 16 h. After stringent washing with 50% formamide in 2× standard sodium citrate, the sections were counterstained with 4′,6-diamidino-2-phenylindole II in mounting medium (125 ng/ml, Vysis, Bergisch Gladbach, Germany) and visualized under a Zeiss Axioplan 2 microscope using a HBO103 lamp and the appropriate filters for three fluorescence dyes.

Results

The clinicopathological features of the patients are summarized in Table 1. There were three males and three females, aged 11–78 years (mean 51±11 years; median 58 years). In all cases, the tumors arose at the lateral side of the tongue. In one case (no. 3), there were multiple tumor nodules, localized at both sides of the tongue (Fig. 1). All lesions were treated by local excision. Follow-up information in five cases (range from 4 to 159 months; mean 69± 25 months; median 59 months) revealed one local recurrence in case no. 3 6 months after initial surgical treatment, and the patient died 8 months later on complications of ischemic heart disease. Autopsy was not performed.

Grossly, the tumors had the appearance of lipoma, i.e., they were yellow-tan, lobulated, and covered by intact mucosa. Microscopically, all lesions were partly circumscribed, but not encapsulated; focally, the neoplasms infiltrated into the surrounding striated muscle and fibrous tissue (Fig. 2). The tumors were of lobular arrangement, composed of adipocytes with striking variations in size and shape having hyperchromatic nuclei. Scattered lipoblasts, both univacuolar and multivacuolar, were present in four cases. Four cases had the features of lipoma-like ALT (Fig. 3), whereas in two cases, prominent interstitial fibrillary sclerosis (Fig. 4) was in keeping the diagnosis of sclerosing ALT. Additionally, in two cases only, isolated spindle-shaped primitive looking stromal cells were found, presumably of a precursor nature. Mitotic activity was very low; only few typical mitoses were found in all the slides examined. Foci of dedifferentiation were not present (not even in the recurrent case (no. 3)).

Immunohistochemically, the tumor cells revealed expression of vimentin (five of five), of S100 (five of five), of mdm-2 (three of five; Fig. 5), and of CDK4 (four of five; Fig. 6). Proliferative antigen Ki-67 was positive in less than 0.5% of tumor cells. Two cases (nos. 1 and 3) were examined also by FISH. Amplification of mdm-2 gene was

found in both cases (Fig. 5, inset), whereas amplification of CDK4 gene was present in one case (no. 1) only. The results of immunohistochemical and FISH analysis of expression and amplification of mdm-2 and CDK4 proteins/genes are summarized in Table 2.

Discussion

Liposarcoma, first described by Virchow in 1857 (as cited by DeWitt et al. [3]), is the most common mesenchymal malignancy of adulthood, arising in deep soft tissues of the extremities and in the retroperitoneum and in the abdominal cavity. However, its occurrence in the head and neck region, particularly within the oral cavity, is rare. In the largest review of 23 cases of LS of the oral cavity [4], the tongue was the preferred site in 52% (12 of 23) cases, whereas in the second largest series of 18 cases of LS of the oral cavity and salivary glands [5], LS occurred most frequently in the buccal mucosa in 39% (seven of 18) of cases, respectively. Other anatomic locations included lip, floor of mouth, gingiva and alveolar mucosa, soft palate, and parotid and submandibular gland [4, 5].

Since the comprehensive review of LS of the tongue from 2005 [2], analyzing a total of 32 cases included in two large series [4, 5] and in several case reports [6–18], only one paper reporting two additional cases has been published [3]. Thus, together with our cases, there are only 40 cases of LS of the tongue reported so far.

Compared to LS of other parts of the body, LS of the tongue occurs in older patients with the mean age of about 60 years [2]. However, it may affect younger persons as well, since two of our patients were aged 11 and 27 years, respectively; the former appears to be the youngest patient reported so far. According to gender distribution, LS of the tongue shows a male-to-female ratio of about 2.5:1 [2] which is higher than that for LS in other locations [19].

Two gross patterns of LS of the tongue have been recognized—solitary or multiple nodules, the former being by far the commonest. Typically, the tumor presents as a submucosal mass covered by intact mucosa, occurring on lateral and/or dorsolateral aspects of the tongue. The clinical diagnosis usually includes benign tumors, e.g., fibroma, lipoma, and neurogenic and salivary gland tumors [2]. Some rare neoplasms which show predilection for tongue involvement, e.g., low-grade myofibroblastic sarco-

Fig. 1 Multinodular atypical lipomatous tumor at the lateral margin of the tongue (case no. 3)

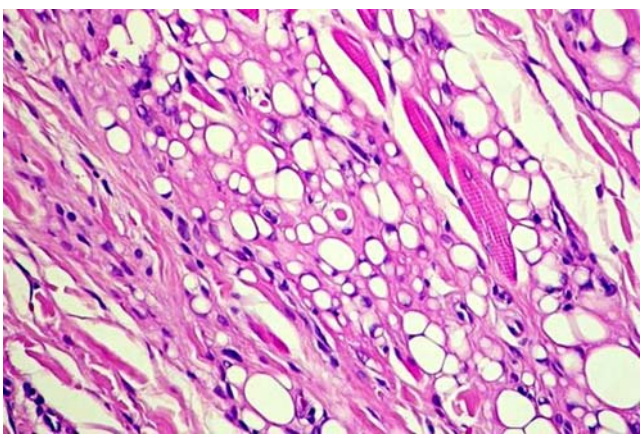

Fig. 2 Focal infiltration of tumor cells among bundles of skeletal muscle (HE, original magnification ×200)

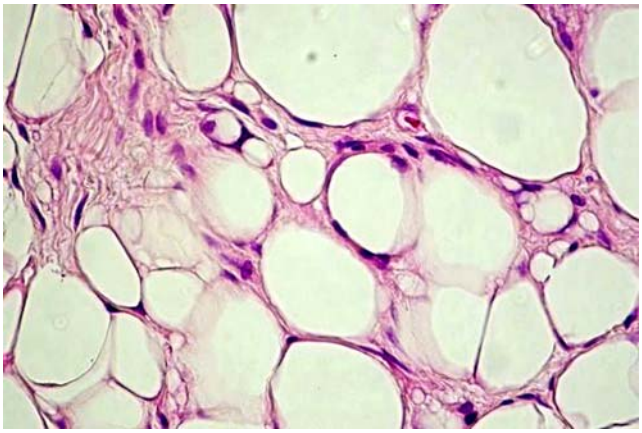

Fig. 3 Isolated lipoblasts interspersed among mature adipocytes (HE, original magnification ×400)

ma [20, 21] and ectomesenchymal chondromyxoid tumor [22], may enter the differential diagnosis as well.

Regarding the LS variants, the most LSs of the tongue are of ALT subtype, comprising about 75% of cases, followed by myxoid/round cell and dedifferentiated variants [2]. This distribution differs from LSs of retroperitoneal and of head and neck origin, which are dominated by myxoid/round cell variant in 50% and in 40% of cases, respectively [19, 23]. The majority of cases of ALTs of the tongue show features of the lipoma-like subtype, while only several cases display, usually focally, the sclerosing subtype pattern [2].

The differential diagnosis of ALT of the tongue includes particularly a lipoma with regressive changes and an intramuscular lipoma. Traumatization of lipoma due to repeated biting may lead to degenerative changes—edema, fibrosis, and entrapment of adipocytes within the scar tissue—thus mimicking appearance of the sclerosing variant of ALT. However, the typical hallmark of ALT—hyperchromatic nuclei—is typically absent. The vacuolated histiocytes present in areas of fat necrosis may simulate lipoblasts; however, their origin may be demonstrated using immunohistochemical detection of lysosome-associated antigens, e.g., CD68 or lysozyme. Presence of a central intranuclear vacuole, so-called *Lochkern*, which is considered either an intranuclear cytoplasmic lipid invagination or a cutting artifact and may mimic a lipoblast, may eventually disappear on thinner sections. Despite its infiltrative growth pattern, intramuscular lipoma is composed of more uniform adipocytes and lipoblasts are absent. Since ALT may, although rarely, occur in younger patients as shown above, a lipoblastoma enters the differential diagnosis. However, lipoblastoma is most commonly found within the first 3 years of life, and it frequently displays myxoid stroma with plexiform vascular pattern on microscopy, both these characteristics being not the features of ALT. In addition, the cytogenetic hallmark of lipoblastoma, i.e., rearrangement of chromosome 8q11–13 [1], is absent in ALT whereas an amplification of mdm-2 and CDK4 genes is seen in the latter [24]. Being the second most common type of lipoma in the oral and maxillofacial region, spindle cell/pleomorphic lipoma (SC/PL) should be included in the differential diagnosis as well [25]. Contrary to ALT, SC/PL shows no striking variation of size and shape of the adipocytic cells, atypical and/or hyperchromatic nuclei are absent, frequently displays thick rope-like collagen bundles—the latter being extremely useful diagnostic feature—and shows mdm-2- and CDK4-negative immunohistochemical profile. Furthermore, SC/PL is characterized by monosomy or partial loss of chromosomes 13 and/or 16; these cytogenetic findings are absent in ALT [1].

Immunohistochemically, the ALT shows consistent expression of vimentin and of S100, although the spindle cell component may feature variable results of the latter [2]. In addition, expression of three novel antigens was detected in ALTs [24]. These include mdm-2, a nuclear phosphoprotein able to inhibit the p53 transactivating domain [26], CDK4 with catalytic kinase function, and HMGI-C, a transcription factor [27]. The genes coding all these proteins are located in the chromosomal region 12q13–15. These DNA sequences are the major constituents of the supernumerary ring and giant rod chromosomes, the cytogenetic hallmarks of ALTs being present in about 93% of the cases [28–31]. In one series [24], the expression of mdm-2, CDK4, and HMGI-C was found in 50%, in 100%, and in 83% cases of ALTs, respectively, whereas all lipomas were mdm-2 negative and CDK4 and HMGI-C expression was detected in only 11% and 44% cases of lipomas, respectively. In our study, which is the first series of ALT of the tongue where immunohistochemical expression of both mdm-2 and CDK4 was performed, we have obtained similar results. Thus, immunohistochemical detection of both mdm-2 and CDK4 may be

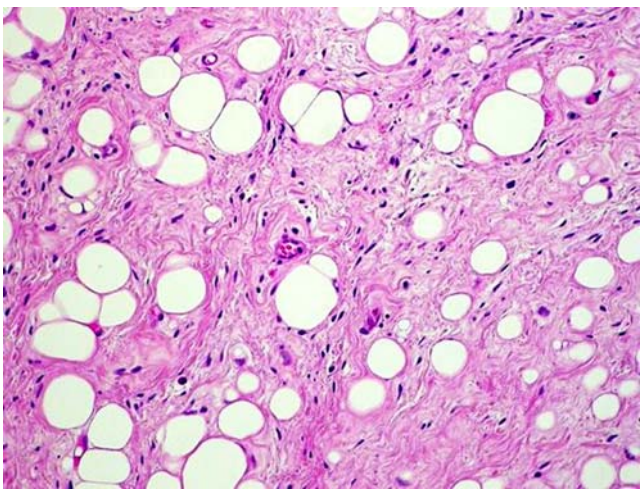

Fig. 4 Prominent interstitial sclerosis (HE, original magnification ×200)

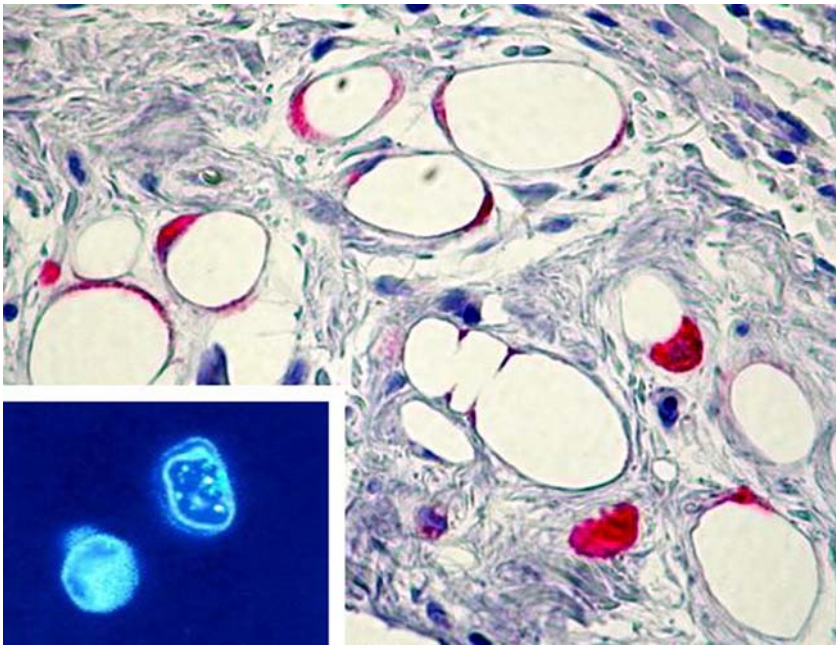

Fig. 5 Nuclear expression of mdm-2 in the majority of tumor cells (original magnification ×400). *Inset*: Amplification of mdm-2 gene as multiple green signals in the nucleus of a tumor cell (original magnification ×1,000)

useful in differential diagnosis of lipoma versus ALT. On the other hand, the above stated data have led some investigators to a hypothesis that lipomas and ALTs may be two extremes of the molecular, genetic, and morphological continuum [24, 32].

The optimal treatment for ALT of the tongue is wide surgical excision with free margins. Among the reported cases of ALT of the tongue, including our cases, 15% (six of 40) of tumors had recurred and 7.5% (three of 40) lesions demonstrated multiple recurrences (up to five times) during a follow-up period ranging from 4 months to 37 years (mean 6±9 years; median 2 years). Although 5% (two of 40) of the published cases displayed foci of dedifferentiation [4, 5], no metastases from lingual ALT have been reported so far.

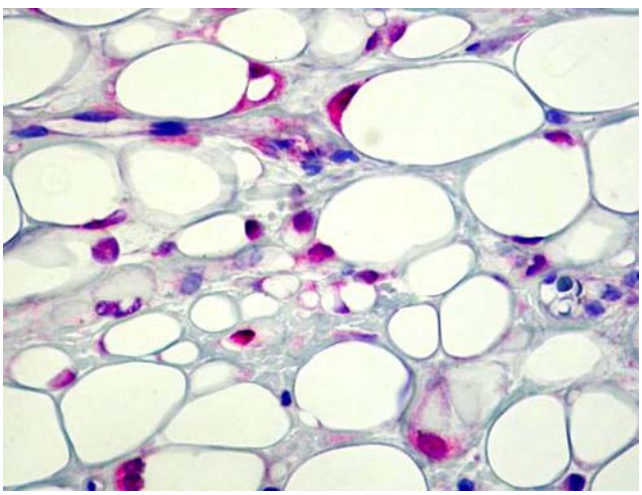

Fig. 6 Nuclear expression of CDK4 in the majority of tumor cells (original magnification ×400)

In summary, we report six new cases of ALT of the tongue—a rare neoplastic entity which should be always considered in the differential diagnosis when dealing with adipocytic lesion in this particular location. To the best of our knowledge, this is the third largest series reporting occurrence of ALT in this anatomic area and the first one where both immunohistochemical analysis of mdm-2 and CDK4 proteins expression and FISH analysis of genes amplification were used in the diagnostics. Although the diagnosis of ALT can be made on hematoxylin–eosin, our results and data of other investigators indicate that both these markers may be of help in the differential diagnosis of ALT versus lipoma. Based on current data, the use of term ALT over the designation WDLS is strongly recommended for tumors occurring in the tongue to prevent inadequate

Table 2 Results of immunohistochemical and FISH analysis of expression and amplification of mdm-2 and CDK4 proteins/genes

treatment. Most ALTs of the tongue behave in a nonaggressive fashion; however, they may recur locally if incompletely excised. Thus, long-term follow-up of the patients is mandatory.

CASE REPORT

Intestinal type of mucinous borderline tumor arising from mixed epithelial and stromal tumor of kidney

Peiguo G. Chu · Sean K. Lau · Lawrence M. Weiss · Zhong Jiang

Received: 13 May 2009 / Revised: 22 July 2009 / Accepted: 24 August 2009 / Published online: 15 September 2009

Abstract We report a mucinous borderline tumor arising from a mixed epithelial and stromal tumor of left kidney (MESTK). The patient was an 82-year-old woman who presented with gross hematuria and recurrent urinary tract infection for years. The patient had a cytoscopy with a retrograde pyelogram, which indicated a dilated left kidney with a central mass lesion. Subsequently, she underwent a radical left nephrectomy. Cross-sections of left kidney showed a 4.5×3.5×1.5 cm ill-defined cystic lesion with mucinous and solid areas. Histologic sections of the lesion showed numerous variable-sized dilated cysts with fibrous, fatty, vascular, and smooth muscle stroma. The cysts were lined by a various types of epithelium, including single layer of flat, cuboidal and mucinous epithelium, urothelium, intestinal epithelium, and endocervical epithelium. In areas, the mucinous epithelium showed complex proliferation with stratification, papillae formation, and nuclear atypia, resembling that of an ovarian mucinous borderline tumor, a colorectal tubular adenoma, or a low-grade appendiceal mucinous carcinoma. Immunohistochemically, the mucinous borderline tumor showed a colorectal phenotype, being strongly positive for CK20, CDX-2, and MUC2. There was no invasive mucinous tumor identified. We believe that this case represents the first reported example of mucinous borderline tumor arising from a MESTK.

Introduction

Mixed epithelial and stromal tumor of the kidney (MESTK) is a rare renal tumor, which is composed of a mixture of stromal and epithelial elements [1–3]. The tumor is usually composed of many large and small cysts lined by different types of epithelium. The most common epithelial elements are single layer of flattened or cuboidal cells [4, 5], followed by urothelium [4]. The stroma is usually composed of fibroblasts and smooth muscle cells. While MESTK has a strong association with the female sex and hormonal milieu, adult cystic nephroma (ACN; more common than MESTK) can affect both sexes and, on occasion, may have a hormonal association [6]. Despite the facts that there is considerable overlap between both tumors morphologically and both tumors have a similar molecular profile [6, 7], the relationship between CAN and MESTK is still highly controversial. Some authors believe that MESTK often display features of Müllerian differentiation [8].

The vast majority of cases of MESTK follow a benign clinical course. Nephrectomy is the treatment of choice [3, 6]. However, rare cases with heterologous epithelial or malignant stromal components have been reported. Yang et al. [9] described a case of MESTK with cervical and intestinal differentiation, which contained Paneth and goblet cells. Beiko et al. [10] reported a case of MESTK

with estrogen receptor expressing müllerian type epithelium. Cases of malignant MESTK have been reported [11–15]. All three cases had a sarcomatoid stromal component, while the epithelial components were benign. To our knowledge, borderline or malignant epithelial tumors in a MESTK have not been described in literature.

Here, we report the first case of mucinous borderline tumor arising from a MESTK-exhibiting mucinous, intestinal, and endocervical epithelium.

Case report

The patient was an 82-year-old woman with a clinical history of stage I breast cancer diagnosed 8 years prior to presentation. She presented to her urologist with a history of gross hematuria and recurrent urinary tract infections. She had no clinical and radiologic evidence of gastrointestinal or ovarian malignancy. The patient first had a cystoscopy with a retrograde pyelogram, which indicated a dilated left kidney with hydronephrosis. She then underwent left ureteroscopy and a ureteral stent replacement. At the time, she was noted to have a 1.5-cm renal mass in the left upper calyx. The patient then underwent a left radical nephrectomy. The patient is alive and well without recurrent disease 2 months after surgery.

The left kidney weighed 361 g. The cut surface of the left kidney showed dilated calyces ranging from 1.5 to 2.0 cm in diameter (Fig. 1). In the center of the kidney, there was a 4.5×3.5×1.5 cm ill-defined cystic mass with solid areas and a mucinous appearance. The dilated calyces grossly communicated with the mass.

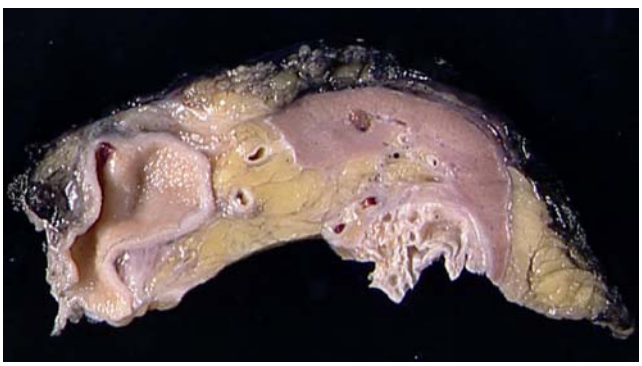

Fig. 1 Gross appearance (part of tumor) of formalin-fixed mixed epithelial and stromal tumor of the kidney. Residual normal kidney is present in the *right upper field*. The cystic tumor with solid and mucinous areas is present in the *right lower field*. The dilated calyx is present in the *left field*. Entrapped fatty and vascular tissue are present between the tumor and the dilated calyx

Materials and methods

The specimen was formalin-fixed and routinely processed for light microscopy. Fifteen tissue blocks were submitted for histologic examination. Immunohistochemistry was performed in a Dako Autostainer (Dako, Carpinteria, CA) using the dual Link Envision+ Detection System with antibodies directed against keratin 7 (clone OV-TL 12/30, dilution 1:2,000, Dako), keratin 20 (clone IT-KS.20.8, dilution 1:8, APR, Belmont, MA), CDX-2 (clone CDX2-88, dilution 1:50, Biogenex Laboratories, San Ramon, CA), MUC2 (clone Ccp58, dilution 1:100, Novocastra Laboratories, Newcastle, UK), PAX-2 (polyclonal, dilution 1:60, Zymed, Carlsbad, CA), WT-1 (clone 6F-H2, dilution 1:50, Dako), CD56 (clone NK-1, dilution 1:50, Novocastra Laboratories), HMB-45 (clone HMB-45, dilution 1:400, Dako), and ER-α (clone 1D5, dilution 1:600, Immunotech, Marceille, France), and PR (clone PR88, dilution 1:100, Biogenex Laboratories).

Microsatellite instability/mismatch repair (MSI/MMR) protein expression was performed by immunohistochemical staining with antibodies against MLH-1 (clone G168-15, dilution 1:5, BD Biosciences, San Jose, CA), MSH-2 (clone FE11, dilution 1:100, Calbiochem, Gibbstown, NJ), MSH-6 (clone 11/MSH6, dilution 1:50, BD Biosciences), and PMS-2 (clone A16-4, dilution 1:25, BD Biosciences).

Results

Pathology

The tumor was characterized by macrocysts, microcysts, and clusters of tubules (Fig. 2a). The cysts were lined by single layer of flattened, cuboidal epithelium (Fig. 2b), and urothelium (Fig. 2c). In areas, mucinous epithelium (Fig. 3) and intestinal-type mucosa was present with prominent Paneth and goblet cells (Fig. 2d). In other areas, endocervical mucosa was present (Fig. 2e). The stroma between cysts was composed of predominantly fibroblasts and smooth muscle cells with marked chronic inflammatory cell infiltration. In addition, there were large-caliber blood vessels and fatty tissue (Fig. 1, middle). Adjacent to benign mucinous epithelium, there were multiple foci of borderline mucinous tumor (Fig. 3a). The tumor was composed of intracystic complex mucinous epithelial proliferation with stratification and filiform papillae formation. Occasional Paneth cells were present at the base. The nuclei were hyperchromatic and slightly enlarged with occasional mitotic figures present. The overall histologic features resembled mucinous borderline tumor of the ovary or pancreas, a low-grade mucinous tumor of the appendix, or

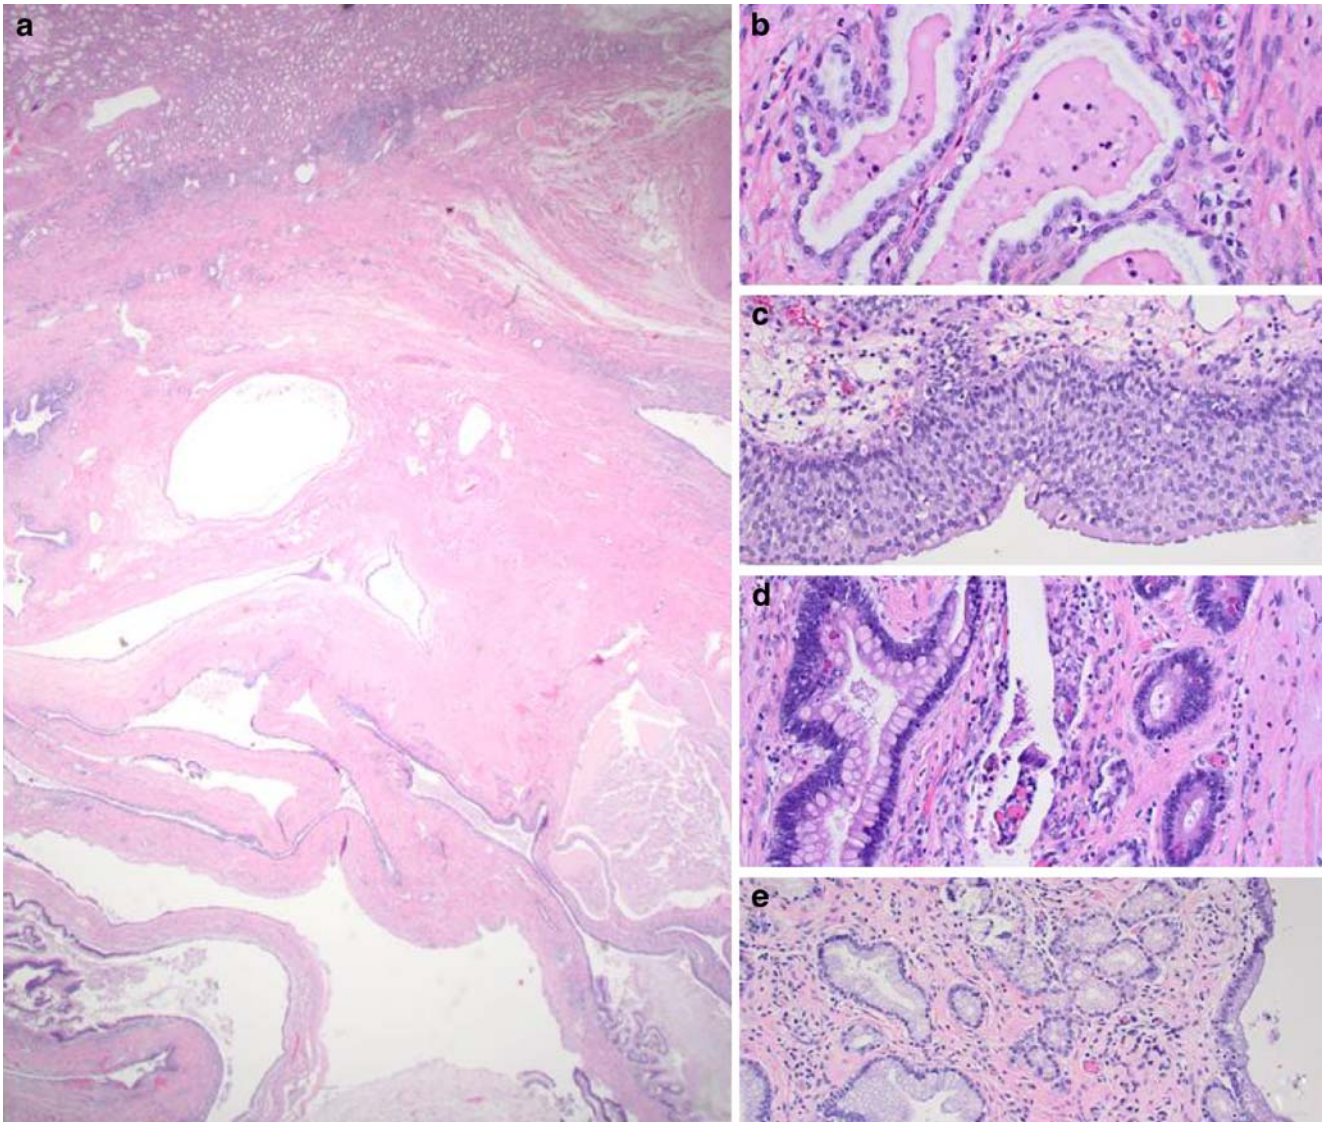

Fig. 2 In low power magnification (×20; **a**), the mixed epithelial and stromal tumor of the kidney adjacent to normal renal tissue is seen (*top*) and shows numerous variable-sized cysts with abundant stroma. Two foci of mucinous borderline tumor are seen in the *left lower* and *right lower* corners. On high power magnification, different cystic lining epithelia are seen, including simple cuboidal epithelium (**b**, ×200), urothelium (**c**, ×200), intestinal mucosa with Paneth and goblet cells (**d**, ×200), and endocervical mucosa (**e**, ×200)

colorectal tubular adenoma. No invasive mucinous tumor was identified.

Immunohistochemistry

Immunohistochemically, the flattened and cuboidal epithelial cells were positive for CK7 (Fig. 3b) and PAX-2 (Fig. 3c) and negative for CK20, CDX-2, and MUC2, suggesting renal tubular differentiation. In contrast, the benign mucinous epithelium next to the mucinous borderline tumor (Fig. 3a, insert) was strongly positive for CK7 and CK20 and negative for CDX-2, an immunophenotype similar to that of an ovarian mucinous tumor. The borderline mucinous tumor was strongly positive for CK20 (Fig. 3d), CDX-2 (Fig. 3e), and MUC2 (Fig. 3f), and was negative for CK7, suggesting a colorectal immunophenotype. The stromal cells were focally positive for ER and PR, with the strongest nuclear staining in stromal cells surrounding the mucinous borderline tumor. The stromal cells were negative for WT1 and CD56.

MSI/MMR protein immunohistochemistry

The mucinous borderline tumor cells were positive for MLH-1, MSH-2, MSH-6, and PMS-2, providing no evidence for microsatellite instability, mismatch repair.

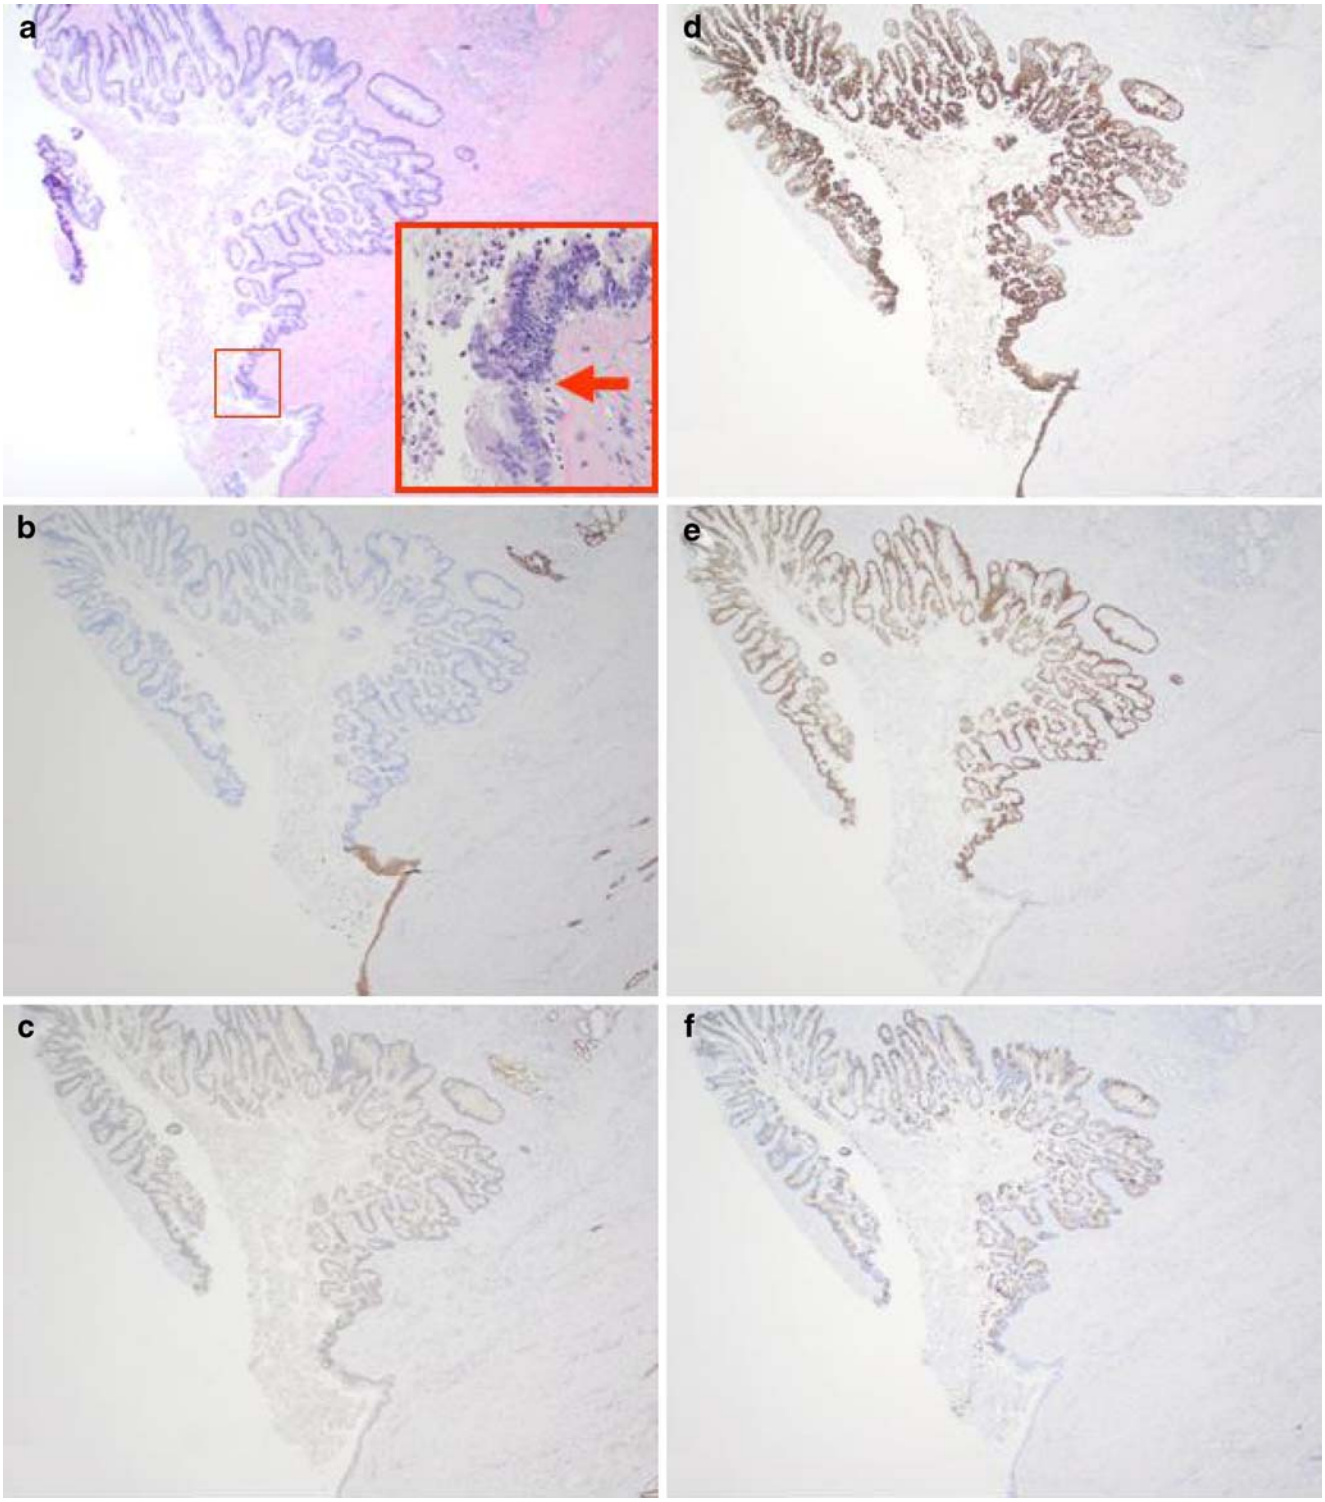

Fig. 3 A mucinous borderline tumor (**a**, ×40) is seen adjacent to benign mucinous epithelium (**a**, *insert*, ×400). The *arrow* marks the transition point between benign mucinous epithelium (*lower portion*) and the mucinous borderline tumor (*upper portion*). The benign mucinous epithelium is positive for CK7 (**b**, ×40) and CK20 (**d**, ×40) and negative for PAX-2 (**c**, ×40), CDX-2 (**e**, ×40), and MUC2 (**f**, ×40), whereas the mucinous borderline tumor is positive for CK20, CDX-2, and MUC2 and negative for CK7 and PAX-2. The small tubules and cysts lined with single layer of flattened or cuboidal epithelia (*right upper* and *right lower fields*) are positive for CK7 and PAX-2 and negative for CK20, CDX-2, and MUC2

Discussion

The patient described in the present study had characteristic clinical and histological features of MESTK, including repeated urinary tract infection, ureteral dilation, and a multicystic renal lesion with abundant stroma. Although MESTK is a rare benign renal tumor, several large case studies have described this lesion [4, 5, 7], and MESTK is recognized in the recent WHO classification of tumors of the urinary system as a distinct entity [2]. MESTK has very similar clinical, histological, and molecular features to that of ACN [6, 7, 9].

Two unusual histologic features make the present case different from previously reported MESTKs. First, unlike most described cases, the current case has unique epithelial components: columnar mucinous epithelium, intestinal mucosa, and endocervical mucosa. The columnar mucinous epithelium showed benign histology and was associated with marked chronic inflammation, suggesting a metaplastic process. Immunohistochemically, the benign mucinous epithelium was strongly positive for CK7 and CK20, which is an immunophenotype similar to that seen in ovarian mucinous tumor [16] and appendiceal low-grade mucinous carcinoma [17]. One case of MESTK associated with intestinal and endocervical mucosa was reported in the literature [9]. In both the current and reported cases, the intestinal epithelium contained Paneth and goblet cells, while the endocervical mucosa was composed of mucinous glands. Both epithelial components showed no cytological atypia.

Second, a mucinous borderline was present adjacent to the mucinous epithelium. Borderline mucinous tumors or other malignant epithelial components have not been reported in MESTK. However, seven MESKT cases with malignant stromal components have been reported. Five of these cases showed a fibrosarcoma-like component with a positive immunohistochemical staining of vimentin, smooth muscle actin, and muscle-specific actin. Two of these patients died of disease [15], and other three patients lived well at the time of description [11, 12]. One case showed stromal cells with rhabdoid features and positive immunohistochemical staining for WT1, CD99, and CD56. This patient was alive 17 months after nephrectomy [14]. One case had carcinosarcoma component with malignant epithelial component resembling endometrioid adenocarcinoma [13]. It is important to rule out a metastatic low-grade mucinous tumor from the ovary, appendix, or other gastrointestinal locations. The mucinous borderline tumor in the current case appeared to arise de novo in the MESTK because (1) there was no clinical and radiological evidence of ovarian or gastrointestinal tumor, (2) histologically, the mucinous borderline tumor merged with the adjacent mucinous columnar epithelium (Fig. 3a, insert), and (3) immunohistochemically, the mucinous tumor cells were strongly positive for CK20 and CDX-2 and negative for CK7, WT1, and ER. The latter three markers are usually expressed in ovarian mucinous tumors.

Immunohistochemical studies for MSI/MMR protein defects showed the borderline mucinous tumor to be strongly positive for MLH-1, MSH-2, MSH-6, and PMS-2. Thus, the defects in MSI/MMR proteins are unlikely to be involved in the neoplastic transformation of the mucinous borderline tumor.

The stromal component in the current case contained fibroblasts, smooth muscle cells, large-size vessels, and fat. Despite its morphological similarity to renal angiomyolipoma, the smooth muscle cells, perivascular cells, and fat were negative for HMB-45 and melan-A by immunohistochemistry, suggesting that they represented entrapped benign fatty and muscular and vascular tissue rather than a neoplastic process. Ovarian like stoma has been reported in mucinous tumors of other locations, such as the pancreas. Ovarian-like stroma is also typically identified in MESTK and CAN, owing its positivity for ER and PR. Similar to previously reported cases, the stromal cells in the current case were also positive for ER-α and PR but negative for WT1 for CD56. In contrast, true ovarian stromal cells are typically negative for ER-α and positive for WT1 and CD56 [18]. Therefore, the ER-α positive stromal cells in MESTK have a different immunophenotype from that of ovarian stroma, and therefore, they should not be regarded as true ovarian stroma.

In summary, we report what we believe to be the first case of a mucinous borderline tumor arising from a MESTK. Immunohistochemically, the borderline mucinous tumor had an identical immunophenotype to that of colorectal adenoma and carcinoma but different from that of an ovarian mucinous tumor. Caution should be taken in surgical resection of the lesion because, as with mucinous neoplasms of other organs, its rupture could potentially lead to pseudomyxoma peritonei.

Conflict of interest statement We declare that we have no conflict of interest.

LETTER TO THE EDITOR

The term *cor bovinum* in anatomical pathology

Georg Reith · Bernd Busch · Marcel A. Verhoff

Received: 31 July 2009 / Revised: 9 September 2009 / Accepted: 14 September 2009 / Published online: 13 October 2009

Keywords Cor bovinum · Historical definition · Diagnostic criteria · Minimum weight

Dear Sir:

The term *cor bovinum* or ox heart is found in pathology literature as a somewhat arbitrarily used analogy for an enlarged heart. Thus, the German benchmark textbook *Pathologie* from 1999, which was edited by Remmele, uses the term to describe hearts weighing more than 600 g but less than 1,000 g, while, interestingly, referring to weights exceeding 1,000 g as an *extreme enlargement*. We, therefore, thought that it would be interesting to shed light on the historical origin and use of this quaint term.

Our research revealed that two authors can claim credit for coining the term *cor bovinum*. Even if he did not yet use the exact term [1], William Cowper was the first to compare an extremely enlarged human heart to the heart of an ox in a case study on aorta valve stenosis. A second trail leads to Giovanni Battista Morgagni, who, in his 1761 opus, *De sedibus et causis morborum per anatomen indagatis*, says, "…the heart, however, was so large, that it was in size like that of an ox." Here, in the Latin original, the term *cor bovinum* is first used for an enlarged heart [2].

In deciding whether Cowper or Morgagni should receive credit for the term, one must take into account that the two were probably familiar with each other. Morgagni, at least, frequently referred to the English surgeon and anatomist in his text [2]. It is, therefore, quite possible that Morgagni adopted the analogy from Cowper.

In subsequent centuries, the term kept cropping up in pathology textbooks and manuals. In his 1887 *Pathology* manual, Mönkenberg explains [3] that older authors used the terms *cor bovinum* and *aneurysma totale cordis* to describe general hypertrophy and dilation of the heart. In 1852, Virchow used the expression, *ox heart*, to describe seriously dilated hearts [4]. *Cor bovinum* was used both by Cohnheim in 1877 and Brugsch in 1947. Interestingly, in a handbook published by Kaufmann in 1931, the term *cor bovinum* could still be found, but it no longer appeared in the 1955 edition. While the descriptions of *cor bovinum* are similar in these sources, neither a clear definition of the term nor a weight specification is included.

The term first appears in connection with a specific weight in Remmele's 1984 manual. The weight given here is 600 g. This weight is also quoted in Blümke's textbook *Pathologie* from 1995. A paper from 2001 even designates all hearts exceeding a weight of 500 g as being *cor bovinum* (Praxis 90: 1964–1972).

Weight specifications as diagnostic criteria, thus, appear to be of modern origin, and we conclude that the term *cor bovinum* was not historically associated with a specific weight. Although weights of over 1,300 g have been described for human hearts, in direct comparison, the hearts of Jersey cattle, which is the smallest known race, weigh at least 1,800 g [5].

Cor bovinum should, thus, primarily be understood as a descriptive rather than a diagnostic term.

Histological heterogeneity of Ewing's sarcoma/PNET: an immunohistochemical analysis of 415 genetically confirmed cases with clinical support

Antonio Llombart-Bosch · Isidro Machado · Samuel Navarro · Franco Bertoni · Patrizia Bacchini · Marco Alberghini · Apollon Karzeladze · Nikita Savelov · Semyon Petrov · Isabel Alvarado-Cabrero · Doina Mihaila · Philippe Terrier · Jose Antonio Lopez-Guerrero · Piero Picci

Abstract Ewing's sarcoma (ES)/peripheral neuroectodermal tumor (PNET) are malignant neoplasms affecting children and young adults. We performed a study to typify the histological diversity and evaluate antibodies that may offer diagnostic/prognostic support. In total, 415 cases of genetically confirmed paraffin-embedded ES/PNET were analyzed on whole sections and in tissue microarrays. This study confirms the structural heterogeneity of ES/PNET, distinguishing three major subtypes: conventional ES (280 cases); PNET (53 cases); and atypical ES/PNET (80), including large cells, vascular-like patterns, spindle pattern, and adamantinoma-like configuration. All cases presented positivity for at least three of the four tested antibodies (CD99, FLI1, HNK1, and CAV1). CAV1 appeared as a diagnostic immunomarker of ES/PNET being positive in CD99-negative cases. Hence, the immunohistochemical analysis confirmed the diagnostic value of all four antibodies, which together cover more than 99% of the tumors, independently of the histological variety. The univariate analysis for survival revealed atypical ES as the only histological parameter apparently associated with less favorable clinical outcome, particularly in the subgroup of patients treated with surgery. In conclusion, the diagnosis of atypical ES is a challenge for the pathologist and needs support from molecular techniques to perform an optimal differential diagnosis with other small round cell tumors.

Introduction

Ewing's sarcoma (ES) of the bone configures a family of highly malignant neoplasms in children and young adults; the histology is constituted by undifferentiated small round cells distributed in a homogeneous pattern

without any particular architectural definition [1–3]. Occasionally, Homer-Wright pseudorosettes can be detected, a fact that has given support for a neuroectodermal nature, thus being also named peripheral neuroectodermal tumor (PNET) [4–7]. Atypical variants of this tumor have been described [4–12] due mainly to a high degree of cell heterogeneity or to the presence of pseudovascular structures [13]. In addition, neoadjuvant chemotherapy or radiotherapy induces tumor cell changes producing major structural anaplasia [14]. Thus, the histological diagnosis of this tumor is difficult [13–15]. Moreover, a number of small round cell tumors (SRCT), mostly located outside the bone, show a histologically similar configuration making its diagnosis even more difficult. The differential diagnosis of ES/PNET, compared with other malignant SRCT, is occasionally extremely complex or almost impossible when using only histological methods [7, 13–17].

Immunohistochemistry (IHC) has been reported to provide crucial support to the identification of these neoplasms as well as to the differential diagnosis when compared to other SRCT. Among the most well-recognized antibodies regularly expressed in this tumor are MIC2 (CD99) [15, 18–20], HNK1 (Leu7, CD57) [21–24], Fli1 [15, 22, 25, 26], and more recently, caveolin-1 (CAV1) [27]. Therefore, the simultaneous use of several antibodies becomes mandatory to histologically confirm an ES/PNET. Nevertheless, the definitive value of these markers for diagnosis and prognosis remains a matter of debate.

ES/PNET are cytogenetically characterized by a specific reciprocal translocation between chromosomes 11 and 22 in over 90% of cases, as well as other less frequent chromosomal rearrangements [t(21;22), t(7;22), t(2,22); 28–32], promoting the rearrangement of the *EWS* gene with one of the members of the *ETS* family of genes, mainly with the *FLI1* gene [33–39]. In this regard, cytogenetics and molecular biology have provided new tools for diagnosis as well as for the characterization of this group of SRCT, becoming today a necessary requisite before any therapeutical approach can be clinically undertaken.

The pathologists of the Prognosis and Therapeutic Targets in the Ewing Family of Tumors Consortium (PROTHETS, a 6FP grant EC project) undertook an extensive study, collecting SRCT from several laboratories participating in the project in order to gain a better view of the histology of this neoplasm and its microscopical diversity, as well as to typify those antibodies that could offer a better diagnostic support as well as prognostic information. To this end, a large number of formalin-fixed paraffin-embedded SRCT were collected and, after an extensive review and genetic confirmation, 415 ES/PNET cases were retained for the present study.

Material and methods

Patients and samples

A total of 857 SRCT were collected and made available for study at the Department of Pathology, University of Valencia Estudi General (UVEG). In 34 cases, only slides were obtained as these cases had been submitted for second expert opinion and no paraffin blocks were available. The centers of origin of the remaining cases were as follows: 447 from Instituto Ortopedici Rizzoli (IOR), Bologna, Italy; 183 from UVEG, Valencia, Spain; 111 from Blokhin Russian Cancer Research Center, Moscow and the Clinical Oncological Center, Kazan, Russia; 54 from Orthopedic Institut of Kiev, Ukraine; 32 from Hospital General de Mexico DF, Mexico; 12 from Children's Hospital, Iasi, Romania; nine from Institute Gustave Roussy (IGR), Villejuif, France; and two from Instituto Nacional de Oncologia y Radioterapia (INOR), La Habana, Cuba. The tissues were fixed in buffered formalin and paraffin embedded at the local laboratories. Solutions of formic acid/formalin, hydrochloric acid, or ethylenediaminetetraacetic acid were used as standard decalcifier agents for each institution [40].

Approval for data acquisition and analysis was obtained from the ethics committee of all the institutions involved in the study. The clinical data were reviewed and stored within a specific database.

Out of these 823 SRCT, 166 cases were excluded from the study due to technical problems, insufficient material, poor preservation resulting from overdecalcification, or massive tissue necrosis. Another 242 cases were not considered because genetically they were either negative or not informative for *EWS* rearrangements, leaving a total of 415 ES/PNET for inclusion in the present study.

The source of the analyzed material was known for 324 cases, the distribution being as follows: 272 primary tumors (84%), 22 disseminated primary tumors (7%), nine recurrences (3%), and 21 metastases (6%). For statistical considerations, disseminated primary tumors, recurrences, and metastasis were grouped in the same category (disseminated disease).

Histology

Following previous publications [5, 13, 15, 17, 22, 41], several histological varieties of ES/PNET are considered: conventional or classical ES, large cell ES with epithelioid cells, clear cell with hypernephroid cells, ES with spindle cells, vascular-like with hemangioendothelial features, ES with neuroectodermal features (isolated pseudorosettes),

PNET showing numerous well-configured Homer-Wright rosettes, synovial sarcoma-like PNET, sclerosing PNET, adamantinoma-like ES. In addition to this morphological subtyping, other structural parameters were reviewed in order to obtain supplementary criteria for prognosis, as previously described by several authors in primary ES before treatment [42–45]. It should be noted that these criteria were verified on the complete histological slide. The following histological structures were analyzed:

Presence/absence of necrosis: negative, either no or minimal necrosis (<25%) and positive (>25%) of the whole slide.

Chessboard or filigree pattern: presence of string-like figures motivated by the infiltration of tumor cells within a stroma displaying high sclerosis and causing a dense collagen response.

Lobular pattern: distribution of thin reticular fibers, scalloping the tumor cells in nests or lobules.

Mitotic count: detection of at least five or more mitosis in ten consecutive, randomly selected high power fields at a ×40 magnification. When fewer mitotic figures were found, the count was considered as negative.

Immunohistochemistry

For practical reasons and due to the large number of cases in the study, we have limited the immunophenotyping of the ES/PNET to a panel of four antibodies (Table 1). The choice of these antibodies was decided after an analysis of the literature, taking into account their confirmed expression in this tumor type and, therefore, excluding other immunomarkers, such as epithelial or neuroectodermal, that have been tested without major diagnostic or prognostic relevance [5, 7, 10, 13, 15–17, 22, 25, 26, 45–59]. The histopathological analyses were performed on the whole tissue sections. In addition, 24 tissue microarrays (TMAs) were constructed. Each TMA included two representative cores for each case (1 mm of diameter). Sections, 4-µm-thick, were processed for IHC. Antigen retrieval was performed by pressure cooker boiling at 1.2 atm for 3 min in 10 mmol/L citrate buffer (pH 6.0). The labeled streptavidin–biotin (LSAB) method (Dako) was performed, followed by revelation with 3,3-diaminobenzidine as conventional protocols. All sections were evaluated independently by three pathologists (IM, SN, and ALLB).

In order to test for the most appropriate antibody for CD99, four different clones of commercially available monoclonal antibodies, namely, HBA71, 013, HO36-1.1, and MEM131 [19, 60–62], were evaluated in a set of 157 cases with the objective of determining their sensitivity and specificity [63]. CD99 positivity was considered as "+3" when the stain was present in all tumor cells mainly defining the membrane, while the cytoplasm was either negative or also positive. When a lower delimitation of the cell membrane with coloring of the cytoplasm occurred, these were deemed "+2" when all the cells were stained, while scanty cell membrane or cytoplasmic staining in isolated groups of cells was noted as "+1." Negative staining was considered for no or very weak staining. Antibody positivity was scored in both the complete histological slide as well as in the TMA (core diameter 1 mm, two cores of the most representative fields from each case).

Molecular biology and fluorescence in situ hybridization

RNA was extracted and tested in all tumors with reverse transcription polymerase chain reaction (RT-PCR) in order to detect any of the following translocations: *EWS/FLI1*, *EWS/ERG*, and *EWS/FEV* as previously described [30]. In addition, a fluorescent in situ hybridization (FISH) analysis was carried out with the *EWSR1* break-apart probe on the TMA. More details are described elsewhere [39].

Statistical analysis

A FileMaker database was constructed and implemented to collect the main clinical, histopathological, and genetic data of all patients included in the project.

For the statistical analysis, we used binary variables reflecting the positivity status of the measures (yes or no). Association with histopathological parameters, all categorical, was also assessed using a chi-square test to determine homogeneity or linear trend for ordinal

Table 1 Antibodies used for the immunohistochemical analysis

Antibodies	Source	Clone	System	Dilution	Pretreatment
CD99	Dako	Monoclonal mouse HBA-71	LSAB	1/50	Citrate buffer (pH 6.0) pressure cooker boiling
FLI-1	Santa Cruz	Rabbit polyclonal	LSAB	1/50	Citrate buffer (pH 6.0) pressure cooker boiling
HNK	Cell line ATCC, Valencia	–	LSAB	10 µ/ml	Citrate buffer (pH 6.0) pressure cooker boiling
CAV1	Santa Cruz	Rabbit polyclonal	LSAB	1/200	Citrate buffer (pH 6.0) pressure cooker boiling

variables. The significance level was set at 5%. To study the impact of the histological, immunohistochemical, and molecular factors on the progression-free survival (PFS) and overall survival (OS), the Kaplan–Meier proportional risk test (log rank) was used [64, 65]. PFS is considered as the proportion of patients with no evidence of local or distant recurrence during follow-up, whereas OS reflects the proportion of patients alive (with or without disease) at the time of the last clinical review. Only cancer-specific deaths were considered for the statistical analysis of the OS. Evidence of the relative risk for each patient was also provided by means of a Cox proportional hazards model using stepwise selection to identify the independent predictors of poor outcome [66]. All the statistical analyses were carried out using the SPSS (version 15.0.1, SPSS, Chicago, IL, USA).

For the prognostic evaluation, we analyzed 217 patients with localized genetically confirmed ES/PNET. Due to the retrospective nature of the series and the variety of institutions involved, it was not always possible to obtain complete clinical information for some cases, such as margins, type of surgery, or TNM stage. Hence, given the limited quality of the clinical information, the survival data herein presented should be considered with reserve. Therefore, the variables used in the prognostic evaluation included: clinical (age, sex, location of the tumor, and type of treatment), histological (histological varieties, necrosis, lobular pattern, filigree pattern, and mitosis), immunohistochemical (CD99, HNK1, Fli1, and CAV1), and molecular parameters (fusion gene type).

Results

The characteristics of the series included in the present study are listed in Table 2. For the prognostic evaluation, only patients from IOR (198 cases) and UVEG (19 cases) with localized primary tumors (nondisseminated primary tumors) were considered, making a total of 217 patients. The median age of the series was 17 years (range=1–99 years) and the male–female ratio was 1.6. Sixty percent of tumors were appendicular skeleton. Seventy-six patients (35%) were treated with surgery and chemotherapy, whereas the remaining cases were treated with radiotherapy, chemotherapy, and/or surgery. The median follow-up was 39 months (range=0.17–452 months) with an OS of 55%.

Histology

Among the 415 ES/PNET cases, the following histological varieties were found:

Conventional or classical ES (264 cases, 63%) is defined as a tumor constituted by a diffuse and monotonous proliferation of homogeneous small round blue cells (in hematoxylin and eosin [H/E] due to the dark staining of the small nuclei; Fig. 1a, b) and, in some cases, adopting a perivascular distribution with a variable amount of necrosis extending about 200–250 μ distant from the most proximal vessel. Cell pleomorphism and mitosis are scarce (about two to three per ×40 in ten consecutive fields).

PNET (53 cases, 13%) are mainly represented by the existence of typical Homer-Wright neural rosettes provided with a central core (Fig. 1b, c). In addition, fibrillar structures appear as cytoplasm projections, while the tumor is lobulated by reticular fibers (Fig. 2e). The number of rosettes varies from isolated to numerous in continuous transitions, appearing within monotonous fields of conventional ES. We considered all cases in which these structures were present as PNET, independently of the degree of differentiation and the number of rosettes seen.

Large cell ES (33 cases, 8%): this histological variant is consistent with a SRCT that possesses cell and nuclear pleomorphism with large abundant acidophilic cytoplasm. The nuclei are voluminous, round or oval, occasionally binucleated, and contain one or more prominent nucleoli (Fig. 1e). The reticular network is more prominent with a tendency to lobulation. The cells may contain a large amount of glycogen within the cytoplasm adopting a clear cell hypernephroid appearance (Fig. 2a). In addition, the cells occasionally adopt a more spindle-like configuration with fusiform nuclei, affecting more than 50% of the tumor fields (Fig. 1f). This histological particularity can appear in both conventional ES and in the large cell subtype.

ES/PNET with vascular-like, hemangioendothelial features (nine cases, 2%): the cells display a pseudoendothelial pattern conforming vascular-like spaces, lined by tumor cells that progressively elongate and cover lacunae filled with erythrocytes and plasma material (Fig. 2b). These cells, lining the surface of the vessel-like spaces, lack basal membrane and are in continuity with the more solid cellular areas that maintain a typical ES configuration.

Regarding the varieties of *synovial sarcoma-like ES*, *sclerosing ES*, and *adamantinoma-like ES* [15], none of these subtypes were considered as an independent entity in our material. The presence of sclerotic areas is quite frequent in ES/PNET and is associated with tumor extension into cortical bone or with areas of soft tissue invasion (Fig. 2c, f), as well as with secondary interstitial hyaline deposits. Also, no true *adamantinoma-like ES/PNET* were identified, but we did observe cases in which the cells focally adopt a palisading architecture being sustained by a collagen basal-like membrane that could mimic an adamantinoma ES (Fig. 2d). All these cases were

[a] Data available from 217 cases

included within the category of atypical ES. In order to homogenize these ES/PNET varieties in larger statistical groups, the 415 cases were regrouped into three larger categories according to their predominant morphological criteria: conventional–typical ES [280 cases (67%)], PNET with the presence of neuroectodermal traces [53 cases (13%)], and atypical ES comprising all varieties distinct from the two above-mentioned types [82 cases (20%)]. The main histological findings are summarized in Table 3.

Immunohistochemistry

All sections were evaluated independently and read blinded by all three pathologists (IM, SN, and ALLB) with a high concordance rate between all examiners. Full concordance existed between whole sections and TMA sections by IHC for each pair of cores.

CD99 expression

Of the 415 cases, 402 (97% of the total) were valid for CD99 immunostaining. All but four cases expressed CD99 from a low to a high intensity (99%; Table 4). The majority of cases (289) presented both a membranous and cytoplasmic staining (+3; Fig. 3a), while a diffuse dense cytoplasm coloring was seen in 81 cases (+2). Finally, in 28 cases, there was a light cytoplasmic or membranous staining (+1). There were no differences in CD99 expression with respect to the distinct histological varieties of ES/PNET.

Fli1 expression

This antibody stains the cell nuclei of the tumors but is also present in endothelial cells and in the lymphocytes of the stroma. Eighty-nine percent of cases (344 from a total of 388 informative cases) expressed Fli1 with high intensity (Fig. 3b), while 44 cases were negative (11%; Table 4). As seen with CD99, no relationships could be found between Fli1 expression and the histological subgroups of ES/PNET.

HNK1 staining

HNK1 expression was detected in 215 cases out of 404 informative cases (53%; Fig. 3c, Table 4). Interestingly, PNET (57% of cases) and especially atypical ES/PNET (64%) stained HNK1 in a higher proportion than conventional ES/PNET (49%; $p=0.045$).

Caveolin-1 expression

In our series, CAV1 was expressed in 96% of cases (368; Fig. 3d), while only 5% of tumors (17 cases) resulted negative (Table 4). No association with ES/PNET histological varieties or tumor progression was observed. However, CAV1 correlated highly with CD99 ($p<0.0001$) and, interestingly, the four CD99-negative cases expressed CAV1.

Association of the analyzed parameters with tumor progression

Taking into account the type of material analyzed, primary tumors vs. disseminated disease, we compared the difference in frequencies between these two groups for each of the different parameters analyzed in order to depict an association with tumor progression. The results are listed in Table 5. No association with progression was observed with the histological varieties of ES/PNET, although disseminated tumors were characterized by a high mitotic count. None of the immunohistochemical diagnostic markers, except Fli1, demonstrated association with tumor progression (Table 5).

Table 4 Immunohistochemical expression of the diagnostic markers

CAV1	17 (4)	368 (96)

Molecular genetic studies

The diagnosis of Ewing's sarcoma family of tumors (ESFT) in all cases was genetically confirmed by FISH *EWSR1* break apart and/or RT-PCR positive results. These results are described in more detail elsewhere [39].

Progression-free and overall survival

Tables 6 and 7 show the results of the univariate and multivariate analysis for both PFS and OS. The multivariate analysis revealed that the lobular pattern ($p=0.044$) and the type of treatment ($p=0.00037$) constituted independent prognostic factors for PFS, probably due to the presence of inoperable cases ($n=63$) in the radiotherapy group. The same trend was observed for OS where the type of treatment remained as an independent prognostic factor ($p<0.0001$).

In order to avoid the influence of treatment type on prognostic behavior, two groups of patients were considered. The surgery group composed of 76 patients who received surgery with chemotherapy and the radiotherapy group composed of 141 patients in whom radiotherapy was included in their treatment regimen (78 patients with surgery and 63 patients without surgery). Tables 8 and 9 show the most relevant associations between the analyzed parameters and follow-up for the surgery group of patients. Interestingly, the histological variety of ES/PNET constitutes the unique independent prognostic factor for both PFS and OS (Tables 8 and 9). The atypical ES/PNET being the variety with the worst behavior (Fig. 4a, b). However, this association was not observed in the radiotherapy group in which only Fli1 expression provided favorable prognostic information in the univariate analysis for OS ($p=0.036$). No independent prognostic factor emerged from the multivariate analysis.

Discussion

Several unresolved problems remain regarding the histological diagnosis of ES/PNET due to the plurophenotypic histology and the diverse response to immunohistochemical staining. These facts have led to the need for molecular support in order to confirm the presence of any of the already-described genetic rearrangements, thus making morphology subsidiary to the molecular diagnosis. A major aim of the PROTHETS EC project (http://www.prothets.org) was to confirm the validity of histology and IHC as tools for diagnosis based on the experience obtained from the review of a large number of samples and adequate selection of immunostaining.

The present study, based upon a series of 415 genetically confirmed ES/PNET cases, substantiates the structural heterogeneity of this family of tumors in which three major

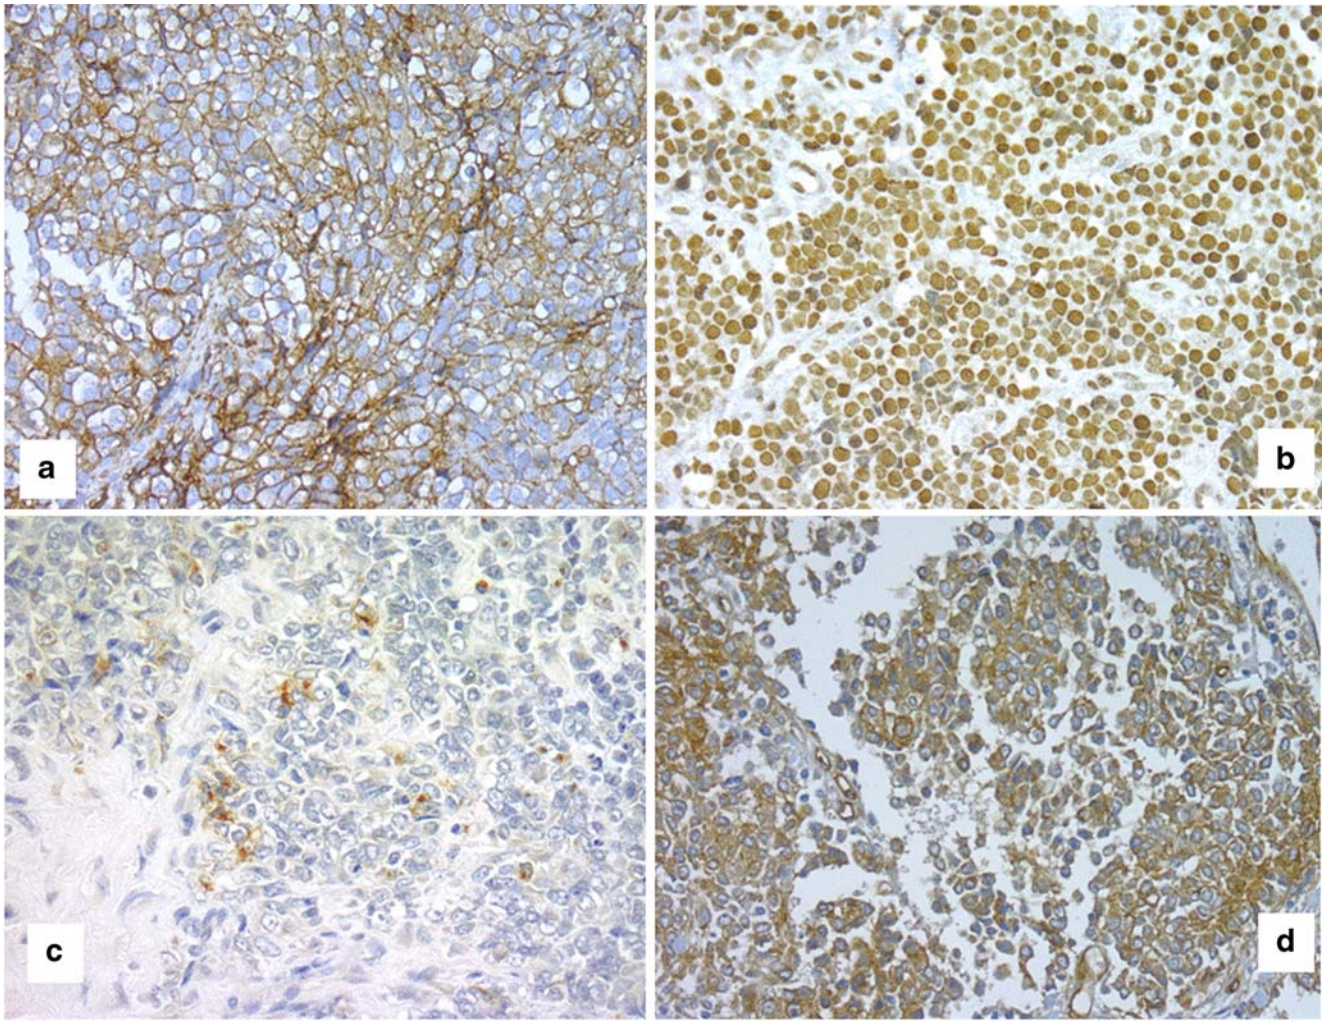

Fig. 3 **a** CD99 (HBA71) membranous staining (+++) in PNET (×40), **b** Fli1 nuclear staining (+++) in classic ES (×40), **c** HNK-1 cytoplasm staining (+) with focal dot-like pattern/Golgi staining (×40), **d** CAV1 cytoplasm and membrane staining (+++) in ES and endothelial cells as positive control (×40)

subtypes were distinguished: conventional or classical ES (67%), PNET with neuroectodermal phenotype (13%), and atypical ES/PNET (20%). The present results are similar to those described by other authors. Folpe et al. [15] observed 43 ES (73%) with typical features within a series of 66 ES cases; also in this publication, the PNET constituted 16%. In our series, a total of 82 cases were classified as atypical ES which displayed a heterogeneous histology when compared to conventional ES or PNET, comprising neoplasms composed of large cells with irregular nuclear contours (33 cases, 8%) or offering a vascular-like hemangiomatous appearance (eight cases, 2%). In addition, atypism of another 41 (10%) tumors was consistent when major structural variations that appeared within a conventional ES, including the presence of other microscopical components such as spindle cells, desmoplasia, sclerosis with a hyalinized matrix, focal adamantinoma-like, and chessboard or filigree configuration, together with a variable extent of necrosis and hemorrhages. These atypical ES have been described previously by our group and other authors [10, 13, 16, 17, 41], not only in bone, but also in soft tissues [12, 15, 67–69].

An additional point in the PROTHETS project was the search for histological patterns that could provide prognostic significance when evaluated on the H/E histological slide without any special immunostaining support. In previous publications, the extent of necrosis seen in the histological slide, together with presence of a "chessboard or filigree pattern" constituted by nests of tumor cells extending outside the bone invading soft tissue and clustered by dense hyalinized stroma, have been described as prognostic indicators of higher malignancy [16, 45, 70]. In the present study, none of these findings influence prognosis for the patients.

In a univariate analysis, the only histological pattern associated with poor clinical outcome was atypical ES

Table 5 Association of histological patterns with tumor progression

CAV1	302	244 (96)	45 (96)	0.986

compared to conventional ES or PNET subtypes, especially in the subgroup of patients treated with surgery in which the histological subtype constituted an independent prognostic factor. These findings confirm the controversial issue [45, 71–74] on the significance of neuroectodermal differentiation associated to a different clinical outcome. In addition, no difference in disease-free survival, tumor progression, or presence/absence of metastasis was detected when analyzing the remaining histological parameters.

We also analyzed the value of several immunomarkers for diagnostic and prognostic purposes. Regarding the most commonly used marker, CD99 (p30/32mic2), we were able to confirm previous findings [15, 18, 19, 22, 25, 58] that have shown how CD99 expression constitutes a very reliable maker for the diagnosis of this family of tumors. This antigen is also expressed in a number of other SRCT (rhabdomyosarcoma, synovial sarcoma, and small cell anaplastic osteosarcoma) [17, 41, 56, 58, 75] but the staining reactions are generally weak and focal. These findings limit the specificity of this antibody to some extent and may cause difficulties for the diagnosis of ES/PNET when used alone as a single immunomarker.

The most significant observation was that all but four cases expressed CD99 with a high or moderate intensity (+++/+), either membranous or cytoplasmic, or both. The four negative cases for CD99 were histologically conventional ES and were tested with the other CD99 monoclonal antibodies (HO36-1, O13, and MEM131) [63] obtaining similar negative results. However, these cases were positive for the *EWS* rearrangements by FISH and RT-PCR, thus confirming the existence of CD99-negative ES/PNET, but in such a limited number of cases as to in fact make this result an exception.

There were no statistical differences regarding intensity and distribution of CD99 expression patterns and the three major histological varieties of ES/PNET. Furthermore, no distinction was found between CD99 expression and tumor progression when analyzing the clinical situation of the patients (primary tumors, disseminated primary tumors, recurrences, and metastasis). In consequence, we confirm that CD99 expression is the most reliable immunohistochemical marker for ES/PNET, as has previously been observed in less numerous series of cases [15–17, 22, 41, 58, 76].

In many studies, Fli1 immunostaining [15, 22, 25, 26, 77, 78] as well as HNK1 (CD57) [23, 46, 53, 79–82] have been described as reliable markers for ES/PNET. Nevertheless, all authors agree that both markers lack specificity and their sensitivity is quite variable. In our material, 89% of tumors expressed Fli1 with high intensity, although as with CD99, no relationship was found between Fli1 expression and the histological subtypes. However, we report an association between Fli1 expression and a better OS in the group of patients treated with radiotherapy. In most of the human ES/PNET, Fli-1 is the target of a characteristic chromosomal-balanced translocation t (11;22) (q24:q12), which results in the production of the *EWS/FLI-1* fusion gene, and ES/PNET cases harboring the *EWS/FLI-1* transcript which seem to have a better prognosis than those containing other *EWS/ETS* transcripts have been described [83]. In our series, all studied cases carried a *EWS* rearrangement and the overexpression of Fli1 distinguished a group of patients with better outcome.

Unlike Fli1, only 53% of cases expressed HNK1. A relationship was found between HNK1 expression and the histological ES subtypes, the proportion of positive cases being higher in PNET and atypical ES. However, no relation with prognosis was seen.

CAV1 is a membrane protein that participates in the formation of caveolae [84]. The function of CAV1 is still under intensive investigation [85]. High expression of CAV1 leads to inhibition of cancer-related pathways, such as growth factor signaling pathways. However, certain

cancer cells that express CAV1 have been shown to be more aggressive and metastatic because of a potential for anchorage-independent growth [86]. Particularly in the case of ES, CAV1 has been described as a key determinant of tumorigenicity and could be considered as a potential target of new molecular therapeutic strategies. In these tumors, CAV1 is a direct target of the *EWS/FLI1* chimeric proteins, being overexpressed in a high proportion of cases [27], and has, therefore, been proposed as a potential diagnostic marker for ES/PNET [87]. The positivity of CAV1 antibody has been communicated in several carcinomas and sarcomas [27, 86, 88–98]. The experience of our group confirmed the high sensitivity of this antibody in ES/PNET when compared to other neuroectodermal and mesenchymal neoplasms such as neuroblastomas, undifferentiated synovial sarcomas, chondrosarcomas, and osteosarcomas (data not shown). In this study, CAV1 presented intense positivity in the cytoplasm of 96% of the ES/PNET, independently of the histological subtype or the clinical stage of the tumor. This is the first report to confirm the value of this antibody as a diagnostic marker. Nevertheless, as has also been indicated for CD99, this expression lacked prognostic significance.

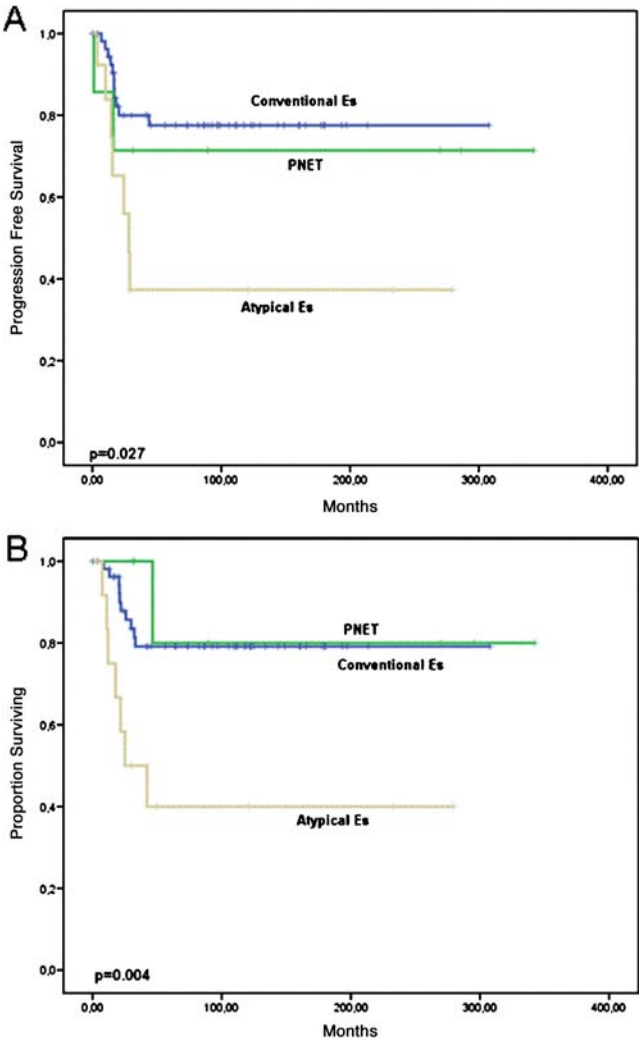

Fig. 4 Kaplan–Meier plots representing the effect of the three main histological varieties of ES/PNET on the PFS (**a**) and OS (**b**) in the group of patients treated with surgery and chemotherapy

In conclusion, the study of a large series of 415 ES/PNET, genetically confirmed by RT-PCR or FISH, corroborates the heterogeneity of the histology of the ESFT in which at least three clearly differentiated phenotypes exist: conventional ES, PNET, and atypical ES. Atypical ES, based upon the clinical data included in this study, seems to present a worse clinical outcome when compared to the two former subtypes. Moreover, the immunohistochemical analysis confirmed the diagnostic value of CD99 (HBA71), HNK1, Fli1, and CAV1, which together cover more than 99% of ES/PNET tumors, independently of the histological variety or clinical stage. All cases expressed at least three out of the four tested markers. Therefore, without questioning the additional value of molecular techniques such as FISH or RT-PCR, we confirm that adequate support can be provided for the diagnosis of ESFT based on the microscopical analysis by combining the immunostaining of these four antibodies. Particular attention has to be paid to the atypical ES in which histology might not be diagnostic and the clinical behavior more problematic. Here, the support of molecular techniques is mandatory in order to exclude an SRCT other than ES/PNET.

Aberrant expression of p27^{Kip1}-interacting cell-cycle regulatory proteins in ovarian clear cell carcinomas and their precursors with special consideration of two distinct multistage clear cell carcinogenetic pathways

Received: 16 August 2009 / Revised: 27 September 2009 / Accepted: 29 September 2009 / Published online: 24 October 2009

Abstract We have previously reported that alterations of p27^{Kip1}-interacting cell-cycle proteins frequently occur during the development of endometriosis-associated ovarian clear cell adenocarcinoma (CCA; Yamamoto et al., Histopathology in press, 20). However, CCA also occurs in association with clear cell adenofibroma (CCAF). In this study, the expressions of p27^{Kip1}-interacting proteins, i.e., p27^{Kip1}, Skp2, Cks1, cyclin A, cyclin E, and the Ki-67 labeling index (LI), were analyzed in 25 CCAFs (11 benign and 14 borderline) and 15 CCAF-associated CCAs, and compared with the expression status of each protein in the 23 previously studied endometriosis-associated CCAs. Although aberrant expression of all p27^{Kip1}-interacting proteins was more frequent in the CCAF-associated CCAs than in the benign CCAFs, statistical significance was found only for Cks1 overexpression. The frequencies of p27^{Kip1} downregulation and overexpression of Skp2 and cyclin A were significantly lower in CCAF-associated than in endometriosis-associated CCAs ($P<0.05$, respectively). The frequencies of p27^{Kip1} downregulation and Skp2 over expression in borderline CCAFs were significantly lower than those in atypical endometriosis components in endometriosis-associated CCAs ($P<0.05$, respectively). Mean Ki-67 LI increased significantly through benign (4.9%) to borderline (11.1%) CCAF and to CCAF-associated CCA (30.6%), but the latter two values were significantly lower than those in atypical endometriosis (21.4%) and endometriosis-associated CCA (46.9%; $P<0.05$, respectively). These data suggest that accumulated alterations of p27^{Kip1}-interacting proteins may accelerate the development of CCAs regardless of their carcinogenetic pathways, but that tumor cells in the CCAF-associated pathway appear to show slower cell-cycle progression than those in the endometriosis-associated pathway, possibly accounting for the distinct clinicopathological features of the two CCA subtypes.

Introduction

Clear cell adenocarcinoma (CCA) accounts for 5–10% of all epithelial ovarian cancers in Western countries,

whereas for unknown reasons, it accounts for more than 20% in Japan [1–6]. CCA has a characteristic histology and is highly chemoresistant, resulting in an extremely poor prognosis when surgical cytoreduction is insufficient [1–4]. Although several chemotherapeutic regimens against CCA have been developed, including platinum analogues, taxanes, etoposide, and camptothecin, mortality has remained largely unchanged [7, 8]. Therefore, a better understanding of the pathways driving neoplastic transformation and tumor growth in CCA is needed to provide an insight into the disease and facilitate early identification and development of novel targeted therapeutic strategies.

Despite a lack of data on cause–effect relationships, evidence has emerged for a close association between endometriosis and ovarian CCA, and many investigators have suggested that ovarian endometriosis can give rise to CCA [9–15]. Additionally, atypical endometriosis, in which the endometrioid epithelium shows cytological and/or structural atypia, has been recognized as a precancerous lesion for some CCAs [11–13, 15]. Therefore, a transformative pathway from endometriosis to CCA may exist, and the molecular basis of this putative pathway has been described, i.e., genetic instability or DNA aneuploidy in endometriotic lesions and loss of heterozygosity or mutation of the tumor suppressor gene *PTEN* in both endometriosis and co-existing CCA [16–19].

Dysregulation of the normal cell-cycle machinery is integral to the process of neoplasia, and there is compelling evidence for loss of cell-cycle control in the development and progression of most human malignancies. Recently, we have reported that cumulative aberrations of $p27^{Kip1}$-related cell-cycle regulators are highly associated with the development of ovarian CCA presumably arising in endometriosis [20]. Our data suggested that downregulation of $p27^{Kip1}$ and overexpression of cyclin E and Cks1 may be associated with the early steps of endometriosis-associated clear cell carcinogenesis [20]. Moreover, overexpression of Skp2 and cyclin A may be late events and play a significantly important role in the atypical changes or malignant transformation of endometriosis [20].

Besides endometriosis, clear cell adenofibroma (CCAF), a major form of benign or borderline ovarian clear cell tumor, may also be able to give rise to CCA [1, 4, 21–25]. The CCAF components co-existing with CCA often contain both apparently benign clear cell adenofibroma (benign CCAF) and CCAF with cellular and structural atypia (borderline CCAF) [21–23]. Borderline CCAF is rare, accounting for 5–8% of all ovarian clear cell neoplasms, and benign CCAF is even rarer [21, 22]. However, another study at our institution demonstrated that CCAF components co-existed in 21% of surgically resected CCAs [23].

Moreover, in comparison with CCAs lacking CCAF components, CCAs with CCAF components show several distinct clinicopathologic characteristics, i.e., a lower frequency of co-existing endometriosis, a higher frequency of histologically low-grade tumor with tubulocystic proliferative architecture, and a correlation with better prognosis [23]. These data suggest that two possible distinct carcinogenic pathways contribute to the clinicopathological features of CCA. Up to now, however, little is known about molecular backgrounds to explain the differences between the two putative pathways of clear cell carcinogenesis.

In the present study, we histologically reviewed a number of surgically resected cases of ovarian CCA and selected cases with CCAF components. Using immunohistochemistry, we examined the altered expression of $p27^{Kip1}$ and $p27^{Kip1}$-interacting cell-cycle regulators, i.e., Skp2, Cks1, cyclin A, and cyclin E, and cell proliferation activity assessed in terms of the Ki-67 labeling index (LI) in the benign and borderline CCAF components and co-existing CCA components and compared them. Moreover, the results were also compared with those for the pathway of endometriosis-associated ovarian clear cell carcinogenesis reported previously [20]. It was anticipated that this information would provide not only a better understanding of the development of ovarian CCA but also suggest potentially promising treatment options for these carcinomas with distinct carcinogenetic pathways.

Materials and methods

Cases analyzed and histological features of CCAF

The research protocol was approved by the ethics committee of the National Defense Medical College, Tokorozawa, Japan. Seventy-nine cases of primary ovarian CCA were identified from the files of the Department of Laboratory Medicine, National Defense Medical College Hospital, Japan. These 79 cases of CCA had been surgically resected between 1988 and 2007, and the patients had not undergone chemotherapy or radiation therapy before surgery. All specimens were formalin-fixed and paraffin-embedded, and 4-μm-thick sections were prepared for hematoxylin and eosin staining. All pathology specimens were reviewed at our institution, and the tumors were classified according to the criteria of the World Health Organization [4].

The histological criteria for benign CCAF and borderline CCAF have been described previously [21–25]. In short, benign CCAF was a surface epithelial-stromal tumor containing tubulocystic epithelial components embedded in a fibromatous stroma (Fig. 1a). The epithelial cells were polygonal, flat, or hobnail in shape with clear, slightly granular, or eosinophilic cytoplasm, and nuclear atypia and

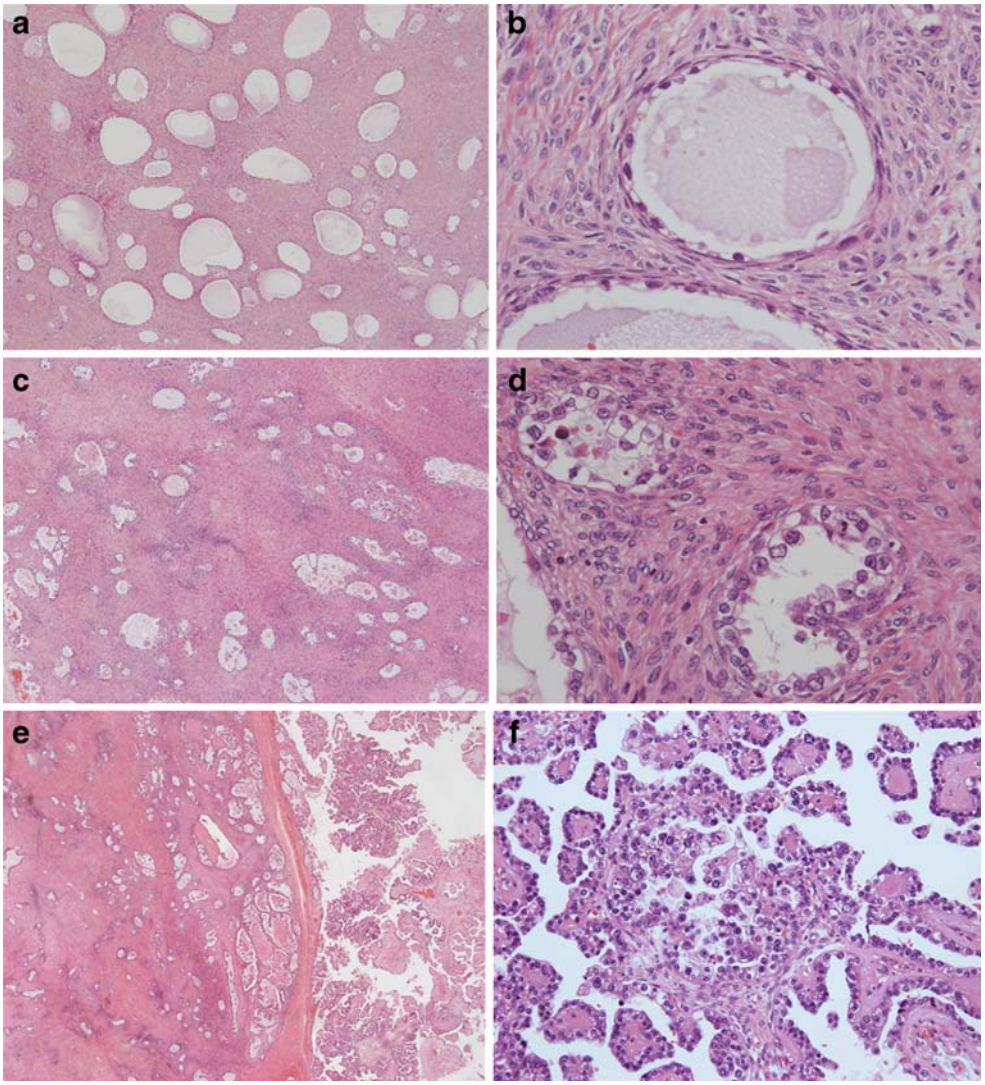

Fig. 1 Histological features of ovarian clear cell adenofibroma (CCAF) co-existing with clear cell adenocarcinoma. Benign CCAF: (**a**) a CCAF component shows simple cystic glands separated by wide fascicles of fibromatous stromal cells; (**b**) glands are delineated by monolayers of cuboidal or flattened glandular cells with clear cytoplasm and uniform nuclei. Borderline CCAF: (**c**) glands of various sizes and shapes are focally crowded; (**d**) glands are delineated by one to three layers of cells with clear cytoplasm and mildly pleomorphic and hyperchromatic nuclei. **e** Histological continuum between borderline CCAF (*left field*) and clear cell adenocarcinoma (*middle to right field*). **f** High-power view of clear cell adenocarcinoma component in **e**. HE stain, original magnification, ×20 for **e**; ×100 for **a** and **c**; ×200 for **f**; ×400 for **b** and **d**

epithelial stratification was minimal (Fig. 1b). In borderline CCAF, cellular (i.e., nuclear pleomorphism and stratification of the epithelium) and structural (i.e., size irregularity and crowding of the tubulocystic architecture) atypia were evident (Fig. 1c, d).

Consequently, 15 (19%) of the 79 CCA cases were found to have CCAF components. Of these 15 cases, ten (67%) had both benign CCAF and borderline CCAF components, four (27%) had borderline CCAF component only, and one (7%) had a benign CCAF component only. Therefore, 11 benign CCAF components, 14 borderline CCAF components, and 15 CCAs containing adjacent CCAF components were analyzed by immunohistochemistry.

Among the 15 cases enrolled, endometriotic lesions were found in three (20%): endometriosis in the uterine adnexa contralateral to the tumor in two cases and endometriosis in the adnexa ipsilateral to the tumor in one case. However, these endometriotic lesions were not regarded as synchronous with co-existing CCA because they were present at only a small focus located distantly from the main tumor. For this reason, they were not analyzed by immunohistochemistry.

Immunohistochemistry

All selected formalin-fixed, paraffin-embedded specimens were cut into 4-μm-thick serial sections and analyzed by immunohistochemistry. The primary antibodies used were those against $p27^{Kip1}$ (sc-528, rabbit polyclonal, dilution 1:100, Santa Cruz Biotechnology, Santa Cruz, CA, USA), Skp2 (2C8D9, mouse monoclonal, dilution 1:100, Zymed, San Francisco, CA, USA), Cks1 (4G12G7, mouse monoclonal, dilution 1:250, Zymed), cyclin A (sc-56299, mouse monoclonal, dilution 1:100, Santa Cruz Biotechnology), cyclin E (sc-481, rabbit polyclonal, dilution 1:100, Santa Cruz Biotechnology), and Ki-67 (MIB1, mouse monoclonal, dilution 1:100, DAKO, Glostrup, Demark), and the

immunohistochemistry protocols were the same as those described previously [20]. Non-neoplastic lymphoid tissue (tonsil) was used as a positive control for all the antibodies used. Sections without the primary antibody were used as negative controls.

Evaluation of immunohistochemical staining

Immunohistochemical staining was evaluated only in areas with well-preserved tissue morphology and located distant from necrosis or artifacts. Nuclear immunostaining for $p27^{Kip1}$, Skp2, Cks1, cyclin A, cyclin E, and Ki-67 was calculated as the percentage of positive epithelial cells among a total of 500 epithelial cells encountered in at least five to ten representative high-power fields. Although cells showed a range of staining intensities, moderately to strongly stained nuclei were considered to be positive. The results of immunohistochemistry were evaluated independently by two observers (S.Y. and K.M.), and any discrepancies between them were resolved by consensus using a multi-headed microscope. However, in all the cases examined, inter-observer discrepancy did not affect the expression status when the cut-off used for aberrant expression positivity described below was employed.

Except for Ki-67, the criteria used for assignment for aberrant expression of each protein was based on published criteria: $p27^{Kip1}$ was considered to be downregulated if <50% of nuclei were stained [26–28], Skp2 was considered to be overexpressed if >10% of nuclei were stained [28, 29], Cks1 was considered to be overexpressed if >40% of nuclei were stained [29], and cyclin A and cyclin E were considered to be overexpressed if >10% of nuclei were stained [28]. For Ki-67, the percentage of cells stained was taken as the LI.

Statistical analyses

Statistical analyses were performed using the StatMate III software package (ATMS, Tokyo, Japan). The frequency of overexpression or downregulation of each examined protein in the various components was compared using Fisher's exact test or chi-squared test. For a comparison of Ki-67 LI among the various histological components, the Kruskal–Wallis test was used, followed by the multiple comparison test. Differences at $P<0.05$ were considered to be statistically significant.

Results

Table 1 summarizes the results for all of the proteins examined.

Downregulation of $p27^{Kip1}$

Downregulation of $p27^{Kip1}$, as defined by <50% of the cells showing positive staining, was seen in the only one (9%) of 11 benign CCAFs (Fig. 2a, b), one (7%) of 14 borderline CCAFs, and two (13%) of 15 CCAs (Fig. 2c). No statistically significant differences in the frequency of

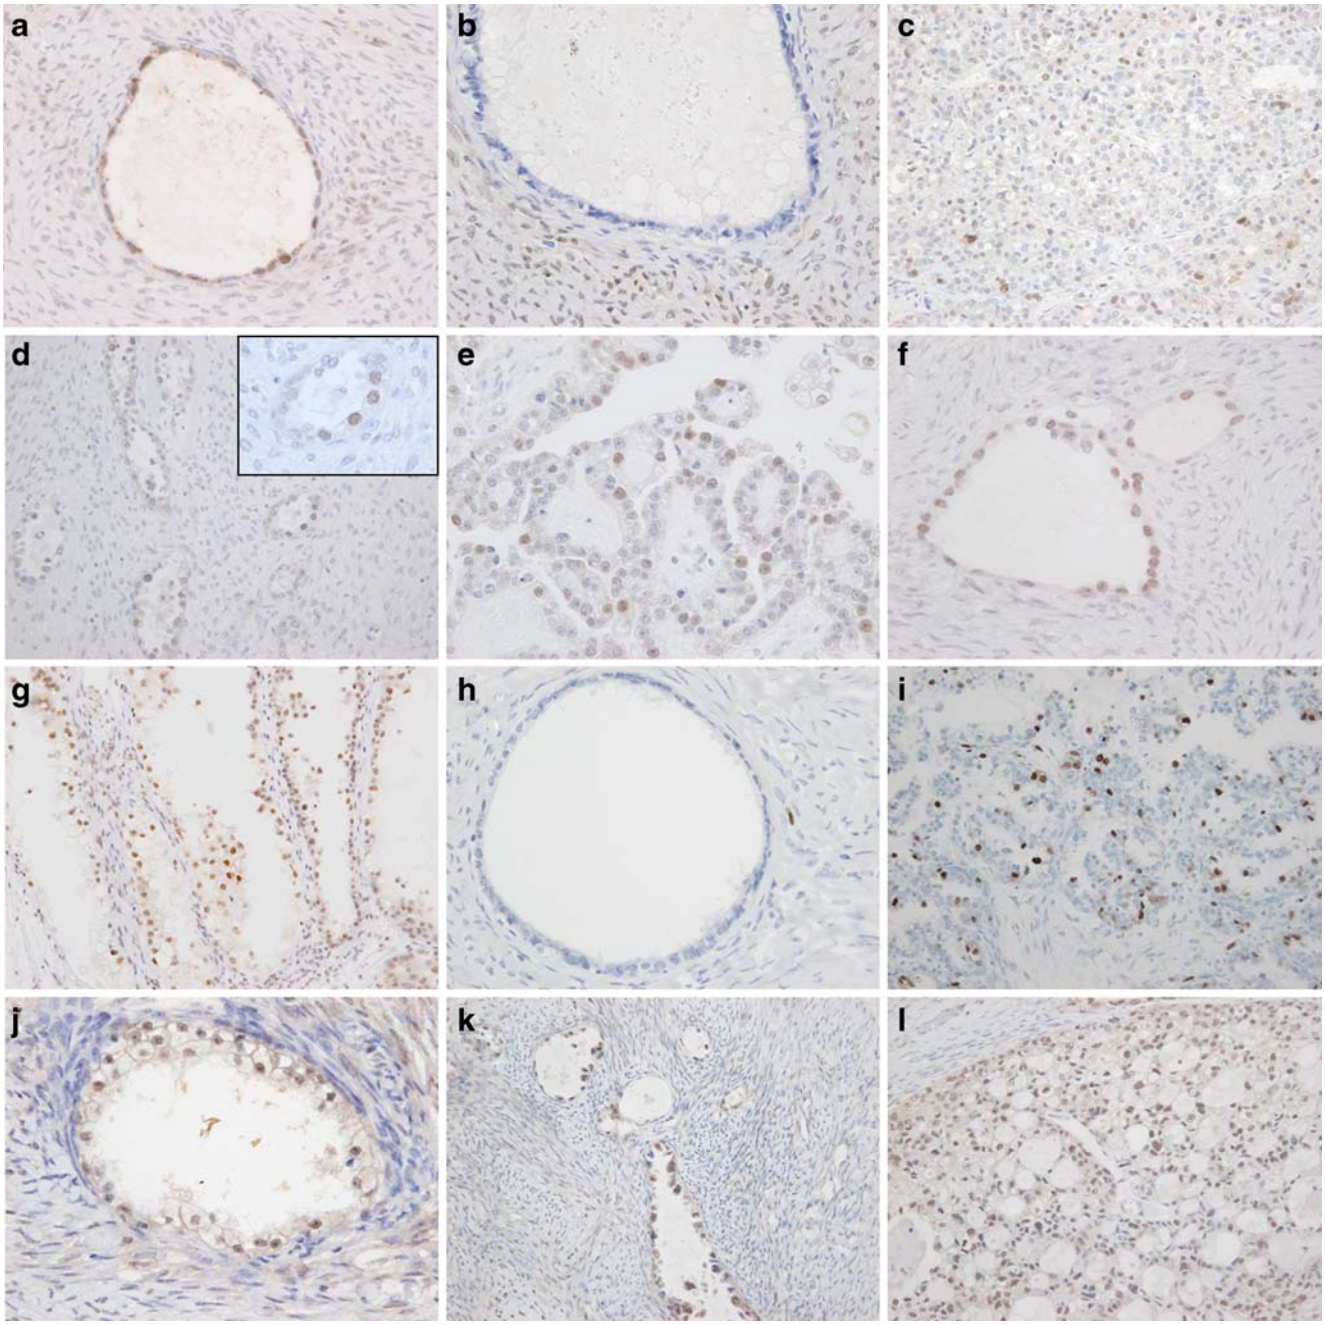

Fig. 2 Expression of $p27^{Kip1}$-interacting cell-cycle regulators in ovarian clear cell adenofibroma (CCAF) and co-existing clear cell adenocarcinoma. Immunohistochemistry for $p27^{Kip1}$ (**a**–**c**), Skp2 (**d**, **e**), Cks1 (**f**, **g**), cyclin A (**h**, **i**), and cyclin E (**j**–**l**) in the benign CCAF (**a**, **b**, **f**, **h**, **j**), the borderline CCAF (**d**, **k**), and clear cell adenocarcinoma (**c**, **e**, **g**, **i**, **l**). $p27^{Kip1}$ was positive in most of the benign CCAF (**a**). **b** and **c** show the $p27^{Kip1}$-downregulated benign CCAF (**b**) and clear cell adenocarcinoma (**c**) components in a CCAF-associated carcinoma. Note the stromal cells in **b** showing weak to moderate diffuse immunoreactivity for $p27^{Kip1}$. The borderline CCAF (**d**) and clear cell adenocarcinoma (**e**) components with Skp2 overexpression, showing immunoreactivity in more than 10% of the tumor cells. Benign CCAF (**f**) and clear cell adenocarcinoma (**g**) components with Cks1 overexpression, showing immunoreactivity in more than 40% of the tumor cells. Cyclin A is negative in the epithelial components of the benign CCAF but shows scattered positivity in a stromal cell (**h**). A clear cell adenocarcinoma showing immunoreactivity for cyclin A in more than 10% of the tumor cells (**i**). Benign CCAF (**j**), borderline CCAF (**k**), and clear cell adenocarcinoma (**l**) components with cyclin E overexpression, showing immunoreactivity in more than 10% of the tumor cells. Immunoperoxidase stain, original magnification ×200 for **c**, **d**, **g**, **i**, **k**, and **l**; ×400 for **a**, **b**, **d** inset, **e**, **f**, **h**, and **j**

$p27^{Kip1}$ downregulation were evident among the histological components. In one case that showed $p27^{Kip1}$ downregulation in the benign CCAF component, the co-existing borderline CCAF and CCA components also showed $p27^{Kip1}$ downregulation.

Overexpression of Skp2

Overexpression of Skp2 was not observed in the benign CCAF components. Only one (7%) of 14 borderline CCAF components and three (20%) of 15 CCAs demonstrated Skp2 overexpression (Fig. 2d, e). In this case, where borderline CCAF demonstrated Skp2 overexpression, the co-existing CCA component also retained Skp2 overexpression. No statistically significant differences in the frequency of Skp2 overexpression were evident among the histological components.

Overexpression of Cks1

Overexpression of Cks1, as defined by positivity in >40% of the cells, was seen in four (36%) of 11 benign CCAF components (Fig. 2f), nine (60%) of 15 borderline CCAF components, and 12 (80%) of 15 CCAs (Fig. 2g). There were statistically significant differences in the frequency of Cks1 overexpression between the benign CCAF and CCA components (P=0.032). In all cases that showed Cks1 overexpression in the benign CCAF component, the co-existing borderline CCAF or CCA components retained their Cks1 overexpression.

Overexpression of cyclin A

No overexpression of cyclin A was observed in benign or borderline CCAF components (Fig. 2h). As only one (7%) of 15 CCAF-associated CCAs demonstrated overexpression of cyclin A (Fig. 2i), the differences in frequency of overexpression did not reach a significant level. The case in which the CCA component showed cyclin A overexpression was different from that in which the CCA component showed Skp2 overexpression.

Overexpression of cyclin E

Overexpression of cyclin E was seen in six (55%) of 11 benign CCAFs (Fig. 2j), 11 (79%) of 14 borderline CCAFs (Fig. 2k), and 13 (87%) of 15 CCAs (Fig. 2l). Although the frequency of cyclin E overexpression in the CCA components tended to be higher than that in the benign CCAF components, the difference was only marginally significant (P=0.085). In all cases that showed cyclin E overexpression in the benign or borderline CCAF component, the co-existing CCA retained cyclin E overexpression.

Proliferative activity assessed by Ki-67 labeling index (LI)

The Ki-67 LIs (mean ± standard error (SE)) were 4.9±1.06 in the benign CCAF components, 11.1±1.21 in the borderline CCAF components, and 30.6±3.03 in the CCA components. Significant differences in the Ki-67 LIs were observed between borderline CCAF and CCA components (p<0.01; multiple comparison test followed by Kruskal–Wallis test).

We then looked for any correlation of Ki-67 LI with the expression of $p27^{Kip1}$-interacting cell-cycle regulators and also correlations of aberrant expression among the $p27^{Kip1}$-interacting cell-cycle regulators examined in benign CCAF, borderline CCAF, and CCAF-associated CCA components. However, no significant correlation was disclosed for any of the marker combinations.

Comparison of aberrant expression of $p27^{Kip1}$-interacting proteins and Ki-67 LI between the CCAF-associated and endometriosis-associated clear cell carcinogenetic pathways

Figure 3 graphically illustrates the cumulative aberrant expression of $p27^{Kip1}$-related cell-cycle regulators in the CCAF-associated ovarian clear cell carcinogenetic pathway, compared with the corresponding expressions in the endometriosis-associated clear cell carcinogenetic pathway described previously [20].

The frequency of $p27^{Kip1}$ downregulation in CCAF-associated carcinomas was significantly lower than that in endometriosis-associated carcinomas (13% vs 48%, P=0.030). Moreover, the frequency of $p27^{Kip1}$ downregulation in borderline CCAFs was significantly lower than that in the atypical endometrioses in endometriosis-associated carcinomas (7% vs 40%, P=0.049).

The frequency of Skp2 overexpression in the CCA components of CCAF-associated carcinomas was significantly lower than that in endometriosis-associated carcinomas (20% vs 91%, P<0.0001). Moreover, the frequency of Skp2 overexpression in the borderline CCAF components of CCAF-associated carcinomas was significantly lower than that in atypical endometriosis components of endometriosis-associated carcinomas (7% vs 48%, P=0.022).

The frequencies of Cks1 overexpression in the benign CCAF, borderline CCAF, and CCAF-associated carcinoma components were higher than those in non-atypical endometriosis (36% vs 19%), atypical endometriosis (64% vs 33%), and endometriosis-associated carcinomas (80% vs 65%), respectively, but the differences for each combination did not reach statistical significance.

The frequency of cyclin A overexpression in the CCAF-associated carcinomas was significantly lower than that in endometriosis-associated carcinomas (7% vs 87%, P<

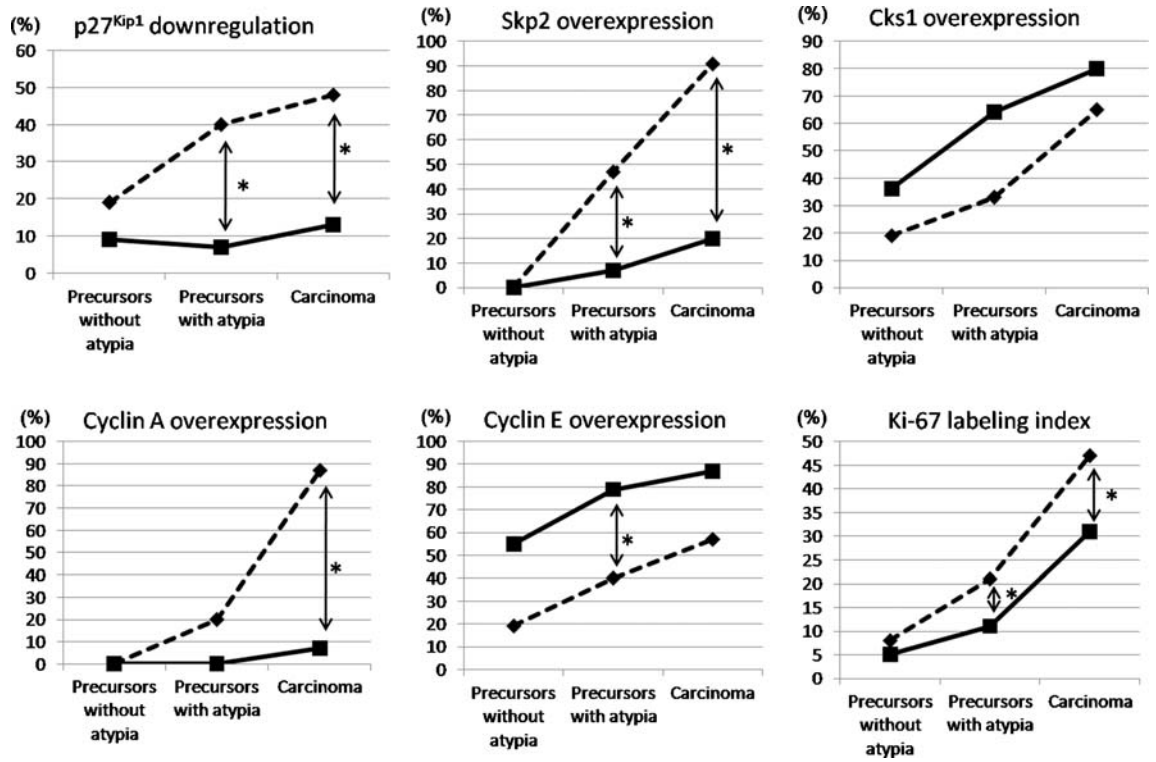

Fig. 3 Accumulated aberration of $p27^{Kip1}$-interacting cell-cycle regulatory proteins and the Ki-67 labeling index during the development of ovarian clear cell adenocarcinoma. Data are presented as the percentage of lesions positive for aberrant protein expression (downregulation of $p27^{Kip1}$, overexpression of Skp2, Cks1, cyclin A, and cyclin E) or as the Ki-67 labeling index. Precursors without atypia indicate the components of benign CCAF or non-atypical endometriosis. Precursors with atypia indicate the components of borderline CCAF or atypical endometriosis. The *solid lines* represent the data for the CCAF-associated pathway obtained in the present study; the *broken lines* represent the data for the endometriosis-associated pathway obtained from the previous study [20]. *Left–right arrow with asterisk* indicates statistically significant differences in the proportions of lesions demonstrating the stated aberration of the protein expression examined

0.0001). Cyclin A overexpression in borderline CCAF components of CCAF-associated carcinoma was less frequent than in atypical endometriosis components of endometriosis-associated carcinomas (0% vs 20%), but not to a statistically significant degree.

The frequencies of cyclin E overexpression in the benign CCAF, borderline CCAF, and CCAF-associated carcinoma components were significantly higher than those in the non-atypical endometriosis (55% vs 19%), atypical endometriosis (79% vs 40%), and endometriosis-associated carcinoma components (87% vs 57%), respectively. With regard to cyclin E overexpression, there was a statistically significant difference between the borderline CCAF and atypical endometriosis components (P=0.041), and marginally significant differences were found between the benign CCAF and non-atypical endometriosis components (P=0.050) and between CCAF-associated carcinomas and endometriosis-associated carcinomas (P=0.052).

The mean Ki-67 LI of CCAF-associated carcinomas was significantly lower than that of endometriosis-associated carcinomas (30.6 vs 46.9, P<0.01, by multiple comparison test followed by Kruskal–Wallis test). Moreover, the mean Ki-67 LI of borderline CCAF in CCAF-associated carcinomas was significantly lower than that of atypical endometriosis in endometriosis-associated carcinomas (11.1 vs 21.4, P<0.05, by multiple comparison test followed by Kruskal–Wallis test). The mean Ki-67 LI in benign CCAF of CCAF-associated carcinomas was lower than that in non-atypical endometriosis in endometriosis-associated carcinomas (4.9 vs 8.4), but the difference was not statistically significant.

Discussion

Our previous studies have demonstrated that a proportion of ovarian CCA can be derived from CCAF, and that CCA with CCAF components may constitute a distinct clinicopathological entity in ovarian CCAs [23–25]. One of our studies suggested that in comparison with CCAs lacking CCAF components, CCAs with CCAF components show several distinct clinicopathological features, e.g., infrequent coexistence of endometriosis, histologically lower tumor grade with tubulocystic architecture, and a better prognosis [23]. However, none of the findings were able to account

for the distinct clinicopathological characteristics of the CCAF-associated carcinomas.

In the present study, the frequencies of aberrant expression of all $p27^{Kip1}$-inetracting cell-cycle regulators examined in CCAF-associated CCAs were higher than those in the benign CCAF components, suggesting that accumulated aberration of these cell-cycle regulators is at least associated with the development of CCAF-associated CCA of the ovary. Moreover, overexpression of Cks1 and cyclin E was frequently observed in histologically benign CCAF lesions, and the frequency of this overexpression was increased in borderline CCAF and coexisting CCA components, suggesting that it might play a role in the malignant transformation of CCAF.

However, in contrast to the endometriosis-associated CCAs reported previously, Skp2, cyclin A, and $p27^{Kip1}$ were not altered so frequently in CCAF-associated carcinomas, suggesting that the magnitude of alterations of these proteins in the CCAF-associated pathway may not be so high in comparison with the endometriosis-associated carcinogenetic pathway [20].

Additionally, cell proliferative activity determined by Ki67 LI was significantly lower in CCAF-associated carcinomas than in endometriosis-associated carcinomas. Furthermore, Ki-67 LI was significantly lower in the borderline CCAF components of CCAF-associated carcinomas than in the atypical endometriosis components of endometriosis-associated carcinomas.

Skp2, an F-box protein necessary for DNA replication, was originally identified as a protein that interacts with the cyclin A–CDK2 complex [30]. It has been reported that increased Skp2 overexpression is associated with cyclin A overexpression and also with reduced $p27^{Kip}$ expression [31–33]. Skp2 protein is reportedly a negative prognostic factor in ovarian carcinomas [34, 35]. In our previous study, aberrant expression of $p27^{Kip1}$, cyclin A, and Skp2 was positively correlated with cell proliferative activity, as represented by Ki67 LI, in atypical endometriosis and invasive carcinoma components [20]. Moreover, Skp2 overexpression was highly correlated with $p27^{Kip1}$ downregulation in atypical endometriosis, suggesting that increased Skp2 overexpression may have a causative role in decreasing the expression of $p27^{Kip1}$ and the resulting overexpression of cyclin A, during endometriosis-associated ovarian clear cell carcinogenesis [20].

When taken together, the results of the previous and present studies may be able to explain the relatively better clinical outcome of CCAF-associated CCAs in terms of the relatively lower frequencies of overexpression of Skp2 and cyclin A and downregulation of $p27^{Kip1}$. Less frequent alterations of these cell-cycle regulators might account for the lower proliferative activity of cancer cells in comparison with endometriosis-associated carcinomas. Although follow-up data (i.e., patients' survival) on the cases presented were of interest, sample size was relatively small, and sufficient long-term follow-up data were not available for some of the cases, therefore, not mentioned in this study.

Itamochi et al. [36] suggested that the chemoresistant nature of ovarian CCA, which is the primary reason for its lethality, may result from the low proliferative activity of the tumor cells. In their study, CCAs with a high Ki-67 LI showed relatively better chemosensitivity and better prognosis when compared with CCAs showing a low Ki-67 LI [36]. However, the cases studied by Itamochi et al. [36] were limited to those at advanced stages (FIGO stages III or IV) with measurably residual tumors, and they did not subclass CCA from the viewpoint of co-existing precursor lesions. In contrast, our previous study demonstrating a better prognosis of CCAF-associated carcinomas included a larger number of early stage tumors (FIGO stage I or II; 72% of the cases) and cases that had been treated by optimal cytoreduction (79% of the cases) [23]. Therefore, the present data suggesting that low cell proliferative activity itself may account for the better prognosis of patients with CCA, especially those who have undergone optimal cytoreduction, may not necessarily be discordant with those of Itamochi et al. [36].

The study by Shimizu et al. [37] demonstrated that in comparison with other histologic subtypes (i.e., serous adenocarcinoma, mucinous adenocarcinoma, or endometrioid adenocarcinoma), ovarian CCA showed significantly high expression of $p21^{WAF1/CIP1}$ and cyclin E. However, in their study, cyclin E overexpression was not associated with tumor cell proliferative activity, as assessed by Ki-67 LI, a finding consistent with our present study. From the comparison study for aberrant expression of cyclin E between the CCAF-associated and endometriosis-associated clear cell carcinogenetic pathways, it could be speculated that cyclin E overexpression would have influence on CCAF-associated carcinogenesis equal to or greater than on endometriosis-associated carcinogenesis at the precursor stage, with and without atypia. The cyclin E-CDK2 complex is primarily regulated by the CDK inhibitors $p27^{Kip1}$ and $p21^{WAF1/CIP1}$ [38, 39]. Because, in this study, $p27^{Kip1}$ was not frequently downregulated in CCAF-associated carcinoma, alteration of $p21^{WAF1/CIP1}$ protein appears to be of interest, although downregulation of $p21^{WAF1/CIP1}$ is reportedly less frequent in CCAs than in non-clear cell carcinomas [37, 40].

In summary, we have demonstrated that cumulative alterations of cell-cycle regulators, especially $p27^{Kip1}$-interacting proteins, are associated with ovarian clear cell carcinogenesis but that the frequencies of some of these alterations, and the Ki67 LI, are significantly lower in CCAF-associated CCAs and their precursors than in

endometriosis-associated CCAs and their precursors. These results suggest that the former show slower cell-cycle progression and lower cell proliferative activity than the latter. Differences in the expression levels of these cell-cycle regulators appear to account for differences in the rates of tumor progression and metastatic potential, and consequently prognosis, between CCAF-associated and endometriosis-associated CCA of the ovary.

Acknowledgments This work was supported in part by a grant-in-aid for promotion of defense medicine from the Ministry of Defense, Japan (S.Y., H.T., and O.M.), and by a grant-in-aid for cancer research from the Ministry of Health, Labour, and Welfare, Japan (H.T.). The authors are thankful to Ms. Kozue Suzuki for technical assistance with immunohistochemistry.

Conflict of interest statement The authors declare no actual or potential conflicts of interest in this study.

Abstract While squamous cell carcinoma (SCC) is the most common tracheal malignancy, few reports describe the pathologic considerations that may guide intraoperative decisions and prognostic assessment. We reviewed 59 tracheal SCC treated between 1985 and 2008 by segmental resection of the trachea, including resection of the carina in 24% and inferior larynx in 14%. We classified these tumors by grading histologic differentiation and microscopic features used in SCC of other sites. Of 59 tumors, 24% (14 of 59) were well differentiated, 49% (29 of 59) were moderately differentiated, and 27% (16 of 59) were poorly differentiated. Unfavorable prognostic factors were tumor extension into the thyroid gland (all of five so-afflicted patients died of tumor progression within 3 years) and lymphatic invasion (mean survival 4.6 versus 7.6 years). Keratinization, dyskeratosis, acantholysis, necrosis, and tumor thickness did not predict prognosis. As surgical resection is the only curative treatment; the surgeon should establish clean lines of resection using, as appropriate, intraoperative frozen section. The pathologist can provide additional important prognostic information, including tumor differentiation and extent, invasion of surgical margins, and extension into the thyroid.

Introduction

Although squamous cell carcinoma (SCC) accounts for more than half of all tracheal tumors [1], the pathologic features in resection specimens and the impact of these features on survival have only been described in small series [2]. At least two staging systems have been proposed for tracheal malignancies; one, a cross-sectional analysis of a national cancer database by Bhattacharyya, is based on retrospective tumor–node–metastases (TNM) documentation correlated with survival statistics in 41 squamous cell carcinomas, 19 adenoid cystic carcinomas, and 32 tumors of other histology [3], although a TNM staging system validated by clinical and pathologic evidence for this disease does not exist. The other, by Macchiarini, is a nonvalidated TNM classification [4]. Both classifications are intended to be applied to all histologic types of tracheal cancer.

We describe specific pathologic features of primary tracheal SCC in a large series of surgical specimens from a single institution to identify prognostic predictors of survival.

Materials and methods

A retrospective analysis was conducted of consecutive patients who underwent resection for primary SCC of the trachea from 1985 to 2008 at Massachusetts General Hospital (MGH) and for whom pathology slides or blocks were available. All except four patients were included in a previous report describing the surgical results [5]. We

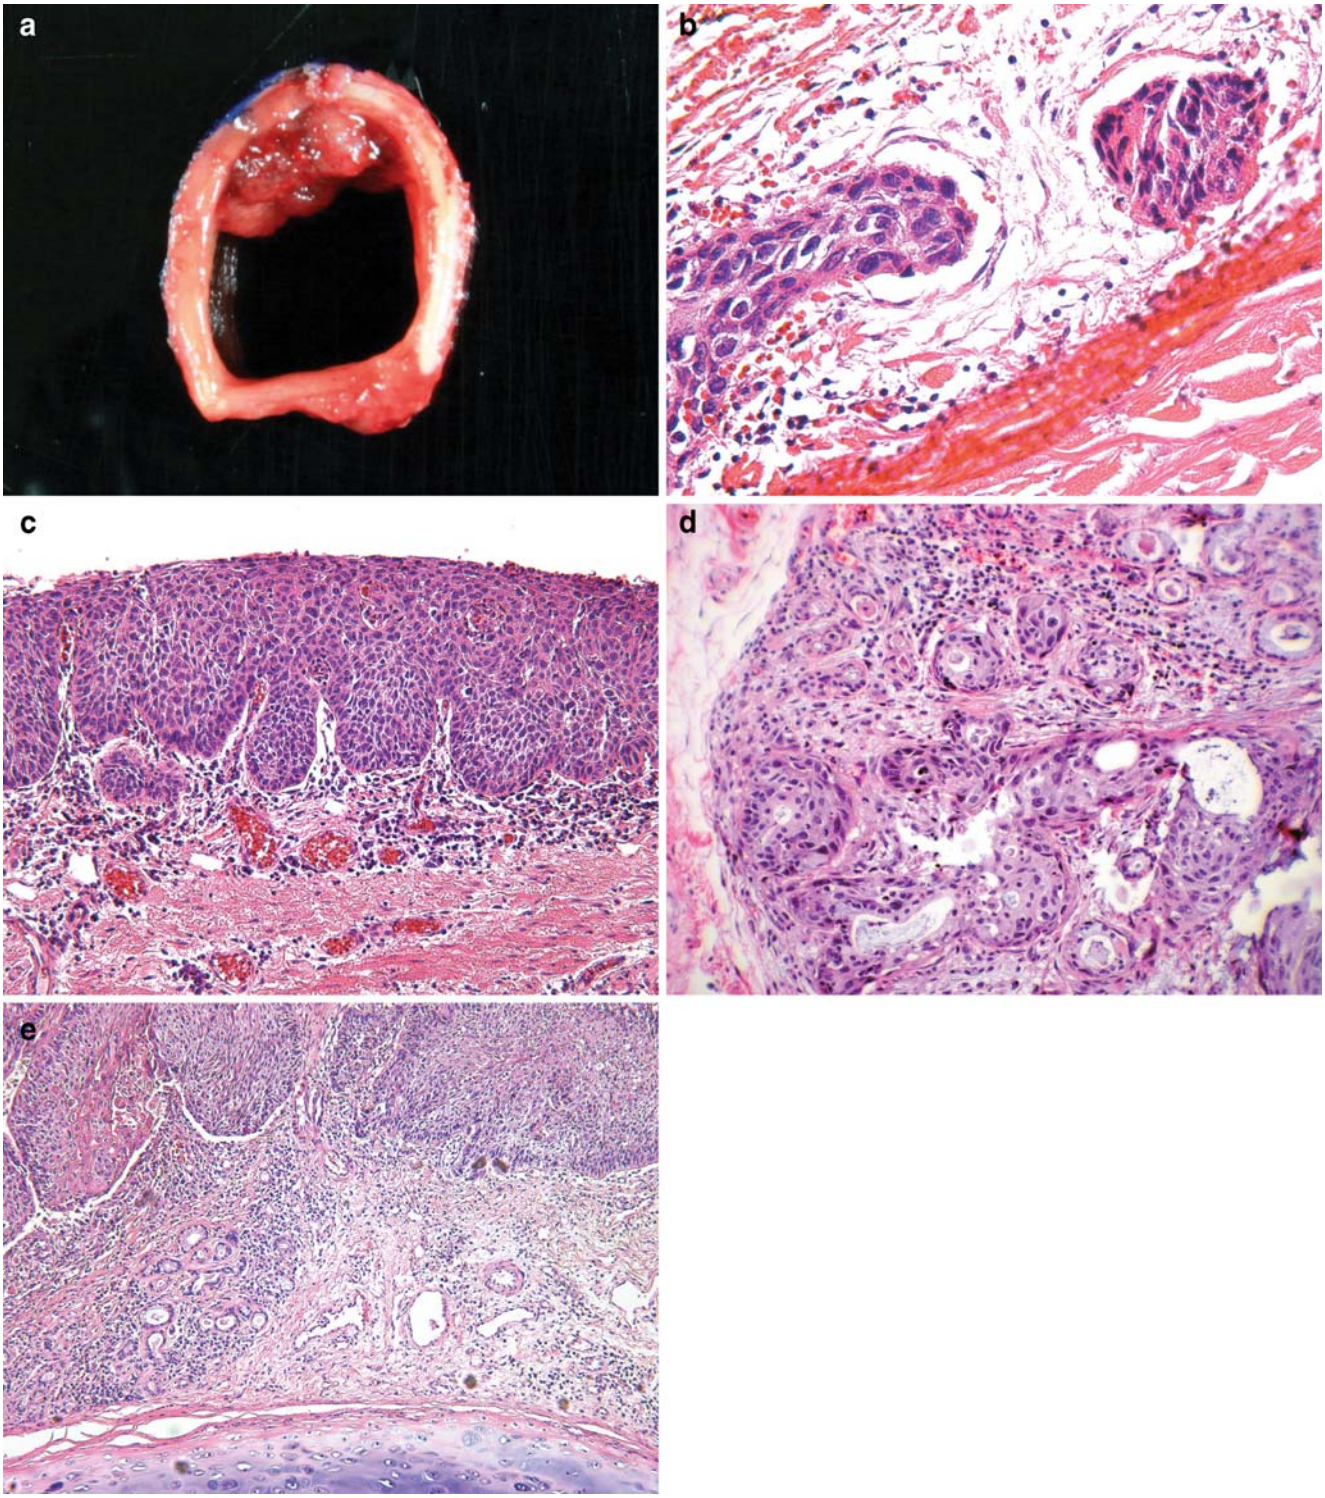

Fig. 1 **a** Cross section of trachea with exophitic tumor attached to anterior wall; **b** lymphatic invasion in peritracheal adventitia; **c** squamous cell carcinoma in situ, with full thickness replacement of epithelium by cells with hyperchromatic nuclei and lack of surface maturation; **d** cancerization of mucus ducts and glands by malignant squamous cells but no invasion beyond basement membrane; **e** squamous cell carcinoma invading from surface epithelium into lamina propria and eliciting inflammation and fibrosis but not as far as tracheal cartilage (bottom)

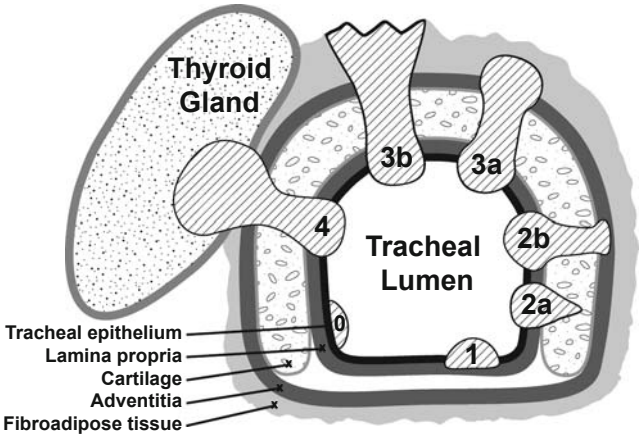

Fig. 2 Depth of invasion in tracheal squamous cell carcinoma ranked by levels. Tumor invaded between cartilage plates and not through the cartilage. Level definitions: *0* carcinoma in situ, *1* infiltrating lamina propria, *2a* abutting or extending between cartilage, *2b* invading beyond cartilage, *3a* invading peritracheal fibroadipose tissue, *3b* abutting soft tissue resection margin, *4* invading into thyroid gland

included one patient in whom a second resection at MGH completed tumor excision after a first resection elsewhere. One patient underwent three resections, but only the first, for tumor resection, was included in this study. Pathology reports, operative reports, and hospital charts were reviewed to exclude laryngeal cancer and tumors of the lung that extended to the carina. The MGH institutional review board approved the most recent protocol (no. 2008-P-000113) in January 2008.

Types of resection

The surgical technique has been detailed previously [6]. For standard tracheal resection, a sleeve of trachea was removed with end-to-end reconstruction, resulting in two airway margins and a radial soft tissue margin. When tracheal resection was combined with laryngectomy, cervical or mediastinal end-tracheostomy was required. For laryngotracheal resection, the tumor was removed with a portion of infraglottic larynx while preserving at least one recurrent laryngeal nerve not involved with tumor. Reconstruction was achieved by shaping the remaining trachea to conform to the laryngeal defect. Carinal resection was performed with or without concomitant lung resection resulting in either two or three airway margins, respectively. Systematic lymph node dissection is assumed to interfere with the tracheal blood supply and was therefore not performed. Regional lymph nodes were often not included in the specimen if not grossly enlarged. Absence of tumor at the airway margins was confirmed by frozen section, unless the limits of resection had been reached, and no additional trachea could be removed.

Pathologic review and tumor data

In all reviewed cases, photographs of the resected specimen (Fig. 1a) and slides stained with hematoxylin and eosin were retrieved. Slides were recut from stored blocks if necessary. Pathologic review of two or more slides per case was done in each case by a senior pulmonary pathologist (E.J.M.), on average four to six slides of the tumor itself and additional slides of resection margins and lymph nodes. The following histologic features were scored: degree of differentiation based on degree and extent of nuclear pleomorphism, using the criteria for well, moderately, or poorly differentiated subtypes in the Armed Forces Institute of Pathology *Atlas of Tumor Pathology* [7]; tumor thickness, defined as the distance from the luminal tumor surface to the farthest extent of invasion; keratinization; necrosis; dyskeratosis; acantholysis; and lymphatic invasion (Fig. 1b). Since no TNM-based staging system currently exists for tracheal carcinoma, depth of tumor invasion into the tracheal wall was scored according to a system devised for the study as shown in Fig. 2, with both squamous cell carcinoma in situ (Fig. 1c) and invasion of carcinoma into tracheal mucus glands and ducts (so-called cancerization, Fig. 1d) considered level 0 and superficially invasive (Fig. 1e) as grade 1.

Further, operative and pathology reports were reviewed for length of resection in the long axis of the airway and the presence of tumor metastasis in lymph nodes. Since lymph node excision in tracheal resection occurs merely sporadically, we combined cases with positive lymph node biopsy and cases with lymphatic invasion on histologic examination in order to provide a meaningful, albeit restricted, analysis.

Adjuvant radiotherapy

Postoperative radiotherapy was usually recommended at a dose of 54 Gy 6 to 8 weeks after resection and often administered outside Massachusetts General Hospital.

Follow-up

Patients and the MGH cancer registry were contacted for follow-up information. The Social Security Death Index was searched. Patients were determined to have died if name, date of birth, and social security number matched. The survival period began on the day of operation and was concluded by death.

Statistical analysis

Overall survival after airway resection was calculated using the Kaplan–Meier procedure with the log rank test

Table 1 Survival according to pathologic subgroups

Pathologic subgroup	Number	Percent	Mean survival (years)	*P* value	Survival (%)	
					5-year	10-year
Tumor differentiation						
Well differentiated	14	23.7	8.8	0.164	73	55

implemented in the SPSS 14.0 statistical software program (SPSS Inc, Chicago, IL), in contrast to the earlier report that used an actuarial method [5]. Categorical variables were compared with the chi-square test, and covariate analysis was done with Pearson's bivariate analysis.

Results

Since 1985, 75 patients have undergone surgical resection for tracheal SCC at Massachusetts General Hospital. There were no operative deaths. Slides or blocks were retrieved in 64 cases, of which five were excluded: there was no viable tumor after radiotherapy in three patients, a cutaneous SCC occurred at a tracheostomy site in one, and two separate SCC were present in one other patient, of which only one was resected. Thus, the study included 59 cases.

Overall characteristics

There were 44 men (75%) and 15 women (25%) with a mean age of 61.9 years (range 29 to 79 years). Prior locoregional or preoperative radiotherapy was administered in 24% (14 of 59). Resection involved trachea only in 63% (37 of 59), trachea and carina in 24% (14 of 59), and trachea and larynx in 14% (eight of 59) of cases. Mean length of resected airway was 3.2 cm (range 1 to 6 cm).

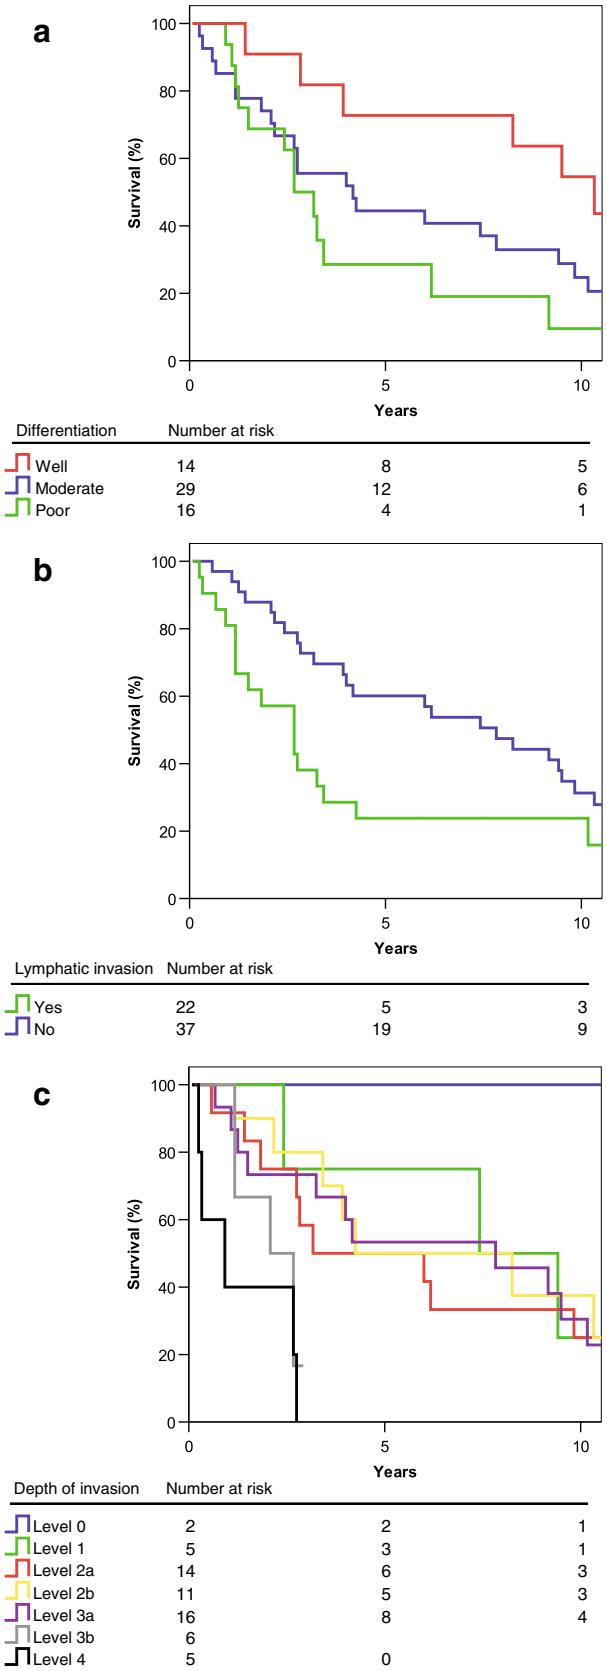

Fig. 3 **a**–**c** Overall survival according to: **a** tumor differentiation, **b** lymphatic invasion, **c** depth of tumor invasion

Pathologic characteristics are listed in Table 1. Postoperative radiation was documented in 42.4% of patients (25 of 59). We know of no patient who received postoperative chemotherapy.

Follow-up and overall survival

Mean follow-up in 59 cases was 5.5 years (range 1 month to 18.3 years). Survival information was complete in 90% of patients (53 of 59). Mean survival was 6.5 years, and the 5- and 10-year survivals were 46% and 27%, respectively. Table 1 shows the survival calculated for each subgroup.

Differentiation

A majority of tumors had moderate differentiation, while close to half were equally distributed between well and poorly differentiated. Survival was longer in well-differentiated tumors, though this difference was not significant (Fig. 3a). Survival in well-differentiated carcinomas was 8.8 years versus 5.8 years in the group of moderately and poorly differentiated carcinomas combined (P=0.117).

Keratinization, necrosis, dyskeratosis, and acantholysis

Two thirds of tumors (39 of 59) showed keratinization. Focal or extensive necrosis was present in 48% (28 of 59) and 20% (12 of 59), respectively. Necrosis was present significantly more frequently in moderately and poorly differentiated tumors (82%, 37 of 45) compared to well-differentiated tumors (21%, three of 14; P<0.001). Dyskeratosis was seen in 59% and acantholysis in 27%.

Survival was not significantly correlated with the presence or absence of keratinization, necrosis, dyskeratosis, or acantholysis.

Lymphatic invasion

In 22 cases (37%), there was tumor in peritracheal lymphatics on histologic examination (seven cases), a tumor-positive lymph node biopsy was present (nine), or both (six). In the other 36 cases (61%), neither lymphatic invasion nor lymph node metastasis was demonstrated. Lymphatic invasion was correlated with the degree of differentiation: histologic lymphatic invasion or tumor-positive lymph node biopsies were present in one of 14 well-differentiated (7%), 13 of 29 moderately differentiated (49%), and nine of 16 poorly differentiated (56%) tumors (P=0.015). Survival in patients without lymphatic invasion was higher than when lymphatic invasion was present (P=

Table 2 Pathologic characteristics according to depth of invasion

Depth of invasion	Number	Percent	Well differentiated		Lymphatic invasion		Tumor thickness >2cm	
			N	%	*N*	%	*N*	%
Level 0	2	3.4	2	100.0	0	0.0	0	0.0
Level 1	5	8.5	2	40.0	0	0.0	0	0.0
Level 2a	14	23.7	5	35.7	1	7.1	0	0.0
Level 2b	11	18.6	4	36.4	5	45.5	2	18.2
Level 3a	16	27.1	1	6.3	7	43.8	6	37.5
Level 3b	6	10.2	0	0.0	4	66.7	1	16.7
Level 4	5	8.5	0	0.0	5	100.0	0	0.0
Overall	59	100.0	14	23.7	22	37.3	9	15.3

0.049, Fig. 3b). There was no difference in survival between patients who had lymphatic invasion only versus patients with positive lymph nodes only, versus both (P=0.382).

Depth of invasion

Carcinomas in situ (level 0) were uncommon, while tumor invaded peritracheal fibroadipose tissue (level 3a) in 16 cases (27%), extended to the soft tissue resection margin (level 3b) in six cases (10%), and invaded the thyroid gland (level 4) in five cases (8%; Table 2). While both patients with carcinoma in situ were alive without disease 9.6 and 15 years after resection, there was no difference in survival between levels 1, 2 (a and b), and 3a (Table 1 and Fig. 3c). Incomplete resection and involvement of the thyroid gland were both negative prognostic markers: mean survival was 2.1 years in patients with tumor at the soft tissue resection margin (level 3b) and 1.4 years when tumor invaded the thyroid gland (level 4), both significantly lower than in other levels of invasion (P=0.025 and P<0.001, respectively). Lesser levels of invasion were associated with a higher incidence of well-differentiated histology (P=0.018) and a lower incidence of lymphatic invasion (P=0.002).

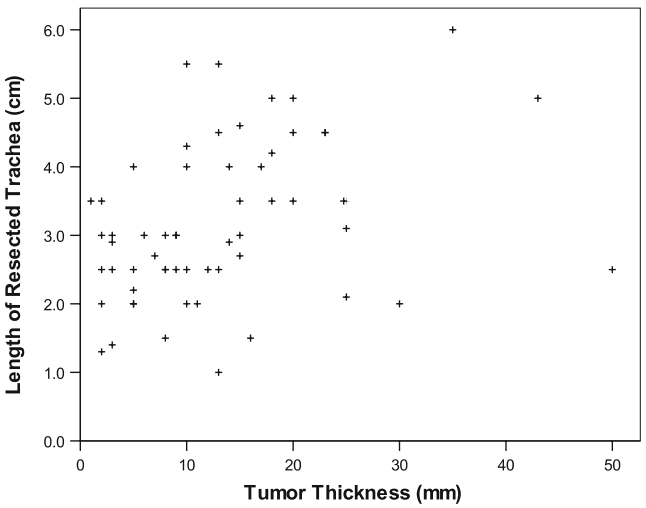

Fig. 4 Correlation between thickness and length of resected tracheal tumor. Each data point represents one tumor specimen

Tumor thickness

Mean tumor thickness was 1.3 cm (median 1.1 cm, range 0.1–5.5 cm). Tumors were 2 cm or smaller in 85%. Within this range, tumor thickness had no significant impact on survival (P=0.650). Tumors of greater thickness were associated with resections of greater (>3 cm) length (P= 0.008), although there were two resections of 2.0 and 2.5 cm in length of trachea with a tumor of 3 and 5 cm in thickness, respectively (Fig. 4, correlation coefficient 0.364). Tumors >2 cm in thickness had no different survival than tumors of 2 cm or less (P=0.353). Tumors >2 cm in thickness more frequently invaded peritracheal fibroadipose tissue (six of nine, 67%) than smaller tumors (ten of 50, 20%; P=0.004) but were not associated with levels 3b or 4 (Table 2).

Discussion

In this pathologic review of primary tracheal squamous cell carcinoma, the largest series to date, we show that completeness of resection, involvement of the thyroid gland, and lymphatic invasion are histopathologic features with important prognostic value. Increasing depth of invasion into the tracheal wall is associated with a loss of histologic differentiation and lymphatic invasion. Although survival in well-differentiated carcinomas is higher, this difference is not significant and may be attributed to the higher incidence of lymphatic invasion in moderately and poorly differentiated carcinomas. Further, we observed that

resected tracheal SCCs are mostly small tumors (median thickness 1.1 cm) and that tumor thickness within this range did not significantly affect prognosis. A possible explanation for this finding is that thickness may result from the exophitic portion of the tumor and thus is not conditioned on deeper invasion into the tracheal wall. A higher proportion of larger tumors, however, exhibit lymphatic invasion, a significant predictor of survival.

Surgical resection may lead to excellent survival even when the tumor violates the boundaries of the trachea and invades peritracheal fibroadipose tissue. To provide the best chances of survival, it is however important for the surgeon to achieve negative soft tissue resection margins. When faced with a tracheal SCC growing into the thyroid gland, our findings indicate that surgical resection should be applied to carefully selected patients, and palliative therapy may be considered when complete resection is otherwise compromised. Further, the pathologist reviewing SCC of the trachea should be aware of the importance of lymphatic invasion and specifically investigate the tumor for the presence of this feature.

There are some limitations to our study. We retrospectively analyzed large pathologic specimens of tracheal SCC, and only resected cases were included. Tumors growing into vital organs such as the heart or the great vessels and tumors involving long segments of airway judged unresectable were treated at the Massachusetts General Hospital but are not included in our study. We might have underestimated or misjudged the histologic characteristics, as only a limited number of representative slides for each case were available during histologic review; further, there were only five cases with invasion of the thyroid gland.

Tracheal SCC is a rare tumor, and few centers acquire proficiency in its surgical treatment. The dissemination of whatever prognostic information is available assumes therefore a greater importance. We confirm that lymphatic invasion predicts prognosis, while depth of invasion could not be correlated with survival, except for a marked decline when tumor was present at the resection margin or invaded the thyroid gland. We therefore conclude that even in cases where tumor invades peritracheal fibroadipose tissue, excellent survival can be achieved provided the patient undergoes surgical resection and the resection is complete. Positive resection margins in turn predict treatment failure. Our previous report showed that outcome in patients with unresected tumors is worse than in patients that underwent resection [5], a finding supported here by the poor prognosis in patients with incomplete resection. Thus, tumor resectability, usually dictated by tumor length in the long axis of the airway and invasion of vital organs, may possibly be the single most important prognostic factor in this very distinct type of cancer.

Conflicts of interest and funding None of the authors has had nor currently has any financial or personal relationships with other people or organizations that could inappropriately influence (bias) their work. There are no conflicts of interest. There were no sources of funding other than departmental funds.

Overexpression of Aurora B is associated with poor prognosis in epithelial ovarian cancer patients

Yi-Jen Chen · Chun-Ming Chen · Nae-Fang Twu · Ming-Shyen Yen · Chiung-Ru Lai · Hua-Hsi Wu · Peng-Hui Wang · Chiou-Chung Yuan

Received: 14 August 2009 / Revised: 13 September 2009 / Accepted: 14 September 2009 / Published online: 17 October 2009

Abstract Recent studies have indicated that Aurora B expression is related to cell proliferation and prognosis in many cancers, but its association with epithelial ovarian carcinoma is not fully understood. Therefore, we examined the Aurora B kinase expression in epithelial ovarian cancer patients. Using immunohistochemistry, the expression levels of Aurora B and phosphohistone H3 (Ser^{10}) (mitosis-specific marker) were measured in 156 patients with epithelial ovarian cancer. The expression levels of Aurora B at the protein and messenger RNA levels were examined using Western blotting and reverse transcriptase polymerase chain reaction. In total, 53 tumorous ovarian samples (34.0%) showed Aurora B overexpression, which was significantly higher than that found in the 15 normal ovarian tissue samples (0%, $p=0.006$). The overexpression of Aurora B was also significantly higher in cases showing phosphohistone H3 (Ser^{10}) overexpression (44.3% vs. 27.4%, $p=0.03$). In addition, the expression of Aurora B in poorly and moderately differentiated carcinomas of the ovary was significantly higher than in well-differentiated carcinomas (53.6% vs. 28.2% vs.10.0%, respectively, $p=0.02$). The overexpression of Aurora B was significantly higher in cases with lymph node metastasis ($p=0.01$) and a positive ascites cytology ($p=0.008$). Overall, the Aurora B overexpression group demonstrated a significantly shorter progression-free survival ($p=0.001$) and overall survival ($p=0.023$) than the Aurora B low expression group using univariate analysis (log-rank statistic). Aurora B is an effective predictor of aggressive epithelial ovarian carcinoma in terms of differentiation, metastasis, and prognosis.

Introduction

Ovarian cancer is a common gynecological malignancy in Western countries and represents the fifth leading cause of death due to cancer among women [1]. More than 70% of presenting cases are already in an advanced stage of the disease at diagnosis. Despite advances in cytoreductive surgery and in chemotherapy regimens, therapeutic failure and disease progression are still quite frequent [1]. The prognosis of patients with ovarian carcinoma depends mainly on the stage of disease and, to a lesser extent, on the patient's age, the volume of residual disease following cytoreductive surgery, and the histological type and grade

of cancer [2]. The identification of additional prognostic parameters would be very helpful when developing a therapeutic strategy, particularly for patients with advanced disease.

Aurora B is a chromosomal passenger protein critical for accurate chromosome segregation, cytokinesis [3, 4], protein localization to the centromere and kinetochore, correct microtubule-kinetochore attachment, and regulation of the mitotic checkpoint. Aurora B is localized on the centromeres from prophase through to metaphase–anaphase transition [5–7]. A significant overexpression of Aurora B has been observed in thyroid, colorectal, and hepatocellular human cancer cell lines [8–10]. Furthermore, it has been observed that overexpression of Aurora B produces aneuploid cells with a malignant and aggressive phenotype, which suggests that the protein's aberrant expression is correlated with human tumorigenesis. Aurora B expression has been associated with cell proliferation and prognosis in thyroid cancer, lung cancer, hepatomas, prostate cancer, and endometrial cancer [11–15]. In a recent study, Kulkarni et al. [16] demonstrated that Aurora B is significantly associated with tumor grade and ploidy status in epithelial ovarian carcinoma. Therefore, it is reasonable to study whether Aurora B expression might have clinical significance in patients with ovarian cancer.

Histone H3 is a protein involved in chromosome condensation and mitotic entry and its phosphorylation at $Ser^0$is mediated by Aurora B [3–7]. The phosphorylation of histone H3 is a rare event in interphase cells and is a process that almost exclusively occurs during mitosis [17]; thus, phosphohistone H3 (PHH3) is a mitosis-specific marker [18]. However, the correlation between Aurora B protein and PHH3 in epithelial ovarian carcinoma is still unclear. To answer this question, we assessed the association of this mitosis-specific marker with Aurora B in ovarian cancer.

In this study, we used an immunohistochemical method to determine the expression of Aurora B and PHH3 (a mitosis marker) in surgical ovarian tumor specimens from ovarian cancer patients. The correlation between Aurora B, PHH3, and clinicopathological parameters was evaluated. The expression of Aurora B in ovarian cancer was also analyzed by reverse transcription–polymerase chain reaction (RT-PCR) and Western blotting. Finally, the prognostic significance of Aurora B expression was examined using the patient follow-up data.

Materials and methods

Study cohort

This study included 156 ovarian cancer patients who had been admitted, treated, and followed-up at the Division of Gynecologic Oncology, Department of Obstetrics and Gynecology, Taipei Veterans General Hospital, Taiwan, between January 1992 and December 2006. Written informed consent was obtained from all patients enrolled in this study. The study has been performed with the approval of Taipei Veterans General Hospital ethics committee (VGHIRB no. 97-08-19A). The patients were selected on the basis of available histological material. The histological specimens were reviewed by a gynecological pathologist (Dr. Lai). Pathological specimens were assessed using the WHO criteria for histological subtype and nuclear grade [19–21]. The median age of the patients was 53 years, and the mean age was 54.62±12.27 years (range, 26–87). Of these patients, 57 (40.1%) had stage I or II cancer, and 85 (59.9%) had stage III or IV cancer. Histologically, serous adenocarcinoma was the most frequent type of cancer presenting in this group (34.0%). The clinicopathological characteristics of the patients are shown in Table 1.

The following clinical information was obtained directly from patients' hospital notes: date of birth, date of diagnosis, operative findings, Federation of International Obstetricians and Gynecologists (FIGO) stage based on the findings at clinical examination, and surgical exploration together with cytology results, CA125 values at diagnosis and relapse, date of relapse, date of last follow-up, and date and cause of death [2].

The 156 cases had undergone primary staging or debulking surgery. Optimal debulking surgery (n=99) was defined as the presence of a residual tumor <1 cm after the procedure. In contrast, if the residual tumor was ≥1 cm, the surgery was then defined as suboptimal debulking (n=29). Seventy-two patients were treated with six cycles of cisplatin-based combination chemotherapy with a minimum total dose of 400 mg/m^2 of cisplatin 2–3 weeks after initial surgery. The cisplatin-based combination chemotherapy regimen consisted of either the cyclophosphamide plus cisplatin (CP) regimen or the cisplatin, adriamycin and cyclophosphamide (CAP) regimen. Seventy-eight patients were treated with six cycles of paclitaxel-based combination chemotherapy 2–3 weeks after initial surgery. This chemotherapy regimen consisted of paclitaxel plus cisplatin or paclitaxel plus carboplatin. Most patients were reviewed after completing treatment every 3–6 months for 5 years and annually thereafter.

Immunohistochemistry

Four-micron sections were cut from formalin-fixed ovarian tissue embedded in paraffin blocks and then mounted onto silane-coated slides. Sections were dewaxed in xylene and rehydrated in a graded alcohol series (100%, 95%, 75%, and 60%) and ddH_2O; antigens were retrieved by boiling in a citrate buffer (pH 6, target retrieval solution; Dako, Carpinteria, CA, USA) for 5 min. Endogenous peroxidase

was inhibited by 3% H_2O_2 (R&D Systems, Minneapolis, MN, USA). Sections were incubated in primary antibody overnight at 4°C. Anti-Aurora B and PHH3 (Ser^{10}) polyclonal antibody (Abcam, Cambridge, UK) was diluted to 1:100 in antibody diluent (Dako) in the immunohistochemical staining procedures [16, 22]. Following overnight incubation, secondary biotinylated antibodies and streptavidin–horseradish peroxidise-conjugated reagent (R&D Systems) were applied to the sections. Immunoreactive complexes were detected using the peroxidase substrate 3-amino-9-ethyl-carbazole (R&D Systems). Slides then were counterstained with aqueous hematoxylin (Thermo Shandon, Waltham, MA, USA) and mounted on a crystal mount (Biomeda, Foster City, CA, USA).

Quantification of immunohistochemical staining

Two observers independently examined the immunohistochemistry slides. The specific staining by each antibody was identified in the nucleus. We utilized an immunohistochemical score (IHS) based on the German ImmunoReactive score; this method has been shown to provide approximate data based on an image analysis-based scoring system [23]. The IHS is calculated by combining an estimate of the percentage of immunoreactive cells (quantitative score) with an estimate of the staining intensity (staining intensity score): No staining is scored as 0, 1%–10% of cells stained scored as 1, 11%–50% as 2, 51%–80% as 3, and 81%–100% as 4. Staining intensity is rated on a scale of 0–3, with 0 being negative, 1 being weak, 2 being moderate, and 3 being strong. The raw data are converted to the IHS by multiplying the quantity and staining intensity scores. Theoretically, the scores could range from 0 to 12. An IHS score of 9–12 is considered strong immunoreactivity, 5–8 is considered moderate, 1–4 is considered weak, and 0 is scored as negative. Aurora B and PHH3 expressing at a moderate to strong level in the nucleus was considered to be overexpression; in contrast, Aurora B and PHH3 expressing at a negative to weak level was to be considered low expression. There were no major differences in overall interpretation of the IHC results between the two pathologists (Chiung-Ru Lai and Ching-Fen Yang).

Western blotting

To confirm the antigenic specificity of the antibodies used for immunostaining, Western blotting was performed as described previously [24]. In brief, seven fresh tissue specimens (two normal ovarian tissue samples, two samples of well-differentiated ovarian carcinomas, and three samples of poor-differentiated ovarian carcinomas) were homogenized and lysed in 0.5 mL NaCl, 0.5% NP-40 (Neu-Ulm, Germany), 1 mmol/L phenylmethylsulfonylfluoride (Sigma Chemical, St Louis, Mo, USA), 1 μg/mL aprotinin (Boehringer Mannheim, Indianapolis, Ind), 1 μg/mL leupeptin (Boehringer Mannheim), and 20 μg/mL tosyl phenylalanyl chloromethyl-ketone (Boehringer Mannheim). The lysates were centrifuged at 13,000×*g* for 20 min at 4°C, and the supernatants were then stored at −70°C until they were used. Extracts equivalent to 50 mg of total protein were separated on sodium dodecyl sulfate–polyacrylamide gels (10% acrylamide). The proteins were then transferred to a nitrocellulose membrane (Amersham, Buckinghamshire, UK) by applying 100 V for 60 min using a plate electrode apparatus (Semi Dry Blotter II; Ken En Tec, Copenhagen, Denmark). The filters were blocked for 1 h in Tris-buffered saline Tween-20 (TBST) consisting of 0.2 mol/L NaCl, 0.2% Tween-20, and 10 mmol/L Tris (pH 7.4), containing 5% nonfat dry milk and 0.02% NaN_3. Subsequently, the filters were incubated with antibodies against Aurora B (Abcam; diluted 1:1,000) and β-actin (Biomakor, Rehovot, Israel; diluted 1:5,000) in TBST containing 5% milk. Finally, they were incubated in

anti-mouse or anti-rabbit IgG (Amersham; diluted 1:5,000) in TBST containing 2% milk. The filters were washed several times with TBST after each step. The bound antibodies were detected using an enhanced chemiluminescence system (Amersham).

Semiquantitative RT-PCR

To assess the mechanism of the expression, the messenger RNA (mRNA) of Aurora B was investigated using RT-PCR. The primers for Aurora B were determined using the GenBank database (http://www.ncbi.nlm.nih.gov/blast) and are listed below. Total RNA was isolated from the same seven tissues used in the Western blotting. RNA extraction and gene amplification have been described previously [22, 25]. Briefly, total RNA was extracted from a frozen tissue sample using the Strata-Prep total RNA Miniprep kit (Stratagene, La Jolla, CA, USA), according to the manufacturer's instructions. First-strand complementary DNA (cDNA) was generated by reverse transcription from 1 μg total RNA using the SuperScript III first-strand synthesis system (Invitrogen, Carlsbad, CA, USA), according to the manufacturer's instructions. Approximately, 50–100 ng cDNA was used for amplifying the Aurora B gene (primers, 5′-CCTGAG CACCCTGCCCCAGCGAG-3′ and 5′-GCAGCTCCTTG TAGAGCTCC-3′) and the internal control, the GAPDH gene (primers, 5′-TGATGACATCAAGAAGGTGGTGAA-3′ and 5′-TCCTTGGAGGCCATGTGGGCCAT-3′). The PCR conditions were 4 min at 94°C, 35 cycles for 60 s at 94°C, 30 s at 52°C, 80 s at 72°C, and a final 7 min extension at 72°C. The amplified products were resolved on 1.5% agarose–ethidium bromide gel electrophoresis.

Statistical analysis

The relationship between Aurora B and PHH3 (Ser^{10}) overexpression and between Aurora B expression and the various clinicopathological parameters were analyzed by Fisher's exact test, the χ^2 test or linear by linear association. Progression-free survival (PFS) was calculated from the date of surgery to the date of relapse or the date last seen, whereas overall survival (OS) was calculated from the date of diagnosis to the date of death or the date last seen. Survival curves were plotted using the Kaplan–Meier method [26]. Statistical differences in survival between the different groups were compared by the log-rank test and univariable Cox regression model [27]. Multivariate analysis (Cox proportion hazard model) with forward stepwise progression was used to analyze the role of clinicopathological parameters and Aurora B staining as prognostic factors [28]. Statistical analysis was performed using SPSS statistical software (Chicago, IL, USA). Statistical significance was set at $p<0.05$.

Results

Aurora B and phosphohistone H3 (Ser^{10}) are overexpressed in human ovarian cancer

Immunohistochemistry was carried out on 156 paraffin-embedded samples obtained at the time of primary surgery and compared with 15 normal ovarian tissue samples. Normal ovary was obtained from 15 women (mean age, 54±3.55; range, 31–58) who received hysterectomy and oophorectomy for uterine prolapse ($n=15$). We cut the surface area of normal ovary for Western bolt. Aurora B and (Ser^{10}) were found to express in the nucleus (Fig. 1c, e, and f). Fifty-three tumor samples (53/156, 34%), including 21 serous adenocarcinomas, two mucinous adenocarcinomas, 15 endometrioid adenocarcinomas, three clear cell adenocarcinomas, and 12 unclassified ovarian cancers, were associated with Aurora B overexpression, which is significantly higher than the negligible expression (0/15, 0%) found for the control group of 15 normal ovarian tissues ($p=0.006$; Fig. 1a). Sixty-one tumor samples (61/156, 39.1%) were associated with PHH3 (Ser-10) overexpression, which was significantly higher than the low expression (1/15, 6.7%) found in the control group of 15 normal ovarian tissues ($p=0.011$; Fig. 1d).

Aurora B overexpression is associated with various clinicopathological parameters, including histotypes, cell differentiation, and lymph node metastasis

We found that overexpression of Aurora B in high-grade serous carcinoma of the ovary was significantly higher than that in endometrioid carcinomas (8/13, 61.5% vs. 33/106, 31.1%, $p=0.033$ one-sided Fisher's exact test) and significantly higher than that in non-high-grade serous carcinomas (8/13, 61.5% vs. 15/49, 30.6%, $p=0.043$ one-sided Fisher's exact test). It is noteworthy that the mucinous adenocarcinoma gave an overall lower frequency of Aurora B overexpression (10.5%). We found that overexpression of Aurora B in poor and moderately differentiated carcinomas of the ovary was significantly higher than that in well-differentiated carcinomas of the ovary (53.6% vs. 28.2% vs. 10.0%, respectively, $p=0.02$, linear by linear association). Overexpression of Aurora B was also significantly higher in cases with lymph node metastasis (50.8% vs. 27.3%, $p=0.01$) and positive ascites cytology (44.4% vs. 20.0%, $p=0.008$).

Expression of Aurora B in tumor cells by Western blotting and RT-PCR

Western blotting showed a specific band for Aurora B at 41 kD (Fig. 2). The expression of the Aurora B protein was

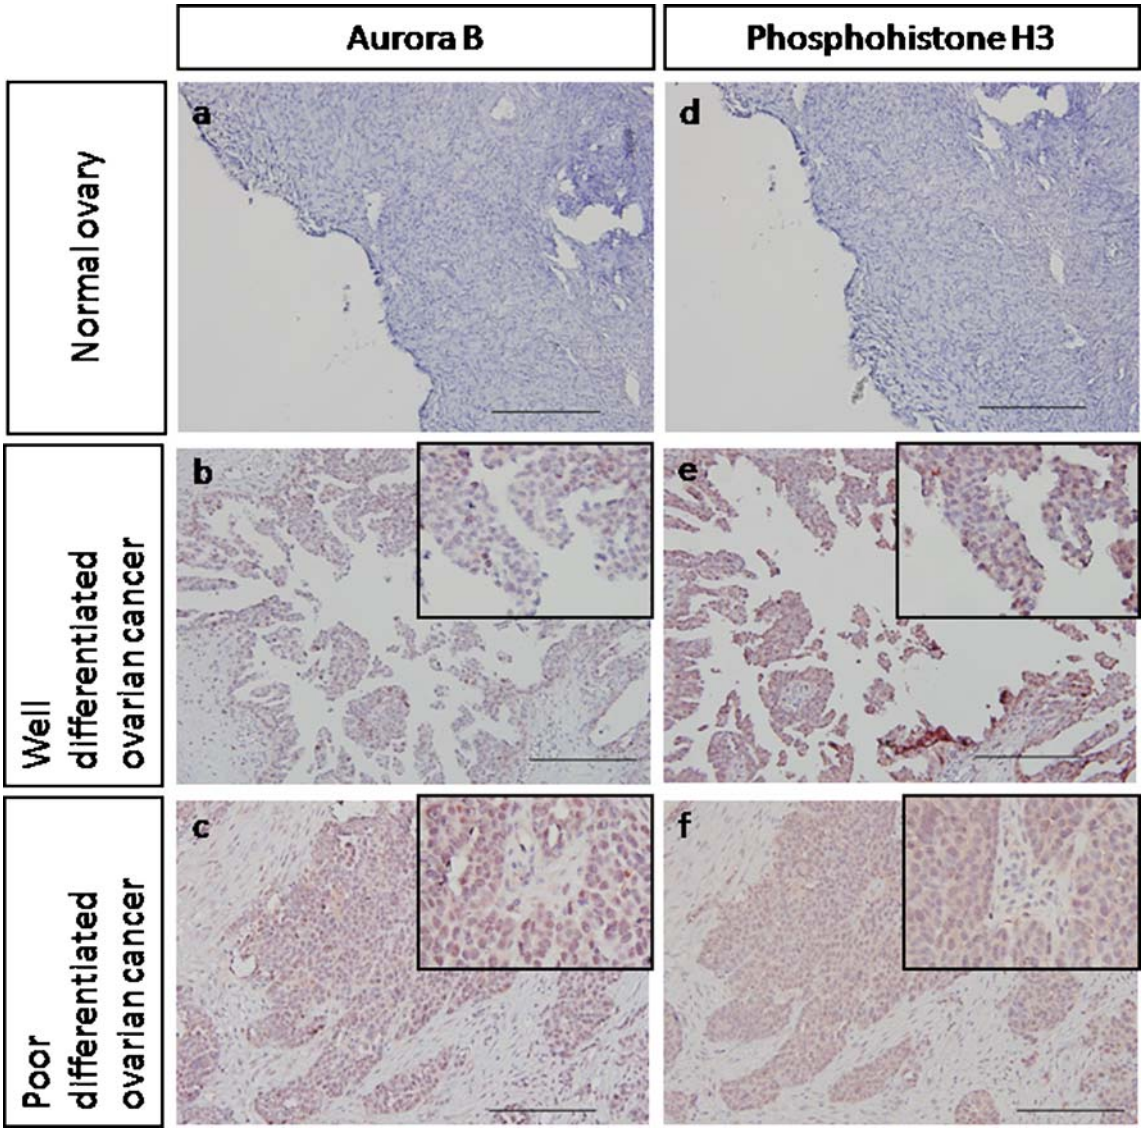

Fig. 1 Immunohistochemical staining for Aurora B and phosphohistone H3 (Ser[10]) in normal ovary and ovarian carcinoma. The normal ovarian epithelium exhibits negative staining of Aurora B (**a**). In the well-differentiated ovarian carcinomas, Aurora B-positive cells are sporadic in the tumor (**b**). In contrast, in poorly differentiated ovarian cancer, Aurora B-positive cells are present throughout the tumor (**c**). Expression patterns of Aurora B and phosphohistone H3 (Ser[10]) appear to be similar in serial sections of the same cases. **d**–**f** Original magnification, ×200; **b**, **c**, **e**, **f** higher magnification (×400) images are inserted. *Scare bars*, 100 μm

negative in all samples of normal ovarian tissue and was positive in all samples of the ovarian carcinoma tissue (case 3, endometrioid carcinoma; case 4, low grade serous carcinoma; case 5, endometrioid carcinoma; and cases 6 and 7, high grade serous carcinoma). The expression of the Aurora B protein was slightly increased in cases of well-differentiated carcinomas of the ovary and was markedly increased in all cases of poorly differentiated carcinomas of the ovary. These results are consistent with the immunohistochemical data on Aurora B for normal ovaries and for ovarian carcinoma.

The reverse transcriptase polymerase chain reaction studies showed a specific band of 209 bp for Aurora B (Fig. 2). The expression of Aurora B mRNA was increased in the carcinoma samples (n=5) compared to the normal ovary samples (n=2). In ovarian carcinoma, the mRNA expression of Aurora B was markedly increased in four cases but was very weak in the remaining case. Thus, Aurora B mRNA levels seem to be largely correlated with the protein expression levels.

Aurora B expression is associated with PHH3 (Ser[10]) expression

We next compared the expression of PHH3 (Ser[10]) with Aurora B expression in the ovarian cancer tissues. Expression patterns of PHH3 (Ser[10]) and Aurora B

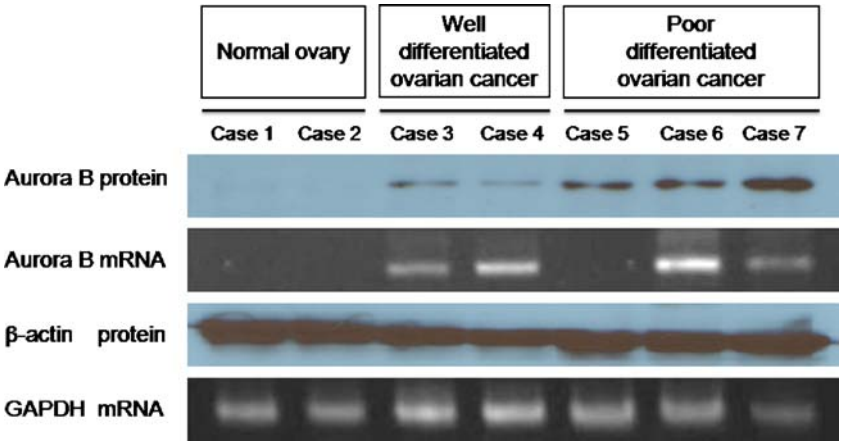

Fig. 2 Results of Western blotting and RT-PCR for Aurora B in normal ovary and epithelial ovarian cancer. Overexpression of Aurora B in epithelial ovarian cancer can be seen. Aurora B mRNA levels are largely correlated with protein levels (case 3, endometrioid carcinoma; case 4, low grade serous carcinoma; case 5, endometrioid carcinoma; cases 6 and 7, high grade serous carcinoma)

appeared to be similar in serial sections of the same cases (Fig. 1). The overexpression of Aurora B was significantly higher in cases with PHH3 (Ser^{10}) overexpression (44.3% vs. 27.4%, $p=0.03$; Table 2).

Aurora B overexpression is associated with prognosis

OS follow-up data were available for 149 patients. There was no progression data for seven patients, so PFS data were available for 142 patients only. The median follow-up period was 1,073 days (range, 0–4,825 days). During this period, 77 (51.7%) patients died of the disease, and recurrence of the disease was observed in 77 (54%) cases.

Using univariate analysis, we found that the Aurora B overexpression group (median, 727 days, 95% confidence interval, 301–1,133) demonstrated a significantly shorter PFS than the Aurora B low expression group (median, 3,896 days) ($p=0.001$, log-rank statistic; Fig. 3a). The Aurora B overexpression group (median 1,418 days, 95% confidence interval, 836–2,000) also demonstrated a significantly shorter OS than the Aurora B low expression group (median, 2,482 days; 95% confidence interval, 1,233–3,731; $p=0.023$, log-rank statistic; Fig. 3b). Univariate Cox regression analysis for the variables of stage, high-grade serous carcinoma, optimal cytoreduction, and Aurora B was applied. Hazard ratios and p values are presented in Tables 3 and 4. Stage, high-grade serous carcinoma, suboptimal cytoreduction, and Aurora B were significantly correlated with poor PFS and OS. Finally, multivariate analysis using the Cox proportional hazards model was conducted, incorporating the variables of stage, high-grade serous carcinoma, optimal cytoreduction, and Aurora B. Both stage and suboptimal cytoreduction remained significant predictors of a poor PFS ($p<0.05$; Table 3). However, only the stage remained a significant predictor of OS in ovarian cancer (Table 4).

Using univariate analysis, high PHH3 (Ser^{10}) expression was not associated with poor PFS, with a median survival of 772 days vs. 1,353 days ($p=0.203$, log-rank statistic). Furthermore, high PHH3 (Ser^{10}) expression was not associated with poor OS, with a median survival of 1,492 vs. 1,780 days ($p=0.305$, log-rank statistic).

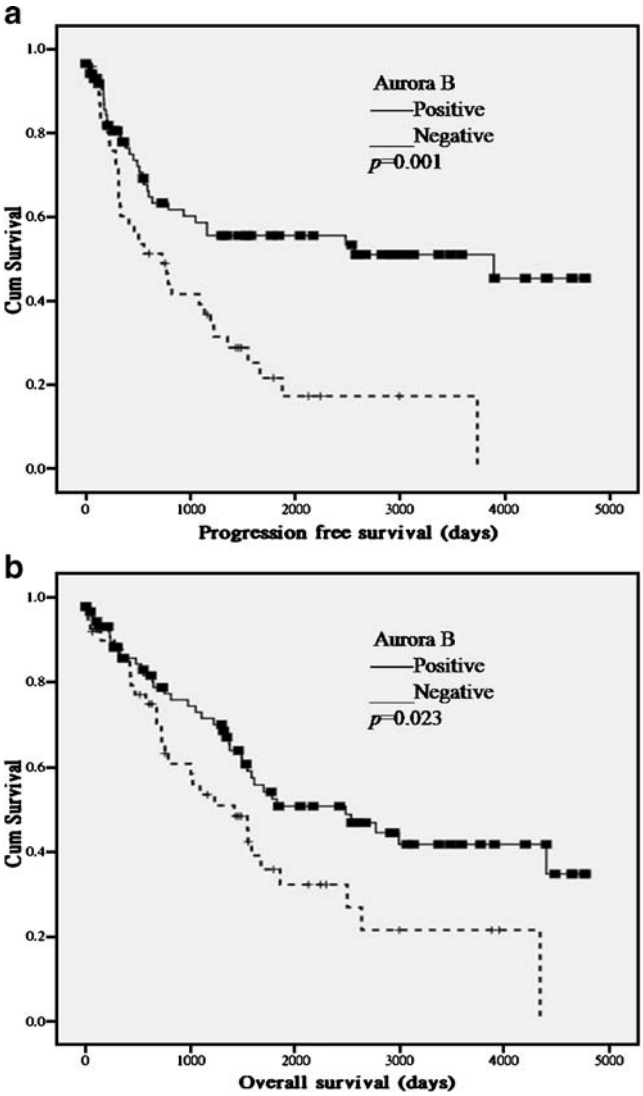

Fig. 3 Progression-free survival and overall survival curves for ovarian cancer according to Aurora B status. Survival curves were plotted using the Kaplan–Meier method. The Aurora B overexpression group (median, 727 days; 95% confidence interval, 301–1,133) demonstrated a shorter PFS than the Aurora B low expression group (median, 3,896 days; $p=0.001$, log-rank statistic; **a**). The Aurora B overexpression group (median, 1,418 days; 95% confidence interval, 836–2,000) also demonstrated a shorter overall survival than the Aurora B low expression group (median, 2,482 days; 95% confidence interval, 1,233–3,731; $p=0.023$, log-rank statistic; **b**)

Discussion

The key findings in this study are that Aurora B is much more frequently overexpressed in ovarian cancer than in normal ovaries and that the expression of Aurora B is related to epithelial ovarian cancer prognosis. Aurora B, a chromosome passenger protein that localizes to centromeres in early mitosis and then the spindle midzone in anaphase, is required for histone H3 phosphorylation, chromosome biorientation, the spindle assembly check point, and cytokinesis [29, 30]. Overexpression of Aurora B produces multinuclearity and increases ploidy; these are important factors during human cancer development [4, 6]. The serine 10 motif of histone H3, selectively phosphorylated in the G2/M phase of the cell cycle, is regulated by Aurora B kinase and is considered to have several important roles, including various ones in chromosome segregation [31–33]. However, the mechanism of histone H3 phosphorylation and the role of cell kinetics remain unclear. Since recent

HR hazard ratio

studies have identified histone H3 protein as an important substrate of Aurora B kinase [34], nuclear localization of Aurora B is functionally important. Our immunostaining analysis showed a high PHH3 (Ser^{10}) index in ovarian cancers compared with non-cancerous tissue. This result suggests that the increased phosphorylation of histone H3 might have effects on the malignant transformation of ovarian epithelial cells and could act as a molecular marker reflecting carcinogenesis in ovarian cancer. Our study showed a correlation between PHH3 and Aurora B expression immunohistochemically Using immunohistochemical analysis of a large series of tumors, we showed frequent expression of Aurora B and PHH3 (Ser^{10}) in ovarian cancer samples, whereas normal ovarian tissue was negative for this phenomenon. Our study also showed a correlation between Aurora B and PHH3, a mitosis marker, immunohistochemically. This result is in agreement with those of other studies [35, 36]. Taken together, our findings also suggest a role for Aurora B and PHH3 (Ser^{10}) as tumor markers in ovarian cancer.

Our study also showed that Aurora B expression increases as tumor differentiation decreases. This observation is supported by previous findings where Aurora B expression inversely correlated with the degree of differentiation of other types of tumor, including colon cancer [19], hepatocellular carcinoma [10], prostate cancer [14], endometrial cancer [15], and thyroid carcinoma [8]. More recently, a well-designed study by Kulkarni and colleagues [16] showed that there was a significant correlation between Aurora B and tumor progression with epithelial ovarian cancer. We suggest that Aurora B may be involved in the development of malignant phenotypes, such as poor differentiation or multinuclear cells [6]. In this context, the mechanisms by which Aurora B has been proposed to promote tumor progression are loss of mitotic control and abnormal proliferation [6, 8, 15].

In the present study, we also found that Aurora B expression was strongly associated with lymph node metastasis in ovarian cancer. These observations are supported by previous findings that Aurora B expression is correlated with lymph node metastasis of other types of tumors, including oral cancer [37]. The detailed mechanism of metastasis caused by Aurora B overexpression is still unknown. In the future, we will examine the correlation between Aurora B overexpression and migration or invasion by ovarian cancer cells.

Overexpression of Aurora B has been related to a poor prognosis in recent reports of endometrial carcinoma and lung cancer [12, 15]. In our study, among the biomarkers tested, only Aurora B could predict the prognosis of the ovarian cancer patients. However, multivariate analysis failed to show that expression of Aurora B is an independent prognostic factor. This is due partly to the highly significant associations between the biomarkers and tumor grade and stage, making it difficult to separate its independent effects. Furthermore, Aurora B is an effective predictor of aggressive epithelial ovarian carcinoma in terms of differentiation and metastasis in our result. Thus, the immunohistochemistry of Aurora B provides significant information that cannot be obtained from staging alone.

The possible mechanism of an Aurora B-induced poor prognosis is probably through the phosphorylation of

Table 4 Univariate and multivariate cox regression analysis of clinicopathological parameters and Aurora B status as predictors of overall survival in ovarian cancer patients

HR hazard ratio

histone H3, a direct impact on the process of ovarian carcinogenesis, or a high proliferation rate. Thus, the molecular effects of Aurora B on cancer prognosis are not completely clear. In future study, we will compare Aurora B and Ki67 staining to try to more clearly study this possibility. The limitation of our work was that we were using a non-quantitative methodology of RT-PCR to investigate the mRNA of Aurora B in only five carcinoma samples. Although this result needs further validation, our findings might be important for the clinical management of these patients.

Another limitation of our study is that we do not perform microdissection to collect the epithelial component of normal ovary. Even though we cut the surface area of normal ovary for Western bolt, but the ovary tissue still contain some stroma. It is possible to dilute the expression of Aurora B in the epithelium of normal ovary. However, these results for Western blot are consistent with the immunohistochemical data on Aurora B for normal ovaries.

In conclusion, Aurora B expression was well correlated with differentiation, metastasis, PFS, and OS in epithelial ovarian carcinoma. The study shows its value as a clinical relevant marker and as a potential therapeutic target for human ovarian cancer.

Authors' contributions Yi-Jen Chen carried out immunohistochemical staining, performed the statistical analysis, and drafted the manuscript. Chun-Ming Chen carried out the RT-PCR, Western blot and drafted the manuscript. Chiung-Ru Lai assessed the pathological specimens and evaluated the immunohistochemical score. Nae-Fang Twu, Ming-Shyen Yen, Hua-Hsi Wu, and Peng-Hui Wang participated in the design of the study and provided patients' data. Chiou-Chung Yuan conceived of the study and participated in its design and coordination. All authors read and approved the final manuscript.

Acknowledgments We thank Ching-Fen Yang for her evaluation of the immunohistochemical score. We appreciate Professor Ralphy Kirby's help in improving the style of written English. We thank Dr. Muh-Hwa Yang for his involvement in revising the manuscript. We are grateful for the assistance of Miss Tsui-Ying Huang in completing the RT-PCR and Western blots. This research was supported, in part, by grant 96-VGH-B1-010 from Veterans General Hospital and by a grant from the Ministry of Education "Aim for the Top University" Plan. This study was also supported by research grants from Yen-Tjing-Ling Medical Foundation (CI-97-6).

Conflict of interest statement We declare that we have no conflict of interest.

Abstract Immunosuppressive factors derived from the tumor and nontumor cells present in the tumor microenvironment contribute to tumor escape from host immune attack. Recently, the tryptophan-catabolizing enzyme indoleamine 2,3-dioxygenase (IDO) derived from both the tumor cells and surrounding nontumor cells was found to function as a critical immunosuppressive factor. While the expression of IDO is intensively under investigation in many types of cancers, little information is available in esophageal squamous cell carcinomas (ESCC) thus far. In this study, we have therefore investigated the cellular localization of IDO in 45 ESSCs and ten morphologically normal esophageal tissues; the correlation of IDO with clinicopathological parameters was also analyzed. Immunohistochemistry (IHC) analysis revealed that the density of IDO-positive cells was increased in ESCCs relative to controls ($P<0.01$). These cells were distributed as clusters and formed a patchy pattern in both the cancerous epithelium and the surrounding noncancerous cells. Double IHC further confirmed that many IDO-positive cells in the tumor stroma were smooth-muscle-actin-alpha-positive myofibroblasts, CD68-positive macrophages, and S100-positive dendritic cells. Statistical analysis showed that the densities of IDO-positive cells were not significantly correlated with tumor clinical parameters (tumor invasion depth, node metastasis, and TNM stages) and lymphocytic infiltration. Our current findings suggested that the increased IDO expression in ESCCs is from a mixed cellular source (both cancer cells and noncancerous cells). Further studies on immune cell functional analysis are required in the future.

IDO	Indoleamine 2,3-dioxygenase
IHC	Immunohistochemistry
ESCC	Esophageal squamous cell carcinoma

Introduction

Esophageal cancer is a highly aggressive lethal malignancy worldwide with regional variations in incidence [1–3]. Asian countries have a high incidence, and the predominant histological type of esophageal cancers is esophageal squamous cell carcinoma (ESCC), which is in contrast with the reports from Western counties that a high incidence of esophageal adenocarcinoma was found. Our location (Henan Province, North China) has been reported to have the highest incidence of esophageal cancer in the world [2], and ESCC accounts for over 90% cases. In our

Table 1 Basic clinicopathological information of ESCC patients

	Number	Tumor invasion			Lymph node involvement		Metastasis		TNM stages		
		T1	T2	T3	N0	N1	M0	M1	I	II	III
ESCC	45	1	9	35	35	10	45	0	1	34	10

province, over the past 40 years, there has been a strong attempt to make an early diagnosis for patients with ESCC, since an improved prognosis is heavily dependent on the disease stage. Unfortunately, the metastasis is often observed at the time of diagnosis, and curative surgery becomes impossible in many patients with ESCC. The prognosis is still very poor.

To seek potential therapeutic strategies for these ESCC patients with metastasis, a better understanding of the mechanisms of tumor cell growth control and progression is necessary. Several lines of evidence suggest that tumor cells can grow by escaping from the host immune system control and the malignant potential is significantly influenced by host immunity. One of the tumor's abilities to escape immune attack is to inhibit antitumor immunity by producing immunosuppressive factors [4, 5]. Indeed, a growing body of evidence has suggested that a variety of immunosuppressive factors derived from the tumor cells and surrounding cells contribute to the establishment of regional immunosuppressive networks in patients with ESCC [6–9]. Recently, indoleamine 2,3-dioxygenase (IDO), an intracellular enzyme that catalyzes the initial and rate-limiting steps in the metabolism of the essential amino acid tryptophan along the kynurenine pathway, is found to be increased and functions as a critical immunosuppressive factor in many types of human cancers [10–18]. However, little information is available concerning the expression of IDO in ESCC. The first study concerning IDO expression in patients with ESCC was reported by Sakurai et al. [19]. They showed that the mRNA level of IDO was remarkably increased in either the cancerous tissue or blood as compared with the controls. Furthermore, their statistical analysis suggested that the ESCC patients with higher levels of IDO expression had a worse survival rate than the IDO expression group with lower levels. It has been demonstrated that a variety of cells in the tumor microenvironment contribute to the IDO expression; IDO immunoreactivity is identified in both the cancer cells and the surrounding noncancerous cells (i.e., macrophages and dendritic cells) in many types of cancers [12, 20–22]. However, the phenotypic analysis of IDO expression in ESCCs is still lacking. In this study, we therefore investigated the cellular expression pattern of IDO in the tumor microenvironment and analyzed whether the IDO-positive cell density influenced the clinicopathological features in patients with ESCCs.

Materials and methods

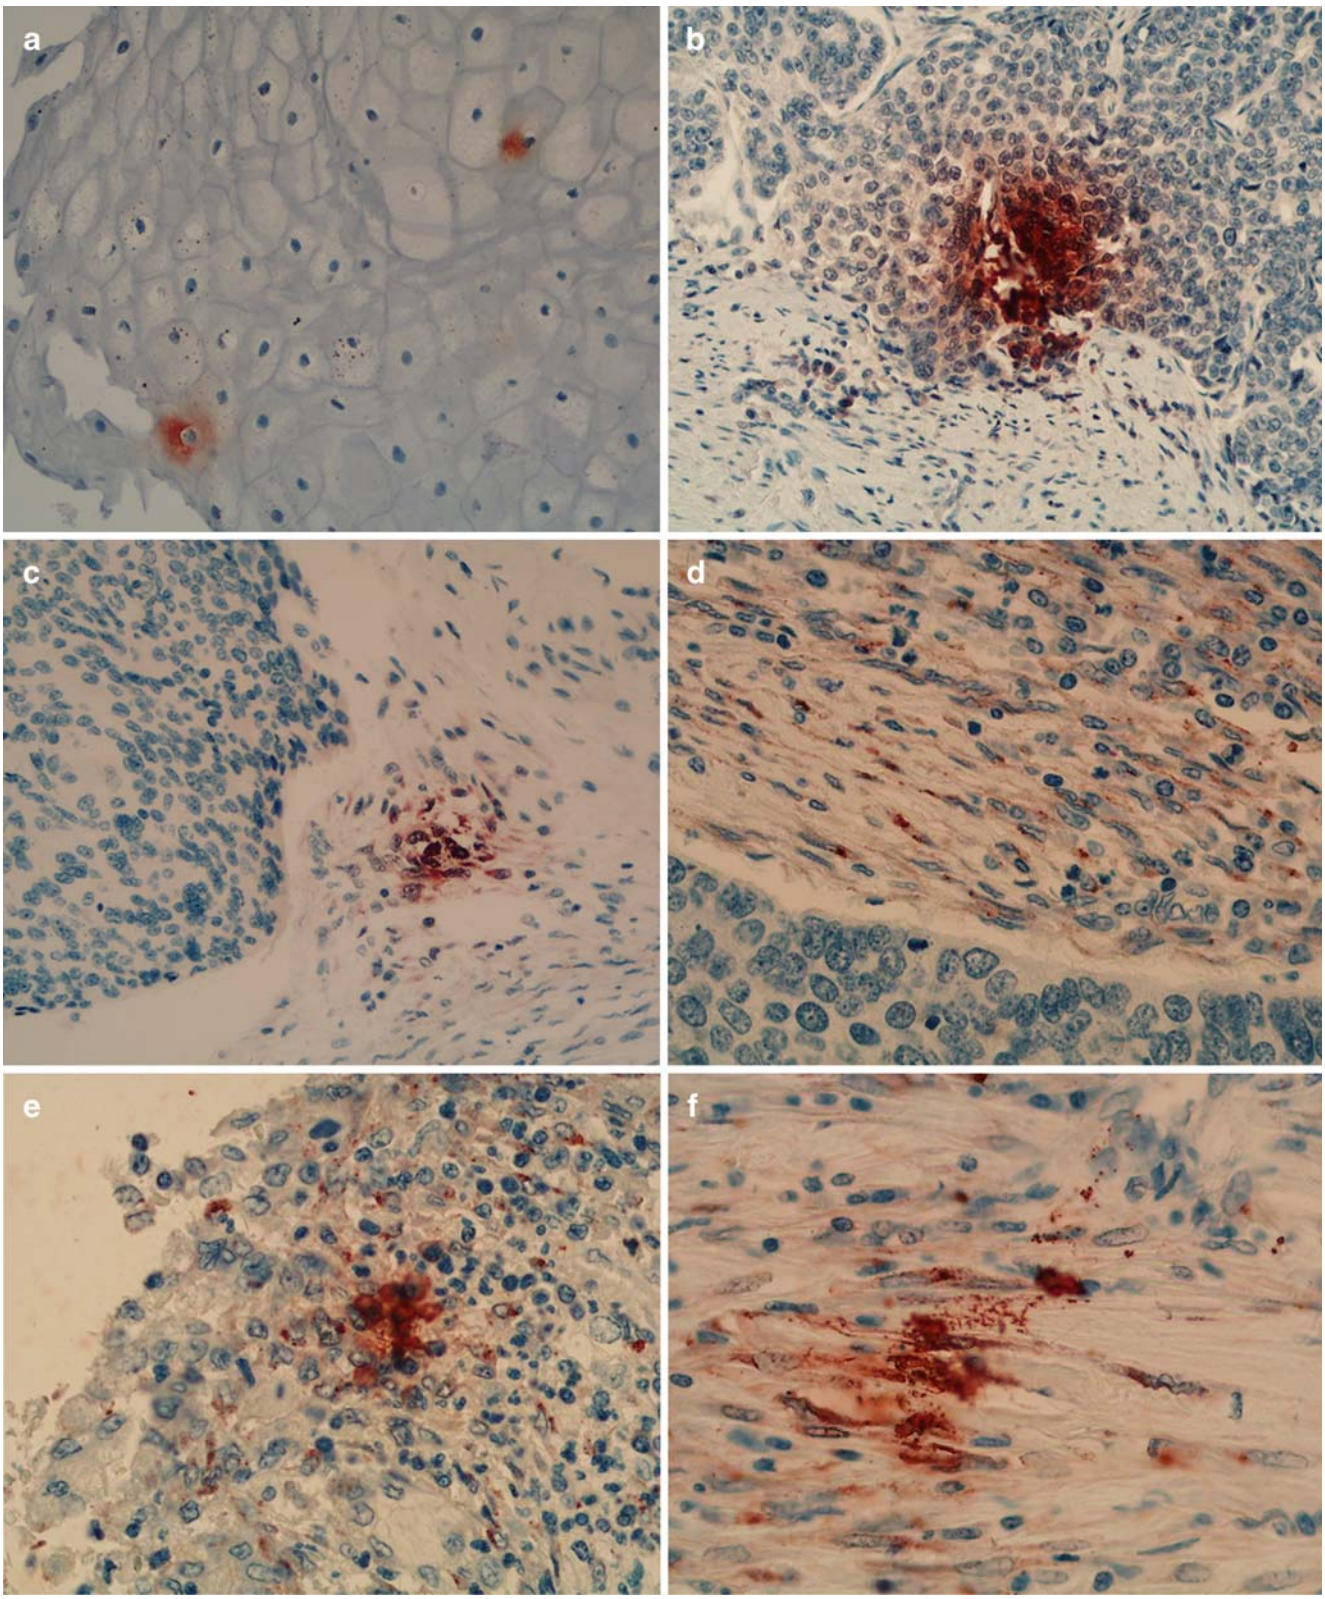
Tissue specimens from ESCCS and controls

Forty-five surgical ESCC paraffin blocks tracked from the tissue bank in the Departments of Pathology, the Fourth Affiliated Hospital of Zhengzhou University, between August 2003 and November 2008 were included in the study according to the guidelines of the protocols approved by the institutional review board. There were 28 men and 17 women ranging in age from 32 to 76 years. The tumor location was in the upper third in seven patients, in the middle third in 25 patients, and in the lower third in 13 patients (for other information, see Table 1). None of the ESCC patients received immunomodulatory therapy, chemotherapy, or radiotherapy before surgery. Ten morphological normal esophageal mucosa without pathological evidence taken by endoscopy examinations served as controls (male/female 7/3; age 26–76 years; three were taken from upper third, four from middle third, and three from lower third esophagus).

Immunohistochemical examination of IDO and tumor-associated lymphocyte expression in the tumor microenvironment

Immunohistochemistry (IHC) was performed in 4-μm sections with Vectastatin Elite Universal ABC-HRP kits (Vector Lab., Burlingame, CA, USA) according to the manufacturer's instructions and our published methods [23, 24]. Antigen retrieval was achieved by incubating the

Fig. 1 Examination of the IDO expression patterns in the tissues of ESCCs by single IHC and DIHC. IDO-positive cells were only observed in low density in the control mucosa **a**), but they were present as cluster and formed a patchy distribution pattern with a high density in ESCC epithelium **b**) and surrounding noncancerous cells **c**). In tumor stroma, many of them had fibroblast morphological features (**d**), leukocytes (**e**), and microvessels (**f**). DIHC further confirmed that those IDO-positive surrounding noncancerous cells (*brown* in **g**, **h**, **i**) were myofibroblasts (*red color*, labeled by SMA-alpha in **g**), macrophages (*red color*, labeled by CD68 in **h**), and dendritic cells (*red color*, labeled by S100 in **i**). (**a**–**c**, single IHC, counterstained with hematoxylin, original magnification ×200; **d**–**f**, single IHC, counterstained with hematoxylin, original magnification ×400; **g**–**i**, DIHC, without nuclear counterstaining, original magnification ×400)



sections with ready-to-use Proteinase K solution (Dako, Carpinteria, CA, USA) for 10 min (for IDO IHC) or boiling sections in 0.01 M sodium citrate buffer (pH 6.0) through microwave processing for 15 min (for CD3 IHC), respectively. Then, the sections were incubated with the mouse anti-human IDO monoclonal antibody (working dilution 1:400, Oriental Yeast Co., Ltd., Tokyo, Japan) or anti-CD3 polyclonal antibody (1:50; Dako, Carpinteria, CA, USA)

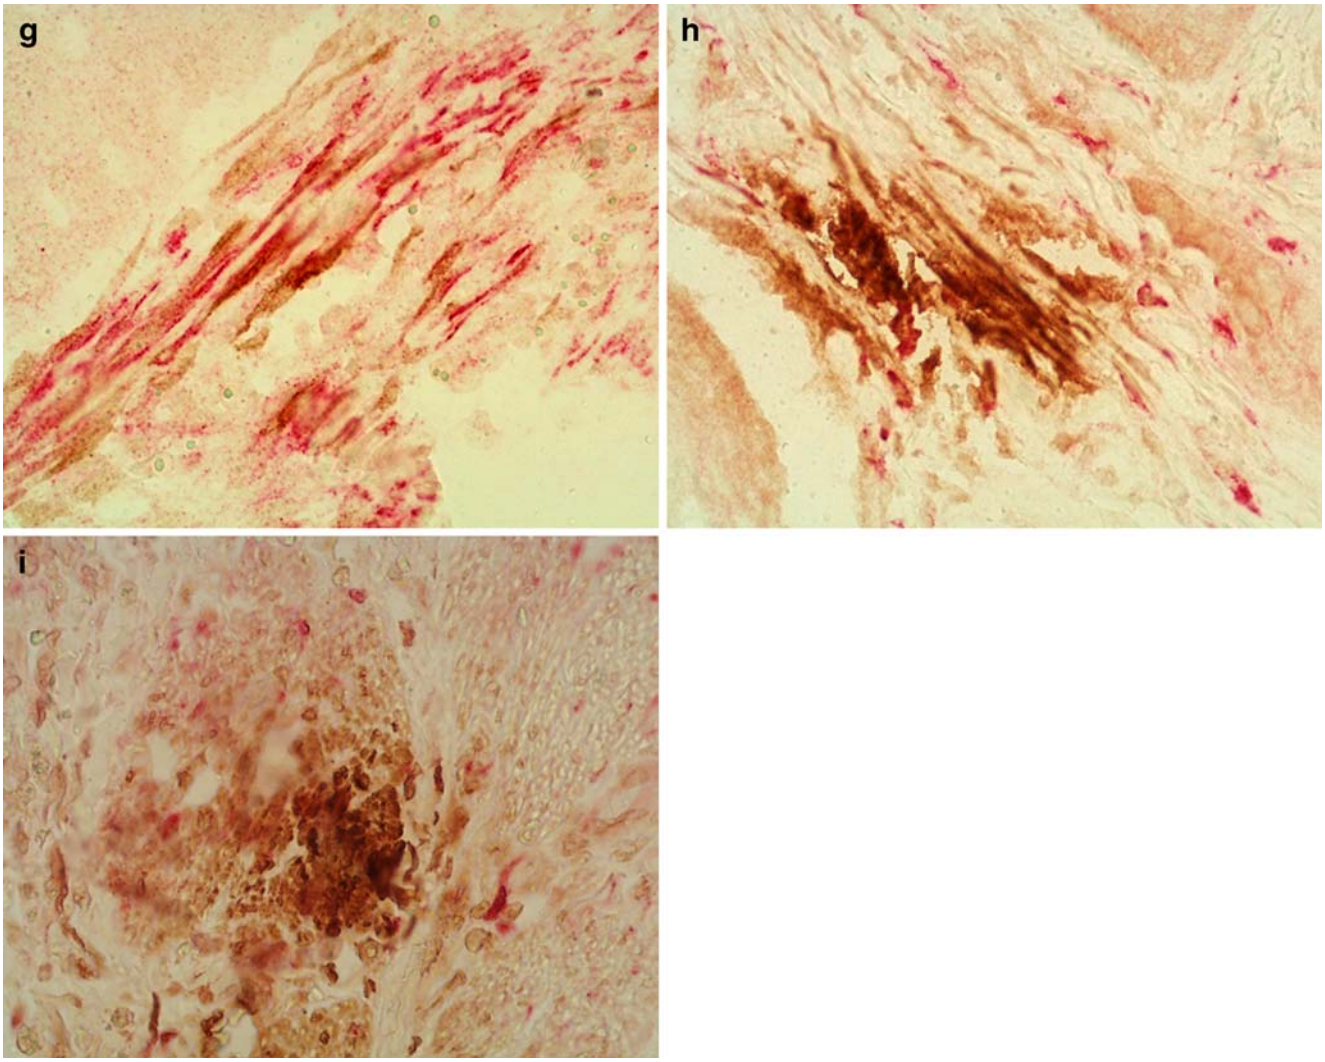


Fig. 1 (continued)

overnight at 4°C. 3-Amino-9-ethylcarbazole (Vector Laboratories, Burlingame, CA, USA) was used as chromogen and Mayer's hematoxylin as the counterstain. The negative control slides were performed routinely: (1) primary antibodies were substituted with the isotype-matched control antibodies; (2) secondary antibody was substituted with phosphate-buffered saline.

Double immunohistochemical identification of cellular phenotypes of IDO in the surrounding noncancerous cells

Since the expression of IDO in cancer cells was easily identified by the specific morphological features, here, we have only examined the cellular phenotypes of IDO in the tumor stromal cells. Double IHCs (DIHCs) were performed using EnVision G72 Doublestain System kit (Dako Demark, Glostrup, Denmark) with antibodies IDO/smooth muscle actin (SMA) alpha (to label myofibroblasts), IDO/CD68 (to label macrophages), and IDO/S100 (to label dendritic cells; monoclonal anti-SMA-alpha, anti-CD68, and anti-S100 antibodies were all purchased from Dako, Carpinteria, CA, USA) according to the manufacturer's instructions and the method described in our publications [25, 26]. In brief, the slides were incubated for 30 min with anti-IDO antibody after antigen retrieval and then incubated with labeled polymer–horseradish peroxidase–antimouse and antirabbit antibodies for 10 min at room temperature. Peroxidase activity was detected with the enzyme substrate 3,3′-diaminobenzidine tetrachloride. After quenching the enzyme reaction, the slides were incubated in Doublestain Block at room temperature for 4 min to block endogenous phosphates. The slides were then incubated with anti-S100, anti-CD68, and anti-SMA-alpha antibodies individually for 15 min at room temperature. After washing, the slides were incubated with rabbit/mouse link

for 10 min and then labeled with polymer–alkaline phosphates antimouse and antirabbit antibodies for 10 min. *Permanent Red* substrate solution was used for the visualization.

Morphometric evaluation

Since the numbers of IDO-positive cells in ESCCs were much lower than in other types of human cancers [10, 13, 15, 20, 27, 28], we used an absolute quantitative method for the IDO-positive density evaluation. The cells with IDO immunoreactivity were counted in malignant epithelium, intratumor stroma, and stroma in invading edges in at least five optical high-power magnification fields (×400) with abundant distribution from each slide. CD3-positive lymphocytes were scored according to the method described in our previous publication [29]. The average values per slide were used for statistical analysis.

Statistical analysis

Results were expressed as mean ± standard error of the mean unless otherwise stated. For statistical analysis of data, the Mann–Whitney tests were used. The level of significance was defined as $P<0.05$.

Results

The expression pattern of IDO in the tumor microenvironment of ESCC

In normal esophageal tissue sections, faint IDO immunoreactivity was occasionally observed in mucosal cells (Fig. 1a; normal controls taken by endoscopic forceps had little stroma; therefore, we could only describe the expression of IDO in mucosal cells). In contrast to the normal controls, the ESCC sections showed intense immunoreactivity for IDO in the cancer epithelium (Fig. 1b) and in the surrounding noncancerous stromal cells as well (Fig. 1c). Most IDO-positive cells were present as clusters and formed a patchy distribution pattern in the cancer epithelium and tumor stroma (Fig. 1b, c). IDO-positive cells in the tumor stroma had various morphological features; many of them were fibroblasts (Fig. 1d), and some were leukocytes (Fig. 1e) and microvessels (Fig. 1f). The intensity of IDO immunoreactivity in tumor cells (Fig. 1b), stromal immune cells (Fig. 1e), and microvessels (Fig. 1f) was stronger than that in fibroblasts (Fig. 1d). Increased IDO expression was confirmed by IDO-positive cell quantification, which showed a significant increase in IDO-positive cell density in the tumor microenvironment as compared with the normal mucosa (see Fig. 2). A particular high density of IDO-positive cells was demonstrated in the invading edges of ESCCs (see Fig. 2). In addition, the IDO-positive cell densities in the compartments of cancer epithelium and tumor stroma were significantly higher than that in the adjacent noncancerous epithelium and nontumor stroma (ESCC vs. adjacent mucosa 0.83±0.23 per field vs. 1.83±0.83 per field, $P\leq0.01$; ESCC tumor stroma vs. adjacent nontumor stroma 3.97±0.73 per field vs. 0.90±0.72 per field, $P\leq0.05$).

The influence of the total IDO-positive cell density on the clinicopathological features in patients with ESCCs was analyzed. The results showed that total IDO-positive cell densities were not significantly correlated with tumor invasion depth, node metastasis, and TNM stages (see Table 2). In addition, statistical analysis showed that the density of CD3-labeled lymphocytes in patients with high IDO cell density (≥10 per field) and with low IDO cell density (≤10 per field) was not different (low IDO cell group vs. high IDO cell group 2.33±0.16 per field vs. 2.59±0.17 per field, $P\geq0.05$).

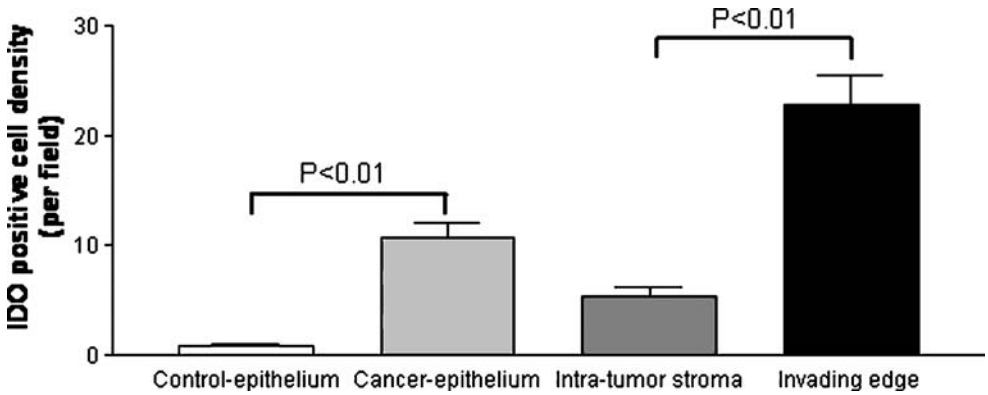

Fig. 2 Graphic analysis of IDO-positive cell densities in ESCCs. The IDO-positive cell density was significantly increased in the ESCC cancer epithelium (*light gray bar*) as compared with the controls (*white bar*); a particular high IDO-positive cell number was observed in the invading edges of ESCCs (*black bar*) as compared with the intratumoral stroma (*dark gray bar*). (The Mann–Whitney test was used for the statistical analysis)

Table 2 The correlation of the total IDO-positive cell density with clinicopathological factors

Factors	Total IDO cell density (field)	*P*
Tumor invasion depth		
T1/T2	12.92±3.66	>0.05
T3	15.25±1.97	
Lymph node involvement		
N0	14.91±1.87	>0.05
N1	18.83±5.37	
TNM stage		
I/II	14.50±1.88	>0.05
III	19.76±4.82	

Cellular phenotypes of IDO in the tumor stroma

The expression of IDO in cancer cells and microvessels can be easily identified by their specific morphological features. However, to identify IDO expression in immune cells (dendritic cells and macrophages) and myofibroblasts in the tumor stroma, DIHCs with specific antibodies (IDO/CD68, IDO/CD, and IDO/SMA alpha) need to be performed. The DIHC results revealed that IDO immunoreactivity could be frequently observed in SMA-alpha-positive myofibroblasts (Fig. 1g), CD68-positive macrophages (Fig. 1h), and S100-positive dendritic cells (Fig. 1i) in the tumor stroma.

Discussion

Immunosuppressive factors derived from the tumor microenvironment play a major role in extending immune escape and facilitating cancer progression. Since the study of Uyttenhove et al. showed that IDO expressed by the tumor cells have an immunoregulatory effect and reduce antitumor T cell attack in a marine tumor model [30], growing evidence from many studies carried out in different human cancers has demonstrated that IDO is expressed by both the tumor cells and nontumor cells in the tumor microenvironment [17]. In the present study, we revealed an increased IDO-positive cell density in the tumor microenvironment of ESCCs and identified that IDO is expressed by tumor cells and many types of cells in the tumor stroma.

IDO is an intracellular enzyme that catalyzes the initial and rate-limiting steps in the metabolism of the essential amino acid tryptophan along the kynurenine pathway [31]. Accumulated evidence has suggested that IDO could be a critical immunosuppressive factor and play an important role in inducing immune tolerance [32, 33]. Our present study has observed an increased number of IDO-positive cells in the microenvironment of ESCCs; these cells were both tumor cells and surrounding noncancerous stromal cells. Quantitative results showed that the IDO-positive cells were ~8 per field in the cancer epithelium and ~5 per field at the site of tumor stroma between cancer epithelium but significantly more common at the site of invading edges (~19 per field). As compared with the reported IDO densities in other types of human cancers [10, 13, 15, 20, 27, 28], IDO-positive cell density in the present study was lower. However, the IDO-positive cell densities were still significantly higher in ESCCs than in controls (see Fig. 2; $P \leq 0.01$). Sakurai et al. have reported that elevated IDO mRNA was found in ESCCs [19]. It is most likely that such increased IDO cell density may represent an increased IDO expression in the tumor microenvironment. In agreement with the findings of Sakurai et al., we also showed that the density of IDO-positive cells did not correlate to tumor invasion, lymph node metastasis, or TNM stage (all $P \geq 0.05$), although the IDO-positive cell densities are slightly increased, paralleling the degree of increase of these parameters. This may be because many factors released from the tumor cells and stroma cells participate in immunosuppression, and IDO only induces immunosuppression to a certain degree [34]. Since the ESCC samples in our study were procured very recently, survival follow-up analysis is not yet available. To further examine IDO-positive cell's prognostic significance, long-term follow-up and large sample studies will be required in the future.

Increased infiltration of immune cells and activated fibroblasts in the tumor stroma is one of the common histological features in ESCCs [35–38]. These cells in the tumor stroma may function as a double-edged sword because they play an important role in both the anticancer response [39, 40] and in favoring cancer progression in some certain conditions [26, 41, 42]. By both the quantitative and qualitative techniques, IDO has been found to be expressed by many types of cells in the tumor microenvironment including tumor cells, fibroblasts, endothelial cells (microvessels), dendritic cells, and macrophages in various cancers [12, 20, 43, 44]. In line with those studies, we were also able to observe IDO immunoreactivity in ESCCs in many types of stromal cells including microvessels, immune cells, and fibroblasts by single IHCs and DIHCs with specific antibodies (see Fig. 1). Those findings suggest that the IDO in ESCCs is most likely from a mixed cellular source, and tumor stroma is an active participant in local immunoregulation.

In addition, the suppressive effect of IDO on T cell function has been reported; we therefore examined the influence of IDO expression on infiltrating lymphocyte number in the tumor microenvironment; however, no statistically significant differences were noted between low and high IDO cell groups ($P > 0.05$). Possible explanations may be: first, T cell's function and number are

regulated by many factors [34]; secondly, T cell contains various subtype groups with different functions [39]; however, the influence of IDO on the different subtype T cells is still unclear; and finally the T cell function changes may be greater than the density changes. Thus, the functional analysis on certain subtype T cell is necessary for the comprehensive understanding of the IDO's effect on host immune functions in ESCCs.

In conclusion, our current findings suggest that increased expression of IDO in ESCCs is from a mixture cellular source in ESCCs and may potentially play an essential role in inducing immune tolerance. Since the use of IDO inhibitors as a possible cancer therapy has been intensively discussed in other types of cancers [45], its potential as a therapeutic application in ESCCs should be investigated in the future.

Acknowledgments We express our sincere gratitude to Ms. Dana Frederick, Department of Cell Biology, University of Massachusetts Medical School, for manuscript proofreading

Abstract Prostate involvement is a major prognostic element in urothelium carcinoma staging after radical cystoprostatectomy (RCP) for muscle invasive bladder cancer. While appropriate pTNM stage is necessary for adequate treatment, no standard procedure exists up to now for macroscopic sampling of the prostate in RCP in daily practice. We therefore propose a protocol where examination of the whole prostatic urethra (PU) is possible, without using whole mount sections. From 2008 to June 2009, RCP were sampled according to a macroscopic protocol permitting the whole length and the underlying stroma of PU to be visualized. Data were compared with our series or RCP from 2000–2007, when the PU was evaluated with a more simple protocol. One hundred and one specimens were examined between 2000–2007, 25 until June 2009. In the latter series, we found pT4 bladder cancer in 36% versus 21%, C*is* in the PU in 28% versus 14%, and additional prostate cancer was seen in 44% compared with 13% (p=0.0004) in the 2008–2009 group versus the 2000–2007 group, respectively. Our proposed protocol better detects prostate involvement by bladder cancer, therefore providing a better final stage of the patients. We propose a macroscopic protocol where the whole PU and the underlying stroma can be examined without the use of whole mount sections. Data are similar to those published in the recent literature, where whole mount sections were used. This protocol also permits better detection of concomitant prostate carcinomas.

Introduction

In case of muscle invasive urothelial carcinoma (UC), radical cystoprostatectomy (RCP) is the gold standard of treatment [1]. Appropriate sampling of RCP specimen is necessary to obtain correct pTNM stage and treatment.

Staging UC in the prostatic urethra (PU) is controversial. The PU mucosa and large prostatic ducts that empty into the urethra are also lined by the same urothelium. In case of invasion of the PU, prostatic ducts or acini with UC without invasion of the prostatic stroma, the tumor has to be considered as pT*is*, making no difference whether it is a primary tumor or extension of an already existing UC of the bladder. In case of involvement of the underlying prostatic stroma, the UC becomes a pT4 tumor [2]. The proximity of prostatic urethra and bladder neck facilitate spreading of in situ carcinoma into prostatic urothelium. Many patients

with involvement of the bladder neck have spread of UC into the PU. To determine that the carcinoma does not invade the stroma of the underlying gland is a very important challenge in pathology. Up to now, no standard protocol for sampling the prostate in RCP specimens has been established. It is left to the pathologist to decide how many blocs should be taken. Montironi et al. suggest in a recent paper whole-mounted prostate sections with inclusion of the whole gland [3].

We propose a different protocol, permitting visualizing of the whole PU without the time-consuming technique of whole mount sections.

Materials and methods

We have collected 126 RCP specimens between January 2000 and June 2009. After taking material for snap frozen specimen if possible, the RCP was fixed in 10% neutral buffered formalin, 15 times the volume of the total specimen. Fixation lasted between 24 to 48 h according to the specimen's size. The following protocol was used for the samples from 2000–2007. After orientation and measuring and describing the RCP specimen, the apex, a slice in the middle of the prostate and a slice at the base of prostate were taken. Afterwards, the bladder was sampled according to necessity of macroscopic aspects.

From 2008 to 2009, the new standardized protocol was applied. After orientation, measuring, and describing the lesions and macroscopic findings, the RCP specimen was cut sagitally to separate the right and left half from anterior to posterior. Photos were taken systematically. Prostate tissue was inked to be able to mark resection margins precisely in case of concomitant prostate cancer as well as in case of invasion of the prostate by UC (Fig. 1). The most apical portion of the prostate was transected and submitted as for cone biopsies of cervix for evaluation of the apical margin, according to the Stanford protocol. Then the urethra was taken on both sides (right and left) in its total length to be able to study the whole PU (Fig. 2). The next step was sampling the bladder neck according to macroscopic findings including a sample of seminal vesicles and prostate tissue. Prostate samples were taken in the middle of the prostate (1 to 2 slices according to the size of the prostate). The procedure was similar on both sides (Fig. 3). Afterwards, the bladder was sampled according to the recommendations published by Lopez-Beltran et al. [4]. Tumors were classified according to the WHO classification 2004.

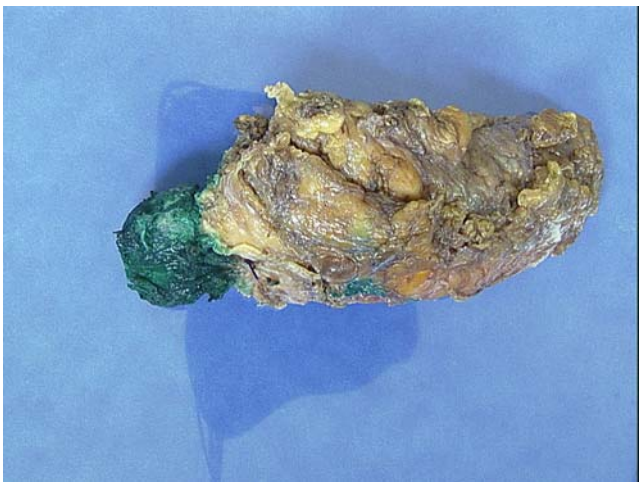

Fig. 1 The RCP specimen was oriented, prostate tissue was inked

Results

Between 2000 and June 2009 126 RCP were sent to our institution (Department of Pathology, Hôpital La Pitié-Salpetrière). All specimens examined before 2004 were reclassified according to the WHO classification 2004. Stages of the bladder tumor were distributed as follows (see Table 1). Between 2000 and 2007, we collected 101 RCP and 25 between 2008 and June 2009. Patients' age ranged from 39–85 years (mean, 70; median, 69; see Table 2).

Vascular invasion in perivesical fat was seen in 47 (37%) patients, 14 (11%) had C*is* in the bladder associated with invasive bladder tumor. Amongst the 30 pT4 patients, three

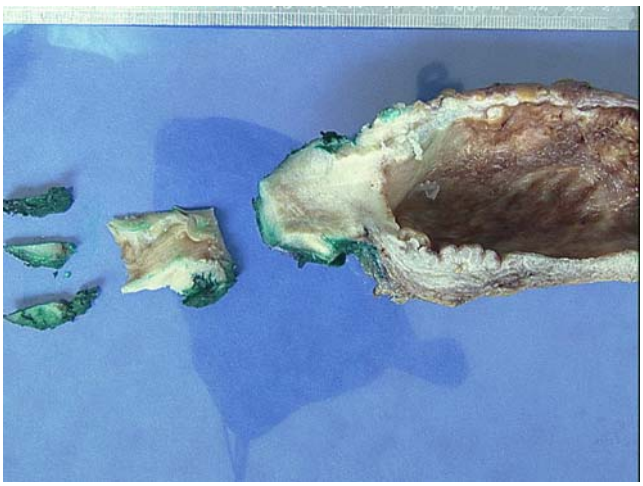

Fig. 2 Dissection of the most apical portion of the prostate, prepared as for cone biopsies of cervix for evaluation of the apical margin, the urethra was taken on both sides (right and left) in its total length to be able to study the whole PU (Fig. 2).Then we sampled the bladder neck according to macroscopic findings including a sample of seminal vesicles and prostate tissue. Prostate samples were taken in the middle of the prostate (1 to 2 slices according to the size of the prostate). The procedure was similar on both sides

were found to have urothelial carcinoma with an important squamous component, four had a micropapillary component in 20% to 80% of the tissue, all of these four cases displayed vascular invasion, and five had either particular bladder tumors or particular findings associated (one adenocarcinoma, one urothelial carcinoma with rhabdoid differentiation, one poorly differentiated carcinoma, one carcinoma had developed in a bladder substitution, and finally one patient had associated schistosomiasis, but no squamous component).

In our series, 24 patients (20%) were found to have concomitant adenocarcinoma of the prostate. Amongst them, five were considered as pT2a, three as pT2b, eleven as pT2c, one pT3a, 2 as pT3b, and two as pT4, both invading the bladder (immunohistologically confirmed). In the group 2000–2007, 13 cases (13%) of associated prostate cancer were described as compared with 11 cases (44%) in the recent group (p=0.0004).

When comparing cystoprostatectomies 2000–2007 data to 2008–2009, increasing numbers of PU invasion (plus 14%, nonsignificant), invasion of the prostatic stroma (18%, trend towards significance, p=0.08), and detection of concomittant prostate carcinoma (p=0.0004) could be observed with the new protocol (see Table 4). With this new protocol, six cases (24%) showed as well PU C*is* and invasion of the prostate (Fig. 4). One pT4 case with PU involvement displayed foci of C*is,* but without prostatic stroma invasion, the UC invaded the rectum. Increasing incidence of insignificant prostate carcinoma could also be observed.

A relationship between the presence of vascular invasion and micropapillary carcinoma (p=0.01), but also between vascular invasion and positive lymph nodes (p=0.0001) could be observed.

Table 1 Stages of RCP between January 2000 and June 2009

pT stage	Number of cases
pT0	0
pTa	1
pTis	3
pT1	10[a]
pT2	30
pT3a	11
pT3b	40
pT4	30

[a] Substaging (none according to the WHO classification 2004) was made for pT1 tumors, one case was pT1a; nine was pT1b

Table 2 Comparison of pT stages between 2000–2007 and 2008–2009

pT stage	Number of cases, 2000–2007 in %	Number of cases, 2008–2009 in %
pT1	9%	4%
pT2	25%	20%
pT3a	9%	8%
pT3b	32%	32%
pT4	21%	36%

Lymph nodes status were as follows (see Table 3)

Discussion

Sampling RCP specimens and correct staging are essential to decide on postsurgical treatment of urothelial carcinomas of the bladder [3, 5]. Up to now, no standard protocol has been established dealing with the method and extent of prostate sampling in RCP specimens.

We present a protocol where the PU of an RCP specimen can be examined as a whole without any lack of material. Using this new protocol, we could demonstrate that prostatic UC involvement is a common finding in more than a third of patients. Our results also showed that we were able to diagnose an increasing numbers of C*is* in the PU and increasing invasion of prostatic stroma (pT4). The

Table 3 Lymph node invasion of RCP between January 2000 and June 2009

pN stage	Number of cases, 2000–2007 in %	Number of cases, 2008–2009 in %
N0	72%	76%
N1	13%	8%
N2	12%	12%
Nx	4%	5%

Table 4 Comparison of prostate involvement by UC in our series

	2000–2007	2008–2009
invasion of PU	14 (14%)	7 (28%)
invasion of prostate stroma	18 (18%)	9 (36%)
prostate cancer	13 (13%)	11 (44%)
insignificant prostate cancer	2 (2%)	3 (12%)

current series come up with a 36% prostatic involvement, which is close to the results published by Shen et al., who included the prostate specimen in 5-mm intervals in the transverse plan from the apex to the base on whole mount sections [6]. Shen et al. found 32% of prostatic involvement in their series and specifically describe 21% of C*is* in the PU and prostatic ducts/acini, as compared with 24% of urothelial involvement in the prostate in our current series. These results are also close to those of Mazzucchelli et al., who worked one whole mount sections of 248 RCP and found 37.9% of UC involving the prostate [7].

Several disadvantages exist by using whole mount sections in prostate sampling. First of all, it is time-consuming and technically more demanding. Whole mount sections require well-trained technicians and new material for inclusion, cutting the blocs and different slides. In case of a need for immunohistochemistry, standard procedures cannot be deployed. Therefore, whole mount section technique is not commonly used.

Extension of UC in the PU is certainly underestimated [8], although it has significant prognostic importance. Direct extension of UC into the prostate has the worst prognosis as is reflected by the WHO 2004 classification, which stages these tumors as pT4. It has also a worse prognosis than nonstromal C*is* in the PU. Prostatic involvement has also been shown to be associated with a higher frequency of nodal metastasis and worse survival.

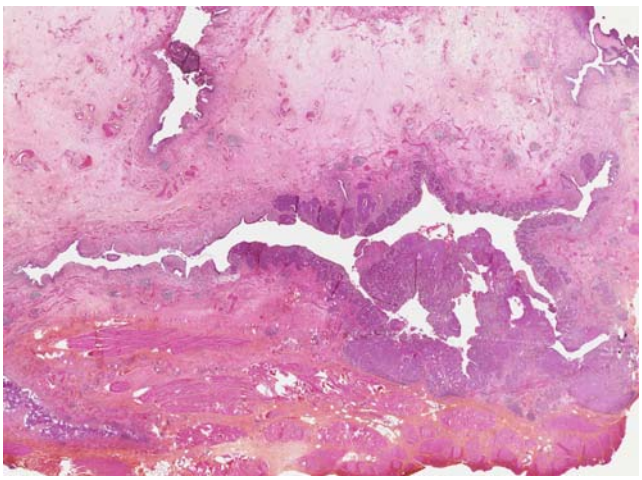

Fig. 4 Histological aspect of the whole urethra. Invasion of prostatic tissue and *Cis* of urothelium (HES, ×2.5)

Shen et al. demonstrated that UC involvement of the PU and lymph node metastasis were highly significant and independent prognostic factors for patients' survival [6].

On the other hand, Ayyathurai et al. found that involvement of PU did not alter the survival predicted by the primary bladder stage, but stromal involvement of the prostate always had poor prognosis, regardless of the mode of invasion [9].

Several studies have shown that there are different mechanisms of prostate invasion by UC. Development and pathogenesis of UC in the PU might be linked either to synchronous transformation of the prostatic and bladder urothelium or to pagetoid spread from an existing UC in the bladder into the PU. Another possibility is direct transmural invasion. In the last case, the stage immediately becomes pT4, either via posterior perivesical growth or directly through the bladder neck [10, 11]. The dominant mechanisms seem to be intraurethral spread with following transmural invasion. [6, 12]. Several studies suggested that transmural penetration has a worse prognosis than non-contiuous or intraurethral spread [12, 13]. Esrig et al. found that UC in the PU or ducts does not influence the prognosis as predicted by the primary bladder stage alone. But prostatic stromal invasion arising intraurethrally significantly decreased survival.

Since we have been able to show that in case of standardized sampling, an invasive component is found in the majority of cases, and all C*is* cases in the PU in the 2008–2009 group displayed stromal invasion, the method we describe might have significant clinical impact. Amongst the nine graded pT4 patients between 2008–2009, six received early additional chemotherapy, although the value of adjuvant systemic chemotherapy remains controversial, and follow-up in our series is not sufficient to prove real benefit. One patient died 4 days after surgery; two patients did not receive any therapy, one because of cardiac pathology, the other was affected by Alzheimer's disease. When comparing our two series, we can hypothesize that approximately 15% of patients were undergraded between 2000 and 2007 and did not receive additional treatment.

Additionally, we were able to demonstrate an increasing number of associated prostate cancers. With the new protocol, 44% adenocarcinomas of the prostate were found. These results are comparable to the series of Revelo et al., who found 41% of unexpected prostate cancers in RCP specimens [14]. These results are also in line with those of Montironi et al., who observed 49.6% of prostate cancers in RCP, of which he considered 18.7% insignificant [3]. In our study, five patients displayed nonsignificant prostate carcinoma, 2% in the group 2000–2007, 12% in the second group.

In conclusion, our study clearly demonstrates the importance of studying the whole PU. It prevents underestimation of its involvement and makes correct staging possible. For example, finding stromal invasion of the underlying prostate can be important for additional treatment decisions and prediction of patient's prognosis. Our protocol is a good alternative for sampling of the prostate of RCP specimens with similar results as published in the literature for whole mount sectioning. This proposed protocol better detects prostate involvement by bladder cancer, therefore providing a better final stage of the patients. A practical advantage, however, is that this technique permits to avoid whole mount sections, which is not available for everybody. This protocol is easy to use, and is not more time-consuming than other macroscopic protocols.

CASE REPORT

Metastatic potential of an aneurysmal bone cyst

Addy C. M. van de Luijtgaarden · Rene P. H. Veth · Piet J. Slootweg · Pauline M. Wijers-Koster · Leo J. Schultze Kool · Judith V. M. G. Bovee · Winette T. A. van der Graaf

Abstract Aneurysmal bone cysts (ABCs) are benign bone tumors consisting of blood-filled cavities lined by connective tissue septa. Recently, the hypothesis that ABCs are lesions reactive to local hemodynamics has been challenged after the discovery of specific recurrent chromosomal abnormalities. Multiple cases of malignant transformation of ABC into (osteo)sarcoma have been described, as well as a number of cases of telangiectatic osteosarcoma which had been misdiagnosed as ABC. We herewith document a case of a pelvic ABC metastatic to the lung, liver, and kidneys. Diagnosis was confirmed by the presence of a break in the *USP6* gene, which is pathognomonic for ABC, in a pulmonary metastasis of our patient. Sarcomatous transformation as an explanation for this behavior was ruled out by demonstrating diploid DNA content in both the pulmonary lesion and the primary tumor.

Introduction

Primary aneurysmal bone cysts (ABC) account for 1–2% of all primary bone tumors and are usually present in the first two decades of life [1]. They are composed of blood-filled spaces separated by connective tissue septa that contain fibroblasts, osteoclast-type giant cells, and reactive woven bone [2]. The pathogenesis of primary ABC is still incompletely understood. In the past, ABCs were considered reactive lesions caused by altered local hemodynamics. More recently, it was shown that primary ABCs contain recurrent chromosomal abnormalities [3–13]. This suggests that primary ABCs are true neoplasms [1]. The differential diagnosis of primary ABC includes other giant cell-containing tumors of the bone, particularly giant cell tumor (GCT) [14]. ABC-like areas can also be seen in association with other tumors such as chondroblastoma (secondary ABC). Furthermore, cases of sarcomatous transformation of ABCs, often occurring after exposure to ionizing radiation, and of misdiagnosed telangiectatic osteosarcoma have been recognized. However, even without sarcomatous transformation, ABC may metastasize as is described in this report.

Clinical history

A 48-year-old woman was referred to our hospital for treatment of a giant ABC of the left ilium, measuring 27.6×22.4×15.9 cm (Fig. 1). Her medical history comprised of a hysterectomy for uterine cervical carcinoma in 1995, strumectomy for adenomatous thyroid hyperplasia in 1998,

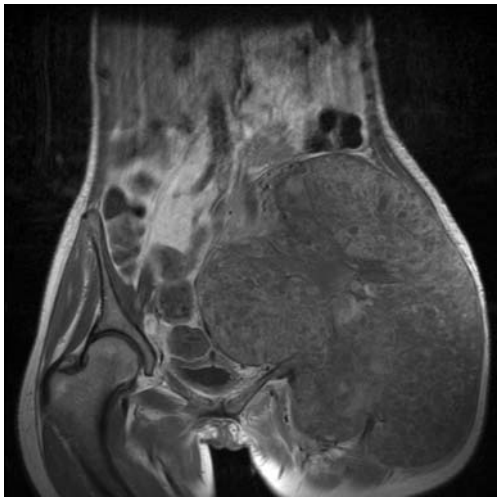

Fig. 1 Magnetic resonance image of the pelvis on admission showing a large ABC of the left ilium

and type II diabetes mellitus since 2004. For the ABC, she had been treated elsewhere with embolization (coiling and alcoholic zein injection; Ethibloc, Ethicon, Johnson & Johnson, New Brunswick, NJ, USA) and repeated surgery, all over a 1-year period. Wide local excision had not been achieved due to massive hemorrhage during surgical interventions. In our hospital, preoperative embolization and percutaneous intralesional alcohol injection were performed and staged resection of the alcohol-treated areas combined with cryosurgery was attempted. Furthermore, off-label systemic treatment with the monoclonal antivascular endothelial growth factor (VEGF) antibody bevacizumab (Avastin; Roche, Basel, Switzerland; Genentech, South San Francisco, California, USA) 10 mg/kg administered intravenously every other week was applied to reduce bleeding tendency. The latter was based on the reports by Kumta et al. and Shinde et al. showing VEGF positivity in 100% and 50% of primary ABCs, respectively [15, 16]. In our patient, plasma and cyst fluid VEGF levels were determined by enzyme-linked immunosorbent assay and found to be elevated (1.12 and 16.5 ng/ml, respectively; in-house control series of 23 healthy women: plasma average=0.166 ng/ml, range=0.028–0.966 ng/ml).

This strategy facilitated near-complete resection of the ABC by limiting intraoperative blood loss. However, clinical heart failure developed in our patient, prompting the discontinuation of bevacizumab. This was followed by a rapid regrowth of the pelvic lesion. After a total of seven surgical sessions, the patient's condition no longer allowed surgical interventions and it was decided to apply radiotherapy at a total dose of 39 Gy. Unexpectedly, at this time, radiographical treatment evaluation showed previously undiscovered lesions in both lungs and in the left kidney. Widespread metastatic behavior of this until then judged benign bone neoplasm was suspected, while differential diagnosis included secondary ABC in a yet unidentified primary bone malignancy, malignant transformation of ABC, misdiagnosed GCT, or telangiectatic osteosarcoma. The patient's condition no longer allowed any treatment and she died 2 years after ABC was first diagnosed. At autopsy, metastases were found in both lungs, both kidneys, and the liver.

Materials and methods

Pathology

Formalin-fixed paraffin-embedded specimens were available from all resections of the primary tumor. Sections from all samples were stained by the hematoxylin and

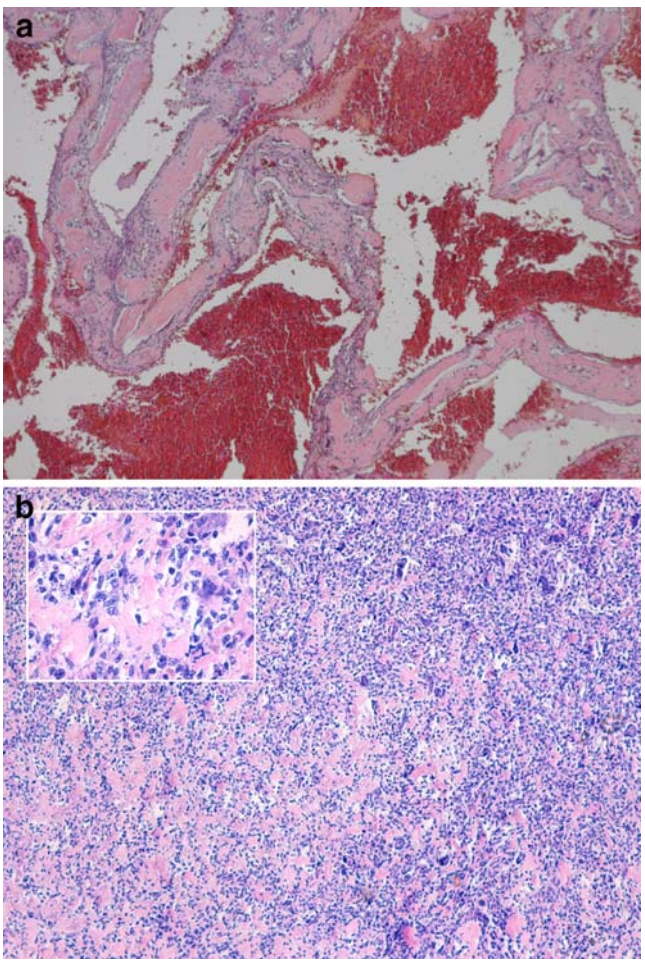

Fig. 2 **a** Photomicrograph of material from the first excision (hematoxylin and eosin, ×50) showing a blood-filled cavity and solid component containing strands of woven bone with interspersed fibroblasts. **b** Photomicrograph of the lung lesion removed at autopsy. A low-powered (hematoxylin and eosin, ×50) and high-powered (*inset*, hematoxylin and eosin, ×200) view show that no blood-filled cystic cavities were found at this site; the lesion only resembled the solid parts of the pelvic location

eosin method and re-examined for evidence of malignancy by multiple expert pathologists (PS, JB, and independent multidisciplinary revision by the Netherlands Committee on Bone Tumors).

Image cytometry

Three samples (two were obtained from the primary tumor at referral to our hospital and during the last resection, respectively, and the third was a pulmonary metastasis obtained during autopsy) were selected for DNA quantification by image cytometry. At least two 50-μm-thick sections were obtained of each sample followed by a 4-μm hematoxylin and eosin section to check for representativeness. An adaptation of the method described by Hedley [17] was used for cell nuclei extraction from the sections. The obtained suspensions were filtered with a Partec 50-μm CellTrics filter (Partec, Münster, Germany) and prepared into a monolayer by cytospin. Nuclei were stained with Feulgen's stain and periodic acid Schiff. The samples were evaluated using a cytometric image analysis system (QPATH, Leica Imaging Systems, Cambridge, UK) that consists of an automated microscope with a digital camera connected to a computer that runs DNA analysis software. Of each specimen, 5,000 nuclei were scanned and a minimum of 2,000 images of tumor cell nuclei were manually selected avoiding debris, necrotic or cut cells, and cell clusters. Lymphocytes were used as the standard internal controls. Histogram quality was evaluated by integrated optical density (IOD) values and its coefficient of variation (CV); $15 \leq IOD \leq 25$ and $CV \leq 5\%$ were considered acceptable. Criteria for ploidy classification were taken from the guidelines of the European Society for Analytical Cellular Pathology [18].

Fluorescence in situ hybridization

Fluorescence in situ hybridization (FISH) was performed on the lung metastasis using BAC probes flanking the *USP6* gene, largely as described [19].

Results

Histological examination of material obtained from the primary tumor in the pelvis during the first surgical procedure showed a multicystic lesion with blood-filled spaces (Fig. 2a). The septa consisted of fibroblasts which showed no cytological features of malignancy such as nuclear atypia or an increased number of mitoses. Interspersed were woven bone fragments. No evidence of an underlying primary lesion causing secondary ABC, neither of evident malignant transformation of ABC, GCT, nor telangiectatic osteosarcoma was found. The morphology of the primary lesion was thus consistent with a primary ABC. The other excision specimens subsequently obtained from this pelvic tumor showed similar histology. The lung lesion resembled the solid parts of the pelvic location; no blood-filled cystic spaces were found here (Fig. 2b). Again, no cytological features of malignancy were found. The three samples (two obtained from the primary tumor and one pulmonary lesion) that were evaluated for DNA content were diploid. FISH performed on the pulmonary lesion showed a break in the *USP6* gene in up to 43% of the nuclei: 24% of the nuclei showed segregation of the signal in addition to two normal (colocalization) chromosomes 17 (Fig. 3, left panel), 15% of the nuclei showed two normal chromosomes 17 and a single red signal (Fig. 3, middle panel), 4% showed one colocalization and one segregation of the signal (Fig. 3, right panel).

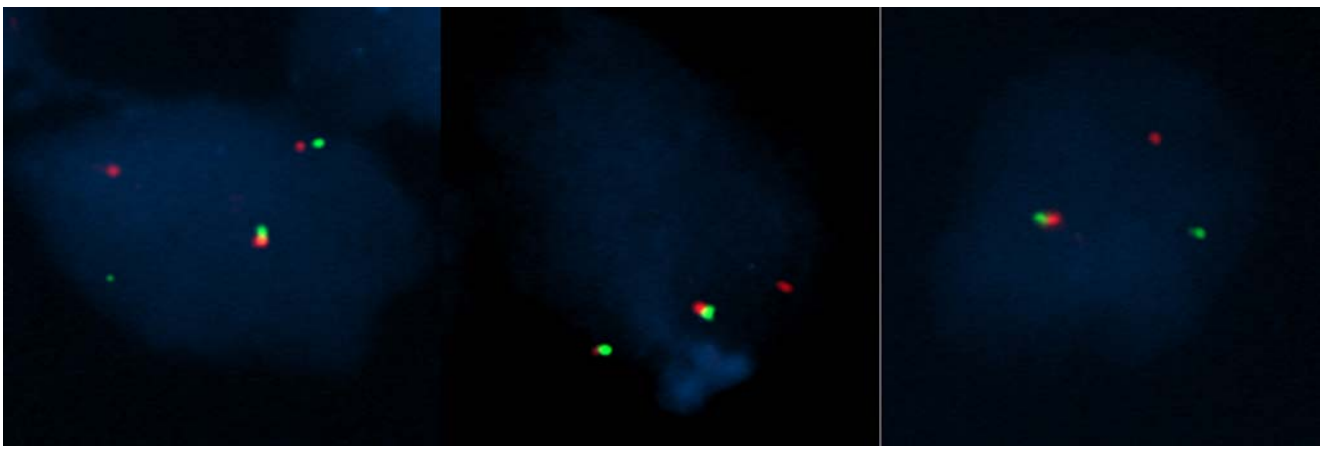

Fig. 3 FISH images of the lung lesion removed at autopsy using BAC probes flanking the *USP6* gene showing segregation of the signal and colocalization of two normal chromosomes 17 (*left panel*), two normal chromosomes 17 and a single red signal (*middle panel*), and one colocalization and one segregation of the signal (*right panel*)

Discussion

Since the discovery of recurrent chromosomal abnormalities, of which t(16;17)(q22;p13) is the most frequent [3–13], primary ABC is no longer considered a reactive lesion but rather a true benign neoplasm [1]. The t(16;17) translocation was later shown to relocate the promoter of CDH11, a gene that is strongly expressed in bone, in front of the *USP6* gene (TRE2, TRE17) [8]. Over the past few years, a series of different translocations has been described in ABC [8, 13], all resulting in oncogenic activation of the *USP6* gene on chromosome 17p13. Thus, the pathogenesis of most *primary* ABCs involves upregulation of USP6 transcription driven by other highly active promoters [20]. The mechanism by which USP6 upregulation causes ABC formation has not yet been elucidated. USP6 rearrangements were shown to be restricted to the spindle cells and were absent in the multinucleated giant cells, inflammatory cells, endothelial cells, and osteoblasts [8]. This suggests that the neoplastic spindle cells induce a vigorous, reactive host response mimicking young granulation tissue, explaining why for a long time the lesions were regarded reactive [8]. The majority of ABC patients are treated by local curettage combined with intraoperative adjuvant therapy (e.g., cryosurgery or phenol application) with local control rates as high as 70–90%. Almost all cases of recurrence can be treated by re-resection [1].

To our knowledge, there are no previous reports of metastatic behavior of primary ABC. Therefore, we considered the possibility of secondary ABC in a yet unidentified primary bone malignancy, malignant transformation of ABC, misdiagnosed GCT, or telangiectatic osteosarcoma. ABC-like areas can be seen in association with GCT, occasionally overgrowing the underlying primary tumor, and ABC can contain solid areas strongly resembling GCT [21]. In contrast with ABC, GCT may metastasize in 2–3% of cases, particularly to the lungs. The diploid DNA content we found cannot exclude GCT with metastatic potential [22, 23]. However, while chromosome 16 and 17 abnormalities have been found infrequently in GCT [24–26], the t(16;17)(q22;p13) translocation [8, 27] and USP6 upregulation [8] are absent in reported cases. We also tested three GCTs and could not detect a USP6 rearrangement (data not shown). Thus, it seems highly unlikely that our case represented metastasizing GCT of bone. Moreover, the USP6 rearrangement was demonstrated in the lung metastasis, indicating that, even if from the beginning it had been ABC secondary to and totally overgrowing an underlying primary bone lesion such as GCT, it is the ABC part that metastasized. Moreover, USP6 rearrangements have not been found in secondary ABC so far [19].

Telangiectatic osteosarcoma and ABC can be radiologically identical and histologically very difficult to distinguish [28–30]. Nuclear atypia and an increased number of mitoses favor telangiectatic osteosarcoma. As an additional diagnostic tool, several reports have suggested the use of DNA cytometry to distinguish these entities. Whereas ABCs are known for diploid DNA content, telangiectatic osteosarcomas show complex karyotypes and numerous gains and losses [31–33]. Moreover, in ABC, CDH11-USP6 fusions as well as USP6 upregulation are pathognomonic, while they are absent in osteosarcoma [8, 9]. So, the diploid nature of the lesion in our case, both in primary as well as metastatic deposits, adequately rules out telangiectatic osteosarcoma as an alternative diagnosis.

In summary, in our patient, all histological samples obtained over a 2-year period were consistent with ABC while lacking cytological features of malignancy. Absence of malignant transformation was supported by DNA content analysis: three selected samples including a pulmonary metastasis all had diploid DNA content. Finally, we found a rearrangement of the *USP6* gene by FISH in 43% of nuclei in the pulmonary lesion, which is within the highly variable range of positive cells (7–82%) reported for ABC [19].We ruled out sarcomatous transformation or GCT as cause of the metastatic behavior and confirmed the diagnosis of ABC by our FISH data.

It can be hypothesized that the numerous surgical and interventional radiological manipulations that were necessary in our patient have facilitated the hematogenous spread of ABC cell clusters. Furthermore, though bevacizumab proved successful in reducing bleeding tendency, recent reports about antiangiogenic therapy-induced malignant progression of tumors to increased invasion and accelerated metastasis raise concern about a similar effect in our patient.

Acknowledgements We thank Dr. K. Szuhai for the help with the FISH analysis and the Netherlands Committee on Bone Tumors for their critical reappraisal of all histological samples obtained from this patient.

Abstract Vascular endothelial growth factor C (VEGF-C) is a well described chemotactic and growth factor for lymphatic endothelial cells. Its inhibition leads to suppression of lymphatic and distant metastases in mouse models. In ovarian cancer, the relationship between VEGF-C expression and tumor behavior has not yet been determined by a quantitative method *in vivo*. Therefore, we used a new technique of RNA extraction from formalin-fixed paraffin-embedded tissue samples and determined the expression levels of VEGF-C mRNA in a study group of 97 ovarian cancer patients. Expression levels were correlated with clinicopathological features and patient survival. High VEGF-C expression was associated with worse overall ($p=0.0393$) and progression-free ($p=0.0155$) patient survival. In the subgroups of serous tumors and high-grade tumors, VEGF-C mRNA was still a negative indicator for patient survival ($p=0.0190$ and 0.0311, respectively). A trend was observed among patients with high clinical stage ($p=0.0634$). In multivariate survival analysis VEGF-C mRNA retained its prognostic influence on progression-free survival ($p=0.006$, $HR=0.319$ with a 95% confidence interval of 0.142–0.720). High VEGF-C expression was further associated with an increased residual tumor mass after primary cytoreductive surgery. We found no correlation of VEGF-C expression with tumor grade, FIGO stage, lymph node, or distant metastases. Our study demonstrates that high VEGF-C expression is associated with aggressive tumor behavior in ovarian cancer. mRNA extracted from paraffin-embedded tumor samples is suitable for VEGF-C gene expression studies.

Introduction

Being the most common cause of death from malignancy of the female genital tract, ovarian cancer represents the 5th most common cause of cancer death in women [1]. Even though primary treatment with extensive surgery and adjuvant chemotherapy with paclitaxel/carboplatin is often successful in the first place, high relapse rates are observed. Overall 5-year-survival for patients with advanced ovarian cancer is only 25–45% [1, 2]. Therefore, an early detection of high-risk patients and new therapeutic strategies for advanced-stage patients are needed. Translational research on tumor tissue is very attractive to identify new prognostic markers and new targets for a tailored therapy. The tissue

archives of pathologic departments harbor large amounts of formalin-fixed paraffin-embedded (FFPE) tumor tissue samples, which together with data on clinicopathological features and follow-up are valuable sources for translational research projects in oncology. Until recently, RNA analysis from FFPE tissue was limited by low quality of the extracted RNA due to fragmentation of RNA and chemical modifications such as protein-RNA interactions [3, 4]. However, in the last few years, there have been some successful attempts proving that FFPE tissue is suitable for gene expression studies, especially by quantitative real-time polymerase chain reaction (PCR) [5–10]. In this study, we used a new RNA extraction technique to assess gene expression in archival FFPE tissue samples from ovarian carcinoma surgical specimens.

Vascular endothelial growth factor-C (VEGF-C) is a well-described chemotactic factor for lymphatic endothelial cells, and its overexpression leads to enhanced lymphangiogenesis and lymph node metastasis in animal cancer models [11–13]. It has also been shown to directly enhance the invasiveness of ovarian cancer cells in vitro [14].

VEGF-C belongs to the gene family of vascular endothelial growth factors and is secreted as a precursor molecule, which is processed by extracellular proteases. Overexpression of VEGF-C is a frequently seen feature of human cancer [15].

The affinity to its receptor vascular endothelial growth factor receptor 3 (VEGFR3), which is expressed on lymphatic endothelial cells in adult tissues, increases upon cleavage towards its major form. VEGFR3 is also expressed on a variety of cancer cells, among them ovarian cancer cells, where it mediates the action of VEGF-C in an autocrine manner [14]. Ovarian cancer spreads besides direct intraperitoneal and hematogenic routes also via lymph vessels. However, although the detection of the soluble tissue factor VEGF-C might be more suitable on the RNA than on the protein level, VEGF-C mRNA expression has not yet been determined in ovarian carcinoma. Therefore, we examined VEGF-C mRNA expression by kinetic reverse transcriptase-polymerase chain reaction (RT-PCR) in 97 epithelial ovarian cancer tissue samples that were formalin-fixed and paraffin-embedded for diagnostic purposes and examined a possible impact of VEGF-C mRNA expression levels on prognosis as well as a correlation with clinicopathological features.

Patients, materials, and methods

Study population and histopathological examination

The study group consisted of patients with primary epithelial ovarian cancer. All patients underwent radical surgery with the aim of maximal cytoreduction at the Department for Gynaecology and Obstetrics, Charité University Hospital (Berlin, Germany), between 1992 and 2005. Resection specimens were formalin-fixed and paraffin-embedded to render a diagnosis at the Institute of Pathology, Charité University Hospital, Berlin, Germany. Hematoxylin and eosin (H&E) stained sections were cut from paraffin-embedded blocks and used for histopathological evaluation. After histopathological diagnosis, the remaining tissue blocks were stored at room temperature. An experienced pathologist (C.D.) reevaluated tumor histopathology and grading. Grading of the tumors was assessed using the Silverberg grading system [16]. Patients were managed with extensive cytoreductive surgery followed by standard combination chemotherapy. Patients were selected by availability of both tissue material and follow-up data. The study was approved by the ethics committee of the Charité University Hospital.

RNA extraction from formalin-fixed paraffin-embedded tissue samples

RNA was extracted from formalin-fixed paraffin-embedded tissue samples of 126 patients by an automated method developed by Siemens Healthcare Diagnostics (Cologne, Germany). A 10-μm thick section was cut from each paraffin block and transferred to a 1.5-ml tube. All tumor samples included in the study contained at least 60% tumor tissue as evaluated by H&E staining. RNA was extracted using a technique based on magnetic beads. In brief, the FFPE section was deparaffinized in xylol and rehydrated in graded solutions of ethanol. The pellet was dried at room temperature for 10 min and subsequently lysed in lysis buffer and SDS for 5 min at 95ºC. Proteinase K was added and incubated for 2 h at 56ºC with shaking. A binding buffer and the magnetic beads were added for binding of the nucleic acids to the beads for 15 min at room temperature with shaking. On a magnetic rack, the supernatant was removed and the beads were washed several times with washing buffers. After addition of an elution buffer and incubation for 10 min at 70ºC with strong shaking, the supernatant was transferred to a new tube. This was followed by DNAse I treatment (NEB, Ipswich, MA, USA) according to the protocol provided by the manufacturer.

Kinetic RT-PCR

Intron-spanning primers and TaqMan fluorogenic probes for VEGF-C gene and the housekeeping gene *RPL37A* were provided by Siemens Healthcare Diagnostics (Cologne, Germany). All reactions were performed on an ABI Prism 7900 instrument (Applied Biosystems, Foster City, CA,

USA) using the Super Script III One-Step qRT-PCR Kit (Invitrogen, Karlsruhe, Germany) according to the manufacturer's instructions and a reaction volume of 10 μl on 384 well plates. PCR conditions were as follows: 30 min at 60°C for reverse transcription and 2 min at 95°C for Taq activation followed by 40 cycles of 95° for 30 s and 60°C for 60 s. All measurements were performed in triplicates. Cycle threshold (CT) values, which indicate the (interpolated) number of PCR cycles until the fluorescence reached its threshold, were determined. After initial measurement of RPL37A, its CT value was adjusted to 26 by dilution of each sample. Subsequently, the measurements for VEGF-C and RPL37A were performed in triplicate. Forty-ΔCT values were calculated as follows: $40-(CT_{VEGFC}–CT_{RPL37A})$. For quality control of raw data, the following preliminary conditions had to be fulfilled for each sample: CT value of the housekeeping gene was in a range between 22 and 28. At least two values were available for each sample and each gene whereas the single values differed by not more than 1 CT. CT values>40 were excluded. Ninety-seven samples met the quality criteria and were finally included in the statistical evaluation. Twenty-nine cases were excluded.

Statistical evaluation

Statistic analyses were computed using SPSS 15 (SPSS, Chicago, IL, USA), GraphPad Prism 4 statistical software (GraphPad Software, San Diego, CA, USA), and JMP 5.0.1.2 (SAS, Cary, NC, USA). The Mann–Whitney and Kruskal–Wallis tests were used for correlation with clinical and pathological features. For grouped data, Fisher's exact test was performed. Survival curves were compared by the Kaplan–Meier method and the log rank test. The Cox regression model was used for multivariate survival analysis. In general, p values<0.05 were considered as statistically significant. VEGF-C mRNA virtual copy numbers were divided in two groups. The cut-off point for survival analysis was chosen by application of a Chi-square based partitioning model of the JMP software.

Results

Study group of patients

The median age at diagnosis was 58 years with a range between 34 and 80 years. The medium follow-up time for event-free patients was 38 months (range, 2–83 months). In the follow-up period, 21 patients (21.6%) died. The median follow-up time for patients with non-progressive disease was 32 (0–67) months. Forty-six patients (47.4%) experienced disease relapse. Most patients had high-stage, high-grade serous adenocarcinomas in accordance with the general population of ovarian cancer patients. Data on adjuvant therapy were available for 92 patients; 89 (96.7%) received standard chemotherapy with a platinum compound and paclitaxel. Two FIGO stage I patients did not receive chemotherapy. The distribution of all clinicopathological factors is given in Table 1.

Expression of VEGF-C in ovarian cancer

RNA was isolated from archival tissue samples, and the expression of VEGF-C mRNA was determined by kinetic RT-PCR. The data distribution as illustrated in Fig. 1 shows

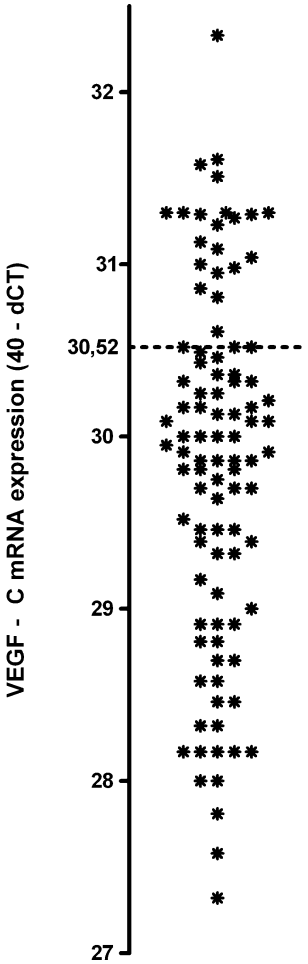

Fig. 1 Expression of VEGF-C in ovarian cancer: distribution of mRNA levels. *Dotted line*, cut-off for survival analysis

a separation of the study cohort in two groups of cases with low and high VEGF-C mRNA expression, respectively. The cutoff for statistical analyses was chosen as described above and defined as 30.52.

Correlation of VEGF-C expression with clinical and pathological features

We observed a correlation between higher VEGF-C expression and the residual tumor size after primary surgery (p=0.037, Fig. 2a). No significant correlation was found between VEGF-C expression and patient age (age≤60 vs. age>60 years; p=0.3495 years), histological type (serous and undifferentiated vs. other; p=0.9725), Silverberg grade (grade 1–2 vs. grade 3; p=0.0967), FIGO stage (FIGO I-II vs. III-IV; p=0.8078), pT stage (pT1–2 vs. pT 3; p=0.8331), or pN stage (pN1 vs. pN0, p=0.4812, Fig. 2b).

Impact of VEGF-C expression on patient survival

VEGF-C mRNA expression revealed its prognostic value in univariate survival analysis. Patients whose tumors expressed high levels of VEGF-C mRNA had a significantly shorter overall survival than patients with low VEGF-C expressing tumors (p=0.039). A favorable prognostic influence of low VEGF-C expression could also be observed for progression-free survival (p=0.016, Fig. 3). Other significant factors for overall and progression-free survival were tumor grade (p=0.011 and p=0.032, respectively), pN (p=0.006 and p<0.001), and residual tumor size <> 2 cm (p=0.001 and p=0.015).

In an exploratory multivariate survival analysis including VEGF-C expression as well as tumor grade, lymph node metastases, and residual tumor size, only a small residual tumor size after surgery was an independent predictor for favorable overall survival (p=0.008, hazard ratio (HR)= 0.176 with a 95% confidence interval (CI) of 0.048 to 0.642). However, in Cox regression analysis for progression-free survival, VEGF-C mRNA retained its prognostic influence (p=0.006, HR=0.319 with a 95% confidence interval of 0.142–0.720). Other significant factors were the postoperative residual tumor mass after surgery (p=0.024, HR=0.330 with a CI of 0.126–0.846) and lymph node metastasis (p=0.008, HR=0.362 with a CI of 0.170–0.770).

VEGF-C expression in ovarian cancer subgroups

We analyzed the influence of VEGF-C mRNA in the most important ovarian cancer subgroups. VEGF-C mRNA was still a negative predictor of overall and progression-free survival and in the subgroups of serous tumors (p=0.0190 and 0.0375, respectively), the group of high-grade (G2-3) tumors (p=0.0311 and 0.0010, respectively). In the group of patients with high clinical stage (FIGO III-IV), a trend could be observed (p=0.0634 and 0.0612, respectively; Fig. 4).

Discussion

Our study demonstrates that high VEGF-C mRNA expression in ovarian cancer is associated with poor patient

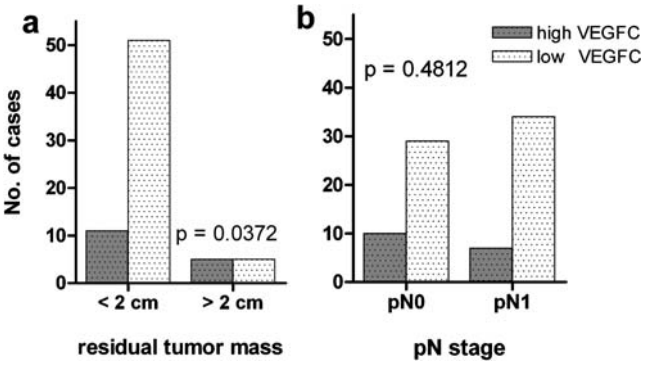

Fig. 2 **a** Correlation of VEGF-C expression with residual tumor mass after primary surgery. **b** Correlation with pN stage (Fisher's exact test, 2-tailed)

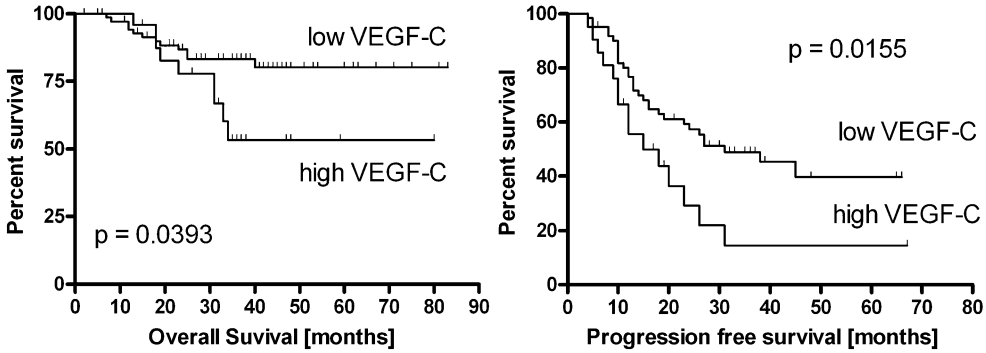

Fig. 3 Kaplan–Meier analysis. VEGF-C mRNA is a positive prognostic factor in ovarian cancer for overall (p=0.0393) and progression-free survival (p=0.0155, log rank test)

outcome and is an independent predictor of progression-free patient survival. Although we do not provide a direct comparison between VEGF-C mRNA determinations in fresh frozen and FFPE tissue, our study indicates that formalin-fixed paraffin-embedded tissue is suitable for the determination of VEGF-C gene expression using kinetic RT-PCR. The successful validation of markers identified in fresh frozen tissue after transfer into formalin fixed tissue analysis has recently been published for the prognostic role of estrogen receptor 1 mRNA expression in ovarian cancer [17, 18]. To our knowledge, this is the first study to determine VEGF-C expression in epithelial ovarian cancer using kinetic RT-PCR and the first to assess VEGF-C mRNA expression in formalin-fixed paraffin-embedded tissue samples. Although the determination of mRNA may not always directly reflect expression of the corresponding protein, in the case of a soluble tissue factor like VEGF-C, the analysis of mRNA levels seems more reasonable.

Our data characterize VEGF-C overexpression as a feature of aggressive ovarian carcinomas. The association with the strong prognostic factor residual tumor mass might explain the lack of independent prognostic value of VEGF-C expression on overall survival. We found a negative impact of high VEGF-C expression on patient outcome in the subgroups of serous tumors and high-grade tumors. A trend could be observed for patients with advanced clinical stage. However, the value of these data may be limited due to small patient subgroups.

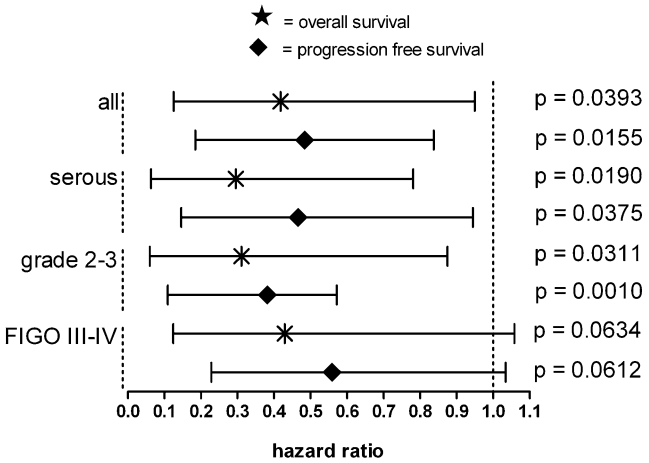

Fig. 4 Expression of VEGF-C mRNA in ovarian cancer subgroups: serous tumors, high grade tumors, and tumors with high clinical stage (log rank test, hazard ratio with 95% confidence interval)

In line with our findings, overexpression and association of VEGF-C with poor overall survival is described in a variety of human cancers [19, 20]. In ovarian cancer, a correlation of VEGF-C with lymph node metastases and worse overall survival is described by several studies using immunohistochemistry. In a study on 59 epithelial ovarian carcinomas, an increase of immunoreactivity was found from benign and borderline tumors towards invasive carcinomas. The expression correlated with lymph node metastases and peritoneal metastases outside the pelvic cavity. High levels of VEGF-C were also associated with worse patient survival [21]. Another study describes the correlation of VEGF-C with tumor grade, clinical stage, and lymph node metastases [22]. In a study on 80 specimens of ovarian cancer, patients with lower VEGF-C expression had a higher five-year survival rate than those with high expression. There was also a correlation between VEGF-C expression and peritoneal metastases outside the pelvic cavity and lymph node metastases [23]. In a study examining 73 ovarian carcinomas, a correlation is described between VEGF-C expression and clinical stage as well as lymph node metastases outside the pelvic cavity [14].

Contrary to the studies cited above, we did not detect an association between VEGF-C expression and nodal state, which indicates that VEGF-C mRNA expression in contrast to VEGF-C protein expression, might not be a predictive factor of lymph node metastasis but might rather reflect other mechanisms by which VEGF-C exerts an influence on tumor aggressiveness.

In vitro studies have elucidated the impact of VEGF-C expression on tumor progression. In cultured ovarian cancer cells, the influence of VEGF-C expression on tumor invasiveness was described as well as a correlation of VEGF-C expression with increased expression of matrix metalloproteinase 2 (MMP-2). An autocrine mechanism of

induction of invasiveness was proposed via VEGF-C-induced MMP-2 expression. This correlation could be confirmed in vivo [14]. VEGF-C exerts its effect on lymphatic endothelial cells through activation of tyrosine kinase receptors, manly VEGFR-3. In lymphatic endothelial cells, VEGFR-3 stimulation is followed by protein C-dependent activation of the p42/p44 mitogen-acivated proteine kinase (MAPK) pathway and induction of Akt phosphorylation [24, 25]. The VEGFR-3-mediated pathways are well described in lymphatic endothelial cells and VEGF-C levels have been shown to correlate with lymph node metastases in several human cancers [25]. However, VEGFR-3 is not solely expressed on lymphatic endothelial cells but also on a variety of different cancer cells, among them ovarian cancer [23], but also prostate cancer [26], leukemia [27], lung adenocarcinoma [28], colorectal carcinoma [29], head and neck cancer [30], and cervical cancer [31]. Thus, VEGF-C may affect cancer development or progression by direct effects on tumor cells. The VEGF-C/VEGFR-3 axis plays an important role in promoting invasion and metastasis of lung adenocarcinoma cells in vitro [28]. Transfection of cells with VEGF-C increased invasive abilities, and expression of both VEGFR-3 and VEGF-C led to an enhancement of invasion in an autocrine manner of stimulation. Blockade of the axis had inhibitory effects on cell invasiveness. Neural cell adhesion molecule CNTN-1 was described as downstream mediator of VEGF-C/VEGFR-3-induced invasion and metastasis through activation of Src/p38 MAPK-mediated C/EBP signaling. CNTN-1 regulates rearrangement of F-actin cytoskeleton and facilitated invasive behavior of carcinoma cells in vitro [28]. Inhibition of VEGF-C leads to inhibition of cellular motility in breast cancer cell lines demonstrating another mechanism of VEGF-C action in vitro [32]. Furthermore, VEGF-C also binds to other receptors like VEGFR-2, which main ligand is VEGF-A and neuropillin (NRP) pointing at another possible interaction with downstream effector cascades [33].

Our finding of an unfavorable prognosis of VEGF-C overexpression may reflect direct autocrine and paracrine effects of VEGF-C on cellular oncogenes. Further studies are needed to investigate the influence of VEGF-C expression on ovarian cancer cells for a better understanding of the VEGF-C action in this tumor.

In summary, VEGF-C expression as detected by quantitative RT-PCR (qRT-PCR) in RNA extracted from FFPE tissue provides additional information to detect high-risk tumors among patients with epithelial ovarian cancer. The validation of these data in future studies including larger numbers of patients seems promising.

Abstract Mammary phyllodes tumors (PTs) are uncommon fibroepithelial neoplasms. On the basis of histologic criteria, PTs can be divided into benign, borderline, and malignant groups; however, the histologic distinction of PTs is often difficult and arbitrary. In breast cancer, promoter hypermethylation is a common phenomenon, but there are no data available concerning methylation status in PTs. The aim of this study was to assess whether the methylation profiles support the classification of PTs into three subgroups. A multiplex, nested, methylation-specific polymerase chain reaction approach was used to examine promoter methylation of five genes (GSTP1, HIN-1, RAR-β, RASSF1A, and Twist) in 87 PTs (54 benign, 23 borderline, and 10 malignant). Immunohistochemical staining for GSTP1 was performed using tissue microarray blocks to determine whether GSTP1 promoter hypermethylation correlated with loss of GSTP1 expression. There was a trend of increasing methylation frequency with increasing grade of PTs. The methylation frequency of all genes and the mean number of methylated genes in borderline and malignant PTs were higher than those in benign PTs; however, there were no statistically significant differences between borderline and malignant PTs. GSTP1 promoter hypermethylation was associated with loss of GSTP1 expression ($p<0.001$). These results suggest that PTs segregate into only two groups on the basis of their methylation profiles: the benign group and the combined borderline/malignant group.

Introduction

Phyllodes tumors (PTs) are rare tumors characterized by myoepitehlial and luminal epithelial component arranged in clefts surrounded by an overgrowing hypercellular mesenchymal component typically organized in leaf-like structure [1].

Several grading systems have been proposed consisting of either two or three subgroups [2–4]. Recently, the 2003 WHO classification of tumors proposed a classification of breast PTs in three categories (benign, borderline, and malignant). This grading system does have some correlation with the biological behavior of PTs [1]. It is important to distinguish benign from borderline and malignant PTs because the former do not metastasize [4]. Tumor grade has been correlated with expression of Ki-67, c-kit, vascular endothelial growth factor (VEGF), p53, CD10, and epidermal growth factor receptor (EGFR) [5–11]. Accurate classification of PTs continues to be challenging under many circumstances; therefore, additional biological markers based on molecular changes are needed.

There is mounting evidence that breast cancer develops by gradual accumulation of interacting epigenetic and genetic events over time [12]. Most recent studies of PTs have concentrated on the genetic changes detected in the tumors [13–15]. On the basis of patterns of chromosomal changes

by comparative genomic hybridization (CGH), Laé et al. classified PTs into two categories (benign and malignant) instead of three categories [13].

DNA methylation is an enzyme-induced chemical modification that usually occurs in cytosine–guanine dinucleotide rich regions (CpG islands) at the gene promoter sites. Aberrant promoter methylation of tumor suppressor genes has been established as an important epigenetic mechanism for gene silencing [16, 17]. Although inactivation of multiple tumor suppressor genes by aberrant promoter hypermethylation has been reported in breast cancer [12, 18, 19], methylation status in PTs has not been well documented in the literature with only one published report in a small series of eight PTs [14].

The purpose of this study was to assess whether the methylation profiles support the classification of PTs into three subgroups. A multiplex, nested, methylation-specific polymerase chain reaction (MSP) approach was used to examine promoter methylation of five genes [glutathione *S*-transferase pi gene (GSTP1), HIN-1, retinoic acid receptor-β (RAR-β), ras association domain family member 1 (RASSF1A), and Twist] in 87 PTs (54 benign, 23 borderline, and 10 malignant). These genes were selected because they are frequently methylated in breast cancer, but not in normal breast tissues [12, 18, 19]. We also studied the expression of GSTP1 protein by immunohistochemistry and compared its expression with GSTP1 methylation status.

Materials and method

Tumor samples

The histologic files of the four participating institutions (Chonnam National University Medical School Hospital, Chonnam National University Medical School Hwasun Hospital, Cell In All Private Clinics, and Foryou Private Clinics) between January 1999 and January 2009 were searched for PTs of the breast. Tumor tissue use was approved by the local ethical committee.

At least two pathologists reviewed and graded the cases as benign, borderline, or malignant PTs according to the WHO guidelines [1]. A total of 87 cases were reviewed, including 54 benign, 23 borderline, and 10 malignant PTs. These were obtained from 84 patients, with one tumor from each of 81 patients and two tumors (including the original and recurrent tumors) from each of three patients. One representative paraffin block from each case was subjected to methylation study and immunohistochemistry.

Sodium bisulfite treatment and MSP

For DNA extraction, one 5-μm tissue section was deparaffinized with xylene. On a mirror-imaged hematoxylyn–eosin-stained slide, the region of interest was manually scraped off to ensure a specific cell population of more than 80% in the preparation. The scraped tissue was extracted in 27 μL TNES (10 mM Tris, pH 8.0, 150 mM NaCl, 2 mM EDTA, 1% SDS) containing 3 μL proteinase K for 4 h at 52°C. The tissue extract was heat inactivated at 99°C for 10 min and separated by centrifugation at 13,000 rpm for 30 s. A 13.5 μL sample of the supernatant was used as a DNA source for sodium bisulfite treatment [20]. DNA was heated 10 min to 99°C, quick chilled, and incubated with 1.5 μL of 2 mol/L NaOH for 30 min at 42°C. Freshly prepared 3.6 mol/L sodium bisulfite containing 1 mmol/L hydroquinone was mixed with DNA, then overlaid with oil, and incubated at 55°C for 5 h in the dark. The sample was desalted using ion exchange columns (Amersham, Piscataway, NJ, USA). DNA was precipitated with 200 μL absolute alcohol, washed with 70% ethanol, air-dried, and resuspended in water (20 μL). Samples were stored at −80°C until use.

The methylation status of the five different genes was analyzed by MSP using a multiplex, nested PCR approach, as described previously [19]. Step 1 of the nested MSP was performed with primer sets (sense and antisense) for all five individual genes in each reaction. Step 1 primers contained no CpG dinucleotides and flanked the CpG-rich promoter regions of their respective targeted genes. Hence, these primers did not discriminate between methylated and unmethylated nucleotides after bisulfite treatment. A negative control for the assay (water only) and unmethylated (human sperm) and methylated (MDA-MB-231 breast cancer cells) DNA controls were included in each set of multiplex step 1 reactions. Depending upon the starting amount of DNA, PCR products from step 1 reactions were diluted (1:5 to 1:1,000) in water and subjected to the second step of the MSP reaction. This incorporated two sets of primers for each gene (labeled as unmethylated or methylated), which were designed to recognize differences arising from bisulfite-induced modifications of unmethylated cytosines. All of the primer sequences and PCR conditions for this nested MSP approach have been published previously [21–23]. The PCR products underwent electrophoresis on 2% agarose gel and were visualized under UV illumination using ethidium bromide staining. Any tumor sample that reliably yielded a PCR product in the methylated reaction was considered positive for promoter hypermethylation.

Tissue microarray construction

The arrays were constructed with a 2-mm punch on the Beecher arrayer. The array layout in grid format was designed using Microsoft Excel. Hematoxylin-and-eosin-

stained sections of PTs were reviewed, and the area of interest was marked on the slide. Using a marker pen, the corresponding region was circled on the archival "donor" paraffin block. The samples were then arrayed on to a "recipient" blank block. A total of 82 PTs were subjected to at least one punch per case; 78 cases had two microarray cores and four cases had one core.

Immunohistochemistry

Immunohistochemical analysis of GSTP1 protein expression was performed by the avidin–biotin–peroxidase complex method. Sections were deparaffinized and were placed in a microwave oven with a 2.1% citric acid buffer solution (pH 6.0) for 10 min to retrieve the antigens. After microwave processing, the sections were incubated overnight at 4°C with primary anti-GSTP1 antibody (1:100 dilution, clone GSTpi, Novocastra, Burlingame, CA, USA). The streptavidin–horseradish peroxidase (Research Genetics, Huntsville, AL, USA) detection system was applied, followed by 30 min of incubation at room temperature. After washing, the tissue sections were developed with a peroxidase substrate solution (3,3-diaminobenzidine tetrahydrochloride). The sections were counterstained with hematoxylin, dehydrated, and mounted. For negative controls, sections were treated similarly with the exception of the primary antibody. Because the epithelial component mostly displayed a reaction pattern as seen in the normal breast, GSTP1 immunohistochemical staining was only assessed in stromal components. GSTP1 expression was considered to be positive when >10% of stromal cells exhibited cytoplasmic or nuclear staining [24]. For cases with more than one TMA core, the decision of positivity was based on the average percentage of positive cells.

Statistical analysis

The linear by linear association for trend was used to assess the statistical significance in the proportion of samples in which methylation was detected with increasing grade of PTs. The trend of methylation increase with PTs grade was determined using the Spearman's rank correlation test. The χ^2 test was used to determine the difference in methylation frequencies between groups. One-way ANOVA was used to assess the differences of age and tumor size between the benign, borderline, and malignant PTs. When there was a statistically significant difference between three groups of PTs, the Bonferroni correlation was used to compare the difference. For all statistical analyses, the SPSS system for personal computer (version 13.5 for windows; SPSS INC., Chicago, IL, USA) was used, and $p<0.05$ was regarded as statistically significant.

Results

Clinicopathological characteristics

For the benign, borderline, and malignant PTs, the mean age was 40, 43, and 43 years, respectively, and the mean tumor size was 4.0, 5.4, and 5.5 cm, respectively. There was an increase in tumor size with increasing degree of malignancy, but the differences were not statistically significant. The median follow-up period was 30 months (range, 4–103 months). Nine patients experienced recurrent disease (seven benign and two borderline). Six of these had positive margins. The mean time to recurrence was 24 months, with a median of 22 months and range of 10–47 months. The original and recurrent tumors of three patients with benign PTs were included in this study. Histologically, two recurred as benign PTs and one recurred as a malignant PT.

Frequency of promoter hypermethylation

Representative examples of the MSP products obtained from step 2 of the nested MSP analysis for five genes are shown in Fig. 1. The frequency of methylation of each gene locus in benign, borderline, and malignant PTs is shown in Table 1. There was a trend of increasing methylation frequency with increasing grade of the PTs. Statistically significant differences among the three subgroups of PTs were found in all of the genes, except for GSTP1. Overall significant differences in methylation frequency were observed for HIN-1 ($p<0.005$), RAR-β ($p<0.001$), RASSF1A ($p<0.001$), and Twist ($p<0.001$; Table 1). In particular, RAR-β, RASSF1A, and Twist methylation frequency were significantly higher in borderline ($p<0.005$, $p<0.005$, and $p<0.001$, respectively) or malignant ($p<0.05$, $p<0.005$, and $p<0.01$, respectively) PTs compared to benign PTs; the methylation frequency was similar between borderline and malignant PTs. HIN-1 methylation frequency level was also higher in borderline

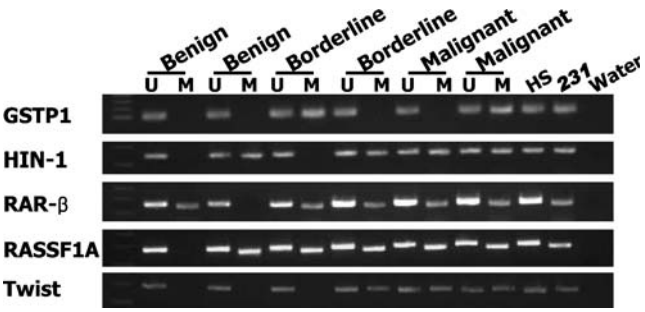

Fig. 1 Representative results of nested methylation-specific PCR analysis for HIN-1, GSTP1, RAR-β, RASSF1A, and Twist in phyllodes tumors of the breast. *Lanes U* and *M* correspond to unmethylated and methylated DNA, respectively. DNA from human sperm (*HS*) and MDA-MB-231 (*231*) breast cancer cell line served as positive controls for unmethylated and methylated genes, respectively. Water served as negative control

Table 1 Frequency of methylation in benign, borderline, and malignant phyllodes tumors

Gene	Frequency of methylation			*p* value			
	Benign (*n*=54)	Borderline (*n*=23)	Malignant (*n*=10)	Linear by linear	Be vs. Bo[a]	Be vs. Ma[a]	Bo vs. Ma[a]
GSTP1	6 (11.1%)	6 (26.1%)	3 (30.0%)	0.062	0.097	0.140	1.000
HIN-1	20 (37.0%)	14 (60.9%)	9 (90.0%)	0.001	0.054	0.004	0.123

[a] Analyzed by χ^2 test

or malignant PTs compared to benign PTs; however, a statistically significant difference was only found between benign and malignant PTs ($p<0.01$). The methylation frequencies for HIN-1 did not differ significantly between borderline and malignant PTs.

The mean numbers of methylated genes were 1.63, 3.13, and 3.70 in benign, borderline, and malignant PTs, respectively. The differences between the benign and borderline and between the benign and malignant PTs were statistically significant ($p<0.001$ and $p=0.001$, respectively). A statistical difference was not detected between borderline and malignant PTs. There was a significant trend toward increased numbers of methylated genes with the increased grade of PTs (Spearman's $\rho=0.658$, $p<0.001$; Fig. 2). No differences were observed between the nonrecurrent and recurrent PTs for either the methylation frequency of all genes or the mean number of methylated genes (data not shown).

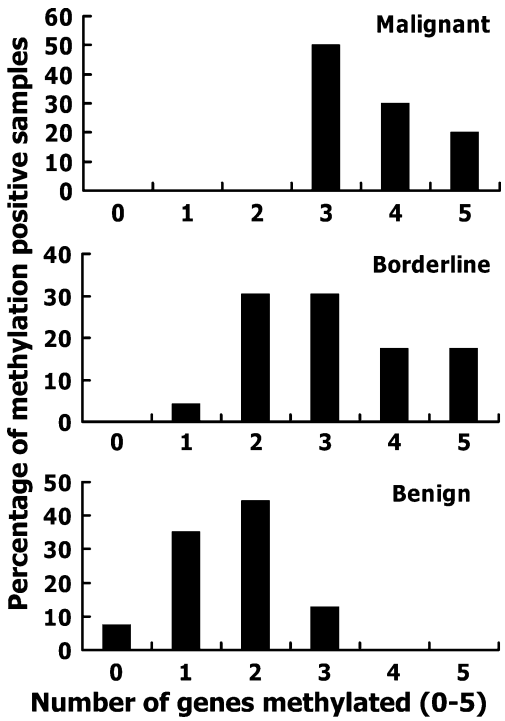

Fig. 2 Gene methylation increases with severity of phyllodes tumors. The trend was statistically significant ($p<0.001$)

Immunohistochemical analysis of GSTP1

Immunohistochemical staining using anti-GSTP1 antibody was performed to determine if GSTP1 promoter hypermethylation correlated with loss of GSTP1 expression. The epithelial and stromal cells of PTs showed both nuclear and cytoplasmic immunoreactivity for GSTP1 (Fig. 3). Loss of GSTP1 expression (negative) was observed in eight of 54 (14.8%) benign, four of 24 (17.4%) borderline, and three of 10 (30.0%) malignant PTs. Loss of GSTP1 expression was almost exclusively restricted to stromal cells. When the GSTP1 expression was compared against the methylation status of GSTP1, GSTP1 expression was more frequently lost in PTs with GSTP1 methylation than in PTs with unmethylated GSTP1 ($p < 0.001$; Table 2).

Discussion

This is the first large study comparing methylation profiles in the three subgroups of PTs. In this study, we have shown statistically significant differences in the methylation frequency and in the mean number of methylated genes between benign and borderline and between benign and malignant PTs. A statistical difference was not detected between the borderline and malignant PTs. On the basis of their methylation profiles, PTs can be segregated into two groups: the benign group and the combined borderline/malignant group.

Histologically, PTs are classified as benign, borderline, or malignant on the basis of stromal hypercellularity, cellular pleomorphism, mitotic rate, character of margins, stromal pattern, and existence of heterogeneous stromal elements [1]. Because only the borderline and malignant PTs metastasize, it is very important to distinguish benign from borderline and malignant PTs [4]. However, the

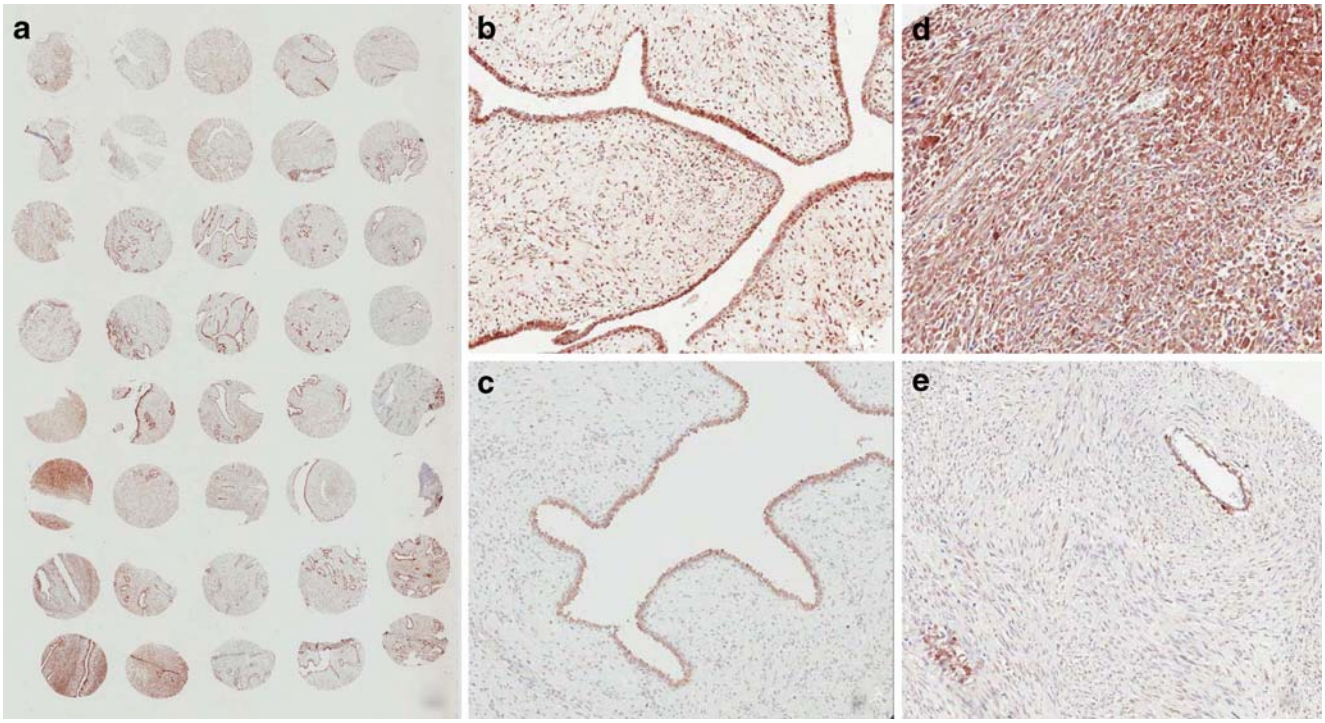

Fig. 3 Immunohistochemical staining of GSTP1 using tissue microarray blocks (**a**). Benign (**b**) and malignant (**d**) phyllodes tumor show diffuse nuclear and cytoplasmic staining representing a positive expression of GSTP1. Loss of GSTP1 expression is observed in benign (**c**) and malignant (**e**) PTs. Stromal cells were negative but epithelial cells were positive for GSTP1

distinction based on histological criteria between benign and borderline/malignant PTs can be difficult. Thus, many additional biological markers have been evaluated to distinguish benign from borderline/malignant PTs.

Many biological markers have been used in the evaluation of PTs. Stromal expression of Ki-67, p53, c-kit, VEGF, and EGFR was associated with grade of PTs [5–8, 11]. Benign, borderline, and malignant PTs differentially expressed CD10, p53, Ki-67, and c-kit [9, 10]. Expression of these markers significantly increased in borderline and malignant PTs vs. benign PTs, but there was no difference between borderline and malignant PTs.

Many genetic, epigenetic, and environmental factors contribute to the development of cancers. Most recent studies of PTs have concentrated on the genetic changes detected in the tumors. In a series of 30 PTs (nine benign, 12 borderline, and nine malignant), Laé et al. analyzed chromosomal changes detected by CGH in comparison with histological data [13]. Borderline and malignant PTs could not be differentiated on the basis of their genomic imbalances (e.g., presence and number of chromosomal changes and presence of 1q gain and/or 13q loss). Conversely, benign tumors could be significantly differentiated from the group composed of borderline and malignant tumors. This suggests that a classification of phyllodes tumors of the breast into two categories (benign and malignant) better reflects the genetic reality. Lv et al. also confirmed that molecular CGH features of borderline and malignant PTs were similar [15]. They used CGH to identify chromosomal aberrations in 36 cases of benign, borderline, or malignant PTs of the breast. That study demonstrated that in benign PTs, the number of gains and losses were in balance, while in the borderline and malignant groups, gains occurred more frequently than losses. A difference in chromosomal aberrations between borderline and malignant PTs was not evident. However, based on cluster analysis of array-CGH in 126 PTs (37 benign, 41 borderline, and 48 malignant), Jones et al. found more similarity between benign and borderline PTs compared to malignant tumors [14].

Table 2 GSTP1 expression in phyllodes tumor according to GSTP1 promoter methylation

	GSTP1 negative	GSTP1 positive	*p* value
GSTP1 unmethylated	7 (10.4%)	60 (89.6%)	<0.001
GSTP1 methylated	8 (53.3%)	7 (46.7%)	

Aberrant promoter methylation of tumor suppressor genes has been established as an important epigenetic mechanism for gene silencing [16, 17]. In this study, we have demonstrated a significant correlation between the promoter hypermethylation of GSTP1 and the data obtained

from immunohistochemical analyses. Promoter hypermethylation of GSTP1 resulted in the loss of GSTP1 protein expression in samples with methylation. These data provide evidence that GSTP1 promoter hypermethylation is a major mechanism involved in GSTP1 gene inactivation, resulting in impaired GSTP1 function during PTs development. However, PTs without GSTP1 hypermethylation were also negative for GSTP1 expression. These observations suggest that promoter hypermethylation is not the only mechanism of silencing the GSTP1 gene. Other mechanisms are implicated in the GSTP1 gene silencing in such tumors.

Although aberrant promoter hypermethylation has been well reported in breast cancer [12, 18, 19], there have not been many reports on the methylation status in PTs. There is only one study that has described the methylation of the p16 gene in eight borderline and malignant PTs [14]. They revealed p16 methylation in two of three malignant and five of five borderline PTs. In the present study, we graded PTs into benign, borderline, and malignant subgroups according to the guidelines of the WHO [1]. A panel of five gene promoters involved in breast carcinogenesis was assessed by nested MSP. Nested MSP is reported to be more sensitive than conventional MSP [25]. Methylation frequencies of HIN-1, RAR-β, RASSF1A, and Twist were significantly higher in borderline or malignant PTs than in benign PTs. However, no differences were observed between borderline and malignant PTs. The mean number of methylated genes was significantly different between benign and either borderline or malignant PTs, whereas the mean number of methylated genes was similar between borderline and malignant PTs. Promoter hypermethylation may aid in distinguishing benign from borderline or malignant PTs. This study provides evidence that borderline and malignant phyllodes tumors cannot be differentiated on the basis of promoter hypermethylation. Our study is limited by the small number of cases and by a relatively modest number of genes tested. Further studies with larger sample sizes and more genes are required to validate our results.

No association was identified between the methylation of each gene and the recurrence of PTs. Whether aberrant promoter methylation in PTs is associated with prognosis remains to be elucidated by long-term follow-up of our cohort.

In summary, we show for the first time that borderline and malignant PTs display similar promoter methylation profiles. These results suggest that PTs segregate by methylation profiles into only two groups: benign and borderline/malignant PTs.

ORIGINAL ARTICLE

Encapsulated apocrine papillary carcinoma of the breast—a tumour of uncertain malignant potential: report of five cases

Melanie Seal · Christine Wilson · Gregory J. Naus · Stephen Chia · Terry C. Bainbridge · Malcolm M. Hayes

Received: 4 June 2009 / Revised: 24 August 2009 / Accepted: 1 September 2009 / Published online: 28 October 2009

Abstract Five cases of an unusual encapsulated apocrine papillary tumour are reported. All presented as cystic masses in the breast of women aged 44–84 years. Imaging studies showed a complex cyst often with one or more mural nodules. The key histological features are similar to those of classical encapsulated papillary carcinoma in that myoepithelial cells were absent within the papillary structures and at the periphery of the cyst. All were pure apocrine in type and showed variable degrees of cytological atypia and mitotic activity. All lacked evidence of malignancy in the breast tissue outside of the lesion. Sentinel lymph node biopsies performed in three of the cases were negative for metastases, and all have behaved in a benign fashion.

Introduction

Encapsulated papillary carcinoma (intracystic) of the breast (EPC) is a rare entity representing approximately 0.5–2.0% of all breast tumours [1]. Traditionally considered to be a variant of ductal carcinoma in situ (DCIS) characterised by papillary carcinoma within a cystically dilated duct, many authors now believe these tumours have malignant potential. This is based on evidence that they lack a myoepithelial cell layer at their periphery which pathologists consider a determinant for invasion. Furthermore, there have been case reports of intracystic papillary tumours metastatic to axillary lymph nodes and distant sites [1–3].

We present five cases of encapsulated apocrine papillary carcinoma of the breast and evaluate the clinical outcome of these patients. The objectives of this study are to describe the clinical, radiological, and pathological findings of these rare tumours and to discuss their malignant potential. Our goal is to aid clinicians and pathologists to make treatment decisions for patients who present with this diagnostic challenge.

Materials and methods

The clinical records, radiographical images, and pathology slides from five patients with suspected EPC of apocrine type seen during 1995–2009 at our centre were reviewed. Full ethics approval was obtained before commencing study.

Hematoxylin and Eosin (H&E) stained slides were available in all cases, and blocks were obtained for immunostaining of myoepithelial cells using a Ventana Benchmark XT autostainer. The antibodies used and staining protocols are summarised in Table 1.

Results

Clinical data

The clinical details are summarised in Table 2. All patients underwent partial mastectomy, and three had sentinel lymph node procedures. One patient received radiotherapy to the breast. None received systemic therapy. Although four patients had further biopsies, all were negative for malignancy, and no patient had recurrence. The length of follow-up in each case is given in Table 2.

Breast imaging

Mammograms were obtained in all cases. Four of the five patients showed soft tissue masses ranging in size from 3 to 12 cm (Fig. 1). Ultrasound examination showed a complex cyst with a mural nodule or intracystic papillary lesion in four patients. These nodules measured between 8 and 16 mm (Fig. 2). One case showed pleomorphic calcifications within the mass located in the cyst. One patient had multiple mural nodules with increased vascularity seen on Doppler ultrasound within them.

Table 2 Patient demographic information, treatment, and outcome

	Case 1	Case 2	Case 3	Case 4	Case 5
Age (years)	44	44	84	50	50
Clinical presentation	Patient palpated a new mass	Recurrent cyst requiring repeated drainage over several years. Mammogram showed area of concern	Bilateral recurrent cysts requiring drainage. New onset mastalgia in left breast	Bilateral recurrent cysts with pain (left>right)	Recurrent left breast cyst
Surgery	Left partial mastectomy	Left partial mastectomy and sentinel lymph node biopsy	Left partial mastectomy	Left partial mastectomy with reexcision and sentinel lymph node biopsy	Left partial mastectomy and sentinel lymph node biopsy
Radiation	No	42.5 Gy in 16 fractions	No	No	No
Systemic therapy	No	No	No	No	No
Follow-up (months)	36	17	41	7	3
Further procedures	Right breast biopsy for nodularity on clinical exam—negative for malignancy	Left breast pain with abnormal mammographic findings. Left breast biopsy—negative for malignancy	Left breast biopsies×2 due to new nodularity and pain at site of scar—negative for malignancy	MRI - bilateral cysts and enhancement at 6 o'clock right breast. US—hypoechoic nodular lesion. Biopsy—tubular adenoma	None
Postexcision recurrence	None	None	None	None	None
Status	Alive	Alive	Alive	Alive	Alive

Pathological findings

Core biopsies were performed in four patients—two were interpreted as malignant (high-grade apocrine DCIS and low-grade apocrine papillary carcinoma), one as apocrine neoplasm of uncertain malignant potential, and one as fibrocystic change with apocrine metaplasia. These all went on to partial mastectomies with two requiring fine wire localisation prior to surgery. The cytology of the fine needle aspirates performed prior to excision in four of the cases showed apocrine cells and histiocytes that were interpreted as consistent with fibrocystic change.

Macroscopic findings

All cases showed a cystic mass that ranged in size from 1.2 to 4.5 cm. The cysts were received in a collapsed state which accounts for the discrepancy between the gross size and the size measured on imaging studies. The entire papillary component of the lesion was submitted for histological evaluation in all cases, and the encompassing cyst wall was sampled extensively. No other gross abnormalities were identified. The adjacent tissue was sampled in all cases. Fibrocystic changes were identified in the adjacent breast tissue.

Microscopic findings

All lesions were largely cystic with one or more papillary nodules attached to the wall of the cyst. A true papillary architecture characterised by cores of sclerotic fibrovascular stroma was observed within the tumours (Fig. 3). In all cases, the papillary structures were covered by a layer of proliferated apocrine cells (Fig. 4). The apocrine cell layer varied in complexity from a single cell layer through to multilayered epithelium forming a pseudopapillary and/or cribriform architecture. Apocrine cells also lined the cyst wall in all cases. There was no evidence of an infiltrative pattern outside the wall of the cyst. The apocrine cells showed a variable degree of cytological atypia but nuclear

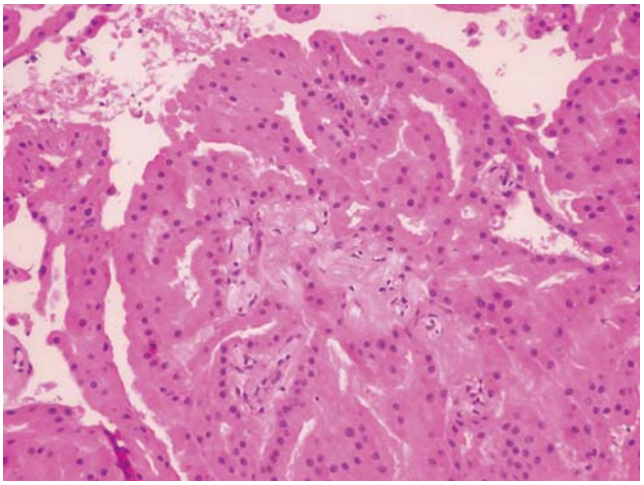

Fig. 4 Papillary structures covered by apocrine cells (H&E×100)

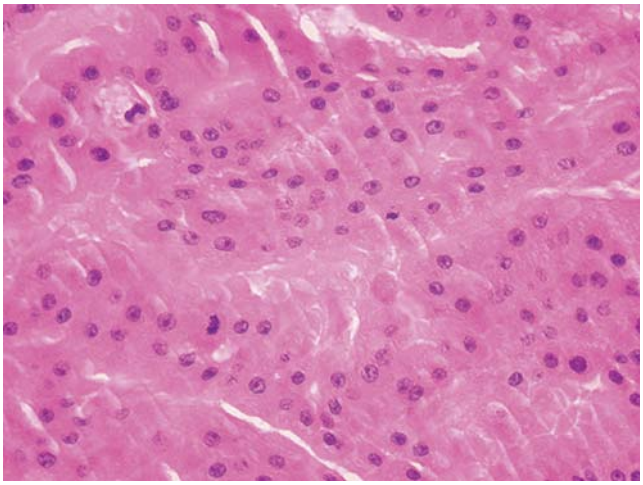

Fig. 6 Mitoses present within the apocrine cells of the papillary processes (H&E×200)

pleomorphism was mild in three cases. One case showed large nuclei with prominent nucleoli (Fig. 5). Mitoses were seen within the apocrine cells in four cases but no atypical mitoses were detected (Fig. 6). There was no zonal necrosis but individual cell necrosis was seen focally in all but one case, possibly attributable to ischaemia. Two cases contained calcifications. Lymphovascular invasion was absent. There was no evidence of in situ or invasive disease in the surrounding breast tissue but one case had a nearby focus of atypical ductal hyperplasia (ADH). Three patients underwent sentinel lymph node biopsies which were negative for metastases.

Immunohistochemical features

In all five cases, the presence of myoepithelial cells was investigated using a panel of immunostains (Table 1). No myoepithelial cells were detectable within the papillary structures or at the periphery of the cyst (Figs. 7 and 8). The normal adjacent breast tissue provided good internal control staining. Three of the five cases were tested for oestrogen receptor, progesterone receptor, and Her2–neu and were found to be negative. The apocrine nature of the lesions was confirmed by positive immunostaining for gross cystic disease fluid protein-15 (GCDFP-15; Fig. 9).

Discussion

Encapsulated (intracystic) papillary carcinomas often present as a palpable mass in the subareolar region most frequently in older women. They may be associated with nipple discharge which in some instances is blood-tinged. The associated cysts can vary in size from a few centimetres to 10 cm. [4]. Mammography of these

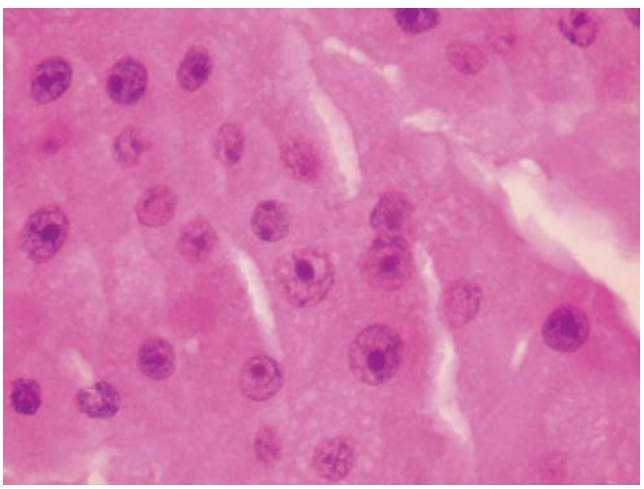

Fig. 5 Atypical apocrine cells lining the papillary processes in one case (H&E×400)

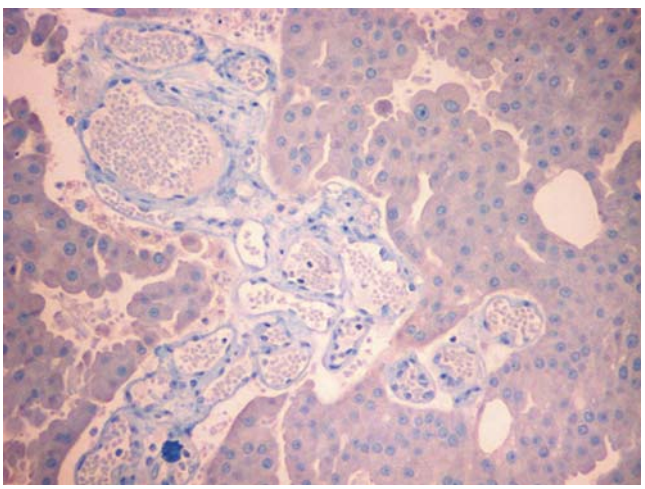

Fig. 7 Immunostain for p63/heavy-chain myosin exhibiting absence of myoepithelial cells within the papillary processes (×200)

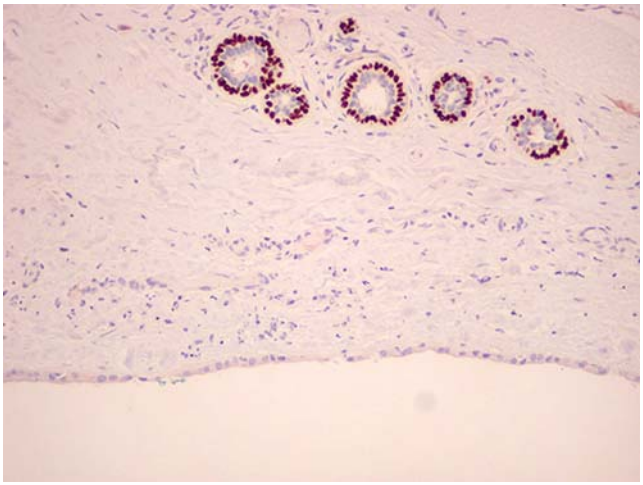

Fig. 8 Immunostain for p63 to show absence of myoepithelial cells at the periphery of the cyst and normal adjacent lobules (×200)

carcinomas reveals a well-circumscribed mass [5]. They are often single, ill-defined, and lobulated and occasionally show microcalcifications. Ultrasonographic findings include a hypoechoic lesion with posterior enhancement and a cystic portion that may show septation [6].

Originally thought to be a form of DCIS arising within a cyst, EPC is now thought to be a carcinoma with "expansile" or "pushing" invasion [2, 4, 7, 8] akin to the invasive pattern of nodular high-grade invasive ductal carcinomas. This conclusion is based on the absence of myoepithelial cells within the lesion and at its periphery, and because a few cases have been described to develop metastatic spread to the regional lymph nodes [3]. However, it has been shown that in some breast proliferations the myoepithelial cells show reduced staining or complete loss of expression of some myoepithelial markers [9, 10]. Alternatively, it has been argued that the myoepithelial cells could appear to be falsely absent due to attenuation secondary to distention of the cyst [11], and indeed, some cases otherwise acceptable as EPC show small foci of residual myoepithelial cells in the cyst wall that do not negate the diagnosis. Furthermore, given the observation that absence of myoepithelial cells is known to occur in some benign "infiltrative" lesions of the breast such as microglandular adenosis, this cannot be used as an absolute indicator of invasive malignancy. Other authors still consider EPC to be an in situ process because of the presence of basement membrane material at the periphery of the lesion [12]. However, one of the cases included in that report showed micrometastases to the axillary nodes which makes a purely in situ lesion improbable. Nevertheless, clinically malignant behaviour in EPC is distinctly unusual especially in lesions that measure less than 2 cm in diameter [13]. Moreover, most cases are treated effectively with complete surgical excision only. Currently, it is our practice pattern to recommend a sentinel lymph node biopsy at the time of wide excision but not an axillary lymph node dissection. Others recommend that EPC be treated the same as DCIS [13].

We report five patients with a pure apocrine papillary intracystic tumour very similar to classical EPC of the breast. These tumours are cystic and contain one or more mural nodules with a papillary architecture lined by apocrine epithelial cells that are apparently of one type. Furthermore, they lack identifiable myoepithelial cells both within the papillary component and at the periphery of the cyst. Care was taken in this series of cases to ensure that the myoepithelial layer was absent by performing multiple immunostains for these cells on many blocks from each case. Furthermore, the entire papillary component of the lesion was examined, and the cyst wall was sampled generously. Although several cytological and architectural patterns of EPC have been recognised [14, 15], to the best of our knowledge, a purely apocrine variant has not been described in the pathology literature. Certainly, there are no follow-up studies of lesions of this type upon which to base logical management decisions. There are two case reports of apocrine carcinomas that presented as cystic lesions [16, 17]. Both of these lesions showed focal infiltration beyond the wall of the cyst, and one case showed apocrine DCIS in adjacent ducts. In both cases, the apocrine cells showed cytological features of malignancy.

In most breast proliferations, particularly in papillary lesions, the presence of apocrine cells favours a benign process [13]. However, there is evidence that some apocrine lesions are clonal, are associated with ADH [18], and may progress to malignancy [19–23]. The absence of definite cytological features of malignancy including marked nuclear enlargement; marked variation in nuclear size, macronucleoli, irregular nucleoli, atypical mitotic figures,

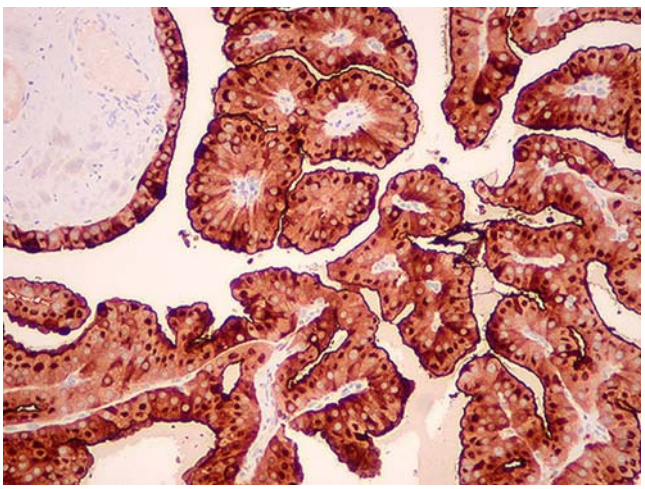

Fig. 9 Immunostain for GCDFP-15 confirming the apocrine nature of the lesion (×100)

and necrosis; and the absence of DCIS in the adjacent breast argue in favour of a benign lesion. Rigid cytological criteria for malignancy are a prerequisite for distinguishing between atypical apocrine adenosis and apocrine malignancy within the small tubular units of adenosis [20, 24], but low-grade apocrine DCIS involving large ducts outside of adenosis lesions may not show those overt cytological features of malignancy [25–28]. Benign apocrine cysts usually have a double layer of apocrine cells and myoepithelial cells while benign papillomas have myoepithelial cells within the papillary processes [29–31]. However, it has also been reported that benign apocrine lesions in the breast sometimes lack myoepithelial cells [32]. Therefore, this lesion could be interpreted as intracystic apocrine papillary hyperplasia or an intracystic apocrine papilloma.

In order to comply with the traditional terminology of World Health Organization classification of breast tumours, we have chosen to adopt the terminology of "encapsulated apocrine papillary carcinoma" for the lesion described herein. However, we stress that the malignant potential of this lesion has not yet been proven, and these lesions are probably best considered to be tumours of uncertain malignant potential for the purposes of clinical management. Furthermore, the term tumour is used in a broad way to indicate the uncertainty as to whether or not this lesion is a form of papillary hyperplasia or a true neoplasm. If neoplastic, distinction between papilloma and EPC remains an academic debate. Although the behaviour of the apocrine variant of EPC appears to be favourable based on this series of five cases, this study is limited by the small sample size and the short follow-up, particularly relevant to a low-grade malignancy. Since, in the available literature, there are no reports of such lesions behaving in a malignant fashion clinically, and since none of the cases has recurred or metastasized, we prefer to regard them as of uncertain malignant potential. This terminology is used to indicate to clinicians that this lesion should not be treated in the manner of typical invasive ductal carcinoma of the breast. In particular, the role of radiotherapy in the management of these lesions requires more evidence that these lesions are clinically malignant.

Conflict of interest statement We declare that we have no conflict of interest.

Abstract CpG island methylator phenotype (CIMP) refers to a subset of colorectal cancers (CRCs) that are characterized by concordant hypermethylation of multiple CpG island loci. CIMP+ CRCs have peculiar clinicopathological features. However, controversy exists over prognostic implications of CIMP in CRCs. We analyzed 320 cases of CRCs for their CIMP status using the MethyLight assay and determined clinicopathological features and prognostic implications of CIMP alone or in combination with microsatellite instability (MSI). With methylation of five or more markers among eight markers examined, CIMP+ tumors were significantly associated with female gender, proximal tumor location, poor differentiation, nodal metastasis, more advanced cancer, *BRAF* mutations, MSI, and poor prognosis (all P values <0.05). Ogino's combined eight-marker panel outperformed the Ogino and the Laird five-marker panels in detecting these features. Of the four molecular subtypes generated by the combination of CIMP and MSI status, the CIMP+/MSI− subtype showed the worst clinical outcome (P=0.0003). However, poor prognosis of CIMP+/MSI− subtype was found to be attributed to *BRAF* mutation. In conclusion, the CIMP+/MSI− subtype tends to present with distinct clinicopathological and molecular features and shows the worst clinical outcome among the four molecular subtypes of CRCs.

Introduction

Epigenetics describes transmission through cell division of heritable changes in phenotype that do not involve DNA sequence changes. The underlying mechanisms for epigenetic transmission include DNA methylation, histone modification, and transmitted chromatin structure. Among these, the alteration of DNA methylation patterns is known to be a key component for altered gene expression associated with human cancers. Promoter CpG island hypermethylation is found in virtually all tissue types of human cancers and acts as an important mechanism for inactivation of tumor suppressor genes and tumor-related genes [1, 2]. Promoter CpG island hypermethylation and its associated histone modifications render the chromatin structure of a gene promoter into a closed compact structure inaccessible to transcription factors, which results in the inactivation of gene transcription [3]. Human cancer cells have both genetic changes and epigenetic changes in tumor-related genes. Recent studies have demonstrated that promoter CpG island hypermethylation is more frequent than genetic changes in human colorectal cancers [4, 5], which suggests that promoter CpG island hypermethylation is a potential mechanism of colorectal carcinogenesis.

In addition to two known molecular pathways in colorectal carcinogenesis, which involve chromosomal instability (CIN) and microsatellite instability (MSI), a third epigenetic instability pathway has been proposed by Dr. Issa's group [6]. The CpG island methylator phenotype (CIMP) refers to a subset of colorectal cancers (CRCs) that

occur through the epigenetic instability pathway. CIMP+ CRCs are characterized by widespread hypermethylation of promoter CpG island loci, which results in the inactivation of the involved genes. In the study of Weisenberger et al. [7], the presence of CIMP+ CRCs has been well documented; these tumors are distinct from CIMP− CRCs because of the higher methylation frequencies or higher methylation levels of the examined CpG island loci. A growing number of studies has consistently demonstrated close associations between CIMP+ CRCs and proximal colon location, MSI, and a high frequency of *BRAF* mutation, regardless of the methodology and CIMP marker panels used [7–11]. However, a marked controversy exists over the prognostic implications of CIMP: Some studies suggest an adverse effect of CIMP on survival of CRC patients [12–14], whereas other studies suggest little prognostic value of CIMP [15]. Furthermore, Ogino et al. [16] reported that CIMP was an independent predictor of good prognosis in colon cancers, which is contrary to previous findings. These differences may be related to differences in the methodology and CIMP marker panel used to determine CIMP status in these studies. The association of good prognosis with CIMP+ tumors was produced using MethyLight technology, whereas poor prognosis in CIMP+ tumors was seen using methylation-specific polymerase chain reaction (PCR) or combined bisulfite restriction analysis. Except for the study by Ogino et al. [16], no data are available regarding the prognostic implications of CIMP+ CRCs determined by MethyLight technology.

In the present study, we used MethyLight technology and analyzed 320 CRC cases for CIMP and MSI status and characterized the clinicopathological and molecular features of the CIMP+ CRCs. We then assessed the independent effect of CIMP and the combinatorial effect of CIMP and MSI on patient outcome.

Materials and methods

Tissue samples

Formalin-fixed, paraffin-embedded archival tissues from 320 CRC patients were retrieved from the Department of Pathology, Seoul National University Hospital (Seoul, Korea). These patients had undergone curative surgery at Seoul National University Hospital between 1999 and 2002. The selection was solely on the availability of archival tissue blocks for the study, and we did not exclude patients with a family history of CRCs. However, CRC patients treated with neoadjuvant therapy were excluded from the study. Clinicopathologic information including age, sex, histological differentiation, tumor location, tumor stage, and overall survival were obtained from these 320 patients. Tumor staging was based on the pTNM staging system of the American Joint Committee on Cancer (AJCC). The histological differentiation was determined using the World Health Organization criteria. This study was approved by the Institutional Review Board.

DNA extraction and bisulfite modification

Through light microscopic examination, we marked tumor areas where tumor cells occupied 50% or more of all cells and represented the main histology and differentiation of the tumor. Non-tumorous portions in matched CRC were obtained from normal colorectal mucosa and were confirmed by microscopy to be tumor free. Ten serial 10-μm-thick histologic slides of formalin-fixed tumor and normal tissue blocks were used for manual microdissection. Dissected tissue samples were subjected to tissue lysis using proteinase K lysis buffer. Sodium bisulfite conversion of genomic DNA was performed as described [17].

DNA methylation analysis

DNA methylation analyses were performed using MethyLight as previously described [18]. We quantified DNA methylation in eight CIMP markers—*CACNA1G*, *CDKN2A* (*p16*), *CRABP1*, *IGF2*, *MLH1*, *NEUROG1*, *RUNX3*, and *SOCS1*. The oligonucleotide sequences of the primers and probes used have been described [7]. The PCR conditions were as follows: initial denaturation at 95°C for 10 min followed by 50 cycles of 95°C for 15 s and 60°C for 1 min. *M.Sss*I-treated genomic DNA was used as a reference sample for complete methylation to determine the percentage of fully methylated alleles (percentage of methylated reference (PMR)) at a particular locus. The PMR value was calculated by dividing the *GENE*/*ALU* ratio of a sample by the *GENE*/*ALU* ratio of the *M.Sss*I-treated human genomic DNA sample and multiplying by 100 [19]. We considered a CpG island locus methylated if the PMR value was >4.

Optimal panel for CIMP determination

For the MethyLight-based determination of CIMP, three kinds of CIMP marker panels were available: Dr. Ogino's original five-marker panel (*CACNA1G*, *CRABP1*, *MLH1*, *NEUROG1*, and *p16*) [8], Dr. Laird's five-marker panel (*CACNA1G*, *IGF2*, *NEUROG1*, *RUNX3*, and *SOCS1*) [7], and Dr. Ogino's combined eight-marker panel (*CACNA1G*, *CRABP1*, *IGF2*, *MLH1*, *NEUROG1*, *p16*, *RUNX3*, and *SOCS1*) [21]. To determine which CIMP marker panel was optimal for CIMP diagnosis, the three CIMP marker panels were screened against 196 CRC cases. For the five-marker panels, CRC cases were considered CIMP+ if at least three of the markers were methylated; for the combined eight-

marker panel, cutoff values of five and six markers were each tested for CIMP determination. CIMP+ tumors defined by the three CIMP marker panels were compared regarding their associations with previously known clinicopathological features of CIMP+ CRCs, including poor prognosis, older age, female predominance, proximal colon location, poor differentiation, high frequency of *BRAF* mutations, and high frequency of MSI. Overall, the combined eight-marker panel with a cutoff value of five outperformed the five-marker panels and Dr. Ogino's combined eight-marker panel with a cutoff value of six in most comparisons based on the accuracy of association (Fig. 1 and Supplementary Table 1). Thus, we used the combined eight-marker panel with a cutoff value of five for subsequent determination of CIMP.

Mutation analysis of KRAS codons 12 and 13 and BRAF codon 600

KRAS codon 12 and 13 mutations were assayed by PCR–restriction fragment length polymorphism (RFLP) analysis, and suspected cases were confirmed by direct sequencing of the *KRAS* gene [20]. *BRAF* mutations were assayed using PCR–RFLP analysis and confirmatory sequencing as described [20].

Microsatellite analysis

The MSI status of each tumor was determined based on an examination of microsatellite markers (D2S123, D5S346, D17S250, BAT25, and BAT26). We classified MSI status

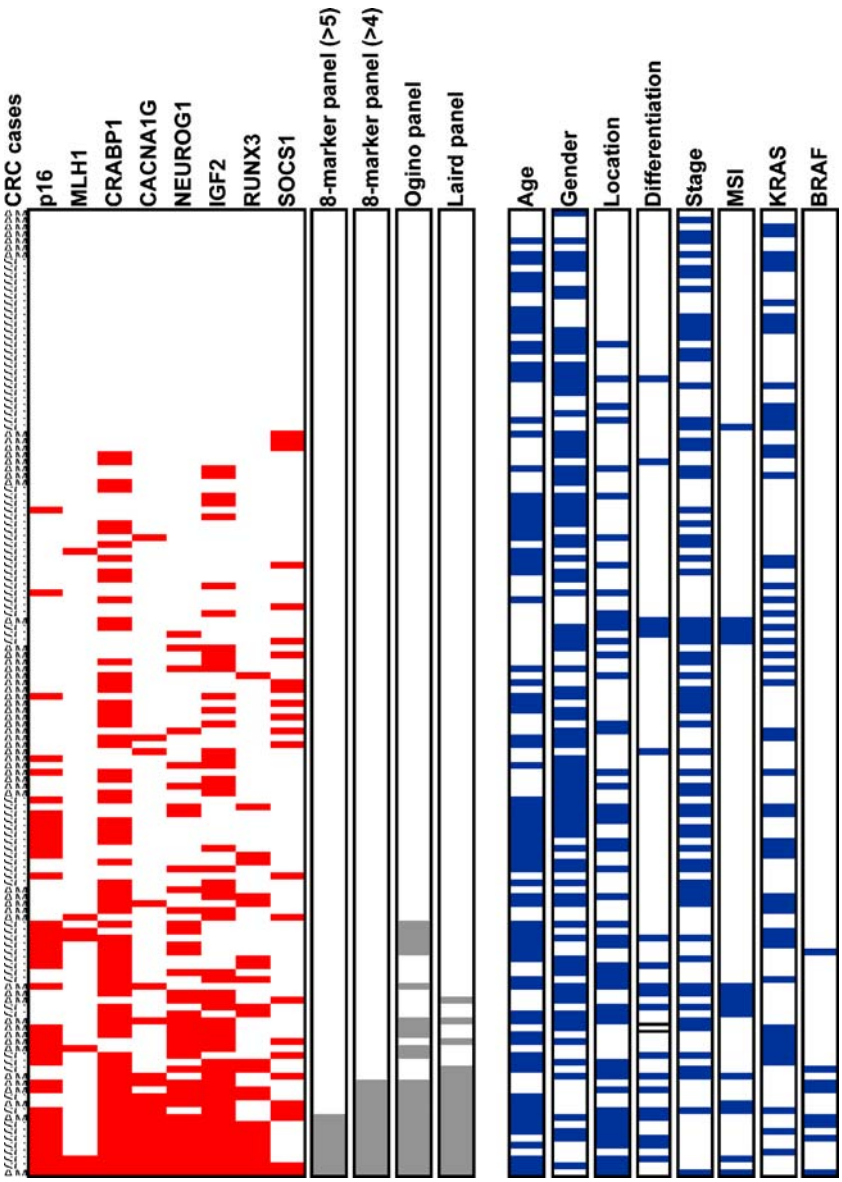

Fig. 1 Summary of comparative analysis among CIMP marker panels. *Red bars* indicate the presence of methylation in CIMP marker columns, and *gray bars* indicate CIMP+ status in four differently defined CIMP columns. *Blue bars* indicate older age (>61 years) in the *age column*, female in the *gender column*, proximal colon in the *location column*, poor differentiation in the *differentiation column*, higher stage (III, IV) in the *stage column*, MSI+ status in the *MSI column*, presence of mutant forms of *KRAS* in the *KRAS column*, and presence of mutant forms of *BRAF* in the *BRAF column*

[b] A total of 284 cases were analyzed for *KRAS* mutation

as follows: MSI+ tumors had instability at two or more microsatellite markers, and MSI− tumors had instability at no more than one marker.

Statistical analysis

All statistical analyses were conducted using SPSS software version 12.0 (SPSS, Inc., Chicago, IL, USA). Pearson's chi-square test was used to test associations between clinicopathologic or molecular variables and CIMP+ tumors defined by different CIMP marker panels. Pearson's chi-square test was used to compare the frequency of each clinicopathological or genetic parameter in CRCs by four molecular subtypes. To compare the means of numeric variables among three or more groups, an analysis of variance test was used. Survival was measured from the date of resection of CRC to the date of death or the last clinical review before August 29, 2007. The average follow-up time (from surgery to death or the last follow-up) was 63.5 months (range, 1–99 months). Crude overall survival rates were assessed using the Kaplan–Meier log-rank test, and using Cox proportional-hazards regression models, multivariate analysis was performed in a backward manner to determine association between survival and CIMP, adjusting for variable suggested to be prognostic factors on univariate analysis. Hazard ratios and 95% confidence interval (95% CI) for death were computed using Cox survival modeling. All reported *P* values are two-sided, and *P* values of less than 0.05 were considered to indicate significance.

Results

Distinct clinicopathological features of the CIMP+/MSI− subtype

To study clinicopathological features of CIMP and MSI, we analyzed an additional 124 CRC cases, giving a total of 320 cases that were classified into four molecular subtypes (CIMP+/MSI+, CIMP+/MSI−, CIMP−/MSI+, and CIMP−/MSI−) using the eight-marker panel with a cutoff of five. The CIMP−/MSI− subtype was the most common, comprising 78.8% of CRCs, whereas the CIMP+/MSI+ subtype was the least common, comprising 3.8% of CRCs (Table 1). When these four molecular subtypes were compared regarding their associations with several clinicopathological features, the CIMP+/MSI− subtype (7.8%) showed close associations with proximal colon location, frequent poor differentiation, frequent nodal metastasis, frequent distant metastasis, high cancer stage, high frequency of *BRAF* mutation, and low frequency of *KRAS* mutation (Table 1). In survival analysis, the CIMP+/MSI− subtype showed the worst clinical outcome, whereas the CIMP−/MSI+ subtype showed the best clinical outcome (Fig. 2). These differences were statistically significant (Kaplan–Meier log-rank test,

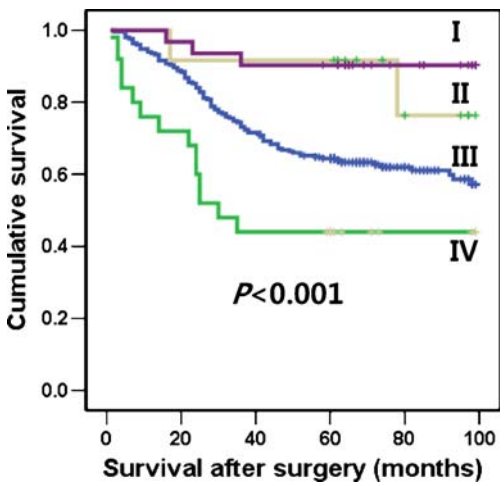

Fig. 2 Kaplan–Meier survival analysis in four molecular subtypes of colorectal cancers (n=318) according to status of CIMP and MSI. *I* CIMP−/MSI+ (n=31), *II* CIMP+/MSI+ (n=12), *III* CIMP−/MSI− (n=250), *IV* CIMP+/MSI− (n=25)

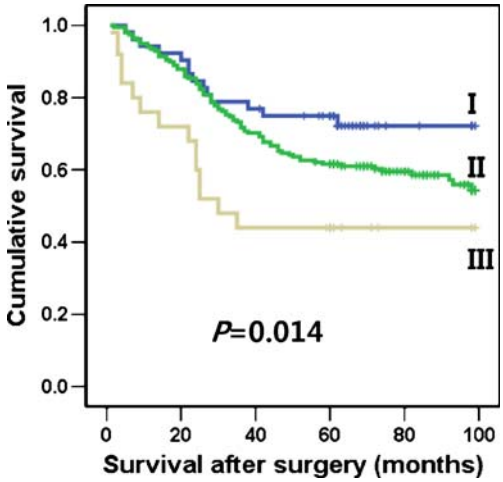

Fig. 3 Kaplan–Meier survival curves in MSI-negative colorectal cancers (n=275) according to CIMP status. *I* CIMP-0, *II* CIMP-low, *III* CIMP-high (or CIMP+). CIMP-low tumor was defined as a tumor with methylation at one to four DNA methylation markers

P<0.001). These results suggest that CIMP+/MSI− CRCs have distinct clinicopathological features.

The relationship between the degree of methylation and survival

A close association of CIMP+ with poor prognosis for MSI− CRC patients was still found after introduction, in the survival analysis, of CIMP-low group and resultant separation of CIMP− CRCs into CIMP-0 (lack of methylation in eight markers) and CIMP-low (with one to four methylated markers; Fig. 3). CIMP-low CRC patients showed clinical outcomes better than those of CIMP+ (or CIMP-high) CRC patients but worse than those of CIMP-0 CRC patients. When clinicopathological or molecular features were correlated with methylation status in MSI− CRCs, CIMP-low CRCs were similar to CIMP-0 CRCs in the examined features except for *KRAS* mutation (Table 2). *KRAS* mutation was more common in CIMP-low CRCs (45%) than in CIMP-0 (24%) or CIMP-high (14%) CRCs (P=0.001).

The effect of BRAF mutation on the prognostic effect of CIMP

In the present study, MSI− CRCs showed significantly different clinical outcomes depending on CIMP status, and particularly, the clinical outcomes of CIMP+/MSI− CRCs were worse than those of CIMP−/MSI− CRCs (P<0.001). In order to identify whether the prognostic effect of CIMP was related to the presence of *BRAF* mutation, we stratified MSI− CRCs into four subtypes according to CIMP and *BRAF* status: CIMP+/*BRAF*+, CIMP+/*BRAF*−, CIMP−/*BRAF*+, and CIMP−/*BRAF*−. CIMP+/*BRAF*+ CRCs showed worse clinical outcome than that of CIMP+/*BRAF*− CRCs, which was similar to that of CIMP−/*BRAF*− CRCs. This result clearly indicates that the worse clinical outcome of CIMP+/MSI− CRCs was clearly associated with the presence of *BRAF* mutation (Fig. 4).

Overall survival according to CIMP, MSI, and mutations of KRAS and BRAF

Survival was analyzed in 318 patients; two patients were excluded because of loss to follow-up. Univariate relationships between clinicopathogical or molecular factors and

the overall survival are summarized in Table 3. The factors showing significant associations with poor survival were poor differentiation, high cancer stage (AJCC), and older age (>61 years), whereas the factor significantly associated with good prognosis was MSI+ status. However, CIMP+ status was not a statistically significant factor. When we separated our study cases into colon cancer group and rectal cancer group (Table 4 and Supplementary Table 2), CIMP+ status was a significant factor in colon cancer group. For colon cancer group, besides CIMP+ status, older age, high cancer stage, MSI+ status, and *BRAF* mutation were significant factor associated with prognosis of colon cancer patients and differentiation was marginally significant. To determine association between CIMP and survival, multivariate analysis was performed with adjustment for above five variables, revealing that CIMP+ status was not an independent prognostic factor for colon cancers.

Discussion

MSI and CIN are two important mechanisms of genetic instability in CRCs, but they cannot account for all CRCs because a proportion of CRCs have neither MSI nor CIN [22, 23]. A potential mechanism capable of filling the gap is CIMP, which is characterized by widespread hypermethylation of multiple promoter CpG island loci. CIMP has now been recognized as a potential alternative mechanism for genetic instability driving molecular diversity in CRCs. CIMP appears to overlap MSI, because a considerable proportion of sporadic MSI+ CRCs arise as a consequence of CIMP-related hypermethylation of *MLH1*. Recent studies suggested that CIMP and CIN are mutually exclusive pathways [24, 25].

Since the introduction of the CIMP concept to the molecular carcinogenesis of CRCs, many investigators have attempted to characterize the clinicopathologic and molecular features of CIMP+ CRCs using their own CIMP marker panels and cutoff values. Despite the lack of a reference marker panel, associations with proximal colon location, MSI, and a high frequency of *BRAF* mutation have been virtually consistent findings for CIMP+ CRCs. However, inconsistent findings among an accumulating series of studies include older age, female predominance, high frequency of *KRAS* mutation, poor differentiation, and poor clinical outcomes. Furthermore, the proportion of CIMP+ tumors in all CRCs varied from 48% and 12%. These inconsistencies are related to the fact that laboratories have developed their own tools to define CIMP, and the variety of approaches has made it difficult to compare results from different groups. It is necessary to define uniform criteria for CIMP. The technology for performing quantitative methylation analysis and producing high-throughput analysis, e.g., MethyLight or pyrosequencing, is likely to be adopted as the reference technology for CIMP diagnosis. For the MethyLight technology, the eight-marker panel appears to be superior to the five-marker panels based on the findings of the present study and that of Ogino et al. [21]. However, for the pyrosequencing methodology, CIMP marker panels have not been as thoroughly evaluated.

In contrast to the findings of Ogino et al. [26] that CIMP+ colon cancers had a better prognosis than CIMP− colon cancers and that CIMP was an independent prognostic factor, our study showed that CIMP was not an independent

prognostic factor for colon cancers. At present, we cannot explain why such a difference exists in the prognosis of CIMP+ tumors between the Ogino study and ours. In contrast to those studies reporting CIMP as an independent prognostic marker of poor prognosis in CRCs [12, 13], our study showed that CIMP was not a prognostic factor in CRCs and not an independent prognostic factor in colon cancers. The association of CIMP+ status with poor prognosis, which was statistically significant in colon cancer patients, remained no longer significant after adjusting for *BRAF* mutation. Previous studies reporting CIMP as an independent prognostic factor in CRCs did not analyze *BRAF* mutation in study samples and thus did not take the effect of *BRAF* mutation into consideration for the analysis of the association between CIMP+ status and prognosis of CRC patients [12, 13]. However, in the study of Barault et al. [14], CIMP+ status was closely associated with poor prognosis of MSI− colon cancers, and this association remained significant in multivariate analysis adjusted for age, stage, and *BRAF* and *KRAS* mutational status. The CIMP marker panel and methylation analysis technology used in the study of Barault et al. were classic five-marker panel (*MLH1*, *MINT1*, *MINT2*, *MINT31*, and *p16*) and methylation-specific PCR, respectively, and different from the panel and the analysis technology of the present study.

Compared with studies using Western patient populations, the present study showed discrepancies in the following respects: (1) the proportion of CIMP+ tumors in all CRCs, (2) the proportion of CIMP+ tumors in MSI+ CRCs, and (3) the rate of *BRAF* mutation in overall CRCs. In our study, 12% of CRCs were CIMP+, compared to 18% in the Ogino study [21]. Of MSI+ CRCs, 30% were CIMP+, compared to 71% in the Ogino study [21]. Studies having looked at specific causes of MSI+ CRCs not caused by germline mismatch repair gene mutation reported that majority (83–100%) of these cases have *MLH1* methylation [27–30]. Based on such a high frequency of *MLH1* methylation in MSI+ CRCs, Western researchers propose that virtually all sporadic MSI+ CRCs occur through the epigenetic instability pathway, with loss of *MLH1* gene expression through promoter CpG island hypermethylation. If this contention is true, the following interpretation can be deduced from our findings: either three quarters of MSI+ cases should be hereditary or our methylation assay had a lower sensitivity for detection of CIMP. The latter is unlikely because we tested and corroborated the precision of the MethyLight technology by comparing the results of the MethyLight analysis with those of bisulfite genomic sequencing in cancer cell lines (data not shown). The former possibility is also unlikely because we randomly selected study cases from the surgical files of our department without information about familial history. Our results suggest the possibility that sporadic MSI+ cases develop through mechanisms other than *MLH1* hypermethylation, including *MLH1* or *MSH2* gene mutation. Thus, it is plausible that there are ethnic differences in the causation of sporadic MSI+ CRCs, which explains the discrepancy in the percentage of CIMP positivity in MSI+ CRCs between Western data and the present study.

The rate of *BRAF* mutation (4.8%) in our CRC cases was similar to the rate (4.2%–9%) in other East Asian CRC studies [31–33], but lower than that in US, West Asian, and European CRC studies (9.5%–20.9%) [15, 34–36]. The rate of *BRAF* mutation was still low (6.1%, 11/181) when we excluded rectal cancers. However, the rate of *KRAS* mutation (101/285, 35.4%) was similar to that in other studies, regardless of geographic or ethnic differences (32%–34%) [9, 31, 37, 38]. The sensitivity of *BRAF* mutation detection could have been influenced by the mutation analysis methodology and use of the formalin-fixed paraffin-embedded tissues. But the former is unlikely because the enriched PCR–RFLP assay provides a highly sensitive means of detection and is capable of detecting one mutant allele in the presence of 1,000 normal alleles. In addition, we repeated *BRAF* mutation analysis at codon 600 (V600E) using real-time PCR-based allelic discrimination [36], giving the same result [20]. And it is also unlikely that use of the formalin-fixed tissue yielded lower detection of *BRAF* mutation because no difference was found in the mutation analysis of *BRAF* between the use of formalin-fixed tissues and the use of methanol-fixed tissues in a preliminary study (data not shown). At present, we cannot provide a satisfactory explanation for the discrepancy in *BRAF* mutation rates and the similarity of *KRAS* mutation rates between Western and East Asian CRC cases. Another point to address is the relationship between *BRAF* mutation and CIMP. One series of studies suggested that *BRAF* mutation is closely associated with sporadic MSI+ CRCs [39, 40], but this is disputed by recent studies indicating that *BRAF* mutation is closely associated with CIMP rather than MSI [16, 24]. Our study supports the close association of *BRAF* mutation with CIMP, because the *BRAF* mutation rate in CIMP+/MSI− CRCs was similar to that in CIMP+/MSI+ CRCs (33.3% and 37.5%, respectively).

In our study, CIMP+/MSI− CRCs exhibited the worst clinical outcomes among four molecular subtypes, which was attributed to *BRAF* mutation. However, *BRAF* mutation without CIMP was not associated with worse clinical outcome, which was consistent with our previous study [20]. Thus, CIMP+/MSI− CRCs with *BRAF* mutation pursued dismal clinical behavior, and the association of this molecular subtype with worse clinical outcome remained significant in multivariate analysis after adjusting for stage, differentiation, and age (data not shown). Because of the worse clinical outcome, molecular diagnostic tests to identify this subtype will be necessary in clinics, and targeted therapy against *BRAF* could be considered in the first-line adjuvant therapy.

Lastly, in our study, a close association of *KRAS* mutation with CIMP-low status was found for MSI− CRCs, which is consistent with the findings of the study of Ogino et al. [41] and furthermore in accordance with the study of Barault et al. using different CIMP marker panel and DNA methylation analysis technology [14]. Except for a strong association of *KRAS* mutation, CIMP-low tumors were similar to CIMP-0 tumors in several clinicopathological features, including *p53* mutation [41], suggesting that CIMP-low tumors might be derived from CIN pathway. Because tubulovillous adenoma or villous adenoma harbors higher frequencies of *KRAS* mutation and CpG island hypermethylation than those of tubular adenoma [42–44], tubulovillous or villous adenomas might be precursor lesions of CIMP-low CRCs. To support this speculation, a further study analyzing carcinoma–ex adenoma samples for their methylation status in each component will be necessary to identify whether CIMP-low CRCs tend to have tubulovillous or villous adenoma as their contiguous adenoma.

In conclusion, we analyzed 320 CRC cases for CIMP and MSI status and determined the prognostic implications of CIMP status in CRC patients. The CIMP+/MSI− subtype showed the worst clinical outcome among the four possible molecular subtypes of CRCs, and the worse clinical outcome of CIMP+/MSI− subtype was attributed to *BRAF* mutation.

Expression of MMP-10, MMP-21, MMP-26, and MMP-28 in Merkel cell carcinoma

Sari Suomela · Virve Koljonen · Tiina Skoog · Heli Kukko · Tom Böhling · Ulpu Saarialho-Kere

Received: 26 August 2009 / Revised: 14 October 2009 / Accepted: 23 October 2009 / Published online: 17 November 2009

Abstract Merkel cell carcinoma (MCC) is an aggressive cutaneous tumor with poor outcome and increasing incidence. We examined by immunohistochemistry the expression of three novel matrix metalloproteinases (MMPs)—MMP-21, MMP-26, and MMP-28—in 44 primary MCC tumors and six lymph node metastases while MMP-10 served as a positive control. Their mRNA expression was also studied in the UISO MCC cell line basally and after various stimulations using quantitative real-time PCR. MMP-28 was observed in tumor cells of 15/44 samples especially in tumors <2 cm in diameter (p=0.015) while 21/44 specimens showed MMP-28 in the tumor stroma. Expression of MMP-21 was demonstrated in tumor cells of 13/43 samples. MMP-26, instead, was positive in stromal cells (17/44) and its expression associated with tumors ≥2 cm in diameter (p= 0.006). Stromal expression of MMP-10 was the most frequent finding of the studied samples (31/44), but MMP-10 was detected also in tumor cells (17/44). Most of the metastatic lymph nodes expressed MMP-10 and MMP-26. MMP-10, MMP-21, and MMP-28 mRNAs were basally expressed by the UISO cells, and the corresponding proteins were detectable by immunostaining of cultured cells. IFN-α and TNF-α downregulated MMP-21 and MMP-28 expression. Our results suggest that novel MMPs may have a role in MCC pathogenesis: especially that MMP-26 expression in stroma is associated with larger tumors with poor prognosis. Expression of MMP-21 and MMP-28 seems to associate with the tumors of lesser malignant potential. We also confirm the previous finding on the role of MMP-10 in MCC pathogenesis.

Introduction

Merkel cell carcinoma (MCC) is a rare primary neuroendocrine carcinoma of the skin, although the age-adjusted incidence of MCC has tripled between 1986 and 2001 in the USA [1]. It is a potentially fatal disease, and the

reported 5-year relative and disease-specific survival rates depend on the stage of the disease at presentation [2, 3]. The typical clinical course of the disease is rapid progression of the primary tumor with early and frequent metastasis to the regional lymph nodes. Several studies have established a close correlation between poor overall survival and large tumor size (≥2 cm) [4, 5]. MCC usually occurs in sun-damaged skin, the most common site being the head and neck region [6]. Ultraviolet irradiation and, very recently, the Merkel cell polyomavirus have been associated with the pathogenesis of MCC [7–9]. Interestingly, the incidence of MCC is abnormally high (8%) among immunosuppressed patients [10, 11], and HIV patients, with weakened immunity, have a 13.4-fold risk of acquiring MCC [12].

Matrix metalloproteinases (MMPs) are a group of 24 human enzymes that play a role at all stages of cancer progression from initiation to metastatic spread. Besides degrading various extracellular matrix and basement membrane proteins, they regulate growth factor activation, angiogenesis, inflammation, and apoptosis [13]. MMPs are regulated not only transcriptionally and translationally, but also by proenzyme activation and by specific inhibitors, tissue inhibitors of metalloproteinases (TIMPs) [14]. In a previous study on 33 MCCs, significant associations were found between metastatic tumor spread and high expression of MMP-7 and MMP-10 and their inhibitor TIMP-3, while the expression of MMP-1, MMP-2, MMP-3, MMP-13, and MMP-14 did not associate with prognosis [15]. In another study on 23 MCCs, high expression of MMP-1 and MMP-3 were significant negative prognostic factors [16] whereas no association was observed with the expression of MMPs-2, MMP-9, and MMP-14.

We have recently studied the role of several novel MMPs, such as MMP-21 [17], MMP-26 [18], and MMP-28 [19] in skin cancer. The aim of the present study was to elucidate the role of more novel MMPs in the biological behavior of MCC in vivo and in culture, correlating the findings with tumor size and presence of metastatic lymph nodes. MMP-10 was studied based on previous reports on its expression and prognostic significance in MCC. MMP-12 and MMP-8 were included since no previous data exist on them in MCC and since they have been suggested to have anti-tumor effects in certain cancer subtypes [13].

Materials and methods

Tissue samples

Individuals diagnosed with MCC in Finland within the time period of 1979 to 2004, were identified from the files of the Finnish Cancer Registry, which has coverage close to 100% of all malignancies diagnosed in Finland [20]. Clinical data were extracted from the hospital case records and records of the primary care centers. This study comprised 44 patients, 27 females (aged 59–95 years) and 17 males (aged 35–90 years), diagnosed with MCC (Table 1). Only two of the patients were immunosuppressed. Staging system from Memorial Sloan Kettering Cancer Center was used to stage the patients at the time of the MCC diagnosis [3]: briefly, stage I (T1N0M0, primary tumor <2 cm; no nodal involvement, no systemic metastasis), stage II (T2N0M0, primary tumor ≥2 cm; no nodal involvement, no systemic metastasis), stage III (any T, N1, M1; any tumor size, nodal involvement, no systemic metastasis), and stage IV (any T, any N, M1; any tumor size, nodal involvement, systemic metastasis). One primary tumor sample was collected from each patient. The diagnosis of MCC was then confirmed with immunohistochemical analysis: primary tumor samples were stained with hematoxylin and eosin, and immunohistochemistry using antibodies for cytokeratin-20 (CK-20, DakoCytomation, Glostrup, Denmark) and thyroid transcription factor-1 (TTF-1; Novocastra, Balliol Business Park West, Benton Lane, Newcastle Upon Tyne, UK) [21] was performed. The requirements for histological diagnosis of MCC were that tissue morphology was compatible with MCC by light microscopy and that the cancer cells stained positively for CK-20 and negatively for TTF-1. Although a few cases of MCC can be CK-20 negative, we used CK-20 positivity combined with TTF-1 negativity as inclusion criteria, to avoid the possibility that we studied tumors other than true MCCs. The longest diameter of the tumor was measured from hematoxylin and eosin stained slides, and in case of a large tumor, the diameter reported in the hospital case records was accepted. Tumor size (the greatest surface dimension) was measured from hematoxylin–eosin stained slides and documented as <2 cm or ≥2 cm. None of the patients received chemotherapy or radiation therapy preoperatively. In addition, six lymph node metastases were analyzed. The study was conducted in accordance to the Declaration of Helsinki principles and approved by the corresponding Ethical Review Board of the Helsinki University Central Hospital.

Immunohistochemistry

Immunohistochemistry was performed by the streptavidin–biotin–peroxidase complex technique (DakoCytomation, StreptABComplex/HRP Duet, Mouse/Rabbit, Glostrup, Denmark and Elite Goat (MMP-12) or Rabbit (MMP-21) IgG Vectastain ABC kit, Vector laboratories, Burlingame, CA, USA) or the antibody–polymer detection technique (PowerVision, Poly-HRP IHC Kit, ImmunoVision Technologies Co, Brisbane, CA, USA). Diaminobenzidine or 3-amino-9-ethylcarbazole was used as chromogenic substrate and Mayer's hematoxylin as counterstain. Monoclonal

*Immunosuppressed; semiquantitative evaluation of immunosignal is described in Materials and methods

T Tumor cells, *S* surrounding stroma

antibodies were used to stain MMP-8 (10 ug/ml, 115-13D2, EMD Biosciences Inc., La Jolla, CA) and MMP-10 (1:300, 5E4, Novocastra Laboratories, New Castle upon Tyne, UK). Polyclonal antibodies raised by us against a synthetic peptide were used for MMP-21 [22], for MMP-26 (1:120, a gift from Prof. K. Isaka, Tokyo Medical University) [18], MMP-28 (1:100, M5066 Sigma-Aldrich, St. Louis, MO), and MMP-12 (1:80, SC-12361, Santa Cruz Biotechnology, Santa Cruz, California). MMP-10 and MMP-8 were pre-treated with 1% trypsin solution for 30 min at +37°C and MMP-26 and MMP-28 in a +95°C water bath for 25 min (Dako retrieval solution pH6; Dakocytomation). The incubation conditions for the antibodies were: +4°C overnight for MMP-28 and MMP-12, 2 h at RT for MMP-10, and 1 h at +37°C for MMP-26. For negative controls, parallel sections of the same samples were processed using preimmune sera or normal rabbit or mouse immunoglobulin. The positive controls used throughout the staining were formalin-fixed, paraffin-embedded sections of squamous cell cancers (MMP-10 and MMP-21), sarcoidosis (MMP-12), endometrium (MMP-26), and chronic wounds (MMP-8). Neutrophils, macrophages, and plasma cells were histologically identified from immunostained and corresponding hematoxylin–eosin stained sections by an experienced pathologist (T. B.).

Scoring

The intensity of MMP staining was scored independently in a blinded manner by two investigators (U. S-K. and T. B.). The investigators re-evaluated all specimens with discordant scores, and consensus score was used for further analyses. In MMP staining, the semiquantitative intensity of cytoplasmic expression was analyzed under a light-field microscope at ×100 magnification using a scale-marking staining intensity as follows: 0=less than 20 positive cells; 1=20–50 positive cells; 2=50–200 positive cells; 3=over 200 positive cells.

Cell cultures

The MCC cell line UISO, which has been established from a primary MCC tumor of a 46-year-old woman [23], was grown in RPMI 1640 supplemented with 10% fetal bovine serum, 100 U/ml penicillin, and 0.1 mg/ml streptomycin at 37°C in a humidified atmosphere of 5% CO2 and 95% air as previously described [24]. The medium was changed twice a week. UISO cells were also grown on Lab-Tek Chamber Slides and fixed with formalin for immunostaining 48 h after initiation of the culture [25]. To study the regulation of MMP-21, MMP-26, and MMP-28 expression, UISO cells were plated on tissue culture plates and allowed to reach 70–80% confluence. Then, the cells were depleted of serum overnight prior to stimulation with interferon (IFN)-α (10 and 50 U/ml), tumor necrosis factor (TNF)-α (10 and 50 ng/ml), or vascular endothelial growth factor (VEGF; 10 and 50 ng/ml; all from Sigma, St. Louis, MO). At 24 h and 48 h, the cells were lyzed, and total RNA was extracted using RNeasy Mini-Kit (Qiagen, Chatsworth, CA) as instructed by the manufacturer. Cells given fresh serum-free medium were used as controls. All treatments were carried out in triplicate, and the results were confirmed in at least three independent experiments.

Conventional and qRT-PCR

RNA was reverse transcribed to cDNA with SuperScript™ III First-Strand Synthesis System for RT-PCR (Invitrogen, Carlsbad, CA) with oligo dTs as primers and used as a template for conventional or for quantitative real-time polymerase chain reaction (qRT-PCR). Primers for MMP-10 were designed using the computer program Primer3 (http://frodo.wi.mit.edu/primer3/input.htm) and were 5′-GAC CTG GGC TTT ATG GAG ATA TT-3′ (forward) and 5′-GCT TCA GTG TTG GCT GAG TGA A-3′ (reverse). Primers and probes for MMP-21, MMP-26, and primers for MMP-28 were as described previously [17, 26, 27]. Human GAPDH (glyceraldehyde-3-phosphate dehydrogenase) labeled with VIC™ reporter dye (Pre-developed TaqMan™ assay reagents for endogenous control human GAPDH, Applied Biosystems, Warrington, UK) was used as an endogenous control in TaqMan™ (Applied Biosystems) qRT-PCR and GAPDH primers 5′-GGG AAG GTG AAG GTC GGR-3′ (forward) and 5′-GCA GCC CTG GTG ACC AG-3′ (reverse; Primer3) in conventional PCR and LightCycler® 480 SYBR Green (Roche Diagnostics, Mannheim, Germany) qRT-PCR. Placenta poly (A) RNA (Ambion, Austin, TX; MMP-10, MMP-21, and MMP-26) and total RNA prepared from A549 cells (overexpressing MMP-28) were used as positive controls. Conventional PCR assays were performed as described previously [25]. The reaction products were run on a 2.5% agarose gel, stained with 5 ng/ml ethidium bromide, and visualized under ultraviolet light. qRT-PCR reactions were performed with the the Applied Biosystems 7500 Fast Real-Time PCR System (MMP-21, MMP-26, and GAPDH) or the Roche Diagnostics LightCycler® 480 System (MMPs-10 and MMP-28 and GAPDH) with standard protocols. PCR amplifications were performed in 25-µl volumes in separate reactions. TaqMan™ qRT-PCR for MMP-21 and MMP-26, and GAPDH were run as described before [24]. MMP-10 and MMP-28 and GAPDH with LightCycler® 480 System were run in 15 µl SYBR Green mix containing 500 nM of forward and reverse primers, 5 µl of the undiluted cDNA, and 1× LightCycler 480 SYBR Green I Master mix (Roche Diagnostics). The PCR was started with 5 min pre-incubation at 95°C,

followed by a total of 45 cycles of 10 s denaturation at 95°C, 5 s annealing at 55°C and 8 s elongation at 72°C. The specificity of the SYBR Green primers was tested by running a melting curve after the qRT-PCR. The primers were ordered from Oligomer (Helsinki, Finland) or Sigma-Proligo (www.sigmaaldrich.com).

Statistical analysis

Statistical significance of the immunohistochemical scores were calculated using the Fisher's exact test. Statistical significance of the differences in mRNA expression levels in qRT-PCR analyses was calculated using the two-sample Student's *t* test. *P* value under 0.05 was considered as significant.

Results

Immunohistochemical detection of MMPs in primary MCC tumors

MMP-21 was expressed by MCC tumor cells in 13/43 cases and in eight samples by stromal neutrophils (Fig. 1a,

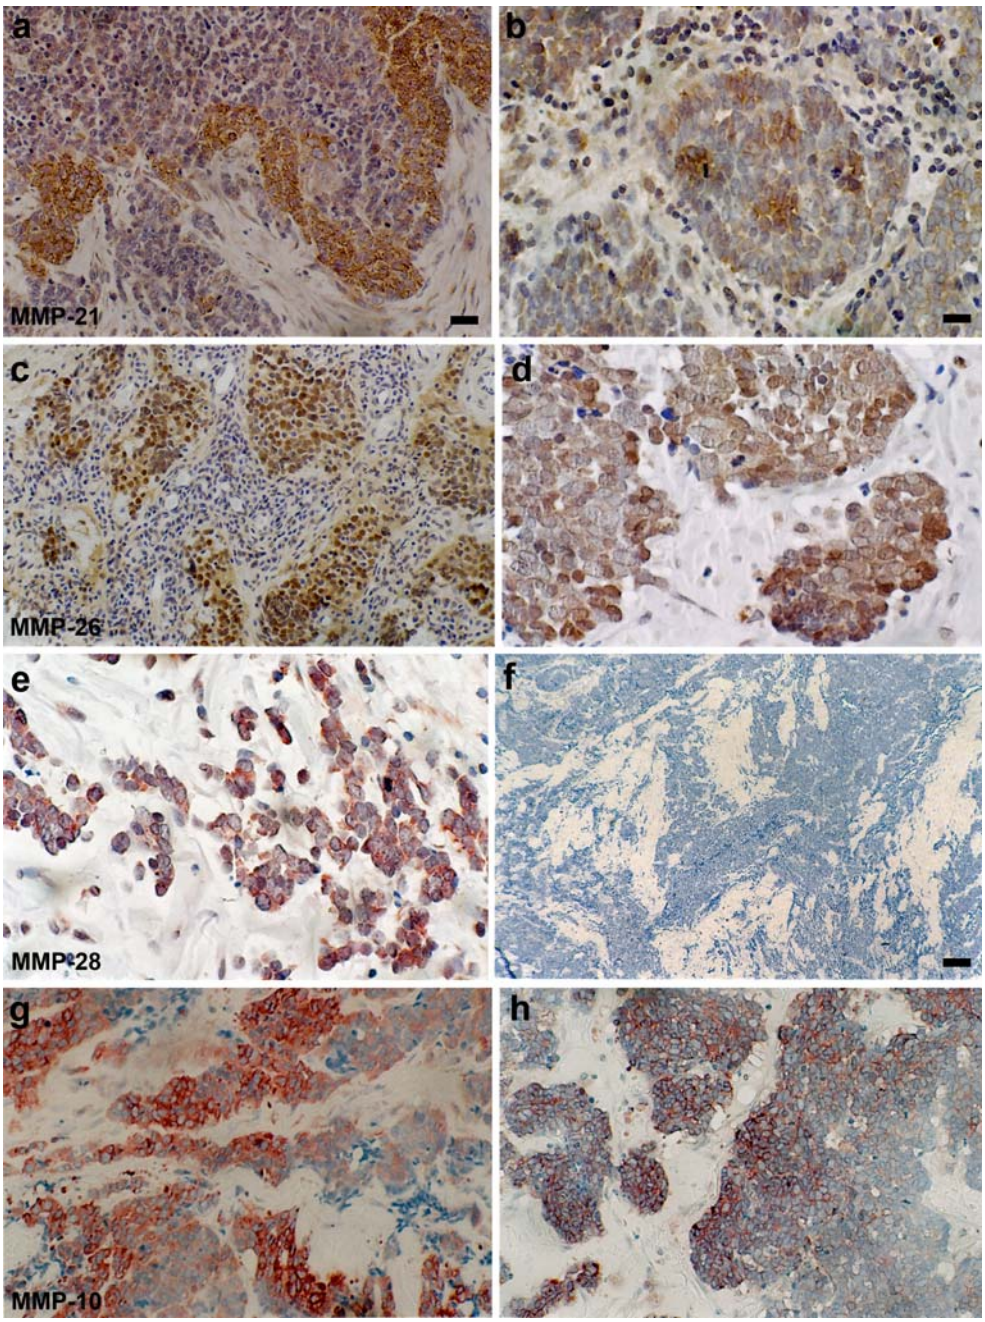

Fig. 1 Expression of MMP-21, MMP-26, MMP-28, and MMP-10 in MCC and its metastases. **a** Positive immunosignal for MMP-21 in tumor cells of a primary MCC and in a lymph node metastasis (**b**). **c** Staining for MMP-26 in a primary tumor and in metastasis of a lymph node (**d**). **e** Expression of MMP-28 in Merkel cells of a primary tumor. **f** Negative control for MMP-28. **g** Expression of MMP-10 in tumor cells and in a metastasis (**h**). Scale bars: 12 μm (**b**, **d**, **e**), 25 μm (**a**, **c**, **g**, **h**), 125 μm (**f**)

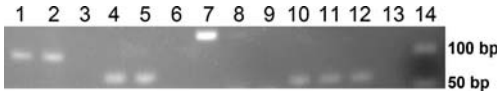

Fig. 2 MMP-10, MMP-21, and MMP-28 are expressed in UISO cells by conventional PCR. Specific primers for MMP-21 (lanes *1–3*), MMP-28 (*4–6*), MMP-10 (*7–9*), and GAPDH (*10–13*) were used. cDNA from UISO cells was used on lanes *2*, *5*, *8*, and *12*. Placenta (lanes *1*, *7*, and *10*) and A549 cells overexpressing MMP-28 (lanes *4* and *11*) were used as positive control and water (lanes *3*, *6*, *9*, and *13*) as negative control. Molecular weight ladder is on lane *14*

Table 1). None of the samples with MMP-21-expressing neutrophils had metastasized to the lymph nodes, while those tumors with lymph node metastasis (n=16) were all devoid of MMP-21 in the stroma (p=0.04).

MMP-26 (matrilysin-2) was expressed in only seven MCCs by tumor cells and by inflammatory cells, such as neutrophils, in 17/44 samples (Fig. 1c, Table 1). Stromal expression of MMP-26 was most intense in larger tumors (10/14 vs. 7/30, p=0.006). Invasion of tumor cells to dermal vessels was more common if MMP-26 expression was encountered in stromal cells, but this finding did not reach statistical significance (p=0.067).

MMP-28 (epilysin) was expressed in 15/44 MCCs in tumor cells (Fig. 1e, Table 1) and in 21/44 specimens by stromal cells, such as neutrophils and plasma cells. Tumors <2 cm in size were more likely to express MMP-28 in tumor cells than tumors with a diameter of ≥2 cm (14/30 vs. 1/14, respectively, p=0.015).

MMP-10, studied as a control [15], was observed in MCC tumor cells in 17/44 samples but in the stroma in 31 specimens in macrophages and lymphocytes (Fig. 1g, Table 1). In our samples, MMP-10 was most likely to be expressed by tumor cells in tumors of stages 2 or 3 (5/5 vs. 12/39, p=0.006).

Twenty-seven MCC samples were stained for MMP-12, and they were generally negative (data not shown). MMP-8 staining in 31 samples did not reveal positive tumor cells; only occasional neutrophils were positive in five samples (data not shown).

Immunohistochemical detection of MMPs in metastases of MCC

Sixteen of the 44 MCC patients had metastasis to the lymph nodes at the time of operation (Table 1). Eight patients

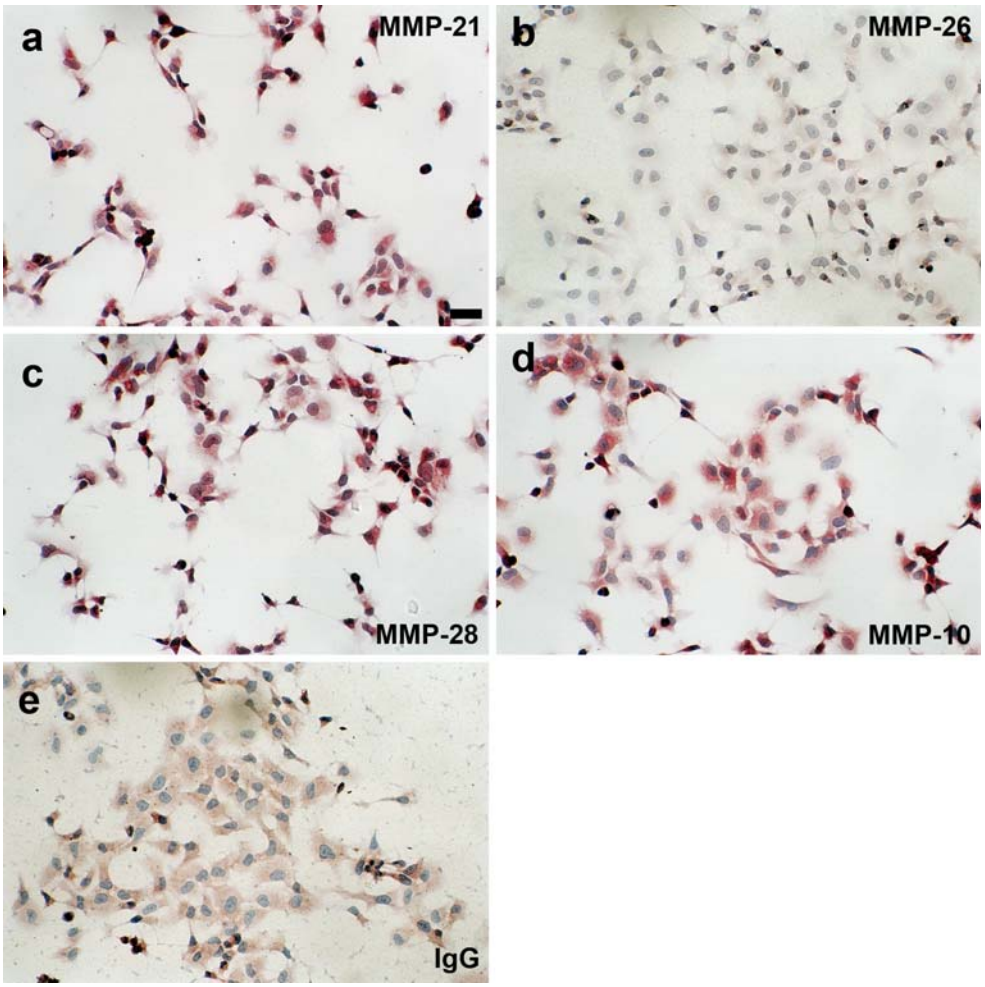

Fig. 3 Expression of MMP-21, MMP-26, MMP-28, and MMP-10 in UISO cells by immunohistochemistry. **a** MMP-21, MMP-28 (**c**), and MMP-10 (**d**) are expressed in the cytoplasm in the MCC cell line UISO. **b** MMP-26 was not expressed in UISO cells. **e** The corresponding negative mouse IgG control. Scale bar: 25 μm

developed systemic metastasis. We evaluated the MMP profile of six of the lymph node metastases by immunohistochemistry. MMP-21 expression was seen in cancer cells of one lymph node metastasis, and another lymph node metastasis had MMP-21 expression in inflammatory cells (Fig. 1b). MMP-26, however, was expressed in cancer cells of four metastatic lymph node samples and in the stroma of all metastases (Fig. 1d). None of the lymph node metastases expressed MMP-28 in tumor cells (data not shown). MMP-10 was expressed in macrophages or lymphocytes (6/6) and tumor cells (5/6) of the metastasis samples (Fig. 1h).

Expression and regulation of MMPs in UISO cells in vitro

To study whether UISO cells are able to express any of the MMPs found in tissue sections in culture, quantitative Taqman PCR was performed. In unstimulated cells, MMP-21 mRNA was expressed at low levels (at 33 cycles) whereas MMP-28 expression was more abundant (at 28 cycles). Very low expression of MMP-10 was detected (at 37 cycles) whereas no MMP-26 mRNA was found. This was confirmed by conventional PCR (Fig. 2). Analogously, when UISO cells cultured on Lab-Tek chamber slides were immunostained, expression of MMP-10, MMP-21, and MMP-28 proteins were detected, while staining for MMP-26 was negative (Fig. 3).

In order to understand the regulation of the studied MMPs in UISO cells, we cultured these cells in the presence of MCC-related cytokines or growth factors. Total RNA from these cells was analyzed using the TaqMan or SYBR Green quantitative real-time PCR [17, 27]. After 24 and 48 h of stimulation with IFN-α and TNF-α, a significant downregulation of MMP-21 and MMP-28 expression was observed (Fig. 4). VEGF did not affect the expression of any of the MMPs studied (data not shown). MMP-26 mRNA levels remained unaltered after various stimulations (data not shown).

Discussion

Due to the aggressiveness of MCC, novel targeted therapies are urgently needed for this rare neoplasm. To our knowledge, this is the first report on the expression of MMP-8, MMP-12, MMP-21, MMP-26, and MMP-28 in

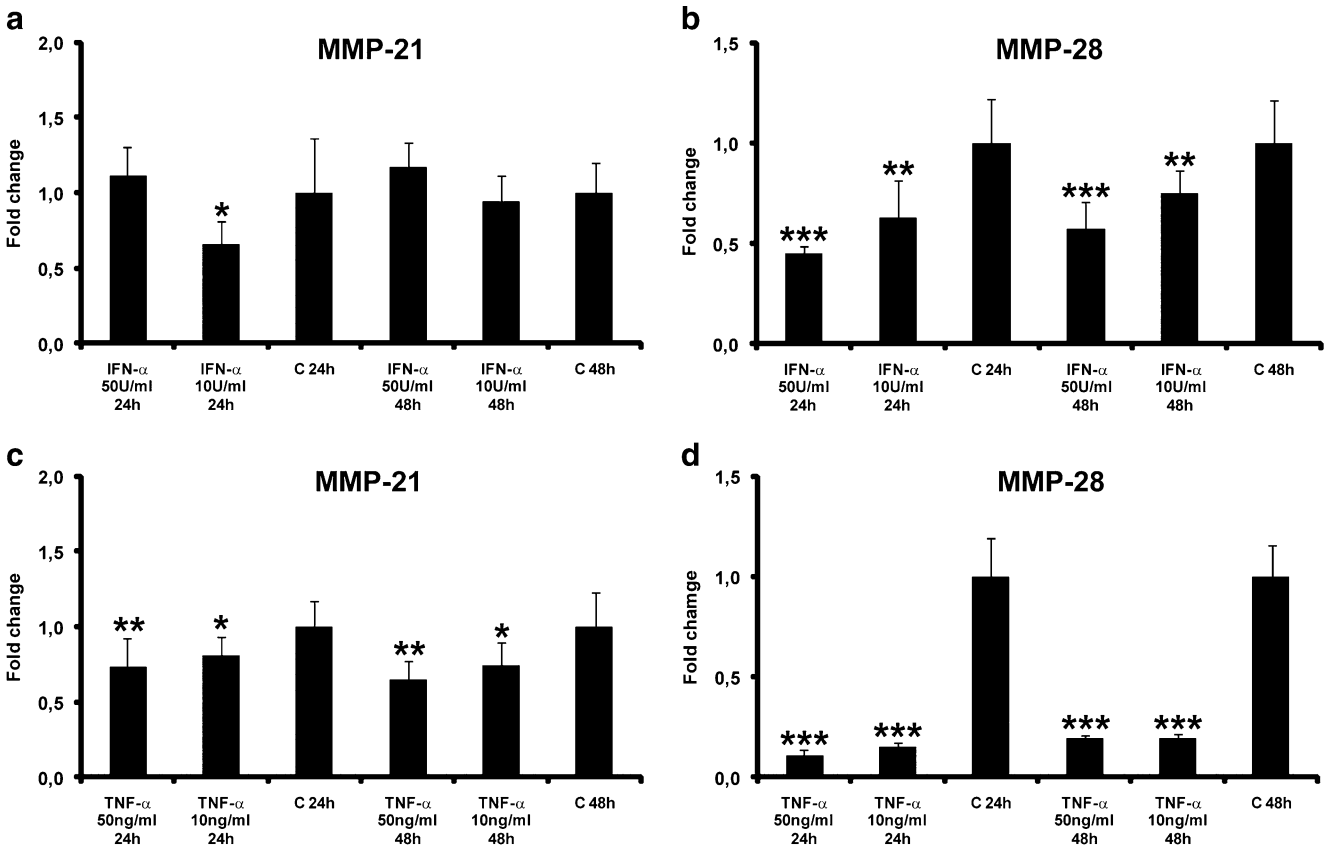

Fig. 4 Regulation of MMP-21 and MMP-28 expression in UISO MCC cell line as assessed by quantitative real-time PCR. MMP-21 and MMP-28 are significantly downregulated by IFN-α (a and b, respectively) and by TNF-α (c and d, respectively).The RT-PCR results are shown as mean fold changes relative to mRNA levels from corresponding control cells, assigned the value 1, +SEM (n=3) **p* value<0.05; ***p* value<0.01; ****p* value<0.001

MCC in vivo and in MCC cells in vitro. Furthermore, there is no data on the presence of MMPs in MCC lymph node metastases: here, we show that MMP-10 and MMP-26 may contribute to the rapid dissemination of MCC.

Tumors require angiogenesis to grow beyond a certain size. Positive regulators of angiogenesis include MMPs-1, MMP-2, MMP-9, MMP-10, and MT-MMPs [28]. Expression of MMP-7 and MMP-10 in MCC has been shown to correlate with VEGF expression levels [15]. We found MMP-10 capable of cleaving, e. g., pro MMP-1, MMP-2, and MMP-13, in most of our MCC samples confirming the importance of MMP-10 in MCC pathogenesis. Our results suggest that the more aggressive stage 2 and 3 tumors are associated with MMP-10 expression more often than stage 1 tumors. MMP-10 was also the most abundant MMP in metastasis samples.

MMP-26 is expressed in normal endometrial cells but in some carcinomas as well [29]. Our group has suggested MMP-26 not only to be associated with cancer but also with connective tissue remodeling during wound repair and pathobiology of various benign skin disorders [30]. MMP-26 has been linked to favorable prognosis in breast cancer patients, suggesting this protease to have anti-tumor properties [31]. Our present findings of stromal MMP-26 expression in especially larger tumors and in lymph node metastases suggest, however, that MMP-26 may, in some cancers, have a more notorious character. This agrees with our results on MMP-26 in esophageal [32] and pancreatic cancers [25].

In our MCC samples, MMP-21, cloned by our group [22], was the least expressed novel MMP in stroma and not associated with metastasis to the lymph nodes. It is also expressed in basal and squamous cell carcinomas [17] and may serve as a marker of malignant transformation of melanocytes in initial stages of tumorigenesis but not with micrometastases and poor outcome [19]. On the other hand, macrophages of granulomatous skin lesions and fibroblasts in dermatofibromas express MMP-21 [30]. MMP-21 has gelatinolytic activity, but its specific substrates are not known [33]. MMP-21 is upregulated by transforming growth factor-β1 in keratinocytes [17] and is a putative target of β-catenin transactivation in promoter analysis [34].

Here, we show that MMP-28, a proteinase thought to be involved in epithelial to mesenchymal transition [35], is expressed in primary MCC but not in lymph node metastases. Interestingly, tumors especially <2 cm in size expressed MMP-28 in tumor cells. MMP-28 is expressed in several normal tissues, suggesting a function in tissue homeostasis [36]. The role of MMP-28 seems to vary depending on tumor type as it is not overexpressed in melanoma [19] or colon cancer [37] but is upregulated in oral SCCs [38]. An interaction between TGF-β and MMP-28 has been suggested [36].

We also studied the regulation of MMP-21, MMP-26, and MMP-28 in UISO cells by VEGF, the expression of which correlates with aggressive behavior of MCC [15], but it did not alter the transcription of these MMPs. Instead IFN-α and TNF-α, used in the treatment of MCC [39–41], downregulated MMP-21 and MMP-28. Thus, some of the non-surgical therapeutic modalities for MCC may partly function through inhibition of proteolysis and angiogenesis via decreasing the levels of MMPs.

All the studied novel MMPs were expressed in less than half of the primary tumors either in tumor cells themselves or in stromal cells. Importantly, MMP expression is often associated with the supporting "host" cells rather than the tumor cells [28] emphasizing the importance of the microenvironment in tumorigenesis. The microenvironment contains several resident cell types (fibroblasts and vascular cells) and migratory cells derived from the bone marrow. Tumor-associated macrophages are able to produce several MMPs, and they may have both pro- and anti-tumor activities. Macrophage MMP-12 is required for the generation of angiostatin, an inhibitor of angiogenesis. Neutrophils produce MMP-8, which is supposed to have a protective role in cancer development [42]. Expression of MMP-8 or MMP-12 was not observed in MCC which may partly explain the aggressive behavior of these tumors.

In conclusion, our results show that several novel MMPs are upregulated in MCC tumors and cell lines and based on their expression in MCC metastasis, MMP-10 and MMP-26, in particular, may associate with aggressive disease.

Acknowledgments We thank Prof. Das Gupta and Dr. Roland Houben for UISO cells, Prof. Jorma Keski-Oja for MMP-28-overexpressing A549 cells, Ph. D. Jenita Pärssinen for contributions in the early phases of this study, and Ms. Alli Tallqvist and Ms. Jonna Jantunen for skillful technical assistance. This study was supported by the Academy of Finland, Finnish Cancer Foundation, Finska Läkaresällskapet, Helsinki University Central Hospital Research Fund (TYH2009233), Finland and Cancerfonden, the Swedish Research Council, and Edvard Welander–Finsen Foundation (TS), Sweden. Prof. Saarialho-Kere passed away during the processing of the manuscript. This article is dedicated to her memory.

ORIGINAL ARTICLE

Immunosuppressive cytokine Interleukin-10 (IL-10) is up-regulated in high-grade CIN but not associated with high-risk human papillomavirus (HPV) at baseline, outcomes of HR-HPV infections or incident CIN in the LAMS cohort

Abstract Bypassing the local immunological defense reactions in the cervix is one of the prerequisites for human papillomaviruses (HPV) infections to progress to intra-epithelial neoplasia (CIN). The role of potent immunosuppressive cytokines, e.g., interleukin-10 (IL-10), depressing these local virus-specific immunological responses is incompletely studied. To assess, whether IL-10 expression in cervical HPV lesions has any implications in the outcome of HPV infections or disease progression to CIN. Baseline cervical biopsies from 225 women of the LAMS study sub-cohort were analyzed for IL-10 expression using immunohistochemistry, to assess its associations with CIN grade, and high-risk HPV (HR-HPV) at baseline, as well as in predicting outcomes of HR-HPV infections, and development of incident CIN1+ and CIN2+ in this longitudinal setting. Expression of IL-10 in cervical lesions was up-

regulated most often in high-grade CIN, and IL-10 over-expression retained its value as independent predictor of CIN2+ (odds ratio (OR)=4.92) and CIN3+ (OR=7.51) also in multivariate model, including HR-HPV and several known covariates of IL-10 expression. Up-regulation was not related to HR-HPV detection, and showed no relationship to HR-HPV viral loads. Using longitudinal predictive indicators (SE, SP, PPV, NPV), IL-10 expression was of no value in predicting (1) the outcomes of HR-HPV infections, or (2) the surrogate endpoints (incident CIN1+, CIN2+) of progressive disease. IL-10 over-expression (along with HR-HPV) was one of the independent covariates of CIN2/3. This immunosuppressive cytokine might play an important role in creating a microenvironment that favors progressive cervical disease and immune evasion by HR-HPV.

Keywords High-risk HPV · Immunosuppressive cytokines · Interleukin-10 · Th cells · CIN · Viral outcomes · Disease progression · Longitudinal predictive values · Surrogate endpoints

Introduction

Practically all cervical carcinomas (CC) are caused by high-risk human papillomavirus (HR-HPV) infections, whereas the low-risk HPV (LR-HPV) types are rarely found in CC or its precursor (CIN) lesions [1–6]. This divergent oncogenic potential of LR-HPV and HR-HPV is mainly attributable to the differences of the two major viral oncoproteins (E6 and E7) to interact with the key regulatory cellular proteins, p53 and pRb [1, 4, 7–9]. While E6 of the HR-HPV (but not LR-HPV) initiates degradation of the p53 tumor suppressor protein, HPV E7 of HR-HPV (but not LR-HPV) binds to pRb resulting in G1/S transition of the cell cycle [1, 4, 7–11]. These two viral oncoproteins also play an important role in the processes, whereby HR-HPVs avoid recognition by the host immune surveillance mechanisms, leading to persistent HR-HPV infections, with increased risk of developing CIN and CC [1–4, 12, 13].

Both innate and adaptive immunity is needed to recognize and combat viral infections [1, 4, 12, 13], but HPV has developed several ingenious mechanisms on how to evade recognition by both of those. Of key importance in evading the innate immunity is the intraepithelial HPV life-cycle itself, which leaves little room for antigen presenting cells (APC) to recognize the virus [12, 13]. T lymphocytes are the key mediators of the adaptive immune system, consisting of two major subsets: CD4+ and CD8+ T cells [12, 13]. CD4+ T cells can be further subdivided into two subsets (Th1 and Th2) according to the profile of their cytokine expression. While Th1 cytokines (e.g. IFN-γ) enhance cell-mediated immunity (CMI), Th2 cytokines (interleukins (IL)) IL-4, IL-5, IL-6, IL-10, and IL-13 contribute to activation of humoral immune responses [12].

Of all these Th2 cytokines, IL-10 is of particular interest, because of its known anti-immune and anti-inflammatory properties [14, 15]. This cytokine is the first identified member [16] of a large family of ILs, with highly divergent biological functions [14, 15, 17]. Thus, IL-10 has (1) potent inhibitory effects on T-cell proliferation and inflammation, (2) it depresses the production of Th1 cytokines, and (3) in addition, IL-10 inhibits costimulatory activity of APCs, and (4) down-regulates MHC class II expression by monocytes [14, 15, 17, 18]. These properties make IL-10 the single most potent immunosuppressive cytokine and its increased expression could contribute to the development of cancer, because of suppressed Th1 cytokine production and concomitant absence of T-cell activation in tumor microenvironment [14, 15, 17, 18].

In the uterine cervix, such an immunosuppressive milieu would favor the development of immunological tolerance rather than immunological recognition of HPV antigens [12, 13]. Being produced by different type of cells, including keratinocytes [14, 15], IL-10 might potentially contribute to the development of such an immunosuppressive milieu in the uterine cervix. Until now, the specific role of IL-10 in cervical carcinogenesis has attracted little attention, despite some analysis on different cytokines in CIN and CC lesions [17, 19–22].

To further define the role of IL-10 in HR-HPV-associated cervical carcinogenesis, we analyzed a series of cervical biopsies derived from 225 women included in the Latin American Screening (LAMS) study cohort (n= 12,114) in Brazil and Argentina [23–26]. The study aimed to assess whether the expression of IL-10 is associated with (1) the grade of CIN, and (2) HR-HPV type at baseline, and whether it has any influence on (3) the outcome of these HR-HPV infections, or (4) development of incident CIN1+ and CIN2+ in this longitudinal setting.

Material and methods

General study design

The ongoing LAMS study is a multi-center screening trial targeting the female populations at different risk for CC in two Latin American countries, Brazil and Argentina [23]. At their baseline visit, a total of 12,114 consecutive women attending the four partner clinics: Campinas (CA), Sao Paulo (SP), Porto Alegre (PA), Buenos Aires (BA), were screened for HPV and CIN using eight different diagnostic tools, as detailed before [23–26]. Women that had a positive result with any of these diagnostic tests were examined by colposcopy (and biopsied) at their second visit. In addition,

a 5% random sample of PAP-negative women were recalled for a new PAP test at 12 months, as were 20% of those HCII negative, to assess the rates of incident PAP smear abnormalities and HPV infections, respectively [25, 26]. The women with biopsy-confirmed low-grade CIN comprise the prospective cohort (n=1,011), followed-up for a minimum of 24 months. All high-grade lesions were promptly treated and followed-up for the same period, using repeated PAP test, colposcopy, and HCII assay at 12-month intervals. For the present analysis of IL-10, baseline biopsies taken from 225 of these women were available.

Prospective follow-up

Using the above criteria, women were allocated in the prospective cohort, scheduled to be monitored in the clinic at 6-month intervals for a minimum of 24 months. A total of 1,011 women completed at least one FU visit including examination by PAP smear, visual inspection with acetic acid (VIA)/visual inspection with lugol's iodine, colposcopy, and biopsy, in case of abnormalities [24–26]. The mean FU time at this writing is 21.7 months (SD, 8.09 months; median, 24.2 months; range, 1–54 months).

Outcomes and endpoints of cervical lesions and HR-HPV infections

For the present analysis, the data of these 1,011 women were analyzed for the different surrogate endpoints of progressive disease: (1) progression to CIN1+, and (2) progression to CIN2+, as well as for different outcomes of their HR-HPV infections, including (1) incident infections, (2) virus persistence, and (3) HPV clearance. Progression to CIN1+ was based on detection (in baseline biopsy-negative woman) a biopsy-confirmed CIN1+ lesion in any of the consecutive FU visits. As a progression to CIN2+ was defined, any case where biopsy-confirmed progression from baseline negative, NCIN, or CIN1 biopsy was established in the subsequent FU-visits [27]. Times to progression into CIN1+ and CIN2+ were calculated from the baseline visit to the respective FU visit when the progression event was first detected. Progression rates were calculated dividing the numbers of progressed cases by women months at risk (WMR) and expressed per 1,000 WMR. Three outcomes of HR-HPV infections were recorded; incident, persistence, and clearance. As an incident HR-HPV infection, we recorded an appearance of positive hybrid capture 2 (HC2) test (at 1 pg/ml RLU/CO cut-off) among baseline HR-HPV-negative women at any of the FU visits. HR-HPV was considered cleared if the HC2 assay was negative at the last FU visit. Persistent HR-HPV infections were women in whom two or more subsequent HC2 assays were HR-HPV positive, and in whom the infection was not cleared at the last FU visit. Times to these three outcomes were also calculated and expressed as cases/1,000 WMR.

Methods

Because detailed in a series of recent reports [23–27], the methods used in the LAMS study are described here only as far as pertinent to elaborating the data necessary for the present analysis.

Epidemiological questionnaire

All women who gave their consent to participate (n= 12,114) filled in a detailed inquiry concerning the risk factors of HPV, CIN, and CC. This structured questionnaire contained questions exploring the reproductive history, sexual history, current sexual practices, sexual hygiene, medical history, smoking habits, and contraception [23].

Papanicolaou (Pap) smears

In the LAMS study, we compared the performance of three methods of cervical cytology: conventional PAP and two different LBC techniques (DNA-Citoliq®; Digene Brazil, Sao Paulo, and SurePath®; TriPath, Durham, NC, USA) [24]. In the present analysis, only the results of the conventional PAP test were used.

Directed punch biopsy

Directed punch biopsies (and cone biopsies) were fixed in formalin, embedded in paraffin, and processed into 5-µm-thick hematoxylin-eosin (HE) stained sections for light microscopy, following the routine procedures. All biopsies were examined among the daily routine in the Pathology Departments of the partner clinics in both studies, and diagnosed using the commonly agreed CIN nomenclature. The pathologists were also asked to notify the HPV-suggestive morphological changes in flat lesions with no CIN, i.e., HPV-NCIN (flat condyloma) [23, 24]. The slides from two of the centers (CA, SP) have been subjected to re-examination by two pathologists of the EC partners (ME, KS). The consensus diagnosis of the panel was considered as the final diagnosis.

Detection of HPV DNA by hybrid capture 2 assay

Primary HPV detection was done by HC2 assay, using cervical swabs (collected by a physician) and self-sampling devices (tampons), as described previously [23, 26]. HC2 assay (n=4,694 tests) was performed using the automated HC2 test system according to the manufacturer's protocol.

The samples were analyzed only for the presence of HR-HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68. The usual limit of 1 pg/ml of HPV 16 DNA was used as the positive control (CO), i.e., samples were classified as HR-HPV positive with the RLU/CO ≥1.0 pg/ml cut-off.

Immunohistochemical detection of IL-10

A total of 225 slides from the same number of women were available for immunohistochemical (IHC) analysis of IL-10. In brief, 4-μm-thick sections were cut on ChemMate Capillary Gap Microscope slides (Dako A/S, Glostrup, Denmark) and kept overnight at +55°C, deparaffinized in xylene, and rehydrated in graded alcohol. Before IHC, IL-10 antigen retrieval was done by heating the tissue sections in buffer of 10 mM Tris, 1 mM EDTA (pH 9.0) with a microwave oven for 10 min (600 W). The IHC staining for IL-10 was performed with the Dako TechMate™ 500 Plus Autostainer using monoclonal IL-10 antibody (MAB217; R & D Systems, Inc., Minneapolis, USA) diluted 1:50 and the reagents from Dako REAL-kit (Dako, Glostrup, Denmark). The sections were washed with distilled water and TBS-buffer. Then, the sections were stained with the primary antibody and the secondary biotinylated antibody (anti-mouse IgG) for 30 min. Endogenous peroxidase activity was blocked using 5% hydrogen peroxide for 3×2 min 30 s. This was followed by incubation with streptavidin peroxidase for 30 min. The counterstaining was performed with hematoxylin for 1 min, and the immunoperoxidase reaction was developed using 3, 3′-diaminobenzidine for 3×5 min. Finally, the sections were washed with distilled water and mounted with Aquamount (BDH Laboratory Supplies, Poole, England). Negative controls were similarly processed by omitting the primary antibody, and biopsies from tonsilla were used as positive controls.

Evaluation of the IHC staining for IL-10

In normal mature squamous epithelium, expression of IL-10 is invariably present, being cytoplasmic and confined to the cells in the basal cell layer of the epithelium (Fig. 1). In metaplastic squamous epithelium, IL-10 expression was often slightly increased in intensity, and also extended to the epithelial layers beyond the basal cells (Fig. 2). In CIN lesions, IL-10 expression was variable (normal or up-regulated), significant up-regulation being mostly confined to high-grade CIN (Figs. 3 and 4). In all biopsies, IL-10 expressing cells were also encountered among the inflammatory cell infiltrates in the connective tissue underlying the epithelial lesion (Figs. 1, 2, 3, and 4). In the original grading of the IL-10 staining, a semi-quantitative scoring into four categories was used, as follows: 0=no expression; 1=weak staining (equivalent to normal squamous epithelium); 2=

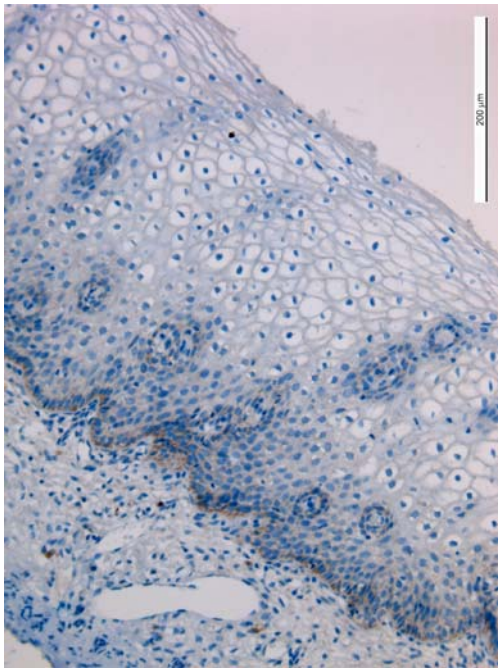

Fig. 1 Normal cervical epithelium with characteristic expression pattern of IL-10. IL-10 is regularly present, as cytoplasmic staining confined to the cells in the basal layer. In underlying connective tissue, scattered IL-10+ lymphocytes are also seen (IHC for IL-10, original magnification ×50)

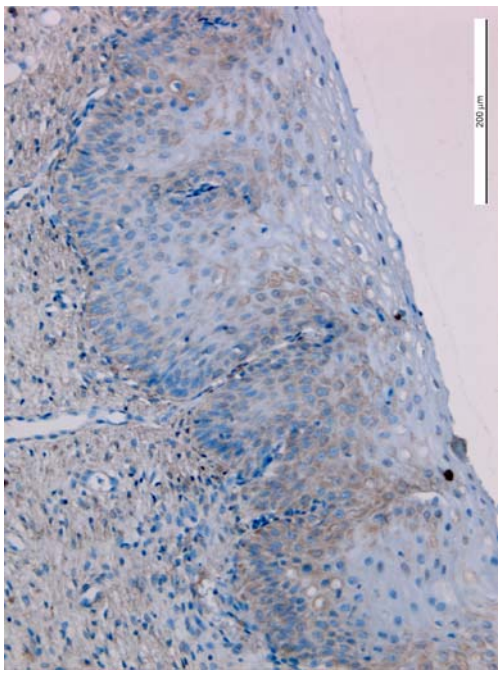

Fig. 2 Another site of squamous epithelium with characteristic features of metaplasia. As compared with the mature squamous epithelium in Fig. 1, cytoplasmic expression of IL-10 is extending to parabasal and lower intermediate layers. Staining is scattered in distribution, with some focal condensations. (IHC for IL-10, original magnification ×100)

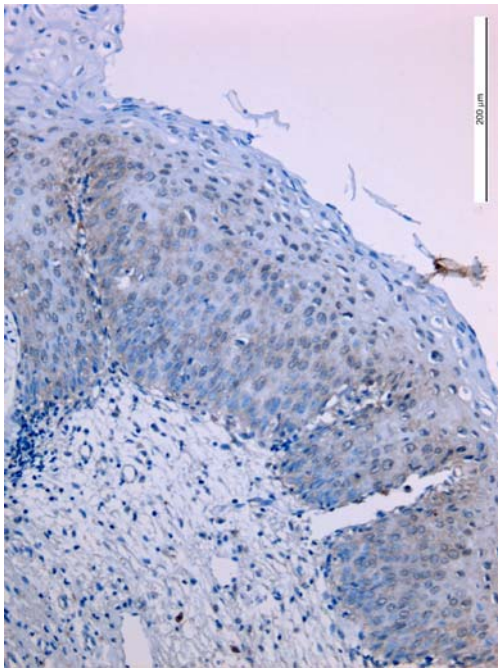

Fig. 3 A flat epithelial lesion with characteristic morphological features of HPV infection, associated with CIN2. IL-10 positive cells are confined to the dysplastic cells within the lowermost two thirds of epithelial thickness (CIN2 area), but also some koilocytes seem to be positive. A few IL-10+ lymphocytes appear in the underlying stroma (IHC for IL-10, original magnification ×100)

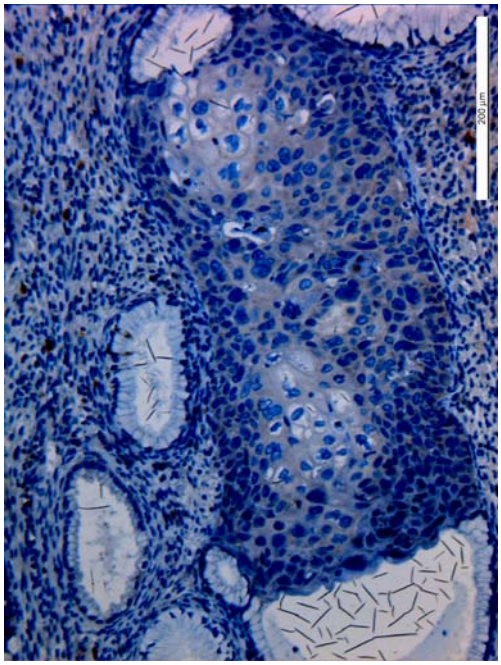

Fig. 4 A high-grade CIN3 lesion penetrating into an underlying glandular opening. IL-10 expression is found throughout the full thickness of the epithelium, indicating marked up-regulation. The staining is diffuse but its intensity shows some variability. In adjacent stroma, a few IL-10+ lymphocytes and macrophages are scattered among a loose inflammatory cell infiltrate (IHC for IL-10, original magnification ×250)

slightly to moderately increased staining (intermediate cells are stained); 3=strongly increased staining (all layers show positive IL-10 staining). In statistical analysis, the staining result was also treated as a dichotomous variable (normal vs. increased) to enable calculating the risk estimates (OR). In this analysis, no attempt was made to enumerate the cells expressing IL-10 among the inflammatory cell infiltrates.

Statistical methods

Statistical analyses were performed using the SPSS® and STATA software packages (SPSS for Windows, Version 16.0.2.1, and STATA/SE 10.1). In order to rule-out a selection bias caused by the non-systematic selection of the cases for IL-10 assessment, we compared the key clinical and epidemiological features of the 214 subjects who had material available for IL-10 assessment with those of the entire (1,011) LAMS cohort, forming three groups: women who had not undergone biopsy, women who underwent biopsy but the material was not available for IL-10 assessment and the study group (IL-10-available). Frequency tables for categorical variables were analyzed using the chi-square test. A multivariate linear model was fit to assess the distribution of these key epidemiological and clinical variables across the groups. In the subsequent analyses, using the IL-10 available subset, likelihood ratio (LR) or Fisher's exact test were used to assess the significance. Differences in the means of continuous variables were analyzed using non-parametric tests (Mann-Whitney) or analysis of variance (ANOVA). Performance indicators (sensitivity, specificity, PPV, NPV, and their 95% CI) for IL-10 as predictor of baseline CIN2/3 or HR-HPV, as well as the longitudinal predictive values for the three viral outcomes and incident CIN1+ and CIN2+, were all calculated using STATA/SE software and the algorithm of Seed et al. [28], which also calculates the area under ROC curve (AUC). In all tests, the values $p<0.05$ were regarded statistically significant.

Results

Table 1 depicts the key epidemiological and clinical features of the women that attended follow-up consultations during the prospective phase of the LAMS study, considering the availability of cervical biopsies and material for immunohistochemistry. Only women of the "IL-10 available" group were included in subsequent analyses. Most women (66.4%) were HPV-positive at baseline, on average they were 33 years of age at enrollment and most (70.3%) started sexual activity before 18 years of age. Approximately 40% of the sample consisted of current users of

[a] Semi-quantitative viral load determined by the RLU/CO ratio in hybrid capture 2 assay, log-transformed

hormonal contraception, and the same proportion of the women was of past or current smokers. Roughly 20% of the women had had four or more sexual partners during their lifetime. Multivariate analysis disclosed a slight, and clinically not significant, imbalance in HPV positivity rates between the groups formed considering the availability of material for histopathological analysis (p=0.03). These rates ranged from 64.7 in women that had a cervical biopsy, but whose material was not available for IHC, to 67.8% in women included in the present analysis (IL-10 assessment performed). No other imbalances in clinical and epidemiological features between groups were found.

The expression of IL-10 in cervical biopsies as related to the lesion grade is summarized in Table 2. There was a significant linear trend of increasing up-regulation of IL-10 (p=0.008) in parallel with increasing grade of CIN, with a major drop in normal expression upon transition from CIN2 to CIN3. When dichotomized (normal vs. increased), up-regulated IL-10 expression predicted CIN3+ with OR=3.66 (95% CI 1.76–7.6; p=0.001) and CIN2+ with OR=3.36 (95% CI 1.77–6.38; p=0.0001).

Table 3 depicts the association of IL-10 expression with the HR-HPV detection and semi-quantitative viral load measured by the HC2 assay. IL-10 expression pattern (3-tier grading) was clearly not related to detection of HR-HPV, showing similar distribution among HR-HPV+ and HR-HPV samples (p=0.313). Similarly, dichotomized expression was not associated with HR-HPV detection either: OR=1.60 (95% CI 0.76–3.35; p=0.201). The log-transformed semi-quantitative HR-HPV viral loads were not directly related to up-regulation of IL-10 (p=0.086). Not unexpectedly, when the performance indicators were calculated, IL-10 was not a useful marker of HR-HPV, with AUC=0.546 (95% CI 0.477–0.615).

Expression of IL-10 in the baseline biopsies was related to the outcomes of HR-HPV infections as presented in Table 4. IL-10 expression did not bear any relationship to the subsequent outcomes (incident infections, clearance, persistence) of HR-HPV infections during the follow-up, and no useful information was obtained calculating the longitudinal predictive values for the three outcomes. As to the time to clearance and time to incident HR-HPV (not calculable), there were no differences related to IL-10 expression.

Table 5 gives the data on IL-10 as predictor of the two surrogate endpoints of progressive disease (incident CIN1+, CIN2+). The 3-tier grading of IL-10 expression was practically identical in the baseline biopsies that subsequently progressed to incident CIN1+, with no significant difference. Longitudinal performance indicators did not provide any useful values, with AUC=0.472. The same is true with IL-10 as predictor of incident CIN2+ (AUC=0.506). However, NPV exceeds 90% implicating that

Table 4 Expression of IL-10as predictor of different outcomes of HR-HPV infection

Endpoint	IL-10 expression						*p* value		Longitudinal performance indicators of dichotomous (I/N) IL-10

AUC area under ROC curve, *I/N* increased vs. normal

normal IL-10 expression precludes progression to CIN2+ with high accuracy (95% CI 82.4–96.3%). Times to progression to CIN1+ or CIN2+ were identical in different categories of IL-10 expression (data not shown in the Table).

Discussion

The first evidence on local immunological reactions as important mediators of host resistance against HPV infection [12, 13] was obtained in skin warts, where dense infiltrates of inflammatory cells were described in regressing lesions [13]. In the early 1980s, these studies were extended to cervical HPV lesions using newly introduced monoclonal antibodies to enumerate the cell subsets within these tissue-infiltrating lymphocytes (TIL) [29, 30]. Different subsets of lymphocytes (B cells, T helper cells; T suppressor cells) were present in abundance among these TILs, located subjacent to but also within the HPV lesions, CIN and CC [29, 30]. In addition, other types of immunocompetent cells, including Langerhans cells and natural killer cells were also detected among these infiltrates [31, 32]. Being hampered by the fact that serial samples were not available for analysis, these early studies failed to establish any meaningful correlations between the dynamic changes in TIL subsets (e.g., Th/Ts ratio) and the clinical outcome of HPV infections in a longitudinal setting [33, 34].

These enumeration studies have been subsequently complemented with the functional data on interleukins as key regulators of both humoral and CMI responses [12–15].

AUC area under ROC curve, *I/N* increased vs. normal

Since its identification in 1989 [16], a huge amount of data have accumulated on IL-10 [14, 15]. It is now well established that IL-10 is produced by several different immune and non-immune cells, including T helper type 2 (Th2) cells, subsets of regulatory T cells designated as Tr1, Th1, and Th17 cells, CD8+ T cells, monocytes, and stimulated macrophages, some subsets of dendritic cells, B cells, as well as some granulocytes (eosinophils and mast cells) [14, 15]. Importantly, also some non-immune cells are rich sources of IL-10, most notably keratinocytes, epithelial cells, and even tumor cells [14, 35].

Including keratinocytes in this list of IL-10 secreting cells increases the interest in this cytokine as a potential modulator of cervical HPV infections, particularly through its known potent immunosuppressive effects [14, 15, 17, 18]. All these properties are potent enough to make IL-10 as an impending contributory factor in the development of cancer [14, 15]. Consistent with this, IL-10 expression has been shown to have increased in several different human malignancies (reviewed in [14]). Interpretation of these data is not straightforward, however, because elevated IL-10 expression can occur for multiple reasons with opposite implications, e.g., expressed by tumor cells themselves (suppressing antitumor responses), or produced by activated cells as a sign of a host antitumor reaction [14].

Taken the known complexity of the mechanisms whereby host immune responses attempt to control HPV infections on one hand and the cunning mechanisms developed by the virus to evade this control on the other hand [12, 13], there is little doubt that multiple potential sites of interaction between IL-10 and HR-HPV could exist in the microenvironment of CIN and/or CC. Under these circumstances, one could expect seeing some differences in IL-10 expression as related to (1) the grade of CIN, and (2) HR-HPV detection, as well as to (3) the outcome of these HR-HPV infections, and (4) development of incident CIN1+ and CIN2+, all having been examined in the present study. Instead of measuring cytokines in the serum [19] or in immune cells within TILs [20, 22], the present study analyzed the expression of IL-10 in the epithelial cells of CIN lesions, to assess whether the IL-10 expression patterns in cervical lesions have any associations with these four outcomes.

In the present study, IL-10 expression could be identified in practically all cervical biopsies, including normal epithelium and all grades of CIN (Table 1). IL-10 in normal squamous epithelium is confined to the basal cells, with rare extension to parabasal cells. IL-10 expression in normal cervical epithelium has been reported for the first time only recently, when Mindiola et al. [36], using a similar IHC approach, described increased IL-10 expression in normal epithelium adjacent to CIN or CC lesion. Using this IL-10 pattern in the normal squamous epithelium as a reference, we noticed that the expression of IL-10 seems to increase almost in parallel with the increasing grade of CIN. This is in full agreement with the observations reported in the recent studies using a similar approach [17, 36, 37]. In studies using different technique (e.g., RT-PCR for mRNA or cytokine tests in peripheral blood), IL-10 expression was shown to be decreased in HIV patients [22] as well as in CC as compared with CIN [20].

Interestingly, increased expression of IL-10 was shown to be associated with decreased risk of CIN2/3 lesions, when controlled for potential confounders using a multivariate model [38]. This is in sharp contrast to the present study, where up-regulated IL-10 expression predicted CIN3+ with OR=3.66 and CIN2+ with OR=3.36. When controlled for the most important confounder (HR-HPV), IL-10 up-regulation retained its significant association to both outcomes, with common OR=4.6 (95%CI 2.03–10.64) and OR=5.6 (95%CI 2.43–13.08) for CIN3+ and CIN2+, respectively (p=0.0001). However, it must be emphasized that these results were obtained with radically different methodologies. First, the IL-10 detection was performed using RT-PCR [38], contrasted to IHC in the present study. However, the most striking methodological dissimilarity is the fact that the quantification of IL-10 has been performed in cervical cytological specimens [38], collected with cytology brush, which may impart a wide variability of concentrations of the protein depending on how the collection has been done. Other analytical features of both studies, e.g., control variables used to balance for clinical factors contributing to CIN development, may also have partially contributed to these conflicting results.

In our series, up to 60% of CIN2 lesions still retained only weak expression of IL-10, equivalent to that found in the normal epithelium. In alignment with the recent reports [36, 37], IL-10 expression reached a peak in CIN3 lesions, of which only 44.4% retained the baseline profile, and almost 14% showed a significant over-expression (Table 1). It is tempting to speculate that this obvious up-regulation upon transition from CIN2 to CIN3 might bear some association with HR-HPV. In such a case, up-regulated IL-10 in these high-grade lesions could implicate a progressively increasing immunosuppression in a microenvironment favoring progressive cervical disease. This concept does not seem to hold true, however. Instead, the present data (Table 2) indicate that the expression profile of IL-10 is completely unrelated to the detection of HR-HPV in these lesions. Albeit previously described [17] (and confirmed by us) in typical HPV-harboring cells, IL-10 expression was shown to be completely unrelated to the detection of HPV also in another recent study [36]. In addition, we demonstrated no association between IL-10 expression and viral load of HR-HPV in the present series. As expected, then, IL-10 was not a useful marker of HR-HPV (AUC=0.546), unlike some other

markers ($p16^{INK4A}$, Survivin and hTERT) recently established as such [39].

Considering the potent immunosuppressive properties of IL-10 in the local microenvironment [14, 15, 17, 19–22], one would expect that its abundant expression should have some unfavorable impact on (1) the outcome of HR-HPV infections or (2) progression to CIN. This concept was challenged in the present study, however, when we failed to provide any confirmatory evidence to support the view that IL-10 expression could modify these viral and clinical outcomes. Thus, incident HR-HPV infections, virus clearance or HR-HPV persistence did not show any direct association with IL-10 expression (Table 3). Similarly, there was practically no difference in the baseline IL-10 expression patterns among progressive and non-progressive lesions (Table 4), and IL-10 was of no value in discriminating the incident CIN1+ and CIN2+ cases from those that did not progress.

Like studies enumerating immunocompetent cells among TILs in the baseline biopsies [29–34], also the present study suffers from the failure to provide any longitudinal data from the biopsies taken at FU visits [23, 27]. It is to be emphasized that like the traffic (recirculation) of immunocompetent cells in the cervix, also the production of immune regulatory cytokines (like IL-10) is a highly dynamic process [14, 15], being balanced and counterbalanced by a multitude of local and systemic stimuli that are impossible to record in single biopsies without a longitudinal setting. As recently discussed, several regulators of cytokine expression are currently known, including age, days since the last intercourse, current use of OC, current cigarette smoking, period of menstruation) [38], which are potential confounders of any analysis of IL-10 expression alone. To test the impact of these covariates, we constructed a multivariate model, including HR-HPV and the following potential confounders of IL-10 expression: age, time since last menstruation, current use of OC, and current smoking. Interestingly, the significant association of IL-10 with CIN2 and CIN3 was not confounded, but IL-10 retained its value as independent covariate of both CIN2 and CIN3 endpoints (together with HR-HPV, age and use of OC; data not shown).

In alignment with other recent reports [17, 36, 37], IL-10 up-regulation in the baseline biopsies was most consistently associated with high-grade CIN. The expression profile of this cytokine was unrelated to HR-HPV or its viral load, however, and was not a predictor of viral outcome and disease progression in a longitudinal setting. Together with HR-HPV, age and use of OC, IL-10 was an independent covariate of CIN2/3, suggesting that this immunosuppressive cytokine might play an important role in creating a milieu that favors progressive cervical disease. To better understand the role of IL-10 as a potential means contributing to the effective immune evasion by HR-HPV, several questions remain unanswered. Among these is the question whether HPV (like EBV, EHV2, Pox, CMV) [14, 15] does, indeed, have IL-10 gene homologs in their genome. Taken the close amino acid sequence homology between these known viral IL-10s and human IL-10 [14], one cannot exclude the possibility that IL-10 expression recently reported in koilocytes [17] and confirmed by observations in the present study might not be due to IL-10 of a viral (HPV) origin.

Abstract Malignant peripheral nerve sheath tumor (MPNST) is a rare soft tissue sarcoma. We established a new human MPNST cell line (designated FMS-1) from MPNST of the right brachial plexus of a 69-year-old woman with NF1. The cell line has been maintained for >24 months with >100 passages. FMS-1 cells showed a fibrosarcoma-like or epithelioid pattern in the heterotransplanted tumor, compared with a fascicular growth pattern of short-spindle tumor cells in the primary tumor. Immunophenotypically, FMS-1 cells showed almost the same characteristics as the primary tumor. Cytogenetic and molecular analyses revealed a deletion in exons 5-8 of the p53 gene. Epidermal growth factor receptor (EGFR) and cyclooxygenase (COX)-2 were expressed in FMS-1 cells. To improve the highly aggressive course and poor prognosis and establish new therapeutic methods, molecular genetic and biological characterizations of MPNST are required. Thus, FMS-1 cells might be useful for investigating biological behaviors and developing new molecular-targeting antitumor drugs for MPNST expressing EGFR or COX-2.

Introduction

Malignant peripheral nerve sheath tumor (MPNST), also called malignant schwannoma or neurofibrosarcoma, is a rare soft tissue sarcoma, accounting for approximately 5% of soft tissue sarcomas. Approximately half of MPNSTs manifest in patients with neurofibromatosis type 1 (NF1; von Recklinghausen disease) [1], and patients with NF1 have a 5–10% lifetime risk of MPNST [2, 3].

MPNST frequently shows highly aggressive behavior, resistance to multi-agent chemotherapy, and fatal metastasis. About 60% of patients with MPNST die of the disease and the overall 5- and 10-year survival rates are 34% and 23%, respectively [1]. Therefore, to improve the aggressive course or prognosis, new therapeutic developments including molecular-targeting drugs based on molecular genetic and biological characterizations of MPNST are required.

To the best of our knowledge, only nine human MPNST cell lines from eight patients with MPNST have been reported to date [4–9]. However, these cell lines have been adequately investigated from the perspectives of molecular genetics and biological behaviors. To clarify the biological behavior of MPNST, the present study established and characterized a new MPNST cell line, FMS-1, derived from a patient with NF1. Moreover, for the purpose of developing the potentialities for new therapeutic targets of MPNST, since there is no established remedy for MPNST other than surgical exclusion,

we also investigated whether epidermal growth factor receptor (EGFR) and cyclooxygenase (COX)-2 are over-expressed in FMS-1.

Materials and methods

Case report

A 69-year-old Japanese woman with a past medical history of NF1 on the basis of clinical findings (multiple cutaneous neurofibromas and café au lait spots) was admitted to our hospital with a 6-year history of palsy in the right arm. Physical examination showed a tumor in the right axilla, and her illness was clinically diagnosed as right brachial plexus palsy due to brachial plexus tumor. Magnetic resonance imaging revealed a tumor in the right brachial plexus involving the right subclavian/axillary artery and vein, measuring 173×93×77 mm in size. This lesion was hypointense on T1-weighted imaging and intermediate to hyperintense on T2-weighted imaging, showing diffuse enhancement on Gd-enhanced T1-weighted imaging. No distant metastases were found on radiological analysis. Light microscopy of incisional biopsy specimens from the right brachial plexus tumor showed diffuse proliferation of short spindle-shaped cells with focal arrangement in a fibrosarcoma-like pattern and occasional large pleomorphic cells (Fig. 1). Spindle-shaped and pleomorphic cells showed atypical nuclei, and mitotic figures were frequently seen. Immunohistochemically, tumor cells were positive for vimentin, S-100 protein, and nerve growth factor receptor (NGFR). Characteristics from light microscopy and immunohistochemistry led us to a diagnosis of MPNST. The criteria for diagnosis of MPNST have previously been outlined by Fletcher [10, 11]. The patient had not undergone any therapy such as palliative operation, chemotherapy, or radiotherapy, as the patient and her family were hoping to avoid therapy. The patient died of the disease 5 months after biopsy.

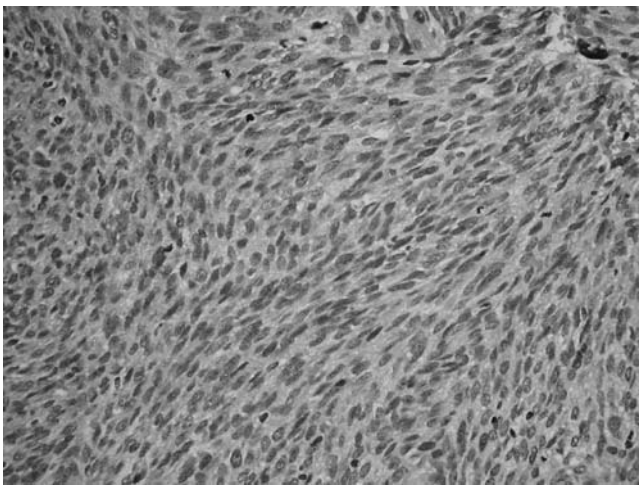

Fig. 1 Histology of the primary right brachial plexus tumor. Tumor cells show diffuse proliferation and are short spindle-shaped cells arranged in a fibrosarcoma-like pattern, accompanied by scattered pleomorphic cells (hematoxylin and eosin, ×200)

Establishment of cell line

Tumor cells were obtained from the biopsy specimen. The tumor tissue was cut into small pieces measuring about 0.5×0.5×0.5 mm with a scalpel, rinsed with phosphate-buffered saline twice. After the treatment with 0.25% trypsin-EDTA solution (Sigma, St. Louis, MO, USA), cells were cultured at an initial concentration of 1.0×10^6 viable cells/ml in RPMI-1640 medium (#R8758; Sigma) supplemented with 15% heat-inactivated fetal calf serum (FCS; JRH Biosciences, Lenexa, KS, USA), 50 units/ml penicillin G and 50 μg/ml streptomycin. Next, cells were inoculated into 100-mm plastic dishes (BD Falcon #353003; BD Biosciences, Franklin Lakes, NJ, USA) and incubated at 37°C in a humidified atmosphere with 5% CO_2. The culture medium was changed twice per week. To harvest and transfer the cell line, cells were treated with 0.25% trypsin-EDTA solution after reaching a sub-confluent state. The cell line has been maintained for >24 months under these culture conditions.

Morphological study

Growth and morphology of cultured cells in vitro were observed using an inverted microscope. Morphological characteristics were further determined by May-Giemsa staining on cytospin preparations and by hematoxylin–eosin staining on paraffin-embedded sections.

Immunohistochemistry

Immunohistochemical analysis was performed on the primary tumor, cultured cells at the 48th passage and heterotransplanted tumors using the streptavidin-biotin complex method. Antibodies used in this study are summarized in Table 1.

Cell population doubling time

To determine the doubling time, 3.5×10^5 cells at the 49th passage were seeded on 35-mm plastic dishes (BD Falcon #353046; BD Biosciences) with fresh culture medium containing 15% FCS. Dishes were harvested, and the number of viable cells in each dish was counted using the dye exclusion test (0.1% trypan blue in phosphate-buffered saline) every 24 h for 7 days.

Table 1 Antibodies used in the present study

Antibody	Clone	Dilution	Source
Vimentin	V9	1:1,000	Dako[a]

Heterotransplantation

Severe combined immunodeficiency (SCID) mice (lcr/scid, female) and athymic nude mice (BALB/cA-nu/nu, female) were purchased at 6 weeks old from CLEA Japan (Tokyo, Japan) and kept under sterile conditions. All animal experiments were performed under the control of our committee in accordance with the Guidelines on Animal Experiments at Fukushima Medical University, the Japanese Government Animal Protection and Management Law (No. 105) and the Japanese Government Notification of Feeding and Safekeeping of Animals (No. 6). Mice were given a single subcutaneous injection of 1×10^7 cells at the 65th passage from cultured cells in the log phase of growth.

Cytogenetics

Karyotype analysis of FMS-1 cells at the 71st passage was performed commercially by SRL (Tokyo, Japan) using the trypsin G-banding technique.

Polymerase chain reaction-single strand conformational polymorphism (PCR-SSCP) and direct sequencing analysis for p53 gene

Genomic PCR-SSCP in p53 gene exons 5-8, which are considered the mutational hot spot for this gene, was performed on FMS-1 cells at the 78th passage (Mitsubishi Kagaku Bio-Clinical Laboratories, Tokyo, Japan). Moreover, oligonucleotide sequences in exons 5–9 of the p53 gene were analyzed by direct sequencing. DNA samples were extracted from FMS-1 cells at the 80th passage using Sepagene (Sanko-Junyaku, Tokyo, Japan), in accordance with to the protocol provided by the manufacturer. Using Takara Ex Taq HS polymerase (Takara Bio, Shiga, Japan), 0.5 μg of DNA was amplified in a total volume of 50 μl. The sequencing primers were as follows [12]: exons 5-6 (sense), 5′-TTCCTCTTCCTGCAGTACTC-3′; exons 5–6 (antisense), 5′-AGTTGCAAACCAGACCTCAG-3′; exon 7 (sense), 5′-GTGTTGCCTCCTAGGTTGGC-3′; exon 7 (antisense), 5′-CAAGTGGCTCCTGACCTGGA-3′; exons 8–9 (sense), 5′-CCTATCCTGAGTAGTGGTAA-3′; exons 8–9 (antisense), 5′-CCAAGACTTAGTACCTGAAG-3′. These primers were obtained from Sigma-Aldrich Japan (Hokkaido, Japan). PCR was performed as follows: denaturing at 94°C for 10 min followed by 30 cycles of amplification (94°C for 1 min, 60°C for 1 min, and 72°C for 1 min) and a 10-min extension at 72°C, in a thermal cycler (i-cycler, Bio-Rad Laboratories, Hercules, CA, USA). One microliter of the PCR product was applied for PCR under conditions consisting of 1 cycle of 95°C for 5 min and 25 cycles of 95°C for 30 s and 60°C for 30 s by the direct sequencing method (Thermo Sequenase core sequencing kit with 7-deaza-dGTP; Amersham, Cleveland, OH, USA). Subsequently, oligonucleotide sequences of exons 5–9 of the p53 gene were analyzed using a sequencer (SQ-5500, Hitachi, Tokyo, Japan) and compared with the germline sequences recorded in the GenBank database.

Western blotting analysis for EGFR and COX-2

Protein samples were separated from cell pellets of FMS-1 cells at the 66th passage. Methods for Western blotting analysis, reagents and antibodies (EGFR (1,005; sc-03, 1:1,000 dilution; Santa Cruz Biotechnology, Santa Cruz, CA, USA) and COX-2 (H-62; sc-7951, 1:200 dilution; Santa Cruz Biotechnology)) used in this study were the same as previously described [13]. The FPS-1 cell line, derived from human undifferentiated pleomorphic sarcoma and established in our laboratory [14], was used as a positive control for EGFR and COX-2 proteins.

RNA preparation and reverse transcription-PCR (RT-PCR) analysis for EGFR and COX-2 mRNA expression

Total RNA from FMS-1 cells at the 64th passage was isolated using ISOGEN reagent (Wako Pure Chemical Industries, Osaka, Japan) according to the manufacturer's protocol. Methods and sequencing primers were the same as previously described [13]. The FPS-1 cell line [14] was used as a positive control for EGFR and COX-2 mRNAs.

Results

Immunohistochemical analysis for p53, EGFR, and COX-2 on primary tumor cells

Primary tumor cells showed strong immunopositivity for EGFR and COX-2 (Table 2), but no immunoreactivity for p53.

Establishment of cell line

A new human MPNST cell line, designated FMS-1, was established from the right brachial plexus tumor of a patient with NF1. Doubling time of this cell line was approximately 38.5 h. The cell line has been stably maintained for >100 passages (a period of >24 months). Cultured cells comprised small, polygonal, or short-spindle-shaped cells with occasional large pleomorphic cells (Fig. 2). Loss of contact inhibition was observed. Immunohistochemically, cultured cells were positive for vimentin, S-100 protein (Fig. 3a), CD57, CD56, neurofilament, NGFR, CD99, protein gene product 9.5, AE1/AE3, Ki-67, EGFR (Fig. 3b), and COX-2 (Fig. 3c), but were negative for neuron-specific enolase, synaptophysin, CD34, desmin, α-smooth muscle actin, and p53 (Fig. 3d; Table 2).

Heterotransplantation

The FMS-1 cell line showed successful heterotransplantation into SCID mice and athymic nude mice. In two of two SCID mice and one of two nude mice given a single subcutaneous injection of FMS-1 cells, a tumor with a diameter of approximately 15 mm developed 9 weeks after inoculation (Fig. 4a). The cut surface of the xenografted tumor was solid and white. Under light microscopy, the tumor of SCID mouse showed various morphological patterns: spindle-shaped cells arranged in a fascicular and fibrosarcoma-like herringbone pattern (fascicular area, Fig. 4b) or focally in a nuclear palisading pattern (palisading area, Fig. 4c). An epithelioid-cellular area was also observed in the same tissue fragment (epithelioid area, Fig. 4d). Microscopically, tumor in nude mouse showed diffuse proliferation of epithelioid tumor cells with frequent mitotic figures (Fig. 4e). Focally, short-spindle-shaped tumor cells showed a structured fascicular pattern. A nuclear palisading pattern was not observed in tumor in nude mouse. No metastases were found at other sites, such as the brain, lungs or liver, in either SCID or nude mice. FMS-1 cells and heterotransplanted tumor cells showed almost the same immunophenotype as primary tumor cells. Primary tumor cells, FMS-1 cells, and heterotransplanted tumor cells all expressed EGFR and COX-2, but not p53 (Table 2).

Table 2 Immunohistochemical reactivity of primary tumor, FMS-1 cell line (in vitro), and heterotransplanted tumor (FMS-1 in nude mouse; in vivo) to various antibodies

[10], add(15)[8], −16[10], −17[10], −17[10], −17[6], add(17)(q25)[10], add(17)[2], +18[3], −19[8], add(19)(p13)[4], −20[10], −20[8], −21[3], −22[10], −22[10], add(22)(q13)[10], add(22)[8], +der(?)t(?;8)(?;q13)[6], +mar1×2[5], +mar2[9], +mar3[4], +1–4mar; cp10 (Fig. 5).

PCR-SSCP and direct sequencing analysis for p53 gene

In the FMS-1 cell line, PCR transcripts of the exons 5–9 or 5–8 of the p53 gene were not amplified both by PCR or PCR-SSCP. Direct sequencing was unable to show meaningful results (data not shown).

Western blotting for EGFR and COX-2 proteins

Western blot analysis demonstrated that FMS-1 and FPS-1 cells as a positive control expressed both EGFR and COX-2 proteins (Fig. 6).

RT-PCR analysis for EGFR and COX-2 mRNA

RT-PCR analysis showed both EGFR and COX-2 mRNA in FMS-1 cells, and also in FPS-1 cells as a positive control (Fig. 7).

Discussion

We established the FMS-1 cell line from human MPNST in a patient with NF1. FMS-1 cells showed various morphological characteristics in heterotransplanted tumor, with short-spindle-shaped tumor cells structured in a fascicular pattern, or polygonal cells with atypical nuclei arranged in an epithelioid pattern with scattered uninucleated anaplastic cells. An epithelioid component was observed in the heterotransplanted tumor, but not in the primary tumor. FMS-1 cells in vitro and in vivo showed almost the same

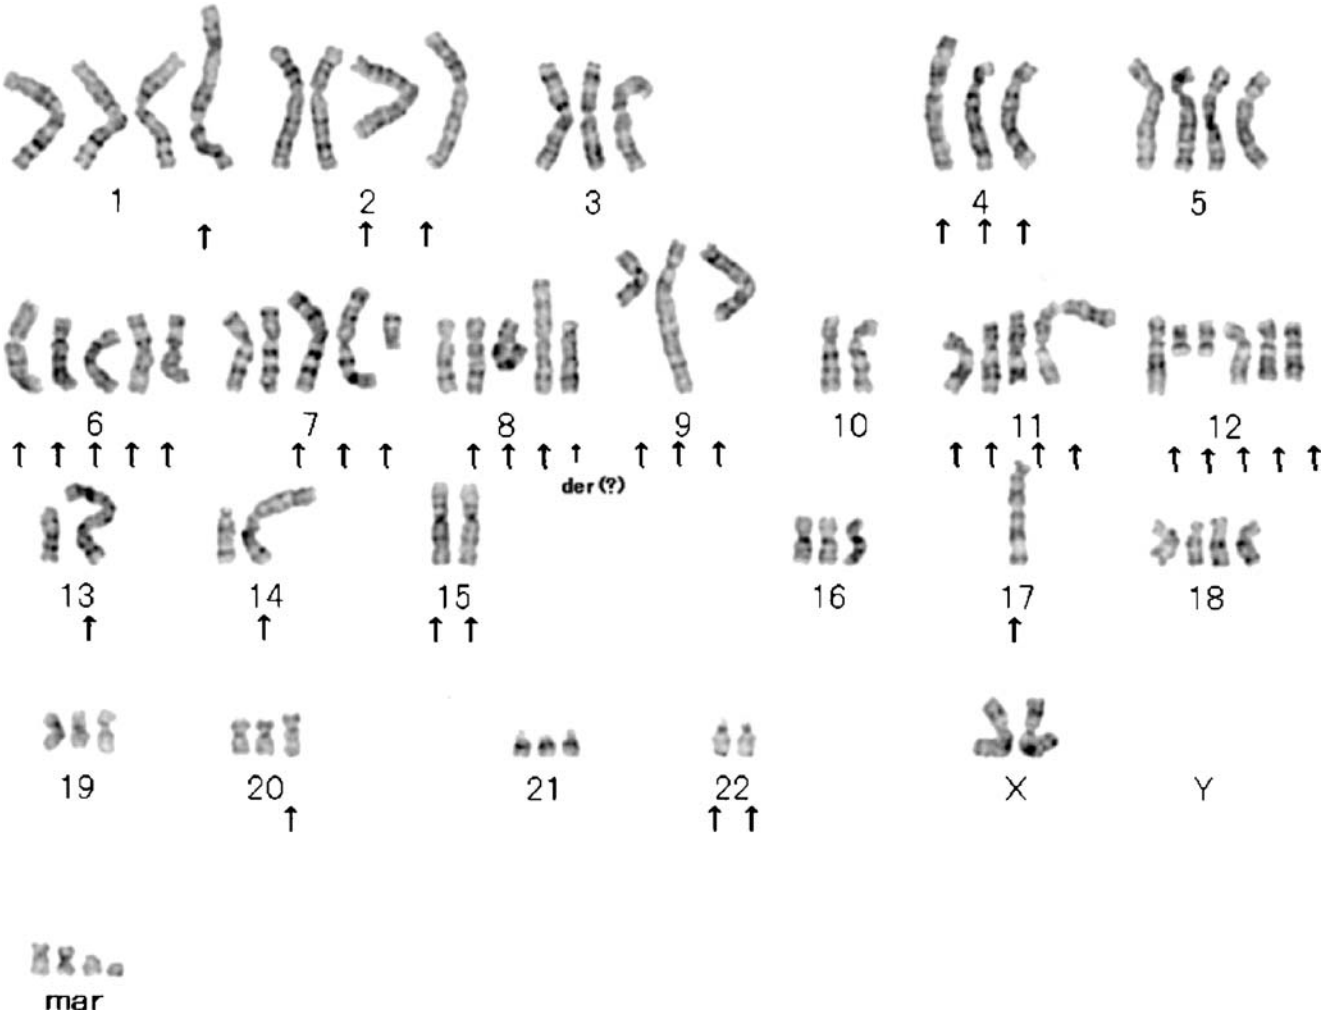

Fig. 5 Representative G-banded karyotype of the FMS-1 cell line at passage 71, exhibiting the following abnormal complement: 79, XX, −X, −X, der(1)add(1)(p36)add(1)(q21), add(2)(p23)×2, −3, −4, add(4)(p16), der(4)add(4)(p15)?t(4;11)(q35;q23)×2, +6, +add(6)(p11)×3, der(6;15)(p10;q10)×2, +7, +add(7)(p22)×2, del(7)(q11), +8, +add(8)(q21)×2, add(8)(p11), +der(?)t(?;8)(?;q13), −9, add(9)(q21), add(9)(q32), der(9)t(8;9)(q11;p13), −10, −10, del(11)(p15)×2, der(11)add(11)(p15)del(11)(q23), der(11;13)(13qter→13p11::?::11p15→11q23:), +12, +12, +del(12)(q13)x2, del(12)(q24q24)x3, −13, −13, der(13)t(13;13)(p11;q12)ins(13;?)(p11;?), −14, −14, add(14)(p13), −15, −15, add(15)(p13)×2, −16, −17, −17, −17, add(17)(q25), −19, −20, −21, −22, −22, add(22)(q13)×2, +mar1×2, +mar2, +mar3, +1–4mar. *Arrows* indicate the abnormal chromosomes

immunophenotype as primary tumor cells, suggesting MPNST, and FMS-1 was thus thought to be derived from the primary MPNST. Only immunoexpression of the neurofilament and CD99 shows difference between in the primary tumor and in the FMS-1 (in vitro and in vivo). Previously, there are no reports concerning with the expression of neurofilament or CD99 in MPNST. We speculate that difference of the circumstance of tumor cells lead to different immunoreactivity in tumor cells.

Mutations of two tumor suppressor genes, NF1 gene and p53 gene, reportedly participate in malignant tumorigenesis for patients with NF1 (2-stage carcinogenesis) [15]. Especially, alterations of NF1 gene is highly observed in NF1-associated MPNST [16]. Chromosome 17 loss parallels molecular evidence of allelic loss at the NF1 locus (17q11.2) in sporadic and NF1-associated MPNSTs, in addition to functional inactivation of the p53 tumor suppressor gene localized to 17p13.1 [17–20]. Bridge et al. reported that loss of chromosome 17 (chromosome 17 monosomy) is found in 43% of MPNST cases [21]. Cytogenetic analysis of FMS-1 confirmed chromosome 17 monosomy. Although mutation analysis of NF1 gene was not performed and PCR transcripts of p53 gene were not amplified by PCR or PCR-SSCP, loss of chromosome 17 seems to be related to the process of carcinogenesis in FMS-1 cells. Previous studies of the p53 gene in MPNST identified deletions and other mutations in approximately 29–75% of this tumor [18, 19, 22]. Previous immunohistochemical analysis showed overexpression of p53 gene product protein without clarified p53 gene mutation in

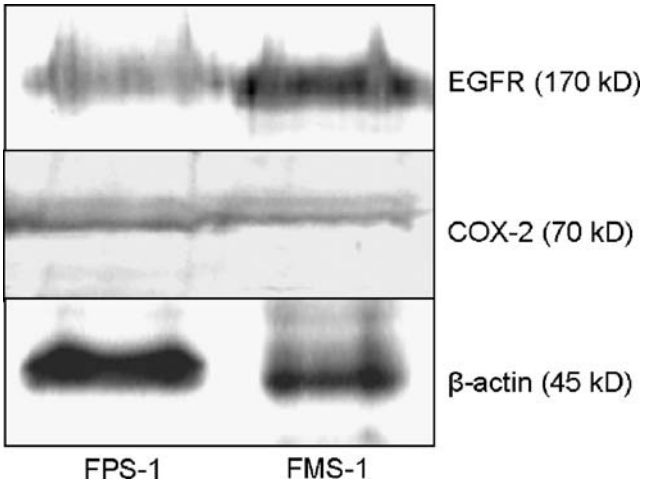

Fig. 6 Western blot analyses of EGFR (170 kD), COX-2 (70 kD), and β-actin (45 kD; loading control) proteins from FMS-1 and FPS-1 (positive control) cell lines. Bands of membranous protein EGFR and cytoplasmic protein COX-2 are detected

MPNST cases [23]. On the other hand, several cases or cell lines of other malignancies with a nonsense mutation have shown undetectable or low levels of p53 gene product protein [24–26]. We speculate that complete immunonegativity for the p53 gene product protein of primary tumor and FMS-1 cells both in vitro and in vivo (heterotransplanted tumor) were attributable to the clone harboring a serious mutation, particularly deletion of the p53 gene.

EGFR is a receptor tyrosine kinase and is widely expressed in a variety of epithelial malignancies [27]. EGFR activation promotes tumor growth by increasing cell proliferation, motility or angiogenesis, and by blocking apoptosis [28]. Recently, some EGFR tyrosine kinase inhibitor has seen clinical use against carcinomas, and antitumor effects on several types of malignancies including sarcomas have been investigated. Expression of EGFR and its ligands in sarcomas including MPNST has been reported [29–33]. Particularly, Holtkamp et al. had reported the effectiveness of erlotinib (EGFR tyrosine kinase inhibitor) and transzumab (humanized antibody targeting the extracellular domain of erbB2) against MPNST cells in vitro [34]. Our data also indicate that EGFR is a potential target in the treatment of MPNST patients and FMS-1 is useful for such investigations.

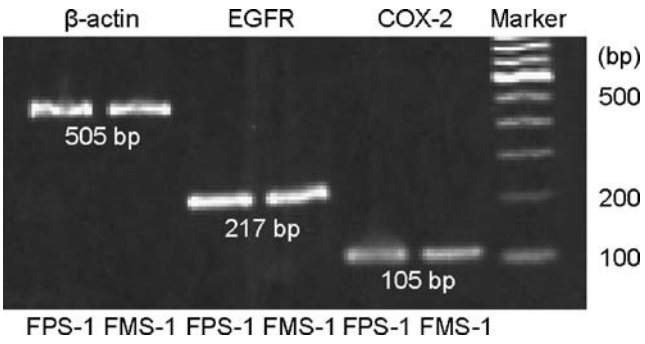

Fig. 7 RT-PCR analysis of EGFR and COX-2 mRNA in FMS-1 and FPS-1 (positive control) cell lines. *Lane 1*, marker, 100-bp DNA ladder; *Lanes 2* and *3*, β-actin (505 bp); *Lanes 4* and *5*, EGFR (217 bp); *Lanes 6* and *7*, COX-2 (105 bp). EGFR and COX-2 mRNA are detected

COX, also known as prostaglandin H2 synthase or prostaglandin endoperoxide synthase, is the key enzyme in the conversion of arachidonic acid to prostanoids [35]. Two COX genes have been cloned. COX-1 is a constitutive enzyme produced constantly in most tissue types, and is probably responsible for the production of prostanoids under physiological conditions. COX-2 is undetectable in most normal tissues, but can be induced in various cell types by pro-inflammatory agents, growth factors and carcinogens [36]. Overexpression of COX-2 is found in a variety of malignancies, including carcinomas, lymphomas and some sarcomas. In addition, COX-2 activation promotes tumor growth through the production of prostaglandin E2, which may block apoptosis or activate vascular endothelial growth factor and angiogenesis [37]. Recent studies have shown antitumor effects of some selective COX-2 inhibitors for sarcomas, particularly for osteosarcomas [38–43], as well as for carcinomas. No reports appear to have described COX-2 expression in MPNST, but COX-2 might offer a novel target for therapy against MPNST or to prevent malignancy in NF1 patients.

FMS-1 cells expressed both EGFR and COX-2. Crosstalk between EGFR and COX-2 has recently been found [44, 45], and cooperative cell-growth inhibition by combined treatment using an EGFR tyrosine kinase inhibitor and a selective COX-2 inhibitor in some carcinomas has been reported [46–49]. However, combined antitumor effect of an EGFR tyrosine kinase inhibitor and a selective COX-2 inhibitor in sarcoma has yet to be described. The FMS-1 cell line may thus be useful for investigating the antitumor effects of EGFR tyrosine kinase inhibitors combined with selective COX-2 inhibitors.

Conclusions

We have established a new human MPNST cell line, FMS-1, derived from a patient with NF1. FMS-1 cells show almost the same morphological characteristics and immunophenotype as the primary tumor cells that are characteristic of MPNST, and displayed a loss of chromosome 17 and lack of the p53 gene product protein as well as expression of EGFR and COX-2. The FMS-1 cell line will prove useful for investigating biological behaviors and developing therapies against MPNST.

Acknowledgments The authors would like to thank Mrs. Hiromi Kaneko and Miss Satomi Hikichi for their skillful technical assistance.

Conflict of interest statement We declare that we have no conflict of interest.

Received: 18 July 2009 / Revised: 23 September 2009 / Accepted: 16 October 2009 / Published online: 12 November 2009

Abstract A case of a colonic carcinoma showing a pancreatic acinar cell differentiation is described for the first time. A 65-year-old woman underwent surgical resection for an ulcerated protruding tumour of 4×2.5 cm in size on the anterior wall of the sigmoid colon. Histologically, tumour cells were organized in acinar structures resembling pancreatic acini and in solid nests and ribbons or diffusely infiltrated as poorly cohesive cells. Lymph nodes and femur metastases displayed the same histological features. The ultrastructural analysis of the primary tumour indicated the presence of zymogen-like granules in the cytoplasm of tumour cells. Immunohistochemically, both acinar and diffuse patterns of growth showed an intense staining for trypsin, chymotrypsin and BCL10 and a weaker immunoreactivity for lipase and carboxyl ester hydrolase. Most tumour cells were cytokeratin 20, CDX2 and p53 positive; whereas, mucin (MUC)2 immunoreactivity was observed only in the signet ring cells present in the diffuse pattern and chromogranin A in rare isolated tumour cells. No immunoreactivity was observed for cytokeratin 7, MUC1, MUC5AC, pancreatic amylase or PDX1. There was no evidence of a pancreatic acinar cell carcinoma or of heterotopic pancreatic tissue. A colonic origin ought to be suspected when a metastatic carcinoma of unknown primary shows an acinar differentiation.

Introduction

Acinar cell carcinoma of the pancreas is a rare malignant epithelial tumour representing 1–2% of all exocrine pancreatic neoplasms. It is composed of relatively uniform tumour cells arranged in acinar and solid structures. The diagnosis of acinar cell carcinoma requires immunohistochemical demonstration of the production of pancreatic enzymes, such as trypsin, lipase and chymotrypsin by tumour cells or ultrastructural demonstration of zymogen granules [1, 2]. In the gastrointestinal tract, other than in the pancreas, tumours with acinar cell differentiation have been described in the stomach [3–5] and jejunum [6] but, to our knowledge, no colonic localization has been reported in the literature.

Here, we report the first case of colon cancer with acinar cell differentiation.

Clinical history

A 65-year-old woman was hospitalized for intestinal occlusion. The colonic endoscopy showed a circumferential constriction just before the sigmoid-rectal junction. The patient underwent surgical resection, and a colonic segment of 15.5 cm was removed. Macroscopically, an ulcerated lesion of 4×2.5 cm in size was present on the anterior wall of the colon. Metastases were observed in eight of 17 regional lymph nodes.

Eighteen months later, a right femur metastasis appeared and the patient died with diffuse metastases to dorsal vertebrae and ribs 24 months after surgery.

Materials and methods

Immunohistochemical studies were performed on formalin-fixed paraffin-embedded sections using a peroxidase polymeric detection system (Ultravision, LabVision, Fremont CA) and 3-3′ diaminobenzidine as a chromogen. The primary antibodies used for staining are listed in Table 1.

For the ultrastructural study, samples of the tumour were retrieved from the paraffin block. After paraffin removal by chloroform the samples were fixed for 2 h at 4°C in a mixture of 2% paraformaldehyde and 2% glutaraldehyde in 0.05 M pH 7.3 cacodylate buffer and embedded in epoxy resins. Thin sections were counterstained with uranyl acetate and lead citrate and examined with a Philips (Morgagni 268 D) electron microscope.

Results

Histological findings The tumour extended from the mucosa, throughout the muscularis propria, into the adipose tissue under the serosa. It was characterized by two main intermingled growth patterns: acinar-solid and diffuse (Fig. 1a). In mucosa and submucosa, the acinar-solid pattern was prevalent: tumour cells were organized in acinar structures resembling normal pancreatic acini (Fig. 1b) and in solid nests and ribbons.

Foci with acinar architecture were also present in the muscularis propria and in the adipose tissue and were accompanied by a diffuse growth of single tumour cells that infiltrated separately.

The acinar and solid areas consisted of clusters of cuboidal to pyramidal cells separated by fine fibrous strands. The nuclei were round to oval, with single nucleoli. Nuclear atypia was moderate. Cytoplasms were moderately abundant, prevalently eosinophilic, with PAS positive fine granules. In acinar structures, tumour cells had basally located nuclei and surrounded small undefined lumina.

By contrast, the diffuse growth pattern was characterized by poorly cohesive, diffusely infiltrating, pleomorphic tumour cells with irregular-shaped nuclei and various degrees of atypia. The cytoplasms, more or less abundant, were clear or eosinophilic. Signet ring cells with cytoplasmic accumulation of Alcian Blue positive mucus were also present.

The adjacent non neoplastic colonic mucosa showed a normal appearance. Lymph nodes and femur metastases displayed all the histological features described in the primary tumour: acini, ribbons, solid nests and isolated cells were present.

Immunohistochemical findings Both acinar and diffuse patterns showed an intense immunostaining for trypsin (Fig. 1c), BCL10 (Fig. 1e) and chymotrypsin (Fig. 1f) and a

weaker immunoreactivity for lipase (Fig. 1d) and carboxyl ester hydrolase. No pancreatic amylase immunoreactivity was observed in tumour cells. MUC2 immunoreactivity was present in the cytoplasm of most of the signet ring cells. Rare superficial tumour cells showed weak MUC6 immunoreactivity; whereas, no positivity was observed using MUC1 and MUC5AC antibodies. Most tumour cells were CK20, CDX2 and p53 immunoreactive, while no nuclear staining for PDX1 or cytoplasm immunoreactivity for CK7 was present.

Scattered isolated chromogranin-positive endocrine cells were also present among exocrine tumour cells.

Both lymph nodes and bone metastases displayed BCL10 and CEH immunoreactivity, the former displayed intensely and the latter more weakly. A light trypsin and lipase immunoreactivity was observed only in the lymph node metastases.

Ultrastructural findings Observed with the electron microscope, the neoplastic cells forming the acini showed some secretory granules, accumulated in the apical cytoplasm. The granules measured approximately 210 nm in diameter and showed a dense homogenous matrix, suggesting a zymogen-like aspect (Fig. 2). Among them, sparse cells had irregularly shaped endocrine-type secretory granules, accumulated in the basal cytoplasm, similar to those of intestinal enterochromaffin cells [7]

Discussion

The histological aspect of the present case of carcinoma suggested a pancreatic acinar carcinoma, but it occurred in the colon and the patient did not have a primary pancreatic neoplasm. The results of immunohistochemical and ultrastructural studies confirmed the acinar cell differentiation hypothesised on the basis of the histological features. In particular, electron dense zymogen-like granules were ultrastructurally documented in the cytoplasm of tumour cells. As far as enzymatic production was concerned, in addition to trypsin, the expression of which has already been documented

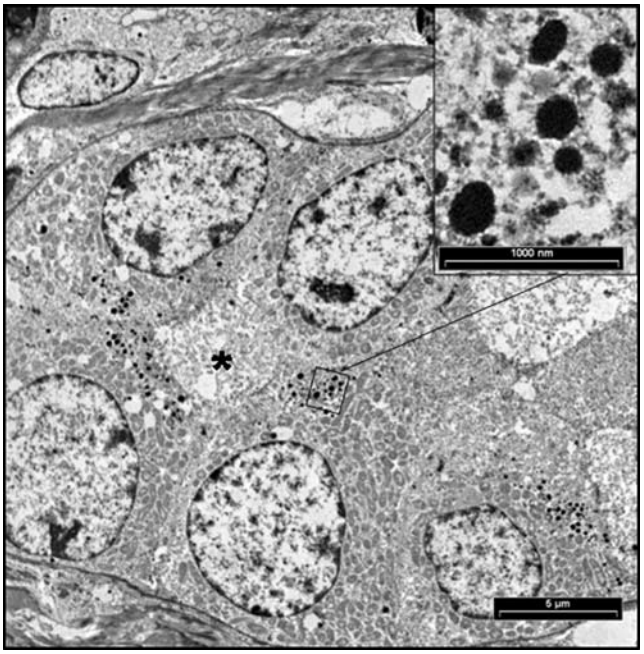

Fig. 2 Ultrastructural picture of an acinar structure. The acinar cells show dense homogeneous secretory granules (*inset*) accumulated in the apical cytoplasm. The acinar lumen is indicated by *asterisk*

in ordinary type colorectal carcinomas [8, 9], tumour cells showed immunoreactivity for other pancreatic enzymes such as lipase, chymotrypsin and carboxyl ester hydrolase (CEH). CEH is a glycoprotein secreted by pancreatic acinar cells [10] and lactating mammary gland [11] involved in cholesterol and lipid-soluble vitamin ester hydrolysis and absorption. It has been previously observed in pancreatic acinar cell carcinomas [12, 13] but not in pancreatic ductal adenocarcinomas. As recently demonstrated by La Rosa et al. [14], its presence in tumour cells may be proved immunohistochemically using a specific anti-CEH antibody as well as an anti-C-terminal BCL10 monoclonal antibody, because the C-terminal extremities of both CEH and BCL10 protein share the same amino acidic sequence. Tumour cells showed a weak immunoreactivity for CEH and a stronger positivity for BCL10. In addition, lymph nodes and above all bone metastases, which suffered from the hard decalcification treatment, were more intensely stained by anti-BCL10 than by anti-CEH antibody, confirming the major sensitivity of the anti-C-terminal BCL10 antibody in detecting carboxyl ester hydrolase.

In the literature, a few carcinomas with acinar cell differentiation have been described in the stomach [3–5] and in the jejunum [6]. For some of them, an origin from heterotopic pancreatic tissue has been suspected [6]. Pancreatic rests have been documented both in the stomach and in the small intestine [6, 15] but not in the large bowel. No evidence of heterotopic pancreatic tissue was observed in our case and all the clinical investigations excluded the possibility that the tumour could be a metastasis of a pancreatic acinar carcinoma. The most likely hypothesis about the histogenesis of the tumour is that it could have developed from a colonic stem cell with the potential for pancreatic differentiation. Indeed, most tumour cells expressed CK20 and CDX2, a transcription factor indispensable for intestine development [16] and a specific marker of adenocarcinomas of intestinal origin [17, 18], and displayed p53 nuclear accumulation which is a frequent genetic alteration in colorectal tumours but is not involved in the pathogenesis of pancreatic acinar cell carcinomas [19]. On the contrary, no tumour nuclei were immunoreactive for pancreatic and duodenal homeobox-1 (PDX-1), a transcriptional activator of several genes essential for the early development of pancreatic exocrine, endocrine and duct cells, duodenum and antrum [20–22].

A few cases of gastric carcinomas with acinar cell differentiation occur as mixed exocrine-endocrine tumours [4, 5]. Although endocrine cells were present in our case, they were so scattered that we cannot consider our case a composite glandular-endocrine tumour.

The fast negative evolution of the disease was unusual, more similar to pancreatic acinar than colonic carcinomas. In colonic adenocarcinomas, the spreading is preferentially via lymphatic or blood vessels to regional lymph nodes and the liver, whereas our patient developed bone metastases and died within 2 years. Enzyme production by tumour cells could explain, at least in part, the aggressive behaviour and the poor prognosis observed in this particular case. In fact, trypsin seems to promote, both directly and indirectly through the activation of other proteinase cascades, proliferation, invasion and metastases [9]. Yamamoto et al. [9] observed that, in colorectal carcinomas, trypsin expression at the invasive front correlated significantly with depth of invasion, lymphatic and venous invasion, lymph node and distant metastasis as well as recurrence.

To our knowledge this is the first reported case of colonic carcinoma showing a pancreatic acinar differentiation. Taking into account that lymph node and bone metastases of our case displayed acinar features, a colonic origin ought to be suspected when a metastatic carcinoma of unknown primary shows an acinar differentiation.

Conflict of interests statement We declare that we have no conflict of interest.

OP1.1

Immunohistochemical and electron-microscopic study in Henoch-Schoenlein nephritis

Wozniak A.; Pluta K.; Zurawski J.; Janicka M.; Kaczmarek E.; Zachwieja J.; Piechocka I.; Bulak J.
Department of Clinical Pathology, Karol Marcinkowski University of Medical Sciences, Poznan, Poland

Background Henoch-Schoenlein purpura is a form of systemic vasculitis with deposits of IgA, involving small vessels in skin, gut and glomeruli. Henoch-Schoenlein nephritis (HSN) is the most common secondary childhood nephropathy and leads to ESRD in up to 20% of pediatric patients after 20 years of follow-up.
Methods 44 cases of HSN: 32 children and 12 adults. EM was performed in 6 cases and IH in all. We evaluated mesangial proliferation (Ki-67, PCNA), mesangial expression of α-SMA and podocytes expression of p27.
Results LM study revealed the following grades: II (18), III (15), IV (3) and VI (8) (differences in prognosis between grades were not found). The initial symptoms and outcome were less severe in patients with grade II or III. Presence of glomerular sclerosis was important prognostic marker. EM study was was useful in recognition of early glomerular sclerosis. No significant correlations were found between mesangial cells Ki-67 and PCNA positivity and clinical presentation. Important finding was progressive decrease in p27 positive podocytes with more severe HSN grades. Significant correlations regarding the area of mesangial expression of α-SMA were observed. That expression was stronger in patients, who had foci of infection (independently of HSN grade).
Conclusion(s) The area of α-SMA expression have proved to be a useful marker of mesangial cells activation. The decreased expression of p27 in podocytes of HSN patients suggests their role in disease process. Our study did not demonstrated the prognostic usefulness of proliferation markers (Ki-67, PCNA).

OP1.2

Remodeling of adipose tissue from lipodystrophic patients with LMNA mutations

Cervera P.; Béréziat V.; Verpont M.; Le Dour C.; Antuna-Puente B.; Dumont S.; Somja-Azzi M.; Vantyghem M.; Capeau J.; Flejou J.; Vigouroux C.
Hôpital Saint Antoine, Paris, France

Background A-type lamins, encoded by the LMNA gene, are ubiquitous nuclear intermediate filament proteins that are required for the structural and functional integrity of the nucleus. Inherited laminopathies, due to LMNA mutations, represent a wide spectrum of diseases, including lipodystrophies, with peripheral subcutaneous fat loss, increase visceral fat and metabolic alterations; among them, the Dunningan-type familial partial lipodystrophy (FPLD2; OMIM 151660). The morphological alterations of adipose tissue in laminopathies have not been reported so far. In the present work, we have studied the pathological and ultrastructural alterations of adipose tissue from LMNA-mutated patients, together with the expression of specific adipocytes markers and mitochondrial proteins.
Methods Cervical fat was obtained from three patients with LMNA mutation, from one patient with mtDNA tRNA lys A8344G mutation, from three treated lipodystrophic HIV-infected men and three controls. Light microscopy, immunohistochemical and ultrastructural studies were performed on the fat samples and compared with mRNA assay, performed with the light cycler software (Roche diagnostics) and Western blot analysis.
Results Adipose tissue from LMNA-mutated patients shows a heterogeneous structure with decreased adipose size, altered extra-cellular matrix : thick fibrils invade the intercellular area without macrophages or inflammation, increased fibrosis, mitochondria disturbances, accumulation of prelamin A and altered expression of adipogenic transcription factors.
Conclusion(s) This study show here severe remodeling of adipose tissue from patients with FPLD and metabolic laminopathies. The accumulation of prelamin A could impair SREBP1 function and adipocyte differentiation but also induce oxidative stress leading to fibrosis.

OP1.3
Ultrastructural remodeling of cardiomyocytes during isolated atrial amyloidosis

Mandache E.; Gherghiceanu M.; Macarie C.; Popescu Mircea L.
"V. Babes" National Institute of Pathology, Bucharest, Sector 5, Romania

Background The heart is commonly affected by a localized organ-limited amyloidosis called isolated atrial amyloidosis (IAA). The IAA incidence increases with age, up to over 90%. The fibril protein deposited in this condition is the atrial natriuretic peptide, a hormone synthesized and secreted mainly by atrial cardiomyocytes.
Methods Thirty-six atrial biopsies from the surgery unit have been processed for electron microscopy. The investigation was intended to emphasise the features of cardiac remodelling during atrial arrhythmias (mostly atrial fibrillation).
Results One-third of the biopsies proved to contain small deposits of fibrilar material in the interstitial area, around the cardiomyocytes and/or small vessels with characteristic feature (randomly arranged, nonbranching filaments of about 10 nm in diameter). The ultrastructural features of these minute fibrilar deposits are presented. The close contacts of amyloid fibrils with the peripheral lamina of atrial myocytes are emphasized. They occurred only in the extracellular space. We have noticed the presence of sarcolemal small niches where the fibrils are concentrated. When these niches were deeper, they could be transversely sectioned, giving the false impression of intracellular inclusions. These sites seemed to be placed near the intercellular junctions. On the interstitial side, the peri-myocyte fibrilar deposits had a particular attraction for some particular, slender, interstitial Cajal-like cells, which have the tendency to wrap the fibrils.
Conclusion(s) In LM the atrial myocytes profiles were smaller, having more irregular contours, and appeared dispersed. The myofibrils were centrally gathered, and the mitochondria and glycogen peripherally placed.

OP1.4
A new variant of oralfacialdigital syndrome

Stenram U.; Cramnert C.; Axfors-Olsson H.
Department of Pathology, Lund, Sweden

Background The columnar epithelial cells of the respiratory tract have several cilia. Most other cells of the body have one immotile cilium, called monocilium or primary cillium. Mutations in their genes give strange malformation syndromes, ciliopathies. Respiratory tract symptoms are seldom reported. In these entities nasal/tracheal cilia have only been examined in single cases of Usher syndrome and the polysplenia syndrome.
Methods Case report. A girl presented with polydactyly, high arched palate, tongue lipoma and dysmorphic face. She had respiratory tract problems from birth, atelectasis, pneumonia and later bronchiectasis, and viscous secretions in the middle ears. The fourth ventricle is slightly enlarged. From 4½ years she shows growth retardation. At 5 years she uses a walker outdoors and speaks only short sentences. Electron microscopy of nasal brush biopsies at four occasions revealed almost total ciliary aplasia, but long, sometimes branched microvilli. There were a few cilia in the cytoplasm and also lumens. The basal bodies/centrioles were found deep in the cytoplasm. Some procentrioles were seen.
Results The cases has resemblances with the oralfacialdigital syndrome (OFDS) but in addition respiratory tract problems from birth. This and four other syndromes are due to mutations affecting the basal bodies, which in this case were displaced.
Conclusion(s) Such a cases has not previously been described. It was approved by POSSUM dysmorphology database and London Dysmorphology & Neurogenetics Databases as OFDS, Stenram type.

OP1.5
Ultrastructural characteristics of systemic and localized AL-lambda amyloid deposits

Bély M.; Apáthy A.; Kapp P.
Department of Pathology, Policlinic of the Order of the Brothers of Saint John of God in Budapest, Budapest, Hungary

Background The aim of this study was to define the ultrastructural characteristics of systemic and localized AL deposits.
Methods Amyloidosis was studied in a selected autopsy population of 5 in-patients with B-cell lymphoma and compared with 5 biopsies of extranodal plasmacytoma of epipharynx (nasopharynx) or vocal cord with localized AL deposits. Systemic immunoglobulin light-chain AL.
Results Electron microscopically the filaments or fibrils in systemic or localized AL amyloidosis revealed no morphologic difference, and the pattern of deposition was in both "lake"-like. However, there was a difference (1) in relation to the blood vessels, (2) in the arrangement of filaments, or fibrils within the amyloid deposits. The systemic AL amyloid deposits were always present within the vessel walls, or around the capillaries (with, or without deposits between the collagen fibrils). The localized AL amyloid deposits were never observed within the vessel walls, or between pericytes (excentric deposits may be present near vessels). In case of localized AL amyloidosis electron dense territories of clusters composed of regularly (parallel)

arranged, closely packed filaments and fibrils were present. In some cases this was bordered by circularly arranged, condensed fibrils at the periphery. This type of arrangement corresponded to the "crystalloid like" birefringence of the localized AL amyloid deposits.
Conclusion(s) The free vessels and the "crystalloid like" deposition of amyloid filaments are characteristics of localized AL amyloidosis electron microscopically. The "crystalloid like" arrangement represent the stage dependent maturation (or fragmentation) of deposited amyloid protein filaments, indicative of an advanced stage of deposition.

OP1.6
P53 as a prognostic marker for astrocytic gliomas: a meta-analysis and review

Levidou G.; El-Habr E.; Korkolopoulou P.; Saetta A.A.; Katsougiannis K.; Patsouris E.
National and Kapodistrian University of Athens, Department of Pathology, Athens, Greece

Background For decades researchers have been looking for parameters with an impact on the prognosis of patients with astrocytic tumours. p53 is one of the most widely investigated molecules in human gliomas. We aimed to review comprehensively the evidence for use of changes in p53 immunohistochemical expression in paraffin-embedded tissue specimens to predict astrocytomas mortality.
Methods We conducted a systematic review through December 2007 to identify cohort studies that evaluated p53 immunohistochemical expression as a prognostic marker for astrocytomas. Estimates of significance were extracted from association tests and hazard ratios (HR) with 95% CI. A meta-analysis was performed on the studies that applied Cox models adjusted with tumour grade and patients' age.
Results We reviewed 44 (n=3627) publications, 13 of which included the estimates (HR and 95% CI) derived from Cox regression. The descriptive analysis showed that most of the published articles did not contain information on important variables such as sex and age (27% and 31% of studies), previous treatment, tissue-retrieval and follow-up period (56%). The quantitative synthesis showed that p53 expression in not a significant prognostic factor (combined HR= 1.034, p=0.531). There was no significant between-study heterogeneity and publication bias. Meta-regression analysis selected tumour histologic grade and the publication of patients' treatment details as important factors.
Conclusion(s) After 18 years of research, evidence is not sufficient to conclude whether changes in p53 immunohistochemical expression act as a marker of outcome in patients with astrocytic neoplasms.

OP1.7
Chromosome 1p36 loss and Cox-2 overexpression are independent predictors of recurrence in completely removed meningiomas Grade I and II. Analysis of their association with clinicopathological and immunohistochemical variables

Sanz J.; Ruiz J.; Martinez A.; Hernandez S.; Asenjo J.; Zimman H.
Hospital Clinico San Carlos, Madrid, Spain

Background The WHO grading system is used to clasify meningiomas as grade I (benign), II (atypical) and III (anaplastic). 15–20% of benign and atypical meningiomas will recurr despite agressive surgery with complete removal.
Methods 247 meningiomas grade I and II with a mean follow-up perios of 7.6 years were analyzed with 30 IHC biomarkers and chromosomal loss of 1p36 was analyzed by FISH. Univariate and multivariate analysis for recurrence-free survival of the completely removed meningiomas.
Results Two molecular pathways characterized by the loss of 1p36 and Cox2 overexpression were associated with recurrent meningiomas. The loss of chromosome 1p36 was also associated with necrosis, nuclear atypia and alterations in the AKT/MAPK patway(AKTp, PDGF, CyclinE, p21). The overexpression of COX2 characterized meningiomas with increased celullar stress and overexpression of Growth Factors. (VEGF, PDGF, Her2, MDMD2). The prognostic significance of both pathways has an antagonic effect. MIB1 overexpression was also an important predictor of recurrence.
Conclusion(s) There is a need of new predictors of tumour recurrence for meningiomas grade I and II. We describe two molecular biomarkers: loss of 1p36 and COX-2 overexpression. Thay are associated with molecular pathways consistent with the more aggresive behaviour. Chemopreventive treatment can be used for the subgroup of meningiomas with Cox-2 overexpression.

OP1.8
Mitotic count and brain invasion are independent predictors of recurrence free survival in primary atypical and malignant meningiomas. A study of 86 patients

Pizem J.; Vranic A.; Popovic M.; Coer A.; Prestor B.
Institute of Pathology, Medical Faculty, Ljubljana, Slovenia

Background There is only sparse information about possible prognostic factors in the group of atypical and malignant meningiomas (AMM). Our aim was to evaluate the prognostic significance of various histological and clinical parameters, with an emphasis on mitotic count, brain invasion and Ki67 labelling index, in a series of primary AMM.

Methods We analysed 86 primary AMM, 76 of which were atypical and 10 malignant, diagnosed according to 2000 WHO. Multivariate recurrence free and overall survival analyses were performed.
Results High mitotic count (as a continuous variable), brain invasion and the parasagital-falcine location of the tumour were associated with decreased recurrence free survival in multivariate analysis. Brain invasion was present in 25 of 37 cases in which brain tissue was identified in the tumour specimens. When brain invasion was not included in the analysis due to the limited number of cases in which it could be assessed, high mitotic count, Ki67 index ≥4%, the presence of macronucleoli and parasagital-falcine location were significant predictors of shorter recurrence free survival.
Conclusion(s) Brain invasion and mitotic count as a continuous variable are the two most important parameters associated with survival of patients with AMM. AMM are biologically heterogeneous and recurrence free survival can be further stratified by histological parameters, especially mitotic count, brain invasion and Ki67 labelling index.

OP1.9

Dendritic cells from human peripheral lymphoid tissues express AIRE (autoimmune regulator)

Poliani L.P.; Kisand K.; Marrella V.; Ravanini M.; Notarangelo D.L.; Villa A.; Peterson P.; Facchetti F.
Department of Pathology, University of Brescia, Brescia, Italy

Background Self-reactive T-cells are eliminated in the thymus by central tolerance (CT), a process predominantly mediated by AIRE, a transcription factor driving the expression of tissue-restricted antigens (TRAs). Although remarkably efficient, potentially autoreactive T-cells escape CT selection and reach the periphery, where peripheral tolerance (PT) induction is required to prevent autoimmunity. AIRE-expressing cells (AEC) involved in PT induction have been recently identified in murine lymph-nodes (LN) although their phenotype and evidence in humans have yet to be defined.
Methods We investigated at mRNA and protein level AIRE expression in a large number of human lymphoid and non-lymphoid tissues and characterized AEC phenotype by double-immunohistochemistry and FACS analysis.
Results AEC were exclusively identified in LN, tonsils and mucosal-associated lymphoid tissues. AEC consistently co-expressed HLA-DR, fascin and most of them S100, CD11c and activated dendritic cell (DC) markers (DC-LAMP/CD208, CD40, CD83), suggesting a DC phenotype. Other antigens specific for lymphoid/myeloid, stromal/endothelial and epithelial cell lineages were negative. Cell sorting confirmed the presence in LNs of rare CD45lo/HLA-DRhi +/AIRE + cells with a DC phenotype and expressing TRAs (insulin and CYP17A1). Interestingly, LNs biopsies from different primary immunodeficiencies, particularly when associated with autoimmunity, and lymphadenitis from HIV patients, showed dramatic depletion of AECs, suggesting that normal T-cell homeostasis is crucial to maintain AIRE expression.
Conclusion(s) These data show that human lymphoid tissues contain a rare subset of DCs (most of which with an activated phenotype) expressing AIRE and TRAs and possibly involved in PT.

OP1.10

Isolation of cancer stem cells from dog glioblastoma multiforme

Stoica G.; Lungu G.; Martini-Stoica H.
Texas A&M University, College Station, TX, USA

Background Cancer stem cell migration in gliomas is a multifactorial event regulated by the interactions among a minority of tumor cells with stem cell-like properties and the host microenvironment. Necrosis and angiogenesis in gliomas occurs in a hypoxic environment. A working hypothesis that links tumor hypoxia, necrosis and angiogenesis appears to emerge in dog glioblastoma.
Methods The isolated gliomas cells were cultured in DMEM media and neurobasal media supplemented with growth factors. In vitro flow cytometry determined the phenotype of cancer stem cells isolated from dogs: a grade IV D-GBM and grade I pilocytic astrocytoma (PA). Tumor cells migration assayed using the Matrigel invasion assay. An intracranial orthotopic model using nude mice was utilized for in vivo evaluation of D-GBM tumorigenicity. Immunohistochemistry demonstrated glial and neuronal differentiation.
Results In the present study we demonstrate that glioblastoma multiforme isolated from a Boxer dog (D-GBM) has cells with phenotypical characteristics of CSCs. As a proof of concept, we characterized this cell line's morphophenotype and its specific stem cell markers such as nestin and CD133. CSCs demonstrated glial and neuronal differentiation when exposed to differentiation growth factors in vitro.
Conclusion(s) This is the first report demonstrating the presence of CSCs in dog GBM. Our data also demonstrate the similarity between human and dog GBM and emphasize the importance of studying dog spontaneous brain tumors in order to elucidate the mechanism(s) of tumor dispersal, post surgical reoccurrence, and resistance to therapy.

OP1.11

Silver enhanced in situ hybridisation detects of BK virus DNA in renal biopsies from renal transplant patients

Fritzsche R.F.; Gaspert A.; Pianca S.; Wang L.; Farrell M.; Chen X.; Fehr T.; Tubbs R.; Moch H.
University Hospital Zurich, Zurich, Zurich, Switzerland

Background SV40, BK and JC viruses are members of the polyomavirus family. The BK virus rarely causes disease, but BK virus nephropathy (BKN) is a well known complication of renal transplantations associated with high rates of graft loss. The diagnosis of BKN has to be made histologically by detection of the typical intranuclear viral inclusion bodies. Although the BKN morphology is relatively specific, other viruses have to be ruled out. The detection of BK-virus DNA by PCR can serve as a surrogate marker, but diagnostic confirmation of the infected tubular epithelial cells can be achieved by immunohistochemistry with antibodies directed against SV40.
Methods We have developed a new silver-enhanced in situ hybridisation (SISH) technique for the detection of BK virus in renal transplant kidney specimen. From archival cases, we selected 26 immunohistochemically (SV40 antibody) confirmed polyomavirus infections. We applied the SISH analysis on a Ventana Benchmark platform to detect BK virus infections.
Results The BK virus SISH positivity was highly concordant with the immunohistochemical results using a SV40 antibody. The SISH signal showed a distinct nuclear signal. Interestingly, in most cases less cells and tubules were positive with the SISH signal in comparison to the SV40 staining.
Conclusion(s) BK SISH is a sensitive and specific tool for the detection of BK virus infections in renal transplant patients.

OP1.12

Malaria and malignant non-burkitt-lymphomas. A review of studies from Uganda

Schmauz R.; Wright H.D.
Institute of Pathology, Papenburg, Superfluous, Germany

Background While well recognized for Burkitt-lymphoma, such an association with the remainder of these tumours is not taken into consideration in many and particularly recent studies. Six epidemiological studies from Uganda are therefore reviewed which use geographical comparisons to underline the possibility that malaria plays a major role in lymphomagenesis.
Methods The material is provided by the Kampala Cancer Registry which in the sixties and seventies of the last century covered the whole of Uganda. Information about malarial endemicity was available from a survey conducted during the years 1963–1966.
Results In a meta-analysis two early studies published in 1965 and 1973 show similar geographical distributions for Hodgkin's disease, reticulum cell sarcoma, lymphosarcoma and BL. Two further studies (1970 and 1974) confirm that certain NBL are more common in northern Uganda where BL is of the highest incidence. Finally, aggressive or high-grade HL and NHNBL (1) vary in a similar way in incidence with BL and (2) as the BL are rare or common in areas of low or high malarial endemicity, respectively, with gradients in incidence which are less marked than in BL. This is in contrast to low grade NBL which showed no such regional incidence patterns (1989 and 1990).
Conclusion(s) In studies related to the aetiology of malignant lymphomas in tropical Africa malaria as a causal factor deserves more attention.

Cytopathology

OP2.1

Activity criteria of demyelinization process

Filipovich Nicolaevich A.
Research Institute of Medical Assessment and Rehabilitation, Minsk, Belarus, Minsk, Belarus

Background A latent phase (the first group, 79 patients, 19.9%) is characterized by slight increase in MTA of blood serum (7.6±1.2 units; control group - 3.9±0.82 units; $p<0.001$), decrease of CD4+ in blood (34.8±1.64%) and CIC levels (92.56±3.1).
Methods Clinical methods, immunoassays, myelinotoxic activity (MTA), CT and MRI of cerebrum and spinal cord, myelinotoxic activity (MTA).
Results A slow progradient phase of MS (second group, 156 patients, 39.4%) is distinguished by moderate evident(apparent) increase in MTA of blood serum (22.3; $p<0.01$ in comparison with 1st group), significant decrease of T-lymphocyte in blood serum by 32.4%, CD22+ by 71.1%, CD4+ by 33.9%, CIC levels by 12.4%, along increase in CD8+ by 1.3 times, weak induction of TNF-α at 84.3%; IL-8 at 4.8% patients. An acute phase (third group, 144 patients, 36.3%) coupled with significant increase in MTA of blood serum (40.4± 1.22 units) in comparison with 1st and 2nd groups. Acute condition of MS distinguished by significant increase in blood CD8+, IL-2P+, Ig G,A,M, CIC level along decrease

of T-lymphocyte (51.7%±1.56%) and CD22+ levels. Increase in IL-2P+ at 64.1% patients coupled with significant increased TNF-α и IL-8. In the fourth group (17 patients, 4.4%) fast progress of MS distinguished by high MTA level of blood serum (78.2±4.4 units), persistent immunological changes: increase in CD4+, CD8+, IL-2P+, IgG, IgM, IgA, CIC.

Conclusion(s) Measurement of blood serum MTA and immune reactivity in combination with clinical and MRI findings helps to correctly estimate the rate of demyelinization in multiple sclerosis patients.

OP2.2

KRAS mutation testing on matched cytological and histological specimens of metastatic colo-rectal cancer

Malapelle U.; Russo M.; Salatiello M.; Campione S.; Cozzolino I.; Zeppa P.; Palombini L.; D'Armiento F.; Troncone G.
Università degli studi Federico II, Naples, Italy

Background Metastatic colo-rectal carcinomas harboring a mutation in the KRAS gene do not derive benefit from EGFR targeted therapy. Cytological samples performed on metastasis may represent the only type of specimen available for KRAS mutation testing. To date, studies directly comparing mutation detection rates in cytological and paraffin embedded samples have not been performed yet.

Methods We carried out a retrospective search for cytological cases positive for adenocarcinoma and in which there was an unquestionable evidence of a colorectal cancer origin. Particular care was taken to process also the matched histological samples when available for review. Eighteen cytological cases represented this study series. Eleven fine needle aspiration (FNA) samples (lung $n=7$; liver $n=3$; soft tissue $n=1$) and seven peritoneal washings were assessed for codon 12 and 13 KRAS by direct gene sequencing. Histological samples were available in 13 cases. The same procedure was carried out on the matched cyto-histological samples.

Results Nearly in all instances (17/18; 94%) the cytological specimens were suitable for the molecular analysis. The data from FNA and surgical samples were matched. In this undergoing study, a high rate of concordance between the two samples types is being found.

Conclusion(s) We demonstrated that KRAS mutation can be performed from genomic DNA extracted from metastatic colorectal FNAs and peritoneal washings. This can be of pivotal relevance in patients with advanced colo-rectal cancer whose histological specimens are not available for KRAS testing

OP2.3

Pitfalls in FNA of lipomatous tumours

Pohar Marinsek Z.
Institute of Oncology, Ljubljana, Slovenia

Background At the Institute of Oncology in Ljubljana many soft tissue tumours are operated on the basis of cytology. A correct differentiation between benign and malignant is therefore imperative and specific diagnosis desirable. The objective of our study: morphological analysis of various lipomatous tumours in order to recognize pitfalls which can lead to false cytological diagnosis.

Methods We reviewed FNA samples of 120 histologicaly verified lipomatous tumours, 72 benign and 48 malignant. Characteristics noted: cellularity, cell shape, degree of atypia, presence of capillaries, mixoid background.

Results Pitfalls in benign lipomatous tumours which can lead to incorrect diagnosis of a malignant tumour: 1. Atypia in pleomorphic lipomas; 2. Degenerative changes in lipoma NOS with macrophages simulating lipoblasts; 3. Abundant myxoid material and capillaries simulating myxoid liposarcoma; 4. High cellularity, myxoid material and lipoblasts in lipoblastomas. Pitfalls in liposarcomas which can lead to a false benign diagnosis: 1. Lack of atypia in some well differentiated and myxoid liposarcomas; 2. Presence of spindle cells in dedifferentiated liposarcomas. Pitfalls in recognizing the lipomatous lineage: 1. Round cells in liposarcoma simulating lymphoma and other small round cell neoplasms: 2. Pleomorphic cells in liposarcoma, morphologically indistinguishable from other pleomorphic sarcomas and from pleomorphic metastatic carcinomas.

Conclusion(s) Since there is lack of obvious malignancy features in some liposarcomas and pronounced atypia in certain benign lipomatous tumours, cytopathologists should be cautious in rendering a definitive diagnosis. Myxoid background is very common in lipomatous tumours and represents an important pitfall.

OP2.4

Review of negative or low grade smears in women with invasive cervical cancer in Slovenia

Repse Fokter A.; Strojan Flezar M.; Pogacnik A.; Snoj V.; Primic Zakelj M.
Departrment of Pathology and Cytology, Celje Teaching Hospital, Slovenia, Celje, Slovenia

Background The purpose of this study was to review the smears which were taken from 0 to 3 years prior to the diagnosis of invasive cervical cancer in 2006 and were originally classified as low grade findings or normal.

Methods 59 smears from 37 women obtained between 2003 and 2006 were included in the study. In order to provide more objective assessment, two controls were added to each smear in question. Altogether, 177 smears were reexamined at the laboratory where original diagnosis was performed and then independently by a group of four experienced cytopathologists, members of the advisory board of the national screening programme. To avoid focused reviewing of any slide, the time for screening was limited to that in routine daily work.
Results Of the 37 cases of invasive cervical carcinoma, 19 were squamous cell carcinomas, 15 adenocarcinomas and 3 adenosquamous carcinomas. On reexamination at the laboratory where original diagnosis was made, 19 out of 59 smears were upgraded. After the review by the expert group, 22 smears were upgraded to the diagnosis requiring a biopsy, among them only 4 in patients with adenocarcinoma.
Conclusion(s) A subgroup of smears can be diagnosed as low grade or even negative despite the presence of high-grade findings that are detectable on reexamination, which is in concordance with some previous studies. Nevertheless, true negative smears occured more likely in patients with adenocarcinoma.

OP2.5

Thin layer cytology and immunocytochemistry in pleural fluids and ascites: quick and accurate

Kornegoor R.; Tiemessen N.; Van Benthem J.; Schaap W.; Bülbül M.; Peters M.H.
Gelre Ziekenhuizen Apeldoorn, Apeldoorn, Gelderland, Netherlands

Background Thin layer technique (ThinPrep) is applied successfully on a routinely basis in cervical and pulmonary cytology in our department. Therefore we decided to use this technique in pleural fluids and ascites and test the applicability and usefulness of immunocytochemistry.
Methods In 18 months 237 pleural fluid and 171 ascites (n=408) samples were evaluated. Several immunocytochemistry panels were performed in a 3-hour procedure. Diagnostic procedure and patient outcome was analysed and compared with patients medical history. Cases of malignancy were divided into “known primary”, “unknown primary” and “discordant known primary”.
Results Cellular preservation and nuclear morphology was improved in the majority of cases compared to conventional cytology. 295 body fluids were diagnosed benign, 14 showed atypia and 92 were malignant. There was an unknown primary in 39% (n =36), known primary in 54% (n=50) and discordant known primary in 7% (n=6) of all malignant cases. In 21% immunocytochemistry was performed to distinguish reactive mesothelial cells from carcinoma and to evaluate primary source in case of metastatic tumour. In the discordant known primary’s there were 5 pleural samples of patients, respectively known with breast cancer (n=3), transitional cell cancer and colon cancer. All turned out to have lung cancer. 1 ascites sample showed ovarian metastasis while the patient was known to have breast cancer.
Conclusion(s) Thin layer technique can be used successfully in pleural fluids and ascites diagnostics. Additional immunocytochemistry improves diagnostic accuracy, reduces time required for final diagnosis and can guide clinical approach.

OP2.6

Fractal characteristics of nuclear chromatin in routinely stained cytology are independent prognostic factors in patients with multiple myeloma

Metze K.; Ferro Peixoto D.; Falconi Almeida M.; Adam L.R.; Ortega M.; Lima Passos C.; De Souza A.C.; Lorand-Metze G.I.
University of Campinas, Campinas, SP, Brazil

Background Nuclear texture features examined by computerized analysis can provide important prognostic information. Recently, the fractality of the chromatin structure has shown to be an independent prognostic factor in acute leukemia. In this study we investigated the influence of the fractal dimension (FD) of chromatin on global survival of patients with multiple myeloma.
Methods We studied 78 newly diagnosed patients from our Institution. They were treated according to the Brazilian Multicentric Protocol. Diagnostic work-up consisted of peripheral blood counts, bone marrow cytology, bone radiograms, biochemistry and cytogenetics. The international Prognostic Index (ISS) was used for staging. In every patient gray scale transformed pseudo-3D images of 100 nuclei in May-Grünwald-Giemsa stained bone marrow smears were analyzed. FD was determined by the Minkowski-Bouligand method extended to three dimensions. Goodness-of-fit of FD was estimated by the R2 values in the log-log plots. Uni-and multivariate Cox-regressions were calculated.
Results When stratifying for the ISS stage, both FD and its goodness-of-fit were significant prognostic factors in the univariate analyses. Patients with higher FD dimension or lower goodness-of-fit (equivalent to accentuated “coarseness” of the chromatin pattern) indicated a poor prognosis. In the multivariate Cox-regression, FD, R2, and ISS stage entered the final model, which showed to be stable in bootstrap resampling study.
Conclusion(s) In conclusion, fractal characteristics of the chromatin in routine cytology reveal relevant prognostic information in patients with multiple myeloma.

OP2.7
Rapid pre-screening as a quality assurance measure in cervical cytology

Repse Fokter A.; Sramek Zatler S.; Caks Golec T.
Celje Teaching Hospital, Celje, Slovenia

Background Efficient cytologic interpretation of Pap smears is a crucial factor that contributes to the success of cervical cancer screening. The aim of current study was to assess the diagnostic validity of rapid prescreening as a quality control method in our laboratory.
Methods All consecutive routine conventional Pap smears (n=521) underwent RPS before full screening. 30 to 60 seconds were allowed to prescreen each slide. The threshold for pathologic smear was ASCUS or more. Smear adequacy, infections and presence of endometrial cells, if observed, were not noted on the worksheet. All smears subsequently underwent routine full screening. Results of RPS and full screening were compared.
Results Of a total of 2521 smears, 294 were diagnosed as abnormal (ASCUS and more) after final diagnosis. Of those, 158 were also detected on rapid prescreening. The average sensitivity of RPS was 62.2%. 25 cases were detected on RPS only, among them 15 ASCUS, 8 low-grade squamous intraepithelial lesions and 2 high-grade squamous intraepithelial lesions.
Conclusion(s) RPS is an efficient quality control method. It reduces false- negative rate, but it impacts on the work flow and in case of its implementation to the routine praxis the daily workload of 50 smears per day should be lowered.

OP2.8
Performance appraisail for cytologists: an experience from the United States

Sugrue C.
Long Island Jewish Medical Center, Garden City, New York, USA

Background This presentation intends to discuss the application of objective methods for the performance appraisal of cytologists in an era of great changes in European Cytopathology Laboratories by sharing United States experience.
Methods 1. Identify the role and modalities of a well conducted Performance in the evolving healthcare industry. 2. Demonstrate the United States experience of quality control and quality assurance. 3. Examples of metrix will be demonstrate and discussed
Results This presentation will demonstrate how effectively integrate regulation requirements by creating objective measures for evaluation. Implementatioon of ideas for remediation will also be discussed.
Conclusion(s) Performance Appraisal is an essential tool to monitor and empower staff members in any business and currently is being adopt in the fast evolving healthcare setting.

OP2.9
Preliminary investigation of the clinical relevance of detecting circulating tumor cells by isolation by size of epithelial tumor cells (ISET) technique from cutaneous melanoma patients

Panelos I.; De Giorgi V.; Pinzani P.; Salvianti F.; Paglierani M.; Janoska A.; Grazzini M.; Orlando C.; Santucci M.; Lotti T.; Pazzagli M.; Massi D.
Department of Pathology, University of Ioannina Medical School, Ioannina, Greece
Departments of Clinical Physiopathology, Dematological Sciences and Human Pathology and Oncology, University of Florence, Italy

Background The isolation by size of epithelial tumor cells (ISET) is a direct method for identification of circulating tumor cells (CTC) in the peripheral blood due to their large size. So far, ISET has been applied only to CTC detection from epithelial cancer patients, and has never been validated in cutaneous melanoma patients.
Methods We investigated the presence of CTC by ISET from the peripheral blood of patients with cutaneous melanomas (n=72), melanocytic nevi (n=11), non-melanoma skin tumors (n=4) and healthy volunteers (n=18).
Results CTC were detected neither in the control groups nor in the blood from patients with melanocytic nevi. Conversely, the detection of CTC paralleled tumor progression rising from 7.1% in the in situ melanomas to 32.6% in the primary invasive melanoma category to 66.6% among metastatic melanoma patients (p=0.006). CTC detection was significantly associated with mRNA tyrosinase levels by real-time RT-PCR in blood samples (p = 0.002). No significant correlation was demonstrated between CTC detection and clinico-pathological parameters.
Conclusion(s) We demonstrated that ISET-isolated CTC can be identified in the bloodstream of primary and metastatic melanoma patients. The clinical relevance of this finding is still under scrutiny and the biology of circulating melanoma cells must be carefully investigated.

Dermatopathology

OP3.1
Cell adhesion molecules cadherins E, N, P and Catenins in nevi and melanomas

Stoemmer Erasmus P.; Torres-Galea P.
Forschungslabor Prof Dr. Stoemmer, Augsburg, Bavaria, Germany

Background In vitro experiments on melanoma cells show an important role of cell-adhesion molecules in melanomas. The subtypes of classical cadherins, E-, N-, P-cadherin, are expressed in a cell-, tissue-, and development-specific manner Especially N-cadherin is involved in the tumor-progression in melanomas;
Methods The immunohistochemical expression of E-cadherin, N-cadherin, P-cadherin, Catenins alpha and ß and of CAM CD44v was examined using 60 FFPE various benign and malignant melanocytic tumors (malignant melonomas (SSM, NMM), junctional, compound and dermal nevi, and blue nevi. Provider: E-Cadherin (Biologo, Dr.Schultheiss, Kronshagen, Klon 5H9, IgG1, IHC), N-Cadherin (Biozol, Eching GeneTex.Inc; IgG, polyclonal, IHC); ß-catenin Fisher Scientific Fremont CA USA), H-HAM CD44 Novocastra laboratories LM
Results E-Cadherin: Good membranous and intracytoplasmic expression is found in junctional nevi.. Dermal and especially regressive nevuscells show loss of E-Cadherin.In NMM there is a high expression, whereas SSM and LMM are completely negative. N-Cadherin: Nearly no N-cadherin is found in NMM; in contrast, high cytoplasmic and membranous expression in superficial cells of SSM is seen; in the deeper, seconddary nodular parts of these tumors, no N-cadherin is found. P-Cadherin: is seen in junctional nevus/melanoma cells: in junctional-N, upper parts of compound-N and superficial parts of NMM an SSM; deeper parts are completely negative. ß-Catenin: All junctional nevus/melanoma cells as well as those in deeper parts show a membranous expression H-CAM (CD44v): is positive in all nevus and melanoma cells
Conclusion(s) N-, E and P-Cadherin are involved inmelanocytic tumorprogression and invasivity. Mechanisms are und discussion.

OP3.2

Patterns of MCV in Merkel cell carcinoma (MCC) analyzed by fluorescence in situ hybridization (FISH)

Schmidt A.; Speel E.; Willi N.; Zsikla V.; Baumann M.; Haesevoets A.; Diebold J.; Hofman P.; Kurrer M.; Offner F.; Sauter G.; Cathomas G.
Liestal, Switzerland

Background MCC has recently been associated with a polyomavirus named Merkell cell polyomavirus (MCV). Aim of the study was the evaluation of viral DNA in MCC.
Methods The presence of MCV was analyzed by PCR and visualized by FISH, using a 5 kb biotinylated viral DNA probe.
Results Using PCR, MCV DNA was detected in 51 (74.5%) of 68 tumors; 51 were available for FISH, including 13 (25.5%) PCR negative cases. MCV was detected by FISH in 32 (84.2%) of PCR positive, but in none of PCR negative samples. FISH positive tumors showed 3 distinctive fluorescence patterns: i) a single signal per tumor cells, indicating chromosomal integration (in 25%), ii) a granular fluorescence pattern without a dominant signal spot, indicating episomal viral DNA/RNA expression (in 50%) and iii) a combination of the two patterns described (in 25%).
Conclusion(s) Combining PCR and FISH, 5 groups of MCC can be distinguished: 1) Chromosomal integration of MCV, 2) viral episomal or RNA expression without evidence of chromosomal integration 3) a combined pattern with evidence of integration and episomal/RNA expression, 4) MCV PCR positive tumors lacking any FISH signals and 5) MCC without evidence of MCV infection. Further studies have to elucidate whether these patterns represent different stages of MCC development or distinctive tumor groups.

OP3.3

Analysis of tumor suppressor gene TP53 mutations in atypical vascular lesions of the breast skin following radiotherapy

Santi R.; Cetica V.; Franchi A.; Delfino C.; Cesinaro A.; Miracco C.; Bianchi S.; Santucci M.; Sardi I.; Massi D.
University of Florence, Florence, Florence, Italy

Background Atypical vascular lesions (AVL) arise in the setting of breast-conserving surgical treatment with adjuvant radiation therapy. Clinical and histopathological findings suggest that AVL represent a reactive phenomenon secondary to radiotherapy although it has been suggested that in some cases AVL represent precursors of angiosarcoma. A better understanding of the biology of AVL is essential to establish appropriate patients' management. The aim of the present study was to investigate alterations of tumor suppressor gene TP53 in radiation-induced AVL.
Methods A series of 12 AVL (patients' age range 47–70 years, mean 59 years) developed in the irradiation field of a primary breast carcinoma following radiotherapy was analyzed. Immunohistochemical stainings for CD31, CD34, D2–40, and p53 protein were performed. Exons 4–9 of TP53 gene were analyzed by direct sequencing.
Results Atypical endothelial cells decorating anastomosing vascular channels were constantly CD31 positive whereas stainings for CD34, D2–40 and p53 were weakly and focally positive in the majority of cases. Sequencing analysis of TP53 gene showed the presence of at least one variation in 10 of 12 samples (83%). The most common alteration was P72R, found in 6 samples.
Conclusion(s) The presence of p53 alterations suggests that its mutational inactivation may be implicated in the

pathogenesis of AVL. It is conceivable that the expression of p53 mutant proteins may stimulate vessels' sprouting through ROS up-regulation causing activation of HIF1/VEGF-A pathway. However, further molecular investigations are needed to support this hypothesis.

OP3.4

Cell cycle regulator p16ink4a in cutaneous cylindromas and spiradenomas and its role as a morphogenetic factor

Stoemmer Erasmus P.; Torres-Galea P.
Forschungslabor Prof Dr.Stoemmer, Augsburg, Bavaria, Germany

Background Cutaneous cylindromas and spiradenomas are rare tumors mostly in young female patients. They exist in two different clinical manifestations: spontaneous solitary type in face and sclap and as a multiple variety as Turban tumor (Spiegler- Ancell) and together with trichoepitheliomas, spiradenomas or basal cell carcinomas. Their peculiar architecture is only incompletely undersatood.
Methods Ten spiradenomas and five cylindromas (FFPE) were processed according to conventional histologic and immunohistochemical methods for p16Ink4a, p63 protein S100, smooth muscle actin and proliferationmarker Ki-67 (MIB-1).
Results Defective laminin 5- processing induces characteristical broad PAS-positive hyaline sheath at the periphery of the tumorcomplexes and perhaps their peculiar jig-saw-puzzle pattern. The tumorcomplexes consist out of two different cell types: larger central cells and cuboidal cells at the periphery. Immunohistochemical results: basal cell marker p63 is highly expressed in the nuclei of the peripheral cells of these tumors, whereas p16INK4a is highly expressed in the cvytpolasm and the nuclei central cells in these tumors.
Conclusion(s) P16Ink4a is expressed in cytolasm and nuclei of multiple tumors; but only in cutaneous cylindromas and spiradenom, there is a strict separation between its expression in different compartiments of the tumors. The different expression in these cells may give an explanation for the characteristic two-cell-type architecture of these tumors.

OP3.5

Expression of neural crest stem cells markers in cutaneous amelanotic melanomas

Massi D.; De Giorgi V.; Pizzichetta M.A.; Maio V.; Santucci M.; Canzonieri V.
Dept of Human Pathology and Oncology, University of Florence, Florence, Italy

Background Amelanotic melanoma (AM) shows little or no pigment at visual inspection, thus featuring a diagnostic challenge. Despite recently gained insights on the dermoscopical features and unfavourable outcome of AM, its phenotypic profile has been poorly investigated. Sox proteins are transcription factors that belong to the HMG box superfamily of DNA-binding proteins and play a key role in regulating pigmentation. SOX10 modulates the expression of microphthalmia-associated transcription factor (MITF), which in turn controls genes critical for pigment cell development and pigmentation, including tyrosinase. Members of the SOX family and MITF were found expressed at higher levels in pigmented in comparison with non pigmented melanoma cell lines but there are no data on their expression in relation to melanoma pigmentation status in tissue specimens.
Methods The study included 27 AM (15F/12 M, 47–88 yrs.), retrieved from the authors' archives. Immunohistochemical analyses were performed with anti-SOX10 and anti-MITF antibodies.
Results Moderate to strong SOX10 expression was found in 27/27 cases, irrespective from thickness. MITF nuclear expression was detected in all AM.
Conclusion(s) SOX10 and MITF expression in AM suggests that downstream MITF factors, such as tyrosinase degradation, down-regulate pigmentation in amelanotic cells. Mechanistic studies are needed to prove SOX10 functionality, since MITF induces tyrosinase expression only in presence of functional SOX10. The preservation of transcription factors in AM is also consistent with the possibility that they could play a role in melanoma cell survival and proliferation, possibly affecting the activation of the stem cell marker nestin.

OP3.6

Gene signature of the metastatic potential of cutaneous melanoma: a meta-analysis

Jozsef T.; Balazs G.; Erzsebet R.
2nd Department of Pathology, Budapest, Hungary

Background Despite the stunning success of genomics in defining markers or gene signatures for breast cancer prognosis and predicting therapies, there is virtually no progression in malignant melanoma.
Methods We have evaluated gene signature studies published and collected their publicly available data-bases.
Results Four studies attempted to define the prognostic signature of skin melanoma but only one based the study on the primary tumor resulting in heterogenous signatures with a minimal overlap (MCM3 and NFKBIZ). Four study attempted to define the invasiveness-signature in the primary tumor based on thickness or growth pattern

discrimination identifying a 9-gene overlap which proved to be different from the prognostic signatures. On the other hand, seven studies analyzed various types of metastatic tissues (rarely visceral-, mostly cutaneous or lymphatic metastases) to define the metastasis-signatures, again with minimal overlap (AQP3, LGALS7 and SFN). Using seven GEO-based melanoma datasets we have performed a meta-analysis of the metastasis-gene signatures using normalization protocols. This analysis identified a 350-gene signature, the core of which was a 17-gene signature characterizing locoregional metastases where the individual components occuring in 3 studies: several members of this signature were extensively studied before in context of melanoma metastasis including WNT5A, EGFR, BCL2A1 and OPN.

Conclusion(s) These data suggest that only efficient inter-disciplinary collaboration throughout genomic analysis of human skin melanoma could lead to major advances in defining relevant gene-sets appropriate for clinical prognostication or revealing basic molecular pathways of melanoma progression.

OP3.7

Histopathology of cutaneous GvHD in the era of reduced-intensity conditioning

Fondi C.; Nozzoli C.; Arbarello L.; Avellini C.; Bonoldi E.; Cesinaro A.; Colombetti V.; Fortunato M.; Fratoni S.; Negri G.; Ponzoni M.; Rafaniello P.; Salomone E.; Villari L.; Santucci M.; Bosi A.; Massi D.
University of Florence, Pistoia, Italy

Background In recipients of allogenic transplants with reduced intensity conditioning (RIC) regimens the separation of acute from chronic GvHD before or after day 100 is no longer tenable and there is limited information on the histopathological features observed in GvHD skin biopsies in this context.

Methods Sixty skin biopsies from 55 patients (37 M and 18F) undergoing non myeloablative conditioning regimens were evaluated. 39 received transplants from related donors, 16 from unrelated ones. Stem cell source was bone marrow (n=8), peripheral blood (n=46) and cord blood (n=8). Thirty-two patients developed classical aGvHD, 2 patients late-onset aGvHD, 19 patients classic cGvHD and 7 patients overlap syndrome. GvHD-related deaths were 14/32, 1/2, 3/19 and 2/7, respectively.

Results Histopathological diagnostic categories were no GvHD (n=20), possible GvHD (n=16), consistent with GvHD (n=21) and definite GvHD (n=3). Histopathology in classical aGvHD and cGvHD was similar to that observed in conventional myeloablative transplantation. Biopsies from patients with overlap syndrome showed composite histological features: i) aGvHD with concomitant features of lichenoid cGvHD, ii) sclerodermiform cGvHD associated with basal vacuolar change, as observed in aGvHD.

Conclusion(s) Skin biopsy in GVHD is a snapshot in time and can give false negative results since tissue changes reflect duration of activity and degree of immunosuppressive treatment. Clinical pictures of aGvHD several months post-transplant or cGvHD features within 50–60 days post-HCT can be observed. Biopsies from patients with overlap syndrome may disclose peculiar composite features of acute and chronic GvHD.

OP3.8

Malignant melanomas can be differentiated from atypical nevi by Collagen XVII expression, which can be a target of immunotherapy

Krenacst T.; Kiszner G.; Stelkovics E.; Korom I.; Varga E.; Plotar V.; Orosz Z.; Timar J.; Raso E.
1st Deapartment of Pathology and Experimental Cancer Resrearch, Semmelweis University, Budapest, Hungary

Background Collagen XVII, a transmembrane receptor of laminin-5 is lost in mature keratinocytes but expressed early in squamous cell carcinomas. We detected it in activated melanocytes and melanocytic neoplasias.

Methods Using a mouse monoclonal antibody for the aa507–529 sequence, collagen XVII expression was tested in samples of 9 normal skin, 22 dysplastic- and 20 Spitz nevi, 83 primary and 18 metastatic melanomas, melanoma xenografts and cell lines, which were also treated with collagen XVII antibody. Immunostains were digitalized (Mirax Scan) and analyzed (HistoQuant, 3DHISTECH, Budapest).

Results Malignant melanomas showed moderate-to-strong collagen XVII immunostaining while nevi were negative. In melanomas collagen XVII expression paralleled with atypia, showed positive correlation with vertical growth and elevated expression on the tumor fronts, and it was seen in some HMB-45 or Melan A negative melanomas. Sensitivity and selectivity of melanoma markes were: Collagen XVII 85% in melanomas, 6% in nevi; Melan A 87/92%; S-100 94/90% and HMB-45 72/38%. Constitutive Collagen XVII mRNA and protein expression was detected in melanoma cell lines, primary metastatic and circulating HT199 cells of mouse xenografts and in re-cultured tumors. Collagen XVII antibody reduced cell proliferation, and elevated cell adhesion and apoptosis in a concentration dependent manner in HT199 cells.

Conclusion(s) Collagen XVII, a melanogenesis independent protein is an efficient marker of malignant melanomas differentiating malignant and benign lesions and it can be a target of melanoma immunotherapy. Supported by OTKA_K 62758.

OP3.9

Morphological and immunohistochemical features of atypical fibroxanthoma - potential diagnostic pitfalls

Luzar B.; Calonje Jaime E.
Medical Faculty University of Ljubljana, Institute of Pathology, Ljubljana, Slovenia

Background Genuine focal positivity for CD31 was occasionally observed among referral cases of atypical fibroxanthomas (AFX), leading to erroneous diagnosis of angiosarcoma. The present study gives emphasis on recognizing morphological variants of AFX, on validation of immunohistochemical markers, and on discussing potential diagnostic pitfalls.
Methods Histological features analysed were: ulceration, morphological variants, growth pattern, location in the skin, and vascular/perineural invasion. The antibodies used were CK-MNF116, CK-AE1/AE3, S100, smooth muscle actin, desmin, CD31, and EMA.
Results We analysed 66 AFXs (59 males, 7 females, age 55–95 yrs, mean 77 yrs). All developed on sun damaged skin. Morphological patterns were: pleomorphic spindle and epithelioid cells (60%), predominantly spindle cells (21%), predominantly epithelioid cells (6%), and purely spindle-cell non-pleomorphic variant (12%). Most were localized in the dermis (56%). An expansile (21%) rather than infiltrative (6%) growth into superficial subcutis was noted. No vascular/perineural invasion was seen. Additional changes were haemorrhagic and pseudoangiomatous areas (24%), granular cell change (23%), keloid-like change (9%) regression (9%), myxoid change (8%), osteoclast-like giant cells (4%), clear cell change (2%), and minute foci of necrosis (2%). AFX were consistently negative for S100, CK-MNF116, CK-AE1/AE3 and desmin. Focal positivity for SMA (44%), EMA (24%), and CD 31 (10%) was seen.
Conclusion(s) While SMA and EMA positivity are well recognized in AFXs, genuine focal CD31 positivity is a unique observation. Together with pseudoangiomatous/haemorrhagic areas, CD31 positivity in AFXs represents a potential diagnostic pitfall. This study further expands spectrum of non-vascular CD31 positive lesions.

OP4.1

Diagnostic and histogenetic significance of PAX8 expression in papillary serous carcinoma of the peritoneum

Tong G.; Hemale-Bena D.
Columbia University Medical Center, New York, NY, USA

Background Papillary serous carcinoma (PSC) of the peritoneum (PSCP) is a rare malignant tumor. Itoccurs almost exclusively in women and should be differentiated with peritoneal malignant mesothelioma (PMM), metastatic carcinoma of the peritoneum, peritoneal spread of ovarian epithelial carcinoma (OEC) and breast carcinoma (BC). Although similar to PSC of the ovary (PSCO), Müllerian origin of PSCP has not been confirmed. We investigated expression of PAX8, a new Müllerian marker, in PSCP utilizing immunohistochemistry (IHC).
Methods PAX8 IHC was performed on 7 PSCP (4 with positive ascites and 1 with axillary lymph node metastasis) and TMAs containing 10 PMM of female patients, 33 BC, 28 OEC, and 10 cases of reactive mesothelial cells (RMC) as control tissues, using the avidin-biotin peroxidase method following antigen retrieval.
Results All PSCP were consistently positive for BerEP4, CK7, negative for calretinin and CK20. Staining of ER, PR, WT-1 and CA125 was variable and 5, 3, 5, and 5 of 7 cases were positive, respectively. PAX8 was detected in all primary tumors, ascites, and lymph node metastasis of PSCP. No PAX8 staining was detected in BC, PMM, or RMC. PAX8 was detected in 23 of 28 OEC as previously reported.
Conclusion(s) Expression of PAX8 in PSCP supports its Müllerian origin arising probably from the fimbriae of the fallopian tube as shown for PSCO recently or Müllerian remnants in coelomic epithelium. PAX8 IHC is a useful differential tool in the diagnosis of PSCP in female patients.

OP4.2

A multiinstitutional consensus study on the pathologic diagnosis of ovarian mucinous borderline tumors and adenocarcinomas

Chun Y.; Chang E.; Kim M.; Kwon S.; Park M.; Suh K.; Yoon H.; Hwang T.; An H.; Park J.; Hong S.; Jun S.; Kim I.
Cheil General Hospital, Kwandong University College of Medicine, Seoul, Republic of Korea

Background This study was designed to assess the reproducibility of both the diagnosis and subtypes of ovarian mucinous borderline tumors (MBT) and the mucinous adenocarcinomas(MC).
Methods We collected 218 cases of MBT or MC from 11 hospitals in Korea and reviewed independently by 11 pathologists of the Gynecologic Pathology Study Group using a checklist. The checklist consisted of 4 major histologic categories–benign, MBT, MC and others including metastatic tumor-and 6 subclassification categories-endocervical-like type, intestinal type, microinvasion and intraepithelial carcinoma for MBT, and expansile type and infiltrative type for MC.

Results We excluded 7 cases showing mixed or other cell types and 9 cases having the likelihood of metastatic tumor. Of the remaining 202 cases, the original diagnoses were 37 (18%) MC and 165 (82%) MBT. After consensus study, 163 (80.7%) cases were reclassified as MBT (13 endocervical-like and 150 intestinal). 24 (11.9%) were MC and 9 (4.4%) were benign. Six cases (3.0%) could not get a consensus on diagnosis. The original diagnosis of MC showed low reproducibility and only 11 cases (30%) reached the agreement among more then two thirds of reviewers. But MBT showed a higher concordance rate. The differential diagnosis of MBT with intraepithelial carcinoma and expansile MC was problematic. Confusion with microinvasion and mucin granuloma was noted.
Conclusion(s) We need the more strict diagnostic criteria for the diagnosis of MBT with intraepithelial carcinoma and expansile type of invasion. The concept of MBT with microinvasion should need more qualification and quantification.

OP4.3
HER2 and ovarian cancer

Sarancone S.; Acosta Haab G.; Nocito A.; Frahm I.; Lupo E.; Cáceres V.
Rosario, Santa Fe, Argentina

Background Variable rates of HER2 over-expression/amplification have been reported in advanced ovarian cancers (AOC) with widely discordant results, ranging from 11 to 32%. There is growing interest in its role in prognosis, pathogenesis and treatment implications for AOC patients, due to the future introduction of trastuzumab and pertuzumab therapy. The aim of the study was to examine HER2 over-expression in AOC and to correlate with classic histological features.
Methods 155 H&E-stained, formalin fixed paraffin embedded AOC tissue samples with required criteria were collected HER-2 analysis was performed using policlonal antibody anti Her 2 (DAKO), microwave antigenic recovery, detection system EnVision (Dako) and developed with diaminobenzidine. Results were interpreted as hercepTest® guideline's. 40 cases were also screened by fluorescence in situ hybridization (FISH).
Results HER2 was over-expressed in 16 patients (10,3%), and all were also FISH +, and remaining 139 (89,7%) were score 0. Among, HER2 + patients: 6 were serous, 3 mucinous, 3 endometroid and 4 undifferentiated tumors.
Conclusion(s) HER2+ prevalence in our sample (10.3%) is in line with previously published onesThere was 100% correlation between ICH and FISH. No significant relationship was found among HER2 score and main pathological features. Identifying HER2 + patients enables specific therapy leading to a significant change in treatment and prognosis. Technique standardization is a key to success in identifying HER 2 over-expression in an accurate, precise and truthful way, although patterns may differ from breast cancer.

OP4.4
The prevalence of mix HRHPV infection among women of reproductive age in Tuzla Canton, Bosnia and Herzegovina

Iljazovic E.; Mehinovic N.; Ljuca D.; Avdic S.; Karasalihovic Z.
University Clinical Center Tuzla, Tuzla, Bosnia and Herzegovina

Background The prevalence of high risk Human papilloma virus infection (HRHPV) in woman of reproductive age in Tuzla Canton is around 45%. Mostly, HRHPV infection was identified in women with normal and mildly abnormal PAP smear. We aimed to set out the presence of mix HPV infection (HPV 16, 18, and 45) as one of the most common mix types.
Methods HRHPV DNA was detected by Hybride Capture HRHPV DNA II. In order to identify the presence of mix infection in HRHPV positive women was used the new Digene HPV 16/18/45 Probe Set (for research use only).
Results Most of the tested women had mix HPV infection
Conclusion(s) In one of our previous study HPV 16 was the most common type (> 46%), while HPV 18 and 45 were detected in 1,8% only. Detection of the mix infection of those HRHPV types in women with normal and mild cellular abnormality is important for the follow up intervals and prognosis.

OP4.5
Value of p16INK4a as a marker of progression/regression in cervical intraepithelial neoplasia Grade 1

Castillo P.; Del Pino M.; Garcia S.; Fusté V.; Alonso I.; Torné A.; Ordi J.
Department of Pathology, Hospital Clinic, IDIBAPS, Universidad de Barcelona, Barcelona, Catalunya, Spain

Background Low-grade squamous intraepithelial lesions (LSIL) and their histological counterpart CIN1, frequently regress spontaneously in 1–2 years. Nevertheless, 10–15% of LSIL/CIN1 lesions progress to CIN2/3. p16INK4a has recently been proposed as a biomarker for cervical lesions. In contrast with the consistent positive staining of CIN2–3 lesions, CIN1 show a marked variability in staining, with some lesions being positive and others showing a negative reaction. The objective of this study was to evaluate whether this immunohistochemical variability in p16INK4a

staining could provide information on the evolution of LSIL/CIN1 lesions.
Methods Patients with a histological diagnosis of CIN1 were prospectively recruited (n=138). Simultaneous detection of HR-HPV, and p16INK4a evaluation in the biopsy were performed. Follow-up was conducted every 6 months by cytology and colposcopy, and annually by HR-HPV testing, for at least 12 months (mean 29.0).
Results Progression was observed in 14 women (10.1%); 66 (47.6%) regressed, and 58 (42.0%) had a persistent disease. p16INK4a was positive in 77 (55.8%) initial biopsies. Progression to CIN2–3 was identified in 14/77 (18.2%) women with positive and 0/61 (0.0%) with negative p16INK4a immunostaining (p<0.001).
Conclusion(s) CIN1 lesions positive for p16INK4a have a significantly higher tendency to progress to CIN2–3. Patients with CIN1 lesions negative for p16INK4a rarely progress and may benefit from a less intensive clinical follow-up.

OP4.6
Adhesion molecules and p16 expression in endocervical adenocarcinoma

Fulciniti F.; Carico E.; Giovagnoli R.M.; Losito S.N.; Botti G.; Benincasa G.; Farnetano G.; Vecchione A.
Istituto Nazionale Tumori "Fondazione G. Pascale", Naples, Italy

Background Defects in the E-Cadherin/Catenin adhesion complex have been described in several gynecologic cancers, mainly in cervical, endometrial and ovarian tumors. Fewer studies have recently focused also on the the E-cadherin-catenin complex expression in endocervical adenocarcinomas.
Methods An immunohistochemical study has been conducted on 34 cases of untreated endocervical adenocarcinomas. The E-cadherin and α- and β-catenin complex status has been investigated along with p16INK4a in all studied cases with the aim to study whether the pattern of expression of the Cadherin-Catenin complex could be causally related to the expression of P16INK4a protein. Results were evaluated for statistical significance by a non parametric test (Kruskall Wallis).
Results Endocervical adenocarcinomas were uniformly expressing p16INK 4a except for two cases and all lesions displayed down regulation of the Cadherin-catenin complex, without demonstrating statistically significant differences among the different histotypes. The lack of nuclear accumulation of β-catenin found in this group of lesions probably implies that no alteration of the β-catenin/ wnt metabolic pathway is present in endocervical adenocarcinoma, as opposed to what found in the literature for squamous carcinoma of the cervix. The diffuse expression of p16INK4a protein in this group of neoplasms stresses the important role of high risk HPV infection in neoplastic causation possibly via the viral E7 mediated inactivation of pRB tumor suppressor protein.
Conclusion(s) In consideration of these findings, investigation of downstream β-catenin genes c-myc and Cyclin D1 is sought as possibly contributive in the molecular pathogenesis of endocervical adenocarcinoma.

OP4.7
Investigation of GLUT-1 and galectin-3 in endometrioid and serous carcinomas of the endometrium

Ege Cigdem B.; Akbulut M.; Zekioglu O.; Ozdemir N.
Pamukkale University, School of Medicine, Denizli, Turkey

Background GLUT-1 and galectin-3 have been shown to function in tumor progression and metastatic spread. The aim of this study was to investigate the relationship between GLUT-1 and galectin-3 expression and well-known prognostic factors. 64 endometrial carcinomas, which includes 24 serous type were obtained from previously untreated patients.
Methods Immunohistochemical analysis of 64 carcinomas, 20 endometrial hyperplasia (ten simple hyperplasia and ten complex atypic hyperplasia) and 20 normal endometria (ten proliferative and ten secretory) was performed.
Results The percentage of GLUT-1 expression was found to be significantly higher in serous carcinomas when compared to endometrioid adenocarcinomas. The percentage of GLUT-1 expression was significantly correlated with lymph node metastasis, adnexial metastasis, positive periton cytology and classified stage. GLUT-1 expression was also significantly higher in hyperplasias than normal endometrium. Epitelial and stromal galectin-3 expression was significantly decreased in both endometrioid and serous carcinomas compared to the control group. Stromal galectin-3 expression was also correlated with lymph node metastasis.
Conclusion(s) This study shows that GLUT-1 expression increases from secretory endometrium to hyperplastic endometrium and the two types of carcinoma of the endometrium and provides further evidence of a relationship between atypical hyperplasia and endometrioid carcinoma. GLUT-1 can serve as an indicator of the aggresive potential of endometrial cancers. This investigation suggests decreased expression of galectin-3 to be involved in the pathogenesis of endometrial carcinomas from normal endometrium to carcinoma. Down-regulated stromal expression of galectin-3 in endometrial carcinoma may be involved in lymph node metastasis.

OP4.8

Molecular basis of stromal-parenchymal interactions in foci of active and non-active adenomyosis

Kogan E.; Demura T.; Grechukhina O.; Unanyan A.; Sidorova I.
Scientific centre of obtetrics and gynecology, Moscow, Russian Federation

Background The aim of our study was to investigate molecular aspects of stromal-parenchymal interactions in active and non-active foci of adenomyosis.
Methods The study was performed on serial sections of uteri taken from 94 patients of reproductive age with diffuse adenomyosis (12 non-active and 82 active). Immunohistochemical detection of MMP-1,2,7,9, TIMP-1,4, E-cadherin, COX2, SOD (Lab Vision), PCNA, CD34 (DAKO), Apo, EGF, EGFR (Novocastra) was used. Results were evaluated with the help of quantitative and semi quantitative methods and statistic analysis.
Results Active foci with cytogenic stroma demonstrated relatively low apoptosis, high levels of PCNA and MMPs both in epithelial, stromal and endothelial cells, while non-active had higher levels of TIMPs and increased apoptosis. MMP1, MMP7 were detected predominantly in epithelium of active foci, while MMP2 and 9 were mostly expressed in stroma and endothelium of active adenomyosis. Non-active foci had high levels of TIMPs in epithelium. CD34 was much higher in active foci compared to non-active. Both types of foci revealed similar levels of E-cadherin expression.
Conclusion(s) Adenomyosis is a condition with the disturbances in stromal-parenchimal interactions including misbalance between processes of apoptosis and proliferation, MMPs and TIMPs and high level of neoangiogenesis. Increased stromal expression of MMP2 and 9 which are known to degrade extracellular matrix and trigger neoangiogenesis in active adenomyosis may indicate the aggressiveness of stroma.

OP4.9

Morphogenetic relationships between foci of adenomyosis and basalis of eutopic endometrium

Grechukhina O.; Kogan E.; Demura T.; Unanjan A.; Sidorova I.
Sechenov Moscow Medical Academy, Moscow, Russian Federation

Background Adenomyosis is a very common gynecological disorder. Despite high incidence of the disease precise developmental events leading to the condition remain unknown. The aim of our study was to investigate and compare the expression of markers of proliferation, apoptosis, invasion and neoangiogenesis in foci of adenomyosis and in eutopic endometrium and to assess their potential role in the pathogenesis of the disease.
Methods The study was performed on biopsy samples of uterus taken from 94 women with adenomyosis. Immunohistochemical staining of tissues was performed with antibodies to MMP1,2,7,9, TIMP1,4, E-cadherin, PCNA, Apo, EGF, EGFR.
Results The basal layer of eutopic endometrium and foci of adenomyosis were found to express similar levels of PCNA and Apo, markers of invasion and growth factors with their receptors in epithelium. The functionalis had different molecular features. E-cadherin was highly expressed in epithelium of eutopic and ectopic endometrium. Stroma in foci of adenomyosis showed higher levels of MMP2,9, whilst epithelium was more active in expressing MMP1,7, TIMP1,4, E-cadherin, EGF and EGFR.
Conclusion(s) The obtained data suggests that morphogenesis of adenomyosis is based on the disturbances in stromal-parenchimal interactions in the basal layer of endometrium. Alterations on molecular levels may result in the invasion of the basalis into the myomertium which occurs mostly due to the hyperactivity stromal elements, while epithelial cells reveal prominent cell-to-cell adhesion.

Oral presentations 5

Haematopathology

OP5.1

Diffuse large b-cell lymphoma-clear cell variant. Case report

Manxhuka-Kerliu S.; Petruseska G.; Kryeziu E.; Loxha S.; Kerliu A.; Baruti A.; Shahini L.; Gashi G.
University of Prishtina, Faculty of Medicine, Institute of Pathology, Prishtina, Kosovo, Serbia and Montenegro

Background Diffuse large B-cell lymphoma (DLBCL) is a diffuse proliferation of large neoplastic B lymphoid cells.
Methods. The aim of this study was to report a case of DLBCL-clear cell variant involving the lymph node in the neck, which was clinically suspected for metastatic carcinoma. A 39 years old man presented with rapidly enlarged lymph node in the neck, disclosing B symptoms and fatigue. FNAB disclosed pleomorphic feature. Large excision was performed for histopathology and IH examination.
Results The lymph node biopsy showed a partially nodular growth pattern with 2 distinct components with respect to morphological, phenotypic and genetic features: 1. large nodules / diffuse areas, composed of large cells with slightly irregular nuclei clear cytoplasm, admixed with a

few immunoblasts. Some pseudoadenoid structures were found. In these areas, there was a high mitotic activity, and numerous macrophages with tangible bodies responsible for some starry sky pattern. Stainings for cytokeratins and Mean A were negative. There was strong positivity to vimentin as well. These areas disclosed the following phenotype: CD20+, CD5-, CD10+, bcl-2+, bcl-6+ and exhibited a high proliferative rate (MIB1/Ki67 80%). 2. The areas with folliclura structures were composed of centrocytes and rare centroblasts with a CD20+, CD5, CD10+ (strong), bcl-2+, bcl-6+ phenotype, and a relatively low proliferative index (MIB1/Ki67 20%).
Conclusion(s) A number of high grade B-cell lymphomas, correspond to « de novo » transformation of low grade lymphoma, mainly FL and B-CLL.

OP5.2

Intact B cell follicles identify mixed cellularity (MC) Hodgkin lymphomas (HL) with clinical and prognostic features of lymphocyte rich classical hl (cHL)

Kurrer M.; Giger S.; Korol D.; Renner C.; Moch H.; Probst Hensch N.
Pathologisches Institut, Kantonsspital Aarau, Aarau, Switzerland

Background The WHO distinguishes nodular lymphocyte predominant (LP) HL from cHL. cHL is divided into nodular sclerosis (NS), MC and lymphocyte rich cHL (LR). The WHO separated MC from LR by the presence of eosinophils. Follicular and interfollicular cHL have been described to complement the WHO scheme. We hypothesized that preservation of follicular architecture would reclassify MC as cHL related to LR (LRcHL).
Methods Slides and files were reviewed from 131 patients diagnosed from 1991 to 2007. B cell follicles and absence of sclerosis was used to separate MC and NS from LRcHL. EBER, CD20, CD30 and CD15 was used to separate LP from LRcHL.
Results Review resulted in 65 NS, 19 MC, 32 LRcHL and 15 NP cases. B-symptoms were frequent in MC (11/15) compared to LRcHL (6/28) and LP (1/6). Advanced stage III/IV was seen in 10/52 NS, 12/15 MC, 1/26 LRcHL and 0/5 LP patients. Patients died in 8/65 NS, 6/17 MC, 1/27 LRcHL and 3/14 LP. Male to female ratio was for NS 33:32 (1:1), MC 13:6 (2:1), LR 23:9 (2.6:1) and LP 14:1. MC patients were older, higher stage and B-symptoms were more frequent than in NS and LRcHL. Recurrence was similar in all HL.
Conclusion(s) Follicles imparting a follicular or interfollicular pattern to HL identify a subgroup of MC with clinical features of LR. Other MC patients are older, have B-symptoms, advanced stage and bad outcome.

OP5.3

Aberrant hypermethylation of DAP-kinase cpg island in immune suppression associated B-cell lymphoproliferative disorders/lymphomas and immune competent diffuse large B-cell lymphoma – correlation with EBV-association

Ibrahim Ahmed Hamed H.; Menasce P.L.; Bower M.; Pomplun S.; Naresh N.K.
Imperial College London, London, United Kingdom

Background Post-transplant lymphoproliferative disorders (PTLDs) and HIV-related B-cell lymphomas (BCL) are well known examples of Immunodeficiency lymphoproliferative disorders (IDLDs). Aberrant hypermethylation (AH) of DAP-kinase, a proapoptotic gene, is involved in the pathogenesis of IDLDs. Epstein Barr virus (EBV) has been shown to play a major role in the pathogenesis of IDLDs in the majority of cases. We have investigated whether B-PTLDs and HIV-associated BCL significantly differ from immunocompetent (IC) diffuse large B-cell lymphomas (DLBCL) with regard to AH of DAP- kinase gene. We further correlated AH with EBV association.
Methods DNA was extracted from paraffin sections of 28, 19 and 18 samples of B-PTLD, HIV-related BCL, and IC-DLBCL respectively. In addition, DNA from 8 samples of peripheral blood lymphocytes was used as a control. Methylation specific PCR was carried out for AH detection. EBV association was assessed by In-Situ Hybridisation for EBER RNA on tissue Microarrays.
Results 23/28 of B-PTLD, 16/19 of HIV-lymphomas, and 14/18 IC-DLBCL showed AH of DAP-kinase while normal blood samples were negative. Overall, AH of the DAP-kinase gene was noted in 81% of the Lymphoproliferative disorders/lymphomas and EBV association was noted in 58% cases. While 83% of the cases that lacked DAP-kinase AH were EBV-associated, only 52% of the cases with DAP-kinase AH showed EBV-association ($p=0.045$).
Conclusion(s) 83% of IDLD and 78% of IC-DLBCL showed aberrant DAP-kinase hypermethylation. Hypermethylation status and EBV-association showed an inverse correlation.

OP5.4

Accelerated CLL is a morphological variant involving lymphoid tissues with high proliferation and prognostic implications

Martinez D.; Gine E.; Villamor N.; López-Guillermo A.; Bosch F.; Emili M.; Campo E.; Martinez A.
Hospital Clínic, Barcelona, Spain

Background CLL/SLL has a small lymphocytic component and a proliferative compartment, the proliferative

growth centers (PC). PC's are in similar composition to lymphoid follicles but lack a support of FDC meshwork. Increase of cell size and proliferative activity as well as enlarged and confluent PC may be seen in CLL although the clinical meaning is controversial.

Methods 145CLL/SLL patients diagnosed between the period from 1990–2008 from which a biopsy was obtained were stained with p27, p53 and ki67. The pattern of involvement, presence and size of proliferative growth centers and proliferation were assessed. The clinical and biological data were collected and analyzed.

Results Involvement by CLL/SLL was identified in 103 cases. Enlarged and confluent PC broader than ≥2,5 mm^2, ≥2.4 mitosis and/or ≥30% ki-67 in the PC identified cases with poor survival. A score based on these features classify CLL/SLL patients: patternA (≤ 1 parameter), 84 (82%) and patternB (≥ 2 parameters), 19 (18%) with worse survival from biopsy (34 months vs 80 months; $p=0.0014$). Transformation to DLBCL occurred in 23 cases, median survival of 4 months. Only one pattern B patient transformed to DLBCL. Unfavorable biological risk factors were evenly distributed among all subsets. Pattern B patients presented with high ZAP-70 expression and short lymphocyte doubling time.

Conclusion(s) Expanded PC and high proliferation identifies a group of CLL/SLL patients with poor survival. These patients do not transform to DLBCL and present an intermediate outcome. The term accelerated CLL/SLL is proposed.

OP5.5

Epstein Barr virus genotypes in immunodeficiency lymphoproliferative disorders/lymphomas

Ibrahim Ahmed Hamed H.; Menasce P.L.; Bower M.; Pomplun S.; Naresh N.K.
Imperial College London, London, United Kingdom

Background Immunodeficiency lymphoproliferative disorders (IDLDs) are a group of diseases that range from polyclonal to monoclonal lymphoid proliferations. Post-transplant lymphoproliferative disorders (PTLDs) and HIV-related B-cell lymphomas (BCL) are well known examples of these disorders. They usually develop as a result of some genetic and epigenetic alterations. Epstein Barr virus (EBV) has been shown to play a major role in the pathogenesis of IDLDs in the majority of cases. We have investigated the prevalence of different EBV genotypes among IDLD samples.

Methods We screened IDLDs and immune competent diffuse large B-cell lymphomas (IC-DLBCL) for EBV association by performing In-Situ Hybridization for EBER on tissue microarrays. We preformed PCR analysis with primers directed at EBNA3C to distinguish the two EBV genotypes.

Results We selected 26 B-PTLDs, 12 HIV-BCLs and 2 IC-DLBCL for EBV genotyping. Among B-PTLDs, 24 were of type A (92%) and 2 were of type B. Among HIV-BCLs, 6 were of type A (50%) and 6 were of type B. Differences in the EBV genotype between B-PTLD and HIV-BCL were statistically significant ($p=0.003$). Both cases of IC-DLBCL were of type A. None of the cases examined were positive for both types of EBV.

Conclusion(s) PTLD samples are more frequently associated with EBV type A as compared to HIV-BCLs.

OP5.6

Prognostic markers and angiogenesis in diffuse large B-cell lymphoma and follicular lymphoma

Mezei T.; Gurzu S.; Raica M.; Cîmpean A.; Szentirmay J.; Jung J.
University of Medicine and Pharmacy, Targu Mures, Romania

Background In later years great efforts have been done to elucidate different characteristics of immunohistochemical prognostic markers and tumour angiogenesis. This is especially valid for various solid tumours. There are however only a few papers that discuss microvascular characteristics of malignant B-cell lymphomas. The purpose of this study was to correlate some well known immunohistochemical prognostic markers with microvascular characteristics of two types of malignant B-cell lymphoma: Diffuse Large B-cell Lymphoma (DLBCL) and Follicular Lymphoma (FL).

Methods Randomly chosen 29 cases of DLBCL and 20 cases of FL were used. Conventional immunohistochemical methods were used for both the prognostic markers (Bcl-2, Bcl-6, CD10, MUM1) and to mark microvessels using the CD34 antibody. We measured the endothelial area fraction (EAF), defined by the CD34 positive area and total tissue area fraction, using digital morphometric analysis. DLBCL was divided into GC (germinal center) and nGC (non-germinal center) subtypes, FL into group A and B according to previously published protocolls.
