Mexico, under its Government program, has nationalized its petroleum resources and is directly engaged in the oil business under its national agency, Petromex.

CONTROL OF PRODUCTION IN THE UNITED STATES

While not involving governmental control in the strictest sense, there has evolved in the United States a remarkable procedure combining enforced and voluntary oil production control. Whatever may be said on the side of its not being regimented, the petroleum industry—the thousands of small producers and the great corporations which constitute the second largest industry in the United States—is not the free agent it formerly was. No basic change has been made. No State monopoly or operation has come. There is no nationalization of oil such as has occurred in Russia and Mexico. The principle of State ownership of the sub-soil and the minerals that lie beneath the surface of the earth, which is an old one in law, has no part in the new order. There has been no change in the basic law of the country giving the surface owner title to the sub-soil, and the ruling of an obscure Pennsylvania judge in the early days of the industry that oil was like wild game, belonging to the person reducing it to possession, still prevails. In other words, whatever the landowner could withdraw from the common reservoir he could take and keep irrespective of the fact that he might be draining oil from under his neighbour's land.

This is called the "rule of capture." Undoubtedly it furnished the incentive by which private enterprise in the United States created a major business. It gave to the world products the use of which has become essential to modern civilization. It also provided an incentive that was not economic at all, imposing upon each operator the necessity to capture his oil before it was drained by his neighbour. Thus, fields were overdrilled and produced too rapidly, without regard to good engineering practice and to whether the oil was needed at the time. The "rule of capture" persists, but it has been greatly prescribed through threefold necessity—(1) public demand for the conservation of a valuable and exhaustible natural resource, (2) production instability of oversupply or shortage, descriptively termed "feast or famine," and (3) application of scientific knowledge of oil and gas occurrence and function in an oil pool with improved production methods.

The procedure received its start in 1926 with voluntary proration by producers in Oklahoma. They agreed to restrict their production on a pro rata basis because of overproduction brought about by competitive over-drilling. The term proration is now used more broadly to describe the entire process by which the production of crude oil in the United States is regulated. Accompanying and following the action of the operators in Oklahoma there came an ever-increasing body of sentiment supporting the principles of oil conservation in the interest of sound public policy. This was reflected in the appointment and deliberations of the Federal Oil Conservation Board and, in many oil-producing States, by the subsequent enactment of comprehensive conservation statutes. Arkansas, Kansas, Louisiana, New Mexico, Oklahoma, and Texas passed such laws. The same States enacted economic waste or market-demand statutes. The conservation movement also was furthered by the orders of regulatory bodies in these States, and then, on Aug. 27, 1935, the Federal Congress approved a treaty between the compacting States, creating the Interstate Oil Compact Commission.

Under the compact the States may agree among themselves to apportion to each State its equitable share of the total production needed to supply the national demand. Thereafter the State regulatory bodies having the police power under conservation laws can apportion the production allotment among the fields, pools, and even wells of the State.

In practice, proration is supported to a considerable degree by voluntary conformance on the part of the oil producers. All States producing oil are not members of the oil compact. Those

belonging are Oklahoma, Texas, Kansas, New Mexico, Colorado, and Illinois. While they account for 70% of United States production, that does not mean that the production quotas assigned to these States are always adhered to. Failure to observe quotas restricting fields, or pools, or wells on the part of producers has coined a new phrase in oil terminology, "hot oil." During the competitive development of the East Texas field in the early 1930s, so much "hot oil" was produced and sold that the oil market collapsed. More recently, in 1937 and 1938, the development of many new pools in Illinois flooded the market with "hot oil" despite the fact that Illinois is listed as a member of the Federal Oil Compact.

So great an oil-producing State as California, accounting for 20% of the nation's petroleum output, is not a member of the Federal Oil Compact and has no laws for the regulation of production such as enacted in other oil producing States. But for ten years California has succeeded in establishing a good record of voluntary curtailment. Some idea of the complexities this entails, as well as of what the whole proration quota control procedure entails, may be given by briefly describing California's oil operations which are fairly typical of the major American oil fields.

California has 19,000 oil wells located in 112 separate oil fields and owned by 1,060 separate and distinct individuals, partnerships, and companies. Productive depths of wells range from 400ft. to over 13,000 feet. Capacity to produce ranges from one barrel a day in some wells, to indeterminate amounts in others conservatively estimated to be as high as 25,000 bbl. daily. There are oil fields with as many as eight separate and distinct productive horizons, each of which comprises a separate oil pool. Ownership of wells ranges from individuals with a single well to the Standard Oil Company of California which has more than 3,300. All these wells could produce, it is estimated, in excess of 2,000,000 bbl. daily, nearly two-thirds the actual daily average production of all fields in the United States. Yet consumptive demand for California oil was around 600,000 bbl. daily and production had to be kept as nearly as possible to that figure. The problem of curtailing production of that State and all States is to reconcile and deal equitably with all the varied factors involved. It means compromises of all sorts between the oil producing refiners, non-producing refiners, landowners whose sole source of income is from royalty oil, the promoter-well-owner sometimes inadequately financed, and the strong-minded individualistic producer who would rather not co-operate. A formal group of oil producers, with an oil umpire, works to keep production within bounds by voluntary action in California.

In the States belonging to the Federal Oil Compact, production quotas are recommended based upon scientific information secured through detailed investigations by the U.S. Bureau of Mines. outlining trends of production and consumptive demand. The regulatory bodies establish the production quota. Oil not required for current consumption and reasonable working stocks is kept below ground in its natural reservoir. This, in addition to economic advantages, has the advantage of contributing to the more efficient ultimate extraction of the oil by conserving the natural reservoir energy.

To cope with the "hot oil" situation and to aid the States in their proration efforts, the Federal Congress passed legislation barring "hot oil" from interstate commerce, and Federal authorities seek to enforce this law.

All this is a far cry from the old days of free, competitive drilling and production. The rule of capture has been prescribed in many ways by increasing limitations and exceptions. Not only is the producer prohibited from producing in excess of established allowable production, but he cannot drill without a permit of a regulatory body duly applied for, or locate a well except as the applicable spacing rule, or exception granted, specifies. He cannot penetrate surface water sands without adequate subsequent protective casing, complete a well without a proper casing program and suitable means of shutting off extraneous water, or produce a well except through tubing with restricted flow. He cannot let natural gas escape from his well or use gas in the oil pool as a lifting agency for his oil beyond a permitted gas-oil ratio, and in

many other ways he must subordinate his hitherto unrestricted right of capture to the public policy of the State and adjust it to the co-equal and correlative rights of his neighbour.

A more thorough knowledge of oil conditions in the pool below ground and of productive capacities of producing strata has demonstrated that a uniform spacing of wells and efficient utilization of the reservoir energy inherent in the oil and gas within the pool, will result in the maximum recovery of oil at the minimum cost. This knowledge has promoted the unit operation of some pools, that is, the operation by all surface owners or lessees of the pool as a unit. This may be said to be the ideal operation from the standpoint of conservation and efficiency, but unit operation is still far from being realized as a general policy, and most pools are so held and operated by many competitive interests that each operator still must resort to the rule of capture, with the restrictions noted, to preserve his equity. Unnecessary wells in great numbers are still being drilled. Expressed in other terms, while production has been largely divorced from the effects of the rule of capture by limiting oil withdrawals, drilling has not been freed from this influence to the same extent. In the administration of proration, allowables have usually been allocated on a per well basis rather than in proportion to the underlying oil reserve. This policy not only has stimulated more wells than necessary to extract the oil but it has encouraged drilling in advance of economic requirements.

Nevertheless, in totality the result of control in the United States has been good, and, measured from every standard of appraisal, the accomplishment for greater stability and for conservation of a valuable natural resource has been estimable. With approximately 318,600 wells producing at the end of 1926 and with practically no curtailment, the total production for that year was 770,874,000 bbl., an average of 2,420 bbl. per well per annum. During 1938, with production restricted to minor percentages of the daily capacity of the wells in practically all major producing fields, the total production for the year amounted to 1,213,254,000 bbl. from approximately 350,000 wells, an average of over 3,000 bbl. per well per annum, indicating the increase in the total potential producing capacity of completed oil wells accompanying progressive restraint upon current production.

What is being attempted in the United States by the control procedure in its present stage is the regularizing of the petroleum industry without destroying competition or private initiative and enterprise. The oil business in the United States is the first great industry to have undergone control, having redesigned its economic structure to find, within existing legal background, a practical solution to the complicated problem of unchecked operation under the rule of capture.

WORLD CONSUMPTION OF MOTOR FUEL

National appetite for motor fuel, in other words, motor car registration and use, largely tells the story of the relative position of nations with respect to petroleum consumption. Gasoline, the product of greatest utilization derived from petroleum, fuels over 40,000,000 motor vehicles throughout the world, as well as aeroplanes, tractors, stationary engines, and other power plants. Inasmuch as the United States has 28,000,000 motor cars registered and in use, thus accounting for 70%, a two-fold explanation of that country's overwhelming leadership in petroleum consumption and production is supplied. It must, however, be coupled with recognition of the fact that the United States has been blessed with tremendous oil resources accessible to ready markets and intensively developed until recently under unrestricted competitive methods. With this development emerged one of America's foremost industries. In enterprise and scientific operation, the American petroleum industry has played, since the early days of petroleum, a leading role, not alone in its own country, but throughout the world. That, also, has contributed to the ranking position of the United States in consumption.

The United States accounts for 62% of the total world consumption of all petroleum products. Second only to gasoline in volume of consumption is fuel oil. The United States consumes, both for domestic and industrial purposes, nearly 60% of all the

Europe is going forward on a scale reminiscent of that which accompanied the great growth of American motor car use. An ever-present factor, pointing to further expansion, is armament programs. Not only the motorized land and sea fleets but those of the air, demand more and more gasoline.

WORLD CONSUMPTION OF OTHER PETROLEUM PRODUCTS

World consumption of lubricating oils by geographic zones shows Europe to be the largest consumer. European countries combined account for 42.12% of the total, with the United States consuming 37.76%. Europe and the United States together use four-fifths of the world's kerosene, while the United States alone accounts for 55.70% of the world's consumption of fuel oil. The world's merchant marine is 53% oil-burning, the total petroleum-powered tonnage having increased from 6,000,000 gross tons in 1919 to over 35,000,000 gross tons in 1938.

SCIENTIFIC DISCOVERIES AND IMPROVEMENTS

Growth of Knowledge of Petroleum's Origin, Occurrence, and Composition.—Petroleum, known to antiquity—in fact, predating the dawn of man and appearing in myth and legend—always has been invested with mystery as to its origin, occurrence, and composition, and hence with the dawning and progression of the Age of Science has increasingly lent itself to scientific discoveries and improvements. The classification of petroleum among the minerals is probably as old as the fundamental natural history dividing things into three kingdoms: animal, vegetable, and mineral. Even this classification was not accepted without controversy, for probably there was never a more simple, yet more complex, substance than petroleum to provoke and challenge the chemist, the physicist, and the geologist. It has only been with the building of knowledge upon knowledge furnished by the extension of the commercial development of oil that scientific thought has been able to formulate generally acceptable answers.

While composed principally of hydrocarbons—that is, of hydrogen and carbon—petroleum is rendered complex by the uniting of these two elements in varying proportions with each other and with a number of other elements, thus forming a multitude of compounds each having distinct properties. Petroleum seems first to have been considered a liquid coal or bitumen, the connection between natural gas and petroleum not having been recognized. During the early 19th century, as more was learned of the oils obtained from the distillation of peat, lignite, and coal, the belief grew that petroleum was produced from one or all of these materials by the action of subterranean heat upon solid bitumens. At the same time the theory that petroleum was formed in the earth by chemical reactions in connection with volcanic disturbances, accompanied by great heat, made headway. This is termed the inorganic theory of origin.

As oil development progressed on a commercial scale in the United States and other countries, the organic theory of origin began to be advanced. This held that petroleum was produced by the decomposition or distillation of animal or vegetable matter. It was not until the 20th century that anything like a clear picture of the origin of petroleum was developed and this was made possible because of increasing study of wells drilled for oil and of formations penetrated by the drill. These studies seem to bear out the organic theory. It is generally held that plant and animal organisms were the origin of oil, that these organisms, buried in ancient seas of the geologic yesterday by new mud deposits and sealed from the air, were subjected to slow decomposition and formed the petroleum of commerce. Much is yet to be learned in this field. Important research on the origin and environment of source sediments of petroleum was instituted beginning in 1926 by the American Petroleum Institute under a fund provided by the late John D. Rockefeller and the Universal Oil Products Company of Chicago. Projects underway cover a wide range of inquiry into the still unsolved problems of the origin, occurrence, and composition of petroleum.

Advances in Oil Exploration and Discovery.—In the field of practical scientific research, outstanding strides have been

made, and, as demand for petroleum products increased, science and engineering have played an increasingly important role in the search, recovery, and conservation of oil.

The romantic days of early petroleum history when oil prospectors invoked the aid of an "oil witch" or peach twig or other supernatural devices for "divining," before drilling, the presence of oil, have long since vanished. From the beginning of American oil development in 1859 to 1900, or even later, prospecting was carried out on a casual and random basis. Men drilled on oil and gas seepages, along the beds of streams, along trend lines, at some point where the topography resembled or had a fancied resemblance to some other area which they knew was oil-producing, or for no reason beyond a hunch. The demand for oil was not great;

drilling depths were shallow, and there were enough venturesome souls to find sufficient oil by the crude methods available to them, to meet, and often more than meet, the world's demand.

The old hit-or-miss methods of prospecting were no longer adequate as the automobile and other modern agencies of oil consumption came into being. Geology, which previously had been largely speculative as far as oil was concerned and only used spasmodically, was accepted as a guide to prospecting. Well depths were still relatively shallow, and the beds in which oil was expected to be found were generally more or less parallel to those out-cropping at the surface. A surface dome or anticline could be accepted as indicating with a high degree of probability the existence of a similar dome or anticline in the oil sands. Thus, "surface geology" came to be applied. The earliest mapping of

surface structures was done with clinometers, hand levels, and spirit levels. By 1913 the plane table had come into general use as being superior to the older methods, and most of the surface geology for the purposes of oil prospecting was mapped with the plane table.

The next geological aid to the feverish search for oil came in the early 1920s with a new technique of "subsurface geology" and core drilling. Structures actually penetrated by the drill were mapped and samples of the rock and sand strata studied. This was accomplished by using carefully kept well-logs and by drilling special test wells of small diameter, enabling the geologist to obtain a core or cylindrical segment of the rock penetrated. Information obtainable from the driller's well-log was supplemented by microscopic examination of the samples of formations penetrated by the drill. Laboratories for sample studies were established, and micro-palaeontology became an integral part of the oil business in the United States. Revealed by this method were fossils and mineral grains so small that they could not be seen by the naked eye, and knowledge was gained not only of geologic formations but of the origin, migration, and accumulation of oil by a combination of applied palaeontology and lithology. As these methods have developed, in many cases drillers received instructions in distinguishing characteristics of formations; microscopes often were placed on derrick floors, and electrical logging came into vogue. A knowledge of subsurface structure in advance of drilling has resulted in the discovery of production at depths previously considered impossible. In less than 15 years producing well depth increased from 5,000ft. to 12,000ft., and the subsurface oil producing horizons of the future were no longer delimited.

The widespread use of core drilling was somewhat checked by the development of still another technique—that of mapping underground structure by the use of the reflection seismograph in the early 1930s, a late development in geophysical prospecting. (See GEOPHYSICAL PROSPECTING.) Many of the existing producing areas of the United States would have remained undiscovered without the aid of geophysical instruments. Their use also has facilitated the delineation of subsurface structure conditions in producing areas and has proved the key to a veritable storehouse of previously unknown production.

These methods were first introduced in the Gulf Coast area in the 1920s, with the torsion balance and the refraction seismograph, the latter not to be confused with the reflection seismograph. The torsion balance was a delicate instrument used to measure the slight variations in the gravitational force of the earth and thus to enable the prospector to deduce the shape of a concealed structure. The refraction seismograph was used to recognize different formations by different rates in the speed of transmission of artificially-induced sound waves. By the early 1930s the whole area regarded as prospective territory had been explored—some of it five or six times by different companies. Some 50 or 60 salt domes, practically as many again as the number previously known to exist, were discovered by its use. The expense for geophysical work alone was estimated at from \$20,000,000 to \$30,000,000. At about 1931 the reflection seismograph, a further application of induced earth waves, came into use, and the entire Gulf Coast area began to undergo a resurvey utilizing this new technique. Other geophysical instruments used in oil prospecting were the magnetometer, an application of magnetic measurements; the gravimeter, a further application of gravimetric methods, and devices for applying electric measurements still in the experimental stage in 1939.

During the period from 1926 to 1930, the percentage of major oil pools in the United States discovered by geophysical methods was 9.3%. During the period 1931 to 1935, this had increased to 55%. In 1938 it was estimated that about 75% of the new major oil fields in the United States were being discovered by geophysical methods.

In these advances in oil exploration and discovery methods are found the explanation of the United States' continued leadership in oil production, and of the fact that year after year the country has been able to meet its own and much of the world's oil re-

quirements. It is to be noted that as known pools or producing horizons have been depleted or exhausted, new pools or producing horizons have been found, not alone to take up the slack but to provide the ever greater requirements. Similarly, as a prospecting technique has come to the aid of the producer, has been used and has exhausted its usefulness, another has arrived in time. An even new technique may be some form of soil-gas analysis to supplement geophysical prospecting.

While the cost of actual field operations has increased enormously, the oil per unit field found has increased substantially and the hazard of prospecting also has decreased considerably. It is estimated that with good practice, the cost of finding oil in the early 1920s was 20 to 25¢ per barrel, while in 1938, on volume operation, it was from 10 to 12¢ per barrel. However, not every newly discovered field is directly attributable to scientific advancement. Although, by and large, the drilling of wells is based upon geological data, the "wildcatter," drilling at random, still is a great factor. Not only new pools, but occasionally, new regions and new types of pools, have been found through the drilling of a rank wildcat well. The great East Texas field developed in the early 1930s is a case in point and indicated that stratigraphic, rather than structural, conditions were the controlling factor in the accumulation of the oil. This opened up studies of the order and relative position of the strata of the earth's crust.

In 1937 one out of every eight wildcat tests drilled in the United States was successful. It is estimated that only 12% of wildcating was carried on without some scientific basis, and exploration based upon technical data was shown to be almost three times as effective as random effort.

Advances in Production Methods and Drilling.—Great advances in production technology have come with the increase of knowledge concerning the conditions governing the occurrence of oil. The fanciful ideas prevalent in the early days that oil was found in underground lakes and streams have been replaced by fundamental knowledge of the character of the reservoir rocks. It is known that the rocks or sands in which oil is stored vary greatly in texture and porosity. Frequently oil, itself charged with gas, occupies a zone in the rock overlain by free gas and underlain by water. Gas, oil, and water alike are confined under great pressure. When wells penetrate the oil-bearing portion of the reservoir, this pressure tends to drive the oil out of the reservoir to the surface. The researches that eventually made-over production methods in the United States had their start with efforts to use natural gas and air in rejuvenating old oil fields early in the 20th century. By 1923 the air-gas lift system was installed and operated practically in all new fields in the Mid-Continent, on the Gulf Coast, and in California, principally to increase the oil yield of wells. Production engineering, as a new art, accompanied this development. The old practice had been to let wells produce virtually wide open, the oil being driven up by and with the gas, and the gas allowed to escape in the air. The production engineer applied himself to making better use of the gas as an efficient agent in extracting oil from the ground by preventing its escape and back-pressuring it into the oil sand again. Thus some degree of conservation of natural gas, long having been wasted in the air, was accomplished, as well as prolongation of the life of the oil pool.

In 1924 the theory was advanced that oil in an undisturbed pool was different in character and behaviour from the same oil when raised to the surface of the earth, and that gas dissolved in the oil caused a marked reduction in its viscosity and surface tension. This theory started exhaustive studies, and it was determined that holding as much as possible of the gas in solution in the oil would keep the oil more fluid and, through lowered surface tension, reduce the resistance of the oil to flowing to the well. Thus a function of gas in the reservoir, not before known, was discovered, and in the next 15 years an entirely new system of oil production came into existence. It was furthered by conservation laws in various States and by proration control in the United States.

The maximum benefit of this scientific advance is not attainable

except when an oil pool is operated as a unit, and there are but few pools so operated. But the new production methods made it possible to recover an increasing proportion of the oil originally contained in the reservoir. Flowing wells were regulated to limit the amount of energy used to extract each barrel of oil, thus conserving reservoir energy to be utilized in further extraction

Artificial water flooding of depleted oil fields, as well as artificial gas and air rejuvenation, have been successfully carried on. The use of acid in stimulating production in depleted and new fields was first begun in the United States in 1932. Hydrochloric acid was injected into the producing formation to loosen the oil, with the result that chemical methods for increasing the flow of oil have played an important part where limestone oil reservoirs occur. Between 1932 and 1939 some 14,000 wells have been treated by one process alone, and an analysis of results showed an average of more than 400% increase in the rate of production on a group of more than 1,000 such wells.

Variety and efficiency of drilling tools, as well as improved drilling methods, made it possible successfully to penetrate deeper and deeper into the earth. Devices for surveying and determining inclination of wells were perfected so that straighter holes could be drilled. This reduced wear on equipment and danger of the loss of wells. Intensive studies of the composition of drilling fluids greatly aided in the control of wells and the prevention of blowouts. These and many other improvements enabled the operator to find sands which with cruder methods frequently escaped detection, and to explore to increasing depths in search for lower sands and new pools. By 1939 the handling of oil at the surface was a totally enclosed process. The old methods of open production and storage were obsolete except as to heavy oils produced with little or no accompanying gas. The development of processes for the more efficient use of natural gas underground also was accompanied by the processes for more efficient use above ground, including extraction of natural gasoline and butane.

of the most fortunate discoveries was that cracked gasoline had better anti-knock qualities than ordinary straight-run gasoline. In other words, not only did cracking save the day from a gasoline-volume standpoint, adding millions of barrels annually to motor fuel supply, but it raised the quality of the product. It permitted the motor car designer to build high-compression engines, dependent on anti-knock fuels for satisfactory operation. It gave the motorist the modern high-speed, smooth performing automobile engine. So extensive was the rebuilding of American refineries for cracking operations, that cracking became the backbone of the modern refinery. In 1936, for the first time, more cracked gasoline was produced by U.S. refineries than straight-run gasoline. If only straight-run gasoline had been available it is questionable whether enough crude oil could have been found, much less the necessary refinery capacity built, to fuel the world's 40,000,000 motor cars. The miracle of cracking from a conservation standpoint is that by 1938 it had saved in the ground a round billion barrels of crude oil for future use. Table XIII strikingly reveals the contribution of cracking to oil conservation.

The demands of the omnivorous motorist are still far from satiated and, on top of that, aviation demand for motor fuel has grown apace. Obviously, the question of supply is highly important to civilian and military aviation. In 1928 aviation gasoline was so-called straight-run gasoline of high volatility. That is, it was a regular refinery gasoline produced by straight refining and possibly by the addition of high-volatility natural gasoline. Little attention had been paid to anti-knock value, which then was in no way standardized. That year the U.S. Army Air Corps asked petroleum refinery technicians to develop a fuel of high and standardized anti-knock value. If they could obtain it in sufficient quantities, they said they could develop substantially increased power from the same sized gasoline engines then in use. They issued specifications for anti-knock gasoline of 87 octane-number by existing methods of test. The petroleum refiners succeeded in developing the fuel, and before long U.S. military planes were giving outstanding demonstration of improved flying speed, take-off and climb, and attracting the envious attention of commercial aviation, which demanded its quota of high octane-number aviation fuel. Within a few years fuel of standardized anti-knock quality ranging from 70 to 87 octane-number was available to them. This made aviation history—the establishment of long-distance commercial flying routes, the spanning of continents and oceans. By 1936 the power output of aircraft engines was increased a third or more due to the availability of this fuel. Not only was power output increased but fuel consumption was decreased. In other words, less fuel had to be carried, and load-carrying capacity could be increased—essentials for long-distance commercial flying.

The chemists and refinery engineers did not stop with 70 and 87 octane-number motor fuel, but embarked on an era of new commercial and experimental processing for high quality fuel, the like of which had not been seen in the petroleum industry since the early days of cracking development and expansion. From 87 octane-number, fuels of 95 and 100 octane-number for military purposes were developed, and enough produced to give commercial aviation a taste of them. The development of iso-octane, an almost pure hydrocarbon, added to leaded gasoline, raised octane ratings to 100. Without this super-type motor fuel, cruising speeds of aeroplanes would have remained at from 80 to 100m.p.h. as they were in 1925, instead of 200 and 220m.p.h. attained in 1938.

It is estimated that from \$25,000,000 to \$35,000,000 annually have been spent in America in research and development on the processing side of petroleum refining. Catalysis and synthesis have been the instruments chiefly used, with attention concentrated on more economical production of high octane-number motor fuel. Such processes as polymerization, hydrogenation and other methods of synthesis for obtaining not only superior products for established uses but also important by-products in the chemical field, have come into more or less commercial usage. More actual production of high quality motor fuel, as well as enormously expanded potential yield, became an accomplished fact.

TABLE XIII Crude Oil Conserved by Cracking at U. S. Refineries (In thousands of barrels)

Year	Actual Yield of Gasoline from Crude Oil (Per Cent)	Total Produced from Crude Oil*	Quantity of Crude \$; Have Been Required for Yielding	Actual Oil Run to Stills	Conserved by Cracking	by Cracking (Per Cent)

Progress in Refining and Processing.—In no field of science has more progress been made than in that of petroleum refining and processing. Getting large recovery of high grade gasoline out of crude oil is a modern test-tube miracle if there ever was one. In the early days of the automobile, impending shortage of gasoline constantly threatened. The chemists and refining engineers saved the day by building and operating cracking stills. Whereas in straight-refining only a gasoline yield of from 1 to 6gal. from a 42-gallon barrel of crude oil run by U.S. refineries had been obtained, the developers of cracking processes managed by 1920 to increase the yield to over 10 gallons. They did it by taking the heavy oils like gas oil and fuel oil which, along with gasoline, were produced in straight-refining, and re-running them in specially-built stills under tremendous heat and pressure, cracking the molecules and getting a proportion of light products—gasoline—as a result. In the space of a few years they made over the refining industry, and relieved the tension on gasoline supply.

In the intervening years there have been many improvements in cracking, and much learned respecting the resultant product. One

The polymerization process came into use in the early 1930s. It catches petroleum refinery gases, formerly largely wasted and blown away, and converts them into liquid form. This process is the reverse of cracking. Whereas cracking breaks down the heavier molecules of fuel oil into the lighter ones of gasoline, polymerization combines the smaller molecules of certain gaseous by-products of refining into the chemical components of motor fuel. Installations have been rapid, and polymer gasoline may ultimately vie with cracked gasoline in volume. The hydrogenation process originated in Europe, and was technically perfected in the United States. Its effect was to lend a considerable flexibility to refining, making possible an amazing manipulation of molecular groups. It is also possible by hydrogenation to convert coal and shale into motor fuel. In 1938 announcement was made in the United States of the Houdry catalytic cracking process for petroleum refining, together with the fact that \$35,000,000 would be spent in building commercial units, and that this process would be licensed generally to the entire petroleum industry.

This process apparently opened the way for large quantity sources of high octane-number aviation fuel, and caused it to be stated that not since the cracking process first came into use had there been such a change promised in the potential output of motor fuel. The process adds a catalyst in the cracking operation. In 1937-38, 7,000,000 gal. of aviation gasoline were produced by the process. The yields given showed that 33 or 34 gal. of gasoline may be taken from a 42-gallon barrel of crude oil. This compares with the 1938 gasoline yield by all methods from American refinery operations of 18½ gallons. Tests indicated that the octane-numbers of the gasoline produced by the process were somewhat higher than on gasoline produced by ordinary thermal cracking of similar oils. The finished aviation gasoline, it was revealed, would be approximately 87 to 92 octane-number, and, when used for blending with usual anti-knock agents, 100 octane-number fuel, after addition of tetraethyl lead, would be produced.

In 1938 it was announced that isopropyl ether could be mixed with leaded aviation gasoline to form a fuel that could be made available in sufficient quantities for all commercial needs. Furthermore, a fuel with the proper concentration of this new blending agent could go right through the "ceiling" of commonly accepted methods for anti-knock measurements should there be a call for fuels above the 100 octane rating. Then in 1939 another development in the field of super-fuels was the announcement in the United States of a process called alkylation, which uses waste refinery gases to make curly molecules of hydrocarbon. In the presence of sulphuric acid, it combines an olefin, or non-saturated hydrocarbon such as butane, with a saturated branch-chain hydrocarbon like iso-butane, to produce a blending agent much like iso-octane. Thus, alkylate has been added to the list of blending agents. In view of these developments, it was generally accepted that 100 octane fuel, once considered the "gold standard" of aviation gasoline, had become generally available in commercial quantities.

Advances in the refining art promise almost complete flexibility of refining control, thereby permitting production of any desired percentage of any one of the most important products, and thus relieving storage problems created by seasonal demands. Expected also is satisfactory commercial production of gasoline from the heaviest residual fuel oils; utilization of almost any crude oil to make the highest range refined products—hitherto practically impossible because of peculiar characteristics of some crudes—and the production, without further treating of high octane-number motor fuel and aviation fuel.

One of the most significant angles to the development of 100 octane fuels was the fact that by using them the overall efficiency performance of the gasoline engine closely approached, if it did not equal, that of the Diesel engine. Formerly, the great advantages of the Diesel were its lighter engine weight per horsepower and its lower specific fuel consumption.

The promised volume production of high octane-number gasoline has given the automobile engine designer a chance to enter new realms of achievement. While improvement in octane-number has been brought about to a considerable extent by cracking and

polymerization, one of the chief contributions to this important result was the conception of what actually caused knocking in an engine, and the subsequent research to find a remedy. This brought about the use of additional organic compounds of lead—notably tetraethyl lead. Perhaps 80% of all the gasoline sold through American filling stations in 1938 contained tetraethyl lead. The use of this and other high anti-knock fuels brought an increase in power with a great decrease in both the size and the weight of the automobile engine, with resulting economy to the automobile user.

Another notable contribution of science of direct benefit to the motoring public was the development on a large scale of methods for stabilizing gasoline by removing small amounts of hydrocarbons of very low boiling point, and thus reducing vapour lock. This contribution made possible the development of gasolines which gave dependable service in winter weather; and this, like many other fuel improvements, made its contribution to the advances in the design of the gasoline engine. In this same class, perhaps, should be placed the discovery of those chemical inhibitors against the oxidation of gasoline in storage that reduce the evils of gum formation, and the development of seasonal products such as gasoline designed to give the best results for summer in those sections of the country where the variations in the weather are notable.

The recovery of casinghead, or natural gasoline, has been an important scientific development, for it added to the supply of high grade motor fuel. It came with the development of efficient and economical means for recovering and stabilizing this light gasoline. Natural gasoline methods led to the separation of propane and butane, which were compressed and liquefied and made available in the form of gas in cylinders or steel bottles ("bottled-gas") used wherever it was found unprofitable to run gas mains or establish gas plants. In addition this liquefied gas fuel was used to enrich water gas, and to meet fluctuating loads. Its constant heat value and easy operation made it very convenient to handle, and assured a more uniform performance of power plants.

The processes for stripping hydrogen sulphide from refinery gases and natural gases were developed to a high point of efficiency and economy. They permitted the recovery of the gas utilized as a fuel where the quantity of sulphur is too small to be valuable, or as a source of elemental sulphur where economy dictated that procedure. The process purifies the gas, a particularly important procedure where polymerization is concerned, and, at the same time, supplies by-products frequently of definite value.

In all this work, notable and essential contributions from other fields have been made—among them, the design and construction of huge conversion and catalyst chambers to stand high temperatures and pressures. The perfection of the modern tube still and fractionating tower, to replace the old shell still equipped with air condensers, should be referred to. The important contribution of those long experienced in design, erection, and operation of distillation equipment, heat exchangers, control and recording devices, and the multitude of items which make up the impressive equipment of the modern oil refinery, all have a part in this modern program. The development of treating processes using fuller's earth as the contact catalyst has served to increase the yield and quality of cracked gasoline, as well as lubricating oils, without contributing to the cost of production.

Lubricants have been improved no less than the fuels, and no less importantly. The discovery of inhibitors against the oxidation of gasoline was also important to the lubricating oils in use; and, if improved design of engines has required more of the fuel, it certainly increased the burden upon the lubricant—which has been met by extreme-pressure lubricants and other types essential to successful operation. Lubricating oil has been the subject of intensive research study. The old sulphuric-acid method of refining has been largely abandoned for the modern solvent-refining methods capable of yielding oil of exceptional stability, and at the same time lowering manufacturing costs. Whereas previously unstable fractions were lost to sludge, under these methods all the oil is recoverable, and even the rejected fractions

have been found to contain valuable hydrocarbons of the unsaturated, or aromatic, type which may find their own place in commerce as the starting point of chemical synthesis. The development of propane and similar de-asphalting methods made possible the employment for lubricating oil manufacture, of crudes which might otherwise be regarded as too low in grade for anything except fuel oil. The application of solvent and similar de-waxing methods resulted also in an increased supply of lubricating oil of adequately low solidifying temperature, with consequently improved lubrication in cold weather, with easier engine starting and less cold-weather wear of engine parts.

Solvent-refining methods, both for improving oxidation stability and viscosity-index characteristics, as well as for removing waxes, have been rapidly developed; but research has also shown the possibility of obtaining similar results by the addition of certain synthetic substances for reducing the pour-point of petroleum oils which permit the attainment of the desired low-temperature fluidity without resorting to expensive very low-temperature de-waxing, and at the same time preserve in the oil all its desirable characteristics. Research continued in the attempt to improve the viscosity-temperature susceptibility characteristics, or fluidity at low temperatures, by the addition of various types of heavy synthetic oil. Corrosion inhibitors have been important factors in improvements in oils. Remarkable synthesis of lubricating oils has been made from such diverse substances as paraffin wax and natural gas, an example of molecular rearrangement with a definite service in view.

The benefits to the motoring public resulting from research in lubricating oil include: (1) easier starting in cold weather; (2) lower consumption of lubricants per car-mile; (3) greater mileage from gasoline resulting from better sealing of the piston rings; (4) reduced wear on bearings and other moving parts, with resultant reduction in maintenance costs; and (5) less carbon formation, and as a result less frequent cleaning of piston and cylinder heads. An example of what better lubrication means may be found in the field of aviation. Superior oils produced by extraction methods, and with suitable addition agents, have increased the time of overhaul from 100-to-200 to 500-to-1,000 hours, and at the same time, have contributed to the smooth operation of the modern aeroplane engine. Because of hypoid gears with their extreme-pressure lubricants automobile manufacturers have been able to lower the body of the car, thereby securing greater safety and reduction in weight.

The use of these improved extreme-pressure lubricants and cutting oils extends over into many manufacturing operations, for they permit greatly accelerated production speeds in the fabrication of steels and the working of alloys hitherto impossible. Using these improved cutting oils the average machine shop with the same personnel and equipment can turn out at least 100% more work.

There has been much research in asphalt development, in cooperation with highway engineers and paving technicians. Asphalt has been found more economical in first cost, maintenance, and improvement expense than other surface materials. Notwithstanding the enviable position of the United States as compared with many other countries in the matter of thousands of miles of paved roads, it is not likely that the country's paving program will ever be completed, because there is always the question of secondary or farm-to-market roads and the necessity of rebuilding, straightening, resurfacing, and other factors of road improvement.

A field of great importance, which has scarcely been touched, is the production of solvents and many other chemicals from petroleum as the raw material. The availability in petroleum fractions of the molecules needed for this purpose is known, and these fractions are occurring in an increased number and variety. The American petroleum industry itself has entered the industrial chemical field through the utilization of available hydrocarbons for the manufacture of iso-propyl and the higher alcohols and their ethers and esters, which have been produced from olefins available in the cracked gas. Synthetic ethyl alcohol and other members of the alcohol family of important solvents are derivatives of petroleum through the synthetic route. By making avail-

able aliphatic hydrocarbons in large quantities, an aliphatic chemical industry has been built up which may rival in importance the aromatic chemical industry of which the products derived from coal-tar are the outstanding example.

The petroleum industry also has developed viscous oils and rubber-like products from gaseous hydrocarbons. These polymers have material resistance to acids, alkalis, weathering and aging; and are used as coatings for all sorts of base materials. They are found useful in rubber compounds, improving the latter in many respects. There has also been made available a variety of synthetic resins made from oxidized hydrocarbons.

INCREASED RANGE OF MANUFACTURE AND USE OF PETROLEUM PRODUCTS

Almost the entire American economy depends upon the rapid, uninterrupted, and economical transportation of people and of goods, and, to different degree, the same applies to all advanced countries. But most of the tremendous social and economic changes that have taken place in the United States can be said to be a direct result of the growth and progress of transportation. Development of automotive transportation in the United States, for instance, is one of the greatest economic phenomena of all history. It has put travel upon such an economical, personalized basis as to make self-transportation both practical and universal. At the same time it has contributed to the progress of other forms of transportation which have made progress.

Passenger motor vehicles, privately-owned, in the United States travel about 500,000,000,000 passenger-miles per year. Motor trucks provide annually more than 60,000,000,000 ton-miles of commercial transportation. Motor buses carry some 4,000,000,000 passengers more than 2,000,000,000 miles a year. Aside from making possible the development of automotive transportation, petroleum supplies the fuels and lubricants necessary to the functioning of every other form and medium of transportation.

Petroleum lubricating oils and greases are indispensable to industry, necessary to the continuing operation of every machine, essential to every wheel that turns. Between 1879 and 1929 the value of the output of the factories of the United States increased 14 times to \$70,000,000,000 from \$5,000,000,000. In the same period consumption of petroleum lubricants expanded 40 times to 23,609,000 bbl. from a mere 552,000 barrels. It is inconceivable

that this tremendous advance in industry could have been possible without petroleum lubricants. No satisfactory substitute for petroleum as a lubricant is available. Literally there are hundreds of different petroleum lubricants developed for special purposes and to meet unique industrial demands. A whole new science of industrial lubrication has been developed.

Lubricants formerly used, such as those obtained from whale oil, never could have served growing industrial demand. Whale oil, limited and difficult of production and with output depending largely upon the whim of nature, costs around \$35 a barrel as compared with approximately \$1 for crude oil. Petroleum lubrication, being economical, satisfactory, and constantly available, has made possible the modern machine technology, mass production, continuous operation, widespread transportation, and even the generation of electric power.

Industry has come to depend upon petroleum also for heat and power. In many industries, such as glass, cement, and baking, fuel oil is virtually indispensable to instant and effective control of temperature. In the United States, homes also rapidly have changed from coal to oil heat. There has been an almost universal adaptation of the world's vessels to oil consumption. Nearly every ship built in recent years, and building, has been designed to utilize oil fuel. Mechanization of the world's armies also has placed highest importance upon oil for fueling and lubrication. Until comparatively recently there was a great demand for kerosene, man's first satisfactory illuminant. Kerosene still is an essential of farm life for light, for heat, for refrigeration and, to a degree, as fuel for farm machinery.

These are the more obvious manifestations of petroleum employed as a source of light, of heat, of power, of machine lubrication. Added to them are petroleum as a medicine and petroleum as a road material—*asphalt*. But out of petroleum come products whose number is so great and range of utilization so wide, as to defy listing. From petroleum come alcohols for the hospital and the home, solvents in the making of lacquers, soaps, and essential oils, products that on the one hand kill the parasites on the trees and on the other help to preserve the fruits and vegetables that are shipped in jars and containers.

Grown out of the utilization of the liquefied petroleum gases, propane and butane, is the "bottled gas" industry giving homes in suburban and rural areas fuel for cooking, heating, and refrigeration. Chiefly supplied from natural gas, in the production of natural gasoline, and from refinery gases, these liquefied gases are members of the series of hydrocarbons predominant in gasoline. Normally gases, they are generally liquefied under moderate pressure so as to facilitate storage and transportation. The product is used as a fuel in motor buses and rail cars. Furnishing exceptional heat value and easily controlled, propane and butane also are used as fuels in special industrial processing, and then again—proving their versatility—they may be used in the same

plant as solvents or refrigerants before their final consumption as fuels.

Of increasing importance to the chemical industry are the chemical products recovered from petroleum gases. Cracked gases—ethylene, propylene and butylene—readily enter in chemical combinations. Chemists make from these a product similar to glycerine. Great quantities are used as an anti-freeze mixture for car radiators or as a basis for the manufacture of explosives. Ethylene is used for ripening fruit. The orange growers and the tomato farmers know it. The oxidation of ethylene gives ethylene oxide, a gas widely used as an insecticide for preserving the grain of wood. Also it is applied as a fumigator to ships and buildings.

Propylene and the butylenes are converted into the widely used propyl and butyl alcohols. Their acetates, applied as solvents, made over the paint industry into the lacquer industry. These alcohols are converted by oxidation and dehydration into bodies called ketones. The ketone of iso-propyl alcohol is a remarkable solvent employed in the rayon, explosive, and other industries. The ketone of secondary butyl alcohol, besides being an excellent solvent for many purposes, finds an application in the making of perfumes, and tertiary butyl alcohol is used in the perfume industry for synthesizing artificial musks. It also is employed in the petroleum industry itself to prevent the formation of gum in cracked gasoline, and it is used for artificial resins. These are some of many uses of gases formerly wasted in the air.

Certain petroleum oils have found considerable outlets in the preparation of transparent window-shades, the spraying of coal and coke to reduce dusting, the spraying of trees and plants for killing insects, fungi, termites and other parasites, as well as in the preparation of textile oils, printing inks, paints, and numerous other compositions.

Hydrocarbons as such, are valueless as food, since other elements must be present. Sugar and fats contain oxygen beside carbon and hydrogen. Meat, or to be more scientific, protein matter, contains nitrogen in addition to all these other elements. Hence before petroleum can be utilized as a food these elements must be introduced into the hydrocarbon in their particular form. The chemist has already been successful in producing sugar and fat from petroleum. When hydrocarbons are heated with air, ozone or similar agent, fatty acids may be produced. Such hydrocarbon fatty acids were fed to the German soldiers during World War I, due to the great shortage of fat in Germany at that time. Since fats, such as lard, butter, oleomargarine, are mainly glycerine esthers of fatty acids, there appears to be no reason why the corresponding compound prepared from a petroleum hydrocarbon such as wax should not have food values in the same range.

A pure ethyl alcohol, the active ingredient in Spiritus Frumenti, is being made in large quantities from refinery gases. Oddly enough, petroleum also yields a denaturant which is added to the alcohol to prevent unlawful diversion to this channel. Synthetic wood alcohol or methanol can be easily made from petroleum gases and steam. Acetic acids, the mouth-watering ingredient of vinegar, can also be prepared by oxidation of gases of gasoline. The neutralized sludge obtained by acid treating of petroleum has been found suitable for reducing dusting of coal as well as breaking in transit. Eggs are coated with petroleum white oils before cold storage. Drying oils superior to linseed oil have been pre-

pared from petroleum. Carbon black, an important constituent of rubber tires, is obtained by the burning of petroleum natural gas.

INVESTMENT AND CORPORATE SET-UP

The oil business in the United States is a mass production enterprise, turning out large volumes of standardized commodities at low cost. Mass production, together with certain characteristics of the crude product it deals with, has determined its economic structure and has largely dictated its pattern. Oil, a liquid occurring in widely scattered localities and requiring both "wild-cat" and scientific efforts for discovery, has needed specialized forms of transportation—the pipe line and tanker—invented for the purpose. With no commercial value in its crude state and made up of chemical compounds, it has required refineries to convert it into multiple products and by-products, and a great variety of marketing media as these derivatives are required in standardized form and in small units of sale at numberless points throughout the world. The industry in consequence has been likened to an hour-glass with raw material drawn from innumerable fields, concentrated into channels of flow through the transportation and refining systems, and again deploying into myriad lines of movement to countless points of final consumption. Vast amounts of capital are essential to the operation of this system.

The petroleum industry of the United States utilizes about \$14,500,000,000 of capital, representing the second largest investment of any United States industry. It gives employment to over 1,000,000 workers, constitutes a large customer for a wide range of other industries, and serves practically the entire economy with essential commodities. The industry annually contributes to the national economy a direct cash income estimated at \$4,150,000,000. This comprises salaries and wages to the industry's own

people; royalties, rentals, and bonuses to land-owners, chiefly farmers; payments to other industries for equipment, supplies, and services; a payment to railroads which represents the largest single freight bill for transporting manufactured products; and a tremendous payment of taxes of more than 201 varieties to Federal, State, and local Governments. In its far-flung operations, the industry, with producing activities in 22 States, refining in 32 States, and marketing in all States, utilizes the talent and skill of practically every profession and trade.

The petroleum industry's bill for equipment and supplies adds up to an estimated \$876,000,000 a year, as shown in Table XVII.

Co-ordination of flow from well to market, as well as the ever-growing factor of technology applying to all the industry's operations, has tended to integrate corporate activities, and the expansion of oil utilization itself has brought about great increase in size of the oil corporations as is the case with other expanding American industries. This applies to several former Standard Oil units split up by court decree in 1911 and also to several great independent corporations which have vied with them in size and scope of operations since the beginning of the Gasoline Age. In 1937 the 20 largest companies in the field of crude oil production produced 56.2% of the nation's output, the individual companies ranging from 0.9% to 6.3%. The remaining 43.8% was produced by thousands of smaller enterprises ranging from a small fraction of 1% to 0.9%. For the same year, the 20 largest refiners processed 83.7% of the nation's total crude oil run to stills, ranging individually from 0.6% to 12.3%, while the remainder was refined by several hundred smaller units. The 20 most highly integrated refiners produced 72.5% of their refinery requirements, purchasing the remainder from others. About three-quarters of the business of the petroleum industry is conducted by companies engaged in all branches of the business—production, transportation, refining, and marketing—while the rest is transacted by units operating in only one or two divisions.

This scarcely reveals, however, the competitive set-up, with the separate large corporations, including former Standard Oil units, in active and intensive competition with each other, and

in competition with the vast number of smaller units operating in the various branches of the industry. Among the larger oil companies, integration varies and scope of operations such as marketing territory varies. Of the 23 largest companies, only two were shown to market gasoline in every State. One sold in as many as 45 States, and two in 44 States. All except six marketed their products in more than ten States. In the producing fields there were between 7,500 and 9,000 large and small separate oil operators.

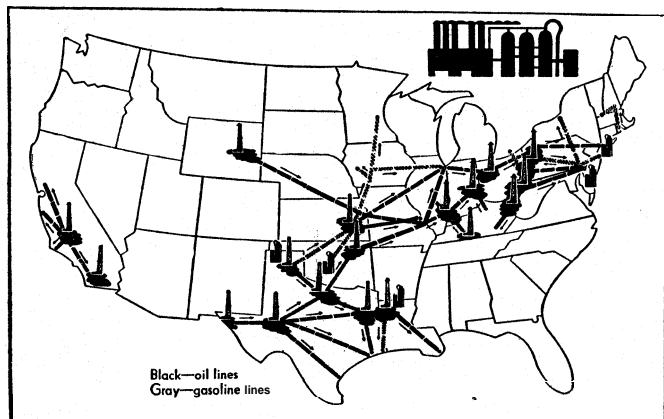

The growth of the American petroleum industry has been very rapid. In 1906 the investment in the industry was estimated at \$750,000,000; in 1911 it had increased to over \$2,000,000,000. Then came the motor car to challenge the industry to produce enough crude oil and gasoline for its omnivorous needs. Within the next 25 years the industry had to put \$11,000,000,000 to \$12,000,000,000 more into facilities to meet this and other challenges levelled at it by petroleum consumption agencies.

PRODUCTION

In 1937 two-fifths of the mineral wealth of the United States was derived from petroleum, and in 1936 oil added \$1,000,000,000 to the income of the States as shown in Tables XVIII and XIX.

To meet the annual need for crude oil some 27,000 new wells must be drilled in the United States every year, and there are nearly 360,000 wells producing oil.

Drilling equipment alone accounts for a little more than half of the petroleum industry's annual bill. Deep drilling practices and technological progress have revealed greater petroleum reserves and have produced more oil, but also have increased in-

FIG. 5.—DIRECTIONAL FLOW MAP OF CRUDE-OIL AND GASOLINE PIPE LINES

dividual operating expenses. The steel industry, in 1937 alone, manufactured for petroleum producers and pipe line operators more than 1,250,000 gross tons of oil-country tubular goods. Every branch of the petroleum industry buys iron and steel products in many forms.

Achievements in the fields of scientific prospecting and production engineering represent a combined factor that has contributed signally to the reduction of costs in production and the enlargement of available supplies, which in turn have gone far toward offsetting the physical losses engendered as a result of competitive drilling under the rule of capture. During the period of proration, 1927-38, the price of crude oil averaged \$1.04 per barrel, with a range in annual averages of \$0.65 to \$1.30 per barrel.

TRANSPORTATION

Crude oil is transported by means of special facilities created by the industry. The two principal types of conveyances used are the pipe line and the oil tanker. Only a small fraction of the crude oil produced is carried by the railroads because pipe lines and tankers offer superior efficiency and lower transportation costs.

For liquids available in sufficient volume with a concentrated market the pipe line affords the most efficient form of overland transportation. While capital costs are substantial, rights of way are not expensive, the operation of the system is automatic

to a high degree, movement is continuous and there is no problem of two-way traffic or return movement of empty facilities. Because of these advantages and the technical efficiency of the modern pumping systems, the average cost of pipe line transportation probably does not exceed 4 mills per ton mile, which contrasts with an average cost of movement by rail of approximately 8 mills per ton mile. Thus, no natural competition can persist between oil pipe lines and the railroads.

The oil pipe lines of the United States constitute a far-flung system connecting the oil fields with the principal consuming centres and water terminals. The aggregate length of lines is approximately 115,000mi., of which 60,000mi. are trunk lines and 55,000mi. are gathering lines—almost one-half of the combined length of all railroad mileage. The pipe lines are in 24 States, but as the equipment is largely below-ground and only marked by an occasional pumping station, its magnitude and importance are not commonly realized. The system consists of trunk lines and what are known as gathering lines, which connect with the flow tanks of individual oil wells. The pipe line, therefore, forms a link between the oil wells and the refineries and the flow of oil is practically continuous from lease to plant.

Pipe lines are by nature large-scale enterprises. The Interstate Commerce Commission in its report on interstate pipe line operation for 1937 listed only 58 companies, which represented about 84% of the pipe line mileage of the country, the remainder being intrastate systems not subject to regulation by the commission. The 58 companies represented a total investment of \$890,000,000; transported 948,000,000bbl. of oil originating on the lines or 1,288,000,000bbl. including duplications; and employed 24,168 men, with an annual payroll of \$45,000,000.

The interstate systems, as well as the lines operating within a single State, are for the most part subsidiaries of integrated oil companies. Of the 58 units listed, only 14 were not affiliated with refining companies and these independent lines represented only 10% of the total trunk line mileage of all interstate lines. Pipe lines have almost invariably been constructed by refining interests which looked upon them as an adjunct to the manufacturing enterprise necessary to insure a continuity of raw material, a partial offset to the variable and shifting nature of crude oil production; they have rarely been built by producing interests or by promoters not already engaged in the oil business. With the evolution of proration the presence of refinery-affiliated pipe lines and a posted market at the well greatly facilitated the practical operation of the mechanism of control.

Pipe lines function as common carriers in cases where demand for this service exists. Although the bulk of the oil is still moved for the account of affiliated refineries, there has been a tendency for two or more companies to unite in the construction of joint facilities. Pipe lines charge specified rates for the movement of oil, and these tariffs for interstate movements are under the supervision of the Interstate Commerce Commission. Pressure has grown for legislation to divorce integrated pipe lines from refining companies on the ground that they tend toward

monopoly and unfair practices. The principal objective of this pressure is to make pipe lines common carriers in actual fact, but the owners stress the relationship of the pipe line as a plant facility.

Pipe line transportation has been successfully applied to gasoline, but the volume moved through pipe lines is only about 10% of the quantity of crude oil transported in this way, and around 15% of the total motor fuel produced. The aggregate length of the gasoline pipe lines of the United States is around 8,000 miles. While this system has not attained its full development, the gasoline pipe line is economically applicable to special situations where transportation by water is impractical. The pipe line movement of gasoline is feasible where there is a supply in excess of nearby requirements and concentrated markets exist into which this supply can be moved. The longest lines have been developed in the central States as a relief to the large manufacturing capacity plants in the Mid-Continent area.

The oil industry also has provided its own facilities for the movement of oil by water. The industry maintains a fleet of 750 tank ships for use on the ocean, the Great Lakes, and rivers and canals, representing an estimated investment of \$530,000,000. Over half the traffic is refined products, and nearly one-third of the crude oil traffic moved is on coastwise, intercoastal, and inland waterways. In 1938 approximately 75% of the domestic crude oil was delivered to refineries by trunk line, 22% by boats, and the remaining 3% by tank car and truck.

Petroleum products are largely shipped by rail or by tank truck, and the petroleum industry is the largest shipper of manufactured products by rail. The industry owns and operates 130,000 motor trucks, of which 40,000 are tank trucks. The petroleum industry has provided the bulk of its own tank cars for rail movement.

FIG. 6.—NUMBER AND CAPACITY OF U.S. REFINERIES

REFINING

The United States petroleum industry's investment in refineries has been estimated at \$3,700,000,000 in 1937. Petroleum refineries are located in 32 States, but about 90% of the total refining capacity of the country is concentrated in 10 States, with Texas in the lead with 29.5%. The seaboard area along the Atlantic and Gulf coast accounts for 41.4% of the country's total capacity; the interior, for 33%; and California, for 20.6%.

On Jan. 1, 1938, there were 561 refining establishments in the United States, of which 431, representing 77% of the total capacity, were operating, 120 were idle, and 10 were under construction. Of the operating plants 24.9% of their total capacity was represented by units with capacity of 100,000bbl. per day or over; 12.9% by units with capacity of 50,000-99,000bbl. daily; 15.3% by units of 25,000-49,000bbl. daily; 25.6% by units of 10,000-24,000bbl. daily, and 21.3% by units below 10,000bbl. daily capacity. Thus, 104 plants represented 78.7% of the operating capacity of the country, while 327 plants accounted for 21.3%. The natural economic advantage of large-scale operation in areas contributory to concentrated markets has tended to develop refining on a mass production basis.

A basic economic problem faced by any manufacturing activity is the maintenance of equilibrium between supply and demand, and this problem presents specialized features in the case of an enterprise involving the production of a range of products from a single raw material. Not only must the supply of the main product

be kept in balance with its demand, but sufficient flexibility in processing and pricing must be developed so that the joint product will be carried off in trade in the proportions in which they are manufactured. In the case of petroleum, gasoline constitutes the main product, and kerosene, distillate, fuel oil, and lubricating oils are the principal joint products. With the demand for each of these products influenced by different economic factors it is apparent that the refining industry constantly faces the necessity of avoiding shortages or overages of one product or the other. It faces an additional problem in balancing its overall operations with the requirements of the market.

The refining industry was practically rebuilt to provide cracking facilities so that the increased demand for gasoline could be met. The result is that cracking plant capacity doubled in ten years, and cracking in 1938 led all production methods, as shown in Table XXVI.

Natural Gasoline.—Closely related to petroleum refining is natural gasoline manufacture, which has played an important

role in the conservation of oil and gas resources and opened up new fields of utilization.

Development of new uses of liquefied gases, recovered at refineries and natural gasoline plants, has built up the use of so-called "bottled gas" in homes, industries, and transportation.

Heating Oils.—The refining industry has found an increasing market for heating oils, these showing in 1937 an increase of 400% over 1936. In 1939 more than 1,650,000 United States homes had oil burners as central heating systems.

MARKETING

The integration of large oil corporations has been less successful in its inclusion of the marketing division—that is, the retail marketing of gasoline—than the other divisions of operation. To recount their excursion into this field and their retreat therefrom, is to tell the story of mammoth competitive struggle affecting the whole industry and the hundreds of thousands who man the gasoline pumps in the United States, as well as of the establishment of a service to the motorist that in its universality and thoroughness surpasses credibility.

By modern standards of American "Big Business," the old Standard Oil monopoly was in incomplete organization. Prior to the dissolution in 1911, it had gone quite a distance in harmonizing crude oil storage and transportation with refining, but it produced little oil and had not developed controlled outlets for its products. At the one end it relied upon independent producers; at the other, upon independent jobbers and retailers. But gasoline had not yet come into the picture; gasoline still largely was a waste by-product. After 1911, however, the motor car took hold rapidly and as rapidly gasoline became the principal, or "money" product of the industry. On that tidal wave, large oil corporations other than Standard Oil came into being. In almost every instance, these were born in the oil fields; that is, they were launched primarily on their huge production sources. The next step was for them to build and operate their own refineries to give their crude oil an assured manufacturing outlet. They

built their own pipe lines to transport their own crude oil to these refineries. The final step was for them to establish their own dealer outlets for gasoline.

It was these companies, rather than the Standard Oil, which set the pattern of complete integration in production, transportation, refining, and marketing. Integration was a development characteristic of corporate growth and operations generally during this period, and, in the case of the oil companies, a natural one because of the high degree of mutual interdependence of the industry's processes, especially pronounced in large-scale operations. For various reasons, it took years of remodelling for some of the divorced Standard Oil units to achieve the same degree of integration as these companies; certain units were wholly marketing, or wholly transporting, or wholly refining companies. The first step was for some of them to get their own production, which they did promptly; the next, was to find marketing outlets for their refined products. At the time of the dissolution and for several years afterwards, the Standard Oil companies did the bulk of the total business in petroleum products, but the new companies, including The Texas Company, Gulf Refining Company, Phillips Petroleum Company, Sun Oil Company, and Sinclair Refining Company and many others, steadily cut into the business of the companies created after the dissolution of the old Standard Oil Company. In territory after territory, the proportion of the total business done by the Standard Oil Company originally operating in that territory decreased over the years. The second notable competitive development was the invasion of each other's territories by the companies into which the old Standard Oil Company had been separated. One of the first such invasions was that of New England by the Atlantic Refining Company, beginning in 1916.

Once a beginning had been made, the movement was very rapid, accentuated by the urge toward integration felt by most of the old Standard Oil successor companies. For instance, the

Standard Oil Company (New Jersey), the parent company, was left with a very large share of the old company's refining capacity, much of which was concentrated in New York harbour. It was left without marketing facilities for its output, and sought as rapidly as possible to secure large outlets for its products. At hand was the then Standard Oil Company of New York, with limited refining capacity and extensive outlets in New York and New England. At one time sales of gasoline by the Standard Oil Company (New Jersey) to the Standard Oil Company of New York were as high as 11,000,000 bbl. a year. But as time went on the Standard Oil Company of New York, like most of the important companies in the industry, sought to make itself a well-rounded unit by acquiring crude oil resources and expanding its refining capacity. The Standard Oil Company (New Jersey), needing outlets badly in New York and New England to replace its decreasing business with the Standard Oil Company of New York, had the alternative of invading the territory with new outlets or buying an established marketing organization in that territory. It elected to buy the Colonial Beacon Oil Company, an established company. This was the start of the Standard Oil Company (New Jersey) into direct marketing which later expanded to cover all the eastern seaboard States and many States of the South and Southwest.

In the meantime, with the growth of motor car use, an amazing gasoline distributing system was evolving. Prior to the rise of automotive transportation, the oil industry was primarily an illuminating oil industry, distributing this product by tank wagon delivery. This method of distribution was ready at hand when gasoline came upon the scene, and, so long as the volume was small, its sale was conducted through the same channels as kerosene—the grocery store, the hardware store, and the blacksmith shop. Garages, however, were soon established for servicing automobiles and provided new outlets for gasoline. The garageman was the first type of gasoline dealer. Then there came the gasoline pump, and with it the filling station, dispensing gasoline and lubricants exclusively. Filling stations at first increased slowly, as cars were not on the roads in sufficient number or concentration to justify heavy investment. It is estimated that in 1920

there were no more than 15,000 filling stations in the United States. But from that time on, filling stations gained terrific momentum, surging ahead with automobile production. As cars increased on the road, they presented the problem of keeping filled nomadic tanks whose thirst could be more fatal to the traveller than the horse's; for the horse could reach the next watering trough, while a car would sputter out and "die" miles short of the nearest filling station or grocery store. This problem was solved by the wayside station, by pumps installed at roadside taverns, hot-dog stands, parking lots, and every conceivable roadside location. All getting their supplies through tank wagon delivery. As a creator of small business enterprise in cities and towns up and down the countryside in the United States, gasoline has had no rival. Gasoline retailing became the sole business of many, a supplemental source of income for thousands upon thousands more—all gasoline dealers or commission agents.

This development had behind it not only the growth of automobile demand for gasoline but the break-neck speed of the increased demand. In 1918 there were 6,000,000 motor vehicles in the United States; by 1925 there were 26,000,000. Moreover, during the early 1920s the mounting supply of crude oil began to build up an economic pressure which sought relief in increased retail outlets. The oil companies did not command sufficient capital at that time to build filling stations rapidly enough themselves,

so they vied with one another to gain more and more new dealers. In this manner a widely scattered army of dealer outlets was established. Even with this, they failed to expand their outlets fast enough to carry off the growing supply, so the surplus was thrown on the wholesale market. Thus an opportunity was created for the entrance of the jobber who purchased this marginal surplus of gasoline and disposed of it in direct competition with the companies from whom he purchased it and through dealers in direct competition with company dealers. The scramble for gallonage on the part of the refiners, or suppliers, involved at times price wars, and a generally unstable price market.

Meantime, enterprising gasoline dealers, not satisfied with one station, started small chains which, in some cases, grew into large State-wide chains. They invested the filling station with a line of services for the motorist that changed its name to "service station." During this time, the large refiners, from a small beginning in owning and operating a limited number of their own stations, went wholeheartedly into direct ownership—proceeding with the final stage of integration, that of gasoline retailing. They took over independent stations and chains, bought up expensive locations, built stations of architectural splendour, launched an era of super-service station extravaganzas. They took a leaf from their dealers' book and went further than they in complete servicing and variety of services and accessory lines. In 1929, retail integration was in full swing, and the result of all the expansion of stations and pump outlets by companies and dealers was a physically efficient, highly convenient but overdeveloped and consequently high cost mechanism. Ubiquitous and duplicated service station facilities constituted a phenomenon that never ceased to amaze the motoring public.

However, over-building and duplication did not involve the motorist in the necessity of paying high prices for his gas. During these years, the price of gasoline actually went down, even to the extent of much more than absorbing mounting taxes levied against gasoline by more and more States. The average U.S. retail price in 1920 was 29.7¢ per gallon; in 1929, 17.9¢; with State gasoline tax included, it was 29.8¢ in 1920, and 21.4¢ in 1929. Besides, the motorist from time to time received the benefits of drastic price wars, and he was being overwhelmed with free services. The downward trend of gasoline prices, even more pronounced in later years, was sufficient evidence of price competition in the petroleum industry, with, of course, com-

petitive drilling under the rule of capture, over-supply of crude oil and technological advances which increased the available supply of gasoline also factors.

Entrance into retail marketing was clearly an attempt, dictated by expediency, of the integrated companies to help stabilize the gasoline price market. From the very beginning, the suppliers generally assumed the responsibility for establishing posted retail prices, which automatically meant the acceptance of responsibility for determining the retailer's margin. Thus, throughout the latter 1920s and early 1930s, retail margins in many areas were set at 3 to 3½¢ per gallon; but companies breaking into new territories, seeking dealers to expand their distribution, frequently offered 46.5¢, and even occasionally 6¢ margins. Besides, they gave other inducements, such as free pumps and other equipment. The dealer's margin came to be known as a "guaranteed" margin. Theoretically, at least, the dealer at the service station could sit back and watch a price war, pocketing his margin and letting the chips fall where they might on the supplying companies. The high proportion of costs in a retail filling station which do not change as gallonage increases has always constituted a strong temptation to resort to price cuts in order to secure more gallonage. Retail station operators with "guaranteed" margins were prone to cut the posted retail price by secret discounts and concessions. The integrated companies with their own stations could not very well initiate price-cutting without embroiling themselves with their own dealers.

The depression starting in 1930 spurred, rather than checked, the growth of gasoline outlets, for many individuals, finding themselves out of their regular employment, invested their limited savings in the gasoline retailing business. But the collapse of values hit the companies having large investment in owned-stations. Moreover, integration of retailing had not worked out in a way to stabilize the vast

TABLE XXXI. Domestic* Oil Burners in Use, by Years

and far-flung retail price market. Stations owned by integrated companies still were but a small percentage of the total outlets, totalling at their peak about 33,000 in number against 164,000 independent stations and 179,000 secondary outlets, and accounting for not more than one-third of the total retail gasoline sales. Some of them began quietly to divest themselves of their own stations. In 1934, according to the Petroleum Administrative Board, approximately 7,700 stations out of the 33,000 company-owned stations had been transferred to lessees. The unloading trend very definitely was accelerated by burdensome chain-store taxes and the more and more pronounced labour factor, with wages going up and hours going down, and later by social security legislation. In the State of Iowa in July 1936, a chain-store law specifically applying to gasoline filling stations, went into effect. This caused the Standard Oil Company (Indiana) to turn back to their original owners or to individual lessees, many of whom were company employees, all its owned- or controlled-stations in that State. Having done this in Iowa, the company acted similarly in following years throughout its extensive marketing territory covering 20 Middle Western States. The "Iowa plan" of voluntary disintegration was fairly launched. Other integrated companies, following the lead of the Standard Oil Company (Indiana) beat a precipitate retreat from gasoline retailing. By 1939 all but a handful of the 33,000 stations owned or controlled by the large oil companies in the early 1930s were being operated by small-business owners or lessees, many of them former employees.

But mere relinquishment of their own stations does not tell all the story of the retirement of the integrated companies from retailing and the consequent renaissance of small business in the gasoline dispensing field. The "Iowa plan" in addition converted all dispensers of gasoline at the 226,000 service stations and at the 182,000 garages, wayside and other stands as well into retailers in fact, rather than dealer-commission men. The marginal contract which insured a fixed margin to the dealer, irrespective of the fluctuations in the retail price, was wiped out by the suppliers. While going in for a surgical remedy, integrated business amputated its entire retailing arm, including the "guaranteed" margin. The suppliers, instead of posting a retail price, posted a

delivered tank wagon price—wholesale price—and left in the hands of the dealer the question of how much he charged the motorist and made out of the transaction himself.

Probably in the whole history of modern American industry there never has been a more dramatic shifting of function than that involved by the large integrated companies giving the retail end of the gasoline business over to the dealer. The shift to the acceptance of responsibility for the retail price by retailers was not made easily. In many sections of the country a hectic period of readjustment began which had not run its course in 1939. Retailers rushed to form associations in many territories and establish prices which were to allow margins of 5¢, 5½¢, and even 6¢ per gallon. But the efforts of retail associations to maintain margins at extremely high levels were soon abandoned, and margins settled back to the 3 to 4¢ level. Local price wars were numerous and secret concessions pushed the margin level below 3¢ in many sections. Jobber groups attacked proration as the imputed source of their troubles. The distributing system of the petroleum industry became the focus of incessant dissension and the source of proposals for regulation and change. To some observers, the adjustment was attributed to the working of economic forces which might force large numbers engaged in gasoline retailing to withdraw over a long period of years thus contributing a solution to one of the major problems of the industry—over-building and duplication of service stations. The problem, however, also was a social one, inasmuch as a great army of people were involved and this introduced an element which tended to make it a potential weapon for far greater governmental control than had yet been exercised over the petroleum industry.

The number of service stations in the United States in 1938 was estimated as 226,000, compared with 121,513 in 1929. There were in 1938 a total of 182,000 secondary outlets such as garages.

Filling stations are not the only physical equipment required for the distribution of gasoline. There are terminals and bulk stations. The terminal is a large depot, usually at seaboard, for receiving the product unloaded from tankers. Other terminals, seldom as large as those along the coast, are located at inland points; and these are usually serviced by pipe lines. The bulk plants are wayside storage stations, comprising a few tanks, a loading rack, and often a ware-

TABLE XXXIII. Average Retail Price of Gasoline in 50 Representative Cities, by Years

 †Partly estimated.

house building, located within trucking distance of the retail outlets. The number of terminals and bulk plants in the United States was estimated in 1938 as about 20,000, having a value of \$348,000,000.

The average retail price of gasoline (excluding tax) in 50 representative cities of the United States declined from 21.06¢ per gallon in 1923 to 14.07¢ per gallon in 1938. During the same period and from the same cities the average gasoline tax, Federal and State, increased from 0.91¢ per gallon in 1923, to 5.44¢ per gallon in 1938. Expressed in dollars per annum per motor vehicle the gasoline tax cost to the motor vehicle user increased from \$4.37 in 1923 to about \$35.75 in 1938.

The American Petroleum Industries Committee estimated that the total amount of taxes collected from the petroleum industry, its products and customers in 1938 amounted to \$1,278,000,000. Reduced to a per barrel basis the aggregate represents \$1.05 per barrel of crude oil produced, against a weighted average price of \$1.18 per barrel. About three-quarters of the total represented State and local levies, while one-quarter was paid into the Federal treasury. About 59% of the total, or \$758,000,000, represented State gasoline taxes.

Besides supplying considerable capital for the development of the oil business abroad, the American petroleum industry imports and exports crude oil and products in substantial volume. In its foreign trade in oil the United States has long had a favourable balance of trade on a dollar basis.

PETROLOGY, the science of rocks, the branch of geology concerned with the investigation of the composition, structure and history of the rock masses building up the accessible portions of the earth's crust (Gr. *πέτρος*, rock). Rocks are usually defined as aggregates of minerals without reference to their state of cohesion. Loose sands, clays, gravels or soils are included among rocks as being mineral masses playing an important rôle in field geology. On the other hand, the less soluble parts of the skeletons of animals and plants may form a considerable portion of rocks as, for example, coral-limestone, lignite and chalk. Lastly rocks may be built up almost wholly of non-crystalline material as obsidian, pitchstone or tachylyte, representing liquids so rapidly chilled that consolidation has occurred in the glassy state. Rocks are the units with which the geologist deals in investigating the structure of the crust, and some varieties cover enormous areas. Granite, sandstone and schist often form whole provinces and build up lofty mountains, while other rock types are of such rare occurrence that they are known only in one or two localities in distant parts of the earth's surface.

Treatment of the Subject.—Broadly speaking, rocks are divided into three great classes, *igneous*, *sedimentary*, and *metamorphic rocks*. In this paragraph the subject matter of that part of the science of petrology concerned with igneous rocks is briefly surveyed; the object is to point out the headings under which particular subjects are treated (there is a separate article on each italicized item). Here we confine ourselves to a discussion of the nature, composition, classification and origin of igneous rocks, and the methods by which they are examined (for the other groups see **SEDIMENTARY ROCKS** and **METAMORPHISM**).

Igneous rocks occur as intrusions or extrusions. The plutonic or deep seated intrusive rocks which cooled far below the surface occur as *batoliths*, *bosses*, *laccoliths* and *veins*, and include *granite*, *syenite* *diorite*, *gabbro* and *peridotite*; related to the granites are *aplite* *greisen*, *pegmatite* and *schorl-rock*; to the syenites, *borolanite*, *monzonite*, *nepheline-syenite* and *ijolite*; to the diorites, *aphanite*, *napoleonite* and *tonalite*; to the gabbros *pyroxenite* and *thermalite*, and to the peridotites, *picrite* and *serpentine*. The hypabyssal intrusive rocks occur as *sills*, *veins*, *dikes*, *necks*, etc., and are represented by *porphyry* and *porphyrite*, *dolerite* and *lamprophyre*; to the porphyries belong *felsite* and *quartz-porphyry*. The extrusive rocks are volcanic and found typically as lava flows; they include *obsidian*, *perlite*, *pitchstone* and *rhyolite*, *phonolite* and *trachyte*, *andesite*, *dacite* and *basalt* (with the related *spilitite*, *tachylyte* and *variolite*), *nephelinite* and *tephrite*.

Intermediate between the sedimentary and igneous rocks comes the group of rocks known as pyroclastic or fragmental volcanic rocks. These include *agglomerate*, some types of *breccia* and *tuff* (see also **VOLCANOES**). The agencies which affect igneous (among other) rocks and modify them are discussed under **METAMORPHISM**, **METASOMATISM** and **PNEUMATOLYSIS**.

Composition of Igneous Rocks.—Though the number of recognized minerals approximates to 1,000, only a comparatively small number are important as rock-formers, more especially if the subdivisions into which the common species are broken up are disregarded. The vast majority of the igneous rocks are built up of less than a dozen groups of minerals. These are (1) quartz, (2) feldspars, (3) pyroxenes, (4) amphiboles, (5) micas, (6) olivines, (7) nepheline, (8) leucite, (9) iron ores and (10) apatite. To this list, for sedimentary rocks, we may add chlorite, kaolin calcite, dolomite, and a few other minerals. Metamorphic rocks are built up largely of the same minerals as igneous rocks but include special species which are foreign to igneous rocks, partly on account of their composition and partly because they appear to require special physical conditions (stress) for their production. The mineralogical nature of a rock is primarily dependent on its chemical composition, but other factors are of first importance in determining the paragenesis of rock-forming minerals, principally the mode of origin of the rock or the physical conditions obtaining during its formation. Two rock masses may

have very much the same bulk composition and yet differ fundamentally in their mineralogical assemblages. Thus, certain lamprophyres rich in biotite have much the same composition as certain leucite-basalts, a hornblendite as a camptonite and so on. Igneous rocks of identical chemical composition but dissimilar mineralogical constitution are said to be heteromorphous. The governing factors are the physical conditions attending consolidation of the rock.

All crystalline rocks have consolidated from solution or from fusion. A granite arises by the consolidation of a liquid at high temperatures and great pressures; a metamorphic rock like mica-schist, on the other hand represents the recrystallization-product of a clay rock under the influence of heat and stress. Throughout this conversion the rock has been essentially solid, recrystallization taking place in the presence of minor amounts of interstitial liquid. Other crystalline rocks, like rock-salt, gypsum, anhydrite, etc., have been deposited from solution in water, mostly owing to evaporation on exposure to the air. The majority of sedimentary rocks, however, consist of a mechanical aggregate of crystalline particles; such are sandstone, clay, etc. The structure of these sedimentary and all pyroclastic rocks is referred to as fragmental.

Origin of Igneous Rocks.—All igneous rocks have solidified from a state of liquidity, the liquid that finally consolidates as rock being technically referred to as magma (Gr. *μάγμα* from *μάσσειν*, to knead). Rock-magma is a complex silicate solution carrying gases, the most important of which is water, which may constitute 5-6% of the mass. The greater part of the clouds given off by active volcanoes consists of steam, with which is associated minor amounts of other gases, the chief being CO₂, CO, HCl, S vapour, oxides of sulphur, H₂S, HF, NH₃, CH₄, Cl, F, H and N. When the magma consolidates the major part of these volatile constituents usually escapes. With very rapid cooling, however, the magma may solidify without crystallization as a volcanic glass, at the same time retaining much of its water. Analyses of pitchstone show not infrequently a content of 5-6% of water, and even higher values are recorded; on the other hand unaltered crystalline igneous rocks seldom show a water content greater than 2%. Here we have almost direct confirmation of the conclusion that the water-content of the magma before crystallization is greater than the water-content of the rock formed from it.

From what source is igneous magma derived? In the older conception of the earth a volcano was pictured as a safety valve of a molten interior, but a close study of igneous action, past and present, clearly negatives any such interpretation. The active vents of Mauna Loa and Kilauea (Hawaii) though only some 20 m. apart, have the summits of their lava columns at a difference of level of 10,000 ft. Yet liquid lava is erupted more frequently and in greater quantity from the higher column. Clearly these two outlets are not directly connected with a common liquid reservoir. Again, neighbouring vents, as those of the Lipari Isles, erupt widely different products, and each may maintain its independent behaviour regardless of what is happening to its neighbour. The conclusion is enforced that each distinct eruptive centre possesses its own reservoir, and we must conceive a number of independent magma chambers underlying an eruptive region. At greater depth these are no doubt connected with some magmatic reservoir of much larger dimensions. In some such common source the close community of petrographic character revealed in the succession of liquids erupted or intruded throughout any given igneous cycle is to be traced.

METHODS OF INVESTIGATION

Macroscopic Characters.—The macroscopic (Gr. *μακρος*, large) characters of rocks, those visible in hand-specimens without the aid of the microscope, are very varied and difficult to describe accurately and fully. The geologist in the field depends principally on them and on a few rough chemical and physical tests; and to the practical engineer, architect and quarry-master they are all-important. Although frequently insufficient in themselves to determine the true nature of a rock, they usually serve for a preliminary classification and often give all the information

really needed. With a small bottle of acid to test for carbonate of lime, a knife to ascertain the hardness of rocks and minerals, and a pocket lens to magnify their structure, the field geologist is rarely at a loss in deciding to what group a rock belongs. The fine grained species may be indeterminable in this way, and the minute mineral components of all rocks can usually be ascertained only by microscopic examination; but it is easy to see that a sandstone or grit consists of more or less rounded, water-worn sand-grains and if it contains dull, weathered particles of felspar, shining scales of mica or small crystals of calcite these also rarely escape observation. Shales and clay rocks generally are soft, fine grained, often laminated and they not infrequently contain minute organisms or fragments of plants. Limestones are easily marked with a knife-blade, effervesce readily with weak cold acid and often contain entire or broken shells or other fossils. The crystalline nature of a granite or basalt is obvious at a glance, and while the former contains white or pink felspar, clear vitreous quartz and glancing flakes of mica, the other will show yellow-green olivine, black augite and grey striated plagioclase.

Microscopic Characters.— But when dealing with unfamiliar types or with rocks so fine grained that their component minerals cannot be determined with the aid of a lens, the geologist is obliged to have recourse to more delicate and searching methods of investigation. With the aid of the blowpipe (to test the fusibility of detached crystals), the goniometer, the magnet, the magnifying glass and the specific gravity balance the earlier travellers attained surprisingly accurate results. Examples of these may be found in the works of von Buch, Scrope, Darwin and many others. About the end of the 18th century, Dolomieu examined crushed rock powders under the microscope and Cordier in 1815 crushed, levigated and investigated the finer ground-mass of igneous rocks. His researches are models of scrupulous accuracy, and he was able to announce that they consisted essentially of such minerals as felspar, augite, iron ores and volcanic glass, and did not differ in nature from the coarser grained rocks. Nicol, whose name is associated with the discovery of the Nicol prism, seems to have been the first to prepare thin slices of mineral substances, and his methods were applied by Witham (1831) to the study of plant petrifications

This method, subsequently of such far-reaching importance in petrology, was not at once made use of for the systematic investigation of rocks, and it was not till 1858 that Sorby pointed out its value. The great work of this investigator was the production of very thin sections of rocks and their systematic examination under the high powers of the microscope. To-day the densest, blackest rock can be made to yield a section of $\frac{1}{1000}$ in. in thickness, so thin and transparent that fine print can be easily read through it, and transmitting light so clearly that the most high powered objectives of the microscope can be used to discern and study the minutest structures it presents with the same facility that they can be employed upon sections of organic material prepared by the microtome. The introduction of this powerful weapon of research, inaugurated a new era in petrology—that of petrography or the descriptive branch of petrology. The optical study of sections of crystals had been advanced by Sir David Brewster, Nicol and other physicists and mineralogists, and it only remained to apply their methods to the minerals visible in rock sections. The pioneer workers who brought quantitative methods into the optical side of the problem were Des Cloiseaux, Rosenbusch, Zirkel, Schuster, Fouqué and Levy. At the present day optical methods for determining minerals with the petrographic microscope are highly developed.

Although rocks are now studied principally in micro-sections the investigation of fine crushed rock powders, which was the first branch of microscopic petrology to receive attention is still in use. A mineral whose optical properties are known can be accurately determined by immersing its powder in liquid media whose indices of refraction are known, and determining the optical constants. In the hands of a skilled petrographer the principal optical constants of a single grain of a mineral can be determined in half an hour. The chief fundamental constants measured are

the principal indices of refraction, the crystallographic orientation of the directions of light-vibration corresponding to those indices, and the amount of absorption of light vibrating in these directions, all for one or more standard wave-lengths of light. The double refraction, optical character, optical axial angle, dispersion of the optic axes and bisectrices, extinction angle and pleochroism are all fixed by the fundamental constants and can be estimated under the microscope.

The immersion media cover a range of optical refraction from that of water (1.333) to that of a selenium—arsenic selenide melt (3.17). The liquids are chiefly organic substances,—acetone alcohol, cinnamon oil, monobrom-naphthalene and methylene iodide. Most minerals have refraction constants ranging in the interval 1.450–1.870, and their refractive indices may therefore be matched by a set of liquids whose refractions cover this range. The modern rotation apparatus whereby thin sections may be tilted from the horizontal so that the axis of the microscope passes through them at different angles has been of inestimable value in measuring accurately the optical constants of a single grain in a rock slice, and is now widely used for the determination of felspar and other mineral species of variable composition. A few measurements on a selected section of a mineral permit the determination of its exact chemical composition and the crystallographic orientation of the section itself. The technical methods employed for the determinations referred to above are largely founded on the use of polarized light.

Mechanical Separation of Rock Constituents.— The separation of the constituents of a crushed powder in order to obtain pure samples suitable for analysis is also extensively practised. The two principal methods adopted involve either the electromagnet or heavy liquids.

By the use of an electromagnet the component minerals of a rock may be separated by varying the strength of the current. A weak magnetic field attracts magnetite, then hematite and ilmenite. Silicates containing iron will follow in definite order, augite, hornblende, tourmaline, olivine and biotite being successively attracted. The degree of attraction is not however proportional to the iron content. The colourless non-magnetic minerals—quartz, felspar, muscovite, nepheline, etc.—remain.

Separation by means of water is not much used in petrographic work. However, a preliminary "panning" as practised by miners is often useful as a means of concentrating rare minerals occurring in very small quantity in the rock before the application of the methods next to be described. Methods of separation of minerals by which they are sorted according to their specific gravities by means of heavy fluids have an extensive application. The fluids used are those which do not attack the majority of the rock forming minerals. Of the many liquids used methylene iodide (sp.gr. 3.32) and bromoform (sp.gr. 2.86) are perhaps the most convenient. For more dense minerals Clerici's solution—an aqueous solution of thallium formate—is best adopted. By concentration the specific gravity can be raised to 4.32 at 60° C so that even the heavier rock minerals can be separated without difficulty. By dilution with water, or, in the case of methylene iodide, dilution with bromoform or benzol, successive crops of minerals may be separated in appropriate separating funnels. In this way a granite may be successively fractionated into its component minerals, biotite (sp.gr. 3.1), muscovite (2.85), quartz (2.65), oligoclase (2.64) and orthoclase (2.56). All these minerals float in methylene iodide: on dilution with benzol they are precipitated in the order given. Rocks like eclogite containing heavier minerals, such as ilmenite (sp.gr. 4.84), garnet (4.20) titanite (3.50) and diopside (3.29), may be similarly separated by means of a thallium formate-water solution.

Micro-chemical Methods.— Chemical methods are frequently of great use. Weak hydrochloric acid will dissolve calcite from a crushed limestone leaving dolomite and silicate minerals, and hydrofluoric acid may be used to extract the glassy base of volcanic and hypabyssal rocks from the pyroxenic minerals. Of much wider use however are microchemical methods for distinguishing minerals under the microscope. They are of special value in discriminating alkali minerals like nepheline, hainiye, nosean,

analcime and sodalite in the ground mass of igneous rocks. The methods depend on selective attack by acids, the formation of distinctive precipitates and the staining of gelatinous residues. Quartz and felspar in fine grained rocks may be differentiated by etching with hydrofluoric acid; quartz remains clear while the surface of the felspar grain becomes cloudy, being altered to aluminium fluosilicate, and may be stained by an aniline dye. This method is particularly useful in discriminating quartz and felspar in fine grained metamorphic rocks in which the felspar is without crystal form, is untwinned and shows lack of cleavage.

Chemical Analysis.—The ultimate chemical composition of a rock is of fundamental importance in determining its nature, and the chemical analysis of rocks is now widely carried out. In rock analysis of the better class as many as 25 constituents are determined and recorded. The most abundant, or major, constituents are stated as oxides, and any rock analysis of good quality records the content of at least nine or ten of these. They are silica, alumina, ferric and ferrous oxides, magnesia, lime, soda, potash and water. These nine oxides make up about 98% of the igneous rocks. Two other oxides are usually determined, TiO_2 and P_2O_5 , as they are represented in the common minor constituents—ilmenite and apatite—titanium being also present in some pyroxenes, amphiboles and micas. Such a chemical analysis is usually sufficient to determine to which of the two great classes, igneous or sedimentary, a rock belongs, and if it is igneous, the position the rock is to be assigned in any of the conventional classifications. In the case of metamorphic rocks it often establishes whether the original mass was a sediment or of igneous origin.

Specific Gravity.—By the balance and the pycnometer the specific gravity of rocks is determined in the usual way. It is greatest in those rocks rich in iron, magnesia and the heavy metals, and least in rocks rich in alkalis, silica and water. Eclogites (sp.gr. 3.5) are among the heaviest of the silicate igneous rocks, while the vitreous lavas of high silicity like obsidian (sp.gr. 2.35) are among the lightest.

ROCK SYNTHESIS

The methods of investigation described above may be grouped together as analytical, in contradistinction to the synthetic investigation of rocks—which proceeds by experimental work to reproduce different rock types and thus to elucidate their origin and explain their structures. Though the experiments of de Saussure (1740–99) on the fusion of granites and porphyries may be said to mark the earliest beginnings of experimental petrology, the era of rock synthesis must be considered to date from the time of Sir James Hall's researches on the fusion of dolerites found in the neighbourhood of Edinburgh. This investigator showed convincingly that the crystalline dolerites (or whinstones) could be fused and consolidated, according to the rate of cooling, either as black glasses resembling natural pitchstones or as crystalline aggregates of minerals much like the dolerites from which they came. Hall's most famous experiments however, were conducted with limestones. Powdered chalk by being heated in gas-tight gun barrels, was converted into a crystalline mass of calcite, thus supporting the contention of Hutton that heat and pressure had consolidated limestones and converted them into marbles. A lapse of almost 50 years occurred before the experiments of Hall were substantiated, when in 1878 the French petrologists Fouqué and Michel Lévy began their extensive researches on the synthesis of minerals and rocks by pyrogenetic methods. They succeeded in producing, by the use of a gas furnace and a nitrogen thermometer such rocks as porphyrite, basalt and dolerite, at the same time obtaining the characteristic textures—porphyritic, ophitic, etc.—by modifying the conditions under which the melts were cooled. With the more siliceous or acid rocks their experiments were much less successful. They advanced for the first time in a convincing manner the explanation that for the crystallization of these rocks the gases, never absent in natural rock magmas, were indispensable mineralizing agents (mineralizers). It is now known that the formation of many minerals is facilitated, or can only be accomplished, in the

presence of volatile constituents, as water, borates, chlorides, fluorides, etc. Not only do they assist in promoting the fluidity of the liquid and facilitate crystallization, but they form essential constituents of some of the important minerals occurring in acid igneous rocks (micas, tourmaline, topaz, etc.).

Among the pioneers in synthetic petrology may also be mentioned Ste. Clair Deville, Senarmont, Berthier, Bourgois, Hautefeuille, von Chrustschoff, Doelter, Morosewicz and Vogt. To Vogt we owe the first comprehensive essay towards bringing the crystallization of igneous rock magmas definitely under the known laws of solution. Beginning a study of a large series of silicate slags, more or less comparable in composition with igneous rocks, he has brought together a large body of information throwing light on the order of crystallization, the composition of the eutectics and the lowering of freezing points of the minerals in slag mixtures, and has directly applied these results to the elucidation of the crystallization processes in natural magmas.

Up to this period the synthetic work, involving as it did the measurement of the melting point of minerals and the succession of crystallization in more or less complex mixtures, though very suggestive, lacked the strictly quantitative element. Experiments were carried out on materials always containing impurities or foreign substances, and the methods adopted for the determination of fixed thermal points as melting points, inversion points or heat changes were of doubtful precision. Since 1904, with the establishment of the Geophysical Laboratory at Washington, synthetic or physico-chemical petrology has entered upon a new quantitative era. The work of this laboratory was undertaken to enter upon a quantitative study of rock formation which should include both the minerals and rocks which are geologically important and those which are economically useful, those formed directly from the magma and those formed by subsequent alteration. The individual problems are in reality problems for physics and physical chemistry; but the delay in their attack has lain in the fact that the measured relations established by the exact sciences have scarcely been of adequate scope to meet the needs of large petrological questions. The great body of physical and physico-chemical measurements have been confined to a temperature region below 100°C , while processes operating in rocks may have extended over a temperature region extending to $1,400^\circ$, an enormous range over which to stretch the application of ordinary methods and one in which the common forms of apparatus will not only fail but are themselves threatened with destruction. The initial work of the Geophysical Laboratory has been primarily to extend the methods of accurate temperature measurement to include the entire field of rock formation from 0° to $1,600^\circ$; the electric pyrometer has reached now such precision that an error of one or two degrees is all that need be expected in measuring temperatures up to $1,600^\circ$; moreover these temperatures can be maintained quite steady for days or weeks at a time. Calorimetric measurements have been improved; specific heats can be determined with great accuracy even at the highest temperatures. At the same time petrographic methods have been advanced so that the crystallographic and optical constants of the very minute crystals obtained in silicate melts can be accurately measured. The investigation of mineral substances under high pressures and high temperatures combined, and in the presence of volatile constituents has also been a subject of study.

With these methods of precision available for the study of rock materials, examination of simple mineralogical systems has been prosecuted. An understanding of the chemistry of the common oxides of rocks and their combinations is essential to the progress of petrology. Already experimental work has been conducted on the combinations of the oxides CaO , MgO , Al_2O_3 , SiO_2 ; the six possible binary systems have been fully worked out and the four possible ternary systems thoroughly studied, while portions of the quaternary system have been successfully explored. Much light has thereby been thrown on the processes taking place during the consolidation of igneous magmas which, though much more complex in their constitution, yet clearly show by petrographic examination closely similar phenomena, as are revealed in the crystallization behaviour of these simpler systems. The applica-

tion of these laboratory investigations to elucidate the origin and evolution of igneous rock types will be considered hereafter under the heading of physical chemistry of igneous magmas.

Classification of Igneous Rocks.—Igneous rocks according to their composition, chemical and mineralogical, their structures and textures, or their mode of occurrence, are subdivided into many groups. Between allied rocks there are, however, no hard and fast boundaries, for by increase or decrease in the proportions of their constituent minerals, they pass by every gradation one into the other. Similarly the distinctive textures of one kind of rock may often be traced gradually merging into those of another. Hence the definitions adopted in establishing rock nomenclature merely correspond to more or less arbitrarily selected points in a continuously graduated series. This is frequently urged as a reason for reducing rock classification to its simplest possible terms and using only a few generalized rock designations.

The earliest attempts at the classification of rocks on modern lines are to be found in the works of Von Leonhard (1823) and Brongniart (1827). These and other efforts, principally by Naumann (1850), Von Cotta (1855) and Roth (1861), while being built on the criteria of composition and structure of rocks, were largely developed from purely macroscopic investigation or ultimate chemical analysis. The pioneer work of Sorby (1858) in preparing transparent microsections of rocks opened the way for the unravelling of the mineral constituents and textures of the finer grained igneous rocks, and rapid advances in the knowledge of the constitution of igneous rocks followed. The classifications of Zirkel (1873) and Rosenbusch (1877) were the first products of the application of the new method of petrographic research, and in these mineral constitution was accorded first place as a basis of subdivision. The effect of microscopic study was to stress the importance of mineralogical and textural characters of rocks to the neglect of other characteristics. Rosenbusch in particular, influenced by the contention principally of Lossen (who urged the significance of the geological relations of igneous rocks, their occurrence and manner of formation), further developed his classification to express the relationship of geological occurrence and texture, and introduced in the second edition of his work a fundamental change.

The new classification is based first on geological position, texture and finally mineral and chemical composition. Igneous rocks are divided thus into three great groups:—(1) Deep seated rocks, (2) Dike rocks and (3) Effusive rocks. Like others before it, it is still essentially a qualitative classification, and at the present day is the one most commonly adopted by petrographers. The latest exposition of Rosenbusch's classification is set forth in his *Elemente der Gesteinslehre* revised by A. Osann (1923).

HABIT OF IGNEOUS ROCKS

Igneous rocks occur essentially in two different ways, either as lavas or intrusions.

Lavas or Effusive Types.—The lavas have been poured out at the surface and have consolidated after ejection, under conditions which are fairly well understood, seeing that they may be examined at active volcanoes in many parts of the world; the intrusive rocks, on the other hand, have been injected from below into cracks and fissures in the strata and have cooled there beneath masses which conceal them from view till exposed by denudation at a subsequent period. The members of these two groups differ in many respects from one another, so that it is often possible to assign a rock to one or other of them on mere superficial inspection. The lavas (or effusive rocks), having cooled rapidly in contact with the air, are mostly finely crystalline or have at least a fine-grained ground-mass representing that part of the viscous semi-crystalline lava flow which was still liquid at the moment of eruption. At this time they were exposed only to atmospheric pressure, and the steam and other gases, which they contained in great quantity, were free to escape; many important modifications arise from this, the most striking being the frequent presence of numerous steam cavities (vesicular structure) often drawn out to elongated shapes subsequently filled up with minerals by infiltration (amygdaloidal structure). As crystallization was

going on while the mass was still creeping forward over the surface of the earth, the latest formed minerals (in the ground-mass) are commonly arranged in subparallel winding lines following the direction of movement, and the larger early minerals which had previously crystallized may show the same arrangement. Most lavas have fallen considerably below their original temperatures before they are emitted. In their behaviour they present a close analogy to hot solutions of salts in water, which, when they approach the saturation temperature, first deposit a crop of large, well-formed crystals (labile stage) and subsequently precipitate clouds of smaller less perfect crystalline particles (metastable stage). In igneous rocks the first generation of crystals generally forms before the lava has emerged to the surface, that is to say, during the ascent from the subterranean depths to the crater of the volcano. It has frequently been verified by observation that freshly emitted lavas contain large crystals borne along in a molten, liquid mass. The large, well-formed, early crystals are generally admitted to be porphyritic; the smaller crystals of the surrounding matrix or ground-mass belong to the post-effusion stage. More rarely lavas are completely fused at the moment of ejection; they may then cool to form a non-porphyritic, finely crystalline rock, or if more rapidly chilled may in large part be non-crystalline rock, or glassy (vitreous rocks such as obsidian, tachylyte, pitchstone). A common and easily recognized feature of glassy rocks is the presence of rounded bodies (spherulites: Gr. *σφαῖρα*, a ball), consisting of fine divergent fibres radiating from a centre; these divergent fibres consist of imperfect crystals of felspar, mixed with quartz or tridymite; similar bodies are often produced artificially in glasses which are allowed to cool slowly. Rarely these spherulites are hollow or consist of concentric shells with spaces between (lithophysae: Gr. *λίθος*, a stone; *φύσα*, bellows). Perlitic structure, which is also found to be common in glasses, consists in the presence of concentric rounded cracks owing to contraction on cooling (see PERLITE).

The phenocrysts (Gr. *φαίνειν*, to show; *κρύσταλλον*, a crystal) or porphyritic minerals are not only larger than those of the ground-mass; as the matrix was still liquid when they formed they were free to take perfect crystalline shapes, not being interfered with by the pressure of adjacent crystals. They seem to have grown rapidly, as they are often filled with enclosures of glassy or finely crystalline material like the material of the ground-mass. Microscopic examination of the phenocrysts often reveals that they have had a complex history. Very frequently they show successive layers of different composition, indicated by variations in colour or other optical properties; thus augite may be green at the centre and various shades of brown outside this; or may be pale green centrally and darker green with strong pleochroism (aegirine) at the periphery. In the felspars the centre is usually more basic and richer in lime than the surrounding faces, and successive zones may often be noted, each less basic than those which lie within it. Phenocrysts of quartz (and of other minerals), instead of sharp, perfect crystalline faces, may show rounded corroded surfaces, with the points of the crystals blunted and irregular tongue-like projections of the matrix into the substance of the crystal; it is clear that after the mineral had crystallized it was partly again dissolved or corroded at some period before the matrix solidified. Corroded phenocrysts of biotite and hornblende are very common in some lavas; they are surrounded by black rims of magnetite mixed with pale green augite. The hornblende or biotite substance has proved unstable at a certain stage of consolidation and has been replaced by a pseudomorph of augite and magnetite which may be partially or completely substituted for the original crystal but still retains its characteristic outlines.

Plutonic or Abyssal Types.—Let us now consider the characteristics of a typical deep-seated rock similar to granite or diorite. That these are clearly igneous is proved by the manner in which they have burst through the superincumbent strata, filling the cracks with ramifying veins; that they were at a very high temperature is equally clear from the changes which they have induced in the rocks in contact with them. But as their

heat could dissipate only very slowly, because of the masses which covered them, complete crystallization has taken place and no vitreous rapidly chilled matter is present. As they have had time to come to rest before crystallizing they are not fluidal. Their contained gases have not been able to escape through the thick layer of strata beneath which they were injected, and may often be observed occupying cavities in the minerals, or have occasioned many important modifications in the crystallization of the rock. Because their crystals are of approximately equal size these rocks are said to be granular; there is typically no distinction between a first generation of large well-shaped crystals and a fine-grained ground-mass. Their minerals have formed, however, in a definite order, and each has had a period of crystallization which may be very distinct or may have coincided with or overlapped the period of formation of some of the other ingredients. The earlier have originated at a time when most of the rock was still liquid and are more or less perfect; the later are less regular in shape because they were compelled to occupy the interspaces left between the already formed crystals which pressed on them. The former are said to be idiomorphic (*i.e.*, having their own characteristic form, Gr. *ἴδιος*, belonging to one's self), the latter are allotriomorphic (Gr. *ἀλλότριος*, belonging to another). There are also many other characteristics which serve to distinguish the members of these two groups. Orthoclase, for example, is the typical feldspar of granite, while its modification sanidine occurs in lavas of similar composition; leucite is common in lavas, very rare in plutonic rocks; muscovite is confined to the intrusives. These differences show the influence of the physical conditions under which consolidation takes place.

Intrusive or Hypabyssal Types.—There is a certain class of intrusive rocks which have risen upwards towards the surface, but have failed to reach it, and have solidified in fissures as dikes and intrusive sills at no great depth. To this type the name *hypabyssal* is often given in distinction to the *plutonic* (or *abyssal*) which formed at greater depths. As might be expected, they show structures intermediate between those of the effusive and the plutonic rocks. They are very commonly porphyritic, not rarely vitreous, and sometimes even vesicular. In fact many of them are indistinguishable petrologically from lavas of similar composition.

The attempt to form a special group of hypabyssal (intrusive and dike) rocks has met with much criticism and opposition. Such a group certainly cannot rank as equally important and equally well characterized with the plutonic and the effusive. But there are many kinds of rock which are not found to occur normally in any other manner. As examples we may cite the lamprophyres, the aplites and the porphyries. These never occur as lava flows or as great plutonic bosses; if magmas of the same composition as these rocks occur in either of these ways they consolidate with different assemblages of minerals and different structures.

Subdivisions of Igneous Rock Class.—In subdividing the plutonic, the hypabyssal and the effusive rocks, the principle is followed of grouping those together which resemble one another

in mineral constitution and in chemical composition. In a broad sense these two properties are interdependent.

Chemical Characters.—Twelve elements (oxygen, silicon, aluminium, iron, calcium, sodium, potassium, magnesium, titanium, phosphorus, hydrogen and manganese) constitute about 99.6% of the earth's crust. Of these oxygen is the most abundant and constitutes 46.59% of the igneous rocks of the crust, the elements given above being placed in their order of abundance. These "petrogenic" or rock elements occur typically as oxides, simple silicates, aluminates, fluorides, chlorides and sulphides. In rock analyses they are stated as oxides. From a computation based on 5,159 analyses Washington and Clarke have arrived at the following as the average percentage composition of all igneous rocks:—SiO₂, 59.12; Al₂O₃, 15.34; Fe₂O₃, 3.08; MgO, 3.49; CaO, 5.08; Na₂O, 3.84; K₂O, 3.13; H₂O, 1.15; TiO₂, 1.05; P₂O₅, 0.3; MnO, 0.12; Inclusive 0.5.

The known igneous rocks show a wide but limited range of composition. As the most abundant and essential rock minerals are either silica or silicates, silica shows the highest maximum and the widest range of these oxides. In some magmatic ores its content falls to zero but rises to 93–96% in rare igneous rocks (northfieldite); alumina reaches a maximum of about 60% in some corundum-bearing syenites; iron oxides have a general range from 15 to under 1%, and magnesia from 25 to under 1%. In some olivine rocks (dunite) it reaches a value of 48%. Lime is highest in some pyroxenites and anorthosites (20–22%), but its general range is from 15% to zero. Soda reaches a maximum of 20% in almost pure nepheline rocks (congressite) but has a general range from 15% to nearly zero. Potash has a maximum 18% in an almost pure leucite lava (italite), but usually varies from 10% to zero. Water in fresh crystalline igneous rocks seldom reaches more than 2% but glassy lavas may contain 10%.

The commonest minerals of igneous rocks are the feldspars, pyroxenes and amphiboles, quartz, and the micas. From a statistical examination of 700 igneous rocks an average composition has been calculated as follows, feldspars 59.5, pyroxenes and amphiboles 16.8, quartz 12.0, micas 3.8, other minerals 7.9 (apatite 0.6, titanium minerals 1.5). This estimate however is clearly only an approximation. Rock minerals have been classified empirically into two groups, according as they are capable or incapable of existing in the presence of free silica, namely saturated and unsaturated minerals. The former group includes such minerals as the feldspars, pyroxenes, amphiboles and micas; and the latter olivine, nepheline, leucite and other feldspathoid minerals.

Certain minerals are as a matter of common observation not found together in igneous rocks. Thus olivine (except fayalite) and quartz do not occur in association, but are represented by rhombic pyroxene. The associations nepheline and quartz, leucite and quartz, pyroxenes or amphiboles and muscovite, are almost unknown among magmatic crystallizations; on the other hand we find certain mineral associations or parageneses to occur frequently; thus aegirine and arfvedsonite, nepheline and nosean, common hornblende and titanite, are well known as faithful com-

Igneous Rocks

Commonest minerals	Acid	Intermediate		Basic	Ultrabasic
	Quartz Orthoclase (and oligo- clase) Mica Hornblende Augite	Little or no Quartz Orthoclase Hornblende Augite Biotite	Plagioclase Hornblende Augite Biotite	No Quartz Plagioclase Augite Hypersthene Olivine	Augite Hornblende Olivine (Basic plagioclase)
Plutonic	Granite	Syenite	Diorite	Gabbro Norite	Peridotite Pyroxenite Hornblendite (Anorthosite)
Hypabyssal	Quartz- Porphyry	Orthoclase Porphyry Orthophyre	Porphyrite	Dolerite	Picrite
Volcanic	Rhyolite Obsidian	Trachyte	Andesite Dacite	Basalt Tachylyte	Limburgite Augiite

panions in igneous rocks. Again some minerals are restricted to particular magmas; melanite, melilite and certain rare zirconium-titanium minerals are almost confined to the alkaline igneous rocks. By inspection of a rock analysis it is frequently possible to state approximately what minerals the rock will contain, but there are numerous exceptions to any rule which can be laid down. The minerals which crystallize from an igneous magma may depend largely on the physical conditions under which the liquid consolidates; accordingly we find rocks of almost identical chemical composition with widely different mineralogical constitution. Such rocks as already noted are referred to as heteromorphic. Some familiar examples of assemblages of this character are mica syenite and leucite basalt, minette and leucite basalt, pyroxenite and allivalite, monzonite and leucite tephrite, hornblendite and websterite.

Certain minerals are practically confined to deep seated rocks, e.g., microcline, muscovite, diallage and almandine garnet; on the other hand leucite is very rare in plutonic rocks, as is also anorthoclase and the variety of potash feldspar known as sanidine. Some of these peculiarities are readily explicable, being dependent on the pressure, temperature, or concentration of volatile constituents in the crystallizing magma. Others still remain as a problem for solution. The subject will be referred to again in a later part of this article.

In the classification generally adopted by petrographers, the silica content of the magma forms a basis of further subdivision of igneous rocks. The division of volcanic rocks into acid, intermediate and basic we owe in the first place to Abich (1841). As applied to igneous rocks in general, those which contain most silica and which if crystallized yield free silica as quartz, are erected into a group designated the "acid" rocks in allusion to the rôle of silica in the mineral kingdom. Those with low silica percentages and rich in magnesia, lime and iron—so that quartz is absent while olivine, pyroxene or calcic feldspar is usually abundant—form the basic group. The "intermediate" rocks include those characterized by the general absence of both quartz and olivine. An important subdivision of the intermediate as well as the basic group contains a very high percentage of alkalis (soda or potash or both), and consequently has minerals such as nepheline, nosean, analcime or leucite, minerals not common in other rocks. This group is often referred to as the alkaline rocks. Lastly a small subgroup rich in olivine (peridotite, dunite), pyroxene (pyroxenite), or calcic feldspar (anorthosite) have been called the "ultrabasic" rocks. They have low percentages of silica but much iron, magnesia or lime. With the exception of the last group, including also ultrabasic lavas as augite and limburgite and a few related rocks as monchiquite, melilite basalt and alnoite, practically all igneous rocks contain feldspar or feldspathoid minerals. In the acid rocks the common feldspars are orthoclase, with perthite, microcline and oligoclase, all having much silica and alkalis. In the basic rocks labradorite, bytownite and anorthite prevail, being rich in lime and poor in silica, potash and soda. Augite and olivine are the common ferromagnesian minerals of the basic rocks, but hornblende and biotite are on the whole more frequent in the acid rocks.

The classification in the two tables that follow is based essentially on the mineralogical constitution of the three great groups of igneous rocks. The alkali rocks containing nepheline and leucite are treated separately, for though they show transitions into the corresponding intermediate and basic rocks (syenites, diorites, gabbros, etc.), they contain many minerals which are unknown in other rocks. In a purely formal classification such as is outlined here they are more conveniently considered as a distinct series. Their genetic relations among themselves and with the other rock types are considered later.

Diaschistic Rocks.—Two groups of rocks not specifically included in the tables form important members of the hypabyssal division of igneous rocks. These are the aplites and the lamprophyres. The aplites are acid leucocratic differentiation products of the granites, syenites, diorites and gabbros, while the lamprophyres are basic differentiates. The two groups are together known as *complementary* or *diaschistic* rocks and usually occur as dikes

or sills in association with the parent rock from which they are derived. Thus the minettes, vogesites and kersantites (*see* LAMPROPHYRE) are complementary to granitic aplites and occur in association with granitic masses. Camptonites and bostonites (syenite aplites) have a parent magma in the essexites or theralites which they accompany.

Nepheline- and Leucite-bearing Rocks

Commonest minerals	Alkali feldspar Nepheline or leucite Augite Hornblende Biotite	Plagioclase (lime-soda) Nepheline or leucite Augite Hornblende (Olivine)	Nepheline or leucite Augite Hornblende (Olivine)
Plutonic	Nepheline syenite Leucite syenite	Essexite Theralite	Ijolite Urtite Missourite
Hypabyssal	Sepheline syenite—porphyry Tinguaite	Essexite and Theralite	Sepheline dolerite
Volcanic	Phonolite Leucitophyre	Tephrite Basanite	Nepheline basalt Nephelinite Leucite basalt

The classificatory scheme here adopted is admittedly artificial for rocks are subdivided without particular reference to their genetic relationships. Even regarded as a classification for a utilitarian end there are many imperfections; the subdivisions are of unequal value and transitional types are not included. The latter however can be accommodated by further subdivision. Many of them have received special names. The quartz syenites may be interpolated between granite and diorite, the tonalites between granite and diorite and so on.

The question may be asked—When is a rock entitled to be recognized as belonging to a distinct species or variety and deserving a name for itself? It must, first of all, be proved to occur in considerable quantity at some locality, or better still at a series of localities or to have been produced from different magmas at more than one period of the earth's history. In other words, it must not be a mere anomaly. Moreover, it should have a distinctive mineral constitution, differing from other rocks, or something individual in the characters of its minerals or of its structures. It is often surprising how peculiar types of rock, believed at first to be unique, turn up with identical features in widely scattered regions; *almöite*, for example, occurs in Norway, Scotland, Montreal, British Columbia, New York and Brazil, *tinguaite* in Scotland, Norway, Brazil, Montana, Portugal, etc. This indicates that underlying all the variations in mineralogical, structural and chemical properties there are definite relationships which tend to repeat themselves, producing the same types whenever the same conditions are present.

Various attempts have been made to introduce a quantitative element into igneous rock classification. These have followed either chemical or mineralogical lines. The principal of these is the *Quantitative chemical classification* introduced by a group of American petrographers. The chemical composition of an igneous rock is here regarded as its fundamental characteristic and a series of subdivisions is erected on this basis. Other criteria are relegated to the background. The completed rock analysis is first interpreted in terms of an ideal set of minerals which constitute the "norm," but which in reality seldom corresponds to the actual composition ("mode"). The rocks are then divided into groups strictly according to the relative proportions of these ideal minerals to one another. The details of the classification need not be described here as they are fully set forth in a treatise specially devoted to this classification (*Quantitative Classification of Igneous Rocks*, Chicago, 1902; *see* Bibliography).

In other systems a quantitative element is introduced by subdividing rocks into groups by arbitrary lines based on mineral percentages: a complicated system framed on these lines is that

devised by A. Johannsen (Journal of Geology, 1917, 1919). In another the prime divisions are erected on a so-called "principle of silica-saturation" (Shand, *Eruptive Rocks*, 1927). In all the effect of the introduction of the quantitative element has been to increase the artificiality of the system and by this means to obscure the genetic relations existing between rock types. For this reason these systems are unlikely to supplant the qualitative classification in general use. It is indeed, largely to the influence of "quantitative classifications" that the bewildering and unnecessary multiplicity of igneous rock names must be ascribed.

A natural classification based on the genetic relationships of the igneous rocks is yet to be framed. The writings of Becker and Vogt contain some essay towards this goal. As a basis, the eutectic relation has been emphasized, the eutectic mixture possessing definite properties and a fixed composition. Experimental work of recent years has clearly shown however that the eutectic relation is only one of a number of possible relations existing between the components of a magma; that its importance has been over-emphasized is abundantly shown by the experimental investigation of silicate melts, and is indeed revealed in the sequence of crystallization decipherable in igneous rocks.

Petrographical Provinces.—As long ago as 1872 Vogelsang had noted that the igneous rocks of certain districts possessed textural or mineral characters in common, serving to distinguish them from the rocks of other districts. The researches of Judd (1886) and Iddings (1892) further substantiated this observation and showed that this community of petrographic character applied to the igneous rocks erupted or intruded during a particular period of igneous activity within the region. To such regions Judd gave the name petrographical provinces and Iddings employed the term *consanguinity* to express the genetic relationship implied in these resemblances among associated rocks. Excellent examples of such petrographical provinces or *comagmatic* regions, as they have been termed by Washington, are the Oslo region of southern Norway characterized by Devonian alkaline intrusions and extrusions; the Roman region characterized by rocks rich in potash; the alkaline province of central Montana; and the Tertiary calc-alkaline province of Hungary. On a larger scale the volcanoes which girdle the Pacific (Andes, Cordillera, Japan, Philippines, etc.) and those which occur on the volcanic islands of the Atlantic, illustrate the same phenomena. The consanguinity in the igneous series of a petrographical province implies that the whole assemblage is derived from some common deep-seated magma, during a period which, while necessarily prolonged, was not of vast duration in a geological sense. The assemblages of a province may and often do show a wide diversity of rock type embracing intrusions and extrusions. Prolonged eruptions have in a few cases a somewhat monotonous character owing to the predominance of one kind of rock. Thus the lavas of the Hawaiian islands are mostly basaltic, as are those of Oregon, Washington and the Deccan, all of which form geological masses of enormous magnitude. In the Oslo district on the other hand the assemblages comprise (among the intrusive rocks) a wide range of type—hornblende, essexite, larvikite, lardalite, nordmarkite, soda—and potash-granites.

Differentiation.—The process by which a magma is split into a variety of partial products is known as Differentiation; its importance from the standpoint of theoretical petrology is very great; it is in point of fact, the fundamental problem of petrogenesis. The variation expressed may appear in two ways; either as a variation in a single rock body, or in an associated series of separate intrusions or extrusions. In the first case a single intrusion shows variation in different parts of its mass, the extreme varieties being usually connected by gradual transition. The contrasted parts are frequently arranged symmetrically with reference to the borders of the mass forming concentric zones in bosses or laccoliths suggestive of a differentiation in situ connected with the cooling of the mass. Most commonly the marginal zones are of more basic composition. Excellent examples of variation of this kind are provided by the gabbro mass of Carrock Fell (Cumberland) with its basic border rich in iron ore, and the shonkinite laccolith of Shonkin Sag, Montana, in which a transition from

syenite to shonkinite becoming denser outwards, occurs, the shonkinite finally passing at the margin into a fine leucite-basalt-porphry. Variation in an associated series, is exemplified by the succession of lavas emitted from a volcanic focus. These may differ considerably from one another. Thus in the Berkeley Hills near San Francisco the volcanic succession is a repeated series of andesites, basalts and rhyolites. In other cases the lavas emitted are much more varied, and while no significant relations in the succession can be discerned, it is to be remembered that a significant order may be obscured by the overlapping of the flows from neighbouring volcanoes. In the simpler cases the order of eruption is one of increasing divergence from an initial type.

Plutonic Complexes.—A series of plutonic rocks intimately associated and localized at a centre constitutes a *plutonic* complex. Such complexes often contain a great diversity of petrographical types ranging from peridotite and gabbro through diorite to acid granite. The succession of these intrusions follows an order of decreasing basicity, the later and more acid rocks usually occupying the greater part of the complex, the earlier, and more basic being subordinate in amount and restricted to the borders of the mass. Excellent examples of such plutonic complexes are provided by the early Devonian intrusions of "newer granites" of the Scottish Highlands (*e.g.*, Garabal hill, Loch Lomond). What then are the factors operating which led to differentiation?

The possible processes leading to heterogeneity in a magma may be considered under (a) those occurring in the liquid prior to crystallization and (b) those occurring during or subsequent to crystallization. Of the first, we may consider (i.) differences of composition set up in a liquid due to a temperature gradient; (ii.) differences of composition due to a pressure gradient; and (iii.) differences of composition due to the separation of distinct liquid phases. Each of these processes has in the past been appealed to to explain the variation seen in an igneous rock mass intruded singly, or in a rock series arising as a result of successive eruptions or intrusions. The type of composition-variation due to a temperature gradient is commonly known as the Soret effect and has been especially applied to explain the variation seen in a single rock body, such as the concentration of the minerals of early crystallization towards a cooling boundary. In a liquid with a temperature gradient, for dilute solutions the concentration varies inversely as the absolute temperature; and it has been thought that by the operation of this process, substances near their saturation point might accumulate at the cooler surfaces. Both theoretical considerations and experimental results clearly indicate however that the actual Soret effect is in fact negligible and such effects as are actually observed are due in reality to departures from the laws of ideal solutions, for if both solvent and solute obeyed osmotic pressure laws there would be no relative concentration of one with respect to the other. The effects of a pressure gradient appear to be of the same order of magnitude and both these processes are now in effect abandoned as factors in differentiation.

The effects possible as a result of the separation of immiscible liquid phases stand on a different basis. Many liquids, homogeneous at high temperatures, separate with falling temperature into two or more non-consolute fractions, and the hypothesis that igneous magmas form such immiscible fractions has been favoured by some petrologists, notably Rosenbusch, Backstrom and Daly. From his own studies Vogt concluded that the rock-forming silicates are freely miscible. The only known case among magmas for which immiscibility can be claimed is that of sulphide-containing silicate melts. Such a magma unmixes at a temperature above the region of crystallization of the usual sulphides, and liquid sulphides, especially those of iron, are separated as liquid drops. These, owing to their greater density, sink to the floor of the magma collecting as a distinct sulphide layer, or, in some cases, the liquid layer may be injected into the surrounding rocks. These sulphide aggregates form important ore deposits. It is among lavas which as a group show the various stages of quenching of liquid magmas that the evidence for immiscibility might be expected; the absence of lavas containing glassy glob-

ules of composition distinct from that of the main mass of lava, goes far to reassure us that immiscibility is not an operating factor in petrogenesis. Recent experimental evidence of immiscibility in silicate liquids has indeed been obtained, but the composition range of liquids which show it is unlike that exemplified by rock magmas. This limited miscibility is found in mixtures of silica with any of the oxides CaO, MgO, FeO, Fe₂O₃, but in a region of very high silica-content. The minimum temperature for the existence of two liquids is in each case only a little below the melting point of silica, or in the vicinity of 1,700° C. The oxides Na₂O, K₂O, Al₂O₃ show no such immiscible region in their silica mixtures, and moreover it requires only a small proportion of any of these miscible oxides to render miscible with silica the oxides which are themselves immiscible with silica. No natural magmas are known which approximate in composition to the region of immiscibility in these melts. It is true that natural magmas contain in addition water, and that its effect is experimentally unknown. Nevertheless if its addition changes the limits of immiscibility so that unmixing becomes a possible factor in differentiation, its behaviour must differ from that of the oxides studied.

Of all the processes suggested as important factors in the differentiation of rocks, crystallization alone seems competent to produce important results. Indeed fractional crystallization is now believed to be the fundamental process in rock differentiation. Either the localization of crystallization or the localized aggregation of crystals is sufficient to produce heterogeneity in a rock magma. The first case, the localization of crystallization, is competent to explain those cases of differentiation in *situ* exemplified by the basic marginal phases of intrusive masses. The mechanism of the process has been much discussed. Examination of igneous rocks early showed that minerals crystallize in a more or less definite order. In general the first minerals to separate belong to a group known as the minor accessories: this includes zircon, apatite, titanite and iron-oxides; then follow in order olivine, augite, hornblende, biotite, plagioclase, orthoclase, microcline and quartz. To this rule there are many exceptions, but the succession given above holds in the great majority of cases. Expressed in this way the more basic minerals precede the less basic: it is known as Rosenbusch's law of decreasing basicity. Accordingly it is supposed that at a cooling boundary there is a precipitation of minerals of early crystallization (basic minerals), the continued growth of many crystals being maintained by diffusion. The completion of this process results in a crystalline mass with a border phase enriched in the minerals of early crystallization.

The rate of diffusion in silicate melts has been the subject of laboratory study and the results obtained show that the possible effects are exceedingly small and incompetent to account for the formation of border phases about large intrusions. The marginal phase indeed appears to represent rather a chilled phase having a composition close to that of the original magma, the more acid phase which it encloses representing a differentiate formed by much slower cooling of the remainder of the magma. The relative movement of crystals with respect to the liquid from which they separated may be of two kinds, (a) movement under the influence of gravity—sinking or floating of crystals and (b) movement by straining off or squeezing out of residual liquid by earth movement. Both of these processes can be applied to explain the more important case of differentiation exemplified by an associated series of intrusions or extrusions. In a crystallizing magma, provided viscosity does not inhibit the free movement of crystalline material, as the first formed crystals are denser than the molten material in which they form, they should sink under the influence of gravity in the liquid. The lower regions of the rock mass into which the crystals sink become enriched, the upper regions impoverished, in the constituents of which they are formed. The sinking of crystals in silicate melts has been both experimentally verified in the laboratory and observed in nature. Darwin long ago (1844) suggested that this process was a potent factor in producing diverse rock types. Turning to the evidence of consolidated rock masses themselves, we find intrusions in which such gravitational segregation is indubitably exemplified.

Thus the concentration of early formed olivine crystals near the base of sheet- or sill-like intrusions has been observed in the case of the quartz-dolerite sill of the Palisades (Hudson river) and the picrite sill of Lugar (Ayrshire). Examples of this nature appear however to be exceptional, and indicate an extreme fluidity of the liquid magma. Most sheets or laccoliths show no heterogeneity throughout the vertical extent of their mass. In other cases where a variation is observed, it is to be ascribed to successive injection of magmas of varying composition.

In the magma basins of the deeper parts of the crust, the case may be conjectured to be otherwise. The retarding influence of viscosity, which appears to prevent any notable gravitative segregation in intrusive sheets cooled comparatively rapidly in those parts of the crust laid bare by denudation, is at deeper levels counteracted by the time factor. The extremely slow rate of cooling in these deeper regions may permit significant settling of crystals, giving rise to a differentiated reservoir more or less stratified according to gravity, more basic at the bottom, more acid upwards. The mechanism by which it is conceived a varied group of liquids becomes drafted off from an intercrustal reservoir and injected to form the igneous rock bodies now made visible by denudation is, of necessity, one into which the element of speculation largely enters. Remelting of successive stratified layers by a gradual use of temperature from the base upwards, together with earth movement, the straining off of residual liquid from a crystalline meshwork under the influence of crustal stress, all are processes to which appeal is made to explain not only the variety among associated igneous rocks injected as plutonic complexes but also the chronological succession of the intrusions themselves.

Assimilation. — Fragments of foreign rock frequently become incorporated in rock magmas, and the mutual reaction between solid and liquid may lead to heterogeneity or the development of new varieties of rock. This process is known as assimilation and has been claimed by some petrologists as an important factor in petrogenesis.

It seems probable that the heat effect connected with the solution of solid rock by a liquid magma is always negative, solution being accompanied by absorption of heat usually of the order of the latent heat of melting. Simple solution demands large amounts of heat which are only available if the liquid possesses great super-heat. Intruding magmas, however, can scarcely be at a temperature much above their crystallization range. Such effects of magma upon its enclosures, as are observed, must therefore be attributed to reaction and precipitation, which in some cases leads simply to an adjustment in the composition and relative proportions of the existing phases, but is also productive of new minerals foreign to the magma, especially if reaction be incomplete. Where igneous rocks have absorbed sedimentary material in any quantity they present distinctive features. Granites which have assimilated shales or slates usually contain minerals such as andalusite, sillimanite or cordierite, which are foreign to normal igneous rocks. Gabbros under similar conditions pass first into norite by the formation of rhombic pyroxene and anorthite at the expense of monoclinic pyroxene and eventually into cordierite norites. Rocks of this character are well developed in Aberdeenshire. In general it may be said that there is little reason to believe that foreign rock is essential to the production of any particular type of differentiate, or that the process of assimilation is an important factor in petrogenesis.

Geographical Distribution of Igneous Rocks.—A study of the geographical distribution of igneous rocks has shown that the earth's surface may be mapped out into more or less definite petrographical provinces, each with its own community of petrographical characters. Strongly contrasted provinces may exist almost side by side, as is seen in the Tertiary Bohemian and Hungarian provinces standing on either side of the Carpathian range, the one characterized by a suite of igneous rocks rich in alkali, the other comprising an assemblage relatively rich in lime, magnesia and iron oxide. The chain of volcanoes that fringes the shores of the Pacific from Tierra del Fuego to Alaska and thence by Japan and the Philippines to Java and Sumatra

represents a province of a larger order, characterized by rocks which have so much similarity in many important features that they are certainly of allied origin. These rocks are all of Tertiary and recent age; their eruptions began in Eocene or Miocene times and have continued with more or less frequent intermissions up to the present day. The igneous rocks of the Atlantic islands from the Azores to Tristan d'Acunha comprise an assemblage of types strikingly different from the Pacific igneous rocks. Each of these magmas has been taken as a type, and referred to as the "Pacific" and "Atlantic" magmas. Chemically the Atlantic (or alkali) rocks are characterized by high percentages of alkalis (potash and soda) in relation to silica and alumina, and mineralogically by the presence of alkali minerals, especially feldspaths (nepheline, sodalite, analcime, etc.). The Pacific (subalkali or calcic) rocks on the other hand show relatively more abundant lime, magnesia and iron oxides. Certain suites of rocks characterized by high potash, and mineralogically by the presence of leucite or abundant potash feldspar and micas have in recent years been separated from the Atlantic suite, though they are perhaps not of co-ordinate importance. Rocks of this character are illustrated by the Quaternary province of the Roman region; Vesuvius belongs to a line of volcanoes (extending from lake Bolsena to the Phlegrean Fields) that have poured out lavas of this character. From their occurrence on the borders of the Mediterranean they are sometimes known as the Mediterranean suite.

When we turn to the igneous rocks of older geological periods the same contrasted suites can be recognized. The midland valley of Scotland has been the theatre of igneous action both in Lower Devonian and Carboniferous times. The igneous assemblages of the two periods show, however, a striking contrast. The earlier lavas are distinctly of the Pacific type including andesites, basalts and rhyolites, while the Carboniferous extrusions and dike rocks include trachytes, teschenites, picrites and monchiquites—an Atlantic assemblage. Petrographical provinces are therefore clearly not permanent—a point to which we shall later return.

Each of the great suites—Pacific, Atlantic and Mediterranean is characterized by a set of rock types which reflects the chemical and mineralogical peculiarities. Arranged in tabular form the typical assemblages of the three suites are as follows:—

PACIFIC:—

PLUTONIC: granites, quartz-diorites, diorites, gabbros, pyroxenites, peridotites, anorthosites.

HYPABYSSAL: granite-porphyrines, porphyrites, dolerites and some lamprophyres (spessartites, odinites).

VOLCANIC: rhyolites, dacites, andesites, basalts.

ATLANTIC:—

PLUTONIC: soda-granites, pulaskites, foyaites, essexites, theralites.

HYPABYSSAL: soda-granite-porphyrines, pulaskite-porphyrines, tinguaites, essexite- and theralite-porphyrines and some lamprophyres (camptonites, monchiquites).

VOLCANIC: pantellerites, soda-trachytes, phonolites, alkali-basalts.

MEDITERRANEAN:—

PLUTONIC: quartz-syenites, syenites, monzonites, shonkinites and missourites.

HYPABYSSAL: syenite-monzonite-etc. porphyries and some lamprophyres (minettes, alnoites).

VOLCANIC: quartz-trachytes, trachytes, latites, ciminities, leucitites and leucite-basalts.

The recognition of these three suites and their distinctive products constitutes without doubt the first step towards a natural or genetic classification of igneous rocks.

Study of the geological relations of igneous rocks clearly reveals that there is a general correspondence both in time and space between igneous action and movements of the earth's crust, whether these be simply vertical movements of elevation and depression or tangential movements of folding and overthrusting which build up great mountain chains. As in crustal movements, so in igneous action, periods of activity have alternated with periods of quiescence. The movements of compression which led to the folded mountain chains fringing the Pacific were accompanied and

followed by widespread vulcanicity and the movements of depression, which in Tertiary times led to the formation of the Great Rift Valley of East Africa, were attended and followed by a great suite of volcanic eruptions. The interdependence of igneous action and crust movement is even of a still more intimate kind, for not only the distribution of igneous rocks, but the distribution of different kinds of igneous rock is seen to stand in unmistakable relation to the great tectonic structures of the earth. The examples referred to above are illustrative of this conclusion. The volcanoes of the Pacific cordillera erupted calcic andesites and basalts, and are associated with granodiorite and quartz-diorite intrusions; the eruptions associated with the African Rift valley are in contrast, being of alkaline type and including soda-trachytes, phonolites and related alkaline lavas. Whether attention is confined to Tertiary igneous rocks or extended to those of earlier date, the conclusion is enforced that rocks of the Pacific suite are closely associated with folded mountain chains and appear in regions subject to movements of compression and lateral thrust, and that the Atlantic or alkaline suites are associated with regions of subsidence, subject to tension and faulting. That a particular region at successive epochs may be the theatre of action of contrasted igneous suites plainly forbids the assumption that the distribution of rock types is due to initial heterogeneity of the crust. Rather it would appear that calcic and alkaline suites are ultimately derived from the same primitive magmas. The manner of their evolution is a problem of great complexity.

The mode of origin of the massive fringes of pegmatite mantling the "older granites" of the south eastern highlands of Scotland may perhaps provide the initial clue to the actual mechanism involved. By Barrow these pegmatite fringes are conceived to represent the acid residual liquid squeezed out from partially crystallized granite magma under the influence of crustal stress. To an analogous process operating at deeper levels, and on a grander scale, Harker has made appeal to account for the separation in a horizontal sense of alkaline and calcic magmas from some common deep-seated stock.

Physical Chemistry of Igneous Rocks.—Natural rock magmas are polycomponent systems with seldom fewer than six or seven oxides, and no adequate discussion of their physical chemistry is at present possible. It is the function of the petrologist to elucidate the nature and behaviour of these complex systems under different physical conditions. In the last 25 years much progress has been made on the experimental side and the foundation for an extended exploration of the crystallization history of silicate magmas has now been laid. The main contributions have come from the Geophysical Laboratory at Washington. Investigations initially concerned with the perfection of experimental methods of attack have been followed by a physico-chemical study of simple oxides and their combinations. As yet these investigations have been almost wholly confined to dry systems but an attack on wet systems with volatile components is already in progress. Systems have now been investigated which approach in their complexity some of the simpler types of igneous rocks and the results obtained justify the conclusion that the fusion and solidification phenomena of igneous rocks are capable of systematic treatment. Starting with pure chemical substances the melting points, dissociation temperatures and inversion points of numerous rock-forming minerals have been determined, and the equilibrium phenomena of two and three component systems involving the commoner oxides of igneous rocks have been quantitatively elucidated. This study has embraced the six binary and four ternary systems of the oxides, CaO, MgO, SiO₂, Al₂O₃, and portions of the quaternary system itself have been explored. The investigation of mineral inversions has provided data throwing light on the temperature of consolidation of igneous magma. Such of these inversions as are enantiotropic or reversible and take place without appreciable lag can be appropriately used as geological thermometers. The inversion of quartz $\xrightarrow{575^{\circ}C}$ β quartz

is a striking example, as it is accompanied by a significant volume change whereby it is possible to recognize whether quartz at ordinary temperatures has crystallized as α or β quartz. The criteria

include complicated twinning and fracturing. It can thus be shown that the quartz of granites has consolidated as β quartz and therefore at a temperature above 575° . The quartz of many pegmatites and igneous quartz veins on the other hand has consolidated as α quartz and therefore below 575° . (Note: some writers use α and β in the inverse senses.) The inversion pseudo-wollastonite $\xrightleftharpoons{1,190^\circ\text{C}}$ wollastonite provides another case, from which it is concluded that wollastonite occurring in rocks has crystallized below $1,190^\circ$.

Some minerals melt with dissociation or incongruently. The most important examples are clinostatite dissociating at $1,557^\circ$ into forsterite and silica, and orthoclase with a dissociation temperature of $1,170^\circ$ yielding leucite and silica. The incongruent melting of these two minerals has important petrogenetic implications which will be noticed hereafter.

Binary Systems.—The manner of crystallization of binary systems is dependent on the mutual relations of the constituents. In the simple case of two independent components each lowering the melting point of the other and not forming solid solutions the completion of crystallization takes place at a definite temperature (the eutectic point) at which both solids separate simultaneously from a solution of fixed composition (the eutectic mixture). Many examples of eutectic crystallization are known among silicates. It frequently gives rise to a graphic texture in which there is an intimate intergrowth of the two phases. The intergrowths of quartz and orthoclase in graphic pegmatites and micro-pegmatite are believed to be eutectic aggregates. This is revealed not only in their simultaneous crystallization but also in their constant relative proportions (quartz 26%, orthoclase 74%). Not all graphic textures can, however, be regarded as evidence of eutectic crystallization, nor do all eutectic mixtures form graphic intergrowths.

The conception of eutectics has played an important part in petrogenetic theory, and—as already noted—Vogt has attempted to recognize in eutectics the basis of a genetic classification of rocks. The eutectic relation is, however, only one of a number of possible relations existing between two or more components of a system. Where two components exhibit perfect isomorphous relations, eutectic crystallization is eliminated and the two substances crystallize as a single phase—an homogeneous solid solution. Of rock-forming minerals exhibiting this relation the plagioclase feldspars are the most important. The equilibrium relations in such a system may be illustrated diagrammatically as in fig. 1. The horizontal line represents the composition, the vertical the temperature. The pure components are albite and anorthite.

FIG. 1

Anorthite (An.) melts at $1,550^\circ$. C. The melting point of albite (Ab.) is fixed close to $1,100^\circ$; its melts are highly viscous and crystallize only with great reluctance. The upper curve of the diagram is the freezing point curve of intermediate mixtures of the two components. It is known as the *liquidus*. The lower curve is the melting point curve, or *solidus*. Above the liquidus all mixtures are liquid, below the solidus all are crystallized. Mixtures of albite and anorthite do not melt at definite temperatures but have a melting or crystallization interval, the lower limit fixed by the solidus, the upper by the liquidus.

Let us consider the phenomena attending crystallization of a mixture of given composition. A liquid of composition Ab_1An_1 as the temperature falls begins to crystallize at A. The crystals in equilibrium with this liquid have the composition B (Ab_1An_4), the liquid being always richer in albite than the crystals with which it is in equilibrium. As the temperature slowly falls the crystals continue to form, at the same time changing in composi-

tion along the solidus curve by continuous reaction with the liquid. Throughout the course of crystallization, this process of reaction proceeds until finally the crystals have the composition D, that of the original liquid, the last drop of liquid having the composition C. If, however, equilibrium between the solid and liquid phases is not continuously maintained, the course of crystallization is extended. At a moderately rapid rate of cooling the first formed crystals of composition B are not adjusted to the liquid, and there results a deposition of new layers upon the first formed crystals, each of composition corresponding to the temperature at which they are formed. When crystallization ceases, as the bulk composition of the crystals is that of the original liquid and the cores of the crystals are richer in anorthite, the outer layers must be enriched in albite. The composition of the outer layer is represented by a point beyond D and that of the final liquid by a point beyond C. The process first described is exemplified in the zonary banding or zoning of the common plagioclase feldspars in igneous rocks. Either very slow cooling or very rapid cooling gives crystals free from zoning; at intermediate rates of cooling, crystallization is accompanied by zoning, and at some definite rate of cooling it might be expected that a maximum zoning would result in which case the final drop of liquid would have the composition of pure albite.

The theoretical investigations of Roozeboom have shown that five types of crystallization of isomorphous substances may occur; in three the mutual solubility of the two components is unlimited, in two it is limited, so that only mixed crystals of certain types may occur. Some of these have been identified in rock-forming minerals, others are suspected though not yet proven.

Ternary Systems.—Crystallization is more complicated in ternary systems than in binary. Roozeboom and Schreinemakers worked out the theory of these systems. To represent their behaviour resort must now be made to a solid figure. All possible mixtures of three components can be represented by points within an equilateral triangle, the apices of which represent the three components. Binary mixtures appear as points on the sides of the triangle. If lines be drawn through any point within the triangle and parallel to its sides, they will cut the sides at distances which represent the relative proportions of the components represented by the point. To represent temperature, vertical ordinates are erected upon the equilateral triangle. The solid figure thus obtained is a triangular prism bounded above by freezing point surfaces meeting in boundary lines. These can be conveniently represented in plane projection. In the simplest ternary systems each pair of the components form a binary eutectic and the three together a ternary eutectic, which represents the composition in the system possessing the lowest fusibility.

The crystallization course of such a simple system may be illustrated in the diagram (fig. 2). A, B and C represent the three pure components, AB, BC and AC represent binary mixtures, and E_{ab} , E_{bc} and E_{ac} the respective binary eutectics. The ternary eutectic is represented by the point E_{abc} within the figure. A liquid of composition a when cooled to the freezing point surface separates crystals of the composition A, the composition of the liquid moving away from A towards b. At b, the liquid becomes saturated for the component C which will begin to crystallize, both A and C crystallizing while the composition of the liquid changes along the boundary curve bE_{abc} . Finally B also begins to crystallize and the ternary eutectic point is reached at which the three components crystallize simultaneously in definite proportions (at E_{abc}) until the whole is completely solidified. This simple ternary system though realized among metallic alloys—for example in the system lead-tin-bismuth, where the ternary eutectic melts at 96° —has not been yet discovered among rock-forming silicates. There the relations are much more complex.

FIG. 2

Occurrence of inversion points in one or more of the components; the formation of binary or ternary compounds with congruent and incongruent melting points; the formation of isomor-

phous mixtures, limited or unlimited, among the phases, are some of the many complications in silicate systems already investigated. As an example of a very complicated system, the ternary system $\text{CaO}-\text{Al}_2\text{O}_3-\text{SiO}_2$ may be briefly noted.

In addition to the three components, there are nine binary compounds, some with enantiotropic inversions; and three ternary compounds, only two of which are stable. The fields meet three together in a large number of quintuple points eight of which are ternary eutectics. Investigation of this system has involved the undertaking of over 7,000 heat treatments and microscopical preparations.

Among the ternary silicate systems that have been studied three in particular are of great importance in the interpretation of the crystallization-history of rock magmas. They include those mixtures from which the phases, plagioclase, pyroxene, olivine,

spinel and silica have separated. An important system is that of diopside—albite—anorthite. The equilibrium diagram is shown in fig. 3. The crystallizing phases are diopside and plagioclase. These mixtures are therefore comparable with simple basaltic or gabbroic magmas on the one hand and simple dioritic (augite-diorite) magmas on the other according to the nature of the plagioclase.

As before, consider the crystallization of a liquid whose composition is represented by the point F. (50% diopside, 50% plagioclase— Ab_1An_1). Crystallization begins with a separation of diopside (supposed to be a simple mineral and not an isomorphous mixture, as it would usually be in rocks) at about $1,275^\circ$. At $1,235^\circ$ the excess of diopside (G) has separated out, and felspar begins to crystallize. It has about 80% anorthite (H). Thereafter diopside and felspar both crystallize, but as the temperature travels along the line EGD from G to M the composition of the felspar changes from H to Z (if we suppose that all the early felspar which is unduly rich in anorthite is stage by stage resorbed). The resulting rock has the mineral composition above stated; but if resorption of felspar is incomplete the last-formed felspar is richer in albite and has a composition T. The felspar crystals in that case are zonal with basic centres. If at any time crystallization is suddenly brought to an end a glassy ground-mass will be formed, which is richer in soda and silica than the original magma and contains zoned felspar crystals. This is exceedingly like what takes place in many basaltic lavas. Again, if the original mixture had been richer in felspar, so that the composition point lay below the line DE, felspar would have crystallized out first. This seems to be in keeping with the structure of many dolerites, which contain felspar partly enclosed in augite crystals of later formation (ophitic structure), while others show that the augite appears in porphyritic crystals and began crystallizing before felspar.

The separation of liquid from crystals can be accomplished not only by zoning but also by the sinking of crystals from the upper layers of the liquid. The resulting liquid is enriched in albite and, under favourable circumstances, the final liquid may approach the albite-diopside eutectic of composition 97% Ab, 3% diopside. The analogy with the differentiation course of gabbroic magma is clear. A mixture rich in diopside and anorthite-rich plagioclase, corresponding to an anorthite-rich gabbro or ecrite may pass to an assemblage rich in more acid plagioclase with subordinate diopside, corresponding to an augite-diorite. We shall see by a study of another system how this differentiation from a basic magma may be extended to the granitic (diopside-granite) stage.

The continuous reaction relation between crystals and liquid in the systems just studied is of fundamental importance in the crystallization-history of magmas. This reaction is common to all solid solution series, and such solid solutions are called *continuous reaction series*. Very similar effects, however, are produced by

FIG. 3

another type of crystallization phenomenon revealed in synthetic melts. In this case an early precipitated phase reacts at a certain temperature with the surrounding liquid and a new phase is precipitated, a reaction process of a discontinuous kind. This reaction is illustrated in the system forsterite (olivine)-silica. Here there are three solid phases, forsterite, clinoenstatite (MgSiO_3) and cristobalite (SiO_2). The monoclinic pyroxene, clinoenstatite, has an incongruent melting point and dissociates at $1,557^\circ$ into forsterite and liquid. From all melts of composition between Mg_2SiO_4 and MgSiO_3 , the first phase to crystallize is forsterite, which continues to separate until the temperature of $1,557^\circ$ is reached, when the olivine reacts with the liquid to form clinoenstatite. When equilibrium is established the resulting crystalline mass consists wholly of olivine and pyroxene. If, however, the opportunity for reaction is inhibited, either by the sinking of olivine crystals or by their enclosure in the reaction product, the course of crystallization is extended and the third phase, silica, is precipitated giving a mass composed of residual olivine, pyroxene and silica.

A reaction relation of this type may effect a series of compounds in a crystallizing melt. These, arranged in their order of succession, constitute a *discontinuous reaction series*. The combined effects of discontinuous and continuous reaction are revealed in the related ternary system diopside-forsterite-silica. Here clinoenstatite forms a complete series of solid solutions (monoclinic pyroxenes) with diopside; they form a continuous reaction series, the crystals in equilibrium with the liquid being relatively enriched in the magnesian end member (MgSiO_3). The effect of hindering the reaction relations is now twofold, the residual liquid (or upper layers of the liquid if sinking of crystals obtains) is enriched in silica and the diopsidic pyroxene, owing to the offset in composition. The lowest point of formation of liquid in the system (there is no ternary eutectic) is the binary eutectic diopside-silica.

Evidence of these reaction processes in natural magmas is by no means wanting. It is seen in zonal banding of plagioclase felspars and pyroxenic solid solutions. One of the most characteristic features of olivine-bearing basic rocks is the occurrence of olivine crystals with rounded outlines—indicative of resorption—or with mantles of pyroxene formed at their expense. In the synthetic melts the unidirectional reaction-relation existing among the mineral phases results in a differentiated liquid or chain of liquids enriched in silica, from early separation of olivine, in albite from early formation of magnesian-rich pyroxene. Similar reactions proceeding in basic (gabbroic or basaltic) magma serve to explain in large measure the differentiation chain of the calc-alkaline rocks, gabbro-diorite-granodiorite, though here the presence of other oxides— K_2O , H_2O —and other volatile constituents is responsible for more complex reactions and new mineral phases not yet included in synthetic investigation.

Volatile Constituents.—The volatile constituents of magmas have a profound influence on the properties of the silicate solution. Their concentration is greatly affected by changes of pressure and temperature, and equilibria in the melt are therefore of a very mobile kind. They reduce the viscosity of the melt, lower the temperature of crystallization, and are responsible for the precipitation of new mineral phases foreign to dry melts. By fractional crystallization these constituents are concentrated in the residual liquid and become responsible for many of the after-effects seen in pneumatolysis, metasomatism and ore deposition. The formation of amphiboles, micas and many other minerals is to be attributed to their presence.

It has been shown that the phenomena associated with the reaction-relation in dry melts appear among the mineral phases of magmatic melts and can be interpreted in like manner. In the light of laboratory experiment available petrographical data permit the conclusion that the pyroxenes, hornblendes and biotites form a discontinuous reaction series, pyroxene reacting with liquid to form hornblende, hornblende to form biotite. Each of these groups in itself as solid solutions is a continuous reaction series. It is in reactions of this kind that the ordered differentiation sequence gabbro-diorite-quartz diorite-biotite-granite, character..

istic of the calc-alkaline rocks now finds explanation; the continual offset in composition of residual liquid in which water accumulates being accomplished by appropriate removal of crystals, either by gravitative settling or squeezing out or filtering of interstitial liquid by earth movement during crystallization.

Volatile constituents are believed to play a prominent part in the evolution of rocks of the alkaline (Atlantic) suite. They are responsible for the desilication of the alkali aluminium polysilicates. Both carbon dioxide and water appear to be the principal agents in this process: Thus, reactions of the type—

may represent equilibrium relations in a residual liquid rich in water (such as the granite stage of differentiation). If the precipitation of alkali-feldspars, biotite and quartz is followed by their withdrawal, the concentration of nepheline molecules will lead finally to the separation of this constituent. Assemblages of nepheline, svenites, urtites and ijolites may be differentiated in this way.

The capacity of CO_2 for desilicating polysilicates is attested by laboratory experiment; and it is not improbable that carbonates, by a process of absorption of limestone in a liquid already alkaline, have been effective in the generation of some alkaline rocks, especially those containing such minerals as calcite, cancrinite, melanite and melilite.

More obscurity surrounds the origin of the potassic or leucitic rocks. Their spatial arrangement in relation to the Pacific and Atlantic suites, no less than their chemical characters reflects their intermediate position. They are characteristic of the region lying between the orogenic zones and the foreland or regions of subsidence. The position of the potassic Roman province in relation to the Alpine orogenic zone on the one hand and the alkaline basin of the west Mediterranean illustrates this relation very clearly. The formation of leucite by dissociation of orthoclase (incongruent melting) is an important reaction in the genesis of some potassic rocks. Normally in the presence of abundant water under cover, the desilication of the polysilicate would appear to proceed a stage further in the formation of the orthosilicate (KAlSiO_4) which is precipitated in biotite—usually at the granitic stage—and the generation of leucite would in some cases appear to be connected with a loss of water from a biotite-rich liquid (e.g., of the composition of minette) by its intrusion or extrusion near or at the surface. Leucite-bearing rocks are rare as plutonic rocks (the leucite being usually replaced by orthoclase and nepheline). The generation of the potassic series may indeed be dependent on a prior differentiation of a magma to a stage in which biotite is accumulated, as revealed, e.g., in mica-rich lamprophyres.

Desilication of potash-feldspar appears then as a characteristic reaction in rocks of the Mediterranean suite. Their relation to the Pacific suite is provided in the equilibria existing between potash-feldspar, biotite, leucite and olivine; to the Atlantic suite in the equilibria between alkali-feldspars, feldspathoids and quartz; in the potassic series desilication of the albite molecule playing a subordinate rôle.

The genetic relations between the three suites are amply attested and enforce the conclusion that no sharp line of division between them is to be recognized. Their source is a common stock magma. Nevertheless we appear to see in the relative distribution of the three series upon the face of the globe, the influence of tectonic processes as an external factor exerting a profound influence on the trend of differentiation.

BIBLIOGRAPHY.—Most text books of geology treat of petrology in more or less detail (see GEOLOGY, § BIBLIOGRAPHY).

Elementary books on petrology include—A. Harker, *Petrology for Students*, 6th ed. (1923); F. Rinne, *Gesteinskunde*, 9th ed. (1923); J. de Lapparent, *Leçons de Petrographie* (1923); L. V. Pirsson, *Rocks and Minerals*, 2nd ed. by A. Knopf (1926); G. W. Tyrrell, *The Principles of Petrology* (1926); F. H. Hatch, *The Petrology of the Igneous Rocks*, 6th ed. (1926); S. J. Shand, *Eruptive Rocks* (1927).

More advanced works include—A. Harlir, *The Natural History of Igneous Rocks* (1909); J. P. Iddings, *Igneous Rocks*, 2 vols. (1909–13) and *The Problem of Vulcanism* (1914); H. Rosenbusch, *Mikroskopische Physiographie*, 4th ed. vol. 2 (1907), and *Elemente*

der Gesteinslehre, 4th ed. by A. Osann (1923); F. v. Wolff, *Der Vulkanismus*, 2 vols. (1914–22); R. A. Daly, *Igneous Rocks and their Origin* (1914); F. W. Clarke, *The Data of Geochemistry*, Bull. U.S.G. Survey, No. 770 (1924); P. Niggli, *Gesteins und Mineral-provinzen* (1923).

For rock minerals:—J. P. Iddings, *Rock Minerals*, 2nd ed. (1911); H. Rosenbusch, *Mikroskopische Physiographie*, 5th ed. by O. Mügge (1925–27); E. S. Larsen, *The Microscopic Determination of the non-opaque Minerals*, Bull. U.S.G. Survey, No. 679 (1921); N. H. and A. N. Winchell, *Elements of Optical Mineralogy*, Pt. II., 2nd ed. by A. N. Winchell (1927).

On the classification of igneous rocks see especially L. Milch, *Die Systematik der Eruptiven gesteine I. II.*, *Fortschritte der Mineralogie*, vols. 4–5 (1913–14); on their geographical distribution see M. Stark, *Petrographische Provinzen*, *Fortschritte der Mineralogie*, vol. 4 (1914); P. Niggli, *Der Tavayannarsandstein und die Eruptivgesteine der jung-mediterranen Kettengebirge*, *Schweiz. Min. Petr. Mitt.*, vol. 2 (1922); C. R. Burri, *Chemismus und provinzielle Verhältnisse der jungeruptiven Gesteine des pazifischen Ozeans und seiner Umrandung*, *Ibid.*, vol. 6 (1926).

A glossary of rock names is contained in A. Holmes, *The Nomenclature of Petrology* (1920). See also K. H. Scheumann, *Ausländische Systematik, Klassifikation und Nomenklatur der Magmengesteine I.* in *Fortschritte der Mineralogie*, vol. 10 (1925).

The classical works on rock synthesis include F. Fouqué—A. Michel Levy, *Synthèse des Minéraux et des Roches* (1882); J. H. L. Vogt, *Silikatschmelzlösungen*, I. (1903), II. (1904). The principal authorities on the analysis and chemical composition of rocks are H. S. Washington, *Manual of the Chemical Analysis of Rocks*, 3rd ed. (1919); W. F. Hillebrand, *Analysis of Silicate and Carbonate Rocks*, Bull. U.S.G., Survey No. 700 (1919); H. S. Washington, *Chemical Analyses of Igneous Rocks*, Prof. Paper U.S.G. Survey, No. 99 (1917). See also Cross, Iddings, Pirsson and Washington, *Quantitative Classification of Igneous Rocks* (1902), for a chemical classification of igneous rocks.

Books devoted to physico-chemical petrology, include above all H. Boeke, *Grundlagen der physikalisch-chemischen Petrographie*, 2nd ed. by W. Eitel (1923). See also P. Niggli, *Die Leichtflüchtigen Bestandteile im Magma* (1920); O. H. Erdmannsdorfer, *Grundlagen der Petrographie* (1924); W. Eitel, *Physikalisch-chemische Mineralogie und Petrologie* (1925); R. H. Rastall, *Physico-chemical Geology* (1927). For experimental work on silicate mixtures see especially the papers published by the workers of the Geophysical Laboratory, Carnegie Institution, Washington, principally in *American Journal of Science*, *Journal of Geology* (1905, etc.).

Much information on rocks is contained in the memoirs of the various geological surveys and in *Quart. Journ. Geol. Soc. of London*, *Mineralogical Magazine*, *Geological Magazine*, *American Journal of Science*, *Journal of Geology*, *American Mineralogist*, *Neues Jahrbuch für Mineralogie* (Stuttgart), *Tschermak's Mineralogische Mitteilungen* (Vienna), *Fortschritte der Mineralogie* (Berlin), etc. (C. E. T.)

PETRONIUS (PETRONIUS ARBITER), Roman satirist, under whose name we have some considerable fragments of a remarkable satire or satirical romance (*Petronii Arbitri Satirae*). We find various references to the author in later writers, e.g., Macrob., *Somn. Scip.*, i. 2.8 "plots full of the fictitious adventures of lovers with which Arbitr occupied himself a great deal," Lydus, *De Magistratibus*, 41 "Turnus and Juvenal and Petronius who by merely pursuing abuse injured the law of satire," Sidonius Apole., *Carm.*, xxiii. 155, etc., but none of these throw any clear light upon the date or personality of the writer. Modern scholarship inclines to identify him with Gaius (so apparently Tac., *Ann.* xvi., 17 and 18, though in both passages the reading is disputed: Titus is given as his praenomen in Plin. N.H. xxxvii. 20 and Plutarch, *Mor.* 60 E) Petronius, the one time favourite of Nero, of whose character a remarkable picture is presented by Tacitus *Ann.* xvi. 18: "Regarding Gaius Petronius a few words must be said by way of retrospect His days were passed in sleep, his nights in social engagements and the pleasures of life. The fame which other men attain by diligence he won by indolence, and he was not considered a debauchee and a profligate, like others who exhaust their substance, but a man of refined luxury. His sayings and his acts, in proportion as they were free and ostentatious of recklessness, were so much the more gladly taken as a type of simplicity. Yet as pro-consul of Bithynia, and presently as consul, he showed himself a vigorous and capable man of affairs. Then declining again upon vice, or aping vice, he was admitted by Nero among the select few of his friends—the arbiter

of elegance, those things only appealing to the jaded emperor's eyes and other senses which the approval of Petronius commended to him. Hence the jealousy of Tigellinus, as toward a rival and superior in the science of pleasure. And so he played upon the emperor's cruelty—the lust which now occupied him beyond all other lusts—charging Petronius with being a friend of Scaevinus. . . . The emperor, as it happened, had at that time started for Campania and Petronius, on reaching Cumae, was arrested. He refused to endure the suspense of fear or hope. Yet he did not put away his life precipitately, but he had his severed veins bound up and again re-opened at his pleasure, while he spoke to his friends, not in serious language or such as might win him fame for his firmness, and listened to them repeating—not anything about the immortality of the soul and the doctrines of the philosophers—but light poetry and frivolous verse. To some of his slaves he gave largesse, to others stripes. He dined too and indulged in sleep, that so his compulsory death might resemble a natural one. Nor did he, like most men in their last moments, flatter in his will either Nero or Tigellinus, or any other powerful person, but he wrote out a full account—with the names of his associates, male and female—of the emperor's excesses and of every novel debauchery. This he sealed and sent to Nero, and then broke his signet-ring in order that it might not be used presently to imperil others." This last act is paralleled by Plin. xxxvii. 20, who tells how the dying Petronius broke a precious bowl to prevent it falling into the hands of Nero.

While the identity of this Petronius with the author of the *Satirae* is perhaps incapable of definite proof (1) the cognomen *Arbiter*—which is not a cognomen in the proper sense, but only a nickname—strongly recalls the expression—*arbiter elegantiae*—applied to C. Petronius by Tacitus; (2) it is clear that the Petronius of Tacitus had the social experience, the temperament, and the ability to compose just such a satire; (3) the internal evidence, vague as it is, seems to suit the age of Nero better than any other. On the other hand, to imagine that the work represents the actual document which Tacitus describes Petronius as sending under seal to Nero is, of course, absurd.

The surviving portions of the work are fragments from the 13th and 16th books. The speaker is one Encolpius, who narrates the adventures of himself and his companions among the towns of southern Italy. The longest and, in many respects, the most important episode is that which is generally known as the *cena Trimalchionis* or Dinner of *Trimalchio*. The scene of the dinner is most probably Cumae (cf. § 53 in *praedio Cumano quod est Trimalchionis*). The giver of the feast, Trimalchio, is a fabulously wealthy freedman (§ 37 "Trimalchio's estates range as far as a kite can fly . . . and as for his slaves, I don't believe a tenth of them know their own master"), and his wife, Fortunata, is a strong-minded lady of the humblest origin. The sketch is a humorous presentation of the vulgarity and ostentation of the wealthy provincial. Next in importance is the episode of the Matron of *Ephesus*, in which, for the first time, so far as we know, that legend is introduced into the literature of the West.

In form and, to some extent at least, in manner, Petronius continues the tradition of the *Satirae Menippeae* of Varro. Thus, passages in verse are freely interspersed in the midst of the prose, the longest (295 hexameters), on the Civil Wars, being probably intended as a parody of Lucan's *Pharsalia*; another (65 iambic trimeters) describing the taking of Troy, then, and until the day of Tryphiodorus, a favourite theme of the minor poet. From the standpoint of literary history the work may be regarded as the forerunner of the novel of adventure—such as flourished in England in the 18th century—the type, that is, which Aristotle would have called "episodic," in which the episodes succeed one another without probable or necessary sequence (Arist., *Poet.* c. ix), and the interest depends, not on the evolution of a skilfully constructed plot, but on the convincing presentation of individual episodes.

The main purpose of the *cena* is the delineation of the rich and vulgar upstart, the *nouveau riche*, *repente dives*, *νέπλουτος*. The type was, of course, well known both in real life and on the stage: Cic., *Phil.* ii. 65, *exultabat gaudio persona de mimo "modo egens*

repente dives." Aristotle describes the state of the *nouveau riche* as "a sort of indiscipline in wealth" (*Rhet.* ii., 16 *ἀπαίδευσία πλούτου*: contrast the erudite *luxu* of Petronius, Tac., *Ann.* xvi. 18). Ostentatious display of wealth in entertaining was a characteristic feature: Plut., *Lucull.* 40, "The daily dinners of Lucullus were the dinners of a *nouveau riche*: not only were there purple-dyed coverlets, cups set with precious stones, choirs and individual artists introduced as interludes, but also he roused the envy of the vulgar with the elaboration of all sorts of meats and curiously prepared sweetmeats." The extreme type of the *nouveau riche* was the newly-wealthy freedman, the "newly-wealthy Phrygian" or Aristoph., *Vesp.*, 1309, the *νέπλουτος ἀπελεύθερος*, who does not know either how to dress properly or how to behave at table (Lucian, *Hist. Conscr.*, 20), who, dining with philosophers, apes their subtleties by propounding the question: "Why do white and black beans alike make pale soup?": only to be silenced by a reminder of his antecedents: "Why do white and black straps alike make purple weals?" (Plut., *Quaest. Conv.*, ii. 12), whose vulgarity reveals itself in an over-anxiety to please his guests: Plut., *Quaest. Conv.*, vii. 3. "To ask what meats and sweetmeats the guest likes best. or to question him about different wines and perfumes," is very vulgar and a mark of the *nouveau riche*, cf. Petron. 48. "If you don't like the wine I'll change it." Trimalchio is a most felicitous presentation of the wealthy parvenu in his parade of his wealth—so frankly vulgar as to become almost an engaging simplicity (§ 48 "I don't have to buy . . . everything is grown on my suburban estate, which I haven't seen yet. I'm told it joins my lands in Terracina and Tarentum. What I wish now is to annex Sicily to my little crofts so that, if I want to go to Africa, I may be able to make the whole journey on my own estates"), his cheap sentimentality (§ 35 *Eheu nos miseros, quam totus homuncio nil est*, cf. § 72), his pretence to learning (§ 48, "I've two libraries, one Greek, the other Latin"), which is only pretence (§ 71 "Gaius Pompeius Trimalchio Maecenatius lies here . . . Pious, brave, faithful, starting from a humble beginning he left a quarter of a million and never listened to a philosopher").

For the student of social manners, as for the student of colloquial language and colloquial idiom, the extant remains are of inestimable value, and, if only on that ground, the loss of the rest of the *Satirae* is one which, in spite of the indecency which mars the work, every scholar must most deeply regret.

BIBLIOGRAPHY.—*Editio Princeps*, Venice (1499). The bulk of the *Cena Trimalchionis* was unknown until Martinus Statilius (Petrus Petitus) discovered at Trau in Dalmatia a ms. (codex *Traguriensis*) containing it (pub. Padua and Paris, 1664). PETROPAVLOVSK, (1) a town in the Akmolinsk district of the Kazakstan A.S.S.R., in 55° N. and 69° E., on the left bank of the Ishim river, where the Trans-Siberian railway crosses it. Pop. (1926) 44,272. The town is a centre for caravan trade from the Kirghiz steppe in corn, cattle, furs, tea, wool and cotton and has an Asiatic appearance.

(2) A port on the eastern shores of Avacha bay in Kamchatka, in the Far Eastern area of the Russian S.F.S.R. in 53° 16' N., 159° E. Pop. (1926) 1,670. The inhabitants are mainly Russians, Japanese, Chinese, Koreans and natives, and the town, which has been growing rapidly recently, is a centre for the fur trade. There are summer sailings to Vladivostok and Japan, but the harbour is frozen from November to May. There is a wireless station, linking with Vladivostok and with the fish canneries in the north of Kamchatka. The Russian Pacific fleet was stationed here for a time and defeated a combined attack by the French and English during the Crimean War. It was transferred in 1854 to Nikolayevsk-on-Amur and ultimately to Vladivostok.

PETRÓPOLIS, a city of the state of Rio de Janeiro, Brazil, in an elevated valley of the Serra da Estrêla or dos Orgãos, 2,634 ft. above sea level and 27 mi. N. of the city of Rio de Janeiro, with which it is connected by a combined railway and steamship

line, and also by a longer railway line. Pop. (1940, including the municipal district) 82,960. Petrópolis is served by the Principe do Grão Pará railway, now a part of the Leopoldina system, which connects with Rio de Janeiro and Niterói on the coast, and with the station of Entre Rios on the Central of Brazil railway. Its favourable altitude gives the city a cool, invigorating climate. The rainfall is abundant, and especially so in summer (Dec. to March) when the humidity is extreme. Vegetation is luxuriant. Its water-power and cool climate are making it an important manufacturing town.

Petrópolis was founded in 1845 by Julius Frederick Knoeller under the auspices of the emperor of Brazil, Dom Pedro II, on lands purchased in 1822. The Mauá railway was opened to the foot of the *serra* in 1854, and the macadamized road (now a good motor road) up the *serra* to the town in 1856. The mountain section of the railway, on the Riegenbach system, was completed in 1883. Petrópolis has since become the summer residence of the diplomatic corps and government officials.

PETROVARADIN (German *Peterwardein*), a town and fortress of Croatia-Slavonia, Yugoslavia, situated on a promontory formed by a loop of the Danube; occupied by the axis in 1941. Pop. 5,101. It is connected with Novi Sad on the opposite bank by a railway bridge and a steam ferry. The fortifications consist of the upper fortress, on a lofty serpentine rock rising abruptly from the plain on three sides, and of the lower fortress, rising from the river on the northern base of the rock.

The fortress is believed to represent the Roman Acumincum, and received its present name from Peter the Hermit, who in 1096 marshalled the levies of the first crusade here. It was captured by the Turks in 1526 and was retained by them for a period of 160 years.

PETROVSK, the name of several Russian towns, the most important being Petrovsk in the province of Saratov, on the Medveditsa, a tributary of the Don, in 52° 22' N., 45° 19' E., and on a branch railway linking with the Volga river. Population 18,000. It has oil pressing and flour mills, and manufactures agricultural machinery.

PETROZAVODSK, the chief town in the Karelian A.S.S.R., of the Russian S.F.S.R. in 61° 41' N., 34° 20' E., on the west shore of Lake Onega, and on the Leningrad-Murmansk railway. Pop. (1939) 69,728.

PETRUS AUREOLUS (ORIOLE), scholastic philosopher and monk of the Franciscan order, lived in the latter half of the 13th century, and died in Paris in 1321 just after his appointment as archbishop of Aix. He was one of the first to attack the realist doctrines of Duns Scotus, and is interesting mainly as the precursor of William of Occam in his revival of Nominalism. He was known as *Doctor Facundus* and *Doctor Abundans*.

PETTENKOFER, MAX JOSEPH VON (1818-1901), Bavarian chemist and hygienist, was born at Lichtenheim, near Neuburg. He studied pharmacy and medicine at Munich, and after working under Liebig at Giessen was appointed chemist to the Munich mint in 1845. Two years later he was chosen extraordinary professor of chemistry in the medical faculty, in 1853 he received the ordinary professorship, and in 1865 he became also professor of hygiene. In 1894, he retired from active work, and on Feb. 10, 1901, he committed suicide. The reaction known by his name for the detection of bile acids was published in 1844. In his widely used method for the quantitative determination of carbon dioxide the gaseous mixture is shaken up with baryta or lime water of known strength and the change in alkalinity ascertained by means of oxalic acid. His name is most familiar in connection with his work in practical hygiene and nutrition.

Pettenkofer gave vigorous expression to his views on hygiene and disease in numerous books and papers; he was an editor of the *Zeitschrift für Biologie* from 1865-82, and of the *Archiv für Hygiene* from 1883-94.

PETTIE, JOHN (1839-1893), Scottish painter, was born in Edinburgh on the 17th of March 1839. At sixteen he entered the Trustees' Academy in Edinburgh, working under Robert Scott Lauder. His first exhibits at the Royal Scottish Academy were "A Scene from the Fortunes of Nigel"—one of the many subjects

for which he sought inspiration in the novels of Sir Walter Scott—and two portraits in 1858. To the Royal Academy in 1860 he sent "The Armourers"; and in 1862 he settled in London, where he joined Orchardson. In 1866 he was elected A.R.A., and in 1874 R.A. Pettie died at Hastings on Feb. 21, 1893.

John Pettie, R.A. (1908), by his nephew Martin Hardie, gives the story of his life, a catalogue of his pictures, and fifty reproductions.

PETTY, SIR WILLIAM (1623-87), English statistician and political economist, born on May 26, 1623, the son of a clothier at Romsey in Hampshire, received his early education at the grammar school there. He studied for some time at Caen, and on his return to England, seems to have entered the Royal Navy. He went abroad again in 1643, and remained for three years in France and the Netherlands, pursuing his studies. In 1647 Petty obtained a patent for the invention of double writing, *i.e.*, a copying machine. In politics he espoused the side of the parliament. In 1648 he was made deputy professor of anatomy at Oxford, and on obtaining the degree of doctor of physic, 1649, was made a fellow of Brasenose college. In 1654, observing that the admeasurement and division of the lands forfeited in 1641 had been "most inefficiently and absurdly managed," he contracted to execute a fresh survey, which he completed in 13 months. On purchasing a large estate in county Kerry, he set up ironworks in that neighbourhood, opened lead-mines and marble-quarries, established a pilchard fishery, and commenced a trade in timber. Besides the office of commissioner of distribution of the lands he had surveyed, he held that of secretary to the lord-lieutenant, Henry Cromwell, and was also during two years clerk of the council. In January 1658 he was elected to Richard Cromwell's parliament as member for West Looe in Cornwall. After the Restoration he returned to England and was favourably received and knighted by Charles II., who was "much pleased with his ingenious discourses." He obtained from the king a new patent constituting him surveyor-general of Ireland. In 1663 he invented a double-bottomed ship, which twice made the passage between Dublin and Holyhead, but was afterwards lost. He was one of the first members of the Royal Society, and sat on its council. He died in London on Dec. 16, 1687.

Petty's Irish survey was based on a collection of social data which entitles him to be considered a pioneer in the science of comparative statistics. He was also one of the first to break away from mercantilist ideas, and he exhibits a statesmanlike sense of the elements in which the strength of a nation really consists. Roscher names him as having, along with Locke and Dudley North, raised the English school to the highest point it attained before the time of Hume. His *Treatise of Taxes and Contributions* contains a clear statement of the doctrine that price depends on the labour necessary for production. Petty is much concerned to discover a fixed unit of value, and he thinks he has found it in the necessary sustenance of a man for a day. He understands the cheapening effect of the division of labour. He states correctly the notion of "natural and true" rent as the remainder of the produce of land after payment of the cost of production; but he seems to have no idea of the "law of diminishing returns." He has much that is just on the subject of money; he sees that there may be an excess of it as well as a deficiency, and regards the prohibition of its exportation as contrary to sound policy. But he errs in attributing the fall of the rate of interest which takes place in the progress of industry to the increase in the quantity of money. He protested against the fetters imposed on the trade of Ireland, and advocated a union of that country with Great Britain.

A complete list of his works is given in the *Athenae oxonienses*. The most important are: the *Treatise of Taxes and Contributions* (1662, 1667 and 1685); *Political Arithmetic*, presented in ms. to Charles II., but, because it contained matter likely to be offensive to France, kept unpublished till 1691, when it was edited by Petty's son Charles; *Quantulumcumque, or a Tract concerning Money* (1682); *Observations upon the Dublin Bills of Mortality in 1681 and the State of that City* (1683); *Essay concerning the Multiplication of Mankind* (1686) - *Political Anatomy of Ireland* (1691). Several papers appeared in the *Philosophical Transactions*. See *Economic Writings of Sir William Petty*, ed. C. H. Hull (2 vols., 1899); W. Roscher, *Study on Petty in Transactions of the Royal Scientific Society of Saxony* (Leipzig).

PETTY SESSIONS: *see* SESSION.

PETUNIA, a genus of plants belonging to the nightshade family (Solanaceae) and containing about 15 species, chiefly South American (southern Brazil and Argentina). The origin of the many hybrid garden forms is almost completely lost in obscurity, and they are hence assigned to *P. hybrida*. The varieties of petunia make admirable specimens for pot culture and for bedding. Many gorgeous, ruffled varieties are in cultivation.

PETWORTH, a town in Sussex, England, 55 mi. S.S.W. from London by the S.R. Pop. (1931) 2,444. Petworth (Peartingaynrth, Peteorde, Puetewird, Pedewurde, Putteworth, Pytteworth, Petteworth) is named in a grant by Eardwulf, king of Northumbria, to St. Peter's church, about 791. Under Edward the Confessor Petworth was an allodial manor held by his queen Edith, and in 1086 Robert Fitz-Tetbald held it of Roger de Montgomery, earl of Shrewsbury. Petworth house dates from the 18th century and is remarkable for the magnificence of its interior, its wood carvings by Gibbons and Ritson, and its collection of pictures. At Bignor nearby are remains of a Roman villa.

PEUTINGER, KONRAD (1465-1547), German humanist and antiquarian, was born at Augsburg. In 1497 he was town clerk of Augsburg, and was on intimate terms with the emperor Maximilian. He was one of the first to publish Roman inscriptions, and his name remains associated with the famous *Tabula Peutingeriana*, a map of the military roads of the western Roman Empire, discovered by Konrad Celtes. Peutinger also edited the *Historia Gothorum* of Jordanes, and the *Historia gentis Langobardorum* of Paulus Diaconus.

The *Tabula Peutingeriana* was first published as a whole by F. de Scheyb (1753); later editions by E. Desjardins (1869-74) and C. Miller (1888); *see also* E. Paulus, *Erklärung der Peutinger Tafel* (1867); Teuffel-Schwabe, *Hist. of Roman Literature* (Eng. trans., 1900).

PEVENSEY, a village in Sussex, England, 65 mi. S.S.E. from London by the S.R. Pop. (1931) 793. It was the landing place of William the Norman on his way to conquer, and was the *caput* of the rape of Pevensey, granted by William to the earl of Mortain, and subsequently became the honour of the Eagle. Some time before the reign of Edward I. the town of Pevensey was made a member of Hastings and shared the liberties of the Cinque Ports. By an act of 1883 it ceased to exist as a borough. The decline of Pevensey was caused by the recession of the sea. The outer wall, with towers, of the castle is Roman, and is generally considered to have enclosed the strong town of *Anderida*. Within are the ruins, principally of the 13th century, but in part Norman, of the castle proper, with a keep and four round towers. The church of St. Nicholas, close to the castle, is Early English. It is doubtful whether Pevensey was the scene of Caesar's landing in 55 B.C.

PEW, a term, in its most usual meaning, for a fixed seat in a church, usually enclosed, slightly raised from the floors, and composed of wood framing, mostly with ornamented ends. Some bench ends are certainly of Decorated character, and some have been considered to be of the Early English period. They are sometimes of plain oak board, 2½ to 3 in. thick, chamfered, and with a necking and finial generally called a *poppy head*; others are plainly panelled with bold cappings; in others the panels are ornamented with tracery or with the *linen pattern*, and sometimes with running foliages. The large pews with high enclosures, known familiarly as "horse-boxes," and common in English churches during the 18th and early part of the 19th centuries, have nearly all been cleared away. The church of Whitby, in Yorkshire, is perhaps the best surviving example of an unaltered interior.

At common law all seats in a parish church are for the common use of all the parishioners, and every parishioner has a right to a seat without paying for it. As against the assignment and disposition of seats by the ordinary, acting through the churchwardens, two kinds of appropriation can be set up (*a*) by the grant of a faculty by the ordinary, and (*b*) by prescription, based on the presumption of a lost faculty. Such faculties are rarely granted now, they were formerly common; the grant was to a man and his family "so long as they remain inhabitants of a certain house in the parish." The letting of pews in parish churches became common in the 16th century, but there are some

earlier instances of the use, for example at St. Ewens, Bristol, in 1455.

See A. Heales, *History and Law of Church Seats and Pews* (1872); Phillimore, *Eccles. Law* (1896), ii. 1424 sq.

PEWTER, an alloy, the basis of which is tin. It is mixed with another metal, generally lead, the proportions varying from six to four parts of the former to one of the latter. Occasionally brass or copper takes the place of the lead. The Rev. William Harrison, writing in the time of Queen Elizabeth, a period when pewter was much in favour, says, "I have been also informed that it consisteth of a composition which hath thirty pounds of kettle brass to a thousand pounds of tin, whereunto they add three or four pounds of tin glass; but, as too much of this doth make the stuff brickle, so the more the brass be, the better is the pewter, and more profitable unto him that doth buy and purchase the same."

Of its antiquity it is difficult to speak with certainty owing to the doubtful meaning of the terms employed. It is said to have been known to the ancient Chinese, and it is claimed to have been made by the Chaldaeans, Egyptians and Greeks. As to its production by the Romans, mention is made by early writers, and all doubt has been removed by the analysis of some of the pewter of the Roman period found at Appleshaw, Hampshire, and now in the British Museum. From early days the rich mines of Cornwall were the repository which supplied the Continent with tin of fine quality: it is therefore only natural to find the use of pewter very common in England and the adjacent countries. The ordinary methods of working the metal were by casting, turning and hammering. The most satisfactory pewter is marked by simplicity, a good outline and an absence of decoration.

The use of pewter followed three main lines: it was employed for church vessels, for domestic purposes, and in a less degree for what might be termed civic functions. In England pewter was already used in the service of the church in early mediæval times. Chalice of pewter had replaced wooden vessels before the end of the 11th century; but, in 1171 the Council of Westminster proscribed this metal and bishops were forbidden "to bless a chalice of pewter." From that time until the 15th century it was customary to bury a pewter chalice with the priest. Various references are found from which it may be inferred that in addition to their silver vessels many churches possessed a chalice of pewter or tin destined to be buried with the priest. Such chalices have frequently been found on the opening of coffins. Cruets for the wine and water of the Mass were also of pewter. After the Reformation and throughout the 17th and 18th centuries a large number of pewter vessels are found, especially flagons. The canon of 1603 ordered that the wine should be "brought to the Communion table in a clean and sweet standing pot or stoup of pewter if not of purer metal." Many such flagons still survive, dating from any time up till the end of the 18th century; they follow the shape of the contemporary silver vessels, the commonest being of cylindrical form with bold scroll handle and flat or domed lid. Alms dishes, patens and collecting plates are also found; a set of four beautiful dishes with enamelled centres dating from the 17th century, belong to the church of St. Katherine Cree in the City of London. Complete sets of communion vessels in pewter are rare. The Elizabethan communion cup with its band of engraved ornament is occasionally to be met with in pewter, a rather puzzling fact when it is remembered how common silver was at that period. It seems clear that generally speaking chalices in pewter were merely a makeshift. The churches of Scotland are much richer in communion plate than those of England. At the time of the Reformation St. Giles's Church, Edinburgh, possessed a pair of pewter candlesticks for the high altar which were evidently considered of value. Till the end of the 18th century pewter was much in use, and more and finer vessels are found there than in England: they comprise communion vessels including the beaker form of cup in common use in the north-eastern parts of the country, basins for collecting alms, and a large number of communion "tokens." On the Continent pewter had a much wider application in church vessels and furniture; while chalices and patens were ordered to be of silver at least in part, the cruets were frequently of pewter. This metal was also used for holy-

ENGLISH PEWTER DISH

Charles II, dish, second half of 17th century, engraved in the centre with the royal arms encircled by the garter, with supporters; surmounted by a helmet, crowned, and having above it a lion and the initials C.R. Beneath is the royal motto. "Dieu et mon droit." Along the inner rim is the inscription, "Vivat Rex Carolus Secundus, Beati pacifici 1662." This plate was presented by a member of the royal family, possibly by George III., to Lord Onslow, in 1765. Diam. 22"

BY COURTESY OF THE DIRECTOR OF THE VICTORIA AND ALBERT MUSEUM

FRENCH AND GERMAN PEWTER PLATES AND SALVERS

1. Large salver, "Temperantia" dish, cast in relief, by François Briot of Lorraine, c. 1580–90, signed F.B. The plate is decorated with figures of Minerva and the seven arts, the four elements, and Temperance in the centre. Diam. 17½ in. (See Plate II., fig. 1, for ewer.)
2. Large salver cast in relief and set with a plaque of Limoges enamel. The band of ornament on the outer rim shows scenes from the parable of The Prodigal Son. French, 1550–70. Diam. 17 11/16 in.
3. Two plates cast in relief: (a) Mark, the arms of Nürnberg, with the initials I.H. South German, dated 1628. Diam. 7⅛ in. (b) Mark, the arms of Nürnberg with the initials B.O. South German, dated 1619. Diam. 6.95 in.

FRENCH AND SWISS PEWTER, 16TH CENTURY

1. "Temperantia" ewer, by François Briot of Lorraine, c. 1580-90. Signed F.B. It is decorated with figures of the three cardinal virtues. Ht. 11 in. (See Plate V., fig. 1, for salver.)
2. Large flagon; a guild tankard of silvered pewter cast in relief, with emblematic figures of virtues, muses, and planets, and on the handle figures of Lucretia and Judith, from designs by Peter Flötner of Nürnberg. Probably Swiss, Zürich, second half of 16th century. Ht. 20 $\frac{1}{4}$ in.
3. Tankard with cover, embossed, the sides containing oval medallions with allegorical figures. French, late 16th century. Style of François Briot. Ht. 7 $\frac{1}{4}$ in. diam. 4 $\frac{7}{8}$ in.

water vessels (*bénitiers*), crosses and crucifixes, chrismatories and aitar candlesticks. In England efforts are now being made to revive the use of pewter for altar furniture; the difficulty formerly presented by the softness of the metal and its liability to denting seems likely to be overcome by a method of hardening.

In domestic life pewter played an important part for many centuries in the past. In England its use is recorded in the 13th century. Edward I. is said to have owned over 300 vessels of pewter. The Pewterers' Company of the City of London had already been in existence for more than a century and a half when Edward IV. in 1473 presented its first charter granting the right of assay. London was not the only place of manufacture; pewter was produced in several other towns, among them being York, Newcastle, Exeter and Bristol. Although in great favour with the nobility and even with royalty in those days, its use soon became secondary to that of silver and with the middle classes it took the same place as silver among the wealthy.

In Elizabethan days Harrison relates that it had attained a high degree of popularity. The old men of his village, he says, had told him of "the exchange of vessels, as of treen platters" into pewter, and wooden spoons into silver or tin. "For so common were all sorts of treen stuff in old time that a man should hardly find four pieces of pewter in a good farmer's house . . . whereas in my time . . . will the farmer think his gains very small . . . if he have not . . . a fair garnish of pewter on his cupboard, with so much more in odd vessel going about the house." The craft of the pewter had obviously reached its zenith at that time, and its popularity continued for at least the two following centuries. Tankards, measures, plates and salvers were produced, the forms following those of silver but with the minimum of decoration, as was fitting for such a metal. Engraving is used at times; the Victoria and Albert museum, London, possesses two large dishes of the time of Charles II. decorated with arms and large flowers and fruit executed in a kind of zig-zag engraving, and a set of plates and dishes of the following century engraved with figure subjects in Hogarthian style. The use of pewter declined during the 19th century, although employed for candlesticks, teapots, spoons and other domestic utensils; its manufacture survives still for tankards and measures such as are needed in inns and in refreshment houses. The *Art Nouveau* movement in the opening years of the present century witnessed an endeavour to revive the manufacture of pewter.

In France pewter is found in the 14th century in the form of drinking vessels, plates and salt-cellars, as well as cooking pots for the kitchen. Companies of pewterers existed in various towns, and the trade was flourishing and vigorous. In the 16th century highly ornamented pieces are found, such as those associated with the name of François Briot, the greatest of French pewterers. His well-known Temperantia salver and ewer are covered with ornament in relief. On the ewer are figures of the cardinal virtues, while on the dish are figures of Minerva and the seven arts, with the four elements. A figure of Temperance occupies the central boss, while the whole of the remaining surface is filled with relief ornament. A medallion portrait of Briot appears on the reverse of the dish. Another salver of similar character shows scenes from the story of the Prodigal Son on the outer rim in relief; two inner borders of strapwork, masks, and other ornament surround a central enamelled boss. Fine examples are preserved in the Cluny museum, Paris. Much good pewter was produced during the 17th and 18th centuries. At the end of the 19th century several craftsmen produced good decorative pewter worthy of the older traditions of the art, and following the style of the 16th century workers.

Germany had an established industry of pewter at Augsburg and Nuremberg in the 14th century, Belgium and Holland perhaps earlier; Switzerland must have been working about the same time, as well as Russia and the Scandinavian countries. There is a greater variety of vessels and a wider application of usefulness than in England or Scotland. The treatment of pewter in relief is much more common, and it may easily be imagined how pewter found a natural home with the wood-panelled German or Swiss room for its setting. A pewter cistern and basin often of fanci-

ful shape was a necessary adornment of the Swiss sideboard, while German hostels afforded much in the way of tankards and other drinking vessels. Some German pieces appear to have been purely ornamental, as for example the plates with portraits of emperors in relief or with medallions of Bible scenes. Caspar Enderlein of Nuremberg imitated the designs of the French pewterer, François Briot, and produced a copy of his Temperantia dish. An unusual treatment of tankards shows a wooden vessel inlaid with pewter scrollwork, while in others the pewter is inlaid with brass.

In Germany and Switzerland are found the enormous cups and flagons which formed the treasures of local trade guilds and similar institutions. Standing cups are as much as three feet in height, and one at least is known approaching four feet. They were frequently surmounted by a figure representing the trade to which they belonged, and a number of labels or medallions hanging from the upper part recorded the names of masters of the guild. Flagons were of capacious dimensions. Perhaps the place of honour may be accorded to an unusually noble example in the Victoria and Albert museum, London, of rather more than 20 in. in height. Round the upper and lower part of the body is a band of plaques of graceful emblematical figures taken from the designs of the well-known German ornamentist, Peter Flötner of Nuremberg. This flagon is Swiss work and dates from the 16th century. In recent years pewter has been produced in Germany at Nuremberg, Crefeld and Munich.

In America pewter was much used in the early colonial households. Some is found dating from the 17th century; but the period which marked its greatest production was the 100 years between 1750 and 1850. Boston appears to have been a main centre of manufacture. Every kind of utensil was made which was in any way requisite for domestic purposes. Some few pieces were produced for church use. Its appearance at a considerably later period than in Europe, and its persistence when other materials were available, prove its great popularity and the hold that it retained upon American taste long after it had ceased to interest the European.

in China, Korea and Japan the manufacture of pewter was known over 1,000 years ago and has continued until the present day. Much was produced in the 17th and 18th centuries, the shapes following those of bronze and porcelain; engraving was frequently added as an enrichment. Pewter was used and still is for rim-mounts of boxes and for decorative inlay. (See also DRINKING VESSELS; METALS; BRONZE AND BRASS; LEAD IN ART; SILVERSMITHS' AND GOLDSMITHS' WORK; TIN; COPPER.)

PFAFF, JOHANN FRIEDRICH (1765–1825), German mathematician, was born on Dec. 22, 1765 at Stuttgart. He studied at Gottingen and Berlin.

From 1788 to 1810 Pfaff was professor of mathematics in Helmstedt; from 1810 till his death, April 21, 1825, he held the chair of mathematics at Halle. His researches bore chiefly on the theory of series, to which he applied the methods of the so-called combinatorial school of German mathematicians, and on the solution of differential equations. His two principal works are *Disquisitiones analyticae maxime ad calculum integram et doctrinam serierum pertinentes* (4to., vol. i., Helmstedt, 1797) and a memoir on partial differential equations in *Abh. d. Berl. Acad.* (1814–1815). His method of integrating partial differential equations of the first order with any number of variables led Jacobi to introduce the term "Pfaffian problem."

PFALZBURG: see PHALSBOURG.

PFEIFFER, IDA LAURA (1797–1858), Austrian traveller, daughter of a merchant named Reyer, was born at Vienna

on Oct. 14, 1797. In 1820 she married Dr. Pfeiffer, a lawyer of Lemberg, who subsequently incurred official persecution and was reduced to poverty. In her later life Mme. Pfeiffer devoted her limited means to extensive travel. Her last journey was in 1846 to Madagascar, where she became involved in a plot to overthrow the government, and was expelled from the country. She died at Vienna on Oct. 27, 1858.

Her travels are described in *Reise einer Wienerin in das Heilige Land* (Vienna, 1843); *Reise nach dem Skandinavischen Norden und der Insel Island* (Pest, 1846); *Eine Frauenfahrt um die Welt* (Vienna, 1850); *Meine Zweite Weltreise* (Vienna, 1856); *Reise nach Madagascar* (Vienna, 1861, with a biography by her son).

PFLANZER-BALTIN, KARL, FREIHERR VON (1855-1925), Austro-Hungarian general, was born at Pecs in Hungary in 1855. On the outbreak of the World War he was charged with the defence of Transylvania, but when the Russians crossed the Carpathians, Pflanze-Baltin, with an improvised division threw himself on this enemy. After fighting with varying success in the southern part of Eastern Galicia and in the Bukovina, the VII. Army under his command was driven back by Brusilov's offensive in June 1916, whereupon he was relieved of his command. In the summer of 1918, entrusted with the command on the Albanian front which was yielding before the attack of the Entente army, Pflanze-Baltin won back, after a brief and powerful attack, the old positions southwards of Fjeri and Berac.

PFLEIDERER, OTTO (1839-1908), German Protestant theologian, was born at Stetten near Cannstadt in Württemberg on Sept. 1, 1839. From 1857 to 1861 he studied at Tübingen under F. C. Baur; and afterwards in England and Scotland. He then entered the ministry, became *repetent* at Tübingen, and for a short time held a pastorate at Heilbronn (1868). In 1870 he became chief pastor and superintendent at Jena and soon afterwards professor ordinarius of theology, but in 1875 he was called to the chair of systematic theology at Berlin, having made his name by his *Der Paulinismus*, published in 1873 (and ed., 1890; Eng. trans., *Paulinism*, 2 vols., 1873, etc.). Other important works are: *Das Urchristentum, seine Schriften und Lehren, in geschichtlichem Zusammenhang beschrieben* (1878; enl. ed. 1902; Eng. trans. 1906); *The Development of Theology since Kant, and its Progress in Great Britain since 1825* (1890), written for publication in England; *Religionsphilosophie auf geschichtlichen Grundlage* (1878; Eng. trans., *The Philosophy of Religion on the Basis of its History*, 1886-1888). *Die Entstehung des Christentums* (1905; Eng. trans., 1906); *Religion und Religionen* (1906; Eng. trans., 1907); and *Die Entwicklung des Christentums* (1907). Pfeleiderer was Hibbert lecturer in London in 1885, and Gifford lecturer at Edinburgh in 1894. He died on July 18, 1908. In New Testament criticism Pfeleiderer belonged to the school of F. C. Baur, but showed a greater disposition to compromise than the early Baur school.

PFLUGER, EDUARD (1829-1910), German physiologist, was born in Hanau and studied under Müller and du Bois Reymond at Bonn. In 1868 he founded the *Archiv für die gesamte Physiologie*, and ten years later opened the new Institute of Physiology at Bonn. His *Untersuchungen über die Physiologie des Electrotonus* (1859) marked the beginning of his life-long researches on metabolism, embryology and respiration. He experimented with cross-fertilization of the eggs of different species of frogs and became interested in the cleavage in the development of the eggs. He was able to show that the seat of respiration is not in the blood or lungs, but in the tissue.

PFORTA or **SCHULPFORTA**, formerly a Cistercian monastery dating from 1140, and now a German public school. It is in the Prussian province of Saxony, on the Saale, 2 m. S.W. of Naumburg. The remains of the monastery include the 13th century Gothic church, recently restored, the Romanesque chapel (12th century) and other buildings now used as dormitories, lecture rooms, etc. There is also the Fürstehaus, built in 1573. Schulpforta was one of the three *Fürstenschulen* founded in 1543 by Maurice duke, and later elector, of Saxony, the two others being at Grimma and at Meissen. Pforta passed to Prussia in 1815.

PFORZHEIM, a town of Germany, in the *Land* of Baden, at the confluence of the Nagold and the Enz, on the margin of the Black Forest, 19 mi. S.E. of Karlsruhe by rail. Pop. (1939) 78,784. Pforzheim is of Roman origin. From about 1300 to 1565 it was the seat of the margraves of Baden. It was taken by the troops of the Catholic League in 1624, and was destroyed by the French in 1689. It has the old palace of the margraves of Baden, and the Schlosskirche, the latter an edifice of the 12th-15th centuries. Pforzheim is the chief centre in Germany for the manufacture of gold and silver ornaments and jewellery.

PHAEDO, Greek philosopher, founder of the Elian school, was a native of Elis, born in the last years of the 5th century B.C. In the war of 401-400 between Sparta and Elis he was enslaved in Athens. He became a pupil of Socrates, who conceived a warm affection for him. It appears that he was intimate with Cebes and Plato, and he gave his name to one of Plato's dialogues. Athenaeus relates, however, that he resolutely declined responsibility for any of the views with which Plato credits him, and that the relations between him and Plato were the reverse of friendly. Aeschines also wrote a dialogue called *Phaedo*. Shortly after the death of Socrates Phaedo returned to Elis, where his disciples included Anchipylus, Moschus and Pleistanus, who succeeded him. Subsequently Menedemus and Asclepiades transferred the school to Eretria, where it was known as the Eretrian school and is frequently identified (e.g., by Cicero) with the Megarians. The doctrines of Phaedo are not known, nor is it possible to infer them from the Platonic dialogue. His writings, none of which are preserved, were in the form of dialogues.

See Wilamowitz, *Hermes*, xiv. 189 seq.

PHAEDRA, in Greek legend, daughter of Minos and Pasiphae. With her sister Ariadne she was carried off by Theseus to Athens, and became his wife. On the way to Eleusis she met Hippolytus, (*q.v.* for the rest of the legend).

PHAEDRUS, Roman fabulist, was by birth a Macedonian and lived in the reigns of Augustus, Tiberius, Gaius and Claudius. According to his own statement (prologue to book iii.), not perhaps to be taken too literally, he was born on the Pierian mountain, but he seems to have been brought at an early age to Italy, for he mentions that he read a verse of Ennius as a boy at school. According to the heading of the chief ms. he was a slave and was freed by Augustus. He incurred the wrath of Seianus, the powerful minister of Tiberius, by some supposed allusions in his fables, and was brought to trial and punished. We learn this from the prologue to the third book. The dates of publication of the fables are unknown, but Seneca, writing between A.D. 41 and 43 (*Consol. ad Polyb.* 27), knows nothing of Phaedrus, and it is probable that he had published nothing then. His work shows little or no originality; he simply versified in iambic trimeters the fables current in his day under the name of "Aesop," interspersing them with anecdotes drawn from daily life, history and mythology. He tells his fable and draws the moral with businesslike directness and simplicity; his language is terse and clear, but thoroughly prosaic. His Latin is correct, and, except for an excessive and peculiar use of abstract words, shows hardly anything that might not have been written in the Augustan age. From a literary point of view Phaedrus is inferior to Babrius, and to his own imitator, La Fontaine; he lacks the quiet picturesqueness and pathos of the former, and the exuberant vivacity and humour of the latter.

In the middle ages Phaedrus exercised a considerable influence through the prose versions of his fables which were current, though his own works and even his name were forgotten. Of these prose versions the oldest existing seems to be that known as the *Anonymus Nilanti*, so called because first edited by Nilant at Leiden in 1709 from a ms. of the 13th century. It approaches the text of Phaedrus so closely that it was probably made directly from it. But the largest and most influential of the prose versions of Phaedrus is that which bears the name of *Romulus*. It contains 83 fables, is as old as the 10th century, and seems to have been based on a still earlier prose version, which, under the name of "Aesop," and addressed to one Rufus, may have been made in the Carolingian period or even earlier. The collection of fables in the Weissenburg (now Wolfenbüttel)

ms is based on the same version as Romulus. These three prose versions contain in all 100 distinct fables, of which 56 are derived from the existing and the remaining 44 presumably from lost fables of Phaedrus. Several scholars have tried to restore these lost fables by versifying the prose versions.

The collection bearing the name of *Romulus* became the source from which, during the second half of the middle ages, almost all the collections of Latin fables in prose and verse were wholly or partially drawn.

The first edition of the five books of Phaedrus was published by Pithou at Troyes in 1596. In the beginning of the 18th century there was discovered at Parma a ms. of Perotti (1430-60), archbishop of Siponto, containing 64 fables of Phaedrus, of which some 30 were new. These new fables were first published at Naples, by Cassitto in 1808, and afterwards (much more correctly) by Jannelli in 1809. Both editions were superseded by the discovery of a much better preserved ms. of Perotti in the Vatican, published by Angelo Mai in 1831. For some time the authenticity of these new fables was disputed, but they are now generally accepted, and with justice, as genuine fables of Phaedrus. They do not form a sixth book, for we know from Avianus that Phaedrus wrote five books only, but it is impossible to assign them to their original places in the five books. They are usually printed as an appendix.

Since Pithou's edition in 1596 Phaedrus has been often edited and translated; among the editions may be mentioned those of Burmann (1718 and 1727), Bentley (1726), Schwabe (1806), Berger de Xivrey (1830), Orelli (1832), Eyssenhardt (1867), L. Müller (1877), Rica (1885), and above all those of L. Havet (Paris, 1895) and J. P. Postgate (*Phaedri Fabulae Aesopiae*, Script. Class. Bibl. Oxon. 1920). For the mediaeval versions of Phaedrus and their derivatives see L. Roth, in *Philologus*, i. 523 seq.; E. Grosse, in *Jahrb. f. class. Philol.*, cv. (1872); and especially the learned work of Hervieux, *Les Fabulistes latins depuis le siècle d'Auguste jusqu'à la fin du moyen âge* (Paris, 1884), who gives the Latin texts of all the mediaeval imitators (direct and indirect) of Phaedrus, some of them being published for the first time.

PHAER (OR PHAYER), **THOMAS** (1510?-1560), English translator of Virgil, was educated at Oxford and at Lincoln's Inn. He published in 1535 *Natura brevium*, and in 1543 *Newe Boke of Presidentes*. He says on the title-page of his version of the *Aeneid* that he was "solicitor to the king and queen's majesties, attending their honourable council in the marches of Wales." He settled at Kilgarran in Pembrokeshire, and combined the study of medicine with his legal practice. He wrote several medical works, and was admitted M.D. of Oxford in 1559. He contributed to Sackville's *Mirroure* for Magistrates, "Howe Owen Glendower, being seduced by false prophecies, toke upon him to be Prince of Wales." In 1558 appeared The Seven First Bookes of the *Eneidos* of Virgil converted into English Meter. He left his task incomplete. The translation was finished by Thomas Twyne in 1584. Phaer was the first to attempt a complete English version of Virgil, the earlier renderings of Surrey and Gawain Douglas being fragmentary.

PHAËTHON, in Greek mythology, was the son of Helios, the sun-god, and the nymph Clymene (Gr. *phaethōn*, shining, radiant). He persuaded his father to let him drive the chariot of the sun across the sky, but he lost control of the horses, and driving too near the earth scorched it. To save the world from utter destruction Zeus killed Phaethon with a thunderbolt. He fell to earth at the mouth of the Eridanus, a river of northern Europe (identified in later times with the Po), on the banks of which his weeping sisters, the Heliades, were transformed into poplars and their tears into amber. The story is most fully told in the *Metamorphoses* of Ovid (i. 750, ii. 366, and Nonnus, *Dionysiaca*, xxxviii). The fall of Phaëthon is a favourite subject, especially on sarcophagi, as indicating the transitoriness of human life.

See G. Knaack, "Quaestiones phaethontae," in *Philologische Untersuchungen* (1885); Wilamowitz-Möllendorff and C. Robert in *Hermes*, lviii. (1883); Frazer's *Pausanias*, ii. 59, which gives interesting parallels; S. Reinach, *Revue de l'hist. des religions*, lviii. (1908).

PHAETON, a low form of horse-drawn carriage also known as pony phaeton, likewise a high carriage with back to back seats. In the United States the term has been quite generally applied to an open type of automobile body with two fixed seats, four doors, folding top and removable curtains (See TOURING CAR.)

PHAGOCYTOSIS is the property possessed by many animal cells of engulfing particles by virtue of their power of amoeboid movement. Primarily this power was directed towards nutrition but in higher organisms it has been developed for different purposes and in pathology at the present day bears a wider meaning. The particle having been engulfed, one of three things may happen: (1) If the particle be digestible the cell secretes a digestive fluid, a food vacuole is formed, the particle is gradually dissolved by the secretion and the products absorbed into the cell substance. (2) If the particle be indigestible, it is retained within the cell for a time and ultimately discharged. The particle engulfed may comprise almost any material, but if it is to serve as a food it must be of animal or vegetable origin. At the time of ingestion it may be dead or living. If living the organism is first killed and then digested or (3) the organism may prove resistant, multiply and finally destroy the cell, when a number of organisms are set free. This is one of the means by which, in the higher organisms, a local infection may become distributed through the organism. Digestion within a cell is fermentative; a proteolytic ferment has been prepared from the bodies of amoebae which is active in acid, neutral or especially alkaline media.

The study of phagocytosis was largely extended in the elaboration of Metchnikoff's view of the nature of immunity. Thus, to take an instance from the sponges, minute organisms, which have penetrated the pores of the sponge are seized by the ciliated or amoeboid cells lining those spaces, and are then killed and digested. It is readily understandable that we should find such cells on the external surface of an organism or lining the alimentary tract. But in addition there are many fixed or wandering cells within the body in which phagocytic power is retained and markedly developed. They remove foreign material or debris which may occur within a tissue. For instance, as the result of an injury, inflammatory process, etc., cells and other structures of a tissue are destroyed. One of the processes preliminary to repair consists in the removal of the resulting debris, which is effected by phagocytes. A similar process is seen with red blood corpuscles which have escaped into a tissue through rupture of capillaries. Foreign particles accidentally gaining admission to a tissue are in many cases removed in a similar manner, e.g., soot particles which have passed through the respiratory surface are largely removed by phagocytes and carried to the bronchial lymphatic glands. Very commonly living organisms effect an entrance through wound surfaces, the alimentary surface, etc., and one of the processes employed for their destruction and removal is that of phagocytosis. Hence the phagocytes are regarded as scavengers of the tissues.

In the above-named instances the phagocytes are chiefly wandering cells brought to the seat of their activity by the blood. In any tissue where the process is going on phagocytes have accumulated in large numbers. They have been attracted to the damaged area by the chemical process of chemiotaxis. At the seat of the change chemical substances are produced (see PATHOLOGY) which act upon the phagocytes, causing them to migrate towards the source—positive chemiotaxis. The same chemical stimulus in a higher concentration may repel the cells—negative chemiotaxis. Instances of this are especially frequent in relation to micro-organisms and phagocytes.

Metchnikoff held the view, and supported it by many experiments that immunity and susceptibility to infective disease are essentially matters of phagocytosis but this eclectic view is now obsolete though it is not denied that phagocytosis plays an important part in removing bacterial and other debris rendered harmless by other means (see IMMUNITY).

As regards the different varieties of phagocytes, leaving apart the cells lining the alimentary tract, a number of free cells possess amoeboid properties as well as also a number of fixed cells. In the latter category are the nerve cells, the large cells of the spleen

pulp and of lymph glands, certain endothelial cells, the neuroglia cells, and perhaps certain cells of connective tissues. Those of greater phagocytic activity are the large splenic and lymph cells, the neuroglia cells and certain endothelial cells. With regard to the wandering cells some are certainly non-phagocytic, for instance the lymphocytes. The polymorphonuclear, the large hyaline and the eosinophil leucocyte are phagocytic. Metchnikoff therefore divided the phagocytes into two classes—the microphages, comprising the polymorphonuclear and the eosinophil cell, and the macrophages, containing the large hyaline cell, the cell of the splenic pulp, the endothelial cell and the neuroglia cell.

The two principal groups of leucocytes are generally spread throughout the vertebrates. Instances of each kind are found even in the lamprey. Cells which show but small differences from the analogous cells of mammals are found in the alligator.

(T. G. B.)

PHAGOTUS, a curious reed instrument, developed by Afra-nio Albanesi of Pavia (16th century) from the ancient Serbian bagpipe or piva. It was shaped like the letter H, the upper part of each side pillar containing the sound-producing tubes, pierced with finger-holes, and the wind supply being provided by an attached air-reservoir in the form of a bag, and bellows.

PHALANGER, a name applied to the members of the diprotodont marsupial family *Phalangeridae* (see MARSUPIALIA).

Phalangers are small or medium-sized woolly coated animals, with long, often prehensile tails, large claws and opposable, nail-less, first hind-toes. They are nocturnal in habit and feed on fruit, leaves and blossoms, though a few are insect-eaters. Several possess gliding membranes between the fore and hind limbs.

The ring-tailed phalangers (*Pseudochirus*) of Australia and New Guinea are the most generalized forms. Allied to them is the Australian "flying-squirrel" (*Petauroides volans*), ranging from Queensland to Victoria. Another flying genus is *Petaurus*, with several species on the Australian continent, Aru Islands and New Guinea. A third parachuting form is the minute *Acrobates pygmaeus* of East Australia.

The cuscuses (*Phalanger*) are arboreal animals, the size of cats. They inhabit the Solomon Islands, ranging thence to the Moluccas and Celebes, being the only Old World marsupials found west of New Guinea. The fur is woolly and the tail prehensile. Nearly allied to these are the Australian forms, of which the brush-tailed phalanger (*Trichosurus vulpecula*), about the size of a small fox, is the best known. Other species are *T. fuliginosus* of Tasmania and *T. canina* of South Queensland and New South Wales.

BY COURTESY OF THE N. Y. ZOOLOGICAL SOCIETY
VULPINE PHALANGER (*TRICHOSURUS VULPECULA*)

PHALANX, the name, in Greek history of the arrangement of heavy-armed infantry in a single close mass of spearmen (Gr. *φάλαγξ*, of unknown origin) (see ARMY: History).

PHALARIS, tyrant of Agragas (Agrigentum) in Sicily, c. 570–554 B.C. He was entrusted with the building of the temple of Zeus Atabyrius in the citadel, and took advantage of his position to make himself despot (Aristotle, *Politics*, v. 10). Under his rule Agrigentum seems to have attained considerable prosperity. He supplied the city with water, adorned it with fine buildings, and strengthened it with walls. On the northern coast of the island the people of Himera elected him general with absolute power, in spite of the warnings of the poet Stesichorus (Aristotle, *Rhetoric*, ii. 20). According to Suidas he succeeded in making himself master of the whole of the island. He was at last overthrown in a general rising headed by Telemachus, the ancestor of Theron (tyrant c. 488–472), and burned in his brazen bull.

After ages have held up Phalaris to infamy for his excessive cruelty. In his brazen bull, invented, it is said, by Perillus of Athens, the tyrant's victims were shut up and, a fire being kindled beneath, were roasted alive, while their shrieks represented the bellowing of the bull. Perillus himself is said to have been the

first victim. There is hardly room to doubt that we have here a tradition of human sacrifice in connection with the worship of the Phoenician Baal (Zeus Atabyrius) such as prevailed at Rhodes. The Carthaginians carried away a brazen bull from Agrigentum to Carthage but it was restored by Scipio.

Later tradition represented Phalaris as a naturally humane man and a patron of philosophy and literature. Plutarch, though he takes the unfavourable view, mentions that the Sicilians gave to the severity of Phalaris the name of justice and a hatred of crime. (Suidas, s.v.; Diod. Sic. ix. 20, 30, xiii. 90, xxxii. 25; Polybius vii. 7, xii. 25; Cicero, *De Officiis*, ii. 7, iii. 6.)

The letters bearing the name of Phalaris (148 in number) are now chiefly remembered for the crushing exposure they received at the hands of Richard Bentley in his controversy with the Hon. Charles Boyle, who had published an edition of them in 1691. The first edition of Bentley's Dissertation on *Phalaris* appeared in 1697, and the second edition, replying to the answer which Boyle published in 1698, came out in 1699. Bentley proved conclusively that the letters were written by a sophist or rhetorician (possibly Adrianus of Tyre, died c. AD. 192) hundreds of years after the death of Phalaris. Suidas admired the letters, which he thought genuine and in modern times, before their exposure by Bentley, they were thought highly of by some (e.g., Sir William Temple in his Essay on Ancient and Modern Learning), though others, as Politianus and Erasmus, perceived that they were not by Phalaris. The latest edition of the Epistles is by R. Hercher, in *Epistolographi graeci* (1873), and of Bentley's Dissertation by W. Wagner (with introduction and notes, 1883); see especially R. C. Jebb, *Life of Bentley* (1882).

PHALAROPE, the name given to birds of the genus *Phalaropus*, of which there are three species. The phalaropes are allied to the sandpipers (*q.v.*), from which they differ in their swimming habits and the lobed membranes that fringe their feet and by the close nature of the lower plumage. They are aquatic birds, spending the winter on the open sea. The male is less brightly coloured than the female and performs the duties of incubation. The red-necked phalarope (*P. hyperboreus*) breeds in the Hebrides and Ireland but the group as a whole is an Arctic one. One species, *P. wilsoni*, is exclusively American, the others extend also to Europe.

PHALLICISM or **PHALLISM**, an anthropological term applied to that form of worship in which adoration is paid to the generative function symbolized by the phallus, the male organ (from Gr. *φάλλος*). The same principle is at the root of the nature worship of Asia Minor, whose chief deity, the Great Mother of the Gods (*q.v.*), is the personification of the earth's fertility: similarly in India worship is paid to divine mothers; the phallus is called *linga* or *lingam*, with the female counterpart called *yoni*; the *linga* symbolizes the generative power of Siva, and is a charm against sterility. The rites classed together as *Sakti puja* represent the adoration of the female principle. Phallic emblems are found in many parts of the world. The tendency, however, to identify all obelisk-like stones and tree trunks, together with rites like circumcision, as remains of phallic worship, has met with much criticism, and the best modern view is that phallicism never developed into an organized cult, e.g., Robertson Smith, *Religion of the Semites*, 3rd ed., pp. 456 and 688.

PHALSBOURG, a town of France, in the department of Moselle, on a plateau (1,080 ft.) above the main road from Sarverne to Nancy and Metz, 25 mi. N.W. of Strasbourg by rail. Pop. (1936) 1,908. The principality of Phalsbourg, of which this town was the capital, originally a part of Luxembourg, belonged in turn to the bishop of Metz, the bishop of Strasbourg and the duke of Lorraine, and passed to France in 1661. The town commands the passes of the Vosges, and was strongly fortified by Vauban in 1680. Of these fortifications only the Porte de France and the Porte d'Alsace remain. Trade is in domestic kirsch.

PHALTAN, a native state of India, in the central division of Bombay, ranking as one of the Satara jagirs. Area, 397 sq.m.; pop. (1931), 58,761. The town of Phaltan is 37 m. north-east of Satara; pop. (1931), 9,596.

PHANARIOTES, a name derived from Phanar, the chief Greek quarter at Stamboul, where the oecumenical patriarchate is situated, and applied to those members of families resident in the Phanar quarter who between the years 1711 and 1821 were appointed hospodars of the Danubian principalities; that period of Moldo-Wallachian history is also usually termed the Pha-

nariote epoch. The active part taken by the Greek princes in the revolt of 1820-21 induced the Porte to revert to the appointment of native princes.

PHANIAS, of Eresus in Lesbos, Greek philosopher and historian, important as an immediate follower of and commentator on Aristotle, came to Athens c. 332 B.C., and joined his compatriot, Theophrastus, in the Peripatetic school. His *Analytica*, *Categoriae* and *De interpretatione*, which were either paraphrases or critical commentaries, seem to have added little to Aristotle's own writings. Alexander of Aphrodisias refers to a work *πρὸς Διόδωρον*, and Athenaeus quotes from another treatise, *Against the Sophists*. He and Theophrastus also carried on the physical investigations of Aristotle; Athenaeus frequently quotes from a work on botany which manifests great care in definitions and accuracy of observation. The chief of his historical works were the *Prytanis Eresii*, which was either a history of his native place or a general history of Greece arranged according to the period of the Eresian magistracy and works on the *Tyrants of Sicily* and on tyranny in general, which are frequently quoted on questions of chronology (e.g., by Plutarch, Suidas, Athenaeus). To the history of Greek literature he contributed works on the poets and on the Socratics, both of which are quoted.

PHANTASMAGORIA, a name invented by a certain Philipstal in 1802 (from Gr. *φάντασμα*, phantasm, apparition; and *ἀγορά*, assembly) for a show or exhibition of optical illusions produced by means of the projecting lantern (see LANTERN). The word has since been applied to any rapidly or strikingly changing scene, or disordered phantasy.

PHARAOH (Par'oh), the Hebraized title of the king of Egypt (q.v.), in Egyptian Per-'o; Pheron in Herodotus represents the same. Its combination with the name of the king, as in Pharaoh-Necho, Pharaoh-Hophra, is in accordance with contemporary native usage: the name of the earlier Pharaoh Shishak (Sheshonk) is rightly given without the title. In hieroglyphic a king bears several names preceded by distinctive titles. In the

IVth Dynasty there might be four of the latter: (1)  identify him with the royal god Horus; the name is commonly written in a frame  representing the facade of a building, perhaps a palace or tomb, on which the falcon stands. (2)  connecting him with the vulture and uraeus goddesses, Nekhabet and Butet of the south and north. (3)  a hawk on the symbol of gold, signifying the victorious Horus. (4)  the old titles of the

rulers of the separate kingdoms of Upper and Lower Egypt, to be read *stni*, "butcher(?)" and *byfi*, "beekeeper(?)." The personal name of the king followed (4), and was enclosed in a cartouche  apparently symbolizing the circuit of the sun which alone bounded the king's rule. Before the IVth Dynasty the cartouche is seldom found: the usual title is (1), and (3) does not occur. In the Vth Dynasty the custom began of giving the king at his accession a special name connecting him with the sun: this was placed in the cartouche after (4), and a fifth title was added: (5)  Si-rē, "son of the Sun-god," to precede a cartouche containing the personal name. The king was briefly spoken of by his title *stni* (see 4), or *hnm-f*, "his service," or *Ity*, "liege-lord." These titles were preserved in the sacred writing down to the latest age. An old term for the royal palace establishment and estate was Per-'o, "the Great House," and this gradually became the personal designation of Pharaoh. (F. LL. G.)

PHARISEES, a sect of the Jews first mentioned by Josephus, (Ant. xiii., 5, 9). Their activity extended over a period of three centuries (from c. 135 B.C.—A.D. 135). They first emerged as an organized party in the reign of John Hyrcanus and were active down to the time of Hadrian. We may assume that the Pharisees occupied a position of considerable influence and power during the reign of John Hyrcanus (135-105 B.C.). Later, in the reign of Alexander Jannaeus (104-78 B.C.) they appear to have quarrelled

with the Maccabean ruler (who, it must be remembered, functioned as high priest as well as king) and the quarrel lasted some time. The breach was healed in the reign of his widow Salome Alexandra (78-69 B.C.). During the New Testament period the Pharisees, as is evident from the pages of the New Testament, played a dominating part in Jewish communal life.

Their general aim was to develop and deepen the work of the earlier *Hasidim* in making the *Torah* the accepted rule of life for the mass of the Jewish people. Their work was astonishingly successful. They made the synagogue a permanent and widespread institution of Jewish life. Here in the weekly assemblages the lectures were read and expounded to the people; the synagogue prayers were developed and made familiar. They also organized a system of elementary religious instruction.

Origin of the Name.—Of the various explanations of the name, the view of Lauterbach is most plausible, that the term (which means "separated" or "expelled") is due to an actual event, viz. the expulsion of the lay teachers from the priestly Sanhedrin. It must be remembered that during the Persian period of the Post-Exilic epoch the schools which perpetuated the teaching of the law were priestly in character and the actual teachers were themselves priests. These earlier *Sopherim* were also responsible for the actual transmission of the text. The system lasted on till the earlier part of the Greek period. Then the earlier simplicity and self-contained character of the Jewish community began to break down under the influence of Greek conditions. This applied also to the teaching of the law to the people. "Laymen arose who had as much influence among the people and with the government as the High-Priest, and they became leaders." These laymen were practically the Pharisaic party who were able to force some of their party into the priestly Sanhedrin. Later a crisis arose in the Sanhedrin and the lay leaders were apparently expelled—hence the name Pharisees. As is well known, the Pharisees stood for the oral law as well as for the written, and one of their chief pre-occupations was to deduce arguments for linking up popular custom with the written text of the Pentateuch. They were thus led to develop an ingenious system of exegesis which in course of time resulted in the development of a vast hermeneutical literature.

In order to estimate Pharisaism aright during its active period it is necessary to remember that it was sharply divided into warring sects and schools. These are probably not exhausted by the rival schools of Hillel and Shammai; and the polemic of Jesus in the Gospels was primarily directed not against the party as a whole, but against one section of it, an extreme wing of the followers of Shammai who were open to the charge of formalism and hypocrisy. It is probable that the Shammaites were in the ascendent at this time; later, after A.D. 70, the milder peace-loving school of Hillel predominated. Pharisaism was the dominant factor in the development of orthodox Judaism, which assumed a more or less permanent form in the Rabbinical system. Its main interest was to bring the sanctions of religion into this life. This tendency also appears in its Messianic doctrine, which it has impressed on all parts of the synagogue liturgy. Its Messiah is not the transcendental and heavenly figure of some of the apocalypticists, but a purely human son of David. See G. F. Moore, *Judaism*; Art. "Pharisees" in *Enc. Rel. and Ethics*. (G. H. B.)

PHARMACOLOGY. In English-speaking countries, and by the majority of German writers, the term pharmacology is applied to the study of the action of chemical substances (as apart from foods) on all kinds of animals, from bacteria up to man; it is, in fact, a comparative study of the action of chemical bodies on invertebrate and vertebrate animals.

Pharmacology is a branch of biology; it is also closely connected with pathology and bacteriology, for certain drugs produce structural as well as functional changes in the tissues, and in germ diseases the peculiar symptoms are caused by foreign substances (toxins) formed by the infective organisms present in the body. The effects of many of these toxins bear a close resemblance to the action of certain well-known drugs, as in the case of tetanus toxin and strychnine, and are studied by the same methods.

The rapid growth of the science of pharmacology has been one of the most striking features of the development of the science

of medicine during the twentieth century.

Organic Chemistry.—The only substances available for medical use a century ago were certain inorganic salts and crude vegetable extracts. The development of organic chemistry provided therapeutics with purified active principles of the crude vegetable extracts, and thus the use of crude preparations of unknown strength was replaced to a large extent by the use of chemical substances of known composition. Organic chemistry rendered a still more important service to pharmacology with the synthesis of organic compounds by which the number of substances available for use in therapeutics was increased indefinitely.

The anaesthetics, ether (1846) and chloroform (1847), were the first synthetic organic compounds to be used extensively in medicine. Twenty years later the first synthetic hypnotic, chloral hydrate, was introduced, and about 1885 the coal tar antipyretics, acetanilide and antipyrin, were discovered. Since then hundreds of new and valuable synthetic drugs have been discovered.

Salvarsan.—The discovery by Ehrlich in 1910 of salvarsan (*q.v.*), a potent remedy for syphilis, established a new method of research which has since yielded other results of great importance and promises to produce even greater successes.

In his search for a substance which would kill the infectious organism of syphilis (*q.v.*), the *Treponema pallidum*, without injuring the patient, Ehrlich started with the knowledge that allied organisms, the trypanosomes, were killed by certain dyes and organic arsenic compounds. Not content with a random examination of the known compounds, he determined quantitatively which types of compounds were the most satisfactory for his purpose and then got new compounds prepared according to a definite plan. He made a systematic examination of a long series of organic arsenic compounds, determining in each case the minimal dose of the drug which would cure an animal infected with trypanosomes (minimal curative dose) and the maximal dose which the animal could tolerate (maximal tolerated dose). He termed the ratio:—

$$\frac{\text{(maximal tolerated dose)}}{\text{(minimal curative dose)}}$$

the therapeutic index, and sought for a drug with the highest possible therapeutic index. The compound salvarsan or arsenobenzole was the 606th arsenic preparation investigated, and in 1910 it was introduced as a remedy for syphilis. Two years later, Ehrlich introduced neosalvarsan or novarsenobenzole, which has to a large extent replaced salvarsan in the treatment of syphilis (see VENEREAL DISEASES). Ehrlich's brilliant success stimulated an intensive investigation of the action of organic metallic compounds upon diseases due to infections by animal parasites.

New Methods.—A number of important new methods of treatment have been discovered. Intramuscular injections of bismuth salts have been found to be of value in the treatment of cases of syphilis which are refractory to the organic arsenicals. Salts of antimony also have been found to have important new therapeutic actions. A century ago the production of subacute antimony poisoning by large doses of tartar emetic was a routine treatment for a very large number of diseases, but the revolt against the "heroic" methods of treatment of disease, in the middle of last century led to tartar emetic being almost abandoned as a therapeutic agent. The drug was discovered to possess the new and important therapeutic action of acting like arsenic as a specific disinfectant for animal parasites (see HOOKWORM). Intravenous injections of antimony salts have been found of great value in treating various diseases due to trypanosomal infection, and also have been found to cure the disease bilharziasis (*q.v.*).

Perhaps the most important internal disinfectant to be discovered is the compound "Bayer 205," a derivative of the dye trypan blue. This substance has a powerful action both in preventing and relieving the trypanosomal disease sleeping sickness (*q.v.*), the worst scourge of tropical Africa.

Mollgaard showed recently that an organic compound of gold, sodium aurithiosulphate, named "sanocrysin" can produce very remarkable curative effects, in a certain proportion of cases of tuberculosis (*q.v.*), but is equally capable of producing deleterious effects, and therefore great care is needed in its administration.

Antiseptics.—The special conditions of World War surgery made the discovery of powerful wound disinfectants an urgent problem, and a number of new disinfectant compounds of great activity were discovered, for example the dye "acriflavine," and the quinine derivatives "vuzin" and "optochin" (see ANTISEPTICS). Although the synthesis of the alkaloid quinine has not yet been effected, nevertheless its chemical structure is known, and it is possible to modify the structure of the alkaloid and thus produce new compounds. Vuzin and optochin are two quinine derivatives which differ from quinine in having a far more potent disinfectant action on bacteria. Another important new wound disinfectant is chloramine-T, an organic chlorine compound which acts by slowly liberating chlorine. The disinfection of the kidney and the bladder is another important problem in which advances recently have been made. A new organic compound termed hexyl resorcinol appears to be a very powerful urinary disinfectant.

Use of Active Principles.—Most of the advances mentioned hitherto have depended upon the discovery of new synthetic organic compounds of greater potency than any known hitherto, but cures for other diseases have been discovered by substituting purified active principles for crude vegetable extracts.

Ipecacuanha has been known for more than a century to benefit amoebic dysentery, but the administration of the drug by mouth was limited by its action as an emetic. Sir Leonard Rogers showed in 1912 that subcutaneous injections of the alkaloid emetine, the chief active principle present in ipecacuanha, usually produced a rapid cure in cases of amoebic dysentery (see DYSENTERY).

Similarly, it has been known for many years that leprosy (*q.v.*) is often benefited by administration of Chaulmoogra oil, but it was found impossible to administer large doses of this oil by mouth on account of its irritant properties. Organic chemists isolated from Chaulmoogra oil certain complex fatty acids named hydnocarpic and chaulmoogric acids, which were believed to be the chief active principles present in the oil. Sir Leonard Rogers in India and Heiser in the Philippines introduced the method of injecting preparations of these purified fatty acids intravenously or intramuscularly and obtained remarkable curative effects even in the cases of leprosy of many years' duration (see LEPROSY). The most striking recent successes of pharmacology have been achieved in the cure of infectious diseases, because in most other serious diseases some vital organ has received irreparable damage, which drugs may alleviate but cannot cure.

Anaesthetics and Hypnotics.—Important progress has, however, been made in the discovery of drugs needed to produce certain temporary alterations in the functions of the body. General anaesthetics are perhaps the most important group of drugs of this class. In 1924 and 1925 acetylene and ethylene were tried as substitutes for nitrous oxide, but at present it is doubtful whether the new gases will prove superior to nitrous oxide.

Many drugs produce some very useful action but have in addition some highly undesirable side action. Cocaine (*q.v.*), for example, is an excellent local anaesthetic, with the grave disadvantage of sometimes producing dangerous effects on the brain. Of the large number of local anaesthetics, which have been synthesised in the hope of producing some complete substitute for cocaine, Novocaine is one of the best known and can replace cocaine completely for many but not for all purposes. Since 1910 a number of new compounds of great potency as local anaesthetics have been discovered, and cocaine may soon be superseded.

Similarly, a host of new and very potent hypnotics have been synthesised in the hope of finding a reliable hypnotic which will not produce a habit, and is perfectly safe. Unfortunately, not much advance has been made in this field. In a few cases important new uses have been discovered for drugs which have been known for many years, such as the discovery in 1918 that quinine, one of the alkaloids present in Cinchona bark or Jesuit's bark, can cure the important disorder of the heart known as auricular fibrillation. (See CINCHONA, ALKALOIDS OF.)

Physiological Features.—The accurate analysis of the mode of action of drugs of well-established reputation has in certain cases greatly increased their value, making it possible to increase their dosage with safety and thus ensuring that sufficient of the

drug is given to produce the physiological effect desired. The administration of digitalis in heart disease is a case where considerable improvements in technique of this character have been effected in recent years.

The study of the actions of extracts of the glands of internal secretion (*see* ENDOCRINOLOGY) is a field common to physiology and pharmacology. In 1886 it was shown that the two diseases myxoedema and cretinism, due to deficiency of the thyroid secretion, and previously considered completely incurable, could be cured by the simple remedy of administering dried thyroid gland by the mouth. In 1922 Banting obtained an extract from the pancreas, which he termed insulin (*q.v.*), and which he proved would relieve the disease of diabetes mellitus (*q.v.*).

There are peculiar difficulties attending the study of the secretions of the endocrine glands. Active principles have been obtained from the parathyroid glands and the ovaries which also promise to be of value as agents for substitution therapy, where the normal secretions of these organs are deficient. Substances have been obtained from other endocrine organs which have no certain value as agents for substitution therapy but are drugs with powerful and interesting pharmacological actions. One such substance, adrenalin, was discovered in 1896, and has been found of great value in producing constriction of small arteries and thus acting as a haernostatic.

Extracts of the posterior lobe of the pituitary gland produce a rise of blood pressure and constriction of plain muscle and since 1916 this extract has been brought into therapeutic use, and is now very extensively used to cause contraction of the uterus, and thus to accelerate childbirth and to prevent the disastrous complication known as post-partum haemorrhage.

Vitamins.—The vitamins (*q.v.*) are biological products which have important pharmacological actions. They are unstable bodies of unknown chemical composition which are present in minute amounts in a large variety of fresh foods, but usually are absent in preserved foods. Several vitamins exist, and a regular supply of all of them is essential to normal development and health. Scurvy and rickets are two examples of diseases caused by vitamin lack. Lemon juice has been known for more than a century to be a specific cure for scurvy, and biochemists have now succeeded in concentrating the vitamins of lemon juice so that a child suffering from infantile scurvy can be given the vitamin equivalent of 20 lemons in a single day. Similarly, cod liver oil has long been recognized as a cure for rickets, and the vitamin of cod liver oil has also been prepared in concentrated form.

Parasitology.—The disease-producing parasites are of two classes, firstly the animal parasites such as the trypanosomes, and secondly the vegetable parasites, the bacteria. Very remarkable successes have attended the preparation of internal disinfectants for the animal parasites, and cures have been found for a number of the worst diseases that afflict mankind; in particular, cures have been discovered for a number of very serious tropical diseases (*q.v.*). Less striking success has attended the endeavour to find disinfectants that will kill bacteria infecting the body, but a certain amount of progress has been made, and any advance in this field is of the greatest importance to the inhabitants of temperate climates, because most of the worst infectious diseases of the temperate zone are bacterial in origin.

BIBLIOGRAPHY.—The most important work for general reference is A. Heffter, *Handbuch der Experimentelle Pharmakologie*, 3 voi. (1920); *see also* A. R. Cushny, *Pharmacology and Therapeutics*, 8th ed. (1924); W. E. Dixon, *Manual of Pharmacology*, 6th ed. (1925); A. J. Clark, *Applied Pharmacology*, 2nd ed. (1926); T. Sollinann, *Manual of Pharmacology*, 3rd ed. Philadelphia, 1926 (bibl.); H. H. Meyer and R. Gottlieb, *Experimental Pharmacology*, 2nd ed. in English, Philadelphia, 1926 (bibl.); E. Poulsson, *Text-book of Pharmacology and Therapeutics*, London, 1923.

PHARMACOPOEIA, a book containing directions for the identification of simples and the preparation of compound medicines, and published by the authority of a government or of a medical or pharmaceutical society. The first work of the kind published under government authority appears to have been that of Nuremberg in 1542.

In England until 1617 such drugs and medicines as were in com-

mon use were sold by the apothecaries and grocers. In that year the apothecaries obtained a separate charter, and it was enacted that no grocer should keep an apothecary's shop. The preparation of physicians' prescriptions was thus confined to the apothecaries, upon whom pressure was brought to bear to make them dispense accurately, by the issue of a pharmacopoeia in 1618 by the College of Physicians of London, and by the power which the wardens of the apothecaries received in common with the censors of the College of Physicians of examining the shops of apothecaries within 7 m. of London and destroying all the compounds which they found unfaithfully prepared. Between 1618 and 1851, 13 editions of the *London Pharmacopoeia* were issued, each tending towards simplification and elimination of many ridiculous and highly compound medicines that had been in vogue for 2,000 years.

The first *Edinburgh Pharmacopoeia* was published in 1699 and the last in 1841; the first *Dublin Pharmacopoeia* in 1807 and the last in 1850.

The preparations contained in these three pharmacopoeias were not all uniform in strength. In consequence of this inconvenience and danger the Medical Act of 1858 ordained that the General Medical Council should cause to be published the *British Pharmacopoeia*, which should be a substitute throughout Great Britain and Ireland for the separate pharmacopoeias. The first *British Pharmacopoeia* was published in 1864. Since then revised editions have been brought out periodically, physicians and pharmacists being consulted in their compilation. But each new edition requires several years to carry out numerous experiments for devising suitable formulæ, so that the current Pharmacopoeia can never be quite up to date. This difficulty has hitherto been met by the publication of such non-official formularies as Squire's *Companion to the Pharmacopoeia* and Martindale's *Extra Pharmacopoeia*, recording all new remedies and their preparations, uses and doses.

National pharmacopoeias now exist in the following countries: Austria, Belgium, Chile, Denmark, France, Germany, Great Britain, Greece, Holland, Hungary, India, Japan, Mexico, Norway, Portugal, Russia, Spain, Sweden, Italy, Switzerland, the United States, Venezuela, Rumania, Finland, Argentina and Servia.

The French *Codex* has probably a more extended use than any other pharmacopoeia outside its own country, being, in connection with Dorvault's *L'Officine*, the standard for druggists in a large portion of Central and South America; it is also official in Turkey. It contains about 1,250 drugs and preparations, or double the average of other modern pharmacopoeias.

Some difficulty has arisen since the passing of the Adulteration of Food and Drugs Act concerning the use of the Pharmacopoeia as a legal standard for the drugs and preparations contained in it. It has been held in the Divisional Courts (*Dickins v. Randerson*) that the Pharmacopoeia is a standard for official preparations asked for under their pharmacopoeial name. But for many drugs and chemicals not in the Pharmacopoeia there is no standard of purity that can be used under the Adulteration of Food and Drugs Act. An important step towards supplying this need has been taken by the publication under the authority of the Council of the Pharmaceutical Society of Great Britain of the *British Pharmaceutical Codex*, in which the characters of and tests for the purity of many non-official drugs and preparations are given as well as the character of many glandular preparations and antitoxins that have come into use in medicine, but have not yet been introduced into the Pharmacopoeia.

'An International Pharmacopoeia.—Attempts have been made by international pharmaceutical and medical conferences to settle a basis on which an international pharmacopoeia could be prepared, but so far without result. (*See* PHARMACY.) On the other hand, a project for an imperial pharmacopoeia which should be adapted to the general and local requirements of all parts of the British Empire has met with better success. With the aid of the medical and pharmaceutical authorities in each of the seventy administrative divisions of the British Empire an Indian and Colonial addendum to the *British Pharmacopoeia* of 1898 was compiled and published in 1900 in which each article receives official sanction in the countries indicated in the monographs.

Several unofficial universal pharmacopoeias have been pub-

lished in England and in France, which serve to show the comparative strength of parallel preparations in different countries. The greatest stumbling-blocks in the way of uniformity are the tinctures and extracts in which the same name does not always indicate the same thing; thus, extract of aconite signifies an extract of the root in the pharmacopoeias of the United States, Japan and Russia, extract of the leaves in the Danish and Portuguese, inspissated juice of the fresh leaves in the Greek, and alcoholic extract of the root in that of Spain and Italy, and alcoholic extract of the dried leaves in the Chilean pharmacopoeia. It appears probable, however, that the growth of pharmaceutical chemistry will indicate, in time, which of those in use form the most active and trustworthy preparations, while the general adoption of the metric system will lead to clearer approximation of strength than hitherto. Homeopathic and eclectic practitioners as well as dentists have also their special pharmacopoeias.

See Martindale and Westcott, *Extra Pharmacopoeia*, 18th ed. 1924-25, 19th ed. vol. i. 1928; *British Pharmaceutical Codex*, London, 1923; *British Pharmacopoeia*, London, 1914; *Squire's Companion to the British Pharmacopoeia*, 19th ed. London, 1916; *Codex medicamentarius Sallieus: Pharmacopée française*, Paris, 1920; *Pharmacopoeia of the United States of America* 10th decennial revision Philadelphia, 1925; *Deutsches Arzneibuch* 6th ed. Berlin 1926. (E. M. Ho.)

PHARMACOSIDERITE, a mineral species consisting of hydrated basic ferric arsenate, $2\text{FeAsO}_4 \cdot \text{Fe}(\text{OH})_3 \cdot 5\text{H}_2\text{O}$. Crystals have the form of small, sharply defined cubes of an olive- or grass-green colour, and occur together in considerable numbers on the matrix of the specimens. On account of its cubic form it was early known as "cube ore;" the name pharmacosiderite alludes to the arsenic and iron present (*φάρμακον*, poison, and *σίδηρος*, iron). The faces of the cube are striated parallel to one diagonal, and alternate corners may be replaced by faces of a tetrahedron. Natural crystals are sometimes honey-yellow to brown in colour, but this appears to be due to alteration. Pharmacosiderite is a mineral of secondary origin, the crystals occurring attached to gozzany quartz in the upper part of veins of copper ore.

PHARMACY, the art of preparing, preserving and compounding medicines, according to the prescriptions of physicians. The term was first used in this sense in 1597. The International Congresses of Pharmacy, held at intervals from 1865 to 1913, afforded opportunity for the discussion of questions of international importance. Much time and effort were expended in the endeavour to produce an international Pharmacopoeia and to ensure that all medicinal preparations should be the same, no matter in what country they were prescribed. The attempt failed, but it paved the way for the adoption of useful international regulations. (See PHARMACOPOEIA.)

International Uniformity.—The congress held in Paris in 1900 recommended that a comparative table should be prepared showing the difference in the strength of medicaments bearing the same name in different pharmacopoeias. This table was considered at a conference of accredited delegates from various nations in Sept. 1902 and a list of preparations was issued upon which agreement as to strength had been reached. An international agreement embodying this list was signed in 1906 by the representatives of 18 nations and, substantially, all the decisions contained in it have been observed in the new issues of the pharmacopoeias of the signatory nations. A similar conference was held in Paris in 1925 to revise some of the decisions of the first conference and to take further steps towards the unification of the pharmacopoeial formulas for potent drugs and their preparations.

The 10th international congress held at Brussels in 1910 decided to establish a *Fédération Internationale Pharmaceutique* for the protection of pharmacy as a profession and as an applied science. The federation was established in 1912 at The Hague with Prof. Van Itallie and Dr. Hofman, the first president and secretary respectively. Twenty-four national societies of pharmacy are now included in it, although Austria, Denmark, Germany, Hungary and Russia have retired since the World War. The *Fédération Internationale Pharmaceutique* has held meetings annually since 1922.

Modern Pharmacy and Science.—The demands made upon the scientific knowledge and technical skill of the pharmacist have

continually increased as shown by successive editions of the British, United States and other pharmacopoeias. The definition of the drugs has become more precise; tests of identity, limits of impurity, methods of assay have been introduced, and the use of the microscope required for the examination of many vegetable drugs. The introduction into medical practice of countless synthetic chemicals, of such organotherapeutical substances as the thyroid gland, pituitrin, etc., and of various vaccines and sera has imposed upon pharmacists the necessity of special study in order to understand them. The same may be said of the X-rays, and of the vitamins, the latter, in an impure form, being used in the form of compressed tablets or of capsules. Hypodermic injections are now commonly supplied sterilised and in ampoules, and the pharmacist must therefore be acquainted with the principles of sterilisation and with the action upon sensitive alkaloids of the heat used and the alkalinity of the glass of which the ampoules have been made.

The Qualifications of the Pharmacist.—In addition, therefore, to a knowledge of chemistry and botany as applied to pharmacy the pharmacist must be an expert microscopist. He must keep himself informed as to the new developments of therapeutics and must be competent to supply such medicines as the physician may prescribe. Disinfection and hygiene also come within his purview. To ensure his competency the *Fédération Internationale Pharmaceutique* agreed that the following subjects should find a place in the studies of the pharmaceutical student: chemistry (analytical, biological, physiological and pathological), pharmacy (chemical and galenic), pharmacognosy, micrography, toxicology, hygiene, legislation, pharmacology, botany, microbiology, mathematics, crystallography, disinfection, sterilisation and optics.

Modern Developments.—Developments in the treatment of diseases and in the nature and quality of the remedial agents required, which are the outcome of scientific research, have a direct bearing upon pharmacy. Barger, Dale, Carr, Stoll and others have shown that ergot contains two extremely powerful alkaloids, ergotoxine and ergotamine, upon which its activity chiefly depends, accompanied by various amines such as tyramine and histamine, which possess a subsidiary efficacy. The two alkaloids are soluble in alcohol but insoluble in water and are easily converted into inactive substances from which they can be regenerated. These discoveries opened the way to a preparation of ergot which has proved very satisfactory.

For a long time the group of oxymethylantraquinone drugs, which includes purgatives such as rhubarb, cascara sagrada, etc., had baffled investigators as the crystalline oxymethylantraquinones or their glucosides failed to explain, quantitatively at least, the action of the drugs. Maeder has isolated from elder buckthorn bark the glucoside glucorhamnin in which two sugar groups are present. The laxative action of glucofrangulin is such that the amount present in the drug corresponds to the activity of the latter. Probably similar glucosides will be found in other members of the group. Kiefer, working upon Cape aloes, showed that the resins previously considered inactive were, on the contrary, strongly purgative and isolated the substance to which the gripping action was due and so made an important step towards a rational preparation of aloes. Bourquelot showed that many enzymes possess a synthetical as well as analytical action and prepared a number of synthetical glucosides and demonstrated the possibility of producing in the laboratory an entirely new class of compounds.

Stabilisation of **Drugs**.—Pharmacists have long desired to make from drugs preparations which should contain the active constituents in the condition in which they exist in the plant. Goris and Arnould made an important step towards solving this problem by proving that the caffeine in fresh kola nuts exists in combination with kolatin, a combination which is broken up by an oxidase present in the fresh nuts. This oxidase can be rendered inactive by steam or alcohol vapour and the combination then remains unaltered when the nuts are dried and preparations made from them. Such treatment, or "stabilisation," of a drug will probably be extensively adopted.

Medicinal Plants.—During the World War large quantities

of medicinal plants were collected in Great Britain, partly wild, partly cultivated. Attempts to place the cultivation upon a satisfactory footing failed, owing to the difficulty of obtaining assistance for the young industry. In France the Government afforded every aid, and under the direction of Perrot the industry is rapidly growing and much information is being collected as to the effects of soil, manures, etc., necessary to produce the best results. In the United States considerable attention has been devoted to selection experiments with drug plants, and marked progress has been made towards the production of the most suitable strains. The extremely high price of santonin led to a search for other sources of that vermifuge.

Educational System in Great Britain.—The Poisons and Pharmacy Act of 1908 allowed a body corporate, and in Scotland a firm or partnership, to carry on the business of a pharmaceutical chemist or chemist and druggist provided that the business, so far as it related to the keeping, retailing and dispensing of poisons, was under the control of a registered pharmaceutical chemist or chemist and druggist. In the second place powers were given to the Pharmaceutical Society to divide the qualifying examination into two parts and to require candidates for the examination to produce satisfactory evidence that they had received a sufficient preliminary practical training in the subjects of the examination. In 1920 the by-laws and regulations necessary for carrying the provisions of the Act of 1908 into effect were drawn up. They came into full force at dates varying from Feb. 1, 1927, to Aug. 1, 1929, and may be briefly summarised as follows.—

Before presenting himself for examination the candidate must have been registered as a student of the Pharmaceutical Society for which purpose he must have passed one of a number of entrance examinations ranging from the junior local examination of Cambridge or Oxford to the matriculation examination of the University of London. After registration he may proceed to the preliminary scientific examination, for which attendance at an approved systematic course of instruction of at least 440 hours in chemistry, botany and physics is necessary. Having passed this, or one of several alternative examinations, he will have to decide whether he will be content with passing the chemist and druggist qualifying examination or aim at the higher qualification by training for the pharmaceutical chemist qualifying examination. In the former case, when giving notice, he must produce a declaration that he has been trained under the direct supervision of a pharmacist in the dispensing and compounding of medicines for 4,000 hours spread over not less than two years in a pharmacy or in the dispensary of a hospital or similar institution approved by the council. He must also have attended an approved systematic course of at least 720 hours in pharmacy, pharmaceutical chemistry, pharmacognosy and forensic pharmacy.

If the candidate elects to proceed from the preliminary scientific examination to the pharmaceutical chemist qualifying examination, then he must be trained for at least 2,000 hours in a pharmacy or hospital and have attended an approved systematic course of at least 1,600 hours in botany, chemistry, pharmacognosy, pharmacy and forensic pharmacy. The statutory examinations in these subjects are conducted by the Pharmaceutical Society.

Thus, whereas in 1920 there was no compulsory curriculum of any kind, the entrant into pharmacy now has to undergo what is practically a two years' approved systematic course of training for the lower qualification and a three years' for the higher; in addition, if he has matriculated, university degrees are open to him. This achievement places the pharmaceutical student in Great Britain on a level with those of most other countries.

Sale of Poisons.—Since the passing of the British Poisons and Pharmacy Act in 1908 the number of substances brought within the range of Part I. of the schedule (those which may not be sold to any person unknown to the seller unless introduced by a person known to both parties and of which the sale must be duly registered) has been much increased. It now includes:

Aconite, aconitine and their preparations; all poisonous alkaloids not specifically named, and their salts and all poisonous derivatives of alkaloids; arsenic and its preparations; atropine and its salts and their preparations; belladonna and all preparations or admixtures (except belladonna plasters) containing 0.1% or more of belladonna alkaloids; cannabis (the dried flowering or fruiting tops of the pistillate plant of *Cannabis sativa*) and the resins prepared therefrom. Cantharides and its poisonous derivatives; coca, any preparation or admixture of, containing 0.1% or more of coca alkaloids; corrosive sublimate; cyanide of potassium and all poisonous cyanides and their preparations; diamorphine (also known as heroin) and all preparations or

admixtures containing 0.1% of diamorphine; diethyl-barbituric acid and other alkyl, aryl or metallic derivatives of barbituric acid, whether described as veronal, propronal, medinal or by any other trade name, mark or designation; and all poisonous urethanes and ureides; digitalin and all other poisonous constituents of digitalis; ecgonine and all preparations or admixtures containing 0.1% of ecgonine; emetic tartar and all preparations or admixtures containing 1% or more of emetic tartar; ergot of rye and preparations of ergots; lead in combination with oleic acid or other higher fatty acids, whether sold as diachylon or any other designation (except machine-spread plasters); nuxvomica and all preparations or admixtures containing 0.2% or more of strychnine; opium and all preparations or admixtures containing 0.2% or more of morphine; picrotoxin; prussic acid and all preparations or admixtures containing 0.1% or more of prussic acid; savin and its oil and all preparations or admixtures containing savin or its oil; strophanthin and all other poisonous constituents of strophanthus; tobacco, any preparations or admixtures of (other than tobacco prepared for smoking and snuff), containing the poisonous alkaloids of tobacco.

By the Dangerous Drugs Act 1920-23 further restrictions have been placed upon the sale of morphine, cocaine, ecgonine, diamorphine, heroin and their respective salts and medicinal opium. Generally stated, these drugs may, with certain exceptions, be supplied only to physicians' prescriptions and a record must be kept of the quantities bought and sold.

The Labelling of Poisons Order, which came into force in Great Britain on Jan. 1, 1926, imposed further conditions upon the sale of poisons (whether contained in Part I. or Part II. of the schedule). This Order and the Act under which it is made require that, in general, every preparation containing as an ingredient any poison to which the Pharmacy Act 1868, as amended, applies shall bear on the label a statement of the proportion which such poison bears to the total ingredients of the preparation. (H. G. G.)

THE UNITED STATES

Education.—By the end of 1939 there was a total of 67 schools of pharmacy in the United States, about 60 of which were enrolled in the American Association of Colleges of Pharmacy. This organization, established in 1900, has had a great influence in raising the standards of pharmaceutical education by voluntary co-operation, since there are no laws covering the subject.

Preliminary requirement for entrance to the study of pharmacy is four years of accredited high school work or its equivalent. The minimum course lasts four years and leads to the degree of Bachelor of Science in Pharmacy (B.Sc. in Phar.), although until 1936 there were two other undergraduate degrees given for shorter courses of study and accepted by most states as qualifying for registration. There are also graduate courses leading to the degree of Master of Science in Pharmacy (M.Sc. in Phar.), and students may take Ph.D. or D.Sc. (Doctor of Science) degrees in pharmacy. The degree of Doctor of Pharmacy (Phar.D.), formerly offered to graduate pharmacy students, was abandoned in 1938, but continued to be conferred as an honorary degree.

Registration Requirements.—There is no national examining or registering body in the U.S. and each state has its own laws applying to the subject. These laws and the procedures growing out of their enforcement have been materially harmonized and rendered more nearly uniform by the National Association of Boards of Pharmacy. By 1939, due to the efforts of this group, pharmacists who passed the state board examinations in any state were allowed to practise in any other state except California or New York, which had not yet agreed to this reciprocity. In addition, most states now require graduation from a recognized college of pharmacy, and all of the states require from two to four years of "drugstore experience."

Laws Affecting Pharmacists.—The laws pertaining to the adulteration of drugs and medicines and the enforcements of legal standards are both state and national in scope. Prior to 1906 there was no federal law and the states alone controlled the situation. The passage of what is known as the Federal Food and Drugs act in 1906 greatly strengthened the control of adulteration and misbranding of drugs. The federal law affected only those products which entered interstate commerce and specifically recognized the standards of the U.S. *Pharmacopoeia* and the *National Formulary* as officially governing drugs and medicines. Since 1906

many state laws have been brought into harmony with the provisions of the federal act, and since the state laws control intra-state transactions, the entire situation is governed.

Another important act is the Harrison Narcotic act, giving police power to the United States government in the control of the distribution of habit-forming drugs such as morphine, cocaine, etc. The provisions of this act require the registration of every physician prescribing certain habit-forming drugs and of every pharmacist dispensing such drugs, as well as control of the manufacturers and jobbers or wholesalers. The U.S. pharmacist must obtain a licence for the sale of alcohol from the department of internal revenue or the treasury department.

In 1938 congress passed a new law affecting pharmacists, the Federal Food, Drug and Cosmetic act, which embodied both additional measures and more effective methods of enforcement than its predecessor. The drug provisions of the new act differed essentially from the 1906 law in the following respects:

(1) The definition of "drug" was broadened so that drugs included not only products intended to cure disease but also products which would affect the structure or functioning of the body.

(2) Under the old law, a drug was adulterated only if its contents did not meet the standards outlined on its own label. The 1938 law required that labels definitely state in what way the ingredients of the drug differed from the standards laid down by the U.S. *Pharmacopoeia*.

(3) The appearance of new drugs on the market was prohibited until their use had been approved by the secretary of agriculture and until rigid safety tests had been made.

(4) The 1906 law had required proof of both falsity and fraud in charges that a drug was misbranded. Since fraud is often almost impossible to prove, the 1938 law stated that a drug would be considered misbranded if the claims made for it by the manufacturer were not supported by medical opinion as a whole.

(5) Habit-forming ingredients in a drug were required to be specifically mentioned on the label.

(6) The 1906 act did not forbid the use of dangerous ingredients in a drug as long as the drug was correctly labelled. The 1938 law defined as adulterated any drug that "is or may be dangerous to health under the conditions of use prescribed in the labelling."

(7) The control of cosmetics came under the law for the first time, and it covered all cosmetics except toilet soap.

Pharmaceutical Manufacturing and Retailing.—Pharmaceutical manufacturing on a large scale has reached a very high state of efficiency in the United States. This does not take into account the nostrum or so-called "patent medicine" business, over which no supervising control whatever is exercised, except in the matter of labelling, where the Food and Drugs act holds the manufacturers of such preparations to strict accountability in connection with claims for composition and curative value. The Federal Trade commission has authority over claims made in advertising. The manufacture of official preparations has almost all been given over to the large-scale manufacturers. In addition there is a great volume of business in nonsecret medicines which physicians are induced to prescribe by name instead of writing a detailed prescription for each patient.

American pharmacy is confronted with a very embarrassing situation in that the professional courses for registration are longer and more exacting and the demand for professional pharmaceutical services seems to be diminishing, notwithstanding the use of professional pharmacists by hospitals and by manufacturing pharmaceutical companies. (C. H. LAW.; X.)

PHARNABAZUS, Persian soldier and statesman, the son of Pharnaces, belonged to a family which from 478 B.C. governed the satrapy of Phrygia on the Hellespont, from its headquarters at Dascylium. Pharnabazus first appears as satrap of this province in 413, when he entered into negotiations with Sparta and began war with Athens. After the war he came into conflict with Lysander (*q.v.*; see also PELOPONNESIAN WAR), who tried to keep the Greek cities under his own dominion, and became one of the causes of his overthrow, by a letter which he sent to the ephors at Sparta.

When in 399 the war with Sparta broke out he again tried to conduct it strenuously. With the help of Conon and Evagoras of Salamis he organized the Persian fleet, and while he was hard pressed on land by Agesilaus he prepared the decisive sea battle which was fought in August 394 at Cnidus under his and Conon's command and completely destroyed the Spartan fleet. He sent support to the allies in Greece, by which the walls of the Peiraeus were rebuilt. But in the war on land he struggled in vain against the lethargy and disorganization of the Persian empire; and when at last, in 387, in consequence of the embassy of Antalcidas to Susa, the king decided to conclude peace with Sparta and to enter again into close alliance with her, Pharnabazus, the principal opponent of Sparta, was recalled from his command in high honours to marry Apame, a daughter of the king (Plut. *Artax.* 27).

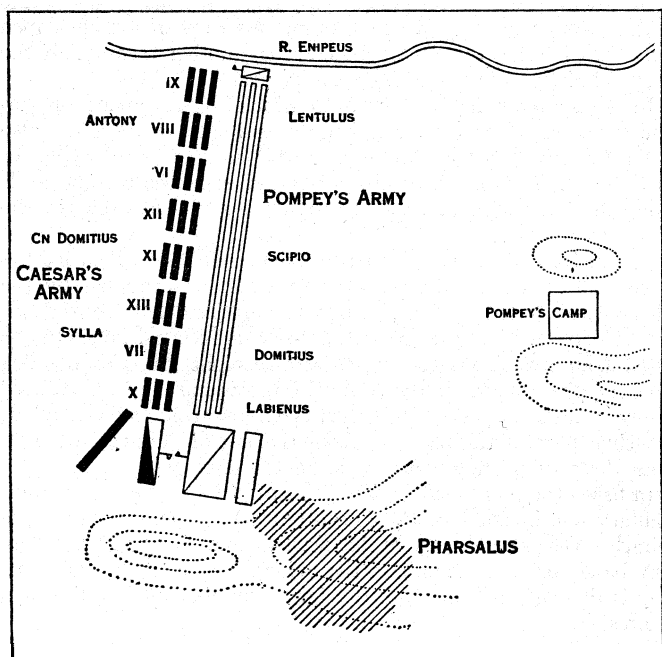

In 385 Pharnabazus was one of the generals sent against Egypt, and in 377 he was ordered to prepare a new expedition against the valley of the Nile. The gathering of the army took years, and when in 373 all was ready, his attempt to force the passage of the Nile failed. A conflict with Iphicrates, the leader of the Greek mercenaries, increased the difficulties; at last Pharnabazus led the army back to Asia. When he died is not known. (ED. M.)

PHARSALUS, BATTLE OF (48 B.C.). The defeat sustained by Julius Caesar at Dyrrachium in May 48 B.C. in no way disheartened him, but it compelled him to change his plan, and that at once. The task before him was a difficult one, namely, to retire before a victorious enemy and cross two bridgeless rivers, the Genusus and Apsus. Leaving 15 cohorts and 300 vessels to guard Dyrrachium, on June 3 Pompey set out toward Heraclea, while Caesar made his way to Aeginium in Thessaly, where he was joined by Cn. Domitius and two legions; this brought his force up to nine—some 24,000 men. He moved eastward and camped northwest of Pharsalus in the plain on the left bank of the Enipeus. There he awaited his enemy, whose army numbered 50,000 infantry, 7,000 cavalry and a large number of light troops. Pompey felt certain of victory, but he overlooked the personal factor and forgot that Caesar *was* his army and that, as one writer says: "The whole body was instinct with his purpose." Caesar felt equally certain of success. The battle was fought on June 29.

Pompey planned to hold Caesar's front with his infantry and mass his cavalry, largely outnumbering Caesar's, on his left wing in order to envelop Caesar's right wing and attack it in the rear. Pompey's right wing rested on the river Enipeus and was protected not only by the steep banks but by a force of some 600 horsemen, as Caesar saw. It was under the command of Lentulus, and was composed of Cilician and Spanish troops—

good soldiers. His left wing numbered the I. and III. legions and was accompanied by Pompey in person. Scipio held the centre with two Syrian legions and the bulk of the cavalry, slingers and archers, under Labienus were massed on the outer flank of the left wing.

Caesar drew up his legions in three lines of cohorts, four in the first, three in the second and three in the third; his men stood eight deep. On the right he placed the X. legion and on the left the

THE POSITION OF THE ARMIES AT THE BATTLE OF PHARSALUS. MAY 48 B.C. WHEN JULIUS CAESAR DEFEATED THE ARMY OF POMPEY

IX. Antony commanded the left, Sylla the right and Cn. Domitius the centre; he himself took up his position opposite Pompey. Thus far his order of battle was normal, but he had noticed the large force of cavalry massed on his enemy's left. Recognising that this mass was intended to outflank him, he drew up a fourth line of chosen cohorts, taken from the third line, and placed six of these cohorts and his small force of horse on his right, telling them that on their courage would depend the results of the battle. The third line he proposed to hold in reserve, and the first and second he ordered not to charge until he required it to. The trumpets were then sounded, and the battle cry of "Venus Victrix" raised, to which the Pompeians answered: "Hercules Invictus."

Pompey had ordered his men to await the enemy's assault, for he considered that when the two forces clinched his troops would be the fresher; but Caesar realising that this was a sign of weakness ordered his legions forward, trusting as he did to the impetus of the charge inspiring them with courage. Mid-way his men paused to regain breath, then advanced again, and when within range the front rank men hurled their javelins and drawing their swords rushed forward, and the two lines clinched. Immediately Pompey launched his cavalry and archers against his enemy's right flank, driving Caesar's cavalry from the field. Then the fourth line came into play, and in place of casting their javelins they closed on the horsemen with the sword "striking at the horses' breasts, and the men's legs and faces." In spite of their numbers the horsemen turned and fled, and the fourth line falling upon the archers and slingers drove them back, then, wheeling to the left, they struck Pompey's front, now locked in battle, on its flank and rear. At once Caesar galloped to his third line and ordered it to advance. This it did, breaking through Pompey's front. When Pompey saw his cavalry routed, despairing of success, he fled to his camp, possibly to rally the fugitives. The camp was eventually assaulted and taken, whereupon Pompey and 30 horse fled to Larissa and embarked for Egypt, where later on he was assassinated by Ptolemy Auletes, or rather by his tutor the eunuch Photinus, for Ptolemy was but a boy of ten. In this battle Caesar

lost 30 centurions and 200 men killed, and Pompey 15,000 killed and 24,000 prisoners. Caesar for political reasons showed great clemency by proclaiming a general pardon. He then organised his prisoners into two new legions and sent them to Asia.

PHARYNGITIS. The pharynx is frequently the seat of a chronic inflammatory condition, usually associated with derangements of the digestive organs, or with syphilis or gout; sometimes it is due to much speaking or to excessive tobacco-smoking—especially of cigarettes. On inspection, the inflamed mucous membrane is seen unduly red and glazed, and dotted over with enlarged follicles. The condition produces irritation and "dryness," with cough and discomfort, which may eventually become chronic. Treatment consists in removing sources of irritation, and in the application of the electric cauterly, of astringent lotions or of mild caustic solutions.

PHARYNX, in anatomy, the cavity into which both the nose and mouth lead, which is prolonged into the oesophagus or gullet below, and from which the larynx or air tube comes off below and in front; it therefore serves as a passage both for food and air. The back and sides of the cavity are formed by the three constrictor muscles of the pharynx, each of which overlaps the outer surface of the one above it, and these are lined internally by thick mucous membrane. Above, the pharynx is attached firmly to the base of the skull and the internal pterygoid plates, so that this part cannot collapse, but below the anterior and posterior walls are in contact, and a transverse section of the pharynx is a mere slit.

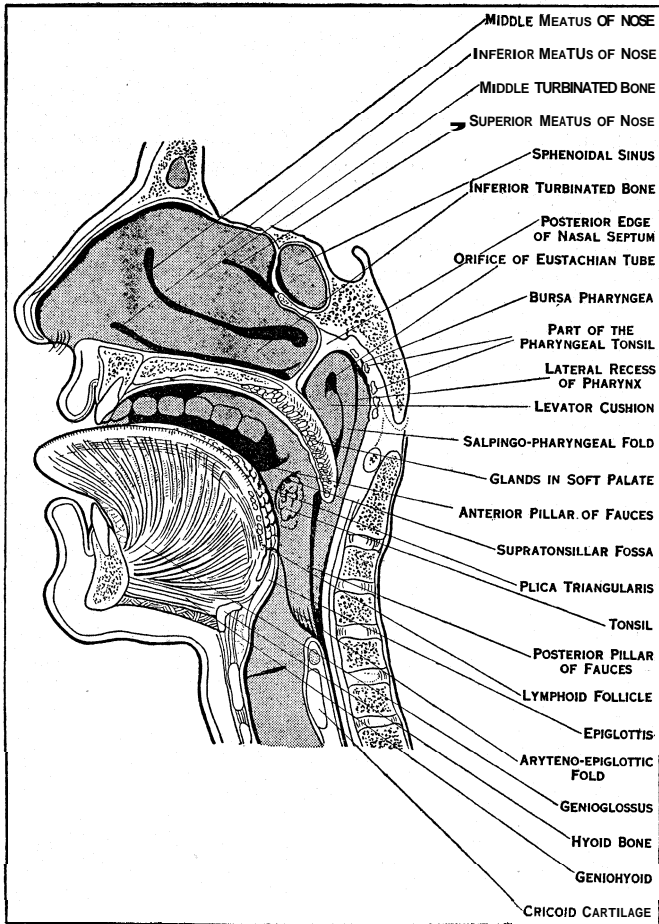

From the front wall, on a level with the floor of the nose and roof of the mouth, a slanting shelf of muscular and glandular tissue covered with mucous membrane, projects downward and backward into the cavity, and divides it into an upper part or naso-pharynx and a lower or oral pharynx (see fig.). This shelf is the *soft* palate, and from the middle of its free border hangs a worm-like projection, the uvula. The whole of the front wall of the naso-pharynx is wanting, and here the cavity opens into the nose through the posterior nasal apertures (see **OLFACTORY SYSTEM**). On each side of the naso-pharynx, and therefore above the soft palate, is the large triangular opening of the Eustachian tube through which air passes to the tympanum (see **EAR**). Behind this opening, and reaching up to the roof of the naso-pharynx, is a mass of lymphoid tissue, most marked in children, known as the pharyngeal tonsil. This tissue hypertrophies in the disease known as "adenoids."

The oral pharynx communicates with the naso-pharynx behind the free edge of the soft palate. Above and in front it is continuous with the cavity of the mouth, and the demarcation between the two is a ridge of mucous membrane on each side running from the soft palate to the side of the tongue, and caused by the projection of the palato-glossus muscle (anterior pillar of the fauces). About half an inch behind this ridge is another, made by the palato-pharyngeus muscle, which gradually fades away in the side of the pharynx below (posterior pillar of the fauces). Between the two pillars is the fossa (tonsillar sinus) in which the tonsil lies.

The *Tonsil* is an oval mass of lymphoid tissue covered by mucous membrane which dips in to form mucous crypts; externally its position nearly corresponds to that of the angle of the jaw. It is very vascular, deriving its blood from five neighbouring arteries. Below the level of the tonsil the anterior wall of the pharynx is formed by the posterior or pharyngeal surface of the tongue (*q.v.*), while below that is the epiglottis and upper opening of the larynx which is bounded laterally by the aryteno-epiglottic folds (see **RESPIRATORY SYSTEM**). On the lateral side of each of these folds is a pear-shaped fossa known as the sinus *pyriformis*. Below this the pharynx narrows rapidly until the level of the

lower border of the cricoid cartilage in front and of the sixth cervical vertebra behind is reached; here it passes into the oesophagus, having reached a total length of about five inches.

The mucous membrane of the naso-pharynx, like that of the rest of the respiratory tract, is lined by ciliated columnar epithelium, but in the oral pharynx the epithelium is of the stratified

SAGITTAL SECTION THROUGH MOUTH, TONGUE, LARYNX, PHARYNX, AND NASAL CAVITY, VIEWING THE SECTION SLIGHTLY FROM BELOW

squamous variety. Numerous racemose glands are present (see GLANDS; TISSUES), as well as patches of lymphoid tissue especially in childhood. Outside the mucous membrane and separating it from the constrictor muscles is the pharyngeal aponeurosis, which blends above with the periosteum of the base of the skull.

Embryology.—The pharynx is partly formed from the ectodermal stomatodaeal invagination (see EMBRYOLOGY and MOUTH) and partly from the fore gut, which is the cephalic part of the entodermal mesodaeum. Up to the fifteenth day (see MOUTH), the bucco-pharyngeal membrane separates these structures, and, though no vestiges of it remain, it is clear that the upper and front part of the naso-pharynx is stomatodaeal while the rest is mesodaeal. The five visceral arches with their intervening clefts or pouches surround the pharynx, and the Eustachian tube is a remnant of the first of these. The second pouch is represented in the adult by the tonsillar sinus, and until lately the lateral recess of the pharynx was looked upon as part of the same, but it has now been shown to be an independent diverticulum. The sinus pyriformis probably represents that part of the fourth groove from which the lateral lobes of the thyroid body are derived.

The tonsil is formed in the second branchial cleft or rather pouch, for the clefts are largely incomplete in man, about the fourth month; its lymphoid tissue, as well as that elsewhere in the pharynx, is formed from lymphocytes in the subjacent mesenchyme (see EMBRYOLOGY), though whether these wander in from

the blood or are derived from original mesenchyme cells is still doubtful. The development of the ventral part of the pharynx is dealt with in the articles TONGUE and RESPIRATORY SYSTEM.

Comparative Anatomy.—In the lower, water-breathing vertebrates the pharynx is the part in which respiration occurs. The water passes in through the mouth and out through the gill slits where it comes in contact with the gills or branchiae.

The lowest subphylum of the phylum Chordata, to which the term *Adelochorda* is sometimes applied, contains a worm-like creature *Balanoglossus*, in which numerous rows of gill slits open from the pharynx, though *Cephalodiscus*, another member of the same subphylum, has only one pair of these.

In the subphylum Urochorda, to which the Ascidiaceans or sea-squirts belong, there are many rows of gill slits, as there are also in the Acrania, of which *Amphioxus*, the lancelet, is the type. In all these lower forms there are no true gills, as the blood-vessels lining the large number of slits provide a sufficient area for the exchange of gases.

In the Cyclostomata a reduction of the number of gill slits takes place, and an increased area for respiration is provided by the gill pouches lined by pleated folds of entodermal mucous membrane; these form the simplest type of true internal gills. In the larval lamprey (*Ammocoetes*) there are eight gill slits opening from the pharynx, but in the adult (*Petromyzon*) they are reduced to seven, and a septum grows forward separating the ventral or branchial part of the pharynx from the dorsal or digestive part. Both these tubes, however, communicate near the mouth.

In fishes there are usually five pairs of gill slits, though a rudimentary one in front of these is often present and is called the spiracle. Occasionally, as in *Hexanchus* and *Heptanchus*, there may be six or seven slits, and the evidence of comparative anatomy is that fishes formerly had a larger number of gill slits than at present.

In the Teleostomi, which include the bony fishes, there is an external gill cover or operculum.

In the Dipnoi or mud fish the work of the gills is shared by that of the lungs, and in the African form, *Protopterus*, external gills, developed from the ectodermal parts of the gill slits, first appear. In the tailed Amphibians (*Urodela*) the first and fifth gill clefts are never perforated and are therefore in the same condition as all the gill clefts of the human embryo, while in the gilled salamanders (*Necturus* and *Proteus*) only two gill clefts remain patent. The gills in all the Amphibia are external and of ectodermal origin, but in the Anura (frogs and toads) these are succeeded before the metamorphosis from the tadpole stage by internal gills, which, unlike those of fish, are said to be derived from the ectoderm.

In the embryos of the Sauropsida (reptiles and birds) five gill clefts are evident, though the posterior two are seldom at any time perforated, while in the Mammalia the rudiments of the fifth cleft are no longer found in the embryo, and in man, at all events, none of them are normally perforated except that part of the first which forms the Eustachian tube. It will thus be seen that in the process of phylogeny there is a gradual suppression of the gill clefts beginning at the more posterior ones.

The soft palate is first found in crocodiles as a membranous structure, and it becomes muscular in mammals. The bursa pharyngea and pharyngeal tonsil are found in several of the lower mammals. In the sheep the latter is particularly large.

PAINTED FOR THE ENCYCLOPEDIA BRITANNICA BY HELEN DAMROSCH TEE-VAN

PHEASANTS AND THEIR ALLIES

This family contains, besides the Pheasants, the Peacock, most magnificent of birds, and the Jungle Fowl, whose domesticated descendants are very useful to mankind. Most of the males are brill-

liantly coloured, while many are adorned with magnificent tails. Their original homes are in Asia, from the Caucasus to Japan and the East Indian Islands

- 1. Reeves' Pheasant (*Syrnaticus reevesi*).
- 2. Lady Amherst Pheasant (*Chrysolophus amherstiae*).
- 3. Golden Pheasant (*Chrysolophus pictus*).
- 4. Indian Peacock (*Pavo cristatus*).
- 5.

- 6. Silver Pheasant (*Gennaeus nyctemerus*).
- 7. Red Jungle Fowl (*Gallus gallus*).
- 8. Germain's Peacock Pheasant (*Polyplectron germaini*).
- 9. Impeyan Pheasant (*Lophophorus impeyanus*).

- 10. Malay Crested Fireback Pheasant (*Lophura rufa*).
- 11. Eastern Chinese Ring-necked Pheasant (*Phasianus torquatus*).

little foundation. This bird, *Phasianus colchicus*, is the type of the family Phasianidae, and is reared in England for shooting (see SHOOTING). It is distributed in a wild state from the Caspian Sea all over south-east Europe. The male is a handsome bird with brilliant plumage and red wattles; the female protectively coloured in mottled brown. The wings are short; the tail is long. The birds are polygamous; they feed on grain, seeds, shoots, and insects and both fly and run well. The nest is on the ground and 11 or 12 olive-brown eggs are laid.

BY COURTESY OF THE PUBLISHER'S PHOTO SERVICE

THE GOLDEN PHEASANT (*CHRYSOLOPHUS PICTUS*)

Pheasants will cross with numerous other gallinaceous birds, including the common fowl; the offspring in this case is called a pero. The British pheasants have in their blood a mixture of two Chinese species, with white neckrings. This mixture, as well as the pure-bred bird, has been introduced into various parts of U.S.A. and Canada. Reeve's pheasant (*P. reevesi*) from northern China has a very long tail. The golden pheasant (*Chrysolophus pictus*), Amherst's pheasant (*C. amherstiae*) and the silver pheasants (*Genmaeus spp.*) are even more beautiful. They are all Chinese birds and are well known in aviaries. The lovely Argus pheasants (*Argusianus*) of Malacca and Siam may measure 6ft. from the beak to the tail in the male; the secondaries of the wings (which are longer than the primaries) have metallic spots resembling eyes. The monals (*Lophophorus*) inhabit the Himalayas. The peacock pheasants (*Chalcurus* and *Polyplectron*) inhabit Burma, Siam, Indo-China, and the Malay region; the plumage is ornamented with metallic eyespots.

The adornments of male pheasants are strikingly displayed in courtship. (See COURTSHIP OF ANIMALS.) The so-called Bohemian pheasant is a very rare variety.

See Tegetmeier, *Pheasants; their Natural History and Practical Management*; Beebe, *Monograph of the Phasianidae* (1918-22).

PHEIDIAS, son of Charmides, universally regarded as the greatest of Greek sculptors, was born at Athens about 500 B.C. Hegias of Athens was his first master. To his early career belong a chryselephantine Athene for Pellene and a Marathon memorial at Delphi. To this period also belongs the great bronze Athene whose helmet and spear could be seen above the Acropolis buildings far out to sea. An Apollo, found in the Tiber, bears so many of Pheidias's known characteristics that it may be Pheidias's own work (Schrader, in *Jahreshefte*, 1911). If so, it is the only original work by him that we have. Our information as to his later career is fuller, but confusing. We know that he made the colossal Zeus at Olympia; that he controlled the artistic activity at Athens under Pericles, and fell into trouble from Pericles's opponents on charges of peculation, and of sacrilege in representing himself and Pericles on Athene's shield. But the order of these events is obscure. All we know is that the Athene Parthenos was dedicated in 438.

It is important to observe that in resting the fame of Pheidias upon the sculptures of the Parthenon we proceed with little evidence. No ancient writer ascribes them to him, and he seldom, if ever, executed works in marble. What he was celebrated for in antiquity were his statues in bronze or gold and ivory. If Plutarch tells us that he superintended the great works of Pericles on the Acropolis, this phrase is very vague. On the other hand, inscriptions prove that the marble blocks intended for the pedimental statues of the Parthenon were not brought to Athens until 434 B.C., which was probably after the death of Pheidias. And there is a marked contrast in style between these statues and the certain works of Pheidias. It is therefore probable that most, if not all, of the sculptural decoration of the Parthenon was the work of pupils of Pheidias, such as Alcamenes and Agoracritus, working on his designs, rather than their own.

Among the Greeks themselves the two works of Pheidias which far outshone all others, and were the basis of his fame, were the colossal figures in gold and ivory of Zeus at Olympia and of Athene Parthenos at Athens, both of which belong to about the

middle of the 5th century. Of the Zeus we have unfortunately lost all trace save small copies on coins of Elis, which give us but a general notion of the pose, and the character of the head. The god was seated on a throne, every part of which was used as a ground for sculptural decoration. His body was of ivory, his robe of gold. His head was of somewhat archaic type; the Otricoli mask which used to be regarded as a copy of the head of the Olympian statue is certainly more than a century later in style. Of the Athene Parthenos two small copies in marble have been found at Athens (see GREEK ART, fig. 38), which have no excellence of workmanship, but have a certain evidential value as to the treatment of their original. Other works of Pheidias were the Lemnian Athene, an Apollo Parnopius and an Aphrodite Urania at Elis.

The fine torso of Athene in the École des Beaux Arts at Paris, which has unfortunately lost its head, may perhaps best serve to help our imagination in reconstructing a Pheidian original.

As regards the decorative sculptures of the Parthenon, which the Greeks rated far below their colossus in ivory and gold, see the article PARTHENON.

Ancient critics take a very high view of the merits of Pheidias. What they especially praise are his elevated ideas of godhead, and these, the expression of the best religious thought of his time, reacted on the religious conceptions of Greece. A copy of the shield that contained his portrait (the "Strangford" shield) is in the British Museum. Pheidias appears as a vigorous, bald-headed old man.

See Petersen, *Kunst des Pheidias* (Berlin, 1873); C. Waldstein, *Essays on the Art of Pheidias* (Cambridge, 1885); Colligna, *Pheidias* (Paris, 1886).

PHEIDON (8th or 7th century B.C.), king of Argos. According to tradition he flourished during the first half of the 8th century B.C. He was a vigorous and energetic ruler and greatly increased the power of Argos. He gradually regained sway over the various cities of the Argive confederacy, the members of which had become practically independent, and (in the words of Ephorus) "reunited the broken fragments of the inheritance of Temenus." His object was to secure predominance for Argos in the north of Peloponnesus. Pheidon assisted the Pisatans to expel the Elean superintendents of the Olympian games and presided at the festival himself. The Eleans, however, refused to recognize the Olympiad or to include it in the register, and shortly afterwards, with the aid of the Spartans, who are said to have looked upon Pheidon as having ousted them from the headship of Greece, defeated Pheidon and were reinstated in the possession of Pisatis and their former privileges. Pheidon is said to have lost his life in a faction fight at Corinth, where the monarchy had recently been overthrown. He made changes in the existing system of weights and measures in the Peloponnesus, and his system was in use at Athens before Solon (Arist. *Ath. Pol.* x. 2), but Ephorus' statement that he first coined silver money seems unlikely.

His date is disputed. Pausanias assigns the Olympiad at which he presided to 748, but the balance of modern authority is in favour of the first half of the 7th century.

See Herodotus vi. 127; Ephorus in Strabo viii. 358, 376; Plutarch, *Amatoriae narrationes*, 2; Marmor parium, ep. 30; Pollux ix. 83; Nicolaus Damascenus, frag. 41 (in C. W. Muller's *Frag. hist. graecorum*, iii.); G. Grote, *History of Greece*, pt. ii. ch. 4; B. V. Head, *Historia Numorum* (1887); F. Hultsch, *Griechische und römische Metrologie* (1882); G. Rawlinson's *Herodotus*, appendix, bk. i., note 8. On the question of Pheidon's date, see J. B. Bury, *History of Greece*, ii. 468 (1902); J. P. Mahaffy, *Problems in Greek History*, ch. 3 (1892); J. G. Frazer's note on Pausanias vi. 22, 2; and especially G. Busolt, *Griechische Geschichte* (2nd ed., 1893), ch. iii. 12. C. Trieber, *Pheidon von Argos* (Hanover, 1880), and J. Beloch, in *Rheinisches Museum*, xlv. 595 (1890), favour a later date, about 580.

PHELPS, EDWARD JOHN (1822-1900), American lawyer and diplomat, was born on July 11, 1822, at Middlebury, Vt. He graduated from Middlebury college in 1840, was a schoolmaster for a year in Virginia and was admitted to the bar in 1843. From 1851 to 1853 he was second controller of the U.S. Treasury, and then practised law in New York city until 1857, when he returned to Burlington. He was one of the founders of the American Bar Association, and was its president in 1880-81.

From 1881 until his death he was Kent professor of law in Yale university. He was minister to Great Britain from 1885 to 1889, and in 1893 served as senior counsel for the United States before the international tribunal at Paris to adjust the Bering sea controversy. He died at New Haven, Conn., on March 9, 1900.

See his *Orations and Essays*, edited by J. G. McCullough, with a "Memoir" by J. W. Stewart (1901); and the memorial address by M. H. Buckham, in *Proceedings of the Vermont Historical Society* (Burlington, Vt., 1901).

PHELPS, SAMUEL (1804–1878), English actor and manager, was born at Devonport on Feb. 13, 1804. He made his first London appearance on Aug. 28, 1837 as Shylock at the Haymarket. After a short season there he was with Macready for about six years at Covent Garden, the Haymarket and Drury Lane successively. In 1844 he became co-lessee of Sadler's Wells Theatre with Thomas L. Greenwood and Mary Amelia Warner (1804–54). Phelps spent 20 years at Sadler's Wells theatre, and raised the house to a leading position in London. Thirty-four of Shakespeare's plays were presented there under his direction. He died on Nov. 6, 1878.

PHENACETIN, a drug crystallizing from water in colourless plates, melting at 135° C. It is soluble in about 70 parts of hot and in about 1,400 parts of cold water. It is prepared by acetylating para-phenetidine, or by heating para-acetylamino-phenol and potassium ethyl sulphate with alcoholic soda to 150° C. It is acetyl-*p*-phenetidine, C₈H₉O·C₆H₄·NHCOCH₃. Para-phenetidine is prepared by treating the sodium salt of para-nitrophenol with ethyl iodide, and reducing the nitrophenetole to para-phenetidine or aminophenetole. The yield may be doubled by diazotizing para-phenetidine, coupling with phenol, ethylating and reducing.

Several compounds related to phenacetin have been introduced into medicine. Triphenin is propylphenetidine; lactophenin is lactylphenetidine; pyrantin is para-ethoxyphenyl succinimide, EtO·C₆H₄·N[CO·CH₂]₂; salophen or saliphenin is salicylphenetidine; amygdophenin is mandelylphenetidine. In addition, several other derivatives have been suggested which have a greater solubility than phenacetin, e.g., phesin, which is the sodium salt of phenacetinsulphonic acid, apolysin and citrophen (citra-phenin), which are citric acid derivatives of para-phenetidin, etc.

Phenacetin is contained in both the British and United States pharmacopoeia, in the latter under the name of acetphenetidin. The dose is 5 to 10 gr. given in cachets or in suspension. When the drug is carelessly made it may contain impurities, producing considerable irritation of the kidneys. The physiological action of phenacetin consists in a sedative action on the sensory tracts of the spinal cord, and a depressant action on the heart, where it tends to paralyse the action of the cardiac muscle. Its chief therapeutic use is as an antineuralgic, and it is of service in migraine, rheumatism of the sub-acute type, intercostal neuralgia and locomotor ataxia.

FROM SCOTT, "LAND MAMMALS OF THE WESTERN HEMISPHERE" (MACMILLAN)
SKELETON OF THE WASATCH CONDYLARTH. IN THE AMERICAN MUSEUM OF NATURAL HISTORY

PHENACODUS, a primitive and generalized hoofed mammal of the Lower Eocene, now extinct. The two best known species are represented by complete skeletons found in the Bighorn basin of Wyoming in 1881. They are of the size respectively of a pig and of a fox, and typically of the family Phenacodontidae of the order Condylarthra.

The teeth of Phenacodus are very short-crowned, with low rounded cusps, the dentition unreduced, the premolars smaller than the molars and of simpler pattern. The feet are five-toed but the first and fifth digits are considerably reduced; the small flattened hoofs resemble those of the tapir. The arrangement of the wrist-bones is serial, the upper row directly overlying the lower ones, as in *Hyrax* and the elephant, instead of alternating as with other hoofed animals. The astragalus in the hind foot is like that of Carnivora with distinct neck and convex rounded head. This character distinguishes the Condylarthra from the higher ungulates as the primitive construction of their teeth distinguishes them from the variously specialized ungulate tooth patterns. The brain was small and of inferior structure. (W. D. M.)

PHENAKITE, a mineral consisting of beryllium orthosilicate, Be₃SiO₄, occasionally used as a gem-stone. In general appearance it is not unlike quartz, for which indeed it had been mistaken, and was on this account named from Gr. φέναξ (a deceiver). It occurs as isolated crystals, which are rhombohedral with parallel-faced hemihedrism, and are either lenticular or prismatic in habit. There is no cleavage, the fracture is conchoidal, and the crystals are sometimes perfectly colourless and transparent, but more often greyish or yellowish and only translucent. The hardness is high, being 7.5–8; the specific gravity is 2.98.

Phenakite has long been known from the emerald and chrysoberyl mine on the Takovaya stream, near Ekaterinburg in the Urals, where large crystals occur in mica-schist. It is also found with topaz and microlite in the granite of the Ilmen mountains in the southern Urals and of the Pike's Peak region, Colorado. Large crystals of prismatic habit have more recently been found in a felspar quarry at Kragero, Norway, and clear lenticular crystals are abundant at San Miguel de Piricicaba, Brazil.

For gem purposes the stone is cut in the brilliant form, of which there are two fine examples, weighing 43 and 34 carats, in the mineral collection of the British Museum. The indices of refraction ($\omega = 1.6540$, $\epsilon = 1.6527$) are higher than those of quartz, beryl or topaz; a faceted phenakite is consequently rather brilliant and may sometimes be mistaken for diamond.

PHENANTHRENE, an aromatic hydrocarbon having the same composition, C₁₄H₁₀, as anthracene (*q.v.*) and found with the latter in distillates from coal tar boiling between 270° and 400° C. The crude solid hydrocarbons from this fraction are separated by crystallisation from various organic solvents (alcohol, acetone, carbon disulphide, etc.), phenanthrene being more soluble than anthracene. The former is also less oxidisable than the latter so that chromic acid treatment removes residual anthracene. Phenanthrene (formula I.) is obtained in colourless needles

or triclinic plates melting at 100–101° C and boiling at 340° C; it exhibits a faint blue fluorescence in solution or when vaporised. Its picrate forms yellow crystals melting at 145° C. Phenanthrene is oxidised by chromic acid to phenanthraquinone (formula II.), obtained in orange needles melting at 198–202° C; it is a typical *ortho*-quinone (see QUINONES) and condenses with *ortho*-diamines to form phenazines (*q.v.*). Distilled with soda lime, phenanthraquinone yields diphenyl and by further oxidation the quinone gives diphenic acid. These reactions serve to establish the constitution of the phenanthrene nucleus (I.). This nucleus is present in certain of the opium alkaloids, and when distilled with zinc dust morphine yields phenanthrene. Many attempts have been made, but with little success, to utilise phenanthrene in colour making.

See A. E. Everest, *The Higher Coal Tar Hydrocarbons* (1927).

PHENAZINE, in organic chemistry, the parent substance of many dyestuffs, e.g., the eurhodines, toluylene red, indulines and safranines. (See DYES, SYNTHETIC.) It may be obtained by passing aniline vapour over lead oxide, or by the oxidation of dihydrophenazine, which is prepared by heating catechol with orthophenylenediamine. It is also formed when *ortho*-aminodi-

phenylamine is distilled over lead peroxide. It crystallizes in yellow needles which melt at 171°C ., and are only sparingly soluble in alcohol. Its formula is $\text{C}_{12}\text{H}_8\text{N}_2$. Sulphuric acid dissolves it, forming a deep red solution. The more complex phenazines, *i.e.*, the naphthophenazines, naphthazines and naphthotolazines, may be prepared by condensing ortho-diamines with ortho-quinones (O. Hinsberg, 1887); by the oxidation of an ortho-diamine in the presence of α -naphthol (O. Witt), and by the decomposition of ortho-anilido (-toluidido-, etc.)-azo compounds with dilute acids. If alkyl or aryl-ortho-diamines be used azonium bases are obtained. The azines are mostly yellow in colour, distil unchanged and are stable to oxidants. They add on alkyl iodides readily, forming alkyl azonium salts.

The symmetrical diaminophenazine is the parent substance of the important dyestuff toluylene red or dimethyldiaminotoluphenazine. It is obtained by the oxidation of orthophenylenediamine with ferric chloride; by oxidizing a mixture of para-aminodimethylaniline and meta-tolylenediamine, toluylene blue, an indamine, being formed as an intermediate product and passing into the red when boiled; and also by the oxidation of dimethyl-paraphenylenediamine with metatolylenediamine. It crystallizes in orange-red needles and its alcoholic solution fluoresces strongly. It dyes silk and mordanted cotton a fine scarlet. It is known commercially as neutral red. Phenazonium salts are known as safranines. (See DYES, SYNTHETIC.)

Phenazone or dibenzopyridazine is an isomeride of phenazine, to which it bears the same relation that phenanthrene bears to anthracene (*qq.v.*). It is formed by reducing diortho-dinitrodiphenyl with sodium amalgam and methyl alcohol. It crystallizes in yellow needles which melt at 156°C . Potassium permanganate oxidizes it to pyridazinetetra-carboxylic acid.

PHENIX CITY, a city of Russell county, Alabama, U.S.A., on the Chattahoochee river, opposite Columbus, Ga. It is on federal highway 80, and is served by the Central of Georgia railway. Pop. 13,862 in 1930 and 15,351 in 1940. It is a residential and industrial suburb of Columbus.

PHENOL CONDENSATION PRODUCT: see CARBOLIC ACID; BAKELITE.

PHENOLPHTHALEIN, an organic compound of the aomatic series which has two uses: (1) as an indicator for acids and bases in volumetric analysis; (2) as a purgative drug. The phthaleins are prepared by condensing phenols with phthalic anhydride, phenol itself giving rise to phenolphthalein together with a small quantity of fluorane, whilst resorcinol under similar conditions yields fluorescein (*q.v.*). The phthaleins on reduction yield phthalines which are derivatives of triphenylmethane carboxylic acid; thus phenolphthalein itself gives phenolphthaline.

Phenolphthalein is obtained when phenol and phthalic anhydride are heated with concentrated sulphuric acid. It crystallizes in colourless crusts (m.p. $250\text{--}253^{\circ}\text{C}$) and is nearly insoluble in water, but dissolves in dilute solutions of the caustic alkalis with a fine red colour, being reprecipitated from these solutions by the addition of mineral acid. It is to this remarkable colour change that its use as an indicator is due. It dissolves in concentrated caustic alkalis to a colourless solution which probably contains salts of a non-quinonoid character. On fusion with caustic alkali, phenolphthalein yields benzoic acid and para-

dihydroxybenzophenone, which shows that in the original condensation the phthalic acid residue has taken the para position to the hydroxyl groups of the phenol.

Fluorane is a by-product of the condensation of phthalic acid and phenol, substitution occurring in the ortho position to the hydroxyl groups of the phenol, so that anhydride formation takes place between these hydroxyl groups. It dissolves in concentrated sulphuric acid with a yellowish-green fluorescence.

Phenolphthalein has extended use as a purgative under such synonyms as purgen, laxoin, laxatol, etc. The official dose is 2 to 5 grains (0.12 to 0.3 grams), but larger doses are given. Phenolphthalein is dissolved in the bile and by the alkali of the intestine, and being irritant to the latter it causes peristalsis. It is partly absorbed and partly excreted by the liver and so acts repeatedly on the intestine, acting for a few days as a mild aperient.

PHENOMENALISM, in philosophy, is a name applied to several different schools of thought which maintain in common that human knowledge (so-called) is confined to phenomena in the broad sense of the term, according to which it denotes generally events or things in space and time. But the schools differ among themselves on the ontological (as distinguished from the epistemological) question relating to the objective source or basis of the phenomena. (1) According to one view it is assumed more or less that there is an objective reality of which the phenomena are the changing appearances, but it is maintained that this ultimate basic reality is beyond the reach of human knowledge, which is limited to the apprehension of appearances adapted to or relative to human powers. In one form or another some such view is maintained by Agnosticism, the critical Philosophy, Empiricism, and Positivism.

(2) Another view is to the effect that there is no permanent substance underlying the ever-changing flux of phenomena; in other words, these ever-changing phenomena are the only reality. This was the view held by Heraclitus among the ancient Greeks, and by Bergson among present-day philosophers, also by others.

(3) Yet a third view would deny the external existence even of phenomena in the ordinary sense of the term (that is, events actually occurring in space and time) and identifies all reality with the mere appearances to or in the mind or mental experiences as such. This view is represented by Shadworth Hodgson, the author of *The Metaphysic of Experience* (1898), and others.

It should be observed that the first kind of phenomenalism (1) is merely epistemological, whereas the other two, (2) and (3), are also ontological. Ontological phenomenalism implies epistemological phenomenalism, but not vice versa. See METAPHYSICS, and KNOWLEDGE, THEORY OF.

PHENOMENOLOGY denotes a new, descriptive, philosophical method, which, since the concluding years of the last century, has established (1) an a priori psychological discipline, able to provide the only secure basis on which a strong empirical psychology can be built, and (2) a universal philosophy, which can supply an organum for the methodical revision of all the sciences.

I. PHENOMENOLOGICAL PSYCHOLOGY

Present-day psychology, as the science of the "psychical" in its concrete connection with spatio-temporal reality, regards as its material whatever is present in the world as "ego-istic"; *i.e.*, "living," perceiving, thinking, willing, etc., actual, potential and habitual. And as the psychical is known as a certain stratum of existence, proper to men and beasts, psychology may be considered as a branch of anthropology and zoology. But animal nature is a part of physical reality, and that which is concerned with physical reality is natural science. Is it, then, possible to separate the psychical cleanly enough from the physical to establish a pure psychology parallel to natural science? That a purely psychological investigation is practicable within limits is shown by our obligation to it for our fundamental conceptions of the psychical. and most of those of the psycho-physical.

But before determining the question of an unlimited psychology, we must be sure of the characteristics of psychological experience and the psychical data it provides. We turn naturally to our

immediate experiences. But we cannot discover the psychical in any experience, except by a "reflection," or perversion of the ordinary attitude. We are accustomed to concentrate upon the matters, thoughts, and values of the moment, and not upon the psychical "act of experience" in which these are apprehended. This "act" is revealed by a "reflection"; and a reflection can be practised on every experience. Instead of the matters themselves, the values, goals, utilities, etc., we regard the subjective experiences in which these "appear." These "appearances" are phenomena, whose nature is to be a "consciousness-of" their object, real or unreal as it be. Common language catches this sense of "relativity," saying, I was thinking of something, I was frightened of something, etc. Phenomenological psychology takes its name from the "phenomena," with the psychological aspect of which it is concerned: and the word "intentional" has been borrowed from the scholastic to denote the essential "reference" character of the phenomena. All consciousness is "intentional."

In unreflective consciousness we are "directed" upon objects, we "intend" them; and reflection reveals this to be an immanent process characteristic of all experience, though infinitely varied in form. To be conscious of something is no empty having of that something in consciousness. Each phenomenon has its own intentional structure, which analysis shows to be an ever-widening system of individually intentional and intentionally related components. The perception of a cube, for example, reveals a multiple and synthesized intention: a continuous variety in the "appearance" of the cube, according to differences in the points of view from which it is seen, and corresponding differences in "perspective," and all the difference between the "front side" actually seen at the moment and the "backside" which is not seen, and which remains, therefore, relatively "indeterminate," and yet is supposed equally to be existent. Observation of this "stream" of "appearance-aspects" and of the manner of their synthesis, shows that every phase and interval is already in itself a "consciousness-of" something, yet in such a way that with the constant entry of new phases the total consciousness, at any moment, lacks not synthetic unity, and is, in fact, a consciousness of one and the same object. The intentional structure of the train of a perception must conform to a certain type, if any physical object is to be perceived as there! And if the same object be intuited in other modes, if it be imagined, or remembered, or copied, all its intentional forms recur, though modified in character from what they were in the perception, to correspond to their new modes. The same is true of every kind of psychical experience. Judgment, valuation, pursuit, these also are no empty experiences having in consciousness of judgments, values, goals and means, but are likewise experiences compounded of an intentional stream, each conforming to its own fast type.

Phenomenological psychology's comprehensive task is the systematic examination of the types and forms of intentional experience, and the reduction of their structures to the prime intentions, learning thus what is the nature of the psychical, and comprehending the being of the soul.

The validity of these investigations will obviously extend beyond the particularity of the psychologist's own soul. For psychical life may be revealed to us not only in self-consciousness but equally in our consciousness of other selves, and this latter source of experience offers us more than a reduplication of what we find in our self-consciousness, for it establishes the differences between "own" and "other" which we experience, and presents us with the characteristics of the "social-life." And hence the further task accrues to psychology of revealing the intentions of which the "social life" consists.

Phenomenological-psychological and Eidetic Reductions.

—The Phenomenological psychology must examine the self's experience of itself and its derivative experience of other selves and of society, but whether, in so doing, it can be free of all psycho-physical admixture, is not yet clear. Can one reach a really pure self-experience and purely psychical data? This difficulty, even since Brentano's discovery of intentionality, as the fundamental character of the psychical, has blinded psychologists to the possibilities of phenomenological psychology. The psychologist

finds his self-consciousness mixed everywhere with "external" experience, and non-psychical realities. For what is experienced as external belongs not to the intentional "internal," though our experience of it belongs there as an experience of the external. The phenomenologist, who will only notice phenomena, and know purely his own "life," must practice an *ἐποχή*. He must inhibit every ordinary objective "position," and partake in no judgment concerning the objective world. The experience itself will remain what it was, an experience of this house, of this body, of this world in general, in its particular mode. For one cannot describe any intentional experience, even though it be "illusory," a self-contradicting judgment and the like, without describing what in the experience is, as such, the object of consciousness.

Our comprehensive *ἐποχή* puts, as we say, the world between brackets, excludes the world which is simply there! from the subject's field, presenting in its stead the so-and-so-experienced-perceived-remembered-judged-thought-valued-etc.world, as such, the "bracketed" world. Not the world or any part of it appears, but the "sense" of the world. To enjoy phenomenological experience we must retreat from the objects posited in the natural attitude to the multiple modes of their "appearance," to the "bracketed" objects.

The phenomenological reduction to phenomena, to the purely psychical, advances by two steps: (1) systematic and radical *ἐποχή* of every objectifying "position" in an experience, practised both upon the regard of particular objects and upon the entire attitude of mind, and (2) expert recognition, comprehension and description of the manifold "appearances" of what are no longer "objects" but "unities" of "sense." So that the phenomenological description will comprise two parts, description of the "noetic" (*νόεω*) or "experiencing" and description of the "noematic" (*νόημα*) or the "experienced." Phenomenological experience, is the only experience which may properly be called "internal" and there is no limit to its practice. And as a similar "bracketing" of objective, and description of what then "appears" ("noema" in "noesis"), can be performed upon the "life" of another self which we represent to ourselves, the "reductive" method can be extended from one's own self-experience to one's experience of other selves. And, further, that society, which we experience in a common consciousness, may be reduced not only to the intentional fields of the individual consciousness, but also by the means of an inter-subjective reduction, to that which unites these, namely the phenomenological unity of the social life. Thus enlarged, the psychological concept of internal experience reaches its full extent.

But it takes more than the unity of a manifold "intentional life," with its inseparable complement of "sense-unities," to make a "soul." For from the individual life that "ego-subject" cannot be disjoined, which persists as an identical ego or "pole," to the particular intentions, and the "habits" growing out of these. Thus the "inter-subjective," phenomenologically reduced and concretely apprehended, is seen to be a "society" of "persons," who share a conscious life.

Phenomenological psychology can be purged of every empirical and psycho-physical element, but, being so purged, it cannot deal with "matters of fact." Any closed field may be considered as regards its "essence," its *εἶδος*, and we may disregard the factual side of our phenomena, and use them as "examples" merely. We shall ignore individual souls and societies, to learn their a priori, their "possible" forms. Our thesis will be "theoretical," observing the invariable through variation, disclosing a typical realm of a priori. There will be no psychical existence whose "style" we shall not know. Psychological phenomenology must rest upon eidetic phenomenology.

The phenomenology of the perception of bodies, for example, will not be an account of actually occurring perceptions, or those which may be expected to occur, but of that invariable "structure," apart from which no perception of a body, single or prolonged, can be conceived. The phenomenological reduction reveals the phenomena of actual internal experience; the eidetic reduction, the essential forms constraining psychical existence.

Men now demand that empirical psychology shall conform to

the exactness required by modern natural science. Natural science, which was once a vague, inductive empiric, owes its modern character to the a priori system of forms, nature as it is "conceivable," which its separate disciplines, pure geometry, laws of motion, time, etc., have contributed. The methods of natural science and psychology are quite distinct, but the latter, like the former, can only reach "exactness" by a rationalization of the "essential."

The psycho-physical has an a priori which must be learned by any complete psychology, this a priori is not phenomenological, for it depends no less upon the essence of physical, or more particularly organic nature.

II. TRANSCENDENTAL PHENOMENOLOGY

Transcendental philosophy may be said to have originated in Descartes, and phenomenological psychology in Locke, Berkeley and Hume, although the latter did not grow up primarily as a method or discipline to serve psychology, but to contribute to the solution of the transcendental problematic which Descartes had posed. The theme propounded in the Meditations was still dominant in a philosophy which it had initiated. All reality, so it ran, and the whole of the world which we perceive as existent, may be said to exist only as the content of our own representations, judged in our judgments, or, at best, proved by our own knowing. There lay impulse enough to rouse all the legitimate and illegitimate problems of transcendence, which we know. Descartes' "Doubting" first disclosed "transcendental subjectivity," and his "Ego Cogito" was its first conceptual handling. But the Cartesian transcendental "Mens" became the "Human Mind," which Locke undertook to explore; and Locke's exploration turned into a psychology of the internal experience. And since Locke thought his psychology could embrace the transcendental problems, in whose interest he had begun his work, he became the founder of a false psychological philosophy which has persisted because men have not analysed their concept of "subjective" into its twofold significance. Once the transcendental problem is fairly stated, the ambiguity of the sense of the "subjective" becomes apparent, and establishes the phenomenological psychology to deal with its one meaning, and the transcendental phenomenology with its other.

Phenomenological psychology has been given the priority in this article, partly because it forms a convenient stepping-stone to the philosophy and partly because it is nearer to the common attitude than is the transcendental. Psychology, both in its eidetic and empirical disciplines, is a "positive" science, promoted in the "natural attitude" with the world before it for the ground of all its themes, while transcendental experience is difficult to realize because it is "supreme" and entirely "unworldly." Phenomenological psychology, although comparatively new, and completely new as far as it uses intentional analysis, can be approached from the gates of any of the positive sciences: and, being once reached, demands only a re-employment, in a more stringent mode, of its formal mechanism of reduction and analysis, to disclose the transcendental phenomena.

But it is not to be doubted that transcendental phenomenology could be developed independently of all psychology. The discovery of the double relativity of consciousness suggests the practice of both reductions. The psychological reduction does not reach beyond the psychical in animal realities, for psychology subserves real existence, and even its eidetic is confined to the possibilities of real worlds. But the transcendental problem will include the entire world and all its sciences, to "doubt" the whole. The world "originates" in us, as Descartes led men to recognize, and within us acquires its habitual influence. The general significance of the world, and the definite sense of its particulars, is something of which we are conscious within our perceiving, representing, thinking, valuing life, and therefore something "constituted" in some subjective genesis.

The world and its property, "in and for itself," exists as it exists, whether I, or we, happen, or not, to be conscious of it. But let once this general world, make its "appearance" in consciousness as "the" world, it is thenceforth related to the sub-

jective, and all its existence and the manner of it, assumes a new dimension, becoming "incompletely intelligible," "questionable." Here, then, is the transcendental problem; this "making its appearance," this "being for us" of the world, which can only gain its significance "subjectively," what is it? We may call the world "internal" because it is related to consciousness, but how can this quite "general" world, whose "immanent" being is as shadowy as the consciousness wherein it "exists," contrive to appear before us in a variety of "particular" aspects, which experience assures us are the aspects of an independent, self-existent world? The problem also touches every "ideal" world, the world of pure number, for example, and the world of "truths in themselves." And no existence, or manner of existence, is less wholly intelligible than ourselves. Each by himself, and in society, we, in whose consciousness the world is valid, being men, belong ourselves to the world. Must we, then, refer ourselves to ourselves to gain a worldly sense, a worldly being? Are we both psychologically to be called men, subjects of a psychical life, and yet be transcendental to ourselves and the whole world, being subjects of a transcendental world-constituting life? Psychical subjectivity, the "I" and "we" of everyday intent, may be experienced as it is in itself under the phenomenological-psychological reduction, and being eidetically treated, may establish a phenomenological psychology. But the transcendental subjectivity, which for want of language we can only call again, "I myself," "we ourselves," cannot be found under the attitude of psychological or natural science, being no part at all of the objective world, but that subjective conscious life itself, wherein the world and all its content is made for "us," for "me." We that are, indeed, men, spiritual and bodily, existing in the world, are, therefore, "appearances" unto ourselves, parcel of what "we" have constituted, pieces of the significance "we" have made. The "I" and "we," which we apprehend, presuppose a hidden "I" and "we" to whom they are "present."

To this transcendental subjectivity, transcendental experience gives us direct approach. As the psychical experience was purified, so is the transcendental, by a reduction. The transcendental reduction may be regarded as a certain further purification of the psychological interest. The universal is carried to a further stage. Henceforth the "bracketing" includes not the world only but its "souls" as well. The psychologist reduces the ordinarily valid world to a subjectivity of "souls," which are a part of the world which they inhabit. The transcendental phenomenologist reduces the already psychologically purified to the transcendental, that most general, subjectivity, which makes the world and its "souls," and confirms them.

I no longer survey my perception experiences, imagination-experiences, the psychological data which my psychological experience reveals: I learn to survey transcendental experience. I am no longer interested in my own existence. I am interested in the pure intentional life, wherein my psychically real experiences have occurred. This step raises the transcendental problem (the transcendental being defined as the quality of that which is consciousness) to its true level. We have to recognize that relativity to consciousness is not only an actual quality of our world, but, from eidetic necessity, the quality of every conceivable world. We may, in a free fancy, vary our actual world, and transmute it to any other which we can imagine, but we are obliged with the world to vary ourselves also, and ourselves we cannot vary except within the limits prescribed to us by the nature of subjectivity. Change worlds as we may, each must ever be a world such as we could experience, prove upon the evidence of our theories and inhabit with our practice. The transcendental problem is eidetic. My psychological experiences, perceptions, imaginations and the like remain in form and content what they were, but I see them as "structures" now, for I am face to face at last with the ultimate structure of consciousness.

It is obvious that, like every other intelligible problem, the transcendental problem derives the means of its solution from an existence-stratum, which it presupposes and sets beyond the reach of its enquiry. This realm is no other than the bare subjectivity of consciousness in general, while the realm of its investigation

remains not less than every sphere which can be called "objective," which considered in its totality, and at its root, is the conscious life. No one, then, can justly propose to solve the transcendental problem by psychology either empirical or eidetic-phenomenological, without *petitio principii*, for psychology's "subjectivity" and "consciousness" are not that subjectivity and consciousness, which our philosophy will investigate. The transcendental reduction has supplanted the psychological reduction. In the place of the psychological "I" and "we," the transcendental "I" and "we" are comprehended in the concreteness of transcendental consciousness. But though the transcendental "I" is not my psychological "I," it must not be considered as if it were a second "I," for it is no more separated from my psychological "I" in the conventional sense of separation, than it is joined to it in the conventional sense of being joined.

Transcendental self-experience may, at any moment, merely by a change of attitude, be turned back into psychological self-experience. Passing, thus, from the one to the other attitude, we notice a certain "identity" about the ego. What I saw under the psychological reflection as "my" objectification, I see under the transcendental reflection as self-objectifying, or, as we may also say, as objectified by the transcendental "I." We have only to recognize that what makes the psychological and transcendental spheres of experience parallel is an "identity" in their significance, and that what differentiates them is merely a change of attitude, to realize that the psychological and transcendental phenomenologies will also be parallel. Under the more stringent *εποχή* the psychological subjectivity is transformed into the transcendental subjectivity, and the psychological inter-subjectivity into the transcendental inter-subjectivity. It is this last which is the concrete, ultimate ground, whence all that transcends consciousness, including all that is real in the world, derives the sense of its existence. For all objective existence is essentially "relative," and owes its nature to a unity of intention, which being established according to transcendental laws, produces consciousness with its habit of belief and its conviction.

Phenomenology, the Universal Science.—Thus, as phenomenology is developed, the Leibnizian foreshadowing of a universal ontology, the unification of all conceivable a priori sciences, is improved, and realized upon the new and non-dogmatic basis of phenomenological method. For phenomenology as the science of all concrete phenomena proper to subjectivity and inter-subjectivity, is *eo ipso* an a priori science of all possible existence and existences. Phenomenology is universal in its scope, because there is no a priori which does not depend upon its intentional constitution, and derive from this its power of engendering habits in the consciousness that knows it, so that the establishment of any a priori must reveal the subjective process by which it is established.

Once the a priori disciplines, such as the mathematical sciences, are incorporated within phenomenology, they cannot thereafter be beset by "paradoxes" or disputes concerning principles: and those sciences which have become a priori independently of phenomenology, can only hope to set their methods and premises beyond criticism, by founding themselves upon it. For their very claim to be positive, dogmatic sciences bears witness to their dependency, as branches, merely, of that universal, eidetic ontology, which is phenomenology.

The endless task, this exposition of the universum of the a priori, by referring all objectives to their transcendental "origin," may be considered as one function in the construction of a universal science of fact, where every department, including the positive, will be settled on its a priori. So that our last division of the complete phenomenology is thus: eidetic phenomenology, or the universal ontology, for a first philosophy; and second philosophy as the science of the transcendental inter-subjectivity or universum of fact.

Thus the antique conception of philosophy as the universal science, philosophy in the Platonic, philosophy in the Cartesian, sense, that shall embrace all knowledge, is once more justly restored. All rational problems, and all those problems, which for one reason or another, have come to be known as "philosophical,"

have their place within phenomenology, finding from the ultimate source of transcendental experience or eidetic intuition, their proper form and the means of their solution. Phenomenology itself learns its proper function of transcendental human "living" from an entire relationship to "self." It can intuit life's absolute norms and learn life's original teleological structure. Phenomenology is not less than man's whole occupation with himself in the service of the universal reason. Revealing life's norms, he does, in fact, set free a stream of new consciousness intent upon the infinite idea of entire humanity, humanity in fact and truth.

Metaphysical, teleological, ethical problems, and problems of the history of philosophy, the problem of judgment, all significant problems in general, and the transcendental bonds uniting them, lie within phenomenology's capability.

Phenomenological philosophy is but developing the main-springs of old Greek philosophy, and the supreme motive of Descartes. These have not died. They split into rationalism and empiricism. They stretch over Kant and German idealism, and reach the present, confused day. They must be reassumed, subjected to methodical and concrete treatment. They can inspire a science without bounds.

Phenomenology demands of phenomenologists that they shall forgo particular closed systems of philosophy, and share decisive work with others toward persistent philosophy.

PHENOMENON, in ordinary language a thing, process, event, etc., observed by the senses (Gr. *φαινόμενον*, a thing seen, from *φαίνεσθαι*, to appear). Thus the rising of the sun, a thunderstorm, an earthquake, are natural "phenomena." From this springs the incorrect colloquial sense, something out of the common, an event which especially strikes the attention; hence such phrases as "phenomenal" activity. In Greek philosophy phenomena are the changing objects of the senses as opposed to essences (*τὰ ὄντα*) which are one and permanent, and are therefore regarded as being more real, the objects of reason rather than of senses which are "bad witnesses." In modern philosophy the phenomenon is the "thing-in-itself," or the noumenon (*q.v.*) or object of pure thought, but the thing-in-itself as it appears to the mind in sensation (*see* especially KANT; and METAPHYSICS). In this sense the subjective character is of prime importance. Among derivative terms are "Phenomenalism" and "Phenomenology." Phenomenalism is either (1) the doctrine that there can be no knowledge except by phenomena, *i.e.* sense-given data, or (2) the doctrine that all known things are phenomena, *i.e.* that there are no "things-in-themselves." "Phenomenology" is the science of phenomena: every special science has a special section in which its particular phenomena are described. The term was first used in English in the 3rd edition of the *Ency. Brit.* in the article "Philosophy" by J. Robison. Kant has a special use of the term for that part of the *Metaphysic of Nature* which considers motion and rest as predicates of a judgment about things.

PHÉRECRATES, Greek poet of the Old Attic Comedy, was a contemporary of Cratinus, Crates and Aristophanes. At first an actor, he seems to have gained a prize for a play in 438 B.C.

The only other ascertained date in his life is 420, when he produced his play *The Wild Men*. Like Crates, whom he imitated, he abandoned personal satire for more general themes, although in some of the fragments of his plays we find him attacking Alcibiades and others. He invented a metre, called after him Pherecratean, which occurs in the choruses of Greek tragedies and in Horace.

A considerable number of fragments from his 16 (or 13) plays has been preserved, collected in T. Kock, *Comicorum Atticorum Fragmenta*, i. (1880), and A. Meineke, *Poetarum Comicorum Graecorum Fragmenta* (1855).

PHERECYDES OF LEROS, Greek mythographer, fl. c. 454 B.C. He is probably identical with Pherecydes of Athens, although the two are distinguished by Suidas (also by I. Lipsius, *Quaestiones logographicae*, 1886). Numerous fragments of his genealogies of the gods and heroes, variously called *Ἱστορίαι*, *Γενεαλογίαι*, *Ἀυτοχθόνες* have been preserved (see C. W. Müller's *Frag. hist. gmec.* vol. i., pp. xxxiv., 70; Jacob, *Frag. d. gr. Historiker I.*, p. 58).

See Christ-Schmid, *Geschichte der griechischen Litteratur* (bibl.).

PHERECYDES OF SYROS, Greek philosopher (or rather philosophical theologian), flourished during the 6th century B.C. He was sometimes reckoned one of the Seven Wise Men, and is said to have been the teacher of Pythagoras. With the possible exception of Cadmus (q.v.) of Miletus, he was the first Greek prose-writer. He belonged to the circle of Peisistratus at Athens, and was the founder of an Orphic community. He was credited with having originated the doctrine of metempsychosis (q.v.), while Cicero and Augustine assert that he was the first to teach the immortality of the soul. Of his astronomical studies he left a proof in the "heliotropion," a cave at Syros which served to determine the annual turning-point of the sun.

In his cosmogonic treatise on nature and the gods, called *Πεντέμυχος* (Preller's correction of Suidas, who has *ἑπτάμυχος* from the five elementary principles: aether, fire, air, water, earth), he enunciated a system in which science, allegory and mythology were blended. A fragment of the "sacred marriage" of Zas and Chthonië has been found on an Egyptian papyrus.

See H. Diels, *Fragmente der Vorsokratiker*, Bd. II. (4th ed., 1922); also O. Kern, *De Orphei, Epimenidis Pherecydis theogoniis* (1888); D. Weil, *Études sur l'antiquité grecque* (1900).

PWIGALIA or PHIGALEIA (Φιγάλια or Φιγαλεία; mod. *Pav-litsa*), an ancient Greek city on the river Neda in the south-west angle of Arcadia, among some of the highest mountains in the Peloponnesus—Mt. Cotylium and Mt. Elasmus.

In 659 B.C. Phigalia was taken by the Spartans, but soon after recovered its independence by the help of the Orasthians. During the struggle between Achaeans and Aetolians in 221 B.C. it was held by Dorimachus, who left it on the approach of Philip V. of Macedon. In common with other cities of Arcadia, it appears to have fallen into utter decay under Roman rule. Several curious cults were preserved near Phigalia, including that of the fish-tailed goddess Eurynome and the Black Demeter with a horse's head, whose image was renewed by Onatas. No autonomous coins of Phigalia are known. Nothing remains above ground of the temples of Artemis or Dionysus and the works of art which existed in the time of Pausanias. A great part of the city wall remains, 2 m. in circuit built in fine Hellenic masonry, with a large square central fortress with a circular projecting tower.

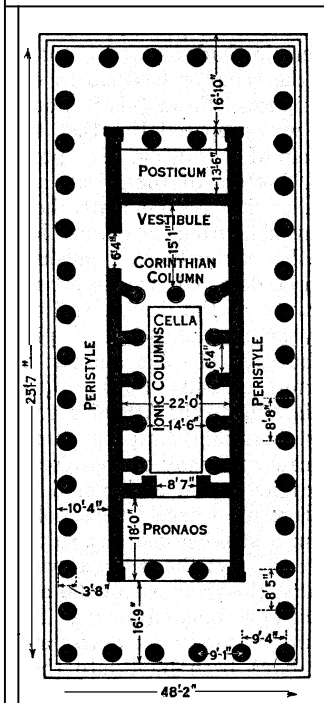

Not at Phigalia itself, but at Bassae, 5 or 6 m. away, on the slope of Mt. Cotylium is a well-preserved temple of Apollo Epicurius. It commemorates relief from a plague in the 5th century. Pausanias (viii. 41) notes it as (next to that of Tegea) the finest in the Peloponnesus, "from the beauty of its stone and the symmetry of its proportions." It was designed by Ictinus, joint architect with Callicrates, of the Parthenon at Athens. Visited earlier by Chandler, Dodwell, Gell and other English travellers, the temple was explored and measured in 1811-1812 by C. R. Cockerell, the internal sculptured frieze of the cella being found almost perfect. This and other fragments of sculpture are now in the British Museum. The colonnade of the temple has

been recently restored by the Greeks.

The temple is of the Doric order, but has an internal arrangement of its cella which is unique. Probably to suit the ground, it lies north and south but the vestibule has a door to the east. It is hexastyle, with fifteen columns on its flanks; thirty-four out of the thirty-eight columns of the peristyle are still standing, with the greater part of their architrave. The internal columns

of the cella are very strangely placed, apparently without symmetry, as regards the interior, though they are set regularly opposite the voids in the peristyle.

With the exception of one at the south end, which is Corinthian, the internal columns are of the Ionic order, and are engaged with the cella-wall, forming a series of recesses, which may have been designed to contain statues. Another peculiarity of this interior is that these columns reach to the top of the cella in one order, not in two as was Doric fashion. These inner columns carried an Ionic entablature, of which the frieze now in the British Museum formed a part. The pediments and external metopes of the peristyle appear to have contained no sculpture, but the metopes within the peristyle on the exterior of the cella had sculptured subjects. The position occupied by the great statue of Apollo is disputed.

PLAN OF THE TEMPLE AT BASSAE

Cockerell, with much probability, placed it facing the eastern side door, so that it would be lighted by the rising sun. The main entrance is at the northern end through the pronaos, once defended by a door in the end of the cella and a metal screen, of which traces were found on the two columns of the pronaos. There was no door between the posticum and the cella. The general proportions of the fronts resemble those of the Theseum at Athens, except that the entablature is less massive, the columns thicker, and the diminution less. In plan the temple is long in proportion to its width—measuring, on the top of the stylobate, 12 5 ft. 7 in. by 48 ft. 2 in., while the Theseum (built probably half a century earlier) is about 104 ft. 2 in. by 45 ft. 2 in.

The material is a fine grey limestone (once covered with painted stucco), but the roof-tiles, the capitals of the cella columns, the architraves, the ceilings and the sculpture, are of white marble. The roof-tiles, specially noticed by Pausanias, are remarkable for their size, workmanship, and the beauty of the Parian marble. They measure 2 ft. 1 in. by 3 ft. 6 in., and are fitted together in the most careful and ingenious manner. Unlike those of the Parthenon and the temple of Aegina, the *ἀρμολί* or "joint-tiles" are worked out of the same piece of marble as the flat ones, for the sake of more perfect fitting and in order to provide greater security against wet.

Traces of painting on various architectural members were found by Cockerell, but they were too much faded for the colours to be distinguished. The designs are the usual Greek patterns—the fret, the honeysuckle, and the egg and dart.

The sculpture is of the greatest interest, as being designed to decorate one of the finest buildings in the Peloponnesus in the latter half of the 5th century B.C.

The frieze, now in the British Museum, is complete; it is nearly 101 ft. long by a ft. high, carved in relief on twenty-three slabs of marble 43 to 1/2 in. thick. The subjects are the battle of the Lapithae and the Centaurs, and that between the Amazons and the Greeks, the two favourite subjects in Greek art of the best period. They are designed with wonderful fertility of invention, and life-like realism and spirit; the composition is arranged so

as to form a series of diagonal lines or zigzags *M*, thus forming a pleasing contrast to the unbroken horizontal lines of the cornice and architrave. The various groups are skillfully united by some dominant line or action, so that the whole subject forms one unbroken composition.

The relief is very high, more than $3\frac{1}{2}$ in. in the most salient parts, and the whole treatment is quite opposite to that of the Parthenon frieze, which is a very superior work of art to that at Bassae. Many of the limbs are quite detached from the ground; the drill has been largely used to emphasize certain shadows, and in many places, for want of due calculation, the sculptor has had to cut into the flat background behind the figures. From this it would appear that no finished clay-model was prepared but that the relief was sculptured with only the help of a drawing. The point of sight, more than 20 ft. below the bottom of the frieze, and the direction in which the light fell on it have evidently been carefully considered. Many parts, invisible from below, are left comparatively rough. The workmanship throughout is unequal, and the hands of several sculptors can be detected. On the whole, the execution is not equal to the beauty of the design, and the whole frieze is somewhat marred by an evident desire to produce the maximum of effect with the least possible amount of labour—very different from the almost gem-like finish of the Parthenon frieze. Even the design is inferior to the Athenian one; most of the figures are ungracefully short in their proportions, and there is a great want of refined beauty in many of the female hands and faces. It is in the fire of its varied action and its subtlety of expression that this sculpture most excels. The noble movements of the heroic Greeks form a striking contrast to the feminine weakness of the wounded Amazons, or the struggles with teeth and hoofs of the brutish Centaurs; the group of Apollo and Artemis in their chariot is full of grace and dignified power. The marble in which this frieze is sculptured is somewhat coarse and crystalline; the slabs appear not to have been built into their place but fixed afterwards, with the aid of two bronze bolts driven through the face of each.

Of the metopes, which were 2 ft. 8 in. square, only one exists nearly complete, with eleven fragments; the one almost perfect has a relief of a nude warrior, with floating drapery, overcoming a long-haired bearded man, who sinks vanquished at his feet. The relief of these is rather less than that of the frieze figures, and the work is nobler in character and superior in execution.

PHILADELPHIA, the Greek name of the ancient Rabbath-Ammon, in Eastern Palestine, commemorating Ptolemy Philadelphus (285–246 B.C.), mod. 'Ammān. Alexander Jannaeus (102–76 B.C.) although lord of the rest of the land east of the Jordan never conquered Philadelphia. With the coming of Pompey (63 B.C.) Philadelphia was made a member of the Decapolis. When Trajan set up the *Provincia Arabia* (A.D. 106) he assigned the town to the new province and Philadelphia advanced with Bostra to greater might and prosperity. Its extensive ruins include a Byzantine basilica, baths, theatre, citadel, temple, etc. (E. Ro.)

PHILADELPHIA, the first city of the State of Pennsylvania, and third in population and manufactures in the United States. It was planned by William Penn and other members of the Society of Friends partly, if not chiefly, as a haven of refuge for persecuted peoples, who like themselves, wished to be guided by the "inner light" of conscience. They called their town Philadelphia (from the Greek *Φιλαδέλφεια*, brotherly love), borrowing a place-name of sectarian significance in Lydia, Asia Minor, seat of one of the seven early churches.

Philadelphia was the Proprietary capital of the Province until 1776; capital of the State until 1799; capital of the United Colonies until 1781; capital of the United States under the Articles of Confederation from 1781 to 1789 and under the Constitution from 1790 to 1800.

Independence Hall. Philadelphia's most celebrated structure,

which is a few squares east by south of the city-hall, is in lat. $39^{\circ} 56' 57.54''$ N.; long. $75^{\circ} 8' 57.5''$ W. Chestnut street pier is 101.6 m. from the Atlantic. An official tabulation of point-to-point airline distances between the Philadelphia Municipal air port and five well-known places follows: New York, 79 m.; Baltimore, 81 m.; Washington, D.C., 119 m.; Pittsburgh, 260 m.; Boston, 283 miles.

Geography.—Between the Delaware river and the nearest mountains, the Kittatinny range, is the 60 m. wide Philadelphia

BY COURTESY OF UNDERWOOD AND UNDERWOOD
INDEPENDENCE HALL. PHILADELPHIA

Piedmont plateau, invitingly fertile, and, in early days, heavily timbered with oak, hickory, chestnut, tulip-poplar, beech, dogwood and laurel. As the city has had much to do with the development of its "back country" so, conversely, the Philadelphia Piedmont plateau, with its many cities, towns and rich townships has contributed greatly to the growth of Philadelphia. And as the Delaware comes down from the north-east, or Minisink country, so the lesser Schuylkill, with its numerous tributaries, comes down from the north-west, out of the anthracite coal-fields, bisecting the Piedmont diagonally, breaking over the last score

or more of falls at tidewater and joining the greater stream at the obviously strategic point of the whole region—the Coaquannock of the Indians; the Ft. Beversrede of the fur-trading Dutch; the Tacony-Tinicum of the Swedes and the Philadelphia of to-day.

Topography.—All of old Philadelphia, with the main part of the new, lies on the peninsula of dry land between the Delaware and Schuylkill—a Dutch word meaning hidden river, or, more literally, skulking creek; the Indian name was Manayunk. But the city spreads south-westward beyond the Schuylkill, over the dike-protected Tinicum lowland (in places 5 ft. below high tide) to Darby and Muckinpalus creeks and extends westward across rising ground from 100 to 200 ft. high, as far as Karakung creek, now Cobb's. Thus the city is both longer (244 m. from the extreme south-west on Bow creek to the extreme north-east point of Poquessing creek and Frankford avenue) and broader (15 m. from Northwestern avenue, and the Schuylkill, Roxborough, to Poquessing creek and Delaware river, Torresdale), than the peninsula, which has three levels—the lowland (Passyunk) section of mud, blue clay and gravels; the elevated section from Spring Garden street to the northern boundary; and the elevated west Philadelphia section to the western boundary.

Sewerage.—Sewerage profits by the natural drainage of small valleys and their watersheds, which involve the utilization of many creeks. It comprises (1941) over 2,000 mi. of sewers, of which approximately one-fourth are main sewers. Diameter measurements of them vary from 1 to 24 ft. So great is the volume of water in some of these creek-sewers (for instance, the Cohocksink and Mill creek) that costly blow-outs have occurred. An oval-shaped sewer in the bed of Mill creek, big side down, permits a freer flow. Subway building has caused much sewer reconstruction and metropolitan development in the old city has necessitated great changes. Since 1910, two extensive sewerage disposal plants have been built. In the lowlands, sewers are clogged by mud brought in by flood tides. The part of the Schuylkill delta below its lowermost reach is cut into by tidal estuaries, forming numerous islands. In this section (40th ward), the sewage problem presents difficulties. But in 1925 work was begun on the Mingo pumping system, by which the sewerage, drained into a central basin, is pumped at the rate of 1,000,000 gal. daily into the 40th ward disposal plant. Prior to the establishment of the Mingo system there were great numbers of unsewered houses in the 40th ward. Throughout the city these now are less than 10,000, as against 60,939 on Jan. 1, 1911.

Water-supply.—Philadelphia built the first municipal water-works in America. Councils authorized a "Wholesome Water" loan (\$203,001.70); and ground for reservoir's was broken on the site of the old British fort at Fairmount, March 12, 1799. The first water was sent through the pipes—then of wood, a little later of cast-iron—on Jan. 27, 1801. Up to 1902, the city's expenditure for water from the Delaware and Schuylkill had been \$56,498,000. Then it became necessary, on account of river pollution to provide for the present comprehensive sand filtration system. There are five filter plants: Torresdale, 52 ac., capacity 220,000,000 gal.; Queen Lane, 16 ac., 100,000,000; Belmont, 14 ac., 55,000,000 (under reconstruction, 75,000,000); Upper Roxborough, 5.6 ac., 20,000,000; Lower Roxborough, 2.7 ac., 8,000,000. East Park distribution reservoir has three basins holding 688,618,000 gal.; Oak Lane reservoir, 2 basins, 70,000,000; Belmont, 40,000,000; five clear-water basins, 127,000,000; four raw-water reservoirs, 609,350,000. The pumping stations have a total capacity of 2,310,000,000 gal. in 24 hours. Consumption in 1940 averaged 319,000,000 gallons daily.

City Plan.—Philadelphia was built on a plan. Penn wanted an open-spaced, well-shaded town, with every dwelling in the centre of its plot. There was eventually a complete departure from this idea. Brick buildings, standing wall to wall and so much alike that a man hardly knew his own house, filled large sections of the 19th century city. Another of Penn's ideas was to have "a promenade on the high bank of the river-front the whole length of the city—a top-common from end to end," after the manner of the celebrated Bomb Quay at Rotterdam. But this detail of the original plan was likewise unexecuted. Penn wanted a 10,000 ac. city; Thomas Holme, his surveyor-general, succeeding Penn's cousin, Capt. William Crispen, used less than a third of that space in the original urban section, making up their due allotment to the first purchasers, or adventurers, by assigning them much larger additional lots in the adjoining Northern Liberties. Penn expected the Delaware and Schuylkill halves of his city to meet at Centre square; but necessity, or convenience, caused the development to be along the Delaware, up and down, rather than in the wooded westward parts of the area plotted by Holme. This area—the nucleus and heart of the present city—was a parallelogram in shape, a mile north and south, and two miles east and west from river to river, with a Delaware front street and a Schuylkill front street. The Broad street of to-day, which extends for 11.7 m. from League island to township line and York road, is 113 ft. wide. At Centre square, Market street, 100 ft. wide, crosses Broad, halving the city, north and south.

The most conspicuous object in Philadelphia is the architecturally much criticized City hall, French Renaissance style, designed by John M. Arthur, Jr., with its tower, 547 ft. 11 in. high, topped by Alexander Calder's colossal bronze statue of William Penn. With its courtyard, it occupies an area of 4½ ac. The public buildings commission—authorized Aug. 5, 1870, abolished July 1, 1901—erected it at a cost of \$25,000,000 (not without public scandal). The foundation stone was laid on Aug. 18, 1872. Here are housed the State and county courts and municipal and county offices. Across the plaza to the north-east is the new City Hall annex, an office building harmonizing with the adjacent Wanamaker and Widener buildings. Old ferry and township roads in Southwark, Passyunk and Moyamensing have been modernized into diagonal avenues, running south-west and north-east. In 1937 the urban area was 128 square miles.

Streets and Bridges.—Philadelphia has 2,000 streets. Houses are numbered decimally, 100 numbers being allotted to each square. Asphalt paving is used chiefly, with vitrified, granite or concrete; total urban mileage 2,098, of which 1,994 are improved.

Floating bridges were erected in the 18th century over the Schuylkill; in the 19th century permanent bridges. White and Hazard's foot bridge was the first wire bridge in the world. Girard avenue bridge was for a time the widest. Ellet's suspension bridge was the first American bridge of the kind. Chestnut street bridge is the largest cast-iron arch-bridge. Below Walnut street the bridges are "swings" and bascules. Spring Garden bridge, like that of Girard avenue, is of wrought-iron, Whipple-

truss type. Green Lane (under construction), is of re-enforced concrete. A fine concrete arch-bridge spans the Wissahickon at Walnut Lane. The Philadelphia-Camden bridge was (1926-29) the longest suspension bridge in the world; construction began Jan. 6, 1922; it was opened July 1, 1926; cost, \$37,196,971. Total length, 1.81 m.; main span, 1,750 ft. between towers; height of towers, 385 ft. mean high water; overall width, 125 ft. 6 in.

Parks.—There are 172 parks and playgrounds, covering 7,859 ac. Playgrounds and recreation centres are supervised by the bureau of recreation, and small parks and squares by the bureau of city property. The Fairmount park commission (13 members, appointed by the common pleas judges) has charge of Fairmount park, 3.845 ac. and 25 other parks, with an acreage of 3,947, of which the largest, Pennypack park, has 1,255 ac.; Cobb's Creek, 621; League Island, 364; Roosevelt Boulevard, 250; Hunting park, 86; Wister's Woods, 42; and Bartram's garden, 37. Fairmount park (with the parkway) is practically continuous from City Hall to the county line on the Wissahickon. It originated in June 1812, with the acquisition of a 5 ac. tract (summer-home of Robert Morris, financier of the Revolution) and was repeatedly enlarged by other purchases, until in addition to Letitia Cottage, it now contains 15 historic mansion houses, two surviving structures of the Centennial Exposition (Memorial hall and the Horticulture building) and hundreds of miles of driveways, avenues, footpaths and bridle paths, beautified at many points of vantage with over 50 bronze groups and figures.

Periods and Landmarks.—There have been four phases in the development of Philadelphia: (1) The well-built, though ill-paved, Colonial trading-town of English Quakers and Episcopalians, Welsh Quakers and Baptists, Germans of various sects, Scotch-Irish Presbyterians and inter-colonial migrants. (2) The rapidly growing city of Franklin and Girard, with its shipyards, ropewalks, fleets and fast-sailing ships, its rich merchants, its skill in handicraft and its undemocratized social order. (3) The 19th century brick-paved, red-brick city that was revolutionized by the application of steam-power to many industries—a period of mill, rail and mine development and of a heavy inpouring of Irish and German immigrants, with skilled workers from British industrial districts. (4) The city that has been transformed during the last quarter of a century by such modern agencies as electricity, steel and concrete, and the extensive use of capital.

The earliest city was centred about High street hill (Second and Market); with its long-vanished "Great Towne House," built in 1707 in the middle of the street. Annexed were the covered markets. Nearby was the Friends' meeting house. The slate-roof house and many two- and three-storey brick dwellings with dormer windows were close at hand. Some of these dwellings still stand. Much like the early proprietary town was the revolutionary city, which had grown five squares westward to the Statehouse.

This building, designed by the famous lawyer Andrew Hamilton and built between 1732 and 1741 became Independence Hall, where the Liberty bell once rang, and is now housed. The bell was made by Thomas Lister of Whitechapel, London, but was twice recast because of brittleness, and was hung in April, 1753. It was cracked, July 8, 1835, while tolling a knell for Chief Justice John Marshall, of the U.S. Supreme Court. This court first sat in an adjoining building (built in 1791) of the same group, later the mayor's office, at the south-west corner of Fifth and Chestnut streets. At the south-east corner of Sixth and Chestnut is the hall (built 1791) where the first U.S. congress sat. City councils, until transferred, used Independence Hall. These buildings (much dwarfed at the present day by massive structures east, south and west, including the Curtis block) have been set apart as public monuments. The Statehouse yard of 1729, or Independence square, belongs to the group; and adjoining is Washington square. Associated with Independence Hall is Carpenters' Hall, owned by the company of Master Carpenters, used as a meeting place by the First Continental Congress (1774-75). This well preserved sample of the brick-layer's art was built in 1770-71.

Other shrines are Franklin's grave (south-east corner Fifth and Arch), the Betsy Ross flag-house (239 Arch), the site of the house in which Jefferson wrote the Declaration of Independence (south-

west corner Seventh and Market), the site of the Philadelphia residence of Gen. Washington (528 Market) and the Chew Mansion, "Cliveden" (Johnson street and Germantown avenue), scene of the critical action at the Battle of Germantown, Oct. 4, 1777.

The 19th century city retained much of its 18th century aspect—uniform houses, with pressed brick fronts, white or green shutters and marble steps and trimmings. These were multiplied, row on row; but not until 1850 was there noteworthy growth west of Broad street. That development came after the Consolidation act. Girard avenue was then Franklin avenue. It was crossed by the northward-growing city, which reached and passed Columbia avenue prior to the International Exposition of 1876 (Centennial). This world's fair greatly aided Philadelphia's industries. The 19th century city continued its expansion along residential lines until the period of latter-day small house demolition and sky-scraper development.

Architecture.—Early dwelling houses and halls reflected English ideas. Something of Sir Christopher Wren's manner is traceable in such structures as Christ church (1727-47), Dr. John Kearsley, amateur architect, and St. Peter's (1761); and Inigo Jones's influence is seen (from prints found in Sir Wm. Chambers's *Treatise on Civil Architecture*) in the street fronts of brick. Many Georgian houses of the 18th century are preserved, Independence Hall being typical. Philadelphia architects in the 20th century have sought to recapture the spirit of colonial times; but the best Georgian restorations and reproductions are not as often seen in the city itself as in the suburban places closely associated with early American history. Grecian influence was shown just before the opening of the 19th century in the works of William Strickland, Thomas Ustic Walter and their followers. Much of Strickland's work has disappeared, save in prints, but the old U.S. Mint, at Chestnut and Juniper, was an example of it; and the Custom house (1824) is a surviving specimen. Pseudo-classic structures—the Bank of the United States, Third street (1795); the first Chestnut street theatre; the church of St. Luke and Epiphany; St. Andrew's P.E. church; St. Patrick's church; and, especially Girard college and Ridgway library—belong to this period.

Latter-day buildings of like impressiveness—the U.S. mint, the art museum, the free library—would seem to be improvements upon the models of the time of Strickland and Walter. Following these designers there was an architectural "dark age" in Philadelphia until the Centennial Exposition caused an awakening. The T-Square club (1883), the school of architecture at the university of Pennsylvania and the Philadelphia Chapter, American institute of Architects, have accomplished much in community, city and regional planning and in influencing architectural designs.

Art, Science and Letters.—Long after its loss of precedence in population, Philadelphia preserved its leadership in art, letters and science. Art development began in the period of Benjamin West, the Peales (Charles Willson, Raphael and Rembrandt), Stuart, Sully and Allston, and continued through the 19th century, with J. W. Jarvis, Henry Inman, C. R. Leslie, Paul Weber, H. J. Thouron, J. R. Lambdin, S. B. Waugh, Thomas Eakins, Thomas P. Anschutz, J. M. Hamilton, John Sartain and Charles Grafly. The Academy of Fine Arts, oldest art institution in the United States, dates officially from 1805, but it actually originated in 1791, growing out of Charles Willson Peale's activities in starting the Columbianum (1794), which next year held an exhibition in Independence Hall. Philadelphia now has 42 art associations, museums, schools and collections, public and private.

On the leveled top of Fairmount, at the point where the parkway joins the park, and looking up the Schuylkill, stands the new \$20,000,000 Pennsylvania Art museum, opened on March 26, 1928. In situation and design, this group suggests the Parthenon and the Acropolis—an impressive Greek imitation, of severity and dignity. This building, in which delicate curves instead of straight lines are used, is of Minnesota stone. The architectural details in the cornice, as well as the 4 ac. of roofs, are of glazed polychrome terra-cotta. Colour is much used. The seven strata in the dolomite quarry from which the stone was secured vary from a pinkish yellow to a yellowish-grey. The museum is the home

of important collections of paintings hitherto inadequately housed. It also offers educational facilities, providing a panoramic history of art for its students and visitors in a series of 37 "period" rooms, in which works of art are shown in their appropriate surroundings.

The American Philosophical society, an outgrowth of Franklin's "Junto" (1727) and the American Society for Promoting and Propagating Useful Knowledge (1766), was organized in 1769. It is housed in Independence square (Frankliniana, 14,000 vol.; library, 80,000). Other scientific societies are the Franklin institute (1824), essentially a society for the promotion of applied science; the Academy of Natural Sciences (1812); the Wagner institute (1851), primarily a society for spreading science among the people; the Spring Garden institute (1851), for teaching useful arts to wage-earning youths; the Commercial museum, containing exhibits illustrating world-wide industrial progress; and the Geographical society.

Early publishers, 17th and 18th centuries, issued Bibles—in German, as well as English,—newspapers, almanacs and magazines. The Ephrata, Saur and Aitken Bibles, Franklin's *Poor Richard's Almanac*, many Quaker books, the early Bradford publications, early magazines (especially Joseph Dennie's Portfolio 1801-37), Pennsylvania histories by Thomas, Budd, Smith and Proud, and Charles Brockden Brown's novels are notable publications. Tom Moore, the poet, and Edgar Allan Poe lived in the city, which was also for a time the home of Longfellow, Holmes, Whittier and Lowell. Godey's (185-77), Graham's (1840-59) and Sartain's magazines as well as Robert Walsh's *American Quarterly Review* (1827-37) were successful publications; and Mathew Cary, George Lippard, Robert Montgomery Bird, with the Hopkinsons—Francis and Joseph—and the Neals—Alice and Joseph C.—won notable names. Later, Walt Whitman, Bayard Taylor, George H. Boker, T. Buchanan Reed and Charles G. Leland were of literary consequence. They were succeeded by S. Weir Mitchell, Frank Stockton, R. H. Davis, Horace Howard Furness, F. E. Schelling, Owen Wister and Agnes Repplier. To-day there are about 200 publishers, including Lippincotts of the third generation.

The newspapers are *The Evening Ledger* (1914); *The Record* (Ind. Dem., 1870); *The Inquirer* (Rep. 1829); and *The Evening Bulletin* (1847). *The Public Ledger*, prominent for many years after 1836, merged with the *Inquirer* in 1934. Outstanding editors: Poulson, Chandler, Forney, McClure and G. W. Childs (*q.v.*).

Theatres and Music.—Philadelphia has well over 200 theatres and moving picture houses. One of the London Hallams, Lewis, was the founder of the Philadelphia stage, in 1754. The original Chestnut street theatre (1793) was burned. The oldest theatre in the United States, Walnut (capacity 1,512), dates from 1809, and was the scene of the triumphs of Wheatley, Cooke, the Wallacks, Kean, Forrest, the Booths, Clarke, Charlotte Cushman and Rachel. The Arch street theatre (1828) was associated with the Drews and Joseph Jefferson, as well as with W. E. Burton and the Davenportes. For a generation, the most noted performers appeared at J. F. Zimmerman's Chestnut street opera house (capacity 1,864), which marked the passing of the old stock company system (1880) and the coming of travelling attractions.

The 17th century German immigrants brought over their music; the Moravians had their organs (called "whistle boxes"). Christ church (Protestant Episcopal), and St. Joseph's (Roman Catholic) helped in the 18th century musical development. The Musical Fund society was organized in 1820; and Musical Fund hall was opened in 1824. All the famous European singers who visited America sang there, and at Concert hall, until the opening of the Academy of Music (capacity, 2,729) in 1857. The Metropolitan opera house seats 3,482.

Philadelphia has an active musical life, with over 60 societies—the St. Cecilia, 1824; Anacreontic, 1830; Apollo, 1833; Maennerchor, 1835; Cecilian, 1875; Orpheus, 1877; Mendelssohn, 1876; Philadelphia Music Festival association, 1882; Treble Clef and Eurydice, 1886. The Philadelphia orchestra was organized in 1900, the Presser Foundation dates from 1916. The Curtis Institute of Music gives free instruction.

Clubs.—Of the 2,000 clubs in Philadelphia the oldest is the

2. The Philadelphia Museum of Art, with the buildings of the Philadelphia aauarium in the middle distance

Schuylkill Fishing company of the state in Schuylkill, which was organized in 1732. The University, Art and Engineers' are notable clubs. There are many of the literary, journalistic and Bohemian cast—Poor Richard, Franklin Inn, Sketch, Plastic, and Pen and Pencil. The New Century, Civic club and Colonial Dames are women's clubs. The Philadelphia (1834) is the most exclusive club; the Union League (1862), the most famous.

Churches, Charities and Hospitals.—Philadelphia has 1,041 churches, of which 108 are Baptist; 119 (synagogues and congregations) Hebrew; 91 Lutheran; 145 Methodist; 121 Presbyterian; 126 Protestant Episcopal; 146 Roman Catholic; 7 Hicksite Meetings and 5 Orthodox meetings. Society of Friends, Dunkards, Mennonites, Moravians, Schwenkfelders and other sects of Penn's time, still thrive. Philadelphia is the cathedral city of the archdiocese of Philadelphia, which has 387 parishes and 1,259 priests of all orders. Five denominations have Divinity schools.

There are 2,500 religious and humanitarian societies in Philadelphia. There is a record of the charitable work of secular societies from the year 1749, and of church societies from the year 1761. The Federation of Charities began in June 1921. The Welfare federation embraces 112 nonsectarian philanthropic agencies in the city and suburbs—homes and hospitals for children, dispensaries, emergency aids, day nurseries, settlements, sanitariums, shelters, etc. In 1941 the sum of \$3,793,000 was subscribed for the federation. The Jewish federation raises a similarly large sum. The Catholic charitable institutions are less closely federated.

Philadelphia has been a medical-surgical centre from early days. Its first hospital, the Pennsylvania, which occupies a square in the old city, was chartered on May 11, 1751. The first school of anatomy was established in 1762; and the first medical college (see PENNSYLVANIA, UNIVERSITY OF, which now has several affiliated hospitals) in 1765. The first medical society was organized in 1768 and the first College of Physicians in 1787. Its Mütter pathological collection is especially notable. Its library contains 174,822 volumes. Other early institutions are Will's Eye hospital (1832); Pennsylvania hospital of the insane (Kirkbride's, 1836); Homeopathic Medical college (Hahnemann's, 1848); and the Woman's Medical college (1850). Blockley, long in disrepute, has been erased from the map, and a modern city hospital erected in its place, at a cost of \$4,000,000. Among the larger hospitals are Lankenau, Methodist, Misericordia, Jefferson and Presbyterian. There are over one hundred hospitals in the city.

Education.—Enoch Flower was the first schoolmaster (1683) in Philadelphia. In 1689, George Keith started the Friends' Public grammar school, called "Friends' Free," being like the English (but unlike the latter-day American) public school; it was chartered in 1701, and became the existing William Penn Charter school. Church and community schools followed. Christopher Dock, who came from Germany in 1714 and who published the first American book on teaching, was the most noted early 18th century teacher. Though the Pennsylvania constitutions of 1776 and 1790 declared for "free schools," they were charity (called "Ragged") schools; and not until 1818 did the present public school system emerge.

Meantime, numerous academies were established such as Germantown (1760) and Episcopal academy (1785). Other institutions developed: College of Pharmacy (1821); Jefferson Medical college (1825); Woman's Medical college (1850); Protestant Episcopal Divinity school (1862); Lutheran Theological seminary (1864); La Salle college (Roman Catholic, 1867); St. Vincent's Roman Catholic Theological seminary (1868); Medico-Chirurgical college (1881), now affiliated with the University of Pennsylvania and Hahnemann Medical college (1848); the Williamson free school of mechanical trades (1888); Drexel institute (1891); and Temple university with a large student-body and many schools, at Broad and Berks. Gratz college (1893) and Dropsie college (1907) were founded in furtherance of Hebrew learning. The University of Pennsylvania (*q.v.*) is the largest educational institution in the city. (See Art, Science *and* Letters for other institutions. For Girard college, see GIRARD, STEPHEN.)

Public Schools.—In 1818 the old board of control gave way to the board of education, and the Lancasterian plan to the common schools. The first Central high dates from 1838; Girls' high, 1859; and Girls' high and normal, 1876. At the end of the 19th century it was manifest that the blight of politics was on the public school, but reforms were successfully inaugurated. Two high schools have been succeeded by 13, with 22 junior high schools. There are evening high schools, evening elementary schools, classes in English and citizenship, classes for handicapped children, vocational schools and summer schools. In 1940 the total enrolment was 258,641 and the disbursements amounted to \$31,751,693. There were 231 public schools in 245 school buildings; of these, 187 were elementary.

Libraries.—Several growths of increasing vigour sprang from the seed sown by Franklin in the "Junto" period of the 18th century—the American Philosophical society already noted, the University of Pennsylvania and the Library company of Philadelphia, organized on July 1, 1731. Franklin was its London agent, 1760–75. It absorbed the association and union libraries and, in 1792, became trustee for the library of James Logan, which, through the benefaction of Dr. James Rush, was nobly housed (1868) in a granite structure of the classic order. The Library company, with its noted collections—Philadelphia material, Civil War books and Americana—has 278,551 volumes. Other libraries (besides those noted under Art, Science and Letters) are those of the Pennsylvania hospital, 1761; the College of Physicians, 1789; the Athenaeum, 1813; the German society, 1817; and the Apprentices', 1820. The free library of Philadelphia, chartered in Feb. 1891, had, in 1941, 32 branches and 4 deposit stations throughout the city; 25 of the branch libraries occupy structures erected from Andrew Carnegie's gift to the city of \$1,500,000. The free library had in 1940, 737,711 volumes, large pamphlet and document collections and a circulation of 3,170,227. The art and music departments are especially rich. There is also a library for the blind. The law library in the City Hall dates from 1802. The Biddle Law library is at the University of Pennsylvania, which, besides the general library (1749)—noted for its Danteana, American and Spanish drama and incunabula—has 15 special sub-libraries. The mercantile library (250,000 volumes) is notably strong in Irish literature, Shakespeare and Junius letters. The Bibliographical Center of Philadelphia listed 280 libraries in the city and environs in 1941, including private collections accessible to students upon application. Historical and genealogical students from all parts gather at the library of the Historical Society of Pennsylvania.

Port.—Transatlantic, coastwise and West Indian trade developed early. Grain, flour and lumber were exported. In 1725, 140 vessels arrived and cleared; in 1735, 427. During the Revolution, Philadelphia became an interstate port, profiting by the imposition of import taxes on goods brought in for transshipment. Marine construction grew apace; and Philadelphia ships and sailors won high repute. The Humphrey model revolutionized frigate building. The old navy yard gave place (1876) to the League island yard. In the Girard epoch (1775–1831) came fast clippers; and, after the Fisk-Fulton-Rumsey-Evans period of steamboat experimentation, came the Liverpool packet service of Thomas P. Cope. Then Peter Wright and Son handled Liverpool boats. The Cope, Winsor, Clyde, Ericsson lines identified themselves with the river. The Corn Exchange (1854) became the Commercial Exchange (1868). Pilot service was established on Oct. 4, 1788. The station for pilot boats is at Overfalls light, 89 mi. from Chestnut street pier. The Philadelphia-to-the-sea 40-ft. channel was under construction in 1941. The Schuylkill channel is from 22–30 ft. deep. Delaware avenue, river-front street, originally 25 ft. wide, has a present width of from 150 to 250 ft., and a length of 20 miles. In the middle of this marginal street are four railroad tracks, including the Belt line, which affords direct track connection for three trunk roads, by means of sidings, with all piers. The port has 40 piers belonging to the city, 159 piers under corporate or private ownership, and 25 U.S. government piers. The main triple-decked tide ater terminal is 1,500 ft. long; can simultaneously berth 15 steamships,

and has 734,372 sq.ft. storage space. At Port Richmond, the Philadelphia Electric company occupies 3,854 ft. of river frontage with one of the largest steam-electric plants in the world. The Reading company's Port Richmond terminal has a river frontage of 1.7 mi., a trackage of 60 mi. and storage for 6,000 cars. It is said to be the largest tidewater terminal in the world. It has a perishable produce terminal, a large grain elevator and also electrically operated ore-loading machinery with a capacity of 1,200 tons per hour. The Pennsylvania railroad has elevators at Girard point. The Greenwich point coal plant handles 500 cars a day.

The water front extends 38.38 mi.; nearly 20 mi. are in use; 100 deep-draught steamships can be docked at once.

Industries.—Industrially, early Philadelphia led all other colonial towns. Diversification was the keynote then, as it is now. Weavers, knitters, wheelwrights, glass-blowers and other craftsmen came with the early German immigration. Germantown set the industrial example. The Quakers, Welsh as well as English, fed the city, and handled much of the money. They were successful merchants, shipowners and shipbuilders. They manufactured paper, cordage and canvas. Streams were readily dammed near Philadelphia, and there were mills on 16 main creeks. Before the Revolution the Wissahickon had 11 mills. Power for mills was drawn in 1829 by the building of Flat Rock dam on the Schuylkill; and Manayunk came into being. Iron was made at Germantown in 1717. The first Philadelphia carpets were made in 1775. Subsequently English weavers came in great numbers. An industrial northwest section, as well as a great northeast section, was developed. Philadelphia, near water but unswept by strong breezes, has a moist climate peculiarly suitable for textile manipulation.

Manufactures.—Philadelphia's prewar (1917) products amounted to \$784,500,000; in 1940 they had exceeded \$2,000,000,000. Six industries manufactured products worth over \$100,000,000 in 1933: textiles, \$327,940,250; food products, \$231,622,227; petroleum and coal products, \$166,544,118; chemicals, \$112,693,592; machinery, \$109,235,202; printing and publishing, \$103,134,476. The chamber of commerce reports that the city led all other U.S. cities in the value of goods produced in the fourteen following fields: petroleum refining, knit goods, sugar refining, paper, cigars and cigarettes, carpets and rugs, clay products, steam packing, plumbers' supplies, lace goods, processed waste, files, cardboard, and upholstery materials.

Transportation.—Philadelphia is the headquarters of the Pennsylvania railroad. The Philadelphia and Reading and Baltimore and Ohio have great terminals in Philadelphia. Intra-urban transit is by electric-subway and elevated trains, or by surface trolley cars. All intra-urban roads are operated by the Philadelphia Transportation company under contract with the city since July 1907. The Frankford "L" was built and equipped by the city at a cost of \$15,603,992 and leased to P.T.C. in 1923. Subways built by the city are similarly leased. The city-built North Broad street subway was completed in 1928, at a cost of \$100,000,000. The Philadelphia Transportation company operates urban and suburban motorbuses. Fifty companies, with 750 buses operate between the heart of the city and 150 of the outlying towns.

Finances.—The first bank in the United States (Pennsylvania bank) was organized in 1781. The Bank of North America was chartered by the Continental congress in 1784. The first building and loan association in the United States was the Oxford Provident and Building association, organized in Frankford (now 35th ward) Jan. 3, 1831. There were in Philadelphia county, Dec. 31, 1940, 648 state-chartered building and loan associations, with total assets of \$107,544,537; on April 30, 1941 there were in Philadelphia 30 federal savings and loan associations with assets of \$34,299,150. There were, in 1941, 37 institutions under the commonwealth of Pennsylvania; 17 operating under federal charter; and numerous private banking houses. National banks reported resources of \$1,250,202,000 and deposits of \$1,129,343,000; while the state banks had resources of \$1,542,887,000 and deposits of \$1,361,880,000, of which \$555,376,000 was in savings banks. Philadelphia is the headquarters of the third federal

reserve district, whose 651 member banks reported (1941) loans of \$1,019,859,000; investments of \$1,379,163,000; reserves of \$700,318,000; and deposits of \$3,452,138,000. The reserve bank itself had assets totalling \$1,326,273,000

City Government.—An act of the assembly, approved on June 25, 1919, regulates the present government of Philadelphia. The mayor, chosen for four years, and 72 other officials (including 32 judges and 28 magistrates, with the receiver of taxes, city treasurer, city controller, district attorney and sheriff) are elected from the city at large. The 22 councilmen, now paid officials serving for four years, are elected from eight state senatorial districts, one for every 40,000 assessed voters. The council is the chief tax-levying body: it fixes the annual budget and possesses legislative powers including the right to override the mayor's veto. Council business is transacted through committees. There are 9 departments of city government: public safety, public works, public health, public welfare, wharves, docks and ferries, city transit, supplies, law, and city architecture. These administrative units are directly under the supervision of the mayor, who appoints the directors. Under the director of public safety are eight bureaus: (a) police; (b) fire; (c) electrical; (d) elevator inspection; (e) boiler inspection; (f) building inspection; (g) maintenance and repairs; and (h) medical. Under the director of public works are bureaus that have charge of water supply and distribution; highways; city property, including supervision of 11 curb markets and 106 small parks and squares; zoning; street cleaning; and lighting and gas. Under the director of public health are the bureaus of health and hospitals, with divisions and dispensaries; and under the director of public welfare are the bureau of recreation, supervising 40 playgrounds and 38 swimming pools and two bureaus dealing with charities and legal aid. Other municipal bodies include an art jury, library trustees, a board of health, a zoning commission, a civil service commission, a pension board, a city planning commission, a gas commission, a sinking fund commission, a tax revision board, and a board of education. Certain offices are known as county offices—those held by the controller, treasurer, district attorney, sheriff, coroner, clerk of quarter sessions, prothonotary, register of wills and recorder of deeds. In 1940 there were 19,149 city employees.

Many courts sit in the city—federal or state; six kinds, including the municipal court organized for special purposes, have jurisdictions coterminous with the city and county. Five registration commissioners, appointed by the governor, have charge of the registration of voters, appointing four district registrars in each of the 1,566 election divisions of the city. Two of the five must belong to the minority party. One of the three elective commissioners, who administer the election machinery, must belong to the minority party.

An important aid to city government is the privately supported citizen's agency, the bureau of municipal research (organized 1908, incorporated 1910), which is managed by a board of trustees.

The assessed valuation of real estate as returned to the city controller by the board of revision of taxes totalled \$2,496,431,938 in 1941; and the personal property \$732,968,980. On Jan. 1, 1941, the gross funded outstanding debt was \$515,345,600, of which the sinking fund held \$150,000,000.

Light and Power.—The city's first gas works date from Feb. 8, 1836. After the consolidation, the combined gas plants were placed under the management of trustees. Political scandals arose and the works were transferred to a bureau of gas; then, by lease, to the United Gas Improvement company, which renewed the lease, Jan. 1, 1928, for ten years. The Philadelphia Gas Works Co. operated the plant under lease after 1938. The Philadelphia Electric company, now consolidated with the United Gas Improvement company, supplies the electric current for light and power. Work on the \$52,000,000 hydroelectric plant of the company at Conowingo, Md., was begun in March 1926 and on March 1, 1928, the first power from its turbines was sent to Philadelphia over two 220,000-volt three-phase lines.

Population.—The population of Philadelphia in 1940 was 1,931,334, according to the federal census figures. First Philadelphia population figures were: (1753) 14,563; (1769)

28,043. Philadelphia's official figures, by decades, follow: (1700) 28,522; (1800) 41,220; (1820) 63,802; (1840) 93,665; (1860, after consolidation) 565,529; (1880) 847,170; (1900) 1,293,697; (1910) 1,549,008; (1920) 1,823,779; (1930) 1,950,961. In 1940, foreign-born whites numbered 331,219; non-white, 251,965. Metropolitan Philadelphia contained 3,201,886 people within an area of 993.89 sqmi. in 1940 and there were over six million within an So-mile radius. This section constituted a tri-state region with 41 towns and cities, 21 in Pennsylvania, 18 in New Jersey and 2 in Delaware. (G. MN.; X.)

PHILADELPHIANS, a sect of religious mystics, founded in London in the latter part of the 17th century. In 1652 Dr. John Pordage (1607–1681), rector of Bradfield, Berkshire, gathered together a few followers of Jakob Boehme, the chief of whom was Jane Lead or Leade (1623–1704). Mrs. Leade had been from girlhood of a mystical temperament, and experienced phantasms which she recorded in a diary entitled *A Fountain of Gardens*, beginning in 1670, in which year the Philadelphian society was definitely organized. In 1693 some of Mrs. Leade's writings were translated into Dutch, and by this means and her acquaintance with Francis Lee (1661–1719), an Oxford scholar who studied medicine at Leyden and became her son-in-law, a connection was opened up with Germany and Holland. In 1703 the Philadelphians drew up their confession, but they made no further progress and soon declined, the Dutch branch withdrawing and the English government forbidding the society to meet.

PHILADELPHUS, a genus of the Saxifragaceae, with about 40 species and more than 100 horticultural varieties, characteristic of North America, southern Europe, and eastern Asia. They are commonly known as mock orange and are often referred to as *Syringa*, which, however, is the proper generic designation of the lilac. They are all deciduous shrubs with opposite entire or toothed leaves, the pith being solid, the lateral buds hidden in the leaf axils. The often showy flowers are solitary or arranged in terminal or lateral racemes, always 4-merous, the petals mostly white, in some varieties somewhat purplish at the base, and with numerous stamens. The fruit is a capsule with many small seeds.

These shrubs are much planted in temperate regions because of their conspicuous white flowers which are frequently very fragrant. The species can be cross fertilized readily and much hybridizing has been done, especially by the firm of Victor Lemoine. Some of the species grow unusually well in dry soils and endure the trying conditions encountered in city gardens. The mock orange is subject to few insect pests and plant diseases and is thus justly popular as an ornamental plant. The growth habit is usually upright with arching branches, most of which originate at the base of the plant. Some varieties are not over 2 ft. high, while others attain a height of 15 ft.

The size of the flower and degree of fragrance varies. Some, like *Philadelphus hirsutus*, *P. pekinensis* and *P. subcanus*, have flowers only three quarters of an inch in diameter, while the flowers of such varieties as "Belle Etoile," "Bicolore" and "Argentine" attain a size of two inches or even more. Many of the species have single flowers but in some hybrids such as "Glacier," "Girandole" and "Virginal" the flowers are double. Fragrance varies considerably, some species and varieties being odourless and others, like the old-fashioned *P. coronarius* being very fragrant. The characteristic odour is the chief reason for the selection of the name "mock orange" to designate these plants.

See A. Rehder, *Manual of Cultivated Trees and Shrubs* (1940) (E. D. Ml.)

PHILAE, an islet in the Nile above the First Cataract, of great beauty and interest, but since the completion of the Aswan dam in 1902 submerged except for a few months yearly, when the water is allowed to run freely through the sluices of the Aswan dam. Philae marks also the end of the cataract region. Ancient graffiti abound in all this district, and on Bigeh, a larger island adjoining Philae, there was a temple as early as the reign of Tethmosis III. About 350 B.C. Nekhnebf, the last of the native kings of Egypt, built a temple to Isis, most of which was destroyed by floods. Ptolemy Philadelphus reconstructed some of this work and began a large temple which Ptolemy Euergetes I. completed, but the decoration, carried on under later Ptolemies and Caesars, was never finished. The little island won great favour as a religious resort, not only for the Egyptians and the Ethiopians and others who frequented the border district and the market of Aswan, but also for Greek and Roman visitors. One temple or chapel after another sprang up upon it dedicated to various gods, including the Nubian Mandulis. Ergamenes (Arkamane), king of Ethiopia, shared with the Ptolemies in the building. Besides the temple of Isis with its birth-temple in the first court, there were smaller temples or shrines of Arsenuphis, Mandulis, Imuthes, Hathor, Harendotes (a form of Horus) and Augustus (in the Roman style), besides unnamed ones. There were also monumental gateways, and the island was protected by a stone quay all round with the necessary staircases, etc., and a Nilometer. The most beautiful of all the buildings is an unfinished kiosque inscribed by Trajan, well known under the name of "Pharaoh's Bed." The decree of Theodosius (A.D. 378) which suppressed pagan worship in the empire, was of little effect in the extreme south. It was not till the reign of Justinian, A.D. 527–565, that the temple of Philae was finally closed, and the idols taken to Constantinople. Remains of Christian churches were disclosed by the thorough exploration carried out in 1895–1896 in view of the Barrage scheme, under the direction of Captain Lyons. The accumulations of rubbish on the island were cleared away and the walls and foundations of the stone buildings were all repaired and strengthened before the dam was completed. The annual flooding now appears to be actually beneficial to the stonework, by removing the disintegrating salts and incrustations. The tops of most of the buildings and the whole nucleus of the temple of Isis to the floor remained all the year round above the water level until the dam was raised another 26 ft.—a work begun in 1907—when the temples were entirely submerged except during July–October. But the beauty of the island and its ruins and palm trees, the joy of travellers and artists, is almost gone.

PHILANTHROPY. Almsgiving is as old as man. In the Egyptian Book of the Dead, as ancient as the Nile pyramids, there is found this memorial ascription: "He gave bread to the hungry, water to the thirsty, raiment to the naked; he gave a boat to the man who had none." Similarly in the ancient Hebrew scriptures we read (Deuteronomy xv. 7 and 8): "If there be with thee a poor man, one of thy brethren, within any of thy gates in thy land which Jehovah thy God giveth thee, thou shalt not harden thy heart, nor shut thy hand from thy poor brother; but thou shalt surely open thy hand unto him, and shalt surely lend him sufficient for his need." And of all the parables to be found in the New Testament none is better known or more deeply burnt into the conscience of Western civilization than that of the Good Samaritan. The Muslim world in like manner preserves the maxim: "Prayer carries us half way to God, fasting brings us to the door of his palace, and alms gains us admission." While the spirit of benevolence that animates all philanthropy is unmistakably reflected from the remote past, it is evident that there has been an evolution in the technique of giving. Various groups of the modern social order resent the idea of alms, regarding such forms of assistance as undemocratic. So the use of the word charity is often avoided. Present day benevolence, philanthropy, no longer content with the cure of human ills after they arise, strives ever to prevent them, and, as a final goal, seeks through constructive effort the positive achievement of health and happiness throughout the world. It is a curious fact that the word philanthropy, which in origin means simply "love to mankind," has

no exact equivalent or synonym in our language. Further, its employment as an English word is comparatively recent, one of its earliest appearances in its present form occurring about 1650 in a sermon by Jeremy Taylor. Moreover, the use of the word to designate some humanitarian activity as "a philanthropy" is a development of the last 50 years.

The purpose of this article is not to discuss the history of ancient and mediaeval benevolence, various aspects of which are treated in the article CHARITY, but to indicate the chief developments that have characterized modern philanthropy since about the beginning of the 19th century.

The Nineteenth Century.—Between 1775 and 1800 there were significant beginnings of that notable philanthropic activity which was to characterize the 19th century. Conspicuous among its forerunners in England were John Howard, pioneer in prison reform, and Sir Samuel Romilly, who sought to abolish the barbaric features of British criminal law. In France Charles Michel Epée laid the foundations of modern instruction for the deaf and dumb, and Jean F. Oberlin laboured effectively for social improvement. Another leader was the American scientist, Benjamin Thompson, afterwards Count Rumford, who organized in Bavaria (1785-95) a system of workshops, called houses of industry, thereby largely suppressing begging.

The change from the domestic to the factory system of manufacture at the beginning of the 19th century brought about a great shift of the labouring population, accompanied by a phenomenal growth of cities, nowhere more striking than in Great Britain between 1800 and 1850 and in the United States between 1850 and 1900. In 1800 London was the only city in Great Britain with a population of over 100,000. The next largest cities were Manchester, Birmingham and Glasgow, each of which had about 75,000 inhabitants. Yet at the end of the century all these places, including London, had multiplied in size from more than seven to nearly ten times. In 1800 Philadelphia, then the largest city in the United States, had a population of 28,000, as contrasted with about 150 American cities of equal or greater population in 1900. Similar urban growth took place in Germany, Belgium and other industrial countries of Europe.

This rapid and unparalleled transfer of people from rural to urban conditions gave rise to problems in social adjustment of immense range and complexity. Accompanied by the progress of democracy, the advance of popular education, the increasing sense of civic responsibility, the application of scientific methods and, above all, the ever-widening permeation of the humanitarian spirit, these social transformations formed the background for the development of the great outstanding philanthropies of our time. Most notable among the results of the philanthropic spirit were the great advance in industrial welfare, the abolition of human slavery, improved housing in cities, enlightened care for the defective classes, immense extension of free public education, the organization of the Red Cross society, the charity organization movement, the social settlement movement, the child welfare movement and the establishment of scientifically equipped hospitals.

Among the most notable philanthropists (on each of whom will be found a biographical article under his name) were: Robert Owen, famous for his model mills at New Lanark and later for his communities in England and America; Jeremy Bentham and the Quaker educator, William Allen (1770-1843). Other leading figures were William Wilberforce whose life-effort was finally crowned in 1833 by the passage of an act abolishing slavery in the British dominions, and Elizabeth Fry, in England, who carried on the cause of prison reform initiated by John Howard.

In the United States Dr. Samuel Gridley Howe advanced the education of the blind, and Thomas Gallaudet, with his sons Thomas and Edward Gallaudet, performed equally conspicuous service in the training of the deaf and dumb. In 1833 Anton Frederic Oxnam, a zealous Roman Catholic student at the Sorbonne, with the aid of Père Sylvain Bailly, organized in Paris the Society of St. Vincent de Paul. Within the century this society expanded into a world-wide agency of Catholic beneficence, whose principles and practices of poor relief influenced the charitable

practice of our time, in Protestant as well as in Catholic countries. In the same year (1833) Theodor Fliedner, a pastor in Rhenish Prussia, established the Protestant order of Deaconesses, at whose first school in Kaiserswerth Florence Nightingale was trained as a nurse. Shortly before (1827) bliss Catherine McAuley established in Dublin the Sisters of Mercy, whose hospitals and schools have become widespread in English-speaking and other countries.

Lord Shaftesbury's long life is the continuous story of factory acts, child labour acts, mining reform, lunatic asylum reform, public health improvement and housing reform. In 1856 Baroness Burdett-Coutts, who devoted a long life and a large fortune to many-sided philanthropy, began building model lodging-houses at Bethnal Green. In 1862 George Peabody, an American banker living in London, gave a fund of £150,000, later enlarged to £500,000, for the construction of dwelling houses for London working men. In 1864 Octavia Hill began her remarkable housing work at Marylebone with funds advanced by John Ruskin.

The English nurse, Florence Nightingale, by heroic service with the British army in the Crimean War (1854-56), revolutionized the care of sick and wounded soldiers in military hospitals. Further reflecting the humane spirit of the age, the Swiss philanthropist, Henri Dunant, provided aid for wounded soldiers on the battlefield by organizing, in 1864, the Red Cross Society. Under the leadership of Clara Barton the American Red Cross Society was established in 1881 and its function later extended (1906) to provide relief in natural calamities. Henry Bergh, of New York, founded, in 1874, the Society for the Prevention of Cruelty to Children. In 1853 Charles Loring Brace founded the Children's Aid Society of New York city, a pioneer organization in the child welfare movement. In 1867 Dr. Thomas John Barnardo opened in Stepney Causeway, London, the first of the so-called "Barnardo homes" for destitute children.

In 1869 a group of prominent men in England, including the earl of Shaftesbury, J. H. Newman and Wm. E. Gladstone, formed in London the first Charity Organization Society in the world. With a group of Oxford men, Canon S. A. Barnett in 1885 founded in Whitechapel, London, the first university settlement, Toynbee Hall. Dr. Stanton Coit in 1886 established in New York the Neighborhood Guild which later became the University settlement. In 1889 Jane Addams began her work at Hull House, Chicago, and in 1893 two nurses, Lillian D. Wald and Mary M. Brewster, established in New York city the now widely known Henry Street settlement.

In the 19th century, also, the political and economic emancipation of the Jewish peoples of western Europe led to a complete reorganization of Jewish benevolence, accompanied by many outstanding achievements in modern philanthropic endeavour. Among these were the notable activities of Sir Moses Montefiore, of England, in ameliorating the lot of unfortunate co-religionists in lands where they were still oppressed, and also the munificent benefactions of Baron Maurice de Hirsch. The latter established the Jewish Colonization Society, which he endowed with some £11,000,000, making it one of the greatest modern philanthropic trusts; in addition, he contributed extensively to hospitals and other charities in London and elsewhere, the total of his benefactions amounting to about £18,000,000.

In the latter half of the century began the philanthropic efforts to advance higher education in the United States, the individual donations eventually exceeding in size those made for any other single beneficent purpose. These benefactions included an immense number of substantial sums to countless institutions, but most conspicuous were endowments of princely magnitude for the more important colleges and universities. Notable among the early benefactors of American education were Peter Cooper, Ezra Cornell, Matthew Vassar and Johns Hopkins. Later Leland Stanford and John D. Rockefeller made munificent gifts for the establishment of universities and the spread of higher education.

Following the Civil War and the emancipation of the slaves, the education of the American Negroes in the Southern States became and still remains an especially worthy object of philanthropic endeavour. Prominent among early contributors of funds or of important personal service to the cause of Negro education

were George Peabody, donor of the Peabody Fund; John F. Slater, founder of the Slater fund; General O. O. Howard, commissioner of the Freedmen's bureau; Samuel Chapman Armstrong, founder of Hampton Institute and a leader in Negro education; and Booker T. Washington, a conspicuously successful Negro educator, who founded Tuskegee Institute.

Another notable expression of educational philanthropy during the latter half of the century was the establishment of free public libraries on an unprecedented scale, especially in the United States. Important among earlier gifts for library foundations were those of John Jacob Astor, James Enox and Samuel J. Tilden, in New York, and John Crerar, in Chicago. Later came individual gifts for great library buildings, as that of Enoch Pratt to the city of Baltimore and of P. A. B. Widener to Philadelphia, and also gifts for thousands of lesser buildings in smaller cities and towns, for the construction of a large number of which Andrew Carnegie made very numerous donations aggregating more than \$60,000,000.

Recent Philanthropy. — At the opening of the 20th century the philanthropic agencies in effective operation immensely exceeded in number, diversity and scope those of any earlier period. Despite the World War (1914-18), there was a substantial advance in every important field of philanthropic endeavour during the first quarter of the new century. In connection with the many phases of this growth two distinctive features developed. One of these was the assumption by the British, French and other European governments of a vast range of social relief which formerly was administered only through private charitable agencies. By parliamentary enactment in Great Britain in 1908 a system of old age pensions was set up. In 1911 came the National Insurance Act, providing against sickness, invalidity and unemployment. Further, in 1928, by the Widows, Orphans and Old Age Pensions Act, a still larger group previously aided through private charity was brought under the scheme of national social insurance.

The second distinctive feature of this period has been the creation of many great philanthropic trusts, especially in the United States. Their underlying constructive purpose is somewhat parallel to that of the British governmental system of social relief. These trusts seek permanent, substantial and far-reaching results through the use of ample funds, efficient organization and modern methods of administration. In the United States alone, where the establishment of such trusts has become a favourite method of the bestowal of large bequests, the total of such funds runs into the thousand millions of dollars. Many philanthropists disapprove of the efforts made by certain benevolent trusts and foundations to perpetuate themselves by restricting their enterprises and expenditures to the interest on invested capital and not only leaving the principal untouched but even adding from time to time to it from unused income. In consequence, various trusts, as the Julius Rosenwald Fund, provide definitely for the expenditure of the entire fund capital as well as income within a specified period.

Among other distinctive gains made in the 20th century have been the effective attacks on disease, as yellow fever, malaria, hookworm, typhoid and tuberculosis; the marked progress in numerous phases of child welfare, and the wide establishment of the juvenile court system in treating youthful delinquents. Important also have been the efforts to promote amicable international relations, as reflected in the Rhodes Scholarships, established (1902) by Cecil J. Rhodes, and (1910) the Carnegie Endowment for International Peace.

The United States. — The spectacular recent change in philanthropy in the United States is the assumption of much greater responsibility for public welfare by the Government, a trend which showed itself in England and other European countries two to four decades earlier.

Until 1933 the pattern in the United States was that educational institutions, hospitals and clinics, research activities and the relief and betterment of social conditions and personal needs were chiefly tasks for private philanthropy, and during the early decades of the 20th century philanthropic gifts to such causes rose to more than \$2,000,000,000 a year. With the coming of the depression, the great increase of human needs together with the

curtailment of private incomes made it imperative that the Government step in.

Since 1933 the Federal Government has given sums to social welfare that completely overshadow any private giving. So great was the shift toward social responsibility that the administration which took office in 1933 became known as the New Deal. The Federal Government increased the scope as well as the expense of its social responsibilities to include social security (annuities to the aged and unemployed), additional public health services, including medical care in hospitals and various forms of public organization of health services, increased support of adult and child education, and greatly enlarged social service, including the distribution of surplus commodities.

For the year 1938-39 it expended for general relief, aid to the aged, the blind, and dependent children, and subsistence payments to farmers \$1,033,806,000, and for wages to workers on various emergency programs of public works and relief projects and for student aid \$2,720,132,000—a total of \$3,753,938,000 for public assistance alone.

Meanwhile, private philanthropy has been curtailed because of the shrinkage in private income and the greater demands made on this income by taxes.

During the period since 1933 foundations have played an increasing part in private philanthropy since their incomes were not cut by taxes and their policies were not affected by the fears and insecurities which beset many rich individuals. Several foundations, especially those of Rockefeller, Rosenwald, and Couzens, have recognized the greater demands upon them by expending large sums from capital as well as from income.

The chief recipients of the largest bequests of private philanthropy are universities and colleges. As a result of these generous gifts, two universities—Harvard and Yale—had in 1939 endowments of over \$100,000,000 each with capital in buildings and plant valued at half as much more. There are in the U.S. some 23 universities with endowments of more than \$10,000,000 each. In addition, over 100 State institutions which do not have permanent endowments receive from State appropriations and elsewhere large incomes, in given instances exceeding \$8,000,000 a year. Interestingly enough, in spite of the depression years, the trend seems to be toward increased gifts to the universities with the largest endowments.

For example, during the nine depression years, the combined gifts and bequests to Harvard, Yale, Chicago, and Columbia exceeded by over \$40,000,000 those received by these four institutions during the nine preceding years of prosperity. Since 1934 the larger institutions of higher education (those having enrolments of more than 1,000) have consistently received more money. In general, however, the smaller institutions are suffering greatly from the curtailment of private giving. (J. Ros., X.)

PHILANTHROPIC ENDOWMENTS

The accumulation of great fortunes in the United States and the peculiar appropriateness of benevolence in a democracy have been accompanied by an exceptional development of endowed philanthropies.

Benjamin Franklin (1706-90) wrote in his will: "Having myself been . . . assisted to set up my business . . . by kind loan of Money . . . which was the foundation of my Fortune, and of all the utility in life that may be ascribed to me, I wish to be useful even after my Death, if possible, in forming and advancing other young men that may be serviceable to their Country." To that end he left £1,000 to the town of Boston and an equal amount to the city of Philadelphia, to be lent at interest to young, married artificers of good character. Estimating that each of these gifts would have increased to £131,000 after 100 years, Franklin requested the expenditure at that time of £100,000 in public works of useful, convenient and agreeable character, and the accumulation of the remainder for another century, when the whole was to be distributed—one-fourth by the city and three-fourths by the State.

In 1891, largely because there had been few borrowers, the Philadelphia accumulation amounted only to \$90,000. Of this,

\$20,000 was left to accumulate for another century; the remainder, accumulated to \$133,000 in 1908, was then added to the endowment of the Franklin Institute, which had been founded in 1824, for the promotion of science and the useful arts.

Of the Boston accumulation of \$391,000 in 1891, \$62,000 was left to accumulate for another century; the remainder, accumulated to \$408,000 in 1904, was then used to build the Franklin Union, an industrial school, an equal sum being given for its endowment by Andrew Carnegie.

George Peabody (1795-1869), a merchant and banker, of Danvers, now Peabody, Mass., and later of London, established, among many benevolences, an institute, with a library, art museum and conservatory of music, in Baltimore, Md., in 1859; a Museum of Archaeology and Ethnology at Harvard college in 1866; an Academy of Science at Salem, Mass., in 1867; and gave £500,000 for the erection of workmen's dwellings in London in 1864, and \$3,000,000 to the Peabody Education Fund in 1867, for "intellectual, moral or industrial education among . . . the Southern and Southwestern states." The fund established and developed public schools until they were taken over by towns and cities; encouraged rural schools and the development of State systems of public education; and promoted the training of teachers by scholarships, and by founding at Nashville, Tenn., in 1875, the Peabody Normal college, which became in 1913 the George Peabody College for Teachers and received the remaining resources of the Peabody Education Fund at its conclusion in 1914.

Andrew Carnegie (1835-1919) carried out his "Gospel of Wealth" by distributing nine-tenths of his fortune in countless gifts—for 8,000 church organs, 3,000 libraries and 500 universities and colleges. Two-thirds of his total distribution of \$350,000,000 went toward the establishment and endowment of eight large, permanent foundations.

(For full particulars of these foundations see CARNEGIE TRUSTS.)

John D. Rockefeller (1839-1937) and John D. Rockefeller, Jr (1874-) have given for philanthropic and charitable purposes more than \$550,000,000, together with \$45,000,000 to the University of Chicago. The larger portion of this was given for the establishment and endowment of four large foundations. (For full particulars of these foundations see ROCKEFELLER BENEFACTIONS.)

Other large foundations are: (1) the Milbank Memorial Fund, incorporated in 1905, by Elizabeth Milbank Anderson, with \$10,000,000, especially for studies and demonstrations of child welfare, mental hygiene and individual and community health; (2) the Russell Sage Foundation, established in 1907 by Mrs. Russell Sage, with \$10,000,000, later increased by \$5,000,000, for the improvement of social and living conditions in the United States, especially through the organization of charity, education, recreation, remedial loans, social legislation, and through libraries, research, surveys, statistics, exhibits and publications; (3) the Commonwealth Fund, established in 1918 by Mrs. Stephen V. Harkness, with \$38,000,000, "for the welfare of mankind," especially through clinics and demonstrations of child health, guidance and mental hygiene; the training of social workers; rural hospitals; and educational fellowships, research and publications; (4) the Juilliard Musical Foundation, of New York, established in 1919 by a bequest of \$20,000,000 from Augustus D. Juilliard, for the musical education of gifted students and of the public; (5) the Duke Endowment, established in 1924, by James B. Duke, with \$40,000,000, increased by bequest in 1925, for Duke university, other universities and colleges, hospitals, the building and maintenance of churches, pensions for clergymen, and the care of orphans in North and South Carolina; (6) the Buhl Foundation of Pittsburgh, established in 1928 by Henry Buhl, Jr., with an original endowment of over \$12,000,000 to stimulate the advancement of human welfare by experiment, demonstration and research, especially through promoting nationally significant programs in the Pittsburgh district in regional economic, social and historical research, higher education, public health, and mental hygiene; (7) the Julius Rosenwald Fund, established in 1917, with

an original capital of \$20,000,000 for the health and education of Negroes, other backward races and persons of small means, with the proviso that both the principal and interest be expended within 25 years after the death of the donor. Mr. Rosenwald has in addition made large contributions of time and money to other civic, philanthropic educational enterprises, including Y. M. C. A.'s and Y. W. C. A.'s for Negroes. Other large philanthropic foundations were endowed by John Simon Guggenheim, John and Mary R. Farkle, Maurice and Laura Falk, Horace H. and Mary A. Rackham, Harvey G. Woodward, Andrew W. Mellon, Charles Hayden, W. K. Kellogg and others.

In the United States in 1938 there were some 700 endowments that fall into the classification of national foundations. At least 250 of these are of sufficient size and scope to lend themselves to careful analysis as to organization and trends in giving. Studies and reports on these foundations have been made and published from time to time by the Twentieth Century Fund and the Russell Sage Foundation as well as by many individual students and critics.

These foundations in 1938 held endowments of approximately \$1,000,000,000 and expended for philanthropic purposes over \$50,000,000 a year even during the depression years.

The general trend among philanthropic foundations is toward limitation of interest to a few special programs. A foundation analysis for 1937 made by the Twentieth Century Fund shows grants in fewer fields than in 1931 and a concentration of interest in certain of the remaining fields. Analysis of the grants of 115 foundations for the year 1937—during which the combined disbursements of these foundations were approximately \$39,000,000—shows that the largest total disbursements were in the field of medicine and public health (in which the Government has been spending about \$512,000,000 annually). These grants exceeded those made by foundations for education by more than \$4,300,000. Social welfare, including grants for general relief purposes, received the third largest total, in spite of the fact that contributions to this work decreased 32% since 1931. These three fields received more than 70% of the sums expended by the 115 foundations reporting.

The fields of physical and biological sciences, in fourth place, and of public administration, in fifth, together received 10% of the total grants.

The growing interest of foundations in Government and public administration and in economics is evidenced by the fact that from 1934-37 grants in these fields were increased by 95% and 52.9% respectively. During the same period, grants to the physical and biological sciences increased by 24.6% while those to the social sciences decreased 71.4%.

There were substantial increases in the fields of the humanities, aesthetics and child welfare.

Strangely enough, considering the state of the world, international relations received less attention from foundations in 1937 than in 1934.

The year 1938 marked the 25th anniversary of the beginning of the modern community chest movement in philanthropy. The first community chest was organized in Cleveland in 1913; in 1938 there were 484 such chests on record, all in the United States and its territories, with the exception of 11 in Canada and 2 in South Africa.

The fears concerning the power of wealth concentrated in foundations and their indefinite continuance of the wishes of their founders, which were formulated by the French economist, Turgot, in 1776, have not been fulfilled. Religious, philanthropic and educational endowments in the United States represent less than 1% of the national wealth; a score of life insurance companies have larger resources than any foundation; a hundred banks have incomes greater than the total new endowments in any year.

The "imposition of the dead hand" is prevented and desirable freedom is assured by such provisions as Mr Carnegie's for spending the income of his endowments for purposes other than those he specified, or Mr. Rockefeller's for spending the principal as well as the income of his gifts, and by legislative provisions in

foundation acts of incorporation or charters that these may be altered or repealed at any time.

Meanwhile the resources of the foundations have given them independence and freedom to concentrate upon particular problems, to carry out comprehensive and continuing studies, experiments and demonstrations. Eminent men have guided them as trustees, and distinguished scholars have collaborated in their studies. Gifts from foundations have greatly encouraged giving to worthy causes; their discriminations have elevated educational standards; their activities have been taken advantage of by many voluntary associations, sundry States and the Federal Government. In fine, the public has come to expect from these privately endowed yet representative foundations much of the aid and guidance that are furnished by government in other countries. An annotated bibliography of the literature concerning American foundations is issued by the Russell Sage Foundation. (C. Fu.; E. R. E.)

PHILARET [THEODORE NIKITICH ROMANOV] (?1553–1633), patriarch of Moscow, was the second son of the boyar Nikita Romanovich. During the reign of his first cousin Theodore I. (1584–98), Theodore Romanov distinguished himself both as a soldier and a diplomatist. On the death of the childless tsar, he was the popular candidate for the vacant throne; but he acquiesced in the election of Boris Godunov, who compelled him, three years later, to take monastic vows under the name of Philaret. Philaret was confined to the Antoniev monastery, but when the pseudo-Demetrius overthrew the Godunovs he released Philaret and made him metropolitan of Rostov (1605). In 1609 Philaret fell into the hands of pseudo-Demetrius II., who named him patriarch of all Russia, though, in fact, his jurisdiction was very limited. On June 2, 1619, he was enthroned patriarch of Moscow. Henceforth, till his death, there were two sovereigns, Tsar Michael and his father, co-regents.

Philaret replenished the treasury by a more equitable and rational system of assessing and collecting the taxes. His most important domestic measure was the chaining of the peasantry to the soil, a measure directed against the ever increasing migration of the down-trodden serfs to the steppes, where they became free-booters instead of tax-payers. The taxation of the tsar's *slyuzhnuie* lyudi, or military tenants, was a first step towards the proportional taxation of the hitherto privileged classes. Philaret formed the nucleus of the subsequently famous Patriarchal Library, and commanded that every archbishop should establish a seminary for the clergy, himself setting the example. He also reorganized the Muscovite army with the help of foreign officers. His death in October 1633 put an end to the Russo-Polish War (1632–33), withdrawing the strongest prop from an executive feeble enough even when supported by all the weight of his authority.

See R. N. Bain, *The First Romanovs* (London, 1905); S. M. Solov'ev, *Hist. of Russia* (Rus.), vol. ix. (St. Petersburg, 1895, etc.).

PHILATELY. It was in 1840 that the first postage stamps for prepayment of letter-postage came into being. Everything in connection with them must date from that period, even to the name of the *stamp* itself, and especially the terms referring to the hobby of collecting postage stamps. The term philately was coined in 1865 by a Frenchman, M. Herpin, who invented it from the Greek *φίλος*, love; *α*, negative; *τέλειον*, to tax. Since the postage stamp was evidence of a letter coming free of charge to the recipient, the postage stamp rendered it *untaxed*. The term caught the popular fancy much more than the previous word *timbromania*, and has become the accepted word to describe stamp-collecting and the study of postage stamps.

The History of the Posts.—Unlike postage stamps, the posts are as old as history itself. Herodotus, the "father of history," speaks with admiration of the post system of the Persians, and his phrase, "Neither snow nor rain nor heat nor gloom of night stays these couriers from the swift completion of their appointed rounds," has been carved over the doors of many post offices.

The first posts were the perquisite of the kings. They were often permitted to carry letters and messages for members of the royal courts and friends of the courtiers, gradually extending their accommodations to merchants. As commerce be-

came appreciated, so the posts became more important. Such as had been allotted to favourites or corporations were gradually recaptured for the benefit of the state (which was often identical with the crown, of course). By the beginning of the 19th century, the theory of the post as a monopoly of the state was accepted everywhere.

The first "postage stamp" in history was not a proof of payment, but the impression of a hand stamp (or what would be known today as a "postmark"). "A stamp is invented," wrote Postmaster General Henry Bishop of Great Britain in a letter dated Aug. 2, 1661, "that is putt upon every letter shewing the day of the moneth that every letter comes to this office, so that no letter Carryer may dare to detain a letter from post to post; which before was usual." These date stamps, known as "Bishop marks," were used in Britain until 1787, after which they were enlarged and expanded until the common postmarks of today developed. A modified form was introduced into the American colonies, where posts had been established (Massachusetts, 1639; Virginia, 1657; New York, 1672; Connecticut, 1674; etc.).

The posts merely carried the letters from town to town, and to put a letter into the posts required delivery at the posting-office—usually the point whence the post departed—or to get one necessitated a visit there. In 1653, however, M. (later Comte) de Villayer established a service of collection and delivery of letters within Paris, and issued wrappers which were sold, each wrapper being proof of the prepayment of the charges of the local post. This was the forerunner of prepaid mail, and the wrapper was the first precursor of the postage stamp. The service ceased after a short vogue, as soon as the novelty wore off. In 1680, William Dockwra set up a Penny Post for London and its suburbs, which was suppressed by the government in 1682 as an infringement of its monopoly of post roads. However, the entire system was incorporated into the British postal system in 1682, with Dockwra himself as comptroller from 1697 to 1700.

The use of embossed "stamps" on documents as evidence of imposts and excise taxes paid, which originated in the Netherlands, was introduced into Britain in 1694. The famous "Stamp tax," or excise tax evidenced by stamps, on commodities for the American colonies of Great Britain was passed in 1765 and repealed the following year, but contributed to the unrest in America which led to the Revolution and independence ten years later. In 1818 the kingdom of Sardinia taxed letters, and evidenced it with such an impressed stamp—not, however, a postage stamp.

Although originally supported by the king's private purse, the postal system was put on a paying basis in 1635, by fixing rates for letters on a basis of distance and by "single," and "double" letters and "per ounce." Thereafter, the rates were changed from time to time, usually upwards. Each rise in charge decreased the total volume of mail, but increased net revenue. The posts were farmed out to the various postmasters general for some years. In 1812 a further increase in rates brought only a slight rise in net revenue, and actually worked a hardship on legitimate business, the rates becoming so high (*4d.* for 15 mi. or less; *5d.* for 15 to 20 mi. and so up to *18d.* for 700 to 800 mi., and *1d.* for each 100 mi. additional).

The First Postage Stamp.—In 1835 Mr. (later Sir) Rowland Hill (*q.v.*) began to study the tax situation, there having been a surplus of revenue. He noted that while reduction of tax rate sometimes brought a reduction of net revenue, the reduction of the tax on coffee by one-half had produced a net increase in revenue of one-half. Furthermore, he determined that postal revenues were falling despite increased rates, while a reduction in postal rates in France had increased the net revenue.

Further inquiry developed that since most letters went through post unpaid, to be collected on delivery, many of these were refused and had to be returned, often to be unclaimed or refused on return, thus necessitating records at every step of the two-way trip, as well as double portage for no revenue. Most illuminating of all was the discovery that the cost of transport per letter was frequently less for a long journey—from London to Glasgow, for example—than for a short one—such as London to Kent—for the long haul went with a greater number of letters

than the short local trip. Hill therefore proposed a radical change; that letters be carried any distance within Great Britain and Ireland for a fixed rate, which he suggested be a penny for each one-half ounce, and that all postage be prepaid. Wrappers and envelopes with the stamp denoting prepayment were to be sold at all post offices, and for the people who wished to use their own stationery he proposed "a bit of paper just large enough to bear the stamp" (he meant the imprint of the post office handstamp), "and covered at the back with a glutinous wash, which might, by applying a little moisture, attach to the back of the letter, so as to avoid the necessity for redirecting it."

Hill's pamphlet, *Post Office Reform*, was issued in Jan. 1837 for private circulation. Parliament investigated, and the postmaster general, Lord Lichfield, reported "of all wild and visionary schemes he had ever heard or read of, it was the most extraordinary." A second edition of the book, for public circulation, had its effect. The public response was loud and strong, the treasury reduced rates to a uniform 4d. per $\frac{1}{2}$ ounce basis, and in 1839, reduced it to Hill's proposed 1d. per $\frac{1}{2}$ ounce regardless of distance, effective Jan. 10, 1840.

Hill was asked by the treasury to work out the details. In 1839, he entrusted the design of the envelope and wrapper to William Mulready, R.A. To secure the "bit of paper," he held a public competition. Over 2,600 essays were entered, but meanwhile Hill had heard of a new process of steel engraving, in which he became interested. The prizes, four of £100 each, were awarded, but the "label" with the glutinous wash on the back was finally produced by the new, revolutionary Perkins process for reproducing steel engravings.

Jacob Perkins, a native of Massachusetts, U.S.A., was an inventor of mechanical devices. In 1819, having invented the D-roller copper-plate press, an engine lathe for engraving copper and steel plates, and the "triple transfer" process of reproducing steel engravings together with the machines to carry it out, he was persuaded to travel to England to interest the Bank of England in the process for producing its notes. The British ambassador to the United States extended the invitation, and though the Bank of England finally decided to proceed with a process then being installed, a grant, reported to be £5,000, was made to Perkins and his partners. Meanwhile, he secured the business of many other banks, for prior to 1844 almost every British bank issued its own notes.

In brief, the essence of the process is: a soft, steel die is engraved with the original intaglio of the proposed finished engraving. This master die is then hardened, and a soft-steel roller is pressed against it in a "transfer press," and rolled back and forth until a transfer in relief is obtained on the roller. A second, third or fourth relief—or even more—can be likewise obtained on the transfer roll, each of them in relief—*i.e.*, the lines that are cut into the original die and which will retain the ink to make the print of the engraving are in relief on the transfer roll. The roll is hardened, in turn. The last stage is to impress the transfer roll against the plate from which the printing is to be done, once more in the transfer press. The relief lines become intaglio lines on the printing plate, exact reproductions of the original die, reproduced as often as wished.

To this inventor's firm, Perkins, Bacon and Petch (later Perkins, Bacon and Co.), Sir Henry Cole, on behalf of Hill, suggested the possibility of securing the contract for the proposed "labels." This was in Dec. 1839.

For Hill's label, the background chosen was an engine-turned lathework which had often been used as a background of bank notes. To use this on the stamp, a die block was impressed with the proper amount of the geometric pattern from the transfer roll. (This same transfer roll was later used to make the background for the Cape of Good Hope triangular stamps of 1853, the St. Vincent one-crown stamps of 1880, and the New Zealand George V series of 1915. It is now in the possession of the Royal Philatelic Society of London.) The size was marked off, and the space for the portrait of the queen was carefully marked. The pattern was transferred to a roll and the space for the queen's head and the unused portion burnished clean. The roll was then

entered on a new die block. The portrait chosen was that engraved by W. Wyon of the royal mint for the medal struck commemorating the queen's first visit to the city of London, in 1837. Henry Corbould made the drawing, and the engraving was made directly on the die by the Heaths, Charles and Frederick. The first die was not used, a second being made. Above the head was a panel with the word "Postage," the upper corners were embellished with a cross *pattée*; below was a panel with "One Penny" or "Two Pence"; in the lower corners were initials.

Hill was afraid of counterfeiting—for this reason, the initials were used. Each plate—there were 11 used for the one-penny value and two for the two-pence the first year—contained 240 stamps; each horizontal row of 12 was therefore valued at as many shillings as the single stamp was worth pence. There were 20 rows, each full sheet being worth in pounds what each stamp was valued in pence. The lower right hand corner of the stamps was lettered, "A" for the first vertical row, "B" for the second, and so up to "L" for the 12th; the lower left corner was similarly lettered "A" for the first horizontal row, "B" for the second, and so to "T" for the 20th. It was thought that any counterfeiter would use only one or two combinations, and any very frequent recurrence of these would apprise the postal clerks of the attempt.

Neither the envelopes and wrappers nor the stamps were ready in January. Hand stamps were used to mark the letters "paid" until May 6, 1840. On May 1, both stamps and envelopes (including wrappers) were ready—the one-penny being black, the twopence blue—and were put on sale but were not valid for postage until May 6. It was Hill's thought that the envelopes and wrappers would be in demand, and adhesive stamps be merely for the exceptional user. In fact, it was the stamps which were in demand, and the printers worked night and day to keep the offices supplied, while the original supply of the envelopes and wrappers was never exhausted in the year they were available for postage.

In the latter part of 1885 James Chalmers, whose father had been a printer in Dundee, advanced the proposition that Hill had "stolen" the idea for the adhesive postage stamp from the elder Chalmers. An unpleasant controversy arose—since both of the principals were dead—which was scotched by Chalmers's own evidence, which gave the date of his father's suggestion as after Hill's (quoted above) had been read into evidence before a parliamentary committee. However, from time to time, copies of Chalmers's vitriolic pamphlets come into the hands of newcomers to philately and provide another tempest in the teapot.

Although Hill's estimate of the loss of revenue was greatly surpassed by the facts—it reached £1,000,000 in 1840 instead of the estimated £300,000—there was never any serious question of reverting to the old system. Prepaid postage, and with it the "adhesive label," which later became the postage *stamp*, had become accepted.

The Usage Spreads.—In 1843 the empire of Brazil issued three values of postage stamps, becoming the second government to use them. These stamps did not contain the portrait of the emperor, but large figures of value on a background of engine-turning, and are popularly known as "bull's-eyes." In the same year two Swiss cantons, Zurich and Geneva, issued stamps. That of Geneva was a double stamp: half paid the postage within one commune, the whole paid it within the canton.

The first adhesive stamp in the United States was issued in 1842 by the semi-official "City Despatch Post" of New York city for local carrier delivery. In 1845 several postmasters in the United States issued stamps to facilitate prepayment of letters—New York city issued a five-cent value; St. Louis issued five- and ten-cent stamps (later adding 20-cent); and the postmaster at New Haven, Conn., issued a five-cent envelope. In the succeeding two years, more postmasters issued a similar local label—all with the tacit consent of the postmaster general, since the postmasters were charged with each letter they forwarded "paid" and the issuing of the stamps was merely their own method of bookkeeping. In 1847 the United States issued stamps of five- and ten-cent value and these "Postmaster's Provisionals" were abandoned. Prepayment became obligatory in 1856.

In 1845 the Swiss canton of Basle issued a stamp; in 1847 the British colony of Mauritius issued two values made locally which have become two of the philatelist's most sought-after rarities. In 1848 Bermuda's postmaster issued a provisional similar in purpose to those of the United States offices between 1845 and 1847. France and Belgium issued their first stamps in 1849, as did Bavaria. In 1850 Austria, Hanover, Prussia, Saxony and Schleswig-Holstein in Central Europe, Spain and the three British colonies of New South

FAMOUS POSTAGE STAMPS (TWICE LINEAR DIMENSIONS)

- Confederate States of America, 5-Cent, 1861. The first general issue of the Confederacy
- and 2A. United States, 5-Cent and 10-Cent, 1847. The first postage stamps issued by the United States of America
- Hawaii, "Missionary." Rare first issue of Hawaii
- British Guiana, "One Penny Magenta," the most valuable stamp in the world. This unique copy, issued in 1856, was valued at approximately \$50,000 in 1943
- Great Britain, "Penny Black." The first adhesive postage stamp, issued May 6, 1840
- Brazil, "Bull's Eye." The first stamps issued in the western hemisphere (1843)
- Cape of Good Hope, "Triangle." Though most types of this design are not rare, they have been sought after by philatelists since they first appeared in 1853
- United States, "24-Cent Inverted Center Airmail." Only one sheet of 100 of this stamp with the plane upside down reached the public, purchased originally in 1918 for \$24. The total value of the stamps in the sheet rose to approximately \$250,000 by 1943
- United States, "\$1.00 Trans-Mississippi." This early commemorative stamp (1898) is noted by collectors as one of the most beautiful
- Switzerland (Canton of Basel). This first issue of Basel became a favourite of collectors

FAMOUS POSTAGE STAMPS (1 1/2 TIMES LINEAR DIMENSIONS)

1. Belgium, "Astrid Mourning Stamp." This beautiful stamp was issued as a memorial to Queen Astrid immediately after her accidental death in 1935.
2. Germany, "50,000,000,000 Mark." Issued during the inflation of 1923
3. Canada, "Bluenose." This postal portrait of the yacht "Bluenose" has been considered by philatelists as among the most beautiful of stamps
4. Guatemala, "U.S. Constitution Issue." A "miniature" or "souvenir sheet." The stamps comprising such sheets are good for postage, but most sheets are sold intact to collectors. (This sheet is reproduced in actual size)
5. India (Bhor state). An example of oriental stamp design
6. St. Louis, Mo.. "Bear." An example of a "postmaster's provisional," issued privately by the postmaster in 1845 before the United States had a general issue of stamps. Other cities using such provisionals included Alexandria, Va., Annapolis, Md., Baltimore, Md., Boscawen, N.H., Brattleboro, Vt., Lockport, N.Y., Millbury, Mass., New Haven, Conn., New York, N.Y., Providence, R.I. and Tusculumbia, Ala. Almost all are of great value
7. Mauritius. "Post Office." so called because the words "post office" rather than "post paid" were used in the design of this locally Drinted Provisional
8. Newfoundland. "Hawker." The first stamo issued for a transatlantic airmail flight (April 1919). It was provisionally made by overprinting a regular issue
9. New South Wales, "Sydney View." This first pictorial issue (1850) became a favourite of collectors
10. U.S.S.R., 1937 airmail. An example of modern stamp design

Wales, Victoria and British Guiana all issued stamps. So did the Swiss Federation, replacing the cantonal issue of previous years, for these stamps were valid in all cantons.

The first British stamps bore no country name, being intended only for internal use. Subsequent issues of Great Britain have likewise been content to bear the legend "Postage" without any designation of the country of issue. The first Brazilian issue was also without a name. The Swiss stamps, seeking to avoid giving offense to German-, French- or Italian-speaking Swiss, were likewise without a country name, subsequent issues have avoided argument by carrying the Latin name "Helvetia," or more recently "Confoederatio Helvetica."

After 1850 the remaining countries of the world began to issue stamps, more being added each year. Some countries began with local issues for the larger cities. Others plunged into national emissions. Following World War I there were numerous new countries and subdivisions which issued stamps, while others ceased to exist as stamp-issuing divisions. Even more recently, there have been new countries of issue—Greenland had no need of definitive stamps until 1938; Hatay did not come into existence until 1939, when it issued stamps immediately. In 1940 it became part of Turkey, and its stamps had no further currency.

The Manufacture of Stamps.—Although the first stamps, those of Great Britain, were made by intaglio printing, not all stamps are so made. There are four basic processes of printing used in making stamps—the *engraved*, or intaglio, process, in which the lines to be reproduced are incised into the surface of the plate and inked, while the surface is wiped clean; *typographed*, or letter-press, where the lines to be printed are raised above the surface and inked; *lithographed*, or offset, where the line to be reproduced is drawn on stone (or, more modern, on a metal plate with a surface simulating that of stone) with an oily ink which attracts the oily ink used to reproduce it, which in turn is repelled by water on the rest of the stone; and *embossed*, where the paper is raised by an incised die struck against a soft platen or "force."

The first stamps were printed on a sheet of paper with no provision for separation one from the other. This required recourse to a knife or scissors to secure individual stamps. Such stamps are known to collectors as *inziperforate*. In 1847 an Irish engineer, Henry Archer, offered a machine to provide stamps with separations. A toothed wheel cut a series of scallops between the stamps, permitting easy tearing of the sheet. Experiments were made by the British post office, and in 1848 the machine was put in service. However, the wheel used to cut the scallops soon became blunted, and also cut the table to pieces rapidly. A new set of wheels with lancet-shaped knives fared little better, so, in 1849, Archer introduced a machine that punched tiny holes between the rows of stamps. Such sheets as were not ruined in experimenting were sold in the regular course of business by the post offices. In 1854 the machine was so far perfected that all British stamps were perforated thereafter.

Philatelists differentiate between these various methods of separating stamps. The first method, which cuts the paper between the stamps but does not remove any of it, is called *rouletting*, and is further differentiated by the pattern of the cutting: *serpentine*, *scalloped* (or *en arc*), *saw-toothed* (or *en scie*), *straight-line* (or *en ligne*), etc. When small portions of the paper are removed, it is termed *perforated*. These, with *inziperforate*, make up the three main classes of separation of stamps.

Philatelists further differentiate stamps by their perforations. To many—though not all—collectors a difference in the number of perforations creates a separate, collectible variety. To obviate differences caused by slight variations in the dimensions of stamps, philatelists measure the number of perforations in 20 mm. Thus, "perf. 12," means that there are 12 holes counted in 20 mm., and so on. Roulettes are similarly counted.

The first stamps, as recounted, were made by private contractors under governmental supervision. Great Britain still contracts with private companies for supplies of stamps. The United States began by contracting for both postage and revenue stamps but, after the Civil War, the treasury department began printing its own tax stamps at the bureau of printing and engraving. In 1885 this bureau bid on the postage stamps, but lost to a private concern, the American Bank Note company. In 1894, however, the bureau was low bidder, and since that time has produced the postage stamps as well as the revenue stamps, hanknotes, currency and bonds.

France also began with a private contractor, and after 28 years transferred the production of stamps to the national mint. Many countries have followed Britain's lead and entrusted their stamps to private concerns—Perkins, Bacon and Co., who produced Britain's first stamps, also produced the original issues of many others. For Chile, for example, they printed the first issue in sheets of the same dimension and layout as the first British issue—which made bookkeeping rather difficult for the Chileans, who use a decimal currency. The British stamps, owing to the pound-shilling-pence currency, are in sheets of 240. Most countries with decimal coinage use sheets of 100.

Stamp Collecting.—No one can say with certainty when stamp collecting began. It must have been subsequent to May 1, 1840, when the first postage stamps were put on sale. The earliest reference to it is in the advertisements of the London *Times* in 1841: "A

young lady, being desirous of covering her dressing-room with cancelled postage stamps, has been so far encouraged in her wish by private friends as to have succeeded in collecting 16,000. These, however, being insufficient, she will be greatly obliged if any good-natured person who may have these (otherwise useless) little articles at their disposal, would assist her in her whimsical project. Address to E.D., Mr. Butt's, Glover, Leadenhall Street; or Mr. Marshall's, Jeweller, Hackney."

That this mania for accumulating, if not collecting, was rather widespread within the year is evidenced by this paragraph in *Punch*, 1842: "A new mania has bitten the industriously idle ladies of England. To enable a wager to be gained, they have been indefatigable in their endeavors to collect penny stamps; in fact they betray more anxiety to treasure Queen's heads than Harry the Eighth did to get rid of them!"

Accumulation led to collecting, in all probability, though there is no evidence of just how or where it started. From the practically simultaneous outbreak of evidence in 1862, it seems evident that collecting was spontaneous and not confined to any one region. Great Britain, France, Germany, Belgium and the United States seem to have had collectors prior to that year.

In the British magazine *Notes and Queries* of June 23, 1860, appears a letter from a schoolmaster recounting that one of his pupils had a collection of 300 or 400 different stamps, and that "Sir Rowland Hill had told him at that time there might be 500 varieties on the whole." He suggests that a list of stamps would be useful and asks if there be any shop in London where stamps were sold and which had a list available. The identical idea must have been surging in other lands, for at that very moment the first recorded catalogue of stamps, one in manuscript, was being issued by Oscar Berger-Levrault in Strasbourg, France. In 1861 he issued his list, *Timbres-Poste*, by lithography from manuscript, while in Paris Alfred Potiquet published a *Catalogue des Timbres-Poste Créés dans les Divers Etats du Globe*. The acceptance of the lists must have been immediate, for Berger-Levrault issued a second edition of his later in the year. In Jan. 1862 M. Moens of Brussels, Belgium, issued his *Manuel du Collectionneur*. In England, Frederick Booty, Dr. Gray and Mount Brown all issued catalogues in 1862, and owing to lack of proper copyright a pirated edition of the latter, listing 1,200 varieties, was issued by A. C. Kline in Philadelphia. Mount Brown issued two more editions of his catalogue, the third edition of 1866 listing 2,400 varieties, inclusive of what is now termed "postal stationery," or envelopes, wrappers and letter sheets, as well as many local issues. In contrast, the standard catalogues of today exclude this latter material and yet the total number of listings, including minor varieties, approaches 180,000.

The first stamp albums were also issued in 1862. Justin Lallier was the genius who originated them in Paris, but he had both French and English editions. He rapidly increased his albums, adding each new variety of which he could learn, and for some years held first place among collectors for the completeness and arrangement of his books. In the latter part of the decade (*circa* 1867) he began to add information about stamp-collecting and lists of literature.

E. Stanley Gibbons issued a catalogue in 1863; the *Gibbons' Catalogue* is one of the major catalogues of Great Britain today. It is issued in two major forms—one a complete list of major and minor varieties, the other a simplified listing cataloguing only major varieties, without reference to differences in paper, shade, watermarks, etc. The former approaches 180,000 listings, the latter is close to 70,000. Another popular catalogue in Great Britain is *Whitfield King's*. In France, the standard is *Yvert et Tellier-Champion*, which is also widely used in Latin America. Germany has three widely used catalogues: *Senf, Michel* and *Kohl*. Switzerland is partial to *Zumstein*, published there. The *Scott Catalogue* of the United States, originating in 1863, is the standard work in that country and in Canada vies with the British catalogues. The same publisher also issues an annual catalogue of United States stamps, specialized most highly and replete with available information on the issues of the country. Both in Great Britain and the United States there are also special catalogues of airmail stamps.

Since the first postage stamps, there have been many stamps issued for other postal charges than letter carrying. The standard catalogues list some 60 varieties of stamps, including ordinary postage. For letters, there are *airmail*, *special delivery*, *registry*, *insured* and *acknowledgment-of-receipt* stamps, *late fee* and *official* stamps—among others. Postal stationery includes *envelopes*, *wrappers* and *postal cards*; and *revenue* and *telegraph* stamps are also sometimes collected.

Airmail stamps are issued especially for letters to be airborne. Italy issued the first of these for an experimental flight in 1917; the first regular issue was that of the United States the following year. Almost every country has issued them since, with the exception of Great Britain and its colonies, though in these countries certain values of the regular postal issues are of denominations primarily for airmail use. *Special delivery*, *registry*, *insured* and *acknowledgment-of-receipt* stamps are for payment of the special fees levied for these services. *Late fee* stamps are sometimes issued to pay the extra postage for letters mailed after the closing of special mails which can, by paying this extra charge, be included. *Official* stamps are issued for the use of governmental departments. Formerly widely

used, they are now largely supplanted by printed franks.

Senzi-postal stamps are issued at a premium over their letter-carrying value, the overage going to some official or semi-official charity. *Postage due* stamps indicate the amount a letter lacks of full payment of the charges, which is collected on delivery. *News-paper* and *parcel post* stamps are for the special duties indicated.

Commemorative stamps are regular postage stamps issued to commemorate some historical or other event to which the government wishes to give prominence. They are a species of governmental propaganda. The first stamps of this kind were issued by New South Wales in 1888, on the 100th anniversary of the founding of the colony. Four and five years later, Argentina (1892) and the United States (1893) issued stamps commemorative of the 400th anniversary of the discovery of America. In 1897 Great Britain and Canada signalized the diamond jubilee of the queen's coronation. Since then, the practice has become universal.

The Philatelic Vocabulary.—As in most hobbies, philatelists use words with special meanings pertinent to their collecting. Some of these words have been coined, others are words from current usage twisted to specific connotations. Many words in the philatelic vocabulary have been internationalized from the French.

Surcharge is a French word which means *overprint*. Either of these terms is used by philatelists to refer to a stamp that has been printed over to change one or several of the original qualifications. Stamps are often surcharged to change the value, usually because there is a shortage of a needed denomination and a surplus of another. Stamps are also surcharged to change the country—such as stamps of one nation used in the territory of another in war or after cession. Another surcharge is applied to change the use of stamps—a revenue stamp may be surcharged for postal duty. Stamps that have been withdrawn have been surcharged to make them valid again.

Precancelled stamps are a particular form of surcharge, a cancellation applied before sale to the user. Only those with special permits are allowed to use precancelled stamps, and these must be employed under strict regulations. They are intended to save unnecessary labour by the post office clerks, and are usually applied to parcels that would require hand cancelling, or for large mailings of identical pieces, or for newspapers or periodicals. Rarely are they used for letters, and then only under special permits and with a proviso that they must be *postcancelled*, i.e., cancelled on the letter as well as precancelled.

Bisects are stamps that have been cut in half—or smaller bits—to serve as postage, such as the 3-cent of the 1869 U.S. issue which was bisected (trisected would be a better term, but philatelists stick to "bisect") to permit the mailing of a number of forms that called for only two cents postage. Such bisects are usually collected only when on the original envelope or mailing piece, and then with a cancellation identifying them with the letter. Some bisects have been also surcharged with the new irrational value—in such case they bear their own proof of *bona fide* and do not need the supporting evidence of the letter. *Postal markings* are the cancellations, postmarks and other hand or machine stampings applied by the post offices to the letter or piece of mail.

A *cover* is the outer wrapping of a piece of mail—the envelope or outer side of a folded sealed letter or the wrapper of a packet. A stamp is *tied to cover* when the cancellation or other *postal marking* falls partly on the stamp and partly on the cover.

Mint is the condition of a stamp as it comes from the post office, with its original gum undamaged and without blemish on its face. A stamp which has lost its gum, but is otherwise unblemished is spoken of as *unused*—no gum, save in rare instances when there was originally no gum, in which case it is still *mint*.

Se-tenant stamps are two or more unsevered from each other. The term is usually applied to unusual pairs or larger pieces in which one or more of the stamps differs from the other. Sometimes two denominations of stamps will be printed in one sheet and a pair of stamps of the different denominations would be described as "a *se-tenant* pair." Or, occasionally, plates have been made with one stamp entered upside down. Such a stamp is said to be *tête-bêche*, and can only be identified when *se-tenant* with one or more of the normal stamps.

A *grill* or *grille* is the impression of a knurled roller on a stamp to break the fibres of the paper so the cancelling ink will soak in and prevent washing to reuse.

Double transfer in engraved stamps is where the impression on the printing plate, either through shifting in the transfer press or an attempt to *re-enter* and deepen the impression has caused portions of the entry to have double lines.

Double impression is where the sheet of paper was put through the press twice, the second imprint shifting slightly from the first one.

Miniature sheet has two meanings. The first is a form of collecting where stamps from the corners, sides, top and bottom are put together to show every possible variety the sheet possesses—nine stamps from a U.S. sheet of 100 would give this effect. More commonly, however, the term is applied to little sheets of 25, 10 or fewer stamps issued as souvenirs of an occasion or a national event. These are also known as *souvenir sheets*.

Coil stamps are issued in long coils—usually 500—for use in mailing or vending machines. Some countries, notably Sweden, prefer coils for post-office clerks in place of sheets, as they are easier to store.

The stamps are usually imperforate on top and bottom (or the two sides) and perforate between the stamps. If imperforate top and bottom, they come from *horizontal coils*: if imperforate on the two sides, from *vertical coils*.

A *block* consists of four or more stamps *se-tenant* so that the horizontal and vertical separations are untouched. Thus, a block of four stamps can only be arranged two wide by two deep.

Plate numbers are sometimes put on the margins of plates, and thus are printed on the sheets, to identify the plate. Sometimes, as with many issues of Great Britain, they are worked into the design and appear on every stamp.

Inverted centres are only possible where two or more plates are used to make a stamp, which is the case when the stamps have two or more colours. Occasionally a sheet will be reversed when passing through the second press, and the centre will be inverted in relation to the frame—though actually the centre may have been printed first, and strictly speaking it is an "inverted frame."

Reprints are stamps printed from the original plates after the stamps are no longer valid for postage. The only reason for doing this is to sell the stamps to collectors, and reprinted stamps are accordingly generally deprecated by philatelists. A few governments have been guilty of this practice, but some of them have been persuaded to allow private parties to indulge. The most notable cases were those of certain Central and South American governments which, in the last decade of the 19th century, entered contracts with the Hamilton Bank Note company, of New York, by which the company furnished a complete series of stamps each year, and after the stamps had been demonetized, was permitted to sell the remainders and such other stamps as it wished to make from the plates. These issues, called *Seebecks* after the president of the company, have suffered accordingly. Certain African countries made similar contracts more recently.

Reprints should not be confused with *reissues*, which are made by governments of stamps which still have franking power, and which irregularly are more scarce and valuable than the original issues.

Remainders are stamps left in the hands of governments after they have been demonetized. Sometimes these remainders are sold in bulk, and accordingly depress the value of unused stamps.

Philatelists are deeply conscious of the kind of paper used for stamps. Chief item in paper-making for stamps is the *watermark*. The watermark is a sign or symbol made in the paper as it is manufactured, exactly as the watermarks in fine bond papers—those thin places that make words or trademarks when you hold a sheet up to the light. For stamps, they may be spaced so as to fall on each particular stamp, or run through the sheet in a recurring pattern, or to fall with one quarter on each stamp, a block making a full pattern. Typical watermarks are the small crown that appears on each of the 1840 stamps of Great Britain, or the "crown and C A" on many colonial stamps; the "USPS" used by the United States between 1895 and 1915, a letter or part of one letter falling on each stamp; or the wavy lines used by Bavaria for early issues, which fell on each stamp and in the margins as well.

Basically, paper is *wove* or *laid*. Wove paper is made on a woven screen, and either presents no appearance other than general opacity when held to the light, or dimly resembles a tiny network, as a woven screen greatly reduced. If the screen be strengthened with heavier wires evenly spaced in one direction, it becomes a laid paper, with these *lay-lines* showing. If these be exceptionally heavy, it is called *batonne* paper, and if the heavy batons be placed perpendicular to lay-lines it is *laid batonne*. A thin onion-skin paper sometimes used for stamps is called *pelure* paper. Paper in which coloured fibres are used, presenting a gray or mottled appearance, is termed *granite* paper. *Silk* paper has tiny threads of coloured silk worked into it, and *silk-thread* paper has one or two very noticeable silk threads laid lengthwise or across it falling on each stamp.

As an example of what constitutes a "different stamp" to collectors, consider the 1-cent green stamp of the United States, issued first in 1912. It was watermarked "single-line USPS," and perforated 12. Also, there were vertical and horizontal coils, perf. 8½. In 1914, still watermarked, it was issued perf. 10, but there were some that were issued perf. 10 vertically and perf. 12 horizontally, and some perf. 12 vertically and perf. 10 horizontally. There were also vertical and horizontal coils, perf. 10. In 1915, the same two coils were issued from plates curved to fit a rotary press; each stamp thus became approximately one millimetre larger in the direction of curvature. In 1916, they were again issued, this time on unwatermarked wove paper, still perf. 10, and also two coils. There were also some issued imperforate, for use in patented mailing machines. Finally, in 1917, they were issued on unwatermarked paper, perf. 11. The same stamp, to all outward appearances, but 15 varieties to the philatelist!

Specialization.—When Mount Brown's catalogue listed 2,400 stamps (1866), a modest collection of 2,000 varieties would contain more than 80% of all stamps. A similar proportion today would necessitate 150,000 varieties. Because of the sheer bulk of such a general collection, most collectors today turn to more or less limited collecting, usually termed *specialization*. For example, they may collect only the stamps of one country, or stamps of one continent, or stamps of one period. Others specialize in collections of certain kinds of stamps—some collect only one issue and study it thoroughly, others

may collect only revenue stamps, or postal stationery, or even Christmas seals, which are not, properly speaking, stamps at all.

Christmas seals were invented by a Danish postal clerk, Anton Hølmboe, in 1903, as a source of revenue for an anti-tuberculosis society. They were used on packets and letters sent at Christmas, and sold for a small sum, the money going to the society. The use spread to the other Scandinavian countries and to the United States, where they are issued each year. While they have no franking power, they are widely used and often collected.

The collecting of one issue, or even of one stamp of an early issue, is one of the deepest studies of philately. The early stamps, especially the engraved ones, were often retouched after transfer, so that each stamp on each plate had minute identifiable characteristics. For instance, it is possible to identify each of the 2,640 specimens of the Great Britain one-penny of 1840—and this is easy, compared to other issues, because the plate position is identified by the check-letters in the corners. It is also possible to identify most of the 2,600 varieties of the 3-cent United States stamps of 1851. This has led to "plating"—the reconstruction of the original sheet, which in turn has led to many interesting discoveries of the ways in which sheets were laid out and manufactured. Dr. Carroll Chase, of New York, so correctly reconstructed the plates of the 3-cent U.S. stamp of 1851 that when an original sheet was found, intact, it was exactly as his studies had indicated.

Specialization in 20th century stamps has been given aid by the establishment of "philatelic agencies" by governments, to sell selected specimens to collectors. The United States established the first of these in 1921, and the success was soon apparent, so that similar agencies were established by many European countries. Russia made traffic in stamps a government monopoly, and Germany followed suit with the establishment of the Nazi party in power. In 1942, the U.S. placed revenue stamps on sale at a special agency for collectors.

The collection of postal markings, both on stamped and pre-stamp covers, is a form of specialization, and the collecting of pre-cancelled stamps is another. *Meters*, machines which print a postal frank on the envelope, have given rise to yet another specialized form. *Telegraph* stamps, issued to prepay telegrams in certain countries, are also collected, usually by specialists.

The forms of specialization are limitless, and the ingenuity of collectors is ever discovering new and individual methods.

Famous Collections.—During the years, many famous collections have been made. Many of these have been dispersed, and passed into others, more or less famous. One of the most famous of all times was the collection of M. Philippe la Rénouillère von Ferrari, an Austrian Subject resident in Paris. During World War I he fled to Switzerland, where he died in 1917. His property was seized by the French government and his collection, which he had formed during 40 years, was sold at auction, realizing more than 26,000,000 francs (£400,000 or \$2,000,000 at the rates of exchange of the day). One unique stamp, the 1-cent British Guiana magenta of 1856, brought approximately \$37,000 when purchased by Arthur Hind, of Utica, N.Y.

Hind's collection, which included the Duveen collection of Mauritius and the Griebert collection of Spain, was sold in 1933-34, after his death. Exclusive of the British Guiana, it brought a gross return of nearly \$1,000,000, in the depth of the world-wide financial depression. The British Guiana stamp was sold by private negotiation for a price reputed to be in excess of \$45,000—the highest price ever recorded for a single stamp.

The outstanding collection in Europe in 1942 was the private collection of H.M. George VI, king of Great Britain. Principally formed by George V, who was a famed philatelist, it was especially rich in British and colonial issues.

There were several famous collections in the United States, but none of them comparable to Hind's accumulations. One of the most bizarre was being sold in 1942-43. It was formed by the late Col. E. H. R. Green, and was especially rich in unusual materials, such as quantities of the "blue-paper" issues of the U.S., the only position blocks of the 24-cent airmail with inverted centre (U.S., 1918) and a number of sheets of the imperforate j-cent carmine error (U.S., 1915). Still in their owners' hands (1942) are the Saul Newbury collection (Chicago), and the Lichtenstein, Steinway and Casparri collections (New York).

The famed Tapling collection was bequeathed to the British museum, and may well be the finest in public hands. The Smithsonian institution collection at Washington, D.C., is especially rich in U.S. stamps, and both Brown university (Rhode Island) and the New York Public Library have been bequeathed fine collections. The postal museums of many European capitals have outstanding collections—Germany, at Berlin; The Netherlands; at Sgravenhage; and the Swedish museum at Stockholm, enriched by gifts from Hans Lagerlof, of New York, are instances.

Philatelic Societies.—Clubs or societies of collectors are to be found in most cities of the world. The American Philatelic society in the United States was founded in 1886, and counted some 5,000 members in 1943. The Society of Philatelic Americans, which had about 3,000 members in 1943 was founded in 1894. The Royal Philatelic society of London is older; it was founded in 1869 and became Royal in 1906. More nearly equivalent to the two American societies is the Junior Philatelic society of England, founded in 1899; and the

American "opposite number" of the Royal is the Collectors' Club of New York. In France, the earliest society was the Société Française de Timbrologie; the more recent Académie de la Philatelie is the leading research group.

In the United States, the philatelic societies are loosely associated in the National Federation of Stamp Clubs, which has not been a major factor save as organizer of one national and several regional stamp exhibitions. In both England and the United States, there are Philatelic congresses, which meet annually.

Stamp Exhibitions.—One of the principal purposes of stamp clubs seems to be the holding of exhibitions from time to time. On a larger scale, the national societies hold annual exhibitions, with awards for exhibits selected by qualified judges.

So international is the collecting of stamps that from time to time there are international exhibitions. In the United States there exists the Association for Stamp Exhibitions, Inc., which sponsored international exhibitions in 1913, 1926 and 1936. The Junior Philatelic society sponsored such in Great Britain in 1913, 1923 and 1932, and the Royal Philatelic society was arranging for one to celebrate the centenary of postage stamps in 1940, which was cancelled because of the outbreak of World War II. One was held in Rio de Janeiro, Brazil, 1938. Others have been held in Vienna (1933), Paris (1925 and 1937), Koenigsberg (1935) and Buenos Aires (1939).

Philatelic Literature.—Perhaps no hobby has been so prolific of literature, both permanent and ephemeral, as philately. The standard catalogues (*see above*) issued annually are generally minor cyclopaedias of the hobby, but there are and usually have been journals in every language, some of which lasted one issue, others ran to 100 issues, some seem to last indefinitely, and all gradations.

It is difficult to speak specifically of monthly or weekly publications, for so many are born but to die anon. The first one of record that was specifically devoted to philately was the British *Monthly Intelligencer*, born Oct. 1862; died three months later. In Dec. 1862 appeared the British *Monthly Advertiser*, which appeared in Jan. 1863 as *The Stamp Collector's Review*. It lasted nearly two years. Moen's, of Brussels, Belgium, published the *Tinzbre-Poste* for many years, starting in 1863, in which year the German *Magazin für Briefmarken-Sammler* began. In 1874 John K. Tiffany published *The Philatelic Library*, a catalogue of philatelic literature in his extensive private library in St. Louis, Mo., U.S.A. This collection of books he afterwards sold to the earl of Crawford, who combined it with his own extensive holdings and bequeathed all to the British museum.

Among the journals founded in the 19th century and still extant are *Mekeel's Weekly Stamp News* (founded 1892) and the *American Philatelist* (published by the American Philatelic society, founded 1887, but with two lapses since), in the U.S.A.; *The London Philatelist* (published by the Royal Philatelic society) and *The Stamp Collectors' Fortnightly*, in England; and *Echoes de la Timbrologie*, in France.

There have been many books on stamp-collecting, especially in specialized fields. Since these appeal to a limited public, they are issued in small editions and few remain long in print. However, they remain in the libraries of the various societies and in private hands, and sometimes come on the market when a collection is sold, for your philatelist usually treasures one or two philatelic books along with his stamps.

BIBLIOGRAPHY.—For an index to philatelic literature: E. D. Bacon, *Catalogue of the Library of the Earl of Crawford, K.T.* (1911) and supplement (1926); *The Philatelic Index* (1925) and supplements. General and introductory: Mannel Hahn, *So You're Collecting Stanzps!* (1940); F. J. Melville, *Modern Stanzp Collecting* (1938); Stanley Phillips, *Stanzp Collecting* (1934) and *Postage Stanzps and Their Stories* (1936). For specialized collecting: John Luff, *The Postage Stanzps of the U.S.* (1905, with a revised edition in preparation, 1942); Dr. Carroll Chase, *The U.S. 3-Cent Stanzp of 1851-57* (1929); Stanley B. Ashbrook, *The U.S. One-Cent Stanzp of 1851-57* (2 vols., 1938); including Dr. Clarence Brazer, *Proofs & Essays*; Elliott Perry, *Carriers and Carrier Markings*; and Mannel Hahn, *The U.S. Post Office, 1851-60*, and *The U.S. 10-Cent Stanzps of 1855-57* (1935); Beverly King and Max Johl, *The U.S. Postage Stanzps of the XX Century* (4 vols. 1933-38); Delf Norona, editor, *Cyclopedia of U.S. Postmarks* (1933); Harry M. Konwiser, *U.S. Stampless Cover Catalog* (3rd ed., 1942); J. B. Seymour, *The Stanzps of Great Britain* (1937); Edw. Denny Bacon, *The Line-Enguved Postage Stanzps of Great Britain* (1920); Chas. Nisson, *The Plates of the Penay Black of 1840* (1916). Forgeries and frauds: Rev. R. B. Earee, *Album Weeds* (1906); F. J. Melville, *Phantom Philately* (1923); Fritz Billig, *Falschungen* (1928). The first deals with forgeries and tests for the originals and the forgeries; the second deals with stamps "without a country," issued to defraud collectors; the third is a series of monographs, some 36 in number, written in German and first issued in Vienna, but the plates were saved by the author when forced to flee to the United States, where these are now printed. They cover the early German and Italian states, the countries of the Balkans, Belgium, Congo, Luxembourg and Russia. (M. HA.)

PHILEMON (c. 361-263 B.C.), Greek poet of the New Comedy, was born at Soli in Cilicia, or at Syracuse. He settled at Athens early in life, and his first play was produced in 330.

He was a contemporary and rival of Menander, whom he frequently vanquished in poetical contests. He lived at the court of Ptolemy, king of Egypt, for some time. Plutarch (*De Cohibenda Ira*, 9) relates that on his journey he fell into the hands of king Magas of Cyrene, whom he had formerly satirized. Magas treated him with contempt, and finally dismissed him with a present of toys. Various accounts of his death are given. Of ninety-seven plays, the titles of fifty-seven and considerable fragments have been preserved. Some of these may have been the work of his son, the younger Philemon.

See A. Meineke, *Menandri et Philemonis reliquiae* (1823, including Bentley's emendations); T. Kock, *Com. graec. frag.*, vol. iii. (1884).

PHILEMON, EPISTLE TO, a New Testament book. A short personal note by the apostle Paul has been preserved, which owes its origin to a romantic episode in the life of a slave, called Onesimus. For some reason he had run away from his master Philemon, a prosperous Christian citizen; it may be inferred that he had also been guilty of pilfering (ver. 18). For either offence he was liable by law to be crucified. In some unexplained way he had come across Paul and been converted to Christianity. This opened a difficult situation. The apostle boldly solved the problem by sending Onesimus back along with Tychicus, who was going to Colossae with Paul's letter to the local church; "I send him with Onesimus, that faithful and beloved brother, who is one of yourselves" (Col. iv. 9). But, not content with this certificate in favour of the converted and penitent slave, Paul sends also a note to his master, bespeaking his Christian interest in Onesimus. It is a brief letter, tactful and charming, in which the apostle, after greeting Philemon and his wife and the local church that met in his house, rejoices over Philemon's character, which, he says, emboldens him to enter a plea for poor Onesimus, now returning to his duty, a very different man from what he was when he ran away. Paul delicately suggests that he would like to have kept the slave beside him, and offers to be responsible for any debts incurred by Onesimus. He hints that this generous action on the part of Philemon will be a personal kindness to himself as well as to the slave. "You count me a partner? Then receive him as you would receive me, and if he has cheated you of any money or owes you any sum, put that down to my account. This is in my own handwriting. I Paul promise to refund it"—not to mention that you owe me, over and above, your very soul. Come, brother, let me have some return from you in the Lord. Refresh my heart in Christ."

Where the letter was written, we do not know. Rome was a natural place of refuge for runaway slaves, who could lose themselves in the huge population easily; if Colossians was written from Rome, so was this note. Where Philemon stayed is also uncertain; he may have been resident at Laodicea or at Ephesus, for though Onesimus accompanied the letter to the Colossian church, it does not follow that Colossae was the seat of his master; indeed as Philemon was converted by Paul, that cannot have taken place at Colossae, which Paul had never visited. Still, Philemon may have shifted his quarters to Colossae.

The letter appears in two second century canons, that of Marcion and the Muratorian, though its lack of dogmatic importance as well as its brevity threw it afterwards into some disfavour among certain circles of the Church.

BIBLIOGRAPHY.—The letter is edited in most commentaries on Colossians (*q.v.*), and by Dr. M. R. Vincent in his edition of Philippians (*International Critical Commentary*, 1897). There are special editions by Rothe (*Pauli ad Philemonem epistolae interpretatio historico-exegetica*, Bremen, 1844), van Oosterzee (*Eng. Tr.* New York, 1868), Oesterley (*Expositor's Greek Testament*, 1910), and others. The social problems of the letter are discussed by Lightfoot in his *Commentary on Colossians*; by J. H. Bernard in *Hastings' Dictionary of the Bible* (iv. 832f.), and in Renan's *L'Antéchrist* (pp. 931). (J. MOR.)

PHILEMON AND BAUCIS, in Ovid (*Metam.*, viii. 610 ff.) a pious Phrygian couple, who hospitably received Zeus and Hermes (for their combined cult in Lycaonia cp. Acts, 14, 12), when their richer neighbours turned them away, they being disguised as wayfarers. As a reward, they were saved from a flood which drowned the rest of the country; their cottage was turned into a temple, and at their own request they became priest and priestess of it, and long after ended their lives at the same mo-

ment, being turned into trees. The story which is a *Märchen* of a well-known type, e.g., *Grimm Kinder- und Hausmärchen*, 87, with the commentary of Bolte-Polivka, combined here with a version of the flood-myth, is perhaps really of local origin, see Calder in *Discovery*, 1922, p. 207 ff.

PHILES, MANUEL (c. 1275-1345), of Ephesus, Byzantine poet. At an early age he removed to Constantinople, where he was the pupil of Georgius Pachymeres, in whose honour he composed a memorial poem. Having offended one of the emperors by indiscreet remarks published in a chronography, he was thrown into prison and only released after an abject apology. Philes' character, as shown in his poems, is that of a begging poet, always pleading poverty, and ready to descend to the grossest flattery.

Editions: the natural history poems in F. Lehrs and F. Diibner, *Poetae bucolici et didactici* (Didot series, 1846); *Manuelis Philae Carminis inedita*, ed. A. Martini (1900); *Manuelis Philae Carmina*, ed. E. Miller (1855-57). See also C. Krumbacher, *Geschichte der byzantinischen Literatur* (1897).

PHILETAS of Cos, Alexandrian poet and critic, flourished in the second half of the 4th century B.C. He was tutor to the son of Ptolemy I. of Egypt, and to Theocritus and the grammarian Zenodotus. His thinness made him an object of ridicule; according to the comic poets, he carried lead in his shoes to keep himself from being blown away. His elegies, chiefly singing the praises of his mistress Battis (or Bittis), were much admired by the Romans. Philetas was also the author of a vocabulary called *Ἀρακτα*, explaining the meanings of rare and obscure words, and of notes on Homer, severely criticized by Aristarchus.

Fragments cited by N. Bach (1828) and T. Bergk, *Poetae Lyrici Graeci*; see also E. W. Mande, *De tribus Philetas carminibus* (1895).

PHILIDOR, FRANÇOIS ANDRE DANICAN (1726-1795), French composer and chess-player, was born at Dreux, on Sept. 7, 1726. He spent many years in travelling on the Continent and in England, meeting and defeating the most noted players of the time, and was regarded as the strongest player and greatest theoretician of the 18th century. Returning to France in 1754, he devoted himself seriously to music, and after producing several works of minor importance brought out at Paris, in the year 1776, his successful light opera, *Blaise le Savetier*, which was followed by a number of others. He died in London on Aug. 31, 1795.

PHILIP, one of the 12 apostles. See APOSTLE.

PHILIP, "the evangelist," is mentioned in Acts vi. 5, as one of "the seven" chosen to superintend certain secular business of the Jerusalem Church, in consequence of dissension between the Aramaic-speaking and Greek-speaking disciples. Luke by mentioning the common meals wishes his readers to connect these officials with the later diaconate, but they seem to have been originally parallel among the Hellenistic Jews to the Twelve among the Hebraists. Philip's was a ministry of the word. He went to Samaria and preached with much success, Simon Magus being one of his converts. He afterwards instructed and baptized the Ethiopian eunuch on the road from Jerusalem to Gaza. His missionary journey ended at Caesarea (Acts viii.). Here he entertained Paul and his companions on their last journey to Jerusalem (xxi. 8). (W. K. L. C.)

PHILIP I. (1052-1108), king of France, eldest son of Henry I. of France and Anne, daughter of Jaroslav I. (d. 1054), grand duke of Kiev, came to the throne, when a child of eight, by the death of his father on Aug. 4, 1060. He had been crowned at Reims May 23, 1056. His minority came to an end in 1066. In the long reign that followed he showed no great ability or energy, and a looseness of morals which embroiled him with the Church. Before he was fifty years of age he became "fond of nothing but good cheer and sleep." But he increased the lands of his house around Paris, maintained order in them, and held his own against William I. and William II. of England, whose power in France far exceeded his own. This he accomplished for the most part by taking advantage of the quarrels among his vassals. During the years 1070-74 he greatly strengthened his position in Flanders by these means. In the struggle between Fulk Rechin and his brother Geoffrey the Bearded for the inheritance of their uncle, Geoffrey Martel (d. 1060), count of Anjou, Philip received

from Fulk in 1069, as the price of his neutrality, Château Landon and the Gatinais. This acquisition linked the county of Sens, acquired in 1055, with the rest of the domain round Paris, Melun and Orleans. War with William I. and William Rufus was chronic but intermittent. In his last years Philip left the duty of repelling the attacks of his Norman and other enemies to his son Louis, associating him with himself, as "king-designate," some time between May 24, 1098, and Sept. 25, 1100.

It was his second marriage which was the cause of Philip's greatest difficulties. On May 11, 1092, he carried off Bertrada, daughter of Simon, baron de Montfort, wife of Fulk Rechin, and prepared to marry her, though his wife Bertha was still living. The bishops, headed by Ivo, bishop of Chartres, refused to attend the ceremony of marriage, but one was found to perform it. Philip's open simony had long been a cause of friction with the papacy. When he added bigamy and adultery, Urban II. excommunicated him. Philip was reconciled with the Church in 1104, and took an oath not to have any converse or society with Bertrada except in the presence of "non-suspect" persons. But they seem to have gone on living together, and even visited Fulk Rechin (Bertrada's husband) in company on Oct. 15, 1106. Philip died at the end of July 1108.

His reign is chiefly remarkable for the steady growth of the royal domain. By his first queen he had four children: Louis VI., who succeeded him; Henry, who died young; Charles; and Constance, who married Hugh I., count of Champagne, and later Bohemund I., prince of Antioch. By Bertrada de Montfort he had three children: Philip, count of Montes; Fleury or Florus, who married the heiress of Nangis; and Cecilia, who married, first Tancred, prince of Galilee and Antioch, and secondly Pons de Saint Gilles, count of Tripoli.

See the *Recueil des actes de Philippe I.*, ed. M. Pron (1908), and B. Monod's *Essai sur les rapports de Pascal II. avec Philippe I.* (Paris, 1907). For notices of the principal chronicles of the time see A. Moliner, *Les Sources de l'histoire de France* (II., esp. p. 307 et seq.).

PHILIP II. (1165-1223), known as PHILIP AUGUSTUS, king of France, son of Louis VII. and Adela, daughter of Theobald II., count of Champagne, was born on Aug. 21, 1165. On Nov. 1, 1179, he was associated with his father as king by being crowned at Reims, and at once his father's illness threw the responsibility of government on him, the death of Louis on Sept. 19, 1180, leaving him sole king. His long strip of royal domain was hemmed in by the Angevin Empire on the west and by the kingdom of Arles on the south-east. Henry II. of England was feudal lord of the greater part of France, practically all west of a line which began at Dieppe and ended at the foot of the Pyrenees more than half-way across to the Mediterranean, while at one point it nearly touched the Rhone. Philip's predecessors had consolidated the Capetian power within these narrow limits, but he himself was overshadowed by the power of his uncles, William, archbishop of Reims; Henry I., count of Champagne; and Theobald V., count of Blois and Chartres. He secured an ally against them, and an addition to the royal domain, by marrying, on April 28, 1180, Isabella or Elizabeth, daughter of Baldwin V., count of Hainaut, and of Marguerite, sister of Philip of Alsace, the reigning count of Flanders, who ceded, as Isabella's dowry, the district afterwards called Artois. On June 28, 1180 Philip made a treaty with Henry II. at Gisors, but from 1181 to 1185 he had to struggle against a feudal league of his Champagnard uncles and other great barons, whose most active member was Stephen I., count of Sancerre (1152-1191). Having secured his position at home, the king turned against Henry II., and by the truce of Châteauroux in June 1187, gained Issoudun and the seigniorship of Fréteval in the Vendômois. Though the truce was for two years, Philip assembled an army in 1188 to invade Normandy, demanding Gisors and the conclusion of the marriage which had been arranged between his sister Alice and Richard of England, who had meanwhile deserted his father. But Richard took the cross, and Philip seized the county of Berry, part of his dukedom. Further reconciliations and conferences followed, and Henry II., just before his death, did homage and surrendered the territories of Graçay and Issoudun. Henry died two days later. Pledges of

mutual good faith and fellowship were exchanged between Philip and Richard of England on Dec. 30, 1189, and they both prepared to go on the crusade.

The Crusade.—Before setting out Philip arranged for the government of France during his absence by the testament of 1190, by which he proposed to rule France as far as possible from Palestine. On the way to Palestine the two kings quarrelled. At the siege of Acre Philip fell ill, and he returned to Paris at Christmas 1191, having concluded on his way an alliance with the emperor Henry VI. against Richard, despite his pledges not to molest his lands. Philip did his utmost by offers of money to prolong Richard's captivity, and, allied with the English king's brother John, attacked Richard's domains. But upon Richard's return the Normans rallied to him, and Philip was defeated at Fréteval on July 3, 1194. He continued the war, generally with ill success, for the next five years. Again a formidable coalition was formed against him, including Baldwin IX., count of Flanders and Hainaut, Renaud of Dammartin, count of Boulogne, Louis, count of Blois, and Raymond VI., count of Toulouse. In Germany, Otto of Brunswick, afterwards the emperor Otto IV., allied himself with Richard, while Philip was supported by Otto's rival, Philip of Swabia. Richard's death, in April 1199, removed his arch-enemy, and Richard's successor, John, concluded the treaty of Le Goulet with Philip on May 22, 1200, ceding to him the county of Evreux, Graçay and Issoudun, and the suzerainty of Berry and Auvergne. John renounced his suzerainty over Brittany and the guardianship of his nephew, Arthur; he engaged not to aid the count of Flanders or Otto IV. without Philip's consent, paid him a relief of 20,000 marks, and recognized himself as his vassal for his continental fiefs.

Conquest of Normandy.—But in 1202 the war was renewed. At an interview at Le Goulet on March 25, Philip demanded the cession of Anjou, Poitou and Normandy to his ward, Arthur. John refused; he was summoned to Paris before the royal judges, and failing to appear was sentenced at the end of April 1202 to lose all his fiefs. Brittany, Aquitaine and Anjou were conferred on Arthur. Philip invaded Normandy, took Lyons-la-Forêt and Eu, and, establishing himself in Gournay, besieged Arques. But John, joined by William des Roches and other lords of Maine and Poitou, jealous at the increase of Philip's power, defeated and took Arthur prisoner at Mirebeau. Philip abandoned the siege of Arques in a fit of fury, marched to the Loire, burning everywhere, and then returned to Paris. But John soon alienated the Poitevin barons, and William des Roches signed a treaty with Philip on March 22, 1203. Then Philip continued his great task, the conquest of Normandy, capturing the towns around the fortress of Château-Gaillard which Richard had built to command the valley of the Seine. Pope Innocent III. tried to bring about peace, but Philip was obdurate, and after murdering Arthur of Brittany John took refuge in England in December 1203. The fall of Château-Gaillard, after a siege which lasted from September 1203 to April 1204, decided the fate of Normandy. Rouen, bound by ties of trade to England, resisted for forty days; but it surrendered on June 24, 1204. The conquest of Maine, Touraine, Anjou and Poitou in 1204 and 1205 was little more than a military promenade, though the castles of Loches and Chinon held out for a year. Philip secured his conquest by lavishing privileges on the convents and towns. He left the great lords, such as William des Roches, in full possession of their feudal power. In 1206 he marched through Brittany and divided it amongst his adherents. A truce for two years was made on Oct. 26, 1206, by which John renounced all claims in Normandy, Maine, Brittany, Touraine and Anjou, but it did not last six months. Then Poitou was thoroughly subdued, and another truce was made in 1208, little more than southern Saintonge and Gascony being left in the hands of John. Philip had reduced to a mere remnant the formidable continental empire of the Angevins, which had threatened the existence of the Capetian monarchy.

Philip then undertook to invade England. He had collected 1,500 vessels and summoned all his barons when Innocent III., having sufficiently frightened John, sent Pandulf with the terms of submission, which John accepted on the 13th of May.

Disappointed of his hopes of England, Philip turned his arms against Ferdinand, count of Flanders. He invaded Flanders and took the chief towns within a week; but he had part of his fleet burned by the English at Damme, and had to burn the rest to save it from falling into their hands. He returned to Paris, and Ferdinand retook most of the towns which had been taken by the king. A war of fire and pillage began, in which Philip and his son Louis burned their way through Flanders, and Ferdinand did the same through Artois.

The **Victory of Bouvines**.—In 1214 came the great crisis of Philip's life. A league including his rebel vassals, Renaud of Dammartin, count of Boulogne, and Ferdinand, count of Flanders, with the emperor Otto IV. and a number of German princes of the Rhine region, had been formed in the north-east, while John of England made one more attempt to recover his heritage at the head of an army of mercenaries, aided by the fickle baronage of Poitou. John landed at La Rochelle on Feb. 10, 1214, and was at first successful. On June 19 he laid siege to La Roche-aux-Moines, the fortress which defended Angers and commanded the Loire valley; but on the approach of a royal army under Prince Louis on July 2 his Poitevin barons refused to risk a pitched battle, and he fled hastily to La Rochelle. The Angevin Empire in France was lost. Meanwhile Philip himself won his greatest victory at the bridge of Bouvines, among the morasses of Flanders. At first taken by surprise, he turned the abortive attack into a complete rout. Renaud and Ferdinand were taken prisoner, and Otto IV. fled from the battlefield. The army of the allies was utterly destroyed (July 27, 1214). The battle of Bouvines, a decisive battle for the history of Germany as well as for France and England, sealed the work of Philip Augustus. The expedition of his son Louis to conquer England can hardly be considered as an incident of his reign, though he was careful to safeguard the rights of the French Crown. More important was the Albigenian crusade, in which he allowed Louis to take part, though he himself, preoccupied with the king of England, had refused time after time to do anything. He treated Simon de Montfort as if he were a royal *bailli*; but it was not in virtue of any deep-laid scheme of his that in the end Amaury de Montfort, Simon's son, resigned himself to leave his lands to the Crown of France, and gave the Crown a power it had never before possessed in Languedoc.

Organisation of France.—Philip II. surrounded himself with clerks and legists of more or less humble origin, who gave him counsel and acted as his agents. His *baillis*, who at first rather resembled the itinerant justices of Henry II. of England, were sent into the royal domain to supervise the conduct of the *prévôts* and hear complaints, while in the south local feudal magnates were given similar powers with the title of *sénéchal*. Feudal service was more and more compounded for by a money payment, and additional taxes were raised. The extension of the system of *sauvegarde*, by which abbeys, towns or lay vassals put themselves under the special protection of the king, and that of *pariage*, by which the possessor surrendered half the interest in his estate to the king in return for protection or some further grant, increased the royal power. The small barons were completely reduced to submission, whilst the greater feudatories could often appoint a castellan to their own castles only after he had taken an oath to the king.

It has been said with some justice that Philip II. was the first king of France to take the bourgeoisie into partnership. He favoured the great merchants, granting them trade privileges and monopolies. The Jews he protected and plundered by turns, after the fashion of mediæval kings. Amongst the subject towns administered by *prévôts* a great extension of the "custom of Lorris" took place during his reign. Philip was the ally and protector of the communes. Before him they were resisted and often crushed; after him they were exploited, oppressed, and finally destroyed. In the case of Senlis he extended the jurisdiction of the commune to all crimes committed in the district. It is true that he suppressed some communes in the newly conquered fiefs, such as Normandy, where John had been prodigal of privileges, but he erected new communes in his own private domain, quite contrary to the custom of other kings. He seems to have regarded them

as a kind of garrison against feudal unruliness, while the rents they furnished increased his financial resources. He created no new types of commune, however, except Peronne, which received a maximum of political independence, the twenty-four electors, who named the *jurés* and other officers, being elected by the *corps de métiers*.

Philip's policy of building up a strong monarchy was pursued with a steadiness of aim which excluded both enthusiasm and scruple. He shrank from no trickery in carrying out his ends, and had no room for pity. He could not even trust his own son with any power, and was brutal in his relations with his queen, Ingeborg. As the result of his steadiness of aim and patient sagacity, at the end of his reign the Crown was victorious over the feudal nobility and the royal domain extended to the frontiers along with royal authority. Artois, the Amienois, Valois, Vermandois, the greater part of the Beauvaisis, Normandy, Maine, Anjou, Touraine, and an important part of Poitou and Saintonge, were added to the domain during his reign. The number of *prévôts* was increased from thirty-eight to ninety-four, and the royal revenue increased from 19,000 livres a month to 1,200 livres a day.

Philip Augustus died on July 14, 1223. He was thrice married. His first wife, Isabella, by whom he had one son, Louis, died in 1189 or 1190. After her death he married Ingeborg or Ingeborg (*q.v.*), daughter of Valdemar I. of Denmark, whom he soon repudiated. In 1196, in defiance of the pope, he married Agnes, daughter of Bertold IV., duke of Meran. This led to his excommunication and brought the interdict upon France, and did more to weaken him than any other act of his. In 1200 he was forced to put away Agnes and to recognize Ingeborg as his lawful wife, but he kept her in prison until 1213. By Agnes (d. 1201) he had a son Philip, called "Hurepel," count of Clemont, and a daughter Mary, who married Philip, count of Namur (d. 1213), and then Henry II., duke of Brabant. Ingeborg lived until 1236.

See A. Luchaire in E. Lavisse's *Histoire de France*, tome iii. 83-284 (Paris, 1904), and literature there indicated; L. Deslisle, *Catalogue des actes de Philippe Auguste* (Paris, 1856 and 1901); A. Cartellieri, *Philip II. August*, Bd. I. *Bis zum Tode Ludwigs VII.* (Leipzig, 1899), Bd. II. *Der Kreuzzug* (1906); and W. H. Hutton, *Philip Augustus* (in the Foreign Statesmen series, London, 1896). A. Molinier, *Les Sources de l'histoire de France* (tome iii. pp. 1-38), gives a complete bibliography of the sources for Philip's reign, including the history of the Third Crusade.

PHILIP III. (1245-1285), surnamed "the Bold" (*le Hardi*), king of France, son of Louis IX. and Margaret, daughter of Raymond-Bérenger IV., count of Provence, was born on April 3, 1245. His funeral monument at St. Denis depicts a man with beardless, square-cut features, but lacking character and animation. The authenticity of this effigy is fairly well borne out by what is known of him from other sources. He had many of the virtues of St. Louis, but neither decision of character nor devotion to duty. He was pious, charitable, of unimpeachable morality, quick-tempered but placable, no great scholar, and only energetic as a hunter. The absence in him of the qualities that fit a man to rule made his court the arena of intriguing factions, which in reality ruled France during his reign of fifteen years. Matthew of Vendôme, abbot of St. Denis, an old servant of Louis IX., acted as Philip's counsellor, so the chroniclers state, throughout the reign; but it was probably with administration, and not policy, that Matthew was chiefly concerned. Philip began his reign in 1270 by falling entirely under the influence of Pierre de la Brosse, who had been surgeon and valet-de-chambre to his father, whom he made lord (sieur) of Langeais, Chatillon-sur-Indre and Damville. His influence lasted until Philip's second marriage in 1274 with Marie, daughter of Henry III., duke of Brabant. She supplied a centre for the enemies of the favourite, who, in 1278, was charged with various crimes, including one of poisoning the king's eldest son, and hanged at Montfaucon. His death left the parties of Marie, the queen, and Margaret, the queen-mother, to struggle for the mastery. The settlement of the claims of the king of England in Aquitaine by the treaty of Amiens in 1279 was a victory for the party of Margaret.

Agenais and southern Saintonge, which fell to the Crown by

the death of Alfonse of Poitiers in 1276, as part of his vast possessions in Aquitaine and Languedoc, were ceded to Edward I. of England in accordance with the treaty of Paris in 1259. Another portion of the heritage of Alfonse, the Venaissin, was ceded to the papacy to redeem an old promise. In general the strong will of Charles of Anjou directed Philip's policy. He secretly urged his nephew's candidature for the imperial crown, left vacant by the death of Richard of Cornwall, king of the Romans, in 1272, but without success. In May 1275 the party of Marie secured for Philip, the king's second son, the hand of Jeanne, the heiress of Navarre and Champagne, along with the guardianship of the kingdom of Navarre during the minority of Jeanne. But early in 1276 Jeanne's mother, Blanche, the widow of Henry III. of Navarre and Champagne, married Edmund, first earl of Lancaster, brother of Edward I.: and she and her English husband kept Champagne until, in 1284, Jeanne came of age.

An expedition of Philip against Castile in aid of the children of his sister, Blanche, proved abortive. Regardless of this warning, he was induced in 1284 to take up the quarrel of his uncle Charles in Sicily, after the Sicilian Vespers in 1282. Two assemblies of barons and prelates were held at Bourges in November 1283 and February 1284 to deliberate on the question. This was a mere matter of form; Marie of Brabant and her party had decided the matter beforehand, and the crown of Aragon, which the French pope Martin IV. had declared forfeited by Peter, was accepted for Charles of Valois, Philip's third son. The project was strongly opposed by Matthew of Vendôme, who was in correspondence with the king of England on the subject. It was the first warlike expedition undertaken by the house of Capet outside France. It proved a disastrous failure. Philip died during a retreat from Gerona on Oct. 5, 1285.

Philip was twice married. On May 28, 1262 he married Isabella, daughter of James I., king of Aragon, who died in 1271. By her he had four children: Louis, who died in 1276; Philip, born in 1268; Charles of Valois, born on March 12, 1270; and Robert, who died young. By his second wife, Marie (d. 1322), daughter of Henry III. of Brabant, whom he married in 1274, he had three children: Louis, count of Evreux; Margaret, who married in 1299 Edward I., king of England; and Blanche, who married Rudolph III., duke of Austria.

Walter, *Die Politik der Kurie unter Gregor X.* (Berlin, 1894); Registers of Gregory X. and Nicholas III., published by the French school at Rome; R. Sternfeld, *Ludwigs des Heiligen Kreuzzug nach Tunis und die Politik Karls I. von Sizilien* (1896); P. Fournier, *Le Royaume d'Arles* (Paris, 1891). For complete bibliography of sources see A. Molinier, *Les Sources de l'histoire de France*, tome iii. 171-187 (Paris, 1903).

PHILIP IV. (1268-1314), called "*le Bel*" or "the Fair," king of France, was the son of Philip III. and his wife, Isabella of Aragon. His reign, which began in October 1285, is one of the most momentous in the history of mediaeval Europe, yet it belongs rather to the history of France and to that of the papacy than to the biography of the king. Little is known of the personal part played by Philip in the events associated with his name, and later historians have been divided between the view which regards him as a handsome, lethargic nonentity and that which paints him as a master of statecraft who, under a veil of phlegmatic indifference and pious sentiment, masked an inflexible purpose, of which his ministers were but the spokesmen and executors. The first view seems to be borne out by the language of contemporary chroniclers. Yet this was the king who brought the papacy under his yoke, carried out the destruction of the powerful order of the Temple, and laid the foundations of the national monarchy of France. In this last achievement Finke finds the solution of a problem which Langlois had declared to be insoluble. In 1302, in the midst of a hostile assembly, Philip cursed his sons should they consent to hold the Crown of any one but God¹; and in this isolated outburst he sees the key to his character. "Philip was not a man of violent initiative, the planner of daring and fateful operations; otherwise there would

¹Wenck, p. 49.

have been some signs of it. His personality was that of a well-instructed, outwardly cold, because cool and calculating man, essentially receptive, afire for only one idea: the highest possible development of the French monarchy, internally and externally, as against both the secular powers and the Church. His merit was that he carried through this idea in spite of dangers to himself and to the state. A resolution once arrived at he carried out with iron obstinacy." Certainly he was no *roi fainéant*. His courage at the battle of Mons-en-Pévèle was the admiration of friend and foe alike. It was against the advice of his tutor, Aegidius Colonna, that on coming to the throne he chose as his counsellors men of the legal class, and the names of his great ministers—Guillaume de Nogaret, Enguerrand de Marigny, Pierre Flotte (d. 1302)—attest the excellent quality of his judgment. He was, too, one of the few monarchs who have left to their successors reasoned programmes of reform for the state.

The greatest event of the reign was the struggle with Pope Boniface VIII. (*q.v.*). The pope went so far in 1296 as to forbid any lay authority to demand taxes from the clergy without his consent. When Philip retaliated by a decree forbidding the exportation of any coin from France, Boniface gave way to save the papal dues, and the bulls issued by him in 1297 were a decided victory for the French king. There was a truce until 1301. After the arrest, by Philip's orders, of Bernard Saisset (*q.v.*), bishop of Pamiers, in that year, the quarrel flamed up again. To ensure the support of his people the king had called an assembly of the three estates of his kingdom at Paris in April 1302; in the following year Guillaume de Nogaret seized the person of the pope at Anagni, an event immortalized by Dante. Boniface escaped from his captors only to die (Oct. 11), and the short pontificate of his saintly successor, Benedict XI., was occupied in a vain effort to restore harmony to the Church. The issue of the conclave that met at Perugia on his death was ultimately determined by the diplomacy and gold of Philip's agents, and the new pope, Clement V., was the weak-willed creature of the French king. When in 1309 the pope installed himself at Avignon, the new relation of the papacy and the French monarchy was patent. It was the beginning of the "Babylonish captivity" of the popes. The most notable of its first-fruits was the hideous persecution of the Templars (*q.v.*), which began with the sudden arrest of the members of the order in France in 1307, and ended with the suppression of the order by Pope Clement at the council of Vienne in 1313.

In 1294 Philip IV. attacked Edward I. of England, then busied with the Scottish War, and seized Guienne. Edward won over the counts of Bar and of Flanders, but they were defeated and he was obliged to make peace in 1297. Then the Flemish cities rose against the French royal officers, and utterly defeated the French army at Courtrai in 1302. The reign closed with the French position unimproved in Flanders, except for the transfer to Philip by Count Robert of Lille, Douai and Béthune, and their dependencies. Philip died on Nov. 29, 1314. His wife was Jeanne, queen of Navarre (d. 1304), through whom that country passed under the rule of Philip on his marriage in 1284; three of his sons, Louis X., Philip V. and Charles IV., succeeded in turn to the throne of France, and a daughter, Isabella, married Edward II. of England.

See the *Chronique* of Geoffrey of Paris, edited by M. Bouquet, in vol. xxii. of the *Recueil des historiens des Gaules et de la France*. Of modern works see E. Boutaric, *La France sous Philippe le Bel* (1861); G. Digard, *Philippe le Bel et le Saint-Sibge* (1900); C. V. Langlois in E. Lavisse's *Histoire de France*, vol. iii. (1901); K. Wenck, *Philipp der Schöne von Frankreich* (Marburg, 1905); H. Finke, *Papsttum und Untergang des Templerordens*, 2 vols. (Münster i. W. 1907), esp. I. ch. ii.

PHILIP V. (c. 1294-1322), "the Tall," king of France, second son of Philip the Fair and Jeanne of Navarre, received the county of Poitiers as an appanage, and was affianced when a year old to Jeanne, daughter and heiress of Otto IV., count of Burgundy. The marriage took place in 1307 when he was thirteen years of age. When his elder brother, Louis X., died, on July 5, 1316, leaving his second wife, Clemence of Hungary, with child, Philip was appointed regent for eighteen years by the parliament

of Paris, even in the event of a male heir being born. Clemence's son lived only four days, and Philip proclaimed himself king (Nov. 19, 1317). The barons all did homage except Edward II. of England, and Philip's position was secured. The war with Flanders, which had begun under Philip IV. the Fair, was brought to an end on June 2, 1320. The revolt of the Pastoureaux who assembled at Paris in 1320 to go on a crusade was crushed by the seneschal of Carcassonne, whither they marched. One of the special objects of their hatred, the Jews, were also mulcted heavily by Philip, who extorted 150,000 livres from those of Paris alone. He died at Longchamp on the night of Jan. 2, 1322.

Philip was a lover of poetry, surrounded himself with Provençal poets and even wrote in Provençal himself, but he was also one of the most hard-working kings of the house of Capet. The insecurity of his position made him seek the support of national assemblies and of provincial estates. He published a series of ordinances organizing the royal household and affecting the financial administration, the "parlement" and the royal forests. He abolished all garrisons in the towns except those on the frontier, and provided for public order by allowing the inhabitants of his towns to arm themselves under the command of captains. He tried hard to procure a unification of coinage and weights and measures, but failed owing to the opposition of the estates. Philip as a reformer was in many ways before his time, but his people failed to understand him, and he died under the reproach of extortion.

See P. Lehugeur, *Histoire de Philippe le Long* (Paris, 1897); E. Lavissee, *Histoire de France* (Tome III., 2); and sources indicated in A. Molinier, *Répertoire des sources de l'histoire de France* (Paris, 1903).

PHILIP VI. (1293-1350), king of France, was the son of Charles of Valois, third son of Philip III., the Bold, and of Margaret of Sicily, and was thus the nephew of Philip IV., the Fair, whose sons, Louis X., Philip V. and Charles IV., died successively without leaving male heirs. He succeeded to the throne on the death of his cousin, Charles IV., in 1328. Before his accession Philip had enjoyed considerable influence, for he was count of Valois, Anjou, Maine, Chartres and Alençon. He had married in 1313 Jeanne (d. 1348), daughter of Robert II. of Burgundy, a determined woman who was long known as the real ruler of France.

When Charles IV. died, in Feb. 1328, his wife was enceinte, and it became necessary to appoint a regency until the birth of the child, who would, if a son, succeed to the throne. At the assembly of barons called to choose a regent, Edward III. of England, the nephew and nearest male relation of Charles IV., put in a claim. Edward III., however, descended from the royal house of France by his mother Isabel, and the barons, probably actuated by an objection to the regency of an English king, decided that neither a woman, "nor by consequence her son, could succeed to the kingdom of France," and Philip of Valois, in spite of his belonging to a junior branch of the family, was elected regent. On the birth of a girl to the queen widow the regency naturally led to the throne of France, and Philip was crowned at Reims on May 29, 1328. Navarre had not accepted the regency, that kingdom being claimed by her husband for Jeanne, countess of Evreux, the eldest daughter of Louis X., the count of Evreux himself being, like Philip of Valois, a grandson of Philip the Bold. The new king secured the friendship of the count by allowing Jeanne's claim to Navarre, in return for a renunciation of any right to Champagne. Edward III. of England, after more than one citation, reluctantly fulfilled (1320-22) the formalities of homage for part of Guienne. Meanwhile Philip VI. had won a victory, which he turned into a massacre, at Cassel (Aug. 23, 1328) over Bruges and the other towns of West Flanders, which under the leadership of Jakob van Artevelde had thrown off the authority of their count, Louis of Nevers. The count of Flanders was reinstated, and maintained his authority by a reign of terror.

Philip VI. enjoyed powerful alliances. In Italy he was allied with his uncle, Robert of Anjou, king of Sicily, and with his former enemy, Galéas Visconti; in the north with the duke of Brabant and the princes of the Netherlands; on the east with the reigning princes of Lorraine and Savoy; with the king of Bohemia and with

Pope John XXII. at Avignon, and his successor, Benedict XII. In 1336 it seemed that the Crusade, for which Philip VI. had long been preparing, would at last start; but the relations with Edward III. of England, always strained, became worse, and within a year France was embarked on the struggle of the Hundred Years' War. The causes which led to war, the conflict for commercial supremacy in Flanders, disputed rights in Guienne, the help given by France to the Scots, and the unnatural situation of an English king who was also a vassal of the French Crown are dealt with elsewhere. (See FRANCE: History.) The immediate rupture in Flanders was due chiefly to the tyranny of the count of Flanders, Louis of Nevers, whom Philip VI. had reinstated. Edward III. had won over most of Philip's German and Flemish allies, and the English naval victory at Sluys (June 24, 1340), in which the French fleet was annihilated, effectually restored English preponderance in Flanders. A truce followed, but this was disturbed after a short duration by the disputed succession to the duchy of Brittany (*q.v.*). A truce made at Malestroit in 1343, at the invitation of the pope, was rudely broken by Philip's violence. Olivier de Clisson, who with fourteen other Breton gentlemen was suspected of intrigue with Edward III., was invited to a great tournament in Paris. On their arrival they were seized by Philip's orders, and without form of trial beheaded. Then followed Edward III.'s invasion of Normandy and the campaign of Crécy (*q.v.*). Philip's army was destroyed; he himself was wounded and fled from the field. He sought in vain to divert Edward from the siege of Calais by supporting the Scots in their invasion of England; but eventually a truce was arranged, which lasted until 1351. Philip VI. died at Nogent-le-roi on Aug. 12, 1350.

Philip VI. met his necessities by the imposition of the hated gabelle or salt tax, which was invented by his legal advisers and he obtained heavy subsidies from the various provinces. Towards the close of his reign he acquired from Humbert II., comte de Vienne, the province of Dauphiné, and Montpellier from the king of Majorca. Philip married a second wife, Blanche of Navarre. By his first wife he left two sons—his successor, John II., and Philip of Orleans, count of Valois.

Déprez, *Les préliminaires de la guerre de cent ans, 1328-1342* (Paris, 1902), based on texts from the English Record Office and the Vatican; Paul Viollet, *Histoire des institutions politiques de la France* vol. ii. (Paris, 1898); and E. Lavissee, *Hist. de France*, vol. iv. pt. i. (1902), by A. Colville. Further references will be found in Nos. 3,095-3,112 and 3,165-3,240 of A. Molinier's *Sources de l'histoire de France*, vol. iv. (Paris, 1904).

PHILIP (c. 1177-1208), German king and duke of Swabia, the rival of the emperor Otto IV., was the fifth and youngest son of the emperor Frederick I. and Beatrix, daughter of Renaud III., count of Upper Burgundy, and brother of the emperor Henry VI. He entered the church, was made provost of Aix-la-Chapelle, and in 1190 or 1191 was chosen bishop of Wurzburg. Philip forsook his ecclesiastical calling and was made duke of Tuscany in 1195 receiving an extensive grant of lands. In 1196 he became duke of Swabia, on the death of his brother Conrad; and in May 1197 he married Irene, daughter of the eastern emperor, Isaac Angelus, and widow of Roger II., king of Sicily. Philip appears to have been designated as guardian of the young Frederick, afterwards the emperor Frederick II., in case of his father's early death. In 1197 he had set out to fetch Frederick from Sicily for his coronation when he heard of the emperor's death and returned at once to Germany. He found growing hostility to the kingship of a child, and the absence of the two Welf claimants, Otto and Henry, the sons of Henry the Lion, made possible Philip's own election as German king at Muhlhausen on March 8, 1198. He was crowned at Mainz on Sept. 8.

Meanwhile a number of princes hostile to Philip, under the leadership of Adolph, the archbishop of Cologne, had elected an anti-king in the person of Otto, second son of Henry the Lion, duke of Saxony. War followed, in which Philip drew his principal support from south Germany. In 1199 he received further accessions to his party and carried the war into his opponent's territory. In March 1201 Innocent III. placed Philip and his associates

under the ban, and began to work for Otto. Otto, aided by Ottakar I., king of Bohemia, and Hermann I., landgrave of Thuringia, drove him from north Germany, and compelled him to seek, in vain, reconciliation with Innocent. The submission of Hermann of Thuringia in 1204 marks the turning-point of Philip's fortunes, and he was soon joined by Adolph of Cologne and Henry I., duke of Brabant. On Jan. 6, 1205, he was crowned again by Adolph at Aix-la-Chapelle, though it was not till 1207 that his entry into Cologne practically brought the war to a close. Philip was then loosed from the papal ban. He was preparing to crush the last flicker of the rebellion in Brunswick when he was murdered at Bamberg, on June 21, 1208, by Otto of Rittelsbach, count palatine in Bavaria, to whom he had refused the hand of one of his daughters. He left four daughters, one of whom, Beatrix, afterwards married his rival, the emperor Otto IV. Philip was a brave and handsome man, and contemporary writers, among whom was Walther von der Vogelweide, praise his mildness and generosity.

Ficker (Innsbruck, 1881); R. Schwemer, *Innocenz III. und die deutsche Kirche während des Thronstreites von 1198-1208* (Strasbourg, 1882).

PHILIP I., king of Macedonia, a semi-legendary prince, son of Argæus, was, according to Herodotus (viii. 137-139) and Thucydides (ii. 100), the third of the Macedonian kings. There is, however, no real evidence for his existence.

PHILIP II. (382-336 B.C.), king of Macedonia, the son of Amyntas II. and the Lyncestian Eurydice, reigned 359-336. At his birth the Macedonian kingdom, including the turbulent peoples of the hill country behind, was very imperfectly consolidated. In 370 Amyntas died, and the troubled reign of Philip's eldest brother, Alexander II., was cut short in 368 by his assassination. His murderer, Ptolemy of Alorus, ruled as regent for the young Perdiccas, Amyntas's second son. In 367 Philip was delivered as a hostage to the Thebans, then the leading power of Greece, where he got to know Epameinondas, whom he greatly admired and whose influence may be traced in Philip's military reforms. When he returned to Macedonia (364) Perdiccas had succeeded in getting rid of Ptolemy; but he fell in 360-359 before an onslaught of the hill tribes instigated by the queen-mother Eurydice, leaving only an infant son. Pretenders sprang up and the kingdom fell into confusion. Philip seized the throne and drove back his rivals. He now began the great task of his life—the creation of the Macedonian national army. Cavalry, the famous "companions," he already had; his work was to produce an efficient force of infantry. This new force of his making consisted of the *hupaspistai* who may have been peltasts on Iphicrates's model, and the phalanx, which in its use for shock tactics on the wing in conjunction with the cavalry shows the influence of Epameinondas, but was less densely packed, and was armed, unlike Greek troops, with a long pike. The first experiment he made with this new organism was brilliantly successful. The hill tribes were broken by a single battle in 358, and Philip established his authority inland as far as Lake Ochrida. In the autumn of the same year he took the Athenian colony Amphipolis, which commanded the gold-mines of Mt. Pangæus. Their possession was all-important for Philip, and he set there a new city, Philippi. Athens was temporarily pacified by assurances that Amphipolis would be handed over to her later on.

He avoided as yet a forward policy, and having taken Pydna and Potidaea soon after Amphipolis, he made them over to the Olynthian confederation (see OLYNTHUS). His marriage with the fierce witch-woman, Olympias, daughter of the Epirote king, falls in this period, and in 356 she bore him his greater son, Alexander. In 353 Philip was ready for strong action. He first attacked Abdera and Maroneia, on the Thracian sea-board, and then took Methone, which belonged to Athens. An overt breach with Athens was now inevitable. In the same summer he invaded Thessaly, where the Aleuadae of Larissa ranged themselves on his side against the tagos Lycophron, "tyrant" of Pheræ. Pheræ called in the help of the Phocian mercenaries, who had profaned Delphi, and Philip was twice heavily defeated. But next year the Macedonian army won a complete victory over the Pheræans

and Phocians. This battle made Philip tagos of Thessaly, and he annexed Magnesia, which included Pagasæ. But on advancing further he found the Athenian expedition which had failed to secure Pagasæ holding Thermopylæ, and withdrew. From 352 to 346 Philip did not again come south. He was active in completing the subjugation of the Balkan hill-country to the west and north, and in reducing the Greek cities of the coast as far as the Hebrus (Maritza). Then, in 349, he opened war upon Olynthus. Athens sent no adequate forces, in spite of the upbraiding of Demosthenes (see his Olynthiacs), and in the spring of 347 Olynthus fell. Macedonia and the regions adjoining it having now been securely consolidated, Philip celebrated his "Olympian" games at Dium. In 347 Philip advanced to the conquest of the eastern districts about the Hebrus, and compelled the submission of the Thracian prince Cersobleptes. Meanwhile Athens had made overtures for peace (see the *De falsa legatione* of Demosthenes), and when Philip, in 346, again moved south, peace was sworn in Thessaly.

The Phocians, who still dominated Delphi and held Thermopylæ, now furnished a pretext to Philip as the champion of Pan-Hellenism and Apollo. The Phocian mercenaries at Thermopylæ were bought off and Philip crossed into central Greece. Here he made Thebes his ally and visited the Phocians with crushing vengeance. The Pythian games of 346 were celebrated at the delivered Delphi under Philip's presidency. Pan-Hellenic enthusiasts already saw Philip as the destined captain-general of a national crusade against Persia (Isocrates, *Philippus*, about 345). And such a position Philip had determined to secure; the Macedonian agents continued to work throughout the Greek states and in the Peloponnesus Sparta soon found herself isolated. Eubœa, too, submitted to Macedonian influence.

But more work had to be done in the Balkan highlands. In 344, or one of the following years, the Macedonian arms were carried across Epirus to the Adriatic and Thessaly was completely reorganized. In 342 Philip led a great expedition north "comparable to nothing in antiquity since Darius' famous march to Scythia." Meanwhile he continued to foster diplomatic relations with various Greek states, and, by conciliatory measures, to support the efforts of the pro-Macedonian party in Athens. But Demosthenes eventually carried the day, and Philip came more or less openly to blows with Athens over Diopieithes's behaviour in the Chersonese. Athens then supported the revolt of Philip's allies in Propontis, and struck a heavy blow at his prestige when his sieges of Perinthus and Byzantium failed in 339. But before marching south he led another expedition across the Balkans into the country now called Bulgaria, and returned to Pella with much spoil but severely wounded in the thigh.

In 338 he once more crossed into central Greece. The pretext was the contumacy shown by the Locrian town Amphissa to the rulings of the Amphictyonic council. Philip's fortification of Elateia filled Athens with alarm. Thebes was induced to join Athens; so were some of the minor Peloponnesian states, and the allies took the field against Philip. This opposition was crushed by the epoch-making battle of Chaeroneia, which left Greece at Philip's feet. Thebes was occupied by a Macedonian garrison; Athens, which had expected a fight to the death, was treated generously. In the following year (337) Philip was in the Peloponnesus and held a congress of the Greek states at the isthmus (from which, however, Sparta held sullenly aloof). The states attending were organized into an Hellenic league, with a constituent council and a supreme judicial court (the Amphictyonic council), acknowledging the military command of Philip and sending contingents for the expedition against Persia that was next in his plans. Philip returned to Macedonia to complete his preparations; an advance force was sent into Asia in the spring of 336. Philip was murdered that year during the marriage festival of his daughter at Aegæ, the old capital of Macedonia. He left, however, in the Macedonian army a splendid instrument which enabled his son within ten years to change the face of the world.

See the authorities under GREECE: *History*. A vivid and masterly sketch of Philip's personality and work is given in D. G. Hogarth's

Philip and Alexander (1897). For economic policy, A. B. West in *Numism. Chron.* (1923) 169.

PHILIP III. [ARRHIDAEPUS], king of Macedonia, was the feeble-minded son of Philip II. of Macedonia by a Thessalian wife. He was chosen by the Macedonian army at Babylon in 323 to be nominal king conjointly with the infant Alexander, and was killed in Macedonia by order of Olympias (317 B.C.). (See MACEDONIAN EMPIRE.)

PHILIP IV., king of Macedonia, was the son of Cassander, king of Macedonia; he reigned only one year (297–296 B.C.).

PHILIP V., king of Macedonia, son of Demetrius II and Chryseis, was an infant at his father's death in 230–229 B.C. His cousin, Antigonus Doseon, administered the kingdom as regent till his death in 221–220 B.C., when Philip was eighteen years old. Philip now ascended the throne and reigned till 179 B.C. His reign was occupied in the vain struggle to maintain the old Macedonian supremacy in the Balkan Peninsula, which became hopeless after the intervention of Rome and the decisive battle of Cynoscephalae (197 B.C.). See ROME: *History*. (E. R. B.)

PHILIP I., the Handsome (1478–1506), king of Spain, son of the emperor Maximilian I., was born at Bruges on July 22, 1478. In 1482 he succeeded to the Burgundian possessions of his mother, Mary, daughter of Charles the Bold. In 1496 he married Joanna, daughter of Ferdinand and Isabella. He died suddenly at Burgos on Sept. 25, 1506.

PHILIP II. (1527–1598), king of Spain, son of the emperor Charles V. and Isabella of Portugal, born at Valladolid on May 21, 1527. Philip was educated in Spain. The emperor, as he moved from one part of his wide dominions to another and in the camps of his armies, watched his heir's education from afar. The trend of his letters was to impress on the boy a profound sense of the high destinies to which he was born, the wisdom of distrusting counsellors, and the necessity for keeping his nobles apart from all share in the conduct of the internal government of his kingdom. Philip grew up grave, self-possessed and distrustful. He was beloved by his Spanish subjects, but utterly without the power of attracting men of other races. Though accused of extreme licentiousness, Philip was probably less immoral than most kings of his time, and he was rigidly abstemious. His power of work was unbounded, and he had an absolute love of reading, annotating, and drafting dispatches. Unhappily for Spain, Charles decided to transmit the Netherlands to his son. In 1543 Philip had been married to his cousin Mary of Portugal, who bore him a son, the unhappy Don Carlos, and who died in 1545. In 1554, Charles summoned Philip to Flanders and arranged the marriage with Mary, Queen of England, in order to form a union of Spain, the Netherlands and England against France. The marriage proved barren. The abdication of his father (Jan. 16, 1556) constituted Philip sovereign of Spain with its American possessions, of the Aragonese inheritance in Italy, Naples and Sicily, of the Burgundian inheritance—the Netherlands and Franche Comté—and of the duchy of Milan. It was a legacy of immense responsibilities and perils, for France was bound to endeavour to ruin a power which threatened her independence. France was beaten at St. Quentin and Gravelines, and forced to make the Peace of Cateau Cambresis (April 2, 1559). But the death of Mary of England (Nov. 17, 1558) and the establishment of Elizabeth on the English throne, put on the flank of Philip's scattered dominions another power, forced no less than France by political necessities to be his enemy. His marriage with Elizabeth of Valois (June 22, 1559), and the approach of the wars of religion, gave him a temporary security from France. Nevertheless, when Philip went back to Spain, in August 1559, he was committed to a life-long struggle, in which he could not prove victorious except by the conquest of France and England.

External and internal influences alike drove Philip into conflict with the Netherlands, France and England. The conflict became one between Protestantism and Roman Catholicism, in which Philip appeared as the champion of the Church. It was a part he rejoiced to play. His persecutions hardened the obstinacy of the Dutch, exasperated the English and provoked a revolt of the Moriscoes. No experience of the failure of his policy could shake

his belief in its essential excellence. Philip had a high ideal of his duty as a king, and had no natural preferences for violent courses. His strong measures in Aragon in 1591 were provoked by extreme misconduct on the part of a faction. When he enforced his claim to the crown of Portugal (1579–1581) he preferred to placate his new subjects by guarding their privileges. He even made dangerous political concessions to win over the gentry. In private life he was orderly and affectionate to his family and servants. He was slow to withdraw the confidence he had once given. In the painful episode of the imprisonment and death of Don Carlos, Philip behaved honourably. He died at the Escorial on Sept. 13, 1598.

As an administrator Philip had all the vices of his type, that of the laborious, self-righteous man, who thinks he can supervise everything, is capable of endless toil, and jealous of his authority. He set the example of the unending discussions in committee and boundless minute writing which choked the administration.

See M. H. Forneron, *Histoire de Philippe II.* (Paris, 1881); M. Hume, *Philip II.* (1897); *Documentos inéditos para la historia de España* (1842, etc.), vols. i., iii., vi., vii., xv., xxi., xxiv., xl., xcvi., cl., ciii., cx., cxi.; L. P. Gachard, *Actes des dats généraux des Pays Bas, 1576–1585* (Brussels, 1861–66); *Calendars of State Papers, Foreign Series Elizabeth* (1863–1901); M. Hume, *Two English Queens and Philip* (1908); C. Bratle, *Philip II., roi d'Espagne* (1912); F. Pérez R. Minguéz, *Psicología de Felipe II.* (1925).

PHILIP III. (1578–1621), king of Spain, son of Philip II., and Anne, daughter of Maximilian II., born at Madrid, April 14, 1578. He inherited the beliefs of his father, but no share of his industry. He left the direction of government entirely to his favourite, the duke of Lerma, and, after the latter's overthrow in 1518, to the new favourite, the duke of Uceda, Lerma's son. Philip's own life was passed amid court festivities, on which enormous sums of money were wasted, or in the practice of childish piety. It was said that he was so virtuous as hardly to have committed a venial sin. He died at Madrid, March 31, 1621.

See R. Watson and W. Thompson, *History of Philip III.* (2 vols., 1876, 1808).

PHILIP IV. (1605–1665), king of Spain, eldest son of Philip III. and Margaret, sister of the emperor Ferdinand II., born at Valladolid April 8, 1605. His reign, after a few years of barren successes, was a long story of political and military decay and disaster. A fine horseman, a keen hunter, and a patron of art and letters, he indulged in these pastimes, leaving the government to his favourite Olivares. When, in 1643, the disasters falling on the monarchy led to the dismissal of Olivares, Philip had lost the power to devote himself to hard work. After a brief attempt at directing the administration of the most extensive and the worst organized monarchy in Europe, he returned to his pleasures and was governed by other favourites. His political opinions were those he had inherited from his father and grandfather. He thought it his duty to support the German Habsburgs and the cause of the Roman Catholic Church against the Protestants, to assert his sovereignty over Holland, and to extend the dominions of his house. The utter exhaustion of his people in a hopeless struggle with Holland, France and England was seen by him with sympathy, but he considered it unavoidable. His court was grossly vicious. Philip IV. died on Sept. 17, 1665.

See A. Cánovas del Castillo, *Estudios del reinado de Felipe IV.* (Madrid, 1889), and the introduction by F. Silvela to the *Cartas de Sor Maria de Ágreda y del rey Felipe IV.* (Madrid, 1885–86).

PHILIP V. (1683–1746), king of Spain, founder of the present Bourbon dynasty, was the son of the dauphin Louis and Maria Anna, daughter of Ferdinand Maria, elector of Bavaria. Born at Versailles, Dec. 19, 1683, he was named heir by the will of Charles II. Carefully educated as duke of Anjou by Fénelon, he was all his life strongly adverse to the moral laxity of most of the princes of his time, and greatly under the influence of his two wives. Maria Louisa of Savoy (d. Feb. 1714), whom he married in 1702, and Elizabeth Farnese of Parma, whom he married in Dec. 1714. His strongest passion was to secure his succession to the throne of France, and in this pursuit he indulged in many intrigues against the house of Orleans, even abdicating in 1724. But when his son Louis died a few months later, he resumed the throne.

See Coxe, *Memoirs of the Kings of Spain of the House of Bourbon* (London, 1815).

PHILIP, LANDGRAVE OF HESSE (1504-1567), son of the landgrave William II., was born at Marburg on Nov. 13, 1504. He became landgrave on his father's death in 1509, and having been declared of age in 1518, was married in 1523 to Christina, daughter of George, duke of Saxony. In 1522 and also in 1523 he assisted to quell the rising of Franz von Sickingen (*q.v.*), who had raided Hesse five years previously, and in 1525 he took a leading part in crushing the rebellion of the peasants in north Germany, being mainly responsible for their defeat at Frankenhausen. About this time Philip adopted the reformed faith. His plans to protect the reformers rested upon two main principles—unity among the Protestants at home and military aid from abroad. The schemes he put forward as one of the heads of the league of Schmalkalden, aimed primarily at overthrowing the house of Habsburg. Envoys were sent to seek aid from France, England and Denmark; Turkey and Venice were looked to for assistance; the jealousy felt towards the Habsburgs by the Bavarian Wittelsbachs was skilfully fomented. Before the formation of the league of Schmalkalden Philip was intimate with Zwingli. In 1526 he had aided John the Constant, elector of Saxony, to form an alliance of reforming princes; and in 1529 he called together the abortive conference at Marburg, hoping thus to close the breach between Lutherans and Zwinglians. Deceived by the forgeries of Otto von Pack (*q.v.*), he believed in the existence of a conspiracy to crush the reformers, and was only restrained from attacking his enemies, in 1528, by the influence of John of Saxony and Luther. In 1529 Philip signed the "protest" presented to the diet at Spire, being thus one of the original "Protestants"; in 1530 he subscribed the Augsburg confession, and helped to form the league of Schmalkalden.

He next restored Ulrich, duke of Württemberg (*q.v.*) to his duchy. Württemberg had passed into the possession of the Habsburgs, and after Philip's brief and victorious campaign in 1534 it was said that the landgrave had done more for Protestantism by this enterprise than a thousand of Luther's books would do. The Concord of Wittenberg, made in 1536, was preparatory to a general attack on the Habsburgs, but war was prevented by the illness of the landgrave and other circumstances. At this point he took a fatal step. His union with Christina was unhappy, and, having fallen in love with Margaret von der Saal (*d. 1566*), he obtained an opinion from Protestant theologians that bigamy was not forbidden by Holy Writ. Luther and Melancthon at length consented to the marriage, but stipulated that it should be kept secret, and it was celebrated in March 1540. The marriage became known, and Philip's friends deserted him. He objected to Luther's counsel to deny the existence of a second marriage. But the general hostility compelled him to come to terms, in 1541, with Charles V. at Regensburg; he undertook to break off relations with France and England and loyally to support the emperor.

From 1526 onwards Philip had been forwarding the progress of the Reformation in Hesse. Catholic worship was suppressed, and the secularized church revenues supplied an endowment of the new university of Marburg. Peace between the emperor and the landgrave was soon broken. In 1542 Philip persuaded the league of Schmalkalden to attack Henry II., duke of Brunswick-Wolfenbüttel, ostensibly in the interests of the Protestant towns of Brunswick and Goslar. The duchy was quickly overrun, and Henry—a Catholic prince—driven out; but the good understanding between the emperor and the landgrave was destroyed, and the relations between Protestants and Catholics became worse than before. Nor was the fissure in the Protestant ranks closed, and Charles took advantage of this disunion to conquer Gelderland and to mature his preparations for overthrowing the league of Schmalkalden. Unlike John Frederick of Saxony, Philip divined, or partly divined, the emperor's intentions, and urged repeatedly that the forces of the league should be put in order. This advice passed unheeded, and when Charles suddenly showed his hand, and in July 1546 issued the imperial ban against the landgrave and the elector, it was seen that the two princes were almost isolated. Fighting began along the upper Danube, and when indecision and want of funds had ruined the league's chances of success, Philip returned to Hesse and sought help from foreign powers; while in April 1547 John Frederick was captured at Mühlberg. After this

defeat the landgrave was induced to surrender to Charles in June by his son-in-law, Maurice, now elector of Saxony, and Joachim II., elector of Brandenburg, who promised Philip that he should be pardoned, and were greatly incensed when the emperor refused to assent to this condition. Philip was sentenced to detention for 15 years, but he was released in 1552, and after the Peace of Passau in this year he returned to Hesse. The landgrave continued the work of reforming and organizing the Church in Hesse. In 1562 he aided the Huguenots with troops, and he was frequently in communication with the insurgents in the Netherlands; but his efforts to form a union of the Protestants were fruitless. Philip, who is sometimes called the Magnanimous, died at Cassel on March 31, 1567.

Rockwell, *Die Doppelhehe des Landgrafen Philipps von Hessen* (Marburg, 1904); K. Varrentrapp, *Landgraf Philipp von Hessen und die Universität Marburg* (Cassel, 1904); and *Philipp der Grossmütige, Beiträge zur Geschichte seines Lebens und seiner Zeit*, published by the *Historischer Verein für das Grossherzogtum Hessen* (Marburg, 1904).

PHILIP, KING (c. 1639-1676), chief sachem of the Wampanoag Indians in America, and the son of Massasoit (*d. 1662*). To Massasoit's two sons, Wamsutta and Metacomet, the English gave the names respectively of Alexander and Philip. Alexander succeeded his father as sachem, and in the same year, while in Marshfield, whither he had gone to explain certain alleged unfriendly acts toward the English, was taken ill; he died on his way home. Philip, who succeeded Alexander, suspected the English of poisoning his brother. The English had grown stronger and more numerous, and had begun to meddle in the internal affairs of the Indians. In 1671 the Plymouth authorities demanded that the Wampanoags should surrender their arms; Philip consented, but his followers failed to comply, and measures were taken to enforce the promise. Philip thereupon went before the general court, agreed to pay an annual tribute, and not to sell lands or engage in war with other Indians without the consent of the Plymouth government. In 1674, when three Wampanoags were executed at Plymouth for the alleged murder of Sassamon, an Indian convert who had played the part of informer to the English, Philip could no longer hold his followers in check. There were outbreaks in the middle of June 1675, and on June 24, the massacre of whites began.

The colony of Connecticut took quick measures of defence, guarded its frontier, maintained its alliance with the Mohegans, and suffered little injury. Massachusetts and Plymouth were slower in acting and suffered great loss. Rhode Island raised no troops, and suffered severely. Early in the autumn Philip went nearly as far west as Albany in an unsuccessful attempt to get aid from the French and the Mohawks and supplies from the Dutch traders. At Deerfield on Sept. 18, about 60 English were killed and the settlement was abandoned. In the spring of 1676 it became evident that the Indian power was waning. The warriors had been unable to plant their crops; they were weaker numerically and more poorly armed than the English, and the latter had also made an alliance with the friendly Naticks and the Niantics. On Aug. 1, 1676 Philip's wife and nine-year old son were captured, and on Aug. 11, an Indian traitor guided the English to the sachem's hiding place in a swamp at the foot of Mount Hope (in what is now the township of Bristol, R.I.) where early the next morning he was surprised, and while trying to escape was killed by an Indian. The head of Philip was sent to Plymouth and set on a pole in a public place, where it remained for a quarter of a century. The struggle was now over in southern New England, but it continued along the north-eastern frontier till the spring of 1678.

Morris, *King Philip's War* (1906). See also *Entertaining Passages Relating to King Philip's War* (Boston, 1716; new ed. with notes by H. M. Dexter, Boston, 1865), the account by Col. Benjamin Church (1639-1718).

PHILIP, JOHN (1775-1851), British missionary in South Africa, was born on April 14, 1775, at Kirkcaldy, Fife. In 1818

he joined John Campbell in his second journey to South Africa to inspect the stations of the London Missionary Society, and in 1822 the Society appointed him superintendent of their South African stations. His anger was aroused by the barbarities inflicted upon the Hottentots and Kaffirs (by a minority of the colonists), and he set himself to remedy their grievances. His influence was seen in the ordinance of 1828 granting all free coloured persons at the Cape every right to which any other British subjects were entitled. During 1826-1828 he was in England, and in the last-named year he published *Researches in South Africa*.

One of Philip's ideals was the curbing of colonial "aggression" by the creation of a belt of native states around Cape Colony. In Sir Benjamin D'Urban, Philip found a governor anxious to promote the interests of the natives. When, however, at the close of the Kaffir War of 1834-35, D'Urban annexed the country up to the Kei River, Philip's hostility was aroused. He came to England in 1836, and agitated against the Cape government. D'Urban was dismissed, and Philip returned to the Cape as unofficial adviser to the government on all matters affecting the natives. He died on Aug. 27, 1851.

See SOUTH AFRICA: *History*; G. M'C. Theal's *History of South Africa since 1795* (London, ed. 1908); *Missionary Magazine* (1836-51); R. Wardlaw's *Funeral Sermon*, 1852.

PHILIPPA OF HAINAUT (c. 1314-1369), queen of the English king Edward III., was the daughter of William the Good, count of Holland and Hainaut, and his wife Jeanne de Valois, granddaughter of Philip III. of France. By a special dispensation of the pope, Philippa was married to her cousin Edward III. by proxy at Valenciennes in October 1327, and landed in England in December. She joined Edward at York, where she was remarried on Jan. 30, 1328. Her marriage dower had been seized by the queen dowager Isabella to pay a body of Hainauters, with whose help she had compassed her husband's deposition. The alliance ensured for Edward in his French wars the support of Philippa's influential kindred; and before starting on his French campaign he secured troops from William the Good, as well as from the count of Gelderland, the count of Julich, and the emperor Louis the Bavarian.

Before 1335 Philippa had established a small colony of Flemish weavers at Norwich, and she showed an active interest in the weaving trade by repeated visits to the town. She also encouraged coal-mining on her estates in Tynedale. Her eldest son, Edward the Black Prince, was born in 1330, and she subsequently bore six sons and five daughters. In November 1342 she became guardian of John of Gaunt and her younger children, with their lands. The anecdotes of her piety and generosity prove her popularity. On a famous occasion her prayers saved the citizens of Calais from Edward's vengeance. There is a generally accepted story, based on the chronicles of Jehan le Bel and Froissart, that she summoned the English forces to meet the Scottish invasion of 1346, and harangued the troops before the battle of Neville's Cross.

Philippa was the patron and friend of Froissart, who was her secretary from 1361 to 1366. Queen's College, Oxford, was not, as is stated in Skelton's version of her epitaph, founded by her, but by her chaplain, Robert of Eglesfield. Her chief benefactions were made to the hospital of St. Katharine's by the Tower, London. She died on Aug. 15, 1369.

See Agnes Strickland, *Lives of the Queens of England*, vol. i. In addition to the account given in his *Chroniques*, Froissart wrote a formal eulogy of her, which has been lost.

PHILIPPEVILLE, a seaport of Algeria, chief town of an arrondissement in the department of Constantine, and 54 m. N. by E. of that city, on the Bay of Stora, in 36° 53' N. 6° 54' E. The population (1936) is 38,895, of whom 27,850 are Europeans. The town is connected by railway with Constantine, Batna and Biskra. The town derives its importance from being the port of Constantine. From Cape Skikda, on the east, a mole or break-water projects 4,592 ft. to the west-north-west, while from Château Vert, on the west, another mole runs out 1,312 ft. to the north, leaving an entrance to the port about 6½ ft. wide. The protected area comprises an outer and an inner basin. The depth

of water at the entrance is about 33 ft., by the quays about 20 ft.

Philippeville occupies the site of successive Phoenician and Roman cities. By the Romans it was named Rusicada. Some parts of the Roman theatre remain. The modern town was founded by marshal Valée in 1838.

PHILIPPI (Turk. *Filibejik*), a city of ancient Macedonia, on a steep hill near the river Gangites (mod. Angista), overlooking an extensive coastal plain on the highway between Neapolis (Kavalla) and Thessalonica. Originally called Crenides (Fountains), it was fortified by Philip II. of Macedon, to command the neighbouring gold mines. In 42 B.C., after the defeat of Brutus and Cassius here by Octavius and Antony, it became a Roman colony, *Colonia Julia Philippensis*, probably increased after the battle of Actium (Col. Aug. Julia Phil.), with the Jus Italicum, and the rank of a "first city." It was twice visited by St. Paul, whose Epistle to the Philippians was addressed to converts here. The site, now uninhabited, is marked by ruins of an amphitheatre and a great temple with inscriptions. To the east is the huge monument of C. Vibius, known to the Turks as Dikelitashlar and to the Greeks as the Manger of Bucephalus.

See Heuzey and Daumet, *Mission arch. en Mactdoine*, Paris (1865), and other authorities in bibliography of MACEDONIA; *Corp. Inscr.* Lat. iii. 1.; S. Casson, *Macedonia, Thrace and Illyria* (1926).

PHILIPPIANS, EPISTLE TO THE, a book of the New Testament. Though Philippi was the first place in Europe where St. Paul preached the gospel, the letter to the local church was one of the last he wrote. Ever since he founded the church, he kept in touch with it (iv. 15f); indeed he had accepted a gift of money from it. But the present letter is an answer to one written by the Philippian Christians, who had enquired anxiously about his health and prospects, assuring him of their prayers, and wondering when he would be able to revisit them (i. 25f). Epaphroditus, who had brought the money, had fallen ill, and the apostle apparently sends him back reluctantly, perhaps with the present letter. It is a friendly missive, which falls into two parts. The first begins by relieving their anxiety about himself, assures them that he hopes to return before very long, and warns them, in the meantime, to preserve their unity (i.-ii.). At this point there is a sudden change in tone. The letter swerves into a passionate denunciation of some errorists or agitators (iii. 1f), after which the writer resumes (iv. 1-7) his counsels to the community. The closing appeal (iv. 8f) is for harmony.

Modern criticism of the epistle is no longer concerned with supposed traces of gnosticism in ii. 6f. The two engrossing questions are (a) the place from which the letter was written, and (b) whether or not it is a literary unity.

The former problem is raised by those who point out that the Greek term "praetorium" ("palace" in the English version of i. 13) does not necessarily mean the Roman barracks of the praetorian guard at Rome, but might conceivably, for example, refer to the palace of Herod at Caesarea (Acts xxiii. 35) or to judicial authorities at a centre like Ephesus, where we know Timotheus was living (Acts xix. 22), and where the apostle was once imprisoned. The data indicating Rome as the place of composition cannot be hastily set aside, *i.e.*, the considerations which involve the latter part of the two years confinement at Rome (Acts xxviii. 30) as the period when the letter was written.

The second problem starts from the abrupt change in iii. 2. It is thought by some (*e.g.*, by B. W. Bacon, *The Story of St. Paul*, pp. 367f) that iii. 2f represents an earlier letter, written in reply to the gift of money, and subsequently added to the later i. 1.-iii. 1, as 2 Corinthians x.-xiii. has been added to an epistle which chronologically it preceded. The partition theories, of which this is the simplest form, imply that two letters have been mutilated and transposed; otherwise, the hiatus at iii. 2 is inexplicable. But the writer may have been interrupted at iii. 1, or something may have occurred which moved him to turn aside sharply. In iv. 4 he echoes the note sounded in iii. 1, and the intervening outburst may be psychologically explained without recourse to any theory of transposition.

He associates Timotheus with him in the address (i. 1), owing to his local ties with Philippi (ii. 22 and Acts xvi. 3f), but the

apostle writes in the first person throughout, even in iv 21; indeed he speaks of his companions as distinct from himself, and iii 17 is no real exception to this. The letter is an affectionate personal message from St. Paul in the evening of his life to a church with which his relations had been exceptionally friendly. Their troubles were not connected with doctrine; the great passage in ii 5f is introduced as a motive to humility, not as specific instruction on the person of Christ. These Macedonian Christians had a naturally affectionate temperament, which affected their religion; the apostle's chief prayer for them is that their emotional warmth may ripen into insight and understanding (i 9f), and his concern for them is solely for their Christian principles of conduct.

The earliest definite traces of the letter in second century literature occur in Polycarp, who had some close interest in the church of Philippi. It passed at once into the early canons of Scripture, and soon was quoted by church fathers like Irenaeus, Clement of Alexandria and Tertullian.

BIBLIOGRAPHY.—In English the older commentaries by Ellicott (5th edition, 1888) and Lightfoot (6th edition, 1891) may be supplemented by H. A. A. Kennedy's in the *Expositor's Greek Testament* (1903), M. R. Vincent's in *The International Critical Commentary* (1897) and a commentary on the English text by M. Jones, *Westminster Commentaries* (1918). The latest German editions are by Lohmeyer (Gottingen, 1928), P. Ewald in *Zahn's Commentar* (1923) and M. Dibelius in *Lietzmann's Handbuch* (1913), but A. Klopper's (1893), Von Soden's (1903) and R. A. Lipsius' *Handcommentar* (1892) are by no means superseded. General studies of the epistle will be found in R. R. Smith's *The Epistle of St. Paul's First Trial* (1899), in Sir W. M. Ramsay's *St. Paul the Traveller* (chapters x and xv) and in Weizsacker's *Apostolic Age* (vol. i, pp. 218f, 279f). Weizsacker dealt the deathblow to the older view that the epistle was non-Pauline, the last traces of which are to be found in van Manen's article in the *Encyclopaedia Biblica* (3703f). (J. MOR.)

PHILIPPICS. Properly, certain speeches delivered by Demosthenes against Philip II of Macedon; hence Cicero's speeches against Antony (Cicero ad *Brutum*, II 3, 4; 4, 2); hence, in modern use, any impassioned invective.

PHILIPPICUS, East Roman emperor (711–713), became distinguished as a soldier under Justinian II. His proper name, which indicates his Armenian origin, was Bardanes. He made some pretensions to the throne on the outbreak of the first rebellion against Justinian; these led to his banishment, by order of Justinian, to Cherson. Here Bardanes successfully incited the inhabitants to revolt, and on the assassination of Justinian assumed the purple. Among his first acts was the summoning of a *conciliabulum* of eastern bishops, which momentarily restored monotheletism. His domains were attacked at once by Terbelis, king of the Bulgarians in Europe, and the Saracens in Asia. The reign of Philippicus was ended by a military conspiracy.

See Gibbon, *Decline and Fall of the Roman Empire* (ed. Bury, 1911), v 195–6.

PHILIPPINE ISLANDS, an archipelago, named after Philip II of Spain, of approximately 7,083 islands, belonging to the United States, about 500 mi. off the S.E. coast of Asia, lying between lat. 4° 23' and 21° 25' N., and long. 116° and 126° E. To the west and north is the stormy China sea, east the Pacific ocean, and south the Sea of Celebes and the coastal waters of Borneo. They extend north and south about 1,152 mi. and east and west about 688 mi.; their shape, if bounded by straight lines, being about that of an isosceles triangle, and their land area 115,600 sq.mi., or about 6,000 sq.mi. less than that of Great Britain. The northernmost island, Y'Ami, is 65 mi. from Formosa, while the southernmost, Saluag, is 30 mi. E. of Borneo. Of the islands only 466 have an area of 1 sq.mi. or more, and only 2,441 have names. Eleven islands have an area of over 1,000 sq.mi. each, namely, Luzon, the most northerly of the large islands, 40,814 sq.mi.; Mindanao, the most southerly, 36,906 sq.mi.; Samar, 5,124 sq.mi.; Negros, 4,903 sq.mi.; Palawan, 4,500 sq.mi.; Panay, 4,448 sq.mi.; Mindoro, 3,794 sq.mi.; Leyte, 2,779 sq.mi.; Cebu, 1,692 sq.mi.; Bohol, 1,534 sq.mi.; and Masbate, 1,225 sq.mi. In addition to the large islands and those with distinct names are various groups, among which may be noted the Babuyanes and Batanes, north of Luzon; the Bisayas (or Visayas), between Luzon and Mindanao; the Cagayan and the Calamian groups, respectively east and north of Palawan; and the Sulu

archipelago, of 448 islands, the chief of which is Jolo.

Physical Features.—The irregular configuration of the archipelago, the coastline of over 12,500 mi., the great extent of mountainous country with the mountains lying close to the sea in many places, the narrow and interrupted coastal plains, the generally northward trend of the river systems and the lakes comprise the salient physical features of the Philippines. The islands have volcanic, coral and all principal rock formations. The mountain ranges for the most part run in the general direction of the main

BY COURTESY OF THE CANADIAN PACIFIC STEAMSHIPS
A PHILIPPINE HUT NEAR GUADALUPE, OUTSIDE MANILA. BUILT ON STILTS TO AVOID FLOODING FROM HEAVY RAINS AND FOR COOLNESS

axes of the islands. The Cordillera Central of Luzon, running north to the Pacific ocean from the northern boundary of the central plain, is the most prominent chain. It consists of two, and, in places, of three, parallel ranges, each of which averages 5,900 ft. in height. The narrow Ilocos or Malaya range, lying close along the narrow west coast, rises in places to over 5,000 ft., and the Sierra Madre, fringing the northeast coast, to over 5,000 ft., and is seldom less than 3,500 ft. It is largely volcanic. This range and the Cordillera Central coalesce in Nueva Vizcaya forming the Caraballo mountains. North of the latter and between the two ranges is the fertile Cagayan valley, about 50 mi. wide. In the southwestern part of northern Luzon are the rugged Zambales mountains, which consist of more or less isolated old volcanic stocks. The central plain of northern Luzon is about 150 by 50 mi. and only about 100 ft. above sea level except near its centre. The greater part of southern Luzon is occupied by isolated volcanoes and irregular masses of hills and mountains. The highest peak is Mayon (7,943 ft.) near Legaspi in Albay province. Through Palawan (about 1 j mi. wide) extends a range with an average height of 4,000 to 5,000 ft. Each of the Bisayan islands, except Samar and Bohol, is traversed longitudinally by a single range with occasional spurs. Several peaks in Panay reach an altitude of 6,000 ft. or over. In Negros is Mt. Kanlaon, a volcano of 8,088 ft., and other peaks reach an altitude of over 6,000 feet. There are several important ranges in Mindanao, the Diuata range along the eastern coast being the most prominent.

West of this lies the fertile Agusan valley, 40 or 50 mi. wide. Farther west and southwest is the valley of the Rio Grande de Mindanao, the largest river in the island, and below the lower course of this river and the southern coast lies a range trending northwest and southeast. On the southern border of the basin of the above river is Mt. Apo (9,690 ft.), the highest peak in the Philippines. About Lake Lanao are a number of volcanic peaks. A low cordillera extends into Zamboanga province. Many of the mountains are covered with dense forests in which are many valuable hardwood timbers. In northern Luzon, the principal mountain tree is the pine. In many places where the forests have been burned away, their place has been taken by cogón or other coarse grasses. The plains lying amid the mountains, e.g., the central plain of Luzon, the Bikol plain of southeastern Luzon, the Cagayan plain of northern Luzon, the central plain of Panay and the Agusan and Cotobato valleys in Mindanao, have the

densest populations of the islands except in Cebu, where the people live mostly on the coastal plain, as the interior is high and rugged. The most important rivers are the Cagayan, Agno, Pampanga, Pasig and Bikol in Luzon; and the Rio Grande de Mindanao and Agusan in Mindanao. The Cagayan flowing northward through northern Luzon, and draining about one-fourth of the island, is the largest river. This river and the Rio Grande de Mindanao and the Agusan are each over 200 mi. long. The Pasig is a most important river commercially. The largest lake in the archipelago is Laguna (Lake) de Bay, located very near Manila.

Geology.—Mountain building is still in progress and evidence of the recent vertical movement of various portions of mountain mass can be measured. The archipelago is the crumpled edge of the Asiatic continental platform. However, the structure is a complex one, for besides faulting and folding, volcanic actions of diverse kinds have taken place. Prior to the Tertiary period there seems to have been a period of intense deformation, when some of the schists were formed. Toward the end of the Miocene period, the Vigo and Batan formations were generally folded, in some places being intensively crumpled and faulted. Another less pronounced period of folding occurred in the Pliocene or early Pleistocene period. The islands were subjected to a great uplift during the Pliocene, Pleistocene and recent periods. A striking similarity exists between the formation in the Philippines and the western coast of America. Practically all the rock types are found in the islands, as well as areas of coral limestone.

Volcanoes and Earthquakes.—The volcanoes are the most conspicuous feature of the landscape, but there is less volcanic activity in the whole group than in a single Hawaiian island. However, all gradations of volcanoes can be seen, from the almost perfect cone of Mayon to old, worn down volcanic stocks whose present form gives little indication of their origin. The several distinct volcanic areas are that of southwestern Luzon (the provinces of Rizal, Cavite, Laguna, Batangas and a portion of northwestern Tayabas); that of southeastern Luzon; the mountain region in Camarines Norte; Negros; Mindanao; Jolo; and a few others. Seismic disturbances are common.

Climate.—The archipelago has a decided variety of climate. The general direction of winds is from north to east, October to January; east to southeast, February to April; and southwest, the rest of the year. Typhoons, often destructive, originate in the Pacific; they strike the islands from the east to the southeast, then curve to the north, sometimes crossing the land to the China sea, sometimes only touching the eastern shores. Seventy-five per cent of them strike the islands from the latitude of Manila northward. Often the greatest loss of life and destruction of property are caused, not by high-velocity winds, but by the concomitant or subsequent torrential rains which cause floods. Temperature differences are really very slight. On the other hand, rainfall differences are important and decidedly variant, and four types of climate are classified upon the basis of rainfall. The first has two pronounced seasons, one dry in winter and spring and the other wet in summer and autumn. This prevails generally over the western part. The second has no dry season but a pronounced rainy period in winter; generally, on the Pacific side. The third has no very pronounced maximum rain period, but a short dry season; generally, over the central plain of Luzon and the central islands. The fourth has no dry season and no very pronounced maximum rain period; generally, in Batanes province, northeastern Luzon, both Camarines, Albay, northern Cebu, northern Negros and most of central eastern and southern Mindanao.

Flora.—About 10,000 species of flowering plants and ferns have been found. The flora is essentially Malaysian, but continental (Himalayan) elements occur in the mountains of northern Luzon, while a few Australian types are found at various

altitudes. There is a small percentage of endemic genera and a very high percentage of endemic species (about 60%). The dominant forest species are usually endemic. Among the grasses of the grasslands are lalang (cogón), and other coarse grasses. The vegetation of the coastal regions (including the mangrove swamps) is practically identical with that of similar areas throughout the Malay archipelago. Considerably more than half the land area of the islands is covered with forests. There are many valuable hardwoods as well as many of the softer variety. About 1,000

BY COURTESY OF THE U.S. BUREAU OF INSULAR AFFAIRS

A HEMP PLANTATION IN THE PHILIPPINE ISLANDS

different woods have a commercial value, among which may be noted apitong, camagón, ipil, lauan, mayapis, molave, narra, tangle, tindalo and yacal. Some timber trees attain a huge size which makes them especially adaptable for tables and other large pieces of furniture. There are many useful kinds of palms, including the coco-nut palm, from which the Filipino obtains food, clothing, fibre for export, coco-nut oil, copra, building material and other products. Useful bamboos and rattans abound. About 900 species of orchids occur, some of them very rare. Several hundred fibres are known, among them the abaci, from which manila rope is made. The forests also yield gums including rubber, various fruits, nuts, spices and drugs, oils and other useful substances.

Fauna.—Mammals are scarce, with the exception of shrews, rats, mice and bats. The edentates are represented by the pangolin (*Manis javanica*). Red or brown deer (*Rusa*) are found in Basilan, Mindanao, Leyte, Samar and the Calamian islands. The mouse deer or chevrotain (*Tragulus nigricans*) is found in Balabac and Palawan. The timarau (*Bubalus mindorensis*), a small buffalo, is peculiar to Mindoro. Carnivores are represented by mongooses (*Mungos palawanus* and *M. parvus*), the binturong (*Arctictis whitei*), an otter (*Aonyx cinerea*), civet cats (*Viverra* and *Paradoxurus*) and a small wildcat (*Felix minuta*) which is also found in Java. At least 56 species of bats are known, many being peculiar to the Philippines. The flying lemur (*Cynocephalus volans*) and tarsiers (*Tarsius*) range from Basilan to southern Luzon. Large fruit bats live in colonies and are sometimes hunted for their flesh and fur. Only one genus of monkey (*Pithecus*) has been found, but it is represented by five species. Five new genera of small mammals (*Celaenomys*, *Chrotomys*, *Rhynchomys*, *Batomys* and *Carpornys*) representing 15 species were discovered some years ago on a small plateau on the top of Mt. Data in northern Luzon, at an altitude of about 3,200 ft. There are about 760 species of birds which show rather strong relationship to those of Borneo. Reptiles and batrachians also abound.

The marine fauna is one of the most abundant known, more than 1,000 species having been found, three-fourths of which at least are used as food. Sharks and rays are caught for their fins, which are prepared for the Chinese market. The fresh-water fish fauna is relatively unimportant. Terrestrial and marine molluscs are abundant, the Philippines having the richest molluscan fauna of any equal area in the world, and many of the shells are of great beauty. Many of the molluscs are edible and of con-

BY COURTESY OF THE U.S. BUREAU OF INSULAR AFFAIRS
WOMEN MAKING CIGARS IN MANILA

siderable local importance. Pearl oysters abound and the pearls of the Sulu archipelago have an international reputation. The shells of *Placuna placenta* are a welcome substitute for window glass. Land molluscs are found in great variety and are remarkable for their beauty. The best sponges of the southern islands are equal to those of the Mediterranean. Coral beds are numerous.

Population and Ethnology. — Population by the 1939 census was 16,000,303, a gain of more than 4,000,000 over the 1928 census. Cebu remained the most populous province (1,068,078) and the island which constitutes it is the densest in population (214.8 per sq.km.). Figures for other leading provinces were: Leyte (915,853), Negros Occidental (824,858), Iloilo (744,022), Pangasinan (742,475), Samar (546,306), Bohol (491,608), Rizal (444,805), Batangas (442,034).

Nationalities of the population in 1939 were as follows: Filipinos 15,833,649, Chinese 117,487, Japanese 29,057, United States 8,709, Spanish 4,627, German 1,149, British 1,053, Russian 237, French 197, Dutch 197, other nationalities not reported 3,941. Occupations are represented by: agriculture 3,456,370; domestic and personal service 3,478,084, professional service 103,415, public service (not elsewhere classified) 49,620, fishing 180,569, forestry and hunting 26,820, mining and quarrying 47,019, manufacturing and mechanical industries 601,335, transportation and communication 203,596, clerical 48,899 and trade 270,766. Of the 8,466,493 reported as engaged in gainful occupations, 3,912,580 were listed as literate and 4,546,496 as illiterate; 7,417 were unreported regarding literacy.

Racially, the population in 1939 was listed as follows: brown 15,758,637, yellow 141,811, Negrito 28,984, white 19,300, American Negro 173, mixed 50,519 and not reported 879. The term "Filipino" in Spanish times meant the same as creole; *i.e.*, an island native of Spanish descent. The Malay natives were known as Indios. The term was disliked by the latter, and after the anti-Spanish revolution they eagerly appropriated the designation "Filipino" which has now been generally accepted.

The aborigines of the archipelago were the Negritos (small blacks), akin to the Australian blacks, Papuans, etc. Once distributed throughout the islands, they were steadily reduced in numbers and habitat by Malay conquests and intermarriage so that the 1939 census reported only 15,556 as using the "Negrito" language, though it is recognized that many others of Negrito blood use other dialects. They are found in Zambales (the Spanish word zambal means a cross between a Negro and an Indian), Pampanga, the Luzon mountains and even in the Bisayas and Mindanao.

The Malay Filipinos are of the same race as those inhabiting the islands farther south. from which the former emigrated in prehistoric times; and there is linguistic evidence of an affinity with the Malagassy of Madagascar and still more of at least a strong Indian influence dating from a very early period. That these Malay immigrants apparently came from different islands in the south accounts for the distinct linguistic and ethnic groups represented by their present-day descendants. These include: Bisayans (7,099,582) with various dialectical subdivisions; Tagalog (4,068,56j); Iloko (2,353,218); Bikol (1,289,424); Pampangan (621,455); Pangasinan (573,752) It will be seen that while Tagalog is spoken by only about one-fourth of the total population, nearly twice as many speak a Bisayan dialect and that more speak English (4,259,549) than Tagalog. Yet the latter is being forced upon all as the "national language."

The Moros (Spanish for Moors) of Mindanao and the islands to the south have come to differ from the other Malay immigrants

largely because of their religion (Mohammedan) introduced by Arab missionaries before the 14th century. The 1939 census reported 245,264 of them speaking Sulu and 4,714 speaking Molbog (probably a dialect of the former) while 159,678 speak Magindanao. The Moros are the most warlike of the Philippine Malays. The Spaniards never conquered them and the U.S. government was obliged to send various punitive expeditions against them. Fighting continued even under the commonwealth government. The Moros are skilled in the manufacture of brassware and weapons, in weaving and wood-carving; but their relations have been closer with their kinsmen to the south than with those of the north, for whom in fact they were a constant menace for centuries.

Among the most promising of the Philippine inhabitants are the mountain peoples, especially those of north Luzon, whose temperate environment favours a more vigorous physical type. Foremost among these are the Ifugao, famous for their successful, though primitive, agriculture, their social structure and animistic beliefs. The Igorots are another interesting mountain group who long anticipated the modern U.S. miner. Of these the Bontoks are the most advanced and have recently been brought under the influence of Episcopalian missionaries. The Tinggians are still another mountain group who have made extensive use of irrigation. The census fails to disclose the real numbers of these mountain people, for nearly all speak another language than their native dialect, Iloko being preferred.

The people of China are the archipelago's nearest civilized neighbours and the source of far more of its culture than is generally suspected. Chinese contacts with the islands may even have antedated the Malay migrations and certainly continued, without serious interruption, until U.S. exclusion laws were applied. About 45.4% of the pure Chinese population of the islands is found in the Manila area; but in virtually every Philippine pueblo, from Aparri to Zamboanga, the "Chino" is a familiar figure, controlling a large proportion of the retail trade and a considerable part of the wholesale. Law-abiding, patient, willing to endure much in the way of discrimination and even oppression, if only he is allowed to conduct the business in which he is engaged, the Chinese merchant is a model resident.

But the 117,487 Chinese which the 1939 census recorded, though they "constitute the largest group of non-Philippine citizens and comprise 70.9% of all foreigners," afford only a slight indication of China's influence in the islands. Because immigrants from that country have mostly been males, they have intermarried with the women of the country, and their offspring—the "mestizo Chino"—has become an important factor in social and political life. José Rizal y Mercado, the national hero, had a Chinese ancestor, as early as the 17th century; many men prominent in national affairs are the sons of Chinese. These examples are multiplied throughout the islands. The Malay character has been strengthened and rendered more efficient by the infusion of Chinese blood.

Agriculture is the chief industry and the *taos* (peasants) are good farmers despite crude methods and primitive implements. Ifugao rice terraces in northern Luzon are among the orient's marvels. In the larger haciendas, chiefly those devoted to sugar, modern agricultural machinery and methods have been introduced.

In 1932 the total land area was 73,214,742 ac., of which commercial forests covered 34,129,694 ac.; noncommercial, 7,755,913 ac.; cultivated land, 15,557,856 ac.; open land, 13,698,974 ac.; fresh marsh, 418,563 ac.; mangrove swamps, 792,670 ac.; other salt marsh, 303,644 ac.; and unexplored, 557,428 ac.

The census of 1939 showed 1,634,726 farms with a total area of 16,531,716 ac., of which 9,769,669 ac. were cultivated land; 2,737,817, idle; 1,809,321, pasture; 1,599,773, forest; other, 615,136.

The average size of the farms was 10.11 ac., and 804,786 were privately owned. The province of Cebu had the largest number of farms, 121,548, followed by Leyte with 100,794, Pangasinan with 86,615 and Nueva Ecija with 78,319. The size of the average farm was also smallest in Cebu, 4.05 ac., followed closely by Ilocos Sur, 4.08 ac., and Ilocos Norte, 4.12 ac. The following provinces had the largest farm acreage: Davao, 812,400; Taya-

BY COURTESY OF THE FIELD MUSEUM OF NATURAL HISTORY

SAVAGE MAN AND WOMAN OF THE PHILIPPINE ISLANDS

bas, 806,849; Negros Occidental, 736,180; and Nueva Ecija, 714,339; the average size of the farms being 31.02, 15.27, 20.50 and 9.11 ac., respectively.

Crops produced in 1938 were of the following quantities and values: (1) rice (palay), the staple native food cereal, 2,538,805 short tons, \$68,211,530, produced in every province, occupying 43.3% of the total cultivated area, but insufficient for home consumption; \$499,874 worth was imported (in 1939, \$2,581,738); (2) maize (corn), 561,490 short tons, \$9,711,815, more than one-half in Cebu province and practically all consumed locally; (3) coco-nuts (of which the Philippines are the largest producer after Netherlands Indies, and the leading exporter, supplying about one-half the world's copra), 3,303,077.809 (trees, 91,178,800, bearing 769,159 short tons of copra and producing 839,013 gal. of home-made coco-nut oil, \$46,063,245, and 17,626,333 gal. of tuba or sap); (4) abaci ("Manila hemp"), 181,788 short tons, \$11,370,015 (Davao is the leading producer with Albay, Sorsogon, Leyte, Samar, Camarines Sur and Surigao following); maguey (39,018,000 lb.); sisal, kapok, cotton, piña and ranee are also grown; (5) sugar and its products (practically all centrifugal), 1,115,574 short tons; basi, 1,616,614 gal.; molasses, 49,954,182 gal., \$56,479,305; foremost export after 1920; chief provincial producers are Occidental Negros, Pampanga, Tarlac, Batangas, Laguna and Iloilo; (6) miscellaneous: tobacco, 79,241,000 lb., \$2,062,730; seventh in world production; Isabela and Cagayan supplied 46% of the Philippine crop; cacao, 1,939,000 lb.; coffee, 21,103,000 lb. Rubber, lumbang and forage grass are also grown; among the fruits are mandarins, oranges and pumelos, bananas, mangoes, lanzones, pineapples, papayas, sugar apples, chicos, soursops, custard apples. Still other crops are pili nuts and peanuts, root crops, sweet and white potatoes, casava, uvi, gabe, tugui, tomatoes, egg-plant, beans, mangoes, cabbage and radishes.

The forest area is estimated at more than 43,700,000 ac., not including 3,200,000 ac. covered with cogón grass, fit for grazing. About 97.5% of the total belongs to the government and is administered by the forestry bureau under a licence system. The volume of standing commercial timber in 1941 was estimated at 464,740,000,000 bd.ft. In 1938, 2,393,510 cum. of lumber were cut; there were 141 sawmills and 7 machine logging outfits, with Americans holding the largest investment in lumber. Among the minor forest products are firewood, charcoal, tanbarks, cutch, gogo, dye barks, Manila copal and elemi, oleoresins, rattan (split and unsplit), diliman, kamagsa, lumbang kernels and nuts.

Livestock in 1939 included carabaos, the farmer's mainstay, 2,918,730; cattle, 1,349,264; horses, 340,432; swine, 4,348,515; goats, 402,173; sheep, 37,653; and an abundance of domestic fowls (chickens, 18,554,480).

Minerals.—From the early Spanish period, attempts were made to develop the coal deposits of the islands. The year of greatest recorded production was 1920, when 58,888 metric tons were mined. Production then dropped to about 22,000 metric tons annually, rising, however, in 1938 to 40,523. Most of the mines were in Cebu; but the largest and only continuous producer was on Batan island in Albay. Government exploring parties have reported promising deposits.

Petroleum formations are known to exist and also oil seeps, gas emanations, bituminous rock deposits and even a few small producing wells. All but a few drilling leases and permits were cancelled and in 1939 all petroleum lands were withdrawn from entry for five years by the Philippine government, pending development of its own plans.

Metals produced in 1939 were, in order of value: gold, iron ore, copper ore and concentrates, chrome ore, silver, manganese ore and lead. The principal gold deposits under development in 1941 were in the Renguet region, near Baguio, Paracale, Masbate, Surigao, Davao and central Luzon. Of the 25 principal mines producing in 1938, all except four were lode mines. The total gold production of the Philippines rose from 160,620 oz. in 1929 to 1,033,037 oz. in 1939—an increase of 643%; values rose from \$3,320,300 to \$36,087,841—an increase of nearly 1,087%. The production of silver likewise increased greatly during the period from 1934 to 1938. In the former year it was 212,610 oz., valued

at \$106,305; in the latter, production was 1,175,192 oz., valued at \$743,578.

In 1934 the production from base metal and nonmetallic mines was less than 6% of the total value of mineral production, gold and silver accounting for more than 94%. However, by the end of 1938, the ratio had risen to 15% and unofficial figures in 1941 confirmed this trend. Principal among the base metals are iron, the value of which rose from \$14,675 in 1934 to \$2,040,323 in 1938; copper, from \$63,084 in 1935 to \$999,981 in 1938; chromite, from \$12,779 in 1935 to \$788,423 in 1938; manganese, from \$6,607 in 1935 to \$499,454 in 1938.

Manufacturing.—Under the commonwealth, industrial progress was speeded in order to strengthen the economic structure; but private manufactures are still in their infancy. A start has been made in sugar, rope, cigar and cigarette and furniture factories, lumber and rice mills and modern factories producing bottles, beer, wine and other liquors, soft drinks, perfumes, cosmetics, roofing tile, soap, leather and rubber shoes, confectionery and hats. In 1941 there were bakeries, print shops and factories for making lard and margarine, pearl buttons (4), pineapple canning (1), cutch (1), cordage (5), matches (1), paints and varnish (4). Fibre hatmaking was a \$500,000 unorganized household industry; 30 embroidery establishments and 15 candy factories were operating in Manila in 1941. Government projects included a cement factory, fish canning, can-making and cotton-spinning plants. Exports of manufactures in 1939 were of the following values: embroideries, \$5,357,072; desiccated coco-nut, \$4,418,748; refined sugar, \$4,282,456; cigars, \$3,145,255; cordage, \$1,586,918; canned pineapple, \$1,707,905; vegetable lard and butter, \$759,074; pearl buttons, \$270,528; other shells, \$33,829; furniture, \$251,526; cutch, \$115,289; hats, \$42,877.

Fisheries.—Of about 1,900 different species of fish, only about 100 kinds are marketed, although a majority are edible. The most common are milkfish, mackerel, snappers, sea basses, porgies, pompanos, mullets, anchovies, barracudas, tunas, bonitos and eels. Fish ponds are of recent development; the first was established in 1863 in Malabon near Manila. Now they exist everywhere about Manila bay and the Gulf of Lingayen. Fish exports in 1939 were chiefly canned tunas, amounting to \$212,883. Other marine products include coral, pearls, shells and sponges; but comparatively few pearls are exported. Among the shells and shell products are mother-of-pearl, trocha, tortoise, green snail shells and shell used for windows.

For the full development of its industries the country needs capital, an adequate supply of dependable and efficient labour and last, but not least, profitable markets.

Transit and Communication.—At the end of 1938 there were 11,907 mi. of roads in the Philippines—6,464 mi. first-class; 3,710 second-class; and 1,733 third-class. Of the total, 6,205 mi. were national and 5,702 mi. were provincial. In Jan. 1939 there were 700 mi. of railway, nearly all narrow gauge, in central and southern Luzon, and 132 mi. (1935) in Panay and Cebu. Bus and truck lines are operated by the railway companies in connection therewith. The Manila Electric company operates a complete system of street railways and bus lines in and about Manila, east-end terminal of the Pan American Airways.

There were 1,021 post offices, 492 first-class, having telegraph or radio, money order and postal savings service; 822 gave free delivery. Foreign air-mail service is maintained with the United States, Hongkong and the Netherlands Indies. Two Philippine air transport companies carry mail from Manila to Baguio, in the north, to Davao, in the extreme south, and to Iloilo, Cebu, Legaspi and Paracale. Four foreign companies furnish adequate cable service and an equal number give radio service with foreign countries. One foreign company maintains a long-distance telephone service within the archipelago and also connects with the United States and elsewhere.

In 1937, 618 vessels and aircraft, with a net tonnage of 2,329,606, came from 16 countries. Interisland trade was served by 2,907 vessels (1937) licensed for domestic trade, 1,545 for coast-wise trade, and 1,362 for bay and river traffic. The port of Manila has ample facilities for ocean-going vessels. The following na-

tional ports are also open to overseas shipping: Iloilo, Aparri, Jolo, Cebu, Davao, Zamboanga, Legaspi and Josk Panganiban. Some 39 national ports and many smaller municipal ports are open to coastwise trade.

Religion and Education. — The Jesuits, who came in 1580, were expelled in 1769 but returned as a missionary and teaching order in 1859 and founded the Manila Ateneo, regarded as the

BY COURTESY OF THE CANADIAN PACIFIC STEAMSHIPS

NATIVE WOMEN OF THE PHILIPPINES GOING TO MARKET IN AN OX-CART

best of high school rank under the Spanish regime. The Capuchins and Benedictines came in the 19th century and a Belgian missionary order and the Christian Brothers after 1898. Gregorio Aglipay, a former Roman Catholic secular priest, together with Isabelo de los Reyes, a layman, founded the Independent Filipino Church shortly after the U.S. occupation. Methodists, Presbyterians, Episcopalians, Baptists, United Brethren, Disciples and Congregationalists came about the turn of the century. Independent Philippine Methodist, Baptist and Disciple churches are offshoots of the parent bodies under native leadership. In 1939 there were: Roman Catholics, 12,603,365; Independent Filipino Church, 1,573,608 (it claims more); Protestants of all sects, 378,361; Moslems, 677,903; Buddhists, 47,852; Shintoists, 13,681; pagans and unclassified, 626,008; miscellaneous, 67,157; no religion, 12,368.

Public schools were hardly known before 1863, when they were authorized by royal decree. A school founded in the 16th century by private bequest, became, in 1601, the College of San José, under the Jesuits, who also founded San Ignacio college. Other religious orders had primary schools and seminaries. The Dominican college of Santo Tomás, founded in the 17th century, later became a royal and pontifical university, which claims to be the oldest of that rank in U.S. territory. Another Dominican school, San Juan de Letran, also continues.

Public schools under U.S. auspices were opened as early as 1900, with soldiers as teachers. In the following year the U.S. transport "Thomas" brought 1,000 U.S. teachers, a few of whom still remained in 1941, though only 80 of the 38,243 teachers reported in 1939 were listed as Americans. The basis of instruction under the U.S. government was English, the aim being to give the Filipinos a common, and at the same time a modern, language. That objective was guaranteed by the Philippine constitution, but efforts were nevertheless made to substitute a native dialect. In March 1939 the enrolment in the public schools was 1,746,452; but more than half the children of school age were out of them, though the schools numbered 10,949. At the same time the enrolment in private educational institutions was 137,187. The University of the Philippines was authorized by an act of the Philippine legislature June 18, 1908. There are also private, non-sectarian institutions known as the University of Manila, the National university and the Far Eastern college. There are some 5,000 school libraries with more than 4,000,000 books. In 1938 there were 45 government hospitals (not including the maternity and children's) with 69,257 patients, excluding the Culion lepers; separate public dispensaries numbered 1,535.

Commerce and Banking. — In 1939 external trade reached \$243,993,862. Exports (not including \$36,836,568 of gold and silver, approximately all of which was shipped to the United States)

were valued at \$121,226,134 and imports at \$122,767,728. Trade with the United States amounted to \$175,559,379 (not including gold and silver), 72% of the total. Purchases from the United States were valued at \$83,427,853, and represented 68% of the total imports. Shipments to the United States amounted to \$92,131,525, approximately 76% of the total exports. The principal imports were iron and steel manufactures (\$20,656,135); cotton goods (\$19,386,268); oils (\$8,484,170); breadstuffs (\$7,638,151); tobacco products (\$6,972,380); and meat and dairy products (\$5,523,890). Exports not mentioned above were sugar (\$49,673,469); copra (\$13,401,248); abaci (\$11,872,487); coco-nut oil (\$9,171,104); tobacco and manufactures (\$7,264,573). Besides the government-owned Philippine National bank, there were five commercial banks, two savings and mortgage banks (postals not included) and six foreign banks. In Aug. 1939 the new government-owned Agricultural and Industrial bank was opened. The total resources of the 14 banks were \$198,255,000.

Finance and Revenue. — Currency is on the U.S. dollar basis, the unit being the peso, stabilized at 50 cents U.S. The exchange standard fund, established to maintain the parity of the peso with the legal tender currency of the U.S., had a net cash balance June 30, 1939, of 48,357,091.38 pesos (\$24,178,545.69). This amount represented 1.18% more than the maximum amount (25%) required to guarantee all Philippine government money in circulation on that date. The per capita circulation at that time, based on an estimated population, was \$6.19. The coinage in circulation consists of silver pesos and half silver pesos, and subsidiary coins in the denominations of one, five, ten and 20 centavos, one centavo being equal to 1/100 of a peso, or to one-half U.S. cent. The treasury certificate fund amounted on June 30, 1939, to 162,078,886 pesos (\$81,039,443), representing 100% of all Philippine treasury certificates in, and available for, circulation.

On June 30, 1939, the bonded indebtedness of the insular, provincial and municipal governments was 148,937,000 pesos (\$74,468,500) for which sinking funds had been provided in the amount of 69,354,071.16 pesos (\$34,677,035.58). From Jan. 1 to July 1, 1939, the insular government collected taxes for its several funds in the amount of 49,275,910.27 pesos (\$24,637,955.14); and 25,552,493.26 pesos (\$12,776,246.63), proceeds of the coco-nut oil excise tax collected in the U.S. and transferred to the Philippines, and 204,858.90 pesos (\$102,429.45) as interest thereon.

Government and Administration. — When Spain colonized the Philippines the natives were living under loose but fairly well crystallized forms of government, the primary unit of which was called "barangay." Society was composed of three classes, viz., serfs, freemen and nobles, and distinct rules governed each class. The Spaniards with great acumen organized their government partly on the native structure, with a governor general as supreme political chief, an *audiencia* or supreme court, provincial or district governments and municipal governments. Immediately

upon conquest, tributes were levied on the natives, who were also given in *encomienda* to the *conquistadores*, officials and favoured Spaniards. In the 19th century there were rather radical changes in the government. The Philippines were represented in the Spanish parliament in 1810, 1812, 1820-23 and 1836-37.

The Spanish colonial government ceased to function in 1898, and was succeeded by a military government under the United States. In Jan. 1899 President McKinley appointed the Schurman commission, which advised the reorganization of municipalities.

In April, 1900, President McKinley appointed the first Philippine commission, which submitted

BY COURTESY OF THE FIELD MUSEUM OF NATURAL HISTORY

TINGUIAN WOMAN SEEDING COTTON AND BRUSHING THE THREAD

all proposed laws to the military governor. Among the first 47 proposed by it and passed within the first few months, the fifth provided for a civil service, which was considerably in advance of that in the United States at that time. Military government ceased on July 4, 1901 (except in certain specified regions where it was maintained until July 4, 1902), at which time Judge Taft became the first civil governor of the Philippines; after his term the title was changed to governor general. The government was made directly dependent on the secretary of war, who organized, as his liaison agency, the bureau of insular affairs which functioned until its abolition July 1, 1939. At that time most of its functions were transferred to the Philippine section of the division of territories and island possessions, U.S. department of the interior. In 1901 the membership of the Philippine commission was increased to seven by the appointment of three additional members, all Filipinos. Shortly afterward, four departments of government were created, viz., interior, commerce and police, finance and justice, and public instruction, each with a member of the Philippine commission as its secretary. In 1901 and 1902 the organization of provincial and municipal governments continued, and by Nov. 10, 1902, 37 provinces had been organized.

On July 1, 1902, congress enacted a provisional enabling or organic act under which the islands were governed until Aug. 29, 1916, when the Jones bill was passed. The organic act of 1902 provided for a general election and the creation of a popular legislative chamber, the Philippine assembly, which was to become the lower house of a Philippine legislature, the Philippine commission to be the upper house. An election of members of the Philippine assembly was held on July 30, 1907. All exclusive legislative power was taken from the Philippine commission and lodged in the legislature, except for territory inhabited by Moros or other Philippine non-Christians. Two resident commissioners were appointed to the congress of the United States, with power to speak on legislation affecting the Philippines but with no vote. In 1908, the Philippine commission was increased by one more Filipino member. In Oct. 1913, President Wilson appointed a new commission, composed of five Filipinos and four Americans. On Aug. 29, 1916, the Jones bill created a legislature with a senate of 24 members and a house of representatives of 91 members (later 92) all elected by popular suffrage except two senators and nine representatives, appointed by the governor general to represent the non-Christian provinces of Nueva Vizcaya, Mountain Province, Agusan, Bukidnon, Cotobato, Davao, Lanao, Sulu and Zamboanga. By virtue of the Jones bill there were six executive departments, each under a secretary, who was assisted by an undersecretary. All these officials except the secretary of public instruction were Philippine citizens. With the exception of the governor general, vice-governor (who was also secretary of public instruction), auditor, deputy auditor, the directors of the Philippine constabulary and of the bureaus of education, agriculture, forestry, science, public works and the coast and geodetic survey, all the departmental secretaries and directors of bureaus were Filipinos.

With the consent of Governor General Harrison, a council of state, consisting of the senate president, speaker of the house and departmental secretaries, was formed to pass on policies and proposed legislation. It ceased to function under Governor General Wood because of the resignation of Filipino members, but was revived by his successor (Stimson) in 1928 and enlarged by Pres. Quezon in 1938 to consist of 12 titular members and such other officials as might be summoned.

The judiciary, after 1938, included the supreme court (7 justices), the court of appeals (15 justices), courts of first instance (62 judges, including those at large), a court of industrial relations (3 judges), municipal courts in chartered cities and justices of the peace (737). All incumbents were Filipinos, appointed by the commonwealth president and confirmed by a legislative committee. These courts were expected to administer what was once Spanish private law but which has been greatly modified by legislation of U.S. origin, as has nearly all the public law except the penal.

There are 48 provinces (excluding Manila) of which 39 are

regularly constituted, with an elective governor, a provincial board and treasurer. Governors of the nine specially organized provinces are elected in five and appointed in four; but all provinces participate in elections of assemblymen and are under supervision of the department of the interior.

There are 936 municipalities (divided into barrios) and 261 municipal districts. Each of the former has an elective mayor, vice-mayor and municipal council and also certain minor officials. The chartered cities, whose officials are appointed by the commonwealth president, are (in order of establishment) Baguio, Zamboanga, Davao, Cebu, Iloilo, Bacolod, Tagaytay, Quezon City, San Pablo, Cavite and Danselan.

History.—The Philippine archipelago first became known to Europeans on March 16, 1521, through Ferdinand Magellan (*q.v.*). But there are authentic Chinese accounts of trading voyages as early as the 10th and 13th centuries, and the contact probably went back much further. A Hindu influence undoubtedly came by way of the Malay peninsula, Java and other islands nearby, and probably reached back to the early centuries of the Christian era. The Hindus influenced the life of the people intimately. Many Sanskrit words in the languages and dialects of the people of the Philippines and the forms of the letters used at the time of their discovery by the Spanish, indicate this.

The second, third and fourth Spanish expeditions were those of Garcia Jofre de Loaisa, of Alvaro de Saavedra and of Ruy López de Villalobos. The next expedition, that of Miguel López de Legazpi (1564–72) was dispatched, like its predecessor, from New Spain, but it was far more carefully planned. Leaving Puerto de Navidad in New Spain, on Nov. 20, 1564, Legazpi reached Cebu in April 1565, where the first permanent settlement was made early in May. But Legazpi, with inadequate forces and resources, meeting prolonged hostility from the Portuguese, who swarmed through the region, at last (1569) moved his main forces to the island of Panay, hoping thereby to have better protection. In 1571 Legazpi made Manila the administrative centre. Thereafter the conquest of Luzon proceeded rapidly, at first principally under Juan de Salcedo, the precocious young grandson of Legazpi. All the archipelago except the Moro islands of Mindanao, the Sulu archipelago and Palawan were in fairly peaceful possession of the Spaniards before 1600. In June 1572 the city of Manila was formally established. In 1574 Manila was attacked by the Chinese Limahong, but he was forced to retire from the island and from the entire group. Several of the provisional governors were churchmen who played into the hands of the ecclesiastics, or catered to their own order.

The Spaniards were accepted easily, even hospitably in many cases, and those coming into closest contact with them began almost immediately to take on the veneer of a superior culture. The conquest was especially easy along the coast and in the low interiors where the Spaniards first went. The principal opposition at Manila in 1570 came from Mohammedans. But that faith was not yet strongly entrenched in Luzon. It was quite different in Mindanao and at various other points in the south. The Spaniards were instinctive enemies of these people, for they had had a seven-century fight in Spain against Mohammedanism. To them the word "Moro" meant Mohammedan, or Moor. Accordingly, they dubbed the Malayan Mohammedans Moros and by this name they are still known. In 1574 the Moros of the Rio Grande de Mindanao offered submission. In 1578–79 Francisco de Sande (1575–80) conducted a fairly successful expedition against the Moros, but the Spaniards were unable to gain any lasting advantage. Until 1837 piratical raids were almost continuous.

The Moros ravaged the coasts far and wide, even threatening Manila itself. The Moros joined often with the Dutch after the latter began to infest oriental waters. In 1848 on Balanguingui island, Governor Narciso Claveria v Zaldúa won the most decisive victory ever gained over the Moros. In 1850 Governor An-

BY COURTESY OF THE U.S. BUREAU OF INSULAR AFFAIRS
SALT WORKS AT MALABON

tonio de Urbiztondo y Eguia destroyed the strongholds on Tonkil island and the next year stormed and captured the town of *Jolo*. This ended the real power of the Moros.

During the interim between Magellan's discovery and the settlement of Manila, the Portuguese actively contested Spanish right to the archipelago. Their hostility ceased only with the union of Spain and Portugal (1580-1640). In 1577 Sir Francis Drake started on the voyage which brought him to the Philippines at Mindanao. Again, in 1587, Thomas Cavendish sailed to the Moluccas and thence back to California to intercept the rich galleon "Santa Ana." He then went to the Philippines, where he tried in vain to capture the shipyard at Iloilo.

The Dutch came next. Their primary object was trade rather than colonies. In 1596-97 Admiral Houtman opened trade with Holland, and during the years 1598-1600 the expedition under Neck and Waryck traded in the Moluccas. In 1600 Oliver van Noordt reached Philippine waters, where he committed various depredations. Dutch vessels now traded for spices and other oriental wares in the Moluccas, harried the coasts and waters of the Philippines and attacked Portuguese, Spanish, Japanese and Chinese shipping. In 1610 Governor Juan de Siiva defeated and killed the Dutch admiral. Francis de Wittert, at Playa Hondo, near Manila, and captured part of his fleet. In 1640 the Dutch captured Malacca and in 1662 they permanently occupied the Moluccas. Their attacks in the Philippines gradually ceased.

In 1762 a British expedition reached Manila on Sept. 22, found the Spanish but ill prepared, and on Oct. 5 captured the city. By the Treaty of Paris in 1763, Manila was restored to Spain.

With Legazpi had come five Augustinians; in 1577 came the Franciscans; in 1580, the Jesuits; in 1587, the Dominicans; and 1605, the Augustinian Recollects. It was the intention of Spain to replace the friars by secular parish priests whenever any mission assumed the character of a parish. But the friars, desirous of retaining their holdings and power, fought secularization and it was never carried out in its entirety. The friars became the storm centre of the gradually increasing Filipino demand for change; the insurrection of 1896 was directed principally against them; and during the later insurrection against the United States they suffered many indignities.

The last Manila galleon left the Philippines in 1811 and returned in 1815. Thereupon the trade was taken over by private persons, exports to the value of 750,000 pesos were allowed and three other ports besides Acapulco were opened to it, namely San Blas, Guayaquil and Callao. In 1766, however, the crown had allowed direct trade between Spain and Manila by one national vessel annually. In 1785 the Royal Company of the Philippines began to trade between Manila and Cadiz; the company ceased to exist in 1830.

In 1809 an English commercial house was permitted to establish itself in Manila, and in 1814 a like privilege was extended to all foreigners, but as a rule, Spaniards were still jealous of foreigners and reactionary decrees in 1828 and 1840 forbade them to sell goods at retail or to do any business in the provinces. The vacillating Spanish policy is seen again in the opening of seven ports to foreign trade in 1830 and their closing the next year. In 1837 Manila was reopened to foreign trade, Iloilo and Cebu in 1855 and 1863. In 1842 there were 39 Spanish shipping and commercial concerns in Manila and about a dozen foreign houses. Various governments maintained consuls, among them Great Britain and the United States.

During the first half of the 19th century, there were only 2,000 to 5,000 Spaniards in the archipelago. Spanish was spoken by some of the natives, principally in Manila and a few other important centres, but the friars had made comparatively little effort to inculcate a knowledge of Castilian. There was no homogeneity among the several native peoples, very largely because of the different languages. Partly because of these conditions, insular representation in the Spanish cortes carried little meaning or a mistaken one to the mass of the population. After the building of the Suez canal, in 1869, ambitious Filipino youths went to Spain and other countries for study. The first daily newspaper was *La Esperanza* (1847). *La Solidaridad* was founded in 1888

in Barcelona, by Graciano López Jaena in the interest of Filipino propaganda, and throughout its course urged reforms both in religion and government. One of its foremost contributors was the precocious Chinese mestizo, Jose Rizal y Mercado. The Filipinos had ample grounds for complaint, especially after 1872. That year some zoo native soldiers at the Cavite arsenal revolted, killed their officers and shouted for independence. Plans for a similar demonstration in Manila failed. The insurrection was quickly suppressed, and led to wholesale arrests, life imprisonment and the execution, among others, of three Filipino secular priests, whose connection with the uprising was not satisfactorily explained.

Meanwhile the gradually expanding idea of Filipino nationality began to manifest itself. The campaign of Rizal, Marcelo del Pilar, López Jaena and Apolinario Mabini, leaders in the "Young Filipino Party," was a protest against both the domination of the friars and economic and administrative caciquism. These aspirations met a sympathetic reception from several governors. But other Spaniards, especially the friars, were diametrically opposed; and much of the old easy and cordial intercourse between the two peoples was changed. Rizal threw himself into the propaganda with eagerness. In 1891 he founded at Hongkong an organization called the Liga Filipina, and in 1892 formed a branch at Manila. He was arrested in 1896 at Barcelona, returned to the Philippines, given a farcical trial and executed on Dec. 30, 1896. At about the time of Rizal's establishment of the Liga Filipina there was also founded an organization called "Supreme Worshipful Association of the Sons of the People," which is generally called the *Katipunan*. The organization was altogether Tagalog and is said to have numbered anywhere from 100,000 to 400,000 members. On Aug. 26, 1896, the actual insurrection broke out. "The cry of Balintawak" is the name given to the first hostilities by the Filipinos. The centre of the revolt was in Cavite province, where Emilio Aguinaldo first came into prominence. Spain sent over reinforcements until there was an army of 28,000 besides a few loyal regiments of native soldiers. A stiff campaign of 52 days brought the defeat of the insurgents, but upon the execution of Rizal, the insurrection broke out again and spread to the provinces of Pangasinan, Zambales and Ilocos. Fernando Primo de Rivera opened negotiations with Aguinaldo and concluded with the insurgents the pact of Biac-na-Bató. Accordingly, Aguinaldo left for Hongkong on Dec. 27, 1897. With the blowing up of the "Maine" on Feb. 15, 1898, actual hostilities broke out between Spain and the United States. (See SPANISH-AMERICAN WAR.) Aguinaldo returned to the Philippines May 19, 1898 and announced renewal of their struggle with Spain. The Filipinos, who had declared their independence of Spain on June 12, 1898, proclaimed a provisional republic with Aguinaldo as president, and on Sept. 9, 1898, moved their capital to Malolos, with Apolinario Mabini, "the mouthpiece of the revolution," as Aguinaldo's chief adviser. On Sept. 15 a revolutionary assembly met and on the 20th ratified Filipino independence. In November and December revolutionary tribunals were organized in the Bisayas.

THE PHILIPPINES UNDER THE UNITED STATES

Relations between the Americans and the Filipinos were unfriendly and steadily grew worse. On Jan. 23, 1899, the Malolos constitution, by virtue of which the Philippines were declared a republic, and which had been approved by the assembly on Nov. 29, and by Aguinaldo on Dec. 23, was proclaimed. Aguinaldo, who had been president of the provisional government, was elected president. On the night of Feb. 4, the inevitable conflict between the Americans and Filipinos surrounding Manila was precipitated. Morning found the Filipinos, who had fought bravely, even recklessly, defeated at all points. While the fighting was in progress, Aguinaldo issued a proclamation of war against the United States. On Feb. 6, the U.S. senate ratified the treaty with Spain, and reinforcements were immediately sent to the Philippines. Antonio Luna, the best trained military man among the Filipinos, was given charge of military operations, but seems to have been greatly hampered by the jealousy and distrust of Aguinaldo, which he fully returned. Luna was murdered, and on March 31, 1899,

Malolos was captured by the U.S. forces. The Filipino government fled northward. In Nov. 1899, the Filipinos resorted to guerrilla warfare, with all its devastating, barbaric features. The capture of Aguinaldo by Gen. Frederick Funston in March 1901 virtually ended the real insurrection, although the last surrender was that of Gen. Miguel Malvar in Samar on April 16, 1902. The major operations of the insurrection were conducted in Luzon, and throughout the army was assisted materially by the Makabebe scouts, who remained loyal to the Americans. Meanwhile, on April 7, 1900, President McKinley instructed the second (Taft) commission to "bear in mind that the government which they are establishing is designed not for our satisfaction nor for the expression of our theoretical views, but for the happiness, peace and prosperity of the people of the Philippine Islands." Nothing was said about independence, although the instructions are often cited in support thereof.

Gov. Taft initiated negotiations with the pope at Rome for the purchase of friar lands (some 400,000 ac.) which were finally bought Dec. 23, 1903 at a price of approximately \$7,250,000. Gov. Taft pledged the credit of the Philippine government for the amount, and bonds were issued therefor. A considerable portion of the lands, of high agricultural quality, were later sold to Filipinos. The pope also replaced the Spanish archbishop and bishops with U.S. prelates.

In 1904 Taft was called home to become secretary of war, but he continued to govern the Philippines from Washington, D.C. In 1905 he took a party of senators and representatives to the islands, at the expense of the Philippine government, and on Oct. 16, 1907, on the eve of his presidential campaign, he opened the first Philippine legislature at Manila, although there was still fighting in the Bisayas and the act of 1902 required a state of "complete peace" before convening the legislature. Among other acts, that body voted to continue both Spanish and English as official languages until 1913, when Spanish was to be dropped. That, however, was never accomplished, and it was expected that, after 1946, Tagalog would be added as an official language. On Aug. 6, 1909, congress passed the Payne bill, granting important trade concessions to the Philippines, and in 1913 the Underwood act provided for complete free trade between the islands and the United States. This concession continued until Jan. 1, 1941.

Gov. Taft was succeeded by Luke E. Wright of Tennessee, who had been a member of the Philippine commission and became the first American to bear the title of governor general. Serving from 1904 to 1906, he was very popular with Americans; but his firm and conservative policy failed to suit the more radical Filipinos and he was transferred to Tokyo as minister. Henry C. Ide of Vermont was the next incumbent of the office. He too was a member of the Philippine commission and had seen service in Samoa during the partition of that group. He was a wise and able administrator but was permitted to remain as governor general for a few months only. He was succeeded by James F. Smith of California, who had come to the islands as a colonel of volunteers and later served on the supreme court and the Philippine commission. It was understood that he was much opposed to accepting the governorship, but that Taft insisted on having a Catholic for the office. Gov. Smith served from 1906 until 1909. On Nov. 11 of that year, W. C. Forbes of Massachusetts was inaugurated as governor general, serving until Aug. 1913, when he was removed. Some of his acts occasioned bitter controversy (such as his deportation, without trial, of a large and prosperous group of Chinese merchants who had been long established in Manila), and his administration was a stormy one. Francis B. Harrison of New York succeeded and served from 1913 to 1921, the longest term of any U.S. governor general.

The Wood-Forbes mission, sent by President Harding in the first year of his administration, reported that the grant of immediate independence would be premature and urged that the U.S. government not be left in a position of responsibility without authority. Wood, a major general in the regular army and the former military governor of Cuba and later of the Philippine Moro province, seemed unusually well equipped for the governor

generalship to which President Harding appointed him, effective Oct. 6, 1921. But by this time the Filipino leaders, having had a taste of power under Wood's predecessor, were in no mood to submit to authority if actually exercised. He administered the government through undersecretaries until 1927, when he died in New York city. Meanwhile, President Coolidge had sent Carmi Thompson of Ohio "to investigate and report" on the Philippines. It was understood at the time that this was a political move to eliminate Thompson from the Ohio senatorial contest; but he made the trip with considerable publicity and likewise reported against the grant of independence, but recommended certain reforms.

Henry L. Stimson of New York was the next governor general. As secretary of war in the Taft administration he had acquired considerable familiarity with Philippine affairs and he had just returned from a successful mission to untangle a difficult situation in a Central American state. Proceeding with tact and caution, he gradually won over the Filipino leaders, obtained some reforms and was about to secure others, when he was called home in 1929 by President-elect Hoover to become secretary of state.

In the following May Dwight F. Davis of Missouri, who had also been secretary of war, was appointed. His administration was uneventful, as was that of Theodore Roosevelt, Jr., who succeeded him in 1932. President F. D. Roosevelt appointed Frank Murphy of Michigan, a strong advocate of independence, who took office as governor general June 15, 1933, and served until Nov. 15, 1935, when he became the first high commissioner in the Philippines. Leaving that post in 1936, Murphy was succeeded by Paul V. McNutt of Indiana, who served until 1939 and took a more serious view of the Philippine situation than did his immediate predecessor. He realized the value of the islands as a source of supply for tropical products and for their mineral wealth, and evidently felt that the grant of independence was a mistake for both countries. But it was now too late to effect any change in the general policy, and McNutt returned to the United States quite disheartened. Francis B. Sayre of Massachusetts, who was appointed to succeed him, arrived in Manila Oct. 21, 1939. He had been on the faculty of Harvard university and later an assistant secretary of state. His prescribed task was to prepare for independence.

For, as early as 1929, the campaign of the Filipinos for that goal had been gaining momentum with new allies, in the United States, among producers of sugar, tobacco, fats and other products and the labour unions which feared the competition of Filipino immigrants. A bill supported by these interests and providing for independence finally passed both houses of congress, was vetoed by President Hoover, passed again over the veto in Jan. 1933, but failed of ratification by the Philippine legislature because of opposition by Manuel Quezon, who, his opponents declared, wished to divert credit from those who had secured passage of the bill in his absence from Washington. This would have been an opportune time to re-examine the whole question; for the Filipinos had now been given their long-sought chance and had rejected it. But the U.S. interests were determined to push the measure through, and the general public in the U.S. was uninformed and indifferent. Quezon hurried to the United States to win President Roosevelt's support for a new bill, differing but little from its predecessor, but (to save the former's face) omitting the important provision reserving absolutely, as in Cuba, sites for naval bases, etc. (These were later to be the subject of "negotiation" and promised to be a fruitful source of trouble.)

The new bill, known as the Tydings-McDuffie act—Public Law No. 127—passed both houses of congress, received presidential approval March 24, 1934, and was ratified by the Philippine legislature on May 1. It provided for independence in 1946, a graduated tax on Philippine exports to the United States (to be collected by said government for a sinking fund for bonded indebtedness) of 5% of the corresponding U.S. duty for the first year, beginning Jan. 1, 1941, and increasing by 5% each subsequent year. This was amended by the act of 1939 (Public Law No. 200), exempting cigars, scrap and filler tobacco, coco-nut oil and pearl or shell buttons, which were all subjected to free

quotas, reducible by 5% each year. Hemp and copra were already on the free list. The U.S. immigration laws were applied, and the annual Filipino quota was limited to 50.

Pursuant to the act, a constitutional convention assembled in Manila July 30, 1934 and remained in session until Feb. 8, 1935, when a draft constitution was approved. It was certified by President Roosevelt on March 23 and ratified on May 14 of the same year by popular vote. It was on the whole a creditable document; but two of its unique features—a single 6-year term for the presidency and a unicameral legislature—were eliminated by amendments adopted in 1939 and approved by President Roosevelt Dec. 2, 1940. After serving six years, President Quezon was re-elected for a four-year term Nov. 4, 1941, but with the understanding—not legally enforceable—that he would give way to Vice-President Osmeña after two years. The Philippine army, which had been trained under the supervision of Douglas MacArthur, son of the last American military governor, was called into the United States service on July 26, 1941, in time for use in meeting the Japanese invasion which began Dec. 8 (Philippine time).

PHILIPPQPOLIS (Bulg. *Plovdiv*), the second town of Bulgaria, capital of the department of the same name, and seat of an archbishopric, is situated on the right bank of the Maritsa, 96 m. E S E of Sofia, and on the main Belgrade-Constantinople railway. Pop. (1934) 99,885, the majority being Bulgars, the remainder chiefly Turks, Armenians, Jews and gypsies. The former Greek colony is now almost extinct. The city lies on and between seven granite rocks which rise abruptly out of the flat and very fertile plain of the Maritsa; the southern Balkans are distant about 25 m., the northern Rhodopes about twelve. The old Turkish Konak, another park, and the gymnasium are near the Maritsa. The "Gate of Hissara" in the old walls is noteworthy. The new town spreads south and south-west of the old.

Philippopolis is a wealthy commercial city, centre of the trade in tobacco, wheat, silk and attar of roses of south Bulgaria. There is also a growing industry in flour-mills, tobacco factories, beer, soap, leather, ink, furniture and sugar.

History.—Eumolpia, a Thracian town, was captured by Philip of Macedon and made one of his frontier posts; hence its name of Philippopolis. Under the Romans, Philippopolis, or Trimontium, was the capital of Thracia. It is said that 100,000 persons were slain when it was captured by the Goths. In 762 it was in ruins when the Emperor Constantine Copronymus settled large colonies of Armenian Paulicians in and around it as frontier guards. It recovered its prosperity under the later Roman Empire, and excited the admiration of the crusaders. Frederick Barbarossa made it his headquarters (1189); in 1205 it was granted

to Renier of Trit. The inhabitants at first welcomed him, but the next year the Greeks declared for the Byzantine emperor, whereupon the Armenians betrayed the city to the Bulgarian tsar, Kaloyan, who massacred its Greek inhabitants, and razed the city to the ground. It recovered again, and became of extreme importance as the centre from which the Bogomils (*q.v.*) derived their doctrines through Armenian teachers. It was retaken by the Greeks in 1262, by the Turks in 1363. It was occupied by Russian troops in 1878, and under the Treaty of Berlin was made capital of the autonomous province of Eastern Roumelia, being united with Bulgaria in 1885 (see BULGARIA: History). In 1928 it was severely damaged by earthquake.

PHILIPPUS, MARCUS JULIUS, Roman emperor A.D. 244 to 249, often called "Philip the Arab," was a native of Bostra in Arabia Trachonitis. Having entered the Roman army, he rose to be praetorian praefect in the Persian campaign of Gordian III., and, inspiring the soldiers to slay the young emperor, was raised by them to the purple (244). Of his reign little is known except that he celebrated the secular games with great pomp in 248, when Rome was supposed to have reached the thousandth year of her existence. A rebellion broke out among the legions of Moesia, and Decius, who was sent to quell it, was forced by the troops to put himself at their head and march upon Italy. Philip was defeated and slain in a battle near Verona. According to Christian writers, he was a convert to Christianity.

See Aurelius Victor, *Caesares*, 28; Eutropius, ix. 3; Zonaras, xii. 19.

PHILIPS, AMBROSE (c. 1675-1749), English poet, was born in Shropshire of a Leicestershire family. He was educated at Shrewsbury school and St. John's college, Cambridge, of which he became a fellow in 1699. His Pastorals opened vol. vi. of Tonson's Miscellanies (1709), which also contained the pastorals of Pope. Philips was a staunch Whig, and a friend of Steele and Addison. In Nos. 22, 23, 30 and 32 (1713) of the *Guardian* he was injudiciously praised as the only worthy successor of Spenser. The quarrel between Pope and Philips which ensued is described by Samuel Johnson as a "perpetual reciprocation of malevolence." Philips had been made justice of the peace for Westminster, and in 1717 a commissioner for the lottery, and when Boulter was made archbishop of Armagh, Philips accompanied him as secretary. He sat in the Irish parliament for Co. Armagh, was secretary to the Lord chancellor in 1726, and in 1733 became a judge. He died in London on June 18, 1749.

His contemporary reputation rested on his pastorals and epistles, particularly the description of winter addressed by him from Copenhagen (1709) to the earl of Dorset. In T. H. Ward's English Poets, however, he is represented by two of the simple and charming pieces addressed to the infant children of Lord Carteret and Daniel Pulteney. These were scoffed at by Swift as "little flams on Miss Carteret," and earned for Philips from Henry Carey the nickname of "Namby-Pamby."

Philips's works are an abridgment of Bishop Hacket's *Life of John Williams* (1700); *The Thousand and One Days; Persian Tales . . .* (1722), from the French of F. Pétis de la Croix; three plays: *The Distrest Mother* (1712), an adaptation of Racine's *Andromaque*; *The Briton* (1722); *Humfrey, duke of Gloucester* (1723). Many of his poems, which included some translations from Sappho, Anacreon and Pindar, were published separately, and a collected edition appeared in 1748.

PHILIPS, JOHN (1676-1708/09), English poet and man of letters, son of Dr. Stephen Philips, archdeacon of Shropshire, was born at Bampton, Oxfordshire, on Dec. 30, 1676. He was educated at Winchester and Christ Church, Oxford. His poem, *The Splendid Shilling*, was called by Addison in *The Tatler* "the finest burlesque poem in the British language." Harley and St. John commissioned him to write a Tory counterblast (Blenheim) to Joseph Addison's *Campaign*. Cyder (1708), one of the earliest of the great didactic poems of the 18th century, is modelled on the *Georgics* of Virgil. *Cerealia, an Imitation of Milton* (1706), although printed without his name, may safely be ascribed to him. In all his poems except *Blenheim* he inserted a eulogy of tobacco. Philips died at Hereford on Feb. 13, 1708/09.

Philips (1927), ed. M. G. Lloyd Thomas; and Johnson's *Lives of the Poets*.

PHILIPS, KATHARINE (1631-1664), English poet, daughter of John Fowler, a merchant of Bucklersbury, London, was born on Jan. 1, 1631. In 1647 she married James Philips, a Welsh royalist. Her home at the Priory, Cardigan, became the centre of a "society of friendship," the members of which were known to one another by fantastic names, Mrs. Philips being "Orinda," her husband "Antenor," Sir Charles Cotterel "Poliarchus." The "matchless" Orinda, as her admirers called her, posed as the apostle of female friendship. Jeremy Taylor dedicated to her his "Discourse on the Nature, Offices and Measures of Friendship," and Cowley, Henry Vaughan, Roscommon and the earl of Cork and Orrery all celebrated her talent. She died of smallpox on June 22, 1664. The literary atmosphere of her circle is preserved in the excellent Letters of Orinda to *Poliarchus*, published by Bernard Lintot in 1705 and 1709.

See E. W. Gosse, *Seventeenth Century Studies* (1883). *Poems, By the Incomparable Mrs. K. P.* appeared surreptitiously in 1664 and an authentic edition in 1667. *Selected Poems*, edited with an appreciation by Miss L. I. Guiney, appeared in 1904. The best modern edition is in *Saintsbury's Minor Poets of the Caroline Period* (vol. i., 1905).

PHILIP THE BOLD (1342-1404), duke of Burgundy, fourth son of John II. of France and Bonne of Luxemburg, was born on Jan. 15, 1342. He earned his surname by his bravery on the field of Poitiers. He accompanied King John into captivity in England. In 1360 he received the title of duke of Touraine, and in June 1363 was entrusted with the government of Burgundy, which John had united to the crown at the death of the last duke of the Capetian family, Philip of Rouvre, in 1361. In September 1363 John made Philip duke of Burgundy, and first peer of France. The donation was ratified at the accession of Charles V. of France; he took possession of the duchy at the end of 1364. Charles appointed him (in 1366) his lieutenant in Champagne and married him in 1639 to Margaret, daughter and heiress of Louis of Mâle, count of Flanders, and widow of Philip of Rouvre.

Philip proved a faithful ally to Charles. He took part in the almost bloodless campaign against the duke of Lancaster, who had landed at Calais; in 1377 he took several towns in French Flanders from the English; and in 1379 relieved Troyes, which had been besieged by the English. On Charles's death Philip found himself, with his brothers, the dukes of Anjou and Berry, in charge of the government of France in the name of Charles VI., who was a minor; and in the absence of the duke of Anjou, who left France in 1382 to conquer the kingdom of Naples, Philip occupied the most powerful position in the realm. He persuaded the young king to intervene in Flanders, where the citizens of Ghent, whose rebellious spirit had necessitated Philip's intervention in 1379, had again revolted under Philip van Artevelde and had expelled Louis of Mâle. On Nov. 27, 1382, the Franco-Burgundian chivalry crushed the rebels at Rosebecke, and on his return the duke of Burgundy took part in repressing the popular movements which had broken out in Paris and other French towns. In 1383 an insurrection in Flanders supported by England gave rise to another French expedition; but in January 1384 the death of Louis of Mâle made Philip master of the countships of Flanders, Artois, Rethel and Nevers; and in the following year the citizens of Ghent decided to submit. At this period Philip sought to ingratiate himself with the emperor by giving two of his daughters in marriage to two princes of the house of Bavaria; he also took an important part in bringing about the marriage of a princess of the same family, Isabel, to King Charles VI.

Hostilities, however, were renewed between France and England. A formidable expedition was prepared under the direction of the duke of Burgundy, and a fleet of 1,400 sail assembled at Sluys; but the enterprise failed owing to the dilatoriness of the duke of Berry. The fatiguing and inglorious expedition in the Netherlands weakened Philip's credit with his nephew, who on his return declared himself of age and confided the government to the ancient councillors of his father, the "Marmousets." The king's madness (1392) restored his uncles to power, and particularly Philip, who after assuring peace by treating with the duke of Brittany and by concluding a truce of twenty-eight years with

England, made strenuous efforts to put an end to the Great Schism, visiting Pope Benedict XIII. at Avignon in 1395 in the hope of obtaining a voluntary resignation from him. For the records in the king's council see CHARLES VI. For a brief period Philip was dispossessed of authority, but he regained it in 1402 and kept it till his death (April 27, 1404). The cathedral of St. Bénigne at Dijon contains his remains, and his tomb (formerly in the Chartreuse of Dijon) is in the Hôtel-de-ville. Philip appears to have governed his territories with sagacity and a certain moderation. He granted numerous privileges to the inhabitants of Dijon, and created in 1386 two *chambres des comptes*, one at Dijon and the other at Lille. He was, in the phrase of a contemporary, "kindly and amiable to high and low and those of middle rank, liberal as an Alexander, noble and pontifical, in court and state magnificent." (R. P.; X.)

PHILIP THE GOOD (1396-1467), duke of Burgundy, son of John the Fearless, duke of Burgundy, and Margaret of Bavaria, was born at Dijon on June 13, 1396, and succeeded his father on Sept. 10, 1419. The assassination of John the Fearless (*g.v.*) drove his successor to the English side. In 1419 Philip signed with Henry V. of England the treaty of Arras, by which he recognized Henry as regent and future heir of the kingdom of France, and in 1420 gave his adherence to the treaty of Troyes. Early in December 1420 Philip entered Paris with the king of England, and subsequently took part in the defeat of the French at Mons-en-Vimeu. By a treaty concluded by Philip at Amiens in April 1423 with the dukes of Brittany and Bedford, John, duke of Bedford, married Philip's sister Anne, and Arthur of Brittany, earl of Richmond, became the husband of Philip's sister Margaret. A few years later discord arose among the allies. When the duke of Bedford besieged Orleans the inhabitants offered to surrender, but to the duke of Burgundy; whereupon Bedford retorted that "he did not beat the bushes for others to take the birds." When this speech reached Philip's ears he withdrew his troops in dudgeon, and concluded a truce with France (1429). Bedford succeeded in conciliating him and in 1430 Philip took part in the campaign against Compiègne.

But another conflict arose between the duke of Burgundy and the English. Jacqueline, countess of Hainaut (see JACOB) the divorced wife of the duke of Brabant and the heiress of Holland and Zeeland, had married the duke of Gloucester, who attempted to take forcible possession of his wife's territories. Philip claimed Brabant as a bequest from his cousin Philip, the late duke, with the result that the Burgundians repulsed the troops of the duke of Gloucester, and Jacqueline was forced to recognize the duke of Burgundy as her lieutenant and heir. Moreover, the duchess of Bedford had died in 1433. Charles VII., who in spite of the efforts of the cardinal of Ste-Croix had hitherto refused to return to France, finally decided to take part in the conferences which were opened at St. Vaast d'Arras on Aug. 6, 1435. Philip agreed to recognize the king of France as his legitimate sovereign on condition that he should not be required to pay him homage during his lifetime. Charles solemnly craved pardon for the murder of John the Fearless and handed over to the duke the counties of Mâcon, Auxerre, Bar-sur-Seine and Ponthieu, and the towns on and near the Somme (Roye, Montdidier, Péronne), reserving the option of redeeming the Somme towns for 400,000 gold crowns. Philip faithfully served the king, aiding him in re-entering Paris and preparing an expedition against Calais, which, however, failed through the ill-will of his Flemish subjects (1436). In 1440 he paid the ransom of Charles of Orleans and married him to Mary of Cleves. In 1442 Philip conspired to give the duke of Orleans a larger share in the affairs of the kingdom.

Philip was frequently disturbed by the insubordination of the Flemish communes. He had to quell seditions at Liège (1430), Ghent (1432 and 1448), Antwerp (1435) and Bruges (1438). Shortly after the final defeat of the citizens of Ghent at Gavre (1453) Philip vowed that he would lead a crusade against the Turks, who had seized Constantinople. The expedition, however, did not take place, and was but a pretext for levying subsidies. In 1459 Philip sent an embassy under the duke of Cleves into Italy to

take part in the conferences preparatory to a fresh expedition against the Turks, but this enterprise likewise fell to the ground. In 1456 the duke of Burgundy had given an asylum to the Dauphin Louis (afterwards Louis XI.), who had quarrelled with his father and had been forced to leave France. Louis repaid his protector by attempting to sow discord in the ducal family of Burgundy, and then retired to the castle of Genappe in Brabant. At Charles VII.'s death, however, Philip was one of the first to recognize the new king, and accompanied him to Paris. During the journey Louis won over the seigneurs of Croy, the principal counselors of the duke of Burgundy, and persuaded Philip to allow him to redeem the Somme towns for the sum stipulated in the treaty of Arras. This proceeding infuriated Philip's son Charles, count of Charolais, who prevailed upon his father to break his pledge and declare war on the king of France. On April 12, 1465, Philip handed over to his son the entire administration of his estates. The old duke died at Bruges on June 15, 1467.

Philip was a great lover of pomp and luxury and a friend of letters, being the patron of Georges Chastelain, Olivier de la Marche and Antoine de la Salle, and the founder of the collection of a ~known as the "Bibliothèque d~ Bourgogne" (now at Brussels), and also of the university of Dôle (1421). He administered his estates wisely; promoted commerce and industry, particularly in Flanders; and left his son a well-lined treasury. He was thrice married: in 1409 to Michelle (d. 1422), daughter of Charles VI. of France; in 1424 to Bonne of Artois (d. 1425); and in 1429 to Isabel (d. 1472), daughter of John I., king of Portugal, when he founded the order of the Golden Fleece. He was succeeded by Charles, afterwards known as Charles the Bold, his only surviving son by Isabel. (R. P.; X.)

PHILISTINES. "Philistine" was the general name for the people of Philistia (Ass. *Palaštu*, *Pilištu*; Eg. *p-r-s-t*), a district embracing the rich lowlands on the Mediterranean coast from the neighbourhood of Jaffa (Joppa) to the Egyptian desert south of Gaza. On the subsequent extension of the name in its Greek form, Palaestina, see PALESTINE.

According to biblical tradition the Philistines are the remnant of Caphtor (Jer. xlvii. 4, Amos ix. 7), and the Caphtōrīm drove out the aboriginal Avvim from Gaza and district, as the Horites and Rephaim were displaced by Edom and Ammon (Deut. ii. 23). These Caphtōrīm, as well as Ludim (Lydians) and other petty peoples, apparently of the Delta, are once reckoned to Egypt (Gen. x. 14). By Caphtor the Septuagint has sometimes understood Cappadocia, which indeed may be valid for its age, but the name is to be identified with the Egyptian K(a)ptar, which in later Ptolemaic times seems to mean Phoenicia, although the earlier Keftiu connoted Crete, and possibly "the south Anatolian coast as far as Cilicia" (Hall). The Cherethites, associated with the Philistine district (1 Sam. xxx. 14, 16, Ezek. xxv. 16, Zeph. ii. 5 seq.), are sometimes recognized by the Septuagint as Cretans, and, with the Pelethites, they form part of the royal bodyguard of Judaean kings (2 Sam. viii. 18, xv. 18, xx. 7, 1 Ki. i. 38, 44; in 2 Sam. xx. 23 the Hebrew text has Carites).

The earliest occurrence of the name "Philistines" outside the Old Testament is in Egypt, where the Purasati (Pulesati) are one of a great confederation from north Syria, Asia Minor and the Levant, which threatened Egypt in the 20th dynasty. They are not among the hordes enumerated earlier by Rameses II. or Merneptah, but in the eighth year of Rameses III. (c. 1194 B.C.); the Purasati (Pulesati) take part in a widespread movement on land and sea. The Syrian States were overwhelmed and the advance upon Egypt seemed irresistible. Rameses, however, collected a large fleet and an army of native troops and mercenaries and claimed decisive victories. The Egyptian monuments depict the flight of the enemy. The sequel of the events is not known, though about a century later the Zakaray are found at Dor, and treat with scant respect the suzerainty of Egypt.

The Egyptian monuments represent the Purasati with a very distinctive feather head-dress resembling that of the Lycians and Mycenaeans. Their general physiognomy is hardly Cilician or Hittite, but European, especially Greek. They fought with a broad-sword and carried a round shield. On archaeological

grounds the Purasati were not Mycenaeans from Crete, despite tradition, but rather from Asia Minor (Lycia, Caria), though they may have passed some time in Crete.

Palestine and the West.—The Philistines appear in the Old Testament as a Semitic or at least a Semitized people. Both the language and the religion were Semitic. The male god Dagon has his partner Astarte (*qq.v.*), and Baal-zebul, a famous oracle of Ekron (2 Ki. i) resembles the local "baals" of Palestine. Philistia seems to be completely Hellenized after the Persian age; but it is not certain that Greek culture pervaded all classes; foreign influence probably always made itself felt upon the coast-towns. The use of the term ἀλλόφυλοι in Maccabaeian and later writings (cf. the contemptuous hatred of Ben Sira, Ecclesiasticus 1. 26, and the author of Jubilees xxiv. 30 sqq.) expresses the conditions of the Greek age and the Maccabean wars. The Mediterranean coast-land was always exposed to incursions of aliens; Carians appear as royal and temple guards at Jerusalem (2 Ki. xi. 4), and old Greek traditions tell of a Carian sea-power and relations between Philistia and Greek lands. Even the presence of Carians and Ionians in the time of Psammetichus I. may be assumed, and as these are planted at Deineh it is noteworthy that this place is also closely associated with a Jewish colony (*viz.*, Tahpanhes, Jer. xliii., *seq.*). In fact, Palestinian intercourse with the West is fairly continuous; and excavation at Beth-shan, Gezer, and other sites, has shown many important indications of Western influence, so that some authorities even recognize a "Philistine" pottery.

History.—The Philistines form a confederation of five cities (Ashdod, Ascalon [Ashkelon], Ekron, Gath and Gaza), which remained unconquered by the Israelites (Josh. xiii. 2 seq., Judges iii. 3; contrast Josh. xv. 45–47, xix. 43). The institution of the Hebrew monarchy (c. 1025 B.C.) follows upon periods of Philistine oppression (Judges iii. 31, x. 7, 11, xiii. 1, 5; see SAMSON; ELI; SAMUEL; SAUL; DAVID). Their subjugation is ascribed to Samuel (1 Sam. vii. 13), Saul (xiv. 47), and David (2 Sam. viii. 1). They evidently recovered their independence, and twice within a short time the northern Israelites laid siege to the border fortress of Gibbethon (1 Ki. xv. 27, xvi. 15). The interrelations of the south Palestinian peoples follows from the unchangeable geographical conditions, and Judah always depended upon its relations with the Philistines on the west and with the Edomites and Arabian tribes on the south-east. "Philistia," with Edom and Beth-Omri (*i.e.*, the Israelite kingdom), paid tribute to the Assyrian king, Adad-Nirari III. (c. 802 B.C.). The omission of Judah is noteworthy. In the later Assyrian period Philistia was mixed up in pro- and anti-Assyrian intrigues, and suffered from Tiglath-pileser (734), Sargon (720) and Sennacherib (700). In the 7th century Gaza, Ascalon, Ashdod and Ekron were Assyrian vassals, together with Judah, Moab and Edom—in all, 22 kings of the "Hittites." Herodotus mentions the Scythian invasion and sack of the temple of Aphrodite Urania (Astarte) at Ascalon, also the prolonged siege of Ashdod by Psammetichus, and the occupation of Kadytis (? Gaza) by Necho. But the Babylonian empire followed upon traditional lines and thrust back Egypt, and Nabonidus (553 B.C.) claims his vassals as far as Gaza. The Persians took over the realm of their predecessors, and Gaza grew in importance as a seat of international commerce. Nehemiah speaks not of Philistines, but of Ashdodites (iv. 7), speaking an "Ashdodite" dialect (xiii. 24); just as Strabo regards the Jews, the Idumaeans, the Gazans and the Ashdodites as four cognate peoples having the common characteristic of combining agriculture with commerce. In southern Philistia, at least, Arabian immigration became more pronounced. In the time of Cambyses Arabs were settled at Jenysos south of Gaza (Herod. iii. 5), and when Alexander marched upon Egypt, Gaza with its army of Arabs and Persians offered a strenuous resistance. On the history of the district see further GAZA; JEWS; MACCABEES; PALESTINE.

Traditions of the Philistines.—The Philistines were prominent in popular tradition, and the story of Isaac and the Philistine Abimelech (Gen. xxvi., cf. xxi. 32) is of great interest for its unbiased picture of enmity, alliance and covenant. But a parallel story (xx.) is without this Philistine background. Similarly,

one account of the Israelite invasion conceived a conquest of earlier giant inhabitants (Anākīm), who survived in Gaza, Gath and Ashdod (Josh. xi. 21 *seq.*, contrast xiii. 3), but were driven out from Hebron by Caleb (Josh. xv. 14, *cf.* Num. xiii. 22, 28). The Philistines themselves are called the remnant of the Anākīm (Jer. xlvi. 5, so the Septuagint), or as Caphtōrīm replace the earlier Avvim (Deut. ii. 23, *see* Josh. xiii. 3). Samuel's great defeat of the Philistines leads to "peace between Israel and the Amorites" (1 Sam. vii. 14); and the migration of the Danites is placed after Samson's conflicts with the *Philistines* (Judges xviii. *seq.*), or is due to the pressure of *Amorites* (i. 34). Even in David's fights with the Philistines in Judah, Jerusalem is Jebusite, neighbouring non-Israelite cities are Hivite or Amorite (Josh. ix. 7, 2 Sam. xxi. 2), and his strange adversaries find a close parallel in the semi-mythical sons of Anak (2 Sam. xxi. 16, 18, 20, 22). In another tradition, however, David is on intimate relations with a Philistine king, Achish (or Abimelech, Ps. xxxiv.), *cf.* Isaac, p. 735. Traditions agree that the Israelites had to fight for their freedom, but antagonism between Philistines and Israelites was not persistent.

See further H. R. Hall, *Camb. Anc. Hist.*, iii. ch. xii. (with bibliography); and the articles on "Philistines" in *Reallexikon d. Vorge-schichte* (illustr. by Gallin) and *Ency. Bib.* (G. F. Moore). (S. A. C.)

PHILISTUS, Greek historian of Sicily, was born at Syracuse about the beginning of the Peloponnesian War (432 B.C.). He was a faithful supporter of the elder Dionysius, and commander of the citadel. In 386 he was banished for secretly marrying the tyrant's niece. He commanded the fleet against Dion, but was defeated and put to death (356). He settled at Thurii, but afterwards removed to Adria, where he remained until the death of Dionysius (366). He was then recalled by the younger Dionysius, whom he persuaded to dismiss Plato and Dion. During his stay at Adria, Philistus occupied himself with the composition of his *Σικελικά*, a history of Sicily in eleven books, down to 363, from which point the work was carried on by Athanas. Cicero (*ad. Q. Fr.* ii. 13) calls him "the miniature Thucydides" (*pusillus Thucydides*).

See Diod. Sic. xiii. 103, xiv. 8, xv. 7, xvi. 11, 16; Plutarch, *Dion.* 11–36; Cicero, *Brutus*, 17, *De oratore*, ii. 13; Quintilian, *Instit.* x. 1. 74; fragments and life in C. W. Müller, *Fragmenta historicorum graecorum*, vol. 1. (1841); C. Wachsmuth, *Einleitung in das Studium der alten Geschichte* (1895); E. A. Freeman, *History of Sicily* (1891–94); A. Holm, *Geschichte Siciliens im Altert.* (1870–98).

PHILLIMORE, SIR ROBERT JOSEPH (1810–85), English judge, was born at Whitehall on Nov. 5, 1810. Educated at Westminster and Christ Church, Oxford, where a lifelong friendship with W. E. Gladstone began, his first appointment was to a clerkship in the board of control, where he remained from 1832 to 1835. Admitted as an advocate at Doctors' Commons in 1839, he was called to the bar at the Middle Temple in 1841, and rose very rapidly. He was engaged as counsel in almost every case of importance that came before the admiralty, probate or divorce courts. He was appointed judge of the Cinque Ports in 1855, queen's counsel in 1858, and advocate-general in admiralty in 1862, and succeeded Stephen Lushington as judge of the court of arches five years later. Here his care, patience and courtesy, combined with unusual lucidity of expression, won general respect. He was the last judge of the old court of the lord high admiral; after the Judicature act he continued to sit as judge for the new admiralty, probate and divorce division until 1883. He wrote *Ecclesiastical Law of the Church of England*, a book which still holds its ground, *Commentaries on International Law*, and a translation of Lessing's *Laocoon*.

PHILLIMORE, WALTER GEORGE FRANK PHILLIMORE, 1st BARON (1845–1929), British judge, was born in London on Nov. 21, 1845, the eldest son of Sir Robert Joseph Phillimore, Bart. (*q.v.*). He was educated at Westminster and Christ Church, Oxford, and was called to the Bar in 1868. He was made a judge in 1913, and promoted to the Court of Appeal in 1913. He retired from the bench in 1916, and in 1918 was raised to the peerage. In 1918 he became chairman of the naval prize tribunal. Lord Phillimore was English representative on the commission which sat at The Hague in 1920 to prepare the scheme of a

permanent Court of International Justice. He died on March 13, 1929.

Lord Phillimore's publications include *Three Centuries of Treaties of Peace and Their Teaching* (1917); he also revised J. H. Blunt's *Book of Church Law* and several of his father's works.

PHILLIPS, EDWARD (1630–?1696), English author, son of Edward Phillips of the crown office in chancery, and his wife Anne, only sister of John Milton, the poet, was born in Aug. 1630 in the Strand, London. His father died in 1631, and Anne Phillips eventually married her husband's successor in the crown office, Thomas Agar. Edward Phillips and his younger brother, John, were educated by Milton. Edward entered Magdalen Hall, Oxford, in November 1650, but left the university in 1651 to be a bookseller's clerk in London. He was tutor to the son of John Evelyn, 1663 to 1672, and in 1677–79 in the family of Henry Bennet, earl of Arlington. The date of his death is unknown but his last book is dated 1696.

His most important work is *Theatrum poetarum* (1675), a list of the chief poets of all ages and countries, but principally of the English poets, with short critical notes and a prefatory *Discourse of the Poets and Poetry*, which has usually been traced to Milton's hand. He also wrote *A New World in Words, or a General Dictionary* (1658), which went through many editions; a new edition of Baker's *Chronicle*, of which the section on the period from 1650 to 1658 was written by himself from the royalist standpoint; a supplement (1676) to John Speed's *Theatre of Great Britain*; and in 1684 *Enchiridion linguae latinae*, said to have been taken chiefly from notes prepared by Milton. Aubrey states that all Milton's papers came into Phillips's hands, and in 1694 he published a translation of his *Letters of State* with a valuable memoir.

His brother, JOHN PHILLIPS (1631–1706), in 1652 published a Latin reply to the anonymous attack on Milton entitled *Pro Rege et populo anglicano*. He appears to have acted as unofficial secretary to Milton, but he published in 1655 a bitter attack on Puritanism entitled a *Satyr against Hypocrites*. In 1656 he was summoned before the privy council for his share in a book of licentious poems, *Sportive Wit*, which was suppressed by the authorities but almost immediately replaced by a similar collection, *Wit and Drollery*.

An extended, but by no means friendly, account of the brothers is given by Wood, *Athen. oxon.* (ed. Bliss, iv. 764 *seq.*), where a long list of their works is dealt with. This formed the basis of William Godwin's *Lives of Edward and John Phillips* (1815), with which is reprinted Edward Phillips's *Life of John Milton*.

PHILLIPS, STEPHEN (1868–1915), British poet and dramatist, was born on July 28, 1868, at Somertown near Oxford, the son of the Rev. Stephen Phillips, precentor of Peterborough cathedral. He was educated at Stratford and Peterborough grammar schools, and entered Queen's college, Cambridge; but during his first term at Cambridge, when F. R. Benson's dramatic company visited the town, he joined it, and for six years played various small parts. In 1890 a slender volume of verse was published at Oxford with the title *Primavera*, which contained contributions by him and by his cousin, Laurence Binyon, and others. In 1894 he published *Eremus*, a long poem of loose structure in blank verse of a philosophical complexion. *Poems* (1897) brought him many readers. George Alexander commissioned Phillips to write him a play, the result being *Paolo and Francesca* (1900), produced at the St. James's Theatre in 1901. Other dramas in blank verse followed: *Herod: a Tragedy* (1900), *Ulysses* (1902), *The Sin of David* (1904), and *Nero* (1906). In these plays, three of which were produced by Beerbohm Tree, the poet's avowed aim was to revitalize the method of the Greek drama. *Paolo and Francesca* was the most successful. He died at Deal, Kent, on Dec. 9, 1915.

See a notice by Arthur Symons prefixed to the edition (1927) of his last play, *Harold*, which was first printed in the *Poetry Review*, Jan. and March 1916; also Sir Sidney Colvin in T. Humphrey Ward's *English Poets* (vol. v. 1918).

PHILLIPS, WENDELL (1811–1884), American orator and reformer, was born in Boston on Nov. 29, 1811. His father, John Phillips (1770–1823), a man of wealth and influence, graduated at Harvard college in 1788, and became "town advocate and public prosecutor," and in 1822 first mayor of Boston. Phillips attended the public Latin school, entered Harvard college before he was 16

and graduated in 1831. He graduated at the Harvard law school in 1834, and was admitted to the bar in Boston. He soon came under the influence of the anti-slavery movement, witnessing in 1835 the mobbing, in Boston, of William Lloyd Garrison.

A meeting was held on Dec. 8, 1837, at Faneuil Hall to express the sentiments of the people on the murder of Elijah P. Lovejoy, at Alton (Ill.) for defending his press from a pro-slavery mob. In the course of the meeting a speech was made in opposition to its general current by James T. Austin, attorney-general of the State, who said that Lovejoy had died "as the fool dieth," and compared his murderers to the men who threw the tea into Boston harbour just before the War of Independence. The speech seemed likely to divide the audience, when Wendell Phillips took the platform. "When I heard," he said, "the gentleman lay down principles which placed the murderers of Alton side by side with Otis and Hancock, with Quincy and Adams, I thought these pictured lips (pointing to their portraits) would have broken into voice to rebuke the recreant American, the slanderer of the dead." This appeal not merely determined the sentiment of the meeting; it gave Wendell Phillips his first fame and determined his career.

Although loving his profession, and this especially for the opening it gave in the direction of public life, he lived henceforth the life of an agitator, or, like his father, that of a "public prosecutor." Accepting unhesitatingly the leadership of Garrison, and becoming like him a disunionist, he lived essentially a platform life, interested in a variety of subjects, but first and chiefly an abolitionist. In 1865, however, after the Civil War, he broke with Garrison over the question of discontinuing the Anti-Slavery Society; and from that date until the society was disbanded in 1870, he, instead of Garrison, was its president. Phillips' style of eloquence was direct and brilliant, but eminently self-controlled. He may be said to have introduced the direct and colloquial manner upon the American public platform. His logic, while never obtruded, was rarely at fault, but he loved the flash of the rapier, and was never happier than when he had to face a mob and utterly foil it by sheer superiority in fencing. The two volumes of his speeches, as edited by James Redpath, were fortunately made from verbatim reports, and they wisely enclose in parentheses those indications of favour or dissent from the audience which transformed so many of his speeches into exhibitions of gladiatorial skill. After slavery had fallen Phillips associated himself freely with reformers occupied in other paths. He contended in later years for prohibition, woman suffrage and various penal and administrative reforms. He died in Boston on Feb. 2, 1884.

Russell, *Story of Wendell Phillips: Soldier of the Common Good* (1914); and George Edward Woodbury, *Heart of Man and Other Papers* (1920).

PHILLIPSBURG, a town of Warren county, New Jersey, U.S.A., on the Delaware river, opposite Easton, Pa.; served by the Central of New Jersey, the Lackawanna, the Lehigh and Hudson, the Lehigh Valley and the Pennsylvania railways and by bus lines. Pop. (1930) 19,255 and 18,314 in 1940 by federal census.

The city rises from the river bottom to bluffs commanding fine views. It has railroad shops and various other manufacturing industries. Phillipsburg was settled about 1750, but it was only a straggling village until the Morris canal was constructed (182j). An iron furnace was established in 1848, and the Central Railroad of New Jersey reached the town in 1852.

It was incorporated in 1861.

PHILLIPSITE, a mineral of the zeolite group; a hydrated potassium, calcium and aluminium silicate, approximating to $(K_2, Ca)Al_2(SiO_3)_4 \cdot 4H_2O$. It varies somewhat in composition, and a variety ("pseudophillipsite") containing rather less silica has the formula $(K_2, Ca)_2Al_4Si_5O_{18} \cdot 9H_2O$. Crystals are monoclinic, but only complex cruciform twins are known, these being exactly like twins of harmotome (*q.v.*), though the phillipsite crystals are usually smaller and more transparent and glassy. Spherical groups with a radially fibrous structure and bristled with crystals on the surface are not uncommon. The hardness is $4\frac{1}{2}$, and the specific gravity 2.2. The species was named in 182j after William Phillips;

French mineralogists call it christianite (after Christian VIII. of Denmark).

Phillipsite is a mineral of secondary origin, and occurs with other zeolites in the amygdaloidal cavities of basic volcanic rocks; e.g., in the basalt of the Giant's Causeway in Co. Antrim and near Melbourne, Victoria, and in leucitite near Rome; while small crystals of recent formation occur in the masonry of the hot baths at Plombières and Bourbonne-les-Bains, France. Minute spherical aggregates embedded in red clay were dredged by the "Challenger" from the bottom of the central Pacific, where they had been formed by the decomposition of volcanic ash.

PHILLPOTTS, EDEN (1862—), British novelist, poet and dramatist, was born in India on Nov. 4, 1862, and educated at Plymouth. He was a clerk for ten years in the Sun fire insurance office, then studied for the stage, but turned his attention to literature, producing a number of successful novels, many of them with a Devonshire setting. Among his more important works are the novels, *Children of the Mist* (1898); *Sons of the Morning* (1900); *Widcombe Fair* (1913); studies of boyhood and adolescence, *The Human Boy* (1899); *The Angle of Seventeen* (1912); plays, *The Farmer's Wife* (1917); *Yellow Sands* (with his daughter Adelaide Eden Phillpotts, 1926); and poems, *The Iscariot* (1912); *Brother Beast* (1928).

PHILLPOTTS, HENRY (1778–1869), English bishop, was born at Bridgwater on May 6, 1778, and was educated at Gloucester College school and Corpus Christi college, Oxford. He was consecrated bishop of Exeter in 1831, holding with the see a residentiary canonry at Durham. In 1819 he had defended the existing poor law and the action of the Government in the "Peterloo massacre." In 1825, he vehemently opposed Catholic emancipation, engaging in a fierce polemic on the subject with Charles Butler (1750–1832). (Henry of Exeter" continued to support the Tory party, even when it passed the Roman Catholic Emancipation Act of 1829. He died on Sept. 18, 1869. The famous Gorham judgment was the outcome of his refusal to institute to the living of Bramford Speke a clergyman George Cornelius Gorham (1787–1857), who had openly disavowed his belief in baptismal regeneration; he denounced the equally famous Tract 90 in his episcopal charge of 1843. See Shutte, *The Life of Dr. Phillpotts* (1863).

PHILO, often called PHILO JUDAEUS, Jewish philosopher, appears to have spent his whole life at Alexandria, where he was probably born c. 20–10 B.C. His father Alexandria was alabarch or arabarch (that is, probably, chief farmer of taxes on the Arabic side of the Nile), from which it may be concluded that the family was influential and wealthy (Jos., *Ant.* xviii. 8, 1). The only event of his life which can be actually dated belongs to A.D. 40, when Philo, then a man of advanced years, went from Alexandria to Rome, to persuade the emperor Gaius to abstain from claiming Divine honour of the Jews. Of this embassy Philo has left a full account (*De legatione ad Gaium*).

The **Hellenistic Jew**.—Philo is the most important representative of Hellenistic Judaism, and his writings give us the clearest view of what this development of Judaism in the diaspora was and aimed at.

Philo appears to have been the greatest of all the Jewish philosophers of the Alexandrian school. On one side he is quite a Greek, on the other quite a Jew. His language is formed on the best classical models, especially Plato. He knows and often cites the great Greek poets, but his chief studies had been in Greek philosophy. His system was eclectic, but the borrowed elements are combined into a new unity with so much originality that he may fairly be regarded as representing a philosophy of his own, which has for its characteristic feature the constant prominence of a fundamental religious idea. Philo's closest affinities are with Plato, the later Pythagoreans and the Stoics. Yet with all this Philo remained a Jew, and a great part of his writings is expressly directed to recommend Judaism to the respect and, if possible, the acceptance of the Greeks. He was not a stranger to the specifically Jewish culture that prevailed in Palestine; in Hebrew he was not proficient, but he had evidently made some study of that language. His method of exegesis is identical in form with that of the Palestinian scribes, and there are coincidences in matter. Philo recog-

nized the Mosaic Scriptures of the Pentateuch as of absolute Divine authority and as containing all truth. The other Jewish Scriptures are also recognized as prophetic, *i.e.*, as the writings of inspired men, but he does not place them on the same lines with the law. Everything that is right and good in the doctrines of the Greek philosophers had already been quite as well, or even better, taught by Moses. Thus, since Philo had been deeply influenced by the teachings of Greek philosophy he actually finds in the Pentateuch everything which he had learned from the Greeks. From these premises he assumes as requiring no proof that the Greek philosophers must in some way have drawn from Moses, a view indeed which is already expressed by Aristobulus. These presuppositions were maintained by an allegorical interpretation of Scripture. With its aid he discovers indications of the profoundest doctrines of philosophy in the simplest stories of the Pentateuch.

His Doctrine of God starts from the idea that God is a Being absolutely bare of quality. All quality in finite beings has limitation, and no limitation can be predicated of God, who is eternal, unchangeable, simple substance, free, self-sufficient, better than the good and the beautiful. To predicate any quality (*ποιότης*) of God would be to reduce Him to the sphere of finite existence. Of Him we can say only that He is, not what He is, and such purely negative predications as to His being appear to Philo, as to the later Pythagoreans and the Neoplatonists, the only way of securing His absolute elevation above the world. At bottom, no doubt, the meaning of these negations is that God is the most perfect being; and so, conversely, we are told that God contains all perfection, that He fills and encompasses all things with His being.

A consistent application of Philo's abstract conception of God would exclude the possibility of any active relation of God to the world, and therefore of religion, for a Being absolutely without quality and movement cannot be conceived as actively concerned with the multiplicity of individual things. And so in fact Philo does teach that the absolute perfection, purity and loftiness of God would be violated by direct contact with imperfect, impure and finite things. But the possibility of a connection between God and the world is reached through a distinction which forms the most important point in his theology and cosmology; the proper Being of God is distinguished from the infinite multiplicity of divine Ideas or Forces: God himself is without quality, but He disposes of an infinite variety of Divine Forces, through whose mediation an active relation of God to the world is brought about.

Mediating Forces.—Philo's conception of the nature of these mediating Forces was self-contradictory. On the one hand they are nothing else than Ideas of individual things conceived in the mind of God, and as such ought to have no other reality than that of immanent existence in God, and so Philo says expressly that the totality of Ideas, the *κόσμος νοητός*, is simply the Reason of God as Creator (*θεοῦ λόγος ἤδη κοσμοποιούντος*). Yet, on the other hand, they are represented as daemons or angels, hypostases distinct from God, individual entities existing independently and apart from Him. This vacillation, however, as Zeller and others have justly remarked, is necessarily involved in Philo's premises, for, on the one hand, it is God who works in the world through His Ideas, and therefore they must be identical with God; but, on the other hand, God is not to come into direct contact with the world, and therefore the Forces through which He works must be distinct from Him. The same inevitable amphiboly dominates in what is taught as to the supreme Idea or Logos. Philo regards all individual Ideas as comprehended in one highest and most general Idea or Force—the unity of the individual Ideas—which he calls the Logos or Reason of God, and which is again regarded as operative Reason. The Logos, therefore, is the highest mediator between God and the world, the firstborn son of God, the archangel who is the vehicle of all revelation, and the high priest who stands before God on behalf of the world. Through him the world was created, and so he is identified with the creative Word of God in Genesis (the Greek *λόγος* meaning both "reason" and "word"). Here again, we see, the philosopher is unable to escape from the difficulty that the Logos is at once the immanent Reason of God, and yet also an hypostasis standing between God and the world. The whole doctrine of this mediatorial hypostasis is a strange

intertwining of very dissimilar threads; on one side the way was prepared for it by the older Jewish distinction between the Wisdom of God and God Himself, of which we find the beginnings even in the Old Testament (Job xxviii. 12 seq.; Prov. viii., ix.), and the fuller development in the books of Ecclesiasticus and Wisdom, the latter of which comes very near to Philo's ideas if we substitute for the term "wisdom" that of (divine) "Reason." In Greek philosophy, again, Philo, as we have seen, chiefly follows the Platonic doctrines of Ideas and the Soul of the World, and the Stoic doctrine of God as the *λόγος* or Reason operative in the world. In its Stoic form the latter doctrine was pantheistic, but Philo could adapt it to his purpose simply by drawing a sharper distinction between the Logos and the world.

The World and Creation, in Philo's doctrine, rest on the presupposition of an absolute metaphysical contrast between God and the world. The world can be ascribed to God only in so far as it is a cosmos or orderly world; its material substratum is not even indirectly referable to God. Matter (*ἔλη*, or, as the Stoics said, *οὐσία*) is a second principle, but in itself an empty one, its essence being a mere negation of all true being. It is a lifeless, unmoved, shapeless mass, out of which God formed the actual world by means of the Logos and divine Forces. Strictly, the world is only formed, not created, since matter did not originate with God.

Philo's Doctrine of Man is also strictly dualistic, and is mainly derived from Plato. Man is a twofold being, with a higher and a lower origin. Of the pure souls which fill airy space, those nearest the earth are attracted by the sensible and descend into sensible bodies; these souls are the Godward side of man. But on his other side man is a creature of sense, and so has in him a fountain of sin and all evil. The body, therefore, is a prison, a coffin, or a grave for the soul which seeks to rise again to God. The highest maxim of Philo's ethics is therefore deliverance from the world of sense and the mortification of all the impulses of sense. In carrying out this thought, Philo differs from the Stoics. The Stoics cast man upon his own resources; Philo points him to the assistance of God, without whom man, a captive to sense, could never rise to true wisdom and virtue. Even in this life the truly wise and virtuous is lifted above his sensible existence, and enjoys in ecstasy the vision of God, his own consciousness sinking and disappearing in the Divine light. Beyond this ecstasy there lies but one further step, *viz.*, entire liberation from the body of sense and the return of the soul to its original condition; it came from God and must rise to Him again. But natural death brings this consummation only to those who, while they lived on earth, kept themselves free from attachment to the things of sense; all others must at death pass into another body; transmigration of souls is in fact the necessary consequence of Philo's premises.

Works.—The titles of the numerous extant writings of Philo present at first sight a most confusing multiplicity. More than three-fourths of them, however, are really mere sections of a small number of larger works. Three such great works on the Pentateuch can be distinguished.

I. The smallest of these is the *Ζητήματα καὶ λύσεις* (Questiones et solutiones), a short exposition of Genesis and Exodus, in the form of question and answer. The work is cited under this title by Eusebius (H.E. iii. 18, 1, 5; Praep. Ev. vii. 13), and by later writers, but the Greek text is now almost wholly lost, and only about one-half preserved in an Armenian translation. Genesis seems to have occupied six books. Eusebius tells us that Exodus filled five books. In the Armenian translation, first published by the learned Mechtarist, J. Bapt. Aucher, in 1826, are preserved four books on Genesis and two on Exodus, but with lacunae. A Latin fragment, about half of the fourth book on Genesis (Phil. Jud. CII. quaest. . . . super Gen.), was first printed at Paris in 1520. Of the Greek we have numerous but short fragments in various Florilegia. The interpretations in this work are partly literal and partly allegorical.

II. Philo's most important work is the *Νόμων ἱερῶν ἀλληγορίαι* (Euseb. H.E. ii. 18, 1; Phot. Bibl. Cod. 103), a vast and copious allegorical commentary on Genesis, dealing with chaps. ii.–iv., verse by verse, and with select passages in the later chapters. The readers in view are mainly Jews, for the form is modelled on the

rabbinic Midrash. The main idea is that the characters which appear in Genesis are properly allegories of states of the soul (τρόποι τῆς ψυχῆς). All persons and actions being interpreted in this sense, the work as a whole is a very extensive body of psychology and ethics. It begins with Gen. ii. 1. for the *De mundi officio*, which treats of the creation according to Gen. i., ii., does not belong to this series of allegorical commentaries, but deals with the actual history of creation, and that under a quite different literary form. With this exception, however, the *Νόμων ἀλληγορία* includes all the treatises in the first volume of Mangey's edition.

III. A work of a very different kind is the group of writings which we may call "An Exposition of the Mosaic Law for Gentiles," which, in spite of their very various contents, present on nearer examination indubitable marks of close connection. In them Philo seeks to give an orderly view of the chief points of the Mosaic legislation in the Pentateuch, and to recommend it as valuable to Gentile readers. The method of exposition is somewhat more popular than in the allegorical commentaries, for, though that method of interpretation is not wholly excluded, the main object is to give such a view of the legislation as Philo accepted as historical. This work has three main divisions: (a) an Account of the creation (*κοσμοποιΐα*) which Moses put first to show that his legislation was conformed to the will of nature, and that therefore those who followed it were true cosmopolitans; (b) the Biographies of the Virtuous — being, so to speak, the living unwritten laws which, unlike written laws, present the general types of moral conduct; (c) Legislation Proper, in two subdivisions — (a) the ten principal chapters of the law, (β) the special laws belonging to each of these ten. An appendix adds a view of such laws as do not fall under the rubrics of the decalogue.

IV. Besides the above-named three great works on the Pentateuch, Philo was the author of a number of isolated writings, of which the following have reached us either in their entirety or in fragments. (1) *Περὶ βίου Μωσέως* (*Vita Mosis*, lib. i.—iii., M. ii. 80—179). (2) *Περὶ τοῦ πάντα σπουδαῖον εἶναι ἐλεύθερον* (*Quod omnis probus liber*, M. ii. 445—470). The genuineness of the writing now possessed by us is not undisputed: but see Lucius, *Der Essenismus* (1881), pp. 13—23. (3) *Εἰς Φλάκκον* (*Adversus Flaccum*, M. ii. 517—544) and (4) *Περὶ ἀρετῶν καὶ πρεσβείας πρὸς Γάϊον* (*De legatione ad Gaium*, M. ii. 545—600). These two works have a very intimate connection. In the first Philo relates how the Roman governor, Flaccus, in Alexandria, towards the beginning of the reign of Caligula, allowed the Alexandrian mob to persecute the Jews. In the second he relates the persecution under Caligula that divine honours should be everywhere accorded to him, and how the Jews of Alexandria in vain sought relief by a mission to Rome which was headed by Philo. These were parts of a larger work, in five books. (5) *Περὶ προνοίας* (*De providentia*). This work has reached us only in an Armenian translation, which has been edited, with a Latin translation, by Aucher (see below), 1822. It is mentioned by its Greek title in Eusebius (*H. E.* ii. 18, 6; *Praep. Ev.* vii. 20 fin., viii. 13 fin., ed. Gaisford). (6) *Ἀλέξανδρος ἢ περὶ 700 λόγων ἔχειν τὰ ἄλογα ζῶα* (*De Alexandro et quod propriam rationem mutua animalia habeant*; so Jerome, *De Vir. Ill.* c. 11); the Greek title is given in Euseb. *H. E.* ii. 18, 6. This also now exists only in an Armenian translation, which has been edited by Aucher. Two small Greek fragments occur in the *Florilegium* of Leontius and Johannes (*Mai, Scr. vet. nov. coll.* vii. 1, pp. 99, 100a). (7) *Ἐπιθετικά*, a writing now known to us only through fragments preserved in Euseb., *Praep. Ev.* viii. 6, 7. (8) *Περὶ Ἰουδαίων*, a title met with in Euseb. *H. E.* ii. 18, 6. The writing is no doubt the same as *Ἡ ὑπερ' Ἰουδαίων ἀπολογία*, from which a quotation is given in Euseb. *Praep. Ev.* viii. 11. To this place also, perhaps, belongs the *De nobilitate* (M. ii. 437—444), which treats of that true noblesse of wisdom which the Jewish people does not lack.

V. The doubtful treatises: (1) *Περὶ βίου θεωρητικοῦ ἢ ἱκετῶν ἀρετῶν* (*De vita contemplativa*); the sole original account of an ascetic community known as the *Therapeutae* (q.v.) having their home on the shores of Lake Mareotis. (2) *Περὶ ἀφθαρσίας κόσμου* (*De incorruptibilitate mundi*), declared unauthentic by Z. Frankel and J. Bernays, has been defended by F. Cumont. (3) *Περὶ κόσμου* (*De mundo*). It is generally agreed that, in L. Cohn's

words, this is "nothing but a compilation from various portions of the *περὶ ἀφθαρσίας κόσμου* and other Philonic works." (4) Two discourses, *De Sampson* and *De Iona*, extant only in Armenian, are unauthentic. (5) *Περὶ τοῦ πάντα σπουδαῖον εἶναι ἐλεύθερον* (*Quod omnis probus liber sit*) may be an early work of Philo, which P. Wendland believes to be the case. (6) *Περὶ προνοίας* (*De providentia*), which we possess as a whole only in an Armenian version, consists of two books, the first of which appears to be in a Christian recension, but there is no reason for denying its Philonic origin.

PHILOCTETES, son of Poeas king of the Malians of Mt. Oeta, a celebrated hero of the Trojan War. Homer merely states that he was distinguished for his prowess with the bow; that he was bitten by a snake on the journey to Troy and left behind in the island of Lemnos; and that he subsequently returned home in safety. In the post-Homeric accounts, Philoctetes or his father had been given the bow and arrows of Heracles (see *HERCULES*) as a reward for kindling the fire on Mt. Oeta, on which the hero immolated himself. Philoctetes remained at Lemnos till the tenth year of the war. An oracle having declared that Troy could not be taken without the arrows of Heracles, Odysseus and Diomedes (or Neoptolemus) were sent to fetch Philoctetes. On his arrival before Troy he was healed of his wound by Machaon, and slew Paris; shortly afterwards the city was taken. On his return to his own country, finding that a revolt had broken out against him, he again took ship and sailed for Italy, where he founded Petilia and Cremissa. He fell fighting on the side of a band of Rhodian colonists against some later immigrants from Pallene in Achaëa. His tomb and sanctuary were shown at Macalla, on the coast of Bruttium.

See Homer, *Iliad*, ii. 718, *Odyssey*, iii. 190, viii. 219; Sophocles, *Philoctetes*, and Jebb's Introduction; *Diod. Sic.* iv. 38; Dio Chrysostom, 52, 59; Philostratus, *Heroica*, 6; Strabo vi. 254; Hyginus, *Fab.* 36, 102.

PHILODEMUS, Epicurean philosopher and poet, was born at Gadara in Coele-Syria early in the 1st century B.C., and settled in Rome in the time of Cicero. He was a friend of Calpurnius Piso, and was implicated in his profligacy by Cicero (in *Pisonem*, 29), who, however, praises him warmly for his philosophic views and for the elegans lascivia of his poems (cf. Horace, *Satires*, 1. 2. 120). The Greek anthology contains thirty-four of his epigrams. Thirty-six treatises attributed to Philodemus were recovered from a villa at Herculaneum.

The *Rhetoric* has been edited by Sudhaus (1892—95); the *De Ira* and the *De Pietate* by Gomperz (1864—65); the *De Musica* by Kempke (1884); *De Vitiis* by Ussing (1868); *De Morte* by Mekler (1886). See *Hercul. Volum.* (Oxford 1824 and 1861); Mayor on Cicero's *De Natura deorum* (1871); Überweg, *Grundriss der Gesch. der Philosophie*, Bd. 1. (1926).

PHILOLAUS (b. c. 480), Greek philosopher of the Pythagorean school, born at Tarentum or at Crotona (so Diog. Laert. viii. 84), was probably a teacher of Democritus. After the death of Pythagoras great dissensions prevailed in the cities of lower Italy. According to some accounts, Philolaus, obliged to flee, took refuge first in Lucania and then at Thebes, where he had as pupils Simmias and Cebes, who subsequently, being still young men, were present at the death of Socrates. Before this Philolaus had returned to Italy, where he was the teacher of

Archytas. He entered deeply into the Pythagorean number theory, particularly dwelling on the properties inherent in the decad—the sum of the first four numbers. consequently the fourth triangular number, the *tetractys* (see *Vit. Pythag.* ap. *Phot. Bibl.* p. 712)—which he called great, all-powerful, and all-producing. The great Pythagorean oath was taken by the sacred *tetractys*. The discovery of the regular solids is attributed to Pythagoras by Eudemos, and Empedocles is stated to have been the first who maintained that there are four elements. Philolaus, connecting these ideas, held that the elementary nature of bodies depends on their form, and assigned the tetrahedron to fire, the octahedron to air, the icosahedron to water, and the cube to earth; the dodecahedron he assigned to a fifth element, aether, or, as some think, to the universe (see *Plut. de Pl. Ph.* ii. 6, *ἐκ δὲ τοῦ δωδεκαέδρου τὴν τοῦ παντὸς σφαῖραν* and *Stob. Ecl. Phys.* i. 10, *ὁ τὰς σφαίρας ὀλκός*). This theory, however superficial from the standpoint of observation, indicates considerable knowledge of geometry and gave a great impulse to its study. Following Parmenides, Philolaus regarded the soul as a "mixture and harmony" of the bodily parts; he also assumed a substantial soul, whose existence in the body is an exile on account of sin.

Philolaus was the first to propound the doctrine of the motion of the earth; some attribute this doctrine to Pythagoras, but there is no evidence in support of their view. Philolaus supposed that the sphere of the fixed stars, the five planets, the sun, moon and earth, all moved round the central fire, which he called the hearth of the universe, the house of Zeus, and the mother of the gods (see *Stob. Ecl. Phys.* i. 488); but as these made up only nine revolving bodies he conceived, in accordance with his number theory, a tenth, which he called counter-earth, *ἀντίχθων*. He supposed the sun to be a disk of glass which reflects the light of the universe. He made the lunar month consist of $29\frac{1}{2}$ days, the lunar year of 354, and the solar year of $365\frac{1}{2}$ days. He was the first who published a book on the Pythagorean doctrines, a treatise used by Plato in the composition of his *Timaeus* and to which the mystical name *Βάκχαι* is sometimes given.

For fragments see Ritter and Preller, *Hist. Phil. Graecae* (1898) and H. Diels, *Die Fragmente der Vorsokratiker*, Bd. I. (4th ed., 1922). See also Boeckh, *Philolaus des Pythagoreers Lehren nebst den Bruchstücken seines Werkes* (1819); Schaarschmidt, *Die augenblicke Schriftstellerei des Philolaus* (1864); Chaignet, *Pythagore et la philosophie pythagoricienne, contenant les fragments de Philolaus et d'Archytas* (1873); Th. Gomperz, *Greek Thinkers* (Eng. trans., 1901), i.; J. Burnet, *Early Greek Philosophy* (3rd ed., 1920); Überweg, *Grundriss der Gesch. der Philosophie*, Bd. I. (1926); also art. PYTHAGORAS.

PHILOLOGICAL ARTICLES. In addition to the general article PHILOLOGY and an outline of the ramifications of Comparative Philology, the subject of GRAMMAR is exhaustively treated. All the main languages of the world have articles of their own, e.g., ARABIC LANGUAGE; CHINESE LANGUAGE; ENGLISH LANGUAGE; FRENCH LANGUAGE; GERMAN LANGUAGE; GREEK LANGUAGE, ANCIENT and GREEK LANGUAGE, MODERN; HEBREW LANGUAGE; ITALIAN LANGUAGE; JAPANESE LANGUAGE; LATIN LANGUAGE; MANCHU LANGUAGE; MONGOLIAN LANGUAGE; POLYNESIAN LANGUAGES; RUSSIAN LANGUAGE; SERBO-CROAT LANGUAGE; SPANISH LANGUAGE; TURKISH LANGUAGE. This is by no means an exhaustive list as many little-known languages are included, e.g., BUSHMAN LANGUAGES. In the event of a language not receiving discussion under its own name it may be discovered under the name of the family to which it belongs, e.g., INDO-EUROPEANS: *Language*; CELTIC LANGUAGES, etc. There is a comprehensive article on the subject of LANGUAGE itself; there are also articles on PHONETICS and PRONUNCIATION.

PHILOLOGY. The word philology is here taken as meaning the science of language, i.e., the study of the structure and development of languages. thus corresponding to linguistics (Fr. *linguistique* and Ger. *Sprachwissenschaft*), but differing from philology, as it is generally understood on the Continent and sometimes in England where it means literary or classical scholarship; to the philologist in the latter sense language is one of the means to the comprehension of the whole culture of some nation, but not an object of study for its own sake, as it is to the philologist in the sense in which the word is here used. Though there has been, and still here and there may be, some antagonism be-

tween the two lines of study, they cannot properly be separated without an injurious onesidedness, as language is closely bound up with the development and expression of the whole cultural life of any nation or race.

Before A.D. 1800.—Though languages were studied in a scientific spirit for many centuries, it is not till the beginning of the 19th century that we see the rise of philology as it is now understood, with the chief stress laid on comparison of related languages and the historical development of their structures.

The Chinese had, centuries before our era, elaborate dictionaries of their own language. Similarly the Assyrians compiled lists of words and syllables with grammatical explanations. But they did not penetrate so deeply into the understanding and analysis of their own language as did the early Indians, whose grammatical investigations have had a far-reaching influence on European philology, especially in the 19th century. It was occupation with the sacred hymns and notably the *Rigveda* that gave the chief impulse to the study: each little detail was handed down with religious fidelity and was therefore carefully examined. We find in India painstaking investigations into phonetics with a minute description of each sound and its formation; further, precise accounts of the changes of sounds in the inflection and formation of words. What was studied was not only the rôle of sounds in isolated words, but also the modification which sounds underwent when words were pronounced in connected speech (*sandhi*). Each word was analysed into its elements: root, affixes to form stems, and inflectional endings, and statistics were given of the occurrence of each of these elements. In this way the earliest contributions were given to the building up of an etymological science. Among the Indian grammarians Panini ranks first; his work has been called "the most complete grammar existing for any language, dead or living."

In Greece philosophers discussed the ultimate origin of language, some holding that words had come into existence by nature, others that they were due to convention. Incidentally they indulged in the wildest etymological guesses. Aristotle gives the first beginnings of a division into parts of speech, and this was further developed by the Stoics, to whom are due those names of the different cases which in their Latin translations are still in use with us. The Alexandrians are of importance through their scholarly treatment of the old classical literature. But the horizon was bounded: no "barbarous" tongue was thought worthy of study, and therefore no true insight into the essence of language could be gained. Roman grammarians did very little beyond imitating their Greek predecessors. Nor did the middle ages produce anything worthy of mention in this brief survey.

From the 16th century onwards we find a growing number of descriptions of single languages, but very little was done for a comparative investigation of languages, except perhaps for the Semitic family. The foolish superstition, however, that all languages descended from Hebrew as the language spoken in the garden of Eden, gave rise to many absurd etymologies. Leibniz was one of the first to entertain saner ideas with regard to the division of languages according to their relationship; like some of his contemporaries he was also interested in the idea of a universal language for scientific purposes. Among valuable works of the 18th century we shall here mention only the comprehensive, but uncritical collections of words and specimens from all the then known languages; the best of them are due to Pallas (1786, 1791) and to Hervas y Panduro (1784, 1800-05); these were superseded by Adelung's *Mithridates* (1806-17). D. Jenisch's *Philosophisch-kritische Vergleichung . . . von vierzehn Sprachen Europens* (1796) is a comparative appraisal of languages chiefly from an aesthetic point of view and thus totally different from what we now understand by comparative philology.

Rise of Comparative Philology.—The discovery of Sanskrit gave a mighty impulse to linguistic studies, though the work of the French Jesuit missionary Coerdoux (1767) with its comparison of Sanskrit with Latin was not printed till 40 years later. More importance was attached at the time to Sir William Jones's often quoted words (1796) in which he drew the conclusion from the grammatical structure of Sanskrit, Greek and Latin that they

had "sprung from some common source, which perhaps no longer exists." This paved the way for the recognition of the great Aryan or Indo-European family of languages, and in 1799 Gyármáthi proved that Magyar (Hungarian) was related to Finnic and thus laid the foundation of Finno-Ugric philology.

In the beginning of the 19th century these sporadic hints were worked up in a more systematic way. The chief impulses came about the same time from three men of genius, the Dane, Rasmus Rask, and the two Germans, Franz Bopp and Jacob Grimm. Rask saw the importance of sound laws and formulated the Germanic consonant shift before Grimm; he classified not only Aryan, but also Finno-Ugric and Dravidian languages and gave an excellent exposition of the methodological principles of the new science. Bopp started from Sanskrit, but successively submitted a greater and greater number of the Aryan languages to penetrating study and wrote the first comprehensive comparative grammar of all these languages—a work which exercised an enormous influence on linguistic studies all over Europe. Grimm was chiefly occupied with the Germanic group and brought out a very important grammar of all the languages of that group with the main stress laid on historic development. Bopp and Grimm had a great number of followers, chiefly in Germany—of the elder generation only one scholar can be mentioned here: Pott, whose etymological investigations cleared much new ground. Chairs of comparative philology were founded in many universities, and periodicals were devoted to the science, the most important for a long time being Kuhn's *Zeitschrift für vergleichende Sprachforschung*. The new points of view (comparative and historical) soon affected all branches of linguistics, and a number of special "philologies" came into existence with similar objects and methods, Romanic philology headed by Diez, Slavic by Schleicher and Miklosich, Keltic by Zeuss. For the classical languages Georg Curtius's researches were of very great importance.

The chief leader in Aryan philology about 1860 was August Schleicher, whose *Compendium der vergleichenden Grammatik* (1st ed. 1861) had far-reaching influence, especially through its insistence on regularity of sound-changes and through its bold attempts at reconstructing theoretical forms of primitive Aryan, which he took as the starting points for his explanations of forms actually existing. But the system was too rigid and rectilinear to do justice to the complexity of linguistic life; the whole was vitiated by the dogmatic assumption that primitive Aryan had a very simple structure with only three vowels (*i, a, u*), and that the whole evolution had taken place in prehistoric times through three periods, a root-period, a period of agglutination, and finally one of inflection, while the historic period had witnessed only decay.

New Views.—A new era may be dated from about 1875, when a series of important discoveries profoundly modified the views of scholars about the primitive structure of our family of languages. The way had to some extent been paved through the sober discussions of the nature of language in general found in the works of J. N. Madvig and W. D. Whitney; of still greater importance was the study of phonetics, which now came to be more generally recognized as the necessary basis of all linguistic investigation. The study of the complicated phonetic systems of living languages shattered the belief in the extreme simplicity of primitive Aryan. The realization of the extremely important part played by analogy formations in the evolution of modern languages led to a wider application of the principle of analogy to the explanation of forms in the older stages. Thus a great many seemingly exceptional forms were explained in a natural way; and a new school of comparativists triumphantly proclaimed that phonetic laws admitted of no exceptions; sound laws and analogy sufficed between them to account for the historic development of forms.

The most important discovery of that period was the "palatal law," by which certain consonantal peculiarities were used to prove that Sanskrit in prehistoric times had had a vocalic system similar to that of Greek, with *e* and *o* in definite cases where Sanskrit as we know it has uniformly *a*. The belief in the absolute primitivity of Sanskrit, which had been a dogma in the

first period, could thus be maintained no longer, and some features of European languages, which had been supposed to be later developments, were now seen to be remnants of the oldest accessible form of the Aryan languages. The theory of the vowel alteration found, for instance, in Greek *λείπω, λέλοιπα, ἔλιπον* and still surviving in English *drink, drank, drunk* (ablaut, gradation or apophony) was completely reversed, the grade *lip* being now considered a weakening of *leip*, instead of being taken as the original stage, of which *leip* was an expansion. Karl Verner discovered the astonishing fact that differences in Germanic consonants, like that between German *t* in *Vater* and *d* in *Bruder*, found their explanation in primeval accent-conditions preserved in their oldest form in Sanskrit only, and that the difference between *s* in English *was* and *r* in *were* was connected with the fact that the singulars of perfect tenses in Sanskrit are stressed on the root, but plurals on the ending. All this opened new vistas and gave fresh impulses to Aryan philology. A codification of Aryan grammar according to the new views was given in Brugmann's *Grundriss der vergleichenden Grammatik der indogermanischen Sprachen* (2nd ed. 1897-1916), while the theoretical basis was worked out in H. Paul's *Prinzipien der Sprachgeschichte* (4th ed. 1909) and B. Delbrück's *Einleitung in das Sprachstudium* (5th ed. 1908); Delbrück also wrote the first comprehensive Aryan syntax (*Vergleichende Syntax der indogermanischen Sprachen*, 1893-1900).

Aryan Languages.—For several decades there had been no doubt as to what languages were Aryan, and the relation to it even of Albanian and Armenian had now been settled. But the 20th century has brought the discovery of new languages belonging at any rate peripherally to the Aryan family, namely Tokharian (really two different languages) and one of the Hittite languages. These present several features not paralleled in the other Aryan languages and not yet sufficiently cleared up in spite of the keen interest and labours of several scholars. Attempts have also been made to demonstrate a more remote affinity between the Aryan and two other great families of languages: that with the Finno-Ugric family seems highly probable.

A most interesting attempt has recently been made to prove a primitive relationship between Aryan and Sumerian (C. Autran, *Sumérien et Indo-Européen*, Paris, 1925). Some of the similarities adduced are very striking, but there are so many difficulties in the grammatical structure of the two languages that the kinship must at present be considered an open question.

Outside the Aryan languages much excellent work has been done, especially since the methods developed in Aryan philology have penetrated into the other domains. In many of them historical research is made impossible by the fact that we have only recent texts and descriptions; but sometimes the co-existence of several related languages permit us to some extent to draw conclusions backwards to a state in which the now separate languages formed one whole: thus with regard to primitive Bantu ("Ur-Bantu"). Some languages found in old inscriptions have baffled all attempts at comprehension, among them Etruscan.

Language and Racial Psychology.—While most of those who have dealt with the general problems of the nature of language and its development have started, as was natural, from the European languages and the great family of languages to which they belong, there have been other scholars whose endeavours have been especially directed towards the understanding of the psychology of language and who have therefore to a great extent gone outside the languages spoken by civilized nations to ascertain relations between the language of a race and its culture and mental characteristics. A pioneer in that direction was Wilhelm v. Humboldt, whose great work on the Kawi language was prefaced by a profound investigation into the differences in structure of the various human languages and their influence on the mental development of man (1836-40). His chief disciple was H. Steinthal, who in numerous works treated of the relation between language, logic and psychology. His best work, *Charakteristik der hauptsächlichsten Typen des Sprachbaues* (1860), was completely remodelled in 1893 by F. Misteli and in this shape is still a most useful survey of the grammatical structure of

some of the most outstanding languages with psychological interpretation. Excellent work was done in the same direction by H. C. von Gabelentz and his son Georg, both of them possessing wide linguistic knowledge and psychological acumen. A small, but very valuable work is F. N. Finck, *Die Haupttypen des Sprachbaus* (Leipzig, 1910), with its analysis of eight select linguistic structures on the basis of one text from each language.

In 1900 the well-known German philosopher W. Wundt, employing the whole apparatus of modern psychologists and part of that of linguists, made an attempt to present a consistent comprehensive survey of linguistic phenomena (*Völkerpsychologie*, I. *Die Sprache*), but his views met with little acceptance on the part either of philologists (Delbrück, Sütterlin) or of philosophers (Marty). A recent school in Germany, headed by K. Vossler, tries to connect grammar with the state of civilization in general and of literature in particular, interpreting linguistic developments and grammatical peculiarities in terms of national psychology.

The psychological aspect and the emotional importance of language in general has been studied recently with great ardour. Among those who have lately contributed to this side of philology are: F. Mauthner, A. Marty, Ch. Bally, E. Cassirer, J. van Ginneken and H. Delacroix.

Language and History.—Linguistic research has very often been invoked to assist in settling historical questions. Important results have been arrived at through investigation of place-names (*q.v.*). The history of a nation's culture can be illustrated through a study of successive strata of loan-words. (See LANGUAGE.) The question of the Scandinavian origin of the Russian empire has been definitely settled through the names in the oldest sources. It is now possible to speak of linguistic archaeology as a separate branch of science, see especially such important works as V. Hehn, *Kulturpflanzen und Haustiere* (6th ed., Berlin, 1894); O. Schrader, *Sprachvergleichung und Urgeschichte* (3rd ed., Jena, 1906); O. Schrader, *Reallexikon der indogermanischen Altertumskunde* (2nd ed. 1917); J. Hoops, *Waldbäume und Kulturpflanzen im germanischen Altertum* (Strasbourg, 1905); S. Feist, *Kultur, Ausbreitung und Herkunft der Indogermanen* (1912).

Languages of the World.—A survey of all the known languages of the inhabited earth with short grammatical sketches and brief specimens was given in Friedrich Muller's *Grundriss der Sprachwissenschaft* (4 vols., Wien, 1876-88). The attempt has never been renewed on so extensive a scale. F. N. Finck, *Die Sprachstämme des Erdkreises* (Leipzig, 1909), gives a bare enumeration of the names of languages, but the great work *Les Langues du Monde* by A. Meillet et Marcel Cohen (Paris, 1924) does not content itself with this, but gives valuable discussions on many problems connected with the present state of linguistic science with regard to some, at least, of the linguistic groups. An extremely bold attempt at proving relationship between all existing languages and thus establishing the monogenesis of human language is found in various works by A. Trombetti, most elaborately in *Elementi di Glottologia* (Bologna, 1923); most philologists prefer not to commit themselves either to this theory or definitely to the opposite theory of polygenesis, but to leave the question open as impossible of solution at present. An equally bold attempt is made in the recent book by Father W. Schmidt, *Die Sprachfamilien und Sprachenkreise der Erde* (Heidelberg, 1926): he tries to group all known languages genetically and then to show intimate connection between a series of phenomena—phonetic traits, such as the distinction between voiced and voiceless consonants, initial and final sounds and sound-groups, morphological peculiarities (number, exclusive and inclusive pronouns, gender, numeral systems), syntactical features (place of genitive and adjective)—on the one hand and on the other hand ancient centres and migrations of cultural phenomena: totemism, agriculture, matriarchy, etc.

Streitberg, *Die Erforschung der indogermanischen Sprachen* (only two volumes of a planned great work have appeared, dealing with Greek, Latin, Celtic, Slavic and Albanian, 1916-17); *Stand und Aufgaben der Sprachwissenschaft, Festschrift für W. Streitberg* (1924); H. Pedersen, *Sprogvidenskaben i det 19. Aarhundrede*

(1924); V. Thomsen, *Geschichte der Sprachwissenschaft* (1927).

For general bibliography see the two works mentioned above, *Les Langues du Monde*, and W. Schmidt, *Die Sprachfamilien*. See also under LANGUAGE and GRAMMAR. (O. J.)

PHILO OF BYZANTIUM, Greek writer on mechanics, flourished during the latter half of the 2nd century B.C. (according to some, a century earlier). He was the author of a large work (*Μηχανική σύνταξις*), of which considerable portions remain.

See ed. by R. Schöne (1893), and W. Schmidt *De Ingeniis Spirituibus* (Latin tr. of Arabic version of a lost original, 1899).

PHILO OF LARISSA, Greek philosopher of the first half of the 1st century B.C. During the Mithridatic wars he left Athens and took up his residence in Rome. He was a pupil of Clitomachus, whom he succeeded as head of the Third or New Academy. According to Sextus Empiricus, he was the founder of the Fourth Academy, but other writers refuse to admit the separate existence of more than three academies (see ACADEMY, GREEK). In Rome he lectured on rhetoric and philosophy, and collected many eminent pupils, amongst whom Cicero was the most famous.

See Gysar, *Die Akademiker Philo und Antiochus* (1849); Hermann, *De Philone Larissaeo* (Göttingen, 1851 and 1855); and Überweg, *Grundriss der Philosophie*, Bd. I. (1926).

PHILOPATRIS, the title of a dialogue formerly attributed to Lucian, but now generally admitted to be spurious. The scene is laid at Constantinople. A certain Triephon, who has been converted to Christianity by a bald, long-nosed Galileean, who was carried up through the air into the third heaven (an evident allusion to St. Paul), meets a friend, Critias, who is in a state of great excitement. Triephon inquires the reason, and the invocation of Zeus by Critias leads to a discussion on paganism and Christianity, in which all the gods proposed by Critias are rejected by Triephon, who finally suggests that Critias should swear by the Trinity. Critias goes on to relate how he had been introduced to a gathering of pessimists, who predicted all kinds of disturbances in the empire and defeat at the hands of its enemies.

The *Philopatris* was for a long time regarded as an attack upon Christianity, and assigned to the time of Julian the Apostate (emperor 361-363). Chronological indications led Niebuhr to ascribe it to the reign of Nicephorus Phocas (963-969), a view now generally supported.

BIBLIOGRAPHY.—Editions by J. M. Gesner (1715) and C. B. Hase in the Bonn *Corpus scriptorum hist. byz.* (1828), vol. xi.; also included in Jacobitz's edition of Lucian (1839). See B. G. Niebuhr, "Ueber das Alter des Dialogs Philopatris" in his *Kleine historische Schriften*, vol. ii. (1843); R. Crampe, *Philopatris. Ein heidnisches Konventikel des siebenten Jahrhunderts zu Constantinopel* (1894); C. Stach, who shows its late origin by linguistic tests, *De Philopatride* (Cracow, 1894); S. Reinach, *Revue archéologique*, vol. i. (1902); and, for further authorities, article by Von Dobschütz in Herzog-Hauck, *Realencyklopädie für protestantische Theologie* (1904).

PHILOPOEMEN (253-184 B.C.), Greek general, was born at Megalopolis, and educated by the academic philosophers Ecdemus and Demophanes or Megalophanes. In 233-2 Philopoemen skilfully evacuated Megalopolis before the attack of Cleomenes III., and distinguished himself at Sellasia (222). The next eleven years he spent as a condottiere in Crete. Elected commander of the League's cavalry on his return, he reorganized that force and defeated the Aetolians on the Elean frontier (210). Appointed to the chief command two years later, he introduced heavy armour and close formation for the infantry, and with a well-trained army beat Machanidas of Sparta, near Mantinea. The new "liberator" was now so famous that Philip V. of Macedon attempted to poison him. In 202-1 Philopoemen drove Nabis, the Spartan tyrant, from Messene and routed him off Tegea. After another long sojourn in Crete he again received the command against Nabis. Though unsuccessful at sea, he almost annihilated Nabis's land force near Gythium, but was prevented by the Roman Flaminius from taking Sparta. In 190 Philopoemen protected Sparta, which meanwhile had joined the League and thereupon seceded, but punished a renewed defection so cruelly as to draw the censure of Rome.

At Messene he likewise checked a revolt (189), but when that city again rebelled, in 184, he was captured in a skirmish and promptly executed. Philopoemen's great merit lies in his having restored

that military efficiency without which the Achaean League (*q.v.*) could never stand.

Polybius' *Histories* (x.–xxiii.) are our chief authority. These and a special treatise on Philopoemen (now lost) were used by Plutarch (*Philopoemen*), Pausanias, (viii. 49–51), Livy (xxx.–xxxviii.), and indirectly by Justin (xxx.–xxxiv.).

PHILOPONUS, JOANNES (JOHN THE GRAMMARIAN), Greek philosopher of Alexandria, lived in the later part of the 5th and the beginning of the 6th century of our era. The surname *Grammaticus* he assumed in virtue of his lectures on language and literature; that of *Philoponus* owing to the large number of treatises he composed. He was a pupil of Ammonius Hermiae, and is supposed to have written the life of Aristotle sometimes attributed to his master. To Philoponus are attributed a large number of works on theology and philosophy. It is said that he was at first a Christian.

The more certain writings of Philoponus consist of commentaries on Aristotle. These include works on the *Physica*, the *Prior* and the *Posterior Analytics*, the *Meteorologica*, the *De anima*, the *De generatione animalium*, the *De generatione et interitu* and the *Metaphysica*. He wrote an attack on Proclus and probably two treatises on mathematics *A Commentary on the Mathematics of Nicomachus*, edited by Hoche (1864 and 1867), and a *Treatise on the Use of the Astrolabe*, published by Hase, the most ancient work on this instrument.

PHILOSOPHICAL ARTICLES. The most important philosophical articles contained in this Encyclopædia may be enumerated in three groups, namely (1) the key articles dealing either with the whole field or with one of the main divisions of philosophy; (2) articles devoted to particular philosophical schools or tendencies in the history of philosophy; and (3) articles dealing with special philosophical problems or topics. In addition to the articles here enumerated there are some 300 shorter articles dealing with various philosophical subjects, and about 400 articles of varying lengths devoted to individual philosophers:—

(1) **Key Articles.**—PHILOSOPHY, HISTORY OF; METAPHYSICS; KNOWLEDGE, THEORY OF; LOGIC; LOGIC, HISTORY OF; LOGISTIC; ETHICS; ETHICS, HISTORY OF; COMPARATIVE ETHICS; SOCIAL PHILOSOPHY; PSYCHOLOGY; PSYCHOLOGY, HISTORY OF; AESTHETICS; VALUE, THEORY OF.

(2) **Articles on Philosophical Schools and Tendencies.**—ACADEMY, GREEK; ARABIAN PHILOSOPHY; CAMBRIDGE PLATONISTS; CARTESIANISM; COMMON SENSE PHILOSOPHY; CYNICS; CYRENAICS; DUALISM; ECLECTICISM; EGOISM; ELEATIC SCHOOL; EMPIRICISM; HEDONISM; HOLISM; IDEALISM; INDIAN PHILOSOPHY; IONIAN SCHOOL OF PHILOSOPHY; JEWISH PHILOSOPHY; MATERIALISM; MEGARIAN SCHOOL; MONISM; NEO-HEGELIANISM; NEO-KANTIANISM; NEO-PLATONISM; NEO-PYTHAGOREANISM; PANTHEISM; PERIPATETICS; PESSIMISM; PHENOMENALISM; PLURALISM; PRAGMATISM; RATIONALISM; REALISM; SCEPTICISM; SCHOLASTICISM; SOPHISTS; SPIRITUALISM; STOICS; TRANSCENDENTALISM; UTILITARIANISM.

(3) **Articles on Special Problems.**—ABSOLUTE; ACCIDENT; ANALOGY; BELIEF; BODY AND MIND; CASUISTRY; CATEGORY; CAUSALITY; DURATION; EMERGENCE; EXPLANATION; FORM; FREE-WILL; IMMANENCE; INDUCTION; INFINITE; INNATE IDEAS; INTUITION; LOGOS; METEMPSYCHOSIS; NATURE; PERSONALITY; PROBABILITY; QUALITIES: *Primary, Secondary and Tertiary*; RELATIVITY; FALLACY: *Material, Verbal, Logical*; SUBCONSCIOUS; SCIENTIFIC METHOD; SPACE-TIME; SUBSTANCE; THOUGHTS, LAWS OF; TRUTH.

(See also **PSYCHOLOGICAL ARTICLES**, and **Articles on RELIGION and THEOLOGY**.)

PHILOSOPHY, HISTORY OF. An adequate account of the history of philosophy would have to include not only the history of ethics, logic, psychology, metaphysics, etc., but also an account of the early history of science. For obvious reasons such a thing cannot be attempted here. Moreover, the histories of ethics, logic, and psychology have separate articles devoted to them, and the articles on aesthetics and theory of knowledge also contain the essentials of their history. As there are also separate articles dealing with the chief schools of philosophy and with the leading philosophers, the present article will only attempt to be a general guide to the study of the history of philosophy.

ANCIENT PHILOSOPHY

To all intents and purposes ancient philosophy is essentially Greek philosophy. This is not to deny the reality and value of Eastern philosophy. It is significant that even Greek philosophy commenced in the Eastern colonies, in Ionia, in Asia Minor, and that it was Ionian philosophers who introduced philosophy into other parts of Greece. It is also significant that Greek traditions refer to the influence of Egyptian teachers upon Thales, Pythagoras, Democritus, Plato and other Greek thinkers. Moreover, India, China and Persia, as well as Egypt, are known to have developed more or less independent world-views of their own. Students of oriental thought can trace therein counterparts of all, or nearly all, the main tendencies of Western philosophy—Monism and Dualism, Materialism and Idealism, Atheism and Pantheism, Pragmatism and what not. One may even point to certain direct oriental influences on Western philosophy in the case of Neo-Platonism in ancient times, in the case of Arabian or Moorish influences in the middle ages, and in the acknowledged influence of Buddhism on so modern a philosopher as Schopenhauer. But, it remains true that Western philosophy from Thales onwards is sufficiently self-contained to warrant separate treatment. And when the ground to be covered is enormous and difficult, it is a great convenience to be able to deal with the main stream of philosophy by itself. But there are separate articles dealing with Brahmanism, Buddhism, Indian philosophy, Arabian philosophy, Jewish philosophy, etc., for those readers who wish to go farther afield.

EARLY GREEK PHILOSOPHY

Ionian Philosophers.—A group of Ionian thinkers first raised the question as to the nature of the substance of which all things are composed, from which they originate, and into which they are dissolved again. Moreover they raised and answered this question in a non-mythological, impersonal manner. They considered *what*, not *who*, had produced all these things. Their answers were always in terms which we may be tempted to describe as *material*. But that would not be quite correct, because as yet no hard and fast line was drawn between the mental and the material. The ultimate matter of which they thought was a living matter—they were consequently not materialists but hylozoists. The Ionian group consisted of the following Milesians:

Thales (?640–550 B.C.) regarded water or moisture as the primary stuff or principle of things. In the then state of knowledge many physical phenomena must have appeared to bear out this view. For water is found in the form of gaseous vapour and of solids as well as in liquid form. In the phenomena of rising vapour and of sunbeams people saw the sun and other fiery bodies “drawing water” for their sustenance, so that water seemed capable of changing into fire. In the earth's absorption of rain, in the formation of deltas, in the alluvial deposits left by torrents, water appeared to be changed into earth. In the formation of dew and in the rising earth mists, earth seemed to change into moisture. And moisture was, of course, realized to be necessary for all living things. In these various phenomena Thales probably thought that he observed examples of the whole cosmic process from water and back into water.

Anaximander (611–547? B.C.) was impressed by the conflicting character of such natural qualities as hot and cold, dry and wet, etc., and could not believe that water could generate things with qualities opposed to its own. He held that primary matter must be something different from any of the known determinate kinds of matter which have resulted from it. He accordingly identified primary matter with the “unlimited,” by which he probably meant something indeterminate, out of which the determinate things, earth, water, air and fire, differentiated or “separated out.” These four kinds, according to Anaximander, arranged themselves in successive layers with earth at the centre, followed by rings of water, air and fire in turn. The sun, moon and stars he regarded as masses of fire, flung off by the world's outer ring of fire, surrounded partly by husks or envelopes of air similarly flung off by the cosmic ring of air. Eclipses, he explained as due to temporary obstructions in the apertures of the air husks of the sun

and moon. Our world, which is only one of many, is cylindrical in form, and swings free in space.

Anaximenes (?590-525 B.C.) identified primary matter with air, because it has the greatest mobility and is indispensable to life. He was the first to attempt to explain the process by which primary matter gives rise to the vast variety of things. The processes he suggested are condensation and rarefaction. By condensation air is changed into water or earth; by rarefaction it is changed into fire. (See IONIAN SCHOOL OF PHILOSOPHY.)

Pythagoreanism.—The early Ionian or Milesian school of philosophy was brought to an abrupt end by the Persian conquest of Ionia. This calamity was followed by a revival of Orphic and similar mystery religions which influenced some of the philosophers, and so led to the foundation of the Pythagorean school.

Pythagoras (?570-500 B.C.) was a kind of philosophical revivalist. Influenced by the reawakening of religious interest among his contemporaries, Pythagoras endeavoured to combine religion with philosophy, and founded at Kroton (in southern Italy) a kind of religious brotherhood with a philosophic bias—something between a cloister and a college, in fact, the prototype probably of the mediaeval universities of Europe. In the history of thought the most noteworthy feature of the teaching of Pythagoras and his school is to be found in the stress laid on "form" rather than "matter," as the ultimate principle of things. The study of music taught Pythagoras that the concordance of a succession of notes depends on certain proportions between the lengths of the strings on which they are produced. He was greatly impressed by this discovery of the importance of proportion. And the discovery was applied in all sorts of directions. For example, one proportion of the elementary qualities of the body (hot and cold, dry and wet) constitutes health; another disease. It was also used as the key to the riddle of the universe. Numerical proportion thus came to be treated as the "principle" of things, in the same kind of way as the earlier philosophers had treated water, fire, etc., as primary matter. The Pythagorean view was expressed in the dictum that "all things are numbers." In order to understand this seemingly odd dictum, it is necessary to realize first of all how numbers were thought of at that time, and how easily numbers were then confused with geometrical figures. Numbers used to be represented by means of dots arranged in geometrical patterns, as they still are on cards and dominoes, e.g.; and numbers were described as triangular, or square, or oblong according to the geometrical arrangement of the dots representing them. Next, it will be observed that this custom rather encouraged the identification of the unit of number with the dot or point. And since lines can be analysed into the points, and planes into the lines, and solids into the planes that bound them, it could easily appear that it is the points that make the lines, that make the planes, that make the solids. And once the point was identified with the unit of number, it could be easily supposed that all things are constructed out of numbers. The Pythagorean doctrine is of importance chiefly because its idea of proportions or configurations was responsible partly for Plato's doctrine of "Ideas" and Aristotle's theory of "Forms." (See PYTHAGORAS.)

The **Eleatic School**, like the Pythagorean school, was founded in southern Italy by an Ionian refugee. Its centre was in Elea. Unlike the founder of Pythagoreanism the founder of the Eleatic school seems to have been nettled rather than carried away by the religious revival of the time, especially by the superstition which accompanied it. But the importance of the school lies in its metaphysics—it has, indeed, been described as the first really metaphysical school.

Xenophanes of Colophon (?570-480 B.C.), the founder of the Eleatic school, is chiefly noteworthy for his very scathing attack on the Homeric, Hesiodic and similar anthropomorphic conceptions of the gods. "Mortals," he remarked, "believe that the gods come into being as they themselves do, that they have senses, voice, body. . . . But if oxen or lions had hands, oxen would make gods like oxen, horses would make gods like horses." He himself believed in one God, altogether different from man. "There is one supreme God . . . like to mortals neither in body nor in thought." In fact, Xenophanes was a pantheist, as seems clear

from his reported utterance: "The All is One, and the One is God." At all events this conception of the unity of Being or of ultimate reality, became the leading tenet of his school.

Parmenides of Elea (?540-480 B.C.) was the most important member of the Eleatic group. He is reported to have considered things "from the standpoint of the notion," that is, presumably, from the standpoint of their being intelligible or thinkable. The chief doctrines ascribed to him are expressed in the statements: "only Being is"; "birthless it is and deathless . . . for ever it stands a continuous One"; "all is full of being . . . no defect is there in it." Apparently he considered it unthinkable that anything should come into being out of nothing or pass into nothing. So he regarded reality as eternal—uncreated and imperishable. There is no empty space, "all is full of being," and so there is no possibility of motion. Reality was apparently a finite, spherical, motionless, continuous plenum, and change, movement and the very existence of ordinary discrete things illusory.

Zeno (?490-420 B.C.) supplied the best known arguments in support of Eleatic monism. His famous paradoxes were intended to show the absurdities involved in the position of pluralism, that is the view that reality is not one but a multiplicity, a many. In opposition to the Pythagorean conception of reality as a multiplicity of spatial units, he argued that if so even a line must consist of an infinite number of points, and if each point has no magnitude then any thing must be infinitely small, but if the point has magnitude then each thing is infinitely great.

Melissus (?440 B.C.) modified the teaching of Parmenides to the extent of regarding reality as infinite. His contention was that if the real were finite it could only be bounded by empty space. Hence Parmenides' rejection of empty space really committed him to the view that reality is infinite. Similarly, he regarded the non-existence of empty space as a reason for the impossibility of the existence of a multiplicity of discrete things. Being is one and immutable and can only be apprehended by thought. (See ELEATIC SCHOOL.)

The arguments of Zeno and Melissus were largely directed against the views of Heraclitus, Anaxagoras and Empedocles.

Heraclitus (?540-475 B.C.) held that fire is the primal matter. The naturalistic trend of thought is very marked in Heraclitus, as is evident from the following fragment. "This one order of all things was created by none of the gods, nor yet by any of mankind, but it ever was, and is, and shall be—eternal fire—ignited by measure and extinguished by measure." Matter as conceived by Heraclitus is always changing and always moving, though its movements often elude our observation.

The world "begins" as a mass of fire, some changing partly into water. The water changes partly into earth and partly into vapour. The vapour returns to fire. The earth changes back to water, and from water to vapour and thence to fire again. And then the cycle of changes begins all over again, each complete stage being marked by a mass of fire at the beginning and at its end. The greatest service rendered by Heraclitus consists in his insistence on what may be called universal law—all changes begin "by measure." As regularity was naturally regarded as a sign of intelligence, Heraclitus posited the existence of "universal reason" side by side with primal matter, or as part of it, and regarded it as the one thing that is permanent in the ceaseless flux of changes. Another idea for which Heraclitus is noteworthy is that of the struggle for existence, which he conceived to characterize all things, and to be good for them.

Anaxagoras (?500-428 B.C.) held that originally there was not one kind of primal matter but a multiplicity of all sorts of parts or "seeds" of things. These were all mixed up in chaotic confusion. But they were sorted out and arranged in an orderly manner by the "intelligence" or "reason" which pervades the universe. This reason is omniscient and omnipotent, but was still conceived by Anaxagoras in a semi-material fashion. This doctrine of the multiplicity of "seeds," through new combinations of which new things come into being, and by the separation of which they cease to be, paved the way for the atomic theory. The conception of "mind" or "reason" as introducing order into things was subsequently adapted by Aristotle. Most important, per-

haps, is the fact that Anaxagoras went to Athens about 462 B.C. and so helped to transplant Ionian philosophy to the city of Pericles.

Empedocles of Agrigentum (?490-430 B.C.) regarded reality as eternal, but not as one. It is composed of a multiplicity of elements or "roots." Of such "roots" there are four kinds, namely, earth, water, air and fire. These four kinds of elements combine to form the various things there are, and which cease to be when the component elements separate again. In order to account for the combination and separation, Empedocles postulated two entities or principles, namely, attraction and repulsion, or "love" and "hate." And as a physiologist he compared the relation of these two entities to the "roots" with the relation of air and blood to the living body. His quaint biological speculations are noteworthy for their implicit assumption of the conception of the "survival of the fittest."

The Atomists.—The pluralist opposition to the Eleatic conception of reality as a static, immutable One, culminated in the atomic theory. This was first formulated by Leucippus (?500-430 B.C.), who first insisted on the reality of empty space, which used to be regarded as "non-being." But the atomic theory is chiefly associated with the name of his disciple, Democritus, who is commonly described as "the father of physics."

Democritus (?460-370 B.C.) is the most important Greek exponent of the atomic theory and the mechanistic method of explanation which is intimately associated with it. According to Democritus atoms and space are the only ultimate realities. The atoms were conceived by him to be of various sizes and shapes. And all the main differences in composite bodies were reduced to differences in the (a) size and shape, (b) position, and (c) arrangement of the atoms composing them. The atoms may thus be described as the alphabet of the universe, and Aristotle actually illustrates these distinctions of Democritus by means of letters of the alphabet. Using Roman instead of Greek letters, the above distinctions may be illustrated as follows: (a) The letters A and M are different in size and in shape; (b) the letters M and W are different in respect of position; (c) The syllables AM and MA are different in respect of arrangement. The last distinction (c) is clearly reminiscent of the "Figure" or "Form" of the Pythagoreans. It is especially worth noting that the Atomists held that the atoms are naturally endowed with motion, and so avoided the problem, which perplexed all subsequent ages until the time of Newton, as to how passive matter was set in motion. The natural mobility of atoms seemed to require a void or empty space for them to move in. Hence the recognition by the Atomists of the existence of space. Now the atoms flitting about in all directions collide, some of them get hooked together and combine in various ways owing to their various shapes; then the larger constellations of them enclose other atoms or smaller clusters of them, and so all sorts of things are produced, including whole systems or worlds. Under certain conditions the various clusters break up again into separate atoms. The systematic attempt to explain everything in terms of matter and motion necessitated then, as subsequently, the denial of the ultimate reality of the so-called secondary qualities—colour, sound, taste, smell, etc. So the atomists dismissed them as mere "conventions," that is, as the effects of human intervention, or as merely subjective or illusory appearances. (See DEMOCRITUS.)

THE GOLDEN AGE OF GREEK PHILOSOPHY

The Sophists.—After their victory over the Persians, the Greeks experienced something similar to the change of general outlook that was brought about by the great World War 24 centuries later. The desire for the good things of life spread among wider circles of people. And there was an increased desire for knowledge, at once as a good thing in itself, as a social and political aid, and possibly as a means to a new orientation after the shock to traditional beliefs and habits which is generally caused by a great upheaval like a war. The general demand for knowledge naturally produced a supply of popular teachers. And so the Sophists came into being. These "wise men," or teachers of wisdom, rendered valuable services to the cause of general

education. They not only helped to create a wider interest in philosophical and other problems but by their criticisms compelled greater thinkers to probe more deeply into the questions raised. Except among reactionaries, who, then, as always, showed hostility to the enlightenment of the people, the Sophists enjoyed a good repute among their contemporaries; it was only long afterwards that the term Sophist became derogatory. The most famous of the Sophists were Protagoras, Georgias, Hippias, and Prodicus. As teachers of the art of debate it was their business to show how to make the best of even a weak case. In order to make a public display of their own skill in the art of defence it would have been futile merely to defend generally accepted views—anybody might do that. They could give much better proof of their skill by defending lost causes, paradoxes, views that seemed strange or even absurd at first—they had to "make the worse case appear the stronger," as Aristophanes complained. The effect of all this was sure to be demoralizing upon some of the young Athenians. And their criticism of existing social and political institutions was no doubt distasteful to some of the propertied and influential people. Hence their unpopularity with some. In the history of philosophy their importance consists mainly in the interest which they aroused in ethical problems and in problems of knowledge. The most important doctrine associated with their name is that enunciated by Protagoras in the dictum: "Man is the measure of all things." By this he meant that there is no such thing as universally valid knowledge. Different people have different views, and for each person that is true which he, honestly and to the best of his ability, believes to be true. Similarly with moral goodness. In a world of merely relative standards, some of the Sophists maintained, it was no good pursuing truth; better to adapt oneself to the practical needs of life in the environment in which he finds himself. (See SOPHISTS.)

Socrates (469-399 B.C.) was counted by his contemporaries among the Sophists. For he, too, was interested in educating young people by means of discussions (though he taught without pay); he also was interested in problems of human conduct rather than in problems about the ultimate nature of reality; and he also did not see absolute truth in the opinions commonly entertained. But, unlike the Sophists, he did believe in the possibility of knowledge, provided it were pursued in the right way. And the way which he proposed is that known subsequently as the Socratic Method (*q.v.*). This method consisted essentially in checking one's ideas by constant reference to relevant instances until they are transformed into universally valid concepts or ideas. In essence it is an inductive method proceeding by elimination, though Socrates applied it to a sphere of problems in which the relevant data could be obtained by merely cross-examining people. Ideas checked and corrected in this way so as to agree with the relevant facts are true, and altogether above the merely fluctuating opinions of men based on bare sense-perception, or tradition, or hearsay. So convinced was Socrates of the possibility of real knowledge, and so impressed with its importance, that he based all else upon it, identifying moral good, or virtue, with knowledge. By thus identifying virtue with knowledge, he may have thought that he also cured morality of the mere relativity which the Sophists had found in it. Yet he was condemned as a corrupter of the young, and died as the first known martyr in the cause of philosophy. (See SOCRATES.)

The Successors of *Socrates*.—As Socrates had never given formal instruction and, moreover, left no writings behind him, it was easy and natural for different people to have different impressions of his teaching.

Aristippus and the *Cyrenaics* laid stress on the cheerfulness of Socrates and his capacity for reasonable enjoyment when an opportunity presented itself. They taught accordingly, a hedonistic ethic, with pleasure as the highest good. (See CYRENAICS.)

Antisthenes and the Cynics on the other hand, were impressed chiefly with Socrates' indifference to hardships of every kind, his readiness to go without things when necessary. They accordingly preached the simple life, and Diogenes carried it so far as to reduce it almost to the life of a dog. (See CYNICS.)

Euclid and the *Megarians* were interested mainly in Socrates'

conception of the nature of real knowledge, namely, that it consists of properly formed concepts, as distinguished from mere opinions based on mere observation. Accordingly, they adopted a rather sceptical attitude towards sense-perception and sense-objects, and developed, in connection with this sceptical propaganda, a form of disputation or eristic which became notorious for its excessive subtlety. But by far the most important of the informal disciples of Socrates was Plato, who, to some extent, shared the views of the Megarians. (See MEGARIAN SCHOOL.)

Plato (427-347 B.C.) first studied philosophy under a follower of Heraclitus. At the age of 20 he came under the influence of Socrates and remained in close touch with him until his death in 399. Plato then travelled for a while in southern Italy where he came into contact with the Pythagoreans. All these influences may be discerned in his philosophy, which they helped to shape. When in 387 Plato opened a school (the Academy) in Athens, the Pythagorean spirit betrayed its presence in the inscription: "Let no one who knows no Geometry come under my roof."

Plato's philosophy is one of epistemological and ontological idealism. The way in which he arrived at it may be briefly indicated as follows: He agreed with Heraclitus that all objects of sense-perception are in ceaseless flux, undergoing incalculable changes. No universal truth can therefore be asserted about this "ever-rolling stream." On the other hand, Plato also agreed with Socrates that real knowledge is possible, but only in the form of concepts or universal truths. So he concluded that the objects of real knowledge are not the ever-changing things of the sensible world, but supra-sensible objects which are immutable and eternal. These supra-sensible, eternal, immutable objects he called "Ideas" or "Forms." The world of change is not, indeed, a mere illusion. But it consists of things that have only a lower degree of reality, things that are but poor imitations of the corresponding "Ideas" after which they are named. Plato thus distinguished two principal types of object and two principal types of cognition corresponding to them. Real knowledge (or science, or the higher kind of cognition) has "Ideas" for its objects. Sense-perception is but "opinion," a lower kind of cognition, which has the world of change for its objects. Or, again, knowledge is concerned with the world of (eternal) Being; "opinion" is concerned with the world of mere "becoming" and passing away.

It is possible that what Plato really meant by his "Ideas" was the "laws" of things and events; that when he described the ordinary things of the sensible world as "copies" of the "Ideas" he simply meant that they conform more or less to those laws; and that the "copies" are poor in the sense that their conformity to law is only approximate, not exact. However this may be, Plato's conception of the world is that of a real system. But it is a teleological system, not a merely mechanical system. He gives expression to this conception by identifying the essence of the universe with "the Good." The conception was probably the result of Socratic influence. Socrates had identified the real character, or essence, of a thing with what it is good for. He had made enemies by his insistence that rulers and generals, etc., are not merely people who catch enough votes to be elected to office, but people who really know the business of a ruler, or of a general, etc., who really are "good for" the end in view. By extending this conception to all things, Plato conceived all things as adapted to various ends, these ends as subordinated or adapted to higher ends, and so on to a final end, "the Good," which is the purpose or ultimate end of the universe as a whole. (See ACADEMY, GREEK; ETHICS, HISTORY OF; KNOWLEDGE, THEORY OF; PSYCHOLOGY, HISTORY OF.)

Philosophy is an attitude of mind as well as a system of ideas. As an inspirer of the philosophic attitude Plato has never been surpassed, and but rarely equalled, if at all. Philosophy needs both the ideas and the attitude. Great philosophic ideas, indeed, are impossible without the philosophic attitude. But there is a kind of enthusiastic attitude that seems to be possible without ideas. And the teaching of philosophy has often suffered from it.

Aristotle. (384-322 B.C.) is in some ways the most important thinker in the history of ancient philosophy. It was he who gave to philosophy the articulation which it has retained more or less ever since. His writings (even in the incomplete and

imperfect form in which they have been transmitted to us) contain contributions, and very important contributions, to all the main departments of philosophy, of most of which he may be regarded as the founder. And besides being the great architect of the whole structure of philosophy, and the most comprehensive or versatile of all philosophers, he also gathers up practically all that was best in ancient philosophy.

For 20 years Aristotle studied in Plato's Academy (367-347), and his own philosophy, though different in many ways from that of Plato, contains important Platonic elements. Undoubtedly Aristotle was more realistic, more empirical than Plato; and that will account for most of the other differences between them. But even that primary difference must not be exaggerated.

The general tendency of Plato's philosophy was to divide the universe into two parts, the relation between which he did not make clear. On the one hand, there was the world of becoming, of change, of sense, enjoying an inferior sort of reality; on the other hand, the world of being, the world of ideas, eternal and supremely real, and only remotely "copied" by the inferior world of change. Such, at all events, was Aristotle's interpretation of Plato, and he did not agree with such a disruption of the cosmos. While agreeing with Socrates and with Plato on the importance of ideas in the sense of concepts, if there is to be real knowledge, he felt that Plato's conception of "Ideas," and their aloofness from the particular objects of sense-perception, offered no explanation at all, for the relation of "copying" was a mere metaphor. Yet the primary business of "ideas" is to explain the world of experience, not merely to constitute an additional world.

The fundamental ontological conceptions in the philosophy of Aristotle are those of Matter and Form. The term Form is essentially equivalent to Plato's "Idea," which was itself an offspring of the Pythagorean "Form." The early Ionians were only concerned with the problem of primary matter; Pythagoras had been so preoccupied with "Form" that he almost forgot matter, or regarded "Form" as the primal matter or stuff of all things; Plato had removed the "Forms" or "Ideas" from the material world into a heaven of their own; Aristotle endeavoured to get a right conception of both matter and form, and of the relation between them. The conclusion at which he arrived was that form is immanent in matter, the ideal is immanent in the material, the universal is immanent in the particular; they are not generally divorced from each other, they are distinguishable but not separable. To understand Aristotle's view it is well to remember that he was the greatest biologist of antiquity, perhaps of all times. Plato was a geometrician, and that before the invention of co-ordinate geometry. His preoccupation was with ideal geometrical figures, eternal and static. His "Ideas" were conceived by his mind after the pattern of these eternal and static figures. Aristotle was a biologist preoccupied with the phenomena of growth and development, the transition from the potential to the actual, from the seed to the embryo, and from the embryo to the fully developed form of animal.

Aristotle, accordingly, was not perplexed by phenomena of change, and did not consider process incompatible with reality. And so he distinguished in all things matter from form, the relatively raw stuff from the relatively finished product. He applied the distinction all round, not to material things only. The distinction naturally cannot be quite the same in all cases, and it is relative in more senses than one. The "form" of a statue is a "shape" as distinguished from the marble which constitutes its "matter"; the "form" of a human character is a certain "organisation" of the instincts and impulses which constitute the raw material before they have been "licked into shape"; the "form" of a plant, an animal, a man consists of a certain "function" — nutrition, sensibility, and reason respectively — which distinguishes it from what is below it in the scale of existence; and so on. Again, nothing is entirely without "form." Even the block of marble has some shape before it becomes a statue; impulses and instincts have some sort of co-ordination at every stage in the process of character formation; and the things which in virtue of their several highest functions are plants, or animals, or men would still be something even in the absence of those functions, only

they would be different; that is, they would have different forms.

In the last resort, even the crudest kind of matter, the so-called four elements (earth, water, air, fire), recognized by Greek philosophers since the time of Empedocles (?483-430), were not regarded by Aristotle as pure formless matter, but as primal matter which had assumed different "forms" in consequence of the different combinations of their ultimate qualities (hot, cold, dry, moist). Pure, formless matter was simply a limiting conception. The whole state of any thing still capable of further development was regarded as "matter" in relation to the process, or function, etc., which would complete it, and which was called its "form"; yet within that so-called "matter" one would as naturally distinguish a "form" or something which distinguished it from a still less developed state or condition (actual or imaginary). In most cases, however, this series of relative distinctions has its limits. A material object, e.g., cannot have less "form" than the four elements have. But there is usually also a limit to the highest "form" which certain kinds of matter can assume. A block of marble may become a statue or an image of some kind; it cannot become a plant, or an animal, etc. An acorn may become a sapling, and this sapling may grow into an oak, but it cannot grow into anything else. Still, though Aristotle believed in the fixity of species, he could compare the great and wonderful variety of things, and arrange them imaginatively in a kind of ascending series or "scale of nature."

Such a scale beginning with the lowest types of matter, with their suggestion of mere "formless" matter as an imaginary limiting case, and ascending through the various forms of life the "matter" of which becomes richer and richer in "forms" (when regarded from below) naturally suggested an upper limiting case; namely, some being who has realized the highest perfection or completeness, who cannot therefore be regarded as "matter" for further development, but only as "form." This highest being Aristotle identified with God. Like Plato's "Good," Aristotle's God was an "Idea" in Plato's sense (the only Platonic idea that Aristotle accepted), and the "end" or final cause of the universe. Aristotle conceived of all things as being somehow drawn towards God, and as going through the various processes of change and motion in consequence of this attraction. In this way, he conceived, God may, by His mere presence, cause all the changes and movements of things without Himself either moving or changing—He is the Unmoved Mover of the universe. For Aristotle, however, God is not the Creator of the universe. For the universe is eternal. Matter is eternal; and all the Forms are eternal, because there is no break in the succession of each Form's individual embodiments in matter. The effect of God's presence in the universe is that as the object of the world's desire He induces the already existing "matter" to develop its potentialities by assuming higher "forms." (See ARISTOTLE; LOGIC, HISTORY OF; ETHICS, HISTORY OF; KNOWLEDGE, THEORY OF; PSYCHOLOGY, HISTORY OF.)

ANCIENT PHILOSOPHY AFTER ARISTOTLE

Greek philosophy continued to flourish more or less for several centuries after the death of Aristotle. But its character was changed in some important respects. Plato and Aristotle attached supreme value to theoretical reflection as such. This is evident from their conception of God, for whom they could conceive no higher activity than thought. But Greek conditions in the latter part of the 4th century B.C. were not favourable to such disinterested thought. After the battle of Chaeronea, in 338 B.C., the Greeks lost their independence, and the Macedonian ascendancy, even if it was not an unmixed evil, created too many practical problems to leave much scope for abstract speculations. People who turned to philosophy did so mainly in search of some kind of moral or religious tonic. Hence the subordination of theoretical to ethical discussions in post-Aristotelian philosophy. The most important of the Greek schools of philosophy after Aristotle were the Epicureans, the Stoics and the Sceptics. They were all interested mainly in the moral problems of human life, and their history belongs chiefly to the history of ethics.

Epicurus (?341-271 B.C.) and the Epicureans put no intrinsic value on knowledge. Its value, according to them, consists entirely

in its usefulness for practical purposes. The study of nature is useful mainly because it emancipates us from groundless fears and superstitions. The study of human nature also has some value as an aid to self-control. But most other studies they despised as learned lumber. Under the circumstances, they were not likely to make any valuable contributions to metaphysical theory. Yet we owe them something. As a reaction against the idealism and teleology of Plato and Aristotle, the Epicureans embraced the atomic theory of Democritus with its mechanistic explanations of all things. Even the soul was regarded as corporeal, "composed of fine particles dispersed all over the body, most nearly resembling wind with an admixture of heat"; for, says Epicurus, "it is impossible to conceive anything incorporeal except empty space"; '(hence those who call soul incorporeal talk foolishly.'" In the 2nd century B.C. Epicureanism obtained a foothold in Rome, and there produced its most famous exponent in *Lucretius* (95-51 B.C.), whose poem, *On the Nature of Things*, contains the classic account of ancient atomism. In ethics they developed the hedonism of the Cyrenaics. While regarding pleasure as the only good, they distinguished different kinds, as well as degrees of pleasure, valuing mental pleasures, especially those resulting from the practice of virtue, above all others. (See EPICURUS; HEDONISM; ETHICS, HISTORY OF.)

Zeno (?336-264 B.C.) and the Stoics also attached no intrinsic importance to knowledge. They valued it only as an aid to virtue and judged truths pragmatically. Just as the Epicureans adopted the atomist philosophy instead of evolving a philosophy of their own, so the Stoics adopted, with modifications, the philosophy of Aristotle, which they changed into a pantheistic view. Substituting the concepts "body" and "soul" for the Aristotelian "matter" and "form," they conceived the universe as an organic whole, having both body (or matter) and soul (or force, or reason). All things are but parts of the one organic universe, which pursues a rational course and directs the development of all its parts. So completely rational and in conformity with universal law was the "One and All" conceived to be that no room was left for arbitrariness or caprice. It is at once God and Nature, Providence and Destiny. A hymn composed by the Stoic Cleanthes (?331-233 B.C.) is one of the most famous expressions of pantheism in the history of literature. With such a conception of nature the Stoics naturally identified virtuous conduct with life according to nature, and this it could only be by being in harmony with the universal reason pervading nature. Rational self-control was set up as the only good, because it makes one independent of external circumstances, free and contented. As with Epicureans so with the Stoics, one of their most celebrated members was a Roman—the Emperor *Marcus Aurelius* (121-180 A.D.). (See STOICS; ETHICS, HISTORY OF; LOGIC, HISTORY OF; PANTHEISM.)

Pyrrho (?360-270 B.C.) and the Sceptics were much more interested in philosophical theory than were the Epicureans or the Stoics. They paid special attention to epistemology. But the conclusions they arrived at were not flattering to human knowledge so-called. Pyrrho was of opinion that things are too incalculable and unaccountable to warrant any conviction whatever, so that the right attitude of mind is one of sceptical neutrality. Such an attitude has its advantages, for it is conducive to peace of mind. Most troubles, he held, are disappointments resulting from rash judgments and anticipations. Those who renounce all claims to knowledge might attain to the same equanimity which the Epicureans and Stoics sought to attain with the aid of knowledge. The most important of the Sceptics was Carneades (213-129 B.C.). He carried on a systematic campaign against the dogmatic assumptions of his predecessors and contemporaries, attacking more especially the tendency of the Stoics and others to identify cosmic regularity with a cosmic reason, the widespread habit of ascribing human attributes to God, the entirely insufficient evidence on the strength of which God's existence was believed in, and the habit of ignoring the existence of unmerited evil in order to exonerate God from all responsibility for it. Even Hume (1711-1776) and other modern sceptics did little more than adapt the arguments of Carneades. (See SCEPTICISM.)

Ethically, the three schools, Epicureans, Stoics and Sceptics,

were really very similar. They all regarded peace of mind as the highest good attainable, and they all emphasized the need of emancipating oneself from the bondage of external circumstances.

Philo (?25 B.C.—A.D. 50) and the *Neo-Platonists*. One result of Macedonian ascendancy has already been pointed out in explanation of the predominance of ethics in post-Aristotelian philosophy. Another effect it had was that it tended to break down national barriers. The different nationalities under Macedonian sway were thrown together, and Greek thinkers were brought into touch with the East. The cosmopolitanism of the Stoics was probably influenced by this. But Neo-Platonism is a more obvious result of the contact between East and West. Alexandria was the great intellectual centre where East and West met together. The East needed more philosophy, the West more religion, and Neo-Platonism was an attempt to make the best of both. The philosophy which had a very marked religious side was that of Plato. The new movement, accordingly, was first regarded as a form of Platonism. Eventually, however, it was re-named Neo-Platonism. Of the early Neo-Platonists the best known is *Philo Judæus* of Alexandria. He was the head of a group of cultured Jews who tried to harmonize Hebrew religion with Greek philosophy. By interpreting the Bible allegorically, Philo sought to read Platonism into Hebraism and Hebraism into Platonism. But Neo-Platonism owes its success mainly to *Plotinus* (A.D. 204–270) and *Proclus* (410–485). This school also may claim a distinguished Roman as one of its adherents; namely, the Emperor *Julian the Apostate* (reigned 361–363).

According to Plotinus, the ultimate source of all things is God, of whom it is impossible to predicate anything, because He is logically prior to anything that can be predicated. Now, God, acting on a creative impulse, created a Spirit (*νοῦς*) somewhat like Himself. This Spirit, acting on a like impulse, created another, namely the World-Soul. This created other souls, and so on until the series of productions in accordance with the law of diminishing spiritual returns ends in that extremely low kind of souls called matter. The process of creation is usually conceived as a kind of emanation, analogous to the sun's emission of light; sometimes, however, creation seems to be reduced to a logical or quasi-logical relationship. The World-Soul (the creation of the first Spirit created directly by God) is conceived as a group or system of spirits very like the Platonic "Ideas," at once thoughts and objects, but perfect and immutable. As the creations or emanations are held to be immanent in the creators, the Neo-Platonist universe in really one spiritual system, all the parts of which are spiritual though in varying degrees. The human soul has fallen from a higher grade of spirituality, and can only regain this by a training in asceticism and mysticism and after a series of successive births. The Neo-Platonism of Plotinus, with its system of graded spiritual emanations from God, was readily adapted to the then prevalent Polytheism and belief in spirits and spectres of all sorts. Greek paganism thus received a new lease of life under Julian the Apostate. Plotinus also criticized the Christian exaggeration of man's place in the universe and of the importance of prayer without work. (See NEOPLATONISM; PHILO; PLOTINUS; PROCLUS.)

Cicero (106–43 B.C.) and the *Eclectics*. Philosophers who neither construct a system of their own nor embrace an existing system as a whole, but adopt and combine parts belonging to different systems, are called eclectics or syncretists. The term Eclecticism is sometimes applied with great latitude so as to include even such comparatively harmonious systems as Neo-Platonism, but is more usually restricted to the less systematic and more loose jointed philosophies. In 146 B.C. Greece became a Roman province, and Rome developed philosophic ambitions without ever succeeding in constructing an independent philosophic system. It was probably in keeping with the essentially practical mentality of the Romans to refrain from speculation beyond a certain point, and to trust their common sense instead of following theoretical adventure "whithersoever it may lead." The most famous eclectics of antiquity were Cicero and Seneca (A.D. 5–65). Both showed marked leanings towards the epistemology of the Sceptics of the New Academy and the ethics of the

Stoics. Cicero also leaned somewhat towards Stoic pantheism, and Seneca has impressed many people as remarkably Christian for a pagan. Of course, there were eclectics outside Rome. Perhaps the best known of them was the Greek, *Plutarch* (A.D. 50–120). (See CICERO; SENECA; PLUTARCH.)

The End of Ancient Philosophy.—In A.D. 529 the Emperor *Justinian* closed the school of philosophy and so brought to an end the first main period in the history of philosophy. During the dark ages, which followed, the writings of the eclectics, and especially those of Cicero, did much to keep alive a knowledge of ancient philosophy and an interest in philosophical problems.

MÆDIAEVAL PHILOSOPHY

Greek philosophy had started as a rational reaction against the mythologies of popular religion, and in Athens at least three Greek philosophers (Anaxagoras, Socrates and Aristotle) suffered persecution, one of them even death, on account of their alleged hostility to popular religion. In the middle ages the tables are turned. Popular religion has the upper hand, and philosophy becomes the handmaid of theology. There is no independent mediæval philosophy. It is not original but borrowed from the past; and it is not free, but subordinate to authority—the authority of books or of an organized Church. This is true more or less not only of Christianity, which played the leading rôle in the middle ages, but also of Judaism and of Islam. When philosophy was not simply denounced and ignored, it was exploited in the interests of the Christian, Jewish or Mohammedan epic, not to say mythology. Some would go so far as to refuse the name philosophy to thought so restricted. But it is impracticable to draw a hard and fast line. On the one hand, even Greek philosophy was, perhaps, never entirely purged of elements of mythology. On the other hand, even mediæval thinkers, by a subtle use of allegorical interpretation, managed to fit Scripture to their philosophy instead of modifying their philosophy to fit Scripture, and so gained a measure of freedom of thought.

PATRISTIC PHILOSOPHY

Mediæval philosophers were for the most part Christian theologians, and a detailed history of their views belongs to the history of Christian dogma rather than to the history of philosophy. Here our business is only with the limited philosophical aspect of that complex and interesting story. Christianity did not set out to be a philosophy, but a moral and religious stimulus. Its interest was in the lowly rather than in the "high-brow." It was suspicious of philosophy and uttered a warning against it. "Take heed lest there shall be any one that maketh spoil of you through his philosophy" (Col. ii., 8). And at least one Apostolic Father (Tertullian) not only did not mind it if his faith was unphilosophical, but was almost proud of it—*credo quia absurdum*. In course of time, however, it was found necessary to make use of philosophy partly in order to repel the attacks of hostile philosophers, partly in order to spread the gospel among philosophically-minded heathens, and partly in order to satisfy the needs or tastes of Christians with a turn for philosophy. Early in the 2nd century already Alexandrian Christians, like Alexandrian Jews, resorted to allegorical Neo-Platonist interpretations, as is clear from the "Logos" doctrine in the so-called *Gospel of St. John*. Some of the "Gnostics" even tried to combine loyalty to Jesus with loyalty to Pythagoras, Plato and Aristotle. For some time, however, the chief use made of philosophy was for purposes of defence (apologetics). This was the case with the Church Fathers, notably *Justin Martyr* (d. 167), *Tertullian* (150–220), *Clemens of Alexandria* (d. 215), *Origen* (185–254), and, above all, *Augustine* (354–430).

The Patristic period, as it is called, is characterized by its Platonic or Neo-Platonist tendency, for which the influence of Augustine secured a certain predominance in Christian thought for a long time afterwards. Augustine had been a sceptic, among other things, before he became a saint, so he felt it necessary to refute scepticism before attempting a constructive philosophy. His method was that adopted later by *Descartes*. There are many things, he said, that are dubious. But there is one thing that is indubitable even in the state of doubt, namely, the actual

experience of doubting. And one could not doubt unless he was alive and thinking, and aware that there is such a thing as truth. So we are certain of something. But how? Not by external perception but by inner intuition. Augustine next proceeds, like Plato, to distinguish two types of reality—an "intelligible world" (of "ideas" or "forms") which is apprehended by intuition, and a "sensible world" (of mere "copies" or "imitations" of the "ideas") which is apprehended in sense-perception. Intuition affords real "knowledge"; sense-perception, mere opinion. Eternal truths (like those of mathematics, for example) are objective and transcendental. They are emanations or radiations from God. The human soul may apprehend them, but does not create them. God, then, is the source of the eternal truths. He creates things by thinking them; and He has created the world out of nothing. But things were not all made by Him directly. God only created matter and endowed it with the seeds of further development. With such changes time came into being; but God is beyond time—He is eternal. Temporal things only endure so long as God maintains them by continuous creation. Man is a miraculous union of an "intelligible" and a "sensible" substance. The soul, as the possessor of eternal truths, is immortal.

Patristic philosophy attained its climax in Augustine, and little else of the thought of that period, and for several centuries afterwards, is of sufficient philosophical interest to be worth mention in a mere outline of the history of philosophy. As a whole Christendom relapsed into intellectual darkness, and did not open its eyes again until several centuries afterwards.

ARABIAN AND JEWISH PHILOSOPHY

Arabian and Muslim Philosophy.—When the Athenian schools of philosophy were closed in 529 many of the teachers migrated to Syria and Persia and stimulated philosophical interest in the Muslim world. This interest was intensified when in 641 the Arabs captured Alexandria, which was then the greatest seat of learning, with a long and honourable tradition behind it. By 711 the Muslims had swept through Arabia, Syria and Mesopotamia, and even along the African coast of the Mediterranean as far as the straits of Gibraltar, and went into Spain. (The "Moors" of Spain were Arabs from Mauretania, that is, North Africa.) In this way philosophy was kept alive in Islam and in due course brought back to Christendom. The most important Muslim philosophers were Al Kindi (d. 870), Alfarabi (d. 950) and Avicenna, or Ibn Sina (980-1037) of Baghdad, and Averroes (1126-1198) of Cordova, in Spain. They were familiar with nearly all the works of Aristotle, and with several of Plato's treatises. Their philosophy was Aristotelian in the main, but blended with Platonism. The most interesting feature in Avicenna is his discussion of the problem which subsequently became one of the most burning questions among the Christian Scholastics, namely, the problem of the relation of the universal to the particulars of which it is predicated—the bone of contention between the so-called Nominalists and Realists of Scholasticism. And his solution was this. Universals existed in the thought of God already before the corresponding particulars came into existence; but they were then embodied in the particulars; and are derived by the human mind from these by a process of abstraction.

Averroes was the most Aristotelian of all the Muslim philosophers, and the most important. According to Averroes, there is a sub-lunar world of imperfection and change, and another, higher, eternal world beyond the stars. Matter is eternal, and contains from the first certain seminal "forms" which develop it from the merely potential to the actual, or final, state, under the influence of the higher "forms," or "intelligences," or in the last resort, of God. The human soul is inseparable from the body, or rather the brain, and perishes with it; but the "reason" that dwells in man is immortal, and by cultivating it man may enter into union with the universal "active reason." (See ARABIAN PHILOSOPHY.)

Jewish Philosophy.—Already in pre-Christian times there existed among the Jews a kind of philosophical mysticism which resembled Neo-Platonism in some respects. It is possible that Philo, the Jewish founder of Neo-Platonism, came under its influ-

ence at one time. This mystical doctrine is known as the *Kabbalah* (Hebrew for "traditional lore"). But it is difficult to trace its history with accuracy, as its two principal documents—the *Sepher Yetzirah* ("Book of Creation") and the *Zohar* ("Book of Splendour")—are compilations which are not much earlier than 900 and 1300 respectively. Side by side with this movement, however, there grew up, a more genuine philosophy under the influence of Plato and Aristotle. This movement had two interesting periods, namely, the Alexandrian period, about the beginning of the Christian era, in which Philo and various other Egyptian Jews flourished, and the Spanish period, from about the 10th till the 14th century, when many Jews vied with the Moors in the cultivation of Platonic and Aristotelian philosophy.

The favourable conditions under which Jews lived, during these centuries, throughout the Muslim world encouraged their participations in the interest which Islam then took in philosophy. In Baghdad and in Cairo, in Cordova and Toledo, they kept abreast of their Muslim neighbours. Numerous as were the Mohammedan schools and sects produced by the study of Greek philosophy, almost every one of them was reflected in contemporary Jewish thought. Traditionalism and anti-traditionalism, rationalism and dogmatism, fatalism and voluntarism, Platonism and Aristotelianism—all these and other tendencies had their Jewish counterparts, and almost every Muslim philosopher of repute had his Jewish double. This does not argue imitation but a similar susceptibility to similar influences. During the 10th and 11th centuries Platonism and Aristotelianism were about equal in favour. The chief Jewish thinkers of this period were Israeli (between 850 and 950), the author of a treatise *On the Elements*; Seadiah (892-942), author of *Faith and Philosophy*; and Bachyah Ibn Pakuda (?1000-1050), who wrote a *Guide to the Duties of the Heart*. To this period belongs also the Jewish Neo-Platonist and poet Ibn Gabirol (c. 1021-c. 1070), whose *Fons Vitae* ("Fountain of Life") was probably the first book to re-introduce Greek philosophy into the West after the close of the dark ages. During the 12th century, Aristotelianism gained in influence, and enjoyed almost undisputed supremacy during the 13th and 14th centuries. The most important Jewish thinkers of this period were Maimonides (1135-1204), author of the *Guide of the Perplexed*; Gersonides (1288-1344) author of *The Wars of the Lord*; and Crescas (1340-1410), author of *The Light of the Lord*.

These Jewish philosophers served the interests of subsequent philosophy in two principal ways. They helped to make the works of Plato and Aristotle accessible to the Scholastics by helping to get them translated from the Arabic versions into Latin, frequently through the medium of Hebrew. (The transmission was thus very roundabout, as the Arabic versions were in their turn usually based on Syriac translations made by the Nestorians from the Greek originals.) But some of them also exercised a more direct influence on the Scholastics. Avicenna's *Fons Vitae* (the Jewish origin of which was not suspected for many centuries) had no small share in moulding the thought of Duns Scotus, among others. And Maimonides exercised an equally strong influence on others, among them the two most important Scholastics, Albertus Magnus and Thomas Aquinas. Maimonides and Crescas also influenced Spinoza in some ways, and both are referred to by him. (See JEWISH PHILOSOPHY.)

SCHOLASTICISM

In the meantime various tendencies were preparing the way for a re-awakening of Christian interest in philosophy. The schools founded throughout France by Charles the Great, in the 8th century, were sufficiently developed in the 9th and 10th centuries to take up some philosophic problems, a faint interest in which had been just kept alive by various mystics and Neo-Platonists. The teachers who taught the so-called seven liberal arts at these schools were known as *doctores scholastici*. (The seven liberal arts were grammar, logic, rhetoric, arithmetic, geometry, astronomy and music.) But the name was applied later to all who taught philosophy and theology, especially at the new universities of Paris, Bologna, Salerno, Oxford and Cambridge, which were all founded during the 11th and 12th centuries.

The chief aim of the Scholastics was to reconcile Christian theology with philosophy. The first prominent Scholastic was John Scotus Erigena (810-877). He insisted on the harmony of Christian dogma with reason, as God is the author of both. Under the influence of a kind of Neo-Platonic mysticism he teaches the idealistic doctrine that things only exist in so far as they are known, that the universal ideas by which they are said to be known are the only ultimate realities and produce the so-called things.

This kind of view about the reality of ideas, now usually called "idealism," was known as "realism" in the middle ages. (Later on "realism" meant, and still usually means, the view that material things are also real, which extreme idealism denied.) In course of time the problem of the reality of universals became a burning question among the Scholastics. It was usually raised in connection with Porphyry's discussion of Aristotle's predicables, but that was a matter of chance; it would probably have arisen in any case in connection with the study of the differences between Platonism and Aristotelianism. Until late in the 11th century, under the predominant influence of Platonism or Neo-Platonism, "realism" was the usual view. Roscelinus (?1050-1121) was the first "nominalist," that is to say, he denied the independent reality of universals, and regarded general terms as mere names. For a long period, however, he had no following. Anselm of Canterbury (1033-1109) was a pronounced realist. He also formulated the characteristic view of Scholasticism that faith must precede knowledge—*credo ut intelligam*.

An innovator was Abelard (1079-1142), famous for his association with Heloise. His view of universals was rather like that of Avicenna. He held that universals are embodied in the individual things. The "forms" or "ideas," however, are conceived by God from all eternity. The human mind only gets to know them by abstraction from particulars. So universals exist *ante res*, in *rebus*, and *post res*. Abelard is noteworthy for his defence of doubt. He claimed a certain value for it inasmuch as doubt leads to enquiry, and enquiry leads to truth. In his ethical treatise *Scito te ipsum* ("Know thyself"—the first separate ethical treatise in the middle ages) Abelard shows himself comparatively tolerant towards pagans, Jews and philosophers or free-thinkers.

The Crusades (1097-1290) brought Christendom into contact with Eastern learning and so helped to promote a fuller knowledge of Platonism and Aristotelianism, especially the latter, as expounded by Arabian and Jewish philosophers. This tendency made a good beginning when in 1085 Toledo fell into the hands of the Christians who thus came into possession of numerous philosophical manuscripts. And the movement reached its climax when in the course of the 13th century Aristotelian manuscripts in the original Greek found their way gradually from Constantinople to the new centres of European learning. Aristotelianism, rejected by the Church in the early part of the 13th century, grew rapidly in favour, especially in the Dominican order, which produced the two greatest Aristotelian Scholastics, namely, Albertus Magnus (1193-1280) and Thomas Aquinas (1225-1274), Albertus wrote voluminous expositions of Aristotelianism with the help of Arabian and Jewish commentators, especially Avicenna and Maimonides. In the realm of natural knowledge he respected the authority of Aristotle as much as he trusted Augustine in the sphere of Christian faith. In fact, it was he who first distinguished sharply between natural and theological knowledge—a distinction of no little importance in the history of Scholasticism, and even later.

Aristotelian Scholasticism culminated in Thomas Aquinas. He also emphasized the distinction between natural and theological knowledge, between the light of reason (*lumen naturale*) and the light of revelation, and even admitted, in principle, the autonomy of the former. In practice, however, he subordinated natural to theological knowledge in the sense of making the former aid to the latter. Philosophy is thus treated as the handmaid of theology, and nature as the mere forerunner of grace, though grace is alleged to crown nature, not to reject it. The distinction, though difficult or impossible to maintain, turned out to be helpful inas-

much as it rendered possible a certain amount of independent thinking in the realm of nature, so long as no reference was made to the concepts of historical Christianity (which constituted the realm of grace). Like Aristotle Aquinas laid great stress on the distinction between matter and form, though he is rather liberal in his conception of the numerous "forms" capable of existing apart from matter. The human soul, though associated with a body, is also capable of separate existence. It is the lowest of the "separate forms," of which there is a scale ascending through all kinds and degrees of angels and spirits (including those which guide the stars and their courses) and culminating in the "absolute form," namely, God. By assuming that God had conferred a measure of autonomy upon nature, Aquinas further facilitated to some extent the possibility of an autonomous philosophy or science. His conception of the character of human knowledge also tended in the same direction. Instead of regarding it (as Augustine had done) as a direct divine illumination, Aquinas conceived it to be produced by images which external objects deposit, so to say, in the soul. Empirical studies thus received some recognition. On the question of universals the view of Aquinas was that one "form" is embodied in all the material objects of the same class, and that their matter is responsible for their particularity and multiplicity. In the case of Angels, etc., that is, immaterial forms, there is no such multiplicity of replicas, so to say—each form is unique. Our knowledge of material objects *qua* particulars comes through our senses, but their "form" is apprehended by the intellect.

The Aristotelianism of the Dominicans was opposed by the rival Franciscan order, the principal representative of which was Duns Scotus (1217-1293). He strongly opposed the intellectualism of Aquinas and repudiated the endeavour to harmonize faith with knowledge, theology with philosophy, and rather emphasized their antagonism. What is true in philosophy may be quite false in theology, which leaves no room for philosophical dialectics. Whereas Aquinas regarded knowledge as primary, and will as dependent on knowledge, Duns Scotus claims primacy for the will, which he treats as the fundamental faculty of the soul. Imagination and conception are entirely subordinate to the will, with which the decision always rests, and which is free from all possibility of coercion. The good is above the true. And the good is good because God has declared it such. (Aquinas maintained that God ordained certain things because they are good.) Things are what they are because God has arbitrarily made them so. And the duty of man is to will to obey God's commands. On the question of universals Duns Scotus upheld the same kind of realism as did Anselm, Avicenna and Aquinas. The doctrine of the primacy of the will was adopted later by Descartes.

The teaching of Duns Scotus concerning the irreconcilable antagonism between philosophy and theology, and concerning the arbitrary character of divine creations and decrees was carried even to greater extremes by William of Occam (d. 1347). He maintained that philosophy is utterly incapable of proving the existence of God, or demonstrating His attributes. From this bankruptcy of the natural light of reason he infers the necessity of revelation. He carries his conception of the good, as the arbitrary decree of God, so far as to maintain that a so-called evil deed is not evil if it is done in the service of God. In opposition to the moderate "realism" of the Dominicans, Occam revived the nominalism of Roscelinus and maintained that universals are merely subjective conceptions, all real things being individual or particular. To posit real universals in addition to the corresponding particular objects is an uncalled for duplication. It was in this connection that he formulated the familiar principle, commonly known as "Occam's Razor," *entia praeter necessitatem non sunt multiplicanda*—the number of entities should not be increased unnecessarily. After Occam, Scholasticism rapidly declined in influence. In one form or another it continued, of course, and continues to this day. It has even enjoyed various revivals. But its power was broken by the onward march of that great combination of forces called the Renaissance or Revival of Learning. (See SCHOLASTICISM; KNOWLEDGE, THEORY OF.)

MODERN PHILOSOPHY

Transition. — subordination to authority was the chief characteristic of mediaeval thought. It took many generations and diverse influences to break the power of ecclesiastical authority, and to secure autonomy for philosophy. No doubt authority was a guide as well as a task-master, a support as well as a rod, during the adolescence of mediaeval thought. Greek thought did not allow itself to be shackled by tradition or by authority. On the other hand, a great deal of the thought of Christendom, even in the "modern" period, can hardly claim to be free from the marked influence of Christian tradition and authority. So it would be a mistake, on the whole, to think of ecclesiastical authority in the middle ages as a tyranny imposed entirely from outside. But thought had to come of age sooner or later. And many influences helped it towards maturity. When Constantinople was threatened by the Turks, the Greek scholars there fled to Italy carrying their classical treasures with them. One of them, *Pletho* (?1355-1450) persuaded Cosimo de Medici to found a Platonic Academy in Florence. With the co-operation of *Marsilius Ficinus* (1433-1499), *Pico de Mirandola* (1463-1494) and others, Platonic and Neo-Platonic philosophy made headway against Aristotelianism on which Scholasticism was based. Writers like *Lorenzo Valla* (1408-1457) attacked Scholasticism for its sins against literary form, and its interest in words instead of things. *Nicolaus Cusanus* (1401-1464) showed pantheistic and scientific leanings, and believed not only in the spherical form of the earth, but also in its rotation about its axis.

Paracelsus (1493-1541) and *von Helmont* (1577-1644) denounced "authority" and mere book learning in the study of natural phenomena; although their own methods had little to commend them. *Telesio* (1508-1588) founded an academy at Naples to promote the study of nature on scientific lines. He embraced the ethics of the Stoics, and introduced the conception of a self-preserving impulse somewhat like that formulated subsequently by Spinoza. Very important in many ways, during this period of transition, was *Giordano Bruno* (1548-1600), whose martyrdom marked the first open breach with the Church. He was at once pantheist and atomist, and gave currency to the conception of "monads" of varying grades with God as "the monad of monads." Some of his ideas reappeared later in Spinoza, Leibniz and Schelling. *Montaigne* (1533-1592) and *Sanchez* (1562-1632) attacked dogmatism with the weapons of scepticism, and pleaded the cause of toleration. But most important of all was the progress of science and the growth of the scientific spirit through the achievements of *Copernicus* (1473-1543), *Kepler* (1571-1630), *Galileo* (1564-1642) and *Newton* (1642-1727); *Vesalius* (1514-1564), *Fabricius* (1537-1619), and *Harvey* (1578-1667); *Gilbert* (1540-1603), *Boyle* (1627-1691) and *Huygens* (1629-1695).

Modern philosophy owes little or nothing to the Reformation. The Reformers (Luther, Calvin and Zwingli) were as intolerant as possible. Luther denounced reason as the mistress of the devil, and Calvin committed Servetus to the flames, in 1553, with as much Christian charity as the Inquisition showed to Bruno in 1600. All that can be said is that the dissensions between the Churches indirectly stimulated a certain amount of independent thought among thoughtful people, and so reinforced a similar tendency encouraged by the mystical movement which, though it only produced few geniuses like Eckhard (1260-1327) and Böhme (1575-1624), had never entirely ceased in Christendom. Francis Bacon (1561-1626) must also be mentioned here. He described himself as the herald of modern thought, and perhaps rightly so. He showed rather less originality than his namesake Roger Bacon, who preceded him by three centuries. But he summed up very effectively all the grievances against Scholasticism. The place of honour as father of the new philosophy is usually given to Descartes. Many of his contemporaries certainly regarded Descartes as the founder of a new philosophy. So one may as well date modern philosophy from Descartes.

FROM DESCARTES TO LEIBNIZ

Descartes (1596-1650), like Bacon and others before him, was

dissatisfied with the state of knowledge in his time. Mathematics was the only study that seemed to be well founded. And he thought that the difference was due to a difference in method. Other studies then followed the scholastic method of citing authorities for and against certain views. With mathematics it was different. It did not depend on authorities, but set out from certain clear ideas (axioms, postulates, definitions) and then proceeded deductively from them to results which were not challenged and contradicted constantly as were the results reached by different thinkers in other fields of study. Descartes resolved, accordingly, to introduce something essentially like the mathematical method into philosophy. The first requisite was a sure starting point, an Archimedean fulcrum, as Descartes called it. In order to discover it he adopted from Augustine the instrument of "methodical doubt" rejecting everything that was open to doubt until he could discover something indubitable. Like Augustine he found that though everything else could be doubted, the reality of the doubt itself could not. "It is easy to suppose that there is no God, no heaven, no bodies, and that we have no hands, no feet, no body; but we can not in the same way conceive that we who doubt these things are not; for there is a contradiction in thinking that that which thinks does not exist when it thinks. Hence the conclusion I think, *therefore I am* is the first and most certain of all that occurs to one who philosophizes in an orderly way" (*Principles of Philosophy*, I., vii.). This conclusion, however, is only accepted because it is "clear and distinct." Hence the general rule that "whatever I apprehend very clearly and distinctly is true" (*Meditation* III.).

Among such very clear and distinct ideas he includes that of God, the axioms of geometry and such already familiar "eternal truths" as *ex nihilo nihil fit*, etc., which he also calls innate ideas, in the sense that they are not derived from experience, but are evolved, in due course, by the immanent power of thought itself. Still, Descartes finds it necessary to prove the existence of God, and his main arguments are borrowed from Anselm and Campanella. Next, relying on the veracity of God, he accepts the reality of the things of the world of experience, with the reservation that error arises when we believe what is not very clear and distinct. Such error is possible because belief or judgment is an act of will according to Descartes, who with Duns Scotus believed in the primacy of the will. As to the nature of real things, God is the only self-existent being (or substance in the strict sense) on whom all other things depend for their creation and continuance. Of created things there are two main types, namely, "extended things," or bodies, and "thinking things" or minds. These are created substances, or substances in a secondary sense. Like Augustine Descartes regarded the material and the mental as so utterly different and opposite that there can be no interaction between them. The union of body and soul in man is simply a miracle, whereby the soul (with the help of *God — concursus Dei*) can *direct* the motion of the body, but not add to it in any way. When discussing problems which do not directly concern God or man, Descartes shows a much more scientific spirit, though his scientific contributions were of little value except in relation to geometry, to which he rendered services of first-rate importance.

Like Galileo, his senior contemporary, Descartes attempted to explain all natural phenomena mechanically and consequently denied the objective reality of secondary qualities. The lower animals he treated as mere automata or machines; and by attributing an imaginary function to the pineal gland and resorting to the antiquated "animal spirits" of Galen, he tried to introduce at least something mechanical into the relation between the body and the soul. This was not consistent with his conception of the opposed natures of bodies and minds. His followers, accordingly, tried another explanation, known as "occasionalism." According to this view, body and soul do not influence each other at all, but any change in either is an occasion for divine intervention in the other, so as to produce a corresponding change. This, of course, is supernaturalism pure and simple; and that is what Cartesian philosophy is essentially. The striking difference between Descartes' leaning toward mechanism in science and **super-**

naturalism in philosophy is readily intelligible as an instance of that distinction between the two spheres of knowledge, the natural and the supernatural, which was a familiar Catholic tradition traceable to Albertus Magnus and Thomas Aquinas. (See DESCARTES; CARTESIANS; KNOWLEDGE, THEORY OF; PSYCHOLOGY, HISTORY OF.)

Hobbes (1588-1679) shared Descartes' respect for mathematics and for deduction, as against the empiricism of Bacon. But, unlike Descartes, he was opposed to supernaturalism, and whereas Descartes confined mechanical explanations within the limits of material nature, Hobbes applied it everywhere, to the mental as well as to the material. The result was a materialistic philosophy. Matter and motion are the only ultimate realities, and explain everything, even knowledge. For all knowledge is derived from sense. "There is no conception in a man's mind, which hath not at first, totally or by parts, been begotten upon the organs of sense." And the sense experiences are produced by the several motions of the matter pressing on the sense organs. "Neither in us that are pressed are they anything else but divers motions; for motion produceth nothing but motion" (*Leviathan*, I., i.). For Hobbes mind is matter, and thought, like every process or change, is motion—"all mutation consists in motion." And the same fundamental tendency characterizes all beings, whether human or not, namely, the tendency to persist in their present condition, whether of motion or of rest. Hobbes does not deny the existence of God. The search for the cause of an effect, and for the cause of that cause, and so on, leads to the thought of an ultimate eternal cause or God; but we "cannot have any idea of him." The chief work of Hobbes belongs mainly to the history of ethics and of political philosophy. (See HOBBS; MATERIALISM; ETHICS, HISTORY OF.)

Spinoza (1632-1677) marks the culmination of the various tendencies of the Renaissance. He vindicated the autonomy of reason against every kind of authority, subordinating even the Scriptures to it. Rationalism expresses itself most characteristically in the attempt to connect things in continuous series or systems of events which suffer no arbitrary incursions from outside in the form of supernatural interventions. The great achievements of that classic age of science were essentially expressions of the rationalism of the 17th century. Yet the rationalism of all the great scientists of the time was fragmentary, one-sided; it was a week-day rationalism handicapped with a Sunday irrationalism. Spinoza was the complete rationalist, the prince of rationalists. He attempted to interconnect the whole of reality in one organic cosmos, which suffered no cleavage into a natural and a supernatural realm, or into a work-day and a Sabbath vista. For Spinoza, the world is a real universe. It is also a real cosmos, orderly through and through, subject to no arbitrariness, not even the arbitrariness of God. The rejection of the supernatural and the arbitrary constitutes the naturalism of Spinoza. But his conception of the universe avoided sacrificing any one part of it to any other, of the material to the mental, or vice versa. While repudiating any reality outside the cosmos (or Nature) he was careful to include within it whatever could claim reality—not only the material and the mental, but also the divine. They all have their place in the cosmic system. In fact God is the cosmic system. For God is conceived as the Perfect Self-existent; and that is just what the cosmos or Nature is—hence *Deus sive Natura*. The All is God, and God is All. This constitutes the pantheism of Spinoza.

The way in which Spinoza arrived at his main conceptions is rather obscured by the geometric method of exposition pursued in his *Ethics*. Briefly it was this. To understand any finite object or event it is necessary to follow up innumerable conditions on which it depends. These ramify in all directions, yet we can never halt, for the conditions invoked are themselves dependent on innumerable others. But a world consisting entirely of dependent objects and events would be unintelligible, inconceivable. There must be some unconditioned, self-dependent, absolute reality, or Substance, to account for the reality of all that is conditioned and dependent. This is usually admitted. But the traditional solution, accepted by Descartes and the greatest scientists

of the 17th century, was that God, a supernatural omnipotent Being, is this self-existent, absolute Being or Substance, who has created all things and maintains them. But the idea of an external Creator did not satisfy Spinoza. His rationalism revolted against the arbitrariness implied in the creation having taken place at one time rather than another; nor could it find in the notion of creation out of nothing anything more intelligible than the problems it was intended to solve. If it is necessary to posit an absolute ground of reality, why not accept the system of reality itself as this self-dependent substance?

This view avoided the unnecessary multiplication of entities, and the difficulties of creation out of nothing. It was also more satisfactory to the religious side of Spinoza's character, for it brought man into more intimate relation with God. Such a view was, of course, only possible in consequence of the friendlier attitude towards Nature which the Renaissance cultivated, as against the hostile association of "the world, the flesh and the devil" characteristic of mediaeval Christianity. With regard to the structure of the cosmic system, the leading ideas of Spinoza may be summarized as follows. God (or Nature or Substance) is not static but dynamic, and exercises all the kinds of energy that there are. It alone is absolutely infinite or absolutely perfect. Each kind of energy that is ultimate, that is, irreducible to any other kind, Spinoza calls an attribute of substance. Spinoza refers to an infinity of such attributes. But by "infinite" he means "complete" (not innumerable) and by "finite" incomplete or fragmentary. Man only knows two such attributes, namely extension and thought, that is, physical energy and mind energy. There may be others; there probably are. Moreover, each attribute is infinite of *its kind*, that is, exhausts everything of its own kind, so that there is no physical energy outside extension, nor mind energy outside thought.

All finite bodies and physical events are "modes," that is, modifications or states, of extension, and all minds and mental experiences are modes of thought. Similarly with the other attributes, if any. All cosmic activities or processes are immanent, not transcendent. And all apparent interactions between the modes of different attributes, say that between the body and soul of man, result from the fact that they are concomitant expressions of the attributes of the one substance. "The order and connection of thoughts is the same as the order and connection of things." Physical effects should be traced to physical causes, and mental experiences to mental causes. The various finite modes come into being and pass away; but not into nothingness—for the One remains in which the many change. God as conceived by Spinoza is not a "personal" God, not however because He is less, but because He is infinitely more than any personality known to man. (See SPINOZA; PANTHEISM; ETHICS, HISTORY OF; KNOWLEDGE, THEORY OF.)

Leibniz (1646-1716) was influenced mainly by his faith in the permanent reality of individual souls. His philosophy, accordingly, is so constructed as to secure the ultimate reality of individuals, and to assure their permanence. To this end two things were felt to be necessary. He had to dissociate souls from physical atoms, and to treat each individual soul as a *kind* of "substance," or self-contained thing. The Cartesian identification of matter with extension (which was widely accepted then) prompted Leibniz to deny the reality of matter altogether. For matter is then infinitely divisible, and no real "atom," nothing ultimate and really indivisible, can be conceived for the construction of the composite bodies of ordinary observation. From this he concluded that all space or all material bodies are mere subjective appearances, not objective realities. Reality, according to Leibniz, consists entirely of souls or spirits of all degrees of development. These are the real "atoms" or "individuals," real unities not made up of parts. Some of them have only a very low degree of consciousness or sub-consciousness, they are in a state of chronic somnolence, so to say; some are in something like a dream state; others are more awake, have clear thoughts, or are even self-conscious; and God, the "monad of monads" is supremely conscious and active. There is an infinity of monads; their gradation is continuous, without a break; and no two are

exactly alike.

To avoid the tendency to pantheism, Leibniz regarded the monads as not interconnected in any way, as incapable of influencing one another—"they have no windows by which anything can come in or go out." But there is one important exception to this, for God has created all other monads, which are "emanations" from the monad of monads. This, of course, makes the supreme monad different in *kind*, not merely different in degree from the other monads. However, having conceived the monads as "without windows" Leibniz has now to explain the appearance of interaction between them—the apparent interaction, *e.g.*, between the assembly of less developed monads which look like a body and that higher monad which is the soul. The problem is very like the problem which confronted the Cartesians, and the solution offered by Leibniz is rather like occasionalism. The ordinary monads do not really interact; each is self-contained, and develops from within, its present being pregnant with its future. But God has so made them all that they act in harmony. It is as if He had wound up so many clocks to keep time together. There is thus a "pre-established harmony" in consequence of which also each monad may be regarded as mirroring the entire universe, or every other monad, from its own point of view.

Like Descartes, Leibniz also follows strictly mechanical methods in dealing with physical problems, but he conceives mechanism to be in the service of teleology, and his general outlook, of course, was essentially teleological. His conception of the relation between the supreme monad and the other monads is obviously supernatural. In his philosophy, as in his public activities, Leibniz tried to bring together too many different elements to succeed in unifying them in one system. Leibniz is also famous for his optimism, that is, for holding the view that the actual world is "the best of all possible worlds." What he meant was that the "pre-established harmony" actually established by God was chosen by Him as the best possible, out of an endless variety of possibilities, in view of the purpose which He had in view. This does not imply that each thing regarded by itself is the best of its kind, or even good. It means only that in order to make any one thing better, the entire scheme of things would have to be different, and, as a whole, rather worse. (See LEIBNIZ; IDEALISM; KNOWLEDGE, THEORY OF; OPTIMISM.)

FROM LOCKE TO HUME

Locke (1632-1704) has the distinction of having given a decidedly epistemological turn to modern philosophy. He relates that five or six friends used to discuss philosophical or theological problems with him, but fruitlessly. So it occurred to him "that before we set ourselves upon inquiries of that nature, it was necessary to examine our own abilities, and see what objects our understandings were or were not fitted to deal with." By "extending their inquiries beyond their capacities" people only "raise questions and multiply disputes, which, never coming to any clear resolution, are proper only to continue and increase their doubts, and confirm them at last in perfect scepticism." Locke attempted to carry out the task which he set himself by means of a descriptive account of human "ideas" or experiences, of which he drew up a detailed inventory in his *Essay concerning Human Understanding* (1690). Locke uses the term "idea" for any "object of the understanding," any object as experienced; and, directly or indirectly, he traces all ideas to experience. This constitutes his empiricism. He rejects innate ideas, maintaining that prior to experience the mind is like a blank paper; but he credits the mind with certain powers. Ideas are of two kinds in respect of their origin. Some are induced by sensible objects—they are "ideas of sensation." Others result from reflection upon such ideas of sensation—they are "ideas of reflection." And the mind not only reflects, but also combines the given simple ideas into complex ones.

Locke believes that there are external things. But the mind does not apprehend them directly; ideas of sensation are at best only "appearances" of things, only copies of them, mediating between them and the apprehending mind. And this is true only of ideas relating to primary qualities (extension, figure, number,

motion, solidity); the ideas of sensation relating to secondary qualities (colour, smell, etc.) are simply secondary or subjective effects produced in us by the primary qualities, and are not copies of anything objective. By combining the simple ideas of sensation and reflection there result complex ideas of substances, modes (*i.e.*, states of substances), and relations. The idea of a substance, or substratum, supporting qualities, etc., corresponding to simple ideas, Locke regards as an invention—he cannot trace it to a simple idea of experience, and he admits that it is vague. Yet he accepts the reality of substances, both physical and mental substances.

Of his own existence, each man is absolutely sure, by intuition; he cannot even doubt it without presupposing it. Of God's existence we are also certain, by demonstration; for our own existence cannot be explained without reference to Him as its cause. But, all the same, the "real essence" of substances is unknowable, and Locke is "apt to doubt a science of physical bodies as out of our reach" beyond merely empirical limits. (See LOCKE; EMPIRICISM; KNOWLEDGE, THEORY OF; PSYCHOLOGY, HISTORY OF.)

Berkeley (1685-1753) set himself the task of opposing the mechanistic methods of explanation generally accepted in his time in consequence of the fashion set by the great pioneers of modern science. He feared that that way lay materialism and atheism. But it was Locke's *Essay* that served him chiefly as the text of his criticism, especially in his *Principles of Human Knowledge* (1710) and the *Three Dialogues* (1713). Locke had maintained that our ideas of primary qualities resemble their external objects, whereas those of secondary qualities have no corresponding objects. Berkeley objected that both kinds of ideas are equally dependent on the mind and there is no more need or justification to assume the objective existence of primary than of secondary qualities. Moreover it is absurd to suppose that an idea can resemble anything that is not an idea. And if it is superfluous to assume the objective existence of primary qualities corresponding to certain ideas of sensation, it is even more unnecessary to assume, with Locke, the independent existence of material substance, of which, strictly speaking, we have no idea at all.

Locke had treated ideas of sensation as things which mediate between the knowing mind and corresponding material objects which they resemble where there is real knowledge; but Berkeley denounces this distinction between ideas and external objects as "the very root of scepticism"—"for how can it be known that the things which are perceived are conformable to those which are not perceived?" (*Principles*, 86). For Berkeley the ideas are the objects of knowledge, and there is nothing beyond them. "All the choir of heaven and furniture of earth, in a word all those bodies which compose the mighty frame of the world, have not any substance without the mind; . . . their being is to be perceived or known . . . consequently so long as they are not actually perceived by me, or do not exist in my mind, or that of any other created spirit, they must either have no existence at all, or else subsist in the mind of some Eternal Spirit" (*Zbid.* § 6). With the substantiality of matter its causality is also rejected. One idea of sensation cannot cause another; it can only suggest it. "The fire which I see is not the cause of the pain I suffer upon my approaching it, but the mark that forewarns me of it" (*Zbid.* § 65). And if one asks how it comes about that there appear to be such regular connections between divers ideas, the answer is "that this is done in virtue of an arbitrary connection instituted by the Author of Nature" (*Theory of Visual Language*, § 43). For spirits or minds are active agents, in fact the only ones.

Mechanistic explanations are therefore illusory. And if one objects (as Hume did soon afterwards) that there seems to be no more reason for assuming a mental substance than a material substance, ideas being the only things known, then Berkeley's reply is as follows: "I myself am not ideas, but . . . a thinking, active principle that . . . operates about ideas. I know that I . . . perceive both colours and sounds: that a colour cannot perceive a sound, nor a sound a colour: that I am therefore one individual principle, distinct from colour and sound, and . . . all other sensible things or inert ideas" (*Third Dialogue*). He admits, however, that he has no "idea" of minds or spirits, only a

"notion." Anyway the net result of Berkeley's speculations is an idealist philosophy according to which the only realities are God, other spirits or minds which He has created, and the innumerable ideas which He has produced and arranged for us to apprehend in certain sequences arbitrarily decreed by Him. (See BERKELEY; IDEALISM; KNOWLEDGE, THEORY OF.)

Hume (1711-1776) pursued the problems and methods of Locke to their extreme conclusion, in the sense that he showed that the kind of empiricism which Locke had advocated leads to positivism in science and scepticism in philosophy. It is one of the ironies of history that the book which Berkeley wrote in order to prevent or to cure scepticism actually infected Hume with it. "He professes [so writes Hume of Berkeley] in his title-page . . . to have composed his book against the sceptics as well as the atheists and freethinkers. But that all his arguments, tho' otherwise intended, are in reality merely sceptical, appears from this, that they admit of no answer and produce no conviction. Their only effect is to cause that momentary amazement and irresolution and confusion, which is the result of scepticism" (*Enquiry Concerning Human Understanding*, section 12, part i.n.). Berkeley had contended that there is not sufficient evidence for assuming material substances or material causality, as we have no ideas of either; but he defended both the substantial nature and causal power of minds or spirits. Hume argued that the same reasons which led Berkeley to reject material substances and material causes are also valid against the assumption of mental substances and mental causes.

Berkeley had tried to save mental substances and mental agency by pleading that we have "notions" of them apprehended by reason, though not "ideas" of experience. But Hume rejected this view of a radical distinction between "reason" and "experience," and submitted everything, even rational judgments, to the test of experience, and insisted on accounting for everything in terms of experience. He accordingly denied the certainty even of so-called mathematical knowledge, and reduced all alleged knowledge or certainty to mere probability. Causality itself he explained away as habitual association of sequent impressions or ideas; and substances as due to the mistaking of similar, recurring impressions for continuous impressions of the same thing. (See HUME; KNOWLEDGE, THEORY OF; SCEPTICISM.)

FROM KANT TO HEGEL

Kant (1724-1804) is the founder of the "critical" philosophy or of "transcendentalism." The stress which Descartes had laid on thought, or subjective experience, in basing his whole system on the cogito ergo *sum*, quite naturally resulted in a divorce between ideas, on the one hand, and the external world on the other. This is clear alike in the idealism of Leibniz and Berkeley, in the empiricism of Locke, and in the scepticism of Hume. The only philosophers of importance who avoided this predicament were Spinoza, on the one hand, and Thomas Reid (1710-96) and the Scottish school, on the other. But the alleged atheism of Spinoza robbed him of real influence; and the "common-sense philosophy" of the Scottish school was not sufficiently subtle to impress speculative minds. Kant attempted a new way of bringing thought and reality into touch once more. Kant himself liked to stress the "critical" character of his philosophy as the new element which he contributed; and consequently called his three great works critiques. He described all his predecessors as "dogmatic" philosophers, because they did not begin their philosophy with a critical examination of human capacity for knowledge.

The way in which Kant attempted to reunite knowledge with reality was briefly as follows. Known objects, according to Kant, are a multiplicity of sense-materials supplied to the apprehending mind which synthesizes them in accordance with certain forms of intuition (space and time) and certain categories of thought (substance and attribute, cause and effect, etc.). What the multiplicity of sense-materials may be before the mind has synthesized them, we do not and cannot know. But they are not produced by the mind, they are only apprehended and moulded by it—they are or pertain to "things-in-themselves." On the other hand, the

forms of intuition and the categories of thought are ways in which the mind in virtue of its own nature moulds or systematizes the multiplicity of disconnected sense-materials so as to adapt them to its own unity. These forms are a *priori* or "transcendental" in the sense that they are not derived from experience, inasmuch, as experience itself would be impossible without them; on the other hand, the multiplicity of sense-material is a posteriori, only given in experience and known through it (though not known "in itself")

These various a *priori* forms of apprehension are not peculiarities of the unity of individual minds as such, but rather express the unity of "consciousness in general" in which individual minds participate, but which is "super-individual." That is how it comes about that there is universal agreement in the use of the a priori forms and categories, instead of individual variations. Anyway, human knowledge does not extend to the intrinsic nature of ultimate reality or "things-in-themselves" but only to their appearances as moulded by the forms of intuition and categories of thought. In Kant's language, human knowledge is of "phenomena" not of "noumena" or "things-in-themselves." And any attempt to apply the a *priori* or "transcendental" forms to what does not fall within the realm of possible human experience, Kant condemned as "transcendent." The existence of God, and the immortality of the soul, e.g., are beyond the realm of possible human experience, and therefore of knowledge though what cannot be known may yet be believed as a matter of faith.

And it is on such "practical reasons" that Kant based the beliefs in the existence of God, in the freedom of the will, and in the immortality of the soul. These things, according to Kant, are postulates of morality. The "categorical imperative," the unconditional character of the sense of duty, can only be understood and justified on the assumption or faith that we are free to do, or "can" do, what we "ought" to do, that there is a God who can duly correlate virtue with happiness, and that there is a hereafter in which the injustices of the present life may be adjusted. Kant's moral philosophy brings out with special clearness a striking feature of his whole method of philosophizing. He does not doubt the validity of the sense of duty or the "categorical imperative"; he acknowledged it, and only draws out its implications or conditions. Similarly, Kant did not question the reality of the external world as conceived by contemporary (Newtonian) science; he accepted it (as Hume the sceptic would not), and tried to elicit the conditions of the validity of that science. (See KANT; ETHICS, HISTORY OF; KNOWLEDGE, THEORY OF; TRANSCENDENTALISM; RATIONALISM.)

Fichte (1762-1814) agreed with Kant in ascribing to mind, or "consciousness in general" (or "absolute self" as he preferred to call it) the forms of intuition and categories of thought which characterize objects of knowledge. But he held that Kant had not gone far enough. Kant had recognized "things-in-themselves" or "noumena" independent of consciousness, and furnishing the sense-materials for experience. These "noumena" could only be vaguely thought about, not perceived, except as moulded in the forms of knowledge, supplied by consciousness. Fichte, however, held that even the "thing-in-itself" is also the product of consciousness. The "absolute self" (in which individual minds participate) is the source of the whole of experience, not of its forms only. It divides itself in experience into a knowing self and a known object, because the development of the moral life needs objects as obstacles to be overcome by moral effort prompted by a sense of duty. Moreover, there must be many minds or selves, if there are to be mutual duties. But they are all the expressions of one moral order, which is the "absolute self" or God. (See FICHTE; IDEALISM.) A philosophy essentially like that of Fichte was taught subsequently by R. Eucken (1846-1926).

Schelling (1775-1854) reverted more or less to the fundamental conception of Spinoza, and tried to vindicate the reality of the material against the efforts of so many modern philosophers to reduce it to mere appearances or ideas. He contended that the beauty of the material world (or Nature, in the narrower sense of the term) gave it a sufficient claim to have a reality of its

own. So he conceived of Nature as an expression or manifestation of the Absolute in the same way as consciousness or mind is. Nature and mind are thus conceived to be related to the Absolute in the same kind of way as the two attributes, extension and thought, were conceived by Spinoza to be related to substance. The Absolute, however, came to be conceived as being in itself neither material nor mental, but something common to both or identical in both. Hence the name "identity philosophy" by which Schelling's system is commonly known. (See SCHELLING; IDEALISM.)

Hegel (1770-1831) is the founder of logical Idealism or Panlogism. He rejected the unknown "thing-in-itself" of Kant and the equally unknown "identity" or Absolute which, according to Schelling, manifests itself in Nature and mind. He denied the opaqueness of ultimate reality and insisted that the entire universe "can be penetrated by thought." Mind and Nature are not merely manifestations or expressions of an otherwise unknown Absolute; they are the Absolute itself. Moreover, mind and Nature, according to Hegel, are not two distinct or parallel realities but integral components of one process of self-revelation. Mind needs for its own development an objective world, or Nature, on which to exercise itself; but this objective world is itself mental, something that is at once appearance and reality—"the real is rational, and the rational is real." The development of this rational reality is a kind of dialectic proceeding by the method of thesis, antithesis, and synthesis, or position, negation and reconciliation. Some thought occurs; it is opposed by another thought, which also turns out to be inadequate; but what is true in each, the thesis and the antithesis, is harmonized and made mutually supplementary in another thought which synthesizes them; e.g., "becoming" is such a synthesis of "being" and "not-being."

The whole world, according to Hegel, is made up of such opposites which are reconciled. The general scheme of the cosmic dialectic is this. First comes "mind in itself," or the system of categories, which are conceived by Hegel, not as mere forms of thought by which unknown things-in-themselves are apprehended, but as ultimate realities; next comes "mind for itself," that is Nature as the self-externalization of "mind in itself"; lastly, comes "mind in and for itself," that is, mind or consciousness coming or returning to itself. This last phase, the mind's coming to itself, has a number of grades or stages. These are: individual mind or subjective consciousness; objective mind or social consciousness as expressed in law, morality, the State; and absolute mind or consciousness active intuitively in art, imaginatively in religion and intellectually in philosophy. Hegel's conception of the cosmic process as a rational dialectic stimulated new views of history and, consequently, a new interest in it. (See HEGEL; KNOWLEDGE, THEORY OF; IDEALISM.)

GERMAN PHILOSOPHY SINCE HEGEL

Materialism.— Various influences combined to occasion a tendency towards materialism about the middle of the 19th century. Idealism had on the whole sided definitely with conservatism in religion and politics. Hegel's dictum, "the real is rational," was readily exploited in a reactionary sense beyond anything that Hegel intended, conservative as he himself had been. The generation inspired by the revolutionary tendencies of 1848 resented this kind of idealism. Stimulated by the microscopic biology of Schwann (who showed the cell to be the unit of plant and animal organisms), by the chemical researches of Liebig, by Schleiden's rejection of vitalism, and by the physical experiments of Mayer, Joule, Colding and Helmholtz, which resulted in the discovery of the principle of conservation of energy, the scientific spirit of the age revolted against the idealists' indulgence in romantic speculation. Industrial progress, advance in the technical arts, and the consequent improvement in economic and material conditions, also helped to stimulate special interest in things material. And the doctrines of the French materialists of the 18th century, La Mettrie (1709-51), Holbach (1723-89) and Cabanis (1757-1808), were ready at hand to be taken up and developed. J. Moleschott (1822-93) described the whole cycle of life in

terms of matter and energy. Matter conditions life, life conditions thought, and thought conditions the will to improve life. Physical conditions are the main determinants of human destiny.

K. Vogt (1817-95) supplemented Moleschott's dictum, "no sulphur, no thought," with the statement that "thought is related to the brain in the same way as bile is to the liver." The same thing had been said already by Cabanis. Vogt did not pretend to know how exactly the brain does produce thought. L. Buchner (1824-99) was the most influential of this group, and his *Force and Matter* (1833) served for a considerable time as the source-book of materialism. He identified force of every kind with movement, and regarded everything as the product of matter and motion which are distinguishable but not separable. He rejected vitalism, held that life is spontaneously generated out of matter under certain conditions, and that mental process is only "a radiation through the cells of the grey substance of the brain of a motion set up by external stimuli." H. Czolbe (1819-73) rejected everything supersensuous and all "transcendental nonsense." But he maintained that the world cannot be derived from any one principle, such as Buchner's "force and matter," but only from a plurality of irreducible principles, including material atoms, organic forces, mental elements, etc., which between them constitute an harmonious and purposive natural system. Like the other materialists in this group, he was inspired by an enthusiasm for humanity and the amelioration of human conditions. (See MATERIALISM.)

Schopenhauer (1788-1860) is the philosopher of "voluntarism" and "pessimism." Just as Hegel, his senior contemporary, had identified ultimate reality with reason, so Schopenhauer, on the contrary, identified it with will, and irrational will to boot. He too, claimed to be developing the philosophy of Kant. For Kant, like Descartes and others before him, had maintained the primacy of the will, on which the whole moral philosophy (including the moral postulates) was based. Will, then, according to Schopenhauer, is the sole reality. Moreover, it is universal, or "will in general" (analogous to the "consciousness in general" of Kant and the German Idealists). There are really no individual things or wills. For individuality is bound up with differences of time and place, which had been shown by Kant to be not real constituents of things-in-themselves, but merely forms of their appearance. Individuality is thus mere illusion. Again, Schopenhauer, like Kant, agreed with the Christian view that the will is essentially evil. It is a will to live at any cost, and knowledge or reason is merely an instrument which it has invented to serve its own evil ends. But there is no satisfying the will to live. All the pains taken to satisfy any desire do not really avail. For the satisfaction of any one desire is only the beginning of another, and the quest is infinite. So life is a welter of painful strivings and unsatisfied cravings which vastly exceed its moments of satisfaction or happiness. The remedy is a kind of Buddhist self-renunciation. By realizing the illusoriness of the individual self and the vanity of its quest for self-satisfaction, man may see through the vanity of life with all its values and pursuits. (See SCHOPENHAUER; PESSIMISM.)

Fechner (1801-87) developed the philosophy known as Panpsychism, that is, the view that the universe is a system or society of souls, of which God is the highest and all-comprehensive soul. According to Fechner material bodies are souls as they appear to other souls, whereas each soul as experienced from within is psychical. In this way he tried to save the reality of matter as well as of mind in psychophysical entities of which they are the outer and the inner side respectively. But he regarded the two sides as parallel without any interaction; and it was largely due to his influence that many psychologists adopted psychophysical parallelism as the working hypothesis in psychology. Fechner tried to combine pantheism with something sufficiently like the monadology of Leibniz to safeguard the interests of finite souls. He identified God with the soul of the universe, and regarded it as embracing all other souls just as larger bodies contain smaller bodies, and nature contains them all. (See FECHNER; PSYCHOLOGY, HISTORY OF.)

Lotze (1817-81) elaborated a philosophy which may be

described as idealistic pantheism. In other words ultimate reality, according to him, is like Spinoza's substance, with thought (or consciousness) for its sole attribute. He agreed with Kant that all known things are merely sensible phenomena; but he rejected Kant's unknown "things in themselves." He agreed with Leibniz in regarding spiritual monads as the causes of material phenomena; but he rejected the view that the monads are substances. The monads, according to Lotze, are only modes or modifications of the one and infinite Substance, God. The interaction of the monads he reduced to the immanent causality of God, who is the sole real cause or agent. The mechanistic character of phenomena Lotze explained by saying that God carries out His immanent activities in accordance with uniform laws. These laws, however, are subordinate to divine ends, the system being teleological as well as mechanistic in part. Human souls, like other monads, are not substances, but modes or activities of the one Substance. Lotze repudiated the method of Hegelian idealism as unscientific. But he tried to save all such idealistic elements as he considered to be in harmony with science and human experience. (See LOTZE; LOGIC, HISTORY OF.) A philosophy essentially like that of Lotze was taught by James Ward (1843-1925) who had studied under him.

Hartmann (1842-1906) adopted and developed Schopenhauer's voluntarism and pessimism. For Schopenhauer reality is essentially will which produces knowledge or representation as an instrument for its satisfaction. For Hartmann, however, representation is on a level with, not subordinate to, will. Together they constitute the "unconscious," which is the "absolute" in his system. With the development of the unconscious its two components differentiate gradually, and the unconscious becomes conscious, even self-conscious, and realizes the tragedy of the will to live. The remedy is so to set the two components of the unconscious, will and representation, into mutual antagonism as to secure eventually their mutual annihilation and eternal peace from the restless and unsatisfying pursuits of life. (See HARTMANN.)

Nietzsche (1844-1900) was influenced chiefly by Kant, Schopenhauer and Darwin. He agreed with Schopenhauer's main theses but drew a different moral from them. Nietzsche, even more than Schopenhauer, so interpreted Kant's theory of knowledge as to deny the very possibility of knowledge, and to reduce all so-called knowledge to mere fiction or artistry. The human mind, in the very act of apprehending reality, transforms it. "Truth (says Nietzsche) is not something which is already there to be found or discovered; it is something which has to be created"—it is "man-made," as the Pragmatists said after him. This does not mean that he lumps all human beliefs together indiscriminately. Only in place of the usual distinction between "true" beliefs and "false" ones, Nietzsche would substitute the distinction between those which are "useful" and those which are not, but without in any way holding that the useful is true, even as a matter of probability.

The epistemological side of Nietzsche's philosophy was developed in the "fictionism" of *Vaihinger's Philosophy of "As If"* (1911, Eng. trans. 1926). Ontologically Nietzsche agrees with Schopenhauer in identifying all reality with will. "It is will that struggles for existence in animate and inanimate nature." For Nietzsche, however, this will is not merely a will to live, but a "will to power." "This universe is a monster of energy, without beginning or end." Nietzsche accepted "will to power" as ultimate reality because his experience convinced him of the reality of desires and impulses as of nothing else; and he considered these a sufficient guide to philosophical construction. Like Schopenhauer, he frequently paints the world in sombre colours. But the shortcomings of the world stimulate him instead of depressing him. And far from accepting Schopenhauer's ideal of a Buddhist saint, he regarded the world as a kind of Greek tragedy affording ample opportunity for heroes to show their mettle. Hence his gospel of energetic life, and his ideal of a "superman" who shall surpass the present type of man as much as man surpasses the ape (See NIETZSCHE.)

Wundt (1832-1920) begins by insisting that human experience

consists of ideas in which subjective and objective factors are inseparably combined. These factors may be distinguished by abstraction. And in physical science the objective factors, or objects, are so habitually abstracted that they come to be regarded as independent things. But this is an error, for "the whole world exists for us only in our ideas," and all that reason posits behind or beyond phenomena must be regarded as transcendent "ideals." Again, the basic reality in experience, "the most proper being of the individual subject," is will, though it is never entirely divorced from feeling and ideas. There are two grades of will, namely, impulsive will and voluntary will. Even impulsive will needs feeling directed to an end, and therefore an idea, but not conscious adoption of a motive, which pertains to voluntary will. He attributes impulsive will to all organisms, and consequently maintains that in organic evolution teleology precedes mechanism, final causes precede and originate mechanical or efficient causes. Wundt describes not only attention but also thinking as will. For it is activity, and all activity is will. (The conception of this "will to believe" was elaborated by William James.) Wundt, in fact, regards the soul as "activity," not substance—it is the entire mental activity associated with a system of bodily activities. The body itself is only an object distinguished by abstraction from the complete experience, of which soul is the subjective factor. There is consequently no psychophysical opposition or interaction, only a psychophysical parallelism. Human knowledge is limited to experience, or phenomena, or ideas. Reason does indeed transcend experience. But it can only posit "ideals," which are matters not of knowledge but, at most, matters of faith. One such "ideal" is God, conceived as the world-will. (See WUNDT; PSYCHOLOGY, HISTORY OF.)

Neo-Kantianism.—The attempt to correct at once the materialism of the time and the absolute idealism which had partly provoked it led to a revival of interest in the philosophy of Kant and a concentration on the problems of knowledge. The movement was initiated by O. Liebmann (1840-1912). In his book *Kant und die Epigonen* (1865) every chapter ends with the refrain, "we must therefore return to Kant." F. A. Lange (1828-75) advanced the movement by means of his *History of Materialism* (1866) in which he attempted to refute materialism by means of arguments based on Kant's theory of knowledge and its repudiation of all knowledge of the ultimate nature of reality, or things as they are in themselves. He insisted that the "matter," "atoms," "forces," etc., by means of which materialists try to account for all things, are not ultimate realities but only auxiliary conceptions of science. In 1871 H. Cohen (1842-1918) published his book on Kant's Theory of Experience, and soon became the leader of the whole movement. He was joined by P. Natorp (1854-1924), his colleague in the University of Marburg, where Lange too had been professor, and the movement consequently came to be known as "the Marburg School" of philosophy. The chief representative of Neo-Kantianism at present is E. Cassirer (1874-). It cannot be said that the Neo-Kantians are agreed on all points. Far from it. What is common to them is the recognition of the importance of understanding Kant and developing his transcendental method. Cohen in particular attempted to do without Kant's aesthetic, to dispense with the assumption of a given sense material, and to begin at once with the transcendental logic. There is no object then to be known; what becomes known only becomes an object in becoming known. Nothing is independent of thought. For thought and being are identical, and the judgment is the unit of both. (See NEO-KANTIANISM.)

POSITIVISM AND EVOLUTIONISM

Comte (1798-1857) was the founder of "Positivism," that is, the view that knowledge is limited to the objects of direct observation or experience. This view is very like the empiricism of Locke and his successors. Comte's positivism, however, was the outcome rather of the influence of Kant's philosophy, according to which human knowledge (as distinguished from faith) is limited to phenomena, and cannot penetrate to noumena or things-in-themselves. What is beyond experience. Comte insisted. is unknowable. It is consequently best to concentrate on tasks

that are within human competence. Such are the pursuits of the sciences and the work of social amelioration. Philosophers, instead of their search for an unknown and unknowable Absolute, should devote themselves to the task of co-ordinating and systematizing the methods and results of the positive sciences. Religion, instead of being the worship of an unknown God and a source of division, sectarian conflict and hatred, should be identified with the service of the cause of mankind—a religion of Humanity. And humanity should be so improved by collective endeavour that it shall become worthy of being viewed as "the great Being," the object of religious service. What Comte had in mind was a grandiose Catholicism without religion, as religion is commonly conceived. Positivism, Comte realized, is a position not readily taken up. First in the history of intellectual growth, comes the theological point of view, and everything is explained by reference to one or more gods who are created in the likeness of men. Next comes the metaphysical stage in which the anthropomorphic Gods are more or less dehumanized and replaced by abstract entities or principles. Then only comes the positivist stage. But even Comte was not a strict positivist. For he severely criticized the actual state of mankind, and pleaded for various reforms according to standards derived, not from observation, but from ideals. (See COMTE; POSITIVISM.)

Mill (1806-73) also may be called a positivist. But in his case the connection with British empiricists is more marked than in the case of Comte. His logic, his utilitarian ethics, and his political economy are all worked out on empirical or positivist lines. (See MILL; LOGIC, HISTORY OF.)

Spencer (1820-1903) admitted an ultimate reality as the ground of the phenomenal world, but regarded it as otherwise "unknown." Inasmuch as he confined knowledge to phenomena, he was a positivist. But his fame rests mainly on his comprehensive attempt at an evolutionary philosophy which brought or forced "all the choir of heaven and furniture of earth" into the evolutionary scheme. The conception of evolution was not new to philosophy. Hegel's philosophy was evolutionary in a sense; but not quite in Spencer's or Darwin's or generally in a scientific sense. According to Spencer the universe commenced as an homogeneous something, which may be called force, or matter and motion, but the inner nature of which is unknown to us. Then by increasing differentiation and specialization there evolved the heavenly bodies (more or less in accordance with the nebular hypothesis of Laplace); the inorganic evolved into the organic (more or less on the lines of Lamarckian and Darwinian biology); differentiation of structure and function in living bodies, and division of labour in industry, etc., followed in due course. And always the amount of energy remains the same in accordance with the principle of Conservation of Energy; it is only redistributed in various ways. The evolutionary process as conceived by Spencer and others was mechanistic in character. This conception subsequently met with increasing opposition. In contemporary philosophy Bergson's theory of "creative evolution" and Lloyd Morgan's theory of "emergence" or "emergent evolution" are intended as a corrective of mechanistic determinism in favour of spontaneity and originality in cosmic processes of many kinds. (See SPENCER; ETHICS, HISTORY OF; EMERGENCE; EVOLUTION AND MIND.)

RECENT AND CONTEMPORARY PHILOSOPHY

Neo-Hegelianism. — Until comparatively recently, British philosophy pursued its own course in almost entire independence of Continental philosophy. Its most characteristic feature was its initial empiricism, though it ended variously in agnosticism, scepticism or even in idealism. When the widespread influence of Kant's critical philosophy asserted itself, it was still used mainly to supplement the agnostic tendencies of native empiricism. In view of Kant's own indebtedness to Hume, this was not unnatural. Anyway, Kant's denial of the possibility of knowledge of things as they are in themselves, and its limitation to phenomena could readily be identified with Locke's and Hume's denial of our knowledge of "substances" and its restriction to "ideas."

The philosophical agnosticism of Hamilton (1788-1856), Mansel (1820-71), Spencer and Huxley (1825-95) may thus be regarded as betraying Continental influence only to a slight extent. The influence of German voluntarism was no greater, probably rather less. Martineau (1805-1900) was probably the only one in his generation to identify God, or the ultimate cause of the universe, with Will. The influence of German Absolute Idealism, however, was much more marked, especially in the logical form in which it was developed by Hegel. It cannot be asserted that Hegelianism had actual followers in England or in America. But Hegelianism harmonized well with the growing revolt against empiricism, and so some of the acutest thinkers in both countries were influenced by it sufficiently to be commonly described as Neo-Hegelians. The most important representatives of the group were Green (1836-82), Bradley (1846-1924), Bosanquet (1848-1923), Haldane (1856-1928) and McTaggart (1866-1925) in England, and Royce (1855-1916) in America—to say nothing of the many well-known representatives who are happily still living. Considering the logical or rational character of Hegel's idealism, it is natural to find that at least two of the Neo-Hegelians have made most important contributions to logic, which they treated in a highly epistemological manner (Bradley's *Principles of Logic*, and Bosanquet's *Logic*). Neo-Hegelianism is essentially a metaphysics of logical coherence, involving a doctrine of varying grades or degrees of reality. Reality, according to Bradley, is in the last resort a system of experience. The finite as such is not illusory, yet not absolutely real, only relatively so: it is entirely dependent upon, and rests within, the Absolute, or entire system of experience. In the broad sense in which the term Neo-Hegelian is here used it may also be applied to the two Italian philosophers, Croce (1866-) and Gentile (1875-), the Dutch philosopher Bolland (1854-1922), and the German Volkelt (1848-1930). (See NEO-HEGELIANISM.)

Pragmatism as a method of evaluating ideas by their practical consequences was formulated by C. S. Peirce (1839-1914) in 1878, and developed more fully by W. James (1842-1910), J. Dewey (1859-) and F. C. S. Schiller (1864-1937). The movement is based partly on psychological considerations, and partly on a dissatisfaction with the intellectualism and deterministic monism of absolute idealism. "Thinking," according to James, "is first and last and always for the sake of doing," and "the conception with which we handle a bit of sensible experience is really nothing but a teleological instrument." The agnostic or relativist side of Kant's teaching, as developed by Nietzsche and Vaihinger in some ways encouraged the substitution of the practically useful for the theoretically true as the standard of value for beliefs. And German voluntarism tended in the same direction. "The 'true,'" according to James, "is only the expedient in the way of thinking, just as the 'right' is only the expedient in the way of behaving." In the circumstances, it was natural that the effort at self-preservation characteristic of finite individuals should express itself in favour of a belief in the ultimate reality and worth of a plurality of finite beings, as against their merely relative being and worth in a monistic "block-universe." Hence the combination of pragmatism with pluralism. (See PRAGMATISM; PLURALISM; TRUTH.)

The New Realism. — In Germany it was idealism that provoked materialism, and materialism occasioned that revival of epistemological interest which produced Neo-Kantianism. With British and American philosophy the case is rather different. It was the materialistic tendencies of empiricism, agnosticism and evolutionism that provoked the idealism of the Neo-Hegelians, and the new realistic tendencies in epistemology have come as a revolt against idealism generally, and subjective idealism more particularly. The present movement was started mainly by G. E. Moore and B. Russell, and has been taken up eagerly by many others in Britain and in America. These thinkers differ in their views in some respects, but they agree in their endeavour to vindicate the independent reality of the objects of human knowledge, and especially of the objects apprehended in perception. (See KNOWLEDGE, THEORY OF.)

Bergson (1859-1941) was the founder of what is variously known as the philosophy of change, of creative evolution, or of duration. Like so many idealist philosophers, his main aim was to vindicate the spiritual principle in nature and freedom in human nature against the mechanistic tendencies of modern science. Somewhat like Fichte he conceived of ultimate reality as something less determinate than consciousness or matter, but from which both consciousness and matter are derived. This ultimate reality is an incessant flux, a creative evolution, or real duration. It is not an inaccessible absolute; it can be apprehended by man. "In the absolute we live and move and have our being: The knowledge we possess of it is incomplete, no doubt, but not external or relative. It is reality itself, in the profoundest meaning of the word, that we reach by the combined and progressive development of science and philosophy." Materiality and spirituality are resultants of processes in opposite directions. Spirituality is the process of concentrated activity in which the past interpenetrates the present; materiality corresponds to a relaxation of this activity.

The evolution of life has taken three divergent directions, the vegetative, the instinctive, and the intelligent or rational. These are not successive stages, but divergent lines of evolution. Instinct is a faculty of using organic instruments; intelligence is a faculty of making and using inorganic tools. Instinct is a kind of unconscious practical knowledge of things; intelligence is conscious thought about relations. Owing to its original function of making tools out of inert matter, intelligence when it develops its theoretical side tends to regard the whole of reality as though it were a dead mechanism. This can be corrected by means of intuition, which is instinct become self-conscious and capable of reflecting upon its objects. It is the function of philosophy to seize, expand and unite such fleeting intuitions which reveal the spiritual life. But intuition must not be divorced from intellection, nor science from philosophy. They must be brought into close relationship if we are to avoid chill mechanism, on the one hand, and illusory mysticism, on the other. For Bergson, not perception but memory was typical of the spiritual or conscious. Perception is simply incipient or nascent action, not consciousness. Memory is real duration, in which the past "gnaws into the future." (See BERGSON.)

B. Croce (1866-) sets out from the Cartesian, or rather Augustinian, contention that thought is what we are most sure of, and then proceeds, like the German idealists, to maintain that it is the only reality that need be assumed. By thought, however, he does not mean merely the thought of finite individuals. Like most idealists he posits a universal mind which is more than any finite individual thoughts can be but which is immanent in them. And whereas Hegel conceived of the dialectic of universal thought as essentially logical in character, though he could not avoid conveying the impression that he also regarded it as a process in time, Croce definitely conceives the cosmic thought process as a process in time, and identifies reality or philosophy (for the two are essentially the same in such an idealistic scheme) with history. Like Bergson and James, Croce rejects the conception of a static, unchanging Absolute, a "block universe" complete once for all. Ultimate reality, as he conceives it, is incessantly changing, ever active, always creative. This cosmic activity has no beginning and no end, but proceeds in cycles. The objects to which thought is always directed are themselves the creations of thought. In fact, the process of thinking, the object of thought, and the distinction between the act and the object of thought, are all of them parts of the same total experience, and it is only by a kind of abstraction that a world of objects is set up as an independent world over and against the world of thought.

In reality the whole universe is just Mind or Spirit, and all differences and distinctions are within it. Of the activities of mind there are two main types, namely, theoretical and practical activities. Theoretical activity is of two principal varieties, namely, intuition and conception. Intuition is the act of creating the materials of thought, and is exemplified most clearly in the creative imagination of the artist. There is no sense material

supplied to the mind from outside, according to Croce; the mind just has intuitions which constitute the material on which conceptual thought operates. Conception or conceptual thinking is the activity which creates and traces relations between intuitions. But the two, intuition and conception, are only distinguishable, not separable. Intuition without conception would be blind; conception without intuition would be empty. The practical activities are all of them volitional processes or functions, for there can really be no "physical" activities in a purely spiritual universe. And like the theoretical functions they also have two aspects or components, namely, a particular or individual aspect and a universal aspect, which are distinguishable but not separable. (See CROCE; IDEALISM; NEO-HEGELIANISM.)

Alexander (1859-1938) was the first British philosopher to attempt a system of philosophy; and that after the prophets had confidently asserted that there would be no more system building in philosophy. His *Space, Time and Deity* (2nd ed., 1928) develops a philosophy which incorporates the new conceptions of space-time, and of emergent evolution, and leads up to a kind of pantheism not altogether unlike that of Spinoza. Ultimate reality is Space-Time, of which space alone and time alone are mere abstractions. Space-Time is a kind of ocean whose whirlpools constitute particular objects. Things, in other words, are differentiated complexes of motion within the one comprehensive system of motion. Space-Time has certain pervasive or "categorical" properties (existence, universality, relation, order, substance, quantity, number, motion, etc.) which characterize everything. Besides these there are various empirical qualities which distinguish different classes of objects, and which emerge only under special conditions. They form a hierarchy. What happens is this. Space-Time spontaneously differentiates into finite collocations of point-instants. The simples of these consist of motions of different velocities and extents of motion. When these objects form certain patterns there emerges the quality of materiality; when certain other conditions are added, there emerges colour; and so on.

When certain physico-chemical complexes arise, life emerges; out of certain configurations of living complexes consciousness emerges. In this hierarchy of objects, those that have the higher qualities also have the lower qualities. But they experience them differently—they "enjoy" their highest quality immediately and inwardly, but only "contemplate" the lower qualities more or less externally. By reasonable extrapolation we may assume that there are higher qualities than consciousness. And the highest of such conceivable qualities is "deity." As consciousness is the highest quality of man so "deity" is the highest quality of God, whose "body" is the whole universe. God is the whole universe as evolving the quality "deity." As time is never complete, higher qualities continue to emerge, and so God is never complete. The world with its *nisus* towards deity stirs in us a longing for God with Whom we are in communion. And practical religion consists in doing our duty so as to advance the progress of the world towards deity. The triumph of good over evil in human affairs is one of the conditions of the emergence of deity, and deity is on the side of goodness. The right attitude towards life is that of intellectual acquiescence coupled with practical efforts towards its amelioration, even though the springs of pain may never be sealed. As to the relation of the finite many to the infinite One, "the One is the system of the many in which they are conserved, not the vortex in which they are engulfed." (See QUALITIES: *Primary, Secondary and Tertiary.*)

PHILOSOPHY AND PHILOSOPHICAL STUDIES.

Philosophy is a general term whose meaning and scope have varied very considerably according to the usage of different authors in different ages. It can best be explained by a survey of the steps by which philosophy differentiated itself, in the history of Greek thought, from the idea of knowledge and culture in general. These steps may be traced in the gradual specification of the term. The earliest uses of the word (the verb *φιλοσοφείν* occurs in Herodotus and Thucydides) imply the idea of the *pursuit* of knowledge; but the distinction between the *σοφός*, or, wise man, and the *φιλόσοφος*, or lover of wisdom, appears first in the Platonic writings, and lends itself naturally to the so-called Socratic irony. The same thought is to be found in Xenophon, and is doubtless to be attributed to the historical Socrates. But the word soon lost this special implication. What is of real interest to us is to trace the progress from the idea of the philosopher as occupied with any and every department of knowledge to that which assigns him a special kind of knowledge as his province.

A specific sense of the word first meets us in Plato, who defines the philosopher as one who apprehends the essence or reality of things in opposition to the man who dwells in appearances and the shows of sense. The philosophers, he says, "are those who are able to grasp the eternal and immutable"; they are "those who set their affections on that which in each case really exists" (Rep. 480). In Plato, however, this distinction is applied chiefly in an ethical and religious direction; and, while it defines philosophy, so far correctly, as the endeavour to express what things are in their ultimate constitution, it is not yet accompanied by a sufficient differentiation of the subsidiary inquiries by which this ultimate question may be approached. Logic, ethics and physics, psychology, theory of knowledge and ontology are all fused together by Plato in a semi-religious synthesis. It is not till we come to Aristotle that we find a demarcation of the different philosophic disciplines corresponding, in the main, to that still current. The earliest philosophers, or "physiologers," had occupied themselves chiefly with what we may call cosmology; the one question which covers everything for them is that of the underlying substance of the world around them, and they essay to answer this question, so to speak, by simple inspection. In Socrates and Plato, on the other hand, the start is made from a consideration of man's moral and intellectual activity; but knowledge and action are confused with one another, as in the Socratic doctrine that virtue is knowledge. To this correspond the Platonic confusion of logic and ethics and the attempt to substitute a theory of concepts for a metaphysic of reality. Aristotle's methodic intellect led him to separate the different aspects of reality here confounded. He became the founder of logic, psychology, ethics and aesthetics as separate sciences; while he prefixed to all such (comparatively) special inquiries the investigation of the ultimate nature of existence as such, or of those first principles which are common to, and presupposed in, every narrower field of knowledge. For this investigation Aristotle's most usual name is "first philosophy" or, as a modern might say, "first principles"; but there has since been appropriated to it, apparently by accident, the title "metaphysics." "Philosophy," as a term of general application, was not, indeed restricted by Aristotle or his successors to the disciplines just enumerated. Aristotle himself includes under the title, besides mathematics, all his physical inquiries. And "philosophy" was used in this wide sense (but often divided into "natural" and "moral" or "mental" philosophy) until comparatively recent times, although some of the special sciences had attained to independent cultivation already in the Alexandrian period. However, as the mass of knowledge accumulated, it naturally came about that the name "philosophy" ceased to be applied to inquiries concerned with the particulars as such. The details of physics, for example, were abandoned to the scientific specialist, and philosophy restricted itself in this department to the question of the relation of the physical universe

to the ultimate ground or author of things. This inquiry which was long called "rational cosmology," may be said to form part of the general subject of metaphysics, or at all events a pendant to it. By the gradual sifting out of the special sciences philosophy thus came to embrace primarily the inquiries grouped as "metaphysics" or "first philosophy." These would embrace, according to the Wolffian scheme long current in philosophical textbooks, ontology proper, or the science of being as such, with its three-branch sciences of (rational) psychology, cosmology and (rational or natural) theology, dealing with the three chief forms of being—the soul, the world and God. Subsidiary to metaphysics, as the central inquiry, stand the sciences of logic and ethics, to which may be added aesthetics, constituting three normative sciences—sciences, that is, which do not, primarily, describe facts, but rather prescribe ends or set forth ideals.

In sum, then, we may say that "philosophy" has come to be understood at least in modern times as a general term covering the various disciplines just enumerated. We shall first of all attempt to differentiate philosophy from the special sciences, and afterwards proceed to take up one by one what have been called the philosophical sciences, with the view of showing how far the usual subject-matter of each is really philosophical in its bearing. The order in which it will be most convenient to consider these disciplines will be psychology, epistemology or theory of knowledge, and ontology, then logic, aesthetics and ethics. Finally, the connection of the last-mentioned with politics (or, to speak more modernly, with jurisprudence and sociology), with the philosophy of history and the philosophy of religion, will call for a few words on the relation of these sciences to general philosophy.

Philosophy and Natural Science.—In distinguishing philosophy from the sciences, it may not be amiss at the outset to guard against the possible misunderstanding that philosophy is concerned with a subject-matter different from, and in some obscure way transcending, the subject-matter of the sciences. Now that psychology, or the observational and experimental study of mind, may be said to have been definitively included among the positive sciences, there is not even the apparent ground which once existed for such an idea. Philosophy has no other subject-matter than the nature of the real world, as that world lies around us in everyday life, and lies open to observers on every side. But if this is so, it may be asked what function can remain for philosophy when every portion of the field is already lotted out and enclosed by specialists? Philosophy claims to be the science of the whole; but, if we get the knowledge of the part from the different sciences, what is there left for philosophy to tell us? To this it is sufficient to answer generally that the synthesis of the parts is something more than that detailed knowledge of the parts in separation which is gained by the man of science. It is with the ultimate synthesis that philosophy concerns itself; it has to show that the subject-matter which we are all dealing with in detail really is a whole, consisting of articulated members. Evidently, therefore, the relation existing between philosophy and the sciences will be, to some extent, one of reciprocal influence. The sciences may be said to furnish philosophy with its matter, but philosophical criticism reacts upon the matter thus furnished, and transforms it. Such transformation is inevitable, for the parts only exist and can only be fully, *i.e.*, truly, known in their relation to the whole. A pure specialist, if such a being were possible, would be merely an instrument whose results had to be co-ordinated and used by others. Now, though a pure specialist may be an abstraction of the mind, the tendency of specialists in any department naturally is to lose sight of the whole in attention to the particular categories or modes of nature's working which happen to be exemplified, and fruitfully applied, in their own sphere of investigation; and in proportion as this is the case it becomes necessary for their theories to be co-ordinated with the results of other inquirers, and set, as it were, in the light of the whole. This task of co-ordination, in the broadest sense, is undertaken by philosophy; for the philosopher is essentially what Plato, in a happy moment, styled him. *συνοπτικός*, the man who takes a "synoptic" or comprehensive view of the universe as a whole. The aim of philosophy (whether fully attainable or not) is to exhibit the

universe as a rational system in the harmony of all its parts; and accordingly the philosopher refuses to consider the parts out of their relation to the whole whose parts they are. Philosophy supplements in this way the abstractions which are inevitably made by the scientific specialist.

For it is evident from what has been said that the way in which we commonly speak of "facts" is calculated to convey a false impression. The world is not a collection of individual facts existing side by side and capable of being known separately. A fact is nothing except in its relations to other facts; and as these relations are multiplied in the progress of knowledge the nature of the so-called fact is indefinitely modified. Moreover, every statement of fact involves certain general notions and theories, so that the "facts" of the separate sciences cannot be stated except in terms of the conceptions or hypotheses which are assumed by the particular science. Thus mathematics assumes space as an existent infinite, without investigating in what sense the existence or the infinity of this *Urding*, as Kant called it, can be asserted. In the same way, physics may be said to assume the notion of material atoms and forces. These and similar assumptions are ultimate presuppositions or working hypotheses for the sciences themselves. But it is the office of philosophy, as a theory of knowledge, to submit such conceptions to a critical analysis, with a view to discover how far they can be *thought out*, or how far, when this is done, they refute themselves, and call for a different form of statement, if they are to be taken as a statement of the ultimate nature of the real. The first statement may frequently turn out to have been merely provisionally or relatively true; it is then superseded by, or rather inevitably merges itself in, a less abstract account. In this the same "facts" appear differently, because no longer separated from other aspects that belong to the full reality of the known world. There is no such thing, we have said, as an individual fact; and the nature of any fact is not fully known unless we know it in all its relations to the system of the universe, or, in Spinoza's phrase, *sub specie aeternitatis*. In strictness, there is but one *res completa* or concrete fact, and it is the business of philosophy, as science of the whole, to expound the chief relations that constitute its complex nature.

The last abstraction which it becomes the duty of philosophy to remove is the abstraction from the knowing subject which is made by all the sciences, including, as we shall see, the science of psychology. The sciences, one and all, deal with a world of objects, but the ultimate fact as we know it is the existence of an object for a subject. Subject-object, knowledge, or, more widely, self-consciousness with its implicates—this unity in duality is the ultimate aspect which reality presents. It has generally been considered, therefore, as constituting in a special sense the problem of philosophy. Philosophy may be said to be the explication of what is involved in this relation, or, in Kantian phraseology, a theory of its possibility. Any would-be theory of the universe which makes its central fact impossible stands self-condemned. On the other hand, a sufficient analysis here may be expected to yield us a statement of the reality of things *in its last terms*, and thus to shed a light backwards upon the true nature of our subordinate conceptions.

Psychology, Epistemology and Ontology.—This leads to the consideration of the main divisions of philosophy—psychology (*q.v.*), epistemology (theory of knowledge) and ontology. A special relation has always existed between psychology and systematic philosophy, but the closeness of the connection has been characteristic of modern and more particularly of English thought. The connection is not difficult to explain, seeing that in psychology, or the science of mind, we study the fact of intelligence (and moral action), and have, so far, in our hands the fact to which all other facts are relative. From this point of view we may even see a truth in Jacobi's dictum as quoted by Sir W. Hamilton: "Nature conceals God; man reveals God." Nature by itself, that is to say, is insufficient. The ultimate explanation of things cannot be given by any theory which excludes from its survey the intelligence in which nature, as it were, gathers herself up. But knowledge, or the mind as knowing, willing, etc., may be looked

at in two different ways. It may be regarded simply as a fact; in which case the evolution of mind may be traced and reduced to laws in the same way as the phenomena treated by the other sciences. This study gives us the science of empirical psychology, or, as it is now termed, psychology *sans phrase*. In order to give an adequate account of its subject-matter, psychology may require higher or more complex categories than are employed in the other sciences, just as biology, for example, cannot work with mechanical categories alone, but introduces the conception of development or growth. But the affinities of such a study are manifestly with the sciences as such rather than with philosophy; and the definitive establishment of psychology as an independent science has already been alluded to. Since it has been taken up by specialists, psychology is being established on a broader basis of induction, and with the advantage, in some departments, of the employment of experimental methods of measurement. But it is not of mind in this aspect that such assertions can be made as those quoted above. Mind, as studied by the psychologist—mind as a mere fact or phenomenon—grounds no inference to anything beyond itself. The distinction between mind viewed as a succession of "states of consciousness" and the further aspect of mind which philosophy considers was very clearly put by Croom Robertson, who also made a happy suggestion of two terms to designate the double point of view:

"We may view knowledge as mere subjective function, but it has its full meaning only as it is taken to represent what we may call objective fact, or is such as is named (in different circumstances) real, valid, true. As mere subjective function, which it is to the psychologist, it is best spoken of by an unambiguous name, and for this there seems none better than Intellection. We may then say that psychology is occupied with the natural function of *Intellection*, seeking to discover its laws and distinguishing its various modes (perception, representative imagination, conception, etc.) according to the various circumstances in which the laws are found at work. Philosophy, on the other hand, is theory of *Knowledge* (as that which is known)."—"Psychology and Philosophy," *Mind* (1883), pp. 15, 16.

The confusion of these two points of view has led, and still leads, to serious philosophical misconception. It is hardly an exaggeration to say that, in the English school since Hume, psychology superseded properly philosophical inquiry. And we find even a thinker with a wider horizon like Sir W. Hamilton encouraging the confusion by speaking of "psychology or metaphysics," while his lectures on metaphysics are mainly taken up with what belongs in the strictest sense to psychology proper, with an occasional excursus (as in the theory of perception) into epistemology. The distinction between psychology and theory of knowledge was first clearly made by Kant, who repeatedly insisted that the *Critique of Pure Reason* was not to be taken as a psychological inquiry. He defined his problem as the *quid juris* or the question of the validity of knowledge, not its *quid facti* or the laws of the empirical genesis and evolution of intellection (to use Croom Robertson's phraseology). Since Kant, philosophy has chiefly taken the form of theory of knowledge or of a criticism of experience. Not, indeed, a preliminary criticism of our faculties or conceptions such as Kant himself proposed to institute, in order to determine the limits of their application; such a criticism *ab extra* of the nature of our experience is essentially a thing impossible. The only criticism which can be applied in such a case is the immanent criticism which the conceptions or categories exercise upon one another. The organized criticism of these conceptions is really nothing more than the full explication of what they mean and of what experience in its full nature or notion is. This constitutes the theory of knowledge in the only tenable sense of the term, and it lays down, in Kantian language, the *conditions* of the possibility of experience. These conditions are the conditions of knowledge as such, or, as it may be put, of objective consciousness—of a self-consciousness of a world of objects and through them conscious of itself. The inquiry is, therefore, transcendental in its nature, and does not entangle us in any decision as to the conditions of the genesis of such consciousness in the individual. When we inquire into subjective conditions we are

thinking of facts causing other facts. But the transcendental conditions are not causes or even factors of knowledge; they are the statement of its idea. Hence the dispute between evolutionist and transcendentalist rests, in general, on an *ignoratio elenchi*; for the history of the genesis of an idea does not contain an answer to—though it may throw light on—the philosophical question of its truth or validity. Speaking of this transcendental consciousness, Kant goes so far as to say that it is not of the slightest consequence "whether the idea of it be clear or obscure (in empirical consciousness), no, not even whether it really exists or not. But the possibility of the logical form of all knowledge rests on its relation to this apperception as a faculty or potentiality" (Werke, ed. Hartenstein, iii. 578 note).

Kant's problem is not, in its wording, very different from that which Locke set before him when he resolved to "inquire into the original, certainty and extent of human knowledge together with the grounds and degrees of belief, opinion and assent." Locke's Essay is undoubtedly, in its intention, a contribution to the theory of knowledge. But, because time had not yet made the matter clear, Locke suffered himself to digress in his second book into the psychological question of the origin of our ideas; and his theory of knowledge is ruined by the failure to distinguish between the epistemological sense of "idea" as significant content and the psychological sense in which it is applied to a fact or process in the individual mind. The same confusion runs through Berkeley's arguments and vitiates his conclusions as well as those of Hume. But appearing with these thinkers as the problem of perception, epistemology widens its scope and becomes, in Kant's hands, the question of the possibility of experience in general. With Hegel it passes into a completely articulated "logic," which apparently claims to be at the same time an ontology or an ultimate expression of the nature of the real.

This introduces us to the second part of the question we are seeking to determine, namely the relation of epistemology to ontology. It is evident that philosophy as theory of knowledge must have for its complement philosophy as ontology or theory of being. The question of the truth of our knowledge, and the question of the ultimate nature of what we know, are in reality two sides of the same inquiry; and therefore our epistemological results have to be ontologically expressed. But it is not every thinker that can see his way with Hegel to assert in set terms the identity of thought and being. Hence the theory of knowledge becomes with some a theory of human ignorance. This is the case with Herbert Spencer's doctrine of the Unknowable, which he advances as the result of epistemological considerations in the philosophical prolegomena to his system. Very similar positions were maintained by Kant and Comte; and, under the name of "agnosticism" (*q.v.*), the theory has popularized itself in the outer courts of philosophy, and on the shifting borderland of philosophy and literature. The truth is that the habit of thinking exclusively from the standpoint of the theory of knowledge tends to beget an undue subjectivity of temper. And the fact that it has become usual for men to think from this standpoint is very plainly seen in the almost universal description of philosophy as an analysis of "experience," instead of its more old-fashioned designation as an inquiry into "the nature of things." As it is matter of universal agreement that the problem of being must be attacked indirectly through the problem of knowledge, this substitution may be regarded as an advance, more especially as it implies that the fact of experience, or of self-conscious existence, is the chief fact to be dealt with. But if so, then self-consciousness must be treated as itself real, and as organically related to the rest of existence. If self-consciousness be treated in this objective fashion, then we pass naturally from epistemology to ontology. (For, although the term "ontology" has been as good as disused, it still remains true that the aim of philosophy must be to furnish us with an ontology or a coherent and adequate theory of the nature of reality.) But if, on the other hand, knowledge and reality be ab *initio* opposed to one another—if consciousness be set on one side as over against reality, and merely holding up a mirror to it—then it follows with equal naturalness that the truly real must be something which lurks unrevealed behind the subject's representation of it. Hence

came the different varieties of a so-called phenomenalism. The upholders of such a theory would, in general, deride the term "ontology"; but it is evident, none the less, that their position itself implies a certain theory of the universe and of our own place in it, and the establishment of this theory constitutes their ontology.

Without prejudice, then, to the claim of epistemology to constitute the central philosophic discipline, we may simply note its liability to be pressed too far. The exclusive preoccupation of men's minds with the question of knowledge during the neo-Kantian revival in the 'seventies of the last century drew from Lotze the caustic criticism that "the continual sharpening of the knife becomes tiresome, if after all, we have nothing to cut with it." Stillingfleet's complaint against Locke was that he was "one of the gentlemen of this new way of reasoning that have almost discarded substance out of the reasonable part of the world." The same may be said with greater truth of the devotees of the theory of knowledge; they seem to have no need of so old-fashioned a commodity as reality. Yet, after all, Fichte's dictum holds good that knowledge as knowledge—*i.e.*, so long as it is looked at as knowledge—is, *ipso facto*, not reality. The result of the foregoing, however, is to show that, as soon as epistemology draws its conclusion, it becomes ontology; the theory of knowledge passes into a theory of being. The ontological conclusion, moreover, is not to be regarded as something added by an external process; it is an immediate implication. The ontology is the epistemology from another point of view—regarded as completing itself, and explaining in the course of its exposition that relative or practical separation of the individual knower from the knowable world, which it is a sheer assumption to take as absolute. This, not the so-called assumption of the implicit unity of being and thought, is the really unwarrantable postulate; for it is an assumption which we are obliged to retract bit by bit, while the other offers the whole doctrine of knowledge as its voucher.

Logic, Aesthetics and Ethics.—If the theory of knowledge thus passes insensibly into ontology it becomes somewhat difficult to assign a distinct sphere to logic (*q.v.*). Ueberweg's definition of it as "the science of the regulative laws of thought" (or "the normative science of thought") comes near enough to the traditional sense to enable us to compare profitably the usual: subject-matter of the science with the definition and end of philosophy. The introduction of the term "regulative" or "normative" is intended to differentiate the science from psychology as the science of mental processes or events. In this reference logic does not tell us how our intellections connect themselves as mental phenomena, but how we ought to connect our thoughts if they are to realize truth (either as consistency with what we thought before or as agreement with observed facts). Logic, therefore, agrees with epistemology (and differs from psychology) in treating thought not as mental fact but as knowledge, as idea, as having meaning in relation to an objective world. To this extent it must lead on to the theory of knowledge. But, if we desire to keep by older landmarks and maintain a distinction between the two disciplines, a ground for doing so may be found in the fact that all the main definitions of logic point to the investigation of the laws of thought in a subjective reference—with a view, that is, by an analysis of the operation, to ensure its more correct performance.

Aesthetics (*q.v.*) may be treated as a department of psychology or physiology, and in England this is the mode of treatment that has been most general. To what peculiar excitation of our bodily or mental organism, it is asked, are the emotions due which make us declare an object beautiful or sublime? And, the question being put in this form, the attempt has been made in some cases to explain any peculiarity in the emotions by analysing them into simpler elements, such as primitive organic pleasures and prolonged associations of usefulness or fitness. But, just as psychology in general cannot do duty for a theory of knowledge, so it holds true of this particular application of psychology that a mere reference of these emotions to the mechanism and interactive play of our faculties cannot be regarded as an account of the nature of the beautiful. Perhaps by talking of "emotions" we tend to give

an unduly subjective colour to the investigation; it would be better to speak of the *perception* of the beautiful. Pleasure in itself is unqualified, and affords no differentia. In the case of a beautiful object the resultant pleasure borrows its specific quality from the presence of determinations essentially objective in their nature, though not reducible to the categories of science. Unless, indeed, we conceive our faculties to be constructed on some arbitrary plan which puts them out of relation to the facts with which they have to deal, we have a *prima facie* right to treat beauty as an objective determination of things. The question of aesthetics would then be formulated—What is it in things that makes them beautiful, and what is the relation of this aspect of the universe to its ultimate nature, as that is expounded in metaphysics? The answer constitutes the substance of aesthetics, considered as a branch of philosophy. But it is not given simply in abstract terms: the philosophical treatment of aesthetics includes also an exposition of the concrete phases of art, as these have appeared in the history of the world, relating themselves to different phases of human culture.

Of ethics (*q.v.*) it may also be said that many of the topics commonly embraced under that title are not strictly philosophical in their nature. They are subjects for a scientific psychology employing the evolutionary method with the conceptions of heredity and development, and calling to its aid, as such a psychology will do, the investigations of all the sociological sciences. To such a psychology must be relegated all questions as to the origin and development of moral ideas. Similarly, the question debated at such length by English moralists as to the nature of the moral faculty (moral sense, conscience, etc.) and the controversy concerning the freedom of the will belong mainly to psychology. If we exclude such questions in the interest of systematic correctness, and seek to determine for ethics a definite subject-matter, the science may be said to fall into two departments. The first of these deals with the notion of duty, and endeavours to define the good or the ultimate end of action; the second lays out the scheme of concrete duties which are deducible from, or which, at least, are covered by, this abstractly stated principle. The second of these departments is really the proper subject-matter of ethics considered as a separate science; but it is often conspicuous by its absence from ethical treatises. However moralists may differ on first principles, there seems to be remarkably little practical divergence when they come to lay down the particular laws of morality. It may be added that, where a systematic account of duties is actually given, the connection of the particular duties with the universal formula is in general more formal than real. It is only under the head of casuistry (*q.v.*) that ethics has been much cultivated as a separate science. The first department of ethics, on the other hand, is the branch of the subject in virtue of which ethics forms part of philosophy. As described above, it ought rather to be called, in Kant's phrase, the metaphysic of ethics. A theory of obligation is ultimately found to be inseparable from a metaphysic of personality. The connection of ethics with metaphysics will be patent as a matter of fact, if it be remembered how Plato's philosophy is summed up in the idea of the good, and how Aristotle also employs the essentially ethical notion of end as the ultimate category by which the universe may be explained or reduced to unity. But the necessity of the connection is also apparent, unless we are to suppose that, as regards the course of universal nature, man is altogether an *imperium in imperio*, or rather (to adopt the forcible phrase of Marcus Aurelius) an abscess or excrescence on the nature of things. If, on the contrary, we must hold that man is essentially related to what the same writer calls "a common nature," then it is a legitimate corollary that in man as intelligence we ought to find the key of the whole fabric.

Philosophy of the State, History and Religion. — In Plato and Aristotle ethics and politics are indissolubly connected. In other words, seeing that the highest human good is realizable only in a community, the theory of the state as the organ of morality, and itself in its structure and institutions the expression of ethical ideas or qualities, becomes an integral part of philosophy. The difficulty already hinted at, which individualistic systems of ethics

experience in connecting particular duties with the abstract principle of duty is a proof of the failure of their method. For the content of morality we are necessarily referred, in great part, to the experience crystallized in laws and institutions and to the unwritten law of custom, honour and good breeding, which has become organic in the society of which we are members. Plato's *Republic* and Hegel's *Philosophie des Rechts* are the most typical examples of a fully developed philosophy of the state, but in the earlier modern period the prolonged discussion of natural rights and the social contract must be regarded as a contribution to such a theory. Moreover, if philosophy is to complete its constructive work, it must bring the course of human history within its survey, and exhibit the sequence of events as an evolution in which the purposive action of reason is traceable. This is the task of the philosophy of history, a peculiarly modern study, due to the growth of a humanistic and historical point of view. Lessing's conception of history as an "education of the human race" is a typical example of this interpretation of the facts, and was indeed the precursor which stimulated many more elaborate German theories. The philosophy of history differs, it will be observed, from the purely scientific or descriptive studies covered by the general title of sociology. Sociology conceives itself as a natural science elucidating a factual sequence. The philosophy of history is essentially teleological; that is to say, it seeks to interpret the process as the realization of an immanent end. It may be said, therefore, to involve a complete metaphysical theory. Social institutions and customs and the different forms of state-organization are judged according to the degree in which they promote the realization of the human ideal. History is thus represented by Hegel, for example, as the realization of the idea of freedom, or rather as the reconciliation of individual freedom and the play of cultured interests with the stable objectivity of law and an abiding consciousness of the greater whole in which we move. So far as the course of universal history can be truly represented as an approximation to this reconciliation by a widening and deepening of both the elements, we may claim to possess a philosophy of history. But although the possibility of such a philosophy seems implied in the postulated rationality of the universe many would hold that it remains as yet an unachieved ideal.

There only remains to be briefly noticed the relation of philosophy to theology and the nature of what is called Philosophy of Religion. By theology is commonly understood the systematic presentation of the teaching of some positive or historical religion as to the existence and attributes of a Supreme Being, including his relation to the world and especially to man. But these topics have also been treated by philosophers and religious thinkers, without dependence on any historical data or special divine revelation, under the title of Natural Theology. Natural Theology is specially associated with the Stoic theories of providence in ancient times and with elaborations of the argument from design in the 18th century. But there is no warrant for restricting the term to any special mode of approaching the problems indicated; and as these form the central subject of metaphysical inquiry, no valid distinction can be drawn between natural theology and general metaphysics. The philosophy of religion, on the other hand, investigates the nature of the religious consciousness and the value of its pronouncements on human life and man's relation to the ground of things. Unity, reconciliation, peace, joy, "the victory that overcometh the world"—such, in slightly varying phrases, is the content of religious faith. Does this consciousness represent an authentic insight into ultimate fact, or is it a pitiful illusion of the nerves, born of man's hopes and fears and of his fundamental ignorance? The philosophy of religion assumes the first alternative. The function of philosophy in general is the reflective analysis of experience, and the religious experience of mankind is *prima facie* entitled to the same consideration as any other form of conscious activity. The certainties of religious faith are matters of feeling or immediate assurance, and are expressed in the pictorial language of imagination. It becomes the function of philosophy, dealing with these utterances, to relate them to the results of other spheres of experience, and to determine their real meaning in the more exact terms of thought.

The philosophy of religion also traces in the different historical forms of religious belief and practice the gradual evolution of what it takes to be the truth of the matter. Such an account may be distinguished from what is usually called the science of religion by the teleological or metaphysical presuppositions it involves. The science of religion gives a purely historical and comparative account of the various manifestations of the religious instinct without pronouncing on their relative truth or value and without, therefore, professing to apply the idea of evolution in the philosophical sense. That idea is fundamental in the philosophy of religion, which therefore can be written only from the standpoint of a constructive metaphysical theory.

It is, indeed, only from the standpoint of such a theory that the definitions and divisions of the different philosophical disciplines adopted in this article can be said to hold good. But those who, like the positivist, agnostics and sceptics, deny the possibility of ontology as a theory of the ultimate nature of things, are still obliged to retain philosophy as a theory of knowledge, in order to justify the asserted limitation or impotence of human reason.

PHILOSTRATUS, "THE ATHENIAN" (c. 170–245), the author of the *Life of Apollonius of Tyana*, which he dedicated to Julia Domna, wife of Alexander Severus and mother of Caracalla (see **APOLLONIUS OF TYANA**). He wrote also *Βίοι Σοφιστῶν* (*Lives of the Sophists*), *Gymnasticus* and *Epistolae* (mainly of an erotic character). Very little is known of his career. It is probable that he was born in Lemnos, studied and taught at Athens, and then settled in Rome. He is said by Suidas to have been living in the reign of Philip (224–249). The common authorship of *Apollonius* and of the *Lives of the Sophists* is confirmed by internal evidence.

The *Lives* are not in the true sense biographical, but rather picturesque impressions of leading representatives. The *Gymnasticus* contains interesting matter concerning the Olympic games and contests. The *Letters* breathe the spirit of the New Comedy and the Alexandrine poets; portions of Letter 33 are almost literally translated in Ben Jonson's *Song to Celia*, "Drink to me only with thine eyes." The *Ἡρωϊκός*, formerly attributed to Philostratus the Athenian, but probably by another Philostratus ("of Lemnos"), is a popular disquisition on the heroes of the Trojan War. His other work is the *Εἰκόνες* (*Imagines*), ostensibly a critical description of 64 pictures in a Neapolitan gallery.

See K. Miinscher in *Philologus* (1907) suppl. X., pp. 469–557. Of works bearing the name Philostratus there is a collected edition by C. F. Kayser (Zurich, 1844; Leipzig, 1870–71), and another by Westermann (Paris, 1849), with Latin translation; these supersede those by F. Morel (Paris, 1608) and Olearius (Leipzig, 1709). There are separate editions of the *Eikones* by Schenkl and Reisch (Leipzig, 1902); of the *Gymnasticus* by Mynas (1858), Daremberg (1858), Volckmar (Zurich, 1862), and especially Julius Jithner (1909), with introd., comments and Ger. trans.; of 73 epistles by Boissonade (1842). The *Life of Apollonius* was first published by Aldus (1502); a French translation by Blaise de Vigenère appeared in 1596; an Eng. trans. of bks. i. and ii. was published (1680) by C. Blount, with notes by Lord Herbert of Cherbury (prohibited in England in 1693, it was reprinted on the Continent); a full translation appeared in 1903. Critical works on the *Eikones* are numerous: K. Friedrichs, *Die Philostratischen Bilder* (1860); Goethe, "Philostrats Gemälde" in *Complete Works* (ed. Stuttgart, 1879); Brunn, *Die Philostratischen Bilder* (1860); A. Bougot, *Une Galerie antique* (1881); E. Bertrand, *Un Critique d'art dans l'antiquité: Philostrate et son école* (1882); Bergk, "Die Philostrate" in *Fünf Abhandlungen zur Geschichte der griechischen Philosophie und Astronomie* (1883); Schmid, *Atticismus* iv. 7, on the attribution of the works, and Überweg, *Grundriss der Gesch. der Philosophie*, Bd. I. (1926).

PHILOXENUS, of Cythera (435–380 B.C.), Greek dithyrambic poet. On the conquest of the island by the Athenians he was taken as a prisoner of war to Athens, where he was purchased by the dithyrambic poet Melanippides, who educated him and set him free. Philoxenus afterwards resided in Sicily, at the

court of Dionysius, tyrant of Syracuse, whose bad verses he declined to praise, and was in consequence sent to work in the quarries. After leaving Sicily he travelled in Greece, Italy and Asia, reciting his poems, and died at Ephesus. According to Suidas, Philoxenus composed twenty-four dithyrambs and a lyric poem on the genealogy of the Aeacidae. In his hands the dithyramb seems to have been a sort of comic opera, and the music, composed by himself, of a debased character. His masterpiece was the *Cyclops*, a pastoral burlesque on the love of the Cyclops for the fair Galatea, written to avenge himself upon Dionysius, who was wholly or partially blind of one eye. It was parodied by Aristophanes in the *Plutus* (290). The popularity of Philoxenus is attested by a complimentary resolution passed by the Athenian senate in 393.

Fragments, with life, by G. Bippart (1843); T. Bergk, *Poetae Lyrici graeci*.

PHILOXENUS (Syriac, Aksēnāyā) (fl. c. 500) of Mabbōg, one of the best of Syriac prose writers, and a vehement champion of Monophysite doctrine. He was by birth a Persian, born at Taḥal, in the district of Bēth Garmai east of the Tigris. He was educated at Edessa. Philoxenus soon attracted notice by his strenuous advocacy of Monophysite doctrine, and on the expulsion of Calandio (the orthodox patriarch of Antioch) in 485 was ordained bishop of Mabbōg (Hierapolis) by his Monophysite successor Peter the Fuller (Barhebraeus, *Chron. eccl. i.* 183). It was probably during the earlier years of his episcopate that Philoxenus composed his thirteen homilies on the Christian life. Later he revised the Syriac version of the Bible, and with the help of his chorepiscopus Polycarp produced in 508 the so-called Philoxenian version, used by the Monophysites during the 6th century. He bitterly opposed Flavian II., who had accepted the decrees of the Council of Chalcedon and was patriarch of Antioch from 498 to 512. In 512 the Monophysites finally ousted and replaced him by their partisan Severus. But Justin I., who succeeded Anastasius in 518, was less favourable to Severus and Philoxenus, and in 519 they were sentenced to banishment. Philoxenus was sent to Philippopolis in Thrace, and afterwards to Gangra in Paphlagonia, where he met his death by foul play in 523.

Of the chief monument of his scholarship—the Philoxenian version of the Bible—only the Gospels and certain portions of Isaiah are known to survive (see Wright, *Syr. Lit.* 14). His thirteen homilies on the Christian life and character have been edited and translated by Budge (London, 1894). Many of his letters survive.

PHIPS or **PHIPPS, SIR WILLIAM** (1651–1695), colonial governor of Massachusetts, was born on Feb. 2, 1651, at Woolwich, Me., near the mouth of the Kennebec river. He was a shepherd until he was 18 and then a ship carpenter's apprentice for four years; worked at his trade in Boston for a year, at this time learning to read and write. In 1687, with a commission from the British Crown, he found, after a search of many years, a wrecked Spanish treasure ship of which he had heard on a voyage to the Bahamas. From it he recovered £300,000, of which he received £16,000 as his share, was knighted by James II., and was appointed sheriff of New England. Poorly educated and ignorant of law, Phips could accomplish little, and returned to England. In 1689 he returned to Massachusetts, and at once entered into the life of the colony. He was soon appointed commander of an expedition against the French in Canada, which sailed in April, 1690, and easily captured Port Royal. A much larger expedition led by Phips in July against Quebec and Montreal ended disastrously. In the winter of 1690 he returned to England, and urged, with Increase Mather, the colonial agent, a restoration of the colony's charter, annulled during the reign of Charles II. The Crown, at the suggestion of Mather, appointed him the first royal governor under the new charter. On reaching Boston in May, 1692, Phips found the colony in a very disordered condition, and though honest and persevering, he was unfitted for the difficult position. In defending the frontier he displayed great energy, but his policy of building forts was expensive and therefore unpopular. Numerous complaints to the home government resulted in his being summoned to England to answer charges. While in London awaiting trial, he died on Feb. 18, 1695.

See Cotton Mather's *Life of His Excellency Sir William Phips*

(1697, republished in his *Mænalæia*, in 1792). Francis Bowen's "Life of Sir William Phipps," in Jared Sparks's *American Biography*, 1st series, vol. vii. (1856); William Goold's "Sir William Phipps," in *Collections of the Maine Historical Society*, series 1, vol. ix. (Portland, 1887); Ernest Myrand's *Sir William Phipps devant Quebec* (Quebec, 1893); Thomas Hutchinson's *History of Massachusetts* (Boston; 3rd ed. 1795); and J. G. Palfrey's *History of New England* (1858-90).

PHLEBITIS, a medical term for inflammation affecting veins. Usually the venous condition results from inflammation in tissue surrounding the vessel and extending to its walls. The vein becomes thickened and can be recognized as a definite, perhaps reddened, and very painful cord if it be superficial, e.g., saphenous vein. When the inflammation extends to the inner coat of the vessel and nutrition of the lining endothelium is impaired, local clotting of blood occurs, the clot being adherent to the vessel wall where it is first formed and extending upwards and downwards within the lumen (see THROMBOSIS AND EMBOLISM). From the primary focus clotting extends also into the tributaries of the vein thus inducing widespread obstruction to the return of blood from the part and consequent oedema. The condition calls for complete rest owing to the danger of dislocating the clot and causing embolism; this danger is greatest when the condition is septic. In most cases, under rest, the inflammation subsides and the primarily affected vein becomes permanently occluded by newly formed fibrous tissue, but circulation in the part formerly drained by the vein is restored by the opening up of collateral channels. In some regions phlebitis is particularly dangerous, e.g., the lateral sinus to which inflammation from middle ear disease may extend with subsequent cerebral abscess or purulent meningitis or general pyæmia. In such cases surgery is the sole hope for the patient.

PHLEGON, of Tralles in Asia Minor, Greek writer and freedman of the emperor Hadrian, flourished in the 2nd century A.D. His chief work was the *Olympiads*, an historical compendium in sixteen books, from the 1st down to the 229th Olympiad (776 B.C. to A.D. 137), of which several chapters are preserved in Photius and Syncellus. Two small works by him are extant: *On Marvels* and *On Long-lived Persons*, a list of Italians who had passed the age of 100, taken from the Roman censuses.

Fragments in C. Müller, *Frag. hist. graec.* iii.; of the *Marvels and Long-lived* in O. Keller, *Rerum naturalium scriptores*, i. (1877); see also H. Diels, "Phlegons Androgenenorakel" in *Sibyllinische Blätter* (1890).

PHLOGOPITE, a mineral belonging to the group of micas (*q.v.*). It is a magnesium mica, differing from biotite in containing only a little iron; $[H,K,(MgF)]_3Mg_3Al(SiO_4)_3$, is the chemical formula and it is named from Gr. *φλογωπός* (fiery-looking), the mineral being sometimes brownish-red and coppery in appearance. Sometimes it is quite colourless and transparent, but usually of a characteristic yellowish-brown colour, and often with a silvery lustre on the cleavage surfaces, hence the trade names "amber mica" and "silver mica" for some varieties. Phlogopite occurs chiefly as scales and plates embedded in crystalline limestones of the Archæan formation, and the cleavage flakes are not quite so elastic as those of muscovite. The mica mined in Canada and Ceylon is mainly phlogopite, and is largely used as an insulator for electrical purposes. In Canada it occurs with apatite in pyroxene rocks associated with Laurentian gneisses and crystalline limestones, the principal mining district being in Hull county, Quebec and near Burgess in Lanark county, Ontario. In Ceylon the mineral forms irregular veins, rarely exceeding one or two feet in width, traversing granulite, especially near the contact of this rock with crystalline limestone.

PHLOX (family Polemoniaceae), a genus of about 60 species, mostly perennial hardy plants of great beauty, natives of North America (a few Asiatic), with entire, usually opposite, leaves and showy flowers generally in terminal clusters. Each flower has a tubular calyx with five lobes, and a salver-shaped corolla with a long slender tube and a flat limb. The five stamens are given off from the tube of the corolla at different heights and do not protrude beyond it. The ovary is three-celled with one to two ovules in each cell; it ripens into a three-valved capsule. Many species and varieties are tall herbs yielding a wealth of

bloom throughout the summer and early autumn. They require a deep, rich and rather heavy loam, and a cool, moist position.

The dwarf perennial species and varieties, the "moss pinks" of gardens, are suitable plants for the rockery, and as edging to beds and borders. They are trailing and tufted in habit, the branches rooting at the nodes. They succeed in poorer soil and drier situations than the tall kinds. Seed is seldom produced. Propagation is effected by cuttings in July and early August, placed in a cold frame, and by division of the plants, which should be lifted carefully, and cut into rooted portions as required. The tufted kinds decay in patches in winter if the situation is moist.

Phlox drummondii and its numerous varieties are half-hardy annuals in Great Britain. It is a small-growing hairy plant, flowering profusely during the summer months. For early flowering it should be sown in heat in March and April and transferred out of doors in June. It succeeds if sown out of doors in April, but the flowering season is later and shorter.

The tall-growing border phloxes are divided into early and late flowering kinds respectively, the former derived mainly from *P. glaberrima* and *P. suffruticosa*, and the latter from *P. maculata* and *P. paniculata*. Owing to the frequent introduction of new kinds, no account of varieties can be given.

Since practically all the species are natives of North America, with handsome representatives in every section of the United States, some have urged adoption of the genus as the floral emblem or national flower of the U.S.

PHOCAEA (mod. *Fokia* or *Fokha*), an ancient city on the western coast of Asia Minor, famous as the mother city of Marseilles. It was the most northern of the Ionian cities, and was situated on the coast of the peninsula which separates the gulf of Cyme, occupied by Aeolian settlers, from the Hermaean Gulf, on which stood Smyrna and Clazomenae. Its position between two good harbours, Naustathmus and Lampter (*Livy xxxvii. 31*), led the inhabitants to devote themselves to maritime pursuits. According to Herodotus the Phocaeans were the first of all the Greeks to undertake distant voyages, and made known the coasts of the Adriatic, Tyrrhenia and Spain. Arganthonius, king of Tartessus in Spain, invited them to emigrate in a body to his dominions, and, on their declining, presented them with a large sum of money. This they employed in constructing a strong wall around their city, a defence which stood them in good stead when Ionia was attacked by Cyrus in 546. Eventually they determined to seek a new home in the west, where they already had flourishing colonies, e.g., Alalia in Corsica and Massilia (mod. Marseilles). A large part of the emigrants proceeded only as far as Chios, returned to Phocaea, and submitted to the Persian yoke.

Phocaea continued to exist under the Persian government, but greatly reduced in population and commerce. Though it joined in the Ionian revolt against Persia in 500 it was able to send only three ships to the combined fleet which fought at Lade. But a Phocæan took the supreme command. It never again played a prominent part in Ionian history. The modern town in the immediate neighbourhood, still known as Fokia, was founded by the Genoese in 1421 on account of the rich alum mines in the neighbourhood. It has a fair natural harbour.

PHOCAS, East Roman emperor (602-610), was a Cappadocian of humble origin. He was still but a centurion when chosen by the army of the Danube to lead it against Constantinople. A revolt within the city soon afterwards resulted in the abdication of the reigning emperor Maurice, and in the elevation of Phocas to the throne. Phocas proved entirely incapable of governing the empire. He consented to pay an increased tribute to the Avars and allowed the Persians to overrun the Asiatic provinces and to penetrate to the Bosphorus. When the African governor Heraclius declared against him, Phocas was deposed with scarcely a struggle (610). He died in the same year on the scaffold.

See J. B. Bury, *The Later Roman Empire* (1923), vol. ii.; Gibbon, *Decline and Fall* (ed. Bury, 1911), vol. 5, p. 65-7050; J. Kulakowsky in "Byzant. Vremmenik" vol. xxi.

PHOCION, Athenian statesman and general, was born about 402 B.C., the son of a small manufacturer. He became a pupil of Plato and in later life was a close friend of Xenocrates. Under

Chabrias he distinguished himself in the great sea-fight of Naxos (376), and subsequently won the confidence of the allies by his justice and integrity. In 351-349 he entered the Persian service and helped to subdue a rebellion in Cyprus. Henceforward he always held a prominent position in Athens, and although he never canvassed he was elected general forty-five times in all. In politics he is known chiefly as the consistent opponent of the anti-Macedonian party. He countered the eloquence of Demosthenes and his supporters by the plain facts of Athens' situation. He helped to defend Aeschines in 343, and secured lenient terms from Philip after the disaster of Chaeroneia (338). He also rendered good service in the field: in 348 he saved the force operating against the philo-Macedonian tyrants in Euboea by the brilliant victory of Tamynae. Under the Macedonian predominance his reputation increased. Though by no means inclined to truckle to the Macedonians, as is shown by his protection of the refugee Harpalus and his spirited campaign in defense of Attica in 322, he won the confidence of the conquerors, and in the restricted democracy which Antipater enforced he became the virtual ruler of Athens. On the restoration of the democracy in 318. Phocion was deposed. He fled to Polyperchon, but was sent back to be tried at Athens. The assembly shouted Phocion down and condemned him to death unheard. Not long after, the Athenians decreed a public burial and a statue in his honour.

See Plutarch, *Life of Phocion*; Holm. *Gk. Hist.* vol. iii. (Eng. trans., London, 1896).

PHOCIS, an ancient district of central Greece (now a department [Phthiotis-Phocis], area, 2,547 sq.mi.; pop. 193,671), bounded W. by Ozolian Locris and Doris, N. by Opuntian Locris on the E. by Boeotia, and on the S. by the Corinthian gulf. The massive ridge of Parnassus (8,068 ft.) traverses the heart of the country. Between this and the northern frontier range of Cnemis (3,000 ft.) is the narrow fertile valley of the Cephissus, along which lie most of the Phocian townships. South of Parnassus the two small plains of Crisa and Anticyra are separated by Mt. Cirphis. Phocis was mainly pastoral.

Its early history is obscure. Its population was reckoned Aeolic, but the dialects are of the West-Greek group, more akin to Doric. There was a tradition that the Phocians once owned land round Daphnus opposite Euboea, and had their frontier at Thermopylae. Later restriction of territory was due to the hostility of Boeotia and Thessaly. The latter in the 6th century even raided the Cephissus valley. In early days Phocians controlled the sanctuary of Delphi. But Delphi constantly strove for independence and about 590 B.C. induced a coalition of Greek states to proclaim a "Sacred War" and free the oracle from Phocian supervision. Thus Phocian influence at Delphi was restricted to the possession of two votes in the Amphictyonic Council.

During the Persian invasion of 480 the Phocians at first joined in the national defense, but their irresolute conduct lost Thermopylae for the Greeks; and at Plataea they were on the Persian side. In 457 an attempt to control the head waters of the Cephissus in the territory of Doris brought a Spartan army into Phocis in defense of the "metropolis of the Dorians." A similar attack on Delphi in 448 was again frustrated by Sparta, but not long afterwards the Phocians recaptured the sanctuary with the help of the Athenians, with whom they became allied in 454. When Athenian land-power declined, Phocian friendship waned, and in the Peloponnesian War Phocis was nominally an ally of Sparta, and had lost control of Delphi.

In the 4th century Phocis was constantly endangered by Boeotian oppression. After helping Sparta to invade Boeotia during the Corinthian War (395-394), the Phocians received assistance from Sparta in 380, but afterwards submitted to the growing power of Thebes. Phocians took part in Epameinondas' earlier inroads into the Peloponnesus, but abstained from the campaign of Mantinea (370-362). In return for this negligence the Thebans secured a penal decree against them for religious offenses from the Amphictyonic synod (356). The Phocians, led by two capable generals, Philomelus and Onomarchus, replied by seizing Delphi and using its riches to hire mercenaries with whose help they invaded Boeotia and Thessaly, and though driven out of Thessaly

by Philip of Macedon, maintained themselves for ten years, until the exhaustion of the temple treasures and the treachery of their leaders placed them at Philip's mercy. In 339 the Phocians began to rebuild their cities; in 338 they fought against Philip at Chaeroneia; in 323 they took part in the Lamian War against Antipater, and in 279 helped to defend Thermopylae against the Gauls.

During the 3rd century Phocis passed into the power of Macedonia and of the Aetolian League, to which in 196 it was annexed. Under Roman rule its league was dissolved, but was revived by Augustus, who also restored to Phocis the votes in the Delphic Amphictyony which it had lost in 346 and enrolled it in the new Achaean synod. The Phocian League is last heard of under Trajan.

PHOCYLIDES, Greek gnomic poet of Miletus, contemporary of Theognis, was born about 560 B.C. A few fragments of his "maxims" have been preserved (chiefly in the *Florilegium* of Stobaeus). A complete didactic poem called *Πολύμημα νοθητικόν* or *γνώμηαι*, and which bears the name of Phocylides, is now considered to be the work of an Alexandrian Christian of Jewish origin who lived between 170 B.C. and A.D. 50.

See fragments and the spurious poem in T. Bergk, *Poetae Lyrici graeci*, ii. (4th ed., 1882); J. Bernays *Über das Phokylideische Gedicht* (1858); *Phocylides, Poem of Admonition*, with introduction and commentaries by J. B. Fenling, and translation by H. D. Goodwin (Andover, Mass., 1879). There is an English verse translation by W. Hewett (Watford, 1840), *The Perceptive Poem of Phocylides*.

PHOEBE (*Sayornis phoebe*), the name given to a familiar American bird belonging to the family *Tyrannidae* (the "American flycatchers"). Distinguished by its dark crown-cap, olive-grey plumage, and the white outer vane to the outer tail feather, the phoebe breeds in eastern North America from the south-west Mackenzie southwards, wintering in southern U.S.A. and Mexico. The bulky nest of moss and mud, lined with grass, hair and feathers, is placed on a beam or under a bridge or bank, often close to or on a building. Say's phoebe (*S. sayi*) is a more westerly species, abundant west of Kansas and Nebraska. The black phoebe (*S. nigricans*) has a more southern range.

PHOEBUS, a common epithet of Apollo (*q.v.*).

PHOENICIA, in ancient geography, the name given to that part of the seaboard of Syria which extends from the Eleutherus (Nahr el-Kebir) in the north to Mt. Carmel in the south, a distance of rather more than two degrees of latitude. These limits, however, were exceeded at various times; thus, north of the Eleutherus lay Aradus and Marathus, and south of Carmel the border sometimes included Dor and even Joppa. The harbours which played so important a part in antiquity are nearly all silted up, and, with the exception of Beirut, afford no safe anchorage for the large vessels of modern times. Sidon, Tyre and Aradus, though now connected with the mainland, were built originally upon islands; the Phoenicians preferred such sites, because they were convenient for shipping and easily defended against attack.

The chief towns of ancient Phoenicia, as we know of them from the Amarna tablets (15th century B.C.) and from Egyptian, Assyrian and the Old Testament documents, were the following: Acco (now Acre or 'Akkā, Judg. i. 31), Achzib (now ez-Zib, *ibid.*), Ahlab (in Assyrian Mahalliba, *ibid.*)—three towns on the coast south of Tyre, Kānāh (Josh. xix. 28), Tyre (Phoen. Sūr, now Sūr), Zarephath or Sarepta (1 Kings xvii. g [now Sarafand]), Sidon (now Šaidā), Berytus (Biruta in Egyptian, Biruna in the Amarna tablets, now Beirut), Byblus (in Phoen. and Hebr. Gebal, now Jebeil), Arka, Som. north of Sidon (Gen. x. 17, now 'Arkā), Sin (Assyr. Siannu, *ibid.*) Simyra (Gen. x. 18, now Šumrā), Marathus (now Amrit) not important till the Macedonian period, Arvad or Aradus (in Phoen. Arwād, now Ruād, Gen. x. 18; Ezek. xxvii. 8, 11), the most northerly of the great Phoenician towns.

Race and Language.—The Phoenicians were an early offshoot from the Semitic stock, and belonged to the Canaanite branch of it. The Phoenicians themselves believed that they had migrated from an eastern shore, probably meaning Babylonia.

By settling along the Syrian coast they developed a strangely un-Semitic love for the sea, and advanced on different lines from the other Canaanites who occupied the interior. They called themselves Canaanites and their land Canaan; such is their name in the Amarna tablets, *Kinahhi* and *Kinahni*; and with this agrees the statement assigned to Hecataeus (Fr. *hist. gr.*, i. 17) that Phoenicia was formerly called *Xvâ* (*Chnâ*) a name which Philo of Byblus adopts into his mythology by making "Chna who was afterwards called Phoinix" the eponym of the Phoenicians (Fr. *hist. gr.*, iii. 569). In the reign of Antiochus IV. and his successors the coins of Laodicea of Libanus bear the legend "Of Laodicea which is in Canaan" (Cooke, North-Semitic Inscriptions, quoted as NSI., No. 149 B 8); the Old Testament also sometimes denotes Phoenicia and Phoenicians by "Canaan" and "Canaanites" (Isa. xxiii. 11; Obad. 20; Zeph. i. 11), though the latter names generally have a more extended sense. But "Sidonians" is the usual designation both in the Old Testament and in the Assyrian monuments (Sidunnu); and even at the time of Tyre's greatest ascendancy we read of Sidonians and not Tyrians in the Old Testament and in Homer; thus Ethbaal, king of Tyre (Jos., Ant., viii. 13, 2) is called king of the Sidonians in 1 Kings xvi. 31. In the Homeric poems we meet with *Sidonioi*, *Sidonē* (Od., iv. 618; *Il.*, vi. 290; Od., xiii. 28 j; *Il.*, vi. 291) and *Phoinikes*, *Phoinikē* (Od., xiii. 272, xiv. 288 seq., etc.), and both terms together (Od., iv. 83 seq., *Il.*, xxiii. 743 seq.). And the Phoenicians themselves used Sidonians as a general name; thus in one of the oldest Phoenician inscriptions (CIS., i. 5=NSI., No. 11), Hiram II., king of Tyre in the 8th century, is styled "king of the Sidonians." But among the Greeks "Phoenicians" was the name most in use, *Phoinikes* (plur. of *Phoinix*) for the people and *Phoinikē* for the land (cf. PHOENIX). The former was probably the older word and may be traced to *phoinos*="blood-red"; the Canaanite sailors were spoken of as the "red men" on account of their sunburnt skin.

Language.—Inscriptions, coins, topographical names preserved by Greek and Latin writers, names of persons and the Punic passages in the Poenulus of Plautus, all show conclusively that the Phoenician language belonged to the North-Semitic group, and to that sub-division of it which is called the Canaanite and includes Hebrew and the dialect of Moab. A comparison between Phoenician and Hebrew reveals close resemblances both in grammatical forms and in vocabulary; in some respects older features have been preserved in Phoenician, others are later, others again are peculiar to the dialect; many words poetic or rare or late in Hebrew are common in Phoenician. Hence we may conclude that the two languages developed independently from a common ancestor, which can be no other than the ancient Canaanite, of which a few words have survived in the Canaanite glosses to the Amarna tablets (written in Babylonian). But in forming an estimate of the Phoenician language it must be remembered that our material is scanty and limited in range; the Phoenicians were in no sense a literary people; moreover, except the inscriptions found at Gebal, now Jebeil, (10th century) and NSI. No. 11, most of the inscriptions are subsequent to the 6th century B.C.; the majority belong to the 4th century and later, by which time the language must have undergone a certain amount of decay. Indirectly, however, the Phoenicians rendered one great service to literature; they took a large share in the development and diffusion of the alphabet which forms the foundation of Greek (Herod., v. 58) and of all European writing. The Phoenician letters in their earlier types are practically identical with those used by the Hebrews, the Moabites, and the Aramaeans of north Syria (NSI., Plates xii., xiii). They passed through various modifications in the course of time; after leaving the mother country the script acquires a more cursive flowing style on the stones from Cyprus and Attica; the tendency becomes more strongly marked at the Punic stage; until in the neo-Punic, from the destruction of Carthage (146 B.C.) to the 1st century A.D., both the writing and the language reached their most degenerate form. As a rustic dialect the language lasted in north Africa till the 5th century A.D. In his sermons St. Augustine frequently quotes Punic words. The oldest specimens of Phoenician writing at

present known have been found at Gebal. In 1922 Montet unearthed the sarcophagus of Ahiaram, incised with a Phoenician inscription in an archaic form of lettering, which bears a close resemblance to the inscription of Abi-baal, discovered some years ago on the same site.

History.—The Phoenicians, in imitation of the Egyptians, claimed that their oldest cities had been founded in remote antiquity; but no certainty can be attached to the traditional chronologies; e.g., Herod., ii. 44; Justin, xviii. 3; Menander in Jos., Ant., viii. 3, 1 and c. *Ap.*, i. 18.

Phoenicia comes into history proper c. 1600 B.C., when the Egyptian empire began to extend in the direction of Asia under Ahmosi (Amasis) I.; who carried his arms into Syria, and conquered at least Palestine and Phoenicia, the latter being the country called *Da-hi* on the Egyptian monuments (Miiller, *As. u. Eur.*, p. 181), Thothmes III. (1503-1449) repeated and consolidated the earlier conquest, and established Egyptian suzerainty over all the petty states of Syria and Phoenicia (see EGYPT: History. I.). For the geography and civilization of Canaan about 1400 B.C. we have valuable evidence in the Egyptian papyrus Anastasi I., which mentions Kepuna (Gubna, Gebal-Byblus) the holy city, and continues: "Come then to Berytus, to Sidon, to Sarepta. Where is the ford of Nat-'ana (? Nahr el-Kāsimiyeh, or a town)? Where is 'Eutu (?Ushu, Palaetyrus)? Another: city on the sea is called a haven, D'ar (Tyre) is its name, water is carried to it in boats; it is richer in fish than in sands." But the fullest information about the state of Phoenicia in the 15th and 14th centuries B.C. comes from the Amarna tablets, among which are many letters from the subject princes and the Egyptian governors of Phoenicia to the Pharaoh. It was a time of much political disturbance. The Hittites (*q.v.*) were invading Syria; nomads from the desert supported the invasion; and many of the local chiefs were ready to seize the opportunity to throw off the yoke of Egypt. The towns of Phoenicia were divided; Aradus, Simyra, Sidon supported the rebellion; Rib-addi, the regent of Byblus, and Abi-melech, king of Tyre, held out for Egypt; but while all the towns made professions of fidelity, they were scheming for their own interests, and in the end Egypt lost them all except Byblus. The tablets which reveal this state of affairs are written in the language and script of Babylonia, and thus show indirectly the extent to which Babylonian culture had penetrated Palestine and Phoenicia; at the same time they illustrate the closeness of the relations between the Canaanite towns and the dominant power of Egypt. After the reign of Amenophis IV. (1376-66) that power collapsed altogether; but his successors attempted to recover it, and Ramses (Rameses) II. reconquered Phoenicia as far as Beirut, and carved three tablets on the rock beside the Nahr el-Kelb (Gressmann, *Texte u. Bilder*² ii. Pl. 1xv.). In the reign of Ramses III. (c. 1200) many great changes began to occur owing to the invasion of Syria by peoples from Asia Minor and Europe, which ended in the establishment of the Philistines on the coast near Ashkelon. The successors of Ramses III. lost their hold over Canaan; the 21st dynasty no longer intervened in the affairs of Syria; but Sheshonk (Shishak), the founder of the 22nd dynasty, about 928 B.C. endeavoured to assert the ancient supremacy of Egypt (cf. 1 Kings xiv. 2 j sqq.), but his successes were not lasting, and, as we learn from the Old Testament, the power of Egypt became henceforward ineffective.

Independence of Phoenicia.—Between the withdrawal of the Egyptian rule in Syria and the western advance of Assyria there comes an interval during which the city-states of Phoenicia owned no suzerain. Gebal had kings of its own, Ahiaram, Ithobaal, Abi-baal, in the 10th century, as recent excavations have shown. The history of this period is mainly a history of Tyre, which not only rose to a sort of hegemony among the Phoenician states, but founded colonies beyond the seas (p. 769). From 970 to 772 B.C. the bare outline of events is supplied by extracts from the Hellenistic historians, Menander of Ephesus and Dios (largely dependent upon Menander), which have been preserved by Josephus, *Ant.*, viii. 5, 3 and c. *Ap.*, i. 17, 18. From the data given in these passages we learn that Hiram I., son of Abi-baal, reigned in Tyre from 970 to 936 B.C. The Tyrian annals, more-

over, alluded to the connection between Hiram and Solomon. Before this time, indeed, the Phoenicians had no doubt lived on friendly terms with the Israelites (*cf.* Judges v. 17; Gen. xlix. 13); but the two nations seem to have drawn closer in the time of Solomon. 2 Sam. v. 11, which brings David and Hiram together, probably antedates what happened in the following reign. For Solomon's palace and temple Hiram contributed cedar and fir trees as well as workmen, receiving in exchange large annual payments of oil and wine, supplies which Phoenicia must have drawn regularly from Israelite districts (1 Kings v. 9, 11; *cf.* Ezek., xxvii. 17; Ezr. iii. 7; Acts xii. 20; Jos., Ant. xiv. 10, 6); finally, in return for the gold which he furnished for the temple, Hiram received the grant of a territory in Galilee (Cabul, 1 Kings ix. 10-14). This alliance between the two monarchs led to a joint expedition from Eziongeber on the Gulf of Akaba to Ophir (?on the east coast of Arabia, see Ophir) for purposes of trade. The list of Hiram's successors given by Josephus indicates frequent changes of dynasty until the time of Ithobal I., priest of Astarte, whose reign (887-855) marks a return to more settled rule. In contrast to Hiram I., king of Tyre, Ithobal or Ethbaal is styled in 1 Kings xvi. 31 "king of the Sidonians," *i.e.*, of the Phoenicians, showing that in the interval the kings of Tyre had extended their rule over the other Phoenician cities. Under Ethbaal further expansion is recorded; Botrys north of Byblus and Aoza in north Africa are said to have been founded by him (Jos., Ant., viii. 13, 2); the more famous Carthage owed its origin to the civil discords which followed the death of Metten I. (c. 851), his next successor but one. According to tradition, Metten's son Pygmalion (c. 860-814) slew the husband of his sister Elissa or Dido; whereupon she fled and founded Carthage (*q.v.*) in Libya (Justin, xviii. 4-6). At this point Josephus's extracts from Menander end, see Schrader, KAT., 3rd ed. 12G ff.).

Assyrian Rule, 876-605 B.C.—From the time of Ethbaal onwards the independence of Phoenicia was threatened by the advance of Assyria. In 868 B.C. Assur-nasir-pal II. "washed his weapons in the great sea," and exacted tribute from the kings of Tyre, Sidon, Byblus and other cities, including Arvad (Keilinschr. *Bibliothek*, i. 109). The inscriptions of his son Shalmaneser III. mention the taking of tribute from the Tyrians and Sidonians in 842 and again in 839; the Byblians are included at the latter date, and among the kings defeated at Karkar in 854 or 853 was Metten-baal, king of the Arvadites (*ibid.*, pp. 141, 143, 173). Thus Shalmaneser established a supremacy which lasted for over a hundred years and was acknowledged by occasional payments of tribute. In 741 Tiglath-pileser III. mentions on his tribute-lists "Hirum of Tyre"; and here a piece of native evidence becomes available. An early Phoenician inscription (*CIS*, i. 5 = *NSI*, No. 11), engraved upon the fragments of a bronze bowl, mentions a certain governor of Qarth-hadasht (or; Carti-Hadasti, "New City," *i.e.*, Citium), "servant of Hiram king of the Sidonians to Baal of Lebanon," showing that this Hiram II. was not only king of Tyre, as the Assyrian inscription calls him, but of Sidon too; and further, that by this time Tyre has established a colony in Cyprus (*q.v.*). In Tiglath-pileser's Philistine campaign of 734 Byblus and Aradus paid tribute, and a king of Tyre, Metten, was forced to do the same (KB. ii. 23). For the period which follows a certain amount of information is furnished by Menander (in Jos., Ant., ix. 14, 2). Elulaeus IX., in Assyrian Luli, who ruled under the name of Pylas, was king of Tyre, Sidon, and other cities at this time (c. 725-690), and at the beginning of his reign suffered from an invasion by Shalmaneser V.; this was probably the expedition against Hoshea of Samaria in 725; "the king of Assyria . . . overran all Phoenicia, but soon made peace with them all and returned back." In the reign of Sargon Phoenicia itself seems to have been left alone, though Cyprus submitted to him in 709; but in the reign of Sennacherib Elulaeus joined the league of Philistia and Judah, in alliance with Egypt and Ethiopia, which aimed at throwing off the oppressive tyranny of Assyria. In the great campaign of 701 Sennacherib came down upon the revolting provinces; he forced Luli, king of Sidon, to fly for refuge to Cyprus, took his chief cities, and set up Tuba'lu (Ethbaal) as king, imposing a yearly tribute (KB.

ii. 91). The blockade of Tyre by sea, significantly passed over in Sennacherib's inscription, is described by Menander; the Assyrian king, however, so far accomplished his object as to break up the combination of Tyre and Sidon, which had grown into a powerful state. At Sidon the successor of Ethbaal was Abd-milkath; in alliance with a Cilician chief he rebelled against Esarhaddon about the year 678, with disastrous consequences. Sidon was annihilated; Abd-milkath fell into the hands of Esarhaddon, who founded a new Sidon on the mainland, peopled it with foreigners, and called it after his own name. The old name, however, survived in popular usage; but the character of the city was changed, and till the time of Cyrus the kingdom of Sidon ceased to exist (KB. ii. 125 seq., 145; KAT³, 88). Tyre also came in for its share of hardship. Elulaeus was followed by Baal, who in 672 consented to join Tirhaka, the Ethiopian king of Egypt, in a rebellion against Assyria. Esarhaddon, on his way to Egypt for the second time, blockaded Tyre, but he did not capture the city itself. His monument found at Zenjirli represents the great king holding Baal of Tyre and Tirhaka of Egypt by cords fastened in their lips; there is no evidence, however, that he actually took either of them prisoner (Gressmann, *Texte u. Bilder*², ii. Pl. lxiii.). Early in the reign of Assur-bani-pal Tyre was besieged again (668), but Assur-bani-pal succeeded no better than his predecessors. Nevertheless Baal submitted in the end, along with the princes of Gebal and Arvad, Manasseh of Judah, and the other Canaanite chiefs; in the island of Cyprus the Assyrians carried all before them (KB. ii. 149 seq., 169, 173). On his return from the Arabian campaign Assur-bani-pal severely punished the rebellious inhabitants of Ushu (Palaetyrus) and Akko (*ibid.*, 229). In Phoenicia, as elsewhere, Assyrian rule created nothing and left nothing behind it but a record of barbarous conquest.

The Neo-Babylonian Period, 605-538 B.C.—In the last crisis of the dying power of Assyria the Egyptians for a short time laid hands on Phoenicia; but after their defeat at the battle of Carchemish (605), the Chaldaeans became the masters of western Asia. Jeremiah's allusion (xxv. 22) in 604 to the approaching downfall of the kings of Tyre and Sidon and the coastland beyond the sea, *i.e.*, the Phoenician settlements on the Mediterranean, seems to imply that the Phoenician states recovered some measure of independence; if they did it cannot have lasted long. In 588 Apries (Pharaoh Hophra) made an attempt to displace the Chaldaean supremacy; he defeated Tyre and Sidon, and terrorized the other cities into submission (*Herod.*, ii. 161; *Diod. Sic.*, i. 68). Some of the Phoenician chiefs, among them Ithobal II., the new king of Tyre, while forced to yield to a change of masters, were bold enough to declare their hostility to the Babylonians. This state of affairs did not escape the vigilance of Nebuchadrezzar. After the fall of Jerusalem he marched upon Phoenicia; Apries withdrew his army, and the siege of Tyre began. For 13 years the great merchant city held out (585-573; Jos., c. *Ap.*, i. 21; *cf.* Ezek. xxvi. 1 seq.). Ezekiel says that Nebuchadrezzar and his host had no reward for their heavy service against Tyre, and the presumption is that the city capitulated on favourable terms; for Ithobal's reign ends with the close of the siege, and the royal family is subsequently found in Babylon. The king appointed by Nebuchadrezzar was Baal II. (574-564), after whose death a republic was formed under a single suffete or "judge" (*shōfēt*). Josephus (*loc. cit.*) is again our authority for the changes of government which followed until the monarchy was revived. At length under Hiram III. Phoenicia passed from the Chaldaeans to the Persians (538), and at the same time Amasis II. of Egypt occupied Cyprus (*Herod.*, ii. 182). There seems to have been no struggle; the great siege and the subsequent civil disorders had exhausted Tyre, and Sidon took its place as the leading state. About this time, too, Carthage made an effort for independence under Hanno the Great (538-521), the real founder of its fortunes; the old dependence upon Tyre was changed for a mere relation of piety observed by the annual sending of delegates (*θεωποί*) to the festival of Melkarth (*Arrian*, ii. 24; *Polyb.*, xxxi. 20, 12). The disasters which befell Tyre during this and the foregoing period might suggest that its prosperity had been seriously damaged. But Tyre always counted for

more in commerce than in politics; and in the year 586, just before the great siege, Ezekiel draws a vivid picture (ch. xxvii.) of the extent and splendour of its commercial relations.

Constitution.—At this point it is convenient to mention what little is known about the constitution of the Phoenician states. All Canaanite analogy speaks for kingship as the oldest form of Phoenician government. In the native inscriptions the chief of the city in Phoenicia itself and in Cyprus is always called king. The royal houses claimed divine descent, and the king could not be chosen outside their members. His power, however, was limited by the wealthy merchant families, who possessed great influence in public affairs. The priest of Melkarth at Tyre was the second man in the kingdom. Associated with the prince was a council of elders; such was the case at Gebal (Byblus) from the earliest times to the latest (Ezek. xxvii. 9); at Sidon this council consisted of 100 members (Diod., xvi. 45), perhaps also at Tyre (*NSI*, p. 129). Inscriptions of the 3rd and 2nd centuries B.C. mention a *Rab* (chief) in Sidon, Cyprus and Gaulus (Gozo); what his position was it is difficult to say; in the colonies he may have been a district governor. During Nebuchadrezzar's time, as we have seen, a republic took the place of the monarchy at Tyre, and the government was administered by a succession of suffetes (judges); they held office for short terms, and in one instance two ruled together for six years. Much later, in the 3rd century B.C. an inscription from Tyre mentions a suffete (*NSI*, No. 8) without adding more to our knowledge. Carthage, of course, was governed by two suffetes, and these officers are frequently named in connection with the Carthaginian colonies (*NSI*, p. 115 *seq.*); but we must be careful not to draw the inference that Phoenicia itself had any such magistrates. Under the Persians a federal bond was formed comprising Sidon, Tyre and Aradus, whose duty it was to contribute 300 triremes to the Persian fleet (Herod., vii. 89), the lesser towns being under the command of the great cities. But federation on a larger scale was never possible in Phoenicia, for the reason that no sense of political unity existed to bind the different states together. Commercial interests dominated everything else, and while these stimulated a municipal life not without vigour, civil discipline and loyalty were but feebly felt. On occasion the towns could defend their independence with strenuous courage; the higher qualities which make for a progressive national life the Phoenicians did not possess.

The Persian Period, 538–333 B.C.—Phoenicia now became part of the fifth satrapy of the Persian empire, and entered upon a spell of comparative peace and growing prosperity. At this period Sidon occupied the position of leading state; in the fleet her king ranked next to Xerxes and before the king of Tyre (Herod., viii. 67); her situation afforded advantages for expansion which Tyre on its small and densely populated island could not rival. In the first half of the 4th century Straton I. (in Phoen. *'Abd-'ashtart* or *Bod-'ashtart*) was king, c. 374–362. He cultivated friendly relations with Athens, indicated in a decree of *proxenia* (Michel, *Rec. d'inscr. gr.* No. 93=*CIG.* No. 87); and the extent to which phil-Hellenic tendencies prevailed at this time in Sidon is shown by the royal sarcophagi, noble specimens of Greek art, which have been excavated in the necropolis of the city. It was in the reign of Straton that Tyre fell into the hands of Evagoras, king of Salamis, who had already supplanted Phoenician with Greek civilization in Cyprus (Isocr., *Evag.*, 62, *Paneg.*, 161; Diod. xv. 2). Straton made friends with Nicocles, son of Evagoras, and with him came to an untimely end through their implication in the great revolt of the satraps, 362 B.C. A new revolt of Sidon against the Persians took place under King Tennes; with the aid of Nectanebus of Egypt, the Sidonians carried the rest of Phoenicia with them and drove the satraps of Syria and Cilicia out of the country. Tennes, however, betrayed his people and opened the city to Artaxerxes III.; then he was executed after he had served the ends of the great king (346 B.C.; Diod., xvi. 41–45). The last king of Sidon was Straton II. (*'Abd-'ashtart*, 346–332) before the Persian empire came to an end.

Towards the close of the 5th century the Phoenician coins begin to supplement our historical sources. From the time of

Darius the Persian monarchs allowed their satraps and vassal states to coin silver and copper money at discretion. Hence Aradus, Byblus, Sidon and Tyre issued a coinage of their own, of which many specimens exist; the coins are stamped as a rule with the emblem or name of the city, sometimes with the ruler's name. Thus from the coins of Byblus we learn the names of four kings, 'El-pa'al, 'Az-ba'al (between 360 and 340 B.C.), Adar-melek, 'Ain-el; from the coins of the other cities it is difficult to obtain much information. The native inscriptions, however, now become available, though most of them belong to the period which follows, and only a few have been discovered in Phoenicia itself. One of the earliest of these is the inscription of Byblus (*CIS*, i. 1=*NSI*, No. 3), dating from the Persian period; it records a dedication made by Yehaw-milk, king of Gebal, and mentions the name of the king's grandfather, Urimilk, but the exact dates of their reign are not given.

The Macedonian Period, 333–69 B.C.—When Alexander the Great entered Phoenicia after the battle of Issus (333 B.C.), the kings were absent with the Persian fleet in the Aegean; but the cities of Aradus, Byblus and Sidon welcomed him readily, the last-named showing special zeal against Persia. The Tyrians also offered submission, but refused to allow the conqueror to enter the city and sacrifice to the Tyrian Heracles. Alexander was determined to make an example of the first who should offer opposition, and at once began the siege. It lasted seven months. With enormous toil the king drove out a mole from the mainland to the island and thus brought up his engines; ships from the other Phoenician towns and from Cyprus lent him their aid, and the town at length was forced in July 332; 8,000 Tyrians were slain, 30,000 sold as slaves, and only a few notables, the king Azemilkos, and the festal envoys from Carthage who had taken refuge in the sanctuary of Melkarth, were spared (Diod., xvii. 40–46). It is not unlikely that Zech. ix. 2–4 refers to this famous siege. For the time Tyre lost its political existence, while the foundation of Alexandria presently changed the lines of trade, and dealt a blow even more fatal to the Phoenician cities.

During the wars of Alexander's successors Phoenicia changed hands several times between the Egyptian and the Syrian kings. From the year 275 "the people of Tyre" reckoned their era (*CIS*, i. 7=*NSI*, No. 9, *cf.* 10). The Tyrian coins of the period, stamped with native, Greek and Egyptian symbols, illustrate the traditional relations of the city and the range of her ambitions. A special interest attaches to these silver tetradrachms and didrachms because they were used by the Jews for the payment of the temple tax as "shekels of the sanctuary" (*NSI*, pp. 351, 44).

Among the Phoenician states we know most about Sidon during this period. The kingship was continued for a long time. The story goes that Alexander raised to the throne a member of the royal family, Abdalonymus, who was living in obscure poverty and working as a gardener (Justin, xi. 10; Curt., iv. 1; Diod., xvii. 47 wrongly connecting the story with Tyre). In 312 Ptolemy, then master of Phoenicia, appointed his general Philocles king of the Sidonians, and a decree in honour of this king has been found at Athens (Michel, No. 387, *cf.* 1,261); but he cannot have reigned long. For at the end of the 4th and the beginning of the 3rd century we have evidence of a native dynasty in the important inscriptions of Tabnith, Eshmun'azar and Bod-'ashtart, and in the series of inscriptions (repeating the same text) discovered at Bostan esh-Shēkh near Sidon (*NSI*, Nos. 4, 5, 6 and App. i.). With Bod-'ashtart, so far as we know, the dynasty came to an end, say about 250 B.C.

After the death of Antiochus IV. Epiphanes in 164 B.C., the kingdom of the Seleucids began to collapse. Berytus was destroyed by the usurper Trypho in 140 B.C. Tyre in 120 and Sidon in 111 received complete independence, and inaugurated new eras from these dates. Byblus and Tripolis fell into the hands of "tyrants" (Strabo, xvi. 2, 18; Jos., *Ant.*, xiv. 3, 2); from 83–69 B.C. the entire kingdom was held by the Armenian Tigranes.

Roman Rule.—At last in 64 B.C. Pompey arrived upon the scene and established order out of chaos. Phoenicia was incorporated into the Roman province of Syria; Aradus, Sidon, Tyre and Tripolis were confirmed in their rights of self-government and in

the possession of their territories. Under the beneficent government of Rome the chief towns prospered and extended their trade; but the whole character of the country underwent a change. During the Macedonian period Greek influences had been steadily gaining ground in Phoenicia; relations with the Greek world grew closer; the native language fell into disuse, and from the beginning of the Roman occupation Greek appears regularly in inscriptions and on coins, though on the latter Phoenician legends do not entirely vanish till the 2nd century AD.: while the extent to which Hellenic ideas penetrated the native traditions and mythologies is seen in the writings of Philo of Byblus. For the purposes of everyday life, however, the people spoke not Greek, but Aramaic. As elsewhere, the Roman rule tended to obliterate characteristic features of national life, and under it the native language and institutions of Phoenicia became extinct.

Navigation, Trade, Colonies.—The Phoenicians were essentially a seafaring nation. Fearless and patient navigators, they ventured into regions where no one else dared to go, and, always with an eye to their monopoly, they carefully guarded the secrets of their trade routes and discoveries, and their knowledge of winds and currents. At the beginning of the 7th century B.C. a Phoenician fleet is said to have circumnavigated Africa (Herod., iv. 42). To the great powers Phoenician ships and sailors were indispensable; Sennacherib, Psammetichus and Necho, Xerxes, Alexander, all in turn employed them for their transports and sea-fights. Even when Athens had developed a rival navy Greek observers noted with admiration the discipline kept on board the Phoenician ships and the skill with which they were handled (Xen., Oec., viii.); all the Phoenician vessels from the round merchant-boat (*γαλῶλος*—after which the island of Gaulus, now Gozo, near Malta, was called) to the great Tarshish-ships, the "East-Indiamen" of the ancient world, excelled those of the Greeks in speed and equipment. As E. Meyer points out, the war between the Greeks and the Persians was mainly a contest between the sea-powers of Greece and Phoenicia. At what period did Phoenicia first rise to be a power in the Mediterranean? We are gradually approaching a solution of this obscure problem. Recent discoveries in Crete (*q.v.*) have brought to light the existence of a Cretan or "Minoan" sea-power of remote antiquity, and it is clear that a great deal of what used to be described as Phoenician must receive quite a different designation. The Minoan sea-power was at last broken up by invaders from the north, and a Carian rule became dominant in the Aegean (Herod., i. 171; Thucyd., i. 4, 8). It was a time of disorder and conflict due to the immigration of new races into the ancient seats of civilization, and it synchronized with the weakening of the power of Egypt in the countries which bordered on the eastern Mediterranean. This was in the 12th century B.C. The Tyrian trader saw that his opportunity was come, and the Aegean lay open to his merchant vessels. Where much is still obscure, all that seems certain is that the antiquity of Phoenicia as a sea- and trading-power has been greatly exaggerated both in ancient and in modern times; the Minoan power of Cnossus preceded it by many centuries; the influence of Phoenicia in the Aegean cannot be carried back much earlier than the 12th century B.C.

A vivid description of the Phoenicians' trade at the time of Tyre's prosperity is given by Ezekiel (xxvii. 12–25), and it shows how extensive were their commercial relations not only by sea, but by land as well. It was they who distributed to the rest of the world the wares of Egypt and Babylonia (Herod., i. 1). From the lands of the Euphrates and Tigris regular trade-routes led to the Mediterranean with trading-stations on the way, several of which are mentioned by Ezekiel (xxvii. 23). In Egypt the Phoenician merchants soon gained a foothold; they alone were able to maintain a profitable trade in the anarchic times of the 22nd and 23rd dynasties (825–650 B.C.), when all other foreign merchants were frightened away. Though there were never any regular colonies of Phoenicians in Egypt, the Tyrians had a quarter of their own in Memphis (Herod., ii. 112). The Arabian caravan-trade in perfume, spices and incense passed through Phoenician hands on its way to Greece and the west (Herod., iii. 107). Between Israel and Phoenicia the relations naturally

were close; the former provided certain necessaries of life, and received in exchange articles of luxury and splendour (Ezek. xxvii. 16–18). Israelite housewives sold their homespun to Phoenician pedlars (Prov. xxxi. 24 R.V.M.); in Jerusalem Phoenician merchants and money lenders had their quarter (Zeph. i. 11), and after the Return we hear of Tyrians selling fish and all manner of ware in the city (Neh. xiii. 16), and introducing other less desirable imports, such as foreign cults (Isa. lxxv. 11). The Phoenician words which made their way into Greek at an early period indicate the kind of goods in which the Phoenicians traded with the west, or made familiar through their commerce; the following are some of them—*χρυσός*, *χιτών*, *βύσσος*, *ὀθόνη*, *μύρρα*, *νάβλα*, *κύπρος*, *φύκος*, *μνᾶ*, *παλλακίς*, *βαίτυλος*. Another article of commerce which the Phoenicians brought into the market was amber.

The Phoenician colonies were all supposed to have been founded from Tyre: with regard to the colonies in Cyprus and north Africa this was undoubtedly true. Cyprus possessed resources of timber and copper which could not fail to tempt the keen-eyed traders across the water, who made Citium (from Kittim, the name of the original non-Semitic inhabitants) their chief settlement, and thence established themselves in Idalium, Tamassus, Lapethus, Larnaka, Qarth-hadasht (Karti-hadasti) and other towns. In the inscriptions of the 4th to 3rd centuries, the Phoenician potentates in the island call themselves "kings of Kition and Idalion" (N.S.I. pp. 55–89).

Homer represents the Phoenicians as present in Creek waters for purposes of traffic, but not as settlers (*Il.*, xxiii. 744). They occupied trading-stations on some of the Aegean islands and on the Isthmus of Corinth. One of their objects was the collection of murex, of which an enormous supply was needed for the dyeing industry; specially famous was the purple of the Laconian waters, the isles of Elishah of Ezek. xxvii. 7. But a great deal of what was formerly assigned to Phoenician influence in the Aegean at an early period—pottery, ornaments and local myths—must be accounted for by the vigorous civilization of ancient Crete. In the Greek world the Phoenicians made themselves heartily detested by their passion for gain (Plato, Rep. iv. 436 A.).

Farther west in the Mediterranean Phoenician settlements were planted first in Sicily, at Heraclea or Ras Melqarth; the islands between Sicily and Africa, Melita (Malta) on account of its valuable harbour, Gaulus and Cossura were also occupied (Diod., v. 12); and a beginning was made with the colonization of Sardinia and Corsica; but farther west still more permanent colonies were established. It was the trade with Tarshish; *i.e.*, the region of Tartessus in south-west Spain, which contributed most to the Phoenicians' wealth; it was said that even the anchors of ships returning from Spain were made of silver (Diod., v. 35). From Gadeira (Punic *Gādēr*, Lat. Gades, now Cadiz), the Sidonian ships ventured farther on the ocean and drew tin from the mines of north-west Spain or from the richer deposits in the Cassiterides; *i.e.*, the Tin Islands. These were discovered to be, not a part of Britain as was imagined at first, but a separate group by themselves, now known as the Scillies; hence it is improbable that the Phoenicians ever worked the tin-mines in Cornwall.

The rich trade with Spain led to the colonization of the West. Strabo dates the settlements beyond the Pillars of Hercules soon after the Trojan War (i. 3, 2), in the period of Tyre's first expansion. Lixus in Mauretania, Gades and Utica, are said to have been founded, one after the other, as far back as the 12th century B.C. Most of the African colonies were no doubt younger; we have traditional dates for Aozza (887–855) and Carthage (813). A large part of north-west Africa was colonized from Phoenicia; owing to these first settlers, and after them to the Carthaginians, the Phoenician language became the prevailing one, and the country assumed quite a Phoenician character.

In the days of Tyre's greatness her power rested directly on the colonies, which, unlike those of Greece, remained subject to the mother-city, and paid tithes of their revenues to its chief god, Melqarth, and sent envoys annually to his feast. Then at the beginning of the 8th century B.C. the colonial power of Tyre began to decline; on the mainland and in Cyprus the Assyrians

gained the upper hand; in the Greek islands the Phoenicians had already been displaced to a great extent by the advancing tide of Dorian colonization. But as Tyre decayed in power the colonies turned more and more to Carthage as their natural parent and protector. For effective control over a colonial empire Carthage had the advantage of situation over far-away Tyre; the traditional bonds grew lax and the ancient dues ceased to be paid, though as late as the middle of the 6th century Carthage rendered tithes to the Tyrian Melqarth. And the mother-country cherished its claims long after they had lost reality; in the 2nd century B.c., for example, Sidon stamped her coins with the legend, "Mother of Kambē (*i.e.*, Carthage), Hippo, Kition, Tyre" (NSI. p. 352).

Manufactures, Inventions, Art.—From an early date the towns of the Phoenician coast were occupied, not only with distributing the merchandise of other countries but with working at industries of their own; especially purple-dyeing and textile fabrics (*Il.*, vi. 289 *sqq.*), metal work in silver, gold and electrum (*Il.*, xxiii. 741 *sqq.*; *Od.*, iv. 615 *sqq.* xv. 458 *sqq.*), and glass-work, which had its seat at Sidon. The iron and copper mines of Cyprus (not Sidon, as Homer implies, *Od.*, xv. 424) furnished the ore which was manufactured into articles of commerce. Egyptian monuments frequently mention the vessels of gold and silver, iron and copper, made by the Dahi, *i.e.*, the Phoenicians (W. M. Müller, *As. u. Eur.*, 306); and in Cyprus and at Nimrud bronze and silver paterae have been found, engraved with Egyptian designs, the work of Phoenician artists (see table-cases C and D in the Nimrud gallery of the Brit. Mus.). The invention of these various arts and industries was popularly ascribed to the Phoenicians, no doubt merely because Phoenician traders brought the products into the market. But dyeing and embroidery probably came from Babylon in the first instance; glass-making seems to have been borrowed from Egypt; the invention of arithmetic and of weights and measures must be laid to the credit of the Babylonians. The ancients believed that the Phoenicians invented the use of the alphabet (*e.g.*, Pliny, *N.H.*, v. 13, cf. vii. 57; Lucan, *Bell. Civ.*, iii. 220 *seq.*); but it is unlikely that any genuine tradition on the subject existed, and though the Phoenician theory has found favour in modern times it is open to much question.

The art of Phoenicia is characterized generally by its dependence upon the art of the neighbouring races. It struck out no original line of its own, and borrowed freely from foreign, especially Egyptian, models. Remains of sculpture, engraved bronzes and gems, show clearly the source to which the Phoenician artists went for inspiration; for example, the uraeus-frieze and the winged disc, the ankh or symbol of life, are Egyptian designs frequently imitated. It was in the times of the Persian monarchy that Phoenician art reached its highest development, and to this period belong the oldest sculptures and coins that have come down to us. A characteristic specimen of the former is the stele of Yehaw-milk, king of Gebal (CIS. i. 1), in which the king is represented in Persian dress, and the goddess to whom he is offering a bowl looks exactly like an Egyptian Isis-Hathor; (Gressmann, *Texte u. Bilder*², ii. Pl. ccviii.). The whole artistic movement in Phoenicia may be divided into two great periods: in the first, from the earliest times to the 4th century B.c., Egyptian influence and then Babylonian or Asiatic influence is predominant, but the national element is strongly marked; while in the second, Greek influence has obtained the mastery, and the native element, though making itself felt, is much less obtrusive. Throughout these periods works of art, such as statues of the gods and sarcophagi, were imported direct at first from Egypt and afterwards mainly from Rhodes. The finest sarcophagi that have been found in the necropolis of Sidon (now in the Imperial Museum, Constantinople) are not Phoenician at all, but exquisite specimens of Greek art. The Phoenicians spent much care on their burial-places, which have furnished the most important monuments left to us. Thus, on the site of Gebal, now Jebel, the French excavators, under the leadership of Montet, 1921-23, have unearthed the fine sarcophagus of Ahiiram, Egyptian in style, and engraved with the earliest Phoenician inscription so far known;

see Gressmann; *Texte u. Bilder*², i. 440; ii. 189-192 and Pl. ccliv. (1927). Besides busts and figurines, which belong as a rule to the Greek period, the smaller objects usually found are earthen pitchers and lamps, glass-wares, tesserae and gems. Of buildings which can be called architectural few specimens now exist on Phoenician soil, for the reason that for ages the inhabitants have used the ruins as convenient quarries. Not a vestige remains of the great sanctuary of Melqarth at Tyre; a few traces of the temple of Adonis near Byblus were discovered by Renan, and a peculiar mausoleum, Burj al-Bezzāq, is still to be seen near Amrit; excavations at Bostan esh-Shēkh near Sidon revealed parts of the enclosure or foundations of the temple of Eshmun (NSI. p. 401); the conduits of Ras el- 'Ain, south of Tyre, are considered to be of ancient date.

Religion.—Like the Canaanites of whom they formed a branch, the Phoenicians connected their religion with the great powers and processes of nature. The gods whom they worshipped belonged essentially to the earth; the fertile field, trees and mountains, headlands and rivers and springs, were believed to be inhabited by different divinities, who were therefore primarily local, many in number, with no one in particular supreme over the rest. It seems, however, that as time went on some of them acquired a more extended character; thus Ba'al and Astarte assumed celestial attributes in addition to their earthly ones, and the Tyrian Melqarth combined a celestial with a marine aspect. The gods in general were called 'elōnim, 'elim; Plautus uses *alonium valomuth* for "gods and goddesses" (Poen., v. I, 1). These plurals go back to the singular form 'El, the common Semitic name for God; but neither the singular nor the plural is at all common in the inscriptions (NSI. pp. 24, 41, 51); 'El by itself has been found only once; the fem. 'Elath is also rare (*ibid.*, pp. 135, 158). The god or goddess was generally called the Ba'al or Ba'alath of such and such a place, a title which was used not only by the Canaanites, but by the Aramaeans (Be'el) and Babylonians (Bel) as well. There was no one particular god called Ba'al; the word is not a proper name but an appellative, a description of the deity as owner or mistress; and the same is the case with Milk or Melek, 'Adon, 'Ammā, which mean *king*, lord, mother. The god himself was unnamed or had no name. Occasionally we know what the name was; the Ba'al of Tyre was Melqarth which again means merely "king of the city"; similarly among the Aramaeans the Ba'al of Harran was the moon-god Sin. As each city or district had its own Ba'al, the "husband" of the land which he fertilized, so there were many Ba'als, and the Old Testament writers could allude to the Ba'alim of the neighbouring Canaanites. Sometimes the god received a distinguishing attribute which indicates an association not with any particular place, but with some special characteristic; the most common forms are Ba'al-ḥammān, the chief deity of Punic north Africa perhaps "the glowing Ba'al," the god of fertilizing warmth, and Ba'al-shamēm, "Ba'al of the heavens" (cf. Dan. xii. 11, xi. 31, etc.). The latter deity was widely venerated throughout the north Semitic world; his name, which does not appear in the Phoenician inscriptions before the 3rd century B.c., goes back at least to 800 B.c. (Aramaic inscription of Zakir, from Hamath.) The worship of the female along with the male principle was a strongly marked feature of Phoenician religion.

To judge from earliest evidence on the subject, the Ba'alath of Gebal or Byblus, referred to again and again in the Amarna letters (*Bēlīt ša Gubla*, Nos. 68-125), must have been the most popular of the Phoenician deities, as her sanctuary was the oldest and most renowned. The mistress of Gebal was no doubt 'Astarte (Astartē in Greek, 'Ashtōreth in the Old Testament, pronounced with the vowels of *bōsheth*, "shame"), a name which is obviously connected with the Babylonian Ishtar, and, as used in Phoenician, is practically the equivalent of "goddess." She represented the principle of fertility and generation; the common epithets *Κύπρις* and *Κυθήρεια* (of Kuthera in Cyprus), Cypria and Paphia, show that she was identified with Aphrodite and Venus. Though not primarily a moon-goddess, she sometimes appears in this character (Lucian, *Dea syr.*, § 4; Herodian v. 6, 10), and Herodotus describes her temple at Ashkelon as that of the heavenly

Aphrodite (i. 105). We find her associated with Ba'al and called "the name of Ba'al"; *i.e.*, perhaps his manifestation. Another goddess, specially honoured at Carthage, is Tanith (pronunciation uncertain); nothing is known of her characteristics; she is regularly connected with Ba'al on the Carthaginian votive tablets, and called "the face of Ba'al"; *i.e.*, his representative or revelation, though again some question this rendering as too metaphysical, and take "face of Ba'al" to be the name of a place, like Peni'el ("face of 'El"). Two or three other deities may be mentioned here: Eshmun, the god of vital force and healing, worshipped at Sidon especially, but also at Carthage and in the colonies, identified by the Greeks with Asclepius; Melqarth, the patron deity of Tyre, identified with Heracles; Reshef or Reshūf, the "flame" or "lightning" god, especially popular in Cyprus and derived originally from Syria, whom the Greeks called Apollo. A tendency to form a distinct deity by combining the attributes of two produced such curious fusions as Milk-'ashtart, Milk-ba'al, Milk-'osir, Eshmun-melqarth, Melqarth-reşef, etc. As in the case of art and industries so in religion the Phoenicians readily assimilated foreign ideas. The influence of Egypt was specially strong (NSI. pp. 62, 69, 148, 154). The Phoenician settlers at the Peiræus worshipped the Assyrian Nergal, and their proper names are compounded with the names of Babylonian and Arabian deities (h'SI. p. 101). Closer intimacy with the Greek world naturally brought about modifications in the character of the native gods, which became apparent when Ba'al of Sidon or Ba'al-shamēm was identified with Zeus, Tanith with Demeter or Artemis, 'Anath with Athena, etc.; the notion of a supreme Ba'al, which finds expression in the Greek *βήλος* and *βααλτις* or *βήλοθης* (the goddess of Byblus), was no doubt encouraged by foreign influences. On the other hand, the Phoenicians produced a considerable effect upon Greek and Roman religion, especially from the religious centres in Cyprus and Sicily. A great number of divinities are known only as elements in proper names, *e.g.*, Sakun-yathon (Sanchuniathon), 'Abd-sasom, Sed-yathon, and fresh ones are continually being discovered. It was the custom among the Phoenicians, as among other Semitic nations, to use the names of the gods in forming proper names and thus to express devotion or invoke favour; thus Hanni-ba'al, 'Abd-melqarth, Hanni-'ashtart, Eshmun-'azar. The proper names further illustrate the way in which the relation of man to God was regarded; the commonest forms are servant ('abd, *e.g.*, 'Abd-'ashtart), member or *limb* (bod, *e.g.*, Bod-melqarth), client or guest (ger, *e.g.*, Ger-eshmun); the religious idea of the guest of a deity had its origin in the social custom of extending hospitality to a stranger and in the old Semitic right of sanctuary.

Sacred Objects and Worship. — Probably like other Canaanites the Phoenicians offered worship "on every high hill and under every green tree"; but to judge from the allusions to sanctuaries in the inscriptions and elsewhere, the Ba'al or 'Ashtart of a place was usually worshipped at a temple, which consisted of a court or enclosure and a roofed shrine with a portico or pillared hall at the entrance. In the court sometimes stood a conical stone, probably the symbol of Astarte, as on the Roman coins of Byblus (see Ohnefalsch-Richter, Cyprus, pl. lvi., the temenos at Idalion). Stone or bronze images of the gods were set up in the sanctuaries (NSI. Nos. 13 seq., 23–27, 30, etc.); and besides these the baetylia (meteoric stones) which were regarded as symbols of the gods. Pillars, again, had a prominent place in the court or before the shrine (*naşab*, *ibid.* pp. 102 seq. and W. R. Smith, *Rel. of Sem³*, pp. 203 ff., 456 ff.); but it is not known whether the sacred pole ('asherah), an invariable feature of a Canaanite sanctuary, was usual in a Phoenician temple. The inscriptions mention altars of stone and bronze, and from the sacrificial tariffs which have survived we learn that the chief types of sacrifice among the Phoenicians were analogous to those which we find in the Old Testament (NSI. p. 117). The ghastly practice of sacrificing human victims was resorted to in times of great distress (*e.g.*, at Carthage, Diod., xx. 14), or to avert national disaster (Porphyry, de Abstin. ii. 56); it was regarded as a patriotic act when Hamilcar threw himself upon the pyre after the disastrous battle of Himera (Herod., vii. 167). The god

who demanded these victims, and especially the burning of children, seems to have been Milk, the Molech or Moloch of the Old Testament. In this connection may be mentioned the custom of burning the chief god of the city in effigy, or in the person of a human representative, at Tyre and in the Tyrian colonies, such as Carthage and Gades; the custom lasted down to a late time (see Frazer, *Adonis, Attis, Osiris*, ch. v.). Another horrible sacrifice was regularly demanded by Phoenician religion: women sacrificed their virginity at the shrines of Astarte in the belief that they thus propitiated the goddess and won her favour (*Rel. of Sem³*, 329, 611 ff.); licentious rites were the natural accompaniment of the worship of the reproductive powers of nature. These temple prostitutes are called *qedēshim qedēshōth*, *i.e.*, sacred men, women, in the Old Testament (*Deut.* xxiii. 18; *I Kings* xiv. 24, etc.). Other persons attached to a temple were priests, augurs, sacrificers, barbers, officials in charge of the curtains, masons, etc. (NSI. No. 20); we hear also of religious guilds and corporations, perhaps administrative councils, associated with the sanctuaries (*ibid.*, pp. 94, 121, 130, 144 seq.).

Mythology and Religious Ideas. — NO doubt the Phoenicians had their legends and myths to account for the origin of man and the universe; to some extent these would have resembled the ideas embodied in the book of Genesis. Two cosmogonies have come down to us which, though they differ in details are fundamentally in agreement. The one, of Sidonian origin, is preserved by Damascius (*de prim. principiis*, 125) and received at his hands a Neoplatonic interpretation; the other and more elaborate work was composed by Philo of Byblus (temp. Hadrian); he professed that he had used as his authority the writings of Sanchuniathon (*q.v.*), an ancient Phoenician sage, who again derived his information from the mysterious inscribed stones (*ἀμμουνεῖς* = *מגזיט*, *i.e.*, images or pillars of Ba'al-hammān) in the Phoenician temples. Philo's cosmogony has been preserved, at least in fragments, by Eusebius in *Praep. evang.*, vol. i. (*Fr. hist. gr.*, iii. 563 sqq.). It cannot, however, be taken seriously as an account of genuine Phoenician beliefs. At the same time Philo did not invent all the nonsense which he has handed down; he drew upon various sources, Greek and Egyptian, some of them ultimately of Babylonian origin, and incidentally, he mentions matters of interest which, when tested by other evidence, are fairly well supported. He shows at any rate that some sort of a theology existed in his day; particularly interesting is his description of the symbolic figure of Cronus with eyes before and behind and six wings open and folded (*Fr. hist. gr.*, iii. 569), a figure which is represented on the coins of Gebal-Byblus (2nd century B.C.) as the mythical founder of the city. It is evident that the gods were regarded as being intimately concerned with the lives and fortunes of their worshippers. The vast number of small votive tablets found at Carthage prove this; they were all inscribed by grateful devotees "to the lady Tanith, Face of Ba'al, and the lord Ba'al-hammān, because he heard their voice." The care which the Phoenicians bestowed upon the burial of the dead has been alluded to above; pillars (*maşşēbōth*) were set up to commemorate the dead among the living (*e.g.*, *NSI.* Nos. 18, 19, 21, 32); if there were no children to fulfil the pious duty, a monument would be set up by a man during his lifetime (*ibid.*, No. 16; cf. 2 Sam. xviii. 18). Any violation of the tomb was regarded with the greatest horror (*ibid.*, Nos. 4, 5). The grave was called a resting-place (*ibid.*, Nos. 4, 5, 16, 21), and the departed lay at rest in the underworld with the *Refāim*, the weak ones (the same word and idea in the Old Testament, *Isa.* xiv. 9, xxvi. 14, 19; *Job* xxvi. 5; *Ps.* lxxxviii. 10 etc.). The curious notion prevailed, as it did also among the Greeks and Romans, that it was possible to communicate with the gods of the underworld by dropping into a grave a small roll of lead (*tabella devotionis*, *NSI.* No. 50), inscribed with the message, generally a curse, which it was desired to convey to them.

PHOENIX, the capital and largest city of Arizona, U.S.A., and the county-seat of Maricopa county; on the Salt river, at an altitude of 1,100 ft., midway between El Paso and Los Angeles.

WEATHER GRAPH OF PHOENIX, ARIZONA. THE MERCURY INDICATES THE NORMAL ANNUAL MEAN TEMPERATURE. AND THE CURVES SHOW THE MONTHLY MAXIMUM, AVERAGE AND MINIMUM MEAN TEMPERATURES. THE BLOCK SHOWS THE POSSIBLE SUNSHINE PERCENTAGE. AND THE SHADED SPOTS INDICATE THE NORMAL MONTHLY PRECIPITATION

It is on federal highways 60, 70, 80 and 89; has a municipal airport; and is served by the Santa Fe and the Southern Pacific railways. The population was 65,414 (74% native white) by the 1940 federal census. The climate of the Salt river valley is mild, dry and clear, and Phoenix is an important health and pleasure resort. The average monthly mean temperature ranges from 51.2° F. in December to 89.8° in July; the average annual precipitation is 7.87 inches; the amount of "possible sunshine" averages 84%. It is estimated that tourists spent \$30,000,000 in the county in 1940. The city occupies 9.7 sq.mi. in a vast saucerlike valley, encircled by mountains, which is irrigated from the Roosevelt dam, 70 mi. N.E., and other projects. Cotton (largely a long-staple variety), alfalfa, lettuce, cantaloupes, grapes, citrus fruits, olives, apricots and other fruits and vegetables are leading crops. Date palms, pepper and eucalyptus trees and the magnificent saguaro cactus are features of the landscape. The state capitol, of native tufa, is set in a 10-acre park, where all the trees and shrubs indigenous to the region are represented. The Papago Saguaro park (1,940 acres) lies 3 mi. E.; 6 mi. S. is the city's mountain park of 14,000 acres; at Tempe, 8 mi. E., is a state teachers college; and the state experimental farm is near Mesa, 15 mi. S.E. Phoenix has an assessed valuation of \$71,000,000 (1940); bank deposits on June 30, 1940, were \$63,696,035; and post-office receipts for 1940 mere \$780,373. Since 1914 it has had a commission-manager form of government. Phoenix was founded in 1871, incorporated in 1881 and became the capital of Arizona in 1889. In 1890 the population was 3,152; in 1900, 5,544; in 1910, 11,134. Between 1910 and 1920 it increased 161%.

PHOENIX, a fabulous bird, sacred to the sun (Gr. Φοῖνιξ, apparently "bright-coloured"; φοῖνιξ also means "a palm-tree"). From statements in a large number of classical and post-classical authors, ranging from the 5th century B.C. (Herodotus, perhaps Hecataeus) to the Middle Ages (Isaac Tzetzes) the following account is obtained: The phoenix was a large bird of very gorgeous plumage, having, according to one or two authorities, a sweet voice. It was always male, the only one of its kind, and lived a long time (various authors give periods ranging from 500 years, the commonest account, up to 12,954; Tacitus, *Annales* vi. 28, 4, gives 1,461 years, which is an Egyptian Sothis period).

At the expiration of that time it made itself a nest of twigs of

spice-trees, on which it died, by setting the nest on fire and burning itself alive. From its body, or its ashes, or the nest, which it had fertilized, came forth another phoenix, either perfect or at first in the shape of a white grub. This young bird, as soon as it was strong enough, took up the body of its father, covered in spices, or the ashes, nest, and all, and flew to Heliopolis in Egypt, where it deposited them on the altar of the Sun. There are numerous variants in detail; sometimes the phoenix goes to Egypt to die, having produced its offspring before dying.

It was not doubted by the majority that the phoenix really was seen now and then in Egypt; Tacitus, *loc. cit.*, and Pliny, *nat. hist.*, x. 2, mention recorded appearances, genuine and otherwise. Attention is therefore drawn by A. Wiedemann to the facts that a bird of the stork kind, the *bennu* or *bannu*, was sacred at Heliopolis and connected with the local sun-worship, moreover, that its name also means a palm-tree. This certainly gives a plausible origin for some parts of the Greek story and accounts for Herodotus's statement (ii. 73, 1) that he saw a picture of it in Egypt; for the *bennu* is to be found on surviving monuments. But it fails to account for the persistent statement that the phoenix is not a native of Egypt, but lives in Arabia, Assyria, Ethiopia or India, nor does the real or pictured *bennu* at all resemble the phoenix as described. Hence it is likely that the ultimate origin of the story, however it may have reached Greece, is to be sought in the mythology of one or another of these countries.

Many commentators still understand the word חול, chol, in Job xxix. 18 (in King James's Version, "sand") to apply to the phoenix. This interpretation is perhaps as old as the (original) Septuagint, and is current with the later Jews. Among the Arabs the story of the phoenix was confused with that of the salamander; and the samand or samandal (Damiri, ii. 36 et seq.) is represented sometimes as a quadruped, sometimes as a bird. It was firmly believed in; for the incombustible cloths woven of flexible asbestos were popularly thought to be made of its hair or plumage, and were in fact, called by the same name (cf. Yaqut i. 529, and Dozy, *s.v.*). The *'anka* (Pers. *simurgh*), a stupendous bird like the roc (ruk) of Marco Polo and the *Arabian Nights*, also borrows some features of the phoenix. According to Kazwini (i. 420) it lives 1,700 years, and when a young bird is hatched the parent of opposite sex burns itself alive.

Ancient and modern authorities are collected and analysed by Türk in Roscher's *Lexikon*, iii. col. 3,450 et seq.

PHOENIX ISLANDS: see PACIFIC ISLANDS.

PHOENIXVILLE, a borough of Chester county, Pennsylvania, U.S.A., on the Schuylkill river, at the mouth of French creek, 28 m. N.W. of Philadelphia; served by the Pennsylvania and the Reading railways. Pop. (1920) 10,484 (80% native white); in 1940 it was 12,282. It has extensive iron and steel works, making steel bridges, architectural steel, boilers and many other products; also underwear, silk and silk hosiery mills. It has a large grinding-wheel industry. Phoenixville was settled in 1732 and incorporated in 1849.

PHOLIDOTA, an order of mammals, comprising only the scaly ant-eaters (Manidae) of Asia and Africa. The order was formerly united with the Xenarthra and Tubilidentata (*q.v.*) as the order Edentata (*q.v.*). (See also PANGOLIN.)

PHONETICS is the science of the pronunciation of languages. It is concerned with the mechanism by which speech-sounds are formed, the manner of combining sounds so as to make syllables, words and sentences, the treatment of speech-sounds in different languages as regards their "attributes" (length, stress and voice-pitch), the *timbre* (acoustic quality) of speech-sounds and groups of speech-sounds, the methods of representing speech-sounds by means of writing (including transcripts for language learners, spelling reform and the writing of languages hitherto unwritten).

Phonetics has two main practical objects: (1) to help learners of foreign languages to hear accurately and to pronounce accurately, and (2) to enable those who are concerned with the spelling or writing down of languages to devise the simplest and most practical system for each language.

Phonetic Analysis.—In order to effect either of these prac-

tical objects it is necessary that a "phonetic analysis" should be made of the language under consideration. The nature and mode of formation of every speech-sound of the language must be ascertained with the greatest possible accuracy; long passages of the language must then be transcribed phonetically by means of a minutely accurate system, with the object of finding out how the sounds may be grouped into "phonemes" (see p. 774). The usage of the particular language as regards the length of sounds, the stress (force-accent) of syllables and the intonation (pitch, musical accent) of words and sentences must be examined in detail. To obtain the best results, the investigations must be made by the "acoustic" method; the results may be corroborated by "experimental" methods.

Analysis by the "acoustic" method can only be carried out by an observer who is a trained phonetician, *i.e.*, a person whose ear has been trained to distinguish and recognize minute shades of sound and who has arrived at a high degree of precision in the control over the movements of his tongue and other parts of the speech-organs—who can in fact already pronounce a large number of difficult foreign sounds and sound-combinations. He must have as a collaborator a native speaker of the language to be analysed—if possible, one with natural linguistic ability. The process of investigation is as follows. The observer gets the native to repeat words and phrases of his language a very large number of times. He may find these words and phrases to be composed of sounds already known to him. If so (and if the language does not present special difficulties in the matter of length, stress or intonation), he will at once be able to repeat them to the native's satisfaction. If the native is not satisfied, it means that the word or phrase contains one or more unfamiliar sounds, or that the language contains some unusual features of length, stress or intonation. To acquire the correct pronunciation, the observer uses his power of making fine adjustments in the positions and movements of his own speech organs. He tries one variation, and then another, until he succeeds in pronouncing the word or phrase to the native's satisfaction. He then knows by his own muscular and tactile sensations what is the exact manner of formation of the unfamiliar sounds of the language. The investigator must make his native collaborator understand that nothing short of pronunciation indistinguishable from that of a native is to be accepted. When necessary, he must test his native collaborator's ear by making intentional mispronunciations. The best results are of course obtained when the observer can train the native himself in methods of phonetic research.

Experimental Methods.—Analysis of pronunciation by the acoustic method may be checked by "experimental" methods, *i.e.*, investigation by apparatus. The most important pieces of apparatus are the gramophone, the phonograph, the phonetic kymograph and the lioretograph (an instrument for enlarging the curves formed by the grooves of gramophone and phonograph records). They are particularly useful in the analysis of length and intonation. The ascertaining of the positions of the tongue and velum and of the shapes assumed by the pharyngeal cavity is facilitated by X-ray photography. Indications of tongue-positions may also be found by the use of a special kind of artificial palate.

Phonetics Applied to the Learning of Foreign Languages.—The following is a brief account of the method of using phonetics in learning a foreign language with the aid of a teacher. The task of the teacher is to make his pupil pronounce the foreign language correctly. Consequently his first aim must be to teach him to make the sounds of that language. This is done by imitation coupled with phonetic theory. Thus if the sound to be taught is the French sound of *u* in *lune*, and, as is usually the case, the English pupil is unable to make it correctly by imitation, the teacher tells the pupil to perform the following exercise, which is based on the theory of tongue and lip positions: Purse up the lips as for the English *oo*-sound, and while holding them in that position, try to pronounce the English *ee*-sound. With a very little practice the French sound of *u* will result. Again, if the pupil is to learn to make the sound *ɿ* (Zulu *hɿ*, Welsh *ɿ*), the teacher, knowing that the sound is a "voiceless l,"

tells him to keep his tongue as if he were going to say an ordinary *l* and then simply blow a strong stream of air through his mouth; this will give a good approximation to the sound, and it can be perfected by a knowledge of the details of the formation of *l*-sounds. If the pupil is to learn to make the German sound of *ch* in *recht*, the teacher, knowing that its tongue-position is almost identical with that of the English *ee*-sound, tells him to keep his tongue as if he were going to say the English *ee*-sound and then merely to blow out a stream of air. If he is to learn to make the Polish sound of *ć* or Pekinese sound written *hs*, the teacher tells him to try to make this German sound and *s* simultaneously, knowing that the attempt to do this will give the right tongue-position. The methods used in the above cases are very simple; in more difficult cases it is often necessary to try several methods before one is found which will enable the pupil to produce the correct sound.

Ear-training.—One of the most important parts of any course of instruction in phonetics consists of "ear-training" or more accurately "cultivation of the auditory memory." The pupil must learn (1) to *discriminate* between one foreign sound and another which on a first hearing may seem to resemble it; (2) to discriminate between foreign sounds and sounds of the mother tongue which resemble them; (3) to remember the acoustic qualities of foreign sounds; (4) to *recognize* foreign sounds with ease and certainty. There is only one method of training the auditory memory, namely "nonsense dictation." The teacher dictates meaningless words made up of sounds of the language to be learnt. The pupil writes what he thinks he hears by means of a phonetic system; then the teacher can see from the transcript whether the pupil has recognized the foreign sounds correctly. When the pupil makes a mistake, the teacher repeats the meaningless word firstly as he originally said it and then in the way written by the pupil; he repeats the two pronunciations a number of times so that the pupil may hear clearly the nature of his mistake. The pupil's course of study should include a large amount of this type of exercise carefully graduated. Thus if the pupil is learning the pronunciation of French, the earlier ear-training exercises would contain easy words such as the following: *petoze*, *vɔʃɛnɛt*, *fakɔna*, *sogɛʒib*. The exercises become progressively more difficult until words are given such as: *pfestriɔʒnwebm*, *uidznezmcɛrlɔ*, *bɑʒvələləʃkeɛ*. (The system of transcription used here and elsewhere in this article is that of the International *Phonetic Association*.) Later on, the exercises are made still more difficult by the introduction of sounds of the pupil's mother tongue.

Phonetic Transcription.—Besides being able to hear the foreign sounds correctly and to make them correctly the pupil must know which are the appropriate sounds to use in words and sentences. This information is best conveyed to him by means of a phonetic notation, *i.e.*, by spelling the words and sentences with an alphabet which provides one letter for each phoneme (see p. 774) of the language. (In certain cases, in order to avoid introducing additional symbols, it is convenient to represent a sound by means of a digraph, *i.e.*, a sequence of two letters; thus the sounds of German *z* and English *ch* are commonly transcribed *ts*, *tʃ*.) The pupil's course of study should therefore include reading from phonetic texts and writing passages of the language phonetically as exercises to be corrected by the teacher. The pupil must also be instructed in the use made of length, stress and intonation in the foreign language. These features of the language should be marked as far as practicable in the phonetic transcriptions.

When the learner is unable to find a phonetically trained teacher of the language, he should make himself familiar with the principles of general phonetics, and thus learn to analyse his instructor's speech and reproduce it accurately. If there exists a good book on the phonetics of the language, he should be able to pronounce intelligibly with its aid. Good gramophone records may also be of considerable assistance.

Phonetics Applied to the Teaching of the Mother Tongue.—The "received" form of a language is a kind of foreign language to those who speak dialects or speak with special "accents." The

methods of teaching "received" pronunciation are therefore similar to those followed in teaching a foreign language. Some of the sounds of "received" pronunciation will be new to the pupil, and must be taught by means of exercises which his phonetically trained teacher invents to suit his particular needs. His natural pronunciation may also differ from "received" pronunciation in other respects, and particularly by the use of a different distribution of known sounds, as when a Londoner makes the last syllable of opposite rhyme with might, or when a native of Lancashire gives to the *u* in butcher the same value as it has in cut. Here phonetic transcriptions are useful for showing the difference of sound.

Phonemes.—When the sounds existing in a given language have been analysed, it is always found that some of them may be regarded as variants of others, which they replace in certain well-defined conditions. A family consisting of one distinctive sound of the language together with the variants which represent it in particular sound-combinations is called a "phoneme." The nature of a phoneme is best shown by examples. The three *k*'s in keep, cool, cot are different sounds, but for practical purposes they may be treated as a single entity; they are said to belong to the same phoneme. The precise *k*-sound used in any particular case is determined by the nature of the neighbouring sounds, and the different varieties are not used for the purpose of distinguishing English words. Similarly the three *t*-sounds in eight, eighth, train belong to one phoneme, because the variants in *eighth* (phonetically *ɛtθ*), train, are dependent upon the neighbouring sounds *θ*, *r*. The French sounds *l̥* and *l̥̥* (voiceless *l*) are members of the same phoneme. *l̥̥* is used in French only in final position when a consonant precedes, as when the word *boucle* occurs at the end of a sentence; ordinary voiced *l* does not occur in this position, and consequently a Frenchman naturally regards the two very dissimilar sounds *l̥* and *l̥̥* as a single entity.

It often happens that sounds which belong to one phoneme in one language constitute separate phonemes in another language; they are consequently used for the purpose of distinguishing words in the second language though not in the first. Thus *l̥* and *l̥̥* are separate phonemes in Welsh, Burmese and Zulu, though they constitute only one phoneme in French (*l̥̥* is transcribed *l̥̥* when it is a separate phoneme). Again *h* and *ç* (the German *ich*-sound) are separate phonemes in German, but *ç* is a member of the *h*-phoneme in Japanese (the sound used when *j* follows). The French sounds of *è* and *é* are separate phonemes in French and are used for distinguishing words in that language; but similar sounds occur in Russian and in Zulu as members of one phoneme, their use being determined in Russian by the nature of the adjacent consonants and in Zulu by a principle of vowel-harmony.

Phonemes are families of sounds occurring in a language as pronounced by a single individual. They must be distinguished from diaphones (see below) which contain sounds used by two or more different speakers of a language.

The simplest system of phonetic transcription of a language is that which provides one symbol for each phoneme of that language. Such a system is known as "broad" transcription. It is unambiguous to the native and to anyone who knows the rules governing the use of the subsidiary members of the phonemes. More detailed transcriptions, providing symbols for subsidiary members of phonemes, are called "narrow" transcriptions. They are useful in comparative work, dialectology, etc.

Diaphones.—Speakers of the same language often do not all use exactly the same sounds. Thus the vowel element of the word *day* is pronounced in several different ways according to the locality and to the social position of the speaker (phonetically *deː*, *deɪ*, *dɛɪ*, *dee*, *dæɪ*, etc.). In such cases it is convenient to have a term to denote the family of sounds consisting of a sound of a language as pronounced by an "average" speaker together with other sounds which are used in place of it by other speakers. Thus the various vowel sounds used in the word *day* by different speakers of English are said to constitute one diaphone in the English language.

Phonetic Symbols.—In nearly every language the number of phonemes is greater than the number of letters in the Roman

alphabet. It is therefore impossible to represent most languages unambiguously by means of the ordinary Roman letters only. So any roman phonetic system, whether designed as a current orthography or as a transcription for the use of language learners, must contain new letters to supplement those of the present Roman alphabet. It can be shown that, on psychological, typographical and pedagogical grounds, specially designed letters are better than ordinary Roman letters with diacritical marks attached. In the designing of new letters several factors have to be taken into consideration, the chief of which is that the printed forms of the letters should harmonize as well as possible with the ordinary Roman characters, so that the general appearance of the printed page may be satisfactory. It must also be possible to write the new letters with ease. It is further desirable that the letters should have italic forms which do not differ from the Roman forms in an essential part of their outline. To ensure legibility it is necessary that each letter should be as different as possible from every other letter. For typographical reasons the letters should, as far as possible, be designed so as to avoid the necessity of kerned types. Kerns at the top or bottom of the type are entirely inadmissible. Kerns at the side are undesirable and must be resorted to as sparingly as possible; but it does not seem possible in a comprehensive alphabet to avoid them altogether. Lastly, it is a great advantage that the phonetic alphabet as a whole should be international, that is to say that each letter should always be used with the same or approximately the same value.

Of the phonetic alphabets hitherto invented only one, that of the International Phonetic Association, complies satisfactorily with the above-mentioned requirements. The next best is the Swedish dialect alphabet (which, in spite of its name, is really international).

Manner of Using a Phonetic Alphabet.—In constructing phonetic orthographies, or in making phonetic transcripts for

FIG. 1.—DIAGRAM ILLUSTRATING ORGANS OF SPEECH

FIG. 2.—TONGUE-POSITIONS OF THE FRONT CARDINAL VOWELS

FIG. 3.—TONGUE-POSITIONS OF THE BACK CARDINAL VOWELS

language students, attention must be given not only to the designs of any special letters that may be required, but also to the manner of using the alphabet. This will depend (1) on the precise purpose for which the alphabet is required, and (2) on the structure of the particular language or languages dealt with. Thus if the writer's purpose is to make a comparative study of related languages he may be obliged to mark distinctions which it would be unnecessary to mark in a transcript of one language for the use of those who wish to learn to speak it.

THE INTERNATIONAL PHONETIC ALPHABET.

		Bi-labial	Labio-dental	Dental and Alveolar	Retroflex	Palato-alveolar	Alveolo-palatal	Palatal	Velar	Uvular	Pharyngeal	Glottal
CONSONANTS	Plosive	p b		t d	ʈ ɖ			c ɟ	k ɡ	q ɢ		ʔ
	Nasal	m	ɱ	n	ɳ			ɲ	ŋ	ɴ		
	Lateral Fricative			ɬ ɮ								
	Lateral Non-fricative			l	ɭ			ʎ				
	Rolled			r						ʀ		
	Flapped			ɾ	ɽ						ʀ	
	Fricative	ɸ β	f v	θ ð	s z	ʃ ʒ	ʃ ʒ	ʃ ʒ	ç ʝ	x ɣ	χ ʁ	ħ ʕ
Frictionless Continuants and Semi-vowels	w ɥ	ʋ		ɹ				j (ɥ)	(w)	ʁ		
VOWELS	Close	(y u u)						Front i y	Central ɨ u	Back ɯ u		
	Half-close	(ɻ u)						ɪ ʏ		ʊ		
	Half-open	(æ ɔ)						e ø	ə	ɤ ɔ		
	Open	(ɑ)						ɛ œ	æ	ɶ	ʌ ɔ	

(Secondary articulations are shown by symbols in brackets.)

OTHER SOUNDS.—Palatalized consonants: ɸ, ɟ, etc. Velarized or pharyngealized consonants: ɰ, ɠ, ɢ, etc. Ejective consonants (plosives with simultaneous glottal stop): p', t', etc. Implosive voiced consonants: ɓ, ɗ, etc. ɮ fricative trill. ɠ, ɢ (labialized ɸ, ɟ, or s, z). ɰ, ɠ (labialized ʃ, ʒ). ɰ, ɠ, ɢ (clicks, Zulu c, q, x). ɰ (a sound between r and l). ʎ (voiceless w). ɤ (a vowel between ø and o). Affricates are normally represented by groups of two consonants (ts, tʃ, dʒ, etc.), but, when necessary, ligatures are used (ɸ, ɟ, ɠ, etc.), or the marks ˘ or ˙ (ts or tʃ, etc.). ɠ, ɢ may occasionally be used in place of tʃ, dʒ. Aspirated plosives: ph, th, etc.

LENGTH, STRESS, PITCH.—: (full length). ˘ (half length). ˈ (stress, placed at beginning of the stressed syllable). ˉ (secondary stress), ˊ (high level pitch); ˋ (low level); ˊ (high rising); ˋ (low rising); ˊ (high falling); ˋ (low falling); ˊˋ (rise-fall); ˋˊ (fall-rise). See *Écriture Phonétique Internationale*, p. 9.

MODIFIERS.—˜ nasality. ˚ breath (ɰ = breathed l) ˚ voice (ɠ = z). ˚ slight aspiration following p, t, etc. ˚ specially close vowel (ɤ = a very close e). ˚, specially open vowel (ɶ = a rather open e). ˚ labialization ɱ = labialized n). ˚ dental articulation (ɰ = dental t). ˚ palatalization (z = ʒ). ˚ tongue slightly raised. ˚ tongue slightly lowered. ˚ lips more rounded. ˚ lips more spread. (e.g. ɱ) syllabic consonant. ˚ consonantal vowel. ɰ variety of ʃ resembling s, etc.

Classification of Speech-sounds.—The above table of the International Phonetic symbols taken in conjunction with the chart of the organs of speech (fig. 1) shows the chief principles of sound classification. The meanings of most of the technical terms describing the various classes of sounds are self-evident. Attention may, however, be called to the following, which require some explanation. The "back" of the tongue is the part which lies normally opposite the soft palate (velum); the "front" is the part which lies normally opposite the "hard" palate; the "blade" is the part which lies normally opposite the teeth-ridge (upper gum, alveolars). "Palatal" consonants are those formed by the "front" of the tongue against the hard palate, such as the English sound of y or the German *ch* in *ich*. "Retroflex" consonants are those made by the tip of the tongue against the hard palate such as the Hindi sounds of ɰ ɠ.

Classification of Vowels.—Vowels are classified (1) according to the position of the tongue, and (2) according to the position of the lips. In forming a vowel the opening between the lips and the distance of the tongue from the palate must be sufficient to ensure that there is no audible friction when voice is emitted. The lips may be spread (as for the English *ee*-sound) or they may have "close" rounding (as in the sound of *u* in *rule*) or "open" rounding (as in the vowel in *long*). The classification of vowels according to tongue positions and the terminology employed in describing vowels is shown in figs. 2, 3 and 4. The relative tongue-positions of vowels may be indicated by dots placed on the vowel figure (fig. 4).

Cardinal Vowels.—In order to give an intelligible description of the vowels of any language, it has been found necessary to establish a system of cardinal vowels. These are the vowels

marked by the large black dots in fig. 4. The eight primary cardinal vowels are represented by the letters i, e, ε, a, ɑ, ɔ, o, u; these are numbered 1 to 8 respectively. Eight secondary cardinal vowels are represented by y, ø, œ, ɶ, ɷ, ʌ, ɤ, ɯ (numbered 9 to 16 respectively). (No letter has been adopted for secondary cardinal vowel No. 12, as it has not been found to exist as a separate phoneme in any language.) They have the same tongue-positions as the primary cardinal vowels, but different lip-positions. Nos. 9 to 13 have lip-rounding, and Nos. 14, 15, 16 have lip-spreading. The tongue-positions of any vowel may be represented by a dot at the appropriate place on the cardinal vowel chart. This marking, together with a description of the lip-position, shows the language learner exactly how the vowel is formed, and gives him a good idea of what it sounds like. Thus a foreign learner who has never heard English can learn to make the vowel of *cat* when he knows that it is half way between cardinal vowels 3 and 4 (ε and a). An Englishman learning Italian without a teacher can get a good idea of what the Italian vowels sound like from a diagram (fig. 5) which shows the relationship of the Italian vowels to the cardinal vowels.

In transcribing particular languages, the cardinal vowel letters are used to represent sounds in the vicinity of the cardinal vowel sounds. The letters, in fact, serve to represent vowels lying within certain areas on the vowel figure as shown in fig. 2. In the comparatively unusual cases when two vowel-sounds within the same cardinal area are used for the purpose of distinguishing words additional vowel-letters have to be introduced. Such are ɰ (used for the English vowel in *sit*), ɥ (used for the English vowel in *put*), ɰ (used for the German vowel in *Glück*). æ is commonly used for the vowel in *cat*, which lies in the left upper

corner of the a-area, though there is no objection to using a for it except in comparative work. Symbols are also required for

vowels. The most important is ə which represents the "neutral" or "intermediate" sound of a in *along*. Others are ɪ, ʉ, which represent unrounded and rounded vowels with tongue-positions intermediate between those of i and u; ɨ is the Russian ɨ and u is heard in the Norwegian *hus* and in a frequent Scottish pronunciation of *book*. The vowel in the London pronunciation of *bird* is represented by ɜ or by a with a length mark (a:).

Intonation.—An important branch of phonetics is that which deals with intonation or the rise and fall in the musical pitch of the voice. In the languages called "tone languages" (e.g., Chinese and most Sudanic and Bantu languages) intonation is used to distinguish one word from another. Thus in Cantonese the syllable *fan* said with a high falling tone means "divide"; said with five other tones it means "powder," "sleep," "burn," "courageous" and "duty" respectively. In the Sechuana language of South Africa *metse* said with a mid level tone on each syllable means "villages," but with a mid-level tone on the first syllable and a high level tone on the second it means "water."

Such tones are best indicated in phonetic transcription by accent marks which by their shapes and positions give a certain graphic representation of the musical values of the tones, thus:—high level tone \bar{a} , low level tone \underline{a} , high falling tone \hat{a} , low falling tone \grave{a} , high rising tone \acute{a} , low rising tone \grave{a} , fall-rise \tilde{a} , rise-fall \tilde{a} , etc. It is sometimes convenient to place the tone-marks before the syllable.

In languages which are not "tone languages" intonation affects the meaning of whole sentences, but it is not an integral part of any word. Intonation then gives "expression" to sentences; it conveys shades of meaning which cannot conveniently be expressed by other means. Thus in English the two meanings of *I beg your pardon* ("I am sorry" and "What did you say?") are distinguished by intonation. It is not practicable to mark this kind of intonation in orthography, though slight indications of it may be given by punctuation marks, the use of italics, etc.

PHONOGRAPH, an instrument for reproducing sound by transmitting to the air the mechanical vibrations of a stylus in contact with a sinuous groove in a moving record. Less specifically the term designates any instrument for recording and reproducing speech. The first audible reproduction of recorded sound was accomplished by Thomas A. Edison in 1877.

The history of most of the technical arts shows that their development takes place irregularly. The introduction of fundamentally new ideas introduces periods of very rapid advance. These periods are followed by intervals during which the development appears much slower and is concerned mainly with the refinement of methods and the adaptation of the new results to commercial processes. The phonographic art is no exception.

Since the last big advance which became commercially prominent in 1925, the improvements have been largely an adaptation of the tools provided, to the production of artistic and commercially valuable results. The tools which were made available by this last advance are completely described under the heading GRAMOPHONE. The major portion of the improvement introduced has dealt with the co-ordination of the results obtainable with the new equipment and the production of a proper artistic effect. As might be expected, this has dealt mainly with the study of the proper acoustic conditions in the space in which the sound is produced.

The early recording by the new process was done largely in small rooms in which the acoustics were well controlled. It was soon found that the acoustic properties of small rooms were totally unsuited to the proper artistic effect when dealing with those types of music which are usually produced in large auditoriums or theatres. A large amount of experimenting was, therefore, done, which showed definitely that the best way to record symphony orchestras, choruses, opera selections, etc., was to place the artists in a small theatre or auditorium, and to arrange them in much the way that they would be arranged were an audience present.

The early experiments indicated two major difficulties with this type of arrangement. First, there appeared to be excessive reverberation; and, secondly, it was difficult to find a situation for the microphone or pick-up device at which interference was

not present in certain frequency regions. (That is, at certain parts of the musical scale.)

It was found by experiment that the time of reverberation, as in small studios, should be approximately .7 to .8 of that required for audience listening. Also, it was found that the portion of the space in which the sound is produced should have surfaces of more reflecting ability than the average indicated for the auditorium, while the space in which the microphone or pick-up device is situated should be as dead or well damped as possible.

In the field of phonograph reproduction, there have been no major developments within the last few years. The trend of the improvements introduced has been towards the use of electric methods rather than mechanical. The wide range of both frequency and loudness, which can be obtained by the use of electric methods and the simplicity with which the loudness can be controlled, is probably mainly responsible for this trend. While for small, low-priced instruments, it is still possible to obtain more faithful reproduction with the mechanical machines, the improvements in the electric methods of reproduction have caused this method to take precedence in the higher priced field.

PHONOLITE, in petrology, a group of alkaline lavas containing much nepheline and sanidine feldspar (Gr. *φωνή*, sound, and

Small rounded enclosures of glass are often numerous in them. The pyroxenes may be pale green diopside, dark green aegirine-augite, or blackish green aegirine (soda iron pyroxene), and in many cases are complex, the outer portions being aegirine while the centre is diopside. Fine needles of aegirine are often found in the ground-mass.

The chemical analyses of phonolites given herewith show that they are very rich in alkalis and alumina with only a moderate amount of silica, while lime, magnesia and iron oxides are present only in small quantity. They have a close resemblance in these respects to the nepheline-syenites of which they provide the effusive types. Most of these rocks are of Tertiary or Recent age, but in Scotland Carboniferous phonolites occur in several localities, e.g., Traprain in Haddingtonshire, in the Eildon Hills and in Renfrewshire; in Brazil phonolites belonging to the same epoch are also known and there are several districts in Europe where Tertiary or Recent phonolites occur in considerable numbers, as in Auvergne (Mont Dore), the Eifel and Bohemia. The Wolf Rock, off the S. of Cornwall and the site of a well-known lighthouse, is the only mass of phonolite in England; it is supposed to be the remains of a Tertiary lava or intrusion. In the United States phonolites occur in Colorado (at Cripple Creek) and in the Black Hills of South Dakota.

Leucite occurs in place of nepheline in a small group of phonolites (the leucite-phonolites), known principally from Rocca Monfina and other places near Naples. When sanidine, nepheline and leucite all occur together in a volcanic rock it is classed among the leucitophyres (see PETROLOGY).

PHORMION, Athenian admiral in the 5th century B.C., was the son of Asopius, of the deme Paeania. He first appears in 440 B.C. when he was sent with reinforcements to the Athenian troops

λίθος, stone). The term "clinkstone" was formerly given by geologists to many fine-grained compact lavas, which split into thin tough plates, and gave out a ringing sound when struck with the hammer. Some of these were phonolites in the modern sense, but as the name clinkstone was used for a large variety of rocks, many of which have no close affinities with one another, it has been discarded and "phonolite" substituted. The group includes rocks which are rich in alkalis with only a moderate percentage of silica; hence they contain no free quartz but much alkali-feldspar (sanidine and anorthoclase) and nepheline. Large plates of sanidine are often visible in the rocks; the nepheline is usually not obvious to the unaided eye. Most phonolites show fluxion structure, both in the orientation of their phenocrysts and in the smaller crystals which make up the ground-mass; and this determines to a large extent the platy jointing. Although vitreous and pumiceous forms are known they are rare, and in the great majority of cases these rocks are finely crystalline with a dull or shimmering lustre in the ground-mass.

Dominant Minerals.—These are sanidine, nepheline, pyroxene, amphibole, various feldspaths and iron oxides. The sanidine is usually in two generations, the first consisting of large crystals of flattened and tabular shape, while the second is represented by small rectangular prisms arranged in parallel streams in the ground-mass; these feldspars are nearly always simply twinned on the Carlsbad plan. They contain often as much soda as potash. The nepheline takes the form of hexagonal prisms with flat ends, and may be completely replaced by fibrous zeolites, so that it can only be recognized by the outlines of its pseudomorphs. In some phonolites it is exceedingly abundant in the ground-mass, and these rocks form transitions to the nephelinites (nephelinitoid phonolites); in others it is scarce and the rocks resemble trachytes containing a little nepheline (trachtyoid phonolites). The feldspathoid minerals, sodalite, hainyene and nosean, which crystallize in isometric dodecahedra, are very frequent components of the phonolites; their crystals are often corroded

before Samos. In 432 he took out reinforcements to the force blockading Potidaea, took over the command from Callias, and completed the circumvallation of the city. He seems to have stayed in the north-east, as in 431 he was co-operating with Perdiccas against the Chalcidians. In 430 he was sent with 30 ships to help the Acarnanians against the Ambraciots. That winter there followed the operations on which his fame is based. He was given 20 ships and stationed at Naupactus, to effect a blockade of Corinth from that side. In the summer of 429 a superior Peloponnesian fleet arrived, and was decisively beaten by Phormion. In a second engagement he was forced to retreat, but turned and again routed his pursuers. He was probably dead by 428.

PHORMIUM or **NEW ZEALAND FLAX** (also termed New Zealand hemp). The plant (*Phormium tenax*) is a perennial of the Liliaceae family and is propagated either by rhizomes or by seed. While termed "New Zealand flax" and also "New Zealand hemp," the plant has no relationship to either flax (*Linum usitatissimum*) or hemp (*Cannabis sativa*). Phormium is a native of New Zealand and, while known to be adapted in many other countries, is not commonly grown for commercial fibre production in any country other than New Zealand.

The thick sword-shaped leaves grow in tufts from the tips of the rhizomes and reach a length of 4 to 6 ft. The flowering stem, which also starts from the tip of the rhizome, grows out through the centre of the tuft of leaves and reaches a height of 5 to 1 1/2 ft. The flowers are usually cross-pollinated though some selfing occurs. The parts above ground die soon after the flowering stage, but the plant continues to live from year to year by new growth from the short, thick underground stems (rhizomes).

Much of the phormium fibre of commerce has come from harvesting the volunteer growth, but considerable quantities have been obtained from cultivated fields. The crop is adapted to a wide range of New Zealand soils, but the greatest yields have

been obtained from well-drained swamp lands.

The plant is grown principally for the fibre which develops in the leaves, and which is separated from the non-fibrous tissues by a process of scraping and washing.

This processing is done in fibre mills by means of special machines designed for the purpose.

The cleaned, dried fibre is arranged in hands ("heads") and then packed in bales, in which form it is exported. The fibre is similar in appearance to such other leaf fibres as abaca (Manila hemp), henequen (Yucatan sisal) and "true" sisal. Its principal use has been for twines and ropes.

(A. H. Wt.)

PHORONIS. *Phoronis* is one of those limbless creatures popularly termed "worms." It is, however, so peculiar in its structure that it is given a class to itself, Phoronidea. There are a good many species found all over the world, but they are so alike that they are placed in a single genus *Phoronis*, although they vary from $\frac{1}{4}$ in. to 6 in. in length. *Phoronis* is marine and lives in a leathery tube from which the fore-part of the body can be protruded. The front part carries a peculiar platform or "lophophore," crowned with beautiful upright tentacles covered with cilia which are in perpetual motion. In *P. hippocrepia* the lophophore is shaped like a horse-shoe and the tentacles are arranged along its edge, those on the concavity of the shoe being somewhat the shorter. All species have lophophores more or less of this shape but the tips of the shoe are in some much more prolonged than in others and even inrolled. The cilia produce a current which sweeps small organisms into the mouth, situated between the outer and inner row of tentacles. It is elongated and slit-like and provided with a covering lip, the epistome, which projects from the concave side of the lophophore. Below the lophophore, on the side of the concavity of the horseshoe, the anus projects as a little papilla. At the sides of the anus two smaller papillae carry the openings of a pair of ciliated tubes which connect the body-cavity with the exterior. These tubes (*coelomoducts*) serve to get rid of the excreta in the body-cavity fluid and to let out the germ-cells when these are ripe.

Since the mouth and anus are close together and the animal has a long worm-like body, it is obvious that the alimentary tube will be U-shaped. The long gullet leads into a globular stomach lying at the lower end of the body, from which the long, slender, ascending intestine leads to the anus. The first part of the intestine where it leaves the stomach is swollen, lined by ciliated epithelium and devoid of glands. The alimentary tube is ensnathed by a true secondary body-cavity or coelom, which is lined by an epithelium the outer layer of which is pressed against the body-wall whilst the inner layer lies against the gut cells. This cavity is divided into two by a horizontal platform just behind the mouth. The front portion communicates with the cavities of the tentacles and of the epistome. This is the lophophoral coelom: the hinder portion, in which the gullet and intestine lie, and into which the coelomoducts open, is the trunk-coelom and is traversed by a median septum or mesentery which ties the outer side of the oesophagus to the body wall: in addition, the oesophagus is anchored by two lateral mesenteries. These mesenteries, however, cease before the stomach is reached. The genital cells appear as thickenings of the inner wall of the coelom and both male and female are produced by the same individual in separate swellings, projecting from the wall of the stomach. The trunk coelom is thus divided into three chambers, a right and left lateral on the convex side of the lophophore and a large rectal chamber on the concave side. In this latter lies the intestine, which is tied to the body wall by its own independent mesentery and is also fused by its side to one of the lateral mesenteries.

Each "coelomoduct" opens into the body-cavity by two funnel-shaped openings lined by cilia, a short one communicating with the lateral chamber and a long slit-like one opening into the rectal chamber.

The nervous system is simple, consisting merely of an interlacing mass of extremely fine fibrils and small nerve-cells which thickens to form a horizontal band passing around the lophophore and giving off a special branch to each tentacle. There is also a thickening in the skin of the epistome.

The life of *Phoronis* consists merely in expanding the front of the body, erecting the tentacles and working the cilia vigorously; the mouth being opened wide to catch whatever fortune brings. On the approach of danger the whole body is withdrawn within the tube. This is effected by bands of longitudinal muscles in the body-wall—the expansion being brought about by circular muscles, which by compressing the body force fluid into the lophophore and engorge it.

The interest of *Phoronis* lies in its strong resemblance to certain *Polyzoa* (*q.v.*). Lankester went so far as to call *Phoronis* the only solitary polyzoan. But *Phoronis* possesses, distinct altogether from the body-cavity, a well-developed blood-system, containing a colourless serum in which float red blood corpuscles. No such organ is found in any polyzoan. This blood-system consists of an "artery" running on the anal side of the gullet to the level of the lophophore where it gives off right and left a vessel to each arm of the lophophore. From these a single vessel goes to each tentacle. This vessel at the base of the tentacle sends a fork to an outer or recipient vessel, which runs along the convex side of the lophophore on each side. The right and left recipient vessels pass downwards, pierce the lophophoral platform and unite on the convex side of the oesophagus to form a single "vein" which below the stomach opens into the artery.

The reproduction raises other questions. The eggs, after being shed, stick to the tentacles and are there fertilized by sperms from another individual. They complete the first stages of their development within the egg-membrane, from which they hatch out as peculiar free-swimming larvae known as *Actinotrocha*. This larva is provided with a ciliated forehead in which a large ganglion is embedded. There is an oblique wreath of ciliated tentacles behind the mouth by which it swims. There is a belt of cilia round the hind end of the body in front of the anus. This larva after feeding for a time and growing greatly in size, develops an intucking of skin on its under-surface, to which a fold of the intestine becomes attached. Suddenly (inside a quarter of an hour) this intucked area is everted, forming a finger-shaped process containing a loop of the intestine which gives rise to the body of the "worm." The ciliated forehead is cast off, as are also the ciliated tentacles, but new tentacles which give rise to the lophophore of the adult are regenerated from their stumps. This larva with its extraordinary life-history has given rise to much speculation. We owe the clearing up of its real affinities to E. S. Goodrich and Shearer, who have shown that *Actinotrocha* is merely a modified trochophore, such as occurs in the life-history of the Gephyrea amongst the Annelida (*q.v.*). The typical trochophore has a broad preoral belt of cilia, the *prototroch*, and a slender postoral one, the *metatroch*, whilst a belt of cilia, the *telotroch*, encircles just in front of the anus.

(E. W. MacB.)

PHORORHACOS, a gigantic extinct Patagonian bird, allied to the Cranes and in some respects recalling the South American *Cariama* bird. About six species of the type genus have been discovered, the most complete being *P. inflatus*, with

BY COURTESY OF THE BRITISH MUSEUM

THE SKULL OF PHORORHACOS LONGISSIMUS, AN EXTINCT BIRD OF PREY

skull, mandible, pelvis, limbs and some of the vertebrae. The skull of *P. longissimus* is about aft. long and 10in. high; that of *P. inflatus* is 13in. long, and this creature is supposed to have stood only 3ft. high at the middle of the back. The under jaw is slightly curved upwards. The strongly hooked upper beak is high, and laterally compressed. The vomer is inconspicuous. The quadrate has a double knob for articulation with the skull, and basipterygoid processes are absent. What little is known of the shoulder-girdle points to a flightless bird, and so do the short wing bones, although these are stout. The pelvis has an ischiadic foramen. The hind limbs are distinctly slender, the tibia of *P. inflatus* being between 15 and 16in. in length.

PHOSGENE or **CARBONYL CHLORIDE**, an extremely poisonous, heavy gas, came into prominence during the

World War (1914–IS), being used either alone or in mixtures both for cloud-gas and shell-gas attacks. It has a nauseating, choking smell, and, even in very small doses has very bad after-effects on the heart and lungs. Phosgene owes its name to the fact that it can be formed by exposing carbon monoxide and chlorine to sunlight ($\text{CO} + \text{Cl}_2 = \text{COCl}_2$), but it is now manufactured by passing the two gases over specially prepared charcoal catalyst (see CATALYSIS). Phosgene can be condensed to a liquid which boils at 8°C under ordinary pressure; it is stored either in steel cylinders under slight pressure or as a solution in toluene. It is very reactive chemically and is used in the dyestuff industry for the manufacture of intermediates. It also reacts rapidly with water to give carbon dioxide and hydrogen chloride (hydrochloric acid): $\text{COCl}_2 + \text{H}_2\text{O} = \text{CO}_2 + \text{HCl}$. (See also CARBON.)

PHOSGENITE, a rare mineral consisting of lead chlorocarbonate $(\text{PbCl})_2\text{CO}_3$. The tetragonal crystals are prismatic or tabular in habit, and are bounded by smooth, bright faces; they are usually colourless and transparent, and have a brilliant adamantine lustre. Sometimes the crystals have a curious helical twist about the tetrad or principal axis. The hardness is 3 and the specific gravity 6.3. The mineral is rather sectile, and consequently was early known as "corneous lead." The fanciful name phosgenite is from phosgene, the old name of carbon oxychloride, because the mineral contains the elements carbon, oxygen and chlorine. At Cromford in Derbyshire it was long ago found in an old lead mine, being associated with anglesite and matlockite $(\text{Pb}_2\text{OCl}_2)$ in cavities in decomposed galena; hence its synonym cromfordite.

PHOSPHATES, salts of phosphoric acid. Phosphoric oxide, P_2O_5 or P_4O_{10} (Tilden and Barnett, *v. inf.*), combines with water in three proportions to form $\text{H}_2\text{O} \cdot \text{P}_2\text{O}_5$ or HPO_3 , metaphosphoric acid; $2\text{H}_2\text{O} \cdot \text{P}_2\text{O}_5$ or $\text{H}_4\text{P}_2\text{O}_7$, pyrophosphoric acid; and $3\text{H}_2\text{O} \cdot \text{P}_2\text{O}_5$ or H_3PO_4 , orthophosphoric or ordinary phosphoric acid. These acids each give origin to several series of salts, those of ordinary phosphoric acid being the most important.

Orthophosphoric acid, H_3PO_4 , a tribasic acid, is obtained by boiling a solution of the pentoxide in water; by oxidizing red phosphorus with nitric acid, or white phosphorus under the surface of water by bromine or iodine; and also by decomposing a mineral phosphate with sulphuric acid. It usually forms a thin syrup which on concentration in a vacuum over sulphuric acid deposits hard, transparent, rhombic prisms which melt at 41.7°C . After long heating the syrup is partially converted into pyrophosphoric and metaphosphoric acids, but on addition of water and boiling the ortho-acid is re-formed. It gives origin to three classes of salts: $\text{M}'\text{H}_2\text{PO}_4$ or $\text{M}''(\text{H}_2\text{PO}_4)_2$; $\text{M}'_2\text{HPO}_4$ or $\text{M}''\text{HPO}_4$; and $\text{M}'_3\text{PO}_4$, $\text{M}''_3(\text{PO}_4)_2$ or $\text{M}''' \text{PO}_4$, wherein M' , M'' , M''' denote a uni-, bi-, and tri-valent metal. These correspond to H_3PO_4 in which one, two or three atoms of hydrogen, respectively, have been replaced by a metal. The three principal groups differ remarkably in their behaviour towards indicators. Those of the first type are strongly acid, the second are neutral or faintly alkaline, whilst the third are strongly alkaline and are decomposed by carbon dioxide: $\text{Na}_3\text{PO}_4 + \text{CO}_2 + \text{H}_2\text{O} = \text{NaHCO}_3 + \text{Na}_2\text{HPO}_4$. The salts of the types NaH_2PO_4 and $\text{CaH}_4\text{P}_2\text{O}_8$ may be obtained in crystal form, but those of the heavy metals are only stable when in solution. All soluble orthophosphates give with silver nitrate a characteristic yellow precipitate of silver phosphate, Ag_3PO_4 , soluble in ammonia and in nitric acid. Since the reaction with the acid salts is attended by liberation of nitric acid: $\text{NaH}_2\text{PO}_4 + 3\text{AgNO}_3 = \text{Ag}_3\text{PO}_4 + \text{NaNO}_3 + 2\text{HNO}_3$, $\text{Na}_2\text{HPO}_4 + 3\text{AgNO}_3 = \text{Ag}_3\text{PO}_4 + 2\text{NaNO}_3 + \text{HNO}_3$, it is necessary to neutralize the nitric acid if the complete precipitation of the phosphoric acid be desired. The three series also differ when heated: the trimetallic salts containing fixed bases are unaltered, whilst the mono- and di-metallic salts yield meta- and pyro-phosphates respectively. Other common precipitants of phosphoric acid or its salts in solution are: ammonium molybdate in nitric acid, which gives on heating a canary-yellow precipitate of ammonium phosphomolybdate, $12[\text{MoO}_3](\text{NH}_4)_3\text{PO}_4$, insoluble in acids but readily soluble in ammonia; magnesium chloride, ammonium chloride and ammonia, which give on standing in a warm place a white crystalline

precipitate of magnesium ammonium phosphate, $\text{Mg}(\text{NH}_4)\text{PO}_4 \cdot 6\text{H}_2\text{O}$, which is soluble in acids but highly insoluble in ammonia solutions, and on heating to redness gives magnesium pyrophosphate, $\text{Mg}_2\text{P}_2\text{O}_7$.

Of the organic phosphates, triphenyl phosphate $(\text{C}_6\text{H}_5)_3\text{PO}_4$, is important, acting as a filler or "dope," and as a substitute for camphor. It is a colourless solid of m.p. 53°C and b.p. 245°C .

Pyrophosphoric acid, $\text{H}_4\text{P}_2\text{O}_7$, is a tetrabasic acid which may be regarded as derived by eliminating a molecule of water between two molecules of ordinary phosphoric acid; its constitution may therefore be written $(\text{HO})_2\text{OP} \cdot \text{O} \cdot \text{PO}(\text{OH})_2$. It may be obtained as a glassy mass, indistinguishable from metaphosphoric acid, by heating phosphoric acid to 215° . When boiled with water it forms the ortho-acid, and when heated to redness the meta-acid. After neutralization, it gives a white precipitate with silver nitrate. Being a tetrabasic acid it can form four classes of salts; for example, the four sodium salts $\text{Na}_4\text{P}_2\text{O}_7$, $\text{Na}_3\text{HP}_2\text{O}_7$, $\text{Na}_2\text{H}_2\text{P}_2\text{O}_7$, $\text{NaH}_3\text{P}_2\text{O}_7$ are known. The most important is the normal salt, $\text{Na}_4\text{P}_2\text{O}_7$, which is readily obtained by heating disodium orthophosphate, Na_2HPO_4 . It forms monoclinic prisms (with $10\text{H}_2\text{O}$) which are permanent in air. All soluble pyrophosphates when boiled with water are converted into orthophosphates.

Metaphosphoric acid, HPO_3 , or more correctly $\text{H}_2\text{P}_2\text{O}_6$ as determined by vapour density (Tilden and Barnett), is a monobasic acid which may be regarded as derived from orthophosphoric acid by the abstraction of one molecule of water, thus $\text{H}_3\text{PO}_4 - \text{H}_2\text{O} = \text{HPO}_3$; its constitution is therefore $(\text{HO})\text{PO}_2$. The acid is formed by dissolving phosphorus pentoxide in cold water, or by strongly heating orthophosphoric acid. It forms a colourless vitreous mass, hence its name "glacial phosphoric acid." It is readily soluble in water, the solution being gradually transformed into the ortho-acid, a reaction which proceeds much more rapidly on boiling. Although the acid is monobasic, salts of polymeric forms exist of the types $(\text{MPO}_3)_n$, where n may be 1, 2, 3, 4 or 6. They may be obtained by heating a monometallic orthophosphate of a fixed base, or a dimetallic orthophosphate of one fixed and one volatile base, *e.g.*, microcosmic salt: $\text{MH}_2\text{PO}_4 = \text{MPO}_3 + \text{H}_2\text{O}$; $(\text{NH}_4)\text{NaHPO}_4 = \text{NaPO}_3 + \text{NH}_3 + \text{H}_2\text{O}$. The salts are usually non-crystalline and fusible. Their solutions on boiling yield orthophosphates, whilst those of heavy metals give a trimetallic orthophosphate and orthophosphoric acid: $3\text{AgPO}_3 + 3\text{H}_2\text{O} = \text{Ag}_3\text{PO}_4 + 2\text{H}_3\text{PO}_4$. Metaphosphoric acid can be distinguished from the other two acids by its power of coagulating albumen, and by not being precipitated by magnesium and ammonium chlorides in the presence of ammonia. For perphosphoric acids, see PHOSPHORUS.

PHOSPHORESCENCE. Physicists apply the word phosphorescence to the emission of light at low temperatures by certain substances (chiefly sulphides), after previous exposure to light or radiation of other kinds. However, common usage has made it applicable to the glow of phosphorus, or of the sea, or of dead fish or meat, or of wood, the "fox-fire" of forests. Phosphorescence of the sea or of flesh, wood, etc., is due to living organisms of various kinds and should more properly be called bioluminescence. Such light is the result of a slow oxidation of material manufactured by the organism.

At least 40 different orders of animals contain luminous species, and also two groups of plants, the bacteria, responsible for the luminescence of flesh, and the fungi, responsible for the luminescence of wood. Either the fine strands of fungus mycelium, which penetrate the wood, or the fruiting body, the mushroom, or both, may be luminous.

The luminous bacteria are so small that individuals cannot be seen by their own light, whereas natural colonies are easily visible. They may be cultured on artificial media and form excellent material for the experimental study of bioluminescence. They are not pathogenic to man but are known to infect living animals, giving rise to a natural luminescent disease of sand-fleas, shrimps and possibly midges, which is eventually fatal. Luminous bacteria may also live symbiotically in definite organs of fish, notably Photoblepharon and *Anomalops* of the Banda islands. Some believe that the luminescence of all luminous animals, even the fire-fly, is due to symbiotic luminous bacteria, but this is far from

proven. The characteristic of the light of bacteria and fungi, which distinguishes them from all other luminous organisms, is its uniformity, shining night and day, independently of stimulation. Other animals light only when disturbed or stimulated.

Phosphorescence of the sea is largely due to Protozoa, of which the Radiolaria, Dinoflagellata and Cystoflagellata (including *Noc-tiluca*) are luminous. The latter two groups may develop in such enormous numbers that the sea is a pink or red by day and a vivid sheet of flame by night. Larger patches of light in the ocean are mainly due to coelenterates, jelly-fish, Siphonophora or Ctenophora (comb-jellies). The latter are often very abundant and show the interesting phenomenon of loss of luminescence in sunlight or on bright illumination by electric light. The luminescence again appears on stimulation after about one-half hour in the dark. The coelenterates contain more luminous species than any other group, the sea pens or pennatulids showing especially brilliant luminescence, which travels along nerves over the colony of polyps in the form of a wave.

Among the Crustacea, Copepoda and Ostracoda (Cypridina) contain many luminous forms while the schizopod and decapod shrimps possess members with true luminous organs or photophores, often consisting of lens, reflector and pigment screens, veritable lanterns on a microscopic scale, earlier mistaken for eyes.

Among the worms, many marine forms and some earthworms are luminous. Among the echinoderms, only the brittle-stars (Ophiuroids) possess luminous members.

Luminous molluscs are represented only by *Pholas dactylus* (a bivalve) and *Phyllirrhoë bucephala* (a nudibranch), together with the cephalopods, of which many members produce light. The cephalopods and deep-sea fish possess the most complex lantern-like luminous organs.

Some centipedes are luminous, as well as the spring-tails, larvae of the fly, *Bolitophila*, which live in New Zealand caves, and beetles (fire-fly, glow-worm and *Pyrophorus* of the West Indies). All stages, including the egg, of some fire-flies are luminous.

Balanoglossus and *Pyrosoma*, primitive chordates, are also luminous. The latter forms large colonies, floating near the surface of the sea, each individual possessing two luminous spots.

Finally, mention should be made of the fish, both elasmobranchs and teleosts, containing luminous members. The deep-sea forms are often bizarre in appearance and sometimes contain the luminous organ on the end of a long process dangled before the animal as a lure for prey.

The sponges, Alcyonaria, Bryozoa, mayflies, termites, spiders and Salpae contain reported luminous forms, whose light-production is, however, doubtful. The light of many phosphorescent animals is not produced by the animals themselves but by symbiotic micro-organisms.

In general, luminous organs or regions are glandular and the luminous material may be ejected (extracellular luminescence) as a slime or a secretion, which in the squid, *Heteroteuthis dispar*, surrounds the animal in the sea water as does the black ink of other squids. Or the luminous material may be consumed within the photogenic cells (intracellular luminescence) as in the fire-fly and organisms possessing photophores. There is always a mechanism for supplying the organ with abundant oxygen, a fact which indicates that the light-production is an oxidation.

Chemical Nature of Bioluminescence.— Knowledge of the chemical nature of bioluminescence has proceeded in four steps. (1) R. Boyle (1667) showed that fungi and bacteria required air (oxygen) for luminescence, becoming dark under an air pump and luminescing again when air was readmitted.

(2) Réaumur (1733) and Spallanzani (1794) showed that water was necessary, that luminous cells could be dried and preserved, in some cases indefinitely, producing light whenever moistened. This fact proves also that bioluminescence is not a process involving definite structural peculiarities of the cell, as is the contraction of a muscle or the conduction of a nerve impulse, which will not occur after drying and moistening.

(3) Dubois, in 1887, found that the photogenic material could be separated into two constituents, luciferin and luciferase, due to marked difference in chemical behaviour. The latter is destroyed

on boiling and behaves like an enzyme or catalyst; the former is heat-resisting and the oxidizable body. These substances can be treated like any other chemical compound, precipitated by certain reagents and redissolved in appropriate solvents. They have been partially purified but their chemical composition is still unknown. Their isolation and synthesis is a matter of time and material.

(4) Harvey (1918) showed that luciferin, after oxidation to oxyluciferin, could be reduced again, that the luminescent process was reversible and of the nature of an oxidative dehydrogenation. It seems most probable that many organisms reduce the oxyluciferin formed during luminescence and thus re-utilize the material again and again, a principle that may in time be adopted in industry as the basis of an efficient method of illumination.

Bioluminescence is often spoken of as "cold light." This does not mean that no heat is produced, but only that very little appears as compared with the ordinary methods of illumination, which depend on the incandescence of carbon particle in flames or of wires through which a current is passing. The rise of temperature in some luminous animals is less than 0.001° C. The light is no different, physically, from any other kind of light—it will affect a photographic plate, can induce chemical reactions, and can be polarized. There are no infra-red or ultra-violet radiations and no penetrating radiations are produced. Hence the luminous efficiency, *i.e.*, the percentage of the radiant energy which is visible, is very high, nearly 100%. This does not tell, however, what the radiant efficiency is, *i.e.*, the percentage of the energy (chemical) of the oxidation process which appears as radiant energy; nor does it tell the overall efficiency, *i.e.*, the energy (chemical) in the food of the animal which appears as visible radiant energy. This is the efficiency in which an illuminating engineer is interested, and studies on luminous bacteria have shown that the overall efficiency of these forms is at least slightly and probably considerably greater than that of a nitrogen-filled incandescent lamp, when calculated from the energy of the coal necessary to run the dynamo that supplies current to the lamp.

The Uses of Luminescence.— Regarding the use of luminescence to the animal, little can be said with certainty. In deep-sea forms, living in perpetual darkness, it would seem that the organs must be lanterns for seeing or recognition, or for attracting prey. Many luminous forms live in light places, and it has been suggested that the luminescence may be a warning to scare away predacious animals which might molest the luminous forms, or a lure to attract creatures upon which the luminous animal feeds. These suggestions remain to be proven, but we do know that in the fire-fly the light acts as a signal or attraction to bring the sexes together. On the other hand, who can suggest the use of light to a luminous bacterium, an organism $\frac{1}{25,000}$ in. in diameter with no nervous reactions of a higher form, or the use to a protozoan, living at the surface of the sea, blown hither and thither by the wind? One is forced to the conclusion that in their case the light is merely fortuitous, a chance phenomenon, accompanying some of the chemical changes in the organism.

It is well known that many substances produce light on slow oxidation (chemiluminescence) and the whole process of light-production by luminous organisms can be so perfectly imitated by such reactions in the laboratory that we may no longer consider it a mysterious or unusual phenomenon.

atomic weight 30.98.) It is never found free, but is widely and abundantly distributed in combination as phosphates (*q.v.*). It is essential to animal and vegetable life, occurring in urine, blood and tissues, and, as calcium phosphate, forming 58% of bones. The element was first obtained in 1669 by Brand of Hamburg, who kept his process secret. In England, however, Kunckel (1678) and Boyle (1680) attempted its preparation and happened to use Brand's method—urine was evaporated to dryness and the residue distilled with sand. In 1775 Scheele prepared it from bones, and these still form one of the chief commercial sources of phosphorus. Degreased bones or mineral phosphates are treated with sufficient sulphuric acid to combine with all the calcium, this sulphate is filtered off, and the filtrate is mixed with charcoal, coke or sawdust, dried in a furnace, and then distilled from Stourbridge-clay retorts at a white heat. The vapours are led through malleable iron pipes into troughs containing water, where they condense. The reactions are:

Modern Processes.—In more modern electrothermal processes, calcium phosphate is mixed with sand and carbon, and fed into a furnace heated by an alternating current. At the high temperature the silica of the sand displaces phosphoric oxide and forms calcium silicate, and the oxide is reduced by the carbon so that the phosphorus vapour and carbon monoxide pass over into a condenser. The silicate remains as a liquid slag and is run off periodically. Other processes seek to produce calcium carbide simultaneously with phosphorus by using only calcium phosphate and carbon, thus obtaining a more valuable by-product. In all cases the phosphorus is cast into sticks either under water or in water-cooled pipes.

Properties.—Perfectly pure phosphorus is a white, transparent waxy solid, its usual yellowish appearance being due to traces of the allotropic "red phosphorus," which is formed by exposure to light. At 25° to 30° C it is soft and flexible, but when cooled it becomes brittle and shows a crystalline fracture. Crystallization from carbon disulphide or sublimation yields large crystals of regular dodecahedra or octahedra, but these fire spontaneously unless protected from the air. It is also soluble in sulphur chloride, benzene, oil of turpentine, and liquefied ammonia or sulphur dioxide. It is a non-conductor of electricity, has density 1.836 at 0° C, melts at 44.3°, and boils at 287° giving a colourless vapour, the density of which corresponds to tetratomic molecules, P₄; above 1,500° C the vapour density indicates dissociation to P₂. The elevation of boiling point of solutions of phosphorus in carbon disulphide, and the depression of freezing point of solutions in benzene, both indicate P₄.

The element is highly inflammable, taking fire in air at 34°, burning with a bright white flame and forming dense white clouds of phosphoric oxide; H. B. Baker has shown, however, that in perfectly dry air or oxygen it can be distilled unchanged. (See DRYNESS, CHEMICAL.) When exposed to air which has not been excessively dried, a stick of phosphorus undergoes slow combustion, as shown by the phosphorescence visible in the dark. In pure oxygen, however, this phosphorescence is not exhibited unless the gas pressure is reduced or the temperature raised; similarly, in compressed air the phosphorescence ceases when a certain pressure is reached. Moreover, the presence of certain substances (*e.g.*, Cl, Br, I, NH₃, N₂O, NO₂, H₂S, SO₂, CH₄, C₂H₄) entirely inhibits the phosphorescence. During the process, oxygen is slightly ionized and traces of ozone are formed. Some of the phenomena accompanying phosphorescence have been ascribed to the oxidation of the trioxide. A very complete bibliography of investigations is given by W. E. Downey (*J. Chem. Soc.*, 1924, 125, p. 349), and H. J. Emeléus (*ibid.*, 1926, p. 1336; 1927, p. 788; 1928, p. 628) gives a further discussion of the inhibition and of the ultra-violet spectrum of the glow. Phosphorus combines directly with the halogens, sulphur and selenium, and most metals burn in its vapour forming phosphides. When very finely divided it decomposes water, giving hydrogen phosphide, and when boiled with water it gives hypophosphorous acid in addition; slow oxidation of wet phosphorus yields hypophosphoric acid.

PHYSICAL PROPERTIES

Allotropic Forms.—Many allotropic varieties of phosphorus have been described but it seems probable that the white and violet forms are the only definite allotropes (see ALLOTROPY), the others being "solid solutions" (see CHEMISTRY, PHYSICAL) of these two. The ordinary yellowish phosphorus is really white when pure, and probably owes its slight colour to a trace of the violet form. The so-called red phosphorus (used for matches) is produced by heating white phosphorus to about 230° C for 24 hours in an inert atmosphere, or to 300° C for a few minutes in closed vessels; a trace of iodine expedites the change. Commercially, the process is carried out in iron pots with air-tight lids which, however, have a long narrow tube open to the air; at first a little phosphorus burns, but this uses up all the oxygen, and the process thereafter continues in an inert atmosphere with no risk of explosion. The product is ground under water, freed from unchanged white phosphorus by boiling with caustic soda, washed and dried. The same form is also produced by submitting ordinary phosphorus to the silent electric discharge, to sunlight or to ultra-violet light. Red and white phosphorus differ greatly: the red does not inflame until heated above 350° C (hence its use in the match industry), is insoluble in all the solvents which dissolve the white, has a higher density (2.2), is stable to air and light, is much less chemically reactive (since its formation from white phosphorus is accompanied by liberation of much heat—3,700 cal. per 31 g), and is non-poisonous.

Hittorf's "metallic" or violet phosphorus is formed by heating phosphorus with lead to redness in a sealed tube, and removing the lead by boiling with nitric acid or by electrolytic means. It is also obtained by heating white or red phosphorus for long periods at high temperatures, the proportion of violet phosphorus increasing with time and temperature. This fact, together with the circumstance that the density of red phosphorus continually increases with the duration and intensity of its heating, suggests that the red form is only an intermediate stage in the production of the violet. (See above.) This variety forms lustrous, heavy, nearly black, minute rhombohedra. A scarlet form was obtained by R. Schenk in 1905, and in 1921, P. W. Bridgman described a black graphitic variety which was obtained by heating ordinary phosphorus at 200° C under a pressure of 12,000 atmos., and which was incombustible, very dense, and conducted electricity. Bridgman obtained also another modification of white phosphorus, with a transition point at -76.9° C under atmospheric pressure. The relationships of these forms to white and violet phosphorus are indefinite. The various forms are probably polymeric, for the red phosphorus is at least as complex as P₈, whereas the white is P₄. Smits postulates two forms P_α and P_β as the basis of all varieties, and, as many of the conversions are very slow, the equilibria involved are probably complex.

Phosphine (phosphoretted hydrogen), PH₃, a gas formed in the putrefaction of organic matter containing phosphorus, was first obtained (Gengembre, 1789) by the action of potash on phosphorus; this was spontaneously inflammable, whereas Davy obtained a hydride which was not spontaneously inflammable by heating phosphorous acid. In 1835 Le Verrier showed that the two gases were essentially identical, and that the inflammability was due to traces of another hydride, P₂H₄. When caustic alkalis are boiled with phosphorus, the impure gas is obtained, and it also results from the action of water on calcium phosphide (unless this is very pure), but the pure PH₃ may be obtained by heating phosphonium iodide with caustic potash. It is a colourless, very poisonous gas, with an offensive odour like that of rotting fish; it can be liquefied at -86° C and solidified at -133°. It is only slightly soluble in water, burns with a luminous flame, fires spontaneously in air at about 0°, and combines violently with oxygen and the halogens. When passed over heated metals, it liberates hydrogen and forms the phosphide. It forms double compounds such as PH₃.2BF₃ and 2PH₃.SiCl₄, gives phosphonium salts, PH₄X, with the halogen acids, and decomposes to its elements when heated out of contact with air. The hydride P₂H₄ can be condensed as a liquid if the impure gas (above) is passed through U-tubes in a freezing mixture. It boils at 57°-58° C, and above

this temperature it breaks down to P_4H_2 , which also results when it is exposed to light or left in contact with hydrochloric acid. The hydride P_4H_2 is a solid obtained by the action of phosphorus trichloride on PH_3 , or of water on phosphorus di-iodide.

PHOSPHONIC SALTS AND OXIDES

Phosphonium Salts.—The *chloride*, PH_4Cl , large transparent cubes can be obtained by direct combination of phosphine and hydrogen chloride at $-30^\circ C$ but decomposes on rise of temperature. The bromide may be prepared similarly or by heating phosphorus with hydrobromic acid at 110° in sealed tubes; it is unstable in air and is decomposed by water. The iodide is readily obtained by mixing phosphorus and iodine in carbon disulphide in a retort, distilling off the solvent, adding the requisite quantity of water and subliming the iodide:

Caustic alkali or more water decomposes it to phosphine and iodide or hydriodic acid.

Just as amines (*q.v.*) are derivatives of ammonia, so phosphine gives rise to primary, secondary and tertiary phosphines, and organic phosphonium bases correspond to phosphonium salts. The primary and secondary phosphines, RPH_2 and R_2PH , are formed when alkyl iodides are heated with phosphonium iodide and zinc oxide to $150^\circ C$, the reaction mixture is treated with water, whereby the primary phosphine is obtained, and the secondary phosphine is liberated from its hydriodide by caustic soda. The tertiary phosphines and quaternary phosphonium salts are formed by the same reaction at higher temperatures ($180^\circ C$) and without the use of zinc oxide. The primary and secondary phosphines are colourless liquids (except methylphosphine which boils at $-14^\circ C$) of unpleasant odour; they react neutral but form salts with acids, and are often spontaneously inflammable; nitric acid oxidizes them to mono- and di-alkylphosphinic acids, respectively, $RPO(OH)_2$ and $R_2PO(OH)$. The tertiary phosphines tend to give derivatives of quinquivalent phosphorus, and therefore readily form addition compounds and are oxidized to phosphine oxides, R_3PO . The quaternary phosphonium salts resemble the corresponding nitrogen compounds, being stable towards aqueous alkalis but converted by digestion with moist silver oxide to the very strongly alkaline phosphonium hydroxide; on heating, they decompose to the phosphine oxide and a hydrocarbon:

The alkylphosphinic acids are colourless crystalline compounds, readily soluble in water or alcohol, and dibasic, whereas the dialkylphosphinic acids are monobasic.

Oxides.—Three oxides are well defined, viz., P_4O_6 , P_2O_4 , P_4O_{10} ; others (*e.g.*, P_4O and P_2O) have been described and also disputed. *Phosphorus oxide*, P_4O_6 , is a product of the limited combustion of phosphorus in air; if the element is burned in a hard glass tube and a rapid current of air is passed over it, the oxide may be condensed in a metal condenser and removed later by warming it. It sublimes in feathery crystals and melts at 22° to a colourless mobile liquid of sp. gr. 1.936 and boiling point 173° . Vapour-density determinations indicate the formula P_4O_6 ; above about 300° in a sealed tube it decomposes to phosphorus and the tetroxide. It is slowly oxidized by air and rapidly by oxygen (with inflammation at 70°) to phosphoric oxide; with cold water it slowly gives phosphorus acid, but with hot water it reacts violently, forming phosphorus, phosphine, phosphoric acid, and other products; hot alkalis decompose it similarly, but cold dilute alkalis form phosphites. Chlorine or bromine converts it chiefly to $POCl_3$ or $POBr_3$, whereas iodine forms the di-iodide, P_2I_4 , and P_4O_{10} ; hydrogen chloride and phosphorus pentachloride react with it as follows:

It combines violently with sulphur to give $P_4O_6S_4$ which sublimes as highly lustrous plates (m.p. 102° ; b.p. 295°) and which is readily decomposed by water to sulphuretted hydrogen and phosphoric acid. Ammonia reacts to give the diamide $P(OH)(NH_2)_2$ and its ammonium salt. Phosphorus oxide has a peculiar garlic-like odour and is very poisonous; the odour and toxicity of phos-

phorus vapour are probably due to this oxide. *Phosphorus tetroxide*, P_2O_4 or better $(PO_2)_n$ since its molecular complexity is not certain, is obtained (see col. 1) as lustrous, deliquescent crystals; it is not the anhydride of hypophosphoric acid (see below), for water decomposes it to phosphorus and phosphoric acids. Phosphoric oxide, phosphoric anhydride (loosely termed "pentoxide"), is P_4O_{10} even at very high temperatures; it is obtained by the burning of phosphorus in excess of air or oxygen, as a soft flocculent powder which sublimes to transparent monoclinic crystals. It reacts violently with water and can be reduced to the element by heating with carbon.

Acids.—Hypophosphorous and hypophosphoric acids, H_3PO_2 and $H_4P_2O_6$ (or $H_2P_2O_3$), have no known anhydrides; phosphorous acid, H_3PO_3 , is derived from P_4O_6 ; meta-, pyro- and ortho-phosphoric acids are derived from P_4O_{10} and are described under PHOSPHATES; perphosphoric acids, H_3PO_5 and $H_4P_2O_8$ are also known. *Hypophosphorous acid*, $H_2PO(OH)$, is prepared as its barium salt by boiling phosphorus with baryta water, removing excess of baryta by passing in carbon dioxide, and crystallizing the filtrate; if this salt is decomposed by the calculated amount of dilute sulphuric acid, the pure acid can be obtained, by careful evaporation of the filtrate under reduced pressure, as white crystals melting at $26.5^\circ C$. It is a monobasic acid and is slowly oxidized in air; on heating it gives phosphine and phosphoric acid. It is usually sold as a solution of sp. gr. 1.137 (about 32%) which is fairly stable. When warmed with copper sulphate solution it produces a red precipitate of the hydride, Cu_2H_2 , thus demonstrating its exceptionally strong reducing properties; its salts are also effective reducing agents. Phosphorous acid, $H_2PO(OH)_2$, is formed from its anhydride, P_4O_6 , or by passing chlorine into melted phosphorus covered with water, the phosphorus trichloride being decomposed *in situ*. The crystals melt at 70° , are very deliquescent, and oxidize in the air; on heating they give phosphine and phosphoric acid. It is an energetic reducing agent and, although normally dibasic, it gives rise to organic esters of the type R_3PO_3 .

Hypophosphoric acid, $H_4P_2O_6$ or $H_2P_2O_3$, occurs among the products of oxidation of phosphorus in moist air or in water; the solution is neutralized by sodium carbonate, and the sparingly soluble lead salt is made, and then decomposed by hydrogen sulphide; sticks of phosphorus immersed in copper nitrate solution are also oxidized to this acid by means of nitric acid. The aqueous solution of the free acid is stable, but it decomposes on concentration unless this be done in a vacuum, in which case the hydrate ($H_4P_2O_6, 2H_2O$) separates and can be dried below 50° to give the acid; this melts at 70° and decomposes. The solution does not readily act as a reducing agent. Owing to uncertainty as to the constitution, formulae such as $PO(OH)_2.O.PHO(OH)$ and $PO(OH)_2$ have been proposed; an ester $(CH_3)_2PO_3$ is known (Rosenheim, 1910), so the salts are probably best regarded as derived from the polymerized acid. Permono- and perdi-phosphoric acids are obtained from phosphoric anhydride or meta- or pyro-phosphoric acids and hydrogen peroxide at $0^\circ C$, large excess of peroxide favouring the production of the di-acid. The salts are also obtained by electrolysis of dipotassium hydrogen phosphate, a high anode current density increasing the proportion of the permono-salt; $K_4P_2O_8$ forms good crystals. The two acids differ in their action on iodides, the permono-acid liberating iodine at once, and the other slowly (compare persulphates, see SULPHUR).

Halogen Compounds.—Phosphorus *trifluoride*, PF_3 , obtained by direct union of its elements, is a colourless, non-fuming gas which liquefies at -10° under 20 atmos., solidifies at -160° , and boils at -95° . It is comparatively stable, is only slowly decomposed by water, and does not attack glass when cold. Phosphorus *pentafluoride*, PF_5 , results from combustion of the element or trifluoride in excess of fluorine, or from the interaction of arsenic trifluoride and phosphorus pentachloride. It is a colourless fuming gas of b.p. -75° and m.p. -83° , and is dissociated by large induction sparks but not by heat (compare PCl_5 and PBr_5); it is readily decomposed by water

and combines with ammonia to give $2\text{PF}_5 \cdot 5\text{NH}_3$. *Phosphoryl fluoride*, POF_3 , is best obtained by heating powdered cryolite with $1\frac{1}{2}$ times its weight of phosphoric anhydride; it is a colourless, fuming gas of m.p. -68° and b.p. -40° .

Phosphorus trichloride, PCl_3 , obtained by passing a slow stream of chlorine over heated red phosphorus or through a solution of yellow phosphorus in carbon disulphide and fractionally distilling the product, is a colourless, mobile liquid of sp.gr. 1.613 (at 0°C) and b.p. 76° , and freezes at -112° . As prepared above, it may be contaminated with PCl_5 , from which it is freed by distillation from excess of phosphorus. Cold water gives hydrochloric and phosphorous acids, and hot water gives red phosphorus and other products. When diluted with hydrogen and led into liquid ammonia, PCl_3 yields $\text{NH}:\text{P}:\text{NH}_2$, which gives $\text{P}_2(\text{NH})_3$ on heating; a similarly diluted mixture, when submitted to the electric discharge, forms the dichloride, P_2Cl_4 , an unstable fuming liquid, boiling and decomposing at 180° . *Phosphorus pentachloride*, PCl_5 , obtained by the action of excess of chlorine on the element or its trichloride, is a pale straw-coloured solid, which sublimes and dissociates on heating, but may be melted at 148° under pressure; the dissociation is repressed by excess of chlorine: $\text{PCl}_5 \rightleftharpoons \text{PCl}_3 + \text{Cl}_2$. Water effects decomposition rapidly in two stages:

The pentachloride is extensively used in organic chemistry, e.g., for replacing hydroxyl groups by chlorine:

Phosphoryl chloride, or phosphorus oxychloride, POCl_3 , may be produced as shown above, or by the interaction of phosphoric oxide on the pentachloride or on hydrogen chloride:

It is a colourless liquid of b.p. 107° and m.p. 1° ; with water it gives hydrochloric and phosphoric acids, with dilute alcohol ethylphosphoric acid, $\text{C}_2\text{H}_5\cdot\text{H}_2\text{PO}_4$, and with absolute alcohol triethyl phosphate, $\text{PO}(\text{OC}_2\text{H}_5)_3$. *Pyrophosphoryl chloride*, $\text{P}_2\text{O}_3\text{Cl}_4$, is also known. *Thiophosphoryl chloride*, PSCl_3 , is formed by direct combustion of sulphur and PCl_3 , by the action of sulphuretted hydrogen, antimony trisulphide or phosphorus pentasulphide upon P_4O_{10} , or by dissolving phosphorus in sulphur chloride and distilling: $2\text{P} + 3\text{S}_2\text{Cl}_2 = 4\text{S} + 2\text{PSCl}_3$. It is a colourless liquid (b.p. 125°), is decomposed by water to acids corresponding to each of the three elements, and gives thiophosphates with alkalis, e.g., $\text{PS}(\text{OK})_3$.

Phosphorus tribromide, PBr_3 , prepared by passing bromine vapour (diluted with carbon dioxide) over phosphorus, or by mixing solutions of the two in carbon disulphide and distilling, is a liquid boiling at 173° and resembling the trichloride chemically. The *pentabromide*, PBr_5 , resulting if an excess of bromine is used in the above preparations, is a yellow solid closely resembling the pentachloride. *Phosphoryl bromide*, POBr_3 (m.p. 45° ; b.p. 195°), and *thiophosphoryl bromide*, PSBr_3 (mp. 38°), both resemble the corresponding chloro-compounds. The action of iodine and phosphorus when dissolved in carbon disulphide (free from sulphur) gives rise to a *di-iodide*, PI_2 or P_2I_4 (m.p. 124°), a *tri-iodide*, PI_3 (m.p. 61°), and possibly a *sub-iodide*, P_4I .

SULPHUR AND NITROGEN COMPOUND

Sulphur Compounds.—Phosphorus and sulphur combine energetically to form a series of sulphides, three of which are well defined, viz., P_4S_3 , P_4S_7 and P_2S_5 (see A. Stock, *Berichte*, 1908 *et seq.*); the first is sometimes used as a substitute for phosphorus in matches, and the last finds application in organic chemistry for replacing oxygen by sulphur. There is also evidence for the existence of PS_6 , P_2S_3 , and possibly P_2S . Thiophosphates (e.g., Na_3PSO_3 and $\text{Na}_3\text{PS}_2\text{O}_2$) result from the dissolution of P_2S_5 in alkalis, whereas by melting it with the sulphides or chlorides of heavy metals, salts analogous to Na_3PS_4 are obtained, which are somewhat unstable in water and still more so towards acids.

Nitrogen Compounds.—Phosphorus pentachloride reacts readily with ammonia to give $\text{PCl}_5 \cdot 5\text{NH}_3$ and thence $\text{PCl}_3(\text{NH}_2)_2$, chlorophosphamide, which is decomposed by water to $\text{PO}(\text{NH})$

(NH_2) or by heat to "phospham," $\text{NH}:\text{P}:\text{N}$, a white infusible, stable solid; when $\text{PO}(\text{NH})(\text{NH}_2)$ is heated it gives "phosphoryl nitride," $\text{O}:\text{P}:\text{N}$. When ammonia and phosphorus pentasulphide react at a red heat they give a *nitride*, P_3N_5 , whereas if the pentoxide is used (in the presence of a trace of water) a series of amides of phosphoric acid result: $\text{PO}(\text{NH}_2)_2(\text{OH})$, $\text{PO}(\text{NH}_2)(\text{OH})_2$ and $\text{PO}(\text{OH})(\text{NH})$. The interaction of phosphorus pentachloride and ammonium chloride in a sealed tube produces a series of chloronitrides, $(\text{PNCl}_2)_n$, where n may be 3, 4, 5, 6 or 7. These give rise to a great variety of complex polymerized compounds by reaction with water.

Therapeutics and Toxicology.—Various preparations of phosphorus are used in the British Pharmacopoeia. The element is essential for the growth of bones in young animals, and hence its compounds are used in rickets. It is also efficient as a nerve tonic in paralysis agitans, locomotor ataxia, impotence and nervous exhaustion. In some skin diseases, such as psoriasis, chronic eczema and acute indurata, phosphorus is useful. The hypophosphites are recommended in pulmonary affections and are used in tonics, and the glycerophosphates stimulate metabolism. Dilute phosphoric acid is used as a gastric stimulant.

Phosphorus is readily accessible in poisonous forms, e.g., in vermin pastes and some matches, and is often taken either intentionally or accidentally. Symptoms of acute poisoning are usually shown after some delay, with nausea, vomiting, and burning sensations in the oesophagus, stomach and abdomen. Emetics and purgatives should be given at once to prevent absorption of the poison. Doses of 3–5 grains of copper sulphate in water at intervals of a few minutes form the harmless copper phosphide. The stomach should be washed out with warm water and then with a 2% solution of potassium permanganate, and this solution should also be given as an enema. Oils, which are effectual in other cases of irritant poisoning, *should not be given*, for they tend to dissolve phosphorus and retain it in the system; the old French oil of turpentine, however, acts as an antidote in allaying the toxic effects. When yellow phosphorus was used in matches, those engaged in the manufacture used to suffer from a form of necrosis, called "phossy jaw" in England; the red form now employed is, however, non-poisonous. (A. D. M.)

PHOTIUS (c. 820–891), patriarch of Constantinople (858–867 and 878–886). The way to public life was probably opened for him by the marriage of his brother Sergius to the princess Irene, sister of Theodora, who, upon the death of her husband Theophilus in 842, had assumed the regency of the empire. Photius became captain of the guard and subsequently first imperial secretary. The dissensions between the patriarch Ignatius and Bardas, the uncle of the youthful Emperor Michael III., brought promotion to Photius. Ignatius was arrested and imprisoned (Nov. 858), and upon refusing to resign his office was illegally deposed, while Photius, although a layman, received all the necessary sacerdotal orders within six days, and was installed as patriarch in his place. Ignatius, continuing to refuse the abdication which could alone have given Photius's elevation a semblance of legality, was treated with extreme severity. His cause was subsequently espoused by Pope Nicholas in a manner highly offensive to the independent feeling of the Eastern Church. Photius felt himself the champion of Eastern Christianity against Latin pretensions; and when in 863 Nicholas finally anathematized and deposed him, he replied by a counter-excommunication. Meanwhile, the situation was suddenly changed by the murder of Photius's patron, Bardas, by order of the emperor Michael, who was himself assassinated by his colleague Basil in the following year (867). The fall of Photius immediately ensued; he was removed from his office and banished about the end of September 867, a few days after the accession of Basil, and Ignatius was reinstated on Nov. 23.

About 876 Photius was suddenly recalled to Constantinople and entrusted with the education of Basil's children. On the death of Ignatius, probably in October 878, Photius again became patriarch. In 879 the legates of Pope John VIII. attended a synod convened at Constantinople, prepared to acknowledge Photius as legitimate patriarch, a concession for which John was

much censured by Latin opinion. But John stood firm on outstanding points of difference, disowned his legates, and again excommunicated Photius. Photius ignored John's action, but a palace revolution caused his banishment (886) to Bordi in Armenia. He is said to have died there on Feb. 6, 891.

Photius shows to no little advantage as an ecclesiastical statesman. His firmness was heroic, his sagacity profound and far-seeing; he supported good and evil fortune with equal dignity; and his fall was on both occasions due to revolutions beyond his control. In erudition, literary power, and force and versatility of intellect he far surpassed every contemporary.

The most important of the works of Photius is his renowned *Bibliotheca* or Myriobiblon (ed. I. Bekker, 1824-1825), a collection of extracts from and abridgments of 280 volumes of classical authors (usually cited as Codices), the originals of which are now to a great extent lost. To Photius we are indebted for almost all we possess of Ctesias, Memnon, Conon, the lost books of Diodorus Siculus, and the lost writings of Arrian.

The Lexicon (*Λέξεων Συναγωγή*), was probably in the main the work of some of his pupils. The only ms. of the Lexicon is the Codex Galeanus, at Trinity College, Cambridge (ed. S. A. Naber, 1864, with introduction on the authorities, critical commentary and valuable indexes). The *Amphilochia* is a collection of some 300 questions and answers on difficult points in Scripture, addressed to Amphilochius, archbishop of Cyzicus (ed. Sophocles Oeconomus, Athens, 1858). Other similar works are his treatise in four books against the Manichaeans and Paulicians, and his controversy with the Latins on the Procession of the Holy Spirit. His Epistles were edited by J. Valettas, London (1864). A large number of his speeches and homilies have been edited by S. Aristarches (1900). The only complete edition is Bishop Malou's in Migne's *Patrologia graeca*, ci.-cv. R. Reifzenstein (*Der Anfang des Lexikons des Photius*, 1907) has published a hitherto unedited ms. containing numerous fragments from various verse and prose authors.

See Cardinal Hergenrother, Photius, Patriarch von Constantinopel (1867-69).

PHOTOCHEMISTRY is that division of physical chemistry which deals with the chemical action of radiant energy on matter, and with the direct production of radiation by chemical reactions. The field of photochemistry might be regarded as being equally as extensive as the range of electromagnetic vibrations; from the tiny ultra-X-rays to the huge waves of "wireless." Actually, limitations exist and photochemical reactions are considered primarily as the transformations of matter associated with radiations between and including the trans-ultra-violet and infra-red radiations. This range includes the visible radiations, and a band on either side of approximately the same width as that covered by the visible radiations. The wave-lengths included are those between $10\mu\mu$ and $1,000\mu\mu$. The micron, μ , a measure of length, is 10^{-4} cm. or 10^{-3} mm., and the millimicron, $\mu\mu$, is 10^{-7} cm. or 10^{-6} mm. The direct production of radiation by chemical reaction is termed *chemiluminescence*. It is differentiated from the radiation produced in such reactions as combustion, by the absence of thermal equilibrium between the matter and the radiation concerned (see RADIATION).

Principle of Photochemical Equivalence. — Previous to about 1910, photochemistry had but one accepted generalization, the absorption law, according to which only the light energy absorbed by a body is active in promoting chemical change. This is a special case of the principle of conservation of energy, which states that energy may be neither created nor destroyed. Nearly a century after the first expression of this law, a principle of photochemical equivalence was put forward, in 1922, by A. Einstein. It is founded on Planck's quantum theory (see QUANTUM THEORY) of radiation, according to which all exchange of energy as radiation between atoms and molecules takes place discontinuously by quanta of finite magnitude $\epsilon = h\nu$, where ν is the frequency of vibration, h a universal constant, equal to 6.55×10^{-27} ergs/sec.; ϵ varies continuously in magnitude with the multiplying frequency ν , but Planck's h is an invariable *quantum* of action.

The photochemical equivalence principle of Einstein states that in a primary photochemical process, the decomposition of one molecule requires one quantum of energy $h\nu$, or that one gram-molecule requires $Nh\nu$, where N is Avogadro's number of gas molecules per litre, 6.06×10^{23} . In his original derivation he

postulates a reversible reaction of simple unimolecular decomposition

the bimolecular "dark" reverse reaction giving the chemiluminescent radiation $h\nu$; the reaction was supposed to occur in a gaseous or dilute system. In a later deduction, this primary photochemical event was supposed to be limited to the excitation of an atom or molecule

the atom or molecule C being raised to a higher energy level. It may be stated at once that this generalization is not so complete or sufficient that all photochemical phenomena can be interpreted by its sole aid. It has, none the less, completely changed the outlook, beside leading to improvements in the technique.

Experiment and Technique. — Modern investigation of a photochemical reaction essentially involves determining its quantum efficiency, in the sense of Einstein's principle. This requires certain elements of technique: — (a) a light source of sufficient intensity adequately monochromatized; (b) exact measurement of the energy absorbed during a given reaction period; (c) distinction of the primary photochemical reaction, if possible, from secondary dark reactions; (d) determination of the molecular "order" of the reaction involved, and analytical measurement of the product of the photochemical reaction proper.

As to the first, there are not many available reactions occurring in light of the visible spectrum range. As visibility coincides fairly closely with the spectral distribution of energy in sunlight — a matter of natural selection — it is obvious that on the whole only systems stable in such illumination will be readily found. Much more frequent are photochemical reactions in the ultra-violet; and artificial light sources rich in these rays are most used in laboratory research, as well as for certain industrial applications. The ultra-violet radiation from electric glow lamps is relatively feeble and does not extend far to the shorter waves. Recourse has to be made to spark and arc discharges. The latter are generally more convenient. The three chief types used may be described as carbon arcs, magnetite and high-melting metal arcs, as tungsten arcs, and metal vapour arcs; of these, the mercury vapour arc in fused quartz is the most important. The spectrum is discontinuous, and it is not difficult to secure approximately monochromatic light at several different wave-lengths by the use of colour screens or ray filters. Unfortunately when the far ultra-violet rays are in question (λ less than $200\mu\mu$) there are no very satisfactory filters available, the best requiring the use of chlorine and bromine gases. When a high degree of monochromatic purity is required, the light must be dispersed and quartz monochromators employed, with great reduction of intensity. With regard to the other requirements, the measurement of the energy absorbed in a reaction is determined with a radiometer (*q.v.*, such as a thermopile, radiomicrometer or bolometer) as the difference between the energy incident upon and transmitted through the reaction mixture; the latter is usually contained in a vessel with plane-parallel quartz walls, and maintained at constant temperature. The distinction of the primary photochemical reaction, the determination of the molecular order and of the quantum efficiency are then matters of interpreting the analytical results for different periods of the reaction.

The fundamental researches on photochemical equivalence were those of E. Warburg. They occupy in the modern era of photochemistry somewhat the position of the classical photochemical investigations by Bunsen and Roscoe in preceding years. Warburg introduced a convenient term, the *quantum efficiency*: this is the ratio of the effective photochemical equivalent ϕ to the ideal photochemical equivalent P . Both ϕ and P are expressed in terms of the number of gram-molecules absorbing and decomposed by one gram-calorie of radiation of frequency ν . When Einstein's law holds $\phi/P = 1$. Tabulated results of several reactions show that relatively few reactions confirm the Einstein relation, among which are some for which the efficiency is actually less than unity, but which give this value when extrapolated back to the start of the reaction. This procedure is justifiable when a

strongly absorbing product is formed. On the other hand there are many reactions whose efficiency (ϕ/P) is much greater than unity, even to hundreds and thousands of molecules per quantum.

Mechanism of Photochemical Reactions.—Although it is true that certain substances are more obviously photosensitive than others, a useful classification of photochemical reactions is not possible in terms either of chemical structures or of types of chemical reaction. This is particularly evident in the field of organic chemistry. The great variety of substances and types of reaction is illustrated in the following table:

Allotropic change in elements	Sulphur Light Rhomb. \rightleftharpoons Amorph. Infra-red
Intramolecular change and isomerization	Fumaric acid \rightleftharpoons Maleic acid $\text{COOH}-\text{C}=\text{H} \rightleftharpoons \text{H}-\text{C}-\text{COOH}$ $\text{H}-\text{C}-\text{COOH} \rightleftharpoons \text{H}-\text{C}-\text{COOH}$
Polymerization and depolymerization	$\text{C}_{14}\text{H}_{10} \rightleftharpoons \text{C}_{25}\text{H}_{20}$ Anthracene \rightleftharpoons Dianthracene $3\text{O}_2 \rightleftharpoons 2\text{O}_3$ Oxygen Ozone
Hydrolysis	$(\text{CH}_3)_2\text{CO} + \text{H}_2\text{O} = \text{CH}_3\text{COOH} + \text{CH}_4$ Acetone Water Acetic acid Methane
Reduction	$2\text{AgCl} = \text{Ag}_2 + \text{Cl}_2$ Silver chloride Silver Chlorine $\text{Fe}_2(\text{C}_2\text{O}_4)_3 = 2\text{Fe}(\text{C}_2\text{O}_4) + 2\text{CO}_2$ Ferric oxalate Ferrous oxalate Carbon dioxide
Oxidation	$\text{PbS} + 2\text{O}_2 = \text{PbSO}_4$ Lead sulphide Oxygen Lead sulphate
Decomposition	$2\text{HI} = \text{H}_2 + \text{I}_2$ Hydriodic acid Hydrogen Iodine
Synthesis	$\text{CO} + \text{Cl}_2 = \text{COCl}_2$ Carbon monoxide Chlorine Phosgene

To obtain a classification it is therefore necessary to search more deeply into the fundamental mechanisms of photochemical reactions. Every advance in knowledge of these will displace a previous classification or system but will supply a better working hypothesis. Einstein's proof of his principle implied that the primary photochemical process is a dissociation of a molecule, e.g., into atoms. Thus in the combination of hydrogen, H_2 , and chlorine, Cl_2 , in light to form hydrogen chloride, HCl , it was assumed that the primary reaction was $\text{Cl}_2 + h\nu = \text{Cl} + \text{Cl}$. Now the photochemical efficiency of the H_2, Cl_2 reaction is very great—it can amount to thousands of molecules of HCl per quantum absorbed. This was explained by the conception of secondary reaction chains (see subsequent section). Primary decomposition of molecules also implies a wave-length limit to a given photochemical reaction; because if the quantum, $h\nu$, absorbed be of less energy than the heat of formation of the molecule, it should be impossible to decompose it directly, and therefore, according to Einstein's principle, the relation of photochemical yield ϕ to the wave-length would have the form shown in fig. 1.

FIG. 1.—DIAGRAM SHOWING HOW PHOTOCHEMICAL YIELD SHOULD INCREASE WITH WAVE-LENGTH

Now cases are certainly known where the wave-lengths active in photochemical change are below the value corresponding to the heat of formation. In fact, the existence of definite photochemical spectrum thresholds has scarcely been demonstrated.

A difficulty of exactly the opposite kind for the primary decomposition of the molecule developed from the investigations of physicists on the energy required to make gas molecules fluoresce. It was shown that at low pressures a molecule of gas can take up many times its heat of formation without decomposing. For example, iodine, I_2 , can absorb and re-emit as resonance-radiation an amount of energy five times its heat of formation. On the modern theory of atomic and molecular struc-

ture as related to the emission and absorption of light, named, after its principal founder, the Bohr theory (see ATOM), these results are explained as follows. The total internal energy of a molecule, however acquired (and understanding by a molecule a multinuclear structure) will consist of:

Energy of rotation + Energy of oscillation + Energy of electron displacements.

The whole energy, and the distribution of this energy, is governed by quantum rules, i.e., it cannot vary continuously, but can only assume a series of finitely differing values, or quantum states. The gain of internal energy of an excited molecule consists primarily in the exaltation of the electron system to higher quantum states, when the oscillation and rotation energies are also altered by the coupling of their periods with those of the electron system. The rotational and oscillation energies are mainly responsible for absorption and emission of infra-red rays. At present there is but slender evidence for direct intervention of these in chemical reactions. A primary chemical decomposition, i.e., one not involving collision with chemically indifferent molecules, might occur by such increase of rotational energy that the centrifugal force exceeded the chemical affinity. Similarly for an excessive increase of oscillation of the parts. Apparently the constitution of molecules is such that this cannot be effected either by direct infra-red absorption or by absorption in the bands corresponding to electronic displacements, but only at frequencies beyond the band spectrum. (A typical molecular band spectrum is illustrated in the article BAND SPECTRA, q.v.) The theory of such spectra is not yet entirely adequate to complete prediction of the distribution of energy in all cases. But certain conclusions are definite. The change in rotational energy on excitation is small enough to be negligible, so that it is quantum-coupled increase of oscillation energy that is critical for dissociation.

The Dissociation of the Molecule.—In the gaseous or independent state, molecules may be classed as heteropolar and homopolar or non-polar (see ELECTROLYSIS), the former having large electrical moments. In the homopolar molecules no such electrical dissymmetry appears. However, not only are molecules of all sorts of intermediate type known, but the polarity of one and the same molecule depends on its environment. If a heteropolar molecule, such as HBr , absorb energy, the increase of oscillation energy is small. An electron of the positive ion is raised to a higher quantum state, thereby inducing stronger, not weaker binding, and no dissociation, e.g., into positive and negative ions, can be expected from the absorption of light. It is not impossible, however, that an electron should be removed from the anion by radiation, although spectra corresponding to the reaction

termed electron affinity spectra are not yet known. In such case we should have dissociation of the molecule into a positive ion, a neutral atom, and an electron, thus:

In homopolar molecules Franck suggests two types of linkage. In one, electrons are shared in common (covalency), e.g., in H_2 and O_2 : "such molecules cannot separate from the normal state adiabatically into two atoms, and the electron jumps associated with the formation and dissociation of these molecules cannot be produced by radiation processes but only through collision." In agreement with this no point of convergence of bands has been observed in the molecular spectrum of hydrogen. A second type of homopolar linkage is, however, of much smaller strength—sometimes termed van der Waal's forces, i.e., akin to the attraction between gas molecules and the chemist's residual affinity operative in molecular association. Here the molecule may take up so much oscillation energy through absorption that it will separate into a normal and an excited atom. There is evidence that the halogen molecules belong to this class. The absorption

spectrum of iodine, which is approximately represented in fig. 2, indicates that the shorter the wave-length, the smaller the interval between the oscillation-quanta, until a real convergence limit appears at about 5,000 A.U. with a strong continuous spectrum beyond. The Angstrom unit, Å.U., = 10^{-8} cm. = $0.1\mu\mu$. Bromine and chlorine also show continuous spectra, of known wave-length limits, 5,200 A.U. for Br₂ and 4,800 Å.U. for Cl₂. This con-

FIG. 2.— DIAGRAMMATIC REPRESENTATION OF A PORTION OF THE ABSORPTION SPECTRUM OF IODINE

vergence limit seems to be critical for dissociation of the molecule; and it may be assumed that *absorption of light of wave-length equal to or shorter than these convergence limits of the band spectra will dissociate the molecule into a normal and an excited atom*. Recent work indicates that the absorption spectrum of oxygen, O₂, is similar to that of iodine but the continuous spectrum lies at a much shorter wave-length. Furthermore, the ultra-violet absorption spectra of HBr and HI during photochemical decomposition were found to be continuous. Hence it is concluded that these molecules also are directly dissociated into atoms by light absorbed in this region.

Types of Photochemical Reaction.— On the basis of comparison of the absorption spectrum with actual photochemical behaviour, we have then a very important division of photochemical reactions into two classes. (This division was clearly suggested by J. Franck, "Elementary Processes of Photochemical Reactions," *Faraday Soc. Symposium*, but more explicitly developed by R. H. Gerke, *J. Amer. Chem. Soc.*, 1927, 49, p. 2671.) In one class, the molecule is merely converted by absorption of radiation into an "excited" molecule,

The resultant excited molecule may: (a) lose energy by radiation (fluorescence, resonance radiation), or (b) lose energy by collision with another molecule, in which case a number of things may happen. The most likely is conversion to heat, as energy of translational motion. The broadening of absorption lines in gases with pressure, and in solutions, the reduction of fluorescence by inert gases, are evidence of energy "damping" of this kind. Another possibility, however, is collision not with an indifferent molecule, but with an acceptor, *i.e.*, a molecule capable of reacting with the excited molecule, or of itself undergoing chemical change. In all cases where the excited molecule itself appears in the photo-product, we have what has been conveniently termed (R. H. Gerke, *loc. cit.*) the *excited reactant* type of photochemical reaction. Some examples are given in the following table:

Reaction	Excited molecule	Type of spectrum	Active radiations, Å.U.	Quanta absorbed per ml. of reaction	Heat effect of reaction
O ₂ = 2/3 O ₃	O ₂	Rand	1,970-1,756	1.04-3.4	Endothermic
NH ₃ = 1/2 N ₂ + 3/2 H ₂	NH ₃	"	2,260-1,515	2-10	"
O ₃ = 3/2 O ₂	O ₃	"	6,700 and u.-v.	..	Exothermic
H ₂ + 1/2 O ₂ = H ₂ O (dry)	O ₂	"	1,970-1,756	..	"
CO + 1/2 O ₂ = CO ₂ (dry)	O ₂	"	1,970-1,756	..	"
CH ₃ ·CHO + 1/2 O ₂ = CH ₃ ·COOH	CH ₃ ·CHO	"	2,800-2,350	..	"

Where, however, the excited molecule does not itself enter into chemical reaction, but colliding with another different molecule induces chemical change in this, we have an *excited sensitizer* or photocatalysed reaction. The first cases of gas reaction

of this type were discovered by F. Weigert (1907), being a number of reactions in which chlorine gas in light produced decompositions or combinations without appearing in the products. A notable example was the sensitized decomposition of ozone by chlorine. Recent experiments on the excitation of mercury vapour in ultra-violet light have widened the field of these reactions and helped to clarify their nature. In experiments on the excitation of gas molecules or atoms by electrons of known velocity (voltage), it was found that for a certain velocity of the electron a bombarded atom became excited and emitted radiation of definite wave-length. The system of the atom plus electron lost kinetic energy just equal to the quantum radiated. But conversely, a slow moving electron colliding with an excited atom might gain kinetic energy, the atom becoming normal without radiating. Such collisions are termed "rayless collisions of the second kind." The same kind of rayless transfer of quantized energy was also found to be possible between atoms and molecules in gases. Cario and Franck showed that mercury atoms, excited by the resonance line λ 2537, could transfer their excess energy to hydrogen molecules, with production of "active" hydrogen, very possibly atomic hydrogen, according to the reactions

A considerable number of such mercury sensitized reactions have now been investigated by H. S. Taylor and others. The intermediate "active" hydrogen has been caused to decompose ethylene, C₂H₄, carbon monoxide, CO, forming formaldehyde, solid polymers, and methane. Some of these excited sensitizer reactions are here tabulated:

Reaction	Absorbing sensitizer	Type of spectrum	Active radiation, Å.U.	Quanta of radiation per mol. reactant	Heat effect of reaction
H ₂ = 2H	Hg	Line	2,536	..	Endothermic
O ₃ = 3/2 O ₂	Hg	"	2,536	..	Exothermic
H ₂ + 1/2 O ₂ = H ₂ O	Hg	"	2,526	..	"
N ₂ O ₅ = N ₂ O ₄ + 1/2 O ₂	NO ₂	Band	4,600-4,000	..	Negligible

In both these "excited molecule" reactions, the chemical yield on the photochemical equivalent basis will very probably not agree with the Einstein equivalence principle, because the excited molecule may lose energy either by fluorescence or by ineffective collisions. Yet the primary event, formation of an excited molecule, is itself regulated by the photochemical equivalence. If, however, the absorbed frequency is equal to or greater than the convergence limit of the band spectrum of the substance, absorption takes place with *primary decomposition*:

and here the yield is in full agreement with Einstein's law. It appears therefore that when absorption takes place of frequencies still low enough for the atom or molecule to resonate, photochemical reaction need only follow indirectly. When, however, the radiation "note" is pitched too high for the system to resonate, the atom or molecule is shattered.

Chain Reactions.— In many exothermic photochemical reactions it is found that the photochemical efficiency may be manifold, up to 10⁶ molecules per quantum absorbed. The most fully studied, though still incompletely unriddled, example is the union of chlorine and hydrogen in light:

In the completest possible absence of water vapour, this reaction does not proceed in ordinary and ultra-violet light within the band spectrum of chlorine, but does so in ultra-violet light at

3,000 Å.U. In the first case, only an excited Cl_2^* molecule is formed, which is unable to activate hydrogen in absence of water. In the second case, primary decomposition into an excited and normal molecule is believed to occur

The chain reaction somewhat as proposed by Nernst probably follows:

In the presence of water vapour, even excited molecules can initiate chains of much greater length. This would signify that "activated molecules" or metastable molecular complexes must be formed of much longer life than the 10^{-8} second usually assigned to excited molecules.

The conception of reaction chains to explain high quantum yields was introduced by M. Bodenstein and developed by W. Nernst. In the type just instanced, implying a primary decomposition reaction, a free atom or group is produced. This reacts with one of the original molecules, forming another free atom or group, and so forth. The process is exhausted by the gradual recombination of the free atoms or groups with each other. In another type, an excited molecule is produced, which activates a molecule of reactant by collision. This activated molecule then forms another activated molecule of the product, and so on. There is therefore a succession of rayless transfers of energy, the chain ceasing again by dissipation of energy in fruitless collisions. It is very possible that in certain cases, particularly where water vapour plays a part, metastable intermediate molecules or groups are formed.

Photochemical Induction, Inhibitors and Water Vapour.—The classical investigations of Bunsen and Roscoe upon the photochemical union of chlorine and hydrogen revealed the existence of a "latent period," during which no combination occurred. They regarded this "induction" as common to all chemical reactions, as required for the overcoming of starting friction. Many explanations were offered of "photochemical induction" until D. L. and M. C. C. Chapman showed it to be due to the presence of specific impurities. These suspend or inhibit the reaction until destroyed by the light or the photochemical change itself. In the hydrogen-chlorine reaction, ammonia is an important inhibitor, as are the oxides of nitrogen. Oxygen again can function as an inhibitor, either by itself accepting hydrogen atoms, or by reacting with excited chlorine atoms. In many reactions, substances may act as negative photocatalysts simply by absorbing exciting radiation.

In certain gas reactions, water vapour may appear as a positive catalyst, as for example in the combination of chlorine and hydrogen in visible light. Explanations range from intermediate hydrates (containing active atoms) to facilitation of an action limited to a polar layer on the walls of the reaction vessel.

Photochemistry and Carbon Compounds.—The number of organic syntheses and decompositions capable of being effected by light has been greatly increased as more efficient sources of ultra-violet light become available. Most of these, however, remain quantitatively unprobed, and so far relatively few have become tools for organic synthesis. The most important investigations in this field at present are those concerned with the quantitative measurement and interpretation of absorption spectra (a notable work is V. Henri's "*Etudes de Photochimie*," 1925), from which we may anticipate certain approximate inductions on the photochemical reactivity of specific groups (or specific linkages), such as $>\text{C}=\text{O}$, $>\text{C}=\text{S}$, $-\text{C}=\text{C}-$, $\text{N}\equiv\text{C}-$, etc., either singly, conjugated in chains or condensed. And this may yield a workable knowledge of relations between photochemical reactivity, unsaturation and the life-periods of free radicals. Among synthetic reactions, the photo-polymerizations of vinyl compounds are perhaps the most interesting, because of the relations of such bodies to organic high-molecular colloids, such as the rubber hydrocarbon $(\text{C}_5\text{H}_8)_x$, starch $(\text{C}_6\text{H}_{10}\text{O}_5)_m$, and cellulose $(\text{C}_6\text{H}_{10}\text{O}_5)_n$ and eventually proteins, $\text{NH}_2(\text{CO}\cdot\text{NH})_m\text{COOH}$.

There are two organic photolyses of quite dominating impor-

tance. These are the retinal process underlying vision, and the green leaf assimilation of carbon dioxide. The photochemical basis of vision consists in the bleaching-out of an organic pigment, "visual purple." This is regenerated in darkness by a secondary chemical process, which appears to be molecular in character. We can represent this process by the symbol

Photosynthesis.—The green leaf synthesis of starch, which is the basis of the great photochemical industry of agriculture, is generally emphatically termed photosynthesis. The riddle expressed in the crude equation

Carbon dioxide + Water form Starch + Oxygen

is by no means solved. The *formaldehyde hypothesis* of Baeyer explains the production of carbohydrates (starches, sugars, cellulose) by a primary formation of formaldehyde

Carbon dioxide + Water form Formaldehyde + Oxygen

by light in the presence of chlorophyll, which is supposed to be followed by a biochemical or photochemical condensation of the formaldehyde

This theory has been strongly supported by B. Moore, D. Berthelot, and recently by E. C. C. Baly, and severely criticized by H. A. Spoehr, whose monograph "Photosynthesis" (*American Chem. Soc. Monographs*, 1925) furnishes a very complete study of the subject. The issue is of capital importance for chemistry, perhaps ultimately for the economy of mankind, since it is concerned with the basic process of food production. Baly and his co-workers claim that the reaction:

can be effected, (a) by ultra-violet rays at 2,060 Å.U., (b) by sunlight in the presence of dyes such as Malachite Green. They also assert that the condensation of formaldehyde to reducing sugars can be effected by ultra-violet rays at 2,900 Å.U. More recently Baly has published further evidence supporting the production of alkaloids by direct photochemical synthesis *in vitro*.

Meanwhile the work of other investigators, notably O. Warburg, R. Wurmser and H. A. Spoehr, following the pioneer efforts of A. Brown and H. Escombe, has shown the actual photochemical efficiency of the chlorophyll sensitizer to be fairly high, perhaps up to 80% of an absorbed quantum being converted into stored chemical energy at moderate light intensities. *Chlorophyll*, the chemical constitution of which has been unravelled by the masterly work of R. Willstätter, undoubtedly acts as a photo-chemical sensitizer, like the dyes used in photographic processes (*q.v.*).

Industrial Prospects.—The total amount of solar energy incident upon the earth's surface is very great. Taking a solar constant of 1.5 calories per sq. cm. per minute, it can be calculated that onto every square mile of the Sahara Desert about 67 billion British Thermal Units of heat are given by the sun in a 6-hour day; the area of this desert is about 2,300,000 sq. miles. If, therefore, only a minute fraction of this heat could be utilized we should be able to realize the prophetic words of a great chemist (G. Ciamician): "The exhaustion of coal will not halt civilization, destined to advance as long as the sun shines. Then our sooty and neurotic age of coal will yield to a purer and calmer epoch, relying upon solar energy for a fortune and a progress without mischance."

PHOTOELECTRICITY. The photoelectric effect is the name given to the power shown by light, X-rays and γ -rays of causing a body to emit electrons, or negative electricity. Light, X-rays and γ -rays are all electro-magnetic radiations differing only in their wave-lengths, that of light being the longest; and it is the electric forces in the radiation, acting on the electrons in the atoms of the body, which communicate sufficient energy to the electrons to set them free from the atom, and even to give them very high velocities. The phenomenon is interesting and important from several points of view, of which the chief is that it represents one of the three fundamental methods of interaction between radiation and matter, the other two being resonance-absorption and scattering. The laws governing this phenomenon are simple to express although difficult to understand, and maintain their validity over an enormous range of wave-length. Ordinary light has a wave-length one million times as great as that of the short γ -rays, but yet the relation governing the speed of the ejected electron is the same in both cases.

The study of the photoelectric effect has raised many points of great interest in connection with our views as to the real nature of radiation, since it brings to light a behaviour apparently irreconcilable with the simple continuous wave-theory used to explain interference. While this disagreement still defies explanation, the effect is sufficiently understood to be of the greatest use in elucidating the structure of the atom. The reason for this lies in the fact that the action of the radiation on an atom is selective. While long wave-length light leads to the ejection of electrons from the outer portions of the atom, the much shorter wave-length X-rays and γ -rays interact chiefly with the innermost electrons. From the nature of this interaction it is possible to obtain information successively about the different electrons in the atom.

The photoelectric effect is not only important from the purely scientific standpoint, but also finds a most important practical application in the construction of the photoelectric cell, which is one of the most trustworthy methods existing for measuring the amount of energy in a beam of light. It has rendered possible the construction of accurate photometers for determining the density of photographic plates, and has given methods for measuring the amount of light emitted by extremely faint stars.

The action of the radiation being to cause the ejection of electrons from atoms, it will be seen that the primary questions regarding each individual process are how fast the electron is ejected and in what direction, and to this must then be added the question of how many electrons are set free each second when radiation of given intensity is incident on matter. More or less satisfactory answers can now be given to these questions, and the history of the subject is best described by reference to those researches which showed how the number and velocity of the electrons depended on the intensity and wave length of the radiation.

Historical and General.—The study of photoelectric effects started in 1887, when Hertz found that ultra-violet light falling on a spark-gap enabled a discharge to pass more easily than when the gap was not illuminated. A year later Hallwachs made the important observation that, while ultra-violet falling on a negatively charged body caused a rapid loss of the charge, no loss of electricity occurred when the body was initially positively charged. It was not very long before the cause of this behaviour was discovered, and in 1899 J. J. Thomson and P. Lenard showed independently that the action of the light was to cause the emission of negatively charged corpuscles identical with the cathode rays in a discharge tube

In the following years a great deal of work was carried out on this peculiar action of light, and attention was first directed to the intensity of the emission and how it depended on the state of the surface of the metal and on the polarization of the light. In 1902 Lenard opened up a new method of investigation by directing attention to the velocity of the ejected electrons. He was able to show that the maximum velocity of the electrons was inde-

pendent of the intensity of the light but did depend on the wave-length. He appreciated quite clearly the difficulties this raised in the way of any explanation, since the obvious suggestion of the ejection being due to a transference of energy from the light to the atoms of the metal by some resonance action was rendered impossible by its lack of dependence on the intensity. It was this work which formed the basis of Einstein's famous paper of 1905. Einstein suggested that the general phenomenon of the conversion of light could be better understood on the assumption that the energy of light radiation was not distributed continuously in space. As radiation spread out from a source he imagined it to remain localized in small bundles, or energy quanta, which became further and further apart as they receded from the source, whilst individually remaining unchanged. He pointed out that when an atom absorbed radiation the simplest assumption would be that a light quantum gives its whole energy to an electron. It was natural to associate the energy of the light bundles with the definite amounts of energy postulated by Planck in his quantum theory of black body radiation. Hence Einstein suggested that, at every act of absorption, the energy received by the electron was $h\nu$, ν being the frequency of the radiation and h a universal constant which should be identical with that occurring in Planck's formula for the black body radiation.

It follows therefore that the maximum energy of the electrons ejected by radiation of frequency ν is

$$h\nu - P,$$

where P represents any work that has to be done in removing the electron from the place where it absorbs to the place where it is observed. We may subdivide this further and write w for the work to remove the electron just clear of the atom, and P' for the work to remove the electron clear of the body as a whole. These quantities w and P' have different values and importance according to the region of wave-length concerned. P' , the work to remove the electron clear of the body, is intimately connected with the work function occurring in Richardson's thermionic equation, and is negligible except in the case of visible light. The quantity w is far more interesting, and depends on the particular position in the atom from which the electron comes. It is a true atomic constant. Up to a certain point we may imagine the electrons in the atom to be arranged in shells, each shell characterized by a certain energy. To remove an electron from a shell and merely to bring it outside the atom with a vanishingly small energy will require the expenditure of a certain characteristic amount of work, w_1, w_2, w_3 , etc., according to whether the electron comes from the first, second or third shell. We see, therefore, that on Einstein's hypothesis, light of frequency ν incident on a collection of such atoms would liberate several groups of electrons of different energies:

$$h\nu - w_1, \quad h\nu - w_2, \quad h\nu - w_3;$$

but that the innermost shells would be untouched if the energy of the quantum $h\nu$ were less than the characteristic energies of the shells w_4, w_5 , etc.

It only remains now to write down the expression for the energy of the electron in order to obtain Einstein's famous equation. For low velocities this may be written $\frac{1}{2}mv^2$, but for high velocities near that of light the correct relativity expression must be used. This is

$$mc^2 \left(\frac{1}{\sqrt{1 - \beta^2}} - 1 \right),$$

where m is the mass of the electron, c the velocity of light *in vacuo*, and β the velocity of the electron. It is frequently convenient to express this energy by giving the potential fall in volts V an electron e must pass through in order to acquire this energy. Then, if e is the charge on the electron in electrostatic units (4.774×10^{-10}), and since 300 volts equal one electrostatic unit of potential, we have finally

$$\frac{V}{300e} = mc^2 \left(\frac{1}{\sqrt{1 - \beta^2}} - 1 \right) = h\nu - w.$$

The equation as written here is more explicit than that originally given by Einstein, and considerable research was needed to establish it, but essentially it was all implied in the original paper. The succeeding sections indicate the main steps by which this prediction was shown to be true and how its details were elucidated.

Proof of the Einstein Law for Light.—The law proposed by Einstein connecting the energy of the photoelectron with the

FROM MILLIKAN, "THE ELECTRON" (UNIVERSITY OF CHICAGO PRESS)

FIG. 1.—MILLIKAN'S APPARATUS FOR DETERMINING THE ENERGY OF PHOTO-ELECTRONS LIBERATED BY LIGHT OF KNOWN WAVE-LENGTH

frequency is noteworthy, not only for its simplicity but also because it introduced Planck's constant h into a fresh domain. It was seven years after Einstein had shown his theory agreed in its general lines with Lenard's experiments before it was established definitely by O. W. Richardson, K. T. Compton and also A. L. Hughes that the energy of the emitted electron did increase proportionately with the frequency, and that the constant of proportionality was approximately equal to the value of Planck's constant h obtained by other means. Subsequently Millikan carried out an extensive research which established the relation so accurately that it is now considered to give one of the most trustworthy values for h . This method is typical of the best method of investigation of the photoelectric effect of light and will be described in some detail. The apparatus is shown in fig. 1, and may conveniently be considered in two parts, as divided by the dotted line. Cast cylinders of the alkali metals (sodium, potassium, lithium) were mounted on an axle in a highly evacuated glass vessel. The actual experiment is carried out by the part of the apparatus to the right of the dotted line, light entering through the window, and falling on the metal surface. Previous work had shown that reliable results could be obtained only when the metal had a clean, fresh surface prepared in *vacuo*, and the apparatus on the left of the dotted line consisted of various devices by which the cylinder of alkali metal could be brought opposite the knife, which was then operated by an electro-magnet outside the tube so as to shave off the outer layer of the alkali metal, leaving a fresh uncontaminated surface. Supposing this to be done the cylinder was then rotated to be opposite the window and the actual experiment could begin. A beam of monochromatic light from a spectrometer passed through the window and fell on the prepared surface, leading to the emission of electrons which were collected by the gauze cylinder, on the right side of the apparatus, connected to a quadrant electrometer. If a small positive potential were then applied to the metal block, the electrons would arrive at the gauze with lower energies, owing to the retarding action of the potential. The maximum energy of emission could thus be measured by finding that positive potential V which just sufficed to prevent any electrons arriving at the gauze and communicating their charge to the quadrant electrometer. The maximum energy of the electrons is then Ve , where e is the electronic charge. Millikan showed to an accuracy of one half of 1% that, with each metal, the energy of the emitted electrons varied linearly with the frequency of the light, and that in each case the constant of proportionality was the same, and equal, within the experimental error, to the values obtained for Planck's constant by other methods.

Photoelectric Effect of X-rays or γ -Rays.—The essential distinction between the photoelectric effect of X-rays or γ -rays and that of light lies in the higher frequency of the former radiations and in the correspondingly greater energy of the quantum.

The energy given to the atom is now measured in tens of thousands of volts or even hundreds of thousands of volts, and not in tens of volts as in the case of light. It is to be expected that different methods of investigation must be used to meet the changed conditions, but besides this there is a shift of the point of interest. The amount of energy transferred to the electron is so large that the energy lost in getting free of the body as a whole is negligible in comparison, but on the other hand the large energy of the quantum enables electrons to be removed from even the innermost orbits of the atom. Radiation of one frequency can thus give rise to a series of electron groups of different energies, according to whether they are ejected from the outer or inner orbits of the atoms. The electrons from the innermost orbits will have used up the greater portion of their $h\nu$, and will therefore emerge with the lowest velocities, whereas those from the outer levels will have energies close to that of the quantum. It will be realized that there is here an admirable method of investigating the inner structure of the atom. By studying the energies of the different groups of photoelectrons and finding how much less these energies are than that of the original quantum, we can ascertain the orbit from which each electron comes, and the general character of its interaction with light under given conditions.

The general type of apparatus which is used in these investigations is shown in fig. 2. The source of the photoelectrons may be either a thin foil on to which X-rays are fired from outside the box, or a wire coated with radioactive material, which, as will be described later, is a copious emitter of photoelectrons. Above the source is a slit which allows a beam of the electrons to pass. This apparatus is placed in an evacuated box between the poles of a large electromagnet, and on application of the magnetic field the beam of electrons is bent round into circular paths. By this process it will be analysed into its different velocities, since the fastest electrons will describe the largest circles, and the slowest electrons the smallest circles. A record of the velocity spectrum of the photoelectrons is obtained by a strip of photographic plate. This is frequently referred to as the focussing method since, as can be seen from fig. 2, the rays leaving the source within quite a large solid angle are concentrated in one spot on the photographic plate. A reproduction of a photograph was taken recently in this way by Prof. H. H. Robinson.

This type of apparatus does not give lines sharp on both sides but only on the high velocity side, and a series of such lines can be seen on the photograph. These show the various groups of electrons ejected from gold atoms by the characteristic $K\alpha$ X-rays of

FIG. 2.—FOCUSSING METHOD OF ANALYSING COMPLEX BEAM OF ELECTRONS BY REFLECTION IN UNIFORM MAGNETIC FIELD

copper ($Cu K\alpha$). On the original photograph it is possible to distinguish no less than 13 groups, some of which are partially superimposed. All of these are due to the absorption of the same frequency radiation, and the difference in the energies of the groups is due to the multiplicity of the electron levels in gold.

This method was first tried by Robinson and Rawlinson in 1913, and owes its development largely to M. de Broglie. Since the frequency of the X-rays used is known from crystal measurements, and the energies of the electron groups can easily be ascertained from the geometry of the apparatus and the value of the

magnetic field, it has been possible to verify Einstein's law with considerable accuracy. The accurate measurements carried out by Robinson have confirmed the truth of this equation to be at least one part in 300. It should, however, be emphasized that the importance of the method is that it provides an admirable means of investigating the electron levels in the atom, and from the intensity of the photograph traces it is possible to estimate the probability of absorption of the radiation by each of the separate levels.

Instead of using X-rays generated in the usual way, it is possible to employ the natural X-rays or γ -rays emitted by radioactive bodies during their disintegration. These are similar to X-rays, only in most cases the frequencies, and therefore the energy of the quantum, are much higher. It was by obtaining photographs by the use of these rays that it was first possible to demonstrate that the γ -rays were sharply monochromatic, and constituted a true characteristic spectrum of the nucleus. This method is particularly interesting in this connection since it forms the only practicable way of measuring the wave-length of γ -rays. The ordinary crystal methods of measuring the wave-length of X-rays are difficult to apply as the wave-length is so short, and before the photoelectric effect was understood only estimates could be made. By investigating the photoelectrons ejected from various metals by the γ -rays, Ellis was able to ascertain the particular portion of the atom from which the electrons were being emitted, and then a simple measurement of their energies, coupled with our X-ray knowledge of the atom, immediately yielded the $h\nu$ of the γ -rays.

An entirely different method of investigation is rendered possible by C. T. R. Wilson's cloud track apparatus in which, by a sudden expansion, moist air enclosed in a suitable chamber is put in a condition of supersaturation. The degree of supersaturation is so chosen that in the absence of any nuclei no condensation occurs. Immediately after the expansion a flash of X-rays is allowed to pass through the chamber, and condensation occurs on the ions that are formed. If suitably illuminated these water drops can be photographed. The X-ray beam was limited to a narrow pencil down the centre of the chamber and five separate photoelectrons were visible. Each of the tracks of these photoelectrons shows the history of a separate absorption of a quantum of energy $h\nu$ by the atom located at the head of the track.

The electrons are ejected with such a high velocity that they can penetrate a considerable distance through the gas. Their path is marked by the ions they form in their passage. In the case of electrons formed by X-rays of lower frequency the speed of ejection is less. This is shown in photographs which reveal the greater tortuosity of the paths and the greater density of the water drops along a track.

The Compound Photoelectric Effect.—This is differentiated from the ordinary photoelectric effect of X-rays by the fact that the absorption of the radiation by an atom leads to the ejection of two electrons, and not one as in the other case. Its existence, although previously suspected, was first clearly demonstrated by P. Auger using the Wilson cloud track chamber method. The gas in the chamber through which the X-rays passed consisted of a small percentage of a heavy gas, such as argon, mixed with hydrogen. The argon is found to be responsible for almost the entire X-ray absorption and the small stopping power of hydrogen allowed the ejected electrons to traverse reasonably large distances and give good tracks.

It might be thought that the double tracks of the photograph only show a normal photoelectric effect by two atoms so close together that the tracks appear to start from the same point, but these double tracks occur far more frequently than would be expected on a probability basis, and it is simplest to consider them to come from one atom by some slight modification of the usual process. It will be seen that the further facts support this hypothesis. If a series of such photographs are taken under exactly the same conditions, with the one exception that the voltage on the X-rays (i.e., the frequency of the X-rays) is increased, it is then found that, while one member of a pair of tracks increases in length as predicted by Einstein's equation, the other shows no

change. This must not be taken to show an exception to Einstein's equation but rather that this second track is due to some process in the atom, admittedly excited by the primary radiation, but yet not directly depending on its frequency. The first action of the radiation is to eject an electron from the atom in the normal photoelectric way, and the second track occurs because the atom is left in what is called an "excited state" that is capable of further changes.

In the article *ATOM* it is explained how for numerous purposes we can picture the electrons in the atom arranged in a series of shells or groups, each characterized by a definite energy. The process of radiation is held to be due to the removal of an electron from an inner group and the subsequent filling up of the gap by one of the electrons previously in an outer group. Now in the compound photoelectric effect the primary effect of the X-rays is to remove an electron from one of the groups of an argon atom, and in the majority of cases this will be from the innermost or K group. The argon atom is now said to be excited in the K group, and a subsequent transition of one of the outer electrons into this vacant place will lead to the emission of one quantum of the argon K radiation. Sometimes this radiation escapes from the atom, but it may be internally absorbed and never escape at all. In this case the argon atom will emit a second photoelectron whose energy, and therefore length of track in the gas, is determined by the frequency of the argon K radiation and not by that of the incident X-radiation. It will, therefore, not change when the frequency of the incident X-rays is changed. It is possible to secure a second and even a third repetition of this interesting process thereby giving rise to the emission of three or four photoelectrons from one atom.

This phenomenon has been described as if an excited atom always emitted its surplus energy first in the form of radiation, but that, on occasion, this could be subsequently reabsorbed in the same atom. It is held by many authorities that it is rather artificial to imagine radiation to be emitted, apparently to exist independently of the atom, and then to be reabsorbed all inside the minute volume of the atom. It is maintained that it is simpler to state at once that an excited atom, that is an atom with greater energy than the normal, has at its disposal two distinct methods of getting rid of its extra energy, either by emitting a quantum of radiation, or by emitting an electron. There is no doubt that this is a difficult point, but a somewhat similar phenomenon occurs among the radioactive bodies, when, in the opinion of the writer, the evidence is strongly in favour of a true internal absorption of radiation.

The phenomenon of radioactivity is due to a disintegration of the central positively charged nucleus around which are the electrons forming the rest of the atom. Frequently accompanying the actual disintegration, which involves the emission of a material particle from the nucleus, either the α - or β -particle, there is also an emission from the nucleus of very high frequency radiation called the γ -rays. These are of the same type as X-rays, but of higher frequency. These γ -rays are quite frequently absorbed in the parent atom in their passage out from the nucleus through the electronic system, and give rise to high speed photoelectrons. As some radioactive bodies emit a considerable number of different frequencies, each of which can be converted in either the K, L, M, N, etc. levels, it will be seen that a great number of photoelectric groups are possible. These may be investigated by the magnetic spectrum method, previously described in the case of X-rays, and illustrated by fig. 2. In this case, however, since the radioactive body is at one and the same time both the source of radiation and of the photoelectrons, it is merely necessary to place a wire coated with the radioactive material underneath the slit to obtain results.

The radioactive body used was Radium B, and the radiations have an average frequency corresponding to about 300,000 volts. The great complexity of the spectrum may be seen from this reproduction which only shows a part of the spectrum; to obtain all of it different magnetic fields would have to be used. The sharpness and narrowness of the lines is noteworthy. The reason for this is that, in this γ -ray case, all the photoelectrons are due

to this internal absorption in the parent radioactive atom, and, since the radioactive material only forms the thinnest imaginable layer on the surface of the wire, all the electrons emerge with their full velocity. In the X-ray case, when there is external absorption, photoelectrons are emitted throughout the body of the source, and, while those coming from the surface will have the greatest energy and will form the sharp edge of the line, those liberated inside the material can also get out, but will lose a portion of their energy in the process. They thus hit the photographic plate nearer the source and produce a long tail to the line.

This case of internal absorption is to some extent analogous to the compound photoelectric effect with X-rays, and here there is evidence that we may regard the γ -ray in all cases to be emitted but sometimes to be reabsorbed. On the one hand is the entire lack of any evidence of any other form of interaction between the nucleus and the electronic structures, which makes it doubtful to assume it in this case. On the other hand it has been shown by Ellis and Wooster that this internal absorption appears to obey exactly the same relations as those found for normal external absorption. If this view be substantiated by future work, we have here an extremely interesting example of a photoelectric effect all occurring within the minute volume of an atom.

The Direction of Emission of the Photoelectron.—A matter of great interest is to ascertain how the initial direction of emission of the electron is associated with the direction of the electric force in the radiation. It is well established that radiation is some type of electro-magnetic disturbance propagated through space in which electric and magnetic forces at right-angles are associated, both also being at right-angles to the direction of propagation. (See ELECTRICITY.) It is to be anticipated that it is the electric force which acts directly on the electron and wrests it from the atom, so that we should expect the electrons to have at least a large component of this motion in the direction of the electric force. The effect of the magnetic force on the electron, when once it is in motion, will be to throw it slightly forward. However, it is scarcely to be anticipated that all the electrons will come out at exactly the same angle to the electric force, since there are many subsidiary effects which will tend to introduce variations and produce a distribution over a range of angles instead of one unique direction.

This phenomenon is most easily studied in the case of the photoelectrons liberated by X-rays and γ -rays, when the velocities are considerable and the electrons have sufficient energy to penetrate several centimetres of a gas. The most fruitful method of investigation is by the Wilson cloud track method, which has already been referred to. If a thin pencil of unpolarized X-rays is sent through a Wilson chamber and the tracks photographed, we can determine at once what is called the longitudinal distribution. The exact direction of the electric vector is always changing, but of necessity it must be always at right-angles to the direction of propagation. If the cloud tracks are photographed with a stereoscope camera we can count the fraction of electrons which are emitted with their directions initially within say 5° of the direction of propagation, between 5° and 10° , and so on, obtaining in this way a distribution curve. The general results are as would be anticipated. Very few electrons travel near the direction of propagation either forward or backwards, the greater number tending to go off more at right-angles in the direction of the electric vector. The distribution curve therefore shows a marked maximum for directions at right-angles to the direction of propagation.

However this is not all, there is a small subsidiary effect which seems to be of great importance. This maximum of the distribution curve is not exactly at right-angles to the direction of propagation, it is shifted a few degrees forward, so that rather more electrons go forward than go back. This becomes more pronounced as the wave-length gets shorter. While for light and soft X-rays it is not to be detected, it may amount to 10° , 20° or 30° for hard X-rays or γ -rays. The primary cause of this asymmetry is to be found in the magnetic forces in the wave-front, but a simple description can also be given on the light-quantum picture. Imagine a quantum of energy $h\nu$ impinging on an electron, being

absorbed, and communicating all its energy to the electron. This quantum is not only characterized by its energy, it will also have momentum of amount $h\nu/c$. If we assume that the other causes responsible for the distribution would only produce a symmetrical spread about the direction of the electric vector, we can say that owing to the momentum of the quantum there should finally be an average forward momentum of amount $h\nu/c$. This does shift the maximum forward by about the right amount; but according to some new measurements by Williams there is not exact agreement—the predicted shift is not large enough. Either some other cause is at work or the electrons in the atom, which are moving forward at the instant the wave passes over them, have a preferential chance of absorbing. This is an interesting point and seems likely to shed fresh light on the details of the interaction of radiation and matter.

Another type of asymmetry has also been investigated. By suitable arrangements a beam of polarized X-rays can be obtained. Suppose this is travelling along the direction of x , and the electric vector in the polarized beam is parallel to the y axis. By taking Wilson cloud photographs close to the direction of the x -axis we can now find how the photoelectrons are distributed in the yz plane. As before a distribution is found, but this time, as would be expected, it is symmetrical. The maximum number occurs parallel to the electric vector and there appear to be very few indeed which come off at right angles to this.

Number of Photoelectrons Ejected.—The discussion so far given has centred round the elementary process of the conversion of a quantum and liberation of a photoelectron, and this process has been shown to be described completely by Einstein's equation. Thus, having treated what happens when a quantum is absorbed, the question now arises how often quanta are absorbed. It is the essential peculiarity of the photoelectric effect that these two points can be separated so completely, the energy of the ejected electron depending only on the frequency and being entirely independent of the intensity of the radiation, whereas the number of electrons ejected is directly proportional to the intensity.

In considering the number of photoelectrons set free it is simplest to go at once to the conception of an absorption coefficient. Suppose I ergs per sec. are incident upon each square centimetre of a very thin slab of matter, of thickness δx , then the number $6n$ of photoelectrons set free per second will be

$$\delta n = \mu \frac{I}{h\nu} \cdot \delta x,$$

where μ is called the absorption coefficient and is a characteristic constant of the material and of the frequency of the radiation. If this is applied to a gas it will give exactly the number of tracks that would be observed by a Wilson cloud apparatus. In the case of a solid it is usually rather complicated to deduce the actual number of electrons that emerge, since the scattering and absorption of the electrons liberated inside the solid are difficult to follow in detail.

It is simplest to consider first the case of the X-rays and γ -rays, and afterwards the absorption effect of one particular set of electrons in the atom, say the K or L electrons. The total absorption of the material is then obtained by adding together the absorption of all the different sets of electrons in the atom. The first point to notice is that absorption, for example by the K electrons of tin, does not start until the frequency is increased to a certain limit. This limit which is characteristic for tin is determined by the condition that the $h\nu$ of the radiation shall be just equal to the work necessary to remove a K electron to the surface of the atom; *i.e.*, absorption commences with the production of photoelectrons of zero energy. From this point onwards, when the absorption is a maximum, it decreases steadily at first about as ν^{-3} , and later, in the γ -ray region, rather less rapidly. The attempt to extend these results towards the region of visible light meets with considerable experimental difficulties, but recently approximate values for the absorption by potassium vapour in the near ultra-violet have been obtained, which may be considered as the extension of the preceding results.

The number of electrons ejected by light engaged the attention

of the early experimenters from rather a different aspect. The experiments were usually carried out with reflecting surfaces of the alkali metals, and an interesting dependence of the number of photoelectrons on the state of polarization of the light was observed. If the light was incident obliquely and was so polarized that the electric vector had a component perpendicular to the surface, the number of electrons ejected was found to be greater

FIG. 3. — PHOTOELECTRIC CELL

than if the electric vector lay wholly in the surface. This phenomenon was investigated in great detail by Pohl and Pringsheim, who found the variation of the emission with change of wave-length of the light when compared on the basis of equal amounts of incident energy. When the electric vector had a component perpendicular to the surface they found a maximum occurred at a certain wave-length, which was not present with the other type of polarization. This led them to effect a division of the whole effect into a normal and a selective effect, the latter showing the maximum.

The important bearing of this subject on the nature of light depends entirely on the surprising fact, expressed by Einstein's equation, that the velocity of the ejected electron is determined only by the frequency of the radiation, and is independent of the intensity of the radiation. This is entirely contrary to what we should expect from a wave motion, yet the phenomena of interference, and in fact the whole of ordinary optics, appear to show indubitably that radiation is a wave motion. This will be apparent if we imagine first a metal plate placed so close to an X-ray tube that the radiation is pouring on to it, and then removed so far away that the radiation is even difficult to detect. On the wave picture one would say that, in the second case, the electric vector in the radiation hitting the plate was very much weaker than in the first, and we would expect that not only would the number of electrons be less but also that the electric vector would be able to transfer much less energy to the electrons, and they would come out with much lower energies.

Whilst the number of electrons is certainly less in strict proportionality to the intensity, the energy of the individual electrons will be the same in both cases. Weak or intense radiation, as long as the frequency remains constant, always gives the same energy to the electrons. This result is quite incompatible with our ordinary ideas of a wave motion, and the simplest way of expressing this is to notice how the alternative picture of light quanta explains the dilemma. If, instead of imagining the radiation to spread out from the source in waves, we imagine the energy to be emitted in bundles or quanta of magnitude $h\nu$ then with intense radiation there will admittedly be more quanta traversing a body, but even with weak radiation the few quanta which do arrive are still the same. They will naturally lead to the ejection of fewer electrons, but when a quantum is absorbed it always involves the transference of the same amount of energy, and the photoelectron will have the same energy as if the density of quanta were far greater. Great difficulties are raised by any attempt to explain interference by a light-quantum picture and the problem of reconciling these two different views has at present not been solved. A fuller discussion will be found in the articles QUANTUM THEORY and ATOM, where it is pointed out that probably both views are correct. The point is that, if we insist on

describing atomic processes in language and concepts used for large-scale phenomena, then inevitably a duality will appear. Radiation must sometimes be pictured as waves, sometimes as particles. How far-reaching is this duality may be seen in the fact that electrons, and other material particles also, behave sometimes in a manner only explicable on a wave basis.

Photoelectric Cells.—The practical application of photoelectricity to measuring light intensities is made by means of the photoelectric cell. In its simplest form this consists of a glass bulb silvered internally, and on this inner coating is deposited a very thin layer of some metal such as potassium. In the centre of the bulb is arranged a collecting electrode supported on a wire sealed directly through the glass, and metallic connection is made to the potassium in the same way. A diagram of such a cell is shown in fig. 3. The cell is sometimes suitably mounted in a light-tight wooden box. The silver is removed from a certain area of the glass so as to allow light to enter into the cell. The collecting electrode is seen at the bottom of fig. 3.

The whole apparatus can truly be described as a photoelectric cell, since, when light enters the bulb, electrons will be ejected from the potassium, which will charge up positively, and will be collected by the central electrode rendering the latter negative. To measure light intensities precautions must be taken to collect the whole of the electron stream liberated, since it is the number of electrons which is directly proportional to the intensity of the light. The method of doing this is to apply a negative potential to the potassium surface as shown in fig. 4, the collecting electrode being practically at the potential of the other end of the battery by connection through the measuring instrument. For considerable intensities of light this may be a sensitive galvanometer, but in most cases some type of electrometer, such as an ordinary quadrant electrometer or the special quick period quadrant designed by Prof. Lindemann, is preferable. The most sensitive arrangement is to measure the rate at which the electrometer charges up, *i.e.*, the rate at which the needle moves, but when it is possible the constant deflection method is far more convenient. It will be noted that while one terminal of the electrometer is connected directly to the collecting electrode, the other is connected to earth, and the constant deflection method consists in connecting a very high resistance, of the order of 10 to 10,000 megohms, across the electrometer. The latter then measures the potential drop across this resistance due to the current through the photoelectric cell. An important precaution is to have a guard ring (*see* fig. 3), consisting of a ring of metal or silvering, in the position shown, and to connect this to earth. This prevents charge creeping over the surface of the glass from the high potential electrode to the measuring instrument. The general working of the cell is rendered far more regular by taking precautions

FIG. 4. — METHOD OF USING A PHOTOELECTRIC CELL

to keep it in a dry atmosphere, as a film of moisture on the surface of the glass renders it virtually a conductor.

While a photoelectric cell constructed in this way gives a qualitative measure of the light entering it, it is certainly somewhat insensitive, and great improvements have been effected by attention to two points. The first is the correct preparation of the light-sensitive surface—potassium in the case already described. It appears that the sensitivity can be greatly improved by the following process. The potassium is carefully purified by distillation, and is finally deposited by the same process inside the

cell. A little oxygen is then admitted, and a glow discharge passed for a few moments. The oxygen is then pumped out and the potassium is left in a very sensitive colloidal state. The second improvement is to admit a small amount of helium into the cell instead of leaving it completely evacuated. The electrons leaving the potassium surface and accelerated by the applied potential now cause ionization by collision, and a greatly increased current is obtained. The one objection is that the current now depends on the applied potential, as can be seen from fig. 5. 'It is usually safe to apply a potential of 200 volts, and at this point a change of 1 volt produces a change of about 1% in the current.

A matter of great practical importance in the use of photoelectric cells is that they are not equally sensitive to all wave-lengths. This can be seen from fig. 6, which shows in arbitrary units the photoelectric effects in potassium, rubidium and caesium cells for equal amounts of incident energy of different wave-lengths. The vertical scale is arbitrary in each case, and the curves do not show the relative sensitivities of the three types of cell. The ratio of the total sensitivities of potassium, rubidium and caesium cells as here constructed is about as 4:2:1, but the

FIG. 6.—CURVES SHOWING HOW THE PHOTOELECTRIC CURRENT, IN POTASSIUM, RUBIDIUM AND CAESIUM CELLS VARIES WITH THE WAVE-LENGTH OF THE LIGHT (THE 3 CURVES ARE INDEPENDENT)

relative sensitivity for any particular colour depends on the wave-length; e.g., for light of 6,000 A.U., the order would be reversed, the caesium cell being most sensitive. A sodium cell can often be used with advantage for light of a shorter wave-length since its

maximum occurs at about 3,400 A.U., For ultra-violet work the envelope is usually of quartz, as glass begins to absorb strongly. It will be realized from these examples that a photoelectric cell cannot be used for comparing directly the intensities of two beams of light unless they are of the same colour, or, more accurately, of the same spectral distribution.

The uses of photoelectric cells are so manifold that a catalogue of them would be monotonous. Briefly they replace the human eye whenever quantitative measurements are needed; e.g., they are frequently used to measure or compare the light arriving at the earth from stars; also, many photometers (see PHOTOMETRY) depend on their use. The density of a photographic plate may be found either by measuring the diminution in intensity of a beam of light passing through it, or alternatively may be put equal to the density of some standard plate when each produce the same weakening of the beam. In either case the essential is to have a quantitative measure of the intensity of a light beam, and for this purpose photoelectric cells are usually used.

PHOTO-ENGRAVING. One of the photomechanical processes, the generic term being applied chiefly to the making of etched metal printing plates or blocks (zinc, copper, brass, etc.), the design being in relief for typographical (letter-press) printing. Parts of the process are also used in the photo-lithographic and rotogravure processes for the production of plates and cylinders.

History.—The first specimens were produced, as far as can be ascertained, during the years 1859-1862 by Col. James in Southampton, by Gillot in Paris, Angerer in Vienna and Husnik in Prague. The name Gillotype was for many years applied in France and England to line etchings.

Photography was not originally used in their production, the image on metal being obtained either by manual design or by lithographic transfer. The introduction of the photographic negative permitted the reduction or enlargement of the original design for reproduction.

"Nature Autotypy," an early reproduction process, furnished copies of natural objects which, while imperfect reproductions in the sense of our present standards, were still good enough to convey the image in multiple editions. Leonardo da Vinci describes the method in his "Codex Atlanticus" (1490-1519): "This paper must be coated with lampblack mixed with sweet oil. The color of the leaves is thinned by applying white lead dissolved in oil, as printers do with typefaces and then it is printed as usual. The leaves (*i.e.* the impression) will appear dark in the depression and light in the raised parts. . . ." Several botanical publications of the late 17th and of the 18th Centuries were illustrated by this method and are still preserved.

Niepcé's early attempts to etch photographic intaglio images on metal sensitized with asphaltum initiated but did not hasten progress in the photomechanical processes. As early as 1841 daguerreotypes were etched in galvanic baths for printing on gravure presses. Donné was the first to show proofs of etched daguerreotypes; Fizeau, Claudet, Berres in Vienna and Grove in England also etched them. Paul Pretsch in London etched them in 1856. He was the originator of the later spray or blast system employed today in etching and was also the first to discover the swelled gelatin process of which many splendid examples are still in existence. The negatives for his work were usually made by the photographer Roger Fenton, using the wet collodion process; the printing plates were electrotypes moulded from the hardened gelatin reliefs.

As early as 1862 Pretsch exhibited at the London Exhibition half-tone plates for letterpress printing. Poitevin, independent of Pretsch's work, pursued the same idea and produced relief electrotypes printing plates from chromated gelatin originals. George Scamoni in Russia experimented and succeeded inde-

pendently in the same process. Swan and Woodbury in England produced the Woodburytype (1863).

In the development of reproduction processes, it was soon realized that the prime necessity for faithful reproduction consisted in finding a means for breaking up the continuous tones of photographs or drawings, reproducing in effect the quarter, half, and three-quarter tones of the subject. Graining and dusting of the printing surfaces, long employed, did not furnish the answer. Talbot recommended as early as 1852 in his gravure process the use of a gauze netting for breaking up the continuous tones into separate printing elements.

As in most inventions, the credit for the invention or discovery of the halftone process of photo-engraving cannot be awarded to any one man.

A one-line glass screen in which parallel lines were scratched on an opaque background is described in a French patent of December 14, 1857, by Berchtold. Burnett published a method of single- and cross-line screens for photography. Screens are mentioned in a patent of 1865 by the brothers Bullock. Egloffstein's patent of the same year can hardly be cited as his lines were engraved on steel and his process met with no success. Swan in 1866 also used line screens and so did Leggo in the United States in 1871, Jaffe in Vienna in 1877, Stephen H. Horgan in 1880. Meisenbach (1882) used a single-line screen which he turned at 90° after half the exposure was made.

To Frederic E. Ives of Philadelphia, Pa., U.S., is due the idea of the optical V which led to the present cross-line screen which he used in his halftone plates, the printing surface of which was a bichromated glue enamel coating.

To the brothers Louis F. and Max Levy, also of Philadelphia, must be accorded the perfected halftone screen (grating) which today is universally used and has not been excelled since 1888.

The Levy brothers coated selected plates of high quality optical glass with an etching ground, in which parallel lines were cut by means of a ruling machine.

The ruled lines were etched with hydrofluoric acid and filled in with Canadian balsam. The lines appeared in sharp contrast. The two diagonally ruled glass plates were faced at an angle of 90°, sealed and later bound together with aluminium frames.

One of the important contributions to the halftone process was the invention of the highlight process. F. J. M. Gerland patented such a method in 1883 and the Bassani Company a mechanical improvement in 1925. The outstanding difficulty in the early days of the process was its inability to meet the demands for printing in quantity, rapidity, and the danger of the ink filling up the spaces between dots. This required the use of highly coated, hard-surfaced and expensive paper. In the last twenty-five years, however, the process has been adapted to almost any kind of specification. Newspaper and poster plates are made through screens as coarse as 40 lines to the inch and pulp paper periodicals carry illustrations, sharp and full of colour, printed from plates up to 110 lines to the inch.

Colour Plates.—Photo-engraved colour plates are made to represent the subjects in the colours of the original colour photographs or coloured designs or from objects in their natural colours.

The early attempts to reproduce colour effects were the manual painting in of the different tints on black and white prints. Later stencils were used, but seldom for superimposed and colour combinations. The simplest form of colour reproduction followed the manual process and used photo-engraved key plates and different plates for each colour or shade. Later shadings and overlapping plates were used to achieve colour nuances and combinations by overprinting.

The three- and four-colour processes used in 1940 are based on a Latin Treatise of 1611 by Dominis who described the additive system of complementary colours. Isaac Newton described light in its colour spectrum (1666). The German Le Blon in 1722, living in Paris, was the first to use three-colour printing with red, yellow and blue printing plates. Clerk Maxwell, the English physicist, was the first to publish (1861) the theory of colour

reproduction by means of three-colour light filters. Ducos du Hauron and Charles Cros, independently of each other, published in 1868 their three-colour processes. The discovery (1873) by H. W. Vogel of optical sensitization led to a great advance in the reproduction of colour copy in monochrome by the use of orthochromatic plates.

The brothers Lumière of Lyon, France, gave the craft the Autochrome which with other colour records by similar processes often serve as a colour guide when the original painting is not obtainable. Modern panchromatic plates are the result of the successive work of Vogel, König, Homolka, Eder, Miethe, Mees, Traube, Lehman, and other modern workers in the field of optical sensitizers. Colour separation negatives are made today on colour-sensitized gelatino-bromide dry plates or on colour-sensitized collodion emulsion. The old-fashioned hand-press in the engraver's shop is now replaced by power presses. Colour reigns and is in steady ascendancy.

Technique.—The accessories necessary for the production of photo-engravings are a camera, a corrected (process) lens with diaphragms, prism and screen. If the wet collodion process is used, properly cleansed glass and a silver bath are required; also the chemicals for development, fixing, and intensification, all of which are in the purely photographic department. The stripping department, where negatives are reversed unless made through a prism, requires stripping collodion and rubber solution, and $\frac{1}{4}$ -inch thick glass upon which the negative films are reversed as to position, either singly or sometimes assembled in a combination form of line and halftone.

The photo-printing department is equipped with a mechanically operated whirler and vacuum printing frame, as well as a heating apparatus for the burning-in of the enamel image with which the polished copper has been coated.

The etching department is equipped with machines in which the plates are etched by hand, by mechanical rockers, by acid, spray, blast, or by electrolysis.

The routing department is equipped with routing machines, circular and jig-saws, planing, squaring, and mounting machines. Plates to be mounted on metal are usually sent to the electrotyper for that purpose.

The engraving room has heating and cooling devices, also small trays containing acid for re-etching small surfaces. Proofing presses range from the old-fashioned hand-press and special engraver's small power presses to large cylinder machines.

Line Plates.—When a negative of a line drawing which has to be made into a line plate has been obtained, a photographic print from it is made on to a piece of metal, usually zinc, which is first thoroughly cleansed. The plate is then coated with a bichromated ammonium solution, sensitive to light. The solution is poured over the plate which is then placed in a whirler in order to insure an even coating.

The negative is next placed with its film side to the coated zinc plate and put into a screw or vacuum printing frame with a plate glass front, in close contact. The printing frame is then exposed to light (usually electric arc), the time of exposure varying according to the density of the negative and the intensity of the light. The plate, after being slightly warmed, is rolled up with a greasy ink.

It is then placed in a tray of clean water and the surface gently rubbed over with absorbent cotton. Where the albumen coating has not been hardened by the action of light, it washes away, leaving those parts which have become insoluble by exposure to light on the plate.

The plate is dried by heat and defective lines retouched. The plate is then powdered with a finely ground topping powder which sticks to the ink providing an effective resist to the acid. The surplus resin is removed and the plate heated to melt the resin.

When the plate is cool, it is ready for etching, by placing in a diluted bath of nitric acid for the first etch; but before doing so, the margins and back of the plate are coated with a varnish which prevents the acid from etching away those parts which are to be left unetched.

STAGES IN COLOUR PHOTO-ENGRAVING

1. **Photographing** a colour subject with a process camera. In the camera is a half-tone screen through which the image passes. The negative is thus divided into a great number of small "dots." In colour photo-engraving, four negatives are usually made, one for each of the primary colours (see Plate III)
2. The negatives are placed on sensitized metal, upon which the subject is photographically printed
3. Etching the plates to subdue certain colours and bring others out, so that the final result will faithfully reproduce the original
4. Making further corrections in the colour values, by finishing and tooling the plates
5. Routing the plates, so that those parts which are not to be reproduced are removed from the printing surface
6. Pulling the colour proofs of the completed photo-engravings

THE PROGRESSIVE STEPS IN FOUR-COLOUR PRINTING

The colours used in four-colour printing are: yellow, red, blue and black. The four colours are separated out by photography, by the medium of colour filters, each filter being the complementary to the colour to be separated. viz: Blue violet for yellow printer; green for red printer; orange-red for blue printer and a light yellow for black printer. Photographic prints are made from the four colour negatives on copper plates; after which the copper plates are etched, and when the blocks (one for each colour) are superimposed one upon the other in the printing press the result is a reproduction of the original in all its combination of colour. In the above, from left to right, the large area is an impression from the yellow plate. Next area is the red plate printed upon the yellow. Third is the blue plate printed upon the yellow and red. The smallest area is the black plate printed upon the three colours. Regularly the four plates are all the same size. In the specimen shown here, successively smaller plates were used to illustrate the progressive printings

The acid is agitated, either by rocking the bath by hand or by machines now generally used for this purpose, in which the acid is sprayed by means of air or mechanical action on to the surface of the plate. When the plate has been a short time in the bath, it is removed, washed and dried by heat, then powdered with "dragon's blood," applied in four directions so that all sides of the lines will be protected from the acid which is apt to "undercut" the lines. The plate is again heated, causing the resinous powder to melt and run down the sides of the etched lines, until the necessary depth is obtained.

A more recent practice which saves much time is flowing a zinc plate with a so-called "cold enamel" solution, eliminating the rolling up with ink. The plate is developed in alcohol and is then ready for etching.

The line process is occasionally used for colour work. The colours are generally made up of a number of "solid tints" or "stipple," the usual method being to take "key prints" from the etched "key plate," "stopping out" or painting in those parts required for the particular colour in which it will be printed. Where stipple or lines are to be introduced, shading mediums ("benday") are usually employed. These consist of gelatin or celluloid sheets with the design of the particular grain, dot, line or stipple in relief.

The film is rolled up with transfer ink and placed face downwards on the plate, which has been gummed over on those parts which are not required, pressure being applied by a roller or squeegee to those parts of the key plate which are to be printed in the particular colour.

Each colour requires a separate plate, which is rolled up, powdered and etched in the usual way.

Halftone Plates.—Halftone engraving is the process by which full-tone subjects in monochrome and colour are reproduced. The negative is made in the usual way, but to provide the necessary reticulated surface the exposure is made through a screen. This may be composed of grains (mezzograph), or what is most general, a series of lines running across each other at right angles. The cross-line screen consists of two sheets of thin plate glass, ruled with diagonal lines of mechanical exactitude. These are engraved into the glass, each piece of glass being ruled at right angles to the other. The lines are filled with a black pigment, leaving transparent spaces between. The two sheets of glass are placed face to face and sealed, the black lines crossing each other and leaving square transparent openings through which the light passes forming a halftone or dot image on the photographic plate or film.

Halftone screens are obtainable in various "gratings" or rulings, ranging from 40 to 400 lines to the inch, though for commercial use they rarely exceed 150 lines. The different rulings are used to suit the grade of work to be reproduced and the class of paper on which the illustration is to be printed. When printing on cheap, coarse paper, such as "news," a 60-line screen is usually employed.

Plates made with fine screens require printing on a highly finished or coated paper. For ordinary "black and white" commercial work, screens from 120 to 150 are used, and for fine colour reproductions, screens from 150 to 200.

The screen is secured in a holder and placed in the camera immediately in front of the photographic plate. The distance—an important factor—is governed by the particular ruling of the screen, the particular subject and the effect desired. When the negative is developed, the tones in the original are represented by a number of dots varying in area according to the tones of the original but of more or less uniform opacity.

The next operation is to make a print from the negative on to a metal plate, usually copper. The solution for coating plates is composed of water, fishglue and ammonium bichromate. The copper plate is polished to remove grease and foreign matter. The sensitive solution is poured on the plate which is then placed in a whirler to distribute the coating evenly.

After printing, the exposed halftone image is developed in water, after which the plate is sometimes placed in a bath of aniline dye, rendering it more visible. The margins and back of the plate

are painted with asphalt or shellac to protect them from the acid.

The fishglue or enamel image, after being burned in, forms the acid resist. The plate is then placed in an etching bath of iron perchloride.

The plate is etched until the fine dots in the higher lights are as small as it is possible to etch them without undercutting the "dots."

The "re-etcher" or "finisher" then continues a series of fine etching by stopping out with an acid-resisting varnish those parts which have been rough-etched, and applying a series of local etchings for the purpose of recording the highest lights.

A proof is then pulled from the plate, compared with the original copy, and still further necessary alterations made. When approved, the plate is "finished" and mounted on wood or metal ready for the printer.

When a vignettted plate is required, the design and close surroundings are protected with varnish and the extreme edges are treated with acid so that the "dots" on the latter are reduced to the smallest point; gradually results are obtained until the dots merge into the white paper without showing a hard edge.

When pencil drawings are to be reproduced in halftone, it is usual to make a "high light" negative in which the high lights of the drawing and the paper on which it is made do not show a "screen." One of several methods may be employed:

(a) direct, when an over-exposed negative is made and certain stops used during the exposure, which tends to make the "dots" in the high lights overlap and become solid, the other tones being brought back to their correct relation by manipulative reduction of dot size;

(b) the *Bassani Apparatus*, which, attached to the camera, causes a slight circular movement of the halftone screen sufficient to veil the highlight dots and makes them disappear in the subsequent intensification of the negative;

(c) a patented diaphragm of the Waterhouse or Groesbeck type, used at one portion of the exposure to transpose the positions of the highlight dots and the spaces between them thus veiling the dots which disappear when intensified; and

(d) *the indirect method*, entailing the use of three photographic plates: first, a continuous tone negative is made of the original, which can be retouched; from this a positive is made through a screen; and from the positive a negative is obtained with the "dots" eliminated from the highest lights, which include the paper surface on which the drawing has been made.

Combination line and halftone plates are frequently made for commercial purposes, either by making two plates, and mounting finished line and halftone plates together; or by making two negatives, one in line and the other in halftone, stripping the films and combining them in their respective positions on one piece of glass which then forms the negative for printing on metal. In this way the combined design is etched on one plate and in one operation.

Halftone Colour Process.—When reproducing colour subjects by the halftone process, the plates are made in the same way as halftones, but the photographic plates must be colour-sensitive (panchromatic); when making the exposure the light not only passes through the prism, lens and screen but also is transmitted through what are known as "colour filters."

Generally considered, these are either dyed (coloured) films of gelatin cemented between two sheets of optical glass (and attachable to the lens by means of special holders), or they may be plain sheets of dyed gelatin, inserted in the barrel of the lens in a slot provided for Waterhouse stops.

The action of the filters is identical, in that the filter allows only rays of light of a certain colour to reach the photographic plate.

A special colour filter is used for each colour negative. Thus, a negative only records the colour and its component tints of one of the fundamental colours of the spectrum.

To make a negative for the yellow printing plate, a blue filter is used; for the red printing plate, a green filter, and for the blue printing plate, a red filter.

The light, passing through the respective filters, prevents the

colours and tints not complementary to the inks in which the printing plates are printed from being recorded on the special photographic plate.

As in the production of the halftone plate, the ruled screen is placed in front of the photographic plate, but for colour work, a circular screen, which can be turned at different angles, is used for each of the colour negatives.

The angles of the screen must be different for each colour to prevent a "pattern" or "moiré" effect when the three colours are superimposed in printing. For one colour, the screen angle is set at 45° from the vertical, and for the others at 75° and 15° respectively.

The negatives are developed, printed on metal and etched in the same way as when making a monochrome halftone plate, but much fine etching, demanding great skill, has to be done in the reproduction of colour subjects.

The "fine etcher" must possess a good knowledge of colour and its analysis so that the final results will approximate the colour original. He must correct the deficiencies of the colour separations. This he does by a series of fine etchings, painting out certain parts and continuing the etching by local application of acid.

This operation may have to be repeated a number of times, and many proofs are pulled from the plates before final satisfactory results are obtained.

It is now usual to include a fourth colour-plate when reproducing coloured subjects. This is usually printed in grey or black; the "colour," however, is not dissected in the ordinary sense of the term, although a yellow filter is used. The fourth plate represents the whole of the tones in the original in their proper relation to each other, and becomes the key plate. The fourth printing allows for cleaner and more rapid working on the printing press, and at the same time provides a depth of colour and "quality" which, owing to the scientific shortcomings of the process, are not always possible to obtain.

The plates are finished in the usual way, mounted usually on metal or sent unmounted to the printer along with progressive proofs which show the shades of colour used in the proofing and their sequence in printing.

Halftone colour negatives are made either by the direct or the indirect method. In the first instance, each colour negative is made in the same way as an ordinary halftone negative, but the exposure is made through a colour filter in addition to the screen, thus recording on the panchromatic plate one of the primary colours and its shades and constituting, when developed, one of the halftone negatives from which a plate will be made to print in a certain coloured ink.

The indirect method entails the use of three or four photographic plates for each colour. The first exposure provides a continuous tone colour-separation negative. It is obtained by making the exposure through a colour filter.

The full-tone negative can be retouched to assist in correcting colour values. From the full-tone negative a continuous tone positive is made and from it the screen negative.

This concludes an outline of the principles and processes of photo-engraving. The casual reader is warned against any attempt to use the chemicals and machinery mentioned. The necessary skill for their employment can only be attained after years of training and practical application of the process.

PHOTOGRAPHIC ART. Although photography was brought into being by artists and would-be artists in search of a new pictorial method, there has been comparatively little work produced in this medium worthy of the name of art. The majority of workers who have attempted to use photography as a means of creative expression have failed because of their inability to recognize and make use of the basic resources of the medium. For many years both photographers and critics failed to realize they were dealing with a new art-form that was essentially different from all the other graphic processes, with the result that photographs were judged solely on the basis of their resemblance—or lack of it—to paintings and drawings.

Before photography could take its rightful place among the graphic arts, it had to be recognized as a new and independent medium, containing its own unique potentialities and limitations, and demanding therefore a new standard of criticism based on the principles and properties of the photographic process.

To understand why this recognition was slow in coming we must examine several factors that have influenced the development and direction of photographic art.

Technical Evolution.—When the first successful photographic processes were made public by Daguerre, Talbot, and Herschel in 1839 (see PHOTOGRAPHY), the procedures involved were still difficult and uncertain and the available tools were extremely crude. Although some quite amazing results were obtained, photography was still in the experimental stage.

The first substantial technical improvement came in the '50s when calotypy and daguerreotypy were replaced by the wet plate or collodion process. But even then the difficulties of cumbersome equipment and clumsy technique were sufficient to discourage all but the most enthusiastic.

The next important change came in the '80s when the whole photographic process was immeasurably simplified by the introduction of dry plates and celluloid film. Then for the first time photography became flexible enough, and the technique involved sufficiently simplified, that it could offer an adequate means of expression to the artist. Since that time films have been improved in speed and colour sensitivity and various accessories have been added to the photographer's equipment, but in all essentials the process used today had been perfected by 1889, just 50 years after the first successful demonstration.

The Painter's Tradition.—Technical limitations were a handicap to the early photographers who attempted to produce work that might rank as art, but a far more serious obstacle lay in the general acceptance of photography as just a new kind of painting. The camera had been the painter's tool long before photography was perfected. In the 18th century painters used a device very like the modern reflex camera; the lens was focussed on the desired view and the image traced by hand on a piece of paper laid on the ground glass. Thus when it became possible to fix the actual image by chemical means the new process was expected to be of primary importance as an aid to the painter in observing and studying nature. However, few painters made use of photography in this fashion because of the time and effort required to master the technical intricacies of the new medium.

A notable exception was the Scotch painter, David Octavius

Hill. The disruption of the Church of Scotland in 1843 inspired him to commemorate the event in a monumental painting, and since it was to include the likenesses of nearly 500 persons, Hill turned to photography for assistance in his gargantuan task. From 1843-47, in collaboration with Robert Adamson, a young chemist, Hill produced a series of calotypes that are today considered masterpieces of photographic portraiture, while the painting these records were made for is deservedly forgotten. Whatever interest Hill's portraits may have aroused at the time, they were soon forgotten and were not rediscovered until the '90s. Meanwhile a battle over the question "Can photography be art?" was being waged on an ever-widening front. Those who contended that it couldn't be were for the most part painters, and their reasons, when carefully scrutinized, all reduce to the fact that since the camera was incapable of producing the equivalent of paintings and drawings it could not produce art. Some photographers were not concerned with the question and contented themselves with making photographs for their own sake, but a growing number felt that the criticism was justified and cast about for means to remove this stigma from their medium.

At first they were content with swathing their models in flowing draperies, or creating genre studies with costumed figures and painted backgrounds, or combining parts of a variety of negatives into one composite print. But wet plates and improved lenses provided a sharp, detailed image that gave their photographs a most unpainterly appearance. To counteract this, soft focus lenses were constructed and retouching led the way to direct pencil work on the negative. Finally new printing processes were devised that enabled the photographer to control his results so completely that he could produce an imitation etching, mezzotint, drawing, or woodblock, at will. This kind of "photo-painting" achieves its ultimate absurdity in pictures where all traces of the original image have been so thoroughly obliterated that it is impossible to guess their photographic origin.

The Photo-Secession. — The first photographer to head a definite movement away from this kind of practice was Alfred Stieglitz. In New York in the early 1900s, as leader of a group called the Photo-Secession, and as editor of two photographic magazines, *Camera Notes* and *Camera Work*, Stieglitz campaigned for a return to "pure" photography—that is, photography unmixed with any other graphic medium. His work and the publications he edited had a profound effect on photography, and the 50 issues of *Camera Work* (published from 1903-17) form a unique and beautiful record of an important chapter in the development of photographic art.

The members of the Photo-Secession considered soft-focus lenses and the various flexible printing processes valid means of control for the photographer, but they eschewed all manual interference with the camera's image as unphotographic. Although many of them continued to follow the painter's tradition as far as their results were concerned, they kept to photographic means in achieving those results and so made the first important step toward a recognition of the proper limitations of the medium.

Pictorialist vs. Purist. — In the years that followed, the reaction against the photo-painting technique was carried to extremes. Photographers who were primarily interested in the technical side of the medium carried "purism" to such lengths as to maintain that no control of any sort should be exercised by the photographer, and that even the "spotting" of dust specks and scratches on negative or print was a violation of the medium. From this reaction came the modern use of the terms pictorialist and purist. If a photographer belonged to the first group, he was supposed to work up his negative by hand and always strive to make his resulting print look like a drawing, etching, etc., while a member of the purist group was supposed to make sharp prints on glossy paper using no control except in choosing his subject matter and camera angle. Actually, no two such clear-cut groups ever existed. Many so-called pictorialists used purely photographic methods, and many so-called purists controlled (but not by manual operations) all of their procedures.

But there were heated debates over purist vs. pictorialist methods and a great deal of misunderstanding was fostered, first by

the failure of both sides to define clearly the terms they employed, and second, by a tendency on the part of many photographers to mistake means for ends and consider the method of production more important than the product itself.

Aesthetic Basis of Photographic Art.— Anyone who has mastered a few simple instructions can make printable negatives with a pocket kodak. Because it is impossible for the untrained beginner to achieve such acceptable results in any other medium, photography has sometimes been called "the easy art." But to bridge the gulf between the taking of such casual snapshots and the production of photographs that can be classed as art is certainly no easy task. To the mastering of his tools and the perfecting of his technique, the photographer must devote just as much time and effort as does the musician or the painter. Since the nature of the photographic process determines the artist's approach, we must have some knowledge of the inherent characteristics of the medium in order to understand what constitutes the aesthetic basis of photographic art.

Photography must always deal with things—it cannot record abstract ideas—but far from being restricted to copying nature, as many suppose, the photographer has ample facilities for presenting his subject in any manner he chooses.

First, an infinite number of compositions can be achieved with a single stationary subject by varying the position of the camera, the camera angle, or the focal length of the lens. Second, any or all values can be altered by change of light on the subject, or the use of a colour filter. Third, the registering of relative values in the negative can be controlled by length of exposure, kind of emulsion used, and method of developing. And finally, the relative values in the negative can be further modified by allowing more or less light to affect certain parts of the image in printing. The photographer is restricted to representing objects of the real world, but in the manner of portraying those objects he has vast discretionary powers; he can depart from literal recording to whatever extent he chooses without resorting to any method of control that is not of a photographic (*i.e.*, optical or chemical) nature.

But the artist's use of these controlling powers must be conditioned by two factors: (1) the nature of his recording process, and (2) the nature of his image. There is a frequent cause of mistaken understanding in the belief that the camera's image reproduces nature as the human eye sees it. On the contrary, its ability to record things as the unaided human eye can never see them is one of the most important attributes of photography. The human eye can focus on but one small area at a time; consequently we observe an object or a scene only by letting our eyes rove over it in a series of short jumps. The assortment of images thus recorded are flashed to the brain which sorts and edits them, automatically discarding some as of no importance and emphasizing others, according to its individual conditioning. The impersonal camera-eye makes no such distinctions; every detail within its field of vision can be recorded instantly and with great clarity. In the time the eye takes to report an impression of houses and a street the camera can record them completely, from their structure, spacing, and relative sizes, to the grain of the wood, the mortar between the bricks, the dents in the pavement. The image that is thus registered has certain characteristics that at once distinguish it from the products of all other graphic processes. In its ability to register fine detail and in its ability to render an unbroken sequence of infinitely subtle gradations, the photograph cannot be equalled by any work of the human hand. For this reason any manual interference with the image at once destroys those very qualities that give the true photograph value as an art form.

From these two facts we may draw an obvious deduction: if the recording process is instantaneous and the nature of the image such that it cannot survive corrective handwork, then it is clear that the artist must be able to visualize his final result in advance. His finished print must be created in full *before* he makes his exposure, and the controlling powers enumerated above must be used, not as correctives, but as predetermined means of carrying out that original visualization. As in the mastery of any other

graphic form, years of experience are necessary in photography before technical considerations can be made entirely subordinate to pictorial aims. The ability to prevision the finished print is the photographer's most important qualification and in order to attain it he must concentrate on learning to see in terms of his tools and processes.

Having chosen the simplest possible equipment (so as not to complicate his task needlessly) he first learns by experiment the potentialities and limitations of each instrument and process. He must learn the field of his lens, the scale of his film and paper emulsions; he must learn to judge the strength and quality of light; he must learn to translate colours into their relative monochrome values and know how those values are affected by the use of different filters.

He must learn the kind of negative necessary to produce a given kind of print, and then learn what kind of exposure and development will produce that negative; then, having learned how those needs are fulfilled for one kind of print, he must discover how to vary the process to get other kinds of prints. Gradually, with experience, this knowledge becomes intuitive; the photographer sees a scene or object in terms of his finished print without having to *think* of these processes any more than a musician playing a piece *thinks* of the whereabouts of the next note he will sound or how much pressure he will use in sounding it.

The Print. — The value of the photograph as a work of art depends primarily on the photographer's *seeing* before exposure, but its artistic value can only be determined by an examination of the finished print.

Exposure records the photographer's seeing; developing and printing execute it; so no matter how fine the original vision, if it has not been faithfully carried out in subsequent procedures the resulting print will suffer. The clarity of image and delicacy of gradation that characterize a fine photograph demand a special kind of surface for their best presentation. A rough surface destroys the integrity of the image; a smooth surface retains it. A shiny or reflecting surface enhances the beauty of image quality, while a dull or absorbing surface tends to obscure it.

For beautiful image quality, the best of the old daguerreotypes have never been equalled. The positives were made directly on the metal base and the small pictures were esteemed for their exquisite rendering of fine detail. The photo-painters, who did away with all things characteristically photographic, often used papers of independently beautiful surface texture for their prints. The result of such a combination is that the paper competes with the image instead of becoming a part of it.

Among modern processes the nearest approach to the fine image quality of daguerreotypes is a waxed or glossy print. Unfortunately glossy paper is still held in general disfavour among artist-photographers. It is said to be harsh and cold and only suitable for commercial work.

These erroneous beliefs are partly a hangover from the heyday of photo-painting and partly due to the difficulty of making good glossy prints. The glossy surface reveals the image with such clarity that minor blunders, which might escape detection on the more veiled, dull-surface papers, are at once exposed. However, the glossy surface has the advantage of a longer scale which makes it possible to reproduce more of the negative and allows a greater latitude in reproducing extremes of tone from the strongest to the most subtle and delicate. When a photographer speaks of the warm or cold tone of a print, he is usually referring to its colour; a cold blue-black as opposed to a warm green-black. But to use such variations of colour to emphasize the feeling of his picture is to misuse his medium. If he prints a snow scene blue-black so that it will look cold and a forest scene green-black so that it will appear warm, he is introducing a foreign element into his monochromatic process just as surely as if he coloured the print by hand. In black-and-white photography the effect of warmth or coldness should be communicated by the values in the print, whose colours should—at the extremes of the scale—be as nearly pure black and pure white as possible. (Use of obvious colour-tone belongs in the province of colour photography.) Obviously then, the longer scale of glossy paper gives greater op-

portunity of producing through the values in the print whatever effect is desired

And lastly, the luminous surface of the glossy paper, by making the image *light-giving*, comes nearer to rendering the effect of the original scene and so heightens the illusion of reality.

A good glossy print reveals the delicacy of subtle gradation, the lucidity of tone, and the brilliant clarity of image, that are unique characteristics of the photographic process.

Subject Matter. — It is impossible to make any sharp distinction between the subject matter appropriate to one graphic medium and that more suitable to another. But in the case of photography we can at least draw a few general conclusions, based on an examination of the work of the past and our knowledge of the special properties of the medium. From the wet plate era we may draw two contrasting examples that serve to indicate a field of endeavour in which the photographer is least likely to be successful. On the one hand we have the work of O. G. Rejlander and Henry Peach Robinson, two men who achieved prominence for their photographic work in England during the '50s and '60s. In their best known pictures (Rejlander's *Two Ways of Life*, and Robinson's *Fading Away*) they attempted to depict allegorical and dramatic situations by combining a number of negatives of posed and costumed figures into composite prints.

On the other hand we have the work of Mathew Brady, Alexander Gardner, and many anonymous photographers who documented the American Civil War. These men were bound by no artistic purpose; their sole aim was to record to the best of their ability every phase and aspect of the hostilities that their clumsy and limited equipment could encompass. Yet it is in these straightforward records that we perceive true photographic quality: here is the tremendous power and appeal of the camera's realism, the intensity of its vision undiluted, and these documents of the past still move us profoundly with their clear, objective picture of the horror and pathos of war. Beside these photographs the artistic efforts of Rejlander and Robinson appear self-conscious, stilted, and artificial. Their carefully posed and costumed figures look absurd and unreal.

Now this comparison makes one fact apparent: the camera lens sees too clearly to be used successfully for recording the superficial aspects of a subject. It searches out the actor behind the make-up and exposes the contrived, the trivial, the artificial, for what they really are.

But if the camera's innate honesty works any hardship on the photographer by limiting his subject matter in one direction, the loss is slight when weighed against the advantages it provides. For it is that very quality that makes the camera expressly fitted for examining deeply into the meaning of things. The discriminating photographer can direct its penetrating vision so as to present his subject—whatever it may be—in terms of its basic reality. He can reveal the essence of what lies before his lens with such clear insight that the beholder will find the recreated image more real and comprehensible than the actual object.

The photograph isolates and perpetuates a moment of time: an important and revealing moment, or an unimportant and meaningless one, depending upon the photographer's understanding of his subject and mastery of his process. The lens does not reveal a subject significantly of its own accord. On the contrary, its vision is completely impartial and indiscriminating. It makes no distinction between important detail and meaningless detail. Selection, emphasis, and meaning, must be provided by the photographer in his composition.

Nowhere has the painter's influence had a more lasting hold on photography than in the field of composition. Photographers who have put to use every other resource of their medium still try to emulate the work of painters in this respect. They consider composition as a thing apart, having no relation to a specific medium, but consisting of a set of tested rules and conventions that must not be contravened. To compose a subject well means no more than to see and present it in the strongest manner possible. The painter and the photographer will have two different ways of doing this because of the basic differences between their mediums. Its capacity for rendering fine detail and tone makes photography

excel in recording form and texture. Its subtlety of gradation makes it admirably suited to recording qualities of light or shadow, and its ability to record sharply everything within the angle of lens-vision from the immediate foreground to the distant horizon carries it far beyond the painter's province. The photographer cannot depend on rules deduced from finished work in another medium. He must learn to see things through his own eyes and his own camera; only then can he present his subject in a way that will transmit his feeling for it to others.

An intuitive knowledge of composition in terms of the capacities of his process, enables the photographer to record his subject at the moment of deepest perception; to capture the fleeting instant when the light on a landscape, the form of a cloud, the gesture of a hand or the expression of a face, momentarily presents a profound revelation of life.

The appeal to our emotions manifest in such a record is largely due to the quality of authenticity in the photograph. The spectator accepts its authority, and in viewing it perforce believes that he would have seen that scene or object exactly so if he had been there. We know that the human eye is capable of no such feat, and furthermore that the photographer has not reproduced the scene exactly; quite possibly we would not even be able to identify the original scene from having seen the photograph. Yet it is this belief in the reality of the photograph that calls up a strong response in the spectator and enables him to participate directly in the artist's experience.

There can be no doubt that photography is potentially a powerful and vital medium of expression. But even today many photographers who attempt to use it as such still cling to the weak effects of photo-painting, while others imitate the work of abstract painters with "shadowgraphs" (recording shapes, shadows, and sometimes a degree of texture by laying various objects on sensitized paper and then exposing it to light).

However, there has been in the past decade a perceptible growth of interest in and understanding of photography as an art medium. Museums are holding more photographic exhibitions every year and private collections of fine photographs are more numerous. The unique advantages that photography offers are being recognized by an increasing number of artists. The camera has extended their visual horizons by opening their eyes to new perspectives and new subject matter.

Conception and execution so nearly coincide in this direct medium that an artist with unlimited vision can produce a tremendous volume of work without sacrifice of quality. But the camera demands for its successful use a trained eye, a sure, disciplined technique, keen perception, and swift creative judgement. The artist who would use his photographic powers to the full must have all these, plus the first requisite for the artist in any medium—something to say.

PHOTOGRAPHY, the science and art of producing pictures by the action of light on chemically prepared (sensitized) materials. (Gr. $\phi\omega\varsigma$, light, and $\gamma\rho\alpha\phi\epsilon\upsilon\omega$, to write.)

The practice of photography depends upon the sensitiveness of silver compounds to light. When silver bromide, dispersed in a suitable medium such as gelatine, is exposed to light, it undergoes a change as a result of which it becomes *developable*. When, after exposure, it is treated with a solution of a particular type having reducing properties, termed a *developer*, the exposed bromide is reduced to metallic silver and forms an image corresponding to the intensity of light to which it was exposed. (See fig. 1.)

After development, the unexposed silver bromide is removed by a suitable solvent which does not attack silver but dissolves the bromide and the picture is then permanent and is said to be *fixed*. The picture thus obtained is a *negative*; that is, the

light parts of the object are the blackest in the picture and the dark parts, which have affected the silver bromide least, are the brightest.

In order to obtain a *positive* picture, in which the light and shade corresponds to that of the original subject, the negative is *printed*. The negative is placed in contact with another piece

FIG. 1.—THE PRODUCTION OF A PHOTOGRAPH

of sensitive material which is exposed to light through the negative, and this gives in turn a positive image. (See Plate I.)

The operations required to produce a photograph are thus:

1. Preparation of the sensitive negative material
2. Exposure in a *camera*
3. Development; with the after processes, fixation, washing, and drying.
4. Preparation of the sensitive positive material
5. Printing
6. Development, fixation, washing, and drying of the print.

In the early days of photography all of these operations were carried out by the photographer, but at the present time the sensitive materials, both negative and positive, are almost always made by manufacturing companies. In many fields of photography only the exposure, including of course the selection of the subject, is actually carried out by the photographer himself, the remaining operations being performed by others.

A wide variety of negative materials, cameras, and printing processes are used in photographic operations, their selection depending upon the particular branch of photography under consideration.

The chief branches of photography are:

Amateur Photography including both the casual taking of photographs for record or amusement and the serious pursuit of pictorial photography as an art.

Professional Photography, which may be subdivided into *Portraiture* and *Commercial Photography*.

Motion Picture Photography (*q.v.*) both professional and amateur.

Radiography, photography by means of X-rays, for medical, scientific and industrial purposes.

Applied Photography, including many uses of photography in connection with the arts and sciences, such as aerial photography, photomicrography, astronomical photography, photographic recording, etc.

To these must be added *colour photography*.

Negative materials are made by preparing a precipitate of silver bromide containing a small amount of silver iodide held in a medium containing enough gelatine to enable it to be set to a jelly when cooled. This suspension is termed the *emulsion*. The melted emulsion is coated upon a support which may either consist of glass, in which case *plates* are produced or may be a flexible cellulose compound, in which case the product is termed *film*.

After setting by chilling and drying, the material is cut to suitable sizes and packed in light-tight containers.

Films are packed as flat films, for use in holders similar to those used for glass plates, cartridge or roll films protected with paper to make them suitable for loading in the daylight, film packs, and as long ribbons for use in the taking of motion pictures.

Cameras are of many varieties, the essentials being a *lens* (D) to form the image, a *shutter* (C) to regulate the duration of the

FIG. 2.—DIAGRAM OF A CAMERA

exposure, a material holder (A) to carry sensitive plates or film, and a connecting shield (B) to protect the sensitive material from light other than that which comes through the lens. This is generally extensible and then takes the form of a bellows. (See fig. 2.)

The cameras used for various purposes are discussed under the section Apparatus.

Positive materials may be used for transparencies, in which case they are lantern slides on glass or positive films (especially for motion picture photography [*q.v.*]). These materials are prepared in exactly the same way as negative materials, the emulsion being modified to give the results desired. Usually, however, negatives are printed upon sensitized paper. Printing papers at the present time are generally coated with a sensitive emulsion prepared either with silver bromide, bromide papers, or with silver chloride, gas-light or *developing-out* papers.

Previously, the most usual types of sensitive paper used were prepared with an emulsion containing free soluble silver compounds and were printed under the negative in strong light until the image was complete—*printing-out* papers. No development was required with these papers, which are, however, almost obsolete now except for the preparation of proofs submitted by professional photographers to customers.

Many other varieties of printing processes are known and some are still being used to a limited extent.

HISTORY

W

Photography was discovered by no one man. It was the outcome of the early observations of the alchemists and chemists on the action of light, a subject that belongs strictly to the domain of photochemistry (*q.v.*). Although the blackening of silver salts was known in 1565, it was not until 1727, when J. H. Schulze, of Germany, used a mixture of silver nitrate and chalk under stenciled letters, that it was definitely recognized that this darkening action was due to light and not to heat. These experiments were important in that, in conjunction with those of K. W. Scheele, 1777, they led to the experiments of T. Wedgwood with silver nitrate on paper and leather in 1802, which were reported to the Royal Institution of London with the suggestion that silver chloride was more sensitive. These were practically failures because of the very long exposures required, and no means were then known of removing the unaffected material and thus stabilizing the image against light.

Camera.—Leaving for the time being the question of the sensitive salts, we may turn to the evolution of the camera. This was the outcome of the old camera obscura, the invention of which is usually ascribed to Baptista Porta, 1553, though its principle had been indefinitely described by Alhazen, 1100; Roger Bacon, 1267; and others. Leonardo da Vinci, who died in 1519, described and pictured a camera obscura in an unpublished manuscript. In 1550 J. Cardan suggested the use of a speculum or concave mirror in front of the instrument, and D. Barbaro, 1568, proposed convex lenses and the use of a diaphragm to secure greater sharpness of the images. E. Danti, 1573, corrected the reversed image by means of a mirror behind the lens, a device still in use. F. Risner, who died in 1580, described in his works published in 1606 the methods of enlarging and reducing, and a portable box in lieu of the cumbersome fixed hut in use until then. Porta in his second edition, 1589, of which an English translation was published in 1658, was the first to introduce the use of the convex lens in the camera. Kepler, the famous astronomer, in his work on optical astronomy, 1604–1611, described the use of a concave lens behind the convex to obtain larger images, and thus anticipated the telephoto lenses of the present day. In J. Zahn's book, 1665, there was described a portable camera obscura with two or three lenses, to secure greater brilliancy of the image, and side wings to shield it from extraneous light; thus with the reversing mirror he antedated a type of modern camera. At the beginning of the eighteenth century the portable camera obscura had become a regular article of commerce and was used to obtain sketches from nature.

The Beginnings of Photography.—A. Senefelder discovered lithography in 1796, but, though it was introduced in Paris in

1802, it was not until 1813 that it became a success and a fashionable hobby. From this date until 1817 J. Nicéphore Niepce was engaged in an examination of the French natural stones to find one suitable for the process. Since he was unable to draw, his son, Isidore, undertook this work, and when the latter was called for military service, Niepce was impelled to produce the images automatically. In conjunction with his brother Claude, Niepce first essayed photography with silver chloride on paper. The light-sensitiveness of iron, manganese, acids, and other compounds was tested, stone, metal, and paper being used as supports. Finally, guaiacum resin was tried and then asphaltum, or bitumen of Judea, which had been in common use as an etching ground since the days of Rembrandt. This, becoming insoluble in its usual solvents by the action of light, gave not only a resist for the etching of metal plates but also transparent images on glass. A successful result was obtained in 1822, and thus it may be said that the first permanent photograph was made in that year by Niepce.

The next three years were required to perfect the process of heliography, as it was called, and in 1826 an etched metal plate was sent to M. Lemaître, of Paris, to be printed. In order that the pictures should be more distinct, they were exposed to the vapors of iodine. The highlights of the plates consisted of hardened bitumen; the shadows, of the bare metal; thus the contrasts were very poor, which led to the use of tin instead of copper. Lemaître suggested silvering copper plates. These two facts are of importance in the subsequent history.

Daguerreotype.—In 1826, Daguerre, a painter who had experimented with silver salts, heard of Niepce's work and approached the latter as to the formation of a partnership. This was consummated in 1829. The work which Daguerre had done with Niepce had drawn their attention to the light-sensitiveness of silver iodide, and Daguerre discovered accidentally that the effect produced by exposing an iodized silver plate in a camera would result in an image if the plate were fumed with mercury vapor. The inventions of Niepce and of Daguerre were published to the world simultaneously by the French Home Minister in a bill presented to the House of Deputies proposing a national reward to the inventors. A full description of their methods was presented on August 19, 1839, at a meeting of the Academy of Arts and Sciences.

The introduction of the Daguerreotype process was attended by complete success. The process required much care and skill. A silvered copper plate was buffed and burnished to a high degree of polish. It was then iodized by careful fuming with iodine, and later (1840) resensitized with bromine, and then given an exposure the duration of which was of vital importance. At first, exposures of minutes in bright sunlight were necessary, but later exposures were secured in a few seconds under favorable conditions. The development was effected by placing the exposed plate over a cup of mercury heated to about 75° C. The image was then fixed with a solution of thiosulphate of soda and toned by treatment with gold chloride. The results obtained were excellent when all the operations had been carried out correctly, and the process flourished, especially for portraiture, until it was superseded by the wet collodion process in 1851.

Calotype.—A preliminary notice of Daguerre's success was made by Arago to the Académie des Sciences in Paris on Jan. 7, 1839. This caused Fox Talbot, an Englishman, to write to Arago claiming priority in regard to the obtaining of a picture in the camera, and having rendered it permanent. Talbot began his experiments in 1834, using the camera obscura with silver chloride and common salt or potassium iodide as fixing agents. A communication was made to the Royal Society of London on Jan. 30, 1839. But not until a month later did he disclose his working method, which then involved silver iodide with excess of the nitrate, and fixation with sodium thiosulphate. The solvent action of this for silver salts had been discovered by Sir J. W. F. Herschel in 1819. Talbot's process was called "Calotype," and the light image was developed with gallic acid, the action of which had been discovered independently by the Rev. J. B. Reade, but had not been published by him.

The developed image on a sheet of Calotype paper was the

exact reverse, as far as light and shade were concerned, of the original image. Such a picture was termed by Sir J. Herschel in 1841 a "negative." Since paper is a semi-transparent substance whose transparency could be increased by waxing or oiling on the side opposite to the image, Talbot was able to obtain true copies or positives of any negative by simple contact printing upon another piece of sensitized paper. Talbot's process should be considered as the first stage in the real line of photographic development, the notable inventions of Daguerre and Niepce being merely bypaths whose chief importance was the mental stimulus they gave to photographic evolution. The disadvantages of Calotype were the somewhat long time required for printing and the structure of the paper.

Herschel suggested the use of glass plates and the deposition of silver chloride thereon. In 1848 Niepce de Saint-Victor, the nephew of Nicéphore Niepce, suggested albumen as the vehicle for the sensitive silver iodide. This process, called "Niepceotype," held its own until 1851, when Scott Archer, an English architect, published his wet collodion process, which is still in use in photo-mechanical establishments.

Collodion Process.—Collodion, a solution of nitrocellulose in alcohol-ether, was first prepared by Maynard of Boston for medical purposes. Schonbein, the Swiss chemist, discovered nitrocellulose in 1846. To a solution of pyroxylin in ether and alcohol, Archer added a soluble iodide, usually with the addition of a little bromide, and coated a clean glass plate with the iodized collodion. In the darkroom, the iodized collodion was sensitized by immersion in a bath of silver nitrate and formed silver iodide with excess of silver nitrate. The plate was exposed wet in the camera, developed by pouring on a solution of pyrogallol containing acetic acid, and fixed with a strong solution of thiosulphate of soda for which cyanide of potassium was later substituted. Archer's collodion process was not patented, and in three or four years it displaced both Calotype and Daguerreotype.

The necessity for preparing the plates immediately before exposure and developing them immediately after considerably limited the practice of photography. Spiller and Crookes suggested bathing the prepared plates in a solution of a hygroscopic salt, so that they could be kept some time both before and after exposure. This was followed by the use of hygroscopic substances of all kinds.

Collodion Emulsion.—In 1864, B. J. Sayce and W. B. Bolton described the preparation of an emulsion of silver bromide in collodion. With this preparation, the nitrates—the by-products of the formation of the silver halide from the nitrate and alkaline halide—were left in the emulsion. In 1874, W. B. Bolton showed that it was possible to wash these nitrates out, and his methods are still followed.

Collodion emulsion was a practical advance on wet collodion but involved no improvement in the matter of sensitivity. Fundamental contributions to this were made by the introduction of alkaline development by Major Russell in 1862. A considerable increase of sensitiveness was obtained with collodion emulsion, but the full fruit of this was reaped only with the introduction of gelatino-silver bromide dry plates.

Gelatine Emulsion.—In 1871, Dr. R. L. Maddox made an emulsion of silver bromide in essentially the same manner as that used for making collodion emulsions but he replaced collodion by gelatine. The matter was followed up by other experimenters, among whom may be mentioned J. Burgess and J. Kennett. Kennett placed on the market a dry, washed emulsion which photographers could dissolve in warm water and use as a coating on glass and thus produce their own plates.

A great amount of experimental work was at once commenced on gelatine emulsions, the records of which filled the photographic journals between 1873 and 1885. The by-product salts were removed by washing. Abney recommended the use of iodide in small quantity with the bromide and found that this made it possible to obtain faster emulsions with less fog. Digestion, or "ripening" as it was called, came into use—long digestion at low temperatures being suggested by Bennett—in 1878, and digestion with ammonia was used in 1876 by J. Johnson and in 1879 by Monck-

hoven, who employed precipitation in ammoniacal solution as the basis of a process of manufacturing dry plates.

In 1877, the commercial plates of the Liverpool Dry Plate Company, Wratten and Wainwright, and B. J. Edwards were introduced, and by 1879 comparatively rapid dry plates were available on the market similar in type to the slower varieties of plates used to-day.

After this period, amateurs gradually ceased their researches, and mass manufacture became general. Considerable increases in sensitiveness were made between 1890 and 1900, but since the latter date there has probably been little advance in the maximum sensitiveness that can be obtained, although materials of high sensitiveness are made with much greater regularity and with greater uniformity than was the case formerly.

It is interesting at this point to record the advance made in photography in terms of the relative sensitivity of the process.

Process	Date	Time of exposure
Heliography	1826	6 hr.
Daguerreotype	1839	30 min.
Calotype	1841	3 "
Wet Collodion	1851	10 sec.
Collodion Emulsion	1864	15 "
Gelatine Emulsion	1878	1 to $\frac{1}{100}$ sec.
Gelatine	1900	$\frac{1}{1000}$ sec.

Colour Sensitivity.—The silver halides are sensitive chiefly to the blue, violet, and ultra-violet rays; hence, all other colours are reproduced as dark greys or blacks. In 1873, H. W. Vogel of Berlin discovered that the addition of certain dyes to the emulsion or immersion of the coated plates in a solution of dye increased the sensitiveness to the less refrangible colours.

Following this, Waterhouse found that eosin sensitized collodion emulsion, and shortly afterwards Clayton and Tailfer found that eosin would sensitize gelatine emulsions. They obtained a patent for its use in England and France, and their plates were placed on the market under the name of "isochromatic" plates. In 1884, eosin was replaced by erythrosine, which was found by Eder to be a better sensitizer, and since that date erythrosine has been used almost exclusively for the use of the so-called "isochromatic" or "orthochromatic" materials. In 1902, Miethe and Traube of Berlin found that ethyl red, an isocyanine dye, gave strong colour sensitiveness as far as the orange of the spectrum, and in 1905, Homolka, working at the Hoechst Dye Works, discovered Pinacyanol, a dye of structure somewhat similar

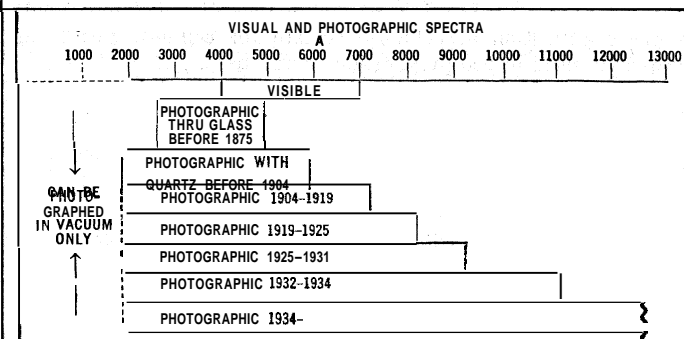

FIG. 3.—PROGRESS IN THE COLOUR SENSITIZING OF PHOTOGRAPHIC MATERIAL

to ethyl red but which sensitizes very powerfully throughout the red.

It was now possible to make "panchromatic" plates, which would photograph the entire spectrum without difficulty, and such plates were placed on the market in 1906.

In recent years enormous progress has been made owing to the discovery of new classes of dye which confer extremely high sensitivity through the visible spectrum and far out into the infrared. (See fig. 3.)

Film.—The weight and fragility of the glass support led to attempts to replace it by lighter and flexible substitutes. In 1884, the film roll system of photography was invented by W. H. Walker, the emulsion being coated on paper, and a machine for

continuously coating photographic paper in long rolls was patented by George Eastman in 1885. The sensitized paper was loaded into a roll holder which could be attached to the back of a camera in the same position as a plate holder. At first, the paper was waxed to reduce the printing time, but later a stripping film was used, this consisting of a temporary paper base coated with soluble gelatine, which in turn was coated with a gelatine emulsion.

This stripping film was used in the first portable roll film camera marketed in 1888—a box type camera with two rolls, a supply spool and the wind-up spool. The pictures were circular, about two inches in diameter, and the operator had merely to point the camera and press the button. When the film was used up, the whole camera was returned to the manufacturing company, who developed and printed the pictures and reloaded the camera.

Eastman made experiments to produce a flexible film from collodion, but the ether-alcohol solutions would give only films which were too thin to be of practical use. Finally the use of wood alcohol as a solvent for nitrocellulose was discovered, and a flexible film base was marketed in rolls in 1889. In the same year, J. Carbutt introduced emulsion coated on flexible sheets of plastic nitrocellulose compound cut from blocks. The new flexible film was applied at once by Edison to the photography of motion pictures.

In 1891, daylight loading film was made. The film was wound on a wooden core inside a light-tight box and black cloth leaders were attached to the ends of the film. Later, the film was wound inside a protective sheet of black paper leaving sufficient over-length to permit loading of the camera without fogging the sensitive film. This was further modified in 1903, when a non-curling film was produced by coating the back of the film with plain gelatine.

In 1913, roll film packing was further modified by spooling the film in a thin and translucent red paper, the film being protected from light by the use inside this of "carbon" paper similar to that used for duplicating on a typewriter. After exposures are made, the photographer can write on the red paper with a stylus through an opening in the back of the camera. The pressure of the stylus removes some of the opaque black carbon from the sheet, so that on exposure to light the film is exposed along the tracks of the writing, and the image develops with the negative and serves for its identification.

In 1895, positive film was introduced for the printing of motion pictures, the film used previously being of the negative variety only. In 1909 slow burning motion picture film was first made by the substitution of cellulose acetate for cellulose nitrate as the plastic used in the preparation of the base.

Another method of packing films was invented in 1903 and was introduced on the market under the name of "film packs." These are now used mostly in cameras of the type originally designed for employment with dry plates.

They have the considerable advantage of not requiring a special roll film back. During recent years flat cut films have taken the place of plates to a considerable extent especially in professional photography.

In 1917, X-ray films coated on both sides with emulsion were introduced. Owing to the transparency of the material to the X-rays, this enables double the density to be obtained, and the use of this film is now general throughout the world, it having almost entirely replaced plates in radiographic work.

In 1923, motion picture film 16 mm. wide on cellulose acetate base was introduced packed in such a manner that it could be loaded into small motion picture cameras without the use of a darkroom. This film was designed for finishing by a reversal process, in which the first negative is removed by a bleaching bath, and a positive is then printed on the remaining silver bromide. In 1932 a similar film 8mm. wide was introduced. The use of these films has led to a great advance in amateur cinematography.

Developing Agents.—In the Calotype process gallic acid was used as the developer for the latent image, but in 1851 Regnault of Paris and Justus Liebig simultaneously discovered the more energetically-acting pyrogallol, which actually allowed shorter ex-

posures to be given. This was used also at first for wet collodion, though it was later replaced by an iron salt, and for dry collodion plates. Until 1861, free silver nitrate was an important ingredient of developers; but in that year Wardley proved that pyrogallol alone could be used. C. Russell and J. Leahy independently announced alkaline pyrogallol development, the former suggesting also an alkaline bromide as restrainer. Even after the introduction of the gelatine plate, pyro-ammonia was the only developer used until 1884, when the alkaline carbonates became general. In 1880 Abney discovered the developing properties of hydroquinone. C. Egli and Arnold Spiller recommended the use of hydroxylamine in 1884. In 1888, M. Andresen of Berlin patented the use of paraphenylene diamine, paratoluidine diamine, and xylidene diamine as developers. In 1891, he patented the use of paraminophenol and its derivatives, especially monomethyl-paraminophenol, known under the trade name of "metol."

Printing Processes.—In turning to the positive processes, the first was with silver chloride and excess of silver nitrate on plain paper, which gave prints with a rather sunken appearance, the image being more or less buried in the fibres of the paper, and daylight was essential for printing. *Blanquart-Evrard*, in 1847, suggested the use of albumen to keep the sensitive salt more on the surface. In the same year, Romieu proposed salting with a mixture of alkaline bromides and chlorides containing gelatine and subsequent floating on silver nitrate solution. A few years later, the first coat of albumen was coagulated and a second applied, which gave a more brilliant glossy surface. The colour of prints obtained on these papers was an unpleasant foxy colour, and to darken this an acid was added to the fixing bath, thus causing sulphur toning. Le Gray, in 1850, proposed the use of a gold salt to improve the colour, and an alkaline gold bath was recommended by Waterhouse in 1858. De Caranza, 1856, recommended the use of platinum in lieu of gold. Albumenized paper made in this way and toned with gold remained the standard photographic printing medium until 1890.

A. Gaudin had suggested an emulsion of silver chloride in collodion for printing-out. This was revived by Wharton Simpson, in 1865. Paper thus prepared was introduced commercially by Obernetter three years later. Humbert de Molard, 1855, proposed to precipitate silver chloride, wash and suspend it in solution of starch or gelatine and paint the mixture on to paper. The same process was revived by Smith and Palmer in 1865 and by Abney in 1882. From this date, gelatino-chloride or printing-out paper came into general use, and eventually completely displaced albumen. Printing-out papers are at present used in Europe, chiefly collodion papers containing a gold salt that obviates the necessity of toning, but in America their use is limited to the production of rough proofs. Commercially they have been superseded by development papers.

Silver bromide with excess silver nitrate was used by Fox Talbot, and J. W. Swan in 1879 patented the use of paper coated with silver bromide emulsion not containing excess silver for development. It did not, however, come into general use until marketed by Eastman and by Just in 1883. Eder and Pizzighelli published, 1881, an exhaustive paper on gelatinochloride of silver with development, and the former, two years later, described a chloro-bromide emulsion. Chloride developing paper was introduced by Marion in England under the name of "Alpha" in 1889, and by Baekeland in America as Velox. Year by year since then the use of this paper has increased, special types, including a great variety of surfaces, being used for amateur and professional work.

Non-silver Printing Processes.—Robert Hunt was the first to utilize the light-sensitiveness of ferric oxalate in combination with a platinum salt in the hopes of obtaining images in that metal. But the process was a failure because he did not recognize that the ferrous salt, formed by the action of light, must form a complex salt in order to reduce the platinum salt to the metallic state. W. Willis in 1878 introduced the first workable platinum process. The great advantage of this process is that the pictures are permanent, as platinum is one of the most resistant of all metals. A modification of the process enables a platinum deposit of a sepia colour to be obtained, and for many

years sepia platinotype was the favourite printing process for results of the highest quality. The high cost of platinum and the ease with which development papers are worked has recently decreased the use of the process.

Vauquelin in 1798 had discovered the light-sensitiveness of silver chromate; Suckow, in 1832, observed that the bichromates were reduced by light in the presence of organic matter. Mungo Ponton, 1839, used paper treated with potassium bichromate. Becquerel, 1840, and Hunt, 1843, made improvements; but Fox Talbot first pointed out, 1852, that bichromated gelatine became insoluble in light, and this was patented as a resist for photogravure, for which it is still used.

Pretsch, Poitevin, Testud de Beauregard, Garnier and Salmon, and Pouncy, 1859, devised carbon processes, in which carbon itself in a finely divided state was used as the pigment in bichromated gelatine. But they failed to recognize the important point that, as the light acted first on the outer surface of the gelatine, those parts underlying the half tones and highlights would still be soluble; hence, on developing with warm water, they would have no anchorage to the support and would be washed away. J. W. Swan in 1864 patented the production of carbon or pigment prints by the transfer of the exposed pigmented tissue to a temporary support, on which it was developed from the back. Practically, his process is in use to-day, and its long scale of gradation, the possibility of using pigments of any colour, and the great stability of the pictures are much in its favour, though the necessity of day or arc-light for printing is against it.

T. Manly, 1905, patented a pigment process in which a developed silver print was squeezed into contact with pigmented tissue saturated with potassium ferricyanide and bichromate. These salts migrated to the silver image, bleached it, and the reduction products wandered back to the tissue, rendering it insoluble in ratio to the amount of silver in the picture, as though the tissue had been exposed to light under the negative. A modification of this, known as "Carbro," was introduced some years ago.

In 1905, G. E. Rawlins reverted to an old process suggested by Mariot in 1866. Gelatinized paper is sensitized with bichromate, dried, exposed under a negative, freed from excess salt, and inked up with a greasy ink, which adheres to only the light-affected parts. Somewhat similar is the bromoil process first suggested in 1907 by E. J. Wall and worked out by Welborne Piper. This utilizes the principle stated by Howard Farmer in 1889 that finely divided silver imbedded in gelatine reacts with bichromates and renders the contiguous colloid insoluble. A bromide print is treated with a hardening and bleaching solution, fixed, washed and dried, then soaked in water, and inked up with a greasy ink, which takes only on those parts where there was silver. These processes have been used particularly by artistic workers, because there is complete control over the gradations and tones of the pictures, and any coloured ink may be used.

There is practically no advance to be recorded in the iron printing processes, which are chiefly used for architects' and draughtsmen's plans, since Herschel's introduction of cyanotype in 1842.

A process in considerable use for copying engineering drawings, etc., depends on the fact that certain diazo compounds are destroyed by light. Paper is coated with them and developed by a "coupler" which combines with the diazo compound not destroyed by exposure, forming a positive dye image.

THE BRANCHES OF PHOTOGRAPHY

Amateur Photography. — The use of photography for making personal records has extended very greatly since portable cameras and sensitive materials were introduced, and the tendency is continually towards a simplification of the work to be done by the user and a diminution in the amount of expert knowledge required to get good results. This has resulted in the establishment of commercial firms to develop and print photographs made by the amateur, so that the great majority of photographs are now taken by those whose knowledge of the subject is limited to that necessary for making the exposures. The cameras used are chiefly

of the folding type using a cartridge of film and are often of very small size. Many now use 35 mm. motion picture film.

The film can be loaded into the camera without the use of a darkroom and removed after exposure for development. For development, the films are hung by clips in deep tanks. They are printed by artificial light upon gas-light or developing-out papers, which are made in different degrees of contrast to suit the negatives obtained. As a general rule the photographic dealers will deliver prints from an exposed roll of film within two days. Enlargements are made upon bromide paper, frequently by means of enlarging cameras in which the focus is automatically maintained correct while the scale of magnification is varied.

In addition to roll films, films in packs are largely used, each separate unit having a tab of paper attached to it by which it can be withdrawn after exposure. A small number of amateur cameras still use plates or flat cut films in suitable holders.

Photographers who prefer to develop their own films usually employ a so-called "developing tank." The film is placed in a wooden changing box, in which it can be wound up with a light-tight flexible apron on to a spool. This spool together with the film is then transferred to a metal tank fitted with a light-tight lid, in which the film is developed.

When a darkroom is employed, the duration of development can be determined by one of three methods:

(1) By observation; the development is carried on until the strength of the image is judged sufficient. This requires much experience and cannot be used with panchromatic materials.

(2) By factorial development; this system was introduced by Alfred Watkins of Hereford, England. The number of seconds that elapse from immersion in the developer to the first appearance of the image is noted. This time is then multiplied by a certain number called the "developing factor," to arrive at the total time of development. The factor depends upon the material used and the composition of the developer. The method gives good results in the hands of an experienced worker.

(3) Development for a fixed time at a definite temperature. This method possesses the maximum of advantage and reliability. It is always used when negatives are developed in tanks and has largely displaced the other methods.

Printing can be done either in a printing frame or with a small printing box in which the negative is placed on a sheet of glass, the paper placed on it, and a platen then brought down which secures contact and simultaneously lights an electric lamp under the negative. A grade of paper suitable to the contrast of the negative is chosen, and exposure is judged from the density of the negative.

Almost all the cameras used in amateur photography are designed primarily for use in the hand and are only occasionally used upon tripods. In addition to the small portable cameras, many amateur photographers use reflex cameras and folding cameras fitted with focal plane shutters. (*See* PHOTOGRAPHY: Apparatus.)

Advanced amateur photographers have contributed very much to the development of photography. They were among the first to employ colour sensitive plates, to use lenses of special types, such as telephoto or extremely wide aperture lenses, to study the printing processes, and to develop the artistic use of photography. (*See* PHOTOGRAPHY: Pictorial.)

Professional Photography. — The earliest photographic portrait appears to be the Daguerreotype taken of his sister by J. W. Draper of New York in 1840. The sitter was made up with white powder and photographed in full sunlight, an exposure of 5 minutes being given. The Daguerreotype process came into general use for portraiture, the plates being protected by glass in small leather cases, and these represented the common form of portraiture until the wet collodion process was introduced in 1851.

The early collodion portraits consisted of a glass negative developed so that the silver deposit was white and backed with a black varnish or material so that they appeared as positives resembling Daguerreotypes. They were sold in cases exactly

resembling those used for Daguerreotypes and are often mistaken for Daguerreotypes at the present time. They are properly known as Ambrotypes.

It was not until about 1860 that Ambrotypes were supplanted by albumen prints made from collodion negatives, these being made generally in two standard sizes—the *carte-de-visite* and cabinet. These were preserved in albums, and the period when the family album was in common use represented that of greatest prosperity for the professional photographer. These portraits were taken in glass covered studios arranged to supply the maximum of daylight. Elaborate backgrounds were used, and studio accessories of ornate and artificial type were commonly employed. Retouching on the negative was used often to an excessive degree, this being necessitated both by the vanity of the sitter and the pronounced ultra-violet sensitiveness of the collodion plate. In considering the evolution of portrait photography, it should not be forgotten that as early as 1843 D. O. Hill in Glasgow had used the Calotype process to make portraits which in dignity and artistic quality rival any that have ever been produced.

The "album" period lasted after the introduction of the dry plate, and modern photographic portraiture may be held to have had its beginnings only about 1900. The albumen process, however, was superseded by shiny, purple, gold-toned printing-out papers.

The modern development of portraiture has been influenced largely by "home portraiture" and by the use of artificial light in the home or elsewhere. The first arose from the entry into the profession of artists, usually without studio experience, who believed that they could obtain more characteristic portraits in the everyday surroundings of patrons, and of experienced photographers who operated over a wide field without the need of maintaining an expensive studio. This type of photography has become very successful.

Artificial light was introduced primarily to make the photographer independent of the vagaries of the weather. Since the use of artificial light made any large room suitable for use as a studio, and the influence of home portraiture encouraged the replacement of artificial backgrounds and accessories by the natural surroundings of a room, the studio has lost much of its artificial character.

In a reaction from the elaborate backgrounds of the 'gos, many photographers employed almost perfectly plain backgrounds for portraiture, these being conspicuous in the work of Hollyer, Craig Annan, and Furley Lewis in England, of Hofmeister and Perscheid in Germany, and of MacDonald in New York.

At the present time portraits of the better class are usually supplied of large size, 6 X 8 in. and upwards, and in folding mounts which protect the surface of the print.

In the United States negatives are taken very largely on flat sheets of portrait film, developed in tanks in a vertical position, and printed either by contact on developed chloride papers or by enlargement on bromide or chloro-bromide papers. The use of enlargement for making portrait prints has increased greatly owing to the introduction of automatically focusing projection printers. In Great Britain much printing is still by contact on bromide paper and on the more sensitive grades of chloro-bromide. Retouching is still used very largely in portraiture, but the increasing use of panchromatic materials tends to diminish its extent.

In addition to the high grade professional portraiture discussed here, there is a very large industry in the supply of cheap portraits to the masses, especially in the large cities and the pleasure resorts. The negatives are taken by artificial light on strips of film or in a camera so arranged that several can be taken on one plate and are printed as rapidly as possible on strips of paper which are usually cut to the size of post cards or even smaller. A still cheaper grade of portrait is produced by the "ferrotype" process on dry collodion coated on black japanned metal, this being the modern representative of the Ambrotype process. Similar pictures made with wet collodion have survived from 1860 as "tintypes."

A more recent introduction consisted of an automatic apparatus

by which on the introduction of a coin into a slot a series of photographs were taken and finished by a reversal process, a strip of positives on paper being delivered to the customer in a few minutes.

Commercial Photography.—In addition to portraiture the professional photographer has been accustomed to make miscellaneous photographs of buildings, machinery, or articles of merchandise which might be required for commercial purposes, but in the last 20 years this branch of photography has developed so greatly that it has become the work of a specialized group of "commercial photographers," and except to a small extent it is no longer carried on by portrait photographers.

The work of the commercial photographer is of the most varied character, but it may be divided into three sections according to whether the photographs are intended for use as a record, often necessary in engineering and construction work, to replace samples for the salesman to carry in soliciting orders, or for use in advertising. In the second field the photographs are often coloured by hand, a process which is almost obsolete in other branches of photography but which is rendered necessary by the absence of any cheap and satisfactory process of natural colour photography upon paper. Photographs for use in advertising may be designed either to represent the article, as in those employed for catalogue illustrations, to show the actual use of the article in the hands of the consumer and thereby to create a desire for it, or merely to attract attention. This field of commercial photography gives great scope for artistic composition and has developed very greatly of recent years.

Two characteristics of commercial photography are its use of suitably trained models, who are chosen with the greatest care, and the employment of special means for the photography of coloured objects.

Panchromatic materials and light filters were adopted by commercial photographers as soon as they were available, and a thorough understanding of their use is essential to satisfactory work at the present time. The apparatus used in commercial photography is remarkable chiefly for its adaptability and portability; it is necessary to photograph all kinds of objects in all sorts of places, and only a small portion of the work can be done in the studio.

Commercial photography is growing rapidly, a fact evident from the extensive use of photographs in advertisements.

Applied and Scientific Photography.—Photography is used in science and industry primarily to make a record which can then be studied and measured. It can also be used to facilitate the copying of documents, etc., photographic methods having the advantage of accuracy and speed. For this work a so-called "Photostat" camera is used in which a roll of paper is employed on which the document is recorded. (See Plate III., fig. 2.) The result is in the form of a negative and for many purposes these negatives are satisfactory; if positives are required, the negatives are re-photographed in the same camera.

In addition to its use in libraries, and so forth, for circulating extracts from books or copies of letters and other documents, photographic recording is now used very largely for the preparation of legal records, especially in connection with real estate. For such purposes a special "ledger" paper is used coated with emulsion on both sides, so that the photographs can be bound into books in the minimum space.

For the photography of ancient or falsified documents use is made of ultra-violet light, by means of which it is possible to decipher palimpsests, forgeries and so on.

Another application of photography to recording is that of the so-called "Factograph" camera. (See Plate III., fig. 3.)

This camera includes a spool of sensitive paper on which the record can be made, a lens and lighting box being placed in front of it so that when the camera is pressed down on an object such as a metre dial to be photographed lamps supplied by dry batteries will illuminate it. The object will then be in focus on the paper and many records can be made in quick succession.

Another special device carrying out the same idea is that due to G. L. McCarthy, who has designed a camera intended to

photograph upon a strip of motion picture film all the checks passing through a bank. This camera, which is known as the "Recordak," provides a permanent record which greatly diminishes the risk of fraud. A more recent form of this camera, known as the "News Recordak" is employed to photograph newspapers on 35 mm. film, so providing an enormous reduction in storage space.

Special cameras have also been designed for photographing the inside of rifle barrels in order to study the erosion of the bore, for lowering into oil wells in order to photograph the shaft, and for use with cystoscopes to photograph the interior of the body. All these cameras involve the optical principles of the periscope (*q.v.*).

An interesting application of photography is the so-called "gun camera" designed by the Royal Air Force in 1916 and used for the training of military aviators. (*See Plate III., fig. 1.*) With this camera, which resembled in shape a machine gun, an aviator in training engaged in mock combat photographed his adversary, and on development the film showed the accuracy of his aim. High speed motion picture cameras, enabling photographs to be taken at speeds of several thousand a second are much used for the study of fast moving mechanisms.

The greatest application of photography is, however, to general recording. The use of photography for recording the movement of physical instruments is mentioned as early as 1876 in Tisandier's handbook of photography. As a rule, any physical instrument can be made to record photographically. Thus, a galvanometer reflects a beam of light by means of a mirror, the movements of which are controlled by the current in the instrument. If the light is allowed to fall on a photographic material which is moving, a record will be obtained. Convenient cameras for this purpose use plates allowed to fall at uniform rates or rotating drums covered with paper or film.

A very wide application of photographic recording is found in the oscillograph, which is used for many purposes in addition to its primary one of recording the wave form of intermittent or alternating electric currents.

The electrocardiograph is an oscillograph adapted to the recording of the very weak currents produced by the heart.

The applications of photographic recording are innumerable; its use for magnetographs and seismographs should, however, be mentioned. (*See fig. 4.*) When the mirror is attached to a diaphragm, sound can be recorded and analysed. (*See MOTION PICTURES.*)

In connection with science, photography is used (1) for recording visible images; (2) for integrating radiation over long periods; (3) for detecting invisible radiation; (4) for measuring the intensity of radiation. Classes 1 and 2 covering the recording of visible images whether for a long or a short time cannot, of course, be separated and cover between them by far the most important applications of photography.

Astronomical Photography.— One of the branches of science to which photography is of the greatest importance is astronomy. At the present time visual observation in astronomy has been replaced almost entirely by photography. A photographic plate is used in the focal plane of the telescope, and the observer's work is reduced to directing the telescope towards the object to be photographed and correcting any irregularities in the driving clock, which would produce a shift in the position of the image upon the plate.

In the case of reflecting telescopes, the photographic focus is, of course, identical with the visual focus, since mirror systems do not involve chromatic aberrations, and for this reason as well as because of their lower cost, all modern telescopes of the largest size are of the reflecting type. A certain number of refractors have been made with photographic correction of their lenses, but most of the large refractors are corrected only for visual rays, and with these photography is done on green sensitive plates through a strong yellow filter, so that the record is made by green light.

Stellar positions are now determined entirely photographically, the micrometer eyepiece no longer being used. In this connection, the astrographic chart should be mentioned. (*See ASTRONOMY.*) A notable advance made possible by photography is the accurate determination of the parallax of the nearer stars. The number of stars observable has been greatly extended by photographic means, the 100 in. reflector at Mount Wilson recording stars of the twenty-first magnitude; that is, about one million times fainter than the faintest stars visible to the naked eye. And it may be confidently anticipated that the projected 200 inch reflector, when completed and used photographically, will make a proportionate increase.

Spectroscopy.— In spectroscopy (*q.v.*), visual observation has also been replaced by photography. The ease, indeed, with which the ultra-violet and violet parts of the spectrum could be photographed has led perhaps to an undue amount of attention being concentrated on those regions. The photography of the longer wave-lengths of the visible spectrum became possible only after the discovery of the isocyanine and carbocyanine dyes, at the beginning of the twentieth century. Using the new sensitizing dyes discovered in 1931 and the following years it is possible to photograph the spectrum as far as 1,350 $m\mu$ with ease. (*See Plate III., fig. 6.*)

In the ultra-violet, ordinary photographic plates are satisfactory down to 230 $m\mu$, but below this the absorption of the gelatine becomes serious. V. Schumann first investigated the short wavelength region from 120 $m\mu$ to 200 $m\mu$ by means of plates prepared with a minimum of gelatine. Recently, satisfactory photographs have been made in this region on ordinary plates sensitized with fluorescent bodies.

Photomicrography.— The application of photography to

microscopy covers a wide range. Small cameras are fitted to ordinary visual microscopes and used to make records of value chiefly for reference. In a more elaborate apparatus, a camera on a stand is swung over the vertical microscope, but for serious photomicrography, it is usual for the camera and microscope to be mounted on large stands or preferably on one rigid optical bench together with the illuminating system.

Recently, special photomicrographic apparatus has been built, in which the ordinary microscope is replaced by a part of the optical bench itself, such apparatus being particularly designed for the photomicrography of metal specimens.

For many years, the highest powers of the microscope were used only for the examination of bacteria and of test objects, such as the minute structure of diatoms, but the demands of the metallurgists and of research bacteriologists are now reaching to the utmost limit of the resolving power of the microscope.

Since resolving power is limited by the wave-length of the light used, photomicrography with ultra-violet light is now of value. It has been used with remarkable results in the fields of biology and is also being applied to the study of the minute structure of metallic alloys.

Apparatus for this purpose designed by A. Kohler was introduced by Carl Zeiss in 1914.

In the photography of stained specimens the control of the colour of the light is of great importance, and for this purpose sets of light filters have been designed by means of which stains can be photographed by light exactly complementary to that which they transmit. The maximum contrast is thus obtained.

Phototopography.—Col. Laussedat of the French army was the pioneer in the application of photography to surveying, and since photographic surveying is more suitable for mountainous countries, it was in the Alpine regions of Europe and the mountain chains of Canada that the largest areas were first surveyed photographically. Dr. Deville, late surveyor-general of the Dominion of Canada, studied the subject very exhaustively and wrote a number of books on the subject, and the Russian surveyors have also used photographic methods on a large scale, especially in their surveys of Siberia.

In order to make a photographic survey, two photographs are taken of the same area from different known positions which are plotted on the map. Lines are then drawn from the positions to each identifiable point on the map and object in the photograph until the complete survey is accomplished, this plotting being done after the manner of a plane table survey but with the advantage that the detailed plotting is done in the office and is therefore independent of the weather, the only work done in the field being the photography. The cameras used for the purpose are of rigid construction and have levelling mounts so that they can be levelled precisely. Elaborate photo-theodolites have been devised for the purpose, notably a beautiful instrument designed by Zeiss, but simpler cameras are also quite satisfactory provided that they are rigidly made. (See Plate III. fig. 4.) No considerable area can, of course, be mapped without a skeleton of positions determined relatively to each other with precision, and the primary triangulation is therefore made over the area to be mapped, other points then being interpolated from the photographs.

Another method of photo-surveying is by the use of the principle of stereoscopy. Two photo-theodolites are put at the opposite ends of a measured base and exposures made in which the same objects are included. From the photographs distances can be measured by the use of the stereo-comparator designed and perfected by Prof. Pulfrich of the optical research establishment of Carl Zeiss at Jena. A notable advance in this field of stereoscopic photo-surveying was made when Captain von Orel of the Austrian army developed the stereo-autograph, which is a three-dimensional pantograph which can be used in conjunction with a stereo-comparator and will plot a map directly from the photographs. Stereo-photo-topography is now the most advanced of photographic methods of survey; its accuracy is high, and it is very rapid. Its drawbacks are the high cost of the instruments, the necessity for base measurement, which is not always easy, and the considerable weight to be transported. (See Plate IV.)

Aerial Photography.—Photography from the air is utilized for military purposes as well as for surveying. Its use during the World War was very extensive, thousands of negatives being taken every day by the armies. The first aeroplane cameras were modifications of standard cameras with usually a focal plane shutter, and the material was generally plates carried in holders and later in magazines adapted for quick changing. Hand-operated cameras using magazines were later developed and were used largely in 1916 and 1917. Later, semi-automatic plate cameras were designed in which the observer released the shutter while the mechanism at the same moment operated the changing of the plates. In the last years of the World War (1914-1918) these cameras were made of very considerable size as well as of very considerable weight, sometimes as many as 50 plates each of which measured 18 cm. × 24 cm. in size and were carried in a camera at one time.

Towards the end of the World War film cameras were developed which were capable of carrying rolls of film giving 100 exposures 18 × 24 centimetres in size. The great advantage which cameras of this kind have over other cameras is, of course, the light weight of the material used. In the year 1918 entirely automatic film cameras were made, the changing of the film and the exposure being carried out by means of a motor which might be either electrical or driven by the wind. (See Plate V., fig. 1.) Automatic film cameras are now used almost exclusively, in view of their superiority over plate cameras.

From the photographic point of view the most important phenomenon encountered when working from a great height, as in an aeroplane, is the scattering of the light by the atmosphere, an effect which is generally known as haze. Since this scattering is greater for shorter wave-lengths of light, it can be eliminated to a considerable extent by the removal of the blue light and by the use of only longer wave-lengths. In order to accomplish this, the materials used are generally sensitive to red light, and filters can be used with satisfactory results as to exposure; under such conditions great penetration through hazy atmosphere is possible. Excellent photographs have been taken from the greatest height reached by an aeroplane, and by balloon from the stratosphere.

While aerial photography is an immense aid to the military both for the detection of enemy operations and also for the preparation of maps, its application to precision surveying is subject to limitations. It is not possible to note with sufficient accuracy the height and angle of the aerial camera for a map to be made without correction for errors, and consequently aerial surveying requires the provision of bases of known position on the ground which can be included and used to scale and correct the photograph. This limits its use in surveying (*q.v.*) since such measured bases are not always available. Nevertheless there are many purposes for which aerial surveying is very well adapted. A fire survey of a city can be made with sufficient accuracy by aerial photography at less than one-tenth of the cost of a corresponding ground survey. This makes it possible to repeat the fire surveys of rapidly growing cities at much more frequent intervals than could be done otherwise. Surveys of lakes and forests can be carried out by the aeroplane rapidly and with sufficient accuracy for many different purposes. (See ARCHÆOLOGY; SURVEYING.)

Radiography. (See RADIOGRAPHY; X-RAYS, NATURE OF.)—In this branch of photography very special conditions of work are involved. From its introduction in 1896, when X-rays were discovered by Röntgen, the field of radiography—almost entirely in connection with its medical application—has grown until at the present time approximately as many negatives are taken by means of X-rays as are made in portrait studies.

The earlier radiographs were made on plates of the same type as those used for portraiture; improvements were made by the introduction of large quantities of silver salt into the emulsion, while later attempts were made to load the emulsion by the addition of salts of other metals in such a way that the absorption of the X-rays would be increased and high sensitiveness obtained. There is reason to believe that these attempts were based on an incorrect understanding of the laws of the absorption of the

X-rays. A considerable advance in the technique was made when double-coated film was introduced, a special X-ray emulsion being coated on both sides of the film, so that the image was formed half on the front and half on the back. It is customary to use such films in combination with one or more, generally two, so-called intensifying screens. These intensifying screens consist of a layer containing calcium tungstate coated on a suitable support. The calcium tungstate fluoresces under the influence of the X-rays, transforming a portion of the X-rays into light which is active photographically. The general method of working, therefore, is to expose the film in a cassette; that is, a holder in which the film is pressed into contact with an intensifying screen on each side.

One of the great difficulties in obtaining radiographs of good quality, especially when photographing through portions of the body of considerable thickness, is the presence of scattered radiation or secondary X-rays produced by the scattering of the primary X-rays in the tissues. Measurements have shown that the scattered radiation generally accounts for as much as three-fourths of the entire density of a radiograph taken through the body, and since this scattered radiation does not contribute to the formation of the image, it naturally produces a great lowering of contrast and general loss of detail and quality. The best method of eliminating this is the use of what is known as the "Potter-Bucky" diaphragm, which consists of a grid formed of strips of lead foil pointing toward the source of the X-rays. This diaphragm is placed between the subject photographed and the film. In order to prevent its forming shadows, the diaphragm is moved during exposure, and under these conditions the strips of lead cut out much of the scattered radiation, which is not proceeding from the source of X-rays but is scattered in all directions, and thus enable the image to be formed to a much greater extent by the direct X-rays coming from the focal point. (See fig. 5.)

For dental work the film is supplied in special packages to be held inside the mouth, usually with a backing of lead foil to stop secondary radiation and to enable the package to be moulded to the shape of the mouth. Dental radiography has been extended very rapidly, and radiographs of the teeth are among the most valuable guides to the operations of the dental surgeon.

(C. E. K. M.)

THEORY OF PHOTOGRAPHY

The Sensitive Material.— If a photographic negative be examined under a microscope, it will be seen to consist not of a continuous homogeneous surface but of discrete, small silver grains occurring chiefly in clumps. (See Plate V., fig. 3) These silver grains are derived from the structure of the original sensitive emulsion. This is shown in Plate V., fig. 4, where we see that the developed grains correspond in general form and position to the undeveloped silver bromide grains from which they were produced.

If the emulsion is removed from a sensitive film and spread out under a microscope in a thin layer, it will be seen that the silver bromide is in the form of crystals, these being usually flat crystals, generally hexagonal or triangular in shape. (See Plate V., fig. 5). These crystals are very small, $\frac{1}{10,000}$ in. or less across; there are great numbers of them in a film, several thousand million in a square inch, and their size depends upon the way in which the emulsion was made.

If an emulsion is made by adding a solution of silver nitrate

to one of bromide in the absence of gelatine, the silver bromide formed will settle out in coarse flocks, but if a small quantity of gelatine be added to the solution, the silver bromide will be precipitated in a much finer form and will remain in suspension. In making an emulsion, therefore, gelatine is added to the bromide solution, and the mixture is brought to the proper temperature, then the silver nitrate solution is added, and the whole is heated.

When first mixed, the emulsion by transmitted light appears of a deep ruby colour. As heating is continued, the colour changes, becoming finally a bluish gray. Examination of the precipitate by means of X-rays has shown that the silver halide is crystalline from the beginning, the changes in colour and absorption being due merely to an increase in the size of the crystals. As this increase in size proceeds, the emulsion gains in sensitivity, but the chief increase in sensitivity occurs after the bulk of the gelatine has been added. After the emulsion is set it is cut up by squeezing it through a sieve and then washed to remove the soluble salts. It is then further ripened to obtain the sensitiveness required.

The sensitiveness obtained depends to a very large extent upon the particular kind of gelatine used, some gelatine giving high sensitiveness, while other samples, apparently of the same chemical and physical properties, will not give good sensitiveness however long the heating is continued. As will be shown later, this has been found to be due to a small impurity carried in the gelatine.

The crystals in an emulsion vary very greatly in size, their size and distribution being controlled by the conditions under which the emulsion was precipitated and digested. The sizes of grains which occur in an emulsion are directly connected with photographic properties of that emulsion.

When the grains cover a wide range of sizes, the emulsion is suitable for making negatives; it usually has a high degree of sensitiveness and a low degree of contrast. When, on the other hand, the grains are small and uniform, the emulsion has a high degree of contrast and a lower sensitiveness, such emulsions being used for positive film or lantern slide making.

If we suppose that the same amount of photo-chemical product (latent image) makes either a large or a small grain developable, then, other things being equal, the larger grain contributes a larger amount of silver to the image and thus gives more density for the same amount of light action than a smaller grain. For this reason alone, emulsions containing large grains would be more sensitive than those containing small grains, but experiment has shown that this is not the only factor and that, on the average, larger grains require less light action to become developable than small grains. Further, it has been shown that the seat of this sensitiveness is concentrated in specks in the grains, and the sensitiveness of the grain depends upon the presence and the number of these sensitive specks.

Since they differ in nature from the silver bromide, it was suspected that the specks were derived from the gelatine, since some gelatines give emulsions which are much more sensitive than others. A material was extracted from gelatine which was identified by Dr. S. E. Sheppard with allyl mustard oil, which in ammoniacal solution becomes allyl thiocarbamide. Allyl thiocarbamide reacts with silver bromide, and the compound of the two in alkaline solution produces silver sulphide, so that the sensitizing specks may consist of minute traces of silver sulphide on the surface of the silver bromide grain. The ripening process in the preparation of gelatine-bromide emulsions may therefore be ascribed partly to the growth of grains of larger sizes from those of small dimensions and partly to the production of the sensitizing specks of silver sulphide on the surface of the grain. Silver itself may also be associated with the specks.

The exact action of light upon the silver halide and the nature of the product which renders the grains developable is not well understood, although recent work is tending to define the issue and to suggest that we are not far from the complete solution of the problem. The exposed silver halide, which changes to silver in development, is known in photography as the "latent image." and the problem of the nature of the latent image has been a

FIG. 5.—DIAGRAM SHOWING USE OF POTTER-BUCKY DIAPHRAGM

subject of speculation from the earliest days of the science.

The theories put forward as to the nature of the latent image may be roughly divided into physical and chemical:

The physical theories include theories of disintegration and of depolymerization as well as theories of the formation of the image without involving any assumption as to its actual nature, such as the theories of molecular strain and of photo-electric emission of electrons.

The latent image has certain definite chemical properties. It is normally stable, since it has been known to persist for many years. Its fundamental property is that of facilitating the deposition of silver in a reducing agent, such as a developer. It can be destroyed by powerful oxidizing agents, such as chromic acid or acid permanganate. These properties seem to call for the existence of some definite chemical individual, and it would appear, therefore, that the latent image must consist of some reduction product of silver bromide. Those which have been suggested are silver sub-bromide and metallic silver.

The existence of silver sub-bromide is doubtful; the formula AgBr_2 has been proposed but it has never been prepared in a pure state. All attempts to prepare it have resulted in mixtures or solid solutions of silver bromide with metallic silver. While the theory that silver sub-bromide was the material of the latent image was accepted for many years, it is now generally agreed that the image consists of metallic silver in very small amounts formed by the reduction of silver bromide.

When light falls upon a crystal of silver bromide, therefore, it produces a small quantity (perhaps a few hundred or a few thousand atoms) of silver. The size or condition of this speck of silver determines whether or not it will act as a nucleus to make the crystal developable. The production of the silver appears to be greatly facilitated by the existence on the crystal of small specks of foreign material, presumably, from Sheppard's work, mainly silver sulphide. The mechanism of this action is still under discussion.

Dr. Sheppard and his colleagues have developed a theory which they term the "concentration speck theory," according to which the action of the sensitizing speck is to concentrate the energy falling upon the silver bromide and enable silver to be liberated at the boundary of the speck. Toy and Trivelli have suggested independently that the chief action of light is to increase the conductivity of the silver bromide, and Trivelli suggests that an electrolytic action then ensues as a result of which metallic silver is deposited in contact with the silver sulphide speck. Hickman and others have postulated that a sensitizing speck must be an acceptor for the halogen set free, and many mechanisms have been suggested for the reaction. Much work remains to be done on this problem, however.

Development.— In the process of development, the bromine is removed from the crystals of silver bromide, which are transformed into coke-like masses of metallic silver. With some developers, the silver takes the form of the silver bromide grains, while with others the grain is entirely broken up and distorted and is merely replaced by an equivalent amount of metallic silver. (See Plate V., figs. 6, 7, 8.) There are many chemicals which will reduce silver bromide to silver, but in order to act as a developer it is necessary that the solution should have the power of turning exposed silver bromide into metallic silver and should not be able to act on unexposed silver bromide, since if the solution acted on the unexposed as well as the exposed grains, the whole film would darken, and we should not get an image at all. Only a very limited number of substances have the power of distinguishing between exposed and unexposed grains of silver bromide, and there are therefore only a few substances which are suitable for use as developers. With the exception of ferrous oxalate and one or two other inorganic compounds which have fallen into disuse, all the developing agents used are phenolic or amino compounds derived from benzene or naphthalene.

The chief developing substances are pyrogallol, or *pyro* as the photographer calls it; hydroquinone; and methylparaminophenol, which is known under trade names such as "metol" and "elon." All of these developing substances are chemically related

to benzene.

It was shown by Lumière and Seyewetz and by Andresen that in order to be practically useful developers must contain at least two hydroxyl groups or two amino groups or one hydroxyl and one amino group attached to the benzene nucleus in the para or ortho position; meta compounds have no developing power.

The three developing agents chiefly used are thus hydroquinone,

which is para-dihydroxybenzene and is made by the oxidation of aniline and the reduction of the quinone formed; metol or methylparaminophenol,

which can be produced by the methylation of paraminophenol or by various other less direct reactions; and pyrogallol, trihydroxybenzene,

which is produced by the distillation of gallic acid.

In addition to these three, there are a large number of similar compounds which can be used as developing agents and for which advantages are sometimes claimed. In all probability, however, the three compounds given above will supply all the needs of the photographer.

Two compounds which have some wide use, however, are paraminophenol,

which is intermediate in its properties between methylparaminophenol and hydroquinone; and diaminophenol, or amidol, which is used for the development of papers.

With the exception of diaminophenol, these compounds are unable to reduce silver bromide in neutral or acid solution, and in order to make a "developer" alkali must be present in the solution. On the other hand in the case of the aminophenols the developing agents are used in the form of salts of the bases; thus, metol is the sulphate of methyl-paraminophenol, and it is usual to employ the chloride of paraminophenol and of diaminophenol. Enough alkali must therefore be added initially to liberate the base itself, which is usually insoluble in water, and to redissolve it as the alkaline phenolate. The most convenient alkali is sodium carbonate, and a typical developer would thus consist of pyrogallol with sodium carbonate added to it. As is well known, however, alkaline pyrogallol absorbs oxygen from the air very rapidly and would soon darken and lose its developing power. In order to make a developer keep, a small quantity of sodium sulphite is added to the solution. The sulphite protects the developer from oxidation and thereby enables it to retain its full developing power, although the sulphite, when used alone, possesses no developing power whatever.

The essential constituents of a developer, therefore, are the developing agent—pyro, hydroquinone or metol; the alkali, which is generally sodium carbonate; and the preservative, which is sodium sulphite. In addition, it is usual to add a small amount of alkaline bromide, which will act as a restrainer and prevent

the development of unexposed silver bromide, giving rise to what is known as "fog."

The various developing agents behave somewhat differently. Suppose, for instance, that we make up two developers, one with hydroquinone and the other with metol, and start to develop a film in each at the same time. In the metol developer the image will appear very quickly, and will appear all over the film at the same time, the less exposed portions which, of course, were the shadows in the picture, appearing at the same time as the highlights. On the other hand, with the hydroquinone the image will appear more slowly, and the most exposed portions, or the highlights, will appear first, so that by the time the shadows have appeared on the surface of the film the highlights will have acquired considerable density. If development is stopped as soon as the whole image is out, the negative developed in metol will be very thin and grey all over, while that developed in hydroquinone will have a good deal of density in the highlights. Thus, of these two developers we may say that metol gives detail first and then slowly builds up density, while with hydroquinone the detail comes only after considerable density has been acquired. It is for this reason that these two developing agents are used in combination; the hydroquinone gives the density and the metol the detail, and together they make a satisfactory developer.

These differences in the behaviour of developing agents are due to a property of the developer which is commonly known in photography as the *reduction potential*.

The reaction of development may be represented by the following general equation:—

The sodium salt of the reducing agent symbolized by R reacts with silver bromide and forms metallic silver, the oxidation product of the developing agent, which is symbolized by R', and sodium bromide.

The reaction will go in either direction according to the driving force available, and, in practice, quinone, the oxidation product of hydroquinone, together with sodium bromide, will bleach a silver negative, transforming the metallic silver into silver bromide. Now, the driving force in the direction from left to right depends upon the reduction potential of the developer. This is opposed by the reaction in the opposite direction, which is dependent on the concentration of soluble bromide and of developer oxidation product in the solution, so that if the bromide be increased, the rate of the reaction will be lowered. It is thus possible to measure the reduction potential of a developer by the effect of potassium bromide on development, as was originally suggested by S. E. Sheppard. A careful study of this was carried out by A. H. Nietz, who gives what are probably the most reliable data for the developers as follows:—

Developer	Relative energy
Ferrous oxalate	0.3
p-phenylene diamine hydrochloride (no alkali)	0.3
p-phenylene diamine hydrochloride (alkali)	0.4
Hydroquinone (standard)	1.0
p-phenylglycine	1.6
Hydroxylamine	2.0
Toluhydroquinone	2.2
p-aminophenol (hydrochloride)	6.0
Chlorhydroquinone	7.0
Dimethyl p-aminophenol (sulphate)	10.0
Monomethyl-p-aminophenol (sulphate)	20.0
Diaminophenol	30-40

A developer much used for negative making was pyrogallol. Owing to the fact that pyro is changed during development into a yellow substance, some of which remains associated with the silver in the image, pyro tends to give a slightly yellowish image, which has very much greater printing power than the plain silver image. The yellowish stain is prevented from forming by sulphite, so that the more sulphite there is in a developer, the less colour the deposit will show. Pyro is, therefore, used only for the development of negatives, prints on paper or positive films in motion picture work being developed with metol and hydro-

quinone. Recently there has been a tendency to replace pyro by metolhydroquinone also for negative development.

When a film is developed, it is only the grains of silver bromide which have been changed by the action of light that are affected by the developer. The grains that have not been changed are not affected.

At the beginning of development, there are a great many ex-

FIG. 6.— DEVELOPMENT OF EXPOSED GRAINS IN A FILM WHICH IS HALF DEVELOPED IN ONE MINUTE

1st column, at beginning; 2nd, after 1 minute; 3rd, after 2 minutes; 4th, after 3 minutes; 5th, after 4 minutes; 6th, after 5 minutes

posed grains ready to be developed, and then as development proceeds, these exposed grains are turned into grains of black silver, so that the number of developable grains decreases during development until at last there are no developable grains left, all those which can be developed have been acted upon, and the development of the image ceases. The rate at which the grains develop depends upon the number of exposed but undeveloped grains left, and as the grains are developed and the number of undeveloped grains remaining becomes less, fewer and fewer grains develop in each minute, until finally it is not worth while to prolong the development in order to get any more density. (See fig.-6.)

The growth of the image during development is referred to as a growth of density; that is to say, the density is a measure of the number of grains of silver which are produced at any given point. These grains of silver, after the film has been cleared by the fixing bath, obstruct the passage of light through the film.

The density of an image is measured in units which are based on the amount of silver which will let through $\frac{1}{10}$ of the light, so that if only $\frac{1}{10}$ of the light falling on the negative gets through a certain part of it, that portion of the negative is said to have a density of 1. Similarly, when only $\frac{1}{100}$ of the light incident is transmitted, that part of the negative is said to have a density of 2. The blackest part of a negative may have a density of perhaps 2, the middle tones 1 or less, and the shadows, perhaps $\frac{1}{10}$. (See fig. 7.)

FIG. 7.— DENSITIES OF VARIOUS PARTS OF A NEGATIVE
1st division, shadows; 2nd, halftones; 3rd, highlights

(See fig. 8.) It grows rapidly at first, when there are many grains to be developed, and then more slowly until, finally, when the exposed grains are all developed, the negative will not give any more contrast however long development may be prolonged, and a continuation of development will result only in the production of fog. The final contrast which can be obtained depends upon the kind of emulsion used. The fast emulsions, such as the negative emulsions, give moderate contrast, but the slow emulsions,

The difference of density between the darkest portion and the lightest portion of the negative is called its *contrast*.

Since the contrast depends chiefly upon the density of the highlights, it grows during development just as the density does.

such as those used for copying purposes or for making lantern slides, are especially made to give great contrast when development is prolonged. (See fig. 9.)

The temperature coefficient of development is about 2 for 15° F, although it varies somewhat with the developer. Thus, if the development time at 65° be 4 min., it will be about 2 min. at 80° F, and about 8 min. at 50° F. Tables and curves showing

FIG. 8.—THE GROWTH OF CONTRAST DURING DEVELOPMENT

the relation between the time of development and the temperature are in common use in photography. Fig. 10 shows such a curve supplied for use of X-ray workers giving the time of development for a standard developer at various temperatures.

After **Processes.**—After development, the undeveloped silver bromide is removed by immersion of the negative or print in what is called the "fixing" bath. There are only a few substances which will dissolve silver bromide, and the one which is universally used in modern photography is sodium thiosulphate, $\text{Na}_2\text{S}_2\text{O}_3$, which is known to photographers as hyposulphite of soda, or more usually as "hypo"—the name hyposulphite of soda being used by chemists for another substance. Cyanide is used as the fixing bath in the wet collodion process, because it will dissolve silver iodide while thiosulphate will not. It is not desirable for use with gelatin-bromide plates, however.

A negative or print transferred to the fixing bath invariably carries some developer with it, and if this developer accumulated in the bath it would cause stain or fog. It is customary, therefore, to add acid to the fixing bath to neutralize the alkali from the developer and prevent this action. If free acid is added to a thiosulphate solution, it is decomposed forming sulphur. This can be prevented, however, by the addition of sulphite which "preserves" the bath. Weak acids are used so that a relatively large quantity can be employed without making the bath too acid. Acetic acid is generally used. Materials are also added to the fixing bath to prevent softening of the gelatin. The commonest is alum, and a typical fixing bath therefore contains 20% to 30% of its weight of hypo, about 1% of anhydrous sodium sulphite

FIG. 9.—THE GREATEST CONTRAST WITH DIFFERENT EMULSIONS

and of potassium alum, and 3% of 28% acetic acid. The developer alkali carried over by the negatives or prints to the fixing bath tends to neutralize the acetic acid and eventually may cause a sludge of alumina to form in the bath, and decrease its ability to harden. This tendency to sludge can be reduced by adding boric acid to the fixing bath. This also extends the hardening life of the solution.

The rate of fixing depends upon the concentration of the hypo and on the temperature. It increases to a maximum with about 40% hypo and decreases with stronger solutions owing to a de-

crease of the swelling of the gelatine and consequent difficulty of penetration.

A very important operation in photography is the washing of the negatives and prints in order to remove from them the chemicals of the fixing bath. If an exhausted fixing bath has been used, silver compounds will be present during washing, and it is most important that they should be removed by complete washing.

The rate of washing depends largely upon the rate of diffusion of hypo out of the film into the water, provided the water in contact with the material is continuously removed. In washing,

FIG. 10.—GRAPH SHOWING TIME OF DEVELOPMENT FOR X-RAY FILM AT VARIOUS TEMPERATURES

the amount of hypo remaining in the gelatine is continually halved in the same period of time as the washing proceeds. An average negative, for instance, will give up half its hypo in two minutes, so that at the end of 2 min., half the hypo will be remaining in it; after 4 min., one-quarter; after 6 min., one-eighth; after 8 min., one-sixteenth; 10 min., one-thirty-second, etc. It will be seen that in a short time the amount of hypo remaining will be infinitesimal. This, however, assumes that the negative is continually exposed to fresh water, which is the most important matter in arranging the washing of either negatives or prints.

Reduction.—When a negative is too dense, it is sometimes reduced. By reduction in photography is meant the removal of some silver from the image so as to produce a less intense image. Thus, in the case of an over-developed plate there will be too much density and contrast, and the negative may be reduced to lessen this. In the case of an overexposed negative there may not be an excess of contrast but the negative will be too dense all over, and in this case what is required is the removal of the excess density.

All the photographic reducers are oxidizing agents, and almost any strong oxidizing agent will act as a photographic reducer and will remove silver, but various oxidizing agents behave differently in respect to the highlights and shadows of the image. Reducing solutions can be placed in three classes:—

- A. Cutting reducers
- B. True scale reducers
- C. Flattening reducers.

A. The cutting reducers remove an equal amount of silver from all parts of the image and consequently remove a larger proportion of the image from the shadows than from the highlights of the negative. The typical cutting reducer is that known as "Farmer's" reducer. This consists of a mixture of potassium ferricyanide and hypo, the potassium ferricyanide oxidizing the

silver to silver ferrocyanide and the hypo dissolving the latter compound.

Another cutting reducer is permanganate. The permanganates are very strong oxidizing agents, and if a solution of permanganate containing sulphuric acid is applied to a negative, it will oxidize the silver to silver sulphate, which is sufficiently soluble in water to be dissolved.

B. Proportional reducers are those which act on all parts of the negative in proportion to the amount of silver present; hence they exactly undo the action of development, since during development the density of all parts of the negative increases proportionally. A correctly exposed but over-developed negative should be reduced with a proportional reducer. Unfortunately, there are no single substances which form exactly proportional reducers, but by mixing permanganate, which is a slightly cutting reducer, with persulphate, which is a flattening reducer, a proportional reducer may be obtained.

C. In order to have a flattening reducer, we require one which acts very much more on the heavy deposits than on the light deposits of the negative and which will consequently reduce the highlights without affecting the detail in the shadows. Only one such reducer is known, and this is ammonium persulphate. Ammonium persulphate is a powerful oxidizing agent and attacks the silver of the negative, transforming it into silver sulphate, which dissolves in the solution. It must be used in an acid solution and is somewhat uncertain in its behaviour, occasionally refusing to act, and always acting more rapidly in measure as the reduction progresses.

Intensification.— Intensification is photographically the opposite of reduction, the object being to increase contrast. This is done by the deposition of some other material on the silver image. A silver image, for instance, can be very much intensified by toning it with uranium, the reddish-brown uranium ferrocyanide having very great printing strength and converting a weak negative into one having a great effective contrast for printing purposes. Usually, however, intensification is performed by depositing a silver, mercury, or chromium compound upon the image, and many photographic intensifiers depend upon the use of mercury. Experience has shown that mercury intensified images are not usually as stable as images produced by chromium intensification.

The mercuric intensifier consists of a solution of mercuric chloride, a few drops of ammonium chloride or hydrochloric acid being added to the solution. When the silver image is placed in this, it reacts with the mercuric chloride and forms a mixture of silver chloride and mercurous chloride. The bleached image, which appears white, can then be treated in various ways. If it is developed, for instance, both the silver chloride and the mercurous chloride will be reduced to the metal and to every part of silver there will be added an equal part of mercury. Instead of using a developer, the image may be blackened with ammonia, which forms a black mercury-ammonium complex and produces a high degree of intensification.

A very powerful method of intensification, used chiefly for negatives made by photo-engravers, is obtained by bleaching with mercuric chloride and blackening with silver dissolved in potassium cyanide. The use of the cyanide cuts the shadows very slightly at the same time that the highlights are intensified, so that a great increase in the contrast of the negative is obtained. This is usually known as the *Monckhoven* intensifier.

In the case of the chromium intensifier the silver image is bleached with a solution of bichromate containing a very little hydrochloric acid, bichromate being an oxidizer of the same type as permanganate or ferricyanide. The image is then re-developed and will be found to be intensified by the deposition of a chromium compound. This intensifier has found increasing favour owing to the ease and certainty of its operation and the permanency of the intensified image.

Sensitometry.— The first quantitative measurements of the result of the action of light on photographic materials were made by Sir W. de W. (then Captain) Abney in 1874. (Abney, *Phil. Mag.*, 48, pp. 161-165, 1874.) He constructed an instrument by

which the transparency of the developed image could be measured, and by means of this he demonstrated that within limits the transparency of the deposit varied inversely as the logarithm of the exposure.

In 1890, F. Hurter and V. C. Driffield (*Jour. Soc. Chem. Industry*, vol ix., p. 455, May 7, 1890) published a classic paper entitled "Photo-Chemical Investigations and a New Method of Determination of the Sensitiveness of Photographic Plates," in which they studied systematically the relation between exposure, development, and the deposit of silver produced in the photographic process. They first defined the photographic density *D* as being the logarithm of $1/\text{transparency}$, or the logarithm of the opacity, which was defined as the inverse of the transparency.

Thus, if we have a light of intensity *I* incident upon a photographic deposit, and *I'* is transmitted,

$$T \text{ (the transparency)} = I'/I,$$

$$O \text{ (the opacity)} = I/I' = 1/T,$$

$$D = \text{density} = \text{logarithm of } I/I' \text{ or } -\log I'/I.$$

The following table of relations between density and transmission will be convenient:

Density	Transmission	Density	Transmission
0.0	1	1	1/10
.3	$\frac{1}{2}$	1.3	1/20
.6	$\frac{1}{4}$	2	1/100
.9	$\frac{1}{8}$	3	1/1000

Hurter, Driffield and others showed experimentally that the density *D* of a given silver deposit was proportional to the mass of silver per unit area contained in the deposit. It has recently been shown by Sheppard and Ballard that the relation is only approximate and that there may be considerable departures from true proportionality with variations of exposure and development. A deposit transmitting approximately one-tenth of the incident light, that is, having a density of 1, is given by about 1/10 mg. of silver per square centimetre of the film.

Basing their studies on their definition of density, Hurter and Driffield exposed photographic plates for definite times to a standard candle by means of a rotating wheel with cut-out sectors of various angles. The plates were developed in a non-bromided developer, fixed, washed, dried, and the densities plotted on a

FIG. 11.— CHARACTERISTIC CURVE OF AN EMULSION

chart with the logarithms of the exposure time ($\log_{10} E$) as abscissae and densities as ordinates, as is shown in the accompanying diagram. (See fig. 11.)

This shows what is known as the characteristic curve of an emulsion. There are three fairly well defined regions of the curve. Thus, from A to B we have the initial part convex to the log *E* axis, which may be termed the region of "underexposure"; between B and C, known as the period of "correct exposure," the increase of density is practically constant for each increase of exposure, being arithmetical for each geometric increase of

exposure; in the third region, from C to D, this arithmetical increase falls until the density becomes constant; this is the region of overexposure.

By prolongation of the straight-line portion of the curve, the log E axis is cut at a point which Hurter and Driffield termed the "inertia," which, when divided into a factor, gives the "speed" of the plate.

Hurter and Driffield adopted the factor 34 and provided that the "inertia" should be expressed in "candle-metre-seconds"; that is, seconds of exposure at one metre distance from one British standard spermaceti candle. The speeds so obtained were applicable to an exposure metre called the "Actinograph," which they designed. It is common in England to publish so-called "H. and D." speeds for photographic materials. Such speeds are not, however, always determined in accordance with the specifications of Hurter and Driffield. At the present time exposures are made to an electric lamp. There is no general agreement as to a satisfactory method for evaluating speeds, although the question is being discussed internationally.

The spermaceti candle being quite obsolete as a standard light source, the character of the source to be adopted is of great importance, since its photographic effect will depend upon its colour. One candle power of daylight has more than ten times the photographic effect of one candle power of light from a spermaceti candle. As most plates are exposed to daylight, it might be assumed that this should be the standard adopted; but the practical difficulties of ensuring a constant illumination of constant spectral composition are insuperable. The standard candle is notably poor in ultra-violet, violet, and blue radiations, being distinctly yellow in colour. The same objection applies to the Hefner-Alteneck amyl acetate lamp, which was used in Germany as standard.

It is impossible to examine in detail all light sources suggested, but it has now been agreed to use a lamp standardized to work at a colour temperature of $2,360^{\circ}$ K with colour filters to reduce its spectral composition to the equivalent of sunlight.

The spectral composition of the light is all important in view of the ever-increasing employment of colour-sensitive materials.

As was shown originally by Abney, an intermittent exposure does not give the same effect as a continuous exposure for the same total time. The use of a rapidly rotating sector is, therefore, undesirable, and instruments giving continuous exposures should be used.

Another important factor is the failure of the reciprocity law, $E=It$. As was first shown by Abney (*Proc. Royal Soc.*, 54, pp. 143-147, 1894), the effect of an exposure is not independent of

FIG. 12. — GRAPH SHOWING RELATION BETWEEN DENSITY AND INTENSITY, It BEING CONSTANT

the intensity. Recent work has shown that the curve showing the relation between density and intensity, It being constant, has a maximum, this point being referred to as the "optimum" intensity. (See fig. 12.) The shape of the curve as well as its absolute values vary with the type of the emulsion and also with the wave-length of the light that is used. The work of Jones, Hall and Webb has shown the great importance of the reciprocity law in sensitometric work.

It is therefore desirable that exposures in sensitometric instruments should not only be continuous but of the intensity level likely to be used in practice.

The original photometer with two light sources used by Hurter and Driffield has been superseded by various optical instruments for measuring the densities, and these in turn appear likely to be superseded by physical photometers, such as those employing photo-electric cells. The density obtained depends on whether

FIG. 13. — CHANGE OF DENSITY AND GAMMA WITH TIME OF DEVELOPMENT

it is read in contact with a diffusing screen, such as opal glass, or whether it is observed by parallel light from a collimator. With the latter, as was pointed out by Abney, Chapman Jones, and Callier, much of the incident light is scattered, so that the density has a higher value than when measured by completely

diffused light. The ratio between $\frac{\text{density of parallel light}}{\text{density of diffused light}}$ was

termed Q by Callier; it varied in amount from approximately unity to values as high as 1.6. The value of Q for average negatives is about 1.4.

Recently graduated wedges of neutral tint have been used very largely in sensitometry both for exposing and for the measurement of densities.

A point of considerable importance in speed determination is that of the fog inherent in the emulsion and developed without light action. Hurter and Driffield assumed that this was constant throughout all densities, or, in other words, through all exposure periods; but such is not the case, there being actually more fog in the underexposed parts than in the more exposed parts, because there is less silver bromide available and also more bromide set free here than in the less exposed parts.

Returning to fig. 11, it will be observed that the tangent of the angle at which the straight line meets the exposure axis is marked a . This angle is of great importance in photography, since it defines the contrast of the image. The tangent of the angle, that is, the slope of the straight line, was termed γ by Hurter and Driffield and was called the "development" factor, since its value depends upon the time of development. During development, the value of γ increases, the increase tending to reach a limiting term, gamma infinity (γ_{∞}), which measures the extreme contrast of which a plate is capable. Thus, if we develop for different times plates which have been given a series of exposures increasing in geometrical proportion, measure the densities, and plot the resulting curves, we shall get the result shown in fig. 13, in which are shown curves corresponding to development times of 1 min., 2 min., 3 min., 5 min., and 6 min., while T_{∞} corresponds to the maximum development that can be given before the contrast diminishes owing to fog.

If now we plot γ or density as a function of time, we get a curve of the type shown in fig. 14. It will be seen that the value of γ increases rapidly at first and then more slowly, finally reaching a limit γ_{∞} . This is an exponential curve, the rate of development

being proportional to the amount of exposed halide remaining to be developed, so that the reaction is identical in form with that of a chemical reaction of the first order. The velocity of the reaction of development depends therefore upon the value of $\gamma\infty$ which is a property chiefly of the sensitive material although also, to a minor extent, of the developing solution, and of K , the velocity constant of development, which is dependent upon the composition and temperature of the developer.

When bromide is present in a developer, the straight-line portions of the characteristic curve when produced do not meet upon

FIG. 14.— γ T CURVE, SHOWING GROWTH OF γ WITH INCREASING TIME OF DEVELOPMENT

the exposure axis but at a point somewhat below it, the effect of bromide being equivalent to a constant depression of density in the straight line portion of the curve. (See fig. 15.)

The photographic characteristics of printing papers can be measured by a procedure similar to that used for negative materials, but in this case it is not the mass of reduced silver which is of chief importance but its relative reflecting power. The reflection density is thus the logarithm of the reciprocal of the reflecting power ($D = \log_{10} 1/R$), the reflecting power being measured with illumination at 45° to the plane of the paper. The characteristic curves obtained with different times of development are shown in fig. 16, and it will be seen that the effect of increase in time of development is to produce a regression of the inertia without change in γ except in the very earliest stages, where the curves are usually of a distorted form. The following constants may be derived:—

Constant	Symbol	Significance
(a) Maximum (reflection density)	D_{max}	Highest attainable density.
(b) Contrast element (reflection density)	$\frac{dD}{d \log_e I}$	Differential.
(c) Gamma element (reflection density)	γr	Value of (b) for straight-line portion, or at inflexion-point.
(d) Latitude element (reflection density)	L	Range of intensities reproduced on straight-line portion.
(e) Rendering power (reflection density)	R	$\frac{10L}{S}$
(f) Total scale (reflection density)	S	Range of intensities reproducible by density differences.
(g) Standard exposure (reflection density)	E_s	The exposure in m.c.s. necessary to print through a negative density of 2.0.

Tone Reproduction. — When a photograph of a natural object is made, the form can be represented only by differences in brightness. The accuracy with which the form is represented depends upon the precision with which the tones of the original subject are

reproduced, and this question, generally known as the *theory of tone reproduction*, is fundamental to every photographic application.

Psychologically, it is the apparent brightness which is of importance, but this can conveniently be treated as the physical brightness modified and interpreted by the eye and brain, and since it can be shown that the apparent brightness is proportional

FIG. 15.—BROMIDE DEPRESSION CURVE. BROMIDE IN THE DEVELOPER CAUSES A DEPRESSION OF THE CONVERGENCE POINT

to the physical brightness throughout a wide range, it is generally sufficient for tone reproduction in photography to deal with the physical tones in the original and the reproduction.

The differences in brightness which occur in nature may be produced by differences either in the reflecting power of the different portions of the subject or by differences in the illumination. Since in natural scenes both the reflecting power and the illumination vary, some parts of a landscape consisting of clouds in sunlight and others of dark rocks in the shade, the range of contrast is often very considerable. For photographic purposes a scale or contrast of 1 to 4, in which the brightest thing is only four times as bright as the darkest, is very low, and such a subject would be called flat; a contrast of 1 to 10 is a medium soft contrast; 1 to

FIG. 16.—CHARACTERISTIC CURVE OF PAPERS WITH INCREASING TIMES OF DEVELOPMENT. INCREASING TIME OF DEVELOPMENT PRODUCES REGRESSION OF INERTIA WITHOUT AFFECTING γ EXCEPT DURING INDUCTION PERIOD

20, a strong contrast; 1 to 40, very strong; and 1 to 100, an extreme degree of contrast. All these degrees of contrast occur in subjects such as landscapes, street, and seashore scenes.

When a photograph is made, the operation is done in two separate steps. A negative is first made, in which all the tones of the original are inverted, the brightest part of the subject being represented by the deposit of silver in the negative which lets through the least amount of light, and the darker parts represented by the transparent areas; this negative is then printed upon a sensitive paper to form a print in which the scale of tones is again reversed.

In order to study the relation of the tones of the print to those of the original subject, the changes of those tones must be followed through both steps. In the making of the negative, the reproduction of tone will depend upon the characteristic curve of the photographic material shown in fig. 11.

If the exposure is so arranged that all the tones of the original subject fall on the straight-line portion of this curve, the inverse reproduction in the negative will be proportional, and if, in addition to this, development is so arranged that the negative has a γ , that is, slope of the straight line, of unity, then the reproduction will be correct. In the print it is necessary that γ should also be unity or, if the γ of the printing material is not unity, it is necessary that the γ of the negative should be modified suitably, so that γ_{neg} multiplied by $\gamma_{\text{pos}} = 1$.

As is seen by reference to fig. 16, the straight-line portion of a paper curve is usually short, and it is necessary, moreover, in printing to utilize at least the underexposed portion of the paper curve. In making a paper print, therefore, the tone values are always distorted to some extent, especially those in the highlights corresponding to the underexposed portion of the paper curve, only the portion of the picture falling on the straight-line portion of the characteristic curve of the paper being correctly rendered.

The computation of the tone reproduction given in any photographic operation is of great importance, especially in the applications of photography, such as processes of colour photography or of the reproduction of sound; and for the methods which are used, the papers by F. F. Renwick and L. A. Jones should be consulted.

Resolving Power.—The resolving power of photographic materials may be defined as the closeness of two adjacent images which can be just distinguished. It is limited primarily by what is termed the irradiation or spreading of the image due to diffusion of the light in the film. This spreading of the image has been investigated by astronomers and used as a basis for a method of stellar photometry. (See PHOTOMETRY, CELESTIAL and PHOTOGRAPHY, CELESTIAL.)

In addition to the irradiation factor, the resolving power depends upon the development factor attainable in the material. The sharpness of an image, in fact, is theoretically equal to the development factor divided by the turbidity factor. Both of these factors are functions of the wavelength of the light used in exposure, so that the resolving power is naturally dependent upon the colour of the light. In addition to these two factors, a psychological factor enters into the resolution of the image.

The practical resolving power of photographic materials can be measured by photographing (see fig. 17) and measuring the extent to which the lines are resolved.

Photographic images on development show with low power magnification, as used in projection and enlarging, a granulation which is objectionable in such operations. L. A. Jones and N. Deisch have shown that it may be measured and numerically expressed on the assumption that the graininess is directly proportional to the distance at which it becomes just visually imperceptible, this being compared with the distance at which a structure of known period, e.g., a fine cross-line screen, just disappears. Suppose a screen of 2,000 lines to the inch to be equivalent in this way to a given granularity of the developed image; the latter may be said to have a graininess of 2,000.

The Photography of Coloured Objects.—Since photography makes a black and white reproduction of the tones of natural objects, all of which are to some extent coloured, the way in

which different colours are reproduced in photography is of considerable importance. The earlier photographic materials were sensitive only to violet and ultra-violet light, and if an object containing blues, greens, and reds was photographed, the greens and reds were rendered dark while the blues were rendered much lighter than they appeared to the eye.

Following Vogel's discovery of the sensitizing power of dyes, this inaccuracy in rendering was to some extent mitigated by the introduction of so-called "orthochromatic" materials which, however, were sensitive only to the yellow-green in addition to their normal blue-violet and ultra-violet sensitiveness and were therefore unable to render the full scale of colours as seen by the eye.

After the production of the isocyanine and carbocyanine sensitizers, *panchromatic* plates were introduced, sensitive to the whole visible spectrum. These plates still retain the high sensitiveness to blue, violet, and ultra-violet characteristic of photographic materials generally, but by the use of light filters (*q.v.*) with them, it is possible to obtain an *orthochromatic* rendering; that is, one in which the reproduction of the different colours follows very closely their relative brightness as they appear to the eye. This is accomplished by the use of a yellow filter which absorbs all of the ultra-violet and most of the blue-violet, reducing the effective sensitivity of the material approximately to that of the eye.

By the use of yellow filters, therefore, and panchromatic plates and films, approximately correct colour rendering is now used very largely in practical photography. Sometimes, however, subjects have to be photographed which are visible to the eye by virtue of their colour contrast. Suppose we have two objects, one contiguous to the other and separated purely by their colour contrast, such as, for instance, a yellow straw stack against a deep blue sky. In this case, orthochromatic rendering would produce a photograph in which both would have the same intensity, and they would be indistinguishable. It is necessary in this case to use a colour filter which will introduce a certain amount of incorrect rendering in order to reproduce the colour contrast. This filter may, for instance, be a red filter, in which case the straw stack will appear brighter than the sky or, it may be a blue filter, in which the sky will appear brighter than the stack. The choice of such filters is an important task for the skilled photographer. Contrast filters are used very largely in photography for special purposes. They are of great value in photomicrography and are used in commercial photography to a large extent. The deepest possible filter is also used in aerial photography in order to take advantage of the power of the longer wave-lengths to penetrate haze. (C. E. K. M.)

PHOTOGRAPHIC MANUFACTURE

The manufacture of photographic sensitive materials is a very specialised industry. Approximately 40,000 people are employed in the whole photographic industry throughout the world, about 20,000 being engaged in the manufacture of materials sensitive to light, with which this section deals, and the remainder in the manufacture of cameras and in the wholesale distribution of the products to the retailer.

With the introduction of the gelatine dry plate, the preparation of materials by photographers for themselves diminished very rapidly, and the manufacture of ready-prepared material took its place. The first dry plates appear to have been placed upon the English market in 1877. In 1880 the manufacture of gelatine dry plates was general in England and was commencing in Belgium, Germany, France, and the United States.

Until 1900 the photographic industry was usually carried on in small factories under the direct personal control of the founder. At the present time, however, photographic manufacture is organized chiefly in modern factories manufacturing on a large scale, and using specially designed machinery at every step of the process. In the largest of these factories, the output of motion-picture film alone exceeds 150,000 miles yearly. Over 5,000,000 lb. of cotton are used each year for the manufacture of film, and over three tons of pure silver bullion are used each week. The total power required exceeds 20,000 h.p., and the consumption of coal is over 500 tons a day.

The process of manufacture may be divided into three distinct

FIG. 17.—FAN TEST OBJECT, USED FOR MEASURING THE RESOLVING POWER OF PHOTOGRAPHIC MATERIALS

sections: (1) The preparation of the base; (2) the preparation of the emulsion; (3) the coating of the emulsion on the base and the cutting and packing of the material so prepared.

Preparation of the Base. Glass Plates.—Photographic glass is the specially selected, best quality of thin sheet glass made in a factory which prepares sheet glass for all purposes. Even under the best conditions, only about a quarter of the sheets made are fit for photographic use, the remainder being used for glazing. Photographic glass is made very largely in Belgium in the factories near Charleroi, and in England at St. Helens. A considerable amount is also made in the United States. The glass is supplied cut to sizes which are multiples of those used by photographers. The glass arrives packed in straw in boxes holding usually about two gross sheets, and after unpacking and preliminary inspection, is cleaned by an automatic machine into which it is fed. The glass plate is received between rollers and passes through a strong solution of soda between revolving brushes which remove the dirt from the surface, and at the end of the machine is coated with a substratum, usually a weak solution of gelatine containing chrome alum, by means of which the emulsion is made to adhere to the glass. The glass is then dried in a heated oven, examined for defects, and if passed is packed in a tray and transferred to the coating room.

Film Base.—In the manufacture of film base the first step is the preparation of cotton linters for nitrating, the treatment consisting of cleansing the linters very thoroughly and drying them. They are then nitrated in centrifugal machines, and when they have absorbed the necessary amount of nitrogen, 12 to 13%, the resulting nitro-cotton is soused in water and the washing commenced. This washing is a long process, and is continued until the material is entirely free from absorbed acid, after which it is dehydrated, the water being then displaced by alcohol. The dehydrated nitro-cotton is then dissolved in tumbling barrels or mixers in suitable solvents, those commonly employed being acetone and methyl alcohol, and at the same time the so-called softeners, such as camphor, are added, these resulting in a flexible film. The viscous nitro-cotton solution, which appears rather like honey, is known in the United States as dope. This is now spread out into a thin film by coating it on a travelling surface. In the United States the coating is generally done on large wheels about four feet across and about fifteen feet in diameter which rotate slowly about their axes so that by the time one rotation is completed the solvents have been evaporated sufficiently to set the film, which can be stripped off the wheel, and dried further by passing over drums. The operation is thus continuous, the film base, as it is called, being prepared in rolls of about 2,000 feet. In Europe it is customary to coat a film about 24 inches wide upon a metallic belt from which after one rotation the film can be stripped in the same way as from a drum. The surfaces of these belts and drums must necessarily be prepared very carefully, the wheels being usually made with a highly polished nickel surface, while the makers of the belt machines recommend that they be coated with gelatine. The film has a high polish on both surfaces and may be used at once or stored or seasoned until required. Before coating with emulsion, one side is treated with a substratum, which is really an etching solution that slightly roughens it, and gives a tooth that holds the emulsion firmly. For camera film, the back is coated with a non-curling coat of hardened gelatine, which, imposing an expansion strain on this side, equalizes that of the emulsion on the other. Camera or roll film base is about $3\frac{1}{4}$ thousandths of an inch thick; motion picture film, about $5\frac{1}{2}$ thousandths; and cut film, such as portrait and X-ray, which are used flat, about $7\frac{1}{2}$ thousandths. Still thicker cut films are sometimes used, about 10 thousandths, but the celluloid for these is cast into blocks and then sliced, the knife marks being removed by heat polishing.

Since cellulose nitrate is highly inflammable, itself supplying the greater part of the oxygen which it requires for combustion, much work has been done on the preparation of film which is not inflammable. The most promising substance for this purpose is cellulose acetate, prepared by treating hydrated cellulose with acetic acid and acetic anhydride in the presence of a suitable cata-

lyst. Acetate film burns with about as much difficulty as thick paper, and should it catch fire it is very easy to extinguish. This acetate base is used under all conditions where proper precautions against fire cannot be taken, as where films are used in homes or schools. Sixteen millimetre film for amateur cinematography is made only on acetate base.

Photographic paper base is generally made by mills which specialise in its manufacture, but in the United States the bulk of the photographic paper base is made in the factory where the rest of the production of photographic paper is carried on. The paper is prepared very largely from rag stock, although refined cellulose from wood is sometimes added. After inspection the raw rag stock is washed and digested and is then treated in the beater until it will make a homogeneous, strong sheet. Great care is necessary to exclude traces of impurities and especially of metals such as copper and iron from the paper stock. The composition differs with the purpose for which the paper is used. The finest kinds are prepared from linen rags, which are bleached with gaseous chlorine or hypochlorites, any excess being removed by treatment with sulphites or thiosulphates which are then washed out. Any residual trace of colour is neutralized by the careful addition of a complementary colour, such as indanthrene blue, or if a chamois or toned base is desired the bleaching may be omitted or indanthrene yellow added. A resinous soap is usually incorporated with the fibres and precipitated with alum, and the paper may be later subjected to a sizing with gelatine. Throughout all its treatment great care must be exercised to avoid the occurrence of metallic particles, which would act prejudicially on the sensitive emulsion. The paper is generally cast about 41 in. in width and from 500 to 1,000 yd. in length. It is calendered either to give it a closer texture or higher surface or to impart some special linen or fabric-simulating finish.

The paper is usually given a coating of baryta before it receives the photographic emulsion. In this process a suspension of baryta (barium sulphate) in gelatine is coated over the surface of the paper, several coatings being sometimes applied, and not infrequently the paper is calendered after baryta coating in order to get a perfectly smooth glossy surface. Baryta-coated paper is transferred to the emulsion coating-room in rolls of about 2,000 feet.

Emulsions.—Emulsions are of two general types: washed and unwashed. Emulsions to be coated on glass or film are always washed. In the first case the precipitation of the silver salts is effected by adding a solution (about 10% in strength) of silver nitrate to a small quantity of gelatine dissolved in a solution of the halide salts which, in the case of negative emulsions, are usually potassium bromide containing a small proportion of potassium iodide. When precipitation is complete, the emulsion is digested in order to produce an increase of sensitiveness, and the bulk of the gelatine is added so that when cooled it will set to a jelly. Instead of increasing the sensitiveness of the emulsion by holding it at a high temperature for some time, it may be digested at a lower temperature in the presence of ammonia, and not infrequently the silver nitrate is precipitated with ammonia and then re-dissolved in excess before the precipitation of the halide is commenced. The set emulsion is cut up into small portions and is washed in running water in order to remove any excess of halide salts and also the soluble nitrate produced in the reaction. After washing it is given a final digestion and is ready for coating upon the base.

The emulsions used for printing papers are of three general types: bromide papers, which are made with a washed emulsion essentially identical with that used for coating upon glass and film for use in making lantern slides and positive motion pictures; unwashed chloride emulsions in which the emulsion is coated on the paper in the form in which it is mixed without any removal of the soluble salts by washing; and emulsions also made without washing but in which the silver salts are a mixture of chloride and citrate, and in which there is free silver nitrate present. These papers darken visibly when exposed to light and thus give a printed-out image which is then toned and fixed.

Coating and Packing.—Dry plates are coated by passing the

prepared glass sheets on a travelling belt under some device through which the emulsion is allowed to spread out over the surface of the glass. This may take the form, for instance, of a trough with a slit in the bottom or of a stepped weir down which the emulsion flows, reaching the plate by means of a flap which rests lightly on the surface of the plate. The coated glass travel forward on to a belt or rollers which are kept wet with ice-cold water, and there the emulsion sets. At the other end of the machine the plates are taken off, placed on the racks, and dried slowly and evenly. They are then cut to the requisite sizes by means of machines using diamonds and are packed in boxes of one dozen for supply to the market.

The most usual size of plates are $2\frac{1}{2}'' \times 3\frac{1}{2}''$, $4'' \times 5''$, $5'' \times 7''$, $8'' \times 10''$, $11'' \times 14''$, and $14'' \times 17''$, in the United States; $4\frac{1}{4}'' \times 3\frac{1}{4}''$ ("quarter plate"), $6\frac{1}{2}'' \times 4\frac{3}{4}''$ ("half plate"), $8\frac{1}{2}'' \times 6\frac{1}{2}''$ ("whole plate"), $12'' \times 10''$, and $15'' \times 12''$, in Great Britain (where the larger dimension is given first for inch sizes, the contrary practice being used in the United States); and 6×9 cm., 9×12 cm., 10×15 cm., 13×18 cm., 18×24 cm., 24×30 cm., and 30×40 cm., in countries using the metric system.

For coating both film and paper the same type of machine may be used. (See Plate II., fig. 1.) The stock roll of the base is carried on a mandrel, freely revolving, and is led over and under rollers that keep it taut, to the coating trough into which the fluid emulsion is fed continuously and automatically at the rate at which the base takes it up. The base passes under a roller, dipping into the emulsion, and it hugs this so tightly that no emulsion finds its way on to the back. The temperature and viscosity of the emulsion are kept constant, and the thickness of the coat is determined by the rate of travel of the base through the emulsion—the faster the travel, the thicker the coat, and vice versa. The coated base then passes up a vertical run-up, which allows the film of emulsion to even itself out, or it passes over a chill roll and then through a refrigerating chamber, where cold air is blown on to the emulsion surface and thoroughly sets it. Leaving this chamber, the film is automatically looped into festoons varying from five to twenty feet in length and travels slowly through the drying tunnels. To these is supplied heated air which has been thoroughly washed with water sprays to remove all dust and deleterious gases. The humidity and temperature of the air used for drying is adjusted very carefully and it is usually recirculated through the system, being driven in at one end of the drying room and exhausted at the other, and then reconditioned before entering the drying chamber again. Frequently the festooning apparatus makes a right-angled turn so that the prepared material is reeled up side by side with the coating machine; the operations of coating, drying, and reeling are continuous and automatic.

Motion picture film is slit from the original roll to the exact width required, 35 mm. ($1\frac{3}{8}$ in.) in the case of standard film, and before packing is perforated on the edges in accordance with the standard gauge used for the cameras and projection machines. The maker's name and private mark are light impressed on the margins, becoming visible only on subsequent development, while on negative film every foot is numbered in order to aid in the identification of the scenes. Negative film is supplied not only coated with ordinary emulsion, but also panchromatized, which gives far better rendering of all colours and permits considerable shortening of exposures, especially under the artificial illuminants, such as the Mazda and other lighting systems now so much in vogue in the studios. The speed of the emulsion is very high and a special hypersensitized film is obtainable, which places in the hands of an operator the possibility of photographing poorly lighted subjects. Positive film is supplied either on nitrate base, that used most generally, or on acetate safety base, which is slow-burning. For amateur motion picture photography film is supplied 16 mm. in width on slow-burning acetate base only and is supplied in lengths of 100 ft. packed with paper leaders at the ends and on a special protective spool so that the cameras can be loaded in daylight. This film is made to be reversed directly to a positive so that the same film that is used in the camera is employed for projection.

The camera or cartridge film is slit to the required widths, cut

to the desired lengths, and spooled on wooden cores with light-excluding metal flanges. A light-protecting apron of black paper is wound with the film, so that the cartridge may be inserted in the camera in daylight; or red paper with an inset of carbon paper is used instead of the black, so that records may be made on the film after exposure. Film is also cut into sheets, to each sheet being attached a numbered tab, and the sheets are assembled into a film-pack, which is usable in any ordinary plate camera. After each exposure, the tab is pulled, which draws the exposed film to the back of the pack, and the tab is torn off and thrown away.

For X-ray work, the film is coated on both sides with emulsion; this gives greater contrast and better rendering of shadow detail, for the rays can penetrate both emulsion layers with but little loss of action. The film is used in holders like those for plates, except for dental work. Films for this purpose are packed in special flexible, light-tight holders ready for use.

Paper is cut from the roll into sheets, and the sheets stacked on the top of each other are cut by means of guillotines to the size required for the market, each sheet being inspected for defects before packing. (G. EA.)

COLOUR PHOTOGRAPHY

In 1810 J. T. Seebeck obtained a coloured effect by exposing to the spectrum silver chloride which had been darkened by exposure to light. This experiment has often been repeated, but as the colours obtained cannot be fixed, it has no practical value.

In 1891 G. Lippmann of Paris produced the first picture by interference heliochromy, although the possibility of doing so had been pointed out by W. Zenker in 1868, Lord Rayleigh in 1887, and O. Wiener in 1890. In this method a perfectly transparent, grainless emulsion is coated on plate glass and exposed through the back with the sensitive surface in contact with a reflecting surface, such as mercury. The incident light is reflected back on itself, giving rise to interference, thus setting up stationary or standing waves in the emulsion with their crests or loops exactly half a wave-length apart. These standing waves produce exposure effects so that on development, the silver is deposited in laminae half a wave-length apart and reflects light of double the separation, giving bright colours. Unfortunately the plates are very insensitive, and as the results can be viewed only in the hand or by projection with a special outfit, the method is not in general use.

Tricolour Photography. — The methods which are used at the present time for reproducing objects in colours by photography are dependent upon the suggestion made by Clerk Maxwell in 1861. Any colour may be reproduced by a mixture of the three primary colours, red, green, and violet. In order to reproduce any colour, therefore, we may analyze the different proportions of these three primary colours in it and then synthesize the colour by superimposing the three primaries upon a screen in projection. To illustrate this, Maxwell took three photographs of a coloured ribbon: one through a red solution, one through a green solution, and a third through a blue solution. From these three negatives, three transparencies were made, each of which was projected by means of the coloured light by which it was taken, Maxwell adding a fourth picture taken and projected by yellow light.

In 1869 Ducos du Hauron published a small book on colour photography, in which he laid down the principles of three-colour photography, on which all later work has been based, and at approximately the same time Charles Cros published an article in which he had independently come to much the same results. Du Hauron's book is astonishingly complete and contains a very clear account of the two fundamental processes of colour photography including their application by different methods. These processes are known as the "additive" (that employed by Maxwell) and the "subtractive" processes.

The practical development of colour photography was, however, delayed for many years by the difficulty that the photographic materials available were sensitive only to the blue and violet of the spectrum; it was with the greatest difficulty that materials sensitive to the whole visible spectrum could be obtained, and with such materials very long exposures were required.

AERIAL COLOUR PHOTOGRAPHY

First adopted for general service use by the U.S. armed forces in World War II, the film (Kodacolor Aero) used in taking the pictures on this page revolutionized aerial reconnaissance photography. At the upper left is a colour photograph which shows the shallow and deep parts of water along a shore line. The ribbonlike formations are sand bars. At the upper

right is a rainbow photographed at low altitude. Below, part of a city photographed from an altitude of 15,500 ft. Special filters counteract the haze. This colour film was processed in navy laboratories without the necessity of using special equipment

Colour photograph of a golf course taken from a U.S. navy plane at a shutter speed of $1/150$ sec., with an $f.8$ diaphragm opening. A navy type

F-56 (Fairchild) camera was used, having a focal length of $8\frac{1}{4}$ " and a plate size of $6\frac{5}{8}$ " x 7"

The introduction of colour sensitizing by Vogel in 1873 first made colour photography possible, and the introduction of the isocyanine and carbocyanine sensitizers at the beginning of the 20th century made it practical.

The Additive Process.—Clerk Maxwell's picture was projected on to a screen by means of optical lanterns and was thus the so-called "additive" process; that is to say, the colours were formed by adding light to light. This method was also used by du Hauron and Cros in a special instrument called a chromoscope, in which the three pictures were viewed in superposition, a plan later used and developed by F. E. Ives also.

F. E. Ives developed the additive process in practice. He took photographs through three dyed gelatine filters upon materials sensitised with the best dyes available at that time and projected the transparencies by means of triple lanterns devised for the purpose, these synthetic colour pictures giving extremely good colour reproduction upon the screen.

The production of the negatives can be accomplished by three different methods. For stationary objects where an interval between the exposures is of small importance, it is convenient to fit the filters and sensitive plates into a sliding back attached to an ordinary camera. Exposures are then made through the three filters in succession either upon a single panchromatic plate or on three separate plates.

For the photography of moving objects, it is, of course, impossible to use successive exposures, and a great number of cameras embodying beam splitting methods either by means of prisms or by reflectors have been designed. The chromoscope already referred to as a "viewing" instrument can be converted into a camera in which mirrors are used for separating the three beams. Other cameras use elaborate combinations of prisms for the same purpose. In such cameras it is often convenient to use separate plates, since it is rather difficult to arrange for the three images to fall upon a single surface.

A system invented originally by du Hauron is to have the sensitive surfaces superposed on each other and to build up a plate or film pack; thus, in front, there may be placed a slow, very transparent yellow-dyed, blue-sensitive film; behind this, a moderately transparent film sensitive to green and dyed red or with a red filter attached to it; behind this again, a red-sensitive film. In this way, the blue record is made on the first film, the green record on the second, and the red on the third. A considerable number of patents have been taken out for variants of this method.

The Subtractive Process.—The subtractive process, which was described originally by du Hauron, depends upon the production of colours by subtractive absorption instead of by the addition of the colours to each other in projection. Suppose that over a sheet of yellow gelatine, which will absorb the blue light, is put a sheet of magenta gelatine, which will absorb the green light; then, since the yellow absorbs the blue light, and the magenta the green light, only the red light is transmitted; a red image can thus be obtained either by projecting it through a red filter or by putting a magenta image on the top of a yellow one. In the same way a green image can be obtained by putting a blue-green one on the top of a yellow one, when the yellow will cut the blue out of the blue-green and leave only green.

In working the subtractive process, the three negatives are printed in coloured dyes, the picture taken through the red filter being printed on gelatine dyed blue-green, the one taken through the green filter on gelatine dyed magenta, and the one taken through the blue filter on gelatine that was dyed yellow. Now, if the three are cemented together in register, the resulting transparent colour picture will reproduce the colours of the original subject and will be a transparency which can be viewed in the hand, or examined in front of an artificial light, or projected in a lantern.

Printing Methods.—Subtractive methods have naturally attracted the most attention for giving prints on paper.

The carbon process was used by du Hauron, the negatives being printed upon carbon tissue containing a pigment of colour complementary to that of the filter. After development, the three

images are transferred to a temporary support, and then re-transferred to a permanent support in accurate register. This method gives excellent results but requires considerable skill.

Very good results have also been obtained by the use of a process in which gelatine containing transparent dye was coated on thin film base. After sensitising with bichromate, this can be printed through the back and developed with hot water, so that a coloured relief image is obtained on the film. The three images can then be transferred in superposition on to a paper support without the use of double transfer.

A modification of the carbon process, suggested by T. Manly under the name of "Ozobrome" and later revived by H. F. Farmer as the "Carbro" process, is also used for colour work. In this a silver image is squeezed into contact with pigmented gelatine saturated with bleaching solutions whose reduction products harden gelatine. These chemicals migrate into the silver image film, and the reduction products return to the tissue, rendering it insoluble in ratio to the amount of metallic silver present in the image. The tissue is then treated exactly as in the carbon process. Bromoil transfers are also used by some artistic workers.

In addition to these processes, colour images have been made by using for dyes the mordanting power of chemical compounds and especially the ferrocyanides of the metals. The ferrocyanides of uranium, copper, vanadium, and silver, and the iodide or sulphocyanide of silver mordant basic dyes very strongly. From the negatives silver images are therefore prepared and transformed into these compounds. The blue image is commonly composed of iron ferrocyanide itself, this being a very suitable shade of blue for colour work. Yellow and red images are obtained by mordanting basic dyes, such as auramine and safranin, on to transparent deposits of metallic compounds. The three images are then superposed as usual.

In one group of processes the dye images themselves are transferred from the printing plates, which are formed of colourless reliefs, these being stained up and then placed in contact with gelatine so that the dye migrates and forms an image in the gelatine. Such processes are known as "imbibition" processes. The transfer plates may be made in several ways: thus, bichromated gelatine on film may be exposed through the back and developed with hot water, or a silver image produced by exposure through the back of an ordinary emulsion coated film may be caused to harden the gelatine either during development, since some developers harden the gelatine contiguous to the image, or by treatment with a bath similar to that used in the ozobrome process already referred to. After treatment, a relief can be obtained by washing off the unhardened gelatine with hot water, and after removal of the silver a colourless relief is obtained. In a process known as the "Pinatype" process, bichromated gelatine is exposed under a positive and is then treated with dye which penetrates only the soft gelatine, the hard gelatine remaining uncoloured. This dye can then be transferred by imbibition to a layer of soft gelatine coated on paper, and the three images can be transferred in turn to produce a colour picture.

In a modification of this, used in motion picture colour photography, the local hardening is produced not by the light exposure of a bichromated surface but by the formation of a silver image and its treatment with a bleach bath which hardens the gelatine in contact with the developed silver.

There are numerous modifications of these printing processes all of which can be employed with more or less success but all of which require a considerable amount of skill if really good results are to be obtained.

The largest field for the subtractive process of colour photography is in connection with the use of the printing press. The three negatives are used for the production of printing plates, usually by the half-tone process, and prints from the three plates, frequently with a fourth black plate added, are superimposed, the plates being printed in red, blue, and yellow inks which are approximately complementary to the colour of the taking filters. This three or four colour half-tone process is very widely used for the preparation of illustrations and is by far the greatest application of colour photography. (See PHOTO-ENGRAVING.)

Screen Plate Processes.—In his book, Ducos du Hauron suggested a modification of the additive process which has since become of practical importance and is known as the "screen plate" process. He suggested that the surface of the glass plate or film might be covered with tiny filters—red, green, and blue—the sensitive emulsion being coated on top of these and photographed through the filters.

A modification of this method was suggested by J. Joly of Dublin and by J. W. MacDonough of Chicago in 1892; the colour elements were on a glass plate which was pressed during exposure into close contact with a separate panchromatic plate after development of the negative; a positive in silver was made in the usual way and viewed in contact with a special viewing screen, in which the colours approximate those required by theory. This method is employed in the Finlay process much used in recent years, particularly for work in the studio and in the field for making colour originals from which three-colour printing plates can be made. Any number of duplicate colour transparencies can be made from one original negative.

In 1907 Messrs. Lumière and Co., of Lyons, brought out their "Autochrome" plates in which they utilized an irregular screen composed of coloured grains. Glass plates are coated with an adhesive medium over which there is spread a mixture of starch grains, of microscopic fineness, stained violet, green, and orange, the interstices being filled in with fine carbon powder, to form a tri-colour screen, dark by reflected, and of a pinkish, pearly appearance by transmitted, light. This is varnished and coated with a thin panchromatic emulsion of gelatino-silver bromide. The plates are exposed in the camera from the back, through the tri-colour films, a special compensating orange-yellow screen being used also before or behind the lens. They are then developed as usual, producing a negative coloured image in the complementary colours, which is then reversed so as to produce a positive coloured image showing the picture in its proper colours. The results thus obtained are remarkably good and practically solve the problem of direct colour photography in a simple and fairly inexpensive manner, the results being of course confined to transparencies.

In recent years other screen plate processes of this type have been introduced. They include the Agfacolor plates and film, in which stained resin grains are used instead of the starch grains of the Autochrome process. In Dufaycolor, the emulsion is coated on a screen ruled on the glass or film support to give a regular pattern.

Screen plates are conveniently studied under the following heads:—

- I. Method of production of the screen.
- II. Examination of the screen as a whole.
- III. Examination of the filter units.
- IV. Examination of the emulsion.
- V. Adjustment of the compensator and emulsion to the filters.

I. The screen may be either regular or irregular. The methods of production may be classified as follows:

- (1). Ruled lines. Method used by Joly and MacDonough.
- (2). Dusting-on methods. Employed to produce irregular screens in the Autochrome, Agfa, and Lignose processes.
- (3). Printing by means of dichromated colloids. These are used in the Warner-Powrie, Finlay and Duplex processes.
- (4). Various methods of section cutting. The best known example is the Krayn screen introduced in Germany in 1907 and taken off the market shortly afterwards.
- (5). The use of mechanical printing or a combination of mechanical printing and dyeing. The Omnicolor and the Lumière regular screens, neither of which was marketed commercially, were made in this way, as is the Dufaycolor screen now in use.
- (6). Other processes. A variety of patents have been taken out for experimental screens which must be classed under this heading.

II. The screen as a whole when examined should appear to be of a neutral shade. This is known as the "first black condition." The adjustment is obtained by alteration of the area of the units as far as possible rather than by adjustment of the depth of

colour. The total visual absorption should be as low as possible.

III. The separate filter units should have the purest possible colours, preferably without overlap in the spectrum. The best possible compromise is for a red filter transmitting from λ 590 upwards; a green filter from λ 590–490; and a blue filter from λ 500 down to the violet. The size of the screen units is determined by their invisibility. In order to get bright colours, however, it is necessary that they should not be too small, since otherwise the emulsion will not have sufficient resolving power, and the images behind the units will overlap. For regular screens the units should not be larger than $\frac{1}{800}$ nor smaller than $\frac{1}{750}$ of an inch. For irregular screens it is necessary that the units should not be larger than one-third the dimension of regular screens, since the average unit will tend to be a clump of about 10 grains; that is, having approximately three times the diameter of the single unit.

IV. The emulsion should be sensitive to the whole visible spectrum and of a resolving power depending on the size of the units. In the case of the small units of irregular grains, its resolving power must necessarily be high, so that the emulsion must be slow and fine grained. It must also be coated in very close contact with the screen, since otherwise the scattering of the light in the intervening space will affect the colour.

V. The emulsion should be so sensitized that the effects produced under the red and green filters are equal if possible. The compensating filter used on the lens can then be adjusted to the emulsion and to the filter units, so that the "second black condition" is fulfilled; that is, a scale of greys is rendered as grey after exposure, development, and reversal.

The effective speed of a screen plate is governed by three factors: (1) The sensitiveness of the emulsion; (2) the multiplying factor of the screen; (3) the multiplying factor of the compensator. The effective speed of the screen plates on the market is lower than that of normal negative materials, although at the present time they are fast enough to enable snapshots to be made.

Owing to the very thin emulsion necessary to give sufficient resolving power, the latitude of the process is small, and in subjects with wide contrasts the shadows may be underexposed, while the highlights lose colour owing to overexposure and the consequent irradiation. Except with very flat subjects, there is practically no latitude in the exposure given in the camera, the results depending entirely upon the accuracy with which the exposure is determined.

One drawback to screen plates lies in the fact that they must be viewed as transparencies, either by projection or in a simple viewing device. The magnification under which they can be viewed is limited by the fact that the image is broken up into small units.

A process which is in some respects analogous to the screen plate process is one invented by R. Berthon in which film is embossed on the back with minute lenses. A tricolour diaphragm is then placed at the lens of the camera and the film is exposed through the back so that the lenses form images of the coloured filters on the emulsion.

After exposure and processing by reversal, the film is projected with a multi-colour diaphragm attached to the lens of the projector, and the colours of the original object are thus reconstituted on the screen. This process is used entirely in motion picture work.

Bleach-out Processes.—Since many dyes are destroyed by the action of light, and since Grotthus and Draper showed that dyes are bleached by light of the colour which they absorb, it is clear that a printing process can be produced by mixing three colour dyes which are sensitive to light. Thus, if we make a mixture of auramine—which is bleached by blue light; erythrosine—which is bleached by green light; and methylene blue—which is bleached by red light; and coat this mixture in a layer of paper, we shall get a black surface. Now, if this be printed under a coloured original, the dyes which absorb the colours will bleach, and a coloured reproduction will be obtained, the accuracy of which will depend upon the correct adjustment of the conditions. The most important of these conditions is the relative sensitiveness of the different dyes and the choice of dyes which have the correct ab-

sorption. Since dyes such as those mentioned have little sensitiveness to light, it is necessary to increase it by sensitizers, and a great deal of work has been done in this field in the development of suitable sensitizers, of which the best known are Anethol and compounds of a similar nature.

A commercial bleach-out paper was placed on the market under the name of "Utocolour" paper and was employed particularly for the printing of screen plate originals. The results obtained were not very satisfactory, however, and great difficulties have been experienced in achieving any improvement in the process. It is difficult to adjust the three dyes to equality of bleaching. It is very difficult to remove the sensitizer and the bleached dye, and it is particularly difficult to stabilize the unbleached dye so as to produce a permanent picture. These various difficulties have prevented the process from coming into any general use. (For colour photography as applied to motion picture work, see MOTION PICTURES.)

APPARATUS

Photographic apparatus may conveniently be discussed under the following heads:—(1) Cameras and their construction, (2) Enlargers, (3) Stands, (4) Lenses, (5) Light Filters, (6) Shutters, (7) Exposure Meters, (8) Developing and Printing apparatus and, finally, (9) Studio and Darkroom appliances. In the case of Cameras and Lenses further subdivisions of topic will be needed. Owing to the multiplicity of models it will be necessary to curtail greatly the space devoted in former editions to historical development in order to deal at all adequately with features of construction, in relation, more particularly, to modern types. Even here severe compression has rendered unavoidable the omission of many details of mechanical and optical interest. For

closer study of these the reader is referred to the works particularized in the short bibliography appended to this Section.

Incidentally, the consideration of photographic apparatus is complicated by continuous, practical developments in all types of gear. Camera construction, and to some extent the manufacture of lenses and other gear, has hitherto been influenced mainly by three factors, the introduction of dry plates, enabling development of the latent image to be postponed indefinitely, the substitution of gelatine film for glass, and the perfection of methods of enlargement. Two factors are being added—the improvement of existing processes of colour photography and the swift expansion of cinematography—the effect of which is already pronounced. Today the production of amateur cine-cameras is enormous and, although "still" photography can never be completely ousted by motion picture production, the design and supply of apparatus for the former is being as strongly influenced by the latter as the popularity of the old "stand" camera was by the appearance of the revolutionary Kodak.

CAMERAS AND ENLARGERS

The original aim of the pioneers in Photography was to fix the image in the camera obscura (*q.v.*), and Wedgwood and other early workers chiefly employed that cumbersome apparatus in their experiments.

Historical.—Between 1816 and 1839 Nicéphore Niepce, Fox Talbot and Daguerre used smaller box cameras, and it is on record that the expanding bellows-body principle was applied to some of the first cameras made in France for the production of Daguerreotypes. In England this construction was not adopted until much later, the usual practice being to make the camera in the form of two open boxes, one sliding within the other in order to provide the adjustment necessary for focussing. The two parts were supported on a rigid baseboard, the adjustment being fixed by a screw. A portable stereoscopic camera with parallel bellows

FIG. 18.—FOLDING "KODAK"

designed by J. Atkinson in 1857 was followed in 1858 by C. T. H. Kinnear's lighter pattern with conical bellows for general work. Thenceforward the manufacture of British cameras progressed rapidly in the hands of P. Meagher, G. Hare, W. Watson and other competent makers, one of the later models of the last-named, known as the "Premier," having survived to the present day as a typical "square-form" pattern for technical work.

Information on early cameras will be found in the photographic journals, in C. Fabre's *Traité encyclopédique de photographie*, Vol. 1, and in J. M. Eder's *Ausführliches Handbuch der Photo-*

graphie, 2nd ed., Vol. 1, pt. ii.

With the advent of dry plates the demand for more portable cameras increased and has continued steadily to the present day when, the limit of compactness having probably been reached, attention is being concentrated on the provision of various movements, and of accessories such as shutters and finders, with no loss of rigidity and no increase of weight or bulk. Up to 1888, when the roll-film camera known as the "Kodak" was introduced by the Eastman Co. of Rochester, U.S.A., the early portable cameras were for the most part on the lines of the present "hand-or-stand" type.

Roll-film quickly produced a succession of Kodaks, box-form and collapsible, the latter culminating in a folding design which has been widely imitated in this country and on the Continent. To-day the output of roll-film cameras greatly exceeds that of any other type, but several other forms continue in request. Continuous roll Cinema film, cut films, either film-packs (*q.v.*) sheaths, have increased the popularity of the extremely portable "hand-or-stand" cameras, such as the "Sybils" of Newman and Guardia and the more substantial "Una" of James Sinclair and Co. Stereoscopic cameras of exquisite workmanship and extreme precision such as those of J. Richard, Voigtlander and Leitz have many users. The Reflex, both ordinary and folding, is a favourite for Nature study and other special work, and collapsible cameras, based on the original Goerz-Anschütz pattern, are very freely employed for Press photography.

The outstanding feature of latterday camera manufacture is the preponderance of instruments to take plates and films of the smaller sizes including those taking 35 mm. cinema film. With modern emulsion negatives made with "vest-pocket" cameras will yield excellent enlargements. Naturally this facility appeals to the average amateur and also in a measure, to professionals. In fact to-day the enlarger is complementary to the camera to such an extent that in any modern photographic exhibition the proportion of contact prints from negatives taken directly in cameras is conspicuously small.

Construction.—In some portable cameras the application of the "fixed focus" principle renders any focussing adjustment superfluous, but otherwise the latter is a primary constructional requirement. Today most focussing is accomplished automatically. In the earlier cameras the extension—almost invariably by means of leather bellows pleated accordion-wise—was regulated by an endless screw operated from the front or back. The method is occasionally employed in big copying apparatus, but has been largely supplanted by a rack-and-pinion action, on the back of the camera if the bellows are parallel and on the front where conical bellows are racked out from the back. The front, sometimes the back also, is kept rigid by struts or other supports affixed to the baseboard, and the lens, usually mounted on a sliding panel, can be lowered or raised to modify the amount of foreground included. Convergence of vertical lines caused by tilting the camera can be corrected by a swinging back or front, which enables the base of the sensitive plate to be kept horizontal, and its sides vertical, irrespectively of the tilt. A "swing-back" or a "side-swing" is also occasionally useful for bringing into focus a foreground, or a near object on one side or the other of the subject, without "stopping down." Focussing is ordinarily carried out with stand cameras by viewing the image formed by the lens on the piece of finely ground glass constituting the *focussing* screen, a cloth being thrown over the camera to exclude extraneous light. In some cameras, notably those of the reflex type, a focussing chamber enables the focussing cloth to be dispensed with, and in most hand cameras the focussing screen is replaced by the finder (*q.v.*). For certain scientific purposes it is preferable to focus on a piece of plain glass with a focussing magnifier which thus virtually becomes the eyepiece of a telescopic system; but "aerial focussing," as it is called, is unsuited to ordinary photography in which composition of the subject as a whole must be studied.

The focussing screen, and, later, the dark slide or other receptacle for the sensitive plate or film is now usually held at the back of stand cameras in a frame which is reversible for pictures

taken with the plate lengthwise or upright.

"Dark slides" to hold sensitive plates or cut films in sheaths are made to interchange with the focussing screen, the sensitive surface of the plate or film being in accurate register with the ground surface of the screen. Slides are commonly made to hold two plates or films back to back, with a metal partition to prevent the passage of light. There are two patterns, "book-form," hinged to open like a book, and solid, the latter generally known as plate-holders. With some hand cameras single metal slides are supplied. In all slides light is temporarily excluded from the front of the plate or film by a sliding or roller shutter which is removed or opened, of course, for exposure.

In the case of *studio cameras* (*q.v.*) a "repeating slide" enables two plates to be quickly exposed in succession without removing the slide itself. In field cameras other methods are adopted, both to facilitate speedy consecutive exposures and to permit the carriage of a number of plates or cut films in less space than is possible with separate slides or plate-holders. Some patterns of changing-box are very compact and convenient. The usual construction is in the form of a box with a sliding door at the back, to the open top of which a small bag of light-tight material is affixed. The sliding door at the back having been removed the plates or cut films in sheaths are packed into the box, and a spring at the back ensures constant and even pressure upon all the sheaths in the pack, with the result that the front plate or film is always in register with the focussing screen. In the front of the box there is, as in the case of the ordinary dark slide, a shutter which is withdrawn for, and replaced after, exposure. The front plate after exposure is either lifted or levered up into the bag at the top of the box, and transferred to the back.

Slides, plate-holders and changing-boxes have largely been superseded for amateur use by roll-film cameras based on the Eastman Kodak system. In the earlier applications of the latter the roll of film was carried on a spool in a separate holder with removable back and shuttered front, which thus became a sort of changing-box. But the roll-holder is now incorporated in the camera itself, with appreciable increase of portability and convenience and no loss of efficiency. The film itself in a long strip sufficient for several exposures is backed by a longer strip of black paper on which at suitable intervals the number of the exposure is boldly stamped. The excess of black paper at either end of the film provides a safety covering during the process of loading the spool into the camera, and thus enables the latter operation to be performed in daylight. In practice, the lens being normally capped by a central shutter, the back of the camera is removed, and the spool inserted at one side of the roll-holding arrangement. At the other side an empty slotted spool should be in position. The seal of the full spool having been broken a portion of the safety covering is unwound and threaded into the slot of the empty spool. The back, which is provided with a small red "window," is now replaced. By means of a winder more of the black paper is wound off until the number (1) appears in the little red window. The section of film for the first picture is now in position.

An alternative method of daylight loading is provided by the film-pack system whereby cut films are interleaved with pieces of black paper provided with numbered tags, the whole pack being backed by a sheet of metal provided with springs. By pulling out one of the tags a sensitive film is brought into position for exposure, the preceding film having been simultaneously displaced. Much progress has been made in packing film, methods of loading and transfer, with the result that backings may be entirely eliminated or specially treated to protect against unusual exposure, such as X-rays. Nearly all loading to-day is integral with the camera and actuated by automatic or semi-automatic means.

With all hand cameras some form of *finder* is required. The earliest finder was a second camera, and this idea survives in twin-lens and binocular cameras although a combined "single" unit has been developed. It is an attachment either of the "direct-vision" kind, with or without a lens or lenses, or in the form of an angled reflector in which an image produced by a miniature lens, and which represents on a small scale the image transmitted by the lens in actual use, is viewed by the photographer,

either on the mirror itself, or on a tiny ground glass screen. The simplest form of direct-vision finder is a wire frame which, held at a correct distance, represents the proportions of the plate, the view included being identical with that photographed. In other direct-vision finders the subject is collected in a small rectangular negative lens, and this miniature image, accurately proportioned to the size of the plate, is viewed through an eye-hole or eye lens.

TYPES OF PHOTOGRAPHIC CAMERA

There are two principal kinds of photographic camera, studio and field, the former type a comparatively small category almost

FIG. 19.—"ENSIGN" STUDIO CAMERA AND STAND

exclusively used by professional portraitists. The *studio camera* forms as a rule part of a combination (fig. 19), in which a substantially built stand, capable of adjustment as to height and inclination, is included. Such a combination should be movable to any part of the studio, preferably on casters. The camera is fitted with square bellows and focussing is by a double rack and pinion movement, sometimes supplemented by a draw-out extension for quickly obtaining a coarse focus. Extra rigidity is given to the fully extended instrument by a wooden centre frame. The front has a rising and falling movement and is very solidly built to carry large and heavy portrait lenses. In many cameras of this type there is an internal flap shutter which can be worked noiselessly by a bulb. Prior to recent changes which have greatly modified the appearance of both, the main difference between a studio and a field camera lay in the back arrangement.

Field cameras are of many sorts and sizes and include several classes to which separate attention is being given. But the description "field" may be said to belong properly to the kind of camera used in the open, and on a stand, for general work which is not ordinarily attempted in the studio, such as large groups and *genre* studies in natural surroundings, as well as architecture and landscapes. Such a camera must be reasonably portable if plates of a fair size have to be exposed, and it should possess, in addition to a swing back (or front) and a rising and falling front, an extension sufficiently variable to enable lenses of relatively long or short focus to be used. Thus a half-plate camera, the lens normally employed with which would probably have a focal length of 8 in., should have a full extension of not less than 16 in. and it should be possible to rack it in to take wide-angle lenses with a focal length of not more than 4 in. As it is essential that a field camera should be quite rigid when fully extended the design of an instrument possessing this qualification, in addition to that of portability, presents some difficulties.

The "square-form" camera equipped with parallel bellows remains a favourite with many for field work, owing to its rigidity and adaptability to all classes of subjects and all types of lens. Only moderate portability, however, is possible with this model, and a rather substantial tripod is needed to support it at all satisfactorily. For sizes above half-plate, accordingly, a lighter form of camera with conical bellows is frequently preferred, and, provided that the design is good, and the material and workmanship all they should be, a field camera on these lines will meet all requirements. Formerly, only a well made conical bellows camera would carry a variable telephoto lens without risk of vibration; today many designs are offered which eliminate or diminish this hazard. Some conical bellows models have baseboards in which a circle has been cut out and a metal ring inserted, thus constituting a tripod head to which ordinary tripod legs can be attached.

Owing to improved facilities for enlargement field cameras in the larger sizes are not now so freely used as formerly, and the convenience of roll film has rendered diminutive Kodaks, Carabines and other "pocket" instruments increasingly popular. But there is an intermediate type which, as an efficient compromise, is perhaps the most useful form of camera in existence. This is well known as a "view camera" having all the features of both studio and field types. This is also known as the "hand or stand" variety. Following Watson's "Alpha" the productions of Newman and Guardia, which owe their perfection chiefly to the mechanical genius of A. S. Newman, and those of Adams, the Houghton-Butcher Co., Ernmann and other makers, are modern examples of "hand or stand" design in which every conceivable requirement is met.

BY COURTESY OF NEWMAN & GUARDIA
FIG. 20.—NEWMAN & GUARDIA "BABY SIZE" SYBIL

In the "Sybils" (fig. 20) of the first named firm extra rigidity is secured by a neat and effective "lazy-tongs" method of extension. Another representative model of this type is the Sinclair "Una" which, while less compact than the "Sybil," is sufficiently portable and only a trifle less efficient than the "square form." The "Sanderson" of the Houghton-Butcher Co. is remarkable for the length of its extension, the latitude of its rising, falling, and swinging front movements, and the ingenious provision made for the use of very short focus lenses.

Collapsible hand cameras are largely used for Press photography. They form a type apart of which the Goerz-Anschütz was the pioneer model. A typical modern camera of this class is the Ross "Panros" (fig. 21) which is not only extremely convenient for hand work but can be so effectively used on a stand that it was adopted by the Royal Engineers for the field equipment of their Printing Companies, by whom it was extensively employed in the World War. Cameras of this kind are fitted with focal-plane shutters (see p. 828) and very rapid lenses, $f/4.5$ being a usual aperture. In the "Ermanox" made by the Zeiss Ikon Co. an Ernstar anastigmat working at $f.1.8$ has been fitted with which instantaneous photographs can be secured in a theatre with ordinary stage lighting.

Magazine cameras in which a number of plates or films are packed and brought forward successively for exposure, somewhat on the principle of the changing-box, are now comparatively seldom used. Unless of the simplest construction, in which case they are bulky, the changing mechanism is apt to give trouble.

BY COURTESY OF ROSS
FIG. 21.—ROSS "PANROS" CAMERA

Binocular and twin-lens cameras represent an endeavour to provide the operator with a view of the object up to and including the moment of exposure. They are literally, as their name implies, combinations of two separate cameras and two separate lenses, the focussing adjustments being correlated so that one half of the combination can be used for focussing, the other for exposing the plate. In the form of an inverted field glass, the focussing screen and the plate taking the place of the two eyepieces, binocular hand cameras are still to be met with, but the twin-lens, which in its later forms was an early "reflex," has been practically superseded by the single-lens reflex.

Modern *reflex cameras* form a class apart in connection with which much ingenuity of invention has been displayed and many patents have been taken out. The principle is explained in the accompanying diagram (fig. 22) but, as in practice the reflex is usually held in the hand, it is now fitted with a collapsible vertical hood which enables the operator to look down through it on to the focussing screen. A second mirror can, if desired, be fitted in

the hood for horizontal viewing, and focussing can be assisted by the use of a binocular focussing magnifier. Constructionally the reflex camera is a box containing a movable mirror interposed between the plate and the lens, and facing the latter at an angle of 45° . This throws up the image on to the horizontal focussing screen, on which it is viewed through the hood. The outstanding mechanical feature of the reflex is the co-ordination of the movement of the mirror with the shutter release. The removal of the former to enable the image transmitted by the lens to reach the plate, and the instantaneous exposure of the latter by means of the shutter, are effected simultaneously. The shutter almost invariably fitted to these cameras is of the focal plane type, and more than a dozen models of reflexes by first-class makers are available. A typical pattern of the reflex camera, with movable mirror, horizontal focussing screen and viewing hood is the "Soho" by Kershaw and made by the Amalgamated Photographic Manufacturers, Ltd. (fig. 23). Reflex studios now take roll-film.

Reflex Camera and design and construction are considered by A. S. Newman in the *Photographic Journal* for 1921, p. 219.

The basic idea of the *Roll-film camera* has already been discussed. The folding Kodak (fig. 18) remains the most popular instrument of the type, and the latest models of it meet practically every need. Substantially the form has not altered although many new features are continually added. The metal door which closes the front of the camera falls down and forms a base-board along which the panel carrying the lens, shutter and finder is drawn out until the required focussing adjustment has been made. In some models the fixed focus principle is applied; in others the focus can be altered, according to an affixed scale, to suit all distances from a few feet to infinity. Great cleverness has been displayed in ensuring the rigidity of both base-board and lens panel. Focussing roll-film cameras, more or less closely resembling Kodaks, but containing various structural modifications, are now made by a number of firms.

For *panoramic* photography various special types of camera have from time to time been introduced in order to satisfy the scientific requirement that, in covering the abnormally wide angles usually embraced in this kind of work, the lens should rotate on its nodal point of emergence. But practically all the earlier panoramic cameras, an account of which was given in the *B.J.A.* of 1892, have disappeared, and even the interesting and efficient little Panoram Kodak (fig. 24), which takes pictures on a section of roll film $3\frac{1}{4}$ in. \times $10\frac{3}{8}$ in. with a lens swinging on its own axis through the arc of a circle, has comparatively few users. A few professional panoramic

cameras, such as the "Cirkut" and the "Corona"—the latter made by the Gundlach-Manhattan Optical Co. of Rochester, U.S.A.—are available. But in modern practice panoramic photographs are commonly made by exposing several plates to cover sections of the complete picture.

Special cameras for *map reproduction*—often of huge dimensions—and for *copying* in connection with "process" work need not be specifically described as to all intents and purposes they are elaborations of the studio form. For *Colour Photography* (*q.v.*) various particular forms of camera and dark slide have

FIG. 22.—REFLEX CAMERA

been devised, more particularly in connection with the taking of the three negatives required for trichrome work on paper. The simplest method of obtaining the latter is separate exposure of three panchromatic plates in ordinary slides, the lens being screened successively by green, red and blue-violet filters. Greater speed is obtained by use of the Sanger-Shepherd repeating slide in which the three filters are placed immediately in front of sections of a long plate, the sections with their respective filters being exposed in quick succession by passing the slide along a frame fitted to the back of an ordinary camera. A modification of this repeating slide has been introduced by F. Newens and there have been more recent developments. A more elaborate system consists in obtaining the three negatives at a single exposure by means of a specially constructed camera in which the image transmitted by the lens is trebled by the addition of prisms, one image reaching its plate directly, the other two reaching theirs by reflection. Other devices accomplish the same result by different methods. In some colour cameras the prisms are replaced by a mirror system, a recent example of the latter type being the special Jos-Pe camera process.

However, at the time of writing it seems very highly probable that the various specialized forms of the one-exposure camera for all of the varied applications of colour-photography will within a brief period of time be rendered obsolete. This important change in the technical practice of colour-photography will be inevitably brought about by the notable improvements in the application of the tripack method. In this new technique a single simultaneous exposure is given to three films packed together. One of these films is green-sensitive, another is red-sensitive, while the third film is blue-sensitive. By this ingenious combination, which greatly simplifies the problem of taking colour-pictures, noteworthy practical advances may be confidently expected throughout the entire field of colour-photography.

The construction of cameras for stereoscopic photography (*q.v.*) has reached a high degree of perfection in models such as the "Verascope" of J. Richard, the Leitz "Heidoscope" and the Voigtlander "Stereoflectoscope," the last two having a reflex finder in which a full size image is shown by a third lens (fig. 26).

In the practice of *Photo-micrography* likewise, a large choice of apparatus is available, ranging from cameras of very long extension with elaborate arrangements for securing correct align-

BY COURTESY OF THE AMALGAMATED PHOTOGRAPHIC MANUFACTURERS
FIG. 23.—"SOHO" REFLEX CAMERA

FIG. 24.—PANORAM "KODAK"

ment to simple attachments for use with ordinary cameras for low power work. In addition to horizontal apparatus some fine cameras have been designed by Zeiss and others to work vertically, while others can be used in conjunction with the microscope.

Although the subject of *Colour Photography* (*q.v.*) is dealt with elsewhere, reference should be made here to the multiple image optical system including the beam-splitter, for photographing plural images involved in stereoscopic and colour pictures. (See Abstracts Royal Photographic Society 1935.)

Since Cinematography, Aerial and X-ray photography are dealt with separately, such apparatus is not discussed here.

BY COURTESY OF HOUGHTON-BUTCHER, GREAT BRITAIN

FIG. 25. — ALDISSENSIGN ENLARGER

Cinematography is dealt with under MOTION PICTURES (see especially MOTION PICTURE TECHNOLOGY by C. E. K. Mees). Aerial photography is treated under AERONAUTICS and AVIATION, also under SURVEYING. X-ray photography is discussed under X-RAYS; X-RAYS AND CRYSTAL STRUCTURE and related subjects.

Enlargers.—The old method of enlarging by direct photography with a short focus lens and an ordinary camera of long extension has for a number of years been largely discarded in favour of the employment of apparatus resembling the ordinary optical lantern. In the modern enlarger (fig. 25) a negative or a transparency takes the place of the lantern slide, the screen being represented by an easel to which a piece of bromide paper or a sensitive plate is, after focussing, affixed. A powerful beam of artificial light is passed, with the help of a condenser, through the negative or transparency and the enlarging lens with the result that an image is projected varying in enlargement according to the distances between the negative and the lens and between the lens and the sensitive surface of the paper or plate. The illuminant may be either electric light or gas, but the former is now generally preferred, partly because it facilitates the construction of vertical enlargers which have some advantages over the horizontal form. A number of automatic enlargers have been designed.

Enlarging can also be carried out without condensers by collecting the rays of an illuminant in a reflector of ellipsoid form from which a parallel beam of sufficient size is passed through the negative. The latter may be held in the dark slide of an ordinary camera which, with its lens, is thus made to take the place of the front portion of an ordinary enlarging lantern.

The *Photostat*, an American invention introduced about 1907

and since greatly developed, is a combined camera and stand with fully automatic mechanism for the reproduction of various kinds of official and commercial documents by unskilled operators in any ordinary well-lighted office. Any scale of enlargement or reduction can be adopted, and copies developed and fixed in not many seconds. A very rapid colour-sensitive paper is used, rendering the system valuable for copying engineers' and architects' plans, etc. See B.J.A. for 1928, p. 180. (See LITHOGRAPHY.)

Stands.—For studio cameras (*q.v.*) as previously noted, stands of substantial "pillar" construction are usually provided. With copying and other large cameras the stand is more often in the form of a table, but also provided with raising, lowering and tilting movements. For enlarging purposes the stand and easel are sometimes combined, runners enabling the conjugate distances to be readily varied. But for all general photographic purposes the tripod form of stand is the most practical, and almost innumerable patterns in wood and metal have been evolved. For very small cameras tripods with telescoping legs of an aluminium alloy and a top of harder metal meet the demand for extreme portability, but for serious work a substantial wooden pattern is greatly to be preferred. The legs should telescope to make them not only more portable but also adjustable to uneven ground. For special work a revolving or tilting head may be desirable, and in some patterns provision is made for increasing the height of the camera from the ground by means of a second raised head. An important new device is a tripod with a universal ball and socket which compensates for weight and tilt of camera.

For the incidental snapshot work to supplement the ordinary tripod, a "unipod" is employed as a support for a tele-

photo or other heavy lens affixed to a camera which is of frail construction.

PHOTOGRAPHIC LENSES

Historical. — The earliest form of photographic objective was an adaptation of W. H. Woolaston's single periscopic meniscus lens as applied by him to the camera obscura in 1812. This was achromatised by C. Chevalier for use about 1839 by Daguerre,

BY COURTESY OF OGILVY & CO.

FIG. 26.—"HEIDOSCOPE" STEREO-REFLEX CAMERA

but was not corrected for chemical focus. The first photographic lens corrected for chromatic aberration (see later under *Construction*), was a doublet made about 1840 by Andrew Ross for H. Collen, and consisting of two achromatic compounds, one at each end of a tube (fig. 27).¹ Many single lenses of good performance were produced by the early photographic opticians, T. Grubb's "Aplanatic" (1857) and "Landscape" (1865), J. H. Dallmeyer's "Wide Angle Landscape" (1884), and "Rectilinear Landscape" (1888) being notable examples.

In 1841 a remarkable advance was achieved by Voigtlander's introduction of a rapid portrait lens designed by Professor Petzval of Vienna (fig. 28), to whom is due the historic condition that the sum of the focal powers of the individual lenses in a photographic combination, multiplied by the reciprocals of their respective refractive indices, should be equal to zero, or $\sum \frac{1}{\mu f} = 0$.

This pioneer portrait lens consisted of two dissimilar achromatic combinations widely separated, the front element being a plano-

¹In the diagrams of lenses which follow, a uniform system of indicating the nature of the glass employed by means of the shading has been adopted.

Flint glass is indicated thus: —

Crown glass of low refractive power thus: —

Crown glass of high refractive power thus: —

(These two are used indiscriminately in lenses made before the introduction of the new Jena glass.)

Extra light flint glass thus: —

In most cases the front of the lens is on the right.

FIG. 27.—FIRST ENGLISH PORTRAIT LENS

convex composed of a biconvex crown cemented to a plano-concave flint, while the back element was a double convex composed of a bi-convex crown separated by an air-space from a concave-convex flint. The form was notably improved by J. H. Dallmeyer who in 1866 reconstructed the back combination by substituting a meniscus crown for the bi-convex positive meniscus for the negative meniscus, reversing the positions, and introducing an air space.

In 1861 J. H. Dallmeyer produced a triplet very fully achromatised, non-distorting, and giving excellent definition, but since obsolete on account of its bulk and slowness.

Between 1841 and 1866 a number of doublets were brought forward by British and Continental opticians with the object of increasing rapidity and eliminating distortion, and towards the end of this period a simple and efficient type of "rectilinears," "symmetrical" and "aplanats" had become established. In the manufacture of these a high degree of excellence was attained particularly by Dallmeyer and Ross in England and by Steinheil in Germany (fig. 29). Wide-angle symmetrical doublets with greatly deepened curves appeared about the same time, some exhibiting remarkable qualities of definition combined with covering power. Dallmeyer's "Rapid Rectilinear," f/8 (1867) set what remained as the standard for photographic lenses for ordinary purposes until the perfection of the anastigmat.

Among slower combinations the "Portable Symmetrical" of Ross was remarkable for its flatness of field and a compactness which enabled a number of lenses of widely different foci to be fitted into the same flange.

The issue in 1886 by Schott and Genossen of the "Jena glasses" formulated by Professor Abbe placed in the hands of photographic opticians a means of eliminating astigmatism by setting high refractivity with low dispersion against low refractivity with high dispersion. Some of the early Jena glasses were unstable and progress in construction was at first slow. In 1888 Dr. Schroeder worked out for Ross an anastigmat afterwards known as the "Concentric Lens" but the first thoroughly successful objective made with Jena glasses was that designed in 1889 by Dr. Paul Rudolph of the Zeiss firm, and classed as Series II. f/6.3. The details of construction are to be found in the Eder *Jahrbücher* for 1891 and 1893. This excellent lens was followed by several other anastigmatic singles and doublets, a new line being struck out by the symmetrical cemented doublet of C. P. Goerz known as the "Dagor,"

which has since been widely imitated. Almost simultaneously the single "Protars" of C. Zeiss came to be combined in doublet form. These improvements soon showed themselves to be as excellent in practice as they were in theory.

In 1895 Taylor, Taylor and Hobson produced a remarkable and entirely novel anastigmat designed by H. D. Taylor and known as the "Cooke" lens (fig. 30). It consists of three single lenses, a biconvex crown in front, and a very flat biconvex crown behind, with a biconcave of light flint in between, and close behind the front crown. Also in 1895 H. L. Aldis calculated for Dallmeyer a new convertible anastigmat consisting of two dissimilar compounds, thus giving a choice of three foci. The "Stigmatic," as it is called, is still issued but in a non-convertible form. In 1902 H. L. Aldis produced at the new works of Aldis Brothers at Birmingham a much simpler anastigmat composed of a

FIG. 28.—PETZVAL PORTRAIT LENS

FIG. 29.—RAPID RECTILINEAR LENS

FIG. 30.—"COOKE" LENS, SERIES III

cemented meniscus in front and a single double convex back lens (fig. 31). Several series have been issued and very widely distributed. In 1902, again, Ross and E. Busch of Rathenow simultaneously produced anastigmats consisting of four separate lenses, the Ross combination, known as the "Homo-centric," being of Jena glasses, while in the Busch "Omnars" as originally constructed normal glasses were employed. In 1907 H. C. and C. Beck made another new departure in the Isostigmat, remarkable as violating the Petzval condition, the inventor's theory being that the condition does not apply to lenses the individual elements of which are separated by large intervals (fig. 32). In 1913 J. W. Hasselkus worked out for Messrs. Ross a singularly fine anastigmat

FIG. 31.—ASTIGMATIC LENS, SERIES III

which has since become famous under the name "Xpres." It is a non-convertible doublet, the conspicuous feature of which is a cemented back combination consisting of three lenses, (1) a biconcave or plano-concave of low refraction, (2) a meniscus of medium refraction, and (3) a biconvex of high refraction.

From 1898 in addition to the above-named, and in partial supersession of the doublets of Zeiss, Goerz, Steinheil and Voigtlander, there has been a steady stream of new lenses, mostly triplets—"Tessars," "Pentacs," "Serracs," "Heliars," "Aviars" and others—chiefly remarkable for increase of aperture (fig. 33). A markedly rapid lens is made by Ross to work at $f/1.3$.

BY COURTESY OF R. & J. BECK
Fig. 32. Beck's "Isostigmat" Lens

In 1891 T. R. Dallmeyer in London, A. Miethe in Berlin and A. Dubosc in Paris simultaneously worked out telephotographic combinations consisting of positive and negative elements, variations in the separation of which produced magnification according to the extension employed.

The principles enunciated and clarified by the pioneers referred to above are the active basis of present-day work on lenses. current experiments are too widespread to permit of cataloguing here but the 1935 trend should at least be noted: namely, that recent developments of fine-grained photographic emulsion for cinema film have stimulated a general demand for smaller cameras and lenses of proportionately short focal length, greater consequent depth of field, greater rapidity, and more critical definition.

CONSTRUCTION OF PHOTOGRAPHIC LENSES

The construction of technically good photographic lenses, of which some indication has been given in the preceding historical summary, depends largely upon the elimination of certain defects of which the principal are (1) Spherical aberration, (2) Coma, (3) Astigmatism, (4) Curvature of field, (5) Distortion and (6) Chromatic aberration. Spherical aberration is due to the fact that a spherical surface does not bend or focus light to one exact point, in other words the rays passing through the edge of such a surface do not focus to the same point as those passing through the centre. It can be partly corrected in a single lens by the use of a diaphragm, and in combinations by varying the curves of the component lenses. Coma and astigmatism are functions of spherical aberration, the first being a blur due to lateral spherical aberration of oblique rays. It is partly eliminated by the diaphragm. Astigmatism manifests itself in inability to focus accurately at the same time both vertical and horizontal lines

BY COURTESY OF CARL ZEISS
FIG. 33.—ZEISS'S "TESSAR"

near the margin of the field. It is partially cured by the use of a small diaphragm, and can be wholly eliminated by the selection of special glasses and the precise calculation of curves. Curvature of field is due to the failure of rays passed by a lens with a spherical surface to come to a focus on the same plane, the defect increasing, like astigmatism, with the obliquity of the rays. Here, too, the diaphragm can be of great service. Distortion is of two kinds, "barrel" and "cushion," a square appearing in the former shape if photographed with a single meniscus lens with the concave side outwards and the diaphragm placed in the front of the lens, and as a "cushion"—i.e., with concave sides—if photographed with a single lens convex side outwards and with the diaphragm behind. It is corrected naturally in symmetrical doublets, since the barrel distortion of one component compensates the cushion distortion of the other. Chromatic aberration is caused by the dispersion of the white light passing through the lens, and is due to the fact that the different coloured rays come to a focus at different distances from the visual focus, according to their wavelengths. It is corrected by compensating lenses of different refractive powers. (See OPTICS.) In the general construction of photographic lenses the defects which were enumerated above, together with a number of others, are neutralized by regulating the curves of the different positive and negative component lenses, the refractive and dispersive indices of the glasses used, and the distances of the refracting surface, in this manner making the objective truly stigmatic or focussing to a point.

The performance of an adequately corrected lens depends chiefly upon its effective aperture or the diameter of the clear ray actually used in impressing the image on the plate. This diameter is not necessarily that of the diaphragm employed, but the latter is used for the purpose of mechanical regulation of aperture, i.e., reduction from "full" to the smallest possible. In early lenses the diaphragms or "stops" were of the Waterhouse pattern, with thin pieces of metal with circular openings of different sizes which could be inserted in a slot in the lens mount. This pattern is still employed in portrait and other large lenses.

A variation is the rotating stop, a circular plate containing a series of apertures which can be brought into position as desired. Most modern lenses are fitted with iris diaphragms which Messrs. R. and J. Beck claim to have been the first to apply to photographic lenses in 1880. These consist of thin leaves of metal or ebonite so arranged that by operating a ring to which they are affixed apertures of different diameters can be formed at will. Several systems of numbering diaphragm apertures are in use, the most common being the F number method in which the aperture marked is the focal length of the lens divided by the effective diameter of the stop. Thus an effective diaphragm opening of $\frac{1}{2}$ in. in the case of a lens of 8 in. focus would be $f/16$. In other words the aperture marked is a definite proportion of the focal length. Another system is the U.S., or Uniform Standard, proposed by the Royal Photographic Society in 1881 and adopted in the Kodaks. This takes $f/4$ as the standard, the markings corresponding to the F. numbers being as follows: f. values, $f/4$, $f/5.6$, $f/8$, $f/11.3$, $f/16$, $f/22.6$, $f/32$, $f/45.2$. U.S. Nos., 1, 2, 4, 8, 16, 32, 64, 128.

On the Continent the sequence of F. numbers is usually 3.16, 4.5, 6.3, 9, 12.5, 18, 25.3, 36, the exposure in each of the last seven cases being, as in the two preceding systems, double that which is found necessary in the case of the preceding number.

PROBLEMS OF FOCUS

The fact that depth of focus is conditioned not only by aperture but also by focal length has an important bearing upon the construction of very large aperture lenses. It is obviously of small use to build a cumbersome and costly lens with a focal length of, say, 12 in. and an aperture of, say $f/3$ for ordinary work, in which the lens would almost invariably need to be stopped at any rate to $f/8$ to secure reasonable "depth." But, with the extended use of diminutive cameras carrying very short focus lenses, the demand for very wide apertures has grown enormously, and

lenses working at $f/3.5$ are now common.

An important consideration in the construction of a photographic lens is the *angle* of view it embraces. If over 50° it is usually described as wide, if under 35° as narrow. The angle depends on the focal length of the lens in relation to the size of the plate, and in practice the focal length should not be less than the diagonal of the plate. In the case of a half-plate this diagonal is 8 in., in that of a quarter-plate 5.3 in. Tables of view angles are published in the B.J.A. showing the number of degrees embraced according to the quotient arrived at by dividing the diagonal of the plate by the equivalent focus of the lens. In the case of an 8 in. lens used on a half-plate, the quotient arrived at being 1, the angle according to the table is 53° .

The term focus is explained in the general article on LENS (*q.v.*), but it may be pointed out here that the equivalent focus of a photographic lens must be measured from the nodal point of emergence which is sometimes in front of the front component.

The historical genesis of the principal forms of photographic lenses having already been discussed, their actual construction, apart from the optical considerations dealt with in the general article on LENS (*q.v.*), may now be glanced at. The single lens is seldom produced commercially to-day except as a component of a doublet or triplet, or in connection with the cheaper amateur outfits. In the latter case it is a simple achromatic meniscus composed of a biconvex crown cemented to a biconcave flint. The single components of the better types of "Rapid Rectilinear" are constructed in a somewhat different manner. Anastigmat singles, such as those used to make up the combinations of the Zeiss "Protar," the Ross "Combinable," the Steinheil "Orthostigmat," the Watson "Holostigmat" and the Voigtländer "Col-linear," are usually triple compounds of special Jena or Chance glasses. In addition to the symmetrical doublets formed by the combination of two simple singles there are a number of variously composed asymmetrical doublets; some with cemented, others with air-spaced components, are also notable combinations which, although assembled in two cells, are more or less frankly triplets. The Zeiss Tessars, which are entirely asymmetrical, consist of three separate components, that in front being a cemented lens, the other two uncemented, the intermediate one being a double concave. In the construction of most modern doublets and triplets air-spaces play an important part. (*See* LENS.) Multiple combinations, such as the Beck Isostigmat, in some forms of which five separate lenses are sometimes used, are uncommon.

One interesting development has been by Zeiss in his use of converging achromatic eyepieces (consisting of two self-contained groups of lenses) for increasing marginal thickness of lens.

Apart from, or in connection with, their standard models some lens-makers have designed *supplementary lenses* to lengthen or shorten the foci of ordinary objectives. In their simplest form such lenses are either long focus negative or positive singles which can be attached to the front of an ordinary objective with, necessarily, some disturbance of the original corrections. As far back as 1894 an advance in this direction was made by Taylor, Taylor and Hobson in connection with their "Cooke" lens by producing a suitably corrected rear extension lens for increasing the focal length. More recently the same principle has been applied by the Zeiss firm to its Tessars in a series of "Distars" and "Proxars," the former lengthening, the latter shortening the focal lengths of the original objectives.

The construction of telephoto combinations is altogether distinct from that of ordinary photographic lenses. It is based on the fact that, if a negative lens is placed behind a positive lens at a separation not less than the difference between their focal lengths (which constitutes the Galilean telescopic condition), and not more than the focal length of the positive element, a photographic combination is formed, the focal length of which increases as the separation is decreased. The "back focus," or distance from the back lens of the combination to the plate, is not, however, correspondingly increased, being dependent wholly on the focal length of the negative element, a very important consideration as it enables considerable magnification of the image transmitted by an ordinary lens to be obtained with the same or less camera

extension. In 1907 Capt. Owen Wheeler introduced a system of combining tele-negatives to produce compounds of extremely short focal lengths, with which magnification up to X 30 is possible with a camera extension of only about 13 inches. A good feature of this system is that by making the rear lens of the combination one of relatively large diameter the covering power is greatly increased. Advantage was taken of this fact in a special complete tele-lens freely used by the Royal Engineers in the World War, which had a focal length of 30 in. and covered a 5×4 plate with a camera extension of 6 in. only.

Originally telephoto lenses were "variable power" ones—*i.e.*, the separation of the elements could be altered at will to produce different magnifications with the same or with different tele-negatives. Also an ordinary photographic lens was generally used as the positive element. These arrangements were defective owing, firstly, to the disturbance of the corrections of the positive by a shifting negative element, and, secondly, to the comparative slowness of the combination due to the fact that the aperture of any telephoto lens is the aperture of the positive multiplied by the magnification. Thus, in the case of a variable power combination in which, in order to obtain good definition, the positive is stopped to, say, $f/11$, the aperture at only 5 magnifications would be $f/55$.

Another drawback in the case of variable power combinations is their liability to internal reflections owing to the relatively long separation of the two elements. This is partially overcome by lining the lens tube with some non-reflecting substance or material, but a more effective plan is to fit a hood on the lens to cut out the extraneous light—a method often adopted with advantage in the case of ordinary objectives.

Variable power telephoto lenses are still used by specialists and extraordinary results are attainable with them. But in modern practice single-focus combinations are much more common. In these the positive element is a cemented single lens of extremely wide aperture, the defects of which are corrected in the negative element. The earliest examples of this form were the $f/9$ Busch Bis-Telar (1905) and the $f/14$ Zeiss "Magnar" (1906), both since improved, but these have been put into the shade by recent productions of Ross, Dallmeyer, Taylor, Taylor and Hobson, Zeiss and others. The principles and construction of the Telephoto Lens are discussed at length by H. W. Lee in the *Photographic Journal* for 1925, p. 392.

See Proc. Physical Soc. of London for 1935, Vol. 47, p. 502, Taylor and Lee for full summary of developments.

TYPES OF LENSES

Little need be added here to the note in the historical summary above on the subject of Portrait Lenses. It is a remarkable tribute to the genius of Petzval that the lines which he laid down in 1841 should be generally followed to-day in the lenses commonly used for portraiture, although naturally modification and improvements have since been introduced by leading opticians. Ross, Dallmeyer, Taylor, Taylor and Hobson in Great Britain, and Voigtlander, particularly, on the Continent, have produced many portrait lenses of great excellence and, occasionally, of gargantuan proportions. In some modern studios, however, the portrait lens of old days is yielding place to the anastigmat, the wide aperture of which places it on a level with the Petzval construction in point of speed, while its more perfect corrections and covering power render it specially serviceable in the matter of studio groups. In simple portraiture, on the other hand, extreme flatness of field is not always desirable, a round-fielded lens giving better "modelling." Since good portraiture has little use for "needle" sharpness of definition artist photographers since the days of Mrs. Julia Cameron have sought in various ways to modify the critical rendering of objects in the same plane by a well-corrected lens. One method of producing "soft" effects is by means of the diffusion created by partly unscrewing one lens of a combination. Latterly soft focus lenses have been produced by several opticians in which diffusion is secured by special computation, the objective being duly corrected for flatness of field, distortion and colour, but yielding an attractively soft image of marked pictorial quality. A third soft focus method is the

employment of uncorrected lenses, as suggested by Bergheim, and carried out in the Dallmeyer-Bergheim lens (1895). Between 1903 and 1906 C. Puyo and L. de Puligny constructed several anachromatic systems for portrait and landscape work. More recently A. C. Banfield has experimented in the same direction with a view to keeping the aberrations in this form of lens within reasonable limits, the result being embodied in the Dallmeyer-Banfield Portrait Astigmat of focal lengths varying from 18 to 30 in. and working with a maximum intensity of $f/6$.

The variety of lenses in use for *field work* is so great that only a brief mention of a few leading models is possible. In these the reputation of the makers for design and workmanship is fully maintained, but it is fair to say that in many less well-known productions the requirements of all but specialists are adequately met, some important earlier patents having run out, and the supply of optical glass of high quality having been considerably expanded by the entry of Messrs. Chance of Birmingham into this field of manufacture. For all-round outdoor work the convertible cemented anastigmat is the most useful form, the performance of the single components in the case of doublets like the Zeiss "Protar," the Ross "Combinable," and the Watson "Holostigmat" being all that could be desired. With all these lenses asymmetrical as well as symmetrical combinations are practicable, thus giving a choice of three foci. In one series of the "Holostigmats" the single components can be used at the remarkably high aperture — for a single — of $f/8.5$. At the same time, the critical definition and increased rapidity possible with triple combinations like the "Tessars" make them extremely popular, their usefulness being enhanced, where desired, by supplementary lenses such as those mentioned above. Of triplets and asymmetrical doublets, with components one or other of which is uncemented or a single glass, a wide choice is available from the lists of Ross, Dallmeyer, Taylor, Taylor and Hobson, Wray and Aldis Brothers in Great Britain, and of Zeiss, Goerz, Voigtlander and others on the Continent, the apertures ranging from $f/2.2$ to $f/6.3$ and the focal lengths from two to three inches up to as many feet.

In field work, more especially in connection with architectural studies in confined spaces, wide-angle lenses are often necessary, and much attention has been paid to this branch of lens construction both before and since the advent of the anastigmat. Of late years wide-angle lenses with comparatively large full apertures — very useful for focussing in dark interiors — have been made by Taylor, Taylor and Hobson, whose VII. B series, superseding their previous "Primoplanes," open to $f/6.5$ and at $f/32$ give sharp definition throughout a field of 100° . The Wide-Angle Aristostigmat of H. Meyer, the 4 in. model of which covers a half-plate at $f/9$, is another successful lens of this type. For the particular purpose of Aerial surveying, but also very useful for many other classes of work, a new wide-angle Ross Xpres, embracing an angle of 50° and covering sharply from centre to margin at the very high aperture of $f/4$, is a remarkable achievement, the report of the National Physical Laboratory on this objective showing extraordinarily good corrections. Where an abnormally wide-angle lens is needed the Goerz "Hypergon," which consists of two hemispherical lenses, and has a frontal star diaphragm to equalize the light, may be used to cover an angle of 135° .

Modern *Telephoto lenses* are, as previously indicated, very different from the early variable power type, and much better adapted to latterday requirements. The magnification is small, at the most X_3 , but this is compensated by critical definition enabling enlargement to be carried out to the same extent as with negatives made with ordinary objectives. For the modern telephoto lens is corrected throughout as carefully as the best ordinary anastigmat, being in fact itself an anastigmat, fully achromatized, free from curvature, spherical aberration and coma, and, within its limits, non-distorting. Also, as now made by half-a-dozen leading opticians, it is rapid enough for all practical purposes, even putting aside the latest "ultra-speed" models in which an aperture of $f/3.5$ has been reached. The only drawbacks are bulk and somewhat restricted covering power, but these do not constitute a high price to pay for a lens which will do very nearly all that the best ordinary lens will do at half the camera extension

required by the latter. An advanced lens of this type is the Ross Three Power "Teleros" which gives an image almost three times as large as that given by an ordinary lens from the same standpoint, and works at $f/6.3$. In the Two Power Teleros the aperture has been widened to $f/5.5$. There is also a Teleros of 40 in. focus, working at $f/8$, which is specially constructed for photographing cricket and other sports. Messrs. Dallmeyer, in addition to their "Grandac" and other variable power telephoto lenses, make a number of fixed-focus objectives giving magnification from X_2 to $2\frac{1}{2}$ and working at apertures from $f/3.5$ to $f/7.7$. The "Ultra-Speed Dallons" are only made in focal lengths up to 12 in. for covering quarter and 5×4 plates, but there is a very useful series working at $f/5.6$, the 24 in. model of which requires an extension of only 12 in. from the back cell to the focussing screen, and covers a whole-plate. Messrs. Taylor, Taylor and Hobson's "Cooke" Telephoto Anastigmats, Messrs. Wray's "Plustrar," the Zeiss "Tele-Tessar" and the Voigtlander "Tele-Dynar" are other fine examples of fixed-separation telephoto lenses. The "Cooke," like the "Dallon," is made with apertures of both $f/3.5$ and $f/5.6$, but with the former in two focal lengths, 8 in. and $10\frac{1}{2}$ in., only.

In colour photography a high order of colour correction is necessary and for three-colour "process" and other colour work in which very great accuracy is essential it is desirable that the correction should be carried to the furthest practicable limit. This is done by means of special computations and glasses in *apochromatic lenses* made by Ross, Taylor, Taylor and Hobson, Zeiss and others. With a view to complete correction for colour a few quartz lenses have been made by British, French and American opticians, and further progress may be expected.

Lenses for cinematography receive mention in the article on MOTION PICTURES, but passing allusion may be made to them here since those employed in cine-cameras are photographic objectives pure and simple, made in most cases to standard formulae. Some extraordinary results have been attained in these tiny lenses, the Dallmeyer "Dalmac" having been adapted to cinematography in the 16 mm. sub-standard size in a variety of models, one of which has a focal length of 1 in. only, with an aperture of $f/1.5$. A number of tele-cine-lenses are also available.

Very short focus photographic lenses are also used in *photomicrography*, but are not so suitable for work at high powers as microscope objectives in conjunction with suitable eye-pieces.

An unusual short focus lens, of especial interest commercially, is that employed in the "Graflex" automatic film camera used for photographing meters in the telephone exchanges, etc.

Light Filters. — The principles on which orthochromatism and panchromatism are based having already been explained (page 814), the discussion of light filters for cutting out some rays and emphasizing others need not occupy much space, although the subject, when closely considered, is of great scientific and technical interest. For the production of such filters various expedients have been tried, including small glass tanks filled with suitably coloured solutions, but in modern practice either specially coloured glasses or dyed gelatine strips cemented between glass squares or discs — preferably "optical flats" — are commonly employed. The making of gelatine "strip" for such filters demands some skill and patience, a perfectly levelled glass plate being required on which to spread the dyed gelatine solution. The latter must, of course, be as clear as possible, and stained a spectroscopically correct colour. A number of suitable dyes are available for making yellow and green filters, for use with orthochromatic plates, and blue (or violet), green and red filters, for panchromatic plates when the latter are employed in three-colour photography. Yellow filters are usually graded according to the extent to which they increase exposure. In addition to giving correct rendering of yellows and greens they are frequently of the greatest value in cutting out haze and enabling clouds and distant hills to be effectively reproduced.

Certain commercial filters, such as the Ilford "Gamma" and the Imperial "Impan," give accurate rendering of all colours when used with panchromatic plates from the same source of supply. The "Impan," by attaining this result, when used with

Imperial "Special B" panchromatic plates, with an exposure only $2\frac{1}{2}$ times that required without a filter, has set a new standard. Literally hundreds of scientific treatises and experiments, many culminating in research developments for which scores of patents have been granted to British, French, German and American investigators, have been contributing factors to the present stage of all but perfect success in use of filters. Today, we are unquestionably on the eve of very widespread and successful use of colour in all forms of photography.

Instantaneous Shutters.—The speed of the modern emulsions necessitates some means of opening and closing a lens in a fraction of a second. To this end a large variety of "instantaneous shutters" has been evolved. The earliest shutters were of the drop or flap pattern, the former merely an oblong strip of wood or metal, with an opening cut in it, and working in a frame fitted to the front of the lens. The dropping of the shutter through the frame effected the exposure by opening and closing the lens. The flap shutter, which is still used in the studio either on the lens or inside the camera, consists of one or two hinged flaps made to open outwards or inwards by either a pinion or a pneumatic ball and tube movement. Later, shutters were made to work between the lenses of a combination on either the rotary or iris diaphragm principle. In the former case a metal disc with an opening in it was revolved by means of a spring; in the latter leaves of metal or ebonite were made to open or close completely. The Goerz "Sector" and the "Georgen Central" were early shutters of this type.

Modern shutters are either of the roller blind or improved sector kind. Roller blind shutters are of two separate types, one in which the blind as a whole opens or closes the lens, difference in speed being obtained by tightening or relaxing the spring of the actuating mechanism; the other in which a slit in the blind passes behind the lens, the speed of exposure being governed partly by the tension and partly by the width of the slit. The ordinary roller blind shutters, of which the Thornton-Pickard (fig. 34) is the standard model, are, within their limits, very effective and dependable. Speeds from about $\frac{1}{15}$ to about $\frac{1}{300}$ sec. can be given by adjusting the spring, and a separate attachment to the bulb enables time exposures up to 3 sec. to be made automatically. The theory of such shutters is explained by Abney in his *Instantaneous Photography* (1895) and by W. B. Coventry in *The Technics of the Hand Camera* (1901). Of the focal-plane shutter, as the slit blind variety is called, there are numerous patterns geared and with adjustable slits to work at speeds from $\frac{1}{10}$ to over $\frac{1}{1000}$ sec. The theory is explained by Coventry (*see above*) and by C. Fabre in *Traité encyclopédique de photographie*, Vol. 1, Suppl. C, 1902. This shutter works immediately in front of the plate and is normally built into the camera. The Goerz-Anschütz pattern is very typical of the entire group of focal-plane shutters.

The central lens shutter is now generally made with only two or three leaves or blades so constructed that practically the opening of all parts of the lens for exposure is simultaneous. Such shutters are made entirely of metal, and in the best patterns the mechanism is of the same precision as that of a watch. The exposure is effected by means of springs supplemented sometimes by an air-brake. A shutter known as the "Multi-speed" has been made to work between the lenses of a combination at speeds up to an alleged $\frac{1}{3000}$ sec., but in the best ordinary models a reputed $\frac{1}{300}$ sec. is the highest speed attainable.

Remarkable advances have been made between 1929 and 1935 both as to the precision and effectiveness of shutters and, as well, to new adaptations of them. The trend is towards shutters that are fully automatic in operation and towards combination of functions with other camera devices. For example, a device controlled by photo-electric cell is now used for operating the diaphragm of photographic and cinematographic cameras accord-

ing to the intensity of light; another device has exposure and iris adjustments coupled with light meter as an in-between-lens shutter; again, a Catadioptric Unit, whereby a controlled amount of diffusion is introduced, is offered. Cameras with flash bulb circuit connections and synchronization are increasingly popular. *See also Photographic Shutters: Methods of Construction and Measuring their Speeds*, by A. S. Newman.

FIG. 35.—"COMPUR" BETWEEN LENSES SHUTTER

Exposure Meters.—The two most common types of exposure meters are actinometric and visual observation, the latter commonly known as "extinction" meters. In the former sensitized paper is exposed to the light falling on the object, and the exposure is based on the time which the paper takes to darken to a certain tint. A narrow strip of specially prepared silver bromide paper which darkens rapidly on exposure to light is usually employed, a fresh section of it being exposed in juxtaposition with a fixed standard tint. The number of seconds, or minutes, counted before the standard tint is reached is called the actinometer time. This is correlated with the known speed of the plate and the stop in use, and the result read off on a dial. The leading British patterns of exposure meters are the Watkins and Wynne, both available in watch form. In the Watkins method plate-speeds are distinguished by numbers, in the Wynne meter by an F number, both designations being roughly comparable with the more precise H and D measurements. In "extinction" meters the visual intensity of the light reflected from the shadows is measured by direct observation. In many patterns, of which the "Heyde" is typical, the instrument is adjusted until the subject viewed in the meter appears to lose its shadow detail. In the well-known "Justophot" of E. Meyer the hand-setting of the instrument is controlled by the moment of appearance of a small numeral as a bright figure in the centre of a dark field. (O. WH.)

Developing and Printing Apparatus.—The apparatus used for producing finished prints from exposed sensitive materials differs according to the conditions under which the work is to be done. An amateur photographer who develops and prints his own photographs uses relatively simple apparatus. A portrait or commercial photographer is equipped to deal with larger sizes and to produce a larger output, while a trade finisher who develops and prints large numbers of films exposed by amateurs uses quite elaborate apparatus.

Plates and flat films are generally developed by amateur workers in flat trays, roll films in a special developing tank in which the film is held in the convolutions of a roll of celluloid which can be immersed in the developing solution. Sometimes plates are placed vertically in the grooves of a tank or of a rack which can be placed in a tank.

In connection with his factorial system of development (*q.v.*), A. Watkins produced in 1894 a factorial calculator and a dark room clock. With the later extension of "time and temperature" and tank developing methods, a number of dark room clocks and tanks of various patterns have been introduced, some of the former being provided with alarms which can be set to ring on the expiration of a given number of minutes, while others merely mark the progress of time on a dial with large hands.

For printing, the simplest method is to place the negative in a "printing frame" used to hold the sensitive paper in close contact with it during exposure to light. Pressure is usually by means of springs acting on a hinged back. Even for amateur use, however, the replacement of other printing materials by developing papers has involved the general employment of simple printing boxes containing an electric light for which the current is controlled by a switch which is actuated when a platen is brought down on the negative and sensitive paper placed in contact with it.

BY COURTESY OF THORNTON-PICKARD CO.
FIG. 34.—MECHANISM OF THORNTON-PICKARD ROLLER-BLIND SHUTTER

Professional photographers develop their plates very largely in tanks, and the flat films, which to a considerable extent have replaced plates in professional work, are developed in holders which are placed in tanks and transferred from the developer to the fixing bath and then to the washing tank and finally to a drying cabinet. In this way a large number of negatives can be handled together and the day's work can be developed and made ready for printing very expeditiously.

Almost all of the printers used in professional work are of the printing box type, exposure being made to electric light operated when the platen is closed over the negative and printing paper. Professional printers are provided with attachments for masking the negatives and for the insertion of special masks of ground glass or celluloid on which local work can be done, so that parts of a negative can be printed to a lesser extent than other portions.

Prints are usually developed in large dishes and after fixing and washing may be dried either on racks covered with muslin or, if the output is very large, on one of the various belt driers.

Commercial photographs are often made with a glossy surface produced by squeegeeing the print on to a lacquered metal plate known as a "ferrottype plate" and are usually mounted in contact with backing cloth or paper in order to stiffen the print.

For mounting prints, a method of dry mounting by means of tissues which have been saturated with shellac is frequently adopted. Tissue and print are laid on the mount in the dry mounting press, in which heat is applied, which causes the shellac to melt, with the result that the print is cemented to the mount.

The business of "photo-finishing," as it is termed in the United States or "developing and printing" (D. & P.), as it is generally known in England, is now a very considerable portion of the photographic industry, many firms developing several million spools of amateurs' cartridge film every year. In the case of the large photo-finishers, the finishing plant collects film through the agency of a number of photographic dealers and returns the finished pictures to the dealers for distribution to the retail customer. Two important factors in the business are the short time in which it is necessary to get the work done, often 24 hours or less, and the great variation in the amount of business throughout the year. The output in England, for instance, being ten times as much at the maximum in August as at the minimum in January. This variation in the amount of business is causing great attention to be paid to the provision of automatic machines in order to diminish to a minimum the amount of skilled labor required. When the rolls of film come in, they are unwrapped in the dark room and numbered, the number being either punched into the film or light-printed on it. They are then held in clips which can be slipped over rods, so that the films with a weighted clip at the end are immersed in deep tanks of developer. After a fixed time of development, they are transferred to a rinse tank, fixed, washed, and again transferred to a drying cabinet.

Several forms of continuous machines have now been devised for developing the rolls of film. In these, the rods carrying the films held in clips are moved continuously by a conveyor system through a system of tanks and finally through a drying cupboard.

The dried negatives go forward to a printing room, where they are printed by contact upon developing paper, the printers being adapted for rapid operation, frequently by foot treadles, and equipped with numbering devices. Automatic power driven printers have been designed and some printers automatically give the correct printing exposure in accordance with the density of the negative.

From the printers, the paper goes to the developers. Most prints are developed in flat trays, rinsed in water and fixed, and are then washed in a rotating cage immersed in flowing water or in a series of flat trays through which water flows, this being the form used particularly in England, where it is known as a "cascade washer." The washed prints are dried by being placed between two fabric belts which travel over a heated drum, these machines being known as "belt driers," which deliver the prints dry within a few minutes.

Glossy prints are dried upon ferrottype plates in cupboards or, with the most recent machines, upon polished metal drums to

which they are carried while wet by traveling belts.

The finished prints may be trimmed at the edges in order to give them a smooth finish and are usually delivered unmounted.

(C. E. K. M.)

Studio and Dark Room Appliances.—Studio Lighting.

—Aside from furniture and blinds for adjustment of lighting by day a feature of most modern studios is the provision made for exposure by artificial light. Of the numerous effective systems in use some employ arc, others half-watt lamps in combination with suitable reflectors. Very serviceable special types of studio lighting apparatus have been evolved. A recently introduced studio lighting accessory is the "spot-light," borrowed from the stage.

Although seldom used in important studios the flash-lamp may be briefly mentioned under this heading. It consists of a pan in which a powder, usually composed largely of magnesium, can be ignited to produce a large flame of highly actinic quality.

Dark Room Fittings.—Mention has already been made of dark room clocks and of developing and bromide printing apparatus. In addition to these every year sees the introduction of new designs of lamps and other dark room equipment of sorts and sizes adapted to the nature and importance of the work in question. Of dark room lamps and lanterns in particular there is an endless variety, the most practical being those in which either white light or light which, while relatively bright, is "safe" for the plates in use, can be turned on at will. The incandescent electric lamp is naturally that chiefly used for such dual arrangements. To the making of different "safelights" suitable for all kinds of plates and bromide papers careful attention has been given, and, in order to cope with the extreme sensitiveness of modern emulsions, lanterns have been devised by Wratten and others in which only reflected light is proved through the safelight. This precaution, however, is being rendered superfluous by the new methods of desensitizing. While these methods are not sufficiently effective to enable very rapid panchromatic plates to be developed by naked candlelight, illumination is permissible after desensitizing which would formerly have been out of the question. The Ilford Co. has introduced a new safelight for use with desensitized panchromatic plates, giving a pleasant green light by which development can be watched in comfort as well as in security. Many others have advanced useful equipment.

PICTORIAL PHOTOGRAPHY

By pictorial photography we mean photography applied to the production of pictures in the accepted artistic tradition, but whether such pictures are to be admitted as art is a matter upon which the critics are still at variance. The subjects with which photography can deal most successfully are those in which realistic representation is permissible and not such as demand an imaginative treatment.

The Nude.—For that reason photography of the nude, which has always been a tempting subject, fails for the most part, not because it presents any greater technical difficulties but because the realism inseparable from photography makes it almost impossible to combine it with an idealistic conception, whilst it is equally difficult to use it convincingly in subjects drawn from ordinary life. To present the nude by photography simply as a study of the beauty of the human form involves firstly the finding of a model of perfect proportions and secondly extreme delicacy of artistic treatment to prevent degeneration into the recording of mere nakedness. In modern times this class of work is mostly done in the studios of the professional photographers who have greater facilities than the amateurs, but however excellent their work may be technically, it is usually quite meaningless from the artistic point of view. The finest use of the nude is to be found in the work of the Americans, especially those living in California where conditions are exceptionally favourable, and particularly in that of Annie Brigman, Arthur Kales and Walter Collinge.

Still Life.—In other directions photography has more scope. Landscape, portraiture, domestic genre and still life all offer ample opportunities to the camera worker with artistic education and a trained eye. Still life, in particular, offers endless possibilities for imaginative treatment by photography and some very beautiful work of the kind has been done in the past by Baron de Meyer, J. M. Whitehead and E. Seymour. It is a branch of photography which the Japanese of the American Pacific coast have developed upon lines of their own in recent times, grafting the American love of startling eccentricities upon their own inborn sense of design. In their aptitude for seeing a pattern or decorative effect in chance combinations of the most commonplace kind they are unequalled. The exploitation of effects of pattern of an eccentric or sensational nature, if it did not actually originate in America, certainly reached its greatest development there some twenty years ago as a method of self advertisement. Such it still remains.

The sounder development of modern pictorial photography shows itself in a feeling for broader and simpler effects, in a stronger sense of pattern and in more attention to the form than to the content of the picture, in other words the picture is no longer expected to tell a story. As a graphic art, photography has certain disabilities, for it cannot suppress facts and cannot omit unwanted details at will. It can modify the presentation of the facts but any suppression or alteration has to be done by subsequent manipulations, usually involving handwork upon the negative or print, the legitimacy of which has been questioned.

IMPROVED PRACTICE

Fox Talbot.—The story of pictorial photography is largely bound up with the progressive improvements in the materials with which the photographer had to work. Fox Talbot's Calotype provided the first method of making pictures by the agency of light and so added photography to the graphic arts. In the year 1833 he was at Lake Como endeavouring to make sketches with the aid of the Camera Lucida but, lacking the necessary skill of hand, sought to devise a means of recording automatically the view as seen on the paper. After five or six years of experiment he was able to demonstrate his discovery of the process which is the basis of modern photography and two years later patented an improvement of this under the name of Calotype. He himself was a scientist rather than artist and it cannot be said that any of his surviving photographs show an artistic impulse.

D. O. Hill.—The first to put the new invention to a pictorial use was a Scottish artist, David Octavius Hill, who, having been present at the meeting at which the disruption of the Scottish Churches occurred, conceived the idea of painting the historic

scene. It involved the inclusion of some hundreds of figures. To get sittings and draw all these portraits would have meant a year or two of labour and many might be dead before he could secure their likenesses. His friend, Sir David Brewster, an eminent scientist of the day, told him of the newly invented photography and at the same time introduced a young student of science, Robert Adamson of St. Andrews, to attend to the technical manipulations. For three years he worked at it and produced that series of portraits of Scottish notabilities that are amongst the greatest, as they are the earliest, masterpieces of the photographic art. An album containing fifty of the original prints of these was issued in 1848 and is now in the possession of the R.P.S.¹

In 1846 Hill returned to his painting, became secretary of the Scottish Academy of Arts and died in 1870 so completely unknown to fame as a photographer that not a single photographic paper chronicled the event. Although references to his pictures occur earlier (*Photographic Journal*, 1854, vol. I., p. 177, also 1864, vol. IX., p. 63), it was not until James Craig Annan began to interest himself in Hill's work in the early nineties and published a series of photogravure plates from the original paper negatives, that he really became known.

It was Hill's artistry and not his photography that achieved greatness and it is well to bear this in mind when pictorial photography is twitted with not having done anything finer than Hill did so many years ago. Such a reproach is no more just than would be a similar one to the artists of today for not excelling Titian and Raphael and Michelangelo. The "Girl in a Flowered Gown" is an example of the work of Hill.

Little is known of any of Hill's contemporaries. Dr. White of Aberdeen used photography for pictorial purposes and a collection of his landscapes was shown at the R.P.S. in December 1922 (*Photo. Journal*, vol. LXIII., p. 5) but the process was as yet so imperfect that the long exposures and lack of colour sensitiveness of the negative material made photography chiefly a recording medium for the scientist, whence arose the tradition of sharp uniform definition that distinguished its practice until the advent of Mrs. Cameron in 1864.

Albumen Paper and Collodion.—The introduction of albumen paper in 1848 and of the collodion process of Scott Archer in 1850 marked the next progression. Picture making was a serious business in those days when the negatives were made the full size of the finished print and had to be sensitized and developed in the field and when enlarging was as yet unknown. Already in the winter of 1851 there was a small group in London meeting regularly and by 1852 this had grown to such an extent that it was felt the time was ripe for a photographic society.

ROYAL PHOTOGRAPHIC SOCIETY

The First Exhibition.—The holding of the first recorded exhibition of photographers at the Gallery of the Society of Arts in December of that year gave an additional impetus and in January 1853 the Photographic Society of London came into being. Other societies quickly followed and photographers multiplied. At the first meeting of the London Society, one of the Vice Presidents, Sir William Newton R.A., a distinguished artist, read a paper in which he put forward several ideas that countered the false standard of pictorialism accepted as the result of its practice by those whose only qualifications were scientific.

The most admired features of a picture at that time, we read, were sharp definition all over and a blank expanse of pure white for the sky. Sir William made two suggestions that were a direct attack upon the existing position. One was that the pictorialist should aim at a broad and general effect for which end it was not necessary that the whole of the picture should be in sharp focus. The other was that artificial means should be adopted to obtain some suggestion of a sky, either by local reduction or by dabbing pigment on the back of the negative to simulate clouds. These rather ruffled the photographers but the heaven worked and by 1862 there was general agreement on the desirability of adding skies to pictures since it was then impossible to secure them on the same plate as the landscape. Already in 1856 a print

¹Royal Photographic Society of Gt. Britain.

of a marine subject by a Frenchman named Le Gray exhibited at the Photographic Society's soiree at King's College had created a sensation and helped to break down the blank-sky convention.

Composites.—The next phase that developed naturally from the prevailing conditions was the production of composite pictures built up from two or more negatives. A method of doing this had been suggested as early as 1848 but the earliest exhibited example known was by Berwick and Annan in 1855 in which a figure had been introduced into a landscape. The first and most famous picture of this kind, of which we to-day have any knowledge, was "The Two Ways of Life" (R.P.S. collection). This interesting picture is a large print measuring 31x16 inches and built up from more than thirty separate negatives, by O. G. Rejlander, a Swede practising as a photographer at Wolverhampton. This remains the most ambitious attempt of its kind. Rejlander sent it to the Manchester Art Treasures Exhibition of 1857 where the original was bought for Queen Victoria. A second copy was purchased by Sir David Brewster who writes that he paid ten guineas for it, and a third copy, now at the R.P.S., was retained by Rejlander himself until 1870. There is no record of his making further use of the composite method although he worked for another twenty years, and all his other pictorial work is mainly in the class of domestic genre in which only one or two figures are used.

His example, however, stimulated Henry Peach Robinson (born at Ludlow in 1830), a young professional photographer at Leamington, to employ his leisure time in attempting similar methods of picture making. He had had some artistic training; he had carved one of the statues of the reredos of Ludlow church and one of his paintings was accepted by the Royal Academy before he was twenty-one. He started life in the bookselling business at Ludlow, Bromsgrove and London and whilst at Bromsgrove in 1850 learnt the daguerreotype process and subsequently Calotype and Collodion in preparation for a photographic career. His earliest pictorial attempts are unknown with the exception of the small "Juliet with the poison bottle" (R.P.S. collection) but in 1858 he produced a picture, entitled "Fading away," from five negatives which was first shown at the Crystal Palace and afterwards at Leeds. It excited a violent controversy on the permissibility of exhibiting so painful a subject (a girl dying from consumption) to the public gaze. Robinson's fame was thenceforward established and for the next thirty years he was the leader of British photography. His style was essentially Victorian, artistically sound but anecdotic. The principal idea was to make the picture tell a story. His three finest works "The Day's work done" (1877) "Dawn and Sunset" (1885) and "Carolling" (1887) are now preserved in the R.P.S. collection. The two former are magnificent examples of albumen printing, measuring 30x21 inches.

Further Inventions.—In the late 'fifties Pouncy's Gum Bichromate process and Poitevin's Carbon process were added to the existing printing media. The former received little attention but Carbon was developed commercially by Swan and the Autotype Co. and was taken up slowly by photographers.

A Notable Amateur.—The advent of Mrs. Julia Margaret Cameron in 1864 marks the next stage in pictorial development. The casual gift of a camera and lens by her daughter led her to take up photography at the age of fifty with all the volcanic energy of her temperament. She was one of a highly gifted family and had been closely associated with Watts and the painters of the Pre-Raphaelite school so that she brought an unconventional mind to the exercise of the new art. Her lens was of an uncorrected type and without waiting to learn the correct adjustments, she proceeded to use it in the manner that suited herself. She broke through all conventions and produced a series of heads distinguished by great breadth of modelling; indeed, in the case of the Carlyle and Herschell, by a violence of treatment that rather horrified the photographers of her time. The reviews of the exhibitions made some caustic comments on her methods (*Photo. Journal*, 1864. Vol. 9, p. 87. 1865. Vol. 10, p. 117) which were perhaps not altogether unjustified. She received, however, praise and encouragement from G. F. Watts and other men

of discernment. As she was on intimate terms with many of the most eminent people of her day, her pictures have an interest beyond that of their artistic merits. The best of her work must certainly rank amongst the photographic masterpieces of all time. "The Guardian Angel" is one of her best known works. She was apt to be careless in her methods. Most of her original silver-albumen prints have now faded and were it not that her principal works were issued in autotype carbon, we could now hardly form a just estimate of her achievement.

Platinotype.—Willis brought out his Platinotype process in 1873 but it made little headway at first as a license was required to work it. Yet it fulfils the chief desideratum of the pictorialist in that it gives an image in permanent pigment on pure paper without the interposition of a gelatine or other film. The Oil Transfer process is the only other one that meets the same requirement. The next few years were occupied in the transition from the wet collodion to the dry gelatino-bromide plate and from albumen to the gelatino-bromide printing papers. Pictorialism shows no very marked movement during this period and it was not until 1888 and onwards that a new move was discernible. The dry plate and the invention of the hand camera were vastly enlarging the numbers who were being attracted to photography as a hobby and this very largely contributed to the advancement of pictorial work. The leading names at this time were Col. Joseph Gale, Frederick Hollyer, Frank Sutcliffe of Whitby, Payne Jennings, B. Gay Wilkinson and J. B. B. Wellington.

THE NEW PICTORIAL MOVEMENT

Dr. Emerson's "Naturalistic Photography" (1887).—The expansion of a lecture by Dr. P. H. Emerson, "Naturalistic Photography," to the Camera Club in 1886, was the beginning of the new movement. Unquestionably this book struck a powerful blow at the many conventionalities which had attached themselves to the practice of photography and had a powerful influence upon the younger pictorialists. In it he lays down that, "naturalism is an impersonal method of expression, a more or less correct reflection of nature wherein (1) truth of sentiment, (2) illusion of truth of appearance (so far as is possible), and (3) decoration are of first and supreme importance." He further advocated the differentiation of focus to secure separation of the planes, closer attention to the rendering of "tone," greater adherence to truth through the study of nature and generally a higher and more intellectual standard.

To what extent Dr. Emerson's book contributed to the new pictorial movement that made itself evident in the late eighties is doubtful. The movement originated no doubt from the ferment in the artistic world due to the influence of the French Impressionist school which was becoming known and appreciated. The leaders of the new pictorialism were George Davison, Alexander Keighley, James Craig Annan, A. Horsley Hinton and Alfred Stieglitz, and the consensus of opinion is that the first visible sign of the break with the older Victorian tradition is to be found in Davison's picture "An old farmhouse" or, as it was called later, "The Onion field." This famous picture received the Photographic Society's medal in 1890. The council of the society consisted mainly of scientists who, beyond holding the annual Exhibition, did little to encourage pictorial work, and as a result the new body of pictorialists soon came into conflict with them.

There was a secession and many whose interests were purely pictorial left the parent society to band themselves together as "The Linked Ring" with definitely pictorial aims and interests, one of which was the holding of a separate exhibition to be known as The Salon. Although the society's neglect of pictorial interests was advanced at the time as the reason, the schism originated in a quarrel in which H. P. Robinson, Davison and the assistant secretary of the Photographic Society were involved. The establishment of this energetic new organisation brought about a veritable renaissance which received a further stimulus by the revival of Pouncy's Gum-Bichromate process in a workable form by Ladeveze, a Frenchman, and by Alfred Maskell and others in England. At last the pictorialists had a really controllable

printing process. Demachy, Le Begue, Puyo and others in France co-operated and our pictorialism took on a new orientation. Two of the finest pictures of this period are Horsley Hinton's "Melton Meadows" and Alex. Keighley's "The White Sail."

American Influence.—By the end of the century the first impetus of the movement was largely spent but a new era began in 1900 when F. Holland Day of Boston, U.S.A., exhibited at the R.P.S. house a collection of some 360 prints by members of the new American School. The exhibition proved a sensation and had a tremendous influence upon British photography, with the result that during the next six years pictorial photography reached a high level that it has never quite touched again.

The influence that was behind this wonderful American development was that strange genius Alfred Stieglitz, who after studying photography in Berlin, returned to New York about 1890 to begin his great task of building up an American School of pictorial photography upon foundations that were practically non-existent. The inspired achievements of the Americans from 1900 to 1908 are eloquent testimony to the success of his great work, for which in 1924 the Royal Photographic Society awarded him its Progress Medal, a unique distinction for a pictorial photographer. It is necessary to name only F. Holland Day, Yarnall Abbott, Gertrude Kasebier, Eduard Steichen, Frank Eugene, Clarence White, Alvin Langdon Coburn, Mrs. Annie Brigman and George H. Seeley to realise the number of photographers of real vision and genius who responded to the inspiration of Stieglitz.

Although the brilliance of the Americans overshadowed to some extent the work of the British school, that too reached a high level of excellence during the same period whilst its effort has been more sustained, so that in the subsequent twenty years British pictorial photography has taken more and more the leading position in the world's work, rather, perhaps, by reason of its sanity and sober pictorial excellence than by any quality of brilliance or progressive novelty of outlook.

The development of the colour sensitive plate, culminating in the Panchromatic plate in 1906, affected pictorial photography but little and even twenty years later, although most photographers use negative material that is orthochromatic to some extent, they are somewhat conservative in their attitude to panchromatics, principally because they are apt to give harsh results unless developed with more discretion than the average photographer possesses.

The introduction of the soft gradation Panchromatic plate by the Ilford Co. in 1928 may serve to break down this prejudice and get rid of the bugbear of "over-correction" which in most cases would be described more correctly as over-development.

The Oil Process.—A new method of printing, the Oil process, was introduced by G. E. H. Rawlins in 1904 and worked out by himself, Demachy in Paris and C. F. Inston in Liverpool. Based upon the action of light upon chromated gelatine, it consists in applying an oil pigment, such as lithographic or printing ink, to the damp gelatine surface by means of special brushes and so building up an image whose development can be controlled and modified according to the skill of the worker.

A very useful modification of this, known as Bromoil, was worked out by C. Welborne Piper in 1907. In this a Bromide print or enlargement is bleached in a special solution and can then be inked up in the manner described. The latest modification consists in transferring the inked image by means of pressure to a sheet of plain paper. This is the transfer process and bids fair to be the chief pictorial printing medium of the future, for the image then consists of a permanent pigment on pure paper, the whole process is under the photographer's control, and as many printings can be superimposed as may be necessary to secure the desired result.

PROGRESS OF PICTORIAL MOVEMENT

Great Britain.—In 1909 internal dissensions brought about the disruption of "The Linked Ring" and the exhibition of that year was the last of the original Salon. A few of the members formed themselves into a Secession which held a small but notable exhibition in 1910 which, however, was not repeated, and the other supporters of the Salon came together under the lead of F. J.

Mortimer and established in 1911 the London Salon which still continues. Amidst all these changes the R.P.S. Exhibition continued its even way. For a year or two after the secession in 1892, the seceders held aloof but gradually they came back and most of the prominent pictorialists exhibited at both shows, so that there was little to choose between the two.

During the World War, and especially towards the end, pictorial photography was carried on under great difficulties and the Exhibitions fell almost to the vanishing point. Since then a gradual revival has set in but it has taken nearly ten years to return to normal. The feature of late years is the levelling up that has taken place in the work of the general body of photographers as well as the great increase in its practice. To the R.P.S. Exhibition of 1928, 460 workers sent in more than two thousand prints.

The position of British photography to-day is largely the result of the highly organized nature of its pictorial efforts, the very large number of photographic societies all over the Kingdom, their grouping into Federations and unions which cater for their needs and stimulate their activities, the scheme by which a large number of the societies are affiliated to the Royal Photographic Society for the same ends, and lastly the R.P.S. itself which has become not only the parent society of the British empire but, to an ever increasing extent, of the American and continental pictorial groups and associations as well. The numerous photographic exhibitions held in Great Britain, of which the most important are the R.P.S. Annual Exhibition, the London Salon, the exhibition of the Professional Photographers Association, the Salon of the Scottish Federation, the Northern Exhibition and the Midland Salon, have done much to foster the growth and appreciation of pictorial photography and afford the British public greater facilities to see good pictorial work than can be found in any other country.

America has several notable Salons held annually at Pittsburgh, Buffalo, Los Angeles, San Francisco and Seattle. The work there is inclined to be decidedly experimental and novelty is perhaps more sought after than beauty though this may be merely a stage in the development and the prelude to the evolution of a style and school such as was possessed in the great days before 1908.

France, under the inspiration of Robert Demachy in 1900, was the leader in photographic pictorialism but since the great men of that period retired from active participation in the foreign exhibitions, the French school is less known outside that country than formerly; although an exhibition of work by members of the French Photographic Society at the R.P.S. in 1926 revealed several new pictorialists of eminence.

Germany and Austria have, during the past thirty years, always held a prominent place in the pictorial movement with individual characteristics of their own. Before the World War the pictures of Duhrkoop, Perscheid, Kuhn and the large gum prints in colours by the brothers Hofmeister were notable features of the leading exhibitions. Since the World War the Germans have not participated to any great extent in foreign exhibitions, but the work of Otto Vogelsang of Pomerania, Dr. Koppitz of Vienna and Franz Drtikol of Prague has shown that there are pictorialists of the front rank.

Other Countries.—Italy has progressed rapidly in recent years under the inspiration of the *Gruppo Piemontese* of Turin and the work of the new school is virile whilst based on the best traditions. Spain possesses one pictorialist of eminence in J. Ortiz Echague but no national school, whilst in the Scandinavian countries the pictorial work appears to be done entirely by the professional photographers of whom Aage Remfeldt of Oslo and Ferdinand Flodin and Dr. H. B. Goodwin of Stockholm are the best known. In Holland and Belgium there are several active workers and Borenbergen and Berssenbrugge in the former and Leonard Misonne in the latter are well known at the exhibitions in this country.

COLLECTION OF PICTORIAL PHOTOGRAPHS

The organized collection of pictorial photographs generally seems to have presented few attractions to any public institutions or to individuals, and it is a regrettable fact that no complete record exists of the achievements of the past. The importance to posterity of such a record was not realised in the early days and, in

any case, the housing and exhibition of such a collection would have presented insuperable difficulties to any body other than a municipal or government institution. Small individual collections have been made no doubt at all times but in only one or two cases could they claim any importance. The Duchess of Sermoneta is known to have possessed a fine collection but it is reported to have been dispersed at her death. Mr. Harold Holcroft of Wolverhampton has made a fairly representative collection of contemporary work during the past thirty years and this will be preserved intact as he has presented it to the Royal Photographic Society.

In the early days, the Prince Consort, who was keenly interested in photography, apparently formed a collection for in 1859 he offered fifty prints to the Photographic Society of London to form the nucleus of a permanent collection. The Society appointed a committee to consider the Prince's suggestion as it then possessed no permanent abode, and that apparently is as far as the matter ever went. If the prints were ever received there is no trace of them now. It was not until after 1890 that the idea of forming a permanent collection was revived and the line taken was to acquire annually the pictures which received medals at the exhibition but even that small effort soon expired and the collection grew in desultory fashion by casual gifts.

In 1923, however, the President, who for once was a pictorialist, organised an effort to make the collection worthy of the society. A ready response was received, many pictures of great historical and pictorial importance were secured, gaps were filled, a curator appointed and the Society's Permanent Collection, although by no means complete, is by far the largest and most representative in the world. The addition of the Holcroft collection adds greatly to its value and importance. Collections of photography have been made by the Smithsonian Institution, Washington, U.S.A., and by the State Museum in Berlin and in recent times Mrs. Milson, a former Lady Mayoress of Sydney, N.S.W. formed a collection of pictorial photographs to become the basis for a permanent collection in Australia, but none of these can compare in size and importance with the R.P.S. collection which contains examples of the work of all the most notable photographers from D. O. Hill to the present day. The further expansion of this collection is assured by the recent gift by Mr. Stephen H. Tyng of New York of a fund for the purchase annually of outstanding examples of photographic art. The administration of this fund is placed in the hands of the Pictorial Group of the R.P.S., an organization within the Society specially designed to encourage and foster pictorial interests in every possible manner.

Photographic Press, Weekly and Monthly.—This, while dealing with pictorial matters, has catered chiefly for the general reader and the publications dealing exclusively with pictorial interests have been comparatively few. The first of this nature in Great Britain was a series of monographs on the work of the leading pictorialists of the day, each volume being devoted to the work of one man and illustrated in photogravure by four of his pictures. The whole was issued in 1890 under the title of "Sun Artists." In 1895 the proprietors of *The Photogram*, a monthly magazine, issued a special volume devoted to an account of the photographic activities of the year in this and other countries, with 90 illustrations of selected pictures. This has grown to be a feature of annual interest and, under the editorship of F. J. Mortimer, F.R.P.S., is now the principal record of the photographic pictorialism of the world. A volume of somewhat similar aim but limited to the pictorial work exhibited at the R.P.S. has since 1926 been issued under the auspices of the Society by F. C. Tilney, F.R.P.S., who supplies a critical commentary on the pictures reproduced. In addition the Society issues in the October number of its *Journal* an account of the year's work both pictorial and scientific, with abundant illustrations. Of late years the *Société Française de Photographie* and the *Gruppo Piemontese* have issued sumptuously illustrated records of the Salons held by them annually, which constitute valuable records of the work done in their respective countries, and now Japan is doing the same on a slightly less ambitious scale in the *Japan Photographic Annual*.

The most beautiful of all these records of photography, however,

we owe to Alfred Stieglitz who, in fifty-four volumes of *Camera Work* issued between 1903 and 1917, gave us the finest pictorial work of the principal masters in photogravure reproduction that are a joy to the connoisseur. This was the most perfect thing of its kind that has ever been attempted and involved Stieglitz in heavy financial loss in return for the devotedly unselfish labours of nearly twenty years.

In conclusion, pictorial photography would appear to have reached a point where no marked progress can be expected along the present lines and we await the coming of the genius who will give a new orientation to its aims. Perhaps the development may be in the nature of a direct colour process for with the addition of colour the scope of photography would be vastly widened.

SUBMARINE PHOTOGRAPHY

Water is often so calm and clear that it might seem easily possible for one above its surface to photograph fishes or other objects beneath it. This may, indeed, sometimes be done, but usually the attempt results in complete failure. The explanation is simple. At the moment of exposure the rays from the near submerged object are sharply focussed upon the plate. But at the same time more intense light from distant objects, out of focus, after being reflected from the water's surface reaches the plate also, which, when developed, consequently shows nothing. To set up an opaque screen shading the water's surface above the subject overcomes the difficulty. Through the shaded area, as through a window, one may photograph what lies below. However, the method is limited in its application. When the water exceeds 3ft. in depth it is usually better to use a submerged camera.

Dr. L. Boutan of Paris—pioneer in this field—between the years 1893 and 1898 attempted submarine photography at the Roscoff laboratory in Brittany with cameras of several sorts and appropriate and ingenious subsidiary apparatus. One of his cameras, made of metal, was directly submersible. Sea-water reached its interior, bathing both lens and plates. Although the result obtained was unsatisfactory because no thoroughly suitable lens was available, the principle seemed good to him. Other trials in which the camera was enclosed in and protected from the water by a metal box, through a glass window in which it looked out, were by comparison highly successful. This sort of apparatus, variously modified, has been used in all later work.

Boutan's cameras were of the simple detective type. Reighard, ten years after, at Tortugas, Fla., first used a reflecting camera protected in a water-tight box weighted down with lead till the window through which the camera looked was submerged, although the focussing hood remained above water and permitted him at all times to see what might be in the field. Excellent pictures were obtained within wading depth, beyond which he did not go.

Williamson Brothers, commercial motion photographers, probably as an independent invention, enclosed not only the camera, but the photographer as well, in a chamber suspended by a non-collapsible open tube from a floating scow. Perfect pictures of the sea bottom and animals in shallow water were obtained in the clear water of the Bahamas, as the scow stood still or was towed slowly along. These writers must be credited with the first attempt to secure a photographic record in colour of submarine life in its natural setting. By using selective filters they secured films which when projected upon the screen gave an idea of the variety of colour upon a tropical reef, but since the yellows registered as reds the attempt can scarcely be considered entirely successful.

Longley, with Reighard's apparatus reduced to manageable size and improved, having recourse again to diving equipment as Boutan had done, gave the submarine camera greater mobility and a wider range of usefulness. It now lends itself to instantaneous or timed exposures of any ordinary subject at moderate depths. In the tropics, where sunlight is intense, snapshots, it is interesting to note, may be taken as readily as upon land, but with somewhat longer exposure. Dr. Paul Bartsch, at-Tortugas, and S. C. William Beebe, in Florida and the West Indies, have succeeded in obtaining pictures with a motion-picture camera similarly employed. Finally, Longley and Martin, working together and employing pound charges of flashlight powder set off electrically above water under a white cotton reflecting screen supported on pontoons by the same motion by which the submerged photographer exposed his plate, demonstrated the feasibility of submarine colour photography. The flash was so bright that even the slowly acting autochrome plate could be used for instantaneous exposures. Some results are shown in one of the plates under MARINE BIOLOGY.

PHOTOGRAPHY IN MEDICINE

There are three principal applications of photography in medical work, namely: (a) Radiography; (b) Photomicrography, and (c) Record photography, *i.e.*, the photographing of patients specimens, apparatus, etc.

The last named section is a particular branch of technical photography and often the results obtained are unsatisfactory or even useless. This is usually because the camera is regarded as an automatic recording apparatus which can only give one impression of a subject. Hence when it is found that the original is reproduced in an unfamiliar form, with essential details unaccented and irrelevant ones exaggerated, it is naturally thought that the process is inefficient. The truth is that the camera will not discriminate between those details which are required and those that are not; but it is possible to accentuate the former by lighting, etc.

Neglecting for a moment the question of colour, a photograph reproduces in a series of tones the light reflected from the corresponding areas of the subject. If the exposure has been sufficient and the development adjusted to the printing paper used, this representation is correct over a considerable range. The conditions specified are not by any means always fulfilled and much of the failure of photographic recording is due to faulty technique at this stage. The range of tones is limited by the white of the printing paper itself and the black of the deepest deposit, which is about 20 to 1 and, if the intensities of the original subject cover a greater range, accurate reproduction is impossible in a print.

The compressing of an extended scale of tones into a shorter range is not very apparent but, on the other hand, there is a typical photographic distortion of the perspective which is often very noticeable. The perspective as reproduced by the lens of a camera is always mathematically correct but may yet appear unnatural to the eye. The explanation lies in the fact that to see the subject as the lens saw it, it is essential to look at the print from a distance equal to that which separated lens and plate when the exposure was made. The photograph which shows abrupt perspective was taken with a lens of short focal length and, if the print is moved up to that distance from the eye, the perspective will be seen to have become normal in appearance.

To avoid this distortion, it is clearly of importance to use a long focus lens. It is impossible to specify the exact length as that depends on the size of plate used. Such a lens is large and expensive and requires a camera with a long extension and plenty of room in the studio. An alternative method is to use a shorter focus lens on a small plate and make an enlarged print provided the loss in detail is not too great.

Another reason for the failure at times of the photograph lies in the difference between the eye and the plate in their response

to light of different colours. An untreated plate is sensitive to the blue and violet end of the spectrum. By treating the plate with certain dyes, it has been found possible to extend the sensitivity first to the green and yellow (orthochromatic plates) and finally to the whole spectrum (panchromatic plates). The latter still retain their excessive sensitivity to the blue end of the spectrum and, in order to obtain a true rendering of the relative intensities of different colours, they must be used with their appropriate light filter. This consists of a piece of dyed gelatine usually yellow in colour placed over the lens.

In some cases, *e.g.*, faint reddish markings on the skin, a correct rendering would be unsatisfactory and here it is necessary to exaggerate the degree of contrast. An ordinary untreated plate, to which red is the same as black is to the eye, will give a more valuable if less correct photograph. Another case where increased contrast is desirable is when the print is to be reproduced by some half-tone process in a publication. The tones of the photograph are broken up into dots and the consequent reduction in contrast implies a somewhat harsher print.

THE PHOTOGRAPHING OF PATIENTS

In the photographing of patients, the most difficult problem lies in obtaining sufficient light. It is frequently necessary to stop down the lens considerably as parts of the subject will be at different distances and the aim of the photographer is a large scale photograph with good detail in every part. Again the slight movement due to breathing, etc., will be sufficient to spoil the finest detail if the exposure is at all prolonged. Hence on both counts, the light must be powerful. Daylight is variable and often not available. In cases where the patient can be moved into a studio, the most serviceable source of artificial light is a battery of large gas-filled electric lamps. The light is under control, any special lighting can be repeated and the volume of light is virtually constant.

Record work in the wards of a hospital is often of extreme difficulty owing to the weakness of the light. Here a magnesium flash lamp enclosed in a fabric bag can often be used. The exposure is practically instantaneous and the bag is afterwards removed and the smoke released outside the room. Care, however, should be taken not to use the apparatus when the slight explosion of the powder might cause distress.

When it is probable that a series of photographs will be required of a subject taken at certain intervals of time, it is most important that the conditions of lighting, position, etc., should not vary, so that the series may be comparable. Especially important is it that each photograph should be taken on the same scale. This is most readily ensured by measuring the distance from the front of the lens to the principal plane of the object and repeating this for the subsequent exposures.

To estimate the value of the degree of reduction, a clearly marked scale divided in feet or inches should be placed at the same distance from the lens as the principal plane of the object and in such a position that it is included in the photograph. The photograph of the scale is measured and the degree of reduction readily calculated.

With the object of making the records more comparative, it is of advantage to work with a series of standard reduction ratios, *e.g.*, $\frac{1}{4}$, $\frac{2}{3}$, $\frac{1}{2}$, etc. The distance lens-to-object is found for each ratio and then the camera placed at that distance and focussed.

The lens for record medical work should be a long focus anastigmat, capable of rendering the finest detail. Very big aperture lenses are seldom of much use in this work owing to their lack of depth of focus. The camera and stand should be rigid with a big range of adjustment. (B. D. H. W.)

PHOTOGRAPHY, CELESTIAL. The invention of photography by Daguerre in 1839 led to a great step in astronomical progress. The first application of the daguerreotype to the science was made by John William Draper of New York who photographed the moon on March 23, 1840, the exposure being 20 minutes. Experiments in the new method were made under the direction of W. C. and G. P. Bond at the Harvard college observatory, with the assistance of Messrs, Whipple and Black,

photographers of Boston, as operators, and the first photograph of the moon was taken there on Dec. 18, 1849, with the 15 in. object glass. A daguerreotype picture of the moon shown in London by George Bond at the Great Exhibition of 1851 attracted much attention.

Historical.—In England, Warren De la Rue, having seen the Harvard pictures, took up the subject and presented to the Royal Astronomical Society, in 1857, positive copies from a negative picture of the moon made by a collodion process that he had found practicable five years earlier. In 1864, Dr. Lewis Rutherford, of New York, made a telescope with object-glass of 11¼ in. aperture so corrected as to bring the photographic rays to focus. About the same time Dr. Henry Draper excelled his father's efforts by taking photographs of the moon with a 15 in. reflector, and early experiments in lunar photography, among them those by Hartnup of Liverpool, should not pass unnoticed.

It is said that the first photograph of a star was a daguerreotype of Vega taken at Harvard observatory on July 17, 1850, but want of sensitiveness made this process rather impracticable, and there was little success in stellar photography until the invention of the collodion plate that was used in America and England in 1852. In November 1857 a photograph of ζ Ursae Majoris with its companion Alcor taken at Harvard was sent for exhibition at the Royal Astronomical Society by W. C. Bond, an exposure of 80 sec. having been given to photograph the 6th magnitude star with the 15 in. refractor. De la Rue at this time was making experiments on the actinic power of Jupiter and Saturn compared with that of the moon, but his photographs did not show any details of the planetary surfaces. Under his direction also, and to his design a photoheliograph was made and set up at Kew observatory for the Royal Society, and the work of taking daily photographs of the sun, that has since been carried on successfully, at Greenwich and elsewhere, began at Kew in March 1858. In an attempt to photograph Donati's comet of that year, De la Rue was not successful though it was photographed by Usherwood, of Walton Common, in 7 sec. with a portrait lens of short focus.

Daguerreotypes of the sun taken by Foucault and Fizeau in 1845, and photographs of the solar eclipses of 1851 and 1854 were interesting as experiments, but the photographs taken by De la Rue and by Secchi of the total solar eclipse in 1860 were the first of this kind of real scientific importance, since they established beyond doubt that the solar protuberances were really appendages of the sun and not of the moon. Ten years later, at the eclipse of Dec. 12, 1870, excellent photographs taken by A. Brothers at Syracuse supplied evidence that the corona was also of solar origin; and from that time a photographic picture of the sun's surroundings has always been an item in the programme of eclipse observation. A series from 1896 to 1922 is published in the *Phil. Trans.* vol. 226 A, and as Appendix to vol. lxiv. of the *Memoirs* of the Royal Astronomical Society.

In the years after 1870 research and experiment in photography generally were made by many, among these being the researches of Capt. W. de W. Abney, R.E., made specially for their application to astronomy. It was decided, mainly at the instigation of De la Rue, that photography should be used by the British expeditions in addition to visual observation for the Transit of Venus in 1874, and a considerable sum was granted for the expense of the work, which, so far as the process was concerned, was put in Abney's charge. He realized that the circumstances of the occasion would make a wet-plate process inapplicable and, after experiments conducted at Chatham, recommended the adoption of an albumen dry process, using a highly bromized collodion and strong alkaline development.

Without attempting to give any complete account of Abney's researches mention of the titles of two papers by him—*On Dry Plate Processes for Solar Photography* and *On the Photographic Method of Mapping the Least Refrangible End of the Solar Spectrum*—will indicate their bearing on astronomy. These papers represent a remarkable achievement in that Abney succeeded in producing a special photographic emulsion, sensitive to red light, which he used to map the solar spectrum far into the infra-red. The limit of Abney's measures at 9867Å apparently was not

reached by any other investigator until the introduction of neocyanin as a sensitizer in 1926.

It was pointed out by the younger Bond that photography might be successfully used to measure the relative positions of stars, of a group, or of double stars and in a letter to the Hon. William Mitchell, dated July 6, 1857, predicted, in effect, the application of photography to stellar astronomy on the magnificent scale that actually exists to-day. Rutherford, in 1864, began to make a long series of photographs of star clusters and of the bright double stars; but measures of these appear not to have been completed. In 1870–84 Dr. B. A. Gould in an expedition to the Southern Hemisphere accumulated negatives of the principal double stars and clusters; but in taking these series the wet plate process was used, and with this it was not possible to give an exposure long enough for faint stars to imprint themselves. With the invention of the gelatine dry plate, which had been used by Huggins for spectrum photography in 1876 and came into general use about 1880, this difficulty did not exist and modern astronomical photography became possible. Circumstances connected with the comet of 1882, which was specially magnificent as seen from the Southern Hemisphere, led to developments. A photograph, taken with a camera strapped for the purpose to the great equatorial of the Royal observatory of the Cape of Good Hope, showed not only the comet but great numbers of faint stars around it, and this at once gave David Gill, H.M. Astronomer at the Cape, the idea of the possibility of making star charts by photography. Effects of various kinds followed. At Paris the brothers Henry of the National observatory were engaged in the laborious task of plotting the positions of stars found by eye observation to make charts of the stars near the Ecliptic; but this work was abandoned and their efforts were devoted to making a telescopic object-glass suitable for photography. Ainslie Common in England turned to the art and with a three foot silver-on-glass mirror took a photograph of the Orion Nebula on Jan. 30th, 1883, with an exposure of 37 min., a feat that earned for him the Gold Medal of the Royal Astronomical Society in 1884, and was referred to as "epoch-marking" by Abney when presenting the medal to another non-professional astronomer for similar work eleven years later. A photograph of this object taken by Dr. Henry Draper of New York on Sept. 30, 1880 is said to be the first of a nebula obtained, but it is agreed that this was not a satisfactory representation. The later recipient of the medal above mentioned was Isaac Roberts, a business man of Liverpool, who in 1885, had made a 20 in. silver-on-glass reflector of nearly a 100 in. focal length for the purpose originally of making star-charts by photography, but altered his plans and devoted the instrument to photographing star-clusters and nebulae. The excellent pictures produced at his observatory at Crowborough, Sussex, are in two volumes published during his lifetime, supplemented by a third prepared and issued by his widow in 1928.

Common's photograph of the Orion nebula led, through Holden, to the acquisition by the Lick Observatory of a 3-foot reflector in 1895. Two mirrors made by Calver, formerly owned by Common, were presented to that institution by Mr. Crossley of Halifax, England, and one of these, refigured by Grubb, forms the essential part of the instrument known by his name. In Keeler's hands it yielded a superb series of photographs of nebulae which for the first time demonstrated the great advantages of the reflecting telescope for certain classes of astronomical photography and led to the construction of the great modern reflectors.

Charts of the Heavens.—The advantage that photographs of clusters and nebulae have over visual observation is obvious. A glance at a photograph shows the whole of the object in all its beauty. The field of view of a telescope is small, and a complete conception of the nebula has to be built up from successive elements. It has already been mentioned that Gill foresaw the possibility of recording the positions of stars from a single plate; the next step was to connect individual plates to make a complete survey of the heavens, as had been, and is, the final aim and purpose of transit-observing. The first effort in this direction was made by Gill, who (1885–89), took photographs covering the sky from the South Pole to declination 18° S. which, measured by

Kapteyn of Groningen, gave approximate co-ordinates and magnitudes of nearly half a million stars that form the Cape Photographic Durchmusterung. In a more ambitious scheme initiated in 1887 by Admiral Mouchez, director of the Paris observatory, 18 observatories of the world combined to make the Astrographic Chart, or a picture of the whole sky, which should show all stars down to the 14th magnitude, to which was added later the making of a catalogue of all stars to magnitude 11, now considered the more important part of the work. Space does not permit description of its details and methods. It must suffice to say that a great portion of the catalogue is already published and that, though some sections of the Chart are completed, the end is not yet in sight.

In this connection mention is to be made of a series of plates that came later, taken by Franklin Adams, a man well known in business circles in the City of London, in 1903, 1904, at the Cape of Good Hope and afterwards at Godalming, Surrey, with a photo-visual objective (v. p. 837) of 10 in. diameter, devised for the work by the firm of Cooke and Sons. These plates each cover an area of $15^{\circ} \times 15^{\circ}$.

The extreme delicacy of the gelatine film, especially during development and fixation, led in the beginning to a certain distrust of measurements made on photographic plates. Experience has shown these fears to be groundless and that photographic methods are well suited to measurements of the most exacting kind. With properly designed instruments, the economic factors are also favourable. A recent undertaking, proposed by Schlesinger, which effectively utilizes these advantages, is the photographic reobservation of the zones of the great Astronomische Gesellschaft catalogue, originally measured with meridian circles at many different observatories. As an early example of astronomical work effected by the measurement of photographs mention may be made of the determination of stellar parallaxes by Pritchard at the Oxford University Observatory in the year 1887, and the remark made at that time that this initiated a new method of finding the distances of stars is amply justified, for to-day many observatories are pursuing that plan. Most researches that depend on the measurement of small distances are now made by means of the photographic plate, close double star observing being an exception. Hertzprung has devised methods involving the use of a grating and colour filters to ensure freedom from error in finding the distance between the components of double stars and their position angles, but it is considered that the photographic method is unsuited for pairs whose separation is less than about a second of arc. Photographing stars through a grating of parallel wires placed before the objective, which produces a pair, or perhaps a series of pairs of diffraction images of each star, is a scheme practised in other branches of modern astronomy and astrophysics.

Besides the advantages already mentioned, others that pertain to the sensitive plate are that its receptivity is cumulative; by continued application it can see where the eye is blind. The impressions are permanent and constitute evidence that can be referred to at pleasure. Faint comets are discovered by photographing the region in which the object is believed to lie and searching the developed plate. A similar method for finding minor planets has been very fruitful and examination of the series of celestial photographs of the Harvard College Observatory has brought to light many Novae that have appeared in past years but have escaped detection. This collection of photographs which has been accumulated systematically over many years constitutes a record of the state of the sky at approximately regular intervals. It has been especially fruitful in the discovery of variable stars.

Modern Applications.—Besides lending its aid to these branches of astronomy of the older kind, photography is now an asset in the newer astrophysics. It was recognized early that the brighter the star the larger the image it imprints on the plate, and hence that it is possible to use photography for purposes of photometry. The relation between the size of the image and the intensity of the star's light is complicated. So many factors difficult of control are involved that an empirical method of calibration is usually employed, though some progress has been made with methods based on the laws of photographic action. Usually a star

is not of the same magnitude photographically and visually because the ordinary plate is sensitive only to the blue and violet rays of the spectrum, whereas it is the yellow light that mainly affects the eye. Since the relative amount of blue and yellow light depends on the colour of the star, the difference between photographic and visual magnitude varies with colour. This difference—colour index—affords a useful measure of this physical characteristic, and, through this, of the star's temperature. Visual magnitudes may be closely reproduced by photographing stars on colour-sensitive plates, through a filter which cuts out the blue and violet light and transmits the green and yellow. The whole field of stellar photometry is thus brought within the reach of photographic methods, with a great gain in precision and homogeneity of results. The equivalent of visual magnitude determined photographically is called photo-visual, and by comparing this with the ordinary photographic magnitude colour index is determined free from any personal eye effects. The colour index of a star correlates with its spectrum, and takes its place as a quality that can be discussed in relation to others such as temperature, mass and motion.

A slight extension of the method has led to interesting and important results in connection with nebulae.

A comparison by Hale of ordinary photographs of the Orion nebula with exposures on panchromatic plates through a red filter shows conspicuous differences in colour in different parts of the nebula which indicate a variation in the mixture and radiation of its gaseous constituents. Again, similar photographs of spiral nebulae by Seares show that the central nuclei of these objects are yellow, in agreement with spectroscopic results, but that the knots and condensations on the spiral arms are blue. These results indicate a characteristic difference in physical conditions in different parts of these nebulae.

Photography through coloured screens or filters of various kinds has been applied recently to the planets. Photographs of Mars and of Jupiter, by Wright of the Lick Observatory, taken with rays of the infra-red portion of the spectrum, with yellow light, and with ultra-violet rays, show distinct differences, consideration of which appears to lead to knowledge of peculiarities of the surfaces and atmospheres of these bodies. Similar photographs of Venus by Ross give important information bearing on the physical characteristics of this planet.

Colour photographs of the kind described represent a crude kind of spectrum analysis, in which attention is directed to the total radiation over a considerable range in wave-length rather than to the number, position and intensity of the spectral lines. The method is important and useful for objects too faint for detailed spectroscopic examination.

The astronomical applications of photography would be seriously restricted were there no means of extending the normal blue-violet sensitivity of the ordinary photographic emulsion.

Vogel in 1873 discovered that various dye substances, notably naphthalinrot, conferred sensitiveness to other spectral regions. His results were confirmed and extended by Becquerel; by Waterhouse, who discovered the efficiency of eosin; by Eder, who introduced erythrosin; and by many others. To Vogel is due the discovery of the effectiveness of cyanin as a red sensitizer, and Miethe, E. König and Homolka, 1898–1905, made extensive studies of a great number of others, which led shortly to the production of panchromatic plates. Dicyanin and, more recently, kryptocyanin and neocyanin have played a great part in extending the sensitivity far into the infra-red. All modern research in colour sensitization has been concerned with the study of dye substances. Abney's special red-sensitive emulsion seems never to have been reproduced.

The first great astronomical achievement resulting from the preparation of colour-sensitive plates was Abney's map of the infra-red region of the solar spectrum to which reference has already been made; the next, Rowland's photographic map of the solar spectrum and the Table of Wave-Lengths of Spectrum Lines, extending from 2975Å to 7331Å, from measurement of photographs. Rowland himself made the photographic plates that he used; the method of colour sensitization he employed is unknown. A recent application of colour photography to astronomy led to Hale's

discovery of magnetic fields in sun-spots. Using Wallace's 3-dye sensitizer consisting of pinacyanol, pinaverdol, and homocol, Hale photographed with the spectroheliograph the distribution of hydrogen (Ha) over the solar disc. The presence of vortex structure centered about sun-spots suggested the possible existence of magnetic fields, which special observations soon fully confirmed.

Spectroscopic observation itself is now almost entirely photographic. In 1863 Huggins obtained photographic images of the spectra of Sirius and Capella but no clearly defined lines were shown, and attempts of this kind were suspended for some years. It is said that the first photograph showing spectral lines of a star was taken by Henry Draper in 1872, and in the years immediately succeeding both these astronomers were successful in this way with the brightest stars. In 1882 each of them obtained a satisfactory photograph of the spectrum of the Great Nebula in Orion. In 1886 a new spectrographic method was initiated at the Harvard College Observatory in connection with a scheme known as the Draper Memorial, a prism being placed before the objective glass by which the spectra of all the stars in the field are formed and photographed simultaneously on the plate. The instrument then used was a photographic lens of 8 in. aperture with a prism 8 in. square fastened before it. The refracting angle of the prism was 13° , and the deflecting edge was placed parallel to the equator, so that breadth could be given to the spectrum by altering the rate of the driving clock. Stars to about the 7th magnitude were thus shown. In 1887 Vogel introduced the photographic method at the Astrophysical Observatory at Potsdam for the determination of stellar radial velocity, and from that time, which is generally said to mark the beginning of accurate work of the kind all important spectroscopic work has been done in this way. Improvements and refinements in design of the spectrograph, especially the introduction of a temperature control for use during observations, were made by Campbell at the Lick Observatory. These afforded a new standard of precision in spectroscopic measurements, and led to an extended programme involving the systematic observation, at Mt. Hamilton and at Santiago, of 6,182 stars mostly brighter than visual magnitude 5.51. The resulting catalogue of radial velocities, issued in 1928, could not have been prepared without the aid of photography.

Photographic methods have proved themselves equally indispensable in every other field of spectroscopic observation. The measurement of the distance of a star from observations of its spectrum, by a method discovered by Adams and Kohlschütter and developed by Adams at Mount Wilson, essentially requires the determination of the relative intensity of certain pairs of spectral lines. Star light, in general, is far below the limiting intensity which would permit even the crudest visual observation of these intensities, and this is often true of laboratory sources of light which must be studied as a means of interpreting the observations of celestial bodies. Even for the sun, which gives an abundance of light, measures are most advantageously made on photographs. In the infra-red and ultra-violet regions, outside the limits of visual perception, photographic methods alone are possible. The novel instrument known as the spectroheliograph conceived independently by Prof. Hale and M. Deslandres, director of the National Observatory, Paris, is an ingenious adjunct to spectral photography. On a plate moving behind a second slit at the rear of a spectroscope at the same rate as the image crosses the primary slit, or by an equivalent device the sun is photographed by the light of a particular wave-length and pictures result which show the calcium or the hydrogen alone, in the successive envelopes of the sun, and so add vastly to our knowledge of its structure. The help that photography brings to eclipse observation by making a complete record of the spectrum of the chromosphere or of the corona in the very short time available on such occasions, that may be studied at leisure, need not be dwelt on.

Photographic Telescopes.—In the ordinary telescopic objective the lenses are so shaped that the rays of the spectrum about the yellow are brought as nearly as possible to pass through the same point as focus, for these are the rays to which the eye is sensitive, but for photography it is the blue and violet rays that must be brought to a focus, for it is these that most affect the

plate. An objective of two lenses may be made to do this, but necessity has led to the making of photo-visual objectives of three lenses that are perfectly or nearly achromatic, and focus all the rays (*v.* p. 836, Franklin-Adams). It is possible to use a visual telescope for photography by adding a correcting lens, or another scheme for the purpose, adopted for the 40 in. refractor of the Yerkes observatory about 1900, is to take photographs through a yellow colour screen or filter placed almost in contact with a yellow-sensitive (Cramer instantaneous achromatic) photographic plate. The yellow screen transmits freely to the plate the sharp yellow image produced by the visual objective and excludes the blue and other wave-lengths which would otherwise destroy the sharpness of the photographed images. Numerous experiments have since been made to find the most suitable filters and plates for special purposes.

Since the mirror brings all rays to the same focus the reflector has an advantage over the refractor. The field of view of the reflector, however, is relatively small. For a focal ratio of 1 to 5 the aberrations of the reflector are disturbing at distances from the optical axis exceeding $12'$ to $15'$, and there is considerable loss in limiting magnitude for even smaller distances, whereas a properly designed refractor affords excellent definition over a field several degrees in diameter. Measures with reflectors are therefore limited to double stars or satellites of planets, or to the determination of proper motions and parallaxes, etc., while the refractor finds advantageous application to general charting and cataloguing purposes.

That the optical possibilities are by no means exhausted is indicated by the quadruplet lens recently designed by F. E. Ross which, with an aperture of 3 inches and a focal ratio of 1 to 7, gives excellent definition over a field of 25° , and in two hours exposure reaches a limiting magnitude of 15.4.

The choice of aperture and focal ratio for a photographic telescope depends on the purpose for which the instrument is to be used and is determined by the same principles that apply in ordinary photographic practice. Increased focal length means increased scale or magnification in the photograph. For a given focal length, increased aperture means greater brightness in the optical image, and hence greater photographic efficiency, which may be utilized either to reduce the exposure time or to photograph fainter objects than would otherwise be possible. For extended objects like planets or nebulae, the brightness of the image is proportional to a^2/f^2 . The photographic efficiency is independent of the linear dimensions, and the chief advantage of a large instrument is that of magnification. At the same time, the instrument must not be too small, otherwise the power of resolution or minimum separation which varies inversely as the aperture, will suffer. For point sources, such as stars, the diameter of the central diffraction disc of the image decreases as the aperture increases. This introduces an additional factor a^2 , whence the brightness is proportional to a^4/f^2 . For a given focal ratio there is in this case an important gain in efficiency with increasing aperture, although it is less than the elementary theory would indicate. Aberrations and absorption and reflection losses in the objective, imperfections in the optical surfaces, and tremor of the diffraction disc, caused by atmospheric disturbances, all operate in diminishing the theoretical gain.

The application of these principles to different classes of observational problems is well illustrated by some of the instruments of the Mount Wilson Observatory. For observations of the sun, both direct and spectroscopic, high magnification is desirable. Since there is an abundance of light, the focal ratio need not be large; and, further, since a moderate aperture affords adequate resolution for photographic purposes, the dimensions chosen for the larger Tower telescope are $a = 1$ foot, $f = 150$ feet, with a ratio of 1 to 150. For the efficient photography of very faint stars, both the focal ratio and the linear dimensions should be as large as possible. Hence in the Hooker reflector we find $a = 100$ inches, $f = 500$ inches, with a ratio of 1 to 5. Under favourable atmospheric conditions, the theoretical gain over the 60-inch reflector, of the same focal ratio, in photographing stars is very nearly attained. Aside from differences of scale, these two instruments are of equal efficiency in photographing nebulae. For planets, however, the 100-in. is practically the more effective. For the same magnification (enlarg-

ing lenses are commonly used in planetary photography) this instrument gives a brighter image than the 60-inch reflector. This permits the use of shorter exposures, which avoids in part the blurring produced by atmospheric disturbances. The useful field, the same for both reflectors, is necessarily small (*v. p.* 837). For photographs covering a large field, a triplet refractor is available ($a=10$ inches, $f=45$ inches, $a/f=1/4.5$). Because of the focal length, the scale is small. Otherwise, this instrument is of about the same efficiency for nebulae as the large reflectors, and because of the large field, is very advantageous for photographing widely extended masses of nebosity. Its large focal ratio makes it an efficient instrument for stars, although the limiting magnitude attainable falls far short of that reached by the reflectors.

The limiting stellar magnitude attainable with a given instrument, as shown by F. E. Ross, does not increase indefinitely as the exposure time is extended. In order that a perceptible image of a star may be recorded, the contrast between sky illumination, which is always present in some degree, and sky illumination plus brightness of the central diffraction disc of the star image, must not drop below a certain minimum value. The effect of sky illumination is determined by the ratio a^2/f^2 ; with the reservations expressed above the brightness of the optical star image varies as a^4/f^2 . Increase in the linear dimensions increases the latter, but not the former ratio. These ratios, together with certain photometric constants, determine the limiting magnitude attainable by prolonged exposure with any instrument. To photograph still fainter stars an instrument of larger aperture must be used.

The plate may be placed in the principal focus of the objective, and the image enlarged afterwards if desired; but the amount of the subsequent enlargement is limited by the grain of the original negative, which is equally enlarged by the copying process. On the other hand, a lens or combination of lenses may be interposed between the objective and the plate to give an enlarged image on the latter. In the Greenwich photoheliograph the image of the sun is enlarged on the plate in this way and the method is often used in planetary photography. For bright objects it is advantageous; but for fainter ones the exposures required may be impractically long. The contrast also suffers, but this may be corrected by subsequent copying on plates of strong contrast.

In the early days of astronomical photography the inferior performance of the driving-clock of the equatorial was found to be a drawback, but this has been remedied, first by the introduction of electrical control and later by improved forms of drive mechanism of which the electro-motor controlled by a pendulum designed by W. P. Gerrish of Harvard is an example. The slight residual irregularities are eliminated by the use of the twin instrument consisting of two parallel telescopes of nearly equal size in the same frame, one of which is used visually by the observer to guide; or otherwise by the double-slide plateholder and duplicate guiding microscopes, to be used on two guiding stars on opposite sides of the field to detect the small rotation which may occur during exposures. (H. P. H.; F. H. S.)

PHOTOGRAPHY, SPARK: see SPARK PHOTOGRAPHY.

PHOTOGRAVURE (MACHINE). Photogravure (machine printed) is a photo-mechanical intaglio printing process. By this method prints are obtained from a plate or cylinder upon which the design is etched below the surface.

The subject to be reproduced is photographed and "reticulated" by means of a ruled screen, the "cavities" varying in depth according to the tones of the original; thus the solids are deeper and contain more ink than the middle tones, while the high lights are represented by the paper. The characteristic of this class of printing is revealed by its velvety depths and satin-like finish.

Machine photogravure was invented by Karl Klietsch, who, in conjunction with a firm of calico printers in Lancaster, produced prints by this method in 1895, although previous to this an employee of the firm, Samuel Fawcett, had been working an intaglio photo-engraving process of his own. The latter assisted Klietsch in perfecting the process now known as "Rembrandt" photogravure. The method of producing prints by the Rembrandt process was kept a close secret, and for many years those

interested in reproductive processes had no authentic information as to how the printing plates were produced. In time, however, prints by similar processes were published, but these, at the time, were not equal to those printed by the Rembrandt process.

The principle of producing photogravure prints by machine is similar to that of printing calico and wallpaper, where engraved copper cylinders are used and printed on a rotary machine.

After the etching of the photogravure plate or cylinder has been completed the printing is of a mechanical character. The etched cylinder turns in a trough of printing ink of volatile qualities (sometimes a "water ink" is used), and as the cylinder rotates a fine steel knife, known as the "doctor," scrapes the surplus ink from the surface, leaving it clean. The cells or cavities, however, representing the tones of the design, retain the ink, which is transferred to a sheet of paper as it passes between the printing and impression cylinders.

Preparing the Printing Surface.—From the photographs of the subjects to be reproduced negatives are obtained. These are carefully retouched and reversed positives are made from them and, when necessary, again retouched. The positives—usually called transparencies—have then to be "planned" or laid out, *i.e.*, fixed by means of gummed tape upon a sheet of plate glass in the positions in which they will be printed.

A carbon print is next obtained on what is known as "carbon tissue" (a sheet of paper coated with a gelatine solution to which has been added a pigment—usually red—and sensitised by immersion in potassium bichromate, squeezed on to a sheet of glass, and dried). A piece of carbon tissue is cut slightly larger than the positives and placed along with the positives in a special pneumatic printing frame from which the air is extracted, thus bringing the positive and tissue into close contact. These are exposed to light, the positives are removed, and another exposure is given to the tissue through a specially ruled screen. The screen "breaks up" the tones of the photograph and provides the reticulation which is necessary for all printing processes. The usual ruling of the screen is 150 or 175 lines to the inch. The carbon tissue is next soaked in water and placed on the copper plate or cylinder which has previously been made chemically clean and free from grease. The tissue is then "squeegeed" in order to remove all moisture and air from between the tissue and the printing surface, which is then dried.

Developing.—The next operation is known as developing, and is done by placing the cylinder or plate, on which the carbon tissue has been fixed, in a tank of water heated to about 104° F and kept agitated until the paper is soaked off and the soluble parts of the gelatine film washed away. The parts where the light passes right through the positive become hard and are insoluble, whilst those parts where the light is retarded by the tones in their various gradations are more or less soluble.

When the development is completed the cylinder, with all that is left of the gelatine film, is removed from the water bath and thoroughly dried. This film acts as a resist to the mordant. All parts of the printing surface which are not required to be etched are protected by an acid-resisting preparation. This is painted on by hand, or, as it is termed, "lacked out."

Etching.—The printing surface has then to be etched, which is done by placing the cylinder in baths of varying concentrations of ferric chloride ranging from 45° to 37° Beaume. The thinner parts of the hardened gelatine acid resist are attacked first by the mordant, the thicker parts requiring further etching by the weaker solutions.

It is possible to use the copper cylinders over and over again, the old work being removed by grinding and polishing. In this way cylinders are prepared to receive the new work. In time, however, the grinding wears the cylinder, but this may be brought back to its original circumference by electrolytic deposition.

Machines.—Sometimes flat plates are used. In this instance the machine is of an ordinary flat-bed type upon which a plate is mounted on a bed and covered over with ink, the "doctor" scraping the surplus ink from the face of the plate back into the trough; the general method, however, is to employ cylinders.

Recently, a method has been invented whereby a thin sheet

of copper is stretched round a cylinder. There is reason to believe that this will supersede the cumbersome cylinders now in use.

The paper is fed into the machines either one sheet at a time or from a reel. The sheet-fed machine is generally used for small editions of art reproductions, whilst those that are reel-fed are used for long runs of magazines and newspaper supplements and other commercial requirements.

In a rotary press the cylinder revolves in a trough of ink, and a few inches above the trough is a "doctor"—a steel plate with a fine edge which has a slight reciprocating movement that scrapes the surplus ink off the surface, the ink dropping back into the trough. The paper, which is on a reel, passes between the etched cylinder and an impression cylinder. In this way an impression of the etched design is transferred to the paper. The paper then passes over a drying drum, and if the sheet is to be "perfected," *i.e.*, printed on the reverse side, it goes through another pair of cylinders before reaching the delivery end of the machine, where the paper is cut up into sheets or delivered folded according to requirements.

It is possible by the photogravure method to print type matter at the same time as illustrations, and successful results are now being obtained when printing colour supplements by machine photogravure.

Machine printed photogravure is known under various names, usually containing a prefix, such as rotogravure, indicating that it is printed on a rotary machine.

PHOTO-LITHOGRAPHY: see LITHOGRAPHY.

PHOTOMETRY is, as its name signifies, the measurement of light (Gr. $\phi\acute{\omega}\varsigma$, $\phi\omega\tau\acute{\omicron}\varsigma$, light, $\mu\acute{\epsilon}\tau\rho\nu$, a measure). Just as metrology includes the measurement of various related quantities, *e.g.*, length, volume and density, so photometry includes the measurement of luminous intensity (candle-power), luminous flux, illumination and brightness. It will be convenient first of all to consider the relationships between these four fundamental quantities and the units in terms of which they are expressed, so that the methods of measurement adopted for each may be more readily understood. Every object which can be seen emits or reflects radiant energy in the form of aether waves which are capable of affecting the retina of the human eye so as to produce the sensation of light. In the case of a self-luminous body (or source of light) such as the sun, a candle or an electric lamp, the light emitted is obtained by the transformation of some other form of energy, generally chemical or electrical. In the case of a body which is not self-luminous the light which it sends to the eye is derived originally from some self-luminous body, and is reflected by it in a manner depending on the character of its surfaces.

The effect produced on the eye by the reception of a given amount of energy per second depends on the wave-length (λ) of the aether waves by which that energy is conveyed; in fact only those waves for which λ lies between about 400 and 750 millionths of a millimetre $m\mu$ can produce the sensation of light at all. As the wave-length changes from the shorter of these limits to the longer, the effect produced on the eye alters in two respects. In the first place the colour of the light changes from violet, through blue, green, yellow and orange to red. In the second place the intensity of the sensation produced by a given rate of influx of energy starts from zero at 400 $m\mu$, rises to a maximum at $\lambda = 555 m\mu$, and then gradually falls away again to zero at 750 $m\mu$. The curve of fig. 1 shows the relative magnitudes of the visual effect produced by the reception of equal amounts of energy per second at different wave-lengths. This curve is called the *lumi-*

nosity curve (sometimes the *visibility curve*) of radiant energy. It is naturally slightly different for each individual, but the curve shown is that now adopted internationally as representing the effect on the "average eye." The scale of ordinates at the left is an arbitrary one so arranged that the ordinate of the curve is unity at the wave-length of maximum luminosity. On this scale the ordinate corresponding to any wave-length is termed the "luminosity factor" of radiant energy at that wave-length.

Luminous Flux.—The light given by every source in common use is composite in character, *i.e.*, the energy is conveyed by waves of various lengths, the distribution of energy among these wave-lengths (or the *spectral energy-distribution*) depending on the source. It is clear that the total effect produced on the eye by a given rate of emission of energy of known spectral distribution can be determined by weighting the energy content at each wave-length in accordance with the *luminosity factor* for that wave-length. The quantity obtained in this way represents, in fact, the efficacy of the energy for producing the sensation of light, and this quantity is termed *luminous flux*. The formal definition of this term is: The rate of passage of radiant energy evaluated according to the luminous sensation produced by it

The unit in which luminous flux is expressed can be more simply defined later. It is sufficient here to state that it is called the *lumen* and that it has been found that for the average eye, one watt of radiant power at the wave-length of maximum luminosity (555 $m\mu$) is equivalent to about 600 lumens. The scale of ordinates at the right of fig. 1 gives the lumen equivalent of 1 watt of power at each wave-length. The watt equivalent of 1 lumen of flux at the wave-length of maximum visibility, *viz.*, 0.0016 watt per lumen, is often termed the *mechanical equivalent of light*.

Luminous Intensity.—The luminous flux emitted from any practical source of light is not distributed uniformly in all directions. In the case of an electric lamp of the vacuum type, for instance, the flux emitted within a cone of given solid angle is greater when the axis of the cone is horizontal than when it is vertical. It follows that some quantity is needed to express the light-giving power of a source in a specified direction. The natural quantity to use for this purpose is the angular flux density in the direction considered. This will be clear from fig. 2. If BLC be a cone of very small solid angle ω , having its apex at L, the position of a source of light, then the angular flux density in any direction such as LA is equal to the flux emitted by L within the cone BLC, divided by the solid angle ω , the ratio being taken in the limit when ω becomes vanishingly small. This ratio is termed the *luminous intensity* of the source L in the direction LA. It will be seen that the definition of luminous intensity is analogous to that of pressure at a point, *viz.*, the ratio of the force exerted on a given surface containing the point to the area of that surface, the ratio being taken in the limit when the area is vanishingly small. The formal definition of luminous intensity is as follows:—The luminous intensity of a point-source in any direction is the luminous flux, per unit solid angle, emitted by that source in that direction. (The flux emanating from a source whose dimensions are negligible in comparison with the distance from which it is observed may be considered as coming from a point.)

The relation between luminous flux and luminous intensity being thus defined, it is possible to choose units for these two quantities such that their magnitudes are related rationally to each other. It so happens that, for historical reasons, the primary photometric unit is that of luminous intensity. This unit is the *international candle*, the magnitude of which was originally defined as the luminous intensity, in the horizontal direction, of a candle of specified dimensions burning at a specified rate. Many years ago this form of standard was found to be unsatisfactory, and it was replaced by flame lamps of various kinds, *viz.*, the Hefner in Germany, the pentane in this country and in America, and the Carcel lamp in France. These standards have been generally abandoned, however, and the magnitude of the unit is preserved by means of specially constructed electric lamps deposited

FIG. 1.—LUMINOSITY CURVE OF RADIANT ENERGY FOR THE AVERAGE EYE

FIG. 2

at the various national laboratories throughout the world, viz., the Laboratoire Central d'Electricité, Paris; the National Physical Laboratory, Teddington, England; and the Bureau of Standards, Washington. The formal definition of the "candle" is as follows:

The unit of luminous intensity is the international candle, such as resulted from agreement effected between the three national standardising laboratories of France, Great Britain and the United States in 1909. The unit of luminous flux is now very simply obtained from that of luminous intensity by considering an ideal source of light which has a uniform luminous intensity of one candle in all directions. The lumen is the amount of flux emitted by such a source within a cone of unit solid angle.

The relationship is shown pictorially in fig. 3 where the ideal point source is imagined at the centre of a sphere of unit radius.

FIG. 3.—RELATION BETWEEN THE PHOTOMETRIC UNITS

Since the solid angle of any cone with its apex at the centre of such a sphere is numerically equal to the area of the spherical surface cut off by the edge of the cone, it follows that the cone shown shaded in the diagram embraces unit solid angle, so that the flux emitted by the source within this cone is 1 lumen. Since the area of the whole sphere is 4π times the square on the radius, it follows a uniform point source of 1 candle emits altogether 4 a lumens. Since the total flux emitted by a source is independent of the way in which that flux is distributed, the total number of lumens given by a source is equal to the average value of its luminous intensity, measured in all directions in-space, multiplied by the factor 4π . The luminous intensity of a source, when expressed in international candles, is termed the candle-power of the source. The average value of the candle-power measured in all directions perpendicular to the geometrical axis of the source is termed the mean horizontal candle-power (M.H.C.P.), while the average candle-power measured in all directions in space is termed the mean spherical candle-power (M.S.C.P.). It will be seen that, for any source, $M.S.C.P. \times 4\pi = (\text{flux output in lumens})$.

Illumination: The Inverse Square and Cosine Laws.—Illumination is measured by the amount of luminous flux which reaches unit area of an illuminated surface. From this definition and the fact of the rectilinear propagation of light there follow at once the two basic laws of photometry, viz., the inverse square and the cosine laws. They will be most clearly understood by reference to fig. 2. If BLC be an elementary cone of light emitted from a source L, the area intercepted by this cone on any plane such as XY varies (i.) as the square of the distance (d) of L from the plane, and (ii.) as the secant of the angle (θ) which the normal to XY makes with the axis LA of the cone. Since the illumination produced by a given amount of flux varies inversely as the area over which that flux is distributed, it will be seen at once that the illumination of a surface varies (i.) inversely as the square of its distance from the source illuminating it (this is the inverse square law), and (ii.) directly as the cosine of the angle between the normal to the surface and the light rays (this is the cosine law).

Now let the average luminous intensity of the source L in all directions lying within the cone BLC be I candles, and let the area intercepted by this cone on the plane XY be s. Then the solid angle of the cone is equal to $(s \cos \theta)/d^2$, and the flux F emitted within the cone is $I(s \cos \theta)/d^2$ lumens. Since, by the definition, the illumination, E, of the surface is equal to F/S , it follows that

$$E = (I \cos \theta)/d^2$$

It will be seen that the magnitude of the unit in which E is measured must depend on the unit used for d, i.e., on the unit of length. If d be expressed in feet, the unit in which E is measured is termed the foot-candle and, clearly, one foot-candle is the illumination produced when an area of one square foot receives one lumen of flux. Similarly, if d be expressed in metres, the unit of E

is the metre-candle or the lux, and one lux is equivalent to an illumination of one lumen per square metre. It will be seen that 1 ft.-candle = 10.76 lux.

Brightness.—The last of the four fundamental photometric quantities is brightness, which is thus defined: The brightness in a given direction of a surface emitting light is the quotient of the luminous intensity measured in that direction, by the area of this surface projected on a plane perpendicular to the direction considered. The unit of brightness is the candle per unit area of surface. Thus if a flame of uniform brightness has an apparent area of one square inch when viewed in a given direction, and if the luminous intensity in that direction be 10 candles, the brightness is 10 candles per square inch. Similarly, if a surface has an area of two square metres and if its brightness when viewed normally is one candle per square metre, it has a luminous intensity of 2 candles in the direction of the normal.

The surfaces of bodies may be divided broadly into two classes, polished and diffusing, according as they reflect specularly the light they receive, after the manner of a mirror, or scatter it in all directions. A surface which scatters the light which it reflects or emits in such a way that it appears equally bright in all directions is called a "perfect diffuser." No such surface exists in perfection, but good white blotting-paper, or ground opal glass provide a fair approximation. It is sometimes convenient to use as a unit the brightness of an ideal perfect diffuser emitting or reflecting one lumen per unit area. It can readily be shown that such a surface has a brightness of $1/\pi$ candles per unit area. Thus the following relationships are derived:

$$\begin{aligned} 1 \text{ lambert} &= 1/\pi \text{ candle per sq. cm.} \\ 1 \text{ millilambert} &= (0.001)/\pi \text{ candle per sq. cm.} \\ &= 10/\pi \text{ candles per sq. metre.} \\ 1 \text{ foot-lambert} &= 1/\pi \text{ candle per sq. ft.} \\ &= 1.076 \text{ millilamberts.} \end{aligned}$$

Absorption, Reflection and Transmission.—It has been said already that bodies which are not self-luminous are visible by reason of the light which their surfaces reflect to the eye. It will be clear that, since a surface which has an illumination of one foot-candle receives one lumen per square foot, its brightness would be one foot-lambert if it were a perfect diffuser and if it reflected all the light it received. Actually, all surfaces absorb some fraction (α) of the light which reaches them and reflect or transmit the remainder, or is termed the absorption factor, while the fractions reflected and transmitted are termed respectively the reflection factor (ρ) and the transmission factor (τ). For opaque bodies it is clear that $\alpha + \rho = 1$, while for all surfaces $\alpha + \rho + \tau = 1$. In general the values of these three quantities depend on (a) the direction of incidence of the light on the surface, and (b) its colour. Only in the case of white or grey surfaces is the colour of the light immaterial. The brightness of a surface due to reflected light is clearly equal to $E\rho/\pi$ candles per square foot or $E\rho$ foot-lamberts, E being the illumination in foot-candles and ρ the reflection factor for the particular conditions of illumination and the direction of view considered.

Every photometric measurement depends, ultimately, upon a measurement of the illumination produced at a surface. In the case of candle-power determination, the source to be measured and a standard of known candle-power respectively illuminate two white diffusing surfaces in a photometer head which is, in essence, a device for enabling the eye to compare the brightness of these surfaces as accurately as possible. The chief conditions for accuracy are (a) that the surfaces shall be presented to the eye side by side with the finest possible dividing line, and (b) that the illumination of one or other of the surfaces may be varied according to a known law, so that the two may be adjusted to equal brightness. This is necessary because the eye cannot measure accurately, but can only judge of a condition of equality.

The Lummer-Brodhun Photometer Head.—The form of photometer head generally used to-day for accurate work is the Lummer-Brodhun contrast-head, the construction of which is shown in fig. 4(A). S is a matt white screen, the two sides of which are respectively illuminated by the two sources to be compared. Light from each side of S is reflected by the mirrors (or total

reflection prisms) M_1 and M_2 to the compound glass cube P . An enlarged view of P is shown in fig. 4(B), from which it will be seen that the cube really consists of two right-angled prisms. One of these, P_1 , is plain, while the other, P_2 has its principal face etched or sand-blasted with the pattern shown shaded in fig. 4(C). The two prisms are pressed together so that the unetched parts of the surface of P_2 make optical contact with the surface of P_1 . The

FIG. 4.—THE LUMMER-BRODHUN HEAD

light from M_1 , therefore, is transmitted through these portions just as if there were no discontinuity. The light from M_2 is also transmitted through these portions of the face of P_1 , but over the remainder, the portion shown shaded in fig. 4(C), it is totally reflected and emerges side by side with the light transmitted from M_1 . It will now be seen that if the eyepiece E is focussed on the interface of P , the appearance of the field is that illustrated in fig. 4(C), the portion shown shaded being occupied by an out-of-focus image of the right-hand side of S , while the portion shown clear is filled by the left-hand side of S . Assuming complete symmetry of the instrument, it follows that when both sides of S are equally illuminated, the field of view will appear uniformly bright, and the lines of demarcation of the various parts will almost vanish if P has been skilfully constructed.

It has been found, however, that this is not the criterion of equality which the eye can appreciate with a maximum of precision, and the accuracy of its judgment can be materially improved if the criterion is changed from equality of brightness to equality of contrast. This is easily arranged by placing two thin glass plates G_1 and G_2 (see fig. 4[B]) so that they are respectively in the paths of the light beams occupying the patches R_1 and R_2 of the field of view (fig. 4[B]). Owing to reflection losses at the surfaces of these plates, their interposition causes the brightness of R_1 to be about 9% less than that of the background to R_2 , while R_2 is the same amount darker than the background to R_1 . It will be seen at once that, with this arrangement, if the two sides of S differ in brightness by 1%, the contrast between patch and background, instead of being 9% in both halves of the field, is 8% in one half and 10% in the other, a difference which is much easier to detect than a simple 1% difference of brightness.

The Photometer Bench. — The simplest method of varying the illumination of one of the comparison surfaces in a photometer head is to move one of the sources towards or away from the head. The law of variation of illumination is then the law of the inverse square. The operation may be carried out most conveniently on some type of photometer bench. This may consist of two parallel steel bars, supported at a suitable distance apart by a rigid iron framework. Upon the bars run three carriages which respectively bear the light sources and the photometer head. These carriages run on spool-shaped wheels so that they move easily on the bars. They are provided with means for raising or lowering the sources, and for enabling them to be turned about a vertical axis. Each carriage also bears a framework on which is engraved a line situated in the vertical plane which is at right angles to the axis of the carriage pillar. This framework moves over a graduated

scale attached to the bench framework. By this means the distances between the centres of any two carriages may readily be found.

The most obvious method of comparing the candle-powers of two sources on the bench would be to place them one on each side of the photometer head, and adjust their positions until a balance was obtained. On the assumption that equality of brightness of the two surfaces in the photometer head implied a similar equality of illumination, the candle-powers of the sources, I_1 and I_2 and their respective distances d and d' from the photometer would then be related thus:— $Z_1/d^2 = Z_2/d'^2$. This assumption, although plausible, is never safe in practice and in all accurate photometry at the present time the substitution method is employed.

The Substitution Method. — A "comparison" lamp of constant, but not necessarily known, candle-power is placed in the carriage at one end of the bench, and this carriage is rigidly attached, by means of a rod, to the carriage holding the photometer head so that the two carriages move on the bench as one unit. Thus one side of the photometer field has a constant brightness. Other lamps can now be placed in turn at the other end of the bench, and the distances can be found at which the illuminations they produce at the photometer will give a balance with this constant brightness. These illuminations must, then, be equal to each other so that, if the candle-powers of the lamps be I_1 , I_2 , etc., and their respective distances from the photometer head at the position of balance, d_1 , d_2 , etc., it follows that $I_1/d_1^2 = I_2/d_2^2 = \dots$. Thus if one of the lamps be a sub-standard of known candle-power, the candle-powers of the other lamps are found at once. In all photometry it is most important that only the light directly emitted by the sources to be compared shall reach the photometer head, and stray light from external sources, or that reflected from objects in the room, must be shut off by means of suitably placed black screens.

Although, owing to its convenience, the inverse square law is that most commonly used as the law governing the illumination of one of the comparison surfaces of a photometer head, there are other laws which are adopted, for special reasons in certain types of instruments. The cosine law is seldom employed, but the proportionality between luminous intensity and area in the case of a surface of uniform brightness is sometimes used to provide what is, in effect a comparison source of variable candle-power. The reduction of intensity of a polarized beam by the rotation of a nicol prism placed in its path

FIG. 5.—PRINCIPLE OF THE SUBSTITUTION METHOD ON THE PHOTOMETER BENCH

(see LIGHT) is a favourite device in spectrophotometry (see p. 844), while a transparent plate of graduated transmission factor (e.g., a small-angle wedge of neutral glass), is also useful for special purposes.

The Sector Disc. — A very accurate method of controlling the illumination of a surface is to interrupt the light reaching it at regular and frequent intervals. It has been found that the apparent brightness of a surface intermittently illuminated bears to the actual brightness when steadily illuminated, the ratio of the time of exposure to the total time, provided the intermittency is sufficiently rapid to avoid any appearance of flicker. This law is known as Talbot's law and, though it has no theoretical foundation, it has been proved experimentally that it holds with great accuracy for all ratios down to 3% or less. The law may be applied by placing in the path of the light to be reduced an opaque disc having a radial slot cut in it, so that the light only reaches the photometer as the slot passes between it and the lamp. If, for instance, there are three slots in the disc, each 6° in breadth, the ratio of reduction is 1/20. Such discs are exceedingly valuable as auxiliaries to other photometric apparatus, but it will be clear that, as their reduction ratio is fixed, they cannot themselves be used to produce the variation of illumination needed in a photometer. For this purpose some form of disc with variable sectors is needed, and many attempts have been made to produce satisfactory apparatus of this kind.

The mechanical difficulties are, however, very great and probably the most satisfactory type of variable sector disc is that in which the disc remains stationary while the beam of light rotates. Fig. 6 shows the principle of the apparatus. The light from the lamp is reflected twice, as shown by the fine line, traverses the slot in the disc S and is again reflected so that it resumes its original direction. The reflecting surfaces may be mirrors or, preferably, the 45° surfaces of rhomboidal prisms as illustrated. In any case the four surfaces are rigidly fixed to one another in the relative positions shown, and the combination is rotated about its horizontal axis. It will be seen that the effect at the photometer surface P is precisely equivalent to that which would be produced by lowering the disc and spinning it in the usual way. As, however, the disc remains stationary, there is no difficulty whatever in making it easily adjustable by the observer, while a setting can be at once read off by having a scale on one disc and an index line on the other.

FIG. 6.—BRODHUN SECTOR DISC

Sub-standard Lamps.—The sub-standards used for candle-power measurement are usually tungsten filament lamps of special construction such as that shown in fig. 7. Great care has to be taken in the manufacture of these lamps so as to avoid fluctuations of candle-power due to loose contacts between the filament and its supporting hooks; the bulb, too, has to be specially selected so that there are no striations in the glass to cause slight alterations of candle-power as the lamp is rotated through a very small angle on either side of the position adopted for the standardization measurement. The candle-power of such a lamp is determined at a standardizing laboratory by comparison with the fundamental standards. The value of candle-power measured is that in the direction normal to the plane of the filament, when a given voltage is applied to the lamp contacts or when a given current is passing through the filament. These quantities have to be very accurately controlled since, in the case of a tungsten filament, a 1% change of voltage, or a 0.5% change of current, produces a change of about 3.7% in candle-power.

Flux Measurement.—Owing to the fact that most light sources are now rated in lumens instead of in candles (see the British Standard Specification for Electric Lamps, issued by the Brit. Engineering Stds. Assn.), the measurement of luminous flux has now become an even more important operation in every-day photometry than the measurement of luminous intensity. The fundamental method of finding the flux output of a source is to measure its candle-power in a very large

number of directions uniformly distributed in space, and thus to obtain the mean spherical candle-power which, when multiplied by 4π gives the flux in lumens (see p. 840). This long and tedious process may be avoided in the case of certain sources, such as a tungsten filament vacuum lamp of ordinary filament form, when the light is distributed fairly symmetrically about the axis. Such a lamp can be spun while the photometric measurements are being made, so that the figure of candle-power obtained at any given angle with the axis is, in reality, the mean value in all directions making this angle with the axis. It is therefore only necessary to make measurements in a limited number of directions, say 20, which lie in a single plane passing through the axis of the lamp.

Apparatus suitable for this purpose is shown in fig. 8 which is almost self-explanatory. The lamp is mounted in a holder which can be rotated mechanically at a speed of, say, 150 revolutions per minute. The mirror system can be turned by hand about the horizontal line passing through the centre of the lamp, the photometer head and the comparison lamp. It can be shown that, if the directions in which the measurements are made be suitably chosen, the arithmetic mean of the 20 individual candle-powers gives the

FIG. 7.—TUNGSTEN FILAMENT STANDARD OR SUB-STANDARD LAMP

mean spherical candle-power with satisfactory accuracy. Such a lamp, then, may be used as a sub-standard of luminous flux, and all that is now required is a method for measuring the flux output from more irregular sources by comparison with this sub-standard.

The Sphere.—The method which is almost universally adopted to-day is based on the demonstrable fact that, if a source of light be placed inside a hollow sphere covered internally with some perfectly diffusing coating, the same amount of light is received at all parts of the sphere surface by reflection from all the other parts. The light received directly from the source naturally differs according to the candle-power distribution of the source, but the light which has been reflected once or more often from the walls of the sphere is distributed perfectly uniformly, no matter how unsymmetrical the original distribution from the source itself may be.

It will now be clear that, in order to compare the total flux from two sources of light, it is only necessary to place them in turn within a sphere of the kind described, to screen a small portion of the sphere surface from spherical candle-power (point-to-point method)

illumination of this screened area in the two cases. The ratio of the illuminations will then be strictly equal to the ratio of the flux outputs of the sources. There are, of course, certain precautions which must be observed in the practical application of the method, owing to the unavoidable departures from the ideal conditions assumed in the theory. The chief of these departures are (i.) lack of perfect diffusion by the internal coating of the sphere, and (ii.) the interference with the reflected flux brought about by the presence not only of the lamp and its accessories but also of the screen necessary to shield the measured part of the sphere surface from the direct light of the lamp.

The illumination of the screened area of the sphere surface may be measured by any convenient method. It is clearly unnecessary that this measurement should be absolute, since only a ratio is involved. One method is to have a small opening in the sphere and to cover this with a window of opal glass or some other translucent material. The luminous intensity of the outer surface of this window in the normal direction is then measured by means of a photometer head and comparison lamp moving on a bench attached to the sphere. Alternatively the sphere opening is left uncovered and the luminous intensity of that portion of the sphere opposite the opening is measured.

The difficulty of constructing a sphere has led to the frequent adoption of a cube as a sufficiently near approximation for work of moderate accuracy. When a cube is used, the light source should be placed in the centre, with its axis of symmetry perpendicular to the line joining it to the window, the latter being in the centre of one face of the cube. It is clear *a priori* that, if the light distributions from the sources to be compared are exactly the same, the form of the enclosure employed is immaterial. So long, therefore, as the distributions do not differ too much, a cube gives quite satisfactory results.

Illumination Photometers.—The third photometric measurement of importance is that of illumination. This is now so universal in illuminating engineering that many different types of portable photometer have been designed as illuminometers. Although these differ in design, each consists of three essential parts, viz., (i.) a test plate or standard surface placed at the spot at which the illumination is to be measured and generally, but not always, detached from the remainder of the instrument; (ii.) a surface inside the instrument, which is illuminated by a small battery lamp in such a way that its brightness can be varied at will by the observer, and (iii.) some form of comparison device for

FIG. 8.—MEASUREMENT OF MEAN SPHERICAL CANDLE-POWER (POINT-TO-POINT METHOD)

comparing the brightness of the internal surface with that of the external test plate.

The most natural form of instrument is one in which the inverse square law is used to obtain the necessary variable brightness. Such an instrument consists, generally, of a long tube blackened internally and containing a lamp in a small diaphragmed enclosure. This enclosure is attached to a rod moved by a rack and

FIG. 9.—HOLOPHANE "LUMETER"

pinion so that the lamp may be brought towards or away from a piece of opal glass placed near the end of the tube. The brightness of the opal glass is compared with that of an external test surface by means of a small Lummer-Brodhun cube viewed through an eyepiece attached to the side of the tube. An inverse square scale is attached to the rod and the constant of this scale is adjusted to unity by previous calibration.

An instrument in which the inverse square law is not employed is the *Holophane* lumeter, shown in fig. 9. The lamp L is enclosed in a whitened box of shallow cylindrical form. This box is provided with a window of diffusing glass W, the light from which illuminates the opaque outer parts of the comparison screen S. The eye views the test surface T through the central transparent part of S, and the two parts of the field are adjusted to equality by altering the exposed area of W. This is achieved by means of a cylindrical shutter which can be rotated about the lamp enclosure by means of the handle H. The shutter is provided with an opening of the form shown in the figure. It will be clear that if W is uniformly bright, the scale of the instrument will consist of two parts, one corresponding to each of the breadths of opening, the scale being even within each part.

In most illumination photometers the scale of the instrument may be extended by the provision of neutral glass screens with transmission factors of one-tenth. If these are inserted between the test surface and the eye, the scale is extended upwards, the instrument reading having to be multiplied by 10 or 100 according as one or both of these screens is inserted. If the screens are inserted between the internal lamp and the comparison surface, the instrument reading must be divided by the appropriate factor. The lamp is supplied from some form of portable battery, preferably, an "accumulator." A rheostat and a voltmeter or ammeter are provided for adjusting the current through the lamp to the value at which the instrument was calibrated. This adjustment has to be made with the greatest possible care since, owing to the characteristics of the small battery lamps which have to be used, an error of 1% in the current setting may result in an error of as much as 10% in the readings.

The calibration of every portable photometer should be checked at frequent intervals. This may be done by setting up the test surface at the zero point of a photometer bench and placing a sub-standard of known candle-power at convenient distances from it so as to give even values of illumination at the surface. The test surface should approximate as closely as possible to a perfect diffuser. Ground opal glass or sandblasted opaque white celluloid are frequently used.

Measurement of Brightness and Reflection Factor.—Any illumination photometer which employs a detached test surface may be used for measuring the brightness of a surface, or its reflection factor if it is not self-luminous. This will be made clear by means of an example. When the instrument is set to a reading of, say, E foot-candles, a balance is obtained when the illumination of the test surface has this value. If, now, the reflection factor of this surface be p , its brightness under these conditions is $E\rho/\pi$ candles per square foot, or $E\rho$ foot-lamberts. Hence if, when the photometer is sighted on any other surface, a balance is

obtained at the mark E on the instrument scale, the brightness of this surface must be $E\rho/\pi$ candles per square foot. Thus to convert the scale of illumination on the instrument to a scale of brightness it is only necessary to multiply by the constant factor ρ/π . Similarly, it is clear that, if two surfaces be equally illuminated, their brightnesses are proportional to their reflection factors. It, therefore, a surface of reflection factor p' be substituted for the test surface of an illumination photometer, the reading obtained will bear to the actual illumination the ratio ρ'/ρ where p is the reflection factor of the test surface.

It will be seen that for the measurement of either brightness or reflection factor a knowledge of p , the reflection factor of the photometer test surface, is necessary. This may be obtained by setting up the surface at one end of a photometer bench, illuminating it with a lamp of known high candle-power at a known distance, and measuring the candle-power I of the surface by means of a photometer head and comparison lamp in the ordinary way. If E be the illumination of the test surface in foot-candles and s its area in square feet, $I = \rho Es/\pi$, so that p is found.

Heterochromatic Photometry.—No mention has so far been made of what is, perhaps, the greatest difficulty in a photometric measurement, viz., a difference of colour between the lights to be compared. The modern electric lamp gives light which is much "whiter," *i.e.*, contains a larger proportion of blue, than that given by the carbon filament lamp.

Since the primary photometric standards are carbon filament electric lamps, operating at an efficiency of about 4.8 watts per candle, it is clear that, at some stage or another in the measurement of modern light sources, large colour differences have to be bridged with as little loss of accuracy as possible. There are three generally recognized methods of doing this, viz., (i.) the cascade method; (ii.) the flicker method, and (iii.) the colour filter method based on spectrophotometry. Each of these methods will be described briefly in turn, but mention must first be made of a peculiarity of the eye which complicates the problem. The curve shown in fig. 1 gives the relative response of the eye to equal amounts of energy at different parts of the spectrum. This curve, however, only applies when the brightness of the field of view is 0.15 candle per square foot or over. Below this limit the curve shifts gradually to the left so that at low brightnesses the maximum is at a wave-length of about 505 $m\mu$. It follows that, if two fields are illuminated, one by red and one by green light, it may quite well happen that, when the brightness of both fields is high, the red may appear the brighter of the two, while, if both be reduced in brightness in the same ratio, the balance may appear to shift over so that the green may appear brighter than the red. This effect is known as the Purkinje effect, and it has to be guarded against by ensuring that the brightness of the field of view is well in excess of the limiting value mentioned above.

In the cascade method of heterochromatic photometry, the colour difference between the two lights to be compared is divided into a number of small steps by the interposition of other sources giving lights of intermediate colour. The method, however, is not entirely satisfactory since, clearly, an observer who weights the "whiter" light, will do so throughout the series of comparisons, and so his errors at each step will add up in the final result.

The Flicker Photometer.—The flicker method depends on the fact that, when the field of view is illuminated alternately by lights which differ in colour and in intensity, flicker due to colour difference vanishes at a lower speed than flicker due to brightness difference. A photometer head constructed on the flicker principle is designed so that the two surfaces which make up the comparison field are presented to the eye, not side by side, but one after the other in rapid alternation. At low speeds the field is observed to flicker whatever the position of the photometer head, but as the speed is raised the flicker gradually decreases until finally it can be made to disappear at one position of the head only. If the speed be maintained at this critical value, a slight movement of the head from the position of balance causes a flicker to appear. The critical speed depends on the colour difference between the lights, being naturally higher the larger the difference. Any increase in speed beyond that just necessary to

remove flicker at the point of balance results in a decrease of sensitivity. It is therefore a first essential of any flicker photometer that it should be provided with an easy and rapid speed adjustment.

It is by no means self-evident that the results obtained by this method will agree with those obtained either by the cascade method or by a direct comparison involving the whole colour

FIG. 10.—FLICKER PHOTOMETER

difference and carried out by a large number of observers using, say, the Lummer-Brodhun photometer. Much experimental work has been done on this subject and it has been found that the two methods are in agreement when the following conditions are complied with in the flicker measurement: (a) a flicker field of about 2° diameter, and (b) a field brightness of about 8 candles per sq. metre. Since a 2° field is very small, and is most tiring for continuous work, the flicker field should be surrounded with a steady extended field of the same or slightly lower brightness.

Many different types of flicker photometer have been developed. Of the more accurate, the one shown in fig. 10 is, perhaps, the simplest in principle, and will serve to illustrate the method. S is a white surface illuminated, by way of the total reflection prism P, by the light from one of the sources to be compared. W is a sector disc, which can be rotated at any desired speed about a horizontal axis. Its surface is white and is illuminated by the other source of light so that, when viewed by the eye at E, the field of view seen through the small aperture A is alternately occupied by W and by S. A is of such a size as to subtend an angle of 2° at E. It is cut with a sharp (back-bevelled) edge in a concave surface F, which is evenly illuminated by the small lamp L. L is adjusted to give F a brightness of about 8 candles per square metre, and the distances of the sources to be compared are then arranged so that the brightness of the field at A has approximately the same value. The test lamp and photometer are then fixed and measurements are made by moving the comparison lamp, the speed of rotation of W being reduced until flicker can be made almost to disappear. Settings of the comparison lamp are then made to the point of minimum flicker. It will be noticed that the criterion of equality used in this instrument is not disappearance of flicker but minimum flicker, as it has been found that in practice this gives a rather more sensitive test of the balance point.

The Spectrophotometer.—The third method for overcoming a colour difference in photometry is to place between the photometer head and one of the sources of light a sheet of some transparent medium of such a colour that it produces a colour-match with the light from the other source. If, then, the transmission

factor of this medium be known for the light given by the source with which it is used, the problem is solved. The only method of obtaining this information is to determine (a) the spectral energy distribution of the source, and (b) the transmission factor of the medium at each wave-length. The overall transmission factor τ is then given by $\int \tau_\lambda K_\lambda E_\lambda / \int K_\lambda E_\lambda$, where E_λ is the energy emitted by the source in a given wave-length interval at wave-length λ and K_λ is the corresponding luminosity factor.

The instrument used for determining both the above sets of data is called a *spectrophotometer*, since it is essentially a device for enabling the intensities of two lights to be compared at any given part of the spectrum instead of as a whole. Every spectrophotometer, therefore, consists of two parts, (i.) a spectrometer (see SPECTROSCOPY) for enabling any given wave-length interval of the lights to be isolated, and (ii.) some device for causing the portions of the lights so selected to illuminate the two parts of a comparison field, and a means for altering the brightness of one part of this field.

The principle will be made clearer by means of an example. Fig. 11 shows diagrammatically the Lummer-Brodhun instrument which consists of an ordinary spectrometer with the addition of a second collimator C_2 and a Lummer-Brodhun cube. The latter is constructed similarly to the cube used in the ordinary photometer head (see p. 841) but the form of the field is that shown in fig. 11. The two sources to be compared respectively illuminate the slits of C_1 and C_2 which may be covered with diffusing glass. For the adjustment to a photometric balance various devices may be used, e.g., a variable slit in one collimator, alteration of the distance of one source from its slit, a sector disc or neutral wedge in one beam, or a pair of nicol prisms (one capable of rotation through a measurable angle) mounted in one of the collimators. The last-mentioned device is used in the Brace-Lemon instrument which is a modification of the Lummer-Brodhun spectrophotometer, the dispersing prism being used also to form the comparison field. This prism is shown in fig. 11. As in ordinary photometry the substitution method is generally employed. The source used as a standard of spectral distribution is frequently a tungsten filament

FIGS. 11, 11A.—LUMMER-BRODHUN SPECTROPHOTOMETER
FIG. 11B.—BRACE-LEMON PRISM

vacuum lamp, since the spectral distribution of this type of lamp is very closely determined by its efficiency. Alternatively any suitable lamp may be used, the spectral distribution of which has been determined at a standardizing laboratory.

One of the most important uses of spectrophotometry is to determine at each part of the spectrum the transmission factor of a coloured medium, a chemical solution, etc. This may be done quite readily by first obtaining a balance for two sources of light at any one wave-length, and then inserting the coloured medium between one of these sources and

the other. The balance point is then

restored. The balance enables the transmission factor of the medium at the particular part of the spectrum isolated to be reduced.

Physical Photometers.—Many attempts have been made at various times to develop some physical instrument which can be used instead of the eye for making photometric measurements. The instruments proposed may be divided, roughly, into three classes. The first of these includes the vast number of chemical photometers in which the illumination is measured by the rate of change it produces in the constitution of some chemical mixture. This form of photometer survives in the photographic

method used in some branches of spectrophotometry and in stellar photometry (see below). The chief disadvantage of the method is, as in all physical photometry, that the response of the sensitive substance to equal rates of energy reception in the form of light of different wave-lengths is quite different from that of the eye. In other words, the luminosity curve of the physical photometer is not even approximately the same as the curve of fig 1. This, clearly, is of no importance in spectrophotometry where the comparison is made separately at each part of the spectrum. The principal difficulty associated with photographic spectrophotometry is the lack of proportionality between exposure (illumination \times time) and blackening. Schwartzchild's law that, for equal photographic densities, $E t^p$ is a constant (p has a value between 0.75 and 1 depending on the plate) holds for short ranges of E and t .

The second class of physical photometer is that depending on the change (usually increase) of electrical conductivity of the element selenium when illuminated. A sensitive selenium bridge (frequently termed *selenium* cell) may be made by winding four strands of fine nickel or platinum wire round a sheet of some good insulator which has been covered on one side with a thin layer of purified amorphous selenium. If two alternate strands of wire are then removed, the remaining strands are separated by a long strip of selenium of the same breadth as the diameter of the wire. By heating the bridge to a temperature of about 180° C for five minutes or longer the selenium is changed to the metallic form and the conductivity of the path between the wire then varies with the illumination of the bridge. Many other forms of cell have been developed for various purposes. This type of physical photometer is not only subject to the disadvantage that its luminosity curve is different from that of the eye and is, moreover, not the same at all intensities of illumination, but it has the additional defect of a lag both in response to stimulation and in recovery after the illumination has been cut off.

Photoelectric Photometry.—The most promising form of physical photometer is the photoelectric cell described elsewhere (see PHOTOELECTRICITY). Although the luminosity curve of any such cell is very markedly different from that of the eye and is, moreover, slightly different even for two cells made similarly with the same photoelectric metal, it has been found that a combination of a potassium cell with a suitable yellow filter (Wratten Kg) gives a curve which approximates to that of fig. 1 sufficiently closely for a device of this nature to be used as a physical photometer.

Various methods may be employed for carrying out a measurement with such a cell-filter combination. The simplest is to have the combination illuminated in succession by the sub-standard and the lamps to be measured, and to balance the photoelectric current in each case by that from a simple photoelectric cell illuminated by a comparison lamp mounted on a bench (see fig. 12). The two cells, with their batteries, are connected in a Wheatstone bridge arrangement and the distance of the comparison lamp from the cell it illuminates can be altered until the electrometer ceases to show a deflection. The illumination of the cell-filter combination is then proportional to I/d^2 provided both cells follow the

FIG. 12.—PHOTO-ELECTRIC PHOTO-METER

same law connecting photoelectric current and illumination. It is unsafe to assume that this is the case over a very extended range of illumination, so that the sub-standard and the test lamps must be arranged to give illuminations of the same order at the cell-filter combination. In the case of a measurement of luminous intensity this can be done quite easily, but when the cell is being used in combination with a sphere or cube for the measurement of luminous flux, some auxiliary means must be adopted for adjusting the value of the illumination. A sector disc may be used since Talbot's law is rigorously obeyed by a photoelectric cell, its response to light being practically instantaneous. For increasing the sensitivity of a photoelectric cell, a three-electrode valve is often

employed. Such a combination will, in conjunction with a suitable galvanometer and chronograph, enable records of a varying illumination (*e.g.*, daylight) to be obtained.

CELESTIAL

The earliest records we possess as to the positions of the stars have always been accompanied by estimations of their relative brightness; the stars being arranged in "magnitudes" according to their apparent luminosities. Thus, in the catalogue of stars published by Ptolemy (c. A.D. 150) but which had probably been formed 300 years previously by Hipparchus, the stars visible to the unaided eye were divided into six classes or magnitudes, the brightest stars being designated "first magnitude stars" and those just visible to the naked eye forming the "sixth magnitude." Each class was further sub-divided into three sub-groups. This process of arranging the stars by eye estimates (with the unaided eye at first and subsequently with the aid of telescopes) was further developed by Flamsteed and the Herschels, and culminated in the work of Argelander, Schanfeld and Krüger, who published three catalogues (1859-62) of celestial co-ordinates and magnitudes known as the Bonn *Durchmusterung*. This catalogue included the enormous number of 324,188 stars. An additional volume containing 133,659 stars south of the equator was published in 1886 and the work was further extended in the southern hemisphere by B. A. Gould, J. M. Thorne and others. In the Bonn *Durchmusterung*, or "B.D.," each magnitude is sub-divided into ten divisions, a decimal notation being used.

So far no attempt was made to define the quantitative relationship between different magnitudes. In modern times a definition due to Pogson has arisen, and we define a difference of one magnitude between two stars as meaning that the light that reaches us from the first star is k times the light which reaches us from the second. The constant k is chosen so as to make a difference of five magnitudes correspond to a light ratio of 100 and this means that we must have $\log_{10} k = 0.4$. We cannot observe all the radiation emitted by a star. If the instrument used for registering the light be the human eye, it will not respond to radiation either in the extreme ultra-violet end of the spectrum or in the extreme infra red. Now if two stars are of different colours, the proportion of the whole radiation represented by the light which affects the eye will be different for the two stars, and the adoption of the above definition as it stands would lead to difficulties. We can retain it, however, for stars of the same colour and then, as far as visual magnitudes are concerned, we define two stars of different colour as being of the same visual magnitude when they appear equally bright to the eye. With the introduction of photographic methods, a photographic scale has arisen defined in the same way; two stars being of equal photographic magnitude when they produce equal photographic effects. Reference will be made below to certain difficulties arising out of these definitions. With regard to the zeros or starting points of these visual and photographic scales, the zero of the measured scale of visual magnitudes has been fixed so that the magnitudes agree approximately with those in the "B.D." for the mean of stars down to the sixth magnitude, whilst the zero of the photographic scale is defined so that for the white stars (of spectral type A₀) of the sixth magnitude (between visual magnitudes 5.5 and 6.5) the visual and photographic magnitudes are equal.

The actual methods of procedure, both visual and photographic, will be given in outline later in this article. In recent years an enormous stimulus has been given to stellar photometry by the realization that it can lead us to good estimates of the distances of remote objects. It was pointed out by Hertzsprung (see STAR), that the period of certain variable stars was related to their absolute magnitude, *i.e.*, to the magnitude that they would appear to have when viewed by an observer at a certain standard distance. By observing the period the absolute magnitude can be deduced, and then, provided the apparent magnitude has been measured, the distance of the star can be inferred. The discovery and elabo-

ration of methods such as these has led to the extension of the photometric scale down to the 20th magnitude. The scale of magnitudes defined numerically can of course be extended on the negative side, and, in point of fact, the visual magnitude of Sirius is -1.4 whilst that of the sun is -26.7 .

MODERN WORK ON VISUAL MAGNITUDES

The bulk of observational work on visual magnitudes has been carried out at Harvard, and at the Harvard station in the southern hemisphere (but a considerable amount has been accomplished at Potsdam), and the standard catalogue of visual magnitudes for the brighter stars is the "Revised Harvard Photometry" (*Harvard Annals*, vol. 50). This catalogue contains the computed magnitudes of 9,110 stars, of magnitude 6.5 and brighter, distributed over the whole sky. A further catalogue (*Harvard Annals*, vol. 54) gives the magnitudes of 36,682 stars fainter than 6.5. The instrument used at Harvard was the meridian photometer designed by the late Prof. Pickering. The principle underlying the instrument is the presentation of two stars in the field of view, the light from one being varied by a Nicol prism until the two stars appear of equal brightness. The ratio in which the incident light has been varied is read off from the angle through which the Nicol has been rotated, and the difference of magnitudes of the two stars thus obtained. The stars were all compared with a standard star, which was the Pole star in the case of the brighter stars and λ Ursae Minoris for the fainter ones.

The photometer (*Harvard Annals*, vols. 14 and 23) consists of two telescopes placed side by side pointing due east, the light from the stars on the meridian being reflected into them by two mirrors inclined at an angle of 45° to this direction. If there were a star exactly at the Pole, one of these mirrors would be absolutely fixed and would constantly reflect the light of this star down the axis of its telescope; in practice a slight motion can be given to the mirror so as to keep in view the polar star selected—as the standard of comparison. The second mirror (which projects a little beyond the first so as to obtain an unobstructed view of the meridian) can be rotated round the axis of the telescope by means of a toothed-wheel gearing, and can thus be made to reflect any star on the meridian down the second telescope; it is also provided with a small motion in the perpendicular direction, so as to command a degree or two on each side of the meridian. Near the common eyepiece of the telescopes there is a double image prism which separates the light received from each into two pencils; the pencil of ordinary rays from one object-glass is made to coincide with that of extraordinary rays from the other, and the two remaining pencils are excluded by a stop. The two coincident pencils then pass through a Nicol prism to the eye of the observer, who by rotating the prism round its axis can equalize them at a definite reading depending on their relative intensities. This reading gives in fact the difference of magnitude between the two stars selected for comparison. It may be remarked that the position of the double image prism is important: It should be just within, not at, the common focus; this position prevents any noticeable colour in the images, and gives the ordinary and extraordinary pencils a sufficient separation at the eyepiece to permit the entire exclusion of one without the loss of any part of the other. If the prism were exactly at the focus, and any part of the superfluous images were admitted, the resulting secondary images would coincide with the others and thus lead to errors in observing. As it is, owing to the construction of the instrument, if the secondary images appeared at all they would do so only as additional stars, near those under observation and too faint to produce any inconvenience.

Each observation consists of four comparisons; after the first two the observer reverses the position of the star images in the field, and also reverses the double-image prism. The former precaution is necessary to eliminate a curious error depending on the relative position of the images, which may amount to several tenths of a magnitude. Errors of this kind affect all estimates of the relative brightness of two stars in the same field, as has been repeatedly shown; a striking instance is given by A. W. Roberts of Lovedale, South Africa (*Mon Not. R A S*, 1897), who found

that his eye-estimations of the brightness of variable stars required a correction depending on the position-angle of the comparison star and ranging over nearly two magnitudes. In the Harvard work on the brighter stars, the magnitude of the pole star was provisionally assumed to be 2.0 at the pole. Each observation had to be corrected for the effect of atmospheric absorption, the coefficient for which was obtained from observations of circum-polars at upper and lower culminations. The provisional magnitudes thus obtained were finally corrected by a constant chosen so as to make the mean magnitude of the circum-polars equal to the mean magnitude of the same stars as given in the "B.D."

Other types of photometer are Zollner's (*Photometrische Untersuchungen*, h. 81), in which an artificial star is taken as the standard of comparison, and Pritchard's, in which the images of stars are viewed through a wedge and the wedge-reading at which the star is extinguished noted.

The comparison of different catalogues of visual magnitudes reveals small systematic differences which arise out of the difficulties of estimating when two stars of different colour are equal in apparent intensity. The observation is complicated by what is known as the "Purkinje phenomenon." If a blue source of light and a red source appear equally bright to the eye, and if the intensity of each be diminished in the same ratio, they will no longer seem equally bright, the blue appearing the brighter. From this cause, magnitudes observed with meridian photometers of different aperture will differ slightly. It becomes obvious that visual magnitudes ought to be referred to some standard instrument, and possibly to some standard observer, and it is difficulties such as these which are at the present time leading to the replacement of visual magnitudes by what are known as photo-visual magnitudes.

PHOTOGRAPHIC PHOTOMETRY

Here, we are dealing with a problem which differs considerably in detail from the visual procedure. We can no longer vary the light of a star by some device such as a Nicol prism until it is equal in brightness to a standard. But on a plate which has been exposed to a field of stars we can at any rate arrange the stars in order of brightness by measuring the diameters of the images, or by estimating their degrees of blackness, and we are then faced with the task of finding a means of relating our measures of blackness or of diameter to the true photometric scale defined as above.

Two principal methods have been employed, the in-focus method and the out-of-focus method. In the in-focus method a field of stars is photographed twice on the same plate, the intensity of the light being reduced in some known ratio for the second exposure. This can be effected by stopping down the aperture of the telescope by a given amount. The plate is placed in the usual position, that is, in the focal plane of the object glass or mirror. For each star we then have two images on the plate whose difference in magnitude is known. Now suppose we measure the photographic effect of each image in some way and denote the measure by D . A simple measure of photographic effect is the diameter of the image, in which case D is the measured diameter. Suppose D_1 and D_2 be the measures on the two images of the same star. The difference of magnitude between these two images depends only on the ratio in which the aperture has been stopped down and is consequently known. We thus get the magnitude difference corresponding to the difference of the measures D_1 and D_2 . In other words, we are relating the scale of our measures of photographic effect to the magnitude scale, and we thus have a means of converting the measures into magnitudes and of obtaining the relative magnitudes of all the stars on the plate.

The principle of the method is as follows. Select a sequence of stars on the plate such that the diameter (or any other measure of photographic effect that may be adopted) of the fainter image of any member of the sequence is equal to the diameter of the brighter image of the next succeeding member. We then have a sequence of stars each member of which differs in magnitude from the following member by a known amount. In other words,

the magnitudes of the stars of the sequence are known, but with an arbitrary zero point. If then, the measured diameters of these stars be plotted against their magnitudes obtained in this way, a curve would be obtained from which the magnitude of any star on the plate can be read off from its measured diameter. In actual practice a mathematical process is used instead of a graphical one. Furthermore, the equality between the fainter and brighter images of two consecutive members of the sequence will not be exact and this must be allowed for.

So far this method only gives a means of determining the relative magnitudes of stars in the same region of the sky and which can therefore be photographed on the same plate, but if we expose every plate a second time on some standard area, the time of exposure being the same, we can determine the magnitudes relatively to some star or stars in the standard area (which may conveniently be the area of the Polar sequence); and it only remains to define the zero. This has been fixed, as already explained, so as to make the photographic magnitudes of the white stars of the 6th magnitude agree with their visual magnitudes on the Harvard scale. Instead of using a stop to reduce the light in a given ratio for a second exposure, it is preferable to use a coarse wire diffraction grating placed over the aperture of the telescope. Each image is then flanked by fainter lateral images differing in magnitude from the main image by a known amount depending on the thickness and spacing of the wires. The subsequent procedure is unchanged, but only one exposure is necessary. In order to give some idea of the appearance of such gratings, it may be mentioned that one of the gratings used at Greenwich in conjunction with the 26-inch refractor consisted of wires 0.69 mm. in diameter and spaced at intervals of 5 mm. (*Monthly Notices R.A.S.*, 1913).

At Harvard the out-of-focus method has been used. In this case a series of exposures are made and for each exposure the plate is placed at a certain distance from the focus. Each star is now represented by a blackened patch on the plate, instead of by the usual image, and the density of the silver deposited in each patch is measured by comparison with a graduated wedge. In the case of the different exposures to the same star at different distances from the focus, the relative quantities of light falling upon unit area of the plate are determined from straightforward geometry, and the relation between the measured densities and the magnitude scale thus determined (*Harvard Annals*, vol. 59). It may be remarked that the out-of-focus method lends itself readily to the determination of the magnitudes of planets. For the purpose of determining the magnitudes of the sun and moon, a pin-hole camera was used by the Harvard observers, and they obtained -25.83 m. for the photographic magnitude of the sun and -11.20 m. for that of the full moon (*Harvard Annals*, vol. 59).

In recent years a great deal of care has been lavished upon the determination of the magnitudes of a sequence of stars extending down to the 20th magnitude and situated at the North Pole of the sky. This having been done the magnitudes of stars in any other part of the northern sky can be obtained by photographing the field and the pole on the same plate and with the same exposure. In order to eliminate atmospheric absorption the exposures should be made at the same altitude. Measures (say of diameter) can then be made of all the stars in each field, and the measures calibrated from the determined magnitudes of the Polar sequence. Several secondary sequences have been determined in this way in various parts of the sky and the work is being pushed into the southern hemisphere.

Colour-indices and Standardization.—The visual and photographic magnitudes are not necessarily the same. A red star, for example, may affect the eye strongly, but its effect on an ordinary photographic plate, which is chiefly sensitive to blue light, may be small. The difference between the photographic and visual magnitudes of a star (which in extreme cases may amount to $1\frac{1}{2}$ magnitude), reckoned in the sense photographic minus visual, is called its colour-index. However, a little consideration will show that photographic magnitudes determined with different instruments (or different plates) will differ from

each other. For example, in a refractor a large portion of the ultra-violet light is absorbed by the lens, and in a reflector this light is let through to a much greater extent. Clearly the photographic magnitudes as determined with these types of instruments will be different. It is necessary to adopt some standard, and the International Astronomical Union, in defining the magnitudes of the standard polar sequence, has adopted the scale of the 60-inch reflector at Mt. Wilson. The magnitudes m of stars in any catalogue can be connected with the standard magnitudes m' , which are referred to the scale of the 60-inch by an equation of the form

$$m = m' + a + bC$$

where C is the colour index and a and b are constants.

At Mt. Wilson Dr. Seares has devised a method of measuring colour-index directly. He photographs stars on colour-sensitive plates through blue and yellow filters and he defines the "exposure ratio" as the logarithmic ratio of the exposure times which produce blue and yellow images of the same size. The results have to be calibrated by comparison with colour-indices, but, this having been done, the method has the advantage of determining the colour directly instead of by differencing two separate magnitude determinations. A further direct measure of colour is provided by the "effective photographic wave-length" of a star. This may be defined as the wave-length of the light from the star which produces the maximum effect on a photographic plate. It is greater for the red stars than for the blue, and may be determined by placing a coarse diffraction grating over the aperture and then measuring the distance on the plate between the central image of a star and the most intense part of the lateral image produced by diffraction (*Monthly Notices R.A.S.*, 82, 1921). Effective wave-lengths having been determined, they can be calibrated by comparison with colour-indices.

Photovisual Magnitudes.—Just as different photographic determinations differ, so will visual observers using different instruments obtain different results. There is also the complication arising from the Purkinje effect. For this reason attempts have been made of recent years to replace visual determinations by photographic ones made on colour-sensitive plates through yellow screens. The resulting magnitudes are called photovisual magnitudes. They are roughly the same as the visual ones, at any rate for the brighter stars, and lend themselves readily to standardization. Photovisual magnitudes have been determined at Mt. Wilson for the stars of the polar sequence. When compared with the Harvard visual results they show differences depending on colour, which become more pronounced for the fainter stars, and may amount to as much as three-tenths of a magnitude for red stars of the 12th magnitude.

Spectro-photometry.—It has been long recognized that the colour-index of a star bears a relation to its surface temperature—the bluest stars being the hottest—and it is immediately suggested that the temperatures of the stars might be calculated from colour-index data. This would be possible if the visual and photographic magnitudes referred to definite wave-lengths, instead, as is actually the case, of being results integrated over a certain range of spectrum. Consequently the satisfactory determination of what are known as effective temperatures can only be obtained by spreading out the light into spectra and confining the photometric measurements to certain definite wave-lengths.

The effective temperature of a star may be defined, for the present purpose, as the temperature of a full radiator or "black body" for which the distribution of the energy in the spectrum most closely fits the observed distribution in the stellar spectrum. It is assumed that if, as is usual, measurements are confined to those spectral regions which are free from absorption lines, the stellar distribution of energy is very nearly that of a black body, and this is probably the case. The principle of the method may be stated thus. If for two stars the ratio of the light reaching us be measured for two separate wave-lengths, and if the effective temperature of one of them, which is thus regarded as a standard star, be known, then the effective temperature of the other can be calculated. The problem is thus reduced to determining this ratio for two separate wave-lengths, or, which comes to the same thing, the difference of magnitude for the two wave-lengths in

question. Actually it is not necessary to determine each of these differences, the *difference* of the differences is all that is required. The object of spectro-photometric measurement is thus to determine what is in reality a colour-index, determined with respect to two definite wave-lengths, say in the blue and the red regions of the spectrum. Then, if the effective temperature of the standard star be known, the effective temperatures of any others can be derived. The standard star need not be an actual star, but an artificial source of light whose effective temperature can be determined in the laboratory.

It is on these lines that research has been pursued at Potsdam, Edinburgh, Victoria, Greenwich and at other observatories. The work is still in its infancy and it is impossible to go into details here. With the exception of Potsdam, photographic methods are employed, and one method is to measure the densities of the silver deposited in the spectra with some form of micro-photometer. It then remains to relate the measures of density to the absolute photometric scale just as in the case of ordinary photometry. A graded series of images in light of the requisite wave-lengths must be imposed on the plate and the measures of density thus calibrated. In the case of the visual work carried out at Potsdam, the spectra were compared at each wave-length with a Nicol prism photometer in a manner analogous to the Harvard visual photometry. The results that have been so far obtained are not altogether accordant, and are subject to revision. The available observational data have been summarized by A. Brill (*Astronomische Nachrichten* 5,539, 1928), who has given a table connecting spectral types and effective temperatures. According to this table, the mean effective temperatures of stars of type Bo is 20,800° Absolute. For type Ao the effective temperature is 1,300° A and for type Go (the solar type) it is 6,050° A for the "giants" and 6,240° A for the "dwarfs." For the very red stars of type Mo Brill gives 3,200° A and 3,420° A for the giants and dwarfs, respectively.

A very recent development is the determination, by photometric methods, of the integrated intensities of absorption lines, *i.e.*, the ratio of the total amount of light absorbed in a line to the amount of light per unit of wave-length in the neighbouring continuous spectrum. Some very promising work on these lines has been carried out at Harvard and it is probable that it will be developed rapidly in the immediate future. (W. M. H. G.)

PHOTON: see COMPTON EFFECT.

PHOTOPERIODISM, the character of a plant causing it to produce blossoms or reproductive parts in a favourable photoperiod or relative length of light and darkness. The natural photoperiod is the length of daylight period, as the long days of summer and the short days of winter. The expression of the genetic character of photoperiodism is, however, modified by temperature. Photoperiodism may influence other biological phenomena, as the migrations and seasonal matings of animals.

W. W. Garner and H. A. Allard of the U.S. department of agriculture first pointed out the practical significance of the reaction of plants to different lengths of day in 1920 (*Jour. Agr. Res.* 18:553-606 [1920]; *Tech. Bul.* 727 [1940]). They defined photoperiodism as "the response of organisms to the relative length of day and night." Their grouping of plants according to photoperiodic response was based upon blossoming. Blossoming was also used in subsequent investigations as an indication of photoperiodism. This practice makes it illogical to define photoperiodism on the basis of normal or optimum growth, as some plants can be induced to blossom at ages, sizes, or in seasons wholly removed from the average. Common examples are the artificially induced fruiting of young two-leaved seedlings of pigweed (*Amaranthus*) and Klondyke cosmos, the first year blossoming of biennials as beets and cabbage, and the blossoming of poinsettia and Christmas cactus in the summer season.

Garner and Allard designated plants which blossom in short photoperiods as "short-day" plants and those which respond similarly to long photoperiods as "long-day" plants. Those which blossom in both photoperiods were classed as an "indeterminate" type. The latter would not exhibit photoperiodism. Eleven to 13 hours is commonly the critical length of night in which short-

day plants initiate blossom primordia. There are exceptions however, such as cocklebur (*Xanthium*), which forms blossom primordia in light periods as long as 15 hours.

Confusion as to the proper grouping of plants arose from the careless practice of giving a photoperiod classification to kinds which blossom in both lengths of day but after different amounts of time.

Short-day conditions are created in the summer season by shortening the light period. More or less elaborate chambers, curtained frameworks, or even small frames or containers to cover small plants or portions of a single plant are used for this purpose. Plants can be grown with one part vegetative and the remainder flowering when the proper photoperiod is supplied locally to a single branch or region along the stem. This is true only of those which have terminal blossoms. Plants which form blossom buds at several nodes will blossom throughout if only a part, such as a single leaf, is given an induction treatment.

Long-day responses are induced in the winter season by illuminating the plants with electric lights for a period of the night beyond the critical length of day for the species. Low light intensities of as little as five foot-candles are sufficient to induce photoperiodic responses. Monochromatic light of a sufficient intensity also initiates characteristic blossom development. The initiation of flowering with light of an intensity of only a few foot-candles appears to place the phenomenon of photoperiodism in a different photochemical category from that of photosynthesis.

The responses of many plants to photoperiod have been found to be modified by temperature (*Jour. Agr. Res.* 56:633 [1938]; 59:699 [1939]). That is, a favourable temperature is also necessary for flowering to occur, although the photoperiod is correct. An unfavourable temperature may prevent blossoming entirely. For example, greenhouse varieties of stocks grow vigorously but fail to blossom at 75° F.; they respond as long-day plants at 65°, and blossom in both long and short days at 55°, the short-day plants however being slower to respond. It has also been demonstrated that the night portion of a daily temperature cycle is the more influential period for the expression of photoperiodism.

Other factors are also known to modify the reproductive response to photoperiod. Among these are plant source (as cuttings), nutrition, water relations, humidity and age.

The geographic and agricultural distribution of plant species is much affected by photoperiodism. This character can be used in breeding programs to extend the adaptability of plants which are commercially or ornamentally valuable.

The effects of photoperiod upon composition or other growth responses, such as root development, stature, branching habit, leaf form, longevity and dormancy may be matters correlated with the reproductive expression rather than items to be considered separately in a definition of photoperiodism.

Other biological phenomena, such as the migration or reproductive cycles of mammals, birds, fishes and insects have been found to be influenced by photoperiodism. This is not a general situation but varies with each species, being less evident in tropical forms. Low light intensities and light of different wave lengths can also induce the reproductive cycle. William Rowan stated that gradually increasing increments of daily illumination are apparently necessary to produce normal effects of photoperiodism. Sudden increases to the full day length are satisfactory for plants. As is the case with some plants, short periods of induction are effective in producing a much prolonged-reproduction cycle.

For literature lists on plants, see A. E. Murneek, *Res. Bul.* 268, Mo. Agr. Exp. Sta. (1937) and Paul R. Burkholder, *Botanical Rev.* 2:1-52; 97-172 (1936); for animals, T. H. Bissonnette, *Wilson Bull.* XLIX, 241-270 (1937) and William Rowan, *Biological Rev.* 13:374-402 (1938). (R. H. Rs.)

PHOTOSPHERE of the sun, the layer from which most of the sun's light is emitted which reaches us directly; *i.e.*, without absorption and re-emission. The sun is a globe of gas with no sharply defined surface, and we look down into it through absorbing layers of very low density; the photosphere may be regarded as the layer which is the limit to which we can see into the interior. (See SUN.)

PHOTOSYNTHESIS. Photosynthesis is the process by which green plants harness the energy of sunlight absorbed by chlorophyll to build carbohydrates from carbon dioxide and water. This reaction is often referred to as assimilation or fixation of carbon.

Fundamental Role of Photosynthesis.—For their subsistence, growth and multiplication all living beings, plants and animals alike, need organic food. The organic foodstuffs are utilized by living cells as building stones and as sources of energy.

The energy stored in the foodstuffs is mainly released by respiration, the reaction in which organic matter combines with the oxygen of the air yielding carbon dioxide and water as final products. The rate at which living beings die and consume each other is so high that they would all disappear from the earth within the lifetime of a human generation, if there were not a process providing for the reformation of organic matter. While there are many ways by which organic substances are decomposed in respiration and similar reactions, there is only one reaction, photosynthesis, which since millions of years has counterbalanced death and decomposition. In the course of photosynthesis the hydrogen of water is used to transform carbon dioxide into carbohydrate; simultaneously the oxygen of the water is liberated as free oxygen gas. Among the many pigments appearing in the plant kingdom only chlorophyll and, to a lesser extent, carotenoids and phycocyanin are known to convert sunlight into chemical energy. Chlorophyll is the green dye whose colour is so characteristic of meadows and forests. The green plants may transform the carbohydrates produced by photosynthesis into fats, proteins and many other substances. Thus, directly or indirectly, all of the organic food of plants or animals depends upon the photosynthetic process. In the cycle of synthesis and death the basic materials, carbon dioxide and water, can be used over and over again, while the energy released upon the destruction of organic matter is lost forever; it is dissipated as heat in space and must constantly be replaced by the sun's radiation.

Rate of Carbon Dioxide Reduction.— In bright sunlight the rate of the photosynthetic reaction is about 15 to 30 times the respiratory rate. A sunflower leaf may gain 9% of its dry weight per hour. Considering that respiration proceeds continuously while photosynthesis occurs only during the hours of light the net rate of the latter is about five times greater. This means an excess of carbohydrate which is partly stored and partly used for the growth of the plant. The non-green plants and the animals, which constitute the heterotrophic organisms, depend upon this excess for their organic food.

The land plants utilize the carbon dioxide present in the air. This averages only 0.03% of the gas volume at the earth's surface. The aquatic plants thrive on the carbon dioxide dissolved as gas or as carbonates in the water. The best estimate for the rate of the total carbon dioxide reduction on earth is a turnover of 10^{11} tons of carbon per year, more than four-fifths of which is contributed by the flora of the oceans. An amount of carbon dioxide equal to the total readily available reservoir passes through the life cycle in about 350 years. The cycle of carbon requires also one of oxygen and of hydrogen. Since both these elements are available in larger quantities, it takes about 2,000 years to renew all the oxygen in the air and 2,000,000 years to decompose all water on earth. The land plants grow faster if supplied with more carbon dioxide than they can now find in nature. One may assume that at the time in the history of our planet, when its crust cooled down below the boiling point of water—the upper temperature limit for the existence of life—there was little or no free oxygen but plenty of carbon dioxide present. It is quite probable that our entire supply of free oxygen, one-fifth of the atmosphere, has been furnished by photosynthesis. Since the chlorophyll system is a highly complicated structure, it is clear that life cannot have started with that particular synthetic reaction which at present is its sole support.

Factors Governing Photosynthesis.— Photosynthesis is influenced by temperature, light intensity, carbon dioxide concentration and water supply as external factors. The internal factors influencing its course are twofold. First the concentration of the pigments and the activity of the enzymatic catalysts involved in photosynthesis. Second, other metabolic reactions, like respiration and fermentation, which have no direct connection with the photosynthetic process. Among the internal factors we have to include also the inherited traits characteristic for different species. It is well known that certain plants can grow in arctic regions and others only in the tropics. It has been found, however, that the chemistry of photosynthesis is identical in lower and in higher plants. For experimental purposes one may choose, therefore, the plant material suitable for the particular measuring device.

Each of the factors influencing photosynthesis may become the one which is mainly responsible for the limitation of the over-all rate. At low light intensities and otherwise favourable conditions photosynthesis proceeds at a rate directly proportional to the incident radiation. Under these circumstances the light energy is utilized with the greatest efficiency. At high light intensities and high temperatures the rate remains a function of the carbon dioxide concentration so long as the mechanism of photosynthesis is not saturated with this substrate. If also carbon dioxide is present in sufficient amounts, the rate is determined by internal factors, most likely by the slowest of several enzymatic processes connected with the reduction of carbon dioxide. Since a truly photochemical reaction is not influenced by changes in temperature which determine the rate of ordinary chemical processes, the rate of photosynthesis remains practically constant in spite of temperature changes as long as the light intensity is the rate-determining factor. This is the case at low or moderate light intensities and high temperatures. Conversely, in bright sunshine and at moderate temperatures photosynthesis is influenced by changes in temperature exactly like other metabolic processes. These observations

on limiting factors were among the first which led to the concept of photosynthesis as consisting of a sequence of photochemical and thermal enzymatic or "dark" reactions. An ingenious way of separating photochemical from dark reactions in the analysis of photosynthesis was first described in 1929. It consists of illuminating a plant with light flashes of very short duration (less than $\frac{1}{1000}$ of a second) separated by dark periods of considerably greater length ($\frac{1}{400}$ of a second to one second). In this way the temperature dependencies just mentioned were clearly demonstrated and it was further shown that most metabolic poisons inhibit not the photochemical but the dark reactions in photosynthesis. Studies of the influence of poisons on the course of photosynthesis performed in analogy to similar investigations in the field of respiration allowed for a separation in theory of reactions preceding the photochemical reduction of carbon dioxide and those following it. The reactions preceding the photochemical conversion are characterized by a reversible fixation of carbon dioxide in the plant cell which is specifically inhibited by cyanide. The reactions after the photochemical process are characterized by the liberation of oxygen, a reaction which is specifically inhibited by hydroxylamine.

Active Pigments.— (See also CHLOROPHYLL, CHEMISTRY OF, PLANTS.) With the exception of bacteria and blue-green algae, the site of photosynthesis is in the chloroplasts, strongly coloured structural units within the plant cell. The green or brown colour of most chloroplasts is due to the chlorophylls and carotenoids. The two green chlorophylls *a* ($C_{55}H_{72}O_6N_4Mg$) and *b* ($C_{55}H_{70}O_6N_4Mg$) were isolated in 1905 and their structure finally established about 1936. The bacterio-chlorophylls *a* and *b*, occurring in purple bacteria, are related pigments whose absorption spectrum is shifted towards the infra-red. The chlorophylls are identical in all plants. They belong, like haematin—the dye responsible for the colour of blood—to the class of porphyrin metal complexes. An important difference between chlorophyll- and haemins exists in their photochemical properties. The presence of a complex bound atom of magnesium does not destroy the typical porphyrin fluorescence of the chlorophylls, but the presence of the heavy metal iron in the haemins quenches the porphyrin fluorescence completely and makes the latter dyes photochemically inert. The slight difference between chlorophyll *a* and chlorophyll *b*—a formyl group ($-C.H:O$) in *b* where *a* has a methyl group ($-CH_3$)—appears to have no relation to their function in photosynthesis. For most practical purposes both chlorophylls can be treated as one pigment.

One of the side chains of the porphyrin ring in chlorophyll is esterified with phytol, $C_{20}H_{40}O$, a colourless alcohol, which also is found as a side chain in vitamin K. The role of phytol in both substances is obscure. Chlorophyll looks green because it is somewhat more transparent for green light than for blue and red, yet green light is equally effective if absorbed. For the wave lengths longer than 7,300 Å chlorophyll is quite transparent. This is the reason why a landscape seen through a dark red filter shows the leaves of trees and the lawn brighter than the surroundings (including the blue sky), an effect familiar from infra-red photography. Chlorophyll is insoluble in water. Extracts can be obtained simply by immersing green leaves into alcohol or acetone. In the cell, chlorophyll is bound to protein. It can be extracted in its combination with protein, in the form of a colloidal aqueous solution, if the plant cells are mechanically crushed.

The carotenoids present in the chloroplasts vary in composition and number with different species of plants. Their chemical structure has nothing in common with that of chlorophyll. The formula for carotin is $C_{40}H_{56}$, for xanthophyll $C_{40}H_{56}O_2$ and for fucoxanthin $C_{40}H_{56}O_6$. Some of these pigments were known to act as photoreceptors in such phenomena as *phototaxis* and *phototropism*, but until 1930 it was believed that only the light absorbed by chlorophyll was available for photosynthesis. Botanists, however, wondered how brown algae, in which most of the incident radiation is absorbed by the yellow pigments, could use light so effectively for growth. In 1941 it was finally established that some of the yellow pigments participate in photosynthesis. The degree at which this takes place varies considerably in different plants. In the diatoms, which are responsible for the bulk of photosynthesis in the ocean, the light absorbed by carotenoids is just as effective as that absorbed by chlorophyll. Similar experiments showed also that phycocyanin, the characteristic pigment in blue-green algae, is photo-effective. No cell, however, was found to reduce carbon dioxide photochemically which did not contain chlorophyll in addition to the other pigments mentioned. To what an extent the pigments of the chloroplasts participate in pure chemical reactions, for instance as intermediary hydrogen donors, is not known.

Efficiency of Photosynthesis.— The average data available to 1943 concerning land plants indicated that between 1 and 3% of the light falling upon a green plant is transformed into chemical energy. Important as this answer may be for problems of agriculture, it is of no value in respect to the theoretical understanding of the process of photosynthesis. Most of the incident radiation is lost by reflection, transmission, and inefective absorption by pigments other than those in the chloroplasts. Only a fraction is absorbed by the active pigments. The efficiency with which this latter fraction is utilized in the course of the photochemical process is of great theoretical interest. It is measured by the minimum number of light quanta necessary to bring one molecule of carbon dioxide to the energetic level of a carbohydrate. After the unspecific losses just mentioned had been

either eliminated or accounted for, it appeared in 1923 as if under optimum conditions four quanta of visible light were sufficient for the reduction of one molecule of carbon dioxide. In the following years these results were the cause of extended theoretical discussions, because four quanta of visible red light correspond to about 160,000 calories, whereas between 150,000 and 180,000 calories are required for the transformation of carbon dioxide to a carbohydrate with a permanent gain of 112,000 calories. All theoretical difficulties dissolved, however, when about 1941 it was established by several investigators that the correct value for the efficiency in photosynthesis is about 10 to 12 quanta of visible light under optimum conditions. Ten quanta represent such an amount of energy that no thermodynamical difficulties arise in respect to any of various theoretical mechanisms proposed. In the unicellular green alga *Chlorella* the quantum yield remains constant over the entire range of the chlorophyll absorption spectrum. This means that expressed in terms of calories the efficiency increases in the direction from blue to red in the spectrum, because the energy content of the light quanta decreases according to the laws of photochemistry. Chlorophyll in the living cell obeys these laws exactly like the chlorophyll sensitizing photochemical oxidations in vitro. An interesting exception to the requirement that each quantum absorbed be equally effective independent of its wave length was observed in the transition region between 6,800Å and 7,300Å, where chlorophyll becomes gradually transparent. The light which is still absorbed in this region is photochemically the less effective the longer its wave length.

Artificial Photosynthesis.—Several claims to the contrary notwithstanding, photosynthesis has never been observed outside the living cell. It was often reported that dry leaves or plant powders release traces of oxygen after being moistened and irradiated. In 1940, it was shown that it is possible to obtain suspensions of chloroplasts from higher plants which can still produce oxygen upon illumination. The chloroplasts have to be suspended in a concentrated solution of ferric oxalate and ferricyanide. Such preparations evolve oxygen for a few minutes at a rate comparable to photosynthesis; simultaneously the ferric salts are reduced to ferrous salts. No carbon dioxide takes part in this photochemical reaction. These experiments show that the chlorophyll complex and the enzyme system concerned with the disintegration of water can be kept active, at least for a short period of time, outside the intact cell.

Products of Photosynthesis.—The photosynthetic reaction is summarized in chemical terms by the equation $n\text{CO}_2$ (carbon dioxide) + $n\text{H}_2\text{O}$ (water) + light = $n\text{O}_2$ (oxygen) + $(\text{CH}_2\text{O})_n$ (carbohydrate). The factor n is introduced because the exact nature of the first carbohydrate to appear in this reaction is unknown. The validity of this equation was established beyond doubt by the following experimental results. First: All measurements of photosynthesis extending over periods longer than 30 minutes showed that the volume of oxygen evolved is exactly equal to the volume of carbon dioxide absorbed; the assimilatory quotient is unity ($\text{AQ} = \Delta\text{O}_2 : \Delta\text{CO}_2 = 1$). Second: the amount of carbohydrate accumulated during 15 minutes of illumination was found to be equivalent to the amount of carbon dioxide taken up during the same time. In the above equation for the over-all process, the carbohydrate formed is symbolized by $(\text{CH}_2\text{O})_n$ and not by CH_2O , the formula of formaldehyde. During a period of 60 years after it had been first proposed in 1870, the hypothesis that formaldehyde is produced in photosynthesis was a favourite assumption in various theories. This hypothesis can now safely be discarded, on account of the following observations: The element carbon has several isotopes. One of these isotopes, with the atomic weight 11, is radioactive. The radioactivity allows one to trace the path of such labelled carbon in the turmoil of constantly changing organic substances in the living cell. All attempts to prove the formation of formaldehyde failed. In 1940 it was shown with the aid of the radioactive carbon that before undergoing reduction, carbon dioxide combines in a reversible enzymatic reaction with a colourless substance of high molecular weight. After the action of light, the radioactive carbon was found to be still present in the same compound, now fixed in a reduced form. This experiment also settled the long disputed question whether carbon dioxide reacts directly with chlorophyll, particularly with the magnesium atom in the molecule. No such reaction occurs. The same experiments revealed that in a growing, photosynthesizing plant, the reduced carbon is quickly distributed all over the cell. After a few minutes of illumination, a very small fraction of the radioactive carbon was found even in the basic skeleton of the extracted chlorophyll. This explains why a definite answer as to the very first reduction product is difficult. In sunflower leaves the bulk of the carbohydrate formed under illumination at low temperatures was found to be cane sugar.

Mechanism of Photosynthesis.—A few species of autotrophic bacteria are known to grow with carbon dioxide as the sole source of carbon in the absence of light. They utilize the energy derived from the oxidation of inorganic compounds, such as ferrous iron salts, sulphur, thiosulphate, hydrogen sulphide and molecular hydrogen. This fact was generally ignored in earlier attempts to understand the mechanism of photosynthesis. The amount of organic matter formed by this means was considered insignificantly small as compared with photosynthesis, and the reduction of carbon dioxide in the dark appeared to be fundamentally different from the photochemical reduc-

tion. In the decade between 1930 and 1940 it became evident, however, that many organisms and tissues from propionic acid bacteria to pigeon liver include carbon dioxide among their metabolic substrates. In these cases a specific enzymatic system provides for the proper coupling between an energy yielding reaction, respiration or fermentation, and a reaction in which hydrogen is transferred to carbon dioxide or its equivalent derivative. The great difference between these oxido-reductions and photosynthesis lies not in the way by which the carbon dioxide molecule is attacked, but in the energy balance. No ordinary metabolic synthesis can end with an over-all gain and storage of chemical energy, because an excess of combustible material, previously synthesized, has to be sacrificed to make the reaction go. In photosynthesis it is the energy of light which in the course of the very reaction furnishes the necessary combustible material or hydrogen donor by the disintegration of water. The utilization of light energy, however, is not sufficient to guarantee a successful accumulation of chemical energy. This was shown by studies on the metabolism of purple bacteria, strongly coloured yellowish, red, or purple unicellular micro-organisms. Because their growth depends on light, they were first believed to photosynthesize like the green plants. Investigations after 1930 proved that purple bacteria are unable to produce molecular oxygen and are unable to reduce carbon dioxide simply with water. In addition to radiant energy they need energetically valuable hydrogen donors. According to the specificity of each species, the purple bacteria require for the assimilation of a certain amount of carbon dioxide an equivalent amount of either sulphur, hydrogen sulphide, thiosulphate, molecular hydrogen, aliphatic acids, or alcohols. In purple bacteria, therefore, the energy of light is not successfully stored as in the green plants, but is partially or completely wasted. The light serves here only as a promoter, as it were, of reactions which might as well be carried on thermally in the dark. However, in 1940 it was found that the photochemical reaction proper is the same in purple bacteria and in green plants. Certain species of unicellular green algae change to a type of metabolism identical with that of some purple bacteria, if they are incubated during a few hours in pure hydrogen gas. Upon subsequent moderate illumination, they reduce carbon dioxide as usual, but they do not evolve oxygen. Instead they absorb the equivalent amount (twice the volume) of hydrogen. Once adapted to the use of hydrogen the same algae can reduce carbon dioxide like the "Knallgas" bacteria, in the dark, if some oxygen is supplied instead of light. Under the influence of an intense irradiation the algae revert to normal photosynthesis with the production of oxygen. This reversible separation of carbon dioxide reduction from oxygen evolution or from the absorption of light demonstrated—what had been postulated long before—that photosynthesis consists of a series of complicated reactions which must be studied separately before the process as a whole is clearly understood. After 1940 all students of the problem agreed that at least three sets of partial reactions may be distinguished. First, the decomposition of water with the aid of light absorbed by chlorophyll, leading, on the one hand, to compounds (as yet unknown) having a surplus of hydrogen and serving as intermediary hydrogen donors, and on the other hand, to compounds having a surplus of oxygen. Second, a transfer of hydrogen from the intermediary donors to carbon dioxide. Third, the disposal of the compounds having a surplus of oxygen. The permanent conversion of radiant energy into chemical energy is possible only because green plants accomplish the task of removing the surplus of oxygen by liberating molecular oxygen and not by consuming hydrogen donors, as do, for instance, the purple bacteria. This picture of photosynthesis requires, among other things, that all the oxygen evolved be derived from water and not from the reduced carbon dioxide molecule. The experimental proof of this postulate was furnished in 1942. Photosynthesizing plants were given water containing some of the heavy oxygen isotope O^{18} , while the oxygen in the carbon dioxide used was ordinary oxygen O^{16} . The oxygen produced by photosynthesis contained O^{18} .

PHRAATES (p-hrah-ah'tās) (PHRAHATES), the name of five Parthian kings.

1. PHRAATES I, son of Priapatius, reigned c. 175–170 B.C. He subdued the Mardi, a mountainous tribe in the Elburz (Justin xli, 5; Isid. Charac. 7). He died young, and appointed as his successor not one of his sons, but his brother Mithradates I (Justin xli, 5).

2. PHRAATES II, son of Mithradates I, the conqueror of Babylonia, reigned 138–127 B.C. He was attacked in 130 by Antiochus VII. Sidetes, who, however, in 120 was defeated and killed in a great battle in Media, which ended the Seleucid rule east of the Euphrates. (See SELEUCID DYNASTY.) Meanwhile the

kingdom was invaded by the Scythians (the Tochari of Bactria), who had helped Antiochus. Phraates marched against them, but was defeated and killed (Justin xlii. 1; Johannes Antioch, fr. 66).

3. PHRAATES III., "the God" (Phlegon, *fr.* 12 *ap.* Photius *cod* 97 and on some of his coins), succeeded his father, Sanatruces, in 70 B.C., at the time when Lucullus was preparing to attack Tigranes of Armenia, who was supreme in western Asia and had wrested Mesopotamia and several vassal states from the Parthian kingdom. Naturally, Phraates declined to assist Mithradates of Pontus and Tigranes against the Romans. (See TRICRANES.) He supported his son-in-law, the younger Tigranes, when he rebelled against his father, and invaded Armenia (65 B.C.) in alliance with Pompey, who abandoned Mesopotamia to the Parthians (Dio. Cass. xxxvi. 45, 51; Appian, *Mithr.* 104; Liv. *Epit.* 100). But Pompey soon overrode the treaty; he acknowledged the elder Tigranes, took his son prisoner, occupied the vassal states Gordyene and Osroene for the Romans, and denied the title of "king of kings," which Phraates had adopted again, to the Parthian king (Plut. *Pomp.* 33, 38; Dio. Cass. xxxvii. 5 *seq.*). About 57 Phraates was murdered by his two sons, Orodes I. and Mithradates III.

4. PHRAATES IV., son of Orodes I., by whom he was appointed successor in 37 B.C., after the death of Pacorus. He soon murdered his father and all his thirty brothers (Justin xlii. 5; Plut. *Crass.* 33; Dio Cass. xlix. 23). He was attacked in 36 by Antonius (Mark Antony), who marched through Armenia into Media Atropatene, and was defeated and lost the greater part of his army. Believing himself betrayed by Artavasdes, king of Armenia, he invaded his kingdom in 34, took him prisoner, and concluded a treaty with another Artavasdes, king of Atropatene. But when the war with Octavianus Augustus broke out, he could not maintain his conquests; Phraates recovered Atropatene and drove Artaxes, the son of Artavasdes, back into Armenia (Dio. Cass. xlix. 24 *seq.*, 39 *seq.*, 44; *cf.* li. 16; Plut. *Antonius*, 37 *seq.*). But by his many cruelties Phraates had roused the indignation of his subjects, who raised Tiridates II. to the throne in 32. Phraates was restored by the Scythians, and Tiridates fled into Syria.

The Romans hoped that Augustus would avenge the defeat of Crassus on the Parthians, but he contented himself with a treaty, by which Phraates gave back the prisoners and the conquered eagles (20 B.C., *Mon. Anc.* 5, 40 *seq.*; Justin xlii. 5); the kingdom of Armenia also was recognized as a Roman dependency. Soon afterwards Phraates, whose greatest enemies were his own family, sent five of his sons as hostages to Augustus, thus acknowledging his dependence on Rome. This plan he adopted on the advice of an Italian concubine whom he made his legitimate wife under the name of "the goddess Musa"; her son Phraates, commonly called Phraataces (a diminutive form), he appointed successor. About 4 B.C. he was murdered by Musa and her son (Joseph. *Ant.* xviii. 2, 4).

5. PHRAATES V., or PHRAATACES, the younger son of Phraates IV. and "the goddess Musa," with whom he is associated on his coins. Under him a war threatened to break out with Rome about the supremacy in Armenia and Media. But when Augustus sent his adopted son Gaius Caesar into the east in order to invade Parthia, the Parthians preferred to conclude a treaty (A.D. 1) by which once again Armenia was recognized as in the Roman sphere (Dio. Cass. lv. 10; Velleius ii. 101). Soon after Phraataces and his mother were slain by the Parthians, about A.D. 5 (Joseph. *Ant.* xviii. 2, 4).

(ED. M.)

PHRANTZA, GEORGE [GEORGIOS PHRANTZES] (1401-c. 1477), the last Byzantine historian, was born in Constantinople. At an early age he became secretary to Manuel II. Palaeologus, and rose to the position of great logothete (chancellor). At the capture of Constantinople by the Turks (1453) he fell into their hands, but managed to escape to Peloponnesus. After the downfall of the Peloponnesian princes (1460) Phrantza retired to the monastery of Tarchaniotes in Corfu. Here he wrote his Chronicle, with an account of the house of the Palaeologi from 1258-1476.

Editions by I. Bekker (1838) in the *Corpus scriptorum hist. byz.*, and in J. P. Migne, *Patrologia graeca*, clvi.; see also C. Krumbacher, *Geschichte der byzantinischen Literatur* (1897).

PWRAORTES, the Greek form of Fravartish, king of Media. According to Herodotus (i. 102) he was the son of Deioeces, and began the Median conquests. He first subjugated the Persians, and then a great many other peoples of Asia, till at last he attacked the Assyrians, but was defeated and killed in a battle, after a reign of 22 years (about 646-625 B.C.; but perhaps, as G. Rawlinson supposes, the 53 years of Deioeces ought in reality to be transferred to him). From other sources we obtain no information whatever about Phraortes; but the data of the Assyrian inscriptions prove that Assur-bani-pal (see BABYLONIA AND ASSYRIA), at least during the greater part of his reign, maintained the Assyrian supremacy in Western Asia, and that in 645 he conquered Susa. The Medians too were subject to him as far as the Elburz and the central Iranian desert.

When after the assassination of Smerdis all the Iranian tribes, the Babylonians and the Armenians rebelled against Darius and the Persian rule, "a man of the name of Fravartish (*i.e.*, Phraortes), a Mede, rebelled in Media and spoke to the people thus: I am Khshathrita, of the family of Uvakhshatra (Cyaxares)." He reigned for a short time, but was defeated by Hydarnes, and afterwards by Darius himself, taken prisoner in Rhagae (Rai), and executed in Ecbatana (520 B.C.; see inscription of Darius at Behistun). (ED. M.)

PHRENOLOGY, the name given to the empirical system of psychology formulated by F. J. Gall, about the year 1800 and developed by his followers, especially by J. K. Spurzheim and G. Combe. The principles upon which it is based are five: (1) the brain is the organ of the mind; (2) the mental powers of man can be analysed into a definite number of independent faculties; (3) these faculties are innate, and each has its seat in a definite region of the surface of the brain; (4) the size of each such region is the measure of the degree to which the faculty seated in it forms a constituent element in the character of the individual; (5) the correspondence between the outer surface of the skull and the contour of the brain-surface beneath is sufficiently close to enable the observer to recognize the relative sizes of these several organs by the examination of the outer surface of the head. It professes primarily to be a system of psychology, but its second and more popular claim is that it affords a method whereby the disposition and character of the subject may be ascertained.

The Faculties and Their Localities.—The system of Gall was constructed by a method of pure empiricism, and his so-called organs were for the most part identified on slender grounds. Having selected the place of a faculty, he examined the heads of his friends and casts of persons with that peculiarity in common, and in them he sought for the distinctive feature of their characteristic trait. Some of his earlier studies were made among low associates, in gaols and in lunatic asylums, and some of the qualities located by him were such as tend to become perverted to crime. These he named after their excessive manifestations, mapping out organs of murder, theft, etc.; but as this cast some discredit on the system the names were changed by Spurzheim, who claimed as his the moral and religious considerations associated with it. Gall marked out on his model of the head the places of twenty-six organs as round enclosures with vacant interspaces. Spurzheim and Combe divided the whole scalp into oblong and conterminous patches (see the accompanying figures) and separated the component faculties of the human mind into two great groups, subdivided as follows:—

- I. Feelings, divided into—
 1. Propensities, internal impulses inviting only to certain actions.
 2. Sentiments, impulses which prompt to emotion as well as to action.
 - A. Lower—those common to man and the lower animals.
 - B. Higher—those proper to man.
- II. Intellectual faculties.
 1. Perceptive faculties.
 2. Reflective faculties.

In the following list the localities are appended to the names, which are mostly the inventions of Spurzheim. Gall's names are placed in brackets. For topography, Broca's names are adopted. Propensities.—I. Amativeness (*Instinct de la génération*),

median, below the inion.

2. Philoprogenitiveness (*Amour de la progéniture*), median, on the squama occipitis.

3. Concentrativeness, below the obelion and over the lambda.

4. Adhesiveness (*Amitié*), over the lateral area of the lambdoidal suture.

5. Combativeness (*Instinct de la défense*), above the asterion.

6. Destructiveness (*Instinct carnassier*), above the ear meatus.

6a. Alimentiveness, over the temporal muscle and above the ear.

7. Secretiveness (Ruse, Finesse), the posterior part of the squamous suture.

8. Acquisitiveness (*Sentiment de la propriété*), on the upper edge of the front half of the squamous suture.

g. Constructiveness (*Sens de mécanique*), on the stephanion.

The organ of Vitativeness, or love of life, is supposed by Combe to be seated at the base of the skull.

Lower Sentiments.—10. Self-esteem (*Orgueil, fierté*), at and immediately over the obelion.

11. Love of Approbation (*Vanité*), outside the obelion.

12. Cautiousness (Circonspection), on the parietal eminence.

Superior Sentiments.—13. Benevolence (*Bonté*), on the middle of the frontal bone in front of the coronal suture.

14. Veneration (*Sentiment religieux*), median at the bregma.

15. Conscientiousness, Believingness (Forster), unknown to Gall; recognized by Spurzheim usually from its deficiency, and placed between the last and the parietal eminence.

16. Firmness (*Fermeté*), median, on the sagittal suture from behind the bregma to the front of the obelion.

17. Hope, not regarded as primary by Gall, who believed hope to be akin to desire and a function of every faculty which desires and left this territory unallocated.

18. Wonder, said to be large in vision-seers and many psychic researchers. A second similar organ placed between this and the next is called Mysterizingness by Forster, and is said to be the

seat of belief in ghosts and in the supernatural.

19. Ideality (Poksie), noted by Gall from its prominence in the busts of poets; said to be the part touched by the hand when composing poetry.

20. Wit (*Esprit caustique*), the frontal eminence.

21. Imitation (*Faculté d'imiter*), disposition to mimicry, placed between Benevolence and Wonder.

Perceptive Faculties.—22. Individuality, over the frontal sinus in the middle line.

23. Form (*Me'moire des personnes*), capacity of recognizing faces; gives a wide interval between the eyes.

24. Size, over the trochlea at the orbital edge.

25. Weight, outside the last on the orbital edge and, like it, over the frontal sinus.

26. Colour, also on the orbital edge external to the last.

27. Locality (*Sens de localité*), placed above Individuality on each side, and corresponding to the upper part of the frontal sinus and to the region immediately above it.

28. Number, on the external angular process of the frontal bone.

29. Order, internal to the last.

30. Eventuality (*Me'moire des choses*), the median projection above the glabella.

31. Time, below the frontal eminence and a little in front of the temporal crest.

32. Tune (*Sens des rapports des tons*), on the foremost part of the temporal muscle.

33. Language (*Sens des mots*), behind the eye.

Reflective Faculties.—34. Comparison (*Sagacité comparative*), median, at the top of the bare region of the forehead.

35. Causality (*Esprit métaphysique*), the eminence on each side of Comparison.

Anatomical and Physiological Considerations.—The teaching of anatomy with regard to phrenology may be summarized thus: (1) the rate of growth of brain is concurrent with the rate of development of mental faculty; (2) there is some degree of structural differentiation as there are varying rates of development of different parts of the cerebral surface; (3) there is no accordance between the regions of Gall and Spurzheim and definite areas of cerebral surface.

That the brain is the organ of the mind is now universally received. While it is probable that certain molecular changes in the grey matter are antecedents or concomitants of mental phenomena, the precise nature of these processes, to what extent they take place, or how they vary among themselves have not as yet been determined experimentally; the occurrence of the change can only be demonstrated by some such coarse method as the altered pulsation of the carotid arteries, the increase of the temperature of the head, the abstraction, during brain-action, of blood from other organs as shown by the plethysmograph, or the formation of lecithin and other products of metabolism in brain-substance.

Psychological Aspect.—There is a large weight of evidence in favour of the existence of some form of localization of function. So little is known of the physical changes which underlie psychological phenomena, or indeed of the succession of the psychological processes themselves, that we cannot as yet judge as to the nature of the mechanism of these centres. So much of the psychic work of the individual life consists in the interpretation of sensations and the translation of these into motions that there are strong a priori grounds for expecting to find that much of the material of the nerve-centres is occupied with this kind of work, but in the present conflict of experimental evidence it is safer to suspend judgment. That these local areas are not centres in the sense of being indispensable parts of their respective motor apparatus is clear, as the function abolished by ablation of a part returns, though tardily, so that whatever superintendence the removed region exercised apparently becomes assumed by another part of the brain. Experimental physiology and pathology, by suggesting other functions for parts of the brain-surface, are thus subversive of many details of the phrenology of Gall and Spurzheim.

The fundamental hypothesis which underlies phrenology as a

system of mental science is that mental phenomena are resolvable into the manifestations of a group of separate faculties. The assumption is contained in the definition that the exercise of a faculty is the physical outcome of the activity of the organ, and in several of the standard works this is illustrated by misleading analogies between these and other organs; thus the organs of benevolence and of firmness are said to be as distinct as the liver and pancreas.

Adverse **Conclusions**.—"Die Schadellehre ist allerdings nicht so sehr Irrthum in der Idee als Charlatanerie in der Ausführung," says one of its most acute critics. Even though no fault could be found with the physiology and psychology of phrenology, it would not necessarily follow that the theory could be utilized as a practical method of reading character; for, although the inner surface of the skull is moulded on the brain, and the outer surface approximates to parallelism thereto, yet the correspondence is sufficiently variable to render conclusions therefrom uncertain. The spongy layer or diploe which separates the two compact tables may vary conspicuously in amount in different parts of the same skull, as in the cases described by Professor Humphry (*Journ. of Anat.*, viii, 137). The frontal sinus, that *opprobrium phrenologicum*, is a reality, not unfrequently of large size, and may wholly occupy the regions of five organs. The centres of ossification of the frontal and parietal bones, the muscular crests of these and of the occipital bones also, differ in their prominence in different skulls. Premature synostoses of sutures mould the brain without doing much injury to its parts. In such cases there are compensatory dilatations in other directions modifying sometimes to an extreme degree the relation of brain-surface to skull-surface. The writer has found such displacements in extremely scaphocephalic skulls; the same is true of accidental deformations due to pressure on the infantile skull before it consolidates.

All these and other cogent reasons of a like kind, whose force can be estimated by those accustomed to deal with the component soft parts of the head, should lead phrenologists to be careful in predicating relative brain-development from skull-shape. Psychology, physiology and experience alike contribute to discredit the practical working of the system and to show how worthless the so-called diagnoses of character really are. Its application by those who are its votaries is seldom worse than amusing, but it is capable of doing positive social harm, as in its proposed application to the discrimination or selection of servants and other subordinate officials.

(A. MAC.; X.)

PHRYGIA, the name of a large district of Asia Minor in ancient times, derived from a people whom the Greeks called *Φρύγες*; i.e., "freemen." Taken at its widest extent, Phrygia comprised the whole north-west and centre of Asia Minor as far as the river Halys and the southern mountain-edge of the penin-

sula, and had sea fronts on the Black sea and the Aegean. But most ancient authors confined the name to an inland district stretching roughly from long. 29° to 32° or 33°, and from lat. 38° to 40°; and the real core of Phrygia at all times lay in the comparatively small plateau between the river Sangarius and the upper course of the Maeander.

Phrygia in its narrower sense is a table-land 3,000-5,000 ft., dotted with isolated mountains that rise to 8,000ft., and intersected by several river-systems, in particular that of the Sangarius in the north-east, of the upper Hermus in the west, and of the upper Maeander in the south. Its deep-cut valleys are well suited to the cultivation of cereals and of the vine, but in general the rainfall of the country is too scanty and irregular for the growth of crops or of forest, and the dry, bare uplands are best adapted to rough grazing. The mineral wealth of Phrygia is inconsiderable. Iron was formerly worked in the district of Cibyra, mercury, cinnabar and copper in the neighbourhood of Iconium; but the most notable product was the marble of Docimium, a white stone streaked with veins of violet.

The principal line of communications across Phrygia was a route which rose steeply out of the Hermus valley and traversed the entire length of the plateau in a somewhat irregular line, proceeding at first in a north-easterly direction to Dorylaeum, thence eastward past Gordium and Ancyra to the old Hittite capital at Boghaz-Keui. This road eventually formed part of the "Royal road," by which the Achaemenid kings of Persia connected Sardes and the Aegean seaboard with their capital at Susa. It appears at all times to have served a military and administrative rather than a commercial purpose. The southern edge of Phrygia was crossed by another trunk road which ascended the valley of the Lycus (a tributary of the Maeander) to Apameia-Celaenae, and thence led to Iconium and across Mt. Taurus into Syria. This route was much used by the Seleucid kings of Syria and by the Romans, and was probably at every period the chief line for commercial traffic to the Aegean sea. The scenery of Phrygia is generally monotonous. Even the mountainous districts rarely show striking features or boldness of character.

The Phrygian Immigration.—It may be taken for granted that the population of Phrygia always contained a large element of that indigenous "Asiatic" stock, whose survival to the present day has been noted by modern travellers. The persistence of this element in ancient times is indicated by the continued prevalence of native Asiatic cults in Phrygia. (See p. 853.) But the Phrygians properly so-called were an immigrant folk. According to Greek tradition they entered Asia Minor from Thrace or Macedonia; and this tradition is confirmed by the fact that their language was certainly Indo-European.

For the date of the Phrygian immigration the best evidence is found in Homer, who represents the Phrygians as rendering aid to King Priam at the siege of Troy, in return for assistance which he had given to them in their wars against the Amazons (=the Hittites?) on the banks of the Sangarius. This story indicates that the Phrygians had entered Asia Minor some time before 1200 B.C. A date not later than 1500 B.C. has been inferred from the furniture of certain burial-mounds in north-western Asia Minor, which resemble the contents of Macedonian tumuli of the early second or late third millennium.

It would appear from Homer that the incoming Phrygians made their principal settlement in the Sangarius valley. Their chief surviving monuments are also found in this valley (at Gordium), and on the adjacent plateau to the south-west of the Sangarius. But it is probable that about 1000 B.C. all the northern and central parts of Asia Minor had come under Phrygian occupation. The extension of Phrygian power to the western seaboard of Asia Minor may be inferred from a somewhat enigmatic Greek tradition, that in the 9th century B.C. they exercised a "thalassocracy" or "lordship of the seas" in Aegean waters, and from the abundance of Phrygian remains on Mt. Sipylus in the lower Hermus valley. The description of Sinope as a "Phrygian" town indicates a Phrygian settlement along the Black sea. Another Greek tradition, that the Armenians were an offshoot of the Phrygian stock, is supported by the resemblance between the

Phrygian and the Armenian tongues.

The expansion of the Phrygians into eastern Asia Minor is proved by the discovery of an inscription in the Phrygian language at Tyana in Cappadocia. This text, it is true, does not appear to be of earlier date than the 8th century B.C. But the presence of Phrygians on the borders of the Euphrates may perhaps be inferred from Assyrian records which relate victories by Tiglath-Pileser I. (c. 1120 B.C.) and by Sargon (717-709 B.C.) over a tribe named the Mushki. The fact that in one of Sargon's inscriptions the chief of the Mushki bears the name "Mita" suggests that the Mushki were Phrygian, or at least had Phrygian rulers, for "Mita" or "Midas" was a common name among the kings of Phrygia proper.

The relation between the Phrygians and the Hittites, who were the predominant people in Asia Minor c. 1500 B.C., is not yet quite clear. The existence of a group of rock-carvings in Hittite style, extending from Ancyra to Sardes and Smyrna, suggests that Phrygia proper may at one time have been under Hittite government, but the character of Hittite influence in north-western Asia Minor still remains uncertain. On the other hand there is little doubt that the decline of Hittite culture and the disappearance of Hittite power from Asia Minor after 1000 B.C. was in large measure due to the expansion of the Phrygians over the peninsula.

Decline of Phrygia.—About 1000 B.C. the Phrygians had penetrated southward in Asia Minor as far as the Hermus and the Maeander, and eastward to the Halys, if not to the Euphrates. But over the greater part of this territory they were unable to consolidate their power, or to extend their culture. East of the Halys they disappear from history about 700 B.C. Their frontage on the Black sea was taken from them by the Bithynians, who probably entered Asia Minor from Europe soon after 1000 B.C. Their access to the Aegean was shut off at some unknown date by the Greek colonists of the coastland and by the Lydians of the Hermus valley. After 800 B.C. the only districts which remained in Phrygian occupation were the tableland between the Sangarius and the Hermus, and the borderland of the Dardanelles and the Sea of Marmora, known later as "Hellespontine Phrygia."

In the 8th century B.C. Phrygia proper achieved a considerable measure of prosperity under a line of kings who had their capital at Gordium and were called alternately "Gordius" and "Midas." The last and greatest of this dynasty was a king Midas who reigned, according to Greek chronologers, from 738 to 695 B.C. This ruler cultivated close relations with the Greeks. He was the first foreign ruler to dedicate offerings to Apollo at Delphi, and he took to wife the daughter of Agamemnon, king of the Aeolic Greek city of Cyme. His name may still be read on his tomb in the "Midas city," one of the most notable remains of Phrygian art.

Soon after 700 B.C. the reign of Midas was brought to a sudden end by the incursion of a Thracian people named the Cimmerians, of which Greeks, Lydians and Assyrians felt the force, but the Phrygians took the full brunt. By the second half of the 7th century the Cimmerians disappeared from Asia Minor without leaving a trace, but Phrygia was now so far enfeebled that it fell under the dominion of the neighbouring kingdom of Lydia.

Phrygia under Foreign Rule.—Under the Lydian rule Phrygia seems to have recovered some of its former prosperity. If the dates usually assigned to Phrygian monuments are correct, Phrygian art reached its highest development about 600 B.C. A resumption of commerce with the Greeks at this period is indicated by finds of Corinthian pottery at Gordium. But after the conquest of Lydia by the Persians (546 B.C.) Phrygia shared in the general decline which now befell western Asia Minor; nothing more is heard of its trade with the Greeks, except that it was a favourite hunting-ground for Greek slaves. It formed one large Persian province, but about 400 B.C. it was divided into two portions, "Great Phrygia" and Hellespontine Phrygia.

After two centuries of uneventful history under Persian rule Phrygia passed into the hands of Alexander of Macedon, who visited Gordium (333 B.C.) and there cut the "Gordian knot"; legend declared that this knot, which secured the yoke to the

shaft of an archaic farm-wagon, had been tied by Gordius, the founder of the Phrygian dynasty, and that whosoever might unravel it should become lord of Asia. After Alexander's death Phrygia became a battle-ground for the contending forces of his former marshals. At first it formed the nucleus of the territory of Antigonus, who set up his capital at Celaenae; but after the decisive action at the neighbouring site of Ipsus (301 B.C.) it was transferred to Seleucus as an annex to the kingdom of Syria.

About 275 B.C. all the Phrygian lands east of the Sangarius came into the possession of a horde of Celtic invaders from the Danube lands and was renamed Galatia. The western portion of Phrygia at the same time was taken from the kings of Syria by the newly-founded monarchy of Pergamum. For nearly a century the Phrygian territory remained a bone of contention between the kings of Pergamum and Syria and the Galatian Celts, until in 189 B.C. the Romans expelled the Syrian kings from Asia Minor, confined the Celts to Galatia, and left the western half of the peninsula under the undisputed control of the Pergamene rulers. After the annexation of the Pergamene kingdom by Rome in 133 B.C., Phrygia west of the Sangarius became part of the province of Asia, and remained in this condition until c. A.D. 300, when the emperor Diocletian constituted it into two independent provinces, Phrygia Prima and Secunda. Under the Byzantine empire the name Phrygia disappeared altogether.

ECONOMIC LIFE AND CULTURE

Economic Conditions.—Phrygia was at all times an agricultural and, still more, a pastoral land. The only industrial products of greater importance were the marble of Docimium, which was exported in large quantities to Rome under the empire, and the dark-coloured woollens of Laodiceia and Colossae (in South Phrygia, on the River Lycus). The southern border of Phrygia, as we have seen, was traversed by a trade route which, in the days of Greek and Roman rule, attained considerable importance. On the other hand the Royal road, which ran through the heart of Phrygia, played no great part as a highway of commerce, and there is no evidence of any notable quantity of traffic having been carried along the valley of the Sangarius. Phrygia's chief source of wealth lay in its grasslands, which produced fine breeds of horses and of sheep. The horses were exported as far as Rome for use in the circus. The sheep provided a clip of wool which supplied the looms, not only of Phrygia itself, but also of Miletus, Pergamum and other Greek centres of the textile industry.

Under economic conditions such as these, Phrygia was always a land of villages rather than of cities. In the days of the native monarchy Gordium and the "Midas city" grew to be considerable towns, and Celaenae (subsequently renamed Apameia) was probably at all times a trading centre of some importance. Under the rule of the Syrian and Pergamene dynasties a number of new cities with a predominantly Greek population were founded, but most of these were little more than garrison towns or settlements of veterans: the only places that require mention here are the industrial cities of Laodiceia and Colossae (noticed above). The villages were usually built on the slopes of the lower hills, near the site of a temple or of a great landowner's manor-house. The soil for the most part belonged to the successive kings or overlords of the Eoutry, to their principal vassals, and to the priesthoods of the more important temples. The actual cultivators lived mostly in a condition of serfdom.

Culture.—The history of Phrygian art is not easy to trace, because the chronological order of the surviving monuments is not yet certain. Its most typical products are rock-cut tombs and houses, and ornamented rock-facades. The entrances to the tombs are often decorated with a gable like that of a Greek temple, supported on pillars in a primitive Dorian or Ionic style. The subjects most commonly represented in the sculptured reliefs are the native goddess Cybele, and pairs of rampant lions, heraldically opposed. Another characteristic ornament consists of a maeander pattern carved in flat relief. The native pottery is ornamented with geometric patterns in matt paint. In the relations of Phrygian art to that of other peoples the one clear point

is that its technique of rock-carving bears close resemblance to that of the Hittites, as exhibited at Bognaz-Keui and in eastern Asia Minor, and was probably borrowed from this people. The meander patterns, which are no doubt in imitation of tapestry work, also appear to have been derived from Hittite models, and it was perhaps through a Hittite medium that the heraldic lions and the Ionic pillars were introduced into Phrygia from Mesopotamia. The gables and the Doric columns of the Phrygian rock-tombs are strongly reminiscent of archaic Greek art, and it is not unlikely that they are Greek in origin. In general, the Phrygian artists were not inventive, but they knew how to adapt to their own uses whatever they borrowed from their neighbours.

Phrygian music is only known to us from the descriptions of Greek critics, who considered it too florid and exciting. Its favourite instrument was a double flute, which the Greeks regarded as the prototype of their own *aulos*. But the double flute was also known in prehistoric Crete, and can therefore not be regarded as a Phrygian invention.

The alphabetic script of the Phrygians bears a closer resemblance to archaic Greek than to Phoenician; but its exact relation to either of these has not yet been determined. It is only represented by a few texts: all the later inscriptions from Phrygia are in Greek or Latin characters. The Phrygian tongue, which may best be studied in the fairly numerous texts (mostly epitaphs) of the early centuries A.D., is akin to Armenian. In the period of Greek and Roman rule it gave way to Greek in the towns, but on the countryside it remained in use until the 5th or 6th century A.D. (*See ASIATIC LANGUAGES.*)

Religion.—The religion of Phrygia was plainly a composite product. The Phrygian immigrants of c. 1200 B.C. brought with them several typical Indo-European gods, such as Papas, the equivalent of the Greek Zeus, and Men, a male moon-deity. The god Sabazius, who was usually equated by ancient writers with the Thracian Dionysus, may be referred to the same group. But the gods of the Phrygian invaders were never able to displace the original Asianic deities, of whom the foremost were Cybele, the "Great Mother," and Attis, a youth who died untimely but in death retained his beauty of figure. This couple, which had several parallels in the religions of the Near East, evidently represented the generative force of nature and the vegetation that withers and blooms with each new season. The worship of these deities was highly orgiastic, and their priests, the so-called "galli," carried their devotion to the point of self-mutilation. The principal sanctuary of Cybele stood at Pessinus, by Mt. Dindymus in central Phrygia, where a hierarchy of priests exercised theocratic rule over the inhabitants of the extensive temple estates. Not only did the cult of Cybele and Attis maintain itself against the religion of the Phrygian newcomers, but it partially absorbed them. Nay more, it more than held its own against the religions of Greece and Rome, and it competed against these on European soil. The worship of Cybele spread to Greece in the 5th century B.C.; in 204 B.C. it was officially established at Rome; in the days of the Roman empire it was carried on the tide of oriental immigration into every part of Italy and penetrated the western provinces as far as the Rhineland and Britain. Thus the religion of Phrygia was its most distinctive contribution to ancient Mediterranean civilization. The influence of the native Asianic religion may also be traced in the various heresies, and especially the heresy of Montanus (himself a Phrygian), that arose in Phrygia after the spread of Christianity. Nevertheless the conversion of Phrygia to Christianity was remarkably early and complete. Christian inscriptions begin there in the 2nd century and are abundant in the third. In all probability the mass of the people had been converted by 300, and Eusebius is no doubt correct in saying that in one Phrygian city at that time every soul was a Christian.

BIBLIOGRAPHY.—(a) *Topography* and Monuments.—Recent records of exploration will be found in the numerous books and articles of Sir William Ramsay, especially in his *Cities and Bishoprics of Phrygia* (1895-97), and in the *Journal of Hellenic Studies* (1882 ff.). The results of the German excavations at Gordium are set forth in Korte, *Gordion* (1904). Art in Phrygia, Lydia, Caria, and Lycia. (Engl. transl., 1892). (c) *Language*.—Most of the surviving texts in Phrygian have been collected by W. M. Calder in *Journ. Hell. Stud.* (1911 and 1913). (d) *Religion*.—Ramsay, in *Hastings' Encyclopaedia of Religion and Ethics*, ix., p. 900-911. (e) *History*.—No comprehensive book on the subject has been written. Much useful information will be found in D. G. Hogarth's chapters in the *Cambridge Ancient History*, vols. ii. and iii. (1924-25). (M. C.)

PHRYNE, Greek courtesan, lived in the 4th century B.C. Her real name was Mnesarete, but owing to her complexion she was called Phryne (toad). She was born at Thespieae in Boeotia, but seems to have lived at Athens. She acquired so much wealth that she offered to rebuild the walls of Thebes, on condition that the words "Destroyed by Alexander, restored by Phryne the courtesan," were inscribed upon them. On the occasion of a festival of Poseidon at Eleusis she laid aside her garments, let down her hair, and stepped into the sea in the sight of the people, thus suggesting to the painter Apelles his great picture of Aphrodite Anadyomene, for which Phryne sat as model. She was also (according to some) the model for the statue of the Cnidian Aphrodite by Praxiteles. When accused of profaning the Eleusinian mysteries, she was defended by the orator Hyperides. When it seemed as if the verdict would be unfavourable, he rent her robe and displayed her bosom, which so moved her judges that they acquitted her. A statue of Phryne, the work of Praxiteles, was placed in a temple at Thespieae by the side of a statue of Aphrodite by the same artist.

PHRYNICHUS. 1. Son of Polyphradmon and pupil of Thespis, one of the earliest of the Greek tragedians. Some of the ancients, indeed, regarded him as the real founder of tragedy. He gained his first poetical victory in 511 B.C. His most famous play was the *Capture of Miletus*. The audience was moved to tears, the poet was fined for reminding the Athenians of their misfortunes, and it was decreed that no play on the subject should be produced again. In 476 Phrynichus was successful with the *Phoenissae*, celebrating the victory of Salamis and especially the deeds of Themistocles, who was choragus. Phrynichus is said to have died in Sicily. He introduced a separate actor as distinct from the leader of the chorus, and thus laid the foundation of dialogue. But in his plays, as in the early tragedies generally, the dramatic element was subordinate to the chorus. According to Suidas, Phrynichus first introduced female characters on the stage (played by men in masks), and made special use of the trochaic tetrameter.

Fragments in A. Nauck, *Tragicorum graecorum fragmenta* (1887).

2. A poet of the Old Attic comedy and a contemporary of Aristophanes. His first comedy was exhibited in 429 B.C. He composed ten plays, of which the *Solitary* (*Μονότροπος*) was exhibited in 414 along with the *Birds* of Aristophanes, and gained the third prize. The Muses carried off the second prize in 405, Aristophanes being first with the *Frogs*, in which he accuses Phrynichus of employing vulgar tricks to raise a laugh, of plagiarism and bad versification.

Fragments in T. Kock, *Comicorum atticorum fragmenta* (1880).

3. **PHRYNICHUS ARABIUS**, a grammarian of Bithynia, lived in the 2nd century A.D. According to Suidas he was the author of (1) an Atticist, in two books; (2) *Τιθεμένων συναγωγή*, a collection of subjects for discussion; (3) *Σοφιστική παρασκευή* or *Sophistical Equipment*. The work was learned, but prolix and garrulous. A fragment contained in a Paris ms. was published by B. de Montfaucon, and by I. Bekker in his *Anecdota graeca* (1814). Another work of Phrynichus, not mentioned by Photius, but perhaps identical with the Atticist mentioned by Suidas, the *Selection* (*Ἐκλογή*) of Attic Words and *Phrases*, is extant. It is a collection of current words and forms which deviated from the Old Attic standard, and is interesting as illustrating the changes through which the Greek language had passed between the 4th century B.C. and the 2nd century A.D.

Editions of the *Ἐκλογή*, with valuable notes, have been published by C. A. Lobeck (1820) and W. G. Rutherford (1881); Lobeck devotes his attention chiefly to the later, Rutherford to the earlier usages

noticed by Phrynichus. See also J. Brenous, *De Phrynicho Atticista* (1895).

4. An Athenian general in the Peloponnesian War. He took a leading part in establishing the oligarchy of the Four Hundred at Athens in 411 B.C., and was assassinated in the same year (Thucydides viii.).

PHTHALIC ACIDS, the name given to the three isomeric benzene-dicarboxylic acids, $C_6H_4(CO_2H)_2$: (1) ortho, or phthalic acid; (2) meta, or *isophthalic acid*; (3) para, or terephthalic acid. The most important is the first, as it forms the starting material in the production of many synthetic dyes and of the synthetic resin, glyptal, glyceryl phthalate.

Phthalic acid was obtained by Laurent in 1836 by oxidizing naphthalene tetrachloride, and, believing it to be a naphthalene derivative, he named it naphthalenic acid; Marignac showed Laurent's supposition to be incorrect, upon which Laurent gave it its present name. It was formerly manufactured by oxidizing naphthalene tetrachloride (prepared from naphthalene, potassium chlorate and hydrochloric acid) with nitric acid, or by oxidizing the hydrocarbon with fuming sulphuric acid, using mercury or mercuric sulphate as a catalyst (German pat. 91,202). These methods have been superseded by a catalytic process in which air and naphthalene vapour are passed over heated vanadium pentoxide; the yield is upwards of 80% of phthalic anhydride, which is readily separated by fractional sublimation from unchanged naphthalene. Phthalic acid forms white crystals, melting at 213° with decomposition into water and phthalic anhydride; the latter forms long white needles, melting at 128° and boiling at 284° .

Phthalyl chloride, $C_6H_4(COCl)_2$ or $C_6H_4(CCl_2)(CO)O$, formed by heating the anhydride with phosphorus pentachloride, is an oil solidifying at 0° and boiling at 275° . In some reactions it behaves as having the first formula, in others as having the second. Phthalyl chloride with phosphorus pentachloride gives two phthalylene tetrachlorides, one melting at 88° and the other at 47° . They cannot be changed into one another, and have been given the formulae $C_6H_4(CCl_2)(COCl)$ and $C_6H_4(CCl_2)_2O$.

Isophthalic acid is obtained by oxidizing meta-xylene with chromic acid, or by fusing potassium meta-sulphobenzoate, or meta-bromobenzoate with potassium formate (terephthalic acid is also formed in the last case). It melts above 300° , and dissolves in 7,800 parts of cold water and in 460 of boiling.

Terephthalic acid, formed by oxidizing para-derivatives of benzene, or best by oxidizing caraway oil, a mixture of camphene and cuminol, with chromic acid, is almost insoluble in water, alcohol and ether; it sublimes without melting when heated.

PHTHISIS (tí'sis), a name formerly given (like "Consumption") to the disease of the lung now known as Tuberculosis (*q.v.*) from the wasting often observed. This wasting depends mainly upon secondary infection of tuberculous areas by pyogenic micrococci and is accompanied by much fever and profuse sweating. Modern tendency is to use the term "phthisis" only when implying the existence of this double infection.

PHYFE, DUNCAN (c. 1768-1854), American cabinet-maker, was born near Inverness, Scotland, in 1768, came to the United States about 1783, and was apprenticed to a cabinet-maker in Albany. He moved to New York city in 1790 where he opened a shop, first in Broad Street, later in what is now Fulton Street. He made chairs, tables, settees, sideboards and other furniture, following his own adaptations of Sheraton and Adam styles and using chiefly mahogany. After 1820 he copied Empire styles. His best period was that in which he was under the influence of Sheraton. Most of the Phyfe furniture is characterized by excellent proportions, graceful curves, the use of reeding and brass ornamentation, the best known motifs being the acanthus leaf, the oak leaf, and the lyre. Duncan Phyfe died in New York, 1854.

PHYLACTERY, a term applied in Matt. xxiii. 5 to the *tefillin* of the Jews on the assumption that these were amulets (*φυλακτήρια*), against physical evil. *Tefillin*, either from *תפיל*, to attach, or *תפלה*, whence *תפלה*, prayer, are certain Pentateuchal texts which, in accordance with Exod. xii. 16 and Deut. vi. 5-9, were to be worn as constant reminders of God during the daily avocations. Hence they were not used on Sabbaths and festivals, as

the day itself was a reminder and the schools and markets were closed. The idea of such an outward sign is common. The modern habit of wearing a cross on a watchchain may be compared. Romans had tablets for memoranda hanging from the wrists. Isaiah xlix. 16 evidently denotes this custom. Possibly the origin is to be sought in tattooing. *Tefillin* are worn on the hand and head, the verses being enclosed in leather boxes fixed in position by leather thongs. The hand phylactery has one compartment, in which the texts figure on one parchment, the head phylactery having four such compartments, each with one text. The extracts are Ex. xiii. 1-10:11-16; Deut. vi. 4-9, xi. 13-21.

BIBLIOGRAPHY.—For further details, illustrations and historical and critical views, see *Jewish Encyclopedia*, *s.v.* For the prayers and meditations, see S. Singer's *Authorized Daily Prayer Book*, pp. 19 *sqq.* For certain Jewish objections see A. Asher's *Collected Writings*, pp. 8-89 (1916, privately printed). Linked with *Tefillin* are the *Mezuzah* (door text) and *Cicith* (fringes). The former is a text containing Deut. vi. 4-9 rolled in a glass or metal tube on the right-hand of each door, so that everyone who enters or leaves shall think of God (see *Jew. Enc. s.v.* Singer, *op. cit.*, p. 292). The latter (see *Jew. Enc. s.v.* Fringes) is based on Numbers xv. 37-41, which ordains the knotted tassel as a mnemonic.

PHYLE, a mountain fortress, on a pass leading from Athens into Boeotia on the south-west end of Mt. Parnes; famous for its occupation by Thrasybulus at the head of the Athenian exiles during the rule of the Thirty Tyrants in 404 B.C. Defending himself with the help of a snowstorm, he succeeded by a night march in seizing Munychia.

PHYLLITE, in petrology, a group of rocks which are in practically all cases metamorphosed argillaceous sediments, consisting essentially of quartz, chlorite and muscovite, and possessing a well-marked parallel arrangement or schistosity, so called from Gr. *φύλλον*, a leaf, probably because they yield leaf-like plates, owing to their fissility. They form an intermediate term in the series of altered clays or shaly deposits between clay-slates and mica-schists. The clay-slates have a very similar mineral constitution to the phyllites, but are finer grained and are distinguished also by a very much better cleavage; in the phyllites also white mica (muscovite or sericite) is more abundant as a rule than in slate, and its crystalline plates are larger; the abundance of mica gives these rocks a glossy sheen on the smooth planes of fissility.

A microscopical section of a typical phyllite shows green chlorite and colourless mica, both in irregular plates disposed in parallel order, with a greater or smaller amount of quartz which forms small lenticular grains elongated parallel to the foliation. Grains of iron oxide (magnetite and haematite) and black graphitic dust are very commonly present. Felspar is absent or scarce, but some phyllites are characterized by the development of small rounded grains of albite, often in considerable numbers. The minute needles of rutile, so often seen in clay-slates, are not often met with in phyllites, but this mineral forms small prisms which may be intergrown with black magnetite; at other times it occurs as networks of sagenite. Other phyllites contain carbonates (usually calcite but sometimes dolomite) in flat or spindle-shaped crystals, which often give evidence of crushing. Very tiny blue needles of tourmaline are by no means rare in phyllites, though readily overlooked. Garnet occurs sometimes, a good example of the garnetiferous phyllite being furnished by the whetstones of the Ardennes, in which there are many small isotropic crystals of manganesian garnet. Hornblende, often in branching feathery crystals, is a less frequent accessory. In some phyllites a mineral of the chloritoid group makes its appearance; this may be ottrelite, sismondine or other varieties of chloritoid, and occurs in large sub-hexagonal plates showing complex twinning, and lying across the foliation planes of the rock.

The structural variations presented are comparatively few. The most finely crystalline specimens have generally the most perfect parallel arrangement of their constituents. The foliation is generally flat or linear, but in some rocks is undulose or crumpled. From the imperfection of their cleavage phyllites are rarely suitable for roofing materials; their softness renders them valueless as road stones, but they are not uncommonly employed as inferior building materials. They are exceedingly common in all parts of the world where metamorphic rocks occur; as in the

Scottish Highlands, Cornwall, Anglesey, north-west Ireland, the Ardennes, the Harz Mountains, Saxony, the Alps, Norway, the Appalachians, the Great Lakes district in America, etc.

(J. S. F.)

PHYLLOXERA, a genus of insects belonging to the group Phylloxerinae of the family *Aphididae* which comprises the aphides (*q.v.*) or plant lice. The Phylloxerinae are sometimes placed in a separate family of their own, since they differ from true aphides in characters exhibited in the wing-veins, and also in the fact that

FIG. 1.—ROOT INHABITING FORM OF THE PHYLLOXERA, WITH ITS PROBOSCIS INSERTED INTO TISSUE OF ROOT OF VINE

the parthenogenetic forms lay eggs instead of producing living young. The genus *Phylloxera* includes over 30 species, the best known being the grape Phylloxera (*P. vastatrix*), which is native to the United States. It was imported into Europe between 1858 and 1863, when American vines were brought over for grafting purposes, and has since reached almost every vine-growing country in the world. The first definite European record was in England in 1863; soon afterwards it was identified in France where it rapidly spread through the vineyards of that country. By 1885 it had extended to most other European grape-producing countries and had reached Algeria, Australia, and the Cape. It was first discovered in California in 1880, but there is evidence that it was present in that State from about 1858, being introduced along with American vines from east of the Rocky Mountains. It was the advent of the highly susceptible European grape that led to the Phylloxera becoming a pest in the Californian vineyards. The presence of this insect is manifested by the vines being stunted and bearing smaller and fewer leaves. When the disease is advanced the leaves are discoloured and galls are present on their under surface. These galls are wrinkled and hairy and their cavity communicates by means of an opening upon the upper surface of the leaf. If the roots be examined, numerous knotty swellings are found upon the smaller rootlets; at first yellowish in colour and fleshy, they finally assume a brown or black colour and become rotten. At the same time the grapes themselves are arrested in their growth and their skins become wrinkled. The damage wrought by the Phylloxera is occasioned by the extraction of the sap by means of the piercing suctorial mouth-parts of this insect, and the subsequent deformation of the plant that is brought about. Millions of acres of vineyards have been destroyed by this pest, and, when at its worst in France, it is stated to have ruined 2,500,000 acres which represented an annual loss in wine-products of £50,000,000.

The complete life-history of Phylloxera is briefly as follows: A single egg is laid by the fertilized female on the bark of the vine where it passes the winter. It hatches in spring into a wingless female or *fundatrix* which, creeping into an opening bud of the vine, forms a gall on the young leaf and lays therein a number of eggs. The latter develop into further wingless forms or *gallicolae* which multiply rapidly and produce new generations of gall-formers on the leaves. Among their progeny there appear, later in the season, wingless females of different behaviour, the *radicolae* (fig. 1), which pass to the roots. The *radicolae* continue reproducing generations of their own kind, but among them winged migrants (fig. 2) eventually appear. These occur from July until October and fly to other vines where they lay two kinds of eggs—small male-producing eggs and large female-producing

FIG. 2.—WINGED MIGRANT FEMALE
Hatched from the egg of the root Phylloxera, this form flies to other vines where it lays parthenogenetically, eggs of two kinds, male and female

eggs. The true sexual forms derived from these eggs (fig. 3) are small wingless individuals with vestigial mouth-parts and an aborted alimentary canal. Fertilization takes place and each fertilized female deposits a single over-wintering egg which hatches into a fundatrix as already described. All the rest of the reproduction of the species is by means of parthenogenesis (*q.v.*).

It is noteworthy that in Europe and California the fundatrices

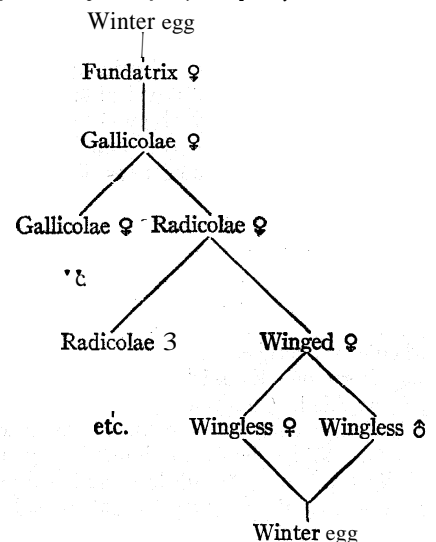

FIG. 3.—MALE AND FEMALE FROM EGGS LAID BY WINGED MIGRANT FEMALE

The female dies after laying a single egg which hatches out in the spring as a female insect known as a fundatrix. This form produces eggs from which are hatched gallicolae. Some of these remain in the buds while others descend to the roots as radicolae

usually fail to develop in the absence of certain American vines and the gallicolae generations are consequently rare. Reproduction and spread are brought about by the radicolae, many of which hibernate and continue multiplying in spring. According to the German authority Boerner, there is a race of Phylloxera found in Lorraine which produces galls on European vines, but not on most American varieties, and he has given this Lorraine race the distinctive name of *pervastatrix*.

Scheme of the complete life-cycle of Phylloxera

Many control measures have been suggested against the Phylloxera but few have been generally adopted in practice. The enforcement of quarantine regulations precluding the distribution of rooted vines from infested areas is important. The utilization of vine-stocks less susceptible to the root-feeding form of the insect is generally recognized. Varieties of American grapes, such as *Vitis riparia*, *V. rupestris*, *V. berlandieri* and their hybrids, are not seriously injured by the radicolae, and by growing these varieties, or using them as stocks upon which the susceptible European varieties have been grafted, injuries by the pest have been greatly reduced. In certain cases the injection of carbon bisulphide into the soil to kill the root form of the insect has been profitable. The flooding of infested vineyards has been a recog-

nized procedure where conditions are favourable.

BIBLIOGRAPHY.—The literature on the Phylloxera is voluminous. Valéry Mayet, *Les Insectes de la Vigne* (1890); B. Grassi, "The Biology of the Vine Phylloxera" (Monthly Bulletin of Agric. Intelligence and Plant Diseases, vol. vi., 1915); W. M. Davidson and R. L. Nougaret, "The Grape Phylloxera in California" (Bulletin 903, U.S. Dept. of Agriculture, 1921), are among the less technical writings. For a full bibliography see B. Grassi, *Contributo alla Conoscenza delle Fillosserine* (1912). (A. D. I.)

PHYSHARMONICA, a keyboard instrument fitted with free-reeds, a kind of harmonium much used in Germany. It resembles a small harmonium, but differs from it in having no stops. The physharmonica was invented in 1818 by Anton Häckel, of Vienna.

PHYSICAL CULTURE is the development of the body by exercise to promote and maintain good health or to correct defects or weaknesses of the body. Benefit to the body is the main object and recreation derived therefrom is incidental. Physical culture in its simplest form is taking exercises such as setting-up exercises or calisthenics. The use of equipment—dumb-bells, wands or weight machines—though not necessary, adds interest and variety to the exercises.

Development.—The value of exercise to promote health and physical strength has probably always been recognized by mankind. In ancient and mediæval times building up of the body was principally for purposes of war, or, as in ancient Greece, preliminary training for sports. Systematic physical culture first appeared during the last part of the 18th century in Germany. In 1774, Basedow founded at Dessau a school in which running, wrestling, riding and manual labour were prescribed as exercise for the students. In 1785, Guts Muth started a system of gymnastics in a school near Gotha, and in 1793 published a book, *Gymnastics for the Young*. At about the same time Nachtigall in Denmark, and Ling in Sweden, were introducing physical training in those countries.

To Professor Ludwig Jahn of Germany should probably go the greatest credit for organizing physical training on a broad scale for the benefit of all the people of the country. Under the direction of Jahn, boys, youths and men of all classes of society took part in exercises for physical development throughout Germany (about 1810). Even with Jahn the idea was physical culture with the ultimate object of physically strengthening the manpower of Germany for war. Physical culture first appeared in the United States and England about 1825, and probably in other European countries at about the same time. It developed slowly between 1825 and 1875. Since 1875, due to the rapid growth of the machine, mechanical transportation and labour-saving devices, the occupations of millions of adults have changed from manual labour to office work; the play of children has been restricted in large densely populated cities, thus the necessity for and practice of physical culture has grown rapidly.

General Rules.—From 10 to 15 minutes daily is sufficient for physical culture exercises; preferably in the middle of the morning or in the afternoon. Exercise immediately before or after a meal should be avoided. Children should be given exercises under the supervision of teachers or parents. If the exercise must be taken before breakfast it should be immediately after rising and be followed by a warm bath and dressing leisurely; if the daily bath is taken at night the exercises should precede the bath. The air in the room should be fresh but not chillingly cold. Clothing should be light and loose. All parts of the body should be exercised during each period even when the object is to strengthen a particular part, but no part should be given more than two exercises in succession. For example, take an arm exercise, a trunk exercise, a leg exercise, etc., following some system of rotation. After an exercise that causes muscular strain, take one that loosens the muscles. Take the breathing exercise at the middle and end of the period. The exercises may be made harder by going to full positions, increasing the cadence or number of repetitions and by the use of equipment. They may be made easier by going to quarter positions and executing slowly. For those who are old or weak the milder exercises should be selected, and regulated to result in good circulation of the blood and loosening up and

exercising the muscles without exhaustion

Attention.—Start the exercises from the position of attention, heels together and on the same line, toes turned out equally at about 45°, weight resting on the balls of the feet, legs straight but not stiff, hips level, stomach drawn in, chest raised, back straight, shoulders back and sloping equally, neck and head vertical, chin raised, body and mind alert. In moving the shoulders back keep the stomach drawn in: otherwise a swayed back position will result. Standing with the back to a flat wall and attempting to make the back touch it from head to heel will indicate how the stomach must be drawn in to make the back straight. Repeat each exercise from 5 to 15 times. Words in parentheses, below, indicate parts of the body that will be benefited.

Exercises. Arms Sideward—horizontal, palms down, fingers extended and joined, arms stretched; (1) Close fists; (2) spread fingers to fullest extent. Repeat ten times. Variations: Move wrists up and down, or right and left, or with a rotary motion. (Fingers, wrists, biceps.)

Arms to Thrust—forearms horizontal and parallel at waist, elbows back, fists closed, back of hands down; (1) Thrust arms to front horizontal, palms down; (2) swing sideward, palms up, forcing shoulders back and chest out; (3) return to front position; (4) return to thrust. (Chest, shoulders.) Variation: At 2 swing arms upward.

Arms Sideward Upward—vertical, parallel, palms facing; (1) Bend trunk to right side; (2) recover starting position; (3) bend trunk to left; (4) recover. (Trunk, side and back muscles.) Variations: Bend trunk 30° forward and backward on 1 and 3. Bend trunk forward and circle right, back, left and forward.

Hands on Hips—thumbs to rear, tips of fingers on point of hip; (1) Quarter bend knees, spreading them and lowering trunk in its erect position as far as possible without raising heels; (2) recover. (Leg muscles and joints, balance.) Variations: Half bend—heels off floor; or full bend—sitting on heels, in all cases body erect.

Hands on Shoulders—tips of fingers touching shoulder, elbows to sides and pressed back, upper arm horizontal; (1) Rise on toes, stretching body upward; at same time extend arms to side horizontal, palms up; (2) recover. (Toes, calves, arms.) Variations: Extend arms forward, or upward, or to the three positions in rotation.

Hands on Hips—(1) Bend neck forward, chin in, stretching back of neck; (2) recover; (3) bend neck backward; (4) recover. Variations: Bend neck to sides or bend forward and circle head right, back, left, forward.

Arms Sideward Upward—lock thumbs, palms to front; (1) Full bend trunk forward, touching floor, knees straight; (2) recover; (3) bend trunk backward; (4) recover. (Stomach and back muscles.) Variations: Spread feet about 18 in. and swing hands down and back between legs, or twist trunk as it bends forward and swing arms to side of legs and backward.

Hop to Side Straddle—feet spread about 24 in., landing on toes and raising arms sideward upward; (2) recover attention on toes. Execute in fast cadence, loosening up all muscles of body.

Lunge forward with right foot 30 to 40 in., right knee bent, raising arms to side horizontal, palms up, upper body erect; (2) bend trunk forward, clasping right knee with both arms; (3) recover first position; (4) recover attention. Repeat lunging with left foot. (General exercise, arms, trunk and legs.) Variations: Lunge to sides and on 2 twist as well as bend the trunk so as to clasp the knee.

Bend to squatting position, hands on floor between the feet, knees spread; (2) extend legs backward, feet together, toes on floor, body straight, supported only on toes and straight arms; (3) recover squatting position; (4) recover attention. (General exercise, arms, shoulders, trunk, back, legs.) Variations: Extend one leg back at a time, alternating; or both legs back and at (3) spread feet 30 to 40 in., at (4) bring feet together; (5) recover squatting position; (6) recover attention.

Lie on Back—hands at sides, palms on floor; (1) Raise right leg to vertical, knee straight, toes pointed upward; (2) lower; (3)

raise left leg; (4) lower; (5) raise both legs; (6) lower. (Trunk.)

Sitting Position—arms to thrust, knees straight. Rowing exercise: (1) Bend trunk forward, extending arms to touch toes; (2) recover erect sitting position bringing arms to thrust with force. (Trunk and chest.)

Leap *in* air 8 or 10 in. (1) toes point down and back, knees straight, legs together, throwing arms upward, sideward and back, head back, looking at ceiling and arching back in midair, all in one count; (2) return to position of attention on toes. (General exercise all parts.)

Hands on Hips—(1) Swing right leg to front horizontal, bending trunk forward and extending left hand to touch right toe, rising on left toe; (2) recover; (3) same with left leg and right arm; (4) recover. (Loosening exercise, leg and trunk.)

Breathing Exercise—(1) Inhale slowly, rising on toes, raising arms forward upward, filling the lungs, raising chest and stretching the whole body upward; (2) exhale rapidly, bringing arms down and back to sides and resume attention. Repeat 5 to 10 times.

PHYSICAL RESOURCES. Though the term "physical" or "natural" resources has no precise definition, it may be taken to designate those things, inert substances, living organisms and effective combinations or products of natural forces, which men utilize to promote their material well-being.

An analytical classification of natural resources might rest on any one of several bases. The historical method might be followed, since it is known that primitive men first made use of vegetable materials, later domesticated animals and finally arrived, at a relatively recent time, at a state of civilization in which the extensive use of minerals is the most important characteristic. As this coincides with fundamental distinctions as to the nature of the resources themselves, it will, in general, be followed here. Another basis of classification might be the human needs which they serve, but such a classification would be confusing, since both vegetable and animal products are used for such diverse purposes as food and clothing, while mineral products as well as the other two are used for shelter. Still another basis of classification might be a division into those resources which men use as a source of energy, and those which are used in connection with its application or production. This classification is also partly followed.

Underlying these considerations is the more fundamental view of natural resources as the principal things that are utilized in the satisfaction of human wants. The most fundamental of these are air, water, food and sunlight. Shelter, clothing and a variety of simple tools are more complex wants and illustrate the kinetic aspect of human needs. The horses, cattle, dogs and other animals of to-day do not (broadly speaking) want anything beyond what the same animals wanted in 5000 B.C., while the wants of men have greatly increased and diversified during the same period. Much of the material that is utilized to-day owes its usefulness to the way in which it satisfies mental and spiritual rather than purely physical needs. Raw materials therefore pass through repeated transformations and modifications before they serve their final end. A symphony concert, heard over the radio, is related in a remote and complex way to the lumps of ore and fragments of wood which are the basic components of the musical instruments. Though natural resources will be here discussed in their material aspects they are also involved, in a most important and essential way, in the mental and spiritual life of men.

Most of the energy-imparting resources have their basal origin in the radiant energy from the sun. The animal products which men utilize, have been derived by metabolism from vegetable life, and this is in turn the product of the action of living cells upon inert substance, resulting from the energy input of the sunlight. E. E. Slosson has estimated that the heat received by radiation from the sun in a growing season in the latitude of Washington, D.C., amounts per acre to more than would be produced by burning over 200 tons of coal, while the heat value of the corn (maize)

grown on an acre in a season amounts to less than that in half a ton of coal. The energy content of coal is ultimately derived from sunlight, and evidence strongly indicates that petroleum and natural gas are decomposition products derived from organic material. Their energy content is derived from the same source.

Water is, similarly, another of the great natural resources, since it is an essential to the life of both plants and animals. The amount of it present in the atmosphere determines, to a large degree, the character of the vegetable and animal life in a given area, while in the descent over the land surface it may be utilized as a perpetual source of power.

The atmosphere is almost never thought of as a natural resource, because it is everywhere present and freely available to all. Yet its oxygen content is essential to all animal life and to the combustion by which power is derived from the hydrocarbons, while its rather small content of carbon dioxide forms, with water and sunlight, the basic components of vegetable life. It also furnishes the mechanism by which water is enabled to maintain its cycle of distribution. Its vital importance as a cooling agent to the human body, considered as a machine, and upon human health, has only become fully recognized within the present century.

Soil, as the rather complex superficial layer which covers the earth's surface is termed, is also an important basic natural resource. It furnishes not only the mineral constituents necessary for plant growth but also the physical conditions which are equally essential. The nature of the soil of a region affects, to a considerable degree, the civilization which may there develop. The character of the soil, in turn, is profoundly affected by climate. Vegetation, forests and animal life are in turn affected by soil and climate, so that these natural resources are complexly inter-related.

The inert natural resources, which may be thought of as static rather than kinetic, may be subdivided into those that are sources of energy, and those which are utilized in other ways. One significant difference is that the first group are destroyed in use, while the others are permanent, to a varying degree. Most of the gold that has been produced is still available, while most of the coal that has been produced has been completely destroyed. The lead in storage batteries, on the other hand, is almost completely salvaged and re-used, while that used in paint is almost completely lost. The steadily growing use of natural resources such as these and the fact that the quantity of each now available by the present methods of production has, in every case, some limit and in many cases one that, at the present rate of increasing consumption, is near enough in the future to be a source of real concern, make it appropriate to include in an article on natural resources a discussion of possible substitutes.

The discussion given below is divided as follows: (1) energy group; (2) metallic and non-metallic group; (3) precious metals group; (4) rare metals group; (5) substitutes for natural resources.
(T. T. R.)

ENERGY GROUP

This classification here includes Animal Life, Vegetation, Soils, Water, Fisheries, Forests, Natural Gas, Coal and Petroleum. A discussion of food supply is given in the article **FOOD SUPPLY OF THE WORLD**. Under the article **SUN** there is a description of this form of energy considered as a natural resource.

I. ANIMAL LIFE

The ability of animal life to perpetuate itself and in addition to supply man with a large proportion of his necessities and comforts has materially aided human progress. Besides being one of the most interesting and valuable of the world's resources, animals have impressed a record of their own on the pages of history. Ancient inscriptions portray the hunt, the feeding of live stock, milking scenes and the slaughter of domestic animals for food.

Man's migrations over the globe and his ability to sustain himself under diverse and adverse conditions have depended largely on animal life. With the camel or horse, man can live in the desert. With sheep he can establish himself in regions of high elevation or sparse vegetation. With the presence of wild life and a few dogs he can inhabit the frigid zones. Under the more

favourable conditions prevailing in temperate climates, man has built up extensive industries, producing meats, hides, wool, milk and other animal products in commercial quantities. For such purposes he has developed breeds and types especially adapted for his own use or for the demands of his markets.

It is clear, therefore, that the greatest usefulness of animal life to man depends on his wisdom and ability in regulating the number and kind of animals under his control so that they may best serve his needs. With the steady increase in human population, there has been a progressive tendency toward the raising of animals for definite human needs rather than depending on wild life. In recent years this trend has also included the breeding and raising of fur-bearing animals.

Live-Stock Production.— In the age-old struggle for the survival of the fittest, certain types of animal life have proved to be especially well adapted to man's requirements. These he has preserved, improved and protected until their production has become a major part of the world's agriculture. It is important to bear in mind that crop production and stock raising are closely allied enterprises, inasmuch as animals consume most crops that are not utilized by man directly. Moreover, land that is too rough for cultivation may support vast herds of cattle, sheep and goats. (See Vegetation below.) Thus live stock serves as a useful balance wheel in the mechanism of human nutrition. Famine rarely occurs in countries where live stock is abundant.

As in the production of other commodities, however, a great number of economic factors are involved. These influence the extent of animal breeding and feeding operations, thus determining the number of animals produced and their age and condition when marketed. As a consequence, animal life as a natural resource is the basis for an industry which, though of great magnitude, varies in extent from year to year, depending on supply and demand. Animal life is an elastic resource, responding closely to the demands made upon it. In most countries the principal domestic animals are counted or estimated periodically and this information serves as a guide for breeding and feeding operations.

Extent of Live-Stock Industry.— As a world resource, cattle exceed all other domestic animals in number and value, aggregating about 698,000,000 head, according to current estimates. This term includes all bovine animals, whether kept for beef production, dairy purposes or as draft animals or beasts of burden. In some countries, notably India, buffaloes are included in cattle estimates. Of the world total, Asia possesses about two-fifths, Europe about one-fifth, with South America, North America, Africa and Oceania following in the order given. Oceania includes Australia and New Zealand. Sheep are the next most numerous domestic animals of economic importance. The world's supply is estimated at about 684,000,000. Of this number Europe has nearly a third, Asia about a fifth and Oceania slightly less than a fifth. South America, North America and Africa follow.

Swine, though much fewer in number than either cattle or sheep, are noteworthy as a food resource owing to their fecundity and early maturity. The adaptability of pork for curing is also worthy of mention as it permits storage and long shipments without refrigeration. Throughout the world, swine are estimated to number about 295,000,000, of which Asia, Europe and North America, respectively, have the largest supply. On the other continents, the swine industry is relatively undeveloped. Though the world's animal resources include a great variety of other stock utilized for food, work and sundry purposes there is a dearth of dependable information regarding their numbers. Even in the case of cattle, sheep and swine, which have just been mentioned as of outstanding prominence, numbers alone give scarcely a true picture of their value to the populations of the various countries. The improved bovine animal, as found in North and South America and in the British Isles, where much attention has been given to breeding for beef production, is vastly different from the beast of burden types in India or Mongolia.

Types of sheep vary greatly, depending on the relative demand for their wool and meat. Similarly, man's influence on animal life has resulted in swine that excel in bacon production or a high yield of lard, depending on the breed selected. Differences in

types of animals extend to horses, goats, poultry and pet stock. These differences have been brought about through systematic breeding for a long term of years, giving rise to the establishment of recognized breeds embodying the conformation and other qualities sought. Record associations for the various breeds have served to maintain uniform standards and otherwise to aid in development and improvement. Live-stock shows and expositions at which prizes are offered for animals of superior merit likewise have been influential in stimulating breeders to their best efforts. In the case of food animals especially man's skill in the selection of breeding stock has greatly increased the utility value of his herds and flocks. Whereas the dressed carcass of an ordinary hog weighs, usually, between 65% and 75% of its live weight, the proportion sometimes exceeds 80% in well-bred, well-managed swine. Moreover, good breeding tends to result in earlier maturity so that animals may be marketed profitably at younger ages, with a resulting saving in feed, labour and other expenses. So highly has this feature of stock raising developed that it is not unusual for a litter of pigs from one sow to weigh a ton or more at six months of age. Improved breeding has numerous practical benefits in the raising of other kinds of live stock. Consequently there is keen competition among progressive stock owners throughout the world in obtaining choice breeding animals.

Since the world's population tends to increase continuously, much study has been given the conservation of animal life in order that it may yield more meat and live stock products per unit of area. In regions where land values have increased there is need also for economic reasons to reduce losses and to seek greater economy in production. As a consequence public officials and stockmen have engaged in co-operative endeavours to combat animal diseases and parasites and to stop the ravages of predatory animals. Improved housing and equipment also have reduced losses from exposure and mortality, especially among young animals.

Veterinary Medicine and Surgery.— Beginning originally in France as a means of saving horses injured in war, there has developed in the more important live-stock countries a system of medical service for animals. The science of veterinary medicine and surgery, though designed chiefly to conserve animal life, has made many direct contributions to human welfare. Knowledge of animal anatomy is the basis for the official inspection of meat and meat food products, and the veterinary inspection of dairy cows safeguards the milk supplies of progressive municipalities. With veterinary medicine there has developed also research into problems affecting the health and well-being of man and animals alike. The discovery, by veterinarians, of means to eradicate tick fever from cattle led shortly afterwards to success in combating malaria and yellow fever in man. Knowledge concerning tuberculosis among animals has led similarly to a reduced incidence of this scourge in the human population, especially among children.

In the light of such information, any statistical measure of the world's animal resources and their usefulness to man in the form of food and clothing must necessarily be incomplete. There can be no accurate appraisal of the service rendered by man's noble friend, the horse, nor by his faithful companion and guarding sentry, the dog. And in the frozen wastes of the globe the oily flesh of animals constitutes the very home fires which maintain human existence. The lower animals are resources which adapt themselves to man's changing needs, and if wisely managed give promise of abundance for many generations to come.

(J. R. MR.)

II. VEGETATION

If the great physiographic divisions are exempted, the earth's surface is marked more distinctly by vegetation cover than by any other feature. This fact early attracted man to the study of vegetation as distinguished from the study of the individual plant. Primitive man recognized the plant cover not only as a source of sustenance and protection, but also as a guide in his hunting and planting his food crops. Studies in vegetation and its relation to the factors of the environment began very early.

In the recognition of a plant community (a term used in a general sense to include all groups, large and small) the following criteria may be employed: Physiognomy, or the general appear-

ance, historically stands in first place, followed closely by floristic composition which has formed the basis of the science of floristic plant geography. Succession seeks to determine whether the vegetation has reached its final stage, complete adjustment to environment. The study of Habitat (see PLANTS: *Distribution and Ecology*) seeks to evaluate climate, soil and biotic factors.

The terrestrial vegetation of the world may be classified into the following great plant types: Forest, Grassland and Desert. The forests of the world may be divided into seven great formation groups covering a world area of about 22,000,000 square miles. Most of this area is valuable timber land, and about 14,000,000 sq.m. are capable of being converted into crop-producing land, of which about 6,000,000 are suitable for warm-weather crops, and 8,000,000 suitable for cool-weather crops. About 3,000,000 sq.m. of forest land are suitable for grazing only. The grasslands of the world are divided into seven great formation groups covering 13,000,000 sq.m. of valuable grazing land. Of this area 3,500,000 sq.m. are suitable for the production of cool-weather crops such as wheat, rye and oats; while 6,800,000 sq.m. are suitable for warm-weather crops such as sorghum and cotton; and 2,700,000 sq.m. are suitable for grazing only. The deserts may be divided into five great formation groups covering a world area of 17,000,000 sq.m., valuable chiefly as grazing land of low carrying capacity and, where water is available, for irrigation farming. The world contains about 26,000,000 sq.m. of land suitable for grazing; about 12,800,000 sq.m. of land capable of producing warm-weather crops, and about 11,500,000 sq.m. capable of producing cool-weather crops. Allowing no waste land it would limit the production area of the world to less than 25,000,000 square miles.

Forests.—Tropical Rain Forest is a luxuriant, evergreen forest with trees of unequal size and height and of varying age forming a dense canopy of thick, leathery leaves, and composed chiefly of Leguminosae, Lauraceae, Myrtaceae, Moraceae and Dipterocarpaceae—a true climax forest with trees of all ages and a mixture of many species. Temperature is uniformly high, air damp, and rainfall 60 to 200 in. per year. Soil is greyish or reddish-brown, poor in humus and containing a large amount of hydrolyzed iron and alumina. Animal life is abundant but chiefly arboreal. Primitive man has lived for the most part at the edge of this forest, and civilized man has utilized natural products such as rubber, gum, wood and bark. Cultivated crops are chiefly tropical such as rubber, sugar cane, cacao and tropical fruits, vegetables and fibre plants, though temperate ones can be grown. This forest covers 3,800,000 sq.m., in Africa, South America and the East Indies.

Temperate Rain Forest is even more luxuriant and varied than the tropical rain forest. It is a many-storied forest, rich in mosses, tree ferns and vines. It consists of the southern conifers such as Podocarpus and *Araucaria*, as well as *Ficus*, *Olea*, *Juniperus* and *Nothofagus*. The temperature is moderate and the rainfall 40 to 80 inches per year. Under cultivation it will produce temperate cereals and fruits. This forest occupies about 550,000 sq.m., chiefly in the highlands of Central Africa, South America, south-eastern Asia, East Indies and Oceania.

Deciduous Forest is characterized by a dense foliage of thin, grass-green leaves which fall and leave bare branches with heavy bark and scale-covered buds during a long, cold rest period. Oak, birch, beech, maple and ash dominate this forest. There are two distinct climatic seasons: a warm, moist season or growth period, and a cold, moist season, or rest period. Precipitation varies from 30 to 70 inches. The soils are either light coloured or grey-brown podsol. Under natural conditions this forest supports a fauna and fruits and nuts for primitive man. It produced much of the wood and hardwood lumber, and has given way to fields of temperate crops and deciduous fruits. There are three great areas of this forest: Eastern United States, western Europe, and eastern Asia. The total area was about 6,500,000 square miles.

Coniferous *Forest* presents a uniform stand of similar evergreen trees, and consists chiefly of pine, spruce and fir. The winter climate is rigorous; rainfall varies from 15 to 100 in. annually; the soil is young but the land is of little agricultural value. This forest is the source of much of the lumber used in commerce. It extends across America and Eurasia south of the tundra and

pushes down over the highland as far as north Africa and Mexico. It covers about 7,600,000 sq.m. of which 5,500,000 are true forest, and 2,100,000 are woodlands. About 1,000,000 sq.m. are suitable for grazing, 40,000 sq.m. suitable for cool-weather crops and 30,000 sq.m. suitable for warm-weather crops.

Dry Forests are deciduous forests in the tropics and are often called monsoon forests. Leafless during the dry period, they have no cold rest period as does the deciduous forest of the temperate regions. These forests are usually composed of leguminous trees. The temperature is high and rainfall 30 to 40 in. during the growth period. Teak and quebracho are valuable forests of this type. The soil produces good crops of warm-weather cereals, vegetables and fruits. This forest is chiefly in Africa, South America, Australia, south-eastern Asia and Oceania, and occupies about 2,000,000 square miles.

Thorn Forest is composed of small thorn trees, vines and succulents. The trees are leafless during the long drought periods and are found in tropical or sub-tropical regions where the annual rainfall is from 10 to 20 in. Legumes, cacti, euphorbias and lilies are important. This area is unfavourable to primitive man and to animals, but produces gums, fruits, rubber and tanbark. It has no value agriculturally without irrigation, and covers about 330,000 sq.m. in Africa, South America, Mexico, Australia and the dryer portions of Asia.

Sclerophyll Brushland is a forest of small trees or a brushland with evergreen sclerophylls ranging from minute ericas to tree-like proteas, oaks and cherries. Botanically it is extremely variable. The temperature seldom falls below 26° F; rainfall is from 20 to 35 in. annually, and there is a drought period of three to five months. It is an unfavourable habitat for man and animals under natural conditions, but under cultivation it is most favourable for the production of citrus and deciduous fruits and cereals, alfalfa and vegetables. This forest covered about 1,100,000 sq.m. chiefly in the Mediterranean region, Cape Province, south-western Australia, central Chile and California.

Grasslands.—In the High Grass *Savanna* the luxuriant grasses range from 5 to 12 ft. high and consist chiefly of species of *Andropogon* and *Pennisetum*. The luxuriant growth period is followed by a drought during which the grasses are burned. Annual rainfall ranges from 25 to 75 in. The area varies each year from a grassy swamp to a dry desert. The natural production is not great, although the larger animals live here, and rubber, oils and ivory are produced. Under cultivation warm-weather crops of great variety can be produced. This savanna covers about 2,800,000 sq.m. in Africa, south Asia and South America.

The Tall Grass Savanna, known as Low Veld or Tree Steppe, consists of grasses from three to five ft. high with trees 10 to 30 ft. high scattered through. The grasses are chiefly andropogons and the trees legumes. The temperature is tropical or sub-tropical with rainfall of 30 to 80 in. It is excellent grazing land. It is a favourable home for primitive man and for civilized man, with rich agricultural lands producing cattle and cool or warm-weather cereals and vegetables. It covers a world area of about 3,900,000 sq.m. in South America, Africa, India and Australia.

Tall Grass, the prairie of North America, the pampas of South America, and the high veld of South Africa, are luxuriant, pure grasslands of blue-stems (*Andropogon*), spear-grass (*Stipa*) and wheat-grass (*Agropyron*). The climate is temperate; rainfall is from 20 to 40 in. annually, and the soil is unusually deep and rich, forming a true *chernozym* in the dryer portion. There is a short drought rest period, followed by a long, cold rest period. It is excellent grazing land; it supported great herds of wild game, and later cattle and horses, which have given way to its utilization as the richest grain fields of the world. It occupied about 1,580,000 sq.m. in the United States (chiefly east of the 100th meridian), Uruguay and the Argentine, south Russia and Siberia, Rumania and Hungary, South Africa and Australia.

Short Grass is only a few inches high, occurring in a temperate region with rainfall of 15 to 30 in., with a long drought and a cold rest period. The grama, buffalo-grass, spear-grass and needle-grass are valuable for grazing. The better portion of this land is used for dry farming. The soil is dark brown with an accumulation of

carbonate at a depth of 8 in. to 3 ft. below the surface. The world area of this grassland is about 1,200,000 sq.m., chiefly in North America, South America, Africa and Russia.

Desert Grass Savanna, sometimes called Orchard or Thornbush Steppe, consists of a carpet of short or low bushy grasses, including grama-grass, buffalo-grass, wire-grasses, and scattered small trees, with leguminous and other shrubs. Rainfall is from 10 to 20 in., and there is a long, hot drought period. About 2,300,000 sq.m. are occupied by this type of grassland; it is valuable as grazing land of low-carrying capacity. About 140,000 sq.m. are valuable agriculturally, producing cotton, sorghums and peanuts.

Mountain Grassland occurs on the high mountains in the tropics. The climate is temperate with 40 to 60 in. of rain. The grasses are chiefly species of blue-stem (Andropogon) (*Eragrostis*) and dropseed-grass (*Sporobolus*). It is generally valuable grazing land, and under cultivation produces temperate crops as well as bananas and coffee and is similar to the Temperate Rain Forest. The world area is about 790,000 square miles.

Marsh Grass occurs in the great swamp areas and consists of coarse grasses. It supports a fauna valuable for meat, furs and ivory, but without drainage is of no agricultural value. The world area is about 100,000 square miles.

Desert Shrub and Desert Grass consists of a sparse cover of low, woody or fleshy plants with desert grasses between. Botanical composition varies greatly, but legumes, composites, cacti and euphorbias are prominent. Rainfall varies from 5 to 20 in. annually. About 10,000,000 sq.m. of this type are valuable as grazing land of low-carrying capacity, but valueless for crop production without irrigation.

Salt Desert Shrub occupies the low, undrained saline basins in all desert regions. It is valuable for grazing land, but for agriculture it must be leached of salt. The world area is about 30,000 square miles.

Desert in the true sense is seldom found, but at least during much of the year many areas seem lifeless. The flora is abundant in species if not in individuals, and the plants are adapted to the extremes of drought and uncertain moisture supply. The world area in Africa, Asia, South America and Australia is about 2,400,000 sq.m. and is of little value.

Tundra (including Alpine Meadow) shows mixed botanical composition. The growth period is short with a long, cold rest period. In summer the temperature rises gradually to 60° or 65° F, and during the continuously dark winters the temperature falls to 40° F below zero. This area is valuable for grazing land, though not especially productive. The circumpolar world area is about 4,400,000 square miles.

(H. L. SH.)

III. SOIL

In an inventory of the world's resources it is as important to consider the soil in its crop-producing capacity as it is to estimate the reserves of coal, copper and oil, substances more commonly thought of in this connection. All of our food, our clothing and many of our utensils, implements and ornaments come either directly or indirectly from the land. (See FOOD SUPPLY OF THE WORLD.)

The crop producing capacity of the soil is, however, a natural resource in a somewhat different way from that represented by coal or oil. These substances have a definite entity and can be estimated in tons and gallons. Once depleted they are manifestly gone. The soil, on the other hand, is a resource because of its ability to produce crop-plants. This capacity varies, it may be much reduced and then be definitely rebuilt.

While an accurate and complete tabulation of the soil resources of the world is impossible, the table in the next column gives some idea of the situation. (See SOIL; AGRICULTURE.)

Besides indicating the magnitude of the soil resources in acres, the table shows the proportion of the landed area available for crop-plants. This in connection with the population has an important bearing on the possible agricultural and silvicultural independence of each country. Such countries as Argentina, Canada, Australia and Russia can support much larger populations. Their forest resources in terms of population are also great.

Table Showing the Approximate Areas of Arable and Forest Lands of Some of the Important Countries of the World

Country	Arable lands			Forest lands		
	Acres in millions	% of land area	Acres per person	Acres in millions	% of land area	Acres per person
Argentine Republic	62.82*	9.1	5.0	264.00	35.8	21.0
Commonwealth of Australia	29.34†	1.5	4.3	90.29	4.7	13.3
Dominion of Canada	58.27‡	2.6	5.6	596.75	25.3	57.5
France	52.22	38.3	1.2	25.51	18.8	.6
Germany	47.97	41.2	.6	30.90	26.5	.4
British India	310.58	46.5	1.1	86.51	12.9	.3
Italy	31.99	41.7	.7	13.96	18.2	.3
Japan (mainland)	14.91	15.7	.2	48.44	51.4	.7
Sweden	9.24	9.1	1.4	55.50	54.8	8.9
Great Britain	11.76	20.9	.2	2.74	4.8	.06
United States	319.84	16.8	2.4	550.00	28.3	4.2
Soviet Russia (U.S.S.R.)	553.29§	10.6	3.3	1,984.55	42.8	11.8

*Possible agricultural area estimated at 250 million acres.

†Will ultimately be greater.

‡Possible agricultural area estimated at 300 million acres.

§Possible agricultural area estimated at 700 million acres.

With our rapidly increasing world population two major soil problems present themselves, first, the possibility of increasing the area of lands growing crops other than forests, and second, methods of preventing soil depletion and consequent crop decrease. The utilization of virgin and well watered grass lands and the reduction of our forest areas have met the first problem in times past. Unfortunately soils have often been deforested and put under cultivation when they should have been left with their forest cover.

The reclamation of swamps and the better drainage of crop-bearing lands have increased the area and effectiveness of the cultivable soils. (See DRAINAGE; RECLAMATION OF LAND.)

The utilization of arid and semi-arid lands is particularly promising in certain countries. Such soils, developed under low rainfall, are potentially fertile. Thousands of acres of arable and very highly productive lands will ultimately be added to that now available for crop production through irrigation (*q.v.*).

Another important means of utilizing semi-arid soils is by dry-land farming. (See AGRICULTURE.) By proper methods of cultivation, moisture is conserved in the soil and carried from one season to the next. Farming operations thus become possible in areas where the annual rainfall is as low as 20 inches.

The second major soil problem relates to the maintenance of soil fertility. Land can not be cropped without certain losses taking place. These losses are four in number: first, erosion or the removal of the surface soil, the most fertile portion, by water or wind; second, the loss of constituents by the drainage of water through the soil, called leaching; third, the removal of nutrients by plants; and fourth, the loss of organic matter as a result of bio-chemical oxidation and the liberation of carbon dioxide.

Water erosion may be controlled by small dams, by terraces, by sod, and by strip-cropping. In spite of such possibilities thousands of tons of fertile soil are swept annually into rivers. In many cases this is the major cause of soil depletion and is closely correlated with deforestation and flood devastations.

The losses through drainage, crop removal and organic oxidation are susceptible of but little control. Farming operations, even the most careful, encourage rather than check such depletions.

The major features of soil fertility maintenance may be very simply set forth if it is taken for granted that the soil drainage is good, that tillage is adequate, that erosion is under control, and that a suitable crop rotation, if possible, is utilized. Under such conditions the problem is to add certain constituents in such amounts and proportions as at least partially to off-set the inevitable losses. At the same time the physiological balance of the plant nutrients should be maintained as nearly as possible.

While plants require fourteen nutrients for their normal growth and probably several more besides, ordinarily only four are likely to become especially critical, namely nitrogen, potassium, calcium and phosphorus. Sulphur also may be a limiting

factor as well as copper, manganese, boron, and zinc.

The nitrogen losses may be met by applying farm manure, turning under crop-residues and by utilizing, either as a crop in the rotation or as a green manure, certain legumes. Commercial nitrogen may be resorted to, although it is generally used to stimulate the crop directly rather than to reduce the drain on the soil nitrogen. Obviously the methods utilized in maintaining the soil nitrogen automatically add organic matter as well. As this material decays and humus is formed a definite ratio is established between the organic matter and the nitrogen. The nitrogen is always in the minimum and apparently controls the amount of humus that finally is present in the soil. The advantage of legumes as green manures over non-legumes is quite apparent, since they obtain nitrogen from the air and are especially rich in this constituent. The soil organic matter besides carrying nitrogen is a source of energy for various bio-chemical transformations and encourages a suitable physical condition of the soil.

The presence of this decaying organic matter tends to make available to plants certain soil constituents, especially potassium. Therefore, it is often unnecessary to add a potassium fertilizer to a soil rich in this element if the organic matter is properly maintained and is actively decomposing.

Many soils are low in active calcium and as a consequence become acid. This deficiency also develops other conditions that may be detrimental to some plants but by no means to all. Liming, therefore, must be resorted to for certain crops and is thus an important feature in the maintenance of soil fertility the world over. (See FERTILIZERS.) The lime not only reduces the soil acidity but also adjusts other physiological soil conditions.

Phosphorus exists in the soil in small amounts and is often very slowly available to plants. In fact it is so slightly soluble as to be lost but sparingly, if at all, in the drainage water. The only way of dealing with this element is by direct addition of phosphorus fertilizers (*q.v.*). As the losses of soil constituents increase, the necessity becomes greater for commercial fertilizers.

IV. WATER

Water is probably the natural resource that is most essential to man's existence on the earth. It furnishes him food and drink and the means of sanitation, transportation, and the production of power. It is unique among the earth's natural resources in that it is recurring by precipitation, is pure in each recurrence, and is not conserved by non-use. The water of precipitation travels over and through the ground, is transpired in part by vegetation, flows in part to the oceans and inland seas, is evaporated from both land and water surfaces, and is again precipitated. This never-ending circulation of water through the earth and air leads to its continuing recurrence on the earth in essentially the same average annual quantities. Although water is polluted by washing the land or by sewage and industrial wastes, the polluting substances are not carried into the air, and the water of precipitation is always essentially pure. Man's activities do not diminish the quantity or impair the quality of water in its subsequent precipitation, do not affect materially its rate of circulation through the earth and air and have no effect on the supply for use by future generations. Conservation of water consists in its legal control in the interest of the public and in its greatest proper use for multiple purposes and to conserve the exhaustible natural resources.

Precipitation varies widely from time to time and place to place and the quantities of water in the ground and on its surface vary accordingly, resulting in periods of high water and of low water—of floods and of droughts. These and other phases of the occurrence of water are beyond the control of man, although their effects may be modified by hydraulic works to augment low-

water flows and to protect flood plains from floods, and by vegetation to reduce erosion. The operation of reservoirs for storage and controlled release of water changes the regimen and therefore the utility of the rivers below them. Since the supply of water in any drainage basin is limited by precipitation, it sets the limits of development: it determines the amount of land that may be irrigated, the size of water-power and steam-power plants, the capacities of industrial establishments, and the growth of cities. In many parts of the world the limits of supply have been reached or are being approached, and water is imported from long distances and at great expense for municipal and irrigation uses.

Surface Water.—Run-off results directly from precipitation, but the rapidity with which run-off follows precipitation depends upon various conditions. In tropical and subtropical lands the sequence is rapid. In the areas from which run-off is supplied mainly by melting snow it is retarded by the length of time water is held in the form of snow. Such areas embrace in general all polar regions and all lands above about 5,000 ft. in the latitude of northern United States and central Europe, and above 12,000 to 15,000 ft. in the tropics. In other areas, if the rainfall is fairly uniform throughout the year as it is in eastern United States and most of western Europe, the distribution of run-off is nearly uniform, but there is considerable reduction during the summer due to greater evaporation. In areas situated in warm temperate and subtropical lands which receive precipitation during a definite rainy season, the run-off is likely to be extremely variable. Streams that flow from areas having permeable soils and subsoils or are underlain by cavernous rocks are likely to have relatively well maintained run-off.

The utility of any stream for power, irrigation or municipal supply, depends in large measure upon the adaptability of its run-off to the demand. Storage must ordinarily be provided to assist in this adaptation. Natural sites available for use as storage reservoirs may contribute largely to the value of the water resources of a drainage basin. Areas that were covered during the glacial period by continental ice sheets or by extensive alpine glaciers generally abound in lakes, which in their natural condition regulate run-off in some degree, and some of these lakes may be converted into reservoirs of large capacity. High rates of run-off and attendant possibilities of power and irrigation development are generally associated with mountainous areas.

Ground Water.—It has been estimated that 50% of the population of the U.S. depends directly upon wells for its water supply and the proportion for the world is no doubt nearly or quite as great. The practicable use of this water is measured by the extent to which it may be replaced by precipitation. The water table may be progressively lowered by excessive pumping. In some places the rate of recharge of the underground water from surface streams may be increased to offset the lowering of the water table, but excessive drafts on the supply inevitably reduce it.

Water-power.—The developed water-power of the world, according to estimates made by the U.S. Geological Survey, was about 23,000,000 h.p. in 1920, 46,000,000 h.p. in 1930 and 63,500,000 h.p. at the end of 1938, an increase of 180% in 18 years.

Summary of Developed Water-power of the World in 1938, and Potential Water-power at Ordinary Low Water in Horse-power

	Developed	Potential
North America	27,000,000	77,000,000
South America	1,400,000	74,000,000
Europe	28,000,000	74,000,000
Asia	6,125,000	151,000,000
Africa	183,000	274,000,000
Oceania	800,000	21,000,000
Total	63,508,000	671,000,000

The estimates of potential water-power are based on data of widely varying completeness and accuracy but they afford a general idea of the water-power resources of the world. It appears that Africa's potential water-power is nearly equal to that of any other three continents. Africa is essentially a great plateau

on which there are large rivers that fall rather abruptly to the sea. Tropical Africa, particularly the Congo, contains a large land area within the belt of equatorial rains, and this fact taken in connection with its characteristic topography gives it the greatest concentration of potential water-power on the globe. Asia comprises vast areas of high mountains and plateaus but in its northern, western and central parts the precipitation is low and in its southern and eastern parts the rainfall is irregularly distributed through the year.

Irrigation.—Nearly one-third of the earth's surface receives only 10 in. of rain or less annually and for another third the annual rainfall is between 10 and 20 inches. On the area receiving less than 10 in. and on much of that receiving up to 20 in., irrigation is generally essential to the production of a profitable crop. The earliest civilization of which we have any knowledge was developed by means of irrigated agriculture. Not until near the Christian era did the world dominion and leadership in art and culture pass to nations inhabiting other than great irrigated lowlands. During the dark ages, irrigation systems were neglected and some were entirely destroyed. With the advent of the Renaissance and the gradual growth of modern civilization, the centres of population gradually shifted to more humid regions and irrigation became relatively less important in the growing of the world food supply.

After 1875 new influences in world affairs gave a decided impetus to irrigation development. Railroad construction has opened up vast areas of arid and semi-arid lands requiring irrigation to bring them to a high degree of crop production. Construction equipment and methods have been greatly improved. Projects are now feasible which, a half century ago, would have been entirely impracticable. Dams are projected and under construction of a height and size undreamed of a few decades ago. Improved standards of living have increased the demand for certain products of irrigated lands such as citrus and deciduous fruits, and increased transportation facilities have made possible their widespread distribution. As a result, the irrigated areas in the newly developed countries of the Western Hemisphere have increased rapidly, and in 1940 it was probable that one-fourth of the globe is dependent for food on the products of irrigated land.

The irrigated area of the world by countries in 1926 was estimated by the U.S. Bureau of Reclamation as practically 200,000,000 ac., made up by continents as follows: North America, 26,834,000 ac.; South America, 6,613,000 ac.; Europe, 14,798,000 ac.; Asia, 140,760,000 ac.; Africa 10,310,000 ac.; Oceania, 1,270,000 ac.; grand total 200,585,000 acres. (N. C. G.)

V. FISHERIES

The important fisheries of the world are found for the most part within the north temperate zone, chiefly between the 40th and 60th parallels of north latitude. In this region conditions are especially favourable to fish life, including large continental shelves with relatively shallow water and extensive coastal indentations, richly supplied with materials from the massed land areas of the region to support an abundant aquatic flora and fauna. The herrings, of which there are some 150 species, represent the most important family of fishes. The species are widely distributed in fresh and salt water and contribute a greater yield than any other family of fishes. They supply the raw materials for the highly important sardine industries of Norway, France, Spain, Portugal and the United States, the extensive herring curing industries of northern Europe and North America, extensive fish meal, fertilizer and oil industries of Norway, United States, Canada and Japan, as well as being widely used for food in the fresh state wherever they are found. As they feed on microscopic plant and animal forms, they are especially important as converters of plankton organisms at one step into food for man.

The gadoid fishes which include the cod, haddock, hake and pollock also rank high in their contribution to man's needs. The annual catch of cod along the Atlantic coast of North America exceeds 1,000,000,000 pounds. These are white-meated fishes, and the fat is stored in the livers, the basis for the cod-liver oil industry. Next in importance are the salmon, noted for their

exceptional food properties, size, beauty and gameness. The family includes not only the salmon but the white fishes, the ciscoes or lake herring and the trouts. The most important members are the five species of salmon native to the North Pacific, entering the tributary rivers in North America and Asia to spawn. The annual catch amounts to about 1,000,000,000 lb. a year and is the basis for the important salmon canning and curing industry.

The mackerels, of which there are about 60 species, are widely distributed and highly prized for food in the areas where they are found in abundance. Included in this family are the highly prized tunas, the true mackerels of the north Atlantic, Spanish mackerel and the bonito. The shell-fish fisheries are also of considerable importance, including some of the choicest products of the sea and valued as food because of their distinctive flavour and their richness in iodine and minerals, essential elements of our diet. The oyster fisheries are of importance in the United States, France and Japan. Lobsters, crabs, clams and shrimp are widely sought after.

The fisheries are a most important source of food. In addition they supply many articles of importance in the arts and industries. Fish meal is gradually winning a place for itself as one of the most valuable protein feeds for hogs, cattle and poultry. Fish fertilizer is generally recognized and widely used as a plant food. The demand for and use of fish oils for soap making, for hydro-generation, including use in lard substitutes, and for many other purposes is increasing. About 150,000,000 gal. of whale oil alone is now produced annually. Shells of molluscs are an important source of raw materials of buttons and various artistic articles. From the shells of the fresh water mussels taken in the Mississippi valley region are produced about 2,000,000,000 buttons per year. From shark hides are made fancy leathers for artistic articles; from fish scales is derived fish scale essence used in the manufacture of imitation pearls; from Japanese pearl farms are derived artificial pearls and from numerous waters of the globe are taken genuine pearls. From the sea-weed industries are derived many products and from the sea itself the indispensable solar salt.

The annual world harvest of fish and fishery products amounts to not less than 35,000,000,000 lb with a first value of about \$760,000,000. In addition there is a very considerable draft on water areas by angler and fisherman for home consumption for which no satisfactory estimate can be made. Among the leading nations of the world in the prosecution of fisheries arranged in the relative order of the magnitude of their fisheries are: Japan with a catch of about 8,100,000,000 lb.; United States with 4,400,000,000 lb.; Soviet Union, 2,900,000,000 lb.; China, 2,800,000,000 lb.; United Kingdom, 2,500,000,000 lb.; and Norway with 1,700,000,000 pounds. These six countries produce about three-fifths of the world's fishery harvest. Among the other nations producing in excess of 1,000,000,000 lb. annually are Germany, Korea and Canada. (L. RA.)

VI. FORESTS

The world production and consumption of wood amounts to approximately 56,000,000,000 cu.ft., which is an average of 32 cu.ft. per caput. About 26,000,000,000 ft. is saw-timber, and 30,000,000,000 ft. is firewood.

Increase of Consumption.—As populations grow and as living standards rise and human wants become more complex, timber consumption increases, in spite of the extensive and growing use of substitute materials, and in spite of the tendency to utilize wood more economically.

In Great Britain timber consumption has increased much more rapidly than has the population. Even in France with a practically stationary population, timber consumption was slowly increasing until 1914; that of Germany more than doubled within the century; in the United States at least four times as much lumber is (1937) used as in 1850. Judging from the rates of increase in these and other important consuming countries, the world's timber needs may be expected to double within approximately 50 years. The per caput consumption in North America of saw-timber (177 cu.ft.) is five times as great as that of Europe, and if the tropical countries south of the United States be disregarded, it is six and one-half times that of Europe. Europe,

South America and Australia use about equal amounts of wood per caput (39 cu.ft.). The proportion of saw-timber to total amount of wood used, however, is quite different, being only one-ninth in South America, two-fifths in Australia and over one-half in Europe. Asia and Africa use comparatively small amounts of wood (9 and j cu.ft. respectively).

The total quantity of wood grown in the world each year is roughly estimated at about 38,000,000,000 cubic feet. If this increment were spread evenly over the whole forest area, it would amount to only 5.1 cu.ft. per acre. It is apparent that the present annual growth of 38,000,000,000 cu.ft. is not replacing the present annual cut of 56,000,000,000 cubic feet. The amount of growth each year represents the growth of only a small part of the forest. Vast areas of virgin forests must be left out of the calculation, because in their present condition there is no net growth in them. If all the forests of the world were placed in a growing condition, with a moderate amount of management and protection against devastation, they could produce annually at least 355,000,000,000 cu.ft. of wood, or nearly 50 cu.ft. per acre.

The World's Timber Supply. — With about 7,500,000,000 ac. of productive forest area in the world, bearing heavy stands of virgin timber, having possible growth many times the world's present timber requirements, it would seem that there is enough timber to last for centuries. This would be true if all kinds of wood were equally capable of satisfying human wants. There are about 2,645,000,000 ac. of softwoods or conifer forests in the world; some 1,204,000,000 ac. of temperate hardwoods or broad-leaf forests, and 3,638,000,000 ac. of tropical hardwoods. Although the softwoods and temperate hardwood forests together form only one-half of the total forest area of the world, 91% of all the timber cut and used comes from the softwood and temperate hardwood forests of the Northern Hemisphere, and only 9% from the tropical hardwoods. The softwood forests are furnishing three-fourths and the temperate hardwoods one-fifth of the construction timber of the world. The temperate hardwoods, in addition, supply three-fourths of all the firewood. The amount of standing timber in the tropics is far greater than the amount remaining in the temperate regions, yet until recently, the tropical forests have played a minor part in supplying the world's timber. There has been prevalent an idea that the tropical forests are composed chiefly of cabinet woods, dyewoods and similar kinds of hard, heavy, deeply coloured wood, suitable for furniture and special uses, but not for construction. Recent explorations have shown that there are many excellent construction woods, equal if not superior to the woods of conifers for use in the tropics because more resistant to decay and termites. Before the tropical forests are able to supply a large part of the world's requirements there must be developed adequate systems of cheap transportation and adequate supplies of efficient labour. Another difficulty is that the tropical forests are mostly composed of a variety of species, intermingled in the greatest confusion, and can be exploited economically only if practically all the important species can be utilized. The crux of the world's timber supply problem, during the next two or three generations at least, lies in the available supplies of softwood and temperate hardwood.

Softwood Supplies. — The softwood forests are very largely confined to the cooler regions of the Northern Hemisphere, although some conifers occur in the Southern Hemisphere. The present growth of conifer timber is about 80% of the present cut. The forest capital is being depleted. The principal conifer regions are: (1) North America, including Canada, the United States, and the Sierras of Mexico; (2) northern Europe and central Europe; (3) Asiatic Russia, Manchuria and part of Japan.

In *Canada* the total amount of accessible merchantable saw-timber is estimated at approximately 61,500,000,000 cu.ft. and of pulpwood 52,000,000,000 cubic feet. The forests are being destroyed from two to two and one-half times faster than they are grown. At a total annual drain upon the forests of 5,000,000,000 cu.ft., the accessible stands of virgin forests would be exhausted in about 25 years. In the *United States* roughly only 300,000,000,000 cu.ft. of softwoods of saw-timber size remain. Softwoods comprise two-thirds of the 13,000,000,000 cu.ft. of

timber used annually and more than three-fourths of the sawed lumber.

Of the paper consumed in the United States, nine-tenths is made of softwoods. To meet its 1936 requirements, the United States cut about one-fifth more than grows each year. *Alaska* has great reserves of virgin timber in her coast forests and will contribute largely to the world trade. *Mexico* has about 20,500,000,000 cu.ft. of pine in mountainous forests at an elevation between 7,000 and 10,000 feet.

Europe is barely capable of meeting its softwood timber needs. Just before the World War Great Britain imported 97% of the timber she consumed; France, Germany, Italy, Belgium and the Netherlands imported approximately 30, 47, 65, 77 and 82% respectively.

The only European countries that have any prospect of increasing their output of softwood timber for any considerable period or even of continuing to export at the present rate are Sweden, Finland, Russia and possibly Southern Europe.

In *Asia*, only western and eastern Siberia are reputed to have enormous supplies of virgin softwood timber. Siberian forests, however, are largely unexplored, and little is known of their actual condition. Of the vast forest area of *South America* only 5% is composed of conifers. The bulk is in southern Brazil and adjacent portions of Argentina and Paraguay. The entire region produces only from one-third to one-half as much softwood timber as Argentina alone buys from the United States and Canada. The other South American countries depend upon the Northern Hemisphere for much of their construction timber.

Africa, although it possesses extensive equatorial forests, does not contain enough softwood timber to furnish even the small amounts required locally for construction purposes. In *Australia*, the softwood supply is inadequate for local needs. Much pine, fir and spruce lumber is imported from North America, Europe and north-eastern Asia. The small area of softwood forest in New Guinea and the other islands of the Pacific is insignificant.

Lord Lovat, after a survey of the softwood forests of the world, arrives at the conclusion that, except in Russia, the main softwood virgin timber reserves will be exhausted before very long, and Europe will have to depend more and more on timber raised by the agency of man; that the United States shortage is likely to come more quickly than that in Europe; that the more the American supply becomes centred in the Pacific coast States, the greater is the probability of the industrial States of north-eastern America coming into the European markets for saw-timber in the same way that they do now for pulpwood; and, finally, that as the United States consumes over 8,000,000,000 cu.ft. of softwoods, as opposed to a total European consumption of 9,000,000,000 cu.ft., the United States advent into European markets will have an important bearing upon European prices.

Temperate Hardwoods Supplies. — Like the conifers the temperate hardwoods are confined chiefly to the Northern Hemisphere and are located fairly close to consuming centres. They as a rule occupy the better soils of the more favourably situated lands and, therefore, have been progressively destroyed to make room for cultivation. The large old timber has been depleted even to a greater extent than that of the softwoods. *Europe* has still extensive areas of hardwood forests and even exports special kinds, such as the oak of Poland and Yugoslavia. On the whole, however, the consumption of hardwoods in Europe greatly exceeds the production. In *Asia*, Japan exports small quantities of oak. Walnut and other hardwoods are exported from Asiatic Turkey and the Caspian region. Siberia has about 30% by area of the temperate broad-leaved forests of the world. Except in the Far East, however, they consist of fairly light stands of aspen and birch, much of it valuable chiefly for firewood or pulp and not to be compared with the hardwoods of the United States and Europe. In *North America* the United States now has the largest supply of temperate hardwoods. The other North American regions have no surplus over their own needs. The original stand of approximately 250,000,000,000 cu.ft. of merchantable hardwoods has dwindled to about one-half of that amount and is being further depleted at the rate of over 5,000,000,000 cu.ft.

a year. The United States uses nearly 3,000,000,000 cu.ft. of hardwood timber a year, exclusive of firewood, or almost one-half of the entire world consumption of temperate hardwood timber. In the temperate region of the Southern Hemisphere including *southern Chile* and *Argentina, portions of New Zealand* and *Tasmania* and the *high mountains of South America* and *Africa*, there are relatively small quantities of valuable hardwood timber, and little or none for export. The outlook for future supplies of hardwoods, however, is probably better than for softwoods, because woods adapted to the same uses can be got from the tropical forests, though they may cost much more. (R. Z.)

VII. NATURAL GAS

Natural gas, like petroleum with which it is closely associated, is one of the major natural resources of the United States. It may occur with petroleum or independent of commercial petroleum in great natural gas fields or deposits. Composed, for the most part, of the hydrocarbons of the paraffin series, carbon dioxide, nitrogen and helium, its composition, however, varies considerably in the different fields. Like petroleum, natural gas development in the United States has been on an ascending scale. In 1938 natural gas production totalled 2,524,700,000,000 cu.ft., compared with 1,555,474,000,000 cu.ft. in 1933. The geographic production together with the amount produced is:

¹Preliminary estimate from *The Oil Weekly*.

²Missouri, South Dakota, Tennessee, Utah, and Washington.

³It is believed that 50 per cent of total production is casinghead gas, produced as a crude petroleum by-product; dry gas wells, which produce natural gas only, account for the other 50 per cent.

Authority: U. S. Bureau of Mines.

Natural gas is produced in Canada in the following territories: Alberta, New Brunswick, Ontario and Saskatchewan.

The enormous use of natural gas for domestic and commercial purposes as a direct fuel with uses similar to that of manufactured gas, is made possible by the piping of the gas from the fields themselves into cities close to, and even far distant from the fields. In 1937 there were over 9,000,000 domestic and commercial natural gas customers, comparing with 6,690,700 in 1933. These domestic and commercial customers accounted for 489,234,000,000 cu.ft. in 1937, and 368,774,000,000 cu.ft. in 1933.

Despite this large consumption, the great bulk of the natural gas produced goes into industrial uses. There is a tremendous consumption in the oil and gas fields, amounting to 691,320,000,000 cu.ft. in 1937. In carbon-black manufacture 341,085,000,000 cu.ft. were consumed; in petroleum refineries, 113,005,000,000 cu.ft.; in electric power plants, 170,567,000,000 cu.ft.; in Portland cement plants, 40,450,000,000 cu.ft., and in other industrial plants, 597,380,000,000 cubic feet. Thus, of the total of 2,443,041,000,000 cu.ft. consumed in 1937, domestic and commercial consumption accounted for 489,234,000,000 cu.ft., and industrial consumption accounted for 1,953,807,000,000 cubic feet. The supply of natural gas comes from more than 45,000 wells, and there is an average of over 2,000 new natural gas wells drilled every year in the United States. Carrying natural gas from the fields to consuming centres is a network of natural gas pipe lines aggregating 182,320 miles. Gas that would formerly have been

wasted is now held in the ground in the oil reservoir to aid in driving the oil out and thus in increasing the ultimate petroleum yield from the sand. Also, in connection with natural gas research and conservation, a great by-product natural-gasoline industry has been developed, utilizing gas that formerly escaped in the air when an oil well was brought in. (L. M. F.)

VIII. COAL

Beginning with the data collected by the 12th International Geological Congress in 1913, there have been a number of attempts to arrive at an estimate of the coal reserves of the world, but consistent results have been handicapped by lack of complete information and by lack of uniformity in the basic premises involved, especially the ultimate depth to which work may eventually be extended. The estimates of world reserves of coal in the table on page 865 are derived from those published by the Reichskohlenrat of Berlin in 1938, to which have been added estimates for Mexico and Brazil, taken from Commodities of Commerce Series No. 3, of the Pan American Union. These estimates include all grades of coal down to a depth of 2,000 metres (6,560 ft.), and are based on the geographical boundaries current at the time of publication, many of which have undergone subsequent alteration. Estimates for Germany, Austria, and France have been reduced somewhat from those of earlier years, while those for Russia have been increased. It will be noted that the reserves listed are not at all uniformly distributed, 50% of the total being in the U.S., 21% in Russia, and 14% in Canada, these three alone accounting for 85% of the total; another 10% is found in China, Australia, Germany and Poland, in the proportion of 3% to the first, and 2% each to the others, bringing the total accounted for to 94%, and leaving only 6% scattered among other countries.

On the basis of the reserves as here reported, ignoring the question of grades of coal and losses in mining, and considering only the tonnages involved and the average rate of production during the five years 1934-38; the total world reserves should last for some 5,500 years, those of the United States 9,570 years, Russia 1,920 years, Great Britain 870 years, Germany 520 years, and France 220 years. Of these more heavily industrialized countries, however, some produce a surplus for export, while others must import to cover their current demands. On the basis of consumption alone, the life of the British reserves would be increased by about one-third and the German by about one-ninth, while the French would be reduced by one-third. It must be remembered, though, that all of these figures would be radically changed by any marked and consistent increase or decrease in the consumption rate. Proper allowances for losses in mining would also materially reduce the life factor; in the past, these losses have sometimes been as high as 100%, but current losses are probably of the order of 25-50%. (G. A. Ro.)

IX. PETROLEUM

In all the countries and areas throughout the world where petroleum has been found to exist or where there has been geological determination of oil possibilities, only in the United States of America have studies been conducted to evolve a fairly scientific basis for estimating oil reserves or resources. Even such estimates made in the United States are subject to misinterpretation due largely to the fact that reserves may be placed in a number of categories, such as proven reserves (those based on actual drilling experience) and unproven reserves (those based on geologic considerations but not yet proven by drilling). There are other qualifications, such as whether certain proven reserves could be profitably exploited under existing conditions. Moreover, any estimates of reserves are subject to constant revision, and it is virtually impossible to obtain comparable figures for various countries reflecting the same degree of accuracy. It also must be borne in mind that only a fraction of the petroleum stored underground, usually associated with natural gas, is, or can be, brought to the surface. Thus it is estimated that in the United States only some 25 to 35% of the petroleum underground in the proven fields is recovered. However, production technique is increasing this recovery as well as, by making possible deeper drilling, opening up reserves hitherto beyond the range of estimate,

There has been substantial and continuing enlargement of the proven recoverable reserves of petroleum in the United States. In 1908, David T. Day, chief geologist of the U.S. Geological Survey, estimated that the ultimate total production from oil fields of the United States would range from a minimum of 10,172,000,000 bbl. to a maximum of 24,680,000,000 barrels. His estimate included previous production, known reserves, and probable production from fields not then discovered. His minimum estimate was reached in actual production as long ago as 1927. The U.S. Geological Survey and U.S. Bureau of Mines revised Day's estimate in 1916, and estimated that the ultimate total would

be 11,000,000,000 barrels. That amount of oil had been produced by the end of 1928. A comprehensive attempt at reserve estimation was undertaken in 1921 by the U.S. Geological Survey and the American Association of Petroleum Geologists. In this effort, a careful analysis was made of all known favorable structures, both producing and untested, based on available knowledge of sub-surface conditions and what was then considered reasonable drilling depths. Their conclusion was to the effect that future recoverable reserves amounted to 9,150,000,000 bbl., of which approximately 5,000,000,000 bbl. were classed as "oil in sight" and about 4,000,000,000 bbl. as "prospective and possible oil."

*Proved reserves are an estimated inventory of recoverable oil, in known fields and by present methods only. They include no estimate of future discoveries nor of greater recovery in known fields from probable advances in the technique of producing oil.

†American Petroleum Institute. All other reserve data from Garfias and Whetsel.
‡Includes Sakhalin and all other Soviet fields.

From American Petroleum Institute; V. R. Garfias and R. V. Whetsel, Foreign Oil Dept., Cities Service Co.; U. S. Bureau of Mines.

This reserve was "exhausted" by actual production prior to the end of 1933.

In 1925, the American Petroleum Institute Committee of Eleven conducted a most exhaustive survey, and concluded that the future reserves recoverable from producing fields by then known methods of production amounted to approximately 5,300,000,000 barrels.

In 1935, a committee of prominent geologists under the auspices of the American Petroleum Institute began making the most exhaustive and scientifically calculated estimates of U.S. petroleum reserves yet attempted, and has continued this practice virtually annually. The first estimate, as of Jan. 1, 1935, placed the proven reserve of crude oil in the United States at 12.2 billion barrels. Subsequently these estimates have been as follows: as of Jan. 1, 1937, 13.1 billion bbl.; Jan. 1, 1938, 15.5 billion bbl., and Jan. 1, 1939, 17.3 billion barrels. Thus each succeeding estimate has increased. These estimates do not count oil available upon the application of secondary recovery methods. They make no allowance for possible reserves in untested areas, but represent only the volume of crude oil recoverable by present known methods from fields now completely developed or drilled, or sufficiently drilled and explored to permit of reasonably accurate calculations.

One of the main causes of the recent increases in the indicated reserve is the revision brought about by the increased efficiencies of improved technique and controlled or delayed production. The size of the proven reserve gives no clue to, and logically cannot be expected to reveal, the imminence or remoteness of scarcity. The proven reserve, so estimated, is merely an estimate of the working stock of petroleum in advance of production, which is quite a different matter from the volume of oil yet to be discovered and to be recovered as additional oil from known deposits by improved methods. The only basis for anticipating an ultimate shortage of United States petroleum is a line of reasoning based on the principle of elimination—that each pool found means one less to be discovered in the future—but the sheer magnitude of the proven reserve sheds little light on the questions: How much oil is yet to be found? and, To what extent will recoveries be increased by improved technique?

The committee of geologists and engineers which made the estimates of reserves for the American Petroleum Institute report: "Large areas within the United States, underlain by sedimentary rocks, are only partly explored for oil reserves, whereas the areas already explored by the best current methods are relatively small. No satisfactory method has been found for assigning a numerical estimate to the amount of oil recoverable from undiscovered deposits. The oil to be discovered in the future is so concealed from observation that an estimate of ultimate reserves in terms of barrels is obviously impracticable. However, we do have a definite, although incomplete, knowledge concerning the existence in an important part of these slightly explored areas of extensive deformation in sedimentary rocks which are productive in neighbouring districts, of deeper prospects. . . . This gives reason to expect that ample discoveries will be made to meet national

requirements for a period of indeterminate length."

Reference also was made to the possibilities of stratigraphic geology. In the past most oil discoveries have been based on the anticlinal theory. The development of the East Texas oil field brought stratigraphic possibilities into prominence. An entirely new field of geology has opened up as a result—the study of flank sands, regional inconformities and up-dip wedging of porosity as possible oil reservoirs. The president of the American Association of Petroleum Geologists, A. I. Leverson, stated in 1936 that there were yet to be discovered oil and gas reserves almost without limit by those who may become adept in stratigraphic analysis, and that, differing from past methods, the possibilities for stratigraphic production could not be quickly exhausted. (L. M. F.)

METALLIC AND NON-METALLIC GROUPS

Under this heading are discussed the most important metallic and non-metallic substances including Iron, Lead and Zinc, Copper, Aluminium, Nickel, Manganese, Tin, Tungsten, Vanadium, Sulphur, Mercury, Silicon and Mica

I. IRON

Broad allowances for incomplete information must be made when considering iron ore resources. While no new immense iron ore fields remain to be discovered in either Europe or North America the remaining four continents are still largely unsurveyed. Of known iron ore reserves 15,000,000,000 tons occur in North America, 12,000,000,000 in Europe and 7,000,000,000 in South America. If it be assumed that the remaining three continents are proportionately as well supplied—and against this assumption there is no geological argument—the conclusion is reached that the world iron ore reserve is a total of 90,000,000,000 tons.

The world, in 1936, produced 141,000,000 tons of iron ore and, in 1937, 172,000,000 tons for a new high record. This production was supplied by many mines, but a few great ore fields were responsible for the bulk of the tonnage. The Lake Superior Region shipped, in 1936, over 40,000,000 tons, and the Lorraine field of France and Luxembourg over 35,000,000. Soviet Russia has risen to third place among the nations with 28,000,000, the British fields ranking fourth with 13,000,000. Sweden shipped over 11,000,000 tons, Germany (including Austria and Czecho-Slovakia) 8,000,000, and the Alabama fields about 5,000,000. After these, ranging down to about 2,000,000 come North Africa, British India, western France, the New York-Pennsylvania magnetite fields, the Malay States and Australia.

The localization of demand may cause more concern than excessive total consumption, for a few ore fields are being drawn upon in exceptional tonnages while other large fields are practically unused. For example, if the present-day drafts continue, our current estimates of known ore reserves in the different great fields suggest that ore of present day grade will be exhausted in the Lake Superior region within 50 years, in Spain and Great Britain within the century, and in Lorraine in less than 150 years.

Estimated Proven Crude Oil Reserve in the United States on Jan. 1, 1939
(Data from American Petroleum Institute)

Rank	State	Reserve	Per Cent of Total	1938 Production	Indicated Life in Years
		Million Barrels		Million Barrels	
1	Texas	9,447.8	54.5	475.6	19.9
2	California	3,188.8	18.4	249.7	12.8
3	Oklahoma	1,162.4	6.7	174.9	6.6
4	Louisiana	1,040.3	6.0	94.8	11.0
5	New Mexico	703.3	4.1	35.8	19.6
6	Kansas	613.2	3.5	59.6	10.3
7	Wyoming	261.1	1.5	19.0	13.7
8	Illinois	242.8	1.4	23.9	10.2
9	Pennsylvania	200.5	1.2	17.4	11.5
10	Arkansas	188.2	1.1	18.1	10.4
11	Montana	104.5	0.6	4.9	21.3
12	Michigan	42.7	0.2	19.2	2.2
13	New York	40.5	0.2	5.0	8.1
14	Kentucky	37.5	0.2	5.8	6.5
15	Ohio	26.4	0.2	3.3	8.0
16	West Virginia	24.5	0.1	3.7	6.6
17	Colorado	17.7	0.1	1.4	12.6
18	Indiana	6.0	—	1.0	6.0
	Total	17,348.2	100.0	1,213.1	14.3

From Joseph E. Pogue, *Economics of the Petroleum Industry*.

As against this far-off threat, it may be seen that on the basis of present drafts the Alabama fields should last 300 years or more, while the vast reserves of Brazil, Cuba and Newfoundland have not yet been drawn upon seriously. It is safe to say that the United States can retain its present leadership in iron and steel manufacture for several decades more. It is probable, however, that soon the old primacy of Great Britain and the present American leadership will, in these heavy manufacturing lines, be challenged by a new European competition based on the Lorraine and Norman ore fields, and upon west European coals and cokes.

With regard to the four continents which are less well known and less developed industrially, existing knowledge of relative ore and fuel supplies permits certain deductions of considerable validity. It may be safely assumed, for example, that the known coal supplies of Asia, particularly in China and India, will justify and encourage a large iron and steel industry as local consumption increases; and that under certain conditions the excess product may be exported so as to become a serious factor in European and North American trade and industry. With regard to South America, Africa and Australia, present knowledge of raw material resources suggests that while Australia may easily become self-supporting in the way of steel and iron products, the other two are likely to become important as exporters of iron ore to coal-rich areas, but not as serious producers of iron and its products. Older conclusions as to iron ore exhaustion have been modified seriously by the fact that, within the past two decades, their bases of deduction have been strikingly changed. For 150 years the world iron industry had increased at the rate of 50% each decade; and most earlier estimates prolonged this past rate of increase into the indefinite future. Now, for the first time in the history of modern industrialism, there has been experienced a period of 15 years in which the world iron industry has not progressed; and there is no reason to assume that, whenever this dead point is finally passed over, the old rate of increase will be resumed. It is indeed far more likely that in the future the iron industry of the world will increase at a far slower rate, possibly not above that of the rate of increase of world population. If so the known ore reserves will last for very many generations (E. C. E.)

II. LEAD AND ZINC

Lead.—No quantitative estimate of the copper, lead and zinc resources of the world has been made and it is doubtful whether a reasonable approximation can be made. Looking backward through 50 years there have been periods when it was thought that the supply of these ores was superabundant and other periods when they have seemed to be scarce and opinion has swung from one extreme to another. Especially has this been true in the instance of zinc. However, as to each of these metals, new discoveries, both geographical and technological, may develop valuable resources out of what was previously unknown or worthless. The only conditions under which the world's resources of minerals can be reasonably forecast are when we may say that at least we have so much, as in the instances of coal and iron. Between these extremes it is always a matter of the equilibrium among production, consumption and price. So far as we can see ahead we shall have a sufficient supply of these metals, but we can not see clearly what price we shall have to pay for them, even through the next 10 years.

The production of lead comes principally from the following districts, their percentages being given. South-eastern Missouri, 8.1; Utah, 4.7; Coeur d'Alene (Idaho), 5.1; Tri-State, covering the contiguous parts of Oklahoma, Kansas and Missouri, 2.7; Mexico, 14.1; Broken Hill, N.S.W., 10.4; Sullivan mine, Kimberley, B.C., 10.6; Bawdwin mine, Burma, 4.7; Yugoslavia, 4.1. These account for about 65% of the world's production. Except in south-eastern Missouri, the mines produce a mixed ore which is milled so as to give an enriched galena product for the lead smelter and a blende product for the zinc smelter. Many of the great lead-producing districts of the past were exploited for lead alone, such as Eureka, Nev., and Leadville, Colo., and exhausted. Lead-producing districts have waxed and waned more generally and more rapidly than either copper or zinc. Because of this and

the failure to make many important new discoveries since 1900, together with the greatly increased demand for lead, experts have taken a pessimistic view and predict a steadily rising price in order to develop poorer ores and remoter mines. About 1925 the new process of selective flotation enabled the profitable mining of large supplies of previously unworkable zinc-lead ores. Lead and zinc production became increasingly interlocked, and now the mines that produce straight lead or zinc ore are few. What will be said hereinafter under "zinc" will therefore apply equally to lead.

Zinc.—The world's greatest resources of zinc ore, mentioned substantially in the chronological order of their exploitation, have heretofore been the mines of Upper Silesia; Franklin, N.J.; the Tri-State district of Missouri, Kansas and Oklahoma; Iglesias in Sardinia; Broken Hill in New South Wales; Butte, Mont.; Kimberley in British Columbia; and Bingham and Park City, Utah. In 1926 these districts produced about 70% of the world's total of 1,250,000 tons of spelter. The remainder was mined in Bolivia, Algeria, Burma, China, Czechoslovakia, France, Germany, Great Britain, Indo-China, Japan, Mexico, Peru, Spain, Scandinavia, Tunis and the United States. Some great mining districts have lived and died, the most noteworthy of these having been Vieille Montagne (now of Belgium) and Leadville, Colo., but many new districts are being exploited. A maintenance of the output of the present large producing districts—Broken Hill, Tri-State, Kimberley and Franklin—at the current rate for another 20 years, at least, may reasonably be forecast.

Estimates of zinc reserves collected from various sources total about 12,000,000 tons for the United States, or about a 20-year supply at the 1937 rate of production, but production from many deposits will be dependent on prices well above the levels current in recent years.

On the other hand new sources of production are being developed as the results of exploration of new territory, the extension of transportation and improvement of metallurgic processes, which not only make it possible to use profitably ores that formerly were considered refractory but also to give an increased yield from all ores. Among the important new districts are Flin Flon, Sudbury, Buchan (N.F.), Broken Hill (N. Rhod.), Roseberry (Tas.), Mount Isa, Cerro de Pasco (Peru), and Trepcja (Yugoslavia). A general upward trend of price was expected in 1925 as a consequence of the increasing scarcity of zinc ore, but the advent of selective flotation changed that outlook almost immediately. Portions of the world, as yet unexplored scientifically, may have great zinc ore possibilities as, northern Canada, Labrador, and Newfoundland; the Andes; Siberia, where there are some great known deposits; Africa, especially in the north and in the Congo region and in Rhodesia; the interior of Australia, and in New Guinea.

The production of ores up to quite recently has been from deposits whereof there have been surface indications. Much of the world's surface is covered by alluvial material which probably hides mineral deposits. We now have new developments in geophysical science and methods that are opening the way to the discovery of such hidden deposits. On the side of requirements, the need for all of these metals steadily increases. Immediately previous to the World War the annual per caput consumption of the United States was about 8 lb. of copper, 9 of lead and 6.5 of zinc. In the principal countries of Europe the average was a little less, especially of copper. In 1929 the American per caput consumption was about 18 lb. of copper, 12 of lead and 10 of zinc. European consumption was, however, still below the pre-war rate. In 1937 the United States consumption was 11 lb. copper, 8 lb. lead, and 8.5 lb. zinc, while Europe had risen to 14 lb. copper, 16 lb. lead, and 11 lb. zinc, as a result of increased rearmament demand. The intimate connection between these metals and the electrical and other important basic industries promises continued increase in demand, while prospects for extensive substitution are limited to the use of aluminium instead of copper for electrical transmission lines. (G. A. Ro.)

III. COPPER

World production of copper for the 10 years ending Dec. 31, 1900, was 4,158,513 short tons; for the 10 years ending Dec. 31,

1927, 13,157,500 tons, and for the 10 years ending Dec. 31, 1939, it was approximately 17,175,000 tons. In the earlier periods, the U.S. furnished 52.3% and 53.9%, and in the last only 28.8%. South America's proportion rose from 8.4% to 16.2% and then to 19.2%. Africa's from about 2% to 5½% and then to 16.2%. Canada furnished 11.8% in the last decade. Africa and Canada are now supplying as large a proportion of the total as the U.S. The following table shows this change:

Proportion of World Production

	U.S.	Africa	Canada	South America
Average yrs. 1916-18 incl.	61.90%	2.67%	3.56%	10.22%
Average yrs. 1937-38 incl.	29.61%	17.31%	11.79%	19.81%

World copper production reached an all time peak in 1937 of 2,503,966, and in 1939 was about 10% under. The following table is an estimate of the sources of potential supplies.

TABLE I. — *Potential World Supply of Newly Mined Copper*

	Short Tons		Short Tons
U. S.	1,000,000	Spain & Portugal	40,000
Cuba	15,000	Yugoslavia	50,000
Mexico	60,000	Germany	40,000
Canada	330,000		
Newfoundland	5,000	Total Europe	130,000
Total N. America	1,410,000	Russia	120,000
Bolivia	5,000	Japan	85,000
Chile	*515,000	India	12,000
Peru	50,000	Other Asia (inc. Cyprus)	50,000
Total So. America	570,000	Total Asia	267,000
Norway	25,000	Belgian Congo	170,000
Sweden	10,000	Rhodesia	*250,000
Finland	15,000	Other Africa	30,000
Total Scandinavia	50,000	Total Africa	450,000
Australia	25,000	Grand Total	2,902,000

*The nature of the Chilean and Rhodesian deposits is such that with additional plant another 100,000 to 200,000 tons could be secured in a year to 18 months from the time active work was started.

The American Bureau of Metal Statistics tabulates copper ore reserves as officially reported, as follows:

	Tons Ore	Tons Copper
United States	1,120,837,213	13,297,700
Canada	299,540,205	8,793,500
South America	1,385,761,105	29,003,800
Africa	608,584,797	26,154,600
Other	53,411,478	1,376,240
Total	3,468,134,918	78,625,840

While most of these official estimates are of recent date, 1937 or 1938, current estimates would doubtless show some increase. In the case of the United States such important producing areas as Butte, Montana, and Jerome, Bisbee, Morenci, and Ajo, Arizona, are not included. In addition there are the European, and Asiatic countries, including Russia and Japan, with a potential production (*see* Table I) of 447,000 tons per annum. It is safe to assume that conservative estimates of reserves in these areas, would bring the grand total to well over 100,000,000 tons of copper metal recoverable by present methods. At the rate of consumption of the past 10 years, this would last nearly 60 years. The total recorded world production of copper from 1800 to the close of the World War in Nov. 1918 was about 23,500,000 tons. In the ensuing 21 years, it has produced and consumed about 33,840,000 tons of newly mined copper. However, there has been little change in the rate for the last two decades. This suggests strongly that the "explosive" effects on consumption of the introduction of electricity has about run its course. In the meantime the electrical industries still absorb in excess of 50% of the production. This represents a decline of perhaps 20% from the peak. There have been increases in the requirements of the building trades, automobiles, air conditioning, refrigeration, etc., and evidence of a growing use in alloy steel.

There is nothing to suggest that the present generation need have any fears of a shortage of copper supplies. There are un-

questionably enormous tonnages of material in the proven districts, which are too low grade to be of commercial value at the present range of cost and price, but would become available when needed. Beyond all this lies the fact that copper is practically an indestructible metal, and the great bulk of that now in use can be reclaimed for new uses, when the structures and machines in which it is incorporated are worn out or become obsolete.

In view of world conditions of 1939, it is interesting to note that more than half of the proven reserves of the world lie within the political boundaries of the United States and the English speaking portions of the British Empire in Canada and Africa, and that another 30% in South America are owned by American capital. Similar proportions hold with respect to present facilities for production. (A. NOT.)

IV. ALUMINIUM

The aluminium content of the earth appears to be concentrated near the earth's surface. F. W. Clarke and H. S. Washington estimate that the earth as a whole contains only 1.79% of aluminium, but that the outer crust, to a depth of 10 m., contains 8.05%. This is equivalent to an aluminium oxide content of 15 to 16%. The ores of aluminium are employed for the production of aluminium, alumina, aluminous abrasives, cement, aluminium chloride, alum, etc. From economic considerations those ores are employed which yield the maximum number of units of alumina per unit of cost. For this reason the pre-eminent ore is bauxite, which contains 50 to 60% of alumina. The bulk of the world's aluminium is produced from alumina extracted from bauxite by digestion with caustic soda—the well known Bayer process. In 1929 about four tons of bauxite would produce a ton of aluminium. Bauxite of commercial grade is available in extensive deposits in Europe, North and South America, Asia and Africa, but the bulk of the production comes from the first three of these continents. E. C. Eckel, upon the assumption that the available bauxite per square mile of area is the same in other continents as in Europe, has estimated the world's bauxite reserves as about 2,500 millions of tons. In 1937 the world's production of bauxite was about 3,700,000 tons. After allowing for substantial annual increases in consumption, therefore, the world's supply will last a long time.

The aluminium industry was in 1928 using the purest bauxite, particularly with respect to silica, and much of the world's supply of bauxite is less desirable for the Bayer process. However, there are other processes being developed which can handle lower grades. Among these are the electric furnace process of C. M. Hall as recently developed by Aluminum Company of America, as well as the processes of Pedersen and Haglund. Other ores of aluminium, particularly certain of the silicates, are proving susceptible to treatment by processes now under development, so that when they become economically important they can be utilized. This will still further extend the available supplies of aluminium ores. The consumption index of aluminium is increasing more rapidly than some of the older, commonly used metals. Up to 1929 aluminium had competed principally with copper and other non-ferrous metals on a price per volume basis. With the greater realization, however, of the economic value of the lightness and strength of aluminium and the development of strong, light alloys, aluminium competition with other metals increased materially, accompanied by continually improving production and fabrication methods. Uses of the compounds of aluminium, as in the abrasive, cement, and chemical industries have also expanded. For all these growing demands, the supply of aluminium appears ample for many years to come. (J. D. E.; X.)

V. NICKEL

While nickel is one of the elements of most common occurrence in the earth's crust, the commercially important ore deposits are confined to two localities, Canada and New Caledonia. Of these Canada is by far the more important, producing (1929) approximately 90% of the world's nickel. While there are numerous other known nickel deposits, it is improbable that this percentage will be much affected for many years. The ore deposits are of two kinds: *sulphide deposits*, where the nickel occurs in conjunction

with copper and sulphur; and *silicate deposits*, where the ore occurs as nickel silicate (generally as a double silicate of nickel and magnesium). The Canadian deposits are typical of the first type, those of New Caledonia of the second type. The known Canadian nickel deposits are located in Sudbury district, Ont., within an area 40 m. long by 30 m. wide. While some 35 deposits of varying size and richness have been located since the original discovery in 1883, only a few of these mines are worked. Thus in 1939 The International Nickel Company was operating the Creighton, Frood, Garson, and Levack mines, and the Falconbridge Nickel Company the Falconbridge mine. On the basis of diamond drilling and other exploratory work it is estimated that there is proven ore in sight of approximately 200,000,000 tons, containing over 7,000,000 tons of nickel. With a world consumption of approximately 100,000 tons of nickel per annum, this is equivalent to 70 years of proven ore.

The New Caledonia deposits, originally discovered in 1865, rapidly assumed primary importance, and from 1875 to 1880 were the chief producers of the world's nickel. In 1905 the New Caledonia deposits were surpassed in production by the Canadian mines, which since that time have maintained their pre-eminence. The peak of New Caledonia production was reached in 1911. It is now a steady producer of about 10% of the world supply. Owing to the character of the New Caledonia deposits it is impossible to give any figures on ore resources, or potential production. It is known that there is still a large amount of ore on the island, and it is believed that New Caledonia will continue to produce nickel for many years. Besides these two localities deposits of nickel ore are known to exist at a number of places. In general these conform in type to one of the two classes mentioned above, but the size and character of the deposits, with the exception of those in Finland, render them non-commercial under present economic conditions. The best known of these are deposits of the sulphide type ores, in Norway, Finland, Sweden, Germany, and South Africa, and the silicate type ores in Celebes, Madagascar, Germany, and Greece. Nickel ores in the United States are comparatively unimportant. (J. F. TH.)

VI. MANGANESE

World resources of manganese may be divided into two classes: manganese ore containing more than 35% manganese; and manganiferous ores containing less than 35% manganese. In countries where manganese ore production is large and consumption small the second class is of small interest, whereas if the opposite conditions prevail manganiferous ores may be of considerable importance. In modern steel-making practice the trend is toward a greater use of high manganese pig iron (*see MANGANESE STEEL*) and manganiferous ores are extensively used in blast furnaces. This practice is particularly useful where the production of ferro-manganese grade ores is small, as the high manganese in the pig iron results in a higher manganese content of the steel during refining and thus in a saving of expensive ferro-manganese. The use of high-manganese iron is common in Germany and Russia, and to a lesser extent in the United States.

The largest resources of manganese ore are in Russia, India, Brazil, Gold Coast, and South Africa. The largest developed deposits are in Russia; the Chiaturi deposit in Georgia (Caucasus) has been estimated to contain 163,000,000 tons of ore, the Nikopol deposit in the Ukraine 90,000,000 tons, and numerous smaller ones 78,000,000 tons, a total of 330,000,000 tons. The deposits of India are numerous, but no recent estimates on reserves are available. The reserves of each of the other leading sources besides Russia are probably of the order of 10,000,000 to 20,000,000 tons. High grade ores are also known to exist, and are mined to some extent, in several other countries, especially Cuba, the Dutch East Indies, China, Chile, Egypt, the former Czechoslovakia, Hungary, Japan, Malaya, Morocco, and Rumania. The reserves of high grade ore in the U.S. are limited to 1,000,000 to 1,500,000 tons, but spiegel grade ores approach 20,000,000 tons, and low grade ores total about 45,000,000 tons, averaging 7% Mn. World production in 1937 was in excess of 6,000,000 tons, but a material proportion of this has gone into stocks. (G. A. Ro.)

VII. TIN

Tin resources of the world are generally—and probably correctly—considered to be smaller than those of any of the other major industrial metals and nearer to exhaustion. Necessarily in making this statement price is a factor to be considered. If the market price soars, deposits of progressively lower grade will become profitable. Likewise, economies to be effected in mining, and higher recoveries resulting from improved methods of ore dressing and smelting will tend to expand the resources of the world. Still another factor is the possibility of discovering new fields of substantial importance, the most likely areas being interior Africa, French Indo-China, Siam, and China. As long ago as 1926 some authorities forecast a fairly uniform rate of production, at about 150,000 tons annually, for ten years to be followed by a gradual decline. However, the most apprehensive observers, today, foresee supplies to meet any reasonable demand for a generation or more.

Production of tin in the major countries is subject to artificial control under Government sanction so that figures of annual output are not necessarily in accord with potential production. However, in 1937 a record-breaking output of 208,000 long tons was recorded and the following percentages consequently reflect reasonably well the normal capacity:

	Toni, Thousands	Per Cent of Total		Toni, Thousands	Per Cent of Total
Malay States	77.5	37.0	China	10.5	5.1
Netherlands			Nigeria	10.4	5.0
Indies	39.8	19.2	Belgian Congo	9.0	4.2
Bolivia	25.0	12.1	Burma	4.6	2.1
Siam	16.5	8.0	All Others	14.9	7.2

For many years the Malay States has been the leading producer, the tin coming exclusively from placer operations. New and larger dredges have been built and the reserves of exploitable ground are larger today than ever before. The Netherlands East Indies yielded second place to Bolivia in 1938, because the Indies output was purposely restricted on account of the low market price for tin. The mines are placers controlled by the Government. Bolivian production once exceeded 45,000 tons, mostly from lode mines, but since 1935 output has been about 25,000 tons annually. The greatest increases for the years 1930-39 have been shown by Siam, China, and the Belgian Congo. Output from the latter was almost negligible up until 1930. Siam promises to become a factor of growing importance. Nigeria, on the other hand, appears to have passed its peak unless entirely new discoveries are made. (A. B. P.)

VIII. TUNGSTEN

The metal tungsten has played a very important part within the last quarter of a century in the progress of the electrical and mechanical arts. Recent developments indicate that its importance will be still greater in the coming years. It is a chief component of tool steels and enters into the manufacture of heat-resisting and non-corrosive steels. Recently tools have been invented consisting of pure tungsten carbide imbedded in a metallic matrix which have quite revolutionized the art of cutting and shaping not only metals but also such unworkable materials as porcelain, glass, bakelite, etc. Tungsten is also used in the light filaments, contact points and X-ray targets of the electrical industry besides entering as a component into magnet steels. With the rapid strides made in radio and television its use in the electric industry may grow to much greater proportions.

The important commercial minerals of tungsten fall under two main groups, the tungstates of the metals iron (ferberite) and manganese (huebnerite), and a mixture of both (wolframite); and the tungstate of calcium (scheelite). Until recently scheelite was the more coveted mineral for metallurgical purposes owing to its greater purity, but progress in smelting and reduction practice has offset this advantage. Nature has provided a very wide-spread mineralogical occurrence of tungsten, both in the primary and secondary formations of the earth. The primary deposits are invariably associated with granitoid rocks and are most important, while secondary deposits form the lesser resources. Tungsten has

been a comparatively cheap metal and it has been the endeavour of producers to get their ore supplies as cheaply as possible. The supremacy of tungsten production has floated from country to country as the surface ore was exhausted and more expensive deeper mining made necessary. Owing to its great importance in munitions work it is the endeavour of the principal Governments of the world to keep their indigenous tungsten resources under development in spite of the lower cost of foreign minerals.

Since 1913 tungsten production has increased by more than four-fold, reaching 34,800 metric tons of concentrates, containing 16,600 tons of metal, in 1937. The outputs of the leading producers and their percentage of the total output in various years is as follows: In 1913—Burma 19%, United States 17%, Portugal 14%, Australia 10%; in 1918—China 33%, United States 14%, Burma 13%, Bolivia 12%; in 1929—China 63%, Bolivia 10%, Burma 9%, United States 4%; in 1937—China 47%, Burma 16%, United States 9%, Bolivia 5%.

No data are available on reserves except in the United States, where the known reserves are estimated to be about equal in amount to the output of the past 20 years, but equal to consumption for only 8 years prior to 1938. Full utilization of these reserves will be dependent on maintaining sufficiently high prices to cover the abnormally high production costs inherent in these low grade mines, which require a heavy tariff protection to keep them going.

(G. A. Ro.)

IX. VANADIUM

The tremendous advances made within the last few years in the transportation industry, be it railroad, automobile or aeroplane, have very markedly brought forth the importance of the metal vanadium. It is always used in the metallurgical industry as an alloy. It is added to metals in very small quantities, yet produces in the finished metal very marked changes in physical properties. The present day mass production in the automotive industry or the developments in the aeroplane motor would not have been possible had it not been for the development of vanadium metallurgy. Vanadium has also played an important part in armaments.

Vanadium is one of the most widely distributed elements in the earth's crust, being present in almost all igneous rocks. However, occurrences of the metal in concentrated mineral deposits are scarce. The chief sources of supply are in Peru, South West Africa, United States, and Northern Rhodesia; these have contributed to recent output in the proportions of 40%, 26%, 19%, and 15%, respectively. Small amounts have also been produced in Mexico, and there are other minor occurrences associated with the iron ores of Sweden, Norway, Luxembourg, France, Germany, Russia, and Japan, but as yet these have little commercial significance. The mineral found in the most important deposit in Peru is patronite, a vanadium sulphide. In Colorado and Utah the occurring minerals are roscoelite, a vanadium silicate, and carnotite, a radium-bearing uranium vanadate. The ores of Mexico and Africa are descloizite and mottramite, complex vanadates of lead, zinc and copper.

The already known resources of vanadium minerals in the world fully assure an adequate supply for probably another generation. At the same time considerable effort is directed towards finding new deposits or further exploiting the known ones. The consumption of vanadium is constantly increasing as new uses are developed, and in 1938 the total known world output was 3,150 metric tons of metal content in ore. The U.S. is the only important consumer with an appreciable domestic supply. Vanadium is an essential constituent of high-speed tool steel, the demand for which has increased tremendously with the expansion of mechanical production. It is also used in heat-resisting and non-corrosive steels. Some recent developments in the chemical industry will tend to make large demands on vanadium resources. Vanadium is beginning to be used in the textile, varnish, linoleum and rubber industries, and a particularly important application seems to be the use of its oxide as a catalyzer in the manufacture of sulphuric acid replacing platinum. Vanadium may also be applied in the agricultural and pharmaceutical industries. Marked strides have

been made in the metallurgical treatment of vanadium minerals so that materials previously considered low grade or useless have been made available to the industry, thus augmenting the sources of raw materials and adding to vanadium reserves. (B. D. S.; X.)

X. SULPHUR

Native sulphur, or brimstone, occurs in many places throughout the world, generally either in beds of gypsum, limestone and associated rocks or in the vicinity of active and extinct volcanoes. The principal extensive deposits are found along the Gulf coastal plain of the United States, in two places in Sicily, at several points on the mainland of Italy, in Japan, Spain, Austria, in the Aleutian islands, Alaska, in the Chilean Andes, South America, in China, India, Russia and in several of the South Sea islands. Until 1905, Sicily controlled the sulphur industry, approximately 85% of the total world's supply being produced in Sicily and Italy.

It was discovered many years ago when drilling for oil that sulphur existed in large quantities in the saline dome formations of the Gulf coastal plain of the U.S. No successful method was devised for winning this sulphur until the development of the Frasch process about 1900. (See SULPHUR.)

With sulphur obtained at low cost by this process, the deposits of Louisiana and Texas became the principal sources for the world, the Sicilian production taking second place. Since 1934 about 78% of the world's supply has been from the Gulf coast field, 13% from Sicily, 6% from Japan, and 3% from other countries.

No recent data are available on the reserves of any of the leading producers, but it is known that they are sufficient to supply the demand for many years, although the current world consumption has grown to some 3,000,000–3,500,000 tons annually. New discoveries are still being made, and moderately extensive deposits are known in other parts of the United States which are not yet commercially profitable. Pyrite ores and waste smelter gases yield considerable amounts of sulphur which supplement the supply of native sulphur.

The chief use for native sulphur is to burn it to sulphur dioxide gas for the manufacture of sulphuric acid or for the production of sulphite liquors for paper pulp manufacture. For certain chemical purposes, especially for the production of agricultural insecticide sprays, and in the manufacture of rubber and sulphuretted products, native sulphur has a distinct field of use. (A. E. W.; X.)

XI. MERCURY

Although about 25 minerals are known which contain mercury, including the native metal, usually in the form of an amalgam, cinnabar (HgS) is the only one found in sufficient quantity to be of commercial importance. The ores as mined seldom average better than 5%, and often only 1%. Since 1913 Italy has furnished 37% of the total output, Spain 32%, United States 16%, Mexico and Russia each 3%, and China and the former Czechoslovakia each 2%, out of an annual total which has varied from 2,000 to 5,000 metric tons. Three mines, the Almaden in Spain and the Idria and Monte Amiata in Italy furnish about two-thirds of the total.

Such early tonnage figures as have been reported on the Italian deposits have been largely offset by production, and it is not known to what extent they have been replaced by new development. In Spain, the Almaden mine has been going for 2,000 years, and is still reported to have reserves for several generations to come. Reserves in the United States are scanty and of low grade, with little prospect for important new discoveries.

The principal uses of mercury are, in order of importance: (1) drugs and chemicals; (2) fulminate for explosives; (3) scientific apparatus; (4) electrical apparatus; (5) pigments for paints, especially marine anti-fouling paint; (6) treatment of felt for hats; (7) amalgamation process for gold and silver recovery. A minor yet important use of mercury is in mercury boilers for the generation of power, this method having a much higher fuel efficiency than the usual type.

(G. A. Ro.)

XII. SILICON

While the element silicon does not occur free in nature, its compounds make up approximately 88% of the earth's crust

Silicon is found in the form of silicon dioxide, either as quartz or as silicates, generally in combination with alumina (clay, shale, feldspar, etc.). Industrially useful and commercially important, silicious resources are consequently generally available in all countries. Of primary importance are hydrous aluminium silicates, broadly termed clays, varying in purity of chemical composition and in physical properties from kaolin, which approaches the pure aluminium silicate, kaolinite, to the shales which contain enough kaolinite to render them workable in ceramic processes. The uses which clays find in industry may be summarized as follows: *kaolins* (white burning clays of high purity) for making paper, porcelain and chinaware, electrical porcelain, wall tile and rubber; *fire clays* (high fusing clays generally with some free silica and 2 to 4% of iron, lime, and alkalis) for fire clay brick and other metallurgical refractories, glass-house refractories, boiler furnaces, incinerators, and in general for use to withstand high temperatures, sewer pipes, chimney tiles, clay and graphite crucibles and in the manufacture of aluminium sulphate; *common clays* and *shales* (miscellaneous rocks which become plastic on grinding in water) for common brick, sewer pipes, building tiles, portland cement, electrical conduit tiles, chemical stoneware.

Silica (silicon dioxide) occurs chiefly as quartz, in the form of sand, sandstone, quartzite rock, vein quartz and rock crystal and also as infusorial earth. Quartz sand and crushed quartzite rocks find uses in abrasives, glass, glazes and enamels, silica refractories, electric furnace products (silicon carbide and many metal-silicon alloys), porcelains, sand lime brick and other ceramic products. Vein quartz or rock crystal is necessary for the production of transparent fused silica, but the translucent material may be made from quartz sand. Large crystals find use in radio transmission. Gannister, a form of quartzite, is employed in manufacturing silica refractories. *Infusorial earth*, or diatomaceous earth, is employed for thermal insulation and for filtering and clarifying in chemical manufacture, and "fuller's earth," which is properly a "clay," is similarly used for bleaching and clarifying oils and fats. Among the useful silicate minerals is feldspar, of primary importance in porcelain, whiteware and other ceramic products, glazes, enamels and glass. The minerals sillimanite, andalusite and kyanite are important raw materials for electrical insulators and also for greatly improved metallurgical refractories. *Asbestos*, a hydrous magnesium silicate (chrysotile) is woven into fire-resisting fabrics and for brake linings, and the shorter fibres are used in shingles and roofing sheets, coverings for the insulation of steam pipes and for parts of electrical equipment. *Talc* and *mica* are also important. (E. W. T.)

XIII. MICA

The commercial importance of mica is due to its highly developed cleavage, which permits the manufacture of dimensioned parts with great accuracy; its transparency; flexibility; stability at high temperatures; and insulating qualities. It is an essential constituent in the ignition system of the internal combustion motor and therefore of great importance in the automobile and aeroplane industries. The rapid development of wireless communication has also been dependent upon abundant supply of high grade mica. Mica production is restricted to the ancient, stable, land masses such as the peninsula of India, central and southern Africa, Madagascar, the Appalachian area in North America and the eastern areas in South America.

The micas of economic importance are of two varieties: *muscovite*, found in many localities; and *phlogopite* found in Madagascar and Canada. India, the United States, Canada and Madagascar produce over 90% of the world's mica. In none of these countries is there any immediate indication of exhaustion of the deposits. Production at recent levels may be maintained for an indefinite period, and continued search for new deposits may be depended upon to add to known resources.

For years the chief sustaining feature of the mica industry was the fact that there was no satisfactory substitute known, except for a few minor applications. In its most essential uses, as an insulator in electrical machinery and appliances, and in high grade condensers (especially for radio work), mica had no competition.

In 1938 a possible substitute was announced, in the product known as "Alsifilm," made from bentonite, a type of clay of which plentiful supplies are available. Favourable development of this product will greatly affect the mica industry, in that it promises to supply a satisfactory substitute for the ordinary electrical uses of mica. Up to mid-1939, however, no way had been found to impart to Alsifilm the peculiar combination of properties required for high grade condenser work. (G. A. Ro.)

PRECIOUS METALS GROUP

This classification includes the platinum group metals (platinum, palladium, iridium, rhodium, ruthenium, and osmium) as well as gold and silver.

PLATINUM METALS

Prior to the World War Russia was not only the leading producer of platinum metals, but was also almost the only producer. Colombia was a very poor second, and other countries hardly entered the picture. During the war Russian output decreased, while the Colombian increased, and during the years of Russian reorganization from 1919 to 1923 Colombia was the leading producer. From 1924 to 1933 Russia was again in the lead, but since 1934 Canada has stood first by a wide margin. South Africa developed into an important producer beginning in 1926, and since 1934 the United States has been increasing. In 1938 Canada stood first, Russia second, South Africa third, United States fourth, and Colombia fifth. During the 25 year period, 1913-1937, world production of platinum metals has more than doubled, reaching well over 500,000 ounces. On the average, about two-thirds of the total is platinum, and most of the remainder is palladium; the outputs of the other members of the group are comparatively small.

Africa. — The first production of platinum metals on a commercial scale in Africa began in 1920, when a small amount of osmiridium was recovered as a by-product in the milling of the Rand gold ores of South Africa. Within a few years production had increased to 5,000-6,000oz. annually, and this may be expected to continue. In 1923 a platiniferous lode was discovered in the Waterberg district, and in 1924 additional discoveries were made in the Lydenburg, Potgietersrust, and Rustenburg districts. with platinum metals content of 2 to 7 dwt. per ton. Enormous amounts of ore have been located in these areas, and by some it is thought that there exist here greater reserves of platinum than are known in all of the other sources in the world. Production has been limited by the high cost of a complicated metallurgical treatment and the prevailing low prices of the platinum metals, but has been sufficient to keep South Africa in second or third place in the list of world producers. An output ranging from 5,000 to 8,000oz. annually has been developed in Ethiopia, beginning in 1926. Since 1929 there has also been an output of a few hundred ounces in Sierra Leone, and since 1934 there has been a variable by-product recovery from the copper refinery in Belgian Congo. Little is known about the extent of the reserves of these smaller producers, but it is pretty well established that the total for the continent is extremely high, but the grade of the ore is so low, and the recovery costs so high, that these reserves will be of much more significance in later years when some of the richer deposits have been more nearly worked out, when prices are higher, or when recovery methods have been further improved and cheapened.

Australasia. — Platinum has been produced in small amounts in several areas in New South Wales, Queensland, Victoria, Papua, and New Zealand, but the total output has never been more than a few hundred ounces annually, and has been declining. Osmiridium has been reported in New South Wales and Victoria, but there has been no recent output. In Tasmania, osmiridium has been found in several localities, but the deposits have been largely worked out, and the output declined to 191oz. in 1938 Papua also occasionally reports a few ounces of osmiridium. No definite information is available on the reserves in any of these localities.

Japan. — Platinum and osmiridium have been reported in numerous gold placers in Japan, mostly in Hokkaido, but production has been only 100-300oz. annually. There is also presumably

some by-product recovery from copper refining.

Europe. — The only source of platinum in Europe is in Russia, which, until recently, was the world's foremost producer, and has, all told, contributed three-quarters or more of the entire world output to date. Platinum was first found in gold mines in the Urals in 1819, and in alluvials in 1823. The primary deposits are in dunites and pyroxenites, and these have been worked on a small experimental scale, but most of the recovery has been from placer deposits along the stream beds leading from the primary sources. Various estimates of the reserves vary from 4,000,000 to 7,000,000 oz., but these are now so old that little dependence can be placed on them. Modern dredge equipment has replaced most of the old hand methods in the alluvial areas. There have been a few reports of platinum occurrences outside of the main Ural areas, but none that seem to be of any great importance.

North America. — Placer platinum occurrences have been reported from a wide variety of localities in British Columbia, but production has been limited to the Tulameen district, about 100 mi. east and slightly north of Vancouver. A production of some 2,000 oz. annually in the 1880's declined to less than 500 oz. in recent years. Canada first came into an important position as a producer of the platinum metals after the establishment of electrolytic refining of nickel on a large scale and the development of methods of recovering the small amounts of the platinum metals associated with the nickel ores of the Sudbury district of Ontario. In the decade from 1929 to 1938 the Canadian output of platinum metals rose from 30,000 oz. to 292,200 oz., 55% of which was platinum and 45% other metals of the group, chiefly palladium. Since 1934, Canada has been the leading producer of platinum group metals, though not in all years the leader in platinum alone. At the end of 1938 there were approximately 220,000,000 tons of nickel ore definitely blocked out in the Canadian nickel mines, but the average platinum content is not known; at the 1938 rate of recovery, this would represent over 10,000,000 oz. of platinum metals, more than half of which is platinum; even though it is questionable as to whether the entire amount of the reserves averages as high in platinum metals as the current ore production, it is evident that there is an enormous potential supply, production from which, however, will be determined primarily by the demand for nickel, rather than by the demand for platinum. On the other hand, being entirely a by-product, platinum from this source can be placed on the market at a lower cost than that from any other source.

Several hundred ounces of crude platinum have been recovered annually from gold placers in California, with smaller amounts from Oregon and occasionally other States, but by-product recovery from gold and copper refining has until recently accounted for the greater proportion of the United States output. As in California, there have been moderate recoveries from gold placers in Alaska, and in addition some recovery from placers worked primarily for their platinum content. Since 1934 platinum placers in the Goodnews bay district have expanded operations, and in 1938 reached an estimated output of 41,000 oz. of crude platinum. This is the first year in which the United States has been able to produce a material percentage of her platinum requirements. No information is available on the extent of the reserves or their probable life, but in any case this area has been responsible for the first really material output of platinum in the United States.

South America. — Platinum was first discovered in Colombia, and the gold-platinum alluvials of the upper San Juan river area supply a fairly large output, although this declined from the high of 70,000 oz. reached in 1927 to less than 30,000 oz. in 1938. Large areas of alluvial ground remain to be worked, but no recent data are available on the extent of the reserves. The gross value of the reserves does not seem to be suffering with continued working, but a progressive change extending back over several years, involving an increase of gold content and a decrease of platinum content in the recoveries indicates a probable continuation of the decrease in output of platinum.

Uses of the Platinum Metals. — Since 1913 the United States has absorbed an average of 45% of the world's total output of new platinum, although during the past few years the proportion

seems to have declined somewhat.

The United States figures will be used to illustrate the utilization of platinum by various industries. The total consumption has varied from a low of 54,600 oz. in 1932 to a high of 156,800 oz. in 1922, and has averaged 114,500 oz., about two-thirds of which has been new metal, and one-third secondary metal, recovered from previous use. The bulk of the industrial consumption is not, as might be supposed, in the chemical and electrical industries; on the average, about 60% of the total consumption has gone into jewellery; the chemical and electrical industries each have taken 13%, dental work 9%, and other uses 5%.

The consumption of palladium is much less than that of platinum, but has been growing, rising in a decade from less than 20,000 oz. to 70,000 oz. in 1937; of this, dentistry took 40,000 oz., electrical work 21,000 oz., and jewellery 8,000 ounces.

The demand for iridium usually ranges between 3,000 and 5,000 oz., although formerly it was somewhat higher. Jewellery is the chief consumer, with the electrical industry second. Uses for the other three metals of the group, rhodium, ruthenium, and osmium, are comparatively small, and no statistics are published.

Summary. — Although the data on reserves are so scattered and incomplete that it is impossible to arrive at any estimate of the total, or their probable life, it is certain that the known reserves are sufficient to supply demand for many years to come, although it will require higher prices than prevailed from 1930 to 1939 to bring much of this metal into the market, especially that from South Africa, unless there are improvements in technology resulting in marked reductions in operating costs. (G. A. Ro.)

GOLD

The gold output of the world previous to the Spanish discovery and exploitation of the Americas was quite small—of the order of 100,000 oz. annually, about one-third of which was produced in Europe and two-thirds in Africa, Asia apparently contributing very little. As a measure of magnitude in comparison with modern outputs, attention might be called to the fact that this was the average daily output in 1938. After the Spanish conquest of South America, production increased, and during the 16th century is estimated to have averaged more than double the preceding output, though it must be remembered that much of the gold brought back to Europe at this time was from stocks accumulated over a long period by the Indians, and not new mine output. During this century the world production was approximately 35% each from Africa and South America, 21% from Europe, and most of the remainder from Mexico. The development of gold production in the various important producing areas of the world is shown in an accompanying table; it is to be noted that the dates shown are those when the area in question became a producer of important amounts, and that in many cases minor outputs had been maintained for longer or shorter periods previous to this date. As time passed, gold production has gradually spread to new areas until nearly every country has some output, current production being reported from something like 85 countries or colonial possessions, although more than 70% of the current output is derived from South Africa, Russia, Canada, and the United States, all of which have appeared in the list of producers within the past century.

Since 1493 the aggregate gold output of the world to the end of 1938, as estimated from various sources, has totalled nearly 1,300,000,000 oz. (equivalent to about 400,000 metric tons), the latter half of which has been produced in the amazingly short period of 30 years, as against 416 years for the first half. As shown by the table, p. 873, the distribution by centuries has been 1.8% in the 16th, 2.2% in the 17th, 4.7% in the 18th, 28.9% in the 19th, and 62.4% since the beginning of the 20th century. South America passed its peak of production in the 18th century, and in the 19th century was far surpassed by the United States, Australia and Russia, while the current century has seen South Africa forge to the front, with the United States second, Australia third, and Russia fourth, and Canada fifth, while the Japanese Empire takes sixth place. These six producers are the only ones with current annual outputs in excess of 1,000,000 oz., and combined account for 75% of the total output, with the remaining 25% di-

vided among some 80 minor producers.

Alluvial mining was formerly the chief source of gold; from 1848 to 1875 it has been estimated that 88% of the output was alluvial, and only 12% from lode mines; by 1890 alluvial gold had dropped to 45%, lode gold had increased to 47%, and 8% was supplied by the recently discovered banket deposits of the Transvaal; the latter continued to increase heavily, to a maximum in 1928-29, when it reached 53% of the total, while alluvial gold shrunk to about 6%, and lode gold to about 41%; in 1938 banket ores furnished 33% of the total, and both alluvial and lode percentages had increased, but no data are available on which an estimate can be based.

The British Empire has for several years been producing about 57% of the world gold output, a decline from the high of 73% in 1929. The chief Empire producers, with their percentages of the 1938 world total are: South Africa (34%); Canada (12%); Australia (4%); Southern Rhodesia (2.3%); Gold Coast (1.6%); India (1%); New Guinea (0.6%); and New Zealand (0.5%).

From 1911 to 1922 there was a decline in world gold production of nearly one-third, partly due to rising costs of operation, and partly to exhaustion of mines; during the later 1920's there was some improvement, but in many quarters the opinion was held that the 1915 high was the zenith of production from the then known areas, and hope for further increase depended on new discoveries. This view, however, failed to foresee the stimulating effect that was later to result from the wholesale abandonment of a fixed price for gold, which was inaugurated by Great Britain in 1931, and gradually spread throughout the world. With the advantage of an increased currency price for their product, gold mines were able not only to meet the rising cost of production, but even to work a much lower grade of ore than had been possible before this change, and as a result the world output has grown each year, the total for 1938 having surpassed the former 1915 high by 63.5%, with only a small proportion of the increase coming from newly discovered areas. During the course of this rise, the former standard price of approximately 85s. per ounce in London and \$20.67 in the United States increased gradually to 168s. in London and \$35 in the United States at the end of 1939.

Gold Consumption.— Though the uses of gold in the arts and industry requires a material percentage of the current output, this has declined sharply in recent years. Data on the subject are incomplete, but so far as they can be traced, the highest industrial consumption since the World War was 7,545,000 oz. in 1922; since this coincided with the low point in production, in 1922 industrial consumption was equivalent to 48.8% of world output of new gold. There then followed an almost unbroken decline to a low of 1,725,000 oz. in 1932, equivalent to only 7.1% of current new production. The average since 1932 has been about 6.3%. Formerly India was a heavy importer of gold, much of which went into jewellery and private hoardings, but in recent years India has been exporting heavily, and the estimated private holdings in the country have been reduced by about 16%. The same has been true, but to a lesser extent, in China and Egypt.

Open circulation of gold coinage having been debarred in nearly all countries, the remainder is held in the public treasuries as backing for currency in circulation. The total amount thus accounted for at the end of 1937 was approximately 750,000,000 oz.,

or 57.8% of the total output since 1493. The accompanying table gives the distribution of the aggregate world output since 1493, as estimated for the end of the years 1913, 1926, and 1937.

World Ore Reserves.— To arrive at an estimate of the world ore reserves requires an extensive knowledge of the character, extent, and richness of each individual deposit of importance, as well as working conditions, cost of operation, and, most important of all, the price to be realized for the product. On none of these are the data available sufficient to enable one to venture an estimate that would have any real meaning, especially so long as price remains a variable. Probably more is known about the Rand area of South Africa than of any other important deposit in the world, and this will serve as a good example of the difficulties to be encountered in making such estimates. Early estimates of the total production to be expected from the Rand started at 76,000,000 oz., and as time passed, increased to 188,000,000 oz.; yet total production to the end of 1927 had amounted to 211,000,000 oz., and at that time reserves were estimated at 118,000,000 ounces. However, from 1928 to 1938 Rand production totalled a further 125,000,000 oz., output had increased from 990,000 oz. to 11,193,000 oz. and was still rising, and the operating companies had an average five years' supply of ore blocked out, with large potential reserves still in the background.

For the past 25 years it has been forecast that the Rand would soon pass its high point and start to decline, but this has not yet come to pass, due to the discovery of new productive areas, to improvements in technology resulting in increased recoveries and reduced operating costs, and, most of all, to the rising price for gold that has prevailed since 1931. It is estimated that this last item alone will add something like 100,000,000 oz. to the potential reserves of the district, as it has made possible the reduction of the average grade of ore treated from 6.5 dwt. per ton in 1929 to 4.3 dwt. in 1939, with still further decrease in prospect.

The difficulty of predicting in advance the combined effect of all of the factors involved, and making an estimate of future output may be illustrated by citing various past attempts. An estimate made in 1914 predicted a Rand output of 2,600,000 oz. for 1938; in 1925 this was raised to 3,750,000 oz., in 1927 to 6,000,000 oz., and a year or two later to 6,700,000 oz., while the actual output eventually attained in that year was 11,193,000 ounces. An estimate of world output made at the same time as the last Rand estimate cited above predicted a world total of 20,000,000 oz. in 1930, with a subsequent reduction to 17,650,000 oz. by 1940; actual output in 1930 surpassed the estimate by only 4%, but that predicted for 1940 had already been doubled by 1937, with the

output still rising at a rate which, if continued, will give for 1940 an output of about 40,000,000 ounces.

Conditions then being as they are, it is impossible to set even an approximate figure for either world ore reserves or for future world output; the most that can be said is that so long as there is maintained a policy of increasing the price of gold to meet rising costs of operation, the world output will continue to increase. Proper adjustment of the price level can be made to yield any output desired, within reasonable limits, so that by concerted action between the leading buying nations, output can be made to increase or decrease, to fit the demand at the time. However, already the question is being raised in some quarters as to what may happen if and when the world reaches a point where it is felt that gold is no longer generally acceptable as a dependable standard of value, and its price comes to be based mainly on its demand as a commodity for industrial consumption; this is the position in which silver has been placed for a long time (except for recent years in the United States), and whether it may also be impending for gold is one of the leading questions of the near future.

(G. A. Ro.)

SILVER

Any attempt to evaluate the world's resources in silver is complicated by the fact that so much of it is produced in connection with other metals, notably lead, copper and gold; almost every gold mine produces some silver and every silver mine some gold. The three largest silver-producing States of the United States are Utah, Montana and Idaho; in the first two silver is produced chiefly in connection with copper, and in the latter in connection with lead ores. About one-third of the silver in the United States is derived from what are primarily copper ores, one-third from lead ores and the remainder from all other kinds, including those which are simply silver ores. The silver content of many of these ores is so low that they could not possibly be worked for silver alone, so that an evaluation of silver resources becomes an estimation of the resources of copper, lead, zinc or other deposits which are important producers of silver.

Silver occurs in rocks of all geologic ages from the oldest to the most recent. It also occurs in nearly all countries of the world, so that nearly all of them are able to produce at least some part of their requirements. China, until recently one of the principal silver-consuming countries of the world, produces very little silver, and it is not understood where its early silver supply was obtained. The Comstock lode in Nevada was discovered in 1859; by 1877 its annual production had reached \$22,000,000 in silver, and for a long period this deposit furnished half the silver output of the United States, its total output of silver to 1900 being estimated at \$220,000,000. Its output since 1886, when most of the deep mines in the lode were abandoned, has been relatively small. With the decline of the Comstock district the Leadville district in Colorado took its place as the greatest silver district of the world. Silver production there reached its peak (over \$11,000,000) in 1881, followed by a gradual decline until 1907, since when it has remained at about \$2,000,000 annually. The silver production of Canada was about 5,000,000 oz. per year until 1905, when the Cobalt district was discovered; in 1910-13 the output was over 32,000,000 oz. per year. Eight years later it was about 13,000,000 oz.; now it is over 20,000,000 annually. The average yearly production of the world for the period 1901-22 was 188,000,000 oz., ranging from 163,000,000 to 226,000,000; in 1937 it was 273,322,943 ounces. Mexico produces about one-third of the total; the United States about one-fourth, and Canada and South America each contribute about one-tenth.

The principal use of silver is in coinage, and the industrial arts. Photographic and chemical uses (which are the only ones in which silver may be said to be consumed) require an annual amount estimated at from 10,000,000 to 20,000,000 ounces. It is evident therefore that there are two reserves of silver, unmined ore and the accumulated stock of metal. It seems certain that the world can produce for a long period enough silver for the uses by which it is actually consumed. How long it can produce enough to supply needs for coinage and industrial arts depends not only on the dis-

covery of new silver-producing districts, and the production of metals with which it is associated, but also to the extent to which silver coins may be replaced with token coins made of other more abundant metals. The policy followed by the United States Government, since 1934, of stimulating domestic production by an artificially high price, while buying in world production in an attempt to raise the price of silver to \$1.29 per ounce, has resulted in an accumulation of an idle stock of over 75,000 tons. It is possible also that other metals may be substituted for silver in its uses in the industrial arts, since developments in the art of chromium plating and in the production of non-corrosive alloy steels make it possible to produce at a reasonable price metal articles that will not tarnish. It is possibly safe to imply that no new silver-producing district like Cobalt will be discovered, and the principal additional supplies of silver for future use are likely to be copper, lead, zinc, and other metal deposits where the large tonnage involved may yield considerable quantities even though the amount per ton is small. However, the copper deposits of Africa, the largest additions to the reserves of that metal recently developed, contain no important silver reserves. (T. T. R.)

RARER ELEMENTS

Cobalt, molybdenum, tantalum and columbium, uranium and radium, and zirconium are included here as representatives of the group of rarer elements, the commercial importance of which is less than that of the metals considered in the previous sections.

Cobalt.—Production in 1938 was estimated at 4,200 metric tons, of which Belgian Congo contributed 36%, Northern Rhodesia 35%, French Morocco 18%, and Canada and Burma each 5%; in addition to these there are minor unknown outputs in Australia, Finland, Germany, Greece, Japan, and China. Other deposits which have not yet been proven of commercial importance are known in Chile, Uganda, Norway, Sweden, New Caledonia, the Caucasus, and Pennsylvania (U.S.A.). The chief ores are smaltite (CoAs_2) and cobaltite (CoAsS), but the metal is also found in a number of non-commercial minerals. In nature its occurrence is usually closely associated with nickel, but curiously enough the world's largest nickel deposit, in the Sudbury district of Ontario, carries no cobalt.

The deposits of Belgian Congo and Northern Rhodesia, which now supply the bulk of the output, are of comparatively recent development, and the Cobalt district of Ontario, which furnished almost the entire supply in the early 1900's, is now the smallest of the leading producers. The reserves seem to be sufficient for any demand likely to be made on them for some years to come, but no specific data are available.

Molybdenum.—The extent to which our knowledge of reserves may be altered in a comparatively few years, and the difficulty in predicting the prospective life of the reserves, is well illustrated by the case of molybdenum. In 1923 it was reported that the Climax mine, near Leadville, Colo., was capable of producing 1,000 tons of ore daily for a period of 30 years; this was equivalent to about 72,000,000 lb. of contained molybdenum, and at the time was considered to be a heavy reserve, in comparison with the demand. Since then molybdenum consumption has increased so rapidly that the known reserves of 1923 would have been exhausted by 1936, but, at that time, instead of exhaustion, reserves were reported at 720,000,000 lb. of contained molybdenum, or ten times the 1923 figure; although in the meantime production had been stepped up to 12,000 tons of ore daily, instead of the 1,000 tons envisaged in the 1923 report, the prospective life of the reserves had been little changed. Incidentally, it is interesting to note that the known reserves of 1923 would have been completely wiped out by the production of the three years 1936-1938.

Although molybdenum minerals have been found to be widely scattered over the United States, commercial production outside of Colorado is limited to Alaska, Arizona, Idaho, Nevada, Utah, and Washington, with 85% of the total from the Climax mine. The United States output has averaged about 90% of the world total, other producing countries, in order of importance, being Mexico, Norway, French Morocco, and Peru. In the decade from 1929 to 1938 world production increased eightfold, from

4,313,000lb. to 36,016,000lb. of metal.

Tantalum and Columbium. — Tantalum associated with columbium or niobium is found widely distributed in many rare-earth minerals, but the chief sources are the minerals columbite and tantalite, two minerals which are identical except for the relative amounts of tantalum and columbium present. The general symbol representing their composition is $\text{Fe,Mn}(\text{Cb,Ta})_2\text{O}_6$, and in various samples the ratio between the iron and manganese and the tantalum and columbium differs. In general, tantalite is high in tantalum and columbite in columbium. Some ores from Australia run as high as 50% to 70% Ta_2O_5 . In the Black Hills of South Dakota and in Connecticut, U.S.A., ores have been found ranging from 10% to 40% Ta_2O_5 . Tantalum ores have also been reported from Maine, Massachusetts, New York, Pennsylvania, Virginia, North Carolina, Colorado and California in the United States, and from Norway, Sweden, Finland, Russia, Bavaria, Italy, and the Malay States. The combined production of tantalite and columbite in 1937 was about 1,000 short tons, of which Nigeria supplied 80%, Belgian Congo 13%, Uganda 3%, Australia 2%, United States 0.8%, and South West Africa, South Africa, Southern Rhodesia, and India the remainder.

Titanium. — Titanium is very widely distributed. Its most important mineral sources are ilmenite (FeTiO_3) and rutile (TiO_2). F. W. Clarke, of the U.S. Geological Survey, stated some years ago that 784 out of 800 igneous rocks analyzed in the Survey laboratory contained titanium. During the year 1937 the production of ilmenite in metric tons was as follows: Malaya, 6,352; Noway, 67,333; Brazil, 234; Canada, 3,837; and India 183,952; and the total production of rutile was about 2,100 metric tons, chiefly from Australia. The deposits of ilmenite ore at Lake Sanford, New York, and Iron Mountain, Wyoming, are estimated to contain many millions of tons, averaging 35% ilmenite. The Titan Co. of Norway owns one of the richest and largest known deposits of ilmenite. The Norwegian deposits of titanium in the islands of Lofoten and Vesterael, and near Rodsand and Solnordal, are very extensive. They are estimated to contain about 500,000 tons, varying from 4%-40% TiO_2 . Norway is said to have a total of 20-25 million tons of titanium minerals.

Radium and Uranium. — Although production data are incomplete, those available, plus estimates for the gaps, seem to indicate a total world output of about 900 grams of radium to the end of 1938, about 49% of which has come from Belgian Congo, 29% from the United States, 9% each from Czechoslovakia and Canada, with minor amounts from Portugal, Russia, England (Cornwall), and South Africa. Beginning in 1923 a heavy output was built up in Belgian Congo, replacing the United States as chief producer. Since 1933 Canada has developed deposits second only to those of the Congo, and by late in 1938 the refinery was producing at the rate of 4 grams of radium monthly, as compared with a maximum of 5 grams monthly in 1929-1930 from the refinery in Belgium, treating the Congo ores. Little information is available on the reserves of the major producers, Congo and Canada, beyond the fact that considerable amounts of ore await future operations. Among the minor producers, a recent report credits the Joachimsthal mine (Czechoslovakia) with reserves of at least 300 grams of radium.

The radium accompanies uranium minerals, usually in pitchblende, and to a lesser extent in carnotite. There are several other uranium minerals, but although their distribution is fairly wide, they are not found in commercial quantities. Roughly, the radium outputs quoted above are an indication of the relative outputs of the uranium minerals.

Zirconium. — The chief mineral sources of zirconium are zircon (ZrSiO_4), baddeleyite and brazilite, both essentially ZrO_2 . Zircite is a commercial name given to the oxide or to a mixture of the silicate and the oxide. Zircon is found chiefly in Ceylon, the Ural Mountains, Greenland and Australia; and in the United States, in commercial quantities, in western North Carolina, at Ashland in Virginia and at Pablo Beach in Florida. It occurs in small quantities associated with many minerals, notably with monazite sands. Baddeleyite, brazilite, zirkelite and zircite (the partially purified ore) come chiefly from Ceylon and Brazil.

In 1937 the production of zircon was 5,251 long tons in Australia and 1,329 tons in India, while exports from Brazil amounted to 2,317 tons; minor amounts have been produced irregularly in French West Africa and Madagascar. The United States imports of 7,957 long tons in 1937 consumed the bulk of the supply, in refractories and ceramics; smaller amounts are used in the production of ferro-alloys, coatings for welding rods, and pure metal. Reserves in all three of the leading producing countries are extensive. (G. A. Ro.)

SUBSTITUTES FOR NATURAL RESOURCES

Any discussion of substitutes for natural resources must be prefaced by a discussion of the meaning of the term substitute. When whale oil was an important illuminant there was much concern as to its future supply and some search was made for possible substitutes. The development of the petroleum industry arose principally from a desire to find a use, in order to provide a market, for an available material and not in response to a search for a whale oil substitute. The electric light, which has so largely displaced the oil lamp, was developed as a demand for something better, not as a demand for a petroleum substitute, for the market has been almost continuously over-supplied with petroleum during the whole period of electric lighting development. It is therefore possible to think of chinaware and porcelain as substitutes for the vessels of wood, horn and metal that preceded them; of glass as a substitute for the oiled paper with which window openings were once closed; of wooden houses as a substitute for skin tents; and of brick houses as a substitute for wooden ones. It is evident that these things are substitutes only in the sense that they replaced something that preceded them, and this because they better served some human need.

The term substitute has come to have a derived sense of something inferior used because that for which it is substituted either is not available in sufficient supply or, because of scarcity, is unduly high in price. The idea of the inferiority of the substitute is one that would be cultivated by those engaged in the production and marketing of the original. In the case of butter substitutes, for example, their production and sale are hampered by legislation which, it is alleged, represents the relative political strength of the interests involved rather than the scientific aspect of the matter. The converse of this situation is presented by various devices which are sold to provide an artificial substitute for the therapeutic effect of sunlight; the producers of devices which give out infra-red rays are not required to furnish any evidence that the devices will produce the effects claimed for them. It will therefore be clear that the economic and social problems involved in the use of substitutes are many and varied. How difficult some of them are of solution can be illustrated by some examples. Suppose a necklace of artificial pearls so skilfully made that only a few of the most expert persons in the world would be able to detect that they were not real pearls, which would cost 10 or 100 times as much as the substitutes. Has the belief in the inferiority of the substitute any other than a sentimental basis?

With inert natural resources the question is more easily determined because the purposes which natural resources serve can usually be set forth in exact chemical and physical specifications. There can be no doubt whether one metal will conduct electricity as well as another, or whether one substance produces the same chemical effect as another for the kind and degree of difference can be measured, the cost can be ascertained, and the relation between the difference in the cost and the service studied. But even in the case of these substances it is sometimes difficult to make a just evaluation. A single substance may be used for a great many purposes, and thus is developed a tendency to carry over its known superiority for one use into another field where it may or may not be also superior. The general considerations involved in this tendency are illustrated with specific examples. Tin is mostly produced in south-eastern Asia and Bolivia, where there is little local use for it, while the United States, which uses over half the world's total output, produces none. About one-third of the metal imported into the United States is used for making tin-plate, and about two-thirds of the tin-plate is used for

making tin cans for packing various commodities. The principal use of tin cans is for preserved foods. It is easily possible to preserve food in ceramic ware jars, and many foods are sold in glass jars, but these jars are heavier and can easily be broken. For most purposes the glass jar is not, therefore, a satisfactory substitute for the tin can, but for specially selected fruits, which are to be sold at a high price, the glass jar is better, because the more attractive appearance of the jar is part of the consideration which enables it to be sold at a higher price. Thus glass is or is not a satisfactory substitute for tin in connection with food preservation, according to the special conditions attending its use.

Tin-plate, in addition to being used for cans, is utilized for roofing purposes; obviously glass could not be so used. Terne plate (an alloy of lead and tin) is, however, used for roofing, but could not be used for food containers as the lead in the alloy produces toxic effects. Collapsible tubes made of tin are extensively used as containers for tooth-paste, shaving cream and various other commodities of a creamy consistence; no satisfactory substitute for tin has been devised for this purpose. Tin foil is used as a wrapping for candy and chewing gum, as a lining for boxes and cartons of cigarettes and for a variety of other purposes. Aluminium foil and lead foil are, to a growing extent, substitutes for this use, but neither has the bright lustre of tin foil. Except for appearance, paraffined paper would serve this use equally well. A variety of attractive transparent, moisture-proof and dust-proof wrapping materials have been placed on the market recently and, for some purposes, they are much better than tin foil, while for other uses they are inferior. Tin when alloyed with copper produces bronze, which has a variety of uses that it best serves. For some of these uses silicon or manganese can be used as the addition agent to the copper, but for others they are not satisfactory. When manufactured for transmission wire, cadmium can be used, with better results than other substances from the transmission standpoint, although not from other considerations. Tin is also used in the alloys employed for bearings in machinery. These alloys are of great variety, depending on the service required of them, and a discussion of possible substitutes would be exceedingly complex. Tin has a variety of chemical uses, two of the most important being for making enamels and weighting silk. In both cases the use of substitutes is possible.

For tin, therefore, various things may be used as substitutes in its various uses, with variable degrees of effectiveness, according to the circumstances of each case. No one can safely prophesy that research will not reveal some substitute that will give equally good service at equal or even less cost and, on the other hand, no one can safely prophesy that it will. The whole subject of substitutes is charged with uncertainty from its very nature. In the search for substitutes several general considerations must be maintained as objectives. The first is that the substitute should be more abundant than that which it replaces; little advantage is gained if a sufficient supply of the substitute material is not available. A second is that the substitution should be real, not fictitious; large quantities of power or of other materials should not be generally involved in making the substitution. Substitutes should, if possible, be locally available, to avoid the burden of transportation cost, and also to avoid the possibility of being dependent on foreign countries for a source of supply. Finally, the substitute should not impose too heavy a task in changing the habits of consumers, or the usual processes of plant operations.

The principal use of manganese is in connection with steel manufacture and for this purpose an alloy containing 80% manganese is usually employed. In America manganese ore of the desired quality has to be imported; domestic ores can be used to make a 20% alloy but less conveniently, as the 20% alloy has to be added while molten, although solid lumps of the 80% alloy that can be employed are commonly used. Substitution of the lower grade alloy is made difficult by this consideration.

Substitutes for gasolene have been much discussed and alcohol is one of the various materials that have been proposed. It has the great advantage that it can be made from vegetable materials that are reproducible. Alcohol cannot, however, be used effectively in an engine built to use gasolene; it needs one specially

designed for it. Its general use as a substitute would therefore involve not only the organizing of industry to produce and distribute the alcohol, but also the replacement of over 20,000,000 gasolene engines. Another possible substitute is gasolene made from oil shale. To mine the shale required to produce any considerable part of the gasolene now used would require the setting up of a mining industry of approximately the same size as our present coal-mining industry, and this industry would have to be in regions that are now very sparsely inhabited because they are arid. Thus not only a shifting of population would be required, but also the provision for water and food supply, housing and other facilities. The task is thus much more complex than the working out of a process whereby gasolene can be made from oil shale.

Substitution of one product for another not only involves the various considerations outlined above, but often requires the finding of adequate markets for by-products. Much has been said about the wastefulness of buying coal in its raw state, and one of the principal subjects for research is the processing of coal to yield coke, gas and a great variety of by-products. The proportions of these various things that can be made are definitely fixed by chemical and engineering considerations, but the markets for them are quite variable, not only from day to day, but over longer periods. The demand for gas may be greater than the demand for the coke produced, or it may be less, and these relations may shift from day to day or week to week. For a time it was difficult to find adequate outlet for the benzol made as a by-product, and it was chiefly used as a substitute for gasolene. However, development of the nitro-cellulose lacquers provided a large demand for benzol at an increased price, and the present supply was in 1929 practically all used for this purpose.

The problems involved in considering substitutes for things which are the result of life processes are even more complex. Citing clothing as an example, changes in human habits and considerations of style are extremely important. Only a few years ago wool and cotton were the principal materials from which articles of clothing were made, but in recent years demands have been transferred so largely to silk and fur that the woollen and cotton textile industries have been seriously affected. Straw, ribbon and other materials were formerly used extensively in making women's hats, but now felt hats are almost universal. To what extent demands for materials may be affected by a change in styles which may be brought about by skilful advertising and merchandising is exceedingly difficult to prophesy. Such changes have some limits imposed by physical conditions; thus wool is used for men's outer garments, because they keep their shape better.

In food products the tendency has been steadily to increase the number, variety and quality over a long period of years, with the result that people are now better nourished than at any previous period in human history. Fruit, for example, instead of being available to only the wealthier class outside the growing season is now a regular article of diet in almost every home all the year round; its greater consumption, it is believed, has led to a decline in the per capita consumption of meat. Sugar and chocolate are also used much more extensively than formerly; these, like most other food products, seem capable of being produced in any amounts that are required. Chewing gum, though not a food, is, however, an example of an organic product for which it may be necessary to find a substitute, as its increasing use bids fair to outstrip the present supply of chicle gum (the principal ingredient), which is the only gum that at the temperature of the mouth is neither too soft nor too hard, and is also free from any objectionable flavour. Rubber illustrates the manner in which public concern over supply of raw materials varies. The demand for rubber was easily met, until the introduction of the automobile forecast a great increase. This caused much concern for future supply and many chemists have worked to discover substitutes. The great increase in rubber production in Malaya shifted attention to schemes to maintain the price of the raw material in the face of production that had increased faster than consumption. If anything equally serviceable can be produced and sold at less cost it will be adopted, but the world

can produce what is needed without necessity for any substitutes.

Raw material for paper manufacture has long been a source of concern. Different materials are used to produce the various grades of paper, but newsprint, which is the largest in demand, is made from wood pulp. For the purpose soft woods are required, and these woods are also the principal kind needed for lumber purposes. Neither newsprint nor lumber has much salvage value and they are largely destroyed by their first use. Some progress has been made in decreasing the demands on lumber for packages, and it has also been found possible to remove the ink from newspapers, though not sufficiently to permit the re-use of the stock for the same purpose. It seems probable that wood and all the other raw materials that are produced as a result of growth can, with care, always be produced in sufficient amounts to meet human needs, so that the problem is really one of producing them at a cost which will not produce some economic shift that disturbs the complex equilibrium in modern industry. Shifts of this sort result from so many other causes in addition to shortage of essential raw materials and human ingenuity has been so successful in meeting them thus far that while the study of substitutes is proper for the engineer and chemist, it does not at present need to be a matter of great public concern.

(T. T. R.)

PHYSICAL UNITS. In order that our acquaintance with any part of nature may become exact we must have not merely a qualitative but a quantitative knowledge of facts. Hence the moment that any branch of science begins to develop to any extent, attempts are made to measure and evaluate the quantities and effects found to exist. To do this we have to select for each measurable magnitude a unit or standard of reference, by comparison with which amounts of other like quantities may be numerically defined. There is nothing to prevent us from selecting these fundamental quantities, in terms of which other like quantities are to be expressed, in a perfectly arbitrary and independent manner, and, as a matter of fact, this is what is generally done in the early stages of every science. We may, for instance, choose a certain length, a certain volume, a certain mass, a certain force or power as our units of length, volume, mass, force or power, which have no simple or direct relation to each other. Similarly we may select for more special measurements any arbitrary electric current, electromotive force, or resistance, and call them our units. The progress of knowledge, however, is greatly assisted if all the measurable quantities are brought into relation with each other by so selecting the units that they are related in the most simple manner, each to the other and to one common set of measurable magnitudes called the *fundamental* quantities.

The progress of this co-ordination of units has been greatly aided by the discovery that forms of physical energy can be converted into one another, and that the conversion is by definite rule and amount. (See ENERGY.) Thus the mechanical energy associated with moving masses can be converted into heat, hence heat can be measured in mechanical energy units. The amount of heat required to raise one gramme of water through 1° C in the neighbourhood of 10° C is equal to about 42 million ergs, the erg being the kinetic energy or energy of motion associated with a mass of 2 grammes when moving uniformly, without rotation, with a velocity of 1 cm. per second. This number is commonly called the "mechanical equivalent of heat," but would be more exactly described as the "mechanical equivalent of the specific heat of water at 10° C." Again, the fact that the maintenance of a μ electric current requires energy, and that when produced its energy can be wholly utilized in heating a mass of water, enables us to make a similar statement about the energy required to maintain a current of one ampere through a resistance of one ohm for one second, and to define it by its equivalent in the energy of a moving mass. Physical units have therefore been selected with the object of establishing simple relations between each of them and the fundamental mechanical units. Measurements based on such relations are called absolute measurements. The science of dynamics, as far as that part of it is concerned which deals with the motion and energy of material substances, starts from certain primary definitions concerning the

measurable quantities involved. In constructing a system of physical units, the first thing to consider is the manner in which we shall connect the various items. What, for instance, shall be the unit of force, and how shall it be determined by simple reference to the units of mass, length and time?

The modern absolute system of physical measurement is founded upon dynamical notions, and originated with K. F. Gauss. The postulate which lies at the base of the study of physics is that in the ultimate issue we can describe all phenomena in terms of mechanical data. Our fundamental scientific notions are those of length, time, and *mass*. Hence, in selecting units for physical measurements, we have first to choose units for the above three quantities.

Fundamental Units.—Two systems of fundamental units are in common use: the British system, having the yard and pound as the standard units of length and mass, frequently termed the "foot-pound-second" (F.P.S.) system; and the "centimetre-gramme-second" system (C.G.S.), having the centimetre and gramme as standard units of length and mass, termed the "metric" system. The fundamental unit of time is the same in both systems, namely, the "mean solar second," 86,400 of which make one solar day. (See TIME.) Since these systems and the corresponding standards, together with their factors of conversion, are treated in detail in the article MEASURES AND WEIGHTS, we need only deal here with such units as receive special scientific use, *i.e.*, other than in ordinary commercial practice. Various secondary units are chosen for special purposes. In astronomy, where immense distances have to be very frequently expressed, a common unit is the mean radius of the earth's orbit, the "astronomical unit" of length, *i.e.*, 92,900,000 miles. For stellar distances astronomers have adopted a unit of length termed the "light year," which is the distance traversed by light in a year; this unit is 63,000 times the mean radius of the earth's orbit. Another unit employed is the par-sec, that is, the distance at which the value of the parallax is one second of arc. For very small lengths, such as the wave lengths of light, the unit selected is a ten-thousand-millionth of a metre, termed an Ångström unit or a "tenth-metre," since it is 10^{-10} metres. Sometimes the thousand-millionth of a metre, the "micromillimetre," denoted by $\mu\mu$, or again the "micron," denoted by μ and equal to one-millionth of a metre is employed. The latter is much used by bacteriologists.

Units in Mechanics.—The quantities to be measured in mechanics (*q.v.*) are velocity and acceleration (dependent on the units of length and time only), momentum, force, energy or work and power, dependent on the three fundamental units. The unit of velocity in the British system is 1 foot per second. The unit on the metric system is 1 centimetre per second. Momentum is defined as the product of mass into velocity; unit momentum is therefore the momentum of unit mass into unit velocity; in the British system the unit of mass is the pound, and in the metric system, the gramme is the unit of mass.

Force, being measured by the change of momentum in unit time, is expressed in terms of the same units in which unit momentum is defined. The natural British unit is the "poundal," the force which in one second accelerates the velocity of a mass of one pound by one foot per second; but it has not come into general use. The metric (and scientific) unit, named the "dyne," is derived in the same way from the centimetre, gramme, and second. The poundal and dyne are related as follows:—1 poundal = 13,825.5 dynes.

A common unit of force among engineers is the "weight of one pound," by which is meant the force equivalent to the gravitational attraction of the earth on a mass of one pound. This unit obviously depends on gravity; and since this varies with the latitude and height of the place of observation (see EARTH, FIGURE OF), the "force of one pound" of the engineer is not constant. Roughly, it equals 32.17 poundals. A pressure is a force per unit area and can be measured in terms of the above units; for example, as lb. wt. per square foot. The standard atmosphere (corresponding to a barometric height of 760 mm.) is often taken as a secondary unit; it is equal to 1,013,600 dynes per centimetre.

Energy or work is measured by force acting over a distance. The scientific unit is the "erg," which is the energy expended when a force of one dyne acts over 1 centimetre. (See ENERGY.) This unit is too small for measuring the quantity of energy associated, for instance, with engines; for such purposes a unit ten million times as great, termed the "joule," is used. As we noticed in the case of units of force, common-life experience has led to the introduction of units dependent on gravitation, and therefore not, invariable; the common British practical unit of this class is the "foot-pound"; in the metric system its congener is the "kilogramme-metre."

Power is the rate at which force does work; it is therefore expressed by "units of energy per second." The metric unit in use is the "watt," being the rate equal to 1 joule per second. Larger units in practical use are: "kilowatt," equal to 1,000 watts; the corresponding energy unit being the kilowatt-second, and 3,600 kilowatt-seconds or 1 kilowatt-hour called a "Board of Trade unit" (B.T.U.). This last is a unit of energy, not power. In British engineering practice the common unit of power is the "horse-power" (HP), which equals 550 foot-pounds performed per second, or 33,000 foot-pounds per minute; its equivalent in the metric system is taken as 746 watts.

Units of Heat.—In studying the phenomena of heat, two measurable quantities immediately present themselves:—(1) temperature and (2) quantity of heat. Three arbitrary scales are in use for measuring temperature (see THERMOMETRY), and each of these scales affords units suitable for the expression of temperature. On the Centigrade scale the unit, termed a "Centigrade degree," is one-hundredth of the interval between the temperature of water boiling under normal barometric pressure (760 mm. of mercury) and that of melting ice; the "Fahrenheit degree" is one-hundred-and-eightieth, and the "Réaumur degree" is one-eighth of the same difference.

Empirical units of "quantity of heat" readily suggest themselves as the amount of heat necessary to heat a unit mass of any substance through unit temperature. In the metric system the unit, termed a "calorie," is the quantity of heat required to raise a gramme of water through one degree Centigrade. This quantity, however, is not constant, since the specific heat of water varies with temperature. (See CALORIMETRY.) In defining the calorie, therefore, the particular temperatures must be specified; consequently there are several calories particularized by special designations:—(1) gramme-calorie, the heat required to raise 1 gramme of water between 15° C and 17° C through 1° C; (2) "mean or average gramme calorie," one-hundredth of the total heat required to raise the temperature of 1 gramme of water from 0° C to 100° C; These units are thus related:—1 common calorie = 0.987 mean calories = 0.992 zero calories. A unit in common use in thermo-chemistry is the greater *calorie*, which refers to one kilogramme of water and 1° C. In the British system the common unit, termed the "British Thermal Unit" (B.Th.U.), is the amount of heat required to raise one pound of water through one degree Fahrenheit; a centigrade unit (C.H.U.) has also been introduced and is rapidly being adopted.

Electrical Units.—We are principally concerned in electrical work with three quantities called respectively, electric current, electromotive force, and resistance. These are related to one another by Ohm's law, which states that the electric current in a circuit is directly as the electromotive force and inversely as the resistance, when the current is unvarying and the temperature of the circuit constant. Hence, if we choose units for two of these quantities, the above law defines the unit for the third. Much discussion has taken place over this question. From the scientific standpoint the current and voltage are most readily defined in terms of forces. The ampere is defined as one-tenth of that current which, flowing in a circle of 1 cm. radius, exerts a force of 2π dynes upon a unit magnetic pole placed at its centre. This unit pole is itself defined in terms of the mechanical force between two such poles; so the ampere is made to depend on mechanical units. Again, voltage \times current \times time is mechanical work and is expressed in terms of ergs or joules. Resistance is voltage divided by current, and thus the corresponding unit of

resistance is defined. But for electric engineering (power and light) the choice is decided by the nature of the quantities themselves. Since resistance is a permanent quality of a substance, it is possible to select a certain piece of wire or tube full of mercury, and declare that its resistance shall be the unit of resistance and if the substance is permanent we shall possess an unalterable standard or unit of resistance. For these reasons the practical unit of resistance, now called the international ohm, has been selected as one of the above three practical electrical units.

It is known that there are two available methods for creating a standard or unit electric current. If an unvarying current is passed through a neutral solution of silver nitrate it decomposes or electrolyses it and deposits silver upon the negative pole or cathode of the electrolytic cell. According to Faraday's law and all subsequent experience, the same current deposits in the same time the same mass of silver. Hence we may define the unit current by the mass of silver it can liberate per second. Again, there is the method already described. Thirdly, the unit of electromotive force may be defined as equal to the difference of potential between the ends of the unit of resistance when the unit of current flows in it.

Apart, however, from the relation of these electrical units to each other, it has been found to be of great importance to establish a simple relation between the latter and the absolute mechanical units. Thus an electric current which is passed through a conductor dissipates its energy as heat, and hence creates a certain quantity of heat per unit of time. Having chosen our units of energy and related unit of quantity of heat, we must so choose the unit of current that when passed through the unit of resistance it shall dissipate 1 unit of energy in 1 unit of time.

British Association Units.—The founders of the modern system of practical electrical units were a committee appointed by the British Association in 1861, at the suggestion of Lord Kelvin, which made its first report in 1862 at Cambridge. (See B. A. Report.) The five subsequent reports containing the results of the committee's work, together with a large amount of most valuable matter on the subject of electric units, were collected in a volume edited by Prof. Fleeming Jenkin in 1873, entitled Reports of the Committee on Electrical Standards. This committee continued to sit and report annually to the British Association since that date until 1912; the whole of the reports have since been reprinted in book form. It is to the labours of this committee, acting in friendly correspondence with international committees, that the present system of electrical measurements is due.

Electrostatic and Electromagnetic Units.—It has throughout been recognized that a second consistent system of electrical units is possible. The unit electrical charge (or quantity of electricity) can be based upon the force between two electric charges. Accordingly, on the electrostatic system the unit of electric quantity is such that $f = q^2 / (Kd^2)$ where q is the quantity of each of two equal charges, d is the distance between them and K is the dielectric constant (or specific inductive capacity) of the intervening medium, that of air being taken as unity. (See ELECTROSTATICS.) The current is then defined as the amount that flows in unit time, and the energy is specified in terms of ergs or joules; thence the unit of resistance is defined by means of the equation $\text{Energy} = RC^2t$. The relation between the electromagnetic and electrostatic system of units is that the absolute EMU unit of current (*i.e.*, 10 amperes) is equal to 3×10^{10} electrostatic units. (See the various articles on ELECTRICITY.)

Practical Electric Units.—The committee of the British Association charged with the duty of arranging a system of absolute and magnetic units settled also on a system of practical units of convenient magnitude, and gave names to them as follows:—

10 ⁹	absolute electromagnetic units of resistance	= 1 ohm
10 ⁸	units of electro-	
	motive force	= 1 volt
$\frac{1}{10}$ th of an	unit of current	= 1 ampere
$\frac{1}{10}$ th of an	unit of quantity	= 1 coulomb
10 ⁻⁹	units of capacity	= 1 farad
10 ⁻¹⁵	units of capacity	= 1 microfarad

Since the date when the preceding terms were adopted, other multiples of absolute C.G.S. units have received practical names, thus:—

10 ⁷ ergs or absolute C.G.S. units of energy	= 1 joule
10 ⁷ ergs per second or C.G.S. units of power	= 1 watt
10 ⁹ absolute units of inductance	= 1 henry
10 ⁹ absolute units of magnetic flux	= 1 weber
1 absolute unit of magnetomotive force	= 1 gauss

(Neither the weber nor the gauss has received very general adoption, although recommended by the committee of the British Association on Electrical Units. Many different suggestions have been made as to the meaning to be applied to the word "gauss." The practical electrical engineer, up to the present, prefers to use *one ampere-turn* as his unit of magnetomotive force, and *one line of force* as the unit of magnetic flux, equal respectively to 10/4π times and 1 times the C.G.S. absolute units. Very frequently the "kiloline," equal to 1,000 lines of force, is now used as a unit of magnetic flux.)

An Electrical Congress was held in Chicago, U.S.A., in Aug. 1893, to consider the subject of international practical electrical units, and the result of a conference between scientific representatives of Great Britain, the United States, France, Germany, Italy, Mexico, Austria, Switzerland, Sweden and British North America, after deliberating for six days, was a unanimous agreement to recommend the following resolutions as the definition of practical international units. These resolutions and definitions were confirmed at other conferences, and at the last one held in London in Oct. 1908 were finally adopted. It was agreed to take:—

"As a unit of resistance, the *International Ohm*, which is based upon the ohm equal to 10⁹ units of resistance of the C.G.S. system of electromagnetic units, and is represented by the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice 14.4521 grammes in mass, of a constant cross-sectional area and of the length of 106.3 cm.

"As a unit of current, the *International Ampere*, which is one-tenth of the unit of current of the C.G.S. system of electromagnetic units, and which is represented sufficiently well for practical use by the unvarying current which, when passed through a solution of nitrate of silver in water, deposits silver at the rate of 0.00111800 of a gramme per second.

"As a unit of electromotive force, the *International Volt*, which is the electromotive force that, steadily applied to a conductor whose resistance is one international ohm, will produce a current of one international ampere. It is represented sufficiently well for practical purposes by $\frac{10,000}{10,7184}$ of the E.M.F. of a normal or saturated cadmium Weston cell at 20° C, prepared in the manner described in a certain specification.

"As a unit of quantity, the *International Coulomb*, which is the quantity of electricity transferred by a current of one international ampere in one second.

"As the unit of capacity, the *International Farad*, which is the capacity of a condenser charged to a potential of one international volt by one international coulomb of electricity. (This unit is far too large for most purposes; one millionth of it is called a microfarad; even a millionth of this is more practical in certain modern applications—it might be called a micro-microfarad or a dimicrofarad, on the analogy of the use of di- in chemical nomenclature.)

"As a unit of work, the *Joule*, which is equal to 10⁷ units of work in the C.G.S. System, and which is represented sufficiently well for practical use by the energy expended in one second by an international ampere in an international ohm.

"As a unit of power, the *Watt*, which is equal to 10⁷ units of power in the C.G.S. System, and which is represented sufficiently well for practical use by the work done at the rate of one joule per second.

"As the unit of inductance, the *Henry*, which is the induction in a circuit when an electromotive force induced in this circuit is one international volt, while the inducing current varies at the rate of one ampere per second."

Rational System of Electrical Units.—The above-described practical system based on the C.G.S. double system of theoretical units labours under several very great disadvantages. The practical system is derived from and connected with an abnormally

large unit of length (the earth quadrant) and an absurdly small unit of mass. Also in consequence of the manner in which the unit electric quantity and magnetic pole strength are defined, a coefficient, 4π, makes its appearance in many practical equations. For example, on the present system the magnetic force H in the interior of a long spiral wire of N turns per centimetre of length when a current of A amperes circulates in the wire is 4πAN/10. Again, the electric displacement or induction D through a unit of area is connected with the electric force E and the dielectric constant K by the equation D=KE/4π. In numerous electric and magnetic equations the constant 4π makes its appearance where it is apparently meaningless. A system of units in which this constant is put into its right place by appropriate definitions is called a rational system of electric units. Several physicists have proposed such systems.

Heaviside's Rational System.--One remedy for the difficulty has been suggested by Heaviside. He proposes to restate the definition of a unit magnetic pole in such a manner as to remove this constant 4π from the most frequently employed equations. His starting-point is a new definition according to which a unit magnetic pole is said to have a strength of m units if it attracts or repels another equal pole placed at a distance of d centimetres with a force of m²/4πd² dynes. It follows from this definition that a rational unit magnetic pole is weaker or smaller than the irrational or British Association unit pole in the ratio of 1/√4π to 1, or .28205 to 1. The magnetic force due to a rational pole of strength m at a distance of d centimetres being m/4πd² units, if we suppose a magnetic filament having a pole of strength m in rational units to have a smaller sphere of radius r described round its pole, the magnetic force on the surface of this sphere is m/4πr² units, and this is therefore also the numerical value of the flux density. Hence the total magnetic flux through the surface of the sphere is

$$4\pi r^2 \times m/4\pi r^2 \text{ units} = m \text{ units};$$

and therefore the number which denotes the total magnetic flux coming out of the pole of strength m in rational units is also m.

It follows, therefore, that if the intensity of magnetization of the magnetic filament is I and the section is s, the total flux traversing the centre of the magnet is Is units; and that if the filament is an endless or poleless iron filament magnetized uniformly by a resultant external magnetic force H, the flux density will be expressed in rational units by the equation B=I+H. The physical meaning of this equation is that the flux per square centimetre in the iron is simply obtained by adding together the flux per square centimetre, if the iron is supposed to be removed, and the magnetization of the iron at that place.

A final question suggests itself: Do the systems of units founded directly upon mechanical quantities constitute finality, or can we proceed to make a further reduction in the number of primary quantities?

There are certain constants of nature which are fundamental, invariable, and, as far as we know, of the same magnitude in all parts of the universe. One of these is the *mass* of the atom, say of hydrogen. Another is the *length* of a wave of light of particular refrangibility emitted by some atom, say one of the two yellow lines in the spectrum of sodium or one of the hydrogen lines. Also a *time* is fixed by the velocity of light in space which is according to the best measurement very close to 3×10¹⁰ cms. per sec. Another natural unit is the so-called *constant of gravitation*, or the force in dynes due to the attraction of two spherical masses each of 1 gramme with centres at a distance of 1 cm. Very approximately this is equal to 648×10⁻¹⁰ dynes. Another natural electrical unit of great importance is the electric charge represented by 1 electron. (See ELECTRICITY.) This, according to the latest determination, is nearly 3.4×10⁻¹⁰ electrostatic units of quantity on the C.G.S. system. Hence, 2,930 million electrons are equal to 1 E.S. unit of quantity on the C.G.S. system, and the quantity called 1 coulomb is equal to 879×10¹⁶ electrons. In round numbers 9×10⁻¹⁸ electrons make 1 coulomb. The electron is nature's unit of electricity and is the charge carried by 1 hydrogen ion in electrolysis. (See CONDUCTION, ELECTRIC, sec. *Liquids*.) Accordingly a truly natural system of physical units

would be one which was based upon the electron, or a multiple of it, as a unit of electric quantity, the velocity of light or fraction of it as a unit of velocity, and the mass of an atom of hydrogen or multiple of it as a unit of mass. An approximation to such a natural system of electric units will be found discussed in chap. 17 of a book on *The Electron Theory*, by E. E. Fournier d'Albe (London, 1906), to which the reader is referred. In addition, in more recent times, a new universal constant has been determined. It is generally known as Planck's constant because it first appeared in Planck's theory of full radiation.

PHYSICS. The old term "natural philosophy" signified an attempt to frame a theory of that part of the material universe which could be explored by observation and experiment, and of which the underlying laws were sufficiently understood to be amenable to mathematical calculation. The science of biology was excluded from its purview, for life was not sufficiently understood to be amenable to treatment of that thorough kind, and similarly the mental sciences were excluded, although an observable material organism was a sensible instrument and mode of manifestation; but even so the subject was a huge one and had to be subdivided. The branch of biological science nearest to inclusion was physiology, being a study of the mechanism involved in the functions of living organisms.

The branch of natural philosophy that advanced most rapidly towards perfection was the mechanics of the heavenly bodies, where the things treated of were comparatively few and far apart, and could readily be dealt with as individuals, so that the laws governing their movements could be formulated with some satisfaction. This branch, under Sir Isaac Newton, became so highly elaborated as to dominate and set an example to the rest; but, after all, astronomy was only a special case of the motion of material bodies, and Galileo had begun the study of ordinary motions on the earth's surface, developing into a complete treatment of their velocities, accelerations and distortions, and partly accounting for them by the fundamental inertia of matter influenced by forces of different kinds, and by the subsidiary properties of elasticity, friction, cohesion and the like.

Matter was always known to exist in three states, solid, liquid and gaseous, each having peculiar properties of its own; and the fluids formed resisting media through which the solids could move. Moreover all these bodies were subject, not only to locomotion in bulk, but to internal vibrations, and for the apprehension of these vibrations we had special sense organs, which enabled them to be examined with special facility, and thereby taught us much concerning the things themselves. Some of these vibrations are known as sound, others as heat, and there was yet a third kind of vibration, appealing to the eye, the effect of which could travel across space empty of matter, which therefore had to be filled with a hypothetical substance called "the ether" (or aether), whose properties are still in doubt.

Apart from these vibrations, which could be originated and absorbed by matter, it was found that matter consisted of particles called atoms, of a definite size and weight, which could enter into combination with each other, and so form the various compounds with which humanity had always been acquainted. A study of this branch of natural philosophy blossomed into the great science of chemistry, while geology took over a study of the history and conditions of the earth's crust. The remaining portions of natural philosophy were grouped in comparatively modern times under

the head *physics*, which, by derivation from *φύσις*, signifies a study of nature so far as it can be reduced by calculation and experiment to a few simple or at least fundamental laws. Those laws, first studied by Galileo, were formulated with masterly precision by Isaac Newton, and throughout the 19th century dominated the field. It was hoped at one time that they would be all-inclusive; the expressed ambition of Newton was that ultimately all observable phenomena might be brought under their sway. A long continued effort was made throughout the 19th century to apply them, not only to matter, but to the ether also—an attempt which failed, and has now, for a time at any rate, been abandoned. Hypothetical attempts were also made to include the phenomena of life and mind under the same fundamental laws of mechanism, without necessarily postulating anything outside and beyond such treatment; these efforts, the basis of a materialistic philosophy, were perfectly legitimate, though they have proved unsuccessful. No one claims that the ordinary laws of physics and chemistry are disobeyed by live things, but it is now fairly admitted that they have to be supplemented, while, with regard to the ether, it is still a question as to how far the simple laws are applicable at all. The very terms inertia, velocity, acceleration, force, are of only doubtful validity except when applied to definite material particles, and even then these properties themselves require elucidation. It may be that no fundamental explanation of even the simplest phenomenon can be satisfactorily and safely given until the laws of the fundamental substance, of which probably matter itself is composed, are better understood and formulated.

The Sub-divisions of Physics.—Meanwhile the science of physics has made gigantic strides, throwing off such branches as sound, light, heat, elasticity, hydrodynamics and the kinetic theory of gases. It was found that, although the atoms of matter were too small to be dealt with individually, the results of their combined action could be formulated statistically, in accordance with the laws of probability; and that, although the atoms of a gas were flying about in all directions at random, yet their number was so great that the pressure on any surface exposed to their random bombardment could be treated as perfectly uniform, except indeed when the exposed surface was extremely small. In the latter case individual atoms might exert a noticeable effect, giving occasionally a one-sided bombardment, and exerting an otherwise inexplicable propelling action on the body exposed to it. Thus originated a discrimination, now universally recognized, between the peculiar activities displayed by very small things and the customary behaviour of things on so large a scale that we can handle and directly apprehend them by our senses.

So far as matter was concerned there seemed little difference between physics and chemistry, except that physics sought to probe into the deeper-seated motions underlying molecular combination, and to investigate not only the anatomical groupings but the actual working of the agencies which rendered those groupings possible. It sought to understand the hidden meaning of chemical affinity and the nature of cohesion generally, and indeed of gravitation too. It was not satisfied with the idea of forces acting at a distance, or of the mere clinging together of polarized particles; it sought to dive down into the hidden meaning of attraction, and to explain if possible the very atoms themselves.
