Steady State Photolysis and Product Analysis of 4-Chloroanisole in Aqueous Solutions

Faten S. M. Abd El-Hameed*, Paul Krajnik, and Nikola Getoff Institute for Theoretical Chemistry and Radiation Chemistry, University of Vienna, Vienna, Austria

Z. Naturforsch. 48a, 799-805 (1993); received April 26, 1993

Aqueous solutions of 4-Chloroanisole (4ClA) of various concentrations saturated with Ar, N_2O , air, and O_2 were photolyzed under steady state conditions using uv-light of 228.8 and 253.7 nm. The reaction products (4-methoxyphenol, 4-chlorophenol, anisole and hydroquinone) were detected by HPLC. Mechanisms which account for these photoproducts are suggested.

1. Introduction

As a consequence of the rapid development of various industries during the last decades and the worldwide application of fertilizers, pesticides etc. in modern agriculture, water resources became heavily polluted. Chlorinated organic compounds are considered as dangerous water pollutants. As an alternative to electron- and γ -rays the use of uv-light has been suggested for degradation of such compounds ([1] and references therein). Further, it has been established that aqueous anisole can eject electrons its S_1 and S_2 excited states [2].

In the present work, 4-chloroanisole (4ClA) was chosen as a model substrate, and its photoinduced decomposition was studied under steady state conditions using monochromatic light of 228.8 and 253.7 nm. In order to elucidate the reactivity of the transients involved in the decomposition process of 4ClA, the solutions were saturated with different gases (Ar, N_2O , air, and O_2). Based on the analysis of final products, a possible reaction mechanism is suggested.

2. Experimental

Light Sourced and Actinometry

Two different low pressure uv-lamps served as light sources. A Hg-lamp (Osram HNS 10 W) with Vycor

Reprint requests to Prof. Dr. N. Getoff, Institut für Theoretische Chemie and Radiochemie, Universität Wien, Währingerstraße 38, A-1090 Wien, Österreich.

filter, which absorbs the 184.9 nm line, provided monochromatic uv-light of $\lambda=253.7$ nm. Using airfree 0.5 mol dm⁻³ ClCH₂COOH as actinometer (light path d=1 cm) with a quantum yield Q (Cl⁻) = 0.37 at 32 °C [3], a light intensity $I_0=6.5\times10^{17}$ hv ml⁻¹ min⁻¹ was determined. Further, a Philips low pressure Cd-lamp emitting at $\lambda=228.8$ nm was also applied. Using the same actinometer system as before, but with higher Cl-yield (0.6) [3], an intensity $I_0=4\times10^{16}$ hv ml⁻¹ min⁻¹ was determined. All uv-irradiation experiments were carried out at 32 °C in a thermostated double walled irradiation vessel with quartz tubes and 4π -geometry, described previously [4].

Preparation of Solutions and Analysis

p-Chloroanisole (Aldrich 99%) was used as received and dissolved in triply distilled water which had been saturated with the corresponding gas before irradiation with uv-light.

The Cl⁻ yield was used as indicator for the degree of substrate decomposition. The Cl⁻ determination was performed according to the method by Florence [5].

Aqueous solutions of 4ClA were irradiated under steady state conditions at $\lambda = 253.7$ and 228.8 nm and subsequently analysed by an HPLC chromatograph (Hewlett-Packard 1050, Sphersorb ODS2 125 nm column; eluent: $\rm H_2O/MeOH = 50/50$ by volume). The HPLC was equipped with a multiple wavelength uvdetector. The absorption of the individual products was detected at 210, 225 and 280 nm, and their identity was confirmed by comparison with the identity chromatograms of standards.

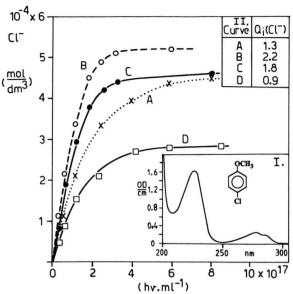

Fig. 1. Photoinduced Cl⁻ formation from 5.0×10^{-4} mol dm⁻³ 4ClA. (A) Airfree solution, (B) in the presence of 2.8×10^{-2} mol dm⁻³ N₂O, (C) in the presence of 0.25×10^{-3} mol dm⁻³ O₂, and (D) in the presence of 1.25×10^{-3} mol dm⁻³ O₂, as a function of the uv-dose ($\lambda = 253.7$ nm) at pH 7. *Insert I:* Absorption spectrum of 1.0×10^{-4} mol dm⁻³ 4ClA in water at pH 7. *Insert II:* Initial Cl⁻ yields ($O_i(\text{Cl}^-)$).

3. Results

The absorption spectrum of 4ClA shows two maxima at 227 and 278 nm (Fig. 1, insert I). On absorption of light 253.7 and 228.8 nm, 4ClA is promoted to its first and second singlet states, respectively. In order to determine the influence of different reaction conditions on the reaction mechanism, solutions of various concentrations and pH under Ar, N_2O , air and O_2 were irradiated.

Figure 1 shows the Cl⁻ yield resulting from 4ClA as a function of adsorbed uv-dose under four different experimental conditions using light of λ =253.7 nm. The quantum yields of photolytically formed Cl⁻ ions, $Q(\text{Cl}^-)$, were calculated from the linear part of the individual curves in Fig. 1. The high Q-values indicate that not only simple homolization of the C-Cl bond is taking place, but at least one additional reaction must be involved.

In all experiments, 4-methoxyphenol was found to be the major product. Anisole, chlorophenol and hydroquinone were also detected in minor quantities. A typical HPLC-chromatogram is presented in Figure 2. It might be pointed out that the product distri-

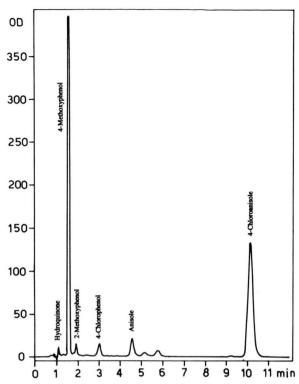

Fig. 2. HPLC separation chromatogram of the photo-induced products from 7.5×10^{-4} mol dm⁻³ 4ClA in the presence of Argon at pH 7, applied dose 5×10^{17} h ml⁻¹ ($\lambda = 253.7$ nm).

bution strongly depends on the experimental conditions.

The pH of the solution had a relatively small influence on the product distribution. The initial quantum yields decreased slightly by changing the pH from 7 to 12 as can be seen by comparing the data of Figs. 3 and 4. This effect is explained by the lower reactivity of O^{-} species in contrast to that of the OH radicals $(OH \rightleftharpoons O^{-} + H^{+}, pK = 11.9)$.

In the presence of 2.8×10^{-2} mol dm³ N₂O, the substrate decomposition is more efficient and the yields of the products are much higher than in the airfree solutions (Figure 5). Rather high product yields were also observed in solutions saturated with oxygen. In this case, the hydroquinone yield increases because of secondary photochemical reactions of 4ClA. Neither products resulting from ring opening-reactions nor peroxides were detected.

On irradiation with uv-light of wavelength λ = 228.8 nm, which promotes the molecule into its second singlet state, no anisole was found (Figure 6). In

airfree solutions all other products were formed with much higher yields than when using uv-light of $\lambda = 253.7$ nm. The change in the substrate concentration did not affect the product distribution essentially.

All analytical data are summarized in Table 1 for a better illustration.

Generally, the formation of dimers originating from the produced radicals (anisole radical, phenoxy radical and chloroanisole radical cation) were expected, however no such products were found in any of the performed experiments.

4. Discussion

4.1. General Considerations

The subsequently presented reaction mechanisms are derived from the analysis of final products observed under given experimental conditions. In airfree solutions all transients resulting from the photolysis of 4ClA, e.g. e_{aq}^- , H, Cl and OCH₃ etc. have the chance to participate in the reaction events. But, in the presence of N_2O , as is well known, the e_{aq}^- are converted into OH radicals:

$$N_2O + H_2O + e_{aq}^- \rightarrow OH + OH^- + N_2$$
 (1)
 $(k=0.91 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$

In the presence of air $(0.25 \times 10^{-3} \text{ mol dm}^{-3} \text{ O}_2)$ as well as solutions saturated with pure oxygen $(1.25 \times 10^{-3} \text{ mol dm}^{-3} \text{ O}_2)$ both, e_{aq}^- and H atoms are transformed into peroxy-radicals:

$$O_2 + e_{aq}^- \rightarrow O_2^-$$
 (2)
 $(k = 2.1 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$ [6]

$$O_2 + H \rightarrow HO_2$$
 (3)

$$(k_3 = 1.9 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1})$$
 [6]

$$HO_2^{\cdot} \rightleftharpoons H^+ + O_2^{\cdot-} \quad (pK = 4.8) [7].$$
 (4)

4.2. Airfree 4ClA Solutions

The increasing yield of chloride-ions formed during illumination of airfree 4ClA solutions indicates the extent of decomposition of 4ClA (see e.g. Figure 1). When uv-light of $\lambda = 253.7$ nm is used for irradiation, formation of the S_1 -state of 4ClA takes place (Fig. 1, insert I). Consequently, several deactivation pathways can be initiated [8]: formation of radical cations (4ClA·+) by electron ejection from substrate, splitting either Cl· or 'OCH₃, and photophysical processes.

used, $Q(e_{aq}^-)=0.12$ was observed [2]. However, when N₂O was applied for scavenging e_{aq}^- the following values were found: for S₁-state $Q(e_{aq}^-)=0.025$ for S₂-state $Q(e_{aq}^-)=0.120$, respectively [8]. The same e_{aq}^- yields are now assumed for 4ClA.

In general it is accepted that radical cations disappear by reaction with water, forming OH-adducts:

OCH₃

$$Cl$$

$$H^{+} + H_{2}O \longrightarrow H^{+} + OH$$

$$Cl$$

$$OH adducts on o-, m-, p- and ipso-positions). (6)$$

As a consequence of this process a number of consecutive reactions are probable, because they can explain the formation of the measured products (see Table 1):

$$OCH_3$$

$$OCH_3$$

$$OH$$

$$OH$$

$$OH$$

$$OH$$

$$CH_3\dot{O} + \bigcirc OH$$

$$(7a)$$

The formation of e_{aq}^- (5a) and of CH₃O⁻ (5c) from anisol has been previously studied [2]. Using ClCH₂CH₂OH as a scavenger for e_{aq}^- and by irradiating the aqueous anisole solutions with uv-light of $\lambda = 253.7$ nm (S₁-state), $Q(Cl^-) = Q(e_{aq}^-) = 0.008$ was found, and when light of $\lambda = 228.8$ nm (S₂-state) was

$$e_{aq}^{-} + \bigodot_{Cl}^{OCH_3} \longrightarrow \bigodot_{\bullet}^{OCH_3} + Cl^{-},$$
 (8)

$$Cl^{-} + H_2O \rightarrow H^{+} + Cl^{-} + OH$$
. (9)

In alkaline solutions the radical cation reacts with OH⁻. For anisole,

$$\begin{array}{c}
OCH_3 & OCH_3 \\
\hline
OCH_3 & OCH_3
\end{array}$$

$$Cl & OCH_3$$

$$OH. \\
OH.$$

a rate constant $k = 1 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ [9] has been found.

The OH-radicals originating from reactions (5c) and (9) can lead to an additional formation of OH adducts:

$$\begin{array}{c}
OCH_3 & OCH_3 \\
 & + OH \longrightarrow OH \\
Cl & (OH-adducts)
\end{array}$$
(11)

These species can decay according to reaction (7a) and (7b) or following the reactions:

and (7 b) or following the reactions:

O-CH₃

OCH₃

$$+$$

OCH₃

The phenoxyl radical, ClC₆H₄O^{*}, has various resonance structures and its fate was discussed in [10]. The OH-adducts can disappear by disproportionation, e.g. according to

(14)

It is also conceivable that a certain fraction of the Cl⁻ atoms reacts with Cl⁻ ions forming the oxidizing Cl₂⁻ species:

Cl + Cl⁻
$$\longrightarrow$$
 Cl₂⁻ (16)
 $k_{16} = 2.1 \times 10^{10} \text{dm}^3 \text{mol}^{-1} \text{s}^{-1},$

$$OCH_3 \qquad OCH_3 \qquad + Cl_2^- \longrightarrow + 2 Cl^-. \tag{17}$$

The so produced 4ClA^+ can follow reaction (6). Reaction (16) and the resulting consecutive processes may explain the rather high Q-yields presented in Table 1. Pulse radiolysis experiments concerning the OH-attack on anisole have been reported in [12].

4.3. 4ClA-Solutions Saturated with N₂O

As already mentioned, under these experimental conditions the yield of OH radicals is equal to that of e_{aq}^- , see also reaction (1). Hence, reaction (11), formation of the OH adduct of 4ClA, and all subsequent reactions will play an essential role in the photochemical process of the system under investigation.

It is further very probable that the electronically excited 4ClA-molecules can also react with N₂O by electron transfer, leading to the formation of 4ClA-radical cation and additional OH radicals:

*
$$\begin{pmatrix} OCH_3 \\ CI \end{pmatrix}$$
 + $N_2O + H_2O \longrightarrow CI$
+ $OH + OH^- + N_2$. (18)

Due to this reaction the yields of p-methoxyphenol and p-chlorophenol are increased and also hydroquinone is formed e.g.:

HO OCH₃ OCH₃ OCH₃ OH
OH + HO OH OH
$$OH OH OH$$

$$OH OH OH$$

$$OH OH OH$$

These considerations are in unison with the obtained results (Table 1; also compare curves A and B in Fig. 1, also Fig. 3 with Fig. 5).

4.4. Oxygenated 4ClA-Solutions

In the presence of oxygen, an adequate process to that expressed by (17) can take place, namely:

*
$$OCH_3$$
 OCH_3 OC

The radical cation (4ClA $^{\cdot +}$), as shown above, can initiate further reactions. Simultaneously with these processes, e_{aq}^- is reacting with O_2 under formation of O_2^- peroxy-radicals (2). The last ones are able to attack the substrate, forming adducts:

$$\begin{array}{c}

OCH_3 & OCH_3
\end{array}$$

$$\begin{array}{c}
OCH_3 & OCH_3 \\
\hline
OCH_3 & OCH_3
\end{array}$$

In addition to this, all radicals present in the solution can be scavenged by O₂ resulting in peroxy radicals, e.g.:

$$\begin{array}{c}
OCH_3 \\
OCH_3 \\
OCH_3
\end{array}$$
(peroxy radical), (22)

- [7] N. Getoff and M. Prucha, Z. Naturforsch. 38a, 589 (1983).

Based on these considerations it is obvious that the formation of anisole in the presence of oxygen is not possible (see Table 1).

5. Conclusion

The steady-state photolysis of aqueous 4ClA solutions saturated with Ar, N₂O, air or O₂ was studied in the pH-range from 7 to 12 using uv-light of 253.7 and 228.8 nm.

In airfree solutions anisole, p-chlorophenol and p-methoxyphenol were obtained as products. In solutions saturated with N_2O , air or O_2 , no anisole was found, but hydroquinone instead.

The yield of Cl⁻ ions was considered as an indicator for the photoinduced decomposition process of 4ClA.

With increasing the substrate concentration also the *O*-values of the products increase.

Rising the pH from 7 to 12 the product yields are decreasing. This can be attributed to the lower activity of O⁻ species, compared to that of the OH radicals.

The formation of oligomers was also observed, but they were not further investigated.
