The electron paramagnetic resonance spectra of  $\text{Cu}^{2+}$  doped  $\text{KHCO}_3$  single crystals were studied at room temperature. The results indicate a substitutional entrance of the  $\text{Cu}^{2+}$  ions in place of the magnetically inequivalent  $\text{K}^+$  sites. The charge compensation is supposed to be fulfilled by proton vacancies. The hyperfine lines were well resolved and the  $^{65}\text{Cu}$  hyperfine coupling tensors were also found. The ground state of  $\text{Cu}^{2+}$  indicates the dominance of the  $d_{x^2-y^2}$  orbital and, therefore, elongation of the polyhedron, similar to a lengthened octahedron.

**Key words:** EPR;  $\text{Cu}^{2+}$ ; Potassium Bicarbonate; Crystal Field; Substitution; Impurity.

## Introduction

The electron paramagnetic resonance (EPR) method can be used for obtaining information about the ground state of a paramagnetic ion and its environmental symmetry of electrical fields produced by the ligands. In particular  $\text{Cu}^{2+}$  has extensively been used as a probe to obtain information about the crystalline electric fields [1–4]. In most of the  $\text{Cu}^{2+}$  doped compounds,  $\text{Cu}^{2+}$  replace divalent cations. However, when a divalent  $\text{Cu}^{2+}$  ion enters the lattice in place of a monovalent cation, an electric charge compensation is supposed to be fulfilled by the vacancy of another monovalent cation, and in some cases it has been found that the magnetic coupling tensors have their principal axes pointing from the divalent ion to the monovalent cation vacancy direction.

Furthermore, in most of the  $\text{Cu}^{2+}$  doped systems investigated so far, the ion was found to have  $d_{x^2-y^2}$  and  $d_{z^2}$  mixed ground states and a smaller hyperfine coupling constant. In view of this, we have now studied  $\text{Cu}^{2+}$  doped  $\text{KHCO}_3$  single crystal to find the ground state of  $\text{Cu}^{2+}$ , its site and the  $^{65}\text{Cu}$  hyperfine coupling tensor. To our knowledge such a study on this crystal has not been carried out so far.

## Experimental

The single crystals were produced by slow evaporation of saturated aqueous solutions of commercially obtained  $\text{KHCO}_3$  powders. The structure of crystalline  $\text{KHCO}_3$  at room temperature is monoclinic

with space group  $P_{21/a}$ , and unit cell parameters  $a = 1.51948$ ,  $b = 0.56307$ ,  $c = 0.37107$  nm, and  $\beta = 104^\circ 56'7''$ . The unit cell contains four molecules [5]. The single crystal study indicates that the  $\text{K}^+$  ion is surrounded by eight oxygen atoms with not much different distances to the  $\text{K}^+$  ion, and the hydrogen atoms constitute the bridges between the oxygen atoms [5].

The EPR spectra were recorded with a Varian E-109 C model EPR spectrometer using 2 mW microwave power and 100 kHz magnetic field modulation. The single crystals were rotated on a Lucit pillar in three mutually perpendicular planes ( $c^*a$ ,  $bc^*$ ,  $ab$ ), and the spectra were recorded at  $10^\circ$  steps. The  $g$  factors were found by comparison with a diphenylpicrylhydrazyl sample of  $g = 2.0036$ .

## Results and Discussions

Two typical EPR spectra of  $\text{Cu}^{2+}$  doped  $\text{KHCO}_3$  single crystals are shown in Fig. 1 for two different orientations of the magnetic field. Figure 1a shows the spectrum in the  $c^*a$  plane,  $30^\circ$  from the  $a$  axis, and Fig. 1b indicates the spectrum in the  $ab$  plane,  $50^\circ$  from the  $b$  axis. The line positions are shown in Fig. 2 in the  $c^*a$ ,  $bc^*$ , and  $ab$  planes. The empty boxes indicate the  $^{65}\text{Cu}^{2+}$  line positions. The spectra belong obviously to  $\text{Cu}^{2+}$ , for which  $S = 1/2$  and  $I = 3/2$ . The  $^{65}\text{Cu}^{2+}$  and  $^{63}\text{Cu}^{2+}$  lines can be clearly observed nearly along the whole spectra, as in Fig. 1a, with the approximate intensity proportion of 0.44, in accord with the abundancy proportion of the isotopes of the

their direction cosines were found by diagonalization [6 - 7]. The results are given in Table 1.

From these experimental results it can be inferred that the  $\text{Cu}^{2+}$  ions enter the inequivalent  $\text{K}^+$  places in

Fig. 2. The line positions of the EPR lines against the magnetic field for  $\text{Cu}^{2+}$  in  $\text{KHCO}_3$  at room temperature. The  $^{65}\text{Cu}^{2+}$  points are indicated by empty boxes.

the  $\text{KHCO}_3$  single crystal. This agrees with the crystal data, since the crystal is a monoclinic and contains 4 molecules in its unit cell. In a monoclinic crystal, at most two inequivalent sites can be observed, and this was what is observed. The charge compensation seems to be fulfilled by hydrogen vacancies between the oxygen atoms. Since the crystal structure indicates eight oxygens at nearly equal distances to  $\text{K}^+$ , they seem to constitute a polygon of ligands around the  $\text{K}^+$  ion [5], as seen in Table 3. The average K-O distance is 0.2843 nm in this table. The principal

values of the  $\mathbf{g}$  and  $\mathbf{A}$  tensors are in agreement with the literature values for the  $^{63}\text{Cu}^{2+}$ , and the principal values of the  $^{65}\text{Cu}^{2+}$  are smaller than those of the  $^{63}\text{Cu}^{2+}$  ions. Therefore, this study reports the principal values of the  $\mathbf{g}$  and the  $\mathbf{A}$  tensors for  $^{65}\text{Cu}^{2+}$ . Furthermore, this study also indicates that the disorder in  $\text{KHCO}_3$  exists only among the hydrogen atoms, and not the other atoms, since otherwise this would destroy the symmetry of the crystal. This conclusion is in accordance with the crystal structure determinations [5].
