Applying  $^{63}\text{Cu}$  NMR technique, we observed exchange between the nonequivalent copper sites in crystalline  $\text{Cu}_6\text{PS}_5\text{Br}$ , known as a member of the mineral “argyrodite”. Below 200 K, where the motion of the copper(I) ion is slow, we could distinguish several nonequivalent copper sites. On increasing the temperature, the chemical exchange between the nonequivalent cation sites was seen on the  $^{63}\text{Cu}$  NMR spectra. We could determine the activation energy for this motion to be  $35 \text{ kJ mol}^{-1}$ , in good agreement with the published ionic conductivity.

**Key words:** Ionic conductor;  $^{63}\text{Cu}$  NMR; Quadrupole interaction.

## Introduction

Compounds of the formula  $\text{M}_6\text{PS}_5\text{X}$  ( $\text{M} = \text{Ag}, \text{Cu}$ ;  $\text{X} = \text{Cl}, \text{Br}, \text{I}$ ) belong to the mineral “argyrodite” and are known as a new family of acentric structures. The argyrodites have a high-temperature structure of space group  $F43m$  [1]. The typical architecture consists of a frame work of interpenetrating distorted icosahedra forming a tetrahedrally packed sublattice, similar to the metal frame work in the Laves phase  $\text{MgCu}_2$  (Figure 1). These materials have recently attracted much interest [1–10] because of their unique physical and chemical properties, e.g., photointercalation [8–10]. Incomplete occupancy of certain cation sites leads to a high ionic conductivity in various compounds [1–3] and order-disorder phenomena accompanied by structural phase transitions [1, 2, 5]. In an X-ray diffraction study [4], the presence of the six nonequivalent Cu sites was proposed, and the cationic conduction was suggested to take place via  $\text{Cu}^+$  ion exchange between nonequivalent sites. Hereafter, we will call the six nonequivalent Cu sites as  $\text{Cu}(i)$  ( $i = 1$  to 6) according to [4].

In order to obtain insight into the ionic conduction mechanism in this system, we performed temperature dependent  $^{63}\text{Cu}$  NMR measurements on  $\text{Cu}_6\text{PS}_5\text{Br}$ .

## Experimental

$\text{Cu}_6\text{PS}_5\text{Br}$  was synthesized by heating a stoichiometric mixture of reagent grade Cu, CuBr, P, and S

Reprint requests to H. Ohki, Department of Chemistry, University of Tsukuba, Tsukuba, 305, Japan.

(Nacalai Tesque Co.) to  $300^\circ\text{C}$  for one hour, and then up to  $700^\circ\text{C}$  for several days in an evacuated quartz tube [2, 3]. The obtained red fine crystals were suspended and washed in ammonia water and then in hydrochloric acid to eliminate  $\text{CuBr}$  and  $\text{Cu}_2\text{S}$ . The samples were identified by X-ray powder diffraction.

A small amount of impurity, probably  $\text{Cu}_2\text{S}$ , was detected.

The  $^{63}\text{Cu}$  NMR spectra were measured with a Bruker MSL-400 spectrometer at a Larmor frequency of 106.60 MHz. The temperature was controlled within  $\pm 1$  K, using a VT-1000 temperature control unit. To obtain the 2D nutation NMR spectra [11], the rf pulse length was increased from 0 to 306  $\mu\text{s}$  every 1.2  $\mu\text{s}$ , and the free induction decay signal after each pulse was sampled. The acquired data were Fourier transformed after zero-filling up to 1024 words in the  $F_1$  dimension. The  $^{63}\text{Cu}$  spin-lattice relaxation time,  $T_1$ , was also measured by the saturation recovery method, using a Bruker MSL-300 spectrometer at a Larmor frequency of 79.58 MHz.

## Results and Discussion

Our NMR measurements were carried out in the temperature range between 183 and 400 K, in which no phase transition was detected in our study of differential scanning calorimetry (DSC), although phase transitions at 178 K, observed by differential thermal analysis, [2], and at ca. 230 [3] and 257 K [5], observed by DSC, were reported.

The  $^{63}\text{Cu}$  NMR spectrum of  $\text{Cu}_6\text{PS}_5\text{Br}$  at 183 K is shown in Figure 2. The length of rf pulse which gave the maximum signal intensity was nearly half that of the  $^{63}\text{Cu}$  signal in  $\text{CuCl}$  having almost zero quadrupole interaction. This means that the observed spectrum corresponds to the "central" transition not shifted by first order quadrupole interaction. This spectrum tells us that there are at least four nonequivalent copper sites in the crystals and is consistent with the X-ray diffraction study [3], although we could not attribute the observed peaks to the nonequivalent Cu sites reported.

The contour plot of the  $^{63}\text{Cu}$  2D nutation NMR spectrum at 185 K is shown in Fig. 3, in which we can distinguish three kinds of nonequivalent sites from the pattern along the vertical ( $F_1$ ) direction. At this temperature, we can safely assume that the Cu ions are statistically distributed between the nonequivalent sites, since the observed spectrum consists of several distinguishable peaks. As for the sites numbered 2, 3 and 4, we could determine the quadrupole coupling constant ( $e^2Qq$ ) and the asymmetry parameter of the electric field gradient (EFG) tensor ( $\eta$ ) in the following manner. We compared experimental and calculated

Fig. 2.  $^{63}\text{Cu}$  NMR spectrum observed at 185 K. At least four nonequivalent Cu sites are seen in the spectrum.

Fig. 3. The contour plot of the 2D nutation NMR spectrum at 185 K. The peaks marked by the brackets could be attributed to nonequivalent copper sites in the crystal because of the difference in the pattern along the vertical ( $F_1$ ) direction.

Table 1. The obtained (left) and calculated (right) quadrupole parameters of the six nonequivalent Cu sites. The calculated EFG values are relative to the maximum.

Site	$e^2Qq/h$ (MHz)	$\eta$	$eq/eq_{\max}$	$\eta$
Cu(1)	—	—	1.00	0.1
Cu(2)	3.6	0.0	0.40	0.4
Cu(3)	6.3	0.2	0.57	0.2
Cu(4)	6.1	0.9	0.38	0.9
Cu(5)	—	—	0.33	0.9
Cu(6)	—	—	0.45	0.8

Fig. 4. The temperature dependence of  $^{63}\text{Cu}$  NMR spectrum at low temperatures. a) 185 K, b) 200 K, c) 220 K. Note that the peaks marked by the asterisks gradually lose their intensity on heating.

Fig. 5. The temperature dependence of  $^{63}\text{Cu}$  NMR spectrum at high temperatures. a) 315 K, b) 330 K, c) 345 K, d) 360 K. A single line was narrowed on heating. The peaks shown by the asterisk are due to impurities.

patterns along the  $F_1$  and  $F_2$  directions, in which the latter pattern corresponds to the normal 1-D spectrum, to get consistent results. The parameters derived here, and the EFG values calculated by the method reported in [12], are given in Table 1. The calculated EFG was obtained by assuming that the  $\text{Cu}^+$  ion is stochastically distributed between the sites, i.e., the given site “sees” the averaged charge of the neighbours. By comparing the relative spectrum intensities and asymmetry parameters, the sites corresponding to  $e^2\partial q$  values are assigned to Cu(2), Cu(3), and Cu(4), as indicated in Figure 3.

On increasing the temperature, we observed the gradual change in the 1-D spectrum shown in Figs. 4 and 5. The peaks indicated by the asterisks in Fig. 4 gradually lost their intensity on heating, and finally all peaks were buried in the noise around 240 K. This means that, on heating, the exchange rate between the two sites marked by the asterisks becomes comparable

to the frequency difference of the two, and then all copper sites become exchangeable. We evaluated the spin-spin relaxation time  $T_2^*$  defined by  $\Delta\nu^{-1}$ , where  $\Delta\nu$  is the full width at the half-maximum. This  $T_2^*$ , which gives the averaged or apparent correlation time of the exchange motion, is plotted against the inverse temperature in Figure 7. The slope gives an activation energy of  $35 \pm 6 \text{ kJ mol}^{-1}$ , which is compatible to the  $36 \text{ kJ mol}^{-1}$  determined by the conductivity measurements [1].

We also measured the  $^{63}\text{Cu}$  spin-lattice relaxation time for the central transition in the temperature range 310–355 K, where a single  $^{63}\text{Cu}$  line was observed. The determined temperature dependence of  $T_1$  is shown in Figure 6. We evaluated the activation energy to be  $11 \pm 3 \text{ kJ mol}^{-1}$ , which is small compared with those obtained from  $T_2^*$  and conductivity measurements. This difference is explainable as follows. In the  $T_2^*$  measurement, we observed the averaging pro-

Fig. 6. The temperature dependence of the  $^{63}\text{Cu}$  NMR spin-lattice relaxation time ( $T_1$ ). The slope of the best fitted solid line gives an activation energy of  $11 \text{ kJ mol}^{-1}$  for the local exchange motion of the  $\text{Cu}^+$  ions.

cess of the quadrupole interaction by the exchange motion among all nonequivalent sites. Since motions in the order of  $10^5 \text{ Hz}$  are effective to  $T_2^*$ , but those of  $10^8 \text{ Hz}$  contribute to  $T_1$ , the motion shortening  $T_2^*$  gives no appreciable contribution to  $T_1$ , if it is slow. On the other hand, the  $T_1$  process governed by the local exchange between e.g.  $\text{Cu}(2)$  and  $\text{Cu}(3)$  sites, which may be fast enough, can cause more effectively the spin-lattice relaxation.

### Conclusion

We could observe the occurrence of the exchanging motion between the nonequivalent copper sites in  $\text{Cu}_6\text{PS}_5\text{Br}$ . Below  $200 \text{ K}$  the motion of the cation is

Fig. 7. The inverse line width  $\Delta\nu$  vs. inverse temperature. The slope of the best fitted solid line in the figure gives an activation energy of  $35 \text{ kJ mol}^{-1}$  for the exchange motion of the  $\text{Cu}^+$  ions.

negligible and we could distinguish several nonequivalent copper sites. On increasing the temperature, the exchange motion among all nonequivalent sites could be seen the  $^{63}\text{Cu}$  NMR spectra. We determine the activation energy for this motion to be  $35 \pm 6 \text{ kJ mol}^{-1}$ , which agrees well with the result from the conductivity measurements.
