Abstract

Ko, C.W. and F. Ruskey, Generating permutations of a bag by interchanges, Information Processing Letters 41 (1992) 263–269.

We present algorithms for generating all permutations of a given bag so that successive permutations differ by the interchange of two elements. One version of the algorithm runs in time linear in the number of permutations.

Keywords: Analysis of algorithms, bag, multiset, permutation, interchange

1. Introduction

A *bag* is a collection of not necessarily distinct elements. Early algorithms for generating all permutations of a bag were developed by Sag [11], Bratley [2], Chase [3], and Hu and Tien [5]. None of these algorithms runs in *constant amortized time*, i.e., time linear in the number of permutations generated. A permutation algorithm has the

interchange property if successive permutations differ by the interchange of two elements. Ruskey and Roelants van Baronaigien's algorithm [10] runs in constant amortized time but does not have the *interchange property*; Chase's algorithm [3] does not have the interchange property but runs in constant amortized time. We present an algorithm that has both properties.

The problem of developing a constant amortized time algorithm for generating bag permutations is given as an exercise by Reingold, Nievergelt, and Deo [9]. However, the solutions manual [4] presents Hu and Tien's algorithm [5] and references two other algorithms, all of which do not run in constant amortized time.

We consider bags over the elements $0, 1, \dots, t$. We represent a bag by a sequence $n = \langle n_0, \dots, n_t \rangle$, where each n_i is the number of

occurrences of i in the bag. Also, $\#n$ denotes the size of the bag, or the sum of the n_i . If $n_i > 0$, $n|_i$ denotes sequence n with n_i decremented by one:

$$n|_i = \langle n_0, \dots, n_{i-1}, n_i - 1, n_{i+1}, \dots, n_t \rangle.$$

An n -permutation is a permutation of bag n . The number of n -permutations is the bag coefficient $C(n)$.

$$C(n) = \binom{\#n}{n_0, n_1, \dots, n_t} = \frac{\#n!}{n_0! n_1! \dots n_t!}.$$

These coefficients satisfy the following recurrence relation:

$$C(n) = \sum_{i=0}^t C(n|_i). \quad (1)$$

2. The algorithms

The bag permutations can be generated by the recursive algorithm that follows from the familiar proof of recurrence relation (1) for bag coefficients; it classifies the permutations according to their first symbol. This leads to algorithm *GenBag* in Fig. 1. Operator \oplus denotes concatenation. The call *GenBag*(n, ε), where ε denotes the empty sequence, generates all n -permutations.

Depending on the order in which the j 's are selected by the **for** statement in line (G5), different recursion trees arise, each of which leads to a different sequence of permutations. Selecting the elements in increasing order prints a lexicographic list of the n -permutations. These recursion trees are in one-to-one correspondence with what we call bag trees.

Definition 1. A labeled ordered tree is an (n, s) -tree if its root is labeled s and, for each $n_i > 0$, its root has a child that is the root of an $(n|_i, i)$ -tree.

When we do not wish to specify the label at the root, we write simply n -tree. An n -tree is also called a *bag tree*. We regard bag trees as being embedded in the plane with the root on the left and leaves on the right. The ordering of subtrees is from top to bottom. To each n -tree T there is a corresponding list $L(T)$ of all n -permutations; this list is precisely the list of permutations printed by *GenBag*. Each permutation can be obtained by traversing T from its root to a leaf and recording the labels of the nodes encountered.

Definition 2. A bag tree T is an *interchange tree* if successive permutations in list $L(T)$ differ by an interchange of two elements.

The following examples illustrate the preceding definitions. For $n = \langle 2, 1 \rangle$, there are exactly four bag trees. The list 001, 100, 010 is not $L(T)$ for any bag tree T . For $n = \langle 2, 2 \rangle$, there is a unique bag tree T such that $L(T) = 0011, 0110, 0101, 1010, 1001, 1100$; however, T is not an interchange tree.

We call a node of a bag tree a *plus-node* if its children are labeled in increasing order and a *minus-node* if they are labeled in decreasing order. A node with only one child is both a plus-node and a minus-node.

Definition 3. An *alternating tree* is a bag tree in which every internal node is either a plus-node or a minus-node and, at each level of the tree,

```

(G1) {Print all sequences  $\pi\alpha$  where  $\alpha$  is an  $n$ -permutation}
(G2) procedure GenBag (  $n$  : array [0.. $t$ ] of natural;  $\pi$  : sequence );
(G3) var  $j$  : 0.. $t$ ;
(G4) begin
(G5)   if  $n_0 = n_1 = \dots = n_t = 0$  then Print(  $\pi$  )
(G6)   else for  $j \in \{p \mid 0 \leq p \leq t \wedge n_p > 0\}$  do
(G7)     GenBag(  $n|_j, \pi \oplus j$  )
(G8)   end

```

Fig. 1. Algorithm *GenBag*.

reading top-to-bottom, plus- and minus-nodes alternate.

We now prove a sufficient condition for a bag tree to be an interchange tree and use it to derive an interchange algorithm.

Theorem 4. *Any alternating tree T is also an interchange tree.*

Proof. Let $\pi = \alpha a \beta c \gamma$ and $\pi' = \alpha b \beta d \delta$ be two successive permutations in $L(T)$, where $a, b, c, d \in \{0, 1, \dots, t\}$, $a \neq b$, $c \neq d$, and $\alpha, \beta, \gamma, \delta \in \{0, 1, \dots, t\}^*$. In words, the first symbols that differ are a and b and the next symbols that differ are c and d . The nodes labeled a and b have a common parent; call the tree rooted at their parent an m -tree—thus, like n , m is a sequence that represents a bag. Nodes c and d have different parents; call the tree rooted at c 's parent a p -tree and the tree rooted at d 's parent a q -tree. There are two symmetric cases, depending upon whether $a < b$ or $a > b$. We discuss only the case $a < b$.

Suppose $a < b$. Since children are labeled monotonically, $m_i = 0$ for all $a < i < b$. This implies $p_i = 0$ and $q_i = 0$ for all $a < i < b$. Since β is common to both π and π' , $p_i = q_i$ for $i \neq a$ and $i \neq b$; further, $q_a = p_a + 1$ and $p_b = q_b + 1$. Because T is alternating, the nodes labeled c and d both have either the largest or the smallest labels among their respective siblings.

In the “smallest” case, we have $c = \min\{i \mid p_i > 0\}$ and $d = \min\{i \mid q_i > 0\}$. We argue that $d = a$ —the proof that $c = b$ is similar.

$$\begin{aligned} & d \\ = & \langle d \text{ is the smallest sibling} \rangle \\ & \min\{i \mid 0 \leq i \wedge q_i > 0\} \\ = & \langle \text{Since } p_i = q_i \text{ for } i < a, \text{ if some such} \\ & \quad q_i > 0, \text{ then } c = d; \text{ but } c \neq d \rangle \\ & \min\{i \mid a \leq i \wedge q_i > 0\} \\ = & \langle q_a = p_a + 1 > 0 \rangle \\ & a \end{aligned}$$

The “larger” case is similar and is omitted. Hence, $a = d$ and $b = c$ in either case. Also, $p|_c = q|_d$ and thus, because T is alternating, $\gamma = \delta$. \square

An interchange tree need not be an alternating tree, since permuting the symbols $0, 1, \dots, t$ changes an interchange tree into an interchange tree but may not maintain the alternating-tree property.

We remove some of the nondeterminism in algorithm *GenBag* so that its recursion tree is an alternating tree (see Fig. 2). We introduce a global boolean array $d[0..n-1]$, where $d_i \equiv$ “the current node at level i is a plus-node”. By $|d|$ and $|\pi|$ we denote the number of elements in array d and sequence π . Note that $|d|$ is the length of the permutations to be generated. The qualifier “by d_k ” in the **for** statement of line (T5) indicates

```

{Array  $d$  is global. Print all sequences  $\pi\alpha$  where  $\alpha$  is an  $n$ -permutation}
(T1) procedure GenAlt (  $n$  : array [0.. $t$ ] of natural;  $\pi$  : sequence );
(T2) var  $j$  : 0.. $t$ ;  $k$  : 0..| $d$ |;
(T3) begin
(T4)   if  $n_0 = n_1 = \dots = n_t = 0$  then Print(  $\pi$  ) else begin
(T4)      $k := |\pi|$ ;
(T5)     for  $j \in \{p \mid 0 \leq p \leq t \wedge n_p > 0\}$  by  $d_k$  do
(T6)       GenAlt(  $n|_j, \pi \oplus j$  );
(T7)     Change(  $d_k$  )
(T8)   end
(T9) end

```

Fig. 2. Algorithm *GenAlt*.

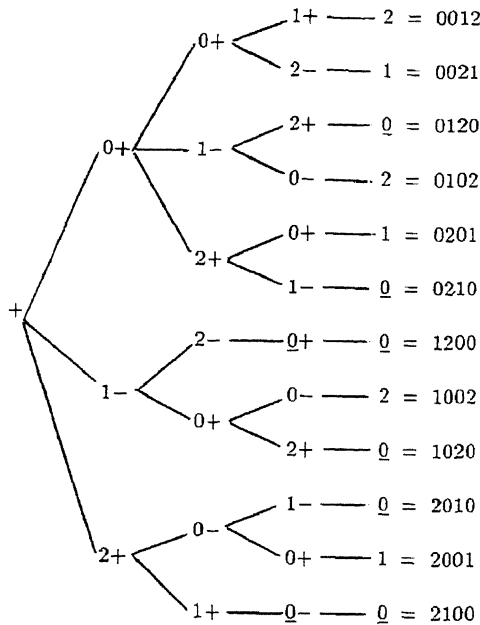

Fig. 3. Recursion tree (A) for $n = \langle 2, 1, 1 \rangle$.

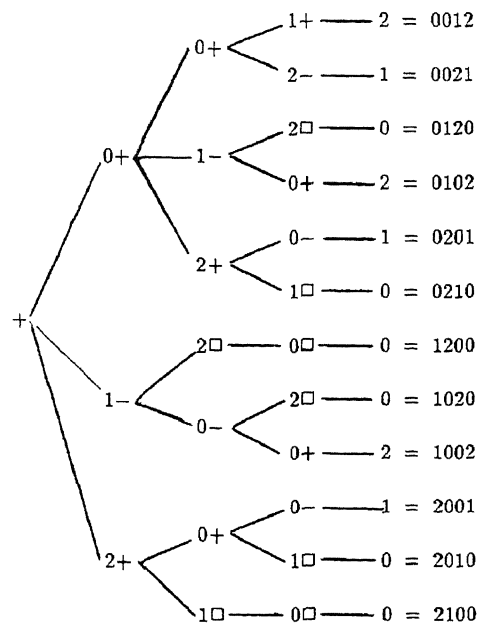

Fig. 4. Recursion tree (B) for $n = \langle 2, 1, 1 \rangle$.

whether the elements of the set are selected in increasing order (d_k is true) or decreasing order (d_k is false). For the initial call $GenAlt(n, \varepsilon)$, the sequence produced will depend on the initial value of array d .

The call $Change(d_k)$ negates d_k if there is more than one i such that $n_i > 0$. Otherwise,

$Change$ can either leave d_k unchanged or negate it arbitrarily; the algorithm is still an interchange algorithm.

Different choices of $Change$ give different versions of $GenAlt$. Two particular choices, which we call Version A and Version B, are specified below.

```

{ Given  $0 \leq k \leq |d|$ ,
  print all sequences  $\pi[0..k-1]\alpha$  where  $\alpha$  is an  $n$ -permutation. }
(A1) procedure GenAltA( k : 0..|d| );
(A2)   var j : 0..t;
(A3)   begin
(A4)     if  $n_0 = n_1 = \dots = n_t = 0$  then Print(  $\pi$  )
(A5)     else begin
(A6)       for  $j \in \{p \mid n_p > 0\}$  by  $d_k$  do begin
(A7)          $\pi_k := j$ ;
(A8)          $n_j := n_j - 1$ ;
(A9)         GenAltA( k + 1 );
(A10)         $n_j := n_j + 1$ 
(A12)       end;
(A13)        $d_k := \text{not } d_k$  {Change( $d_k$ )}
(A14)     end
(A15)   end
    
```

Fig. 5. Version A of Algorithm $GenAlt$.

In Version *A*, $Change(d_k)$ is
 $d_k := \text{not } d_k$.

In Version *B*, $Change(d_k)$ is
if $\max\{n_1, \dots, n_t\} > 0$ **then** $d_k := \text{not } d_k$.

Figure 3 shows the recursion tree for Version *A* with input $n = \langle 2, 1, 1 \rangle$. The +’s and -’s indicate whether the nodes are plus-nodes or minus-nodes. Figure 4 is the corresponding tree for Version *B*; the squares indicate nodes at which d_k does not change. In both figures we assume that, for all $k \in 0..n-1$, the initial value of d_k is true.

In Fig. 5 we show an implementation of Version *A* where π , d , and n are global; then the only parameter of the procedure is k , which is the level of the recursion. The initial call is $GenAltA(0)$.

3. Efficient implementation

We now show how to implement $GenAlt$ to achieve constant amortized time. Our algorithm, given in Fig. 6, follows the general approach of Ruskey and Roelants van Baronaigien [10]. It requires that the symbols have been arranged so that sequence n is in descending order: $n_0 \geq n_1$

$\geq \dots \geq n_t$. Next, it requires eliminating certain nodes in the recursion tree. Define an *i-path* as a path in the recursion tree, all of whose nodes are labeled i and have degree at most one. (The nodes on 0-paths are underlined in Fig. 3.) We will remove all 0-paths from the recursion tree.

For example, consider the case $n = \langle m, 1, 1 \rangle$. The unpruned recursion tree has $(m+5)(m+3)(m+1)/3$ nodes with $(m+2)(m+1)$ leaves. Deleting 0-paths reduces the number of nodes to $(2m+5)(m+1)$.

There are two subtle, but crucial, differences from $GenAltA$. The first is that the test at line (B4) does not include n_0 ; this causes 0-paths to be eliminated. The second difference is that $\pi[k..|d|-1]$ contains all zeroes upon a call $GenAltB(k)$ (which requires that π contain all zeroes at the call $GenAltB(0)$). This restriction allows us to conclude that if all n_i are 0 except for n_0 , then π contains the permutation to be printed. Note that this requirement is satisfied at the recursive call within $GenAltB$. The assignment $\pi_k := 0$ is needed because π should be left unchanged by execution of a call to $GenAltB$.

In order to achieve constant amortized time behavior, maintain the nonzero n_i ’s (only) as a doubly linked list. Then the test $n_1 = n_2 = \dots = n_t = 0$ can be done in constant time (it is equivalent to the length of the list being 1), and the loop

```

      {Given  $0 \leq k \leq |d|$  and  $\pi[k..|d|-1]$  are all zeroes,
      print all sequences  $\pi[0..k-1]\alpha$  where  $\alpha$  is an  $n$ -permutation.}
(B1)  procedure  $GenAltB$  ( $k : 0..|d|$ );
(B2)  var  $j : 0..t$ ;
(B3)  begin
(B4)    if  $n_1 = n_2 = \dots = n_t = 0$  then  $Print(\pi)$ 
(B5)    else begin
(B6)      for  $j \in \{p \mid n_p > 0\}$  by  $d_k$  do begin
(B7)         $\pi_k := j$ ;
(B8)         $n_j := n_j - 1$ ;
(B9)         $GenAltB(k+1)$ ;
(B10)        $n_j := n_j + 1$ ;
(B11)       $\pi_k := 0$ 
(B12)    end;
(B13)     $d_k := \text{not } d_k$  { $Change(d_k)$ }
(B14)  end
(B15) end

```

Fig. 6. Version *B* of Algorithm $GenAlt$.

can be executed in time proportional to the number of iterations, except for recursive calls. Thus the computation time is proportional to the number of recursive calls. We now show that the number of recursive calls is at most four times the number of bag permutations printed. This will complete the argument that the algorithm runs in constant amortized time.

The following two bag coefficient identities will prove useful. The first identity is classic and is simply a restatement of (1); the second may be verified by induction on n_0 .

$$\sum_{i=0}^t \binom{\#n-1}{n_0, \dots, n_{i-1}, n_i-1, n_{i+1}, \dots, n_t} = \binom{\#n}{n_0, n_1, \dots, n_t}, \tag{2}$$

$$\sum_{i=0}^{n_0} \binom{\#n-i}{n_0-i, n_1, \dots, n_t} = \frac{\#n+1}{n-n_0+1} \binom{\#n}{n_0, n_1, \dots, n_t}. \tag{3}$$

The number of nodes of degree one in the recursion tree T of *GenAltB* is equal to the number of nodes on i -paths in T , where $i > 0$. The number of nodes at level $\#n - j + 1$ (with the root at level 0) on i -paths in T is the same as the number of bag permutations specified by $n_0, n_1, \dots, n_{i-1}, n_i - j, n_{i+1}, \dots, n_t$.

For the example of Fig. 4, in Version B the number of nodes on 2-paths at level 4 is 3 (corresponding to 001, 010, and 100), and there are no 2-paths at level 3. Thus, the total number of nodes of degree one is given by the following expression:

$$\begin{aligned} & \sum_{i=1}^t \sum_{j=1}^{n_i} \binom{\#n-j}{n_0, \dots, n_{i-1}, n_i-j, n_{i+1}, \dots, n_t} \\ &= \sum_{i=1}^t \frac{\#n}{\#n - n_i + 1} \\ & \quad \times \binom{\#n-1}{n_0, \dots, n_{i-1}, n_i-1, n_{i+1}, \dots, n_t} \\ &\leq \frac{\#n}{\#n - n_1 + 1} \binom{\#n}{n_0, n_1, \dots, n_t} \\ &\leq 2 \binom{\#n}{n_0, n_1, \dots, n_t}. \end{aligned} \tag{4}$$

All other internal nodes of the tree have degree greater than one, so there cannot be more of them than there are leaf nodes. Thus, the total number of nodes in the tree is at most $4C(n)$.

Finally, we remark that it is also possible to implement Version A in constant amortized time by keeping track of how many 0-paths have been deleted so far at any given level. This does, however, greatly complicate the algorithm. Details may be found in [6].

4. Concluding remarks

When all n_i equal 1, Versions A and B produce the same list of $\#n!$ permutations, and this list appears to be different than any of those produced by the permutation generation algorithms surveyed in [12] or [7].

The proof technique used in [1,9] to show the interchange property is different than that used here. Their proof is inductive and is based on the starting permutation being $0^{n_0}1^{n_1}$ and the ending permutation being $10^{n_0}1^{n_1-1}$. For $t > 1$ the ending permutations are not so easy to specify. For example,

303131122233 and 3033220212

are both ending permutations of (starting from $01^32^33^5$ and $0^212^43^3$, respectively) Version B .

Finally, a ranking algorithm for Version A , similar to the ranking algorithm presented by Lucas, Roelants van Baronaigien, and Ruskey [8], as well as an unranking algorithm can be developed; details may be obtained from the authors.

Acknowledgment

We wish to thank David Gries for his many contributions to the presentation of this paper, for pointing out an error in our original submission, and for reference [7].
