Z. Naturforsch. **49a**, 594–598 (1994); received January 3, 1994

By DTA DSC a phase transition of  $\text{Cl}_3\text{CSO}_2\text{Cl}$  was observed,  $T_{\text{II},1} = 227.4 \text{ K}$ ,  $\Delta H_{\text{II},1} = 7.10 \text{ kJ} \cdot \text{Mol}^{-1}$ ;  $\Delta S_{\text{II},1}/R = 3.63$ ;  $T_m = 418.5 \text{ K}$ ,  $\Delta H_m = 7.46 \text{ kJ} \cdot \text{Mol}^{-1}$ ,  $\Delta S_m/R = 2.14$ . By X-ray powder diffraction, the orientationally disordered solid phase I (plastic phase) was found to be body centered cubic,  $\text{Im}3m$ ,  $Z = 2$ ,  $a = 721.7 (5) \text{ pm}$  at room temperature. The  $^{35}\text{Cl}$  NQR quartet fades out at the transition temperature  $T_{\text{II},1} = T_i$ , and the fade out temperature  $T_i$  is identical for the four  $^{35}\text{Cl}$  NQR lines. The NQR spectrum shows a hysteresis in  $T_{\text{I,II}} - T_{\text{II},1}$ .

## Introduction

Molecules with a quasispherical equipotential surface show a tendency to develop orientational disorder in the solid state. That is, under fixed center of mass, respectively center of the moment of inertia, there is a kind of premelting, coupled to a more or less random orientational disorder, and there is in most cases a pronounced transition from the ordered phase (II) to this state (phase I), which is often called the plastic phase [1].

From the viewpoint of molecular geometry one may distinguish plastic phases formed by a) tetrahedral molecules (having approximately spherical shape) b) molecules composed of two corner-connected tetrahedra with an ellipsoidal van der Waals equipotential surface, classified as octahedral molecules by Nitta [2], such as 2,2,3,3-tetramethylbutane (hexamethylethane) and c) more or less globular molecules such as adamantane [2]. We prefer to differentiate the types of molecules forming a plastic solid phase by the van der Waals (vdW) equipotential surface: a) the group of tetrahedral-spherical molecules (e.g.  $\text{CCl}_4$ ), b) the globular molecules, many cyclic, bicyclic, tricyclic hydrocarbons and aza(diaza) compounds such as 1,4-diaza-[2,2,2]-octane including octahedral molecules such as  $\text{SF}_6$ , and c) the ellipsoidal molecules. The vdW surface of the molecule is a cru-

cial factor for the appearance of orientational disorder and a plastic phase.

$\text{Cl}_3\text{C}-\text{SO}_2\text{Cl}$ , trichloromethane sulfonic acid chloride, is a molecule, with a slightly distorted ellipsoidal surface. The high melting point is one hint for the appearance of a disordered phase. In the following we report the phase diagram of the compound as studied by DTA/DSC, X-ray diffraction, and  $^{35}\text{Cl}$  nuclear quadrupole resonance (NQR).

## Experimental

The commercial compound (Aldrich) was used after purification by sublimation in vacuo (10 mbar). The thermodynamic data were obtained from the purified compound with Setaram DSC 121-DTA/DSC equipment. The melting peak in the DSC is rather sharp, showing very little impurity.

For the X-ray diffraction the molten sample was quenched to liquid nitrogen temperature and studied by powder diffractometry. The powder was located in  $0.5 \text{ mm } \varnothing$  capillaries and examined on a STOE STADIP diffractometer ( $\text{CuK}\alpha_1$ -radiation) at room temperature and at  $240 \text{ K}$ .

$^{35}\text{Cl}$  NQR spectra were measured on a CW-spectrometer working in the superregenerative mode. For temperature control, frequency measurements etc. see [3]. The signal to noise ratio (recorder, time constant  $10 \text{ s}$ ) was  $10-12$ , decreasing slightly with increasing temperature. Near the phase transition point the intensity drops strongly. The line width was for the 4 resonances similar, around  $17 \text{ kHz}$ .

## Results

### Thermodynamics

In Fig. 1 we show the DSC diagram of  $\text{Cl}_3\text{CSO}_2\text{Cl}$ . The following thermodynamic data have been found:

$$T_{\text{II},1} = 227.4 \text{ K}; \quad \Delta H_{\text{II},1} = 7.10 \text{ kJ} \cdot \text{mol}^{-1};$$

$$T_{\text{m}} = 418.5 \text{ K}; \quad \Delta H_{\text{m}} = 7.46 \text{ kJ} \cdot \text{mol}^{-1};$$

$$(\Delta S_{\text{II},1}/R) = 3.63;$$

$$(\Delta S_{\text{m}}/R) = 2.14.$$

$S_{\text{m}}/R < 2.5$  is a strong sign for the formation of a plastic phase below the melting point.

### X-ray Diffraction

The X-ray powder diffraction diagram, taken at 295 K is shown in Figure 2. The observed diffraction maxima have been indexed with a body-centered unit cell with highest possible symmetry  $\text{Im}3\text{m}$ ,  $Z = 2$ . The lattice constant is  $a = 721.7(5) \text{ pm}$ ;  $V_{\text{unit cell}} = 375.97(77) \cdot 10^6 \text{ pm}^3$  and for  $a = 716.2(7) \text{ pm}$ ,  $V_{\text{unit cell}} = 367.42(19) \cdot 10^6 \text{ pm}^3$  at 240 K. Results are summarized in Table 1.

### $^{35}\text{Cl}$ Nuclear Quadrupole Resonance

At 77 K the  $^{35}\text{Cl}$  NQR spectrum of  $\text{Cl}_3\text{CSO}_2\text{Cl}$  was observed several times and discussed [4–7] in connection with the study of the bonds C–Cl and S–Cl. In Fig. 3 we show the temperature dependence of the  $^{35}\text{Cl}$  NQR four line spectrum, which is separated into a group of three lines, belonging to the chlorines of the  $\text{CCl}_3$  and a line at lower frequency, originating from the chlorine bonded to the sulfur atom. There is a smooth decrease of the frequencies with temperature and a common fading out of the four lines at the transition temperature  $T_{\text{II},1} = 227.4 \text{ K}$ . In Table 2 we report the frequencies at some selected temperatures and the coefficients of the power series development

$$\nu = f(T) = \sum_{i=-1}^2 (a_i T^i).$$

The frequencies reported in [6] are 40 kHz higher, and the difference is most probably just the quench frequency. The data reported in [5] deviate from ours also in the direction of higher values.

If one considers the mean temperature dependence of the  $^{35}\text{Cl}$  NQR resonances of the  $\text{CCl}_3$  chlorines, the

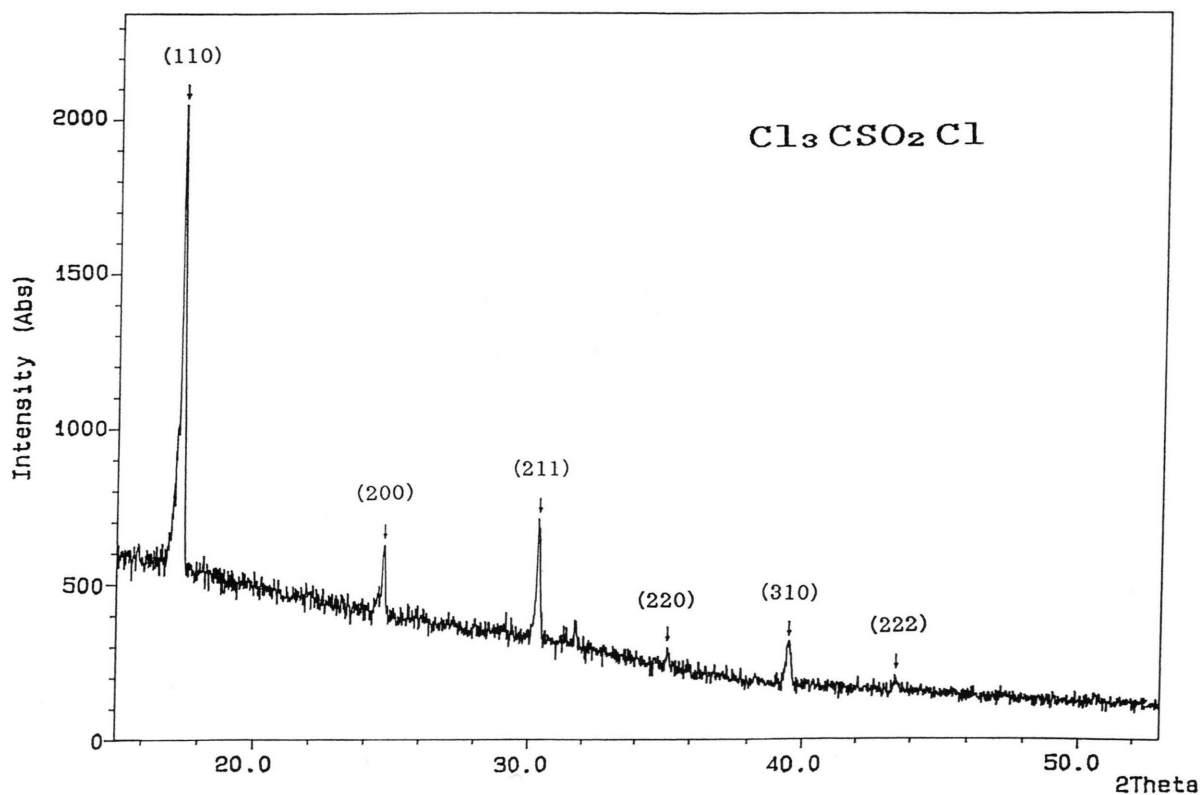

Fig. 2. X-ray powder diagram of the plastic phase I of trichloromethane sulfonic acid chloride,  $T = 295$  K,  $\text{CuK}\alpha$  radiation, Graphite monochromator (002).

Fig. 3. Temperature dependence of the  $^{35}\text{Cl}$  NQR spectrum of  $\text{Cl}_3\text{CSO}_2\text{Cl}$ .

frequencies decrease with increasing temperature due to the librational motions of the molecules in the lattice and the temperature coefficients being in the range for molecules in the solid state [8]; they do not show unusually strong motions in phase II.

We note that the transition phase I → phase II shows a delay in the <sup>35</sup>Cl NQR experiments. Cooling phase I from 20 °C fast (within 10') down 10° below the thermodynamic transition temperature  $T_{II,1}$ , we had to wait for 1 h before the NQR signal was observable. The ordering of the disordered phase is delayed.

## Discussion

From the <sup>35</sup>Cl NQR spectroscopy we find that  $T_f$  is common for the chlorine atoms of the Cl<sub>3</sub>C group and for the SO<sub>2</sub>Cl group of the molecule, showing that the phase transition is connected with a overall orientational disorder of the molecule. From the <sup>35</sup>Cl NQR spectrum we learn also that in phase II the symmetry

of the molecule is 1. The three chlorines of the Cl<sub>3</sub>C group are crystallographically independent. Three different bond lengths C–Cl must appear in the ordered structure. For the free molecule Cl<sub>3</sub>CSO<sub>2</sub>Cl intermolecular distances and angles have been determined by electron diffraction [9].

The plastic phase I of Cl<sub>3</sub>CSO<sub>2</sub>Cl has a very wide range of existence from  $T_{II,1} = 227.4$  K to  $T_m = 418.5$  K. A ratio  $T_m/T_{II,1}$  of 1.84 is not a surprising finding for a molecular plastic crystal with ellipsoidal vdW potential surface. Comparing these data with other ellipsoidal, similarly shaped molecular compounds we find [2]:

|  |                         |
|--|-------------------------|
| (CH <sub>3</sub> ) <sub>3</sub> C–C(CH <sub>3</sub> ) <sub>3</sub> ,     | $T_{II,1} = 148$ K,     |
| Cl <sub>3</sub> C–CCl <sub>3</sub> ,                                     | $T_{II,1} = 344.6$ K,   |
| (CH <sub>3</sub> ) <sub>2</sub> ClC–CCl(CH <sub>3</sub> ) <sub>2</sub> , | $T_{II,1} = 161$ K,     |
| $T_m = 373.7$ K,   | $T_m/T_{II,1} = 2.52$ , |
| $T_m = 458$ K,   | $T_m/T_{II,1} = 1.32$ , |
| $T_m = 434$ K,   | $T_m/T_{II,1} = 2.70$ . |

The phase width of plastic phases composed of ellipsoidal molecules is much wider than that of tetrahedral plastic phases:

|                                    |                         |
|------------------------------------|-------------------------|
| for CCl <sub>4</sub>               | $T_m/T_{II,1} = 1.11$ , |
| CBr <sub>4</sub>                   | $T_m/T_{II,1} = 1.13$ , |
| C(CH <sub>2</sub> OH) <sub>4</sub> | $T_m/T_{II,1} = 1.18$ . |
