The crystal structure of the highest- and second highest-temperature solid phases of choline tetrafluoroborate and iodide was determined by X-ray powder diffraction. The structure in the highest-temperature phase of both salts is NaCl-type cubic ($a = 10.16(2)$ Å, $Z = 4$ for tetrafluoroborate; $a = 10.08(2)$ Å, $Z = 4$ for iodide). The second highest-temperature phase of tetrafluoroborate and iodide is CsCl-type cubic ($a = 6.198(6)$ Å and $Z = 1$) and tetragonal ($a = 8.706(2)$ Å, $c = 6.144(6)$ Å, and $Z = 2$), respectively. DSC was carried out for the iodide, where the presence of three solid-solid phase transitions was confirmed. Enthalpy and entropy changes of these transitions were evaluated.

Key words: Crystal structure; Powder X-ray diffraction; Phase transition.

In [1] we have shown that choline tetrafluoroborate, $[(CH_3)_3NCH_2CH_2OH]BF_4$, in the temperature range from the melting point at 485 K to 160 K has three solid phases named I, II, and III. In Phase I and II, stable between 485 and 402 K and between 402 and 268 K, respectively, isotropic rotation and translational self-diffusion of both cation and anion were observed by ^1H and ^{19}F NMR measurements. From the dynamical behaviour of the ions and the small entropy of fusion (6.4 J K^{-1} mol^{-1}) we concluded that this salt forms ionic plastic crystals in Phases I and II, the structures of which are expected to be of a high symmetry. A similar dynamical behaviour of the cation was observed in choline iodide, $[(CH_3)_3NCH_2CH_2OH]I$, by ^1H NMR [2–5]. Differential scanning calorimetry (DSC) [6] seemed to indicate that this salt undergoes two solid-solid phase transitions at 436 and 367 K with enthalpy changes of 6.23 and 12.8 kJ mol^{-1}, respectively. The isotropic rotation and self-diffusion of the cation in the highest-temperature phase [2, 3] and the second highest-temperature phase [3–5] (named Phase I and II, respectively, in this text [7]) were detected by ^1H NMR. Furthermore, both salts show an unusual phenomenon, i.e. “quenching” of the cationic self-diffusion at the transition point from Phase II to Phase I [1, 3].

In the present study, X-ray powder diffractions in Phases I and II of the two salts were taken. In addition, DSC was carried out for the iodide to confirm the presence of a third highest-temperature phase existing between 366–360 K, as reported by Burnett et al. [5].

$[(CH_3)_3NCH_2CH_2OH]BF_4$ was prepared as described in [1]. $[(CH_3)_3NCH_2CH_2OH]I$ was purchased from Sigma Chemical Co. and recrystallized from ethanol. X-ray powder patterns were taken using a Philips X'pert PW3040/00 diffractometer. DSC was carried out using a Perkin-Elmer DSC7 in the range from 450 to 330 K.

The X-ray powder diffraction angles (2θ) in Phases I and II of tetrafluoroborate taken at ca. 420 and 300 K, respectively, are shown in Table 1. The structure of Phase I could be interpreted by an NaCl-type cubic lattice with $a = 10.16(2)$ Å, $Z = 4$, $V = 1049(7)$ Å^3 and $D_x = 1.209(8)$ Mg m^{-3}, and that of Phase II by a CsCl-type cubic lattice with

$a = 6.198(6)$ Å, $Z = 1$, $V = 238.1(7)$ Å^3 and $D_x = 1.332(4)$ Mg m^{-3}. The "quenching" of the cationic self-diffusion in tetrafluoroborate, therefore, can be understood in terms of the change of lattice structure. The self-diffusion processes, in which the constituent ions in the CsCl-type structure migrate more easily than those in the NaCl-type, were discussed in [8, 9].

Table 2 shows the X-ray data in Phases I and II of the iodide obtained at ca. 460 and 400 K, respectively. The data of Phase I were assigned to an NaCl-type cubic lattice with $a = 10.08(2)$ Å, $Z = 4$, $V = 1024(7)$ Å^3 and $D_x = 1.50(1)$ Mg m^{-3} isomorphous with Phase I of the tetrafluoroborate, while that of Phase II was assigned to a tetragonal lattice with $a = 8.706(2)$, $c = 6.144(6)$ Å, $Z = 2$, $V = 465.7(7)$ Å^3 and $D_x = 1.648(3)$ Mg m^{-3}. The low symmetry of the structure in Phase II of the iodide is consistent with the fact that the activation energy of cationic self-diffusion in Phase II of the iodide is much larger than that of the tetrafluoroborate (105–110 kJ mol^{-1} for the iodide [3, 5] and 62 kJ mol^{-1} for the tetrafluoroborate [1]).

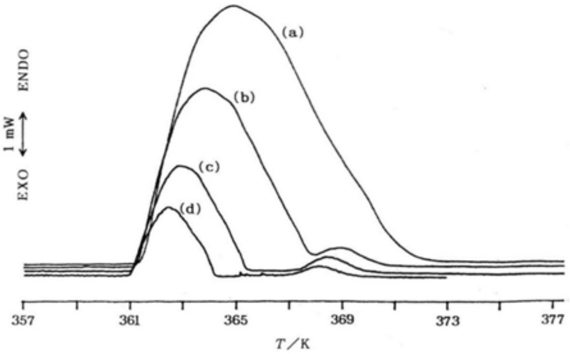

Fig. 1. DSC curves recorded for $[(CH_3)_3NCH_2CH_2OH]I$ around 365 K with heating rates of 10 K min^{-1} (a), 5 K min^{-1} (b), 2 K min^{-1} (c), and 1 K min^{-1} (d).

DSC measured on $[(CH_3)_3NCH_2CH_2OH]I$ with a heating rate of 2 K min^{-1} showed three thermal anomalies attributable to solid-solid transitions at 362, 368, and 435 K, indicating clearly the existence of the fourth solid phase found by Burnett et al. [5]. Corresponding enthalpy (entropy) changes were evaluated to be 11.9 ± 0.1 (32.9 ± 0.3), 0.87 ± 0.04 (2.4 ± 0.1), and 6.19 ± 0.03 kJ mol^{-1} (1.42 ± 0.07 J K^{-1} mol^{-1}) in the same order. When the sample heating rate was raised, the anomaly peak at 362 K overlapped with the peak at 368 K, as shown in Figure 1. This may be the reason why the previous DSC showed only two solid-solid phase transitions.
